Free radicals formed by H(Mu) addition to fluoranthene

Jean-Claude Brodovitch, Brenda Addison-Jones, Khashayar Ghandi, Iain McKenzie, Paul W. Percival, and Joachim Schüth

Abstract: Muonium has been used as an H atom analogue to investigate the free radicals formed by H addition to the polyaromatic hydrocarbon fluoranthene. There are nine unique carbons in the molecule, but only five radicals were detected. Muon and proton hyperfine constants were determined by transverse field μSR and μLCR, respectively, and compared with calculated values. All signals were assigned to radicals formed by Mu addition to C-H sites. There is no evidence for addition to the tertiary carbons at ring junctions.

Key words: muonium, fluoranthene, free radical, hyperfine constants.

Résumé : Les radicaux libres formés par addition de l'atome d'hydrogène à la molécule aromatique du fluoranthène ont été étudiés en utilisant le muonium comme analogue de l'atome d'hydrogène. Il y a neuf carbones non-équivalents présents dans la molécule, toutefois, seulement cinq radicaux libres ont été détectés. Les constantes hyperfines du muon et de certains des protons ont pu être déterminées par spectroscopies μSR et μLCR et les valeurs obtenues ont été comparées à des valeurs calculées. Tous les signaux observés ont pu être attribués aux radicaux libres formés par l'addition de Mu aux carbones portant le groupe C-H; l'addition de Mu aux carbones tertiaires qui joignent les cycles aromatiques ne se fait pas.

Mots clés : muonium, fluoranthène, radicaux libres, constantes hyperfines.

Introduction

One of the interesting questions raised in the past decade of research on fullerenes is how reactivity to radical attack is influenced by curvature of a carbon skeleton (1–3). Consider the addition of a single H atom or other small radical to C_{60} and to C_{70}. In the former case there is only one possible radical product, since all carbons are identical. In contrast, the ellipsoidal C_{70} has five chemically inequivalent sets of carbon atoms, and therefore five distinct radicals could be formed. Of these, the least reactive is the carbon at the "equator" where the curvature is least. Since high reactivity is associated with release of strain energy at a site of high curvature (1), it follows that planar carbon sites would be least reactive.

To test the reactivity of "flat" polyaromatic hydrocarbons (PAHs) we investigated Mu or H atom addition to pyrene, whose carbon skeleton can be considered a fragment of C_{70} (4). Three radicals were identified, but all are formed by Mu addition to secondary carbons at the edge of the molecule, in the same way that cyclohexadienyl is formed by H or Mu addition to benzene. No evidence was found for addition at the tertiary carbon sites that most resemble those of a fullerene.

The present study is an extension of our investigation to fluoranthene (Fig. 1). Although the PAH itself is planar, its carbon skeleton is a common fragment of fullerenes where isolated five-membered rings are surrounded by 6-rings. Since this feature introduces curvature to a fullerene, its presence might promote radical addition at ring junctions in PAHs.

As far as we know there is no literature data on monohydrofluoranthene radicals.

Muon spin rotation and muon level-crossing resonance experiments

Experiments were performed at the M20 muon beam line of the TRIUMF cyclotron facility in Vancouver, BC. The sample was pure fluoranthene sealed oxygen-free in a stainless steel vessel fitted with a thin steel foil window. Its temperature was maintained at $\approx 117°C$ (above the melting point of fluoranthene) by passing fluid from a constant temperature bath (set at 120°C) through the sample mount, which was surrounded by vacuum. A liquid sample was needed to ensure sharp spectral features by averaging anisotropic hyperfine parameters. The alternative to a neat liquid is to use a solution, as in the previous study (4), but this generally leads to less intense radical signals, as a fraction of the incident muons end up in the solvent.

Transverse field muon spin rotation (μSR) and muon (avoided) level-crossing resonance (LCR) spectra were accumulated over a period of several days. Apart from the higher

**Fig. 2.** Part of the Fourier power µSR spectrum from liquid fluoranthene at 118°C in an applied magnetic field of 17.34 kG. The peaks labeled **1–5** are due to free radicals formed by Mu addition to different sites in the fluoranthene molecule.

Fig. 3. Muon level-crossing resonance spectrum from liquid fluoranthene at 117°C.

Table 1. Measured muon hyperfine constants for the five observed Mu-fluoranthenyl radicals and their relative abundance derived from µSR signal amplitudes.[a]

Radical	A_μ (MHz)	Abundance (%)
1	263.87(1)	35.8(7)
2	348.95(2)	26.8(7)
3	347.35(3)	14.2(7)
4	434.86(5)	13.7(6)
5	402.25(6)	9.5(1.1)

[a]Statistical uncertainties are shown in parentheses.

[1] $$\nu_{R1} = \nu_{mid} - \frac{1}{2} A_\mu \qquad \text{and} \qquad \nu_{R2} = \nu_{mid} + \frac{1}{2} A_\mu$$

where

[2] $$\nu_{mid} = \frac{1}{2}\left[\sqrt{A_\mu^2 + (\nu_e + \nu_\mu)^2} - \nu_e + \nu_\mu \right]$$

and ν_e and ν_μ are the electron and muon Larmor frequencies.

The results are summarized in Table 1, which also lists the relative abundances of the five radicals as determined from the signal amplitudes. In principle, nine different radicals could be formed by Mu addition to fluoranthene, since there are nine unique carbons (1, 2, 3, 7, 8, 10a, 10b, 10c, and 3a; all but the last two are doubly degenerate; see Fig. 1). Assignment of the µSR signals to specific radical structures is not possible without further information, so at this stage they are simply labeled **1–5** in decreasing order of intensity.

Interpretation of the LCR spectrum (Fig. 3) is more complicated. Each of the five radicals detected by µSR will also have hyperfine interactions between the unpaired electron and the protons in the molecule. Since fluoranthene has ten protons, each muoniated radical could potentially give rise to ten LCR resonances, with the signals from different radicals distributed in overlapping field regions. In practice only the largest proton couplings are likely to give detectable signals, and the LCR signals will also be scaled by the radical abundances (Table 1). Up to 17 resonances can be distinguished in Fig. 3. Their differential-like shape is a result of square-wave modulation of a small component of the ap-

temperature, the apparatus and measurement procedures were as described previously (4). Spin-polarized positive muons (4 MeV) were extracted from the beam line and stopped in the sample, which was mounted in the HELIOS µSR spectrometer whose magnetic field was aligned along the beam direction. Transverse muon polarization was used for the µSR measurements and longitudinal polarization for LCR, with the positron counters arranged accordingly (4). Figure 2 shows an example of a µSR spectrum at a fixed magnetic field, 17.34 kG. The LCR spectrum displayed in Fig. 3 is a composite of many individual runs over different field ranges. Repeated runs were needed to achieve acceptable signal-to-noise for the weakest signals.

The signals of five radicals are evident in the transverse field µSR spectra; two of them are almost degenerate (close to 60 MHz in Fig. 2). Although each radical gives rise to a pair of muon precession frequencies (ν_{R1} and ν_{R2}; see eq. [1] below), only the lower frequency signals are visible in the range displayed in Fig. 2. (Their higher frequency partners are less intense, mainly because of the limited time resolution of the apparatus.) Measurements at different magnetic fields confirmed the assignment of the signals to muoniated radicals. Their muon hyperfine constants (A_μ) were calculated from theoretical expressions for the precession frequencies (4, 5)

plied magnetic field, which is used to suppress some of the baseline fluctuations (4). The resonances were fitted with a Lorentzian line shape; the fit parameters for the strongest 14 are gathered in Table 2. The few extra features that could not be fitted with physically meaningful parameters are barely above the noise and were ignored in the final analysis.

For protons, the resonance field is given by (4,5)

$$[3] \qquad B_{LCR} \approx \frac{1}{2}\left[\frac{A_\mu - A_p}{\gamma_\mu - \gamma_p} - \frac{A_\mu + A_p}{\gamma_e}\right]$$

where A_p is the proton hyperfine constant (hfc) and γ_μ, γ_p, and γ_e are the magnetogyric ratio of the muon, proton, and electron, respectively. In addition, the width and the amplitude of a resonance are given by

$$[4] \qquad \text{Width} = \frac{1}{2}\frac{\sqrt{\omega_{LCR}^2 + \lambda_{eff}^2}}{\pi(\gamma_\mu - \gamma_p)}$$

$$[5] \qquad \text{Amplitude} \propto \frac{\omega_{LCR}^2}{\omega_{LCR}^2 + \lambda_{eff}^2}$$

where ω_{LCR} is the frequency at resonance and λ_{eff} the effective relaxation rate (muon decay rate plus any additional relaxation contribution),

$$[6] \qquad \omega_{LCR} = \frac{\sqrt{c}\pi A_\mu A_p}{\gamma_e B_{LCR}}$$

and c is the number of magnetically equivalent protons at resonance.

Clearly, to calculate the hyperfine constant of a particular proton from its resonance field position (B_{LCR}) it is necessary to know the value of the muon hfc (A_μ) for that particular radical. Thus, the first step in assigning the LCR resonances is to deduce which resonances correspond to which A_μ values. Our experience interpreting the LCR spectrum of muoniated pyrenyl isomers was beneficial, and following the procedure described in ref. (4) we identified five resonances due to the –CHMu– group. As indicated in

Table 3, the ratio of muon and proton hfcs is in the range 1.20–1.25 after correction for the different magnetic moments (correction factor = 3.183). This muon–proton isotope effect is typical for cyclohexadienyl type radicals and is consistent with zero-point vibrational effects in anharmonic vibrational modes (5, 6).

The remaining resonances from Table 2 are narrower than those assigned to the methylene groups and can be attributed to α protons (protons attached to a carbon that carries significant unpaired spin density). Beyond that one must turn to theoretical prediction to help in the assignment.

Computation and discussion

Model calculations were performed on the nine isomeric H atom adducts of fluoranthene using density functional theory (DFT) as implemented in the Gaussian suite of programs (7). The structures were optimized at the UB3LYP/STO-3G level, and then single-point computations were performed at the UB3LYP/6–31G** level to calculate the hyperfine constants and Hartree–Fock energies.

The molecular geometry for each H adduct radical should also be valid for the muoniated species, within the Born–Oppenheimer approximation. Similarly, electron distributions should be identical for isotopomers. However, zero-point vibrational effects are larger for normal modes involving Mu, and this can result in considerable isotope effects on vibrationally averaged hyperfine interactions. In particular, such effects have been investigated for cyclohexadienyl (6) and HC$_{60}$ (8). In view of the preliminary assignments and hfc ratios indicated in Table 3 we scaled computed proton hfcs by a factor of 1.20 to predict the muon hfc (a factor of

[b]Includes a factor of 1.20 to account for primary isotope effect.
[c]Includes a factor of 0.94 to account for secondary isotope effect.
[d]Accidentally doubly degenerate (see text).

3.183 is also required to account for the magnetic moment). Similarly, taking account of prior experience (4), we used a factor of 0.94 for the corresponding H in a –CHMu– group.

The relative Hartree–Fock energies of the nine H adduct radical isomers are listed in Table 4 together with the corresponding predicted muon hfcs. The hfcs of the first five entries (lowest energies) are well matched to the experimental data, although one cannot exclude the H adduct to carbon 6a on this ground alone. The radicals were thus assigned as in the last column of Table 4. It is significant that, as in the case of pyrene (4), only products of attack at H-bearing carbons are experimentally detected. Otherwise, we would have found a muon hfc without a corresponding –CHMu– proton; Table 3 shows that this was not the case.

The calculations also provide the hfc of each proton for each radical species. Using eqs. [3–6], the LCR field, width, and amplitude (weighted with the radical abundance) of the corresponding signals may be predicted. It is then possible to test if the calculated hfc values are found to be a reasonably close match with experimental data obtained after making an a priori assumption of the muon hfc to use for each level-crossing resonance. The results of our analysis are displayed in Table 5.

In this fashion most of the observed LCR signals were assigned, although ambiguity and inconsistency remain for some of the weaker features observed. For example, in the case of the Mu-1-fluoranthenyl radical (radical **3**), calculations predict four negative hfcs for protons in positions 2 (–9.3 MHz), 8 (–10.8 MHz), 5 (–14.1 MHz), and 10 (–11.1 MHz). Experimentally, in the expected field region only two LCR resonances are observed (at 19.35 kG and 19.47 kG), from which one derives proton hfcs of –9.93 MHz and –13.43 MHz. A

good fit is obtained if it is assumed that each of these resonances is actually accidentally doubly degenerate, which suggests that protons in positions 2, 8 and 5, 10 have, pairwise, very close hfcs not quite reproduced by the calculations.

Conclusions

Five muoniated radicals (out of the possible nine) are formed by the addition of muonium to fluoranthene. Using DFT calculations as guides for the assignment of the various experimental spectral features, the hyperfine constants of the muon and selected protons in the various radicals could be obtained. The results are summarized in Fig. 4, in which all the assigned hfcs are shown on the structure diagrams for the radicals detected. Unlike the situation for C_{60} or C_{70}, there is no evidence of a radical being formed by Mu attack on one of the trigonal carbon sites (positions 3a, 6a/10b, 6b/10a, 10c), although calculations suggest that an attack at position 6a/10b might be possible.

From the hyperfine constants of the α-protons obtained experimentally, it is also possible to deduce the distribution of unpaired π-spin density ρ_α on the corresponding carbon using McConnell's relation (9)

[7] $A_H = Q_\alpha \rho_\alpha$, where $Q_\alpha \approx -75$ MHz

The results are displayed in schematic form in Fig. 5. For clarity, only positive spin densities are displayed. Since the experimental data reported here give no *direct* information on carbon atoms not bearing a hydrogen (such information could be obtained from experiments on ^{13}C enriched fluoranthene), the corresponding unpaired spin density displayed

Fig. 4. Assigned hyperfine constants (in MHz) for the five fluoranthenyl radicals. Alternative assignments or degenerate values for radicals **3** and **5** are shown by question marks.

1	**2**	**3**	**4**	**5**
3-Mu-FA	8-Mu-FA	1-Mu-FA	7-Mu-FA	2-Mu-FA
in Fig. 5 was taken from the calculations. It is apparent that most of the protons adjacent to significant unpaired spin density have been detected in the present experiment. However, the calculations seem to indicate that there is significant unpaired spin density on carbons 1 and 3 of radical **2** and carbons 4 and 6 of radical **4**, and that the corresponding proton hfcs may be measurable. In addition, there are a few cases where negative spin density may be sufficient to give rise to measurable *positive* α-proton hfcs.

It is evident from Fig. 5 that radical **1**, the lowest energy isomer, is also the one with the greatest spread of unpaired π-spin density, consistent with a general notion of resonance stabilization. However, it would be dangerous to infer much from the apparent correlation between A_μ and radical energy (Table 4), since other factors contribute to both the relative energies of the radicals and to the muon hfc. In particular, the hfc depends on geometric factors (the dihedral angle between the C—Mu bond and the z-axis of the π-spin system) and the unpaired spin density on the adjacent carbon atoms (10, 11).

Similarly, the fact that the lower energy radicals were detected and not those corresponding to Mu(H) addition at trigonal carbon sites is related to the energy required to distort the carbon skeletons of the latter. However, it is important to realize that the relative abundance of the radical isomers depends on *kinetic* competition for the various sites, and that this reactivity is determined by the *activation* energy for Mu(H) addition, which is only indirectly linked to the radical (product) energy.

The findings reported in this paper and the preceding study of Mu addition to pyrene (4) show that planar PAHs are not good models to investigate the reactivity of fullerene fragments. Therefore, as the next stage in our exploration of this topic we have undertaken a study of Mu addition to a pyrenophane, a PAH with a curved carbon skeleton (12).

Formation of the charge-transfer exciton in 1,3,5-triphenyl-2-pyrazoline nanocrystals

Hongbing Fu, Debao Xiao, Ruimin Xie, Xuehai Ji, and Jian-Nian Yao

Abstract: A series of 1,3,5-triphenyl-2-pyrazoline (TPP) nanocrystals were prepared by the reprecipitation method. The electronic transitions of TPP nanocrystals have been studied using both absorption and fluorescence spectra. An absorption feature at about 400 nm gradually appeared with increasing nanocrystal size. This feature resulted from the formation of the charge-transfer (CT) exciton in nanocrystals. It was also supported by the longer decay time of the nanocrystal emission from CT compared with that of the solution emission from S_1 at 298 K. On the other hand, the different behavior of the molecular π–π* and n–π* transitions originates from the different overlapping modes of the pyrazoline π orbital and n-electron orbital, according to the molecular model calculations. The nanocrystal emission from both the S_1 and CT states was found at 77 K; moreover, the emission intensity redistributed from S_1 to CT with increasing nanocrystal size. In contrast, at 298 K, only the emission from the CT states was observed, since the thermal fluctuation easily relaxes the excited electrons into CT states through vibration.

Key words: reprecipitation method, organic nanocrystals, charge-transfer exciton, size-dependent property.

Résumé : Utilisant la méthode de reprécipitation, on a préparé une série de nanocristaux de 1,3,5-triphényl-2-pyrazoline (TPP). On a étudié les spectres d'absorption et de fluorescence ainsi que les transitions électroniques des nanocristaux de TPP à l'échelle nanocristalline. Une caractéristique d'absorption aux environs de 400 nm apparaît graduellement avec une augmentation de la taille nanocristalline qui conduit à la formation de l'exciton de transfert de charge (TC) dans les nanocristaux; ceci est supporté par le fait que, à 298 K, le temps de décroissance de l'émission nanocristaline à partir de l'état TC est plus long que celui de l'émission en solution à partir de S_1. Par ailleurs, il semble sur la base de calculs de modèles moléculaires, que le comportement différent des transitions π–π* et n–π* moléculaires trouve son origine dans un mode de recouvrement différent de l'orbitale π de la pyrazoline et de l'orbitale de l'électron n. À 77 K, on a observé une émission nanocristalline tant à partir de l'état S_1 que de l'état TC; toutefois, avec une augmentation de la taille nanocristalline, on observe que l'intensité de l'émission se redistribue de S_1 à TC. Toutefois, à 298 K, on n'observe que l'émission provenant des états de TC puisque la fluctuation thermique permet de faire facilement passer les électrons excités vers les états de TC par le biais de vibrations.

Mots clés : méthode de reprécipitation, nanocristaux organiques, exciton de transfert de charge, propriété qui varie avec la taille.

[Traduit par la Rédaction]

Introduction

In the past decades, the synthesis of semiconductor nanocrystals with controlled size (1–2), shape (3), and composition (4) have paved the way for numerous spectroscopic studies, which assigned the quantum dot electronic states and mapped their evolution as a function of size. One of the most interesting findings is the strong effect of confinement on electron-hole pairs in semiconductor quantum dots, which leads to their size-tunable optical properties (5). This type of confinement is not expected in organic crystals because of the small radius of the Frenkel exciton, which is the reason for the scarcity of reports on the preparation of nanocrystals from general organic molecules (6–11). However, by alternating multiple quantum-well structures grown by organic molecular beam deposition, Forrest and co-workers (12, 13) were able to report the confinement effect on the charge-transfer exciton in 3,4,9,10-perylenetetracarboxylic dianhydride (PTCDA) and 3,4,7,8-naphthalenetetracarboxylic dianhydride (NTCDA). Because of the great diversity of organic molecules compared with inorganic compounds, there is a challenge to extend the research on nanocrystals from metals and semiconductors to the organic field. The electronic and optical properties of organic semiconductors are fundamentally different from those of inorganic metals and semiconductors owing to the weakness of the van der Waals type intermolecular interaction forces (14, 15). To understand how these properties develop as a function of size is of fundamental (16) and technological interest (17).

Pyrazoline derivatives have been widely used as optical brightening agents for textiles and paper because of strong fluorescence (18, 19) and as a hole-conducting medium in

photoconductive materials (20, 21) and electro-luminescence (EL) devices (22). 2-Pyrazolines containing electron donors and acceptors at their 1- and 3-positions have intrinsically large molecular hyperpolarizabilities and are considered to be important organic heterocyclic semiconductors (23). In our previous work, the optical size dependence of nanoparticles of 1-phenyl-3-((dimethylamino)styryl)-5-((dimethylamino)phenyl)-2-pyrazoline (PDDP) was identified and found to originate from the formation of the charge-transfer (CT) exciton. The optical size dependence was found to correspond to increasing nanoparticle size (24). The research outlined in this article is an extension of the above research. For this paper 1,3,5-triphenyl-2-pyrazoline (TPP) nanocrystals of different sizes have been prepared; further, their optical properties have been found to present as a function of crystal size owing to the formation of the charge-transfer exciton. The optical size effects presented by pyrazoline nanocrystals are likely to be important, considering future luminescence applications of organic materials.

Experimental section

Materials

The compound 1,3,5-triphenyl-2-pyrazoline (TPP) was synthesized according to ref. 18 and confirmed by NMR and MS. TPP nanocrystals were prepared as follows: quantities of TPP–ethanol solution (1.0×10^{-3} mol·L^{-1}) were injected, with vigorous stirring, into 10 mL of water using a 100 µL microsyringe. The TPP molecules began to aggregate at once and nanocrystals dispersed in water were obtained. By controlling both the quantity of TPP–ethanol solution injected into water and the temperature, the size of the nanocrystals could also be controlled. For example, when 40 and 100 µL of the TPP–ethanol solution was injected, the final nanocrystal sizes were 60 and 125 nm at 25°C or 90 and 170 nm at 50°C, respectively.

Methods

The UV–vis absorption spectra of the nanocrystals in water dispersion were measured using a SHIMADZU UV-1601 PC double beam spectrophotometer. The steady-state fluorescence excitation and emission spectra were recorded with a Hitachi F-4500 spectrometer. The measurements of fluorescence lifetimes with excitation at 360 nm were performed, with monitoring at 445 nm for the solution and at 465 nm for the nanocrystals, on a Horiba NAES 1100 nanosecond fluorometer. The sizes and shapes of the nanocrystals were observed by means of the field emission scanning electron microscope (JSM-6301F). The mean size and the size distribution of nanocrystals dispersed in water were also evaluated by the dynamic light-scattering (DLS) technique using a Zetaplus BI-9000 (Brookhaven Instruments Corporation, U.S.A.). The same instrument was also used to measure the surface electric ξ-potential of the nanocrystals.

Molecular modeling calculations were carried out using CHEM3D Pro 4.0, which was developed by CambridgeSoft Corporation (Mass., U.S.A.). Molecular modeling was done on a Pentium 266 using an MM2 force field. The structures of two neighboring TPP molecules in the nanocrystals were drawn and the minimum energy of configuration was obtained by energy minimization in vacuum conditions. The

modeling was also done using the PM3 semiempirical quantum mechanical method for a TPP molecule pair in the nanocrystal. The minimization procedure involved systematically altering the coordinates of the atoms and estimating the conformation until a minimum energy configuration was reached.
Results and discussion

We successfully prepared a series of TPP nanocrystals ranging in size from tens to hundreds of nanometers, labelled NC1, NC2, NC3, NC4, and NC5 — corresponding to the average nanocrystal sizes 30, 60, 90, 125, and 170 nm, respectively. The nanocrystal dispersions in water appeared turbid white because of the light scattering property of nanocrystals; moreover, the color deepened as the nanocrystal size increased. Some of the field emission scanning electron microscopy (FESEM) photographs are shown in Fig. 1, in which the average crystal sizes are 60, 125, and 170 nm. These values agree roughly with those determined by the dynamic light scattering (DLS) technique. It can be seen from Fig. 1 that the shape of the TPP nanocrystals is cubic, which suggests that the crystallization of the TPP nanocrystals is good. In the process of observation, the original sharp margins of the cubic nanocrystals was blurred over time by the bombardment of electrons, as a result of the surface effect, which caused a reduction in the melting point (16). The measurements of the surface electric ξ-potential of the nanocrystals shows that they are negatively charged.

Figure 2 displays the UV–vis absorption spectra of different sizes of TPP nanocrystals dispersed in water. For comparison, the spectrum of a dilute TPP–ethanol solution (1.0×10^{-5} mol·L^{-1}), which has three peaks at 240, 305, and 357 nm, is also displayed (Fig. 2(m)). It has been reported that the UV band at 240 nm arises from the phenyl ring (P_{phenyl}), and the other two peaks at 305 and 357 nm are due to the pyrazoline ring n–π* ($P_{n-\pi*}$) and π–π* ($P_{\pi-\pi*}$) transitions, respectively (25–27). No spectral changes were observed when the concentration changed from 1.0×10^{-5} to 1.0×10^{-3} mol·L^{-1}. As the nanocrystal size increases from NC1 to NC5, the P_{phenyl} of the TPP nanocrystal is observed to shift to longer wavelengths, while the $P_{n-\pi*}$ remains at almost the same position. Moreover, the peak in the region of 350~425 nm broadens and its shape changes from symmetric to asymmetric. The asymmetric peak located at approximately 350~425 nm actually consists of two peaks, especially for NC4 or NC5. The one at shorter wavelengths originates from the π–π* transition of TPP molecules. The other at longer wavelengths is strongly affected by the nanocrystal size, becoming vanishingly small for crystal sizes ≤30 nm. This behavior is expected for an aggregate state arising from the π–π orbital overlap of closely stacked TPP molecules in nanocrystals; it is similar to previous observations of absorption by aggregate states in other organic molecular crystals such as α-perylene (28), C$_{60}$ (29), and 3,4,9,10-perylenetetracarboxylic dianhydride (30). In addition, the absorption spectrum of the solution has no detectable peak in the region of 400–420 nm, in contrast to the absorption spectrum of NC1, although the solution concentration of TPP molecules in the system is greater than that of the NC1–water dispersion, which was prepared by injecting

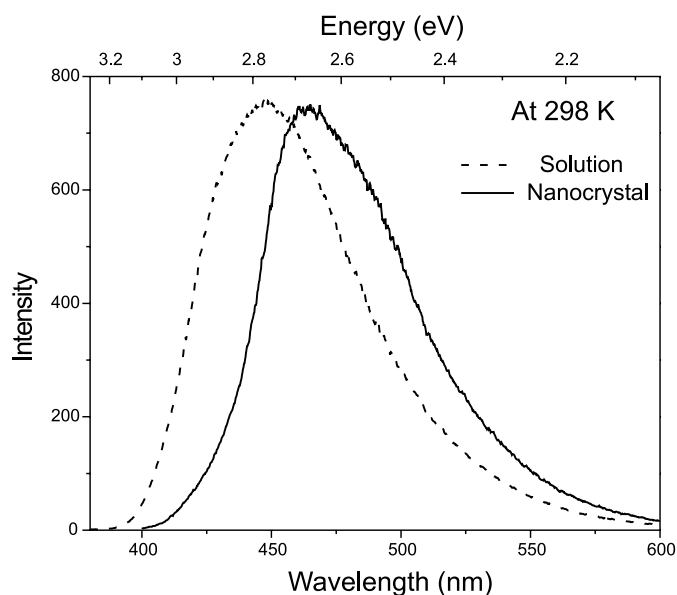
40 μL of a 1.0×10^{-3} mol·L^{-1} TPP–ethanol solution into 10 mL of water at 0°C. From this, we infer that the peak at longer wavelengths is associated only with aggregate formation; we have labelled it P_{CT}.

To accurately determine the detailed behavior of absorption transitions based on nanocrystal sizes, each spectrum in Fig. 2 was fitted to four Gaussian peaks using the parameters provided in Table 1. The inset in Fig. 2 is a sample fit for the spectrum of NC4. The most interesting phenomenon

is that the relative oscillator strength of the π–π^* transition, $F_{\pi-\pi*}$, which was determined from the peak area percentage of π–π^* absorption for the whole absorption of the pyrazoline ring, basically keeps the same value (about 83.5%) for different nanocrystal sizes. On the other hand, $F_{n-\pi*}$ decreases from 14.2 to 4.9%; this decrease is accompanied by an increase of F_{CT} from 3.8 to 10.7% with increasing nanocrystal size (from 30 to 170 nm).


The fluorescence excitation spectra of TPP nanocrystals in Fig. 3 show similar changes to those found in the absorption

spectra. The dashed line in Fig. 4 is the emission spectrum for a 1.0×10^{-5} mol·L^{-1} TPP–ethanol solution, with an asymmetric peak centered at 445 nm. The emission spectrum of NC4, with a peak at 465 nm, presents as a typical example of nanocrystal emission, since the nanocrystal size hardly influences its shape and peak energy. Note that the shape of the nanocrystal emission is similar to that of the solution emission; only the peak energy is red-shifted by 0.12 eV from the value for the dilute solution. Moreover, no significant changes in the emission shape were observed as the pump energy changed from $E = 4.96$ to 3.1 eV for both the solution and nanocrystal. To further clarify their assignment, fluorescence decays were measured for the solution (monitored at 445 nm) and for the nanocrystal (monitored at 465 nm) with the same excitation wavelength at 360 nm. All decay curves shown in Fig. 5 are well described using a single-exponential function with high accuracy. The fluorescence lifetimes of the solution and the nanocrystal were determined to be $\tau_s = 1.43 \pm 0.12$ ns and $\tau_n = 3.86 \pm 0.44$ ns, respectively. Since monomers are the dominant species in the dilute solution, and since the solution emission spectrum does not change with concentration, the solution emission

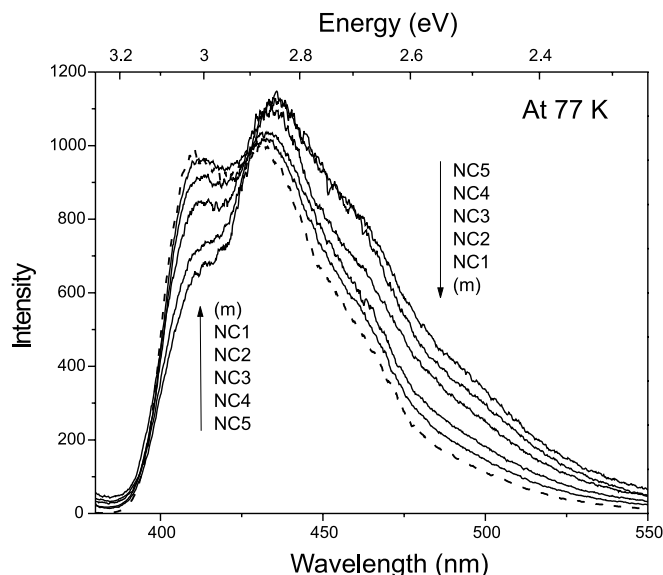
spectrum is assigned to the direct monomer transition from S_1 to S_0. In general, the emission from the intermolecular charge-transfer (CT) state exhibits a longer decay time than that from the initially excited state (31). As stated above, τ_n is about $2.5 \times \tau_s$. Therefore, it is likely that the increased fluorescence lifetime of τ_n results from the emission from CT to the ground state. Returning to Fig. 2, the gradually appearing absorption feature by aggregates at about 400 nm (P_{CT}) reasonably corresponds to the absorption from S_0 to CT.

To interpret the data of Figs. 2–5, we have indicated schematically the various transitions between the lowest energy states found for TPP nanocrystals (Fig. 6). Here, the lower energy of CT, as compared with S_1, is also consistent with this picture, where CT states are found generally at energies lower than the corresponding maxima of the monomer spectrum (14, 15). The difference between the solution and nanocrystals is that the latter presents the transitions involving CT states; the former rarely does. However, the fine structure shown in Fig. 6 cannot be observed at room temperature because of thermal fluctuation. Therefore, we have also measured the emission spectra, with excitation at 360 nm, in liquid nitrogen (temperature 77 K), as shown in Fig. 7.

In Fig. 7(m), the solution emission spectrum measured at 77 K, four peaks are observed at 405, 428, 454, and 482 nm, respectively. The equal spacing between them indicates that

Fig. 6. Proposed transitions for TPP molecules in nanocrystals. The wavy lines indicate the vibrational relaxation process. The dashed arrows indicate those transitions occurring only at 77 K.

Fig. 7. The emission spectra of different sizes of TPP nanocrystals dispersed in water measured at 77 K. The spectrum of a 1.0×10^{-5} mol·L^{-1} TPP–ethanol solution (m). The excitation wavelength is 360 nm.

Fig. 8. The emission spectra of NC4 measured at 77 K using different excitation wavelengths.


they originate from different vibrational states ($v_n = 0, 1, 2, 3$) in S_0. As for nanocrystals, the intensity of the peak at 405 nm, I_{405}, gradually decreases with increasing nanocrystal size; moreover, the low energy tail extends to longer wavelengths simultaneously. The nanocrystal emission at 77 K is different from that at room temperature, as it is influenced not only by nanocrystal size but also by the excitation wavelength λ_{ex}. An example is shown in Fig. 8(a), where the emission spectra of NC4 with different λ_{ex} display this tendency. When λ_{ex} is less than 400 nm, corresponding to excitation directly into S_1,[2] the two low-energy peaks (<450 nm) gradually rise as λ_{ex} increases. When λ_{ex} is bigger than 400 nm with excitation into CT states,[2] the nanocrystal emission is similar to that of the solution and may come directly from the CT states. In Fig. 8(b), we have added the solution emission spectrum (dashed line) — of which the intensity at 405 nm has been adjusted to be equal to I_{405} of NC4 excited at 360 nm — to the emission spectrum of NC4 excited at 405 nm (alternating dashed and dotted line). It is interesting that the sum (dotted line) is superposed with the emission spectrum of NC4 excited at 360 nm (solid line). This indicates that the nanocrystal emission originates from both S_1 and CT at 77 K when excitation energy is above S_1 (cf. Fig. 6). Further, the intensity is redistributed from S_1 to CT with increasing nanocrystal size. The coexistence of emission transitions [S_1–S_0] and [CT–S_0] indicates that the S_1 and CT states are in equilibrium in the nanocrystals at

---

[2] According to the absorption spectra of TPP nanocrystals with parameters listed in Table 1, the wavelength 400 nm (3.1 eV) is just the dividing line between the S_1 and CT states.

Fig. 9. The optimized structure of two neighboring molecules in nanocrystals.
77 K. At room temperature, the S_1 states are efficiently deactivated nonradiatively via the exciton band by thermal activation and energy hopping, and thus only the [CT–S_0] emission can be observed.

Figure 9, the optimized structure of two neighboring TPP molecules in the nanocrystals, provides a clue to help our understanding of how the intermolecular charge transfer occurs in TPP nanocrystals. It can be seen from Fig. 9 that the phenyl and pyrazoline rings of two neighboring molecules overlap to some extent, resulting in their absorption shifting to the lower energy side. Because of the inverse orbital orientation of n electrons the orbital overlap between them is small, leading to the small differences in n–π^* absorption with differing nanocrystal sizes. In 2-pyrazolines, the charge distribution of N-1 (N at the 1-position) changes from negative in the ground state to positive in the excited state because of the conjugated charge-transfer from N-1 to C-3 (23). We infer that the intermolecular charge-transfer may occur from N-1 of one molecule to its neighbors. This should lead to a decrement in the probability of optical transitions that involve the n electrons of nitrogen and is further supported by the simultaneous occurrence of the decrement of $F_{n-\pi^*}$ and the increment of F_{CT} with increasing nanocrystal size, as mentioned above. The increment of F_{CT} reflects the formation process of the CT exciton in TPP nanocrystals.

Summary

In summary, the size-dependent optical properties of TPP nanocrystals were studied using absorption and fluorescence spectra on nanocrystals of different sizes. Their absorption and emission transitions, as compared with those of a dilute solution, have been investigated, as a function of nanocrystal size, at both 298 and 77 K. We found that the optical properties of TPP nanocrystals possess a special size-dependence because of the formation of the charge-transfer exciton and the various interactions between different molecular orbitals according to the molecular model calculations. The present study adds to our understanding of excitons in organic semiconductors.

An ab initio study of conformations and IR spectra of 5-substituted 1,3-cyclopentadienes

Cory C. Pye, James D. Xidos, D. Jean Burnell, and Raymond A. Poirier

Abstract: A computational study of 5-substituted cyclopentadienes is presented. The substituents considered are the group 14–17 elements of the second through fifth periods, saturated by hydrogens as needed to fulfill normal valence requirements. The conformational characteristics are examined and rationalized using bond–antibond interactions and steric arguments. Trends in vibrational frequencies are discussed and compared with experiment where possible.

Key words: cyclopentadiene, ab initio, spectra.

Résumé : On présente les résultats d'une étude théorique de cyclopentadiènes portant des substituants en position 5. Les substituants considérés sont les éléments des groupes 14 à 17, de la deuxième à la cinquième période, saturés par des atomes d'hydrogène pour satisfaire les valences normales requises. On a examiné les caractéristiques conformationnelles et on les a rationalisées en faisant appel à des arguments stériques et d'autres basés sur des interactions liantes et antiliantes. On discute des tendances dans les fréquences de vibration et on les compare avec des valeurs expérimentales lorsque celles-ci sont disponibles.

Mots clés : cyclopentadiène, ab initio, spectres.

[Traduit par la Rédaction]

Introduction

During the course of our investigations of facial selectivity in the Diels–Alder reaction, we found that 5-substituted cyclopentadienes could give a range of facial selectivities from 100% *syn* to 100% *anti* selectivity, simply by varying the substituent (1,2). Although a variety of explanations have been proposed (3–6), our own investigations have suggested that a simple modification of the concept of steric bulk is sufficient to explain this phenomena (7, 8).

The synthesis of 5-substituted cyclopentadienes and their subsequent reaction with dienophiles is useful for validating or refuting theories of facial selectivity, but the existence of these compounds is sometimes fleeting. The identification of these species, once created, needs to be proven. In this paper, various spectroscopic data are calculated and compared to known experimental literature data where available. It is hoped that the following analysis will eventually aid in the experimental detection of other as yet unknown species. In particular, we will give information on the structure and harmonic vibrational frequencies to facilitate comparison with experimental diffraction, microwave measurements, and IR and Raman spectra, respectively. In addition, a full examination of substituent conformation is presented and rationalized.

Method

Calculations were performed using MUNGAUSS (9), Gaussian 92 (10), or Gaussian 98 (11), utilizing the STO-3G (12), 3-21G (13), 6-31G* (14), and 6-31+G* (15) basis sets. Huzinaga's basis sets for Ge-Br (4333/433/4) and Sn-I (43333/4333/44), decontracted in the *sp*-valence region (21/21) and polarization functions added, were used in conjunction with the 6-31G* basis set (16). Cartesian (six) *d*-functions were used throughout except for STO-3G. Diffuse functions were determined in an even-tempered fashion separately for the *s* and *p* shells and then geometrically averaged to give the exponent of an *sp* diffuse shell. These augmented the Huzinaga basis sets for use in conjunction with the 6-31+G* calculations, as in reference (17). The resulting diffuse-*sp* exponents are 0.015 (Ge), 0.019 (As), 0.036 (Se), 0.042 (Br), 0.021 (Sn), 0.026 (Sb), 0.030 (Te), and 0.034 (I). For brevity, the results and discussion using the STO-3G and 3-21G basis sets are presented in the supplementary material[2] (18).

The MP2 calculations utilize the frozen core approximation. Default optimization specifications were normally used. For the 6-31G* and higher basis sets, a frequency calculation was performed at the same level and the resulting Hessian was used in the following optimization. Z-matrix coordinates constrained to the appropriate symmetry were used as required to speed up the optimizations. If symmetry constraints led to a transition state instead of a minimum, this would show up as the presence of one or more imaginary frequencies not belonging to the totally symmetric irreducible representation. The Hessian was evaluated at the first geometry for the first level in a series in order

to aid geometry convergence.

In all tables, bond lengths are given in Ångströms and angles in degrees. A general trend that was noticed is that d-polarization functions added to heteroatoms of the first and second row tend to shorten bonds to adjacent atoms, whereas when they are added to heteroatoms to the third and fourth row they tend to leave unchanged or to increase bond lengths to adjacent atoms. Of course, for first and second row atoms the d-functions are genuine polarization functions in the sense that they augment the basis set with functions of higher symmetry. For third and fourth row atoms, however, these functions may serve partly to describe the more diffuse region of the occupied d-shells in addition to polarizing the atom in the molecular environment.

Results and discussion

Geometry and conformation
1,3-Cyclopentadiene

The structure of cyclopentadiene is presented in Fig. 1. The total electronic energies, selected geometrical data, lower-level conformational energies, predicted IR spectra of synclinal structures, and a short discussion of the lower-level results are found in the supplementary material. Within Hartree–Fock levels the structure varied little with basis set, and the largest structural changes were about 0.015 Å in the C—C bond lengths, 0.012 Å in the C—H bond lengths, and about 1° in the angles (see Table 1 and Supplementary Table S5). At the MP2 level the angles are relatively unchanged; however, the bond lengths are changed. The C—C single bond length decreases by up to 0.01 Å, whereas the C=C double bond increases by 0.025 Å. The C—H bond length increases by about 0.01 Å. The 6-31G** structure differed from the 6-31G* structure only in the last reported significant figure and is not listed, whereas the 6-31+G* differed a little more. The geometry is reasonably close to previous ab initio calculations (19, 20) and to the experimental temperature-independent microwave structures (21–24), but somewhat further from the temperature-dependent X-ray (25), electron diffraction (26) (see Table 2), and NMR (27) structures. The errors at the MP2/6-31+G* level are within 0.01 D ($1\,D = 3.335641 \times 10^{-30}$ C m) (dipole moment; expt = 0.420 ± 0.003 (24)) and 0.01 Å (structure).

In the C_5-substituted cyclopentadienes similar basis set changes occur in the cyclopentadienyl unit. The largest geometry changes upon substitution should occur in the bond lengths and angles adjacent to the substituent.

5-Halocyclopentadienes

The structures of 5-halocyclopentadienes are given in Fig. 1. The picture of 5-fluorocyclopentadiene in particular shows how this diene would react *syn*, as the C—F bond is angled away from the π-system; therefore, it would not have to distort as much for *syn* addition as for *anti* addition (7, 8). Accurate geometries for 5-halocyclopentadienes have not yet been determined experimentally, though all have been prepared (28–30). The X-C-H and X-C-C angles decrease down the group at the 6-31G* level, whereas the H-C-C angle increases (Table 3).

The addition of diffuse functions and of adding correlation has very little effect on the bond angles listed. The effect of adding diffuse functions is to shorten the carbon—halogen bond

length by about 0.005 Å, except for fluorine, for which it increases it by a similar amount. The effect of adding correlation is to decrease the carbon—halogen bond length by up to 0.01 Å, except for fluorine, where the bond length increases by 0.03 Å. These results demonstrate the extreme importance of basis set and correlation effects for fluorine-containing systems.

5-Chalcocyclopentadienes and conformation

No unsubstituted 5-chalcocyclopentadienes have been isolated, presumably because of a rapid [1,5]-sigmatropic rearrangement (i.e., 1,2-hydrogen shift) to give an enol analogue followed by rapid conversion via a 1,3-hydrogen shift to the corresponding ketone analogue (see Fig. 2). 5-Chalcocyclopentadienes have been implicated in the decomposition of substituted dicyclopentadienes (Cp$_2$OX, X = H, COCH$_3$) (31, 32) via a retro-Diels–Alder reaction. The MNDO method estimates that 2,4-cyclopentadien-1-ol is about 30 kJ mol^{-1} less stable than its isomeric enol forms (33), as suggested by the acetate derivative ratios (34). Some examples of substituted derivatives that have been prepared include the pentamethyl-2,4-cyclopentadiene-1-ol and its methyl ether, the analogous thiol and S-oxidized forms (35, 36), and 1-(methylthio)cyclopenta-2,4-diene (37).

Figure 3 gives the structures of all four conformations for all four compounds. Tables S7, S8, S9, and S10 show that the C—C bond is lengthened relative to cyclopentadiene, but this difference decreases quickly down the series. The O-C-C, S-C-C, Se-C-C, and Te-C-C angles are all larger than the corresponding H-C-C angle of cyclopentadiene, as was noted previously for CpF, but this difference also decreases down the series. The H-C-C angle is smaller in both CpOH and CpSH than in CpH, but the other two members of the series show little difference.

Adding correlation increases the C—O and the O—H bond lengths by 0.02–0.03 Å. With the exception of H-O-C, the bond angles seem insensitive to level. The S—C bond length hardly changes when correlation is included, but the S—H bond length increases by about 0.015 Å. Correlation effects on the geometry of CpSeH and CpTeH are similar to that of CpSH. It should be noted that there are relatively few ab initio calculations for organic selenium and tellurium compounds (38–40).

An alternate conformational view of chalcogenocyclopentadienes is shown in Fig. 4. The conformational changes resemble in many respects those presented in reference (41). In general, when there is an eclipsing interaction between the X—H bond and either a C—C or C—H bond the X—H bond shortens (by up to 0.006 Å) and the connecting X—C bond lengthens (by up to 0.017 Å). In general, the H-X-C bond angle increases by at most 1.6° upon eclipsing, but as one goes down a group this increase becomes smaller, especially when comparing the two asymmetric structures. The X-C-H bond angle is anomalously small in the *anti*-periplanar conformers (by up to 5°), but this becomes less pronounced as one progresses down the group. The H-C-C angle changes by at most 2°, but in no obvious pattern. The X-C-C angle undergoes large changes of up to 5°, with the smallest angle consistently being for the synclinal conformer in which the C—C bond is *trans* to the X—H bond. For CpOH, the largest X-C-C angle is found for the anticlinal conformer in which the C—C bond is *cis* to the X-H bond, whereas for the others the *anti*-periplanar conformer gives the largest angle. For the larger atoms, the relation between torsion and X-C-C is fairly flat near the maximum X-C-C angle.

5-Pnictocyclopentadienes

Very recently, the first report of the preparation of unsubstituted 2,4-cyclopentadienylphosphine and arsine appeared (42). The amine and stibine are unknown. Several substituted derivatives are known, such as the cyclopentadienyl difluorophosphine (46–48) and the pentamethylcyclopentadienyl amine (35, 36, 43), phosphine (44), and dichlorostibine (45). In addition, an MNDO study of the [1,5]-sigmatropic rearrangement involving the motion of the phosphorus group has been carried out (49, 50).

cyclopentadienes, but unlike these, the angular parameters are not disposed predominantly to one side of those of CpH, which is most likely a result of the electronegativity changes relative to hydrogen. The parameters of CpPH$_2$ most closely resemble CpH. Diffuse functions have little effect on the geometry, whereas adding correlation effects increases the N—C bond length by about 0.01 Å and the X—H bond length by about 0.015 Å.

An alternate view of conformation of pnictocyclopentadienes is shown in Fig. 6, in which the conformational designation refers to the pnictogen lone pair. If there exists an eclipsing interaction with an X—H bond, then the X—C bond lengthens by up to 0.02 Å, and the X—H bond shortens by as much as 0.008 Å in some cases. An eclipsing interaction can also increase the H-X-C angle by up to 2°. The X-C-H angle is anomalously *larger* in the *anti*-periplanar conformation by up to 5°. The largest X-C-C angle always occurs in the synclinal structure,

in which the nitrogen lone pair is *trans* to the C—C bond in question. The smallest X-C-C angle usually occurs in the *anti*-periplanar structure.

Group 14 cyclopentadienes

The group 14 cyclopentadienes have been the most extensively studied of our series. 5-Methylcyclopentadiene was first separated from its more stable isomers by Csicsery (51) using vapor-phase chromatography, and it constituted about 3% of the total equilibrium mixture. It can also be prepared by the methylation of CpMgBr at 263 K, but this isomerizes to the 1-isomer at 298 K in about 3 h. Further isomerization to an equilibrium mixture of the 1- and 2-isomers occurs within a couple of days (52). The isomerization was shown to proceed by a 1,2-hydrogen shift with an activation barrier of 83.3 ± 1.3 kJ mol^{-1} as determined by NMR (53, 54). Evidence for methyl migration was also seen in trimethylcyclopentadienes with a barrier of about 185 kJ mol^{-1} (55), which agreed well

Fig. 6. Conformation of 2,4-cyclopentadienylamine.

| antiperiplanar | anticlinal | synclinal | synperiplanar |
with the MINDO/3 result of 194.3 kJ mol^{-1} for CpMe (56).

Silylcyclopentadiene was first prepared by the reaction of potassium cyclopentadienide with silyl bromide at 77 K (57). The structure was determined by electron diffraction soon after (58). CpSiH$_3$ undergoes a rapid 1,2-silyl migration (248 K) and a slower 1,2-hydrogen shift (339 K) (59). A joint photo-electron and ab initio study suggested that the fluxional behavior of CpSiH$_3$ may be related to the delocalization of the Si—C bonding orbital with the π-system (60). The activation barrier for silyl migration was determined both from proton (59.4 ± 1.0 kJ mol^{-1}) and ^{13}C NMR lineshape analysis (57.7 ± 0.1 kJ mol^{-1}) (61). An MNDO study overestimates this barrier (99.1 kJ mol^{-1}) (62).

Germylcyclopentadiene was prepared in a similar fashion to silylcyclopentadiene and the NMR behavior suggested a fluxional molecule (63). The X-ray and electron diffraction structure of this compound has been published (64). The trimethyl derivative undergoes a 1,2-shift with a barrier of 38.5 ± 4.2 kJ mol^{-1}, and the corresponding stannane, 32.6 ± 4.2 kJ mol^{-1} (65).

Tables S15, S16, S17, and S18 show that, upon substitution, the C—C bond length becomes slightly longer in the case of CpCH$_3$, but becomes shorter for the higher analogues. The X-C-C and X-C-H angles decrease upon going down a group, with only the CpCH$_3$ angle being larger than cyclopentadiene, whereas the H-C-C angle increases. The effect of correlation is to slightly lengthen the X—H bond lengths.

The existence of only two conformational possibilities simplifies our analysis considerably. The X—C and C—C bonds in the *syn*-periplanar conformer are longer than in the staggered conformer by as much as 0.015 Å and 0.005 Å, respectively, whereas no clear trend exists for the H—X bond length. The X-C-C and H-C-C angles increase and decrease by as much as $2.7°$ and $1.8°$, respectively, upon eclipsing. The X-C-H angle always decreases (except for CpCH$_3$) by up to $1.4°$. No persistent trend for the angles surrounding the substituent emerges.

A comparison between the experimental and our best theoretical structures is given in Table 4. The X—C and X—H distance is overestimated here, whereas no obvious trend is seen for the C—C distance. It is understandable that the hydrogen positions are given with poor accuracy by these diffraction techniques. The calculated results are outside the error bars of experiment because they provide the r_e structure (0 K, bottom of PES), whereas the experiment measures the time-averaged structure at a finite temperature, resulting in a sampling of several vibrational states. It is also possible that the agreement may improve with an extension of the basis set. A microwave-determined structure for these compounds would prove useful in this case,

as with cyclopentadiene itself. In addition, the barrier to rotation could possibly be determined in this way (66).

Conformation energies
Chalcocyclopentadienes

The barriers to rotation are shown in Table 5. The barriers $E_{sc \to spp}$ are compared to the corresponding results for CH$_3$XH at 6-31G* (67) (See Table S20. The '*' represents our calculated value). In general, the methanol analogue barriers are larger for O and S, similar for Se, and smaller for Te. Generally speaking, adding diffuse functions or correlation effects changes the relative potential energies usually by less than 1 kJ mol^{-1}.

Pnictocyclopentadienes

The barriers to internal rotation in 5-pnictocyclopentadienes are shown in Table 6. The preference for an *anti*-periplanar conformer increases as one goes down a period, even though CpNH$_2$ itself assumes the synclinal conformer at 6-31G*. In general the barriers in substituted cyclopentadienes are larger than the corresponding pnictomethanes, as seen from Table S20. The effect of adding diffuse functions or correlation effects is still small, but larger than the effect for the chalcogen-containing systems. Correlation is the more important of the two effects.

Group 14 Cyclopentadienes

From Table 7, the barriers are seen to be relatively insensitive to basis set with the values agreeing quite well at the split-valence level. The barriers are larger than in the corresponding methyl derivatives (see Table S20). Diffuse functions have little effect, but correlation energy seems to be very important here for the silyl-, germyl-, and stannyl-substituted cyclopentadienes. This follows the trend of the increasing importance of correlation energy as the number of attached hydrogens increases.

Discussion of conformation

There are numerous ways of explaining the conformational preferences about a σ-bond, but the approach used in this work will be that taken by Brunck, Reed, and Weinhold (68, 69), which states that the predominant conformational preferences can be explained by bond–antibond interactions. Other studies (70) have used Fourier analysis, but are strictly applicable only to molecules possessing a rough three-fold symmetry axis and thus cannot be applied meaningfully to molecules involving the higher pnictogen series in which the H-X-H angles are closer

to 90° than 109.5°. The justification for our chosen approach will lie in the ease of explanation of the major geometric and energetic conformational trends.

If we consider the *anti*-periplanar form of CpOH, then we can count four *trans* vicinal localized orbital interactions, giving an interaction energy

$$[1] \qquad E_{\text{antiperiplanar}} = 2E_{n,\sigma_{CC}^*} + E_{\sigma_{OH},\sigma_{CH}^*} + E_{\sigma_{CH},\sigma_{OH}^*}$$

Similarly, the synclinal form of CpOH gives

$$[2] \qquad E_{\text{synclinal}} = E_{n,\sigma_{CC}^*} + E_{n,\sigma_{CH}^*} + E_{\sigma_{OH},\sigma_{CC}^*}$$
$$+ E_{\sigma_{CC},\sigma_{OH}^*}$$

The strongest interactions are normally those involving lone pairs donating into vicinal antibonds polarized toward the rotation axis, i.e., corresponding to vicinal bonds (such as C—F)

polarized away from the axis, since in this case the overlap is greatest. The C—H bond is slightly polarized toward the carbon atom — which has the higher electronegativity — and thus its 'antibond' would be slightly polarized toward the hydrogen. This results in poorer overlap with the 'lone pair' than that seen in a C—C antibond. In this case the *anti*-periplanar conformer will be favored. Because the overlap depends on the distance between the axis atoms, the difference in energy between these conformers should decrease as oxygen is successively replaced by sulfur, selenium, and tellurium, which it does. In fact, the two conformers of CpTeH are essentially degenerate on the potential energy surface.

If we consider the *anti*-periplanar form of CpNH$_2$, then we can count five *trans* interactions, giving an interaction energy

$$[3] \qquad E_{\text{antiperiplanar}} = E_{n,\sigma_{CH}^*} + 2E_{\sigma_{NH},\sigma_{CC}^*} + 2E_{\sigma_{CC},\sigma_{NH}^*}$$

Similarly, the synclinal form of CpNH$_2$ gives

[4] $\quad E_{\text{synclinal}} = E_{n,\sigma^*_{\text{CC}}} + E_{\sigma_{\text{NH}},\sigma^*_{\text{CC}}} + E_{\sigma_{\text{NH}},\sigma^*_{\text{CH}}}$
$\qquad\qquad\qquad + E_{\sigma_{\text{CC}},\sigma^*_{\text{NH}}} + E_{\sigma_{\text{CH}},\sigma^*_{\text{NH}}}$

For similar reasons, the synclinal form of CpNH$_2$ will be favored in this case. Because of the quicker drop in electronegativity and longer bond lengths in this case the preference does not

persist down the group and other terms start playing an important role, but the difference is still very slight, being less than 4.0 kJ mol^{-1}. Steric interactions between the *anti*-periplanar hydrogen and the two vicinal C—C bonds in the larger substituents may favor the *anti*-periplanar arrangement because of the closer match in the lengths of these bonds.

The geometry changes also agree with the idea of bond–antibond interactions. The shorter X—H bond in the *syn*-peri-

planar forms is a result of the *cis*-interaction being weaker than the *trans*-interaction, and thus the antibond contribution is lower. The longer X—C bond may simply be explained by stronger steric interactions in the Lewis structure. In the Group IV series, hardly any trend is noticed, because the X—H antibond, being polarized predominantly toward the hydrogen, is a poor acceptor.

For CpOH, the widening of H-O-C in a *syn*-periplanar arrangement is consistent with a simple steric effect, especially with the C—H bond. As one goes down the group, the steric interaction with the C—C bonds become greater leading to the largest angles in the synclinal form. The 'anomalous' smallness of the X-C-H angle in the *anti*-periplanar conformer can be explained simply as the absence of any strong lone pair donation into the C—H antibond, whereas all of the other conformers have either a *cis* or *trans* donation to C—H. For the same reason the smallest X-C-C angle will be that containing no lone pair donation, i.e., *trans* to the X—H bond.

For CpNH$_2$, the "anomalous" largeness of the X-C-H angle in the *anti*-periplanar conformer is consistent with a strong interaction of the nitrogen lone pair with the C—H antibond. Similarly, the largest X-C-C angle occurs for the synclinal structure, in which the nitrogen lone pair is *trans* to the C—C bond in question.

Vibrational frequencies

The vibrational frequencies of cyclopentadiene itself are given in Table 8. Adding diffuse functions hardly affects the frequency (usually within 10 cm^{-1}). Adding correlation effects has a large influence on the frequency, generally decreasing it, although some modes are affected much more than others. The correlated frequency could be predicted from the Hartree–Fock frequency by using a mode-specific multiplicative factor (for example, 0.97 for C(sp^3)—C (or H), 0.962 for C(sp^2)—H, 0.906 for C=C, 0.94 for CH bends, 0.83–0.90 for out-of-plane (oop) H bends, 0.87–0.95 for ring deformations, and 0.92 for CH$_2$ rock, twist, and wags).

The IR spectra of cyclopentadiene and 5-methylcyclopentadiene (51) (% transmittance vs. wavelength) were converted to absorbance vs. wavenumber and compared with the theoretical spectra (MP2/6-31+G*) in Fig. 7. Errors in the experimental estimation of frequencies range from 2–40 cm^{-1}. Because of the lack of an internal standard, the intensity scales will be different. The assignment of modes is fairly straightforward here. The most intense modes observed in liquid cyclopentadiene correlate well with the predicted gas phase results. There appears to be an enhancement of the (predicted) very weak C=C stretching motion (1590, 1640), which appears to be in Fermi

resonance with the first overtone of a ring deformation at 812. The H-C= deformation also appears to be in Fermi resonance (1240, 1290) with the first overtone of the H-C out-of-plane deformation at 664. Of course, we cannot rule out environmental effects or impurities.
The theoretical spectra of the halosubstituted cyclopentadienes are given in Fig. 8. The intense hydrogen out-of-plane deformation, the carbon-halogen stretching motion, and the HCX hydrogen bending motion increases in frequency on progressing from iodine to fluorine. In the fluoro derivative, many bands are predicted to be more intense in the IR spectra compared with the other halogens. This is probably due to the difference in electronegativity between carbon and fluorine, which gives a large bond dipole. Any normal mode that has a significant C-F stretching component would be increased in intensity.

The theoretical spectra of the *anti*-periplanar and synclinal chalcosubstituted cyclopentadienes are given in Figs. 9 and S1. For the *anti*-periplanar series it is the OH and TeH that give the largest number of intense modes. In these cases, the electronegativity of the substituent is sufficiently different from carbon to give rise to a greater number of intense modes. Some trends when comparing the two conformers are the lower C$_5$-H stretching frequency (OH) and HCX deformation frequencies (all) in the synclinal conformers. These indicate that the C—H bond is weaker, which is consistent with strong donation of the chalcogen lone pair into the C—H antibond. If the alcohol is ever observed our predictions suggest that it will predomi-

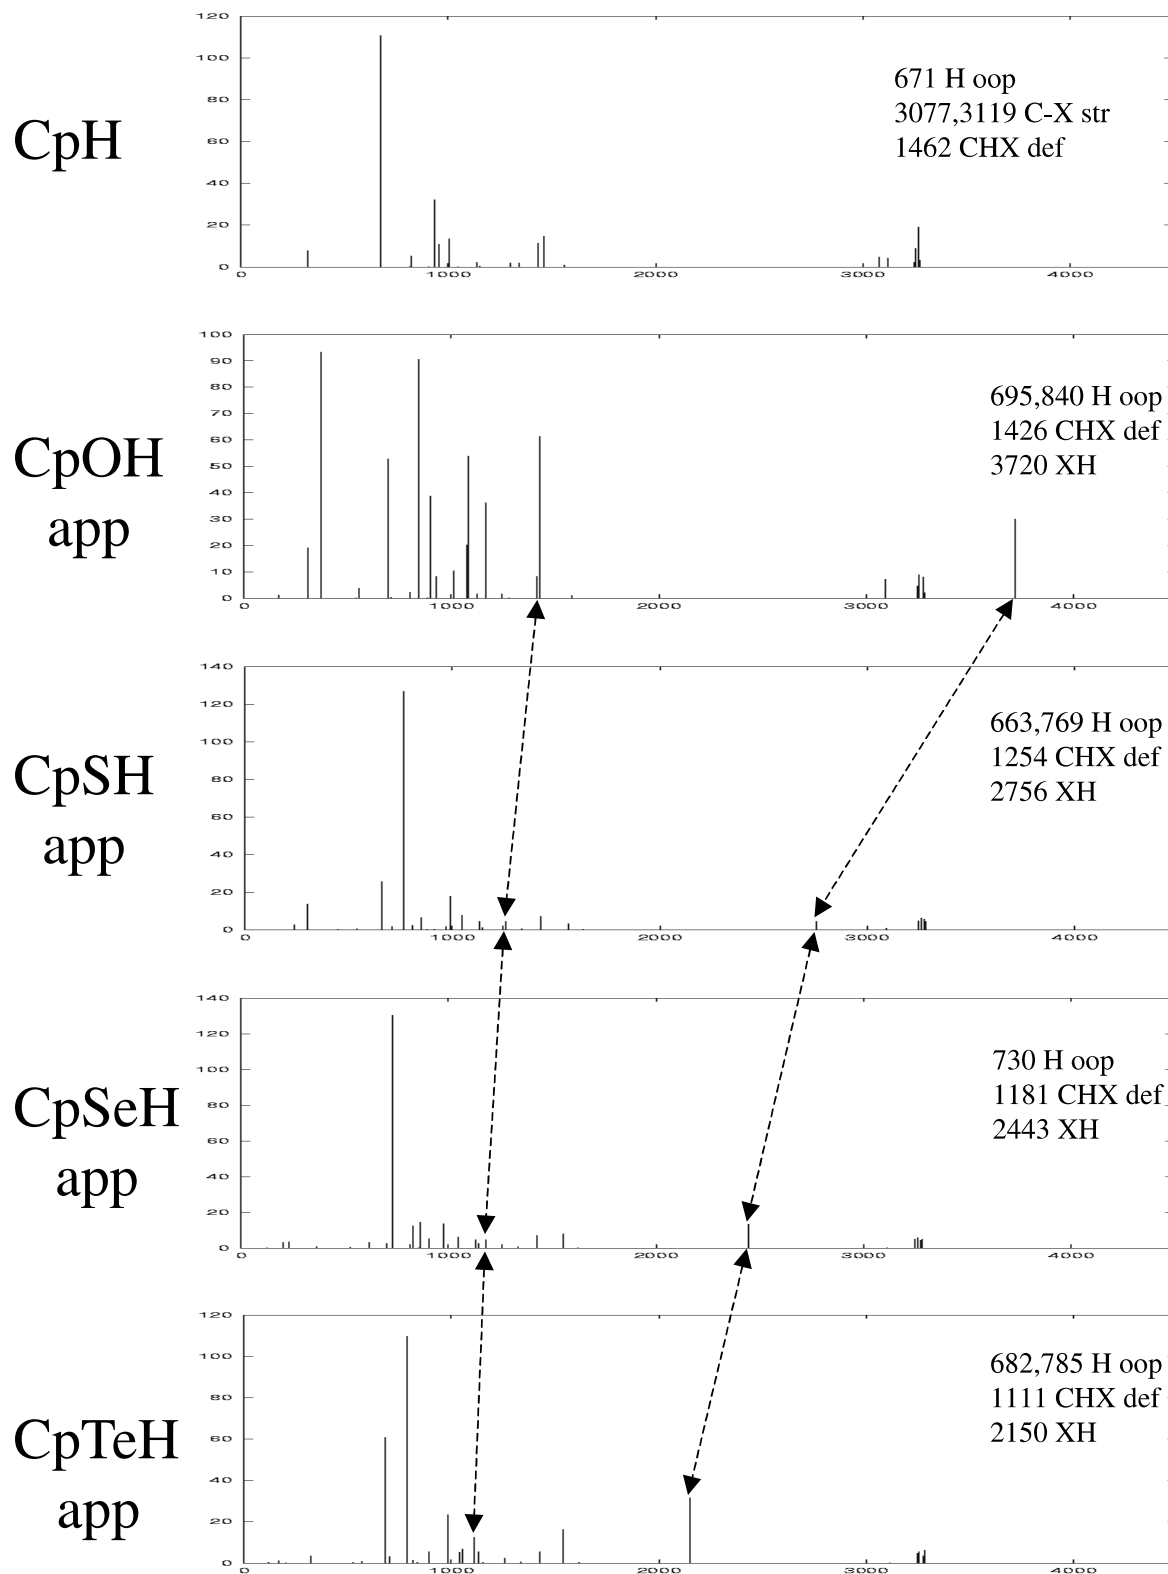
nantly be in the *app* conformer, whereas the higher analogues will have significant contribution from the *sc* conformer, and thus the bands will be averaged out.

The theoretical spectra of the *anti*-periplanar and synclinal

pnictosubstituted cyclopentadienes are given in Figs. 10 and S2. Except for the amine, the spectra of the *app* conformer is similar to the *sc* conformer, as contrasted with the chalcogen cases. Except for the amine, the two X-H stretching modes are

Fig. 9. MP2/6-31+G* frequencies of 5-chalco-1,3-cyclopentadiene.


very intense. The wagging motion of the substituent is also prominent, whereas the bending motion is less intense. The C_5-H stretching frequency (NH_2) and the HCX deformation frequencies (all) are lower in the *anti*-periplanar conformer, which is consistent with interaction of the pnictogen lone pair into the C—H antibond.

The theoretical spectra of the group 14 substituted cyclopentadienes are given in Fig. 11. The H-stretching modes of the

titative designators (vw 95% T, w 90% T, m 65%, s 35%, vs 10% T, vvs 5% T) and then to absorbance. The agreement in both the intensity and frequency axes is very good if one takes into account the standard errors associated with anharmonicity, especially for the modes involving hydrogen stretches.

Conclusions

The structures of 5-substituted cyclopentadienes agree well with most of the available experimental results. A pronounced basis set dependence of the structures is noted in some cases. The conformational trends in geometry and energy can be explained on the basis of bond–antibond interaction, especially where formal lone pairs are involved. Our calculated structures and vibrational spectra agree with available experimental data.

Simultaneous determination of copper, lead, cadmium, zinc, and selenium in cow liver by differential pulse polarography

Güler Somer, Gülbeniz Guliyeva, Güler Ekmekci, and Olcay Sendil

Abstract: A fast and simple method was established for the determination of trace elements in liver. DP polarograms of wet digested liver samples were taken in acetate buffer, pH about 4, for lead, cadmium, and zinc determinations. For copper, addition of EDTA at pH 4 was needed for a better separation from the iron peak. Selenite ion was determined using the hydrogen catalytic peak after the addition of Mo(VI) to the same solution. Trace element levels were different for two separate sections of liver. For the first section (S_1) the quantities were found to be 8.12 ± 0.21 mg g^{-1} Cu, 1.16 ± 0.12 mg g^{-1} Zn, 1.09 ± 0.11 mg g^{-1} Cd, 0.59 ± 0.07 mg g^{-1} Pb, and 2.05 ± 0.22 mg g^{-1} Se, in dry liver. For the second section (S_2) the results were the same for selenium, but Cd was too small to be detected. The other trace element quantities were 0.48 mg g^{-1} Cu, 0.22 mg g^{-1} Pb, and 0.29 mg g^{-1} zinc. The validity of the method was demonstrated with a synthetic sample resembling liver composition. This method enabled the simultaneous determination of heavy trace elements such as copper, lead, cadmium, molybdenum, selenium, and zinc by using an inexpensive instrument and without any separation or pre-concentration procedures.

Key words: cow liver, determination, differential pulse polarography, trace elements.

Résumé : On a développé une méthode simple et rapide pour déterminer les éléments à l'état de trace dans le foie. Afin d'évaluer les concentrations de plomb, de cadmium et de zinc, on a mesuré les polarogrammes à pulsation différentielle d'échantillons frais de foie dans un tampon d'acétate, à un pH d'environ 4. Pour le cuivre, à un pH de 4, il est nécessaire d'ajouter de l'EDTA afin d'obtenir une meilleure séparation du pic du fer. On a déterminé l'ion sélénite en faisant appel au pic catalytique de l'hydrogène après addition de Mo(VI) à la solution. Les concentrations des éléments à l'état de trace sont différentes pour deux sections différentes du foie. Dans la première section (S_1) de foie sec, on a trouvé les quantités suivantes: $8,21 \pm 0,21$ mg g^{-1} de Cu, $1,16 \pm 0,12$ mg g^{-1} de Zn, $1,09 \pm 0,11$ mg g^{-1} de Cd, $0,59 \pm 0,07$ mg g^{-1} de Pb et $2,05 \pm 0,22$ mg g^{-1} de Se. Dans la deuxième section (S_2) les résultats sont les mêmes pour le sélénium, mais les quantités de Cd sont trop faibles pour être détecter. Les quantités des autres éléments présents à l'état de trace sont de $0,48$ mg g^{-1} de Cu, $0,22$ mg g^{-1} de Pb et $0,29$ mg g^{-1} de zinc. On a démontré la validité de la méthode à l'aide d'un échantillon synthétique dont la composition ressemble à celle du foie. Cette méthode permet de déterminer de façon simultanée des traces d'éléments de métaux lourds, tels le cuivre, le plomb, le cadmium, le molybdène, le sélénium et le zinc en faisant appel à des instruments peu coûteux et sans nécessité de procéder à des séparations ou à des préconcentrations.

Mots clés: foie de vache, polarographie à pulsation différentielle, éléments à l'état de trace.

Introduction

The total trace element levels have become of prime importance to aid both the clinician in the diagnosis and treatment of a variety of diseases and the life science researcher in the investigation of the role of trace elements in health and disease. Considering biological research, the role of some trace and ultra-trace elements in the body is very rich

and varied. Some of them are essential to life while others are toxic even at very low concentrations (1–3). Since these elements are taken in mostly by human diet, the determination of their concentration in food is very important. Liver is known to deposit many trace elements; thus, cow liver is a potent source of heavy elements. Unfortunately, very few investigations have been attempted relating to the determination of the concentration of heavy elements. Most of the work has been concentrated on their effect on liver and physiologic body functions (4–6). The effect of ingestion of heliotrope (homeopathic medicine) and copper on the concentration of zinc, selenium, and molybdenum in the liver of the sheep has been studied (4); the ingestion of heliotrope was found to reduce liver concentrations of zinc and molybdenum. The concentration of selenium in the liver was found to increase only when heliotrope was given with copper. The depletion of glutathion in selenium-deficient liver and kid-

ney of rats lead to necrosis in these organs, which is associated with evidence of lipid peroxidation (7). Some elements such as Co, Se, Mo, and Cu in liver have been analyzed by flame and electrothermal AAS after extraction of their complexes with APDC into chloroform (8). These analyses have shown the analytical details and instrument parameters for the determination of these four elements in National Institute of Standards and Technology standard reference material (NIST SRM) bovine liver. In another study, it was found that the quantitative distribution of trace elements (P, Fe, Zn, Cu, Mn, Mo, Co) in the liver lobes of cattle and of pigs was not uniform, as a result of different metabolism in different parts of the organ (9).

Since many elements important in the biological life of the body deposit in the liver, their concentrations have to be determined very accurately. Determination of trace elements in biological samples is usually difficult because of long and tedious digestion procedures and risks of interference problems. The interfering ions have to be separated by pre-concentration techniques such as solvent extraction, ion exchange, or hydride generation. These are all time-consuming procedures, and losses of elements are also possible. It is therefore very important to accomplish the determination with minimum interference problems. With electrochemical methods, the interference problems can be solved by changing only either the supporting electrolyte or the pH (10, 11). These methods require relatively inexpensive instrumentation, are capable of determining elements accurately at trace and ultra-trace levels, and have demonstrated the ability for multi-element determination.

This paper describes a simple polarographic method for the determination of trace elements in liver. In this proposed method there is no need for sophisticated instruments or tedious separation procedures.

Experimental

Materials

A polarographic analyzer (PAR 174 A) equipped with a PAR mercury drop timer was used. The drop time of the electrode was in the range 2 to 3 s (2.37 mg s^{-1}). A Kalusek electrolytic cell with a reference saturated calomel electrode (SCE), separated by a liquid junction, was used in the three-electrode configuration. The counter electrode was platinum wire. The polarograms were recorded with a Linseis (LY 1600) X-Y recorder under the conditions of a drop life of 1 s, a scan rate of 5 mVs^{-1}, and a pulse amplitude of 50 mV.

Reagents

All reagents used were of analytical reagent grade (pro-analysis). Triply-distilled water was used in the preparation of all solutions and at all stages of analysis. The mercury used in the dropping mercury electrode was obtained from Merck (Darmstadt, Germany). Contaminated mercury was cleaned by passing it successively through dilute HNO$_3$ and water columns, in the form of fine droplets, using a platinum wire gauze. The collected mercury was dried between sheets of filter paper. A polarogram of this mercury was taken before use to ensure the absence of impurities.

Stock standard solutions (0.1 M) of Pb, Cu, Cd, and Zn were prepared with triply distilled water from their nitrate and sulphate salts. Selenite stock solution was prepared from SeO$_2$ by dissolving it in hot water. The stock solution of molybdenum was prepared from (NH$_4$)$_2$Mo$_7$O$_{24}$·4H$_2$O. Dilute solutions were prepared before every use to avoid solution degradation.

A 1.0 M acetic acid buffer, pH 4, was prepared as follows: a 1.0 M NaOH solution was added to 1.0 M acetic acid until the chosen pH was reached, according to a pH meter.

Methods

Digestion of the liver sample

According to former studies (9), the deposition of trace elements vary in different sections of the liver. Thus two different sections (S$_1$ and S$_2$) were taken as two separate samples from one cow liver. They were dried for 48 h in an oven at 120°C to remove the water content and to obtain a constant weight. The water content was found to be 72.2%. Samples of dried liver (3.02 g (S$_1$) and 2.90 g (S$_2$)) were transferred into a 100 ml long-necked glass flask. For the digestion of the sample, a concentrated acid mixture of 0.5 ml H$_2$SO$_4$, 5 ml HClO$_4$, and 5 ml HNO$_3$ was added and left to stand overnight. A glass funnel was inserted into the digestion flask to prevent rapid evaporation. The solution was kept in an oil bath at 50°C until the foaming stopped. Then the temperature was increased to 150°C and heating was continued until the evolution of brown fumes of nitrogen oxides ceased. When the digestive sample turned yellowish to deep dark brown, there was a danger of explosion, so 5 ml of nitric acid had to be added; the flask was cooled for about 2 min before addition. Heating was continued until nitrogen oxide fumes were no longer given off. The digestion was completed, with the appearance of white fumes of perchloric acid, when approximately 1.0 ml solution remained. Finally, 2.0 ml of hydrochloric acid was added and heated for at least 20 min to convert all selenium to selenium(IV). The final solution was evaporated to approximately 1.0 mL and cooled to room temperature. The funnel was rinsed with water into the flask and the contents transferred into a 10.0 ml teflon flask, which was made up to the mark with triply-distilled water. Depending on the concentration of each element in the liver, the digests had to be diluted 10, 100, or 500 times before use.

To check the recovery of the elements during digestion, the same digestion procedure was applied to a synthetic sample containing the same elements. The recovery efficiencies were found to be between 95 and 97%.

Voltammetric determination

For the determination of lead, cadmium, and zinc in liver, 10.0 mL of a 1.0 M acetic acid – acetate buffer (about pH 4) in a polarographic cell was deoxygenated by a stream of high-purity nitrogen for 5 min. The DP polarogram was recorded by scanning the potential in the negative direction from 0.0 V to –1.5 V at a scan rate of 5 mV s^{-1}. Then, according to the need, 0.05–0.1 mL digested sample of liver was added, and once more the DP polarogram was recorded. Standard additions were made according to the corresponding element. For the determination of copper, EDTA solution was added so that the final concentration was 0.02 M. The selenium content, on the other hand, was determined using the catalytic hydrogen wave. For this purpose, Mo(VI) had

to be added in 50–100 times larger amounts than the concentration of selenite present.

Results and discussion

Preliminary experiments

Various supporting electrolytes including KCl, HCl, HAc–NaOAc, and HAc buffer with and without EDTA were used over a wide range of pH. The peak potential values of elements that may be present in liver such as Fe, Cu, Pb, Cd, Zn, Ti, Mo, and Se were determined in these supporting electrolytes. Acetate buffer was found to be the most suitable electrolyte because of its ability to function at various pH values and thus enable the separability of the peaks.

Determination of trace elements in liver

The DP polarograms of digested liver samples in acetate buffer at pH 4.2 have peaks at –0.23 V, –0.40 V, –0.60 V, and –0.98 V. Figure 1 is given as an example where copper, lead, selenium, and zinc peaks are observable. The polarogram of the S_1 sample had similar peaks, but the copper peak was off the scale because of its high concentration. By the additions of Pb, Cd, and Zn standard solutions, the peaks at –0.40 V, –0.60 V, and –0.98 V increased, respectively, indicating the presence of these ions, as expected. For the determination of these elements a 10-times dilution was sufficient, but for the determination of copper in the S_1 sample, because of its high concentration (the peak was too large to observe), either a 100-times dilution or a change in current density was required. On the other hand, the solution either had to be diluted or the current range had to be adjusted accordingly for selenium, since the very sensitive method of catalytic polarography had been used in that case.

Determination of selenium

In our earlier polarographic work (12) we observed a hydrogen catalytic peak when Se(IV) and Mo(VI) were present together in a solution. These kinds of catalytic currents are obtained with many organic compounds including amines, proteins, thiols, and phosphines. They are also observed with some inorganic substances, for example, complexes of tungsten (VI) with certain carboxylic acids (13). The catalytic peak obtained with Mo(VI) and Se(IV) has been used for the determination of very low concentrations of both ions in blood (14). The detection limit (signal to noise ratio, S/N = 3) of the method for Mo(VI) and for Se(IV) was 1.5×10^{-9} M. For the determination of one of these ions, the second ion concentration had to be about 10^2–10^3 times higher than the other ion that was being investigated. However, at concentrations higher than 10^{-6} M, this ratio may be 1:1. Although it is not possible to see a peak for selenite at a concentration lower than 10^{-6} M with DPP, by the addition of Mo(VI) a peak at –1.1 V becomes observable, and by standard additions of selenite the amount of it can be determined. The DP polarogram of a 500-times diluted liver sample in acetate buffer, pH 4, is given in Fig. 2(a). The sample had to be diluted 500 times since at lower dilution the catalytic peak was off the scale. As can be seen in Fig. 2 there was no peak for selenium, but by the addition of Mo(VI) a hydrogen catalytic peak at about –1.1 V appeared. At first with further additions of molybdenum it increased, but then it became

Fig. 1. DP polarogram of liver sample S_2: 10.0 mL of a 1.0 M HAc–Ac buffer (pH = 4.2) and 0.1 mL liver sample (10 times diluted).
constant. At that point standard additions of selenite were made for the determination of selenium (Fig. 2(b)). Because of overlapping peaks, zinc usually interferes with the hydrogen catalytic peak; thus, EDTA addition is needed. However, although zinc was present in this sample, because of the 500-times dilution for selenite determination no peak corresponding to zinc was visible. The Se(IV) content for six different samples were determined with the above method, and the following concentrations were found: 2.05 ± 0.22 mg g^{-1} Se in the S_1 sample and 2.08 ± 0.21 mg g^{-1} Se in the S_2 sample.

Determination of copper

According to our preliminary experiments, copper and iron peaks may overlap in acetate buffer with pH about 4. Addition of EDTA, however, enabled their separation: the copper peak was found at –0.23 V and the iron peak at –0.13 V. In the liver sample that was diluted only ten times, the polarogram had a very large copper peak at –0.23 V; thus, the sample solution had to be diluted 100 times. The polarogram for this liver sample, S_1, is given in Fig. 3. As can be seen from the figure, the iron peak, which may appear at –0.13 V, was not observable because of low sensitivity in this medium. According to our previous studies, the current obtained for iron in this medium was ten times smaller than the one that was observed for copper for the same concentration. The copper content was determined with standard additions and was found to be 8.12 ± 0.21 mg g^{-1} in the S_1 sample and 0.48 ± 0.02 mg g^{-1} in the S_2 sample.

Determination of zinc, cadmium, and lead

As mentioned earlier, the polarogram (Fig. 2) of the liver sample had peaks belonging to lead, cadmium, and zinc. Standard addition was used for the determination of their concentrations. The polarograms are given in Figs. 4, 5, and

Fig. 2. Determination of selenium in liver. and 1.16 ± 0.12 mg g^{-1}, respectively. The S_1 sample was also analyzed by flame AAS for zinc content, and it was found to be 1.01 ± 0.24 mg g^{-1}, which was consistent with the result obtained with polarography. In the S_2 sample, however, while no detectable amount of cadmium was observed, lead content was found to be 0.22 ± 0.03 mg g^{-1}, and zinc content was found to be 0.29 ± 0.03 mg g^{-1}. These results are summarized in Table 1. The trace element quanti-

6. In the S_1 sample, lead, cadmium, and zinc concentrations were found to be 0.59 ± 0.04 mg g^{-1}, 1.09 ± 0.11 mg g^{-1},

Fig. 6. Determination of zinc in liver: (*a*) 10.0 mL HAc–Ac, pH = 4.3; (*b*) a + 0.1 mL of the S$_1$ sample; (*c*) b + 0.1 mL of a 10^{-3} M solution of Zn^{2+}; (*d*) c + 0.2 mL of a 10^{-3} M solution of Zn^{2+}; and (*e*) d + 0.2 mL of a 10^{-3} M solution of Zn^{2+}.
ties found in different sections of liver proves that their distribution is not uniform, as mentioned (9) earlier for cattle and pigs.

Proposed procedure

About 1–2 g of dried liver was digested and then diluted to 10 or 100 mL. An aliquot (0.1 ml) was added to an acetate buffer (pH 4) solution, and the DP polarogram was taken. Lead, cadmium, and zinc were determined by standard additions. Then EDTA solution was added, so that its final concentration was 0.05 M, and copper content was determined. For selenite, Mo (VI) was added to obtain the hydrogen catalytic peak, and the selenite content was determined by standard additions of selenite.

Synthetic sample

To check the validity of the suggested method, a synthetic sample containing similar amounts of metal ions present in liver was used. The polarogram of the metal ions in acetate buffer at pH 4 is shown in Fig. 7. The elements present were determined with the proposed method. The results are given in Table 2 with their standard deviations. As can be seen, a good consistency was observed for most of the ions, except cadmium. Only 55% of the quantity of cadmium could be determined. This can be explained by the interference of selenium with cadmium (15), which was further investigated by us.

Conclusions

The present DP polarographic method, which was used for the first time for the determination of heavy elements in liver, enabled the direct determination of their concentration without any separation or pre-concentration techniques.

Fig. 7. DP polarogram of a synthetic sample: (*a*) 9.5 mL of a 1.0 M HAc–Ac buffer; (*b*) 0.1 ml of a 10^{-2} M solution of Cu^{2+}; 0.1 ml of a 10^{-3} M solution of Pb^{2+}; 0.1 ml of a 10^{-3} M solution of Cd^{2+}; 0.1 ml of a 10^{-3} M solution of Se(IV); 0.1 ml of a 10^{-2} M solution of Zn^{2+}.
Electroanalytical methods are quite simple, their sensitivity and selectivity are high, and the instruments used are inexpensive. By digestion of about 1–2 g of sample, dilution to 10–100 ml, and by using 0.1 ml aliquots it is possible to determine the concentration of at least five to six elements si-multaneously. This method can be applied to other biological samples containing complex mixtures of metal ions.

The differing mechanisms of photo-formation of 7-cyanobenzocyclooctatetraene from 7- and 6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

Christopher Owen Bender, Douglas Dolman, Jeremy Christian Foesier, Sherry Lee Lawson, and Kathryn Elvia Preuss

Abstract: It is known that 7-cyanobenzocyclooctatetraene (COT **2**) is a product of the thermolysis and direct photolysis of 7- and 6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**1** and **5**), though the mechanisms of these rearrangements have not been reported. In the present study experiments have been carried out using the deuterium-labelled trienes **1***a* (93%-d_1 at C-6) and **5***a* (93%-d_1 at C-8), which were formed from $2\pi + 2\pi$ photo-closure (direct irradiation) of COT **2***a* labelled at C-8. The results reveal that whereas the thermolysis of **1***a* and **5***a* and the direct irradiation of **5***a* reform COT **2***a*, probably via cleavage of the strained cyclobutene C-1—C-6 bond, the direct irradiation of triene **1***a* gives a differently labelled COT product, containing the deuterium exclusively at C-9. The mechanism proposed for the latter phototransformation is a modification of the Zimmerman di-π-methane rearrangement.

Key words: mechanisms, rearrangements, photochemistry, di-π-methane rearrangement.

Résumé : Il est connu que le cyano-7 benzocyclooctatétraène (COT **2**) est un produit soit lorsqu'on chauffe des solutions des composés cyano-7 et -6 benzo-2,3 bicyclo[4.2.0]octatriènes-2,4,7 (**1** et **5**) ou lorsqu'on les photolyses directement, mais les mécanismes pour les transpositions n'étaient pas données. Ces transpositions ont été réétudiées avec des triènes marqués au deutérium: le triène **1***a* contient 93 %-d_1 à C-6, tandis que le triène **5***a* contient 93 %-d_1 à C-8. Des triènes **1***a* et **5***a* sont issus de l'irradiation directe du COT **2***a* marqué au deutérium à C-8 (93 %). Des études de marquages démontrent que le COT **2***a* se formant thermiquement du **1***a* et du **5***a*, et photochimiquement du **5***a*, dérive vraisemblablement d'une ouverture de la liaison C-1—C-6 des triènes. Par contre, l'irradiation directe du triène **1***a* conduit à COT **2***b* marqué au deutérium uniquement à C-9 (93 %). Un mécanisme modifié de Zimmerman est suggéré pour cette dernière transposition, **1***a* → **2***b*.

Introduction

Routes to cyclooctanoids continue to be of interest because of their wide occurrence in natural products, many of which exhibit potent biological activity, with the anti-cancer drug paclitaxel being a notable example (1). Some time ago (2) we reported that 7-cyanobenzocyclooctatetraene (i.e., 7-cyano-COT, **2**) is the unique product from the thermolysis of 7- and 6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**1** and **5**; note Scheme 1), and the major product from the direct irradiation of **1**. Other products from the direct irradiation of **1** are 7-cyanobenzosemibullvalene (**3**), 4-cyano-7,8-benzotetracyclo[3.3.0.0²,⁴.0³,⁶]oct-7-ene (**4**), and naphthalene. The COT **2** is also formed from the direct photolysis of triene **5**, though only in meager amounts; the main products are 1-cyanobenzosemibullvalene (**6**) and 2-cyanonaphthalene (note Scheme 1). Triplet-sensitized irradiations of either

triene **1** or **5** yield semibullvalenes and naphthalenes but do not generate COT products (2). We now report results from the study of deuterium-labelled derivatives of the trienes (viz. **1***a* and **5***a*, Scheme 2) which show that the skeletal reorganization that occurs in the photoformation of COT **2** from triene **5,** and the thermolyses of **1** and **5**, is different to that observed in the **1** → **2** photoisomerization.

Results

The deuterium-labelled trienes **1***a* and **5***a* (93%-d_1 at C-6 and C-7, respectively) were obtained as outlined in Scheme 2 (yields given in the Schemes are based on amounts of starting materials consumed) from a multistep procedure starting with the readily available 3,4-dibromobenzobarrelene **7** (3). All compounds in the synthetic sequence are either known or are deuterium-labelled derivatives of known compounds. Incorporation of deuterium at C-3 of barrelene **8** was achieved by treating dibromide **7** with 1 equiv of butyllithium, followed by quenching the resulting mono-anion with deuterium oxide. Crude **8** was then converted to the cyanolated derivative **9***a* (52% overall yield from **7**) using cuprous cyanide according to established methodology (4). The final two synthetic steps are known photorearrangements.

1 (R = H)
1*b* (R = D)
The first involves the direct irradiation (Corex filter) of barrelene **9***a* to give the labelled COT **2***a* as the major product (4). In the second step, the COT was photocyclized (direct irradiation at $\lambda \geq 318$ nm, conditions under which the photolabile products absorb no light) to the desired triene **1***a*, along with the alternate closure isomer **5***a* (2).

The assignment of the deuterium attachment at C-6 of **1***a* follows from the reduction in integration signal of the lower-

field bridgehead signal in the proton NMR spectrum. Differentiation between the two bridgehead hydrogens (i.e., H-1 at δ 4.22 and H-6 at δ 4.00) was previously established (2) from spin decoupling results and the observation that the triplet H-6 signal in nonlabelled triene **1** collapses to a doublet in the spectrum of the deuterium-labelled compound **1***b*. As expected, the signal due to H-1 (broad doublet) is essentially unchanged upon replacement of H-5 with deuterium.

Table 1. Hydrogen atom distributions of the nonaromatic positions in deuterium-labelled 7-cyanobenzocyclooctatetraene.

		Hydrogen atom distributions at:[a]			
Entry no.	Origin of 7-cyano-COT	C-5 and C-10 $\delta 6.75$ and $\delta 6.73$	C-6 $\delta 5.95$	C-8 $\delta 6.66$	C-9 $\delta 6.07$
1	Observed for direct hν of barrelene **9a**[b]	2.04H	0.99H	0.07H	0.98H

[a]In each case the aromatic multiplet at $\delta 6.95$–7.06 was set as the normalized integration standard of 2.00H; the other aromatic multiplet at $\delta 7.22$–7.31 gave variable integration values due to the presence of residual CHCl$_3$.
[b]See the experimental section for complete NMR details.
[c]The signal multiplicities were identical to those reported for 8-deuterio-COT (**2a**).

Scheme 3. Observed label locations in products from triene **1a** thermolysis and direct photolysis.
The NMR details are given at the triene structures **1/1b**, in Scheme 2. In the case of triene **5a**, the assignment of the deuterium attachment at C-7 is based on the signal designations previously given to nonlabelled **5** (2).

As indicated above, trienes **1** and **5** are known to revert to COT **2** upon heating (2). In the present study, the NMR spectra of the COT material isolated from the thermolyses (in *n*-nonane at 150°C) of the labelled trienes **1a** and **5a** revealed the same label distributions as were found in COT **2a** originally prepared from barrelene **9a** (i.e., deuterium exclusively at C-8; note the observed ¹H NMR integration values given in Table 1, entries 1, 2, and 7). These findings are consistent with the operation of a mechanism involving cleavage of the strained C-1—C-6 bridging bond of the trienes (see Schemes 3 and 4), and is a ground-state reaction common to other benzobicyclo[4.2.0]octa-2,4,7-trienes (5).

In contrast to the thermal results, NMR analysis of the COT product isolated as the major component from the direct irradiation of labelled triene **1a** shows the deuterium to be uniquely located at C-9 (Scheme 3; note Table 1, entry 3), i.e., the observed COT product is identical to the known β-labelled compound **2b** previously obtained (4) as the major product from the direct irradiation of the C-5 labelled barrelene **9b** (note Scheme 3). Thus mechanistically, the photoformation of COT **2** from triene **1** is not a simple reversal of the $2\pi + 2\pi$ photoclosure process proposed in the generation of triene **1** from COT **2**. The other isomeric products (semibullvalene **3a** and tetracycle **4a**) isolated from the direct irradiation of triene **1a** contain deuterium distributions that are unexceptional and fully compatible with those anticipated by previously described mechanistic routes (2), viz. via a Zimmerman di-π-methane (DPM) rearrangement (6) in the case of **3a**, and a $2\pi_s + 2\pi_s$ cycloaddition in the case of **4a** (4).

Interestingly, the photochemical (direct irradiation) behaviour of triene isomer **5a** differs from that of **1a** in giving COT product (Scheme 4) in which the deuterium distribution corresponds to **2a**, within experimental uncertainty (note

Scheme 4. Observed label locations in products from triene **5a** thermolysis and direct photolysis.
Scheme 5. Mechanisms that do not account for photoformation of COT from triene **1a**.
Table 1, entry 8). The major product from the direct irradiation of **5a** is semibullvalene **6a** labelled at C-7, which is considered to form from a Zimmerman DPM rearrangement (6) involving initial bridging between C-5 and C-7, as proposed in the earlier investigation of triene **5** (2).

Discussion

Previous studies of deuterium-labelled 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes have led to the postulation of at least three mechanistic pathways which may operate in the photogeneration of COTs (7–12). However, none of these pathways (depicted as routes A, B, and C in Scheme 5) can account for the labelling pattern observed in the photoconversion of **1a** to **2b**. Thus, operation of a route A-type mechanism (7–9), which is formally equivalent to a $2\sigma_s + 2\pi_s$ electrocyclic opening (13), would lead to **2a** (not observed). Operation of a route B-type (10–12) or a route C-type mechanism (11), both of which involve the initial formation of a Zimmerman DPM rearrangement diradical **10a**, should give approximately equal amounts of **2a** (not observed) and **2b** (observed) from the thermal reorganization of the proposed

octavalene intermediate **12a**, assuming minor deuterium isotope effects (14, 15).

To rationalize the photoconversion of **1a** → **2b**, we propose a novel mechanism (route D, Scheme 6) which is a modification of the Zimmerman DPM pathway identified as route B in Scheme 5. The modification allows for the rearrangement of the initially formed diradical **10a** to the more stabilized species **13a** (Scheme 6). The transformation of **10a** to **13a** can be viewed as an interconversion between two housane-type species, i.e., **14** → **15**. Interestingly, the diradical **13**, in which favorable stabilization is afforded the radical centres by the cyano and benzo groups, was invoked previously by us (4) to explain the formation of COT **2b** from the direct irradiation of barrelene **9b** (note Scheme 7)[2]. However, lest it be thought that barrelene **9b** is involved in the present case through a two-step process (viz., **1a** → **9b** → **2b**, the primary step would be an excited-state allowed 1,3-shift), we point out that the subsequent photolysis of **9b** would have led not only to COT **2b** but also to the coformation of semibullvalene **6a** and COT **16b** (note Scheme 7) (2). Since neither the barrelene **9b** nor **6a** nor **16b** are observed in photolysates of triene **1a**, at any conversion

---

[2] Following the suggestion of a referee, we note that the same overall skeletal organization of COT **2b** would result from two 1,2-shifts of the cyanovinyl group of triene **1a** via the mechanism given in Fig. 1.

1*a* **X** **2***b* (observed)
level (GC and NMR monitoring), it follows that **9***b* does not feature in the production of COT **2** from triene **1**.

For triene **5***a*, the deuterium results are most readily interpreted in terms of a route A-type mechanism, wherein cleavage of the strained C-1—C-6 bond would be particularly favorable due to the extensive stabilization of the "diradical-like" centres in the proposed transition state, approximated by structure **17***a* (Scheme 8). A similar explanation was

given to account for the facile photoformation of COT **16***b* in the case of triene **18***b*, which also contains a cyano group at a bridgehead location (C-1) (8).

A last point of interest is that the deuterium-labelled triene **1***b* (i.e., deuterium attached to C-5; note structure **1***b* in Scheme 2), which was initially prepared in 1986 to delineate the mechanistic details of the photoformations of semibullvalene **3** and **6** from trienes **1** and **5**, respectively (2), is

Scheme 8. Possible mechanism for photoformation of COT **2***a* from triene **5***a*.
not appropriately labelled to distinguish between operation of the route B- (or C-) type mechanisms (Scheme 5) and the novel pathway proposed here (route D, Scheme 6). Thus, according to either route B (or C) in Scheme 5, or the modified mechanism (route D) shown in Scheme 6, a label at C-5 of the triene becomes a label at C-6 in the COT product.[3]

Experimental

Instrumentation and general procedures

The NMR spectra were recorded on a Bruker 250-MHz instrument in $CDCl_3$ solvent with TMS as the internal standard; the chemical shifts are in δ units and the coupling constants (J) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. The photolysis apparatus consisted of a 450-W Hanovia medium-pressure mercury arc surrounded by a water-cooled quartz immersion well. Unless otherwise stated, the light was filtered through either a cylindrical sleeve of Pyrex or Corex glass, or an aqueous lead nitrate solution (1 g of $Pb(NO_3)_2$ and 100 g of NaBr in 1 L of water; transmittance was 0% below 318 nm) contained in a concentric filter jacket (10 mm path length). Three types of sample cell (A, B, or C) were used. Cell A (250 mL sample volume) consisted of a cylindrical vessel (Pyrex) which surrounded the immersion well. Cell B (200 mL sample volume) consisted of a cylindrical collar (Pyrex) which surrounded the aqueous filter jacket. Both Cells A and B were fitted with gas inlet and outlet ports, and sample solutions were deoxygenated by flushing with argon, before and during irradiations. Cell C (40 mL sample volume) was a test tube-like vessel (quartz), and sample solutions were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations. Column chromatography was carried out on Lobar (Merck; size B, LiChroprep Si 60) or on Silica Gel 60/$AgNO_3$ columns (10:1 by weight). All compounds described in this study are either known or are deuterium-labelled derivatives of known compounds; their purities were estimated to be ≥98% by a combination of NMR and GC analyses.

3-Deuteriocyanobarrelene (9a) from 2,3-dibromo-1,4-dihydro-1,4-ethenonaphthalene (7)

To a magnetically stirred solution of 3.62 g (12 mmol) of 2,3-dibromobenzobarrelene **7** (3) in 90 mL of dry, freshly distilled THF at –70°C was added dropwise 8.90 mL (14 mmol) of 1.6 M butyllithium in hexane over a 15 min period under a nitrogen atmosphere. Stirring was continued for an additional 25 min followed by the dropwise addition of 1.8 mL (99 mmol) of deuterium oxide during 5 min at –70°C. After stirring for 10 min, the cooling was removed and the reaction mixture allowed to warm to room temperature. The mixture was concentrated on the rotovap and distilled water (200 mL) and hexane (200 mL) were added. The aqueous layer was removed and extracted with hexane (100 mL). The combined organic layers were washed with distilled water (2 × 100 mL) and dried ($MgSO_4$). The solvent was removed via the rotovap and the crude 3-deuteriobromobenzobarrelene **8** was converted without purification to 3-deuterio-2-cyano-1,4-dihydro-1,4-ethenonaphthalene (**9***a*) using 2.10 g (23 mmol) of cuprous cyanide, according to the method previously described (4) for the conversion of unlabelled 2-bromo-1,4-dihydro-1,4-ethenonaphthalene to 2-cyano-1,4-dihydro-1,4-ethenonaphthalene. Crystallization of the crude product from 95% ethanol yielded 1.09 g (52%) of **9***a*, mp 65–67°C (lit. (4) value 66 to 67°C for the non-deuterated parent). ^{1}H NMR: 7.61 (dd, 0.06H, residual H-3, $J_{3,4} = 6$, $J_{1,3} = 2$), 7.19–7.3 (m, 2.21H, 2 aromatics and residual $CHCl_3$), 6.86–7.01 (m, 4.04H, 2 aromatics, H-5 and H-6), 5.00–5.10 (m, 2.00H, H-1 and H-4), corresponding to 94%-d_1 at C-3; uncertainties from NMR signal integrations are within ±0.05H for **9***a* and for all subsequent integrations of deuterated compounds.

8-Deuterio-7-CN-COT (2a) from 3-deuteriocyanobarrelene (9a)

A solution containing 1.039 g (5.77 mmol) of labelled cyanobarrelene (**9***a*) in 1 L of cyclohexane was irradiated in four equal aliquots in Cell A (Corex filter) for 40 min each. The photolysates were combined and chromatographed as described previously (4) for the preparation of COT **2** from unlabelled cyanobarrelene, to give 395.1 mg (38%) of 8-deuterio-COT (**2***a*) as the major product, mp 99–101° C (lit.

---

[3] Triene **1***b* does in fact give 7-cyanobenzocyclooctatetraene exclusively labelled with deuterium at C-6 upon direct photolysis (C.O. Bender, P.D. England, and K.E. Preuss. Unpublished results).

(4) value 102 to 103° C for non-deuterated **2**) after recrystallization from 95% ethanol. ^{1}H NMR: 7.22–7.31 (m, 2.67H, 2 aromatics + residual CHCl$_3$), 6.95–7.06 (m, 2.00H, 2 aromatics), 6.75 and 6.73 (d and d, 2.04H, H-5 and H-10, $J_{5,6} = J_{9,10} = 11.5$), 6.66 (d, 0.07H, residual H-8, $J_{8,9} = 4.5$), 6.07 (d, 0.98H, H-9, $J_{9,10} = 11.5$), and 5.95 (d, 0.99H, H-6, $J_{6,5} = 11.5$). Also note ^{1}H NMR data given in entry number 1 in Table 1.

Direct irradiation of 8-deuterio-COT (2a)

A solution containing 366.5 mg (2.04 mmol) of **2**a in 200 mL of cyclohexane was irradiated directly in Cell B (Pb(NO$_3$)$_2$ filter) for 96 h. The photolysate was concentrated to 8 mL and chromatographed (in four 2 mL aliquots) on a Lobar column with 1% ethyl acetate – hexane solvent; the eluant was monitored by UV spectroscopy at λ = 300 nm. The last band from the column contained 116.6 mg (32%) of labelled 6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**5**a). ^{1}H NMR: 7.10–7.30 (m, 4.28H, 4 aromatics + residual CHCl$_3$), 6.46 (d, 1.00H, H-4, $J_{4,5} = 10$), 6.19 (dd, 0.06H, residual H-7, $J_{7,8} = 2.8$, $J_{7,1} = 1$), 6.07 (d, 0.95H, H-8, $J_{8,1} = 1$), 5.85 (d, 0.98H, H-5, $J_{5,4} = 10$), and 4.46 (br s, 0.97H, H-1). The first band from the column contained COT **2**a and triene **1**a, and was rechromatographed in three equal aliquots on a Silica Gel 60/AgNO$_3$ column (0.9 cm × 11 cm; 0.5% ethyl acetate – hexane). The first band gave 93.8 mg (26%) of triene **1**a. ^{1}H NMR: 7.16–7.22 (m, 2.05H, 2 aromatics), 7.06–7.13 (m, 2.07H, 2 aromatics), 6.71 (d, 1.00H, H-8, $J_{8,1} = 1$), 6.42 (d, 1.00H, H-4, $J_{4,5} = 10$), 5.93 (d, 0.98H, H-5, $J_{5,4} = 10$), 4.22 (br s, 1.01H, H-1), and 4.00 (t, 0.07H, residual H-6, $J_{6,1} = J_{6,5} = 4.5$). The second band gave 133.8 mg (37%) of recovered COT starting material (**2**a). ^{1}H NMR: 7.22–7.31 (m, 2.08H, 2 aromatics + residual CHCl$_3$), 6.95–7.06 (m, 2.00H, 2 aromatics), 6.75 and 6.73 (d and d, 1.95H, H-5 and H-10, $J_{5,6} = J_{9,10} = 11.5$), 6.66 (d, 0.08H, residual H-8, $J_{8,9} = 4.5$), 6.07 (d, 0.94H, H-9, $J_{9,10} = 11.5$), and 5.95 (d, 0.96H, H-6, $J_{6,5} = 11.5$).

Thermolysis of triene 1a

A solution of 8.0 mg (0.044 mmol) of **1**a in 4 mL of *n*-nonane was refluxed (ca. 150°C) under a nitrogen atmosphere for 8 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with 3% ethyl acetate – hexane to give 7.1 mg (89%) of 8-deuterio-COT (**2**a) (the ^{1}H NMR data are given in entry 2, Table 1).

Direct irradiation of triene 1a

A solution containing 42.3 mg (0.24 mmol) of **1**a in 40 mL of cyclohexane was irradiated directly in Cell C (Pyrex filter) for 3.2 h. The photolysate was concentrated and chromatographed on Silica Gel 60 (0.9 cm × 7 cm) with 4% ethyl acetate – hexane to remove polymeric materials, and then rechromatographed on a Lobar column with 2% ethyl acetate – hexane solvent; the eluant was monitored by UV spectroscopy at λ = 265 nm. The first band off the column gave 3.3 mg (11%) of naphthalene-d_1. The second band contained a mixture of the triene starting material and COT product. The third band contained ca. 1 mg (2%) of semibullvalene **3**a. ^{1}H NMR: 7.22–7.31 (m, 1.00H, 1 aromatic), 7.03–7.26 (m, 5.14H, 3 aromatics + residual CHCl$_3$), 6.30 (d, 1.03H, H-6, $J_{6,5} = 2.5$), 4.04 (d, 1.02H, H-5, $J_{5,6} = 2.5$),

3.38 (q, 0.09H, residual H-1, $J_{1,2} = J_{1,5} = J_{1,8} = 6.5$), 3.19 (d, 1.03H, H-2, $J_{2,8} = 6.5$), and 2.94 (d, 1.01H, H-8, $J_{2,8} = 6.5$). The last band gave ca. 1 mg (2%) of tetracycle **4**a. ^{1}H NMR: 7.16–7.28 (m, 4.38H, 4 aromatics and residual CHCl$_3$), 4.32–4.36 (m, 2.00H, H-1 and H-6), 3.28 (q, 1.01H, H-5, $J_{5,1} = J_{5,2} = J_{5,6} = 4.5$), and 2.91–2.98 (m, 1.00H, H-2 and residual H-3).

The second band containing the triene starting material and COT product was rechromatographed on a Silica Gel 60/AgNO$_3$ column (0.9 cm × 11 cm; 0.25% ethyl acetate – hexane), monitored by UV spectroscopy at λ = 300 nm. The first band gave 29.0 mg (69%) of recovered triene starting material **1**a. ^{1}H NMR: 7.16–7.22 (m, 1.99H, 2 aromatics), 7.06–7.13 (m, 2.03H, 2 aromatics), 6.71 (d, 1.00H, H-8, $J_{8,1} = 1$), 6.42 (d, 1.00H, H-4, $J_{4,5} = 10$), 5.93 (d, 0.97H, H-5, $J_{5,4} = 10$), 4.22 (br s, 0.99H, H-1), and 4.00 (t, 0.07H, residual H-6, $J_{6,1} = J_{6,5} = 4.5$). The second band gave 7.0 mg (17%) of COT product **2**b. ^{1}H NMR: 7.22–7.31 (m, 2.07H, 2 aromatics + residual CHCl$_3$), 6.95–7.06 (m, 2.00H, 2 aromatics), 6.75 and 6.73 (d and br s, 1.98H, H-5 and H-10, $J_{5,6} = 11.5$), 6.66 (br s, 0.98H, H-8), 6.07 (dd, 0.10H, residual H-9, $J_{9,8} = 4.5$, $J_{9,10} = 11.5$), and 5.95 (d, 1.02H, H-6, $J_{6,5} = 11.5$); also note the ^{1}H NMR data given in entry number 3, Table 1.

Thermolysis of triene 5a

A solution of 8.5 mg (0.047 mmol) of **5**a in 5 mL of *n*-nonane was refluxed (ca. 150°C) under a nitrogen atmosphere for 5.2 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with 3% ethyl acetate – hexane to give 6.0 mg (71%) of 8-deuterio-COT (**2**a); for ^{1}H NMR details note entry 7, Table 1.

Direct irradiation of 7-deuterio-6-cyano-triene (i.e., triene 5a)

A solution containing 20.2 mg (0.09 mmol) of **5**a in 40 mL of cyclohexane was irradiated directly in Cell C (Pyrex filter) for 1.5 h. The photolysate was worked up as in the case of the direct irradiation of unlabelled triene **5** (2) to give ca. 1 mg (5%) of 2-cyanonaphthalene and ca. 1 mg (5%) of 8-deuterio-COT (**2**a); for the ^{1}H NMR details note entry number 8, Table 1; 8.5 mg (42%) of recovered triene **5**a (^{1}H NMR: 7.10–7.30 (m, 4.50H, 4 aromatics + residual CHCl$_3$), 6.46 (d, 1.00H, H-4, $J_{4,5} = 10$), 6.19 (dd, 0.06H, residual H-7, $J_{7,8} = 2.8$, $J_{7,1} = 1$), 6.07 (d, 0.98H, H-8, $J_{8,1} = 1$), 5.85 (d, 1.00H, H-5, $J_{5,4} = 10$), and 4.46 (br s, 1.00H, H-1)); and 7.5 mg (37%) of semibullvalene **6**a (^{1}H NMR: 7.32–7.40 (m, 1.00H, 1 aromatic), 7.06–7.25 (m, 3.10H, 3 aromatics + residual CHCl$_3$), 5.70 (d, 0.95H, H-6, $J_{6,5} = 2.5$), 5.20 (dd, 0.06H, residual H-7, $J_{7,6} = 5.0$, $J_{7,8} = 2.5$), 4.22 (d, 1.01H, H-5, $J_{5,6} = 2.5$), 3.68 (d, 1.01H, H-2, $J_{2,8} = 7.0$), and 3.35 (d, 1.02H, H-8, $J_{8,2} = 7$)).

The use of β-cyclodextrins to enhance the aqueous solubility of trichloroethylene and perchloroethylene and their removal from soil organic matter: Effect of substituents

Salma Shirin, Erwin Buncel, and Gary W. vanLoon

Abstract: This paper describes a systematic study for the evaluation of different substituted β-cyclodextrins (β-CDs), as agents for the enhancement of the aqueous solubility of two major organic pollutants, trichloroethylene (TCE) and perchloroethylene (PCE). The aqueous solubility enhancement occurs through the formation of host–guest inclusion complexes between the CD molecule (host) and the polychloroethylene (guest) and is driven primarily by hydrophobic forces. The CDs evaluated are: methyl-β-CD (Mβ-CD), hydroxypropyl-β-CD (HPβ-CD), carboxymethyl-β-CD (CMβ-CD1, CMβ-CD2), and sulfated-β-CD (Sβ-CD1, Sβ-CD2); the degree of substitution was also varied. Using a 5% (w/v) aqueous CD solution, solubility enhancement factors (S_t/S_o) up to 5.5 and 14 were determined for TCE and PCE, respectively. Binding constants (K_{11}) for TCE with the substituted CDs were evaluated using an ^{1}H NMR technique; these were found to range from 3 to 120 M^{-1}. It was shown that solubility enhancement, as well as the binding constant, is dependent on the type and degree of substitution of the β-CD molecule; the determining factors are discussed. The CDs are also capable of effective removal of PCE and TCE retained by soil organic matter. Thus, a suitably substituted β-CD may be a valuable additive in pump-and-treat protocols for site remediation of polychlorinated organics.

Key words: cyclodextrin, trichloroethylene, perchloroethylene, solubility enhancement, binding constant, soil and water remediation.

Résumé : Dans ce travail, on décrit une étude systématique réalisée pour évaluer l'utilité de diverses β-cyclodextrines substituées (β-CD) comme agents d'augmentation de la solubilité aqueuse de deux agents polluants importants, le trichloroéthylène (TCE) et le perchloroéthylène (PCE). L'augmentation de la solubilité aqueuse résulte de la formation de complexes d'inclusion hôte–invité entre une molécule de CD (hôte) et le polychloroéthylène (invité) et elle résulte principalement de forces hydrophobes. On a évalué les CD suivantes en faisant aussi varier le degré de substitution: méthyl-β-CD (M-CD), hydroxypropyl-β-CD (HPβ-CD), carboxyméthyl-β-CD (CMβ-CD1; CMβ-CD2) et de β-CD sulfatées (Sβ-CD1; Sβ-CD2). Utilisant des solutions aqueuses à 5% (m/v) de CD, on a observé des facteurs d'augmentation de la solubilité (S_t/S_0) de 5,5 et 14 respectivement pour TCE et PCE. Faisant appel à une technique de RMN, on a évalué que les constantes de fixation (K_{11}) du TCE avec les CD substituées varient de 3 à 120 M^{-1}. On a montré que le degré d'augmentation de solubilité ainsi que la constante de fixation dépendent du type et du degré de substitution sur la molécule de β-CD; on discute des facteurs déterminants. Les CD sont aussi capables d'extraire de façon efficace les PCE et TCE qui sont retenus dans les portions organiques du sol. Une β-CD substituée de façon appropriée peut être un additif utile dans les protocoles d'extraction de composés organiques polychlorés réalisés pour remédier à des déversements.

Mots clés : cyclodextrine, trichloroéthylène, perchloroéthylène, augmentation de la solubilité, constante de fixation, remédier à des contaminations de sol ou d'eau.

[Traduit par la Rédaction]

Introduction

Trichloroethylene (TCE) and perchloroethylene (PCE) are among a number of chlorinated organic compounds that have been listed as major organic contaminants in soil and water systems throughout the industrialized areas of North America (1, 2). These two compounds are released into the environment from a variety of industrial sources and are frequently found in aquifers as dense, non-aqueous phase liquids (DNAPLs). The hydrophobic liquids accumulate in relatively large bodies known as pools or as residuals in the form of disconnected blobs and ganglia (2). Because the aqueous solubilities of TCE and PCE are small (200 ppm and 1100 ppm, respectively (2)), only a limited concentration of the DNAPL dissolves in the associated groundwater. In addition, both compounds are resistant to biotic and

Fig. 1. Illustration of the 7 glucose units in β-CD. Substitution can occur at the C-2, C-3, and C-6 hydroxyl functionalities in each unit.
abiotic degradation under most natural environmental conditions. Therefore, the DNAPL is not rapidly removed by either dissolution or degradation and its lifespan in the soil and (or) groundwater system may be on the order of several decades, even centuries. Both TCE and PCE, along with vinyl chloride, one of their daughter products, are considered to be potential carcinogens and mutagens (1, 3). As a result of their environmental persistence and mutagenicity, removal from the subsurface has become a priority, and numerous studies have focused on the environmental remediation of PCE and TCE. The traditional method for remediation of these two and other DNAPL compounds involves pump-and-treat technology where ground water is pumped from the soil, treated chemically or photochemically to destroy the contaminant, and then returned; however, their low aqueous solubility limits the effectiveness of this method (4, 5). In this regard, chemically enhanced dissolution of such organic compounds using surfactants or alcohols is usually considered (6, 7). However, a major problem associated with the use of surfactants and alcohols is that both of them tend to lower the DNAPL–water interfacial tension (8, 9). Lowering of interfacial tension could result in remobilization of DNAPLs in the vertical plane, making the remediation process more difficult. In addition, surfactants tend to be retained in the soil by sorption onto various types of soil particles. To overcome these problems, a new enhanced solubilization strategy involving the use of cyclodextrins may be attractive.

Cyclodextrins (CDs) are cyclic glucose oligosaccharides formed by the action of *Bacillus macerans* on starch (10). Depending on the number of glucose units in the ring, cyclodextrins are classified as α, β, or γ, corresponding to 6, 7, or 8 glucose units, respectively. The donut-shaped molecule has one rim lined with primary -OH groups and another rim lined with secondary -OH groups. The -OH groups are directed outward, providing a hydrophilic exterior, while the interior is substantially hydrophobic, a result of the hydrocarbon portion of the glucose skeleton. The combination of these properties enables cyclodextrins to act as "host" in

forming complexes with other "guest" molecules that are either non-polar or of low polarity and that have a size and shape that is complementary to the cavity dimensions of the CD. Several intermolecular interactions have been proposed to account for the formation of CD–inclusion complexes in aqueous solution. They include van der Waals forces between the guest and host molecules, hydrophobic interaction, release of high-energy H_2O molecules from the CD cavity, and relief of conformational strain in a CD–water adduct upon substrate inclusion. (11).

The ability of CDs to form water-soluble inclusion complexes with a wide range of organic compounds makes them suitable for application in a variety of situations (12) including in the pharmaceutical industry (time-release drugs) and in the manufacture of household items (odour reducing spray). Importantly, cyclodextrins are non-toxic, non-carcinogenic, and environmentally benign. Thus far, β-CDs have been used more frequently than other CDs because of the appropriate cavity size with respect to a wide range of organic compounds. However, underivatized β-CD has the lowest aqueous solubility (1.8 g per 100 mL) compared with α- and γ-CD (14.5 and 23.2 g per 100 mL, respectively) (11). To increase solubility, modification of the -OH groups in the CD molecule can be carried out (11, 13, 14). In principle, any or all of the three -OH groups in each glucose unit of the CD molecule can be functionalized (Fig. 1). Hence, there can be from 0 to 21 degrees of substitution (DS) in each β-CD molecule (three -OH groups per glucose unit and 7 glucose units in each molecule).

The possibility of using derivatized CDs for effecting the remediation of nonpolar and low-polarity organic pollutants in soil and (or) water systems has been investigated in a number of studies (15–23). These reports describe laboratory and field experiments that demonstrate the application of substituted CDs in environmental remediation strategies. In laboratory-based studies, it was found that an increase in aqueous solubility of a range of nonpolar and low-polarity organic compounds, including TCE and PCE, could be achieved using various types of substituted β-CDs such as

Table 1. Substituted CDs used in this work: molar mass and degree of substitution.

Compound	Substituent group R	Degree of substitution (average)	Average molar mass (g mol^{-1})
Hydroxypropyl (HPβ-CD)	-CH$_2$CH(OH)CH$_3$	3–8 (5.5)	1500
Methyl (Mβ-CD)	-CH$_3$	10–16 (12)	1303
Carboxymethyl (CMβ-CD1)	-CH$_2$COO$^-$	3	1375
Carboxymethyl[a] (CMβ-CD2)	-CH$_2$COO$^-$	1–11 (7)	1671
Sulfated (Sβ-CD1)	-SO$_3^-$	3–16 (4)	1543
Sulfated (Sβ-CD2)	-SO$_3^-$	3–16 (14)	2563

[a]Molar mass was determined from the major peak obtained using FAB-MS. For all other CDs, average values provided by the supplier were used.

hydroxypropyl-β-CD (HPβ-CD), methylated-β-CD (Mβ-CD), and carboxymethyl-β-CD (CMβ-CD). For example, aqueous solubility enhancement using 5% HP-βCD ranges from ca. 3 (for TCE) to 147 (for anthracene) depending on the size and other properties of the guest molecule (15).

To evaluate the performance of CDs in the field, HPβ-CD was applied in a waste disposal site (Hill air force base, Utah, U.S.A.) that had been contaminated with TCE as well as with other polar and nonpolar organic compounds (17). Flushing the contaminated aquifer with 10% (w/v) HPβ-CD resulted in significant reduction of the concentration of organic pollutants in the contaminated zone.

The overall goal of the present research is to develop a rational basis for selecting modified CDs that would be most appropriate for maximizing solubilization of PCE and TCE. To this end, we have examined the following: methyl-β-CD (Mβ-CD), hydroxypropyl-β-CD (HPβ-CD), carboxymethyl-β-CD (CMβ-CD1, CMβ-CD2), and sulfated-β-CD (Sβ-CD1, Sβ-CD2); the degree of substitution was also varied. Since an increase of the aqueous solubility of different organic compounds in the presence of CD is believed to be due to guest–host complexation, determination of binding constants (K) is informative in assessing the utility of the CD (24, 25).

Finally, the interaction of hydrophobic organic compounds with organic matter present in soil is of importance in the remediation of contaminated sites. TCE and PCE are known to be retained by soil organic matter, and this is reflected in the relatively large log K_{OW} (octanol–water partition coefficient) values, which are 2.88 and 2.61 for PCE and TCE, respectively (26). The ability of CDs to extract the hydrophobic compounds that are retained by soil into an aqueous medium is an important issue in remediation strategy. To evaluate this, the solubilization of PCE and TCE retained by peat was monitored using solutions of the derivatized CDs. It is shown that a suitably substituted β-CD may be a valuable additive in pump-and-treat technology for site remediation of polychlorinated organics.

Experimental

The following substituted β-cyclodextrins were used as received: hydroxypropyl-(HPβ-CD) (Aldrich), sulfated-(Sβ-CD1), sulfated-(Sβ-CD2), methyl-(Mβ-CD), and carboxymethyl-(CMβ-CD1) (Cerester). In addition, we used car-

boxymethyl-(CMβ-CD2), which had been synthesized in the laboratory of Professor G. R. Thatcher at Queen's University (see below for synthetic procedure). The aqueous solubility of each of the substituted CDs was found to be >50% (w/v). Table 1 lists the properties of the CDs, including the type of substituent group, average molar mass, and degree of substitution. The CDs were used as received. Analytical grade TCE and PCE, with reported purities of 99.5+% and 99+%, respectively, were obtained from Aldrich. HPLC-grade acetonitrile was purchased from Fisher. The D$_2$O (purity 99.9%) used in the NMR experiments was obtained from Cambridge Isotopic Laboratories. International Humic Substance Society (IHSS) Peat had the following elemental composition (%) (27): C 57.1, H 4.49, O 33.9, N 3.60, S 0.65. The organic matter content of this material was reported to be 100%.

Synthesis of CMβ-CD2

To a solution of 4.2 g of NaOH in 98 mL H$_2$O at 70°C was added slowly 57.5 g of β-CD, and the mixture was kept at that temperature for 2 h. A Na-chloroacetate solution, made of 101 g of chloroacetic acid in 100 mL H$_2$O and neutralized with 42 g NaOH, was added drop-by-drop to the β-CD – Na salt solution; after standing for 5 h at 70°C the reaction mixture was poured into 2.5 L CH$_3$OH for precipitation. The solid mass was filtered, washed twice with 150 mL H$_2$O, then redissolved in 100 mL H$_2$O and reprecipitated in 1.5 L CH$_3$OH, followed by washing with 2 × 100 mL water and 2 × 100 mL acetone. Finally, the product was dried under vacuum. The solubility of the compound was >70% (w/v) and the pH of a 1% solution was 7.93. The compound was characterized by ^{13}C NMR and mass spectroscopy.

^{13}C NMR (75.5 MHz, D$_2$O) δ: 178.3 (COOH), 99.4 (CH-anomeric), 81.2 (CH), 72.0 (CH), 70.5 (CH$_2$), 61.7 (CH$_2$), 49.4 (CH), and 30.9 (CH). FAB-MS (using glycerol as the matrix) m/z: 1430.1, 1510.5, 1590.2, 1670.5 (major), 1750.8, 1830.5, and 1911.3.

HPLC conditions

HPLC analysis was performed using a Varian 9002 series solvent delivery system fitted with a Varian 9050 variable wavelength UV–vis detector and Varian Star Chromatographic Workstation Version 4.5 for peak integration. For separation, a C$_{18}$ APEX ODS 5 μ particle size column

(Chromatographic Specialties, 4.6 mm × 250 mm) protected by a guard column was employed. The mobile phase was a 70:30 acetonitrile–water solution that had been filtered through a Millipore system. For both PCE and TCE, the detector was set to a wavelength of 210 nm and the flow rate was 1.0 mL min^{-1}. Under these conditions, the TCE peak appeared at a retention time of ca. 6.5 min while PCE was detected at ca. 9.5 min. A large, irregular peak ascribed to CD also appeared between ca. 2 to 3 min; therefore, elution of the CDs did not interfere with the peak of interest. The method detection limits, measured as 3 times the standard deviation of the blank signal, were 0.12 ppm for TCE and 0.14 ppm for PCE.

Solubility enhancement

The experimental procedure for solubility enhancement of PCE and TCE was adapted from ref. 15. To distilled deionized water (25 mL) containing 1% to 5% concentrations of CD in a 100-mL volumetric flask was added a large excess (above the solubility limit) of TCE or PCE. A control flask that contained only water and the substrate was also prepared. TCE or PCE aqueous mixtures containing CD were then equilibrated by shaking on a wrist action shaker for 48 h at room temperature. Samples were transferred into capped, glass centrifuge tubes and centrifuged at 3500 rpm for 20 min. A 100 or 500 µL portion of the aqueous supernatant was withdrawn using a micropipette and diluted with water in a 10-mL volumetric flask. Samples of the diluted solution were then injected into the HPLC, and both peak height and area of the substrate peak were recorded.

Binding constant

The binding constant (K_{11}) was determined using an ^{1}H NMR titration method (28). For the titration experiments, a 2×10^{-3} M TCE solution in D_2O and ca. 0.4 M CD stock solutions in D_2O were prepared. A 2.00 mL portion of the TCE solution was placed in an NMR tube and the ^{1}H spectrum was recorded using a Bruker AM-400 spectrophotometer operating at 400.1 MHz. Different amounts of CD stock solution were then added successively into the NMR tube containing TCE solution, using a graduated gas-tight Hamilton syringe. After each addition, the solution was thoroughly mixed before the spectrum was acquired. The chemical shift of the ^{1}H peak of TCE was monitored after each addition of CD solution, using the residual solvent proton signal HDO peak (at 4.6 ppm relative to internal tetramethylsilane) as the reference. The final ratio of CD to TCE was such that the CD concentration was present in a 10:1 to 20:1 excess compared with the TCE concentration, depending on the CD being used.

Uptake and release in soil organic matter

A 50 to 100 mg portion of peat was placed in an 8-mL vial, and the aqueous PCE (165 ppm) or TCE (200 ppm) solution was added without leaving any headspace. Each sample vial was prepared in duplicate along with one control omitting the peat, and these were allowed to equilibrate on the shaker for periods of either 1 or 7 days. After equilibration, the sample vials were centrifuged and the supernatant was withdrawn for HPLC analysis without any further dilution. A 5% CD (w/v) solution was then added to the sample

vials, which were again equilibrated for 18 h overnight before analysis. The sample vials were centrifuged and supernatant was withdrawn for analysis by HPLC.

Results

Solubility enhancement

Data obtained for the solubility of TCE and PCE in the presence of varying amounts of different CDs were used to calculate solubility enhancement factors. Under equilibrium conditions and assuming the formation of a 1:1 complex between TCE and CD, eqs. [1] and [2] apply.
[1] $\text{TCE} + \text{CD} \underset{}{\overset{K_{11}}{\rightleftharpoons}} \text{TCE–CD}$

[2] $K_{11} = \dfrac{[\text{TCE} - \text{CD}]}{[\text{TCE}][\text{CD}]}$

where K_{11} is the 1:1 binding constant.

When excess TCE is added to an aqueous CD solution, both free TCE, $[\text{TCE}]_o$, and complexed TCE ($[\text{TCE–CD}]$) will exist in the solution. $[\text{TCE}]_o$ represents the aqueous solubility of the uncomplexed material and remains constant upon addition of increasing amounts of CD. In that situation, the total aqueous solubility of TCE at any CD concentration, $[\text{TCE}]_t$, can be expressed as:

[3] $[\text{TCE}]_t = [\text{TCE–CD}] + [\text{TCE}]_o$

Combining eqs. [2] and [3], $[\text{TCE}]_t = [\text{TCE}]_o(K_{11}[\text{CD}] + 1)$. This relation is generally valid for non-polar and low-polarity organic compounds, and can be expressed in general as $[\text{S}]_t = [\text{S}]_o(K_{11}[\text{CD}] + 1)$. Therefore,

[4] $[\text{S}]_t/[\text{S}]_o = K_{11}[\text{CD}] + 1$

where $[\text{S}]_t$ = aqueous concentration of substrate in the presence of CD and $[\text{S}]_o$ = aqueous solubility, i.e., aqueous concentration of substrate in the absence of CD. The ratio of $[\text{S}]_t$:$[\text{S}]_o$ represents the "aqueous solubility enhancement" of the compound for a given concentration of CD.

It was found that upon addition of increasing amounts of CD the solubility of PCE or TCE increased in a linear fashion. In each experiment the intercept of the linear regression line was found to be unity, within experimental error, in accordance with eq. [4]. The $[\text{S}]_t/[\text{S}]_o$ values, calculated at 5% CD concentration, are listed in Table 2. The 1:1 binding constants (K_{11}) obtained from the slope of plots of eq. [4] are reported in Table 3.

Binding constants (K_{11}) obtained by ^{1}H NMR

In the NMR experiments, as the concentration of CD was increased, the ^{1}H peak for TCE shifted downfield. The observed chemical shift (δ) is the average of the chemical shifts of the nuclei in TCE and the TCE–CD complex, weighted by the fractional occupancy of these states, i.e.

[5] $\delta = f_{10}\delta_{\text{TCE}} + f_{11}\delta_{\text{TCE–CD}}$

where f_{10} = fraction of free TCE and f_{11} = fraction of complexed TCE.

The chemical shift difference (Δ) between free and complexed TCE can be expressed as:

[6] $\Delta = \delta - \delta_{\text{TCE}}$

Table 2. Solubility enhancement factors (standard errors)[a] for PCE and TCE in the presence of 5% substituted CDs.

Compound	HPβ-CD	Mβ-CD	CMβ-CD1	CMβ-CD2	Sb-CD1	Sβ-CD2
PCE	14 ± 0.4 (8.1)[b]	14 ± 0.4 (16.1)[b]	10.9 ± 0.5	2.7 ± 0.6	9.6 ± 0.9	1.1 ± 0.1
TCE	3.1 ± 0.2 (3.4)[b] (2.6)[c]	5.5 ± 0.4 (4.6)[b]	2.2 ± 0.2	1.9 ± 0.1	2.8 ± 0.3	1.1 ± 0.2

[a]Associated error is the standard error of the slope at the 95% confidence level.
[b]Values from ref 18.
[c]Value from ref. 15.

Table 4. Retention of PCE and TCE by soil organic matter.

	Amount of peat (mg per 8 mL of solution)	Amount sorbed[a] after 1 day equilibration (μg g^{-1} peat)	Distribution coefficient[a] K_d (mL g^{-1})	Amount sorbed[a] after 7 days equilibration (μg g^{-1} peat)
PCE[b]	50	6600 ± 800	48 ± 3	6700 ± 600
PCE	100	5400 ± 700	48 ± 4	—
TCE[c]	50	2200 ± 900	14 ± 3	3800 ± 500
TCE	100	3000 ± 300	16 ± 2	—

[a]Average value from multiple measurements ± SD.
[b]Initial [PCE] = 165 ppm.
[c]Initial [TCE] = 200 ppm.

At saturation, the maximum change in chemical shift (Δ_{11}) can be described as (28)

[7] $\Delta_{11} = \delta_{TCE-CD} - \delta_{TCE}$

Combining eqs. [5], [6], and [7]

[8] $\Delta = f_{11}\Delta_{11}$

Combining eqs. [8] and [2] and rearranging gives

[9] $\Delta = \dfrac{\Delta_{11}K_{11}[CD]}{1 + K_{11}[CD]}$

Equation [9] is valid for a 1:1 binding isotherm. For each CD, the plot of chemical shift difference (Δ in ppm) of TCE versus the CD concentration gave a hyperbolic curve that reached a plateau at higher CD concentration. K_{11} was obtained using non-linear regression analysis of the data set in the Graph Pad Prism program byminimizing the sums of the squares of the residuals. Values of the individual analysis of each of the CDs are listed in Table 3. A representative plot for the TCE–Mβ-CD system is shown in Fig. 2.

Retention of PCE and TCE by soil organic matter and extraction by CDs

The retention of TCE or PCE by soil organic matter was calculated by comparing the aqueous concentration obtained from samples containing a given amount of peat and known concentrations of added TCE or PCE with that from controls containing the same concentration of added TCE or PCE only. This allowed for the calculation of distribution coefficients (K_d = concentration of TCE or PCE in peat (μg g^{-1}) / concentration in water (μg mL^{-1})). Table 4 gives the percent retention of these two compounds under different conditions along with K_d values. After 5% CD was added, new retention values were determined (Table 5).

Fig. 2. Plot showing a change in the chemical shift of TCE upon addition of Mβ-CD. The curve has been fitted to the data using Graph Pad Prism.
Discussion

Solubility enhancement

The observed increase in solubility of TCE and PCE upon addition of substituted CDs can be attributed to complexation of the low polarity species within the hydrophobic CD cavity. Solubility enhancement depends on several factors, including size, structure, polarity, and hydrophobicity of the guest molecule (15), as well as size of the CD cavity. As PCE differs from TCE by only one additional Cl atom, size and structure may not be the major factor in this case. However, PCE is less polar and more hydrophobic than TCE, which would favour inclusion for the former. The overall solubility enhancement values for PCE were found to be higher than for TCE (Table 2). Similarly, Boving et al. (18) showed that the enhancement was greater for PCE than TCE

Table 5. Effect of added 5% CD on retention of PCE and TCE by soil peat material.

	Residual amount sorbed[a] (μg g^{-1} peat)	% of sorbed PCE or TCE removed by CDs[b]
PCE + 5% HPβ-CD	640 ± 130	90
PCE + 5% Sβ-CD1	140 ± 40	98
PCE + 5% Mβ-CD	480 ± 50	93
TCE + 5% HPβ-CD	600 ± 150	73
TCE + 5% Sβ-CD1	480 ±160	78
TCE + 5% Mβ-CD	150 ± 60	93

[a]50 mg peat per 8 mL solution and 1 day equilibration.
[b]Values obtained comparing the amount of sorbed PCE or TCE on peat (Table 4) with that present after extraction with CD solutions.

for both 5% and 10% HPβ-CD and Mβ-CD, respectively. Where overlapping data were obtained, most results from their work were in reasonable agreement with the present enhancement factors (Table 2).

Other than the factors noted above, the variation in solubility enhancement values with different CDs can be explained by the presence and nature of the substituent groups on the β-CD molecule. Among the CDs used, Sβ-CD1, Sβ-CD2, CMβ-CD1, and CMβ-CD2 are modified by negatively charged substituent groups. In these cases there would be a repulsive interaction between the negatively charged groups and the π-electron cloud density of the C=C double bond in polychloroethylenes. The repulsive interaction would act as a barrier for an electron-rich guest molecule, disallowing its entry into the cavity; it may also destabilize the inclusion complex. In this situation, formation of the inclusion complex will be both kinetically and thermodynamically unfavorable, which is reflected in the lower magnitude of the solubility enhancement found for these CDs in comparison to the CDs with neutral substituents.

Another factor that may affect the extent of enhancement is the degree of substitution (DS) in the CD molecule. A higher DS could cause steric inhibition for an incoming guest molecule. CMβ-CD2, which showed lower aqueous solubility enhancement for both compounds, has a higher degree of substitution than CMβ-CD1. Moreover, addition of the highly substituted Sβ-CD2 also contributed to the very low enhancement.

Substitution of the CD by neutral substituent groups increases the hydrophobicity of the molecule as a whole, which leads to increased interaction with a hydrophobic guest molecule (29). With TCE, the enhancement factor was found to be largest for methylated-β-CD. The hydroxypropyl group is also neutral but is larger in size compared to the methyl group, so steric interference may again be of importance here (30). In accordance with this argument, TCE showed higher enhancement with Mβ-CD compared to HPβ-CD. Interestingly, however, PCE showed similar enhancement factors with both HPβ-CD and Mβ-CD.

Binding constant

In the CD molecule, the H-3 and H-5 protons of the glucose subunits are projected inwards towards the cavity, and it is these protons that experience a change in chemical shift upon inclusion of a guest molecule, while protons on the outer face are unaffected (31). The observed shifts are a result of the altered magnetic environment due to the presence of the guest molecule. Furthermore, in the inclusion process, protons of the guest molecule also experience changes in their magnetic environment, thus affecting their chemical shift values (24, 25). The magnitude of chemical shift changes for both guest and host depend on various factors, especially the anisotropic effect, altered solvation, and the conformation of the guest molecule inside the cavity. The maximum chemical shift changes for the ^{1}H TCE observed in the experiments conducted here were found to be ca. 0.2 ppm.

Inhomogeneity in the substitution of the CDs used in the present work complicates their observed NMR spectra, causing broadening of some peaks and rendering it difficult to make assignments for individual protons. On the other hand, the guest TCE methine proton gave a sharp peak at 6.6 ppm, and it was possible to follow the change in the chemical shift upon addition of CD. An illustrative figure showing the NMR spectra of both CD and TCE with increasing amounts of CD is provided as Supplementary material.[2] Upon complexation with CD, one sharp downfield-shifted methane peak was observed, indicating that the magnetic environment experienced by the TCE proton is averaged over the environment of the free and bound states. The presence of a singlet can be attributed to a fast equilibrium between the free and bound guest molecules, as is applicable to loosely bound complexes (28).

Since TCE is a considerably smaller molecule (0.155 nm^3) when compared with the size of the CD cavity (0.262 nm^3), the possibility of there being two guest molecules in each host CD (i.e., a 2:1 complex) must be considered. In treating the NMR results, such a possibility was tested by attempting to fit the experimental data to equations for both 1:1 and 2:1 complexation (28). Using the Graph Pad Prism program, converging fits could be obtained for both cases, but the 2:1 situation gave values with extremely large uncertainties, and in some cases K_{21} results were negative. On the other hand, when using eq. [9], which is based on a 1:1 model (28), the same data sets converged to consistent values for K_{11} with relatively small uncertainties (Table 3). The predicted 1:1 binding is supported in the hyperbolic curves generated, with correlation coefficients ranging from 0.98 to 0.99.

A similar situation was encountered in an investigation (32) of the binding of both α- and β-CDs with a large range of small aliphatic and aromatic molecules. Attempts to fit the data sets into a 2:1 model using both calorimetric and ^{1}H NMR measurements were unsuccessful, as the generated parameters were associated with very large errors. The possi-

Fig. 3. Plot of the aqueous solubility enhancement of TCE with different CDs (at 5% concentration) versus respective K_{11} obtained from ^1H NMR experiment. $r^2 = 0.9913$; y intercept = 1.05.

Fig. 4. Plot of aqueous solubility enhancement of PCE with different CDs (at 5% concentration) versus respective K_{11} obtained from eq. [4]. $r^2 = 0.9814$; y intercept = 0.962.
bility of 2:1 binding was excluded based on the poor curve fitting.

Because of the relatively small size of TCE compared to the host molecules, positioning of the TCE inside the cavity may not be specific and loose binding is expected. Notably, the magnitudes of the binding constant values found in this work (Table 3) are small compared to systems where a complementary fit between guest and host was postulated (10, 11, 14, 25).

As noted above for TCE, plots of $[S]_t/[S]_o$ against [CD] according to eq. [4] were linear with intercepts near unity and slopes with values of K_{11}. An alternative method of treating eq. [4] is to plot $[S]_t$ against [CD]. For such plots it has been shown (28) that the slope (= $K_{11}S_o$) is always less than or equal to 1 if only 1:1 complexation occurs. In the present situation, slopes range from 0.2 to 1.0 depending on the CD, again consistent with a 1:1 binding model.

In most cases, for TCE binding with various CDs, we found good agreement (Table 3) between the K_{11} values obtained from solubility and the NMR experimental results. For PCE, however, the NMR method could not be used because of the lack of a proton as a probe for binding. Theoretically, K_{11} could be measured using ^{13}C NMR, but the low aqueous solubility of PCE precluded such experiments. As well, having two tertiary carbons in the PCE molecule contributes to very low sensitivity with respect to ^{13}C NMR. However, the good agreement (Fig. 3) between the K_{11} values for TCE using the two methods gives some confidence regarding the corresponding values obtained for PCE by the single applicable procedure. The plot of $[S]_t/[S]_o$ for PCE against K_{11} according to eq. [4] was linear with a correlation coefficient of 0.981 (Fig. 4) and an intercept close to unity.

Overall, it is concluded that aqueous solubility enhancement occurs because of the formation of a host–guest complex between CD and TCE or PCE, and it is driven primarily by hydrophobic forces. A high degree of substitution results in steric congestion for cavity opening and, consequently, leads to diminished inclusion of the polychloroethylenes examined. Nonpolar substituents in the CD host enhance binding by creating a more hydrophobic cavity. The interplay of these opposing influences gives rise to the magnitude of
binding constants (K_{11}) and solubility enhancements $([S]_t/[S]_o)$ found in the present work.

Extraction of retained PCE and TCE from soil organic matter by CDs

The ability of CDs to solubilize TCE and other hydrophobic compounds that are bound to soils has been previously observed (16). In soil column experiments, enhanced transport of a range of organic compounds has been achieved in this way. Humic acid, a primary component of peat and soil organic matter in general, is a polydisperse polymeric material composed of a three-dimensional aromatic and alkyl chain framework modified by a variety of mostly oxygen-containing functional groups. The substantially hydrophobic nature of this material contributes to the ability of peat to sorb nonpolar and low-polarity organic compounds (33). Table 4 shows the % retention and K_d values for TCE and PCE when equilibrated with IHSS peat in an aqueous medium. It is not surprising, then, that of the two compounds investigated here the more hydrophobic PCE showed greater tendency to be retained by peat than did TCE. As expected, the calculated K_d values were found to be constant, independent of the amount of peat.

In the extraction process, it was found that addition of 5% CD (HPβ-CD or Sβ-CD1 or Mβ-CD) enabled the fairly efficient desorption of PCE or TCE (Table 5); between 2% and 27% of the original material remained after a single extraction. As is predicted from the established K_{11} values, PCE was more efficiently extracted than TCE. Thus, a suitably substituted β-CD may be a valuable additive for extracting and solubilizing polychlorinated organics during site remediation using pump-and-treat methods.

Alkali metal ion catalysis in nucleophilic displacement by ethoxide ion on *p*-nitrophenyl phenylphosphonate: Evidence for multiple metal ion catalysis[1]

Erwin Buncel, Ruby Nagelkerke, and Gregory R.J. Thatcher

Abstract: In continuation of our studies of alkali metal ion catalysis and inhibition at carbon, phosphorus, and sulfur centers, the role of alkali metal ions in nucleophilic displacement reactions of *p*-nitrophenyl phenylphosphonate (PNPP) has been examined. All alkali metal ions studied acted as catalysts. Alkali metal ions added as inert salts increased the rate while decreased rate resulted on M^+ complexation with 18-crown-6 ether. Kinetic analysis indicated the interaction of possibly three potassium ions, four sodium ions, and five lithium ions in the transition state of the reactions of ethoxide with PNPP. Pre-association of the anionic substrate with two metals ions in the ground state gave the best fit to the experimental data of the sodium system. Thus, the study gives evidence of the role of several metal ions in nucleophilic displacement reactions of ethoxide with anionic PNPP, both in the ground state and in the transition state. Molecular modeling of the anionic transition state implies that the size of the monovalent cation and the steric requirement of the pentacoordinate transition state are the primary limitations on the number of cations that can be brought to bear to stabilize the transition state and catalyze nucleophilic substitution at phosphorus. The bearing of the present work on metal ion catalysis in enzyme systems is discussed, in particular enzymes that catalyze phosphoryl transfer, which often employ multiple metal ions. Our results, both kinetic and modeling, reveal the importance of electrostatic stabilization of the transition state for phosphoryl transfer that may be effected by multiple cations, either monovalent metal ions or amino acid residues. The more such cations can be brought into contact with the anionic transition state, the greater the catalysis observed.

Key words: alkali metal ion catalysis, nucleophilic displacement at phosphorus, multiple metal ion catalysis, phosphoryl transfer.

Résumé : Dans le cadre de nos études sur la catalyse par les ions de métaux alcalins et sur l'inhibition au niveau des centres carbonés, phosphorés et sulfurés, on a examiné le rôle des métaux alcalins sur les réactions de substitutions nucléophiles du phénylphosphonate de *p*-nitrophényle (« PNPP »). Tous les ions de métaux alcalins étudiés agissent comme catalyseurs. Les ions de métaux alcalins ajoutés sous la forme de sels inertes augmentent la vitesse alors que l'on observe des diminutions de vitesse lorsque les ions M^+ sont complexés par l'éther 18-couronne-6. L'analyse cinétique indique qu'il pourrait exister une interaction de trois ions potassium, quatre ions sodium et cinq ions lithium dans l'état de transition des réactions de l'éthanolate avec le « PNPP ». Une préassociation du substrat anionique avec deux ions métalliques dans l'état fondamental permet de réaliser le meilleur ajustement des données expérimentales du système du sodium. Cette étude permet donc de mettre en évidence le rôle de plusieurs ions métalliques dans les réactions de substitutions nucléophiles de l'éthanolate avec le « PNPP » anionique, tant dans l'état fondamental que dans l'état de transition. Des calculs de modélisation moléculaire de l'état de transition anionique impliquent que la taille du cation monovalent et les nécessités stériques de l'état de transition pentacoordiné sont les limitations primaires du nombre de cations qui peuvent être amenés à stabiliser l'état de transition et à catalyser la substitution nucléophile au niveau du phosphore. On discute des implications du présent travail sur la catalyse par des ions métalliques sur les systèmes enzymatiques, particulièrement ceux qui catalysent le transfert de groupes phosphoryles qui font souvent appel à de multiples ions métalliques. Nos résultats, tant cinétiques que théoriques, révèlent l'importance de la stabilisation électrostatique de l'état de transition pour le transfert de phosphoryle qui peut être affecté par de plusieurs cations, ions métalliques monovalents ou résidus d'acides aminés; plus on peut amener de tels cations en contact avec l'état de transition anionique meilleure est la catalyse observée.

E. Buncel,[2] R. Nagelkerke,[3] and R.J. Thatcher. Department of Chemistry, Queen's University, Kingston, ON K7L 3N6, Canada.

Introduction

The role of metal ions in the mechanism of phosphoryl transfer reactions (2, 3) has been under extensive investigation owing to the importance of these processes in biological systems (4, 5). The ubiquitous presence of alkali metal ions in biological systems calls for intensive investigation of catalysis by these monovalent ions, but such studies have only rarely been undertaken. The majority of studies have been directed towards the catalytic effects of divalent ions such as Mg^{2+}, Ca^{2+}, Mn^{2+}, Fe^{2+}, Cu^{2+}, and Zn^{2+} in the hydrolysis of phosphate esters (6–8).

We have initiated systematic studies of the influence of alkali metal ions in nucleophilic displacement reactions at carbon, phosphorus, and sulfur centers (9–20). Our previous reports have shown that in the reaction of alkali metal ethoxides and phenoxides with *p*-nitrophenyl diphenylphosphinate **1** (PNPDP), all the alkali metals functioned as catalysts, with the MOEt reactivity order LiOEt > NaOEt > KOEt > CsOEt > EtO⁻ (13, 14). However, with *p*-nitrophenyl benzenesulfonate **2** (PNPBS), both catalysis and inhibition was observed, the reactivity order now being KOEt > CsOEt > NaOEt > EtO⁻ > LiOEt (15, 16).
PNPDP (**1**)
PNPBS (**2**)
PNPP (**3**)

In the present work we have extended our investigations to *p*-nitrophenyl phenylphosphonate **3** (PNPP), as the first monoanionic phosphorus ester in this series, noting the importance of charged phosphate esters in biological systems. In the reaction of **3** with alkali metal ethoxides in ethanol the order of catalytic effectiveness was determined to be LiOEt > NaOEt > KOEt > CsOEt > > EtO⁻, i.e., qualitatively similar to the situation with PNPDP (**1**). However, in-depth analysis shows that the kinds of treatment that we

have applied in the previous cases (i.e., simple ion pair and dissociated ion reaction pathways) are no longer applicable here, but that multiple ion association has to be invoked. Both ground state and transition state interactions are discussed.

Results

The reaction under investigation is shown below with the assumption that the substrate is fully ionized in basic ethanol.

PNPP (**3**)
The rate of the reaction in anhydrous ethanol at 25°C was followed spectrophotometrically by monitoring the formation of *p*-nitrophenoxide ion under pseudo-first-order conditions with the alkoxide in at least 20-fold excess. Excellent first-order kinetics were observed up to 90% reaction and rate constants were obtained from linear log $(A_\infty - A_t)$ vs. time plots. Slower reactions were conducted for only one half-life or less, and rate constants were obtained by an initial rate method. Results are presented in Tables 1–3 and displayed in Fig. 1.

The effect of added complexing agent has been examined; Fig. 2 and Table 4 show the effect of added 18-crown-6 on the rate of reaction of PNPP with KOEt at a constant base concentration. The rate decreased until 1 equiv of complexing agent had been added, after which point increasing the crown concentration had no effect on the reaction rate. The constant rate observed after 1 equiv of complexing agent had been added corresponds to the reaction of free ethoxide with the phosphonate ester on the assumption that cations are fully complexed by the added 18-crown-6 and are unreactive. The average rate constant for the free ethoxide so obtained is $5 \pm 2 \times 10^{-7}$ s⁻¹ M⁻¹.

The role of the metal ion in the reaction mechanism was further investigated by adding metal ions in the form of unreactive salts to reactions of alkali metal ethoxides with **3**. The effect of added LiCl and LiNO₃ on the LiOEt reaction is shown in Table 5. To achieve a substantial [salt]:[base] ratio, a low concentration of base was used for these experiments. The reactions were so slow that plots of absorbance vs. time did not show the curvature expected for first-order reactions. Instead, the absorbance varied linearly with time and zero-order rates were observed. The reported rate constants were determined in the same manner as for initial rates,

converting the change in absorbance per run time, $\Delta A/\Delta t$, to a zero-order rate constant and dividing the rate constant by the substrate concentration to get k_{obs}.

Discussion

Catalytic role of alkali metal ions

The order of reactivity exhibited (Fig. 1) in the present work with PNPP is LiOEt > NaOEt > KOEt > > EtO$^-$, which is qualitatively similar to that observed in our previous work with PNPDP (**1**), but the rates of reaction are much smaller in the present work: k_{EtO^-}(PNPP)/k_{EtO^-}(PNPDP) is ca. 10^{-6}. This is in accord with nucleophilic attack occurring in the present case on an anionic substrate. The increase in rate on addition of the unreactive salts LiCl and LiNO$_3$ to the LiOEt reaction, while moderate (Table 5), is in accord with a catalytic effect of Li$^+$ (see also ref. 1).

Catalysis by alkali metal ethoxide ion pairs

In our previous studies with *p*-nitrophenyl diphenylphosphinate (**1**) as well as with *p*-nitrophenyl benzenesulfonate (**2**) results were analyzed in terms of reactivity by dissociated EtO$^-$ (or PhO$^-$) ions and by the associated EtO$^-$M$^+$ (or PhO$^-$M$^+$) ion pairs (13–17). Since the association constants

of alkali – metal ethoxides in ethanol are known (21), one could calculate the contribution of each species to the two separate reaction pathways (for the case of PhO$^-$M$^+$ the respective contributions could be evaluated by a mathematical treatment) (14). For the phosphinate **1** it was found that for all the alkali metal ethoxides and phenoxides, associated RO$^-$M$^+$ ion pairs were more reactive than free RO$^-$ ions. This could be rationalized in terms of a more effective stabilization of the transition state by M$^+$ than of the ground state. Stabilization energies of the transition state and of the ground state could be evaluated by a method developed originally by Kurz (22) and applied by Mandolini and coworkers (23), Tee (24), and others (25–28). For the sulfonate (**2**) – ethoxide reaction the higher alkali metal ions acted as

[a]No reaction was observed without added salt.
catalysts but Li$^+$ acted as inhibitor, which is indicative of greater stabilization of the ground state than of the transition state (17–19).

Applying the free ethoxide – metal ethoxide ion pair model to the present system, with reaction pathways for both species (Scheme 1), leads to the rate eqs. [1] and [2] where S$^-$ refers to the substrate

[1]   rate = k_{EtO^-}[EtO$^-$][S$^-$] + k_{MOEt}[MOEt][S$^-$]

[2] k_{obs}/[EtO$^-$] = k_{EtO^-} + $k_{MOEt}K_a$[EtO$^-$]

According to eq. [2], plots of k_{obs}/[EtO$^-$] vs. [EtO$^-$] calculated (see Tables S1–S3)[4] using the known (21) values of K_a should be linear. However, it may be seen from the curved nature of the plot in Fig. 3 for LiOEt and the very similar plots for NaOEt and KOEt (not shown) that the ion pair mechanism does not adequately describe the reaction of

Scheme 1. Metal ethoxide ion pair catalysis.

$$\text{EtO}^- + \text{M}^+ + \text{S}^- \xrightarrow{k_{EtO^-}} \text{products}$$

$$K_a \updownarrow$$

$$\text{MOEt} + \text{S}^- \xrightarrow{k_{MOEt}} \text{products}$$
PNPP with metal ethoxides. The upward curvature in Fig. 3 suggests that higher involvement in M$^+$ should be considered.

Catalysis by pre-association mechanism

One can consider a pre-association pathway in which one metal ion associates with the substrate and the consequent reaction of ethoxide with S$^-$M$^+$, along with the parallel reactions of S$^-$ with EtO$^-$ and S$^-$ with MOEt, as shown in Scheme 2.

Fig. 3. Ion pairing treatment of the data for the reaction of PNPP with LiOEt in EtOH at 25°C.
Scheme 2. Pre-association catalysis.

$$EtO^- + M^+S^- \xrightarrow{k_{M^+}} \text{products}$$

$$K_c \uparrow\downarrow$$

$$EtO^- + M^+ + S^- \xrightarrow{k_{EtO^-}} \text{products}$$

$$K_a \uparrow\downarrow$$

$$MOEt + S^- \xrightarrow{k_{MOEt}} \text{products}$$
The rate equation corresponding to Scheme 2 is given in eq. [3] from which eq. [4] follows, which is of the same form as eq. [2].

[3] $\quad$ rate $= k_{EtO^-}[EtO^-][S^-] + k_{M^+}[EtO^-][M^+S^-]$

$$+ k_{MOEt}[MOEt][S^-]$$

[4] $\quad k_{obs}/[EtO^-] = k_{EtO^-} + (k_{M^+}K_c + k_{MOEt}K_a)[EtO^-]$

As before, it follows from eq. [4] that plots of $k_{obs}/[EtO^-]$ vs. $[EtO^-]$ should be linear, but as has already been noted these plots (e.g., Fig. 3) are curved upward thus ruling out the pre-associative mechanism of Scheme 2.

Catalysis by both pre-associative and ion pair mechanism

To explore a pathway involving two metal ions, we consider the possibility of attack on S^-M^+ by MOEt in parallel with the pathways shown in Scheme 2. This mechanism,

Scheme 3. Ion pair and pre-association catalysis.

$$MOEt + M^+S^- \xrightarrow{k_N} \text{products}$$

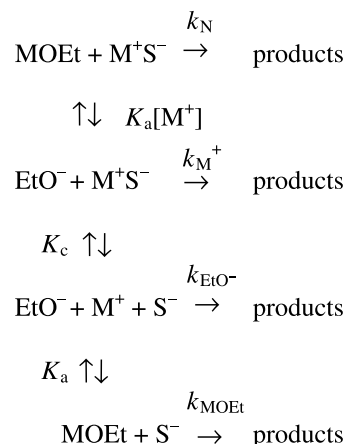
$$\uparrow\downarrow \quad K_a[M^+]$$

$$EtO^- + M^+S^- \xrightarrow{k_{M^+}} \text{products}$$

$$K_c \uparrow\downarrow$$

$$EtO^- + M^+ + S^- \xrightarrow{k_{EtO^-}} \text{products}$$

$$K_a \uparrow\downarrow$$

$$MOEt + S^- \xrightarrow{k_{MOEt}} \text{products}$$


given in Scheme 3, leads to the rate law in eq. [5] from which eq. [6] can be derived where k_N refers to the "new" rate constant for attack of an ion pair on a metal-complexed substrate.

[5] $\quad$ rate $= k_{EtO^-}[EtO^-][S^-] + k_{M^+}[EtO^-][M^+S^-]$

$$+ k_{MOEt}[MOEt][S^-] + k_N[MOEt][M^+S^-]$$

[6] $\quad k_{obs} = k_{EtO^-}[EtO^-] + (k_{M^+}K_c + k_{MOEt}K_a)[EtO^-]^2$

$$+ k_N K_c K_a[EtO^-]^3$$

The relationship given in eq. [6] is more complex, having $[EtO^-]$, $[EtO^-]^2$, and $[EtO^-]^3$ terms, and the previously used plot of k_{obs} vs. an independent variable (for the PNPDP system) is not possible for this relationship. In an attempt to try to fit the experimental data using the relationship presented in eq. [6], a spreadsheet (Lotus 123 (Release 2.01)) was used. Arbitrary values were input for the unknown constants (k_N, k_{M^+}, and K_c) and these values were optimized iteratively until a best fit to the experimental data was observed. Once a relationship was determined, the fit of the calculated values of k_{obs} to the experimental value of k_{obs} was measured using standard linear regression methods present in the Lotus program.

However, no combination of values for the unknown constants could be found for eq. [6] that would satisfactorily fit all the k_{obs} experimental data, especially the data for the higher base concentrations (0.06–0.09 M). Equation [6] contains first-, second-, and third-order terms in $[EtO^-]$. However, it will be shown in the following section that a plot of k_{obs} vs. $[EtO^-]$ has curvature that is adequately fit by a *fifth*-order $[EtO^-]$ term and this curvature cannot be fit by second- and third-order terms. This result is taken to indicate that the proposed mechanism in Scheme 3, involving just two metal ions, is not adequate to describe the reaction of metal ethoxides with PNPP.

Multiple ion catalysis

From attempts to fit the kinetic data to third-order terms in $[EtO^-]$ it became apparent that higher order terms in $[EtO^-]$ were needed to fit k_{obs} over the entire $[EtO^-]$ range studied (0–0.1 M). Given that $[EtO^-]$ is equal to $[M^+]$,

Fig. 4. Curve fitting of the data for the reaction of PNPP with LiOEt in EtOH at 25°C with $[Li^+]^n$, $n = 4, 5, 6,$ and 7 (see Table 6).

Fig. 5. Curve fitting of the data for the reaction of PNPP with NaOEt in EtOH at 25°C with $[Na^+]^n$, $n = 4, 5,$ and 6 (see Table 6).

attempts were made to fit the observed kinetic data to $[M^+]^n$. The relationship being examined is shown in eq. [7], where k_p refers to the rate constant for reaction of free ethoxide with the substrate as mediated by n metal ions. The results are shown in Figs. 4, 5, and 6. Table 6 gives the coefficients and the goodness of the fits (as measured by r^2) for the best fit lines shown in these figures.

The rate increase from reaction of the mono-anion at relatively high concentrations (0.05–0.1 M) of alkali metal ion is consistent with rate constants that are approximately fourth-order in K^+, fifth-order in Na^+, and sixth-order in Li^+, or their kinetic equivalents, as shown below.

[7] $\quad EtO^- + S^- + n[M^+] \overset{k_p}{\rightarrow} products$
[8] $\quad rate = k_{obs}[S^-]$

[9] $\quad k_{obs} = k_p[M^+]^n$

[10] $\quad k_{obs} = 1.42 \times 10^4 \, [Li^+]^6 = 1.42 \times 10^4[Li^+]^5[EtO^-]$

[11] $\quad k_{obs} = 60.8 \, [Na^+]^5 = 60.8 \, [Na^+]^4[EtO^-]$

[12] $\quad k_{obs} = 0.963[K^+]^4 = 0.963[K^+]^3[EtO^-]$

The results are interpreted as approximately three K^+, four Na^+, and five Li^+ ions being involved in the transition states of the respective reactions, assuming there is no pre-association with the ground state. Consideration of metal ion association with the substrate will not affect the calculation of the number of metal ions present in the transition state, as shown below. The number of metal ions appears to be related to the size of the ions, which suggests that size limits the number of ions that may participate with the transition state.

The *role* of the metal ions is not discernible from the above treatment, which only gives an estimate of the *number* of metal ions that associate with the transition state. It should be noted that the use of eq. [9] (based on eq. [7]) as-

Fig. 6. Curve fitting of the data for the reaction of PNPP with KOEt in EtOH at 25°C with $[K^+]^n$, $n = 3, 4, 5,$ and 6 (see Table 6).
sumes a "one-step", or elementary, reaction, which would preclude pre-association of these metal ions with the anionic substrate followed by subsequent attack of ethoxide, a two-step reaction. Pre-association of the substrate with metal ions would *increase* the number of metal ions present in the transition state.

Table 6. Table of the coefficients used to fit $[M^+]^n$ terms to the experimental values of k_{obs} for the reaction of MOEt on PNPP in ethanol at 25°C.

Metal ethoxide system	Coefficient (r^2)				
	$[M^+]^3$	$[M^+]^4$	$[M^+]^5$	$[M^+]^6$	$[M^+]^7$

KOEt	7.63×10^{-2}	**0.963**	11.7	138	
	(0.934)	**(0.990)**	(0.986)	(0.951)	

Note: Equation to be fit: $k_{obs} = (coefficient)[M^+]^n$. See Figs. 4, 5, and 6. The correlation coefficients (r^2) are shown and the terms with the best fit are in bold type. The data for k_{obs} are given in supplementary tables S1, S2, and S3.

Scheme 4. Na$^+$ catalyzed reaction of AcP with Pi.
To further analyze the kinetic data, a detailed reaction mechanism needs to be proposed, which requires assumptions about how many ions interact with the ground state. The data for sodium, for example, could be accounted for by association of one metal ion with the ethoxide and one with the anionic substrate, or, alternatively, by the kinetically equivalent free ethoxide attack on the substrate pre-associated by two metal ions in the ground state, both with possibly four additional ions in the transition state. There are several kinetically equivalent possibilities, which will be discussed below.

Pre-association and multiple ion catalysis — Possible rate laws

An example of the complexity of the analysis of multiple ion catalytic participation is given by Herschlag and Jencks who studied the Na$^+$ catalyzed reaction of the anions acetyl phosphate (AcP) and orthophosphate (Pi) to yield acetate and pyrophosphate (PPi) anions (7). In their analysis they noted that the data was well fit by a fourth-order term in Na$^+$ concentration. When they considered a mechanism that included pre-association of the dianionic substrate they were able to re-analyze their data in terms of the associated rate laws. They interpreted their data in terms of two Na$^+$ ions that bind in the ground state and five additional ions that bind in the transition state. They noted, however, that the data could be interpreted by the kinetically equivalent association of two Na$^+$ ions with AcP dianion, two Na$^+$ ions with Pi dianion, or one Na$^+$ ion with each dianion, all in the ground state. On the basis of the kinetic dependence alone, Herschlag and Jencks have speculated on a possible transition state structure for reaction of the dianions of acetyl phosphate and orthophosphate, with three bridging Na$^+$ ions and with four additional bound Na$^+$ ions not shown (Scheme 4) (7). The transition state for this reaction has a charge of –4 delocalized over seven monovalent and two divalent oxygens. There is thus ample scope for the four additional bound Na$^+$ ions, not shown, to coordinate with several of these oxygens in the transition state.

In an attempt to investigate the possible role of the metal ions in the ground state of the present system, the association of one and two metal ions with mono-anionic PNPP in the ground state was considered. In support for the pre-association of two metal ions in the present system, theoretical ab initio studies of the anion $PO_2H_2^-$ by Streitwieser et al. (29) indicate that the best simple representation of the disodium complex of $PO_2H_2^-$ in the gas phase is the structure Na-O-PH$_2^+$-O-Na, tetrahedral at phosphorus and containing co-linear P—O—Na bonds.

If one metal ion is presumed to associate with the anionic substrate with free ethoxide as the nucleophile, then the following mechanism and associated rate laws may be proposed (Scheme 5). K_a refers to the association of the substrate with either one or two metal ions, k_c refers to the rate constant for the attack of free ethoxide on an uncomplexed substrate, and k'_c refers to the rate constant for the attack of free ethoxide on a metal-complexed substrate.
[13]   rate $= k_{obs}[S]_{total}$

[14]   rate $= k_{obs}[S + S \cdot M] = k_c[S \cdot M] + k'_c [M]^n[S \cdot M]$

[15] $K_a = [S \cdot M]/[S^-][M^+]$

[16] $k_{obs} = (k_c[S \cdot M] + k'_c[M]^n[S \cdot M]) / ([S + S \cdot M])$

[17] $k_{obs} = (k_c K_a[M^+])/(1 + K_a[M^+])$
$$+ k'_c[M^+]^n(K_a[M^+])/(1 + K_a[M^+])$$

Scheme 5. Pre-association with one Na$^+$.
Scheme 6. Pre-association with two Na$^+$.

If two metal ions are presumed to associate with the anionic substrate and free ethoxide is the nucleophile, then the following mechanism and associated rate laws may be proposed (Scheme 6).

[18]   rate = $k_{obs}[S]_{total}$

[19]   rate = $k_{obs}[S + S \cdot M_2] = k_{c2} [S \cdot M_2]$

$$+ k'_{c2} [M]^n [S \cdot M_2]$$

[20] $k_{a2} = [S \cdot M_2]/[S^-][M^+]^2;\ [S \cdot M_2] = K_{a2}[S^-][M^+]^2$

[21] $k_{obs} = (k_{c2}[S \cdot M_2] + k'_{c2}[M]^n[S \cdot M_2])/(S + S \cdot M_2)$

[22] $k_{obs} = (k_{c2}K_{a2}[M^+]^2)/(1 + K_{a2}[M^+]^2)$

$$+ k'_{c2}[M]^n(K_{a2}[M^+]^2)/(1 + K_{a2}[M^+]^2)$$

It was possible to fit the experimental data to the relationships presented in eqs. [17] and [22] using a spreadsheet program. The data for the Na$^+$ system was arbitrarily used to fit to the models presented above. There are several unknown parameters to be placed in the relationships, namely k_{c2}, k'_{c2}, K_{a2}, and n, the number of metal ions associated with the transition state. By putting in arbitrary values for these constants and optimizing them iteratively, it was possible to find several sets of values that fit the experimental values of k_{obs} well, as measured by a linear regression correlation coefficient (r^2). In the previous section a good fit to the experimental data for the Na$^+$ system was given by $n = 5$, so this was the value used for this parameter.

The best fit to the experimental data was found via eq. [22] with $n = 5$ and values from set 8 in Table 7 for the mechanism that had *two* metal ions pre-associated with the substrate in the ground state (Fig. 7, $r^2 = 0.9994$). It is interesting to compare Fig. 7, in which a pre-association term is included in the data treatment, with Fig. 5, in which only the

Table 7. Parameters used in curve fitting (Figs. 7–9).

	Set 1	Set 2	Set 3	Set 4
$k_c(M^{-1}s^{-1})$	1.65×10^{-5}	5.0×10^{-6}	3.9×10^{-6}	3.8×10^{-6}
$k'_c(M^{-6}s^{-1})$	136	70	64	67
$K_a(M^{-2})$	10	60	120	140
Fit (r^2)	0.9987	0.9964	0.9957	0.9957
	Set 5	Set 6	Set 7	Set 8
$k_{c2}(M^{-1}s^{-1})$	4.5×10^{-4}	8.0×10^{-5}	4.8×10^{-5}	3.5×10^{-5}
$k'_{c2}(M^{-6}s^{-1})$	850	190	142	110
$K_{a2}(M^{-2})$	10	60	100	160
Fit (r^2)	0.9982	0.9993	0.9993	0.9994

[Na$^+$]^5 term was used to fit the kinetic data. It may be seen that inclusion of a term for the pre-association of the substrate with two metal ions in the rate law gives a better fit over the low range of sodium ion concentration (0.03–0.06 M).

In the curve fitting, the values assigned to the parameters k_{c2}, k'_{c2}, and K_{a2} were arbitrary. Sets 1–4 and 5–8 are just a few of the many possible values that could be used to fit the data. However, it is important to note that the magnitude of $k_{c(2)}$, the rate constant for the unassociated ethoxide for both sets of parameters ($\approx 10^{-6} – 10^{-4}$) is much smaller in magnitude than that for the corresponding values of k'_{c2} ($\approx 10^1 – 10^2$), the rate constant for the associated ethoxide. This is interpreted as further evidence for multiple ion catalysis.

Proceeding to Li$^+$ and K$^+$ catalysis, Figs. 8 and 9 show sample fits for the plots of k_{obs} vs. [M$^+$], which were calculated based on the rate laws associated with the pre-association of two metal ions with the substrate using the stoichiometry from eq. [22] and $n = 4$ (K$^+$) and 6 (Li$^+$). The arbitrary values for the parameters used are given in the

(Data for k_{obs} in supplementary table S2 and parameters from set 8). Note the goodness of the fit for the entire range of data.

Fig. 8. Multi-ion catalysis treatment, including pre-association of the substrate with two Li$^+$ ions, of the data for the reaction of PNPP with LiOEt in EtOH at 25°C ($r^2 = 0.997$). (Data for k_{obs} in supplementary table S1 and values for the parameters used are $k_{c2} = 1 \times 10^{-5}$ M^{-1}s^{-1}, $k'_{c2} = 2000$ M^{-7}s^{-1}, and $K_{c2} = 1000$ M^{-2}).

figure captions, as well as the correlation coefficients. Good fits ($r^2 > 0.99$) were obtained for both systems.

Pre-association and multiple ion catalysis – Possible mechanisms

It has been shown that alkali metal catalysis of the reaction of ethoxide with PNPP cannot be attributed simply to catalysis by one metal ion, by either ion pair catalysis or a pre-associative mechanism. Even catalysis by two metal ions, as described by a combination of the two modes — namely ion pair catalysis on a single metal-complexed substrate — was not supported by the data treatment. The results of curve fitting the experimental rate data are consistent with the participation of possibly 3–5 metal ions in the transition state, in addition to possible pre-association of metal ions with the ground state. The largest ion (K$^+$) has probably three and the smallest ion (Li$^+$) has probably five ions in the transition state, while Na$^+$ is intermediate, having probably four. The high sensitivity of the observed reaction rates to the concentration of the metal ion suggests that the metal ions lower charge repulsion between the anionic ethoxide nucleophile and the PNPP substrate. Direct binding of metal ions to the reactants by pre-association or ion pairing could lower charge repulsion between the reactants (7).

The data treatment suggests that pre-association of anionic PNPP with probably two metal ions in the ground state, in addition to multiple cations binding in the transition state, may account for the multiple alkali metal ion catalysis
observed for this reaction. A full kinetic analysis was undertaken for sodium based on this multiple ion mechanism, and good fits to the experimental data for all three systems studied were possible with arbitrary values used for the unknown parameters. The unknown parameters were the rate constants for the uncomplexed and complexed ground states and the association constant for the ground state with either one or two metal ions, as well as the number of metal ions added in the transition state.

The mechanism proposed on the basis of the kinetic analysis is just one of several that are possible, but the good agreement with the experimental data is evidence for multiple metal ion catalysis of nucleophilic substitution at phosphorus and suggests possible roles for metal ions in both the ground states and transition states of the reaction.

It is interesting to speculate on the location of the four Na$^+$ ions stabilizing the probable trigonal bipyramidal (TBP) transition state structure for PNPP ethanolysis. This transition state bears a charge of –2 and possesses relatively bulky ligands at one equatorial and both apical positions. In contrast, the TBP transition state structure postulated by Herschlag and Jencks (7) for pyrophosphate formation from acetyl phosphate bears a charge of –4, is stabilized by seven Na$^+$ ions, and possesses no equatorial ligands and no bulky hydrocarbon ligands (Scheme 4). The apical–equatorial metal ion coordination proposed for the TBP intermediate in alkaline phosphatase catalysis and in other metaloenzyme-catalyzed phosphoryl transfer reactions would support the transition state structure shown in Fig. 10a. However,

Fig. 9. Multi-ion catalysis treatment, including pre-association of the substrate with two K+ ions, of the data for the reaction of PNPP with KOEt in EtOH at 25°C ($r^2 = 0.996$). (Data for k_{obs} in supplementary table S3 and values for the parameters used are $k_{c2} = 1 \times 10^{-4}$ M^{-1}s).

Fig. 10. Possible transition state structures for Na+ catalyzed ethanolysis of PNPP (net charge +2): (a) idealized geometry, with structure (b) obtained by semi-empirical calculations with alkyl and aryl groups removed for ease of visualization.

excess of base was used (relative to the phosphonate ester concentration) to ensure pseudo-first-order conditions for all reactions. Rate constants were calculated from at least 30 absorbance readings. Rate constants for reactions involving added metal ions were calculated as the slope of a plot of $\ln(A_\infty - A_t)$ vs. time. Rate constants for reactions involving complexing agents were calculated using initial rate methods (zero-order kinetics) and the data spanned less than one half-life. Plots of absorbance vs. time were linear; therefore, the reported rate constants were determined by converting the observed change in absorbance to a change in concentration of the product and dividing through by the initial concentration of the substrate ($k_{zero} = k_1$ [substrate]).

molecular orbital calculations on a putative TBP intermediate for PNPP ethanolysis stabilized by four Na+ ions show that the steric requirement of the aryl, aryloxy, and alkoxy ligands prevents such an ideal geometry (Fig. 10a). In this crowded pentacoordinate TBP transition state, only a smaller number of the larger metal ions can be brought into contact with the anionic oxygens surrounding phosphorus. Our molecular modeling thus provides support for the stoichiometry of the transition states for catalysis by Li+, Na+, and K+ obtained from the kinetic analysis.

Experimental section

Materials

The general procedure of Williams and coworkers (30) was followed for the synthesis of the phosphonate PNPP (**1**). The crude product was recrystallized from ethanol to a constant melting point (116–118°C, lit. (31) value mp 117–119°C). 18-Crown-6 (Aldrich) was recrystallized from acetonitrile, then dried over P_2O_5 in vacuo. LiCl (Aldrich, Gold Label) and LiNO$_3$ (Merck Suprapur) were dried over P_2O_5 in vacuo.

Kinetic method

The reaction of *p*-nitrophenyl phenylphosphonate (PNPP) with alkali metal ethoxides was studied in anhydrous ethanol at 25°C. The rates of the reactions were determined by monitoring of the formation of *p*-nitrophenoxide spectrophotometrically using either a Varian Cary3 or a Hewlett-Packard 8452A Diode Array spectrophotometer. An at least 20-fold

Molecular modeling

An equilibrium geometry was obtained from geometry optimization at the PM3 level of a putative TBP intermediate ($[p\text{-NO}_2\text{PhOPPh(O)}_2\text{OEt}]^{2-}$). After addition of four sodium atoms and constraint of the four atoms consisting of phosphorus, apical oxygens, and equatorial carbon, an equilibrium geometry was obtained by iterative relaxation of molecular fragments, followed by relaxation of all atoms but the four constrained atoms (Fig. 10b).

Conclusions

Metal ion catalysis is important in many enzyme systems including those that catalyze phosphoryl transfer (4, 31). In the catalysis of reactions at phosphorus, enzymes often employ multiple metal ions; for example, phospholipase C and nuclease P1 employ two or three catalytic Zn^{2+} ions at the active site (4). Whilst divalent metal ions and in particular Zn^{2+} are the most important biological Lewis acid catalysts, catalytic roles for monovalent cations have been suggested in enzymic phosphoryl transfer. The location of two alkali metal ions (Na+ or K+) in addition to Mg^{2+} at the ATP binding site of Hsc70 has been explained in terms of a catalytic role in the ATPase activity of Hsc70 involving stabilization of the pentacoordinate transition state (32). Interestingly, the relative size of Na+ versus K+ is reflected in quite different coordination in the protein crystal structures and presumably different catalytic effects. Similarly, the active site of fructose-1,6-bisphosphatase contains three metal ion binding sites, one of which is a monovalent cation binding site at

which K^+ is postulated to exert Lewis acid catalysis of nucleophilic substitution at phosphorus (whereas the smaller size of Li^+ results in inhibition rather than activation) (33). In some proteins, cationic amino acid residues replace monovalent metal ions, suggesting that monovalent cations mimic the properties of cationic amino acids in stabilizing anionic transition states.

Enzyme models have been reported that demonstrate bifunctional catalysis by two metal ions (34). However, the best metal-containing systems for acceleration of phosphoryl transfer employ lanthanides (35), exchange-inert Co^{3+} systems, and ligand-coordinated Cu^{2+} (36).

The simple system reported herein reveals multiple metal ion catalysis of nucleophilic substitution at phosphorus in a phosphonate monoester monoanion by the monovalent cations Na^+, K^+, and Li^+. More unexpectedly, the detailed kinetic treatment of the data requires possibly three, four, or five cations in the transition state, even though the putative pentacoordinate transition state is only dianionic. The primary limitation to the number of cations involved in the transition state appears to be the size of the cation and steric limitations on the number of cations that can access the oxygen ligands. Our results, both kinetic and modeling, reveal the importance of electrostatic stabilization of the transition state for phosphoryl transfer that may be effected by multiple cations, either monovalent metal ions or amino acid residues. The more such cations can be brought into contact with the anionic transition state, the greater the catalysis observed.

Taxanes in rooted cuttings vs. mature Japanese yew

Qing-Wen Shi, Tracy L. Petzke, Françoise Sauriol, Orval Mamer, and Lolita O. Zamir

Abstract: Two novel taxanes were identified from rooted cuttings of the Japanese yew, *Taxus cuspidata* Sieb. et Zucc. Their structures were characterized as taxa-4(20),11-dien-2α,5α-diacetate-14β-(2′S,3′R)-3′-hydroxy-2′-methylbutyrate-10-β-glucoside (**1**) and 2α,5α,9α,10β-tetraacetoxy-13α-(Z)-cinnamoyloxy-taxa-4(20),11-diene (**2**). In addition, metabolites **3–43** were also characterized in the same cuttings. Taxanes **3–16** as well as three non-taxane metabolites (**17–19**) have not previously been reported in the needles, stems, seeds, or bark of the mature *T. cuspidata* plant, although they have been found in other yews. The known taxanes **20–43** were also detected for the first time in the rooted cuttings of the Japanese yew.

Key words: *Taxus cuspidata*, Taxacae, taxanes, rooted cuttings, metabolites.

Résumé : Deux nouveaux taxanes ont été identifiés pour la première fois dans des boutures de l'if Japonais, *Taxus cuspidata* Sieb. et Zucc. Leurs structures ont été caracterisées : taxa-4(20),11-dien-2α,5α-diacetate-14β-(2′S, 3′R)- 3′-hydroxy-2′-methylbutyrate-10-β-glucoside (**1**) et 2α,5α,9α,10β-tetraacetoxy-13α-(Z)-cinnamoyloxy-taxa-4(20),11-diene (**2**). De plus, les métabolites **3–43** ont été caracterisés dans les boutures de l'if Japonais. Les taxanes **3–16** ainsi que trois métabolites non-taxanes (**17–19**) isolés dans d'autres ifs n'ont jamais été identifiés dans les tiges, graines ou écorce de la plante mature *T. cuspidata*. Les taxanes connus **20–43** ont aussi été detectés pour la première fois dans les boutures de l'if Japonais.

Mots clés : *Taxus cuspidata,* Taxacae, taxanes, boutures, métabolites.

Introduction

The Japanese yew *Taxus cuspidata* Sieb. et Zucc. has been investigated since 1963 and more than 90 taxanes have been found in its needles, bark, stem, or seeds (1–6). Rooted cuttings are used for the production of ornamental yews. The required hormones and environmental conditions for their production are kept confidential by competitive garden centres. We were interested to compare the composition of taxanes in rooted cuttings vs. needles of mature plants. Indeed, we thought it could give us some insights about the biosynthetic pathways of taxanes in yews. Taxinine derivatives lacking constituents on C-7 and C-9 have been isolated from the Chinese yew and *T. baccata*, and are sometimes found in higher yield than paclitaxel (7, 8). Taxanes with a substituent on C-14 are very rare in nature (7–9), but are easily obtained from biotransformation reactions (10). In addition, the only taxanes with a sugar substitution found in nature have been 7-xylosylbaccatin III derivatives (7).

In this study, two novel taxinine derivatives are reported from the rooted cuttings of the Japanese yew (*T. cuspidata* Sieb. et Zucc.). Taxane **1** has a C-10-*O*-glucosyl-group (the first taxane reported with a sugar moiety on ring B) and a C-14β-2′-butyrate. Taxane **2** has a C-13-*cis*-cinnamoyloxy-side chain (Fig. 1). In addition, we characterized 14 taxanes (**3–16**) and three non-taxanes (**17–19**) in the rooted cuttings of the Japanese yew previously isolated in other yews, but found for the first time in *T. cuspidata*. In addition, taxanes **20–43** were found both in rooted cuttings, needles, and stems of *T. cuspidata*, as well as in needles, bark, or roots of other yews (7, 8).

Results and discussion

Characterization of the structures of the novel taxanes 1 and 2

Taxane (**1**) was obtained as a colorless amorphous solid in a very low yield from dried rooted cuttings of the Japanese yew. The molecular composition of **1** ($C_{35}H_{54}O_{13}$) was established from the combined analysis of HR-FAB-MS and 2D-^{13}C NMR spectra. The ^{1}H NMR spectrum of **1** (shown in Table 1) exhibited three-proton signals due to the four

Fig. 2. Taxane **1**: Arrows show the key HMBC correlations (H → C) of **1**. Bold lines indicate the ^{1}H-^{1}H COSY correlations.

methyl groups at δ1.66, 1.16, 1.97, and 0.85 ppm, and two acetyl groups at relatively lower fields (δ2.01 and 2.16 ppm). The ^{13}C NMR signals at δ21.9, 169.7 and δ21.3, 170.0 ppm confirmed this assignment, suggesting **1** had a taxane-type core skeleton. Indeed, the HMBC correlations of H$_3$-18 to C-11, C-12, and C-13 and H$_3$-16 and H$_3$-17 to C-1, C-11, and C-15 revealed that Me-18 was attached to C-12 whereas Me-16 and Me-17 to C-15, implying that **1** has a regular 6–8–6 ring system. The connectivities of the protons on the skeleton of **1** were determined by analysis of the ^{1}H-^{1}H COSY spectrum. Interpretation of ^{1}H NMR, ^{13}C NMR, and HMBC spectra permitted the positional assignment of all the functional groups. The ^{1}H NMR signals at δ5.26 (1H, *br.s*), 4.81 ppm (1H, *br.s*) together with the signals at δ142.2 and 116.7 ppm in the ^{13}C NMR spectrum and δ2.86 ppm (1H, *d*, *J* = 7.0 Hz) in the ^{1}H NMR spectrum are characteristic of an exocyclic methylene with C-3 ring junction proton in a taxa-4(20),11-diene (11). Using H-3 as a starting point, the connectivities from C-3 to C-2 to C-1 to C-14 to C-13 were deduced from the ^{1}H-^{1}H COSY spectrum. The signal at δ5.28 ppm (1H, *br.s*), which correlated with C-3 in the HMBC spectrum, was assigned to H-5. Similarly, using H-5 as a starting point, the spin system derived from C-5 to C-7 was readily interpreted from the analysis of the ^{1}H-^{1}H COSY spectrum. Detailed analysis of the ^{1}H-^{1}H COSY spectrum revealed an α-methyl-β-hydroxybutyrate group. This moiety has been found in several natural taxane analogues (7, 8). The α-methyl-β-hydroxybutyrate group was connected to C-14 as deduced from the HMBC correlations. The similarity of the NMR data of the α-methyl-β-hydroxybutyrate moiety with known taxanes reveals the configuration to be (2S,3R) (12). Taxanes with a C-2, C-5,
C-10, and C-14 oxygenation pattern have an unusual chemical shift of δ59.2 ppm for C-1 in the ^{13}C NMR spectrum (13, 14), a rather unusual chemical shift value for a non-oxygenated methine. Carbon-1 usually resonates at about δ50 ppm (11) when it is a non-oxygenated methine lacking oxygen substitution at C-14. The downfield shifts of H-2 and H-5 signals suggested the position of two acetate groups, and were confirmed by HMBC correlations. An anomeric carbon signal at δ98.2 ppm as well as six hydrogen signals between δ3.35 and 4.42 ppm in the ^{1}H NMR spectrum indicated the existence of one sugar moiety in taxane **1**, and it was assigned as a glucopyranosyl unit from the chemical shift, multiplicity, and coupling constant values. Analysis of the 2D NMR data (COSY, HMBC) as well as the MS fragment of [M-OH-181]$^+$ confirmed the presence of the glucopyranosyl group. The coupling constant *J* = 7.7 Hz for the anomeric proton H-1″ indicated that this moiety is connected to the aglycon via a β-linkage (*J* ~ 6–8 Hz). The anomeric proton H-1″ (δ4.35 ppm, *J* = 7.7 Hz) showed a long-range correlation with C-10 in the HMBC experiment, suggesting the attachment of the glucose at C-10. The chemical shift of H-10 (δ5.23 ppm, 1H) supports this assignment, since the H-10 proton resonates at about δ6.0 ppm (11) when acetoxylated and at about δ5.0 ppm when it is hydroxylated (11). The orientations of the substituents on the taxane skeleton were confirmed by the coupling constants in the proton NMR and the NOESY spectra (Table 1A). We noticed that when the sample was solubilized in CHCl$_3$ it solidified as a gel giving broad signals in the NMR spectrum (Table 1A) which initially suggested we did not have a pure compound and had two isomers instead. Indeed, the ^{1}H NMR showed two doublets at δ4.35 ppm (major peaks) and at δ4.42 ppm (minor peak) for the anomeric proton. The acetone spectrum, however, (Table 1B) gave sharp signals, only one peak for H-1″ confirming the purity of **1**. The strong NOE correlation of H-14 and H-1 and the small coupling constant between H-1 and H-14 suggested that their dihedral angle was about 90°; the C-14 side chain is therefore β and H-14 is α. The chemical structure of **1** was therefore established as taxa-4(20),11-dien-2α,5α-diacetate-14β-(2′S,3′R)-3′-hydroxy-2′-methylbutyrate-10-β-glucoside (**1**). Taxane **1** is the first reported example of a taxane with a glucose substitution on ring B. This is the second report of a C-2-, C-5-, C-10-, and C-14-oxygenated taxane from the Japanese yew, the first one being isolated from the hardwood of this species (9).

Table 1. ^{1}H and ^{13}C NMR spectral data of **1** (500 MHz for ^{1}H NMR, 125 MHz for ^{13}C NMR).

[b]The ^{13}C NMR chemical shifts were extracted from the HMQC experiment (±0.2 ppm). The numbers in italics represent quaternary carbons whose chemical shifts were obtained from the HMBC experiment (±0.2 ppm).

[c]NOESY intensities are marked as strong (s), medium (m), or weak (w).

Compound **2** was isolated as a stable colorless gummy substance. HR-FAB-MS analysis revealed its molecular formula to be $C_{36}H_{40}O_{10}$. Its ^{1}H NMR spectrum (listed in Table 2) showed the characteristic signals of taxanes, including four tertiary methyl groups and four acetyls. The chemical shifts of the characteristic proton resonances due to an exomethylene moiety were observed at δ5.35 and δ4.81 ppm (each 1H, *s*). The HMBC correlations of H$_3$-18 to C-11, C-12, and C-13 and of H$_3$-16 and H$_3$-17 to C-1, C-11, and C-15 revealed that Me-18 was attached to C-12 and Me-16 and Me-17 attached to C-15. Taxane **2** therefore has a regular 6–8–6 ring system. The connectivities of the protons on the taxane skeleton of **2** were determined by analysis of the ^{1}H-^{1}H COSY spectrum.

The presence of a cinnamoyloxy-moiety in **2** was revealed by signals at δ6.26 (1H, *d*, *J* = 12.7 Hz), 6.96 (1H, *d*, *J* = 12.7 Hz), 7.47 (2H, *dd*, *J* = 8.0, 2.1 Hz), and 7.32–7.4 ppm (3H, *m*) in the ^{1}H NMR spectrum. The fragment ions at *m/z* 131 [C$_9$H$_7$O]$^+$ and [M-cinn]$^+$ corresponding to the fission of a cinnamoyl group in the HR-FAB-MS spectrum confirmed this assignment. The unusual appearance of H-2′ and H-3′ as an AX spin system with a coupling constant of *J* = 12.7 Hz instead of the normal *J* = 16.0 to 17.0 Hz indicated that the double bond in the cinnamoyl group was in the unusual (Z)-geometry (15). The chemical shifts of H-2β, 5β, 9β, and H-10α suggested that four acetoxyl groups were attached to C-2, C-5, C-9, and C-10 or C-13, and one remaining cinnamoyl group at C-10 or C-13. We observed NOE between H-2′ and H$_3$-18 in the NOESY spectrum. This would fit if the side chain is at C-10 or C-13. Taxanes with a C-10-cinnamoyl group are not known. Taxanes such as taxinine E
(16) and its analogues (11) have a C-5-cinnamoyl, their NMR spectra is however very different from that of **2**. The three-bond H–C correlation between H-13β and C-1′ was not observed, but the other NMR data supports the assignment of taxane **2** as 2α,5α,9α,10β-tetraacetoxy-13α-(Z)-cinnamoyl-oxy-taxa-4(20),11-diene. The relative stereochemistry of **2** (Table 2) was shown by NOESY correlations to be the same as its analogs (7, 11).

Taxane **1** is the first reported example of a taxane with a glucose substitution on ring-B and the second taxane with a glucose substitution (7, 17). Taxane **2** is the second taxane with a *cis*-cinnamoyloxy side chain; the first taxane with a *cis*-cinnamoyloxy side chain was isolated recently from the needles of the Canadian yew (*Taxus canadensis*) (18). A new non-taxane derivative with a *cis*-cinnamoyloxy side chain was isolated previously from the Chinese yew, *Taxus mairei* (15). Taxane **2** is only the fourth example of a taxane with a cinnamoyloxy side chain at C-13 (18–20).

Characterization of taxanes 3–16

Taxanes **3–16** were isolated from *T. cuspidata* Sieb. et Zucc. rooted cuttings and have also been found in the needles, bark, or stems of other yew species, but they have not been previously reported from the Japanese yew. They were identified by comparing their NMR data with those reported in the literature as 2α,5α,9α-trihydroxy-10β,13α-diacetyl-taxa-4(20),11-diene (**3**) (21), taxinine E (**4**) (7), taxinine A (**5**) (2) 5-cinnamoyltaxicin I (**6**) (22), 2-deacetoxytaxinine B (**7**) (23), baccatin VI (**8**) (24), 1β-dehydroxybaccatin VI (**9**) (7), baccatin IV (**10**) (24), deaminoacyltaxine A (**11**) (25), 7-acetoxy-taxuspine C (**12**) (26), 7-(β-xylosyl)-10-deacetyl-

taxol (**13**) (27), 7-(β-xylosyl)-10-deacetyltaxol C (**14**) (27), decinnamoyltaxinine B 11,12-oxide (**15**) (28), and 15-benzoyl-10-deacetyl-2-debenzoyl-10-dehydro-1(15→11)-*abeo*-baccatin III (**16**) (29). The previously recorded spectral data of 7β-xylosyl-10-deacetyltaxol (**13**) and 7β-xylosyl-10-deacetyltaxol C (**14**) were obtained in a mixture of CDCl₃ and DMSO, and their ¹³C NMR data were not published (27). In this work, we report their ¹H and ¹³C NMR data in acetone-d_6 for **13** and in CDCl₃ for **14**.

Identification of non-taxane metabolites 17–19

The non-taxane metabolites **17–19** were found previously in the yews *T. baccata* (30), *T. media* (31), and *T. canadensis* (32). They were identified as (–)-2-epinortrachelogenin (**17**) (30), (–)-matairesinol (**18**) (31), and taxicatin (**19**) (32) on the basis of spectroscopic methods and these assignments were confirmed by comparing their spectroscopic data with those found in the literature. These compounds are reported for the first time from the Japanese yew.

Identification of known taxanes 20–43

The spectroscopic properties of compounds **20–43** were identical to the literature values. They were characterized as 2-deacetyltaxinine J (**20**) (7), decinnamoyl-taxinine J (**21**)

17 R = OH   **18** R = H

Rooted cuttings composition of taxanes vs. mature plants: Insights on biosynthesis of taxanes in yews?

Initially, we started these studies thinking that it will reveal some information about the biosynthesis of taxanes in yews. Taxanes with sugar moieties were not detected in the needles, stems, or bark of the Japanese yew. However, it could be that the polar fractions containing sugar moieties were not investigated in mature plants. Furthermore, it is quite possible that different parts of the plants have the capability of doing very different chemical reactions. Therefore, we cannot derive simple biosynthetic explanations for these reactions, which might be dependent on many factors. On the other hand, enzymatic extracts from plants of different ages could be useful for biotransformation reactions, which are difficult to perform chemically.

Experimental

General experimental procedures (18, 26)

Plant material

Rooted cuttings of *T. cuspidata* Sieb. et Zucc. were obtained from Cramer and Cramer Nurseries in April 2001.

Extraction and isolation

Ground air-dried whole rooted cuttings of the Japanese yew (*Taxus cuspidata* Sieb. et Zucc.) (148.8 g) were extracted with 900 mL of MeOH by shaking in the dark for 1 day at room temperature. The ground plants were filtered and extracted with fresh solvent every day for a week, twice with 900 mL of MeOH, and four times with a mixture of MeOH:CH$_2$Cl$_2$ (1:1). The combined organic extracts were evaporated under reduced pressure. Water was added to the crude extract and lipids were extracted with hexane. The

aqueous phase was then saturated with NaCl and extracted four times with CH_2Cl_2 (each 750 mL). The combined CH_2Cl_2 extracts were dried over anhydrous sodium sulphate, filtered, and evaporated using a rotary evaporator to yield about 1 g of a dark brown extract.

The CH_2Cl_2 extract was dissolved in a minimum volume of acetone and absorbed onto 1.5 g of silica gel. It was then subjected to normal phase column chromatography on silica gel (silica gel 60, 60–200 mesh, 75 g, bed size 3.3 × 20 cm) and eluted successively with a mixture of hexane and acetone (1:1, 1:2, and 100% acetone). Twenty-seven fractions were obtained: Fr_{1-7} (hexane:acetone, 1:1), Fr_{8-15} (hexane:acetone, 1:2), and Fr_{16-27} (100% acetone).

Fr_1 (32 mg) was applied to reversed-phase HPLC, eluted with a linear gradient of CH_3CN in water from 25 to 100% for 50 min at a flow rate of 18 mL min^{-1} and detected at 215 nm. The material eluted at R_t = 50.37 min (a mixture of **20** and **30**, further separated by preparative TLC in hexane:EtOAc (1:1), **20** (0.8 mg, R_f = 0.70), **30** (0.7 mg, R_f = 0.78)) and 53.90 min (**24** (0.4 mg)) was collected and concentrated. Fr_2 (120 mg) was applied to preparative TLC (six plates (each 20 × 20 cm), hexane:EtOAc (50:60, v/v)) and yielded 12 subfractions (Fr_{2-1} to Fr_{2-12}). The fraction Fr_{2-2} (10 mg) was subjected to semipreparative HPLC, and eluted with a linear gradient of CH_3CN in water (25–100% in 50 min at a flow rate of 3 mL min^{-1} detected at 210 nm) to

give **21** (3 mg, R_t = 33.99 min) and **24** (2.0 mg, R_t = 53.37 min). The subfraction Fr$_{2-3}$ (12 mg) was purified by semipreparative HPLC to give **3** (0.7 mg, R_t = 26.93 min), **21** (1.6 mg, R_t = 34.02 min), and **41** (3.0 mg, R_t = 42.22 min). The subfraction Fr$_{2-4}$ (9 mg) was separated by a semipreparative HPLC to give **5** (2.0 mg, R_t = 31.71 min), **15** (1.2 mg, R_t = 34.58 min), and an impure taxane at R_t = 42.49 min, which was further purified by preparative TLC to give **8** (2.0 mg, solvent hexane:acetone (3:2), R_f = 0.58). The subfraction Fr$_{2-5}$ (9 mg) was separated by semipreparative HPLC to give **28** (0.5 mg, R_t = 28.46 min), **26**, **27** (2 mg, R_t = 39.34 min), and **9** (1.0 mg, R_t = 45.39 min). The subfraction Fr$_{2-6}$ (11 mg) was submitted to HPLC (R_t = 41.40 min) and further purified by preparative TLC

(hexane:EtOAc, 5:6) to give **31** (1.0 mg, R_f = 0.49) and **6** (1.5 mg, R_f = 0.65). The subfraction Fr$_{2-10}$ (11 mg) was separated by semipreparative HPLC and afforded **12** (1.0 mg, R_f = 47.06 min) and **4** (2.0 mg, R_f = 51.35 min). The subfraction Fr$_{2-11}$ (9 mg) was separated by a semipreparative HPLC to give **35** (1.0 mg, R_f = 44.69 min) and **7** (1.0 mg, R_f = 48.43 min). The subfraction Fr$_{2-12}$ (6 mg) was separated by semipreparative HPLC to give **2** (1 mg, R_f = 49.87 min). The fraction Fr$_3$ (110 mg) was applied to preparative TLC (four plates (20 × 20 cm), CH$_2$Cl$_2$:CNCH$_3$ (85:25)) to give 14 subfractions (Fr$_{3-1}$ to Fr$_{3-14}$). The subfraction Fr$_{3-2}$ (10 mg) was subjected to semipreparative HPLC and yielded **11** (3.0 mg, R_t = 21.18 min), **33** (1.3 mg, R_t = 24.58 min), and **23** (2.0 mg, R_t = 26.53 min). The subfraction Fr$_{3-3}$ (9 mg) was applied to semipreparative HPLC and afforded **32** (2.2 mg, R_t = 31.37 min) and **41** (1.2 mg, R_t = 34.71 min). The subfraction Fr$_{3-4}$ (14.7 mg) was separated by HPLC to give **40** (3.2 mg, R_t = 35.61 min) and **41** (1.0 mg, R_t = 34.65 min). The subfraction Fr$_{3-5}$ (8.0 mg) was subjected to semipreparative HPLC and yielded **38** (1.5 mg, R_t = 26.73 min), **36** (1.0 mg, R_t = 30.42 min), and **40** (1 mg, R_t = 35.62 min). The subfraction Fr$_{3-7}$ (7 mg) was applied to semipreparative HPLC to give **10** (1 mg, R_t = 29.71 min) and **39** (1.5 mg, R_t = 38.88 min). The subfraction Fr$_{3-9}$ (4 mg) was applied to semipreparative HPLC to give **40** (2 mg, R_t = 21.24 min). The subfraction Fr$_{3-10}$ (3 mg) was applied to HPLC and yielded **18** (1 mg, R_t = 24.76 min). The subfraction Fr$_{3-12}$ (6 mg) was applied to semi-preparative HPLC and afforded **22** (2 mg) and **29** (1 mg, R_t = 46.30 min). The fractions Fr$_4$ (92 mg) and Fr$_5$ (46 mg) were combined and applied to preparative TLC (four plates (20 × 20 cm), CH$_2$Cl$_2$:CNCH$_3$ (85:30)) and yielded 14 subfractions (Fr$_{4-1}$ to Fr$_{4-14}$). The subfraction Fr$_{4-2}$ (7 mg) was subjected to semipreparative HPLC to give **34** (1 mg, R_t = 28.75 min), **11** (1 mg), **37** (1 mg, R_t = 28.75 min), and **16** (1.0 mg, R_t = 25.15 min). The subfraction Fr$_{4-3}$ (13 mg) was subjected to HPLC and yielded **8** (1 mg), **5** (1 mg, R_t = 24.58 min), and **32** (1.0 mg, R_t = 31.37 min). The subfractions Fr$_{13}$ (18 mg) and Fr$_{14}$ (20 mg) were applied to HPLC to give **43** (2 mg, R_t = 35.61 min), **13** (2 mg, R_t = 27.51 min), **14** (4 mg, R_t = 27.27 min), **1** (1 mg, R_t = 20.39 min), and **19** (2 mg, R_t = 9.23 min).

The oxidation of sulfides by chromium(V)

Carmela R. Jackson Lepage, Lynn Mihichuk, and Donald G. Lee

Abstract: The mechanism for the oxidation of sulfides by $[(me_4\text{-salen})Cr^V(O)(pyO)]CF_3SO_3$, where me_4-salen is 8,8,8′,8′-tetramethylsalen and pyO is pyridine N-oxide, has been investigated. Results from Hammett correlations on the rates of oxidation of substituted thioanisoles, frontier molecular orbital calculations, and product studies are consistent with a mechanism that is initiated by a single electron transfer to give a radical cation intermediate.

Key words: oxidation, chromium(V), sulfides, radical cation, oxygen transfer.

Résumé : On a étudié le mécanisme d'oxydation des sulfures par le $[(me_4\text{-salen})Cr^V(O)(pyO)]CF_3SO_3$ dans lequel me_4-salen correspond à 8,8,8′,8′-tétraméthylsalène et pyO est un N-oxyde de pyridine. Les résultats de corrélations de Hammett avec les vitesses d'oxydation de thioanisoles substitués, de calculs d'orbitales moléculaires frontières et d'études de produits sont en accord avec un mécanisme qui serait initié par un seul transfert d'oxygène conduisant à la formation d'un intermédiaire cation radical.

Mots clés : oxydation, chrome(V), sulfures, cation radical, transfert d'oxygène.

[Traduit par la Rédaction]

Introduction

The reaction between high valent chromium oxo complexes and sulfides is known to result in the formation of sulfoxides (1). However, the mechanism by which an oxygen atom is transferred from chromium to sulfur in these reactions has not been well defined. By comparison with other similar reactions, there appears to be two primary reaction pathways that should be considered. In one mechanism the reaction would be initiated, as depicted in Scheme 1, by an electron transfer from sulfur to the oxidant, followed by oxygen rebound and solvolysis steps. In this process it is apparent that an intermediate radical cation, **1**, is formed by loss of an electron from sulfur in the initial step.

Alternatively, the reaction could proceed by a concerted oxygen transfer mechanism that does not involve the formation of discrete intermediates, as illustrated in Scheme 2. Although nucleophilic attack on an oxygen atom, as proposed in this scheme, may seem improbable, it should be noted that the process results in a concurrent reduction of the chromium and, therefore, could be regarded as a remote nucleophilic attack on the metal. This process does not involve the formation of intermediate sulfur radicals or cations.

The objective of this work has been to distinguish between these two possible mechanisms for the oxidation of sulfides by a well-characterized chromium(V) complex, $[(me_4\text{-salen})Cr^V(O)(pyO)](CF_3SO_3)$, where me_4-salen is 8,8,8′,8′-tetramethylsalen and pyO is pyridine N-oxide. The approach that has been taken is to test for the presence of radical cations by a Hammett analysis applied to the rates of oxidation of substituted thioanisoles, by the use of frontier

molecular orbital calculations, and by a study of the products obtained from the oxidation of sulfides, which would produce radical cations that can react to form aldehydes and disulfides in addition to sulfoxides.

Experimental

The preparation and purification of the sulfides and sulfoxides used in this study have been reported previously (2–4).

Preparation of $[(me_4\text{-salen})Cr^V(O)(pyO)]CF_3SO_3$

Chromium(II) triflate hexahydrate was prepared from the reaction of chromium metal with triflic acid as follows (5): Trifluoromethanesulfonic acid (9.235 g, 61.54 mmol), obtained from Aldrich, was diluted to 10 mL with distilled and degassed water in a Schlenk tube. Electrolytic Cr chips, size ≤6 mm, purity 99.997% (1.692 g, 32.54 mmol), obtained from AESAR, were added to the Schlenk tube. One of the chips was dipped in perchloric acid and rinsed with water before addition to provide a fresh, clean surface on which the reaction could start. The Schlenk tube was evacuated and back-filled with argon. This mixture was heated to 40°C and left to stir for 7 days. The royal blue solution produced was divided into two portions using cannula techniques and placed in argon-filled Schlenk tubes. Some unreacted Cr chips (0.148 g) were recovered. Water and triflic acid were evaporated in vacuo with the aid of a heat gun, leaving a pale blue solid. The yield, calculated from the amount of unrecovered Cr, was 91.2%. A quartz cell with a side arm Schlenk was used to obtain the UV spectrum of this compound in water. A λ_{max}, observed at 714 nm, corresponds

Scheme 1.

Scheme 2.

Table 1. Electrospray mass spectral data for $[(me_4\text{-salen})Cr^V(O)]^+$.
Mass	Relative abundance (%)	
	Theoretical	Experimental
388.11	5.18	5.41
389.11	1.21	2.13
390.10	100.00	100.00
391.11	34.73	35.03
392.11	8.69	9.02
well with that previously reported for chromium(II) compounds (5). There was no maximum at 580 nm corresponding to chromium(III). Since this compound is extremely air-sensitive, it was stored and transferred under argon.

Chromium(II) hexahydrate was ligated with dihydro 8,8,8′,8′-tetramethylsalen (6, 7) and oxidized to the corresponding chromium(III) complex as follows: $(me_4\text{-salen})H_2$ (3.570 g, 11.00 mmol) was placed in a 100 mL round-bottom flask fitted with a stopcock. The flask was evacuated and back-filled with argon. Methanol (45 mL), freshly distilled under an argon atmosphere, was added to the flask, and $[Cr^{II}(H_2O)_6](CF_3SO_3)_2$ (3.23 g, 7.05 mmol) in an argon-filled Schlenk tube was dissolved in methanol (5 mL) and added dropwise to the round-bottom flask through a cannula. The mixture, initially blue, turned brown. Stirring was continued for 5 h at room temperature. The flask was opened to the atmosphere and heated to reflux for 1 h. The mixture was cooled and the solvent removed on a rotoevaporator. Distilled water (80 mL) was added and the mixture stirred for 2 h. The rusty-orange solid that formed was collected in a Buchner funnel and placed in a 70°C oven to dry overnight. This solid was recrystallized from water giving 2.59 g (4.63 mmol, 65.6%) purified product. The UV and IR spectra compared satisfactorily with literature spectra for $[(me_4\text{-salen})Cr^{III}(H_2O)_2]CF_3SO_3$ (6, 8). UV–vis (CH_3CN) (nm) (ε (L mol^{-1} cm^{-1})): 418 (3049), 320 (8376), 286 (15 000), 230 (36 000), 202 (25 000). IR (Nujol) (cm^{-1}): 3389–3553 (b), 2954 (s), 2923 (s), 2854 (s), 1618 (s), 1602 (m), 1551 (m), 1465 (s), 1443 (s), 1401 (w), 1379 (m), 1338 (w), 1284 (m), 1238 (s), 1224 (m), 1173 (m), 1146 (m), 1128 (m), 1027 (m), 958 (w), 907 (w), 880 (w), 843 (w), 797 (w), 752 (m), 639 (m).

This chromium(III) complex was oxidized to the corresponding chromium(V) complex by iodosobenzene as follows: $[(me_4\text{-salen})Cr^{III}(H_2O)_2]CF_3SO_3$ (1.21 g, 0.37 mmol) was placed in a 100 mL round-bottom flask, and 80 mL of HPLC-grade acetonitrile (CH_3CN), obtained from Fisher Scientific, was added along with iodosobenzene (0.60 g, 2.7 mmol), prepared as described in the literature (9). The flask was sealed and the solution stirred. The orange solution that formed initially when the $[(me_4\text{-}$

salen)$Cr^{III}(H_2O)_2]CF_3SO_3$ dissolved became greenish-black, indicative of $[(me_4\text{-salen})Cr^V(O)]^+$. Prior to rate measurements, any unreacted iodosobenzene was removed by filtration, and pyridine N-oxide in acetonitrile was added to produce $[(me_4\text{-salen})Cr^V(O)(pyO)]^+$. UV–vis spectroscopic analysis indicated that this was the same complex that had been previously characterized (6).

In addition to UV–vis spectroscopy, the $[(me_4\text{-salen})Cr^V(O)]^+$ solution was analyzed using electrospray mass spectrometry (ESI-MS) (10). When the expanded experimental spectrum of the M^+ region (m/z 390) was compared with the theoretical spectrum for $C_{20}H_{22}N_2O_3Cr^+$, the isotopic distribution and relative intensities in Table 1 were obtained.

The only mass with a relative abundance that is not within 5% of the predicted value is that of m/z 389.11. That the resulting abundance, 2.13%, is much greater than the theoretical value of 1.21% is not entirely surprising, since the area of a small peak on the shoulder of a very large peak can be substantially altered by isobaric interferences (11). Overlapping peaks with the same nominal mass can result in a large deviation from the expected value for a small peak. The other isotopic distribution peaks, all within 5% of the expected values, along with a good comparison between the UV–vis spectrum of this complex with that reported for the complex previously characterized (6) provide convincing evidence for its structure.

Kinetic methods

The visible spectrum of a solution of $[(me_4\text{-salen})Cr^V(O)]CF_3SO_3$ in acetonitrile decreases in intensity uniformly from 350 to 800 nm. However, when pyridine N-oxide (pyO) is added to the solution, a broad band centered at 628 nm appears (in accordance with work previously described in the literature (6)). Data summarized in Fig. 1 indicate that the intensity of this band increases as the concentration of pyO is increased. The most reasonable explanation for this observation is reversible ligation with formation of a new complex, $[(me_4\text{-salen})Cr^V(O)(pyO)]^+$, when pyridine N-oxide is present. Since the absorbance plateaus when the concentration of pyO is 0.1 M or greater, it can be assumed that the equilibrium expressed in eq. [1] lies substantially to the right under such conditions.

[1] $[(me_4\text{-salen})Cr^V(O)(CH_3CN)]^+ + pyO$

$\rightleftharpoons [(me_4\text{-salen})Cr^V(O)(pyO)]^+ + CH_3CN$
When a reductant is added to these solutions, the band at 628 nm diminishes with time, thus providing a convenient physical change that can be used to monitor reaction rates.

[a]Temperature = 25°C.

Fig. 1. Dependence of absorbance at 628 nm on pyridine *N*-oxide concentration. [[(me$_4$-salen)Cr^V(O)]$^+$] = 2.58 × 10^{-4} M.
Fig. 2. Pseudo-first-order rate plot for the oxidation of thioanisole. [Thioanisole] = 0.341 M. [[(me$_4$-salen)Cr^V(O)(pyO)]$^+$] = 3.69 × 10^{-4} M. Slope = –1.01 × 10^{-3} s^{-1}. r^2 = 0.999.

Fig. 3. Dependence of second-order rate constants on pyridine *N*-oxide concentration. [Thioanisole] = 0.328 M.
Table 3. Effect of added water on rate constants.[a]

[H$_2$O] (M)	$k_2 \times 10^3$ (s^{-1} M^{-1})
0	2.69[b]
0.19	2.64[b]
1.85	2.92[c]

[a][Methyl phenyl sulfide] = 0.341 M; [[(me$_4$-salen)Cr^V(O)(pyO)](CF$_3$SO$_3$)] = 2.40 × 10^{-4} M.
[b][pyO] = 0.115 M.
[c][pyO] = 1.58 M.

For example, when an excess of thioanisole is added to a solution of [(me$_4$-salen)Cr^V(O)(pyO)]$^+$, good pseudo-first-order rate plots are obtained (see Fig. 2). The final product exhibits a spectrum identical to that obtained by adding pyridine *N*-oxide to [(me$_4$-salen)Cr^{III}(H$_2$O)$_2$]$^+$. It is necessary to correct the observed pseudo-first-order rate constants, k_{obs}, obtained from the slope of such plots for a slow reduction of the oxidant that occurs in the absence of added reductant. The corrected pseudo-first-order rate constants, k_1, are obtained by subtraction of the rate constant for the corresponding blank reactions, k_b, from the observed rate constant ($k_1 = k_{obs} - k_b$). The observation that the magnitude of k_1 is di-

rectly proportional to the concentration of added reductant (Table 2) indicates that the reaction is second order overall — first order in oxidant and first order in reductant.

The effect of pyridine *N*-oxide on the reaction kinetics was determined by measuring the rate constants for solutions containing variable concentrations of pyO. As can be seen from Fig. 3, rates are increased by the addition of pyridine *N*-oxide; however, the effect plateaus at about 0.1 M pyO and above. This result is consistent with the absorbance data in Fig. 1 and the previous suggestion that the equilibrium in eq. [1] must be shifted to the right above 0.1 M pyO. To ensure that the effect of pyridine *N*-oxide would be constant throughout this study, its concentration was maintained above 0.1 M in all experiments, the usual working concentration being about 0.3 M.

In a series of similar experiments it was found that addition of water to the solvent had a negligible effect on the magnitudes of the observed rate constants (see Table 3). It is apparent, therefore, that small amounts of moisture would

Scheme 3.
not have an impact on the accuracy of the measured rate constants.

In a typical kinetic experiment, 2.0 mL aliquots of 0.3 M pyO in acetonitrile were added to two 10-mm cuvettes. One cuvette was fitted with a Teflon septa-seal top. Additional solvent (0.1 mL) was added to the other cuvette to compensate for the volume difference that would occur when reductant was added through the septa-seal. An aliquot of freshly prepared oxidant (0.30 mL) was added to each of the cuvettes. They were then flushed with argon for 3 min and sealed. Both cuvettes were placed in the thermostated cell compartment of an HP8452 Diode Array UV–vis spectrophotometer and held at a constant temperature for 29 min. A solution of thermostated and degassed reductant (0.10 mL) was injected through the septa-seal using a microlitre syringe. This cuvette was inverted several times to ensure good mixing and replaced in the thermostated cell compartment. The reaction rates were then monitored at 628 nm. Observed pseudo-first-order rate constants, k_{obs}, were obtained from the data collected from the cuvette containing reductant, and the blank rate constants, k_b, were simultaneously obtained using data collected for the solution in the other cuvette.

Activation parameters

Activation parameters, as defined by application of the Eyring Equation (eq. [2]), were determined by measuring the rate constants at several temperatures and preparing plots of ln k_2/T vs. $1/T$ (12). A typical plot has been reproduced in Fig. 4 and the results are summarized in Table 4. Since both of the proposed mechanisms predict second-order kinetics, the large negative entropies of activation observed are consistent with either Scheme 1 or Scheme 2.

[2] $\ln k_2/T = -\Delta H^\ddagger/RT + \Delta S^\ddagger/R + \ln k_B/h$

Results and discussion

If a radical cation (see Scheme 1) is formed during the oxidation of substituted thioanisoles, it would be stabilized by substituents that could enter into a direct resonance interaction with it, as depicted in Scheme 3. Since resonance of this type requires interaction of the $3p$ orbitals of sulfur with the carbon $2p$ orbitals of the aromatic ring, it may not make a large contribution to the stability of the radical cation; however, it should be sufficient to cause the rates of oxidation of

Fig. 4. Eyring plot for the oxidation of thioanisole. Slope = $–6.04 \times 10^3$ K. Intercept = 8.68. $r^2 = 0.996$.
substituted thioanisoles to correlate somewhat better with Hammett σ^+ substituent constants, as compared with the corresponding σ constants. From a comparison of the plots in Figs. 5 and 6, it can be seen that this is, in fact, the case. The correlation is obviously better when σ^+ substituent constants are used.

A similar direct resonance effect for the intermediate proposed in Scheme 2 would require overlap between a sulfur $3d$ orbital and the $2p$ orbitals of the aromatic ring. Therefore, its contribution to the stability of the transition state would be insignificant, and a better correlation would be expected with σ substituent constants, as observed for the oxidation of sulfides by high valent manganese and ruthenium oxides, both of which exhibit better correlations with σ substituent constants (3, 13, 14). This result, therefore, suggests that the oxidation of sulfides by $[(me_4\text{-salen})Cr^V(O)(pyO)]^+$ likely involves the formation of intermediate radical cations as in Scheme 1.

The observation that sulfoxides are not oxidized by $[(me_4\text{-salen})Cr^V(O)(pyO)]^+$ is also consistent with an electron transfer mechanism. Since the electron density at the sulfoxide sulfur would be decreased by polarization of the S=O bond, as in Scheme 4, the activation energy for electron transfer would be greatly increased. Other oxidants such as permanganate and ruthenium tetroxide, which are believed to proceed by a mechanism similar to the one depicted in Scheme 2, oxidize sulfoxides more readily than sulfides (3, 4).
Also consistent with this conclusion is the observation that the rate of oxidation of 4-nitrothioanisole is too slow to measure under these conditions. In this compound the electron density at sulfur is decreased by resonance, as depicted in Scheme 4. Frontier molecular orbital theory predicts that there should be a direct correlation between the energies of

Table 5. Product distributions for the oxidation of substituted benzyl phenyl sulfides by $[(me_4\text{-salen})Cr^V(O)(pyO)]CF_3SO_3$.

	Product Ratios[a]		
Sulfide	Sulfoxide	Aldehyde	Starting material
Benzyl phenyl sulfide	0.47	—	0.53

Fig. 6. Hammett correlation with σ⁺-substituent constants. From left to right the substituents are 4-methoxy, 4-methyl, 4-fluoro, hydrogen, 4-chloro, and 3-chloro. Slope = –1.64. $r^2 = 0.98$.

Scheme 4.

Fig. 7. Correlation of second-order rate constants with HOMO energies. From left to right the substituents are 3-chloro, 4-chloro, 4-fluoro, hydrogen, 4-methyl, and 4-methoxy. Slope = –410. $r^2 = 0.985$.

the sulfide HOMOs and the rates of reactions initiated by single electron transfers. Assuming that the LUMO of the oxidant is at a higher energy than the HOMOs of the sulfides, increasing the energy of the HOMO should result in a faster reaction (15). When the energies of the HOMOs of the substituted thioanisoles were calculated at the B3LYP/6-31G* level, a good correlation with activation energies was observed (16) (see Fig. 7). This result is most consistent with the mechanism in Scheme 1 where the reaction is initiated by a single electron transfer.

It is also possible to test for the formation of intermediate radical cations by studying the products formed when methoxy-substituted benzyl phenyl sulfides are oxidized. The radical cations formed from these compounds can react to give aldehydes in competition with the formation of sulfoxides in the oxygen rebound step depicted in Scheme 1 (17–19). For example, reaction of 3,4,5-trimethoxybenzyl phenyl sulfide gives only 3,4,5-trimethoxybenzaldehyde and

diphenyl disulfide when oxidized by cerium(IV) ammonium nitrate, a known one-electron transfer oxidant (2). Previous work has indicated that the formation of aldehydes and disulfides is initiated by loss of a proton from the radical cation to give a free radical, **2**, which is known to be readily oxidized to the corresponding aldehyde, as in Scheme 5. Introduction of the methoxy substituents increases the acidity of the radical cation, promoting proton loss and subsequent aldehyde formation.

When the products obtained from the oxidation of benzyl phenyl sulfide, 4-methoxybenzyl phenyl sulfide, and 3,4,5-trimethoxybenzyl phenyl sulfide were compared, the results summarized in Table 5 were obtained. The product ratios were determined using ^{1}H NMR integrals as previously described (2). These data, which show that the ratio of aldehyde to sulfoxide increases from 0 for unsubstituted benzyl phenyl sulfide to 0.10 and 0.55 for 4-methoxybenzyl phenyl sulfide and 3,4,5-trimethoxybenzyl phenyl sulfide, respectively, are most consistent with the reaction mechanism presented in Scheme 1. Oxidations by high valent manganese and ruthenium oxides, which have been proposed to react by a concerted oxygen transfer, as in Scheme 2, give only sulfoxides and sulfones with these same sulfides (2).

Scheme 5.
Although any one of these tests individually do not provide compelling evidence for the electron transfer mechanism, the combined impact of the three tests (i.e., the Hammett analysis, the frontier molecular orbital calculations, and the product studies) is convincing, and it appears that the reaction between sulfides and $[(me_4\text{-}salen)Cr^V(O)(pyO)]^+$ is most likely initiated by a single electron transfer.

It is of interest to note that the oxidation of sulfides by chromium(V) and most other high valent transition metals appears to proceed by different mechanisms. Because the oxidation of proteins and lipids in free radical processes has been associated with the onset of several diseases (20–22), the observed tendency of chromium(V) to react by a one-electron transfer is consistent with the belief that the carcinogenic properties of oxochromium compounds are associated with their tendency to react by free radical oxidation mechanisms. The oxides of manganese, ruthenium, molybdenum, and iron are not carcinogenic, presumably because they react with sulfides by concerted mechanisms that do not involve the formation of intermediate radicals (2, 23).

A diene-transmissive approach to the quassinoid skeleton

Claude Spino, Bryan Hill, Pascal Dubé, and Stéphane Gingras

Abstract: Several tetracyclic molecules were prepared by diene-transmissive Diels–Alder cycloadditions. Control over the stereochemical outcome of the cycloaddition was achieved and the structural features of the precursors affecting the stereochemistry is discussed. Useful information was gathered concerning the factors governing this stereocontrol, which will be indispensable for the future of this strategy.

Key words: quassinoid, anticancer agent, diene-transmissive Diels–Alder cycloaddition, oxadiene, hetero Diels–Alder.

Résumé : On a préparé plusieurs molécules tétracycliques en faisant appel à des réactions de cycloaddition de Diels–Alder à dienes-transmissibles. On a pu contrôler le résultat stéréochimique des cycloadditions et on discute des caractéristiques des structures des précurseurs qui affectent la stéréochimie. Des informations utiles ont été accumulées concernant les facteurs qui gouvernent ce contrôle stéréochimique et celles-ci seront indispensables pour le futur de cette stratégie.

Mots clés : quassinoïde, agent antinéoplasique, cycloaddition de Diels–Alder à dienes-transmissibles, oxadiène, hétéro-Diels–Alder.

[Traduit par la Rédaction]

Introduction

Blomquist and Bailey and co-workers (1) reported the first diene-transmissive Diels–Alder cycloaddition in 1955. They coupled the unstable cross-conjugated triene 3-methylene-1,4-pentadiene **1** with excess maleic anhydride and obtained tetracyclic adduct **3** in moderate yield (eq. [1]) (1). Later, Tsuge and co-workers and others (2–4) investigated a series of intermolecular diene-transmissive [4 + 2]-cycloadditions on simple substituted cross-conjugated trienes. For several reasons that are explained in previous publications, this strategy stayed without a useful application until our report of a diene-transmissive Diels–Alder approach to the synthesis of anticancer quassinoids (eq. [2]) (5). In this synthetic route to quassinoids, a cross-conjugated oxadiene **4** was transformed into tetracycle **6** via an intermolecular hetero Diels–Alder reaction followed by an intramolecular normal [4 + 2]-cycloaddition. In 1999, Fallis and co-workers (6) reported the use of diene-transmissive Diels–Alder reactions for the construction of advanced intermediates toward the synthesis of other terpenoids.

[1]

[2]
Quassinoids are formidable synthetic targets. The extent of the oxygenation of their carbon skeleton contributes to the synthetic difficulties (7). Subtropical shrubs of the plant family *Simaroubaceae* constitute the most common source for these degraded triterpenoid natural products (8). They possess a large spectrum of biological activities, including antiviral, antimalarial, antineoplastic, and insect antifeedant properties (8). Recently reported biological activities have increased the interest in the synthesis of this family of triterpenes (9). The vast majority of quassinoids possess a C-20 picrasane skeleton, of which quassin **7**, glaucarubolone **8**, and bruceantin **9** are typical examples (Fig. 1) (8). We report herein a comprehensive investigation of the diene-transmissive double Diels–Alder approach to quassinoids. The quassinoid numbering and lettering shown in Fig. 1, will be used throughout this manuscript on all structures for ease of reference to the potential target molecules.

Several stereochemical issues arise from the key cycloaddition reactions. The substituents on the cyclohexene ring in **4** direct the incoming ethylvinyl ether to the α face of the diene but they may also affect the stereochemical outcome of the intramolecular Diels–Alder reaction (eq. [2]) (10). The appendages on the exocyclic chain serve to differentiate the energies of the two *endo* transition states (TS) accessible to the intermediate **5** (Fig. 2). They must be brought in with

Scheme 1.
Fig. 1. Three examples of quassinoids.

the exact stereochemistry shown for all-equatorial α-*endo* TS that will lead to the tetracyclic nucleus **6** having the correct stereochemistry for quassinoids.

Synthesis of the precursor oxadienes

Besides the introduction of the ring and chain substituents in **4** with the correct stereochemistry, the formation of the exocyclic double bond with the correct geometry represents a fierce challenge (eq. [2]) (11). Compounding the problem is the fact that the exocyclic double bond in **4** and **5** should preferably be a tetra-substituted double bond (R^3 = Me), otherwise the C-10 methyl group (cf. Fig. 1) would have to be introduced at a later stage of the synthesis, a more difficult (though possible) task than introducing the methyl group as

part of the Diels–Alder strategy. Several ways to construct the exocyclic double bonds were envisioned. It was initially thought that starting with an appropriately substituted cyclohexenone would be most expeditious. In that respect, the known compound **13** (12), derived from (–)-quinic acid, presented itself as an attractive starting material (Scheme 1). Protection of the C-13 alcohol as a TBDPS ether was achieved, and reduction of the lactone in **14** followed by in situ oxidative cleavage of the resulting diol afforded a β-hydroxycyclohexanone, which was dehydrated to the desired substituted cyclohexenone **15d**. For simpler model compounds, 1,4-cyclohexadione monoketal **10** was an adequate starting material. It was reduced with NaBH$_4$ and then protected as its silyl ether **11a** (TBDPSCl, imid., DMF, quant.),

Scheme 2.

benzyl ether **11b** (KH, BnBr, THF, 83%), or PMB ether **11c** (KH, PMBCl, THF, 96%). Conversion of **11a–c** to **15a–c**, respectively, was straightforward as shown in Scheme 1.

Bromination and dehydrobromination of each cyclohexenone **15** gave the corresponding vinylbromide **16** in 80–94% yield (Scheme 2). Subsequent addition of vinyllithium to **16a–d** in the presence of anhydrous $CeCl_3$ afforded **17a–d**, which were converted to the corresponding acetates **18a–d** under standard conditions. Compounds **19a–g**, possessing a tri-substituted exocyclic double bond of *E* configuration, were prepared in one of three ways. Cuprate displacements of allylic acetates **18a–d** with alkylcyanocuprates gave the corresponding products **19a–d** in 89–96% yield (Scheme 2).[2] Alternatively, the palladium-catalyzed substitution of **18a** with malonate furnished **19e** in 81% yield as a single stereoisomer (Scheme 3). Aldehyde **19f** or ester **19g** could be accessed directly from a Claisen rearrangement of **17a**.

Vinyl bromides **19a–d** were separately treated with *n*-BuLi and the resulting vinyllithium intermediates trapped

Scheme 3.

with DMF to give **20a–d** (Scheme 4). The syntheses of **20e** and **20f** were reported elsewhere (5*a*). Compounds **20c** and **20d** were further transformed in four steps to **24a** and **24b**,

---

[2] Compound **19c** was prepared using a racemic cuprate reagent and was isolated as an inseparable mixture of stereoisomers (for clarity, only the diastereomer of interest is shown in Scheme 2). All isomers of **19c** were separated at a later stage (vide infra). Compound **19d** was prepared with the enantiomerically pure cuprate reagent and was isolated diastereo- and enantiomerically pure.

respectively, and **24a** was deprotected under oxidizing conditions to give **25** (Scheme 5).

All synthesized alkenes **19a–g** had exclusively the *E*-geometry. This selectivity is attributable to the flatness of the structural system **19** that brings the vinylic hydrogen and the bromine atom in a rigid *syn*-pentane-like relationship (Fig. 3). Any group larger than hydrogen is likely to raise the energy of the system considerably. Basic MM2 calcula-

tions placed the *Z*-isomer **B** 5.1 kcal mol^{-1} above the *E*-isomer **A** for R = Me.

This finding was corroborated by the fact that not a trace of product **27** was formed starting from compound **26a** or **26b** using any of the reactions described in Schemes 2 and 3 under many different reaction conditions (Scheme 6). Most reactions with **26a** and **26b** gave the starting material back or decomposition products under forcing conditions.

McMurry coupling between **16** and 2-butanone also failed to give any usable yields of an exocyclic alkene (13). The prospect of achieving the stereocontrolled synthesis of this tetrasubstituted double bond appeared bleak. A reaction was needed that would simultaneously generate the required cyclohexene and the tetra-substituted, exocyclic double bond.

A solution to the problem of the exocyclic, tetra-substituted double bond was found in the [4 + 2]-cycloaddition of vinylallene **30** and **32a** and **32b**. The syntheses of **30** and **32a** and **32b** starting from α,β-unsaturated ketone **28** are shown in Scheme 7. The addition of methylcuprate to acetate **29a** yielded **30** accompanied with 27% of a product resulting from the addition on the alkene. This side product was difficult to separate at this stage, but it was innocuous because it is an enyne incapable of undergoing a Diels–Alder reaction. Compounds **29b** and **29c** were first treated with fluoride and the resulting alcohols underwent methylcuprate addition to give high yields of vinylallene **31a** and **31b**, respectively, as 1:1 mixtures of two diastereomers. This time, less than 10% of alkene-addition products were formed in each case.

Vinylallene **30** reacted with methyl fumarate at the refluxing temperature of benzene to give a single cycloadduct **33** (Scheme 8). The structure of **33** was secured by a single crystal X-ray diffraction analysis of a later derivative
41 (vide infra). The temperature at which this Diels–Alder reaction occurs is remarkable considering the steric interactions in the final product. In fact, we have reported the synthesis of a series of cycloadducts like **33**, with much larger substituents around the exocyclic double bond and in some cycloadducts, the exocyclic double bond was twisted by more than 20° (14). It can be argued that the Diels–Alder reaction has an early transition state, the structure of which resembles the starting vinylallene where the severe steric interactions of the cycloadduct **33** are not present.

The dienophile always comes from the least-hindered face of the vinylallene in an intermolecular Diels–Alder cycloaddition (12, 15). This would give a cycloadduct with the wrong geometry of the double bond for quassinoid synthesis (as if R were larger than Me in **33**). It was necessary to attach the dienophile to the tether to accomplish the desired synthesis as shown by the conversion of **32a** and **32b** to **35a** and **35b**, respectively. The yields of cycloadducts **35a** and **35b** were good to excellent and the stereochemistry was completely controlled. The stereochemistry of **35a** was deduced by 2D-NOESY spectroscopy and by analogy with the NMR spectra with that of **33**. Note that the enyne side product formed along with **30** and **31a** and **31b** (cf. Scheme 7) are easily removed at this stage. afforded the required aldehydes **34** and **36** respectively (Scheme 8). The tether in cycloadduct **35b**, was elaborated to enoate-aldehyde **38**, in preparation for the intramolecular Diels–Alder reaction. The deprotection of **35a** and **37** yielded separable diastereomeric alcohols. The subsequent reactions were performed on each isomer separately.

Hetero Diels–Alder cycloaddition

With the problem of the exocyclic double bond solved, efforts were directed at the investigation of the hetero Diels–Alder reaction for the construction of bicyclic adducts. A series of cycloadditions was performed on model compounds **20** and **24**, bearing oxygen or carbon substituents at C-12 and (or) C-13 (Scheme 9). Most quassinoids possess a carbon at C-13 (either methyl or carboxy ester) and an oxygen atom at C-12. The C-13 position is also often linked to an oxygen atom (cf. Fig. 1). Contrary to oxadienes **20a–f**, oxadienes **24a** and **24b** and **25** (cf. Scheme 4) bear a tethered dienophile capable of undergoing an intramolecular Diels–Alder immediately after the hetero Diels–Alder. In these cases, the intermediates **40a–c** are in fact not isolated

(except for 13β,14β-**40c**) and their stereochemistry were therefore deduced from the stereochemistry of the corresponding final tetracycle adducts **48–52** (vide infra). The tether in racemic oxadienes **24a** and **25** contains a chiral center that creates up to four possible diastereomers for each of **40a** and **40c**, respectively. Oxadiene **24b** is homochiral, however, and there are only two possible diastereomers for **40b** (Scheme 9). Table 1 displays the results of the intermolecular hetero Diels–Alder cycloadditions of ethylvinyl ether with **20a**, **20b**, **20e**, **20f**, and **24a** and **24b**, and **25** catalyzed by Yb(FOD)₃. Only the ratios of 14β- to 14α-diastereomers are important to the discussion at this stage.

From earlier studies, we knew that a single carbon substituent R[1] was enough to differentiate between the two faces of the oxadiene (Table 1, entry 3) (5*a*). However, an alcohol or a protected hydroxyl offers little bias for the incoming dienophile, giving nearly equal mixtures of 14β and 14α adducts (entries 2, 5–7). A bulky protecting group is β-face selective (entry 1), presumably because of a preferred conformation **20**-**A** where the protecting group is eclipsed with the carbinol hydrogen at C-13, placing the bulky phenyl rings underneath the oxadiene as drawn in Fig. 4. It seems

obvious that if conformation **20-B** were preferred, it would effectively shield the β-face of the oxadiene. To obtain better results, the oxadiene must be induced to adopt the conformation **20-B** or force the C-13 substituent to orient its atoms away from the α-face. The latter case is exemplified by the isopropylidene-protected C-12/C-13 diol **20f** that was able to hinder sufficiently the β-face of the oxadiene (entry 4) (5*a*). In contrast, protected diol **24b** gave a 3:1 ratio favoring the undesired 13β,14α-**40b** diastereomer (entry 6). Again, the *tert*-butyldiphenylsilyl group is likely responsible for this result, shielding the α-face through a preferred conformation **20-A** (R^2 = OBn, Fig. 4).

In contrast to the results obtained in the hetero Diels–Alder cycloadditions of oxadienes **20a**, **20b**, **20e**, **20f**, **24a** and **24b**, and **25**, results obtained with compounds **34**, **36a** and **36b**, and **38a** and **38b** are particularly helpful (Scheme 10). The cycloadditions of **34**, **36a**, **36b**, **38a**, and **38b** gave only one detectable isomer **41**, **42a**, **42b**, **43a**, and **43b**, respectively. The stereochemistry of **41** was secured from a single crystal X-ray diffraction analysis. Compounds **42a** and **42b** and **43a** and **43b** were characterized by 2D-NMR experiments and their NMR spectra compared well with that of **41**. Most likely, the oxadienes take on conformations **34-B** or **36-B**, forcing the methyl group into a pseudo-axial orientation (Fig. 4).

Intramolecular Diels–Alder cycloaddition

The substituents on ring C and D and the substituents on the tether are able to affect the stereochemical outcome of the intramolecular Diels–Alder cycloaddition. This concern had to be addressed first and two things were known from earlier studies (5a): (a) in absence of substituent on the tether and on the ring (**44**), the β-*endo* TS (cf. Fig. 1) is favored by a factor of six leading to the formation of **45b** as the major product (Scheme 11); (b) two tether substituents in **46** are able to completely reverse this selectivity in favor of

the desired α-*endo* TS (**47a**, Scheme 11). However, it was also evident that an α-C-3 substituent (the α-oxygen of the dioxolane in **47a**) should be avoided as it increases the energy of both α- and β-*endo* TS to the advantage of the α-*exo* TS leading to the formation of **47b**.

Intramolecular Diels–Alder cycloaddition: Results

Since intermediates 13β,14β–**40a**, **40b**, **40c** and 13α,14β–**40a**, **40c** were not isolated, their structures were deduced

from those of the corresponding tetracycles **48–52** (Schemes 12 and 13). Note that intermediates 13β,14α-**40a**, **40b**, **40c** and 13α,14α-**40a**, **40c** (cf. Scheme 9) are of no interest for quassinoids because they possess the wrong 14-α stereochemistry. Although their corresponding tetracycles were isolated and fully characterized, they will not be discussed further.

Aldehyde **24a** (racemic mixture of diastereomers) gave a mixture of cycloadducts, of which **48a**, **48b**, and **50b** could be obtained partially pure (Scheme 12). Each cycloadduct was treated with LiAlH$_4$ and separation of the resulting alcohols yielded pure **53a**, **53b**, and **55a**, respectively, (Scheme 14). The structure of **53a** was deduced from a single crystal X-ray diffraction analysis, which secured the structure of **48a**. The structure of **48b** was correlated with

Scheme 13.

13β,14β-**40b**

TBAF
THF
Δ, 94% → **52a** R = TBS
52b R = H
Scheme 14.
that of **49b** (vide infra) because the structure of **53b** could not be determined unambiguously. The primary alcohol in compound **55a** was silylated under standard conditions to give **55b**, for which an X-ray analysis was obtained, confirming the structure for **50b**. With the structures secured, we were able to determined the ratios of tetracycles in the crude mixture of **48** and **50**. Tetracycles **48a** and **48b** were found in a 1:1 ratio while compound **50b** was the sole tetracycle to emanate from intermediate 13α,14β-**40a**. All of **48a**, **48b**, and **50b** possess the desired 14β-stereochemistry. However, **48b** and **50b** have the wrong configuration at C-5, C-7, and C-10. As explained later, the OPMB group is responsible for the formation of these two diastereomers.

Aldehyde **24b** (diastereo- and enantiomerically pure) gave two tetracycles that were desilylated to separate them more easily. Compound **52a** was the sole product having the 14β-stereochemistry and thus to arise from intermediate 13β,14β–**40b** (Scheme 13). The other tetracycle had the 14-α stereochemistry and must have come from intermediate 13β,14α–**40b**. The stereochemistry of **52b** was determined from careful NMR and 2D-NMR analysis of both tetracycles.

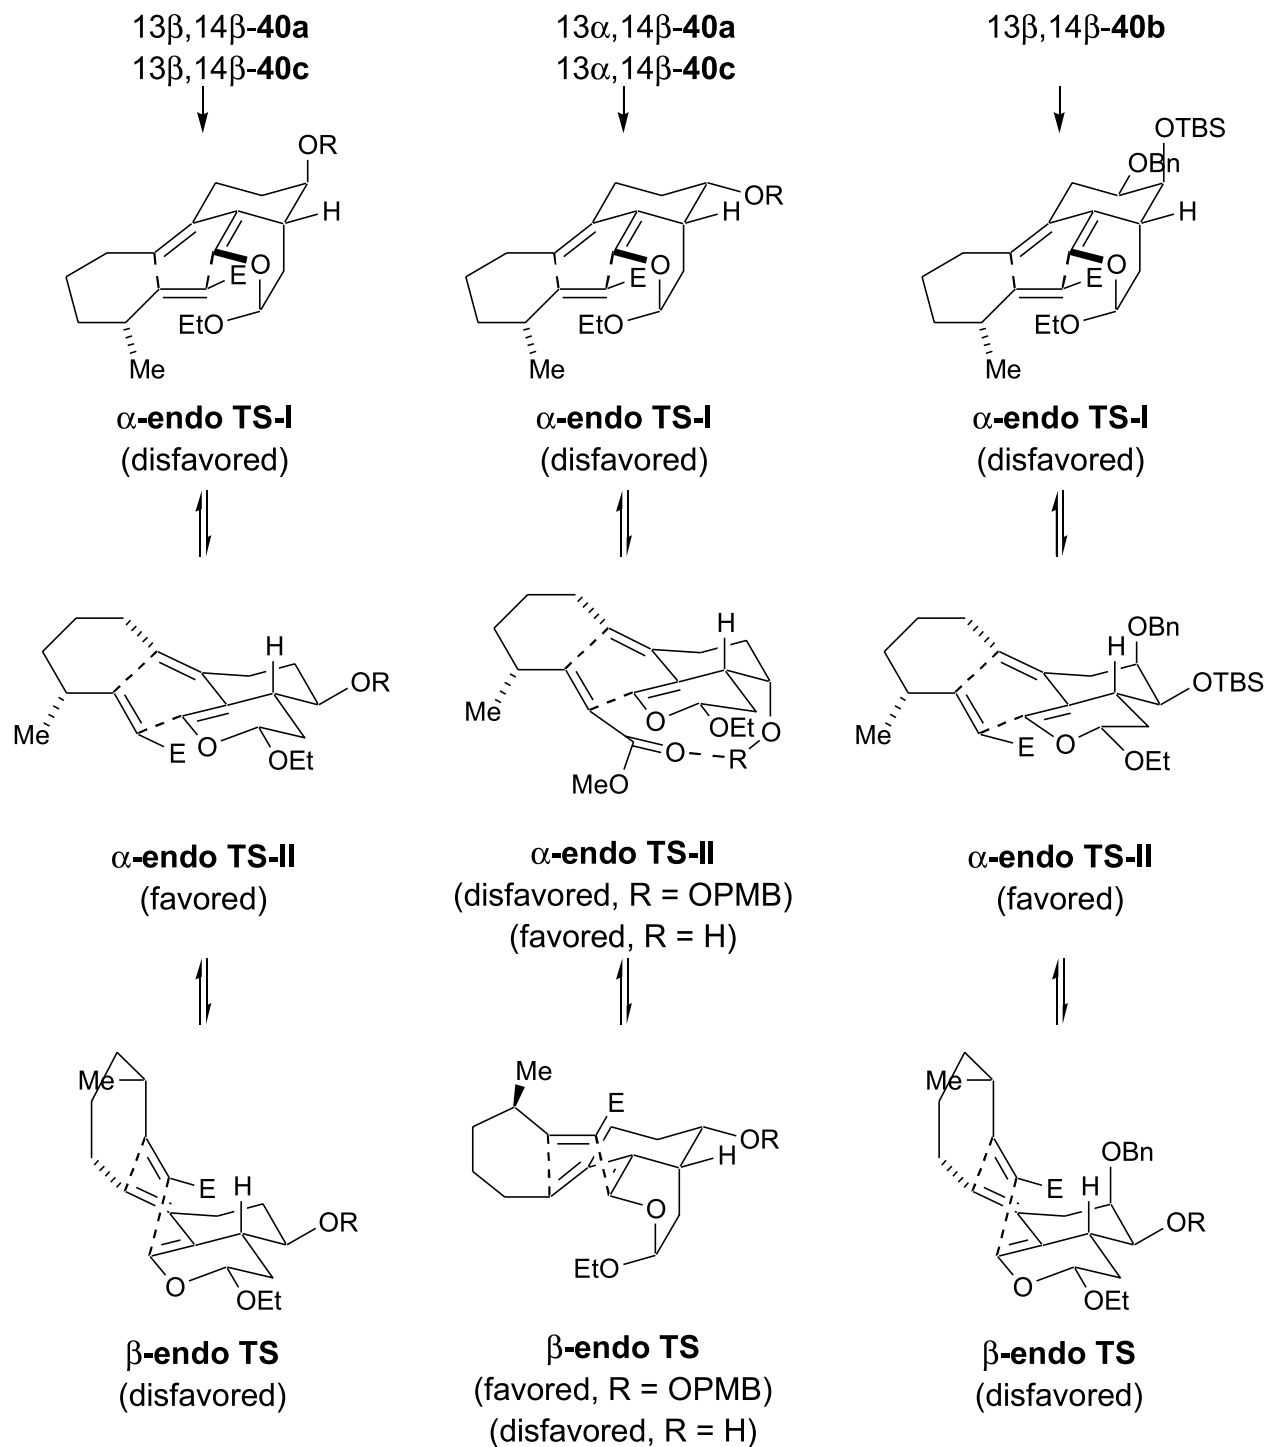
Lastly, aldehyde **25** led to a mixture of cycloadducts, of which **49a**, **49b**, and **51a** were separated and isolated in a pure state (Scheme 12). The stereochemistry of **51a** was deduced from a single crystal X-ray diffraction analysis. Cycloadduct **49b** was silylated to afford **54** that was crystalline and amenable to X-ray diffraction analysis (Scheme 14). Conversion of **49b** to **48b** confirmed the structure of the latter. The now known product **48a** was converted to **49a** using DDQ, which proved the structure of **49a**. With the structure

of each cycloadduct secured, it was established that **49a** and **49b** were formed in a 2:1 ratio and arose from the intramolecular Diel–Alder reaction of intermediate 13β,14β-**40c** (Scheme 12). Cycloadduct **51a** was the sole tetracycle to emanate from intermediate 13α,14β-**40c**. All three diastereomers **49a**, **49b**, and **51a** have the desired 14β-stereochemistry and only **49b**, the minor isomer from 13β,14β-**40c**, has the wrong stereochemistry at C-5, C-7, and C-10. Therefore, removing the PMB group on the C-13 alcohol proved beneficial.

Intramolecular Diels–Alder cycloaddition: Analysis

It was clear, from the cycloaddition of **44**, that a 14β-stereochemistry favors a β-face attack of the dienophile (5a). Fortunately, this trend was partly overcome by the presence of a single methyl group on the tether at C-4 as shown in the conversion of 13β,14β-**40c** into a 2:1 mixture of **49a** and **49b** (Scheme 12). With a protected alcohol (13β,14β-**40a**) the ratio **48a**:**48b** was 1:1. It was particularly informative to observe the cycloaddition results with alcohol 13α,14β-**40c** and PMB-protected alcohol 13α,14β-**40a**. The free alcohol 13α,14β-**40c** gave a single isomer **51a** arising from an α-endo transition state (Scheme 12). By contrast, the protected alcohol 13α,14β-**40a** underwent the IMDAC to give a single adduct **50b** that emerged from a preferred β-endo transition state having the methyl axial.

These results are explained as follows (Fig. 5): two α-endo TS can be considered, namely α-endo TS-I and α-endo

Fig. 5. Possible transition states for the intramolecular DAC of **40a–c**.


TS-II. All α-*endo* TS-Is have the ethoxy group and the dienophile in close proximity resulting in a steric interaction. It is doubtful that any α-attack would take place via α-*endo* TS-I. This is corroborated by MM2 calculations. Therefore, only the α-*endo* TS-IIs will be considered in our analysis and their energies will be compared with that of the β-*endo* TSs.

In the absence of substituents on the ring or on the chain, β-endo TS is favored over α-*endo* TS-II by approximately

2 kcal mol^{-1} (cf. **44** → **45b**, Scheme 11). An α-C-4 methyl group will be axial on a β-endo TS and should destabilize it by roughly 2 kcal mol^{-1}, approximately counterbalancing the advantage β-*endo* TS enjoys when there are no substituents. This is what was observed, 13β,14β-**40a** and 13β,14β-**40c** giving nearly equal mixtures of adducts regardless of the C-13 β-substituent. The slight difference between the ratios of 13β,14β-**40a** and 13β,14β-**40c** may be attributable to small conformational perturbations. However, an α-protected

Scheme 15.
alcohol at C-13 (13α,14β-**40a**) dramatically raises the energy of the corresponding α-endo TS-II (or alternatively, it could force a high-energy conformation like α-endo TS-I). This explains why compound 13α,14β-**40a** gave a single tetracycle **50b** via a β-endo TS. The fact that 13α,14β-**40c** gave only **51a** can only be explained by a hydrogen bond in α-endo TS-II. As a matter of fact, the cycloaddition of alcohol 13β,14β-**40c** was slower than that of alcohol 13α,14β-**40c**, the former requiring benzene at reflux to go to completion while the latter occurs rapidly at room temperature. This is consistent with a hydrogen bond activating the ester in β-endo TS for 13α,14β-**40c**.

If our analysis is correct, two β-substituents at C-12 and C-13 (as in 13β,14β-**40b**) should come together to lead to a single tetracycle resulting from α-*endo* TS-II. Indeed, regardless of the conformation of the C-ring, one of the substituents at C-12 or C-13 has to be pseudoaxial, thereby significantly raising the energy of the β-*endo* TS due to steric interaction with the incoming dienophile (Fig. 5, right). Comparatively, the energy of the α-*endo* TS-II should not be raised as much. We were pleased to find that diene 13 β,14β-**40b** gave a single tetracycle **52a**, thereby confirming our hypothesis (Scheme 13).

There is now a good indication that a single stereo-defined substituent on the tether and two β-substituents at C-12 and C-13 will force the intramolecular Diels–Alder to take place through an α-*endo* TS. Adding a methyl group on the exocyclic double bond should not change anything. However, it became clear in preliminary studies that such a methyl substituent considerably slows down the rate of cycloaddition. For example, compound **41** underwent a clean Diels–Alder cycloaddition reaction at the refluxing temperature of xylenes for 5 days to give **56** as a mixture of two stereoisomers (Scheme 15, ratios and stereochemistry of **56** not determined). While this result indicated that the Diels–Alder is definitely possible, trials with **43a** or **43b** always gave decomposition products because it could not withstand

such harsh conditions. The use of Lewis acids also led to decomposition products only. We have established that the main reason for the decomposition of **43a** and **43b** is the lability of the C-1 oxygen functionality as shown in Scheme 15. We are working to build different models in the hopes of overcoming this obstacle. Those results will be reported in due course.

Experimental section

All reactions were carried out under an argon atmosphere. Ethyl ether, toluene, and benzene were dried over metallic sodium using benzophenone as an indicator, while tetrahydrofuran was dried over both sodium and potassium using the same indicator. Dichloromethane, dimethyl formamide, carbon tetrachloride, 1,2-dichloroethane, triethylamine, pyridine, acetonitrile, and diisopropylamine were distilled over calcium hydride. Hexanes were purchased in anhydrous form from Aldrich. Ethyl vinyl ether was distilled prior to use. Cerium trichloride was purchased in hydrated form and dried at 200°C under high vacuum overnight. Thin layer chromatography was performed using 0.25 mm Silica Gel 60 F254 (EM Science-Merck) and flash chromatography using silica gel Kieselgel 60 (230–400 mesh ASTM).

All NMR spectra were taken in deuterated chloroform on a Brüker AC-300 ([1]H (300 MHz), [13]C (75 MHz)). Chemical shifts are reported in ppm (δ) downfield from tetramethylsilane. The splitting patterns are designated as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), and AB quartet (ABq). The IR spectra were determined on a Perkin-Elmer 1600 FT spectrometer. The IR spectra were determined neat, unless otherwise stated. The melting points were performed on a Mettler Toledo model 62. High- and low-resolution mass spectra (HR-MS and LR-MS) were obtained with a micromass spectrometer ZAB-1F model VG.

tert-Butyldiphenylsilyl ether 11a

To a cooled 0°C solution of cyclohexanedione, mono-ethylene ketal (22.1 g, 141 mmol) and methanol was added, in portions, sodium borohydride (5.35 g, 141 mmol). The reaction was stirred for 3 h before being brought to pH 7 by the addition of 1 N HCl. The mixture was partitioned between dichloromethane and brine, and the aqueous phase extracted with CH_2Cl_2. The aqueous layer was concentrated until a precipitate began to form and this layer was extracted again with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$, filtered, and concentrated. The crude alcohol (22.69 g, 100%) was coevaporated with benzene and used without further purification. ^1H NMR (CDCl$_3$) δ: 3.85 (s, 4H), 3.67–3.66 (m, 1H), 2.67 (bs, 1H), 1.80–1.68 (m, 4H), 1.61–1.43 (m, 4H). ^{13}C NMR (CDCl$_3$) δ: 108.2 (s), 67.7 (d), 64.0 (t), 31.7 (t), 31.4 (t). LR-MS (*m/z* (relative intensity)): 158 ([M]$^+$, 10), 99 (100). HR-MS calcd. for $C_8H_{14}O_3$: 158.0943; found: 158.0937. To a solution of this alcohol (5.00 g, 31.6 mmol), imidazole (5.38 g, 79.0 mmol) in DMF (20 mL) was added TBDPSCl (9.86 mL, 37.9 mmol) at room temperature. The mixture was stirred at room temperature for 4 h before being poured into hexane (30 mL). The layers were separated and the DMF layer washed with hexanes (2 × 30 mL) and ethyl ether (30 mL). The combined hexanes – ethyl ether layer was washed with brine, dried over $MgSO_4$, filtered, and concentrated. The crude residue was purified by flash chromatography eluted with hexanes:EtOAc (9:1) to give 12.5 g (100%) of ketal **11a** as a colourless oil. IR (cm^{-1}): 3446, 3070, 1589, 1472, 1427. ^1H NMR (CDCl$_3$) δ: 7.73–7.65 (m, 4H), 7.45–7.34 (m, 6H), 3.98–3.85 (m, 5H), 1.97–1.88 (m, 2H), 1.71–1.63 (m, 4H), 1.51–1.43 (m, 2H), 1.06 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 135.7 (d), 134.8 (d), 134.5 (s), 129.5 (d), 127.6 (d), 127.4 (d), 108.6 (s), 68.4 (d), 64.1 (t), 31.7 (t), 30.8 (t), 26.9 (q), 19.2 (s). LR-MS (*m/z* (relative intensity)): 339 ([M$^+$ – C_4H_9], 10), 199 (100), 200 (25). HR-MS calcd. for $C_{20}H_{23}O_3Si$: 339.1416; found: 339.1412. Anal. calcd. for $C_{24}H_{32}O_3Si$: C 72.68, H 8.13, O 12.10, Si 7.08; found: C 72.53, H 8.18, O 11.98.

Benzyl ether 11b

To an oil-free suspension of KH (10.19 g, 254 mmol) in THF (400 mL) was added a solution of the same alcohol used to make **11a** (16.4 g, 102 mmol) in THF (50 mL) via cannula at 0°C. After hydrogen evolution had ceased, the mixture was warmed to room temperature and the reaction stirred for 3 h. Benzyl bromide (18.1 mL, 152 mmol) was added neat and the reaction stirred overnight. The reaction was quenched with satd. aq NH$_4$Cl, and the product extracted with CH_2Cl_2. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (hexanes:EtOAc (9:1 to 3:1)) yielded 20.8 g (83%) of ketal **11b** as a colourless oil. IR (cm^{-1}): 3030, 2949, 1370. ^1H NMR (CDCl$_3$) δ: 7.34–7.26 (m, 5H), 4.53 (s, 2H), 3.94–3.92 (m, 4H), 3.56–3.50 (m, 1H), 1.89–1.79 (m, 6H), 1.58–1.53 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 139.0 (s), 128.2 (d), 127.3 (d), 108.4 (s), 74.0 (d), 69.8 (t), 64.2 (t), 31.2 (t), 28.5 (t). LR-MS (*m/z* (relative intensity)): 248 ([M]$^+$, 5), 99 (100), 86 (98). HR-MS calcd. for $C_{15}H_{20}O_3$: 248.1412; found:

248.1408. Anal. calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12, O 19.33; found: C 72.51, H 8.23.

PMB ether 11c

To an oil-free suspension of KH (3.04 g, 75.8 mmol) in THF (200 mL) was added a solution of the same alcohol used to make **11a** (10.0 g, 63.2 mmol) in THF (70 mL) via cannula at 0°C. After hydrogen evolution had ceased (1 h), a solution of PMBCl (10.4 g, 66.4 mmol) and THF (30 mL) was added via cannula. The ice bath was removed and the reaction stirred overnight. The reaction was quenched with satd. aq NH$_4$Cl, and the product extracted with ether (3 × 80 mL). The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (hexanes:EtOAc (3:1 to 1:1)) yielded 16.9 g (96%) of ketal **11c** as a clear oil. IR (cm^{-1}): 2943, 1611, 1513. ^1H NMR (CDCl$_3$) δ: 7.26 (d, 2H, $J = 8.6$ Hz), 6.86 (d, 2H, $J = 8.6$ Hz), 4.45 (s, 2H), 3.92 (s, 4H), 3.78 (s, 3H), 3.52–3.47 (m, 1H), 1.86–1.75 (m, 6H), 1.56–1.53 (m, 2H). ^{13}C NMR (CDCl$_3$): δ: 158.9 (s), 131.0 (s), 128.8 (d), 113.6 (d), 108.4 (s), 73.7 (d), 69.4 (t), 64.2 (t), 55.1 (q), 31.2 (t), 28.5 (t). LR-MS (*m/z* (relative intensity)): 278 ([M]$^+$, 10), 86 (100), 121 (90), 99 (90), 142 (65). HR-MS calcd. for $C_{16}H_{22}O_4$: 278.1518; found: 278.1515. Anal. calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97, O 22.99; found: C 69.05, H 7.95.

Ketone 12a

A mixture of ketal **11a** (12.5 g, 31.6 mmol), THF (226 mL), and 1 N HCl (75 mL) was heated to reflux for 3 h. The mixture was cooled, neutralized by the addition of satd. aq NaHCO$_3$ and extracted with CH_2Cl_2. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated. The product was crystallized by the addition of petroleum ether. Three crystallizations yielded 10.8 g (97%) of ketone **12a** as a white solid; mp: 106.0°C. IR (cm^{-1}): 3069, 1716, 1427. ^1H NMR (CDCl$_3$) δ: 7.69–7.67 (m, 4H), 7.45–7.36 (m, 6H), 4.16–4.13 (m, 1H, $J = 2.6$ Hz), 2.79–2.69 (m, 2H), 2.25–2.17 (dt, 2H, $J = 14.4$, 5.3 Hz), 1.99–1.93 (m, 2H), 1.83–1.78 (m, 2H), 1.09 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 211.5 (s), 135.6 (d), 133.8 (s), 129.7 (d), 127.6 (d), 66.9 (d), 36.9 (t), 33.7 (t), 26.9 (q), 19.2 (s). LR-MS (*m/z* (relative intensity)): 295 ([M$^+$ – C_4H_9], 92), 199 (100). HR-MS calcd. for $C_{18}H_{19}O_2Si$: 295.1154; found: 295.1151. Anal. calcd. for $C_{22}H_{28}O_2Si$: C 74.95, H 8.01, O 9.08, Si 7.97; found: C 74.86, H 8.02, O 8.99.

Ketone 12b

Followed the same procedure as per **12a**, starting with ketal **11b** yielding 7.70 g (94%) of ketone **12b** as a colourless oil. IR (cm^{-1}): 3031, 2941, 1716, 1103. ^1H NMR (CDCl$_3$) δ: 7.37–7.28 (m, 5H), 4.59 (s, 2H), 3.83–3.79 (m, 1H), 2.67–2.56 (m, 2H), 2.30–2.22 (m, 2H), 2.19–2.09 (m, 2H), 2.00–1.89 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 211.0 (s), 138.4 (s), 128.3 (d), 127.4 (d), 127.3 (d), 72.1 (d), 70.1 (t), 37.1 (t), 30.3 (t). LR-MS (*m/z* (relative intensity)): 204 ([M]$^+$, 7), 91 (100). HR-MS calcd. for $C_{13}H_{16}O_2$: 204.1150; found: 204.1152. Anal. calcd. for $C_{13}H_{16}O_2$: C 76.44, H 7.90, O 15.67; found: C 76.44, H 7.95.

Ketone 12c

A solution of ketal **11c** (15.28 g, 54.9 mmol) and PPTS (4.1 g, 16.5 mmol) in wet acetone (550 mL) was heated to reflux for 5.5 h. The mixture was cooled and the solvent removed in vacuo. The residue was taken up in ethyl ether and washed with satd. aq NaHCO$_3$, and brine, dried over MgSO$_4$. Flash chromatography using a mixture of hexanes:EtOAc (3:1 to 1:1) procured 11.89 g (92%) of ketone **12c** as a white solid; mp: 34.9°C. IR (CHCl$_3$, cm^{-1}): 3011, 1708, 1612, 1513. ^{1}H NMR (CDCl$_3$) δ: 7.29 (d, 2H, J = 8.6 Hz), 6.90 (d, 2H, J = 8.6 Hz), 4.53 (s, 2H), 3.81 (s, 3H), 3.82–3.78 (m, 1H), 2.67–2.56 (m, 2H), 2.31–2.22 (m, 2H), 2.17–2.10 (m, 2H), 2.00–1.91 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 211.2 (s), 159.0 (s), 130.4 (s), 128.9 (d), 113.7 (d), 71.8 (d), 69.8 (t), 55.1 (q), 37.1 (t), 30.4 (t). LR-MS (*m/z* (relative intensity)): 234 ([M]$^+$, 35), 121 (100). HR-MS calcd. for C$_{14}$H$_{18}$O$_3$: 234.1256; found: 234.1259. Anal. calcd. for C$_{14}$H$_{18}$O$_3$: C 71.77, H 7.74, O 20.49; found: C 71.82, H 7.88.

Lactone 14

To a stirred solution of known diol **13** (8.05 g, 30.4 mmol), imidazole (10.3 g, 152.0 mmol), DMAP (750 mg, 6.08 mmol), and dichloromethane (300 mL) was added TBDPSCl (7.9 mL, 30.4 mmol) at room temperature. The reaction was stirred for 7 days before being partitioned between water and dichloromethane. The aqueous layer was extracted with dichloromethane, washed with brine, dried over MgSO$_4$, filtered, and concentrated. Purification by flash chromatography eluted with hexanes:EtOAc (9:1 to 6:1 to 1:1) yielded 12.0 g (78%) of silyl ether **14** and 1.82 g (22%) of starting diol **13**, resulting in a corrected overall yield of 100%. [α]$_D$: –48.4° (*c* 1.59, CHCl$_3$). IR (cm^{-1}): 3439, 3069, 1794, 1427. ^{1}H NMR (CDCl$_3$) δ: 7.73–7.59 (m, 4H), 7.44–7.23 (m, 9H), 7.07–7.04 (m, 2H), 4.40 (t, 1H, J = 5.4 Hz), 4.27–4.21 (m, 3H), 3.48–3.41 (m, 1H), 2.84 (d, 1H, J = 11.3 Hz), 2.66 (s, 1H), 2.31–2.13 (m, 3H), 1.08 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 177.8 (s), 137.5 (s), 136.0 (d), 135.6 (d), 133.2 (s), 132.4 (s), 129.9 (d), 129.6 (d), 128.0 (d), 127.6 (d), 127.3 (d), 76.1 (d), 73.3 (d), 72.3 (s), 70.7 (t), 65.8 (d), 36.8 (t), 36.5 (t), 26.8 (q), 19.2 (s). LR-MS (*m/z* (relative intensity)): 445 ([M$^+$ – C$_4$H$_9$], 20), 353 (65), 91 (90), 277 (100). HR-MS calcd. for C$_{26}$H$_{25}$O$_5$Si: 445.1471; found: 445.1465. Anal. calcd. for C$_{30}$H$_{34}$O$_5$Si: C 71.68, H 6.82, O 15.91, Si 5.59; found: C 71.64, H 6.84, O 16.01.

Enone 15a

To a solution of ketone **12a** (10.59 g, 30.0 mmol) and PhSO$_2$Me (4.70 g, 30.0 mmol) in THF (70 mL) was added an oil-free suspension of KH (3.01 g, 75.2 mmol) in THF (60 mL) via cannula at room temperature. The mixture was stirred at room temperature for 30 min before being concentrated to dryness. The residue was partitioned between dichloromethane (100 mL) and 0.5 M aq H$_3$PO$_4$ (50 mL). The layers were separated and the aqueous layer extracted with dichloromethane (2 × 70 mL). The combined organic layers were dried over MgSO$_4$, filtered, and concentrated. The crude residue was taken up in toluene (300 mL) and Na$_2$CO$_3$ (15.9 g, 150 mmol) was added. The suspension was heated to reflux for 30 min, cooled, filtered through Celite, and concentrated. Purification by flash chromatography using

hexanes:EtOAc (20:1 to 9:1) gave 9.80 g (93%) of enone **15a** as a clear liquid. IR (cm^{-1}): 3056, 1824, 1684, 1472. ^{1}H NMR (CDCl$_3$) δ: 7.72–7.67 (m, 4H), 7.48–7.38 (m, 6H), 6.78 (dd, 1H, J = 10.2, 2.5 Hz), 5.86 (d, 1H, J = 10.2 Hz), 4.52–4.47 (m, 1H), 2.52 (dt, 1H, J = 16.4, 4.5 Hz), 2.25–2.17 (m, 1H), 2.15–2.03 (m, 2H), 1.08 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 198.8 (s), 153.1 (d), 135.7 (d), 133.3 (s), 129.9 (d), 129.5 (d), 128.7 (d), 127.7 (d), 67.5 (d), 35.2 (t), 32.5 (t), 26.8 (q), 19.0 (s). LR-MS (*m/z* (relative intensity)): 293 ([M$^+$ – C$_4$H$_9$], 65), 199 (100). HR-MS calcd. for C$_{18}$H$_{17}$O$_2$Si: 293.0998; found: 293.0996. Anal. calcd. for C$_{22}$H$_{26}$O$_2$Si: C 75.38, H 7.48, O 9.13, Si 8.01; found: C 75.44, H 7.40, O 9.11.

Enone 15b

Following the procedure outlined for enone **15a**, enone **15b** was prepared starting from ketone **12b**. The yield of enone **15b** was 3.18 g (70%) isolated as a colourless oil. IR (cm^{-1}): 3031, 2954, 2870, 1693, 1454, 1201, 1093. ^{1}H NMR (CDCl$_3$) δ: 7.38 (m, 5H), 7.00–6.96 (m, 1H, J = 10.4 Hz), 5.99 (dt, 1H, J = 10.6, 1.2 Hz), 4.29–4.23 (m, 1H), 2.65–2.56 (m, 1H), 2.39–2.27 (m, 2H), 2.11–1.98 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 198.6 (s), 150.4 (d), 137.7 (s), 129.6 (d), 128.4 (d), 127.8 (d), 127.6 (d), 127.3 (d), 72.4 (d), 70.9 (t), 35.2 (t), 29.1 (t). LR-MS (*m/z* (relative intensity)): 203 ([M + 1], 48), 220 ([M + NH$_4$], 38), 91 (100). HR-MS calcd. for C$_{13}$H$_{15}$O$_2$: 203.1072; found: 203.1077. Anal. calcd. for C$_{13}$H$_{14}$O$_2$: C 77.20, H 6.98, O 15.82; found: C 77.12, H 7.05.

Enone 15c

Followed the same procedure as per **15a** yielding 7.80 g (82%) of enone **15c** as a colourless oil. IR (cm^{-1}): 2999, 2955, 2836, 1681, 1613, 1514, 1249, 1087. ^{1}H NMR (CDCl$_3$) δ: 7.29 (d, 2H, J = 8.6 Hz), 6.96 (d, 1H, J = 10.3 Hz), 6.90 (d, 2H, J = 8.6 Hz), 5.98 (d, 1H, J = 10.3 Hz), 4.58 (AB quartet, 2H, J = 11.4, 5.9 Hz), 4.27–4.21 (m, 1H), 3.81 (s, 3H), 2.64–2.56 (m, 1H), 2.39–2.29 (m, 2H), 2.09–1.98 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 198.5 (s), 159.2 (s), 150.6 (d), 129.5 (s), 129.3 (d), 129.2 (d), 113.8 (d), 71.9 (d), 70.4 (t), 55.1 (q), 35.1 (t), 28.9 (t). LR-MS (*m/z* (relative intensity)): 232 ([M]$^+$, 40), 122 (60), 121 (100). HR-MS calcd. for C$_{14}$H$_{16}$O$_3$: 232.1099; found: 232.1094. Anal. calcd. for C$_{14}$H$_{16}$O$_3$: C 72.39, H 6.94, O 20.66; found: C 72.40, H 6.90.

Enone 15d

NaBH$_4$ (499 mg, 13.2 mmol) was added to a 0°C solution of lactone **14b** (6.66 g, 13.2 mmol) and ethyl alcohol (45 mL). The reaction mixture was stirred at 0°C for a total of 2 h before being quenched by the slow addition of aq NH$_4$Cl. The ice bath was removed and phosphate buffer and water were added, followed by sodium periodate (3.67 g, 17.1 mmol). The reaction mixture was stirred overnight and the resulting suspension filtered through Celite. The alcohol was extracted with dichloromethane, washed with brine, dried over MgSO$_4$, filtered, and concentrated. Purification by flash chromatography (hexanes:EtOAc, 3:1) yielded 4.67 g (75%) of a keto alcohol as a colourless oil. [α]$_D$: –22.6° (*c* 3.16, CHCl$_3$). IR (cm^{-1}): 3433, 3061, 2930, 2854, 1714, 1471, 1427, 1136, 1112. ^{1}H NMR (CDCl$_3$) δ: 7.76–7.67 (m,

4H), 7.45–7.18 (m, 11H), 4.42 (d, 1H, J = 11.7 Hz), 4.32 (d, 1H, J = 11.7 Hz), 4.17–4.15 (m, 1H), 4.08 (dd, 1H, J = 6.4, 2.3 Hz), 3.84–3.79 (m, 1H), 2.91–2.81 (m, 2H), 2.48 (dd, 1H, J = 14.2, 3.9 Hz), 2.31–2.24 (m, 1H), 1.77 (d, 1H, J = 3.1 Hz), 1.10 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 207.5 (s), 138.0 (s), 136.1 (d), 135.8 (d), 133.6 (s), 132.9 (s), 130.0 (d), 129.8 (d), 128.2 (d), 127.8 (d), 127.5 (d), 127.3 (d), 75.5 (d), 73.5 (d), 70.9 (t), 69.5 (d), 44.8 (t), 43.4 (t), 27.0 (q), 19.3 (s). LR-MS (m/z (relative intensity)): 417 ([M$^+$ – C$_4$H$_9$], 8), 249 (95), 91 (100). HR-MS calcd. for C$_{25}$H$_{25}$O$_4$Si: 417.1522; found: 417.1533. Anal. calcd. for C$_{29}$H$_{34}$O$_4$Si: C 73.38, H 7.22, O 13.48, Si 5.92; found: C 73.41, H 7.35, O 13.32.

To a cooled 0°C solution of the keto alcohol (4.51 g, 9.49 mmol), methanesulfonyl chloride (880 µL, 11.4 mmol), and dichloromethane (32 mL) was added triethylamine (4 mL, 28.5 mmol). After 15 min at 0°C, the reaction was quenched with water. After extraction with dichloromethane, the organic layers were washed with satd. aq NaHCO3, and brine, dried over MgSO4. Filtration, concentration, and purification by flash chromatography (hexanes:ethyl acetate, 3:1) yielded 4.03 g (93%) of enone **15d** as an oil. [α]$_D$: +78.1° (c 3.61, CHCl$_3$). IR (cm^{-1}): 3069, 1682, 1427. ^{1}H NMR (CDCl$_3$) δ: 7.73–7.65 (m, 4H), 7.47–7.24 (m, 11H), 6.60 (dd, 1H, J = 10.3, 3.2 Hz), 5.93 (d, 1H, J = 10.5 Hz), 4.62 (d, 1H, J = 12.2 Hz), 4.60–4.57 (m, 1H), 4.54 (d, 1H, J = 12.2 Hz), 3.84–3.80 (m, 1H), 2.89 (dd, 1H, J = 16.5, 7.1 Hz), 2.43 (dd, 1H, J = 16.5, 3.2 Hz), 1.10 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 197.1 (s), 148.5 (d), 138.0 (s), 135.8 (d), 133.3 (s), 132.9 (s), 129.9 (d), 129.6 (d), 128.2 (d), 127.7 (d), 127.4 (d), 76.6 (d), 71.3 (t), 68.4 (d), 40.9 (t), 26.8 (q), 19.2 (s). LR-MS (m/z (relative intensity)): 399 ([M$^+$ – C$_4$H$_9$], 8), 231 (38), 91 (100). HR-MS calcd. for C$_{25}$H$_{23}$O$_3$Si: 399.1416; found: 399.1422. Anal. calcd. for C$_{29}$H$_{32}$O$_3$Si: C 76.28, H 7.06, O 10.51, Si 6.15; found: C 76.29, H 7.09, O 10.54.

Bromoenone 16a

To a solution of enone **15a** (19.0 g, 54.3 mmol) in CCl$_4$ (500 mL) was added over 1 h a solution of bromine (8.25 g, 51.6 mmol) in CCl$_4$ (100 mL) at 0°C. Once complete the mixture was stirred for 45 min at 0°C before a solution of triethylamine (9.89 g, 97.8 mmol) in carbon tetrachloride (100 mL) was added over a 20 min period. The reaction mixture was stirred for 20 min and filtered. The filtrate was washed with 1 N HCl and satd. aq NaHCO$_3$. The aqueous layers were extracted with ether and combined organic layers dried over MgSO$_4$, filtered, and concentrated. Purification by flash chromatography using a mixture of hexanes:EtOAc (20:1 to 8:1) gave 21.0 g (90%) of bromo-enone **16a** as a white solid and trace amounts of a dibromo-ketone; mp: 78.2°C. IR (cm^{-1}): 3060, 2955, 1699. ^{1}H NMR (CDCl$_3$) δ: 7.68–7.65 (m, 4H), 7.48–7.38 (m, 6H), 7.20 (d, 1H, J = 3.1 Hz), 4.48 (dt, 1H, J = 6.4, 3.1 Hz), 2.76 (dt, 1H, J = 16.7, 5.0 Hz), 2.33 (dt, 1H, J = 16.4, 8.2 Hz), 2.13–2.06 (m, 2H), 1.08 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 190.6 (s), 153.1 (d), 135.7 (d), 132.9 (s), 130.2 (d), 127.9 (d), 124.1 (s), 68.8 (d), 34.7 (t), 32.4 (t), 26.8 (q), 19.1 (s). LR-MS (m/z (relative intensity)): 373 ([M$^+$ – C$_4$H$_9$], 50), 371 ([M$^+$ – C$_4$H$_9$], 48), 199 (100). HR-MS calcd. for C$_{18}$H$_{16}$BrO$_2$Si: 371.0103; found: 371.0098.

Bromoenone 16b

Followed the same procedure as per **16a**. Purification by flash chromatography using a mixture of hexanes:EtOAc (6:1) gave 7.23 g (78%) of bromoketone **16b** as a thick oil. IR (cm^{-1}): 3066, 2959, 2871, 1703, 1454, 1317, 1096. ^{1}H NMR (CDCl$_3$) δ: 7.45 (dd, 1H, J = 13.0, 1.2 Hz), 7.39–7.32 (m, 5H), 4.64 (s, 2H), 4.29–4.24 (m, 1H), 2.84 (ddd, 1H, J = 16.8, 5.6, 4.5 Hz), 2.53–2.32 (m, 2H), 2.18–2.08 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 190.4 (s), 150.5 (d), 137.2 (s), 128.5 (d), 128.0 (d), 127.7 (d), 125.0 (s), 73.6 (d), 71.1 (t), 34.7 (t), 29.0 (t). LR-MS (m/z (relative intensity)): 280 ([M]$^+$, 5), 282 ([M]$^+$, 5), 201 ([M$^+$ – Br], 40), 175 (100). HR-MS calcd. for C$_{13}$H$_{13}$BrO$_2$: 280.0099; found: 280.0107.

Bromoenone 16c

Same procedure as per **16a**. Purification by flash chromatography eluting with a mixture of hexanes:EtOAc (3:1 to 1:1) gave 9.58 g (92%) of **16c** as a white solid; mp: 62.7°C. IR (cm^{-1}): 2955, 1697, 1611, 1513, 1463, 1318, 1249, 1174, 1032, 1000, 817. ^{1}H NMR (CDCl$_3$) δ: 7.42 (d, 1H, J = 3.5 Hz), 7.28 (d, 2H, J = 8.6 Hz), 6.90 (d, 2H, J = 8.6 Hz), 4.57 (s, 2H), 4.27–4.22 (m, 1H), 3.81 (s, 3H), 2.83 (dm, 1H, J = 16.8, 10.7 Hz), 2.47 (m, 1H, J = 16.8, 11.7 Hz), 2.37–2.28 (m, 1H), 2.16–2.04 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 190.4 (s), 159.3 (s), 150.7 (d), 132.0 (s), 129.3 (d), 124.8 (s), 113.9 (d), 73.2 (d), 70.7 (t), 55.2 (q), 34.6 (t), 29.0 (t). LR-MS (m/z (relative intensity)): 310 ([M]$^+$, 8), 136 (27), 121 (100). HR-MS calcd. for C$_{14}$H$_{15}$O$_3$Br: 310.0204; found: 310.0195.

Bromoenone 16d

Followed the same procedure as per **16a**. Flash chromatography eluting with a mixture of hexanes:EtOAc (6:1) gave 9.27 g (94%) of **16d** as a thick oil. [α]$_D$: +81.9° (c 1.81, CHCl$_3$). IR (cm^{-1}): 3069, 2957, 1700, 1427, 1113, 1066, 741, 702. ^{1}H NMR (CDCl$_3$) δ: 7.73–7.63 (m, 4H), 7.48–7.22 (m, 11H), 6.99 (d, 1H, J = 4.2 Hz), 4.58 (d, 1H, J = 12.3 Hz), 4.56–4.52 (m, 1H), 4.50 (d, 1H, J = 12.2 Hz), 3.80 (dt, 1H, J = 7.1, 3.2 Hz), 3.10 (dd, 1H, J = 16.4, 7.7 Hz), 2.60 (dd, 1H, J = 16.4, 3.2 Hz), 1.10 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 189.1 (s), 148.7 (d), 137.6 (s), 135.8 (d), 132.9 (s), 132.6 (s), 130.1 (d), 128.3 (d), 127.9 (d), 127.5 (d), 125.1 (s), 75.9 (d), 71.3 (t), 69.7 (d), 40.3 (t), 26.8 (q), 19.3 (s). LR-MS (m/z (relative intensity)): 477 ([M$^+$ – C$_4$H$_9$], 5), 479 ([M$^+$ – C$_4$H$_9$], 5), 311 (30), 309 (30), 91 (100). HR-MS calcd. for C$_{25}$H$_{22}$O$_3$SiBr: 477.0521; found: 477.0511.

Alcohol 17a

To a 0°C solution of tetravinyl tin (320 mg, 1.41 mmol) in THF (20 mL) was added 1.08 M n-butyl lithium (4.73 mL, 5.11 mmol). After 30 min at 0°C the ice bath was removed and the mixture stirred for 1 h. This solution was added via cannula to a cooled –78°C suspension of CeCl$_3$ (2.86 g, 7.67 mmol) and ketone **16a** (1.10 g, 2.55 mmol) in THF (40 mL). The reaction mixture was stirred for 4 h at –78°C before being quenched with satd. aq NH$_4$Cl. The layers were separated (a portion of 1 N HCl was added for clarification) and the aqueous layer extracted with ethyl ether. The organic layers were washed (brine), dried over MgSO$_4$, filtered, and concentrated. Flash chromatography eluting with a mixture of hexanes:EtOAc (9:1) gave 447 mg and 646 mg of two

diastereomeric alcohols (93%) as thick oils. Less polar isomer: ^{1}H NMR (CDCl$_3$) δ: 7.73–7.65 (m, 4H), 7.46–7.35 (m, 6H), 6.12 (d, 1H, J = 3.6 Hz), 5.72 (dd, 1H, J = 17.1, 10.6 Hz), 5.26 (d, 1H, J = 17.1 Hz), 5.17 (d, 1H, J = 10.6 Hz), 4.15 (q, 1H), 2.18–2.10 (m, 1H), 1.83–1.67 (m, 2H), 1.06 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 141.2 (d), 135.7 (d), 135.4 (d), 133.7 (s), 131.1 (s), 129.7 (d), 127.6 (d), 114.9 (t), 74.1 (s), 68.3 (d), 33.0 (t), 28.2 (t), 26.9 (q), 19.1 (s). More polar isomer: IR (cm^{-1}): 3548, 3435, 3066, 2953, 2861, 1630, 1589, 1471, 1425, 1364, 1323, 1076. ^{1}H NMR (CDCl$_3$) δ: 7.72–7.64 (m, 4H), 7.47–7.35 (m, 6H), 6.10 (d, 1H, J = 3.1 Hz), 5.88 (dd, 1H, J = 17.3, 10.6 Hz), 5.35 (d, 1H, J = 17.2 Hz), 5.27 (d, 1H, J = 10.6 Hz), 4.29–4.23 (m, 1H), 2.07–2.01 (m, 1H), 1.87–1.80 (m, 1H), 1.77–1.70 (m, 2H), 1.06 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 141.0 (d), 135.9 (d), 135.7 (d), 133.7 (s), 129.8 (d), 127.6 (d), 115.3 (t), 74.4 (s), 69.1 (d), 34.1 (t), 29.0 (t), 26.8 (q), 19.1 (s). LR-MS (m/z (relative intensity)): 399 ([M$^+$ – C$_4$H$_9$], 5), 199 (100), 200 (41). HR-MS calcd. for C$_{20}$H$_{20}$BrO$_2$Si: 399.0416; found: 399.0424. Anal. calcd. for C$_{24}$H$_{29}$BrO$_2$Si: C 63.01, H 6.39, Br 17.47, O 6.99, Si 6.14; found: C 62.97, H 6.40, O 6.95.

Acetate 18a

To a 0°C solution of tetravinyl tin (464 μL, 2.55 mmol) in THF (30 mL) was added 1.0 M n-butyl lithium (9.30 mL, 9.30 mmol). After 2.5 h at 0°C this solution was added via cannula to a cooled –78°C suspension of CeCl$_3$ (5.19 g, 13.9 mmol) and ketone **16a** (1.99 g, 4.64 mmol) in THF (70 mL). The reaction mixture was stirred for 5 h at –78°C before being quenched with acetic anhydride (10 mL) and warmed to room temperature. After 30 min, satd. aq NH$_4$Cl was added and the layers were separated. The aqueous layer extracted with ethyl ether, and the organic layers washed with brine, dried over MgSO$_4$, filtered, and concentrated. Flash chromatography eluting with a mixture of hexanes:EtOAc (15:1) gave 786 mg and 1.05 g (79%) of acetate **18a**. Less polar acetate: ^{1}H NMR (CDCl$_3$) δ: 7.72–7.65 (m, 4H), 7.46–7.35 (m, 6H), 6.10 (d, 1H, J = 4.5 Hz), 5.87 (dd, 1H, J = 10.8, 17.4 Hz), 5.23 (d, 1H, J = 10.8 Hz), 5.17 (d, 1H, J = 17.4 Hz), 4.10 (q, 1H, J = 4.3 Hz), 3.00 (dt, 1H, J = 11.7, 3.2 Hz), 2.12 (s, 3H), 1.97–1.89 (m, 1H), 1.82–1.62 (m, 2H), 1.07 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 168.9 (s), 136.4 (d), 135.8 (d), 135.7 (d), 135.2 (d), 133.7 (s), 129.7 (d), 127.6 (d), 116.3 (t), 82.3 (s), 66.7 (d), 28.2 (t), 28.0 (t), 26.8 (q), 22.0 (q), 19.1 (s). More polar acetate: IR (cm^{-1}): 3056, 1743, 1635, 1471. ^{1}H NMR (CDCl$_3$) δ: 7.69–7.63 (m, 4H), 7.45–7.34 (m, 6H), 6.25 (d, 1H, J = 2.5 Hz), 5.88 (dd, 1H, J = 17.3, 10.7 Hz), 5.37 (d, 1H, J = 16.8 Hz), 5.33 (d, 1H, J = 10.4 Hz), 4.42–4.38 (m, 1H), 2.43 (dt, 1H, J = 13.2, 3.8 Hz), 2.03 (s, 3H), 2.00–1.92 (m, 1H), 1.81–1.69 (m 2H), 1.05 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 169.1 (s), 137.9 (d), 136.7 (d), 135.7 (d), 133.4 (s), 129.8 (d), 127.7 (d), 127.6 (d), 124.4 (s), 116.6 (t), 82.4 (s), 69.5 (d), 30.6 (t), 29.8 (t), 26.8 (q), 21.9 (q), 19.1 (s). LR-MS (m/z (relative intensity)): 441 ([M$^+$ – C$_4$H$_9$], 18), 443 ([M$^+$ – C$_4$H$_9$], 16), 241 (100), 199 (70). HR-MS calcd. for C$_{22}$H$_{22}$O$_3$BrSi: 441.0521; found: 441.0529. Anal. calcd. for C$_{26}$H$_{31}$BrO$_3$Si: C 62.52, H 6.26, Br 16.00, O 9.61, Si 5.62; found: C 62.66, H 6.19, O 9.44.

Acetate 18b

Followed the same procedure as per **18a**, starting from **17b**. Flash chromatography using a hexanes:EtOAc (8:1 to 4:1) mixture yielded 2.29 g (83%) of a mixture of acetates **18b** as a colourless oil. Less polar isomer: ^{1}H NMR (CDCl$_3$) δ: 7.36–7.28 (m, 5H), 6.45 (d, 1H, J = 4.5 Hz), 5.95 (dd, 1H, J = 10.8, 17.3 Hz), 5.30 (d, 1H, J = 10.8 Hz), 5.28 (d, 1H, J = 17.5 Hz), 4.59 (s, 2H), 3.88 (q, 1H, J = 4.3 Hz), 2.93–2.83 (m, 1H), 2.09 (s, 3H), 2.07–1.81 (m, 3H). ^{13}C NMR (CDCl$_3$) δ: 169.1 (s), 138.3 (s), 136.3 (d), 132.9 (d), 128.4 (d), 127.7 (d), 116.4 (t), 82.4 (s), 71.4 (d), 70.4 (t), 28.5 (t), 24.9 (t), 22.0 (q). More polar isomer: IR (cm^{-1}): 3030, 1745. ^{1}H NMR (CDCl$_3$) δ: 7.36–7.30 (m, 5H), 6.45 (dd, 1H, J = 3.5, 2.3 Hz), 5.90 (dd, 1H, J = 17.3, 10.7 Hz), 5.38 (d, 1H, J = 17.2 Hz), 5.33 (d, 1H, J = 10.7 Hz), 4.58 (ABq, 2H, J = 22.1 Hz), 4.17 (ddd, 1H, J = 2.3, 5.4, 9.8 Hz), 2.63 (m, 1H, J = 3.2, 12.9 Hz), 2.14–2.03 (m, 2H), 2.09 (s, 3H), 1.80–1.68 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 168.9 (s), 137.8 (s), 136.6 (d), 135.0 (d), 128.3 (d), 127.5 (d), 116.7 (t), 82.2 (s), 74.5 (d), 70.3 (t), 30.5 (t), 26.5 (t), 21.9 (q). LR-MS (m/z (relative intensity)): 368 ([M + NH$_4$], 25), 308 ([M + NH$_4$ – AcOH], 25), 291 ([M$^+$ – AcOH], 25), 211 (100). HR-MS calcd. for C$_{17}$H$_{23}$NO$_3$Br: 368.0861; found: 368.0857. Anal. calcd. for C$_{17}$H$_{19}$BrO$_3$: C 58.13, H 5.45, Br 22.75, O 13.67; found: C 58.22, H 5.35, O 13.74.

Acetate 18c

Followed the same procedure as per acetate **18a**, starting from **17c**. Purification by flash chromatography eluting with hexanes:EtOAc (6:1) yielded 10.01 g (82%) of **20d** as a mixture of two diastereomers. First isomer: ^{1}H NMR (CDCl$_3$) δ: 7.25 (d, 2H, J = 8.6 Hz), 6.88 (d, 2H, J = 8.6 Hz), 6.42 (d, 1H, J = 1.1 Hz), 5.89 (dd, 1H, J = 17.3, 10.7), 5.37 (d, 1H, J = 18.8 Hz), 5.32 (d, 1H, J = 10.9 Hz), 4.50 (ABq, 2H, J = 13.5 Hz), 4.17–4.10 (m, 1H), 3.80 (s, 3H), 2.68–2.58 (m, 1H), 2.22–2.20 (m, 2H), 2.08 (s, 3H), 1.77–1.65 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 169.1 (s), 159.1 (s), 136.5 (d), 135.1 (d), 129.8 (s), 129.2 (d), 125.2 (s), 116.7 (t), 113.7 (d), 82.5 (s), 74.2 (d), 70.1 (t), 55.1 (q), 30.4 (t), 26.5 (t), 21.8 (q). Second isomer: IR (cm^{-1}): 3035, 1744, 1612, 1513. ^{1}H NMR (CDCl$_3$) δ: 7.28 (d, 2H, J = 8.6 Hz), 6.88 (d, 2H, J = 8.6 Hz), 6.43 (d, 1H, J = 4.5 Hz), 5.94 (dd, 1H, J = 17.3, 10.9 Hz), 5.29 (d, 1H, J = 10.3 Hz), 5.25 (d, 1H, J = 17.0 Hz), 4.51 (s, 2H), 3.86 (q, 1H, J = 4.4 Hz), 3.80 (s, 3H), 2.86 (dt, 1H, J = 11.8, 3.4), 2.09 (s, 3H), 2.06–1.99 (m, 1H), 1.92–1.89 (m, 1H), 1.85–1.79 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 168.9 (s), 159.0 (s), 136.2 (d), 132.9 (d), 130.2 (s), 129.1 (d), 128.9 (s), 116.2 (t), 113.6 (d), 82.2 (s), 70.9 (d), 69.9 (t), 55.1 (q), 28.3 (t), 24.7 (t), 21.8 (q). LR-MS (m/z (relative intensity)): 323 ([M$^+$ – OAc], 10), 321 ([M$^+$ – OAc], 10), 184 (40), 121 (100). HR-MS calcd. for C$_{16}$H$_{18}$BrO$_2$: 321.0490; found: 321.0485. Anal. calcd. for C$_{18}$H$_{21}$BrO$_4$: C 56.70, H 5.55, Br 20.96, O 16.79; found: C 56.85, H 5.71, O 16.90.

Acetate 18d

Followed the same procedure as per **18a**, starting from **17d**. Flash chromatography using hexanes:EtOAc (9:1) as the eluent gave 8.77 g (83%) of a single acetate **18d** as a clear oil. [α]$_D$: +126.5° (c 4.443, CHCl$_3$). IR (cm^{-1}): 3068,

1749, 1472. ^{1}H NMR (CDCl$_3$) δ: 7.78–7.74 (m, 4H), 7.44–7.28 (m, 9H), 7.18–7.15 (m, 2H), 5.98 (d, 1H, J = 6.0 Hz), 5.84 (dd, 1H, J = 17.3, 10.7 Hz), 5.20 (d, 1H, J = 10.7 Hz), 5.16 (d, 1H, J = 17.3 Hz), 4.39 (d, 1H, J = 12.0 Hz), 4.30 (d, 1H, J = 12.0 Hz), 4.14–4.12 (m, 1H), 3.38 (dt, 1H, J = 12.2, 3.0 Hz), 3.24 (dd, 1H, J = 12.0, 11.7 Hz), 2.33–2.29 (m, 1H), 2.12 (s, 3H), 1.09 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 168.4 (s), 138.0 (s), 136.1 (d), 134.1 (s), 133.3 (s), 132.5 (d), 129.6 (d), 129.0 (s), 128.1 (d), 127.4 (d), 116.6 (t), 82.4 (s), 73.1 (d), 69.8 (t), 66.2 (d), 32.7 (t), 26.7 (q), 21.8 (q), 19.3 (s). LR-MS (m/z (relative intensity)): 547 ([M$^+$ – C$_4$H$_9$], 1), 399 (100). HR-MS calcd. for C$_{29}$H$_{28}$BrO$_4$Si: 547.0940; found: 547.0947. Anal. calcd. for C$_{33}$H$_{37}$BrO$_4$Si: C 65.44, H 6.16, Br 13.19, O 10.57, Si 4.64; found: C 65.41, H 6.22, O 10.50.

Diene 19a

To a suspension of Mg turnings (336 mg, 13.8 mmol) in ethyl ether (28 mL) was added 1-bromo-5-propene (2.07 g, 13.9 mmol) drop wise, resulting in a refluxing mixture. The reaction was kept at reflux for 3 h, until all the magnesium was consumed. The Grignard was cooled and added via cannula to a suspension of copper(I) iodide (968 mg, 5.08 mmol) in ethyl ether (24 mL) at 0°C. After 25 min at 0°C a solution of acetate **18a** (1.269 g, 2.54 mmol) in Et$_2$O (8 mL) was added via cannula. The resulting mixture was stirred for 1 h at 0°C then quenched by the addition of satd. aq NH$_4$Cl. The product was extracted with Et$_2$O, dried over MgSO$_4$, filtered, and concentrated. The crude residue was purified by flash chromatography (100% hexanes to 25:1 hexanes: EtOAc) to provide 1.24 g (96%) of **19a** as a slightly yellow-coloured liquid. IR (cm^{-1}): 3070, 2930, 2856, 1427, 1105. ^{1}H NMR (CDCl$_3$) δ: 7.69–7.65 (m, 4H), 7.46–7.35 (m, 6H), 6.09 (d, 1H, J = 3.7 Hz), 5.92 (t, 1H, J = 7.4 Hz), 5.79 (ddt, 1H, J = 17.0, 10.2, 6.7 Hz), 5.03–4.92 (m, 2H), 4.33–4.28 (m, 1H), 2.61 (dt, 1H, J = 14.9, 5.9 Hz), 2.23–2.01 (m, 4H), 1.76–1.69 (m, 2H), 1.45–1.37 (m, 4H), 1.06 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 138.8 (d), 135.8 (d), 134.0 (s), 133.9 (s), 133.7 (d), 132.6 (d), 131.7 (s), 129.7 (d), 127.7 (d), 126.1 (s), 114.4 (t), 69.0 (d), 33.6 (t), 31.5 (t), 28.7 (t), 28.6 (t), 27.9 (t), 26.9 (q), 23.0 (t), 19.2 (s). LR-MS (m/z (relative intensity)): 453 ([M$^+$ – C$_4$H$_9$], 6), 451 ([M$^+$ – C$_4$H$_9$], 6), 199 (100), 200 (23). HR-MS calcd. for C$_{29}$H$_{37}$OBrSi: 508.1797; found: 508.1793

Diene 19b

Followed the same procedure as per **19a**, starting from **18b**. The crude residue was purified by flash chromatography (hexanes:EtOAc, 9:1) to provide 737 mg (89%) of **19b** as a colourless liquid. ^{1}H NMR (CDCl$_3$) δ: 7.36–7.27 (m, 5H), 6.32 (d, 1H, J = 3.8 Hz), 5.98 (t, 1H, J = 7.5 Hz), 5.80 (ddt, 1H, J = 17.0, 10.2, 6.7 Hz), 5.04–4.92 (m, 2H), 4.59 (s, 2H), 4.10–4.06 (m, 1H), 2.65–2.60 (m, 1H), 2.37–2.28 (m, 1H), 2.19–1.91 (m, 5H), 1.87–1.77 (m, 1H), 1.47–1.38 (m, 4H). ^{13}C NMR (CDCl$_3$) δ: 138.7 (d), 138.3 (s), 133.2 (d), 131.5 (s), 130.6 (d), 128.3 (d), 127.6 (d), 114.4 (t), 73.9 (d), 70.2 (t), 33.5 (t), 28.6 (t), 28.0 (t), 27.8 (t), 23.0 (t).

Diene 19c

To a cooled –78°C solution of 4-(*tert*-butyldimethylsilyloxy)-3-methylbutyl iodide (4.51 g, 13.7 mmol) in Et$_2$O

(126 mL) was added a 1.31 M solution of *tert*-butyl lithium (20.9 mL, 27.4 mmol). After 5 min this solution was warmed to 0°C and stirred for 30 min before being cooled to –78°C. This cooled solution was added via cannula to a stirred suspension of CuCN (1.22 g, 13.7 mmol) in THF (103 mL) at –68°C. This suspension was stirred for 1 h further before a solution of acetate **18c** (3.48 g, 9.13 mmol) in THF (70 mL) was added via cannula at –50°C. The reaction mixture was gradually warmed to 0°C over 1 h, and stirred 2 h at 0°C before being quenched with a solution of satd. aq NH$_4$Cl:conc. NH$_4$OH (9:1). The mixture was extracted with ethyl ether, washed with brine, dried over MgSO$_4$, filtered, and concentrated. The crude product was purified by flash chromatography using hexanes:EtOAc (15:1) to give 4.43 g (92%) of **19c** as a colourless oil. IR (cm^{-1}): 2952, 2855, 1612, 1513, 1462, 1248, 1089, 1038, 835. ^{1}H NMR (CDCl$_3$) δ: 7.27 (d, 2H, J = 8.6 Hz), 6.88 (d, 2H, J = 8.6 Hz), 6.31 (d, 1H, J = 3.7 Hz), 5.97 (t, 1H, J = 7.4 Hz), 4.51 (s, 2H), 4.08–4.03 (m, 1H), 3.80 (s, 3H), 3.39 (ddd, 2H, J = 9.8, 6.5, 6.0 Hz), 2.66–2.59 (m, 1H), 2.36–2.31 (m, 1H), 2.16–2.09 (m, 2H), 1.98–1.89 (m, 1H), 1.84–1.77 (m, 1H), 1.61–1.52 (m, 1H), 1.46–1.37 (m, 3H), 1.09–1.02 (m, 1H), 0.89 (s, 9H), 0.86 (d, 3H, J = 6.7 Hz), 0.03 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 159.1 (s), 133.2 (d), 131.4 (s), 130.7 (d), 130.3 (s), 129.2 (d), 127.3 (s), 113.7 (d), 73.6 (d), 69.9 (t), 68.2 (t), 51.2 (q), 35.6 (d), 32.8 (t), 28.3 (t), 28.0 (t), 26.6 (t), 25.8 (q), 23.0 (t), 18.2 (s), 16.6 (q), –5.4 (q). Anal. calcd. for C$_{27}$H$_{43}$BrO$_3$Si: C 61.93, H 8.28, Br 15.26, O 9.17, Si 5.36; found: C 61.99, H 8.35, O 9.34.

Diene 19d

Followed the same procedure as per **19c**, starting from **18d**. Purified by flash chromatography using hexanes:EtOAc (25:1) to give 3.79 g (96%) of **19d** as a colourless oil. [α]$_D$: +94.6 (c 1.80, CHCl$_3$). IR (cm^{-1}): 2929, 2856, 1471, 1427, 1361, 1250, 1111, 836, 700. ^{1}H NMR (CDCl$_3$) δ: 7.76–7.64 (m, 5H), 7.44–7.22 (m, 10H), 6.02 (t, 1H, J = 7.3 Hz), 5.90 (d, 1H, J = 5.5 Hz), 4.51 (d, 1H, J = 12.1 Hz), 4.37 (d, 1H, J = 12.1 Hz), 4.33–4.30 (m, 1H), 3.49–3.34 (m, 3H), 2.84–2.81 (m, 1H), 2.62–2.56 (m, 1H), 2.18–2.11 (m, 2H), 1.60–1.37 (m, 5H), 1.08 (s, 9H), 0.89 (s, 9H), 0.87 (d, 3H, J = 6.6 Hz), 0.03 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 138.4 (s), 136.0 (d), 134.9 (d), 134.1 (s), 133.6 (s), 130.5 (s), 130.1 (d), 129.7 (d), 128.2 (d), 127.8 (s), 127.6 (d), 75.4 (d), 70.4 (t), 68.2 (t), 67.8 (d), 35.7 (d), 33.0 (t), 28.5 (t), 27.9 (t), 26.9 (q), 26.6 (t), 25.9 (q), 19.4 (s), 18.3 (s), 16.7 (q), –5.3 (q). LR-MS (m/z (relative intensity)): 691 ([M$^+$ – C$_4$H$_9$], 18), 689 ([M$^+$ – C$_4$H$_9$], 16), 91 (100), 74 (65), 199 (58), 135 (52). HR-MS calcd. for C$_{38}$H$_{50}$BrO$_3$Si$_2$: 689.2482; found: 689.2489. Anal. calcd. for C$_{42}$H$_{59}$BrO$_3$Si: C 67.44, H 7.95, Br 10.68, O 6.42, Si 7.51; found: C 67.65, H 7.90, O 6.38.

Diene 19e

Oil-free NaH (45 mg, 1.129 mmol) was suspended in THF (8 mL) and dimethyl malonate (117 μL, 1.03 mmol) was slowly added at 25°C. The reaction was stirred until gas evolution ceased. Then, this solution was transfered via can-

nula to a solution of acetate **18a** (256 mg, 0.513 mmol) and Pd(PPh)$_4$ (29 mg, 0.026 mmol). The reaction was stirred at room temperature for 1 h before the THF was evaporated. The residue taken up in Et$_2$O and the organic phase washed with brine, dried over MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography using hexanes:EtOAc (15:1) to give 217 mg (74%) of diester **19e** as a colourless oil. ^{1}H NMR (CDCl$_3$) δ: 7.68–7.63 (m, 4H), 7.46–7.33 (m, 6H), 6.13 (d, 1H, *J* = 3.5 Hz), 5.83 (t, 1H, *J* = 7.2 Hz), 4.28 (m, 1H), 3.74 (s, 3H), 3.72 (s, 3H), 3.45 (t, 1H, *J* = 7.6 Hz), 2.73 (t, 2H, *J* = 7.6 Hz), 2.7–2.6 (m, 1H), 2.25–2.17 (m, 1H), 1.8–1.65 (m, 2H), 1.06 (s, 9H).

Diene 19f

To a stirred solution of alcohol **17a** (1.74 g, 3.80 mmol), ethylvinyl ether (50 mL), and triethylamine (1 mL) was added mercury(II) trifluoroacetate (1.62 g, 3.80 mmol) at room temperature. The mixture was stirred a total of 3 days before the solvent was removed in vacuo. The residue was taken up in ethyl ether, washed with 10% aq KOH and satd. aq NaHCO$_3$, dried over MgSO$_4$, filtered, and concentrated. Purification by flash chromatography using a mixture of hexanes:EtOAc (15:1 to 9:1) yielded 1.61 g (88%) of aldehyde **19f**. ^{1}H NMR (CDCl$_3$) δ: 9.79 (s, 1H), 7.72–7.68 (m, 4H), 7.48–7.38 (m, 6H), 6.16 (d, 1H, *J* = 3.7 Hz), 5.87 (t, 1H, *J* = 7.2 Hz), 4.37–4.31 (m, 1H), 2.70–2.63 (m, 1H), 2.60–2.56 (m, 2H), 2.49–2.42 (m, 2H), 2.26–2.21 (m, 1H), 1.80–1.74 (m, 2H), 1.09 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 201.2 (d), 135.7 (d), 134.6 (d), 133.8 (s), 132.9 (s), 129.7 (d), 129.6 (d), 127.6 (d), 125.4 (s), 68.8 (d), 43.2 (t), 31.5 (t), 26.8 (q), 22.9 (t), 20.6 (t), 19.1 (s). LR-MS (*m/z* (relative intensity)): 425 ([M$^+$ – C$_4$H$_9$], 25), 199 (100). HR-MS calcd. for C$_{22}$H$_{22}$O$_2$BrSi: 425.0572; found: 425.0575.

Diene 19g

Alcohol **17a** was dissolved in toluene (2 mL) along with propionic acid (2 drops) and ethyl orthoacetate (575 μL, 3.14 mmol). The mixture was refluxed overnight and the solvent was removed in vacuo. Purification by flash chromatography using a mixture of hexanes:EtOAc (25:1 to 9:1) yielded 38.9 mg (21%) of ester **19g** and 113 mg of starting alcohol (92% corrected yield). ^{1}H NMR (CDCl$_3$) δ: 7.70–7.65 (m, 4H), 7.46–7.36 (m, 6H), 6.12 (d, 1H, *J* = 3.7 Hz), 5.88 (t, 1H, *J* = 7.2 Hz), 4.31 (m, 1H), 4.13 (q, 2H, *J* = 6.9 Hz), 2.70–2.63 (m, 1H), 2.48–2.38 (m, 4H), 2.29–2.15 (m, 1H), 1.80–1.70 (m, 2H), 1.25 (t, 3H, *J* = 6.9 Hz), 1.06 (s, 9H).

Aldehyde 20a

To a cooled –78°C solution of vinyl bromide **19a** (1.10 g, 2.17 mmol) in THF (28 mL) was added 2.0 M *n*-butyl lithium (2.17 mL, 4.34 mmol). After 20 min DMF (1.26 mL, 16.3 mmol) was added at –78°C and the reaction stirred for 1 h further before being quenched with satd. aq NH$_4$Cl. The layers were separated and the product extracted with ethyl ether. The combined organic layers were dried over MgSO$_4$, filtered, and concentrated. The crude aldehyde was purified by flash chromatography (100% hexanes to hexanes:EtOAc (15:1)) to provide 977 mg (98%) of aldehyde **20a** as a

faintly yellow-coloured oil. IR (cm^{-1}): 3069, 2932, 2857, 1696, 1427, 1107. ^{1}H NMR (CDCl$_3$) δ: 9.42 (s, 1H), 7.71–7.67 (m, 4H), 7.47–7.37 (m, 6H), 6.64 (t, 1H, *J* = 7.3 Hz), 6.32 (d, 1H, *J* = 2.9 Hz), 5.78 (ddt, 1H, *J* = 16.9, 10.2, 6.7 Hz), 5.01–4.91 (m, 2H), 4.54–4.48 (m, 1H), 2.55 (dt, 1H, *J* = 15.5, 4.9 Hz), 2.13–1.99 (m, 4H), 1.85–1.77 (m, 1H), 1.73–1.61 (m, 1H), 1.43–1.36 (m, 4H), 1.08 (s, 9H). ^{13}C NMR (CDCl$_3$) δ: 193.9 (d), 151.8 (d), 138.8 (d), 137.1 (s), 135.7 (d), 133.7 (s), 131.3 (d), 129.9 (d), 127.7 (d), 114.3 (t), 68.4 (d), 33.6 (t), 31.2 (t), 28.6 (t), 27.9 (t), 26.8 (q), 22.9 (t), 19.1 (s). LR-MS (*m/z* (relative intensity)): 458 ([M]$^+$, 8), 401 ([M$^+$ – C$_4$H$_9$], 25), 199 (100), 241 (95), 86 (49). HR-MS calcd. for C$_{30}$H$_{38}$O$_2$Si: 458.2641; found: 458.2650

Aldehyde 20b

Followed the same procedure as per aldehyde **20a**, starting with **19b**. The crude aldehyde was purified by flash chromatography (hexanes:EtOAc, 15:1) to provide 320 mg of aldehyde **20b** (74%) as a colourless oil. ^{1}H NMR (CDCl$_3$) δ: 9.56 (s, 1H), 7.38–7.30 (m, 5H), 6.69 (t, 1H, *J* = 7.5 Hz), 6.55 (d, 1H, *J* = 2.9 Hz), 5.80 (ddt, 1H, *J* = 17.0, 10.2, 6.7 Hz), 5.02–4.92 (m, 2H), 4.67 (ABq, 2H, *J* = 18.4 Hz), 4.28–4.26 (m, 1H), 2.62 (m, 1H), 2.19–2.04 (m, 6H), 1.75–1.68 (m, 1H), 1.45–1.39 (m, 4H). ^{13}C NMR (CDCl$_3$) δ: 193.7 (d), 148.6 (d), 138.7 (d), 137.9 (s), 131.7 (d), 128.4 (d), 127.7 (s), 127.6 (d), 114.2 (t), 73.3 (d), 70.6 (t), 33.5 (t), 28.5 (t), 27.9 (t), 27.7 (t), 22.8 (t).

Aldehyde 20c

Followed the same procedure as per aldehyde **20a**, starting with **19c**. The residue was purified by flash chromatography using hexane:EtOAc (9:1) as the eluent, providing 2.73 g (90%) of aldehyde **20c** as a clear colourless oil. IR (cm^{-1}): 2953, 2855, 1698, 1612, 1513, 1248, 1090, 836. ^{1}H NMR (CDCl$_3$) δ: 9.55 (s, 1H), 7.29 (d, 2H, *J* = 8.6 Hz), 6.89 (d, 2H, *J* = 8.6 Hz), 6.68 (t, 1H, *J* = 7.4 Hz), 6.52 (d, 1H, *J* = 2.8 Hz), 4.60 (ABq, 2H, *J* = 18.2 Hz), 4.28–4.23 (m, 1H), 3.80 (s, 3H), 3.43 (dd, 1H, *J* = 9.8, 5.9 Hz), 3.35 (dd, 1H, *J* = 9.8, 6.5 Hz), 2.63 (dt, 1H, *J* = 15.3, 4.8 Hz), 2.22–2.05 (m, 4H), 1.73–1.54 (m, 2H), 1.48–1.34 (m, 3H), 1.12–1.02 (m, 1H), 0.89 (s, 9H), 0.86 (d, 3H, *J* = 6.7 Hz), 0.03 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 193.8 (d), 159.3 (s), 148.8 (d), 138.0 (s), 131.8 (d), 130.1 (s), 129.3 (d), 127.8 (s), 113.8 (d), 73.0 (d), 70.4 (t), 68.2 (t), 55.2 (q), 35.6 (d), 32.9 (t), 28.5 (t), 27.8 (t), 26.6 (t), 25.9 (q), 22.9 (t), 18.3 (s), 16.6 (q), –5.3 (q). LR-MS (*m/z* (relative intensity)): 415 ([M$^+$ – C$_4$H$_9$], 3), 122 (50), 74 (54), 121 (100). HR-MS calcd. for C$_{24}$H$_{35}$O$_4$Si: 415.2304; found: 415.2313.

Aldehyde 20d

Followed the same procedure as per **20c**, starting with **19d**. Purification by flash chromatography using hexane:EtOAc (25:1) as the eluent, provided 2.81 g (80%) of aldehyde **20d** as a clear colourless oil. [α]$_D$: +47.3° (*c* 1.10, CHCl$_3$). IR (cm^{-1}): 3070, 2954, 2856, 1700, 1471, 1427, 1255, 1112, 836, 702. ^{1}H NMR (CDCl$_3$) δ: 9.38 (s, 1H), 7.74–7.65 (m, 4H), 7.46–7.28 (m, 11H), 6.78 (t, 1H, *J* = 7.4 Hz), 6.15 (d, 1H, *J* = 3.5 Hz), 4.61–4.58 (m, 1H), 4.56 (ABq, 2H, *J* = 19.4 Hz), 3.59–3.54 (m, 1H), 3.42 (dd, 1H,

J = 9.7, 5.8 Hz), 3.32 (dd, 1H, J = 9.7, 5.8 Hz), 2.79 (dd, 1H, J = 15.6, 7.2 Hz), 2.24–2.19 (m, 1H), 2.07 (q, 2H, J = 7.2 Hz), 1.57–1.26 (m, 5H), 1.11 (s, 9H), 0.87 (s, 9H), 0.85 (d, 3H, J = 6.6 Hz), 0.02 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 193.4 (d), 148.6 (d), 138.5 (s), 137.5 (s), 135.9 (d), 133.7 (d), 133.3 (s), 129.9 (d), 128.2 (d), 127.7 (d), 127.4 (d), 125.8 (s), 75.2 (d), 71.1 (t), 69.3 (d), 68.2 (t), 35.6 (d), 33.0 (t), 28.6 (t), 28.1 (t), 26.9 (q), 26.6 (t), 25.9 (q), 19.3 (s), 18.3 (s), 16.6 (q), –5.4 (q). LR-MS (*m/z* (relative intensity)): 696 ([M]$^+$, 20), 639 ([M$^+$ – C$_4$H$_9$], 68), 91 (100), 74 (99), 199 (99), 135 (88), 531 (70), 197 (68). HR-MS calcd. for C$_{43}$H$_{60}$O$_4$Si$_2$: 696.4030; found: 696.4037.

Acetal 21a

A solution of aldehyde **20c** (5.15 g, 10.9 mmol), PPTS (547 mg, 2.18 mmol), and ethylene glycol (6.07 mL, 109 mmol) in benzene (140 mL) was heated to reflux for 6 h. The solvent was removed in vacuo and the residue taken up in Et$_2$O. The ether layer was washed with satd. aq NaHCO$_3$, and brine. The combined aqueous layers were extracted once with ethyl ether. The organic layers were dried over MgSO$_4$, filtered, and concentrated to give 5.71 g (100%) of acetal **21a** as an oil. The crude acetal was used in the next step without further purification. IR (cm^{-1}): 3030, 1612. ^{1}H NMR (CDCl$_3$) δ: 7.28 (d, 2H, J = 8.6 Hz), 6.86 (d, 2H, J = 8.6 Hz), 6.21 (d, 1H, J = 2.9 Hz), 5.69 (t, 1H, J = 7.2 Hz), 5.55 (s, 1H), 4.54 (s, 2H), 4.12–4.07 (m, 1H), 4.04–3.99 (m, 2H), 3.97–3.92 (m, 2H), 3.80 (s, 3H), 3.43 (dd, 1H, J = 9.7, 5.8 Hz), 3.33 (dd, 1H, J = 9.7, 6.6 Hz), 2.56 (dt, 1H, J = 15.4, 5.5 Hz), 2.22–2.07 (m, 3H), 2.04–1.94 (m, 1H), 1.74–1.66 (m, 1H), 1.62–1.54 (m, 1H), 1.46–1.32 (m, 3H), 1.08–1.02 (m, 1H), 0.88 (s, 9H), 0.86 (d, 3H, J = 6.7 Hz), 0.03 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 158.9 (s), 135.2 (s), 131.4 (s), 130.7 (s), 129.0 (d), 126.9 (d), 126.4 (d), 113.6 (d), 101.2 (d), 72.5 (d), 69.6 (t), 68.1 (t), 64.7 (t), 55.0 (q), 35.5 (d), 32.8 (t), 28.2 (t), 26.8 (t), 25.8 (t and q), 22.8 (t), 18.2 (s), 16.6 (q), –5.4 (q). LR-MS (*m/z* (relative intensity)): 516 ([M]$^+$, 2), 459 ([M – C$_4$H$_9$], 8), 186 (70), 74 (75), 121 (100). HR-MS calcd. for C$_{26}$H$_{39}$O$_5$Si: 459.2567; found: 459.2574.

Acetal 21b

Followed the same procedure as per **21a**, starting with **20d**. Purification by flash chromatography eluting with a hexanes:EtOAc (15:1 to 6:1) mixture provided 2.46 g (95%) of acetal **21b** as a colourless oil. [α]$_D$: +105.3° (*c* 0.74, CHCl$_3$). IR (cm^{-1}): 3070, 2954, 1471. ^{1}H NMR (CDCl$_3$) δ: 7.77–7.66 (m, 4H), 7.43–7.22 (m, 11H), 5.82 (d, 1H, J = 5.1 Hz), 5.75 (t, 1H, J = 7.1 Hz), 5.54 (s, 1H), 4.52 (d, 1H, J = 12.2 Hz), 4.41–4.37 (m, 2H), 3.91–3.81 (m, 4H), 3.47–3.41 (m, 2H), 3.34 (dd, 1H, J = 9.7, 6.6 Hz), 2.80–2.72 (m, 1H), 2.54–2.47 (m, 1H), 2.17–2.12 (m, 2H), 1.59–1.33 (m, 5H), 1.07 (s, 9H), 0.89 (s, 9H), 0.86 (d, 3H, J = 6.7 Hz), 0.03 (s, 6H). ^{13}C NMR (CDCl$_3$) δ: 138.8 (s), 136.1 (d), 135.7 (s), 134.5 (s), 134.0 (s), 130.7 (s), 129.5 (d), 128.6 (d), 128.1 (d), 127.4 (d), 127.2 (d), 125.3 (d), 101.2 (d), 76.0 (d), 70.2 (t), 68.3 (t), 66.2 (d), 64.7 (t), 35.7 (d), 33.0 (t), 28.5 (t), 27.2 (t), 27.0 (q), 26.9 (q), 25.9 (d), 19.3 (s), 18.3 (s), 16.7 (q), –5.3 (q). LR-MS (*m/z* (relative intensity)): 683

([M$^+$ – C$_4$H$_9$], 30), 91 (100). HR-MS calcd. for C$_{41}$H$_{55}$O$_5$Si$_2$: 683.3588; found: 683.3593.

Alcohol 22a

TBAF (12.6 mL, 12.6 mmol) was added to a solution of acetal **21a** (5.45 g, 10.5 mmol) in THF (105 mL) at room temperature. After 6 h, a solution of EtOAc:ethyl ether (1:1) was added to the mixture. The resulting mixture was washed with satd. aq NH$_4$Cl, and the aqueous layer extracted once with EtOAc:ethyl ether (1:1). The combined organic layers were dried over MgSO$_4$, filtered, and concentrated. The crude residue was purified by flash chromatography using a mixture of hexanes:EtOAc (3:1 to 1:1) as the eluent to give 3.66 g (87% for two steps) of alcohol **22a** as a colourless oil. IR (cm^{-1}): 3441, 2931, 1613, 1513, 1463, 1247, 1172, 1048, 821. ^{1}H NMR (CDCl$_3$) δ: 7.28 (d, 2H, J = 8.6 Hz), 6.86 (d, 2H, J = 8.6 Hz), 6.21 (d, 1H, J = 2.9 Hz), 5.68 (t, 1H, J = 7.2 Hz), 5.55 (s, 1H), 4.54 (s, 2H), 4.12–4.07 (m, 1H), 4.04–3.99 (m, 2H), 3.97 (m, 2H), 3.80 (s, 3H), 3.49 (dd, 1H, J = 9.5, 5.8 Hz), 3.41 (dd, 1H, J = 9.5, 6.4 Hz), 2.58 (dt, 1H, J = 15.3, 5.3 Hz), 2.23–2.09 (m, 3H), 2.01–1.94 (m, 1H), 1.74–1.59 (m, 2H), 1.49–1.35 (m, 3H), 1.17–1.08 (m, 1H), 0.91 (d, 3H, J = 6.7 Hz). ^{13}C NMR (CDCl$_3$) δ: 158.9 (s), 135.2 (s), 131.4 (s), 130.6 (s), 129.1 (d), 126.7 (d), 126.5 (d), 113.6 (d), 101.2 (d), 72.4 (d), 69.6 (t), 67.9 (t), 64.7 (t), 55.1 (q), 35.5 (d), 32.7 (t), 28.1 (t), 26.7 (t), 22.8 (t), 16.4 (q). LR-MS (*m/z* (relative intensity)): 402 ([M]$^+$, 1), 264 (45), 136 (50), 91 (55), 131 (60), 77 (60), 122 (90), 121 (100). HR-MS calcd. for C$_{24}$H$_{34}$O$_5$: 402.2406; found: 402.2397. Anal. calcd. for C$_{24}$H$_{24}$O$_5$: C 71.61, H 8.51, O 19.87; found: C 71.61, H 8.60.

Alcohol 22b

Followed the same procedure as per **22a**, starting with **21b**. Flash chromatography (6:1 to 3:1 to 1:1 hexanes:ethyl acetate, followed by 100% EtOAc) gave 2.10 g (58%) of alcohol **22b** as a clear colourless oil and 908 mg of diol as a by-product. [α]$_D$: +70.6° (*c* 1.33, CHCl$_3$). IR (cm^{-1}): 3439, 3069, 1471. ^{1}H NMR (CDCl$_3$) δ: 7.81–7.70 (m, 4H), 7.46–7.27 (m, 11H), 5.88 (d, 1H, J = 6.0 Hz), 5.80 (t, 1H, J = 7.2 Hz), 5.59 (s, 1H), 4.57 (d, 1H, J = 12.3 Hz), 4.44 (d, 1H, J = 12.3 Hz), 4.46–4.42 (m, 1H), 3.93–3.83 (m, 4H), 3.52–3.47 (m, 2H), 3.41 (dd, 1H, J = 10.5, 6.4 Hz), 2.86–2.78 (m, 1H), 2.58–2.52 (m, 1H), 2.22–2.15 (m, 2H), 1.73 (s, 1H), 1.65–1.61 (m, 1H), 1.56–1.40 (m, 3H), 1.22–1.15 (m, 1H), 1.12 (s, 9H), 0.94 (d, 3H, J = 6.7 Hz). ^{13}C NMR (CDCl$_3$) δ: 138.7 (s), 136.0 (d), 135.6 (s), 134.4 (s), 133.9 (s), 130.6 (s), 129.4 (d), 128.4 (d), 128.0 (d), 127.4 (d), 127.1 (d), 125.4 (d), 101.1 (d), 75.9 (d), 70.2 (t), 68.0 (t), 66.2 (d), 64.7 (t), 35.5 (d), 32.8 (t), 28.2 (t), 27.3 (t), 26.9 (q), 26.7 (d), 19.3 (s), 16.5 (q). LR-MS (*m/z* (relative intensity)): 626 ([M]$^+$, 1), 569 ([M$^+$ – C$_4$H$_9$], 20), 91 (100), 83 (80), 199 (65). HR-MS calcd. for C$_{39}$H$_{50}$O$_5$Si: 626.3427; found: 626.3417. Anal. calcd. for C$_{39}$H$_{50}$O$_5$Si: C 74.72, H 8.04, O 12.76, Si 4.48; found: C 74.61, H 8.01, O 12.79.

Enoate 23a

To a stirred solution of alcohol **22a** (3.02 g, 7.49 mmol) in dichloromethane (61 mL) at room temperature was added Dess–Martin periodinane (4.76 g, 11.2 mmol). After 1.5 h,

ethyl ether (100 mL) was added to the reaction mixture, followed by a solution (100 mL) of $Na_2S_2O_3$ (25 g) in satd. aq NaHCO₃. The mixture was stirred for 5 min until all the solids had entered solution. The layers were separated and the aqueous extracted with ethyl ether. The etheric layer was washed with sad. aq NaHCO₃, water, dried over MgSO₄, filtered, and concentrated, yielding 2.98 g (99%) of an aldehyde as a clear colourless oil that was used in the next step without further purification. IR (cm⁻¹): 2934, 2861, 1722, 1613, 1513, 1462, 1247, 1058, 945, 821. ¹H NMR (CDCl₃) δ: 9.61 (d, 1H, J = 1.9 Hz), 7.28 (d, 2H, J = 8.6 Hz), 6.87 (d, 2H, J = 8.6 Hz), 6.23 (d, 1H, J = 3.0 Hz), 5.66 (t, 1H, J = 7.2 Hz), 5.53 (s, 1H), 4.54 (s, 2H), 4.13–4.07 (m, 1H), 4.04–3.99 (m, 2H), 3.97–3.92 (m, 2H), 3.80 (s, 3H), 2.62–2.53 (m, 1H), 2.37–2.31 (m, 1H), 2.22–2.12 (m, 3H), 2.01–1.93 (m, 1H), 1.76–1.62 (m, 2H), 1.50–1.34 (m, 3H), 1.09 (d, 3H, J = 7.0 Hz). ¹³C NMR (CDCl₃) δ: 205.0 (d), 158.9 (s), 135.0 (s), 131.9 (s), 130.6 (s), 129.0 (d), 126.8 (d), 126.0 (d), 113.6 (d), 101.2 (d), 72.4 (d), 69.7 (t), 64.7 (t), 55.1 (q), 46.0 (d), 30.0 (t), 28.1 (t), 27.8 (t), 26.6 (t), 22.8 (t), 13.1 (q). LR-MS (m/z (relative intensity)): 400 ([M]⁺, 1), 264 (35), 77 (58), 91 (61), 122 (63), 132 (70), 121 (100). HR-MS calcd. for $C_{24}H_{32}O_5$: 400.2250; found: 400.2253.

To a 0°C suspension of NaH (389 mg, 9.74 mmol) in THF (40.5 mL) was added MDEPA (1.78 mL, 9.74 mmol). After 1.25 h at 0°C this clear colourless solution was added via cannula to a solution of the crude aldehyde (2.98 g, 7.49 mmol) in THF (37.5 mL) at 0°C. After 30 min at 0°C the reaction was quenched with satd. aq NH₄Cl and the layers separated. The mixture was extracted with ethyl ether and the combined organic layers dried over MgSO₄, filtered, and concentrated. The crude residue was purified by flash chromatography eluting with a mixture of hexanes:EtOAc (3:1) yielding 2.72 g (80% for two steps) of **23a** as a single isomer. IR (cm⁻¹): 3035, 1712, 1655, 1612, 1513. ¹H NMR (CDCl₃) δ: 7.27 (d, 2H, J = 8.6 Hz), 6.89–6.81 (m, 3H), 6.21 (d, 1H, J = 3.0 Hz), 5.77 (d, 1H, J = 15.7 Hz), 5.65 (t, 1H, J = 7.1 Hz), 5.53 (s, 1H), 4.54 (s, 2H), 4.12–4.06 (m, 1H), 4.04–3.99 (m, 2H), 3.97–3.92 (m, 2H), 3.80 (s, 3H), 3.72 (s, 3H), 2.59–2.52 (m, 1H), 2.32–2.27 (m, 1H), 2.22–2.10 (m, 3H), 2.00–1.94 (m, 1H), 1.74–1.66 (m, 1H), 1.39–1.36 (m, 4H), 1.03 (d, 3H, J = 6.7 Hz). ¹³C NMR (CDCl₃) δ: 167.1 (s), 158.9 (s), 154.5 (d), 135.1 (s), 131.6 (s), 130.6 (s), 129.0 (d), 126.6 (d), 126.3 (d), 119.2 (d), 113.6 (d), 101.2 (d), 72.4 (d), 69.6 (t), 64.7 (t), 55.0 (q), 51.2 (q), 36.3 (d), 35.6 (t), 28.1 (t), 27.8 (t), 26.9 (t), 22.8 (t), 19.2 (q). LR-MS (m/z (relative intensity)): 456 ([M]⁺, 15), 320 (30), 77 (55), 91 (60), 122 (80), 121 (100). HR-MS calcd. for $C_{27}H_{36}O_6$: 456.2512; found: 456.2509. Anal. calcd. for $C_{27}H_{36}O_6$: C 71.03, H 7.95, O 21.03; found: C 71.00, H 7.92.

Enoate 23b

Followed the same procedure as per **23a**, starting with **22b**. The aldehyde (clear colourless oil) was used in the next step without further purification. IR (cm⁻¹): 3069, 2930, 2856, 1724, 1427, 1116. ¹H NMR (CDCl₃) δ: 9.60 (d, 1H, J = 1.9 Hz), 7.76–7.65 (m, 4H), 7.44–7.22 (m, 11H), 5.84 (d, 1H, J = 5.1 Hz), 5.73 (t, 1H, J = 7.2 Hz), 5.52 (s, 1H), 4.52 (d, 1H, J = 12.3 Hz), 4.41–4.37 (m, 2H), 3.91–3.81 (m, 4H), 3.49–3.42 (m, 1H), 2.80–2.72 (m, 1H), 2.51–2.45 (m,

1H), 2.20–2.10 (m, 2H), 1.74–1.69 (m, 1H), 1.51–1.37 (m, 3H), 1.23–1.18 (m, 1H), 1.08 (d, 3H, J = 6.9 Hz), 1.06 (s, 9H). LR-MS (m/z (relative intensity)): 624 ([M]⁺, 1), 567 ([M⁺ – C₄H₉], 25), 199 (100), 91 (92), 135 (60). HR-MS calcd. for $C_{39}H_{48}O_5Si$: 624.3271; found: 624.3261.

The crude enoate from the following step was purified by flash chromatography eluting with a mixture of hexanes:EtOAc (6:1) yielding 1.34 g (66% for two steps) of **23b** as clear colourless oil. [α]ᴅ: +19.5° (c 1.32, CHCl₃). IR (cm⁻¹): 3046, 2929, 2856, 1722, 1427, 1272, 1111, 983. ¹H NMR (CDCl₃) δ: 7.78–7.67 (m, 4H), 7.44–7.23 (m, 11H), 6.87 (dd, 1H, J = 15.7, 8.0 Hz), 5.85 (d, 1H, J = 5.1 Hz), 5.79 (d, 1H, J = 15.9 Hz), 5.74 (t, 1H, J = 7.1 Hz), 5.54 (s, 1H), 4.53 (d, 1H, J = 12.3 Hz), 4.42–4.40 (m, 1H), 4.40 (d, 1H, J = 12.3 Hz), 3.92–3.82 (m, 4H), 3.72 (s, 3H), 3.45 (dt, 1H, J = 10.0, 3.5 Hz), 2.81–2.73 (m, 1H), 2.53–2.47 (m, 1H), 2.34–2.29 (m, 1H), 2.15–2.13 (m, 2H), 1.42–1.39 (m, 4H), 1.08 (s, 9H), 1.05 (d, 3H, J = 6.7 Hz). ¹³C NMR (CDCl₃) δ: 167.2 (s), 154.7 (d), 138.8 (s), 136.1 (d), 135.7 (s), 134.5 (s), 134.0 (s), 131.0 (s), 129.5 (d), 128.1 (d), 127.4 (d), 127.3 (d), 125.6 (d), 119.3 (d), 101.2 (d), 76.0 (d), 70.3 (t), 66.2 (d), 64.8 (t), 51.4 (q), 36.5 (d), 35.8 (t), 28.1 (t), 27.3 (t), 27.0 (q), 19.4 (q). LR-MS (m/z (relative intensity)): 680 ([M]⁺, 2), 623 ([M⁺ – C₄H₉], 35), 91 (100). HR-MS calcd. for $C_{42}H_{52}O_6Si$: 680.3533; found: 680.3526. Anal. calcd. for $C_{42}H_{52}O_6Si$: C 74.08, H 7.70, O 14.10, Si 4.12; found: C 73.97, H 7.77, O 14.12.

Aldehyde 24a

A solution of enoate **23a** (2.67 g, 5.84 mmol), PPTS (440 mg, 1.75 mmol), and wet acetone (117 mL) was heated to reflux for 3 h. The solvent was removed in vacuo and the residue taken up in ethyl ether (200 mL) and washed with saturated aq NaHCO₃ (60 mL) and brine (60 mL). The combined aqueous layers were back-extracted once with ether. The combined organic layers were dried over MgSO₄, filtered, and concentrated. Purification by flash chromatography (hexanes:EtOAc, 3:1) yielded 2.23 g (92%) of aldehyde **24a** as a colourless oil. IR (cm⁻¹): 2932, 2857, 1722, 1694, 1656, 1612, 1513, 1435, 1248, 1072, 822. ¹H NMR (CDCl₃) δ: 9.53 (s, 1H), 7.29 (d, 2H, J = 8.6 Hz), 6.89 (d, 2H, J = 8.6 Hz), 6.84 (dd, 1H, J = 15.7, 8.0 Hz), 6.66 (t, 1H, J = 7.3 Hz), 6.53 (d, 1H, J = 2.8 Hz), 5.77 (d, 1H, J = 15.6 Hz), 4.59 (ABq, 2H, J = 18.4 Hz), 4.28–4.22 (m, 1H), 3.80 (s, 3H), 3.71 (s, 3H), 2.65–2.57 (m, 1H), 2.31–2.26 (m, 1H), 2.20–2.02 (m, 4H), 1.72–1.60 (m, 1H), 1.44–1.37 (m, 4H), 1.03 (d, 3H, J = 6.7 Hz). ¹³C NMR (CDCl₃) δ: 193.7 (d), 167.1 (s), 159.2 (s), 154.5 (d), 149.2 (d), 137.7 (s), 131.1 (d), 129.9 (s), 129.2 (d), 127.9 (s), 119.2 (d), 113.7 (d), 72.8 (d), 70.3 (t), 55.1 (q), 51.2 (q), 36.3 (d), 35.5 (t), 28.0 (t), 27.7 (t), 26.7 (t), 22.8 (t), 19.2 (q). LR-MS (m/z (relative intensity)): 412 ([M]⁺, 3), 122 (100), 121 (75). HR-MS calcd. for $C_{25}H_{32}O_5$: 412.2250; found: 412.2247.

Aldehyde 24b

Followed the same procedure **24a**, starting from **23b**. After purification by flash chromatography (hexanes:ethyl acetate, 6:1) 467 mg (92%) of aldehyde **24b** were collected as a clear colourless oil. [α]ᴅ: +16.4 (c 0.63, CHCl₃). IR (cm⁻¹): 3069, 2930, 2857, 1722, 1698, 1428, 1272, 1112. ¹H NMR

(CDCl$_3$) δ: 9.39 (s, 1H), 7.76–7.68 (m, 4H), 7.48–7.24 (m, 11H), 6.86 (dd, 1H, J = 15.7, 8.0 Hz), 6.80 (t, 1H, J = 7.4 Hz), 6.20 (d, 1H, J = 3.5 Hz), 5.78 (d, 1H, J = 15.6 Hz), 4.64–4.62 (m, 1H), 4.59 (ABq, 2H, J = 21.0 Hz), 3.71 (s, 3H), 3.62–3.58 (m, 1H), 2.81 (dd, 1H, J = 15.6, 7.0 Hz), 2.32–2.20 (m, 2H), 2.14–2.05 (m, 2H), 1.46–1.34 (m, 4H), 1.13 (s, 9H), 1.04 (d, 3H, J = 6.8 Hz). ^{13}C NMR (CDCl$_3$) δ: 193.3 (d), 167.1 (s), 154.5 (d), 149.0 (d), 138.4 (s), 137.3 (s), 135.8 (d), 133.5 (s), 133.2 (s), 133.0 (d), 129.8 (d), 127.6 (d), 127.4 (d), 127.3 (d), 125.9 (s), 119.2 (d), 75.1 (d), 71.1 (t), 69.2 (d), 51.2 (q), 36.4 (d), 35.6 (t), 28.1 (t), 26.8 (q), 19.3 (q). LR-MS (*m/z* (relative intensity)): 636 ([M]$^+$, 10), 579 ([M$^+$ – C$_4$H$_9$], 25), 471 (100), 91 (48). HR-MS calcd. for C$_{40}$H$_{48}$O$_5$Si: 636.3271; found: 636.3277.

Alcohol 25

To a cooled 0°C biphasic mixture of aldehyde **24a** (744 mg, 1.80 mmol), dichloromethane (15 mL), and water (830 µL) was added DDQ (532 mg, 2.34 mmol) resulting in a deep green coloured mixture. The mixture was stirred for 2.5 h at which time the colour had become orange and TLC indicated reaction completion. The mixture was poured into a separatory funnel containing dichloromethane and satd aq NaHCO$_3$. The mixture was vigorously shaken and the layers separated. After extraction with dichloromethane, a brine wash, drying over MgSO$_4$, filtration, and concentration in vacuo, the crude product was purified by flash chromatography (hexanes:EtOAc, 3:1 to 1:1) yielded 367 mg (70%) of aldehyde **25** as a colourless oil. IR (cm^{-1}): 3426, 2930, 2858, 1719, 1694, 1436, 1274, 1199, 1035, 870. ^{1}H NMR (CDCl$_3$) δ: 9.53 (s, 1H), 6.83 (dd, 1H, J = 15.7, 8.0 Hz), 6.65 (t, 1H, J = 7.3 Hz), 6.48 (d, 1H, J = 2.9 Hz), 5.75 (d, 1H, J = 15.7 Hz), 4.57–4.51 (m, 1H), 3.70 (s, 3H), 2.56 (dt, 1H, J = 15.4, 4.9 Hz), 2.32–2.02 (m, 6H), 1.58 (dt, 1H, J = 12.3, 4.4 Hz), 1.43–1.33 (m, 4H), 1.02 (d, 3H, J = 6.7 Hz). ^{13}C NMR (CDCl$_3$) δ: 193.9 (d), 167.3 (s), 154.7 (d), 150.8 (d), 137.5 (s), 131.4 (d), 127.7 (s), 119.2 (d), 66.9 (d), 51.4 (q), 36.5 (d), 35.6 (t), 31.2 (t), 28.1 (t), 26.7 (t), 22.9 (t), 19.3 (q). LR-MS (*m/z* (relative intensity)): 292 ([M]$^+$, 1), 261 ([M$^+$ – MeO], 10), 133 (100), 77 (60), 95 (60). HR-MS calcd. for C$_{17}$H$_{24}$O$_4$: 292.1674; found: 292.1664. Anal. calcd. for C$_{27}$H$_{36}$O$_6$: C 71.03, H 7.95, O 21.03; found: C 71.00, H 7.92.

Acetate 29a

Propyne (1.65 mL, 29.3 mmol) was condensed at –78° C in a 100 mL round-bottomed flask. THF (15 mL) was added followed by a solution of *n*-BuLi (4.66 mL, 1.88 M in pentane, 8.76 mmol). The resulting white suspension was stirred for 1 h at –78° C. Then, (*E*)-1-triphenylmethoxy-3-penten-2-one **28** (1.96 g, 5.72 mmol) in THF (7 mL) was added to the white suspension. The reaction mixture was warmed to –20° C and stirred for 2 h. Acetic anhydride (1.42 mL, 15.0 mmol) was added and the reaction mixture warmed to 0°C. The reaction was quenched with saturated ammonium chloride and the two phases were separated. The aqueous phase was extracted with Et$_2$O, the combined organic fractions were washed with satd. aq NaHCO$_3$, water and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give 2.64 g of **29a** as a yellow oil. Flash

chromatography on silica gel eluting with EtOAc and hexanes (20:80) yielded a white solid (2.04 g, 84%). IR (neat, cm^{-1}): 3058, 1747. ^{1}H NMR (C$_6$D$_6$) δ: 7.67–7.62 (m, 6H), 7.15–6.99 (m, 9H), 6.27 (dq, 1H, J = 15.3, 6.6 Hz), 5.92 (dd, 1H, J = 15.3, 1.6 Hz), 3.88 (d, 1H, J = 9.0 Hz), 3.66 (d, 1H, J = 9.0 Hz), 1.71 (s, 3H), 1.54 (dd, 3H, J = 6.6, 1.6 Hz), 1.47 (s, 3H). LR-MS (*m/z* (relative intensity)): 424 ([M]$^+$, 2), 243 (100), 165 (55). HR-MS calcd. for C$_{29}$H$_{28}$O$_3$: 424.2038; found: 424.2047.

Acetate 29b

Followed the same procedure as per acetate **29a**. Flash chromatography on silica gel eluting with EtOAc and hexanes (10:90) gave **29b** as a colourless oil (4.63 g, 90%). IR (neat, cm^{-1}): 3060, 2930, 1749, 1229, 1100, 837, 704. ^{1}H NMR (C$_6$D$_6$) δ: 7.49–7.45 (m, 6H), 7.36–7.14 (m, 9H), 6.10–5.97 (m, 1H), 5.63 (dm, 1H, J = 15.4 Hz), 4.59 (qd, 1H, J = 6.5, 2.2 Hz), 3.41–3.28 (m, 2H), 2.02 (s, 3H), 1.72 (dd, 3H, J = 6.6, 1.0 Hz), 1.41 (dd, 3H, J = 6.5, 1.8 Hz), 0.86 (s, 9H), 0.07–0.05 (m, 6H). LR-MS (*m/z* (relative intensity)): 568 ([M]$^+$, 1), 243 (100), 165 (50). HR-MS calcd. for C$_{36}$H$_{44}$O$_4$Si: 568.3009; found: 568.3000.

Acetate 29c

Followed the same procedure as per acetate **29a**. Flash chromatography on silica gel eluting with EtOAc and hexanes (5:95) gave a colourless oil (5.36 g, 85%). IR (neat, cm^{-1}): 3059, 2928, 1748. ^{1}H NMR (CDCl$_3$) δ: 7.48–7.44 (m, 6H), 7.33–7.21 (m, 9H), 6.10–5.96 (m, 1H), 5.63 (dm, 1H, J = 14.7 Hz), 4.42–4.36 (m, 2H), 3.39 (d, 1H, J = 9.0 Hz), 3.29 (d, 1H, J = 9.0 Hz), 3.23- 3.11 (m, 4H), 2.03 (s, 3H), 1.85–1.49 (m, 6H), 1.72 (d, 3H, J = 6.5 Hz), 0.86 (s, 9H), 0.06–0.04 (m, 6H). LR-MS (*m/z* (relative intensity)): 700 ([M]$^+$, 5), 640 ([M$^+$ – AcOH], 20), 243 (100), 165 (100). HR-MS calcd. for C$_{41}$H$_{52}$O$_4$S$_2$Si: 700.3076; found: 700.3085.

Allene 30

Copper iodide (2.70 g, 14.2 mmol) and lithium bromide (1.23 g, 14.2 mmol) were suspended in THF (30 mL) and the suspension was cooled to 0° C. A suspension of magnesium bromide (4.73 mL, 3.0 M in Et$_2$O, 14.2 mmol) was added and the resulting yellow suspension was stirred for 0.5 h. Acetate **29a** (1.00 g, 2.36 mmol) in THF (10 mL) was added drop wise and the reaction mixture was stirred for an additional 0.5 h at 0° C. Then, Et$_2$O was added (40 mL) and the mixture was poured into a saturated aqueous NH$_4$Cl–NH$_4$OH (9:1) solution and vigorously stirred in an atmosphere of air for 1 h. The phases were separated, the aqueous phase was extracted with Et$_2$O, the combined organic fractions were washed with water and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give 1.1 g of a yellow oil. Flash chromatography on silica gel eluting with EtOAc and hexanes (5:95) yielded a colourless oil (837 mg, 93%). IR (neat, cm^{-1}): 3058, 1955, 1491. ^{1}H NMR (C$_6$D$_6$) δ: 7.66–7.61 (m, 6H), 7.15–6.99 (m, 9H), 6.08 (dd, 1H, J = 15.8, 1.6 Hz), 5.54 (dq, 1H, J = 15.8, 6.6 Hz), 3.96 (s, 2H), 1.74 (s, 6H), 1.54 (dd, 3H, J = 6.6, 1.6 Hz). LR-MS (*m/z* (relative intensity)): 380 ([M]$^+$, 1), 243 (100). HR-MS calcd. for C$_{28}$H$_{28}$O: 380.2140; found: 380.2147.

Allene 31a

Acetate **29b** (4.60 g, 8.09 mmol) was dissolved in THF (20 mL). Tetrabutylammonium fluoride (16.17 mL, 1.0 M in THF, 16.17 mmol) was added and the orange solution was stirred for 12 h. Then, the mixture was poured into sat. NH_4Cl, the phases were separated, and the aqueous phase was extracted with Et_2O. The combined organic fractions were washed with water and brine, dried over $MgSO_4$, filtered, and evaporated under reduced pressure to give 3.70 g of an orange oil. Flash chromatography on silica gel eluting with EtOAc and hexanes (20:80) gave a fluffy white powder (2.80 g, 76%). IR (neat, cm^{-1}): 3467, 3023, 1738, 1449. ^{1}H NMR (C_6D_6) δ: 7.49–7.44 (m, 6H), 7.33–7.22 (m, 9H), 6.10–5.96 (m, 1H), 5.61 (dd, 1H, J = 15.4, 1.6 Hz), 4.63–4.56 (m, 1H), 3.39–3.30 (m, 2H), 2.04 (s, 3H), 1.73 (dd, 3H, J = 6.6, 1.6 Hz), 1.46 (d, 3H, J = 6.6 Hz). LR-MS (m/z (relative intensity)): 454 ([M]$^+$, 1), 243 (100), 165 (75). HR-MS calcd. for $C_{30}H_{30}O_4$: 454.2144; found: 454.2151.

The cuprate addition on this compound was performed as per allene **30**. Flash chromatography on silica gel eluting with EtOAc and hexanes (20:80) gave **31a** as a white powder (2.54 g, 100%) as a mixture of two inseparable isomers. IR (neat, cm^{-1}): 3588–3146, 3058, 1950, 1448. ^{1}H NMR (C_6D_6) δ: 7.50–7.42 (m, 6H), 7.32–7.21 (m, 9H), 5.85 (dm, 1H, J = 15.7 Hz), 5.49–5.36 (m, 1H), 4.34–4.25 (m, 1H), 3.75–3.65 (m, 2H), 1.86 (d, 3H, J = 1.8 Hz), 1.69 (dd, 3H, J = 6.6, 1.6 Hz), 1.36 (dd, 3H, J = 6.4, 1.8 Hz). LR-MS (m/z (relative intensity)): 409 ([M – 1], 10), 259 (50), 243 (100). HR-MS calcd. for $C_{29}H_{29}O_2$: 409.2167; found: 409.2149.

Allene 31b

Followed the same procedure as per allene **31a**, starting from **29c**. Flash chromatography of the intermediate alcohol on silica gel eluting with EtOAc and hexanes (30:70) gave a white powder (5.09 g, 89%). IR (neat, cm^{-1}): 3407, 3022, 1738. ^{1}H NMR (CDCl$_3$) δ: 7.48–7.44 (m, 6H), 7.34–7.22 (m, 9H), 6.03 (dq, 1H, J = 15.4, 6.6 Hz), 5.62 (dd, 1H, J = 15.4, 1.7 Hz), 4.44 (q, 1H, J = 5.7 Hz), 4.38 (td, 1H, J = 7.0, 1.8 Hz), 3.39–3.30 (m, 2H), 3.26–3.12 (m, 4H), 2.05 (s, 3H), 1.85–1.70 (m, 4H), 1.74 (dd, 3H, J = 6.6, 1.7 Hz), 1.64–1.52 (m, 2H), 1.56 (s, 1H). LR-MS (m/z (relative intensity)): 568 ([M$^+$ – H$_2$O], 3), 508 (5), 243 (100), 105 (100). HR-MS calcd. for $C_{35}H_{36}O_3S_2$: 568.2106; found: 568.2114.

The alcohol was submitted to the cuprate reaction as per the alcohol precursor of **31a**. Flash chromatography on silica gel eluting with EtOAc and hexanes (20:80) gave **31b** as a white powder (4.31 g, 93%) containing an inseparable mixture of two isomers. IR (cm^{-1}): 3559, 3431, 3021, 1952, 1597. ^{1}H NMR (CDCl$_3$) δ: 7.49–7.42 (m, 12H), 7.32–7.21 (m, 18H), 5.86 (dd, 2H, J = 16.0, 1.6 Hz), 5.44 (dm, 2H, J = 16.0 Hz), 4.41 (q, 2H, J = 7.1 Hz), 4.16–4.06 (m, 2H), 3.75–3.65 (m, 4H), 3.27–3.13 (m, 8H), 1.89–1.72 (m, 4H), 1.83 (s, 6H), 1.71–1.48 (m, 8H), 1.70 (dd, 6H, J = 6.6, 1.6 Hz), 1.55 (s, 2H). LR-MS (m/z (relative intensity)): 542 ([M]$^+$, 1), 513 ([M$^+$ – C$_2$H$_5$], 3), 299 (10), 243 (100). HR-MS calcd. for $C_{34}H_{38}O_2S_2$: 542.2313; found: 542.2309.

Diester 32a

Allene **31a** (1.84 g, 4.49 mmol), fumaric acid, monoethyl ester (775 mg, 5.38 mmol), and DMAP (110 mg, 0.90 mmol) were dissolved in CH$_2$Cl$_2$ (40 mL). The solution

was cooled to 0°C and stirred for 0.5 h. DCC (1.11 g, 5.38 mmol) was added in small portions and the reaction mixture stirred for 2.5 h during which time a white precipitate formed. The solvent was evaporated and the product purified by flash chromatography on silica gel eluting with EtOAc and hexanes (15:85) giving **32a** as a colourless oil (2.24 g, 93%) containing a 1:1 mixture of inseparable diastereomers. IR (neat, cm^{-1}): 3039, 1957, 1722, 1449. ^{1}H NMR (C_6D_6) δ: 7.64–7.57 (m, 6H), 7.16–7.09 (m, 9H), 7.06–7.00 (m, 2H), 5.93 (dm, 1H, J = 15.8 Hz), 5.74–5.59 (m, 1H), 5.51–5.39 (m, 1H), 3.94–3.92 (m, 2H), 3.90–3.78 (m, 2H), 1.77 (d, 3H, J = 7.8 Hz), 1.45 (dd, 3H, J = 6.6, 1.6 Hz), 1.36 (t, 3H, J = 6.1 Hz), 0.84–0.80 (m, 3H). LR-MS (m/z (relative intensity)): 537 ([M + 1], 2), 243 (95), 167 (90), 105 (100). HR-MS calcd. for $C_{35}H_{37}O_5$: 537.2641; found: 537.2622.

Diester 32b

Followed the same procedure as per diester **32a**, starting from **31b**. Flash chromatography on silica gel eluting with EtOAc and hexanes (15:85) gave a colourless oil (1.83 g, 88%) containing a mixture of two isomers. IR (neat, cm^{-1}): 3026, 1958, 1723, 1646. ^{1}H NMR (CDCl$_3$, integrated for two isomers) δ: 7.48–7.42 (m, 12H), 7.32–7.20 (m, 18H), 6.85–6.80 (m, 4H), 5.88–5.73 (m, 2H), 5.47–5.37 (m, 4H), 4.42–4.19 (m, 6H), 3.67 (s, 4H), 3.27–3.10 (m, 8H), 1.95–1.74 (m, 14H), 1.71–1.64 (m, 6H), 1.55–1.41 (m, 4H), 1.30 (t, 3H, J = 7.1 Hz), 1.29 (t, 3H, J = 7.1 Hz). LR-MS (m/z (relative intensity)): 623 ([M$^+$ – OEt], 5), 381 (20), 243 (100). HR-MS calcd. for $C_{38}H_{39}O_4S_2$: 623.2290; found: 623.2303.

Cycloadduct 33

Allene **30** (837 mg, 2.2 mmol) and methyl fumarate (634 mg, 4.4 mmol) were dissolved in benzene (10 mL) and refluxed for 12 h. Benzene was evaporated to yield 1.6 g of a yellow oil. Flash chromatography on silica gel eluting with EtOAc and hexanes (5:95) afforded 1.04 g of a colourless oil (90%). IR (neat, cm^{-1}): 3059, 1732, 1448. ^{1}H NMR (CHCl$_3$) δ: 7.46–7.42 (m, 6H), 7.32–7.19 (m, 9H), 5.92 (d, 1H, J = 2.7 Hz), 4.04 (d, 1H, J = 5.1 Hz), 3.75–3.62 (m, 2H), 3.71 (s, 3H), 3.51 (s, 3H), 2.89 (dd, 1H, J = 7.9, 5.1 Hz), 2.43–2.33 (m, 1H), 1.76 (s, 3H), 1.43 (s, 3H), 1.20 (d, 3H, J = 7.2 Hz). LR-MS (m/z (relative intensity)): 524 ([M]$^+$, 0.5), 443 (1), 243 (100), 165 (5). HR-MS calcd. for $C_{34}H_{36}O_5$: 524.2563; found: 524.2569.

Aldehyde 34

Cycloadduct **33** (369 mg, 0.75 mmol) was dissolved in Et$_2$O (2 mL). An 88% aqueous solution of formic acid (23 mL) in Et$_2$O (17 mL) was added and the mixture was stirred for 20 min. It was poured into EtOAc (100 mL). The phases were separated, the organic phase was washed with water, satd. NaHCO$_3$ and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give 215 mg of a yellow oil. Flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) yielded a colourless oil (156 mg, 73%). IR (neat, cm^{-1}): 3454, 1732, 1435. ^{1}H NMR (CHCl$_3$) δ: 5.69 (d, 1H, J = 3.1 Hz), 4.48 (dd, 1H, J = 12.3, 5.5 Hz), 4.13 (dd, 1H, J = 12.3, 5.5 Hz), 4.08 (d, 1H, J = 4.9 Hz), 3.72 (s, 3H), 3.67 (s, 3H), 2.73 (dd, 1H, J = 7.0,

4.9 Hz), 2.51–2.39 (m, 1H), 2.28 (t, 1H, J = 5.5 Hz), 1.82 (s, 3H), 1.79 (s, 3H), 1.10 (d, 3H, J = 7.3 Hz). LR-MS (m/z (relative intensity)): 282 ([M]$^+$, 1), 264 ([M$^+$ – H$_2$O], 5), 232 (20), 204 (100), 173 (85), 145 (60), 91 (30). HR-MS calcd. for $C_{15}H_{22}O_5$: 282.1467; found: 282.1471.

This alcohol (146 mg, 0.52 mmol) was dissolved in CH$_2$Cl$_2$ (5 mL). Dess–Martin periodinane (288 mg, 0.68 mmol) was added and the mixture was stirred for 0.5 h. Et$_2$O (10 mL) was added provoking the formation of a white precipitate. The suspension was neutralized with satd. NaHCO$_3$ (20 mL) containing 5 g of sodium thiosulfate. The resulting bilayered mixture was vigorously stirred for 0.5 h. The phases were separated, the aqueous phase was extracted with Et$_2$O, the combined organic fractions were washed with water and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give 146 mg of **34** as a colourless oil (146 mg, 100%). IR (neat, cm^{-1}): 2954, 2713, 1732, 1694. ^{1}H NMR (C$_6$D$_6$) δ: 9.30 (s, 1H), 6.10 (d, 1H, J = 3.0 Hz), 4.24 (d, 1H, J = 4.2 Hz), 3.26 (s, 3H), 3.20 (s, 3H), 3.05 (dd, 1H, J = 6.3, 4.2 Hz), 2.69 (quint, 1H, J = 7.1, 3.0 Hz), 1.71 (s, 3H), 1.61 (s, 3H), 1.02 (d, 3H, J = 7.3 Hz). LR-MS (m/z (relative intensity)): 280 ([M]$^+$, 50), 221 (65), 161 (100). HR-MS calcd. for $C_{15}H_{20}O_5$: 280.1311; found: 280.1306.

Cycloadducts 35a

Allene **32a** (2.32 g, 4.32 mmol) was dissolved in benzene (100 mL). The solution was refluxed for 15 h. The solvent was evaporated and the crude product (2.75 g) was purified by flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) giving a white powder (1.59 g, 69%) containing an inseparable mixture of two diastereomers. IR (neat, cm^{-1}): 3022, 2978, 1732, 1449. ^{1}H NMR (C$_6$D$_6$, integrated for two isomers) δ: 7.57–7.52 (m, 12H), 7.15–7.01 (m, 18H), 6.38 (d, 1H, J = 7.5 Hz), 6.36 (d, 1H, J = 7.5 Hz), 4.17–4.00 (m, 6H), 3.96–3.70 (m, 6H), 3.32 (dd, 1H, J = 11.2, 4.8 Hz), 3.23 (dd, 1H, J = 11.7, 5.0 Hz), 2.77–2.61 (m, 2H), 1.25–1.02 (m, 12H), 0.99 (d, 6H, J = 7.0 Hz), 0.93 (d, 6H, J = 7.0 Hz). LR-MS (m/z (relative intensity)): 536 ([M]$^+$, 1), 491 ([M$^+$ – C$_2$H$_5$O], 5), 243 (100). HR-MS calcd. for $C_{33}H_{31}O_4$: 491.2222; found: 491.2230.

Cycloadducts 35b

Followed the same procedure as per **35a**, starting from **32b**. Flash chromatography on silica gel eluting with EtOAc and hexanes (20:80) gave a colourless oil (1.41 g, 69%) containing an inseparable mixture of two isomers. IR (neat, cm^{-1}): 3023, 1732, 1597. ^{1}H NMR (CDCl$_3$, integrated for two isomers) δ: 7.48–7.38 (m, 12H), 7.33–7.22 (m, 18H), 6.43 (d, 1H, J = 7.3 Hz), 6.38 (d, 1H, J = 7.0 Hz), 4.82 (dm, 1H, J = 8.4 Hz), 4.49–4.40 (m, 3H), 4.24 (q, 2H, J = 7.1 Hz), 4.23 (q, 2H, J = 7.1 Hz), 3.87–3.73 (m, 4H), 3.68 (dm, 1H, J = 11.6 Hz), 3.59 (dt, 1H, J = 11.3, 2.4 Hz), 3.26–3.12 (m, 8H), 3.04 (dd, 1H, J = 11.3, 4.8 Hz), 2.97 (dd, 1H, J = 11.6, 5.0 Hz), 2.89–2.74 (m, 2H), 1.97–1.52 (m, 12 H), 1.60 (s, 3H), 1.57 (s, 3H), 1.32 (t, 3H, J = 7.1 Hz), 1.31 (t, 3H, J = 7.1 Hz), 0.95 (d, 3H, J = 7.0 Hz), 0.93 (d, 3H, J = 7.0 Hz). LR-MS (m/z (relative intensity)): 668 ([M]$^+$, 3), 381 (20), 243 (100). HR-MS calcd. for $C_{40}H_{44}O_5S_2$: 668.2630; found: 668.2643.

Aldehydes 36a and 36b

Followed the same procedure as for the deprotection of **33** and the Dess–Martin oxidation to **34**. Flash chromatography on silica gel eluting with EtOAc and hexanes (40:60) gave two diastereomeric alcohols as a colourless oils (each 256 mg for a total of 512 mg, 82%). Less polar isomer: ^{1}H NMR (CDCl$_3$) δ: 6.27 (d, 1H, J = 7.0 Hz), 5.08 (q, 1H, 6.8 Hz), 4.42–4.31 (m, 2H), 4.21 (q, 1H, J = 7.2 Hz), 4.21 (q, 1H, J = 7.2 Hz), 3.63 (dt, 1H, J = 10.9, 2.5 Hz), 3.04 (dd, 1H, J = 10.9, 4.8 Hz), 2.86–2.74 (m, 1H), 2.03–2.00 (m, 3H), 1.57 (d, 3H, J = 6.8 Hz), 1.48–1.42 (m, 1H), 1.29 (t, 3H, J = 7.2 Hz), 0.94 (d, 3H, J = 7.1 Hz). More polar isomer: IR (neat, cm^{-1}): 3453, 1732, 1454. ^{1}H NMR (CDCl$_3$) δ: 6.20 (d, 1H, J = 6.9 Hz), 4.74 (q, 1H, J = 6.9 Hz), 4.41 (dd, 1H, J = 12.6, 5.2 Hz), 4.32 (dd, 1H, J = 12.6, 6.2 Hz), 4.23 (q, 2H, J = 7.1 Hz), 3.71 (dt, 1H, J = 11.6, 1.8 Hz), 2.94 (dd, 1H, J = 11.6, 5.1 Hz), 2.80–2.69 (m, 1H), 2.04 (d, 3H, J = 2.4 Hz), 1.56 (d, 3H, J = 6.9 Hz), 1.41 (t, 1H, J = 5.8 Hz), 1.30 (t, 3H, J = 7.1 Hz), 0.95 (d, 3H, J = 7.1 Hz). LR-MS (m/z (relative intensity)): 294 ([M]$^+$, 45), 203 (75), 175 (55), 159 (100). HR-MS calcd. for $C_{16}H_{22}O_5$: 294.1467; found: 294.1473.

Each of the isomeric alcohols were oxidized separately and each crude product obtained was purified by flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) to give a colourless oil. Aldehyde **36a** having the α-methyl group (44 mg, 76%). IR (neat, cm^{-1}): 2981, 2730, 1732, 1699. ^{1}H NMR (CDCl$_3$) δ: 9.55 (s, 1H), 7.04 (d, 1H, J = 6.3 Hz), 5.11 (q, 1H, J = 6.7 Hz), 4.18 (q, 2H, J = 7.1 Hz), 3.62 (dt, 1H, J = 8.5, 2.6 Hz), 3.16 (dd, 1H, J = 8.5, 4.5 Hz), 2.98–2.86 (m, 1H), 1.81 (s, 3H), 1.59 (d, 3H, J = 6.7 Hz), 1.27 (t, 3H, J = 7.1 Hz), 1.17 (d, 3H, J = 7.2 Hz). LR-MS (m/z (relative intensity)): 292 ([M]$^+$, 20), 247 (25), 86 (90), 78 (100). HR-MS calcd. for $C_{16}H_{20}O_5$: 292.1311; found: 292.1315. Aldehyde **36b** having the β-methyl group (42 mg, 70% yield): ^{1}H NMR (CDCl$_3$) δ: 9.57 (s, 1H), 6.97 (d, 1H, J = 6.1 Hz), 4.84 (qd, 1H, J = 7.1, 0.9 Hz), 4.19 (q, 2H, J = 7.1 Hz), 3.69 (dt, 1H, J = 8.4, 2.1 Hz), 3.19 (dd, 1H, J = 8.4, 4.6 Hz), 2.88–2.77 (m, 1H), 1.80 (d, 3H, J = 2.5 Hz), 1.59 (d, 3H, J = 7.1 Hz), 1.28 (t, 3H, J = 7.1 Hz), 1.19 (d, 3H, J = 7.2 Hz).

Enoates 37

Mercuric oxide red (520 mg, 2.4 mmol) was dissolved in THF:water (85:15) (8.2 mL) and BF$_3$·OEt$_2$ (0.30 mL, 2.4 mmol) was added drop wise. Cycloadduct **35b** (800 mg, 1.2 mmol) in THF (2 mL) was slowly added to the orange mixture, which was stirred for 0.5 h. Et$_2$O (30 mL) was added and the resulting precipitate was filtered through a cintered glass. The organic phase was washed with satd. NaHCO$_3$ and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give a white powder (711 mg, 100%) containing an inseparable mixture of two diastereomers. IR (neat, cm^{-1}): 3060, 2724, 1730, 1709, 1598. ^{1}H NMR (CDCl$_3$) δ: 9.77 (s, 2H), 7.48–7.39 (m, 12H), 7.33–7.20 (m, 18H), 6.42 (d, 1H, J = 7.3 Hz), 6.38 (d, 1H, J = 7.0 Hz), 4.84 (dm, 1H, J = 7.4 Hz), 4.43 (dm, 1H, J = 10.1 Hz), 4.24 (q, 2H, J = 7.1 Hz), 4.23 (q, 2H, J = 7.1 Hz), 3.86–3.73 (m, 4H), 3.65 (dm, 1H, J = 11.7 Hz), 3.60 (dt, 1H, J = 11.5, 2.4 Hz), 3.03 (dd, 1H, J = 11.5, 4.8 Hz), 2.97 (dd, 1H, J = 11.7, 5.0 Hz), 2.90–2.75 (m, 2H), 2.52 (t, 4H, J =

5.9 Hz), 2.00–1.65 (m, 8 H), 1.60 (s, 3H), 1.57 (s, 3H), 1.32 (t, 3H, J = 7.1 Hz), 1.31 (t, 3H, J = 7.1 Hz), 0.95 (d, 3H, J = 6.6 Hz), 0.92 (d, 3H, J = 6.6 Hz). LR-MS (m/z (relative intensity)): 610 ([M + NH$_4$], 5), 566 (5), 243 (100). HR-MS calcd. for $C_{38}H_{44}NO_6$: 610.3168; found: 610.3154.

Sodium hydride (58 mg, 60% in oil, 1.44 mmol) was suspended in THF (7 mL) at 0°C. Methyl diethoxyphosphono-acetate (0.27 mL, 1.44 mmol) was added slowly and the mixture was stirred for 0.5 h. The anion was added via cannula to a solution of the above aldehyde (711 mg, 1.2 mmol) in THF (7 mL) at 0°C. After 1 h, the reaction was poured into a saturated solution of NH$_4$Cl, the phases were separated and the aqueous phase was extracted with EtOAc. The combined organic fractions were washed with water and brine, dried over MgSO$_4$, filtered, and evaporated under reduced pressure to give 800 mg of a yellow powder. Flash chromatography on silica gel eluting with EtOAc and hexanes (20:80) gave **37** as a white powder (544 mg, 70%) containing an inseparable mixture of two isomers. IR (neat, cm^{-1}): 3058, 1729, 1657. ^{1}H NMR (C_6D_6, integrated for two isomers) δ: 7.45–7.40 (m, 12H), 7.33–7.22 (m, 18H), 6.95 (dt, 1H, J = 15.7, 6.7 Hz), 6.93 (dt, 1H, J = 15.7, 6.8 Hz), 6.42 (d, 1H, J = 7.3 Hz), 6.38 (d, 1H, J = 7.0 Hz), 5.84 (dd, 2H, J = 15.7, 2.1 Hz), 4.82 (dm, 1H, J = 8.3 Hz), 4.42 (dm, 1H, J = 10.6 Hz), 4.24 (q, 2H, J = 7.1 Hz), 4.23 (q, 2H, J = 7.1 Hz), 3.86–3.72 (m, 4H), 3.74 (s, 3H), 3.73 (s, 3H), 3.66 (dm, 1H, J = 11.7 Hz), 3.59 (dt, 1H, J = 11.3, 2.4 Hz), 3.04 (dd, 1H, J = 11.3, 4.8 Hz), 2.97 (dd, 1H, J = 11.7, 5.0 Hz), 2.88–2.73 (m, 2H), 2.31–2.19 (m, 4H), 1.93–1.50 (m, 14 H), 1.31 (t, 3H, J = 7.1 Hz), 1.30 (t, 3H, J = 7.1 Hz), 0.95 (d, 3H, J = 7.3 Hz), 0.93 (d, 3H, J = 7.3 Hz). LR-MS (m/z (relative intensity)): 666 ([M + NH$_4$], 2), 407 (15), 243 (100), 165 (20). HR-MS calcd. for $C_{41}H_{48}NO_7$: 666.3431; found: 666.3420.

Aldehydes 38a and 38b

Followed the same procedure as per the deprotection of **33** and oxidation to give **34**. Flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) gave two separable alcohols as colourless oils (153 mg, 46% and 153 mg, 46%). Less polar isomer: ^{1}H NMR (CDCl$_3$) δ: 6.97 (dt, 1H, J = 15.7, 6.9 Hz), 6.28 (d, 1H, J = 7.0 Hz), 5.86 (d, 1H, J = 15.7 Hz), 4.89 (dm, 1H, J = 8.9 Hz), 4.40–4.30 (m, 2H), 4.21 (q, 2H, J = 7.1 Hz), 3.73 (s, 3H), 3.61 (dt, 1H, J = 10.8, 2.5 Hz), 3.03 (dd, 1H, J = 10.8, 4.8 Hz), 2.84–2.74 (m, 1H), 2.30 (q, 2H, J = 6.9 Hz), 2.00 (s, 3H), 1.99–1.78 (m, 3H), 1.72–1.60 (m, 1H), 1.57 (s, 1H), 1.29 (t, 3H, J = 7.1 Hz), 0.93 (d, 3H, J = 7.1 Hz). More polar isomer: IR (neat, cm^{-1}): 3480, 1732, 1658. ^{1}H NMR (CDCl$_3$) δ: 6.95 (dt, 1H, J = 15.7, 7.0 Hz), 6.19 (d, 1H, J = 6.8 Hz), 5.86 (d, 1H, J = 15.7 Hz), 4.54 (dm, 1H, J = 10.2 Hz), 4.42–4.29 (m, 2H), 4.22 (q, 2H, J = 7.1 Hz), 3.73 (s, 3H), 3.67 (dm, 1H, J = 11.4 Hz), 2.95 (dd, 1H, J = 11.4, 5.1 Hz), 2.79–2.69 (m, 1H), 2.34–2.23 (m, 2H), 2.04 (d, 3H, J = 2.5 Hz), 2.00–1.55 (m, 4H), 1.30 (t, 3H, J = 7.1 Hz), 0.94 (d, 3H, J = 7.1 Hz). LR-MS (m/z (relative intensity)): 406 ([M]$^+$, 15), 297 (50), 175 (100). HR-MS calcd. for $C_{22}H_{30}O_7$: 406.1991; found: 406.1999.

Each alcohol was then oxidized separately. Flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) gave a colourless oil. Aldehyde **38a** with the α-chain

(180 mg, 87%): IR (neat, cm^{-1}): 2728, 1738, 1714, 1694. ^{1}H NMR (CDCl$_3$) δ: 9.53 (s, 1H), 7.04 (d, 1H, J = 6.3 Hz), 6.97 (dt, 1H, J = 15.7, 7.0 Hz), 5.87 (d, 1H, J = 15.7 Hz), 4.94 (dm, 1H, J = 8.7 Hz), 4.19 (q, 2H, J = 7.1 Hz), 3.74 (s, 3H), 3.61 (dt, 1H, J = 8.5, 2.6 Hz), 3.15 (dd, 1H, J = 8.5, 4.5 Hz), 2.97–2.86 (m, 1H), 2.31 (q, 2H, J = 7.0 Hz), 2.00–1.82 (m, 3H), 1.79 (s, 3H), 1.78–1.60 (m, 1H), 1.27 (t, 3H, J = 7.1 Hz), 1.16 (d, 3H, J = 7.2 Hz). LR-MS (m/z (relative intensity)): 422 ([M + NH$_4$], 15), 405 ([M + H$^+$], 100). HR-MS calcd. for $C_{22}H_{29}O_7$: 405.1913; found: 405.1911. Aldehyde **38b** with the β-chain (52 mg, 100%): ^{1}H NMR (CDCl$_3$) δ: 9.55 (s, 1H), 6.96 (d, 1H, J = 5.6 Hz), 6.95 (dt, 1H, J = 15.6, 7.0 Hz), 5.86 (d, 1H, J = 15.6 Hz), 4.66 (dm, 1H, J = 9.7 Hz), 4.18 (q, 2H, J = 7.1 Hz), 3.73 (s, 3H), 3.63 (dt, 1H, J = 7.4, 2.2 Hz), 3.27 (dd, 1H, J = 7.4, 4.8 Hz), 2.82–2.72 (m, 1H), 2.34–2.25 (m, 2H), 1.96–1.75 (m, 3H), 1.79 (d, 3H, J = 2.2), 1.72–1.60 (m, 1H), 1.27 (t, 3H, J = 7.1 Hz), 1.22 (d, 3H, J = 7.2 Hz).

Cycloadducts 14β-39a and 14α-39a

Followed the same procedure as per the preparation of cycloadduct **39b**. The crude mixture was purified by flash chromatography (mixture of hexanes:EtOAc, 15:1) to provide 145 mg (84%) of cycloadducts as an approximate 4:1 mixture of two separable diastereomers. 14α-**39a**: ^{1}H NMR (CDCl$_3$) δ: 7.7–7.3 (m, 10H), 6.51 (d, 1H, J = 0.5 Hz), 5.80 (ddt, 1H, J = 17.0, 10.3, 6.6 Hz), 5.28 (t, 1H, J = 6.8 Hz), 4.97 (dt, 1H, J = 17.0, 1.0 Hz), 4.90 (dt, 1H, J = 10.3, 1.0 Hz), 4.78 (dd, 1H, J = 7.8, 0.5 Hz), 4.09 (m, 1H), 3.88 (dq, 1H, J = 9.5, 7.0 Hz), 3.55 (dq, 1H, J = 9.5, 7.0 Hz), 2.40–2.33 (m, 1H), 2.21–2.17 (m, 3H), 2.06–1.87 (m, 3H), 1.85–1.77 (m, 2H), 1.48–1.37 (m, 1H), 1.36–1.28 (m, 3H), 1.23–1.07 (m, 2H), 1.21 (t, 3H, J = 7.0 Hz), 1.09 (s, 9H). 14β-**39a**: ^{1}H NMR (CDCl$_3$) δ: 7.7–7.3 (m, 10H), 6.60 (d, 1H, J = 0.5 Hz), 5.81 (ddt, 1H, J = 17.0, 10.3, 6.6 Hz), 5.08–4.90 (m, 3H), 4.94 (dd, 1H, J = 7.8, 0.5 Hz), 4.03 (m, 1H), 3.96 (dq, 1H, J = 9.5, 7.0 Hz), 3.11 (dq, 1H, J = 9.5, 7.0 Hz), 2.55–2.41 (m, 1H), 2.25–2.00 (m, 4H), 1.85–1.79 (m, 1H), 1.77–1.20 (m, 9H), 1.27 (t, 3H, J = 7.0 Hz), 1.05 (s, 9H).

Cycloadducts 14β-39b and 14α-39b

To a stirred solution of aldehyde **20b** (307 mg, 0.990 mmol) and ethyl vinyl ether (4.6 mL) was added Yb(FOD)$_3$ (127 mg, 0.120 mmol) at room temperature. The reaction mixture was stirred for 1 day before a solution of brine was added. This mixture was stirred for about 1 h then separated and the product extracted with ethyl ether, dried over MgSO$_4$, filtered, and concentrated. The crude mixture was purified by flash chromatography (mixture of hexanes: EtOAc, 15:1) to provide 308 mg (81%) of cycloadducts as an approximate 1:1 mixture of inseparable diastereomers. IR (neat, cm^{-1}): 3076, 1640. ^{1}H NMR (CDCl$_3$) δ: 7.35–7.24 (m, 5H), 1 isomer 6.44 (d, 1H, J = 2.1 Hz), one isomer 6.39 (d, 1H, J = 1.9 Hz), 5.80 (ddt, 1H, J = 17.0, 10.3, 6.6 Hz), 5.34–5.26 (m, 1H), 5.03–4.91 (m, 2H), 4.85–4.81 (m, 1H), one isomer 4.67 (d, 1H, J = 11.4 Hz), one isomer 4.64 (d, 1H, J = 12.1 Hz), one isomer 4.47 (d, 1H, J = 11.4 Hz), one isomer 4.42 (d, 1H, J = 12.2 Hz), 4.01–3.91 (m, 1H), one isomer 3.64–3.61 (m, 1H), 3.61–3.53 (m, 1H), one isomer 3.20–3.12 (m, 1H), one isomer 2.64 (dt, 1H, J = 14.3,

3.5 Hz), 2.54–1.94 (m, 7H), 1.83–1.74 (m, 1H), 1.63–1.52 (m, 1H), 1.44–1.29 (m, 5H), 1.26 (t, 3H, J = 7.1 Hz). ^{13}C NMR (CDCl$_3$) δ: 138.9 (d), 138.6 (s), 136.7 (d), 136.4 (d), 134.3 (s), 133.9 (s), 128.4 (d), 128.2 (d), 127.8 (d), 127.6 (d), 127.3 (d), 122.3 (d), 121.5 (d), 116.8 (s), 116.2 (s), 114.2 (t), 100.1 (d), 99.9 (d), 82.5 (d), 74.1 (d), 73.7 (d), 71.0 (t), 70.5 (t), 64.5 (t), 64.4 (t), 39.9 (d), 38.8 (d), 33.7 (t), 33.5 (t), 30.9 (t), 30.1 (t), 29.4 (t), 28.5 (t), 27.7 (t), 27.6 (t), 27.4 (t), 25.4 (t), 21.3 (t), 15.2 (q). LR-MS (*m/z* (relative intensity)): 382 ([M]$^+$, 40), 91 (100). HR-MS calcd. for C$_{25}$H$_{34}$O$_3$: 382.2520; found: 382.2553.

Cycloadducts 40a–c

These cycloadducts were not isolated because they spontaneously underwent the subsequent intramolecular cycloaddition. Their stereochemistries were therefore deduced from the isolation of tetracycles **48**–**51**.

Cycloadduct 41

Aldehyde **34** (140 mg, 0.50 mmol) was dissolved in ethyl vinyl ether (5 mL) and Yb(FOD)$_3$ (79 mg, 0.075 mmol) was added. After 12 h, the solvant was evaporated and a colourless oil was obtained (260 mg). Flash chromatography on silica gel eluting with EtOAc and hexanes (10:90) yielded **41** as a white crystalline compound (167 mg, 95%). IR (neat, cm^{-1}): 2975, 1733, 1640, 1164, 1132. ^{1}H NMR (C$_6$D$_6$) δ: 6.47 (d, 1H, J = 2.3 Hz), 4.83 (dd, 1H, J = 9.3, 2.9 Hz), 4.21 (d, 1H, J = 3.1 Hz), 3.90 (dq, 1H, J = 9.5, 7.1 Hz), 3.38–3.27 (m, 2H), 3.32 (s, 3H), 3.32 (s, 3H), 2.36–2.24 (tm, 1H, J = 11.6 Hz), 1.97 (ddd, 1H, J = 12.7, 4.5, 3.1 Hz), 1.80 (s, 3H), 1.76 (s, 3H), 1.75–1.65 (m, 1H), 1.57–1.46 (m, 1H), 1.10 (t, 3H, J = 7.1 Hz), 0.91 (d, 3H, J = 6.5 Hz). ^{13}C NMR (C$_6$D$_6$) δ: 175.2 (s), 174.8 (s), 141.6 (d), 129.1 (s), 124.6 (s), 114.2 (s), 100.6 (d), 64.5 (t), 52.1 (q), 51.5 (q), 51.1 (d), 47.1 (d), 36.6 (d), 35.5 (d), 33.4 (t), 23.8 (q), 21.7 (q), 17.7 (q), 15.7 (q). LR-MS (*m/z* (relative intensity)): 352 ([M]$^+$, 60), 221 (80), 189 (50), 161 (100), 129 (40), 91 (40). HR-MS calcd. for C$_{28}$H$_{28}$O: 352.1886; found: 352.1875.

Cycloadducts 42a and 42b

Each aldehyde **36a** and **36b** were separately submitted to the same protocol as per cycloadduct **41**. Each crude product was purified by flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) to give a white powder. Cycloadduct **42a**: IR (neat, cm^{-1}): 2977, 1735, 1626. ^{1}H NMR (C$_6$D$_6$) δ: 6.02 (d, 1H, J = 2.3 Hz), 4.74 (dd, 1H, J = 7.5, 3.0 Hz), 4.24 (qd, 1H, J = 7.7, 1.9 Hz), 4.20–4.01 (m, 2H), 3.80 (qd, 1H, J = 9.4, 7.1 Hz), 3.52 (dt, 1H, J = 11.9, 2.5 Hz), 3.31 (qd, 1H, J = 9.4, 7.1 Hz), 3.09 (dd, 1H, J = 11.9, 4.8 Hz), 2.16–2.07 (m, 1H), 1.90–1.82 (m, 1H), 1.74–1.58 (m, 2H), 1.41 (d, 3H, J = 1.9 Hz), 1.11 (t, 3H, J = 7.1 Hz), 1.07–1.02 (m, 6H), 0.90 (d, 3H, J = 7.2 Hz). LR-MS (*m/z* (relative intensity)): 364 ([M]$^+$, 10), 318 (90), 78 (100). HR-MS calcd. for C$_{20}$H$_{28}$O$_6$: 364.1886; found: 364.1888. Cycloadduct **42b**: ^{1}H NMR (C$_6$D$_6$) δ: 6.12 (d, 1H, J = 2.2 Hz), 4.73 (dd, 1H, J = 7.4, 2.6 Hz), 4.28 (qd, 1H, J = 6.8, 1.2 Hz), 4.25–4.02 (m, 2H), 3.79 (qd, 1H, J = 9.4, 7.1 Hz), 3.72 (dt, 1H, J = 11.6, 1.9 Hz), 3.31 (qd, 1H, J = 9.4, 7.1 Hz), 3.07 (dd, 1H, J = 11.6, 6.0 Hz), 2.12–2.01 (m, 1H), 1.93–1.85 (m, 1H), 1.73 (ddd, 1H, J = 13.1, 5.9, 2.6 Hz), 1.62–1.52 (m, 1H), 1.30 (d, 3H, J = 2.4 Hz), 1.10 (t, 3H, J = 7.0 Hz), 1.06 (t, 3H, J = 7.1 Hz), 1.01 (d, 3H, J = 6.8 Hz), 0.89 (d, 3H, J = 7.1 Hz).

Cycloadducts 43a and 43b

Followed the same procedure as per **42a** and **42b**. Isomers **38a** and **38b** were reacted separately. Flash chromatography on silica gel eluting with EtOAc and hexanes (30:70) gave a white powder. Cycloadduct **43a** having the α-chain (41 mg, 72%): ^{1}H NMR (C$_6$D$_6$) δ: 6.89 (dt, 1H, J = 15.7, 6.9 Hz), 6.18 (d, 1H, J = 1.6 Hz), 5.80 (d, 1H, J = 15.7 Hz), 4.74 (dd, 1H, J = 7.4, 2.6 Hz), 4.19 (dm, 1H, J = 10.8 Hz), 4.16 (q, 1H, J = 7.1 Hz), 4.07 (q, 1H, J = 7.1 Hz), 3.81 (dq, 1H, J = 9.4, 7.1 Hz), 3.74 (dt, 1H, J = 11.3, 2.3 Hz), 3.45 (s, 3H), 3.32 (dq, 1H, J = 9.4, 7.0 Hz), 3.05 (dd, 1H, J = 11.3, 5.7 Hz), 2.07–1.94 (m, 2H), 1.79–1.71 (m, 1H), 1.70–1.52 (m, 3H), 1.48–1.20 (m, 4H), 1.36 (d, 3H, J = 2.3 Hz), 1.11 (t, 3H, J = 7.0 Hz), 1.06 (t, 3H, J = 7.1 Hz), 0.89 (d, 3H, J = 6.7 Hz). ^{13}C NMR (C$_6$D$_6$) δ: 173.4 (s), 171.1 (s), 166.6 (s), 148.6 (d), 142.1 (d), 128.8 (s), 126.0 (s), 125.1 (s), 121.8 (d), 99.0 (d), 82.9 (d), 64.2 (t), 60.7 (t), 51.0 (q), 45.0 (d), 39.5 (d), 35.6 (d), 34.5 (d), 33.6 (t), 31.5 (t), 30.9 (t), 24.3 (t), 17.0 (q), 16.6 (q), 15.3 (q), 14.3 (q). Tetracycles 53a and 53b

Aldehyde **24a** underwent the same procedure as per the formation of cycloadduct **41**. The crude tetracycles **48** (186 mg, 0.384 mmol) were isolated in 92% combined yield but only two could be obtained pure and characterized. Therefore, the crude mixture was mixed with LiAlH$_4$ (32 mg, 0.844 mmol) in THF (4 mL). The yield of the combined reduced tetracycles was 80% and the yield of pure tetracycle **53** was 45 mg (21% for two steps) and the yield of **53b** was 30 mg (14% for two steps). Tetracycle **53a**: mp 131.4°C. IR (CHCl$_3$, cm^{-1}): 3506, 3008, 2927, 2857, 1612, 1513, 1380, 1249, 1066, 1035. ^{1}H NMR (C$_6$D$_6$) δ: 7.24 (d, 2H, J = 8.6 Hz), 6.78 (d, 2H, J = 8.6 Hz), 4.52 (d, 1H, J = 11.4 Hz), 4.44 (dd, 1H, J = 9.6, 2.1 Hz), 4.23 (d, 1H, J = 11.4 Hz), 4.07–4.02 (m, 1H), 3.90 (dd, 1H, J = 9.4, 3.0 Hz), 3.87 (dq, 1H, J = 9.3, 7.0 Hz), 3.67–3.66 (m, 1H), 3.32 (dq, 1H, J = 9.3, 7.0 Hz), 3.28 (s, 3H), 3.01 (ddd, 1H, J = 11.5, 8.3, 3.2 Hz), 2.95 (bs, 1H), 2.63 (ddd, 1H, J = 12.6, 4.8, 2.1 Hz), 2.36 (m, 1H), 2.00–1.93 (m, 1H), 1.83–1.78 (m, 3H), 1.66–1.61 (m, 2H), 1.59–1.26 (m, 5H), 1.25 (s, 3H),

1.24–1.00 (m, 3H), 1.06 (t, 3H, J = 7.0 Hz), 0.79–0.70 (m, 1H). ^{13}C NMR (acetone d-6) δ: 160.6 (s), 135.2 (s), 132.8 (s), 130.6 (d), 129.2 (s), 114.9 (d), 103.1 (d), 82.0 (d), 74.1 (d), 71.4 (t), 64.9 (t), 63.6 (t), 56.0 (q), 49.7 (d), 47.9 (d), 45.8 (d), 43.1 (d), 40.4 (t), 38.5 (t), 35.2 (d), 30.1 (t), 28.3 (t), 27.9 (t), 27.0 (t), 24.4 (q), 16.2 (q). Tetracycles 49a and 49b

Aldehyde **25** underwent the same treatment as per the formation of cycloadduct **41**. A mixture of tetracyles **49a** and **49b** was isolated and purified by flash chromatography on silica gel eluting with EtOAc and hexanes (1:3) in 84% combined yield. Of this mixture, **49a** and **49b** could be isolated in pure form in 12 and 7%, respectively (the reported ratio was determined by GC from the crude mixture after characterization of the pure compounds). In this particular case, some of the precursor 13β,14β-**40c** (starting material) could be isolated pure. When 13β,14β-**40c** was refluxed in benzene overnight, it gave 97% of pure tetracycle **49a** and **49b** (same 2:1 ratio). Tetracycle **49a**: mp 159.4°C. IR (cm^{-1}): 3499, 1738, 1434. ^{1}H NMR (CDCl$_3$) δ: 4.50 (dd, 1H, J = 9.7, 1.8 Hz), 3.84–3.77 (m, 2H), 3.65 (s, 3H), 3.47–3.39 (m, 2H), 2.67 (dd, 1H, J = 11.9, 7.2 Hz), 2.36–2.29 (m, 1H), 2.15–2.00 (m, 4H), 1.96–1.76 (m, 3H), 1.67–1.58 (m, 3H), 1.50–1.21 (m, 4H), 1.17 (t, 3H, J = 7.1Hz), 1.02–0.89 (m, 1H), 0.83 (d, 3H, J = 6.1 Hz). ^{13}C NMR (CDCl$_3$) δ: 173.4 (s), 132.8 (s), 124.6 (s), 101.5 (d), 73.3 (d), 69.4 (d), 63.7 (t), 50.9 (q), 49.0 (d), 44.3 (d), 43.0 (d), 41.9 (d), 39.9 (d), 37.6 (t), 36.5 (t), 31.2 (t), 29.2 (t), 26.7 (t), 20.6 (q), 15.0 (q). LR-MS (m/z (relative intensity)): 363 ([M$^+$ – H], 5), 318 (70), 301 (100). HR-MS calcd. for $C_{21}H_{31}O_5$: 363.2171; found: 363.2180. Anal. calcd. for $C_{21}H_{32}O_5$: C 69.20, H 8.85, O 21.95; found: C 69.25, H 8.80. Tetracycle **49b**: ^{1}H NMR (CDCl$_3$) δ: 4.95 (t, 1H, J = 7.2 Hz), 4.28–4.25 (m, 1H), 3.75 (dq, 1H, J = 9.8, 7.1 Hz), 3.66 (s, 3H), 3.46 (dq, 1H, J = 9.8, 7.1 Hz), 3.45–3.36 (m, 1H), 2.91 (t, 1H, J = 8.4 Hz), 2.49 (ddd, 1H, J = 13.6, 6.8, 4.2 Hz), 2.37–2.30 (m, 1H), 2.16–2.05 (m, 2H), 2.02–1.77 (m, 4H), 1.69–1.58 (m, 4H), 1.56–1.42 (m, 4H), 1.28–1.23 (m, 1H), 1.19 (t, 3H, J = 7.1 Hz), 0.92 (d, 3H, J = 7.1 Hz).

Tetracycle 51a

Followed the same procedure as per cycloadduct **41**, starting with aldehyde **25**. IR (cm^{-1}): 3499, 1738, 1434. ^{1}H NMR (CDCl$_3$) δ: 4.61 (dd, 1H, J = 8.2, 2.3 Hz), 4.03–4.01 (m, 1H), 3.88–3.86 (m, 1H), 3.84 (dq, 1H, J = 9.5, 7.1 Hz), 3.66 (s, 3H), 3.44 (dq, 1H, J = 9.5, 7.0 Hz), 2.73 (dd, 1H, J = 11.5, 7.1 Hz), 2.50–2.47 (m, 1H), 2.28–2.20 (m, 2H), 2.15–2.07 (m, 1H), 1.99–1.69 (m, 5H), 1.65–1.44 (m, 4H), 1.38–1.20 (m, 2H), 1.17 (t, 3H, J = 7.1 Hz), 1.12–1.02 (m, 1H), 0.85 (d, 3H, J = 6.5 Hz). ^{13}C NMR (CDCl$_3$) δ: 174.3 (s), 133.0 (s), 123.3 (s), 100.2 (d), 69.8 (d), 66.6 (d), 63.1 (t), 51.1 (q), 49.6 (d), 43.5 (d), 39.6 (d), 38.8 (d), 36.3 (t), 32.3 (t), 29.0 (t), 26.4 (t), 21.5 (t), 20.6 (q), 15.0 (q). Anal. calcd. for $C_{21}H_{32}O_5$: C 69.20, H 8.85, O 21.95; found: C 69.16, H 8.81. X-ray data can be found in the supplementary material.[3]

Tetracycle 52b

Followed the same procedure as per cycloadduct **41**, starting with aldehyde **24b**. Flash chromatography yielded 414 mg (82%) of **52** as a mixture of two tetracycles of which only the one with the 14α-stereochemistry could be isolated pure. Therefore, the crude mixture (440 mg, 0.62 mmol) was treated with a 1.0 M solution of TBAF (2.5 mL, 2.5 mmol) in THF (1 mL). The mixture was refluxed for 4 h before being cooled and concentrated to dryness. The crude residue was purified by flash chromatography (hexanes:EtOAc, 3–1:1) to give 69 mg (24%) of the TBS-hydrolysis product **52b** and 205 mg (70%) of its stereoisomers as amorphous solids for a combined yield of 94%. Tetracycle **52b**: IR (film, cm^{-1}): 3482, 2925, 1736. ^{1}H NMR (C_6D_6) δ: 7.25–7.07 (m, 5H), 4.43 (dd, 1H, J = 9.4, 1.9 Hz), 4.38 (s, 2H), 3.91 (dq, 1H, J = 9.5, 7.1 Hz), 3.80–3.78 (m, 1H), 3.55–3.52 (m, 1H), 3.48 (s, 3H), 3.39 (dq, 1H, J = 9.5, 7.1 Hz), 3.26 (dd, 1H, J = 8.0, 2.3 Hz), 2.59 (dd, 1H, J = 12.0, 7.7 Hz), 2.44–2.37 (m, 3H), 2.05–1.99 (m, 1H), 1.91–1.51 (m, 5H), 1.49–1.19 (m, 5H), 1.14 (t, 3H, J = 7.1 Hz), 0.99 (s, 3H), 0.87–0.76 (m, 1H). ^{13}C NMR (C_6D_6) δ: 172.7 (s), 139.5 (s), 130.6 (s), 128.6 (d), 128.3 (d), 127.7 (d), 126.2 (s), 101.9 (d), 76.7 (d), 74.1 (d), 71.6 (t), 69.4 (d), 63.7 (t), 50.6 (q), 49.3 (d), 43.7 (d), 42.8 (d), 40.5 (d), 39.2 (d), 37.6 (t), 36.9 (t), 30.8 (t), 29.8 (t), 26.9 (t), 21.1 (q), 15.5 (q). LR-MS (m/z (relative intensity)): 424 ([M$^+$ – EtOH], 35), 91 (100), 315 (72). HR-MS calcd. for $C_{26}H_{32}O_5$: 424.2250; found: 424.2248.

Tetracycle 54

Tetracycle **49b** (42 mg, 0.116 mmol) was mixed with imidazole (20 mg, 0.29 mmol), TBSCl (23 mg, 0.151 mmol) in CH$_2$Cl$_2$ (0.5 mL). The mixture was stirred overnight and quenched with water. The aqueous layer was extracted with CH$_2$Cl$_2$ and the combined organic fractions were washed with brine, dried over MgSO$_4$, filtered, and concentrated under reduced pressure. Flash chromatography on silica gel (hexanes:EtOAc, 6:1) of the crude product gave **54** (50 mg, 90%). ^{1}H NMR (CDCl$_3$) δ: 4.93 (t, 1H, J = 7.2 Hz), 4.28–4.25 (m, 1H), 3.76 (dq, 1H, J = 9.7, 7.1 Hz), 3.66 (s, 3H),

3.45 (dq, 1H, J = 9.7, 7.1 Hz), 3.44–3.34 (m, 1H), 2.89 (t, 1H, J = 8.6 Hz), 2.43–2.27 (m, 2H), 2.18–2.07 (m, 1H), 2.05–1.82 (m, 6H), 1.70–1.55 (m, 3H), 1.51–1.44 (m, 3H), 1.20 (t, 3H, J = 7.1 Hz), 1.14–1.08 (m, 1H), 0.91 (d, 3H, J = 7.1 Hz), 0.88 (s, 9H), 0.04 (s, 3H), 0.03 (s, 3H). X-ray data can be found in the supplementary material.[3]

Tetracycles 55a and 55b

Tetracycle **50b** was reduced following the procedure for the reduction of **48a**. The alcohol **55a** was isolated in 80% yield (51 mg). ^{1}H NMR (CDCl$_3$) δ: 7.24 (d, 2H, J = 8.6 Hz), 6.86 (d, 2H, J = 8.6 Hz), 5.02 (t, 1H, J = 7.3 Hz), 4.55 (d, 1H, J = 11.9 Hz), 4.43–4.42 (m, 1H), 4.35 (d, 1H, J = 11.9 Hz), 3.84–3.74 (m, 1H), 3.79 (s, 3H), 3.68–3.60 (m, 2H), 3.48 (dq, 1H, J = 9.8, 7.0 Hz), 3.29 (dd, 1H, J = 11.1, 2.6 Hz), 2.36–2.31 (m, 1H), 2.17–1.89 (m, 9H), 1.76 (d, 1H t, J = 13.8, 7.8 Hz), 1.57–1.39 (m 5H), 1.21 (t, 3H, J = 7.0 Hz), 1.09–0.98 (m, 1H), 0.95 (d, 3H, J = 7.1 Hz), 0.78–0.72 (m, 1H). Alcohol **55a** was protected, as per the protection of tetracycle **49b**, which gave **55b** (186 mg, 100%); mp 221.8°C. IR (cm^{-1}): 3007, 2929, 2856, 1612, 1513, 1249, 1059, 1036. ^{1}H NMR (CDCl$_3$) δ: 7.24 (d, 2H, J = 8.6 Hz), 6.85 (d, 2H, J = 8.6 Hz), 4.97 (t, 1H, J = 7.2 Hz), 4.54 (d, 1H, J = 11.9 Hz), 4.36 (d, 1H, J = 11.9 Hz), 4.21–4.19 (m, 1H), 3.87 (dd, 1H, J = 9.5, 4.4 Hz), 3.79 (s, 3H), 3.76 (dq, 1H, J = 9.9, 7.1 Hz), 3.58–3.56 (m, 1H), 3.48 (dq, 1H, J = 9.9, 7.1 Hz), 3.23 (t, 1H, J = 9.5 Hz), 2.25–2.20 (m, 1H), 2.12–1.88 (m, 9H), 1.66 (dt, 1H, J = 13.7, 7.3 Hz), 1.51 (bs, 3H), 1.47–1.33 (m, 2H), 1.19 (t, 3H, J = 7.1 Hz), 1.15–1.07 (m, 1H), 0.92 (d, 3H, J = 7.1 Hz), 0.87 (s, 9H), 0.01 (d, 6H, J = 2.2 Hz). ^{13}C NMR (C$_6$D$_6$) δ: 174.4 (s), 173.3 (s), 172.1 (s), 135.7 (s), 134.2 (s), 98.4 (d), 63.2 (d), 62.4 (t), 51.7 (q), 51.5 (q), 51.2 (q), 50.9 (d), 44.5 (d), 41.0 (d), 33.0 (t), 36.8 (d), 36.1 (d), 34.4 (t), 32.3 (s), 27.2 (q), 26.8 (q), 19.4 (q), 15.4 (q). LR-MS (m/z (relative intensity)): 456 ([M + NH$_4$], 5), 437 ([M – 1], 30), 393 (100), 361 (70). HR-MS calcd. for C$_{23}$H$_{33}$O$_8$: 437.2175; found: 437.2159.

Conclusion

We have successfully completed an in-depth study of the stereochemical aspect of the cycloadditions involved in the diene-transmissive Diels–Alder strategy. The results clearly show that the stereochemistry of both cycloadditions can be controlled by proper positioning of susbtituents in the precursors. The study also procured useful information about what structural features should be avoided in the cycloaddition precursors that lead to lower selectivity. Importantly, we were able to construct vinyl allene precursors possessing the C-10 methyl group and showed that those precursors underwent two highly stereoselective Diels–Alder cycloadditions. We were not yet able, however, to effect the third and last Diels–Alder reaction in those systems. Current investigations are aimed at solving this difficulty.

From T-antigen to plasmalogen-derived aldehydes: The identification of a marker of colorectal cancer in human rectal mucous

Jiri J. Krepinsky, Gabor P. Kandel, Ka Sing Yeung, Jacek Chociej, Min Chen, Gideon Cohen, Stephen P. Douglas, Rudolf Furrer, Vishal Kukreti, Niculina Lupescu, Enoka Richens, and Keith L. Tanner

Abstract: Recently, a simple noninvasive screening test for colorectal cancer was proposed, based on a hypothesis involving galactose-containing carbohydrate moieties such as the Thomsen–Friedenreich antigen. According to the hypothesis, such carbohydrate moieties, present in the human rectal mucous of patients with colorectal cancer, can be specifically oxidized with galactose oxidase to form substances that, upon reaction with Schiff reagent, yield purple (magenta) coloured compounds. While evaluating this proposed test, we discovered that the colour formation is not due to the proposed reaction between oxidized galactose moieties present in rectal mucous and Schiff reagent. We found instead that the mucous from colorectal cancer patients contains compounds that form purple (magenta) adducts with the Schiff reagent directly, i.e., they do not require oxidation by galactose oxidase. We have identified these compounds as long-chain aliphatic aldehydes, mainly palmitic aldehyde $C_{15}H_{31}CH=O$ and stearic aldehyde $C_{17}H_{35}CH=O$. We have further found that the aldehydes originate from plasmalogens present in the phospholipid fraction of the mucous obtained from colorectal cancer patients. The aldehydes, present in plasmalogens as enol ethers, are released by the acidity of the Schiff reagent and in turn react with the Schiff reagent to form the coloured adducts. Correct identification of these markers could lead to the development of a more accurate colorectal cancer screening tool and to a deeper understanding of colorectal carcinogenesis.

Key words: T-antigen, plasmalogen-derived aldehydes, colorectal cancer marker.

Résumé : Récemment une nouvelle méthode simple et non invasive de dépistage du cancer colorectal a été proposée; elle est fondée sur une hypothèse impliquant des portions de sucre contenant du galactose, tel l'antigène de Thomsen–Friedenreich. Selon cette hypothèse, de telles portions de sucre présentes dans les muqueuses rectales de patients humains atteints d'un cancer colorectal peuvent être spécifiquement oxydées par l'oxydase du galactose pour former des substances qui réagissent avec le réactif de Schiff et qui produisent des composés colorés en violet magenta. En évaluant la méthode proposée, on a découvert que la formation de la couleur n'est pas due à la réaction suggérée du réactif de Schiff et des portions de galactose oxydé présentes dans la muqueuse rectale. On a plutôt trouvé que la muceuse de patients atteints de cancer colorectal contiennent des composés qui, avec le réactif de Schiff, forment directement des adduits colorés en violet magenta, c'est-à-dire qu'il n'est pas nécessaire de procéder par l'oxydation à l'aide d'oxydase du galactose. On a identifié ces composés comme étant des aldéhydes aliphatiques à longues chaînes carbonées, principalement l'aldéhyde palmitique, $C_{15}H_{31}CH=O$, et l'aldéhyde stéarique, $C_{17}H_{35}CH=O$. On a de plus trouvé que ces aldéhydes trouvent leur origine dans les plasmalogènes présents dans la fraction phospholipide de la muqueuse des patients atteints de cancer colorectal. Ces aldéhydes sont présents dans le plasmalogène sous la forme d'éthers énoliques, ils sont libérés par l'acidité du réactif de Schiff et ils réagissent alors avec le réactif de Schiff pour former les adduits colorés. L'identification correcte de ces marqueurs pourrait conduire au développement d'un outil de dépistage plus précis du cancer colorectal et à une meilleure compréhension du développement de ce type de cancer.

Mots clés : antigène T, aldéhydes dérivés du plasmalogène, marqueur du cancer colorectal.

Introduction

Colorectal carcinoma is the second most frequent cause of cancer mortality in men and women in industrialized countries (1, 2). Primary prevention (i.e., averting the development of the tumour by altering risk factors) is not yet feasible, since the etiology of the disease is not adequately understood. Therefore, there has recently been a great deal of interest in secondary preventive measures (i.e., detection at an asymptomatic, curable stage).

Recently, a promising screening test was proposed. It is based on the observation that most colorectal neoplasms express a disaccharide D-Galp(β1-3)-D-GalpNAcα1 (also called Thomsen–Friedenreich antigen or T-antigen) — bound as an O-glycoside to (-)-Ser or (-)-Thr (**I**; Scheme 1) — among the carbohydrate components of colonic mucin. This antigen is usually detected by applying fluorescently labeled peanut agglutinin (PNA) (3, 4) to histological specimens obtained from the tumour. Obviously, obtaining biopsy specimens from neoplasms inside the colon for screening purposes is not possible. Therefore, a technique (5) was proposed whereby this carbohydrate marker could be detected in colorectal mucous collected during digital rectal examination. The technique further assumes that the two galactose moieties in T-antigen are oxidizable by galactose oxidase to C-6 aldehydes in dialdehyde **II**. These two C-6 aldehydes, on subsequent reaction with Schiff reagent (6, 7), would yield an adduct detectable by its purple (magenta) colour (5, 8). Other galactose-containing oligosaccharides were subsequently added to T-antigen as carbohydrate markers of colorectal cancer (9). In addition to being simple and noninvasive, this technique has the advantage that it samples mucous from the whole colorectum because mucous from the total length of the colon flows towards the rectum. (5)

Because of the potential advantage of such a screening test, we initiated its clinical and laboratory evaluation in 1989. In 1991 we discovered unexpectedly that colorectal mucous from individuals with colorectal neoplasia developed a purple (magenta) colour after *direct* addition of Schiff reagent to the mucous specimens, without the treatment with galactose oxidase (10). The oxidation step was somewhat puzzling, since the galactose oxidase treatment could be shortened to 10 min (8) without any effect on the test results, although the oxidation of a terminal galactose to the C-6 aldehyde usually requires 15–30 min at 37°C, while nonterminal galactose units are much less efficient substrates (10). Seeking an explanation to why colorectal mucus from patients with colorectal cancer developed a magenta colour directly upon addition of Schiff reagent, we first found that the component(s) of the mucous responsible for the colour development (referred to as a marker in this article) were soluble in lipophilic solvents. This suggested that the marker could not be a carbohydrate, which should be hydrophilic. We also found that asialofetuin (a suitable model glycoprotein because it contains T-antigen) does not undergo a change in colour when reacted with Schiff reagent, whether treated with galactose oxidase or not.

Since the marker reacted with Schiff reagent *directly*, we speculated that such a marker could become the basis of a simpler and more economical screening test (11) than the test involving galactose oxidase. The elimination of the oxidation step would reduce the costs of chemicals, equipment,

and technician time. The first step toward this practical goal was to identify the chemical structure(s) of the marker(s). In this article we describe both the isolation and the identification of the chemical structure of the markers. Although the objective of this investigation has been the identification of the chemical structure of the markers, patient data gathered while collecting colorectal mucous in the process of the identification of the markers are presented (cf. Fig. 1 for examples). These data suggest that further epidemiologic investigations of the usefulness of the markers in a screening test for colorectal cancer are warranted.

Materials and methods

Materials and general procedures

Thin layer chromatography (TLC) was performed on silica gel 60 plates (thickness 0.25 mm) or preparative plates (thickness 1 mm). Analytical plates were visualized by spraying with 50% aq H_2SO_4 and heating to 200°C. Silica gel (200–400 mesh, Toronto Research Chemicals) was used for column chromatography. PE (brain extract) and PC (heart extract) plasmalogens were purchased from Doosan Serdary Research Laboratories (Toronto, Canada). Schiff reagent was prepared from *p*-rosaniline chloride (#1528, also basic fuchsin or magenta from Sigma Chemical Co.,

Fig. 1. Proportion of positives on five groups of subjects. Mucus examples were (1) from colectomy specimens from colorectal cancer patients obtained in several Toronto hospitals; (2) from individuals scheduled for colonoscopy at the Endoscopy suite, Wellesley Hospital, Toronto, subsequently diagnosed with cancer (mucus specimens were collected immediately before colonoscopy); (3) from individuals scheduled for colonoscopy at the Endoscopy suite, Wellesley Hospital, Toronto, subsequently diagnosed with large (larger than 1 cm in diameter) polyps (mucus specimens were collected immediately before colonoscopy); (4) from individuals scheduled for colonoscopy at the Endoscopy suite, Wellesley Hospital, Toronto, subsequently diagnosed with small (1 cm or smaller in diameter) polyps (mucus specimens were collected immediately before colonoscopy); (5) symptoms-free young adults (without any lavage performed before mucus collection). Note that colorectal cancer often, but not always, develops in polyps.

□ positives	95	23	24	43	4
St. Louis, Mo.) or from basic fuchsin (ICN, Aurora, Ohio). Asialofetuin (A1908 and A4781) and galactose oxidase were purchased from Sigma. HPLC was performed on a variety of silica gel columns (5 μm, e.g., Hypersil) using a Beckman System Gold with a Beckman UV 166P detector or a Varex Evaporative Light Scattering Detector IIA. ^{1}H NMR spectra were recorded at 500 MHz with a Varian Unity spectrometer in the NMR spectroscopy laboratory of the Molecular Medicine Research Centre, University of Toronto. Spectra were obtained in $CDCl_3$, mixtures of $CDCl_3$–CD_3OD containing a trace of TMS (δ = 0 ppm) as the internal standard, or D_2O and are reported using a δ (ppm) scale. Mass spectra were recorded with VG Analytical ZAB-SE, SCIEX API III, or Voyager-Elite MALDI (Perseptive Biosystems) mass spectrometers in the mass spectrometry laboratory, Molecular Medicine Research Centre, University of Toronto. *O*-(2,3,4,5,6-Pentafluorobenzyl)oximes of aldehydes were analyzed by GC–CI(–)-MS (reagent gas: ammonia) using a VG-Trio 2A quadrupole mass spectrometer interfaced to a Hewlett-Packard 5890 Series II gas chromatograph at the Hospital for Sick Children, Toronto. Visible spectra were recorded with a Beckman DU 600 or a Varian CARY 300 Bio UV–Vis spectrometer (in solution or on the plates in transmittance mode). Reflectance scans were executed directly on the plates with a Varian CARY 50 spectrometer with remote reflectance probe.

Isolation of markers from surgical (colectomy) specimens

Mucous collection

Mucous was obtained from colectomy specimens from surgeries performed in operating theatres of several hospitals in Toronto, Ont., Canada. The colectomy specimens were washed with water to remove blood and fecal matter 15–20 min after surgery. Mucous was collected by gently scraping the surface with a small spatula. The scraped mucous was placed into small plastic vials and frozen. One colectomy specimen typically yielded 0.5–1.0 g of mucous; some specimens, however, were much larger. To determine whether the collected mucous gave a colour reaction with Schiff reagent, the frozen vials were allowed to thaw at room temperature for 60 min, and a small amount of mucous on the tip of a spatula was smeared on the support and tested as described in the following section.

Separation of mucous components

Mucous collected as above was pooled (66 g) and lyophilized for 24 h to give a semi-solid residue (6.0 g). This residue was consecutively extracted with hexane, ethylacetate, chloroform–methanol (2:1), modified Folch extraction (12), and water; the final residue after extractions was a gel-like solid (colonic mucin). Ethylacetate extract gave a weak colour reaction with Schiff reagent, while the chloroform–methanol extract gave a very strong colour reaction with Schiff reagent. Both extracts giving colour with Schiff reagent (i.e., positive) were combined and subjected to chromatography on a column of silica gel using solvents of increasing polarity: hexane, ethylacetate, chloroform, chloroform–methanol (with increasing contents of methanol), and methanol. Chloroform–methanol (7:2.5) afforded positively reacting fractions, which were combined and evaporated to dryness to give an amorphous residue containing phospholipids (36.6 mg), which reacted strongly positive with Schiff reagent (using conditions described in the

preceding paragraphs). This fraction was repeatedly chromatographed on a series of silica gel columns using chloroform with a gradient of methanol to give two highly positively reacting fractions, PL-1 and PL-2, which were further analyzed by ^{1}H NMR spectroscopy.

Testing mucous obtained in digital rectal examination

Mucous collection

Mucous samples were collected from individual human subjects by a physician during routine digital rectal examination using a gloved finger lubricated with MUKO or a similar lubricant that would not react with the Schiff reagent under the testing conditions. Informed consent of the tested individuals was obtained as per the protocol approved by the Ethics Committee, University of Toronto. Mucous collected on the gloved finger was smeared onto a support (e.g., glass fibre (Whatman GF) or polyester (polymacron, Dupont, Wilmington, Del.) fabric), showing through an aperture of 1.0–1.3 cm in diameter and fastened between two glass plates (7.5 × 7.5 cm) or sealed between two plastic plates (of microscope slide size). The plates with smeared mucous samples were sent to a laboratory for processing. If processed at the place of collection, the work-up should have started no earlier than 90 min after depositing the sample to obtain sufficient specimen adherence to the fabric. The plates carrying specimens could be stored for short periods of time at room temperature (several days) or stored frozen for prolonged periods of time (several months).

Treatment of mucous specimens with Schiff reagent

Plates carrying mucous specimens were placed in the holder part of a Wheaton glass staining dish (capacity 10 plates), immersed in phosphate buffer (0.1 M, pH 7.0), and washed by gentle agitation for 10 min. The holder was then transferred into a dish containing distilled water and gently agitated for 3 min. The aqueous wash was repeated; any excess water was allowed to drip for 10–15 min to render the plates and the holder visibly dry. The holder was then immersed into a dish containing Schiff reagent for 2 min under gentle agitation followed by three washes with distilled water (3 min each). The plates were removed from the holder and air dried. The pink-red-magenta colour (positive reaction) appeared almost immediately in some cases (or within a few minutes (20–25 min at the most)) after removal from the Schiff reagent.

Preparation of suitable Schiff reagent

Many variations of the reagent are described (6). The Schiff reagent used in this study was prepared as follows: *p*-rosaniline (0.4 g; also basic fuchsin, magenta) was added to distilled water (220 mL) at approximately 95–97°C. The mixture was stirred well, brought to boil for 5 min, cooled to 50°C, and filtered through doubly folded paper filter. Aqueous HCl (1 N, 34 mL) was added to the filtrate with stirring and was allowed to cool to room temperature. Sodium bisulfite (2.34 g) was added and the solution was stirred well — the flask was sealed with parafilm — and stored in the dark at room temperature for 4 days. To the resulting straw-coloured solution was added charcoal (NORIT; 300 mg); the mixture was vigorously stirred for 1.5 min, and the charcoal

was removed by filtration. The resulting colourless solution was stored in a dark-glass bottle at 3–5°C.

Identification of compounds giving colour reaction with Schiff reagent

2,4-Dinitrophenylhydrazones of aldehydes from mucous

Mucous (4.27 g) obtained from a colectomy as described above and giving a colour reaction with Schiff reagent was spread with a spatula on five sheets (10 × 4 cm) of polyester fabric (polymacron) and allowed to dry for 1 h. The sheets were soaked in phosphate buffer (pH 7) for 20 min, then lifted from the buffer, washed with water until all the dark coloured material was removed and the sheets were slightly yellow, and air-dried. The sheets were then cut into smaller pieces (1 × 2 cm) and immersed into a solution of 2,4-dinitrophenylhydrazine hydrochloride (30 mL; prepared by dissolving 2,4-dinitrophenylhydrazine hydrochloride (0.25 g) in 6 N HCl (100 mL)) at room temperature for 30 min. The polyester cuttings were then removed from the reagent solution and washed with water until the eluant remained colourless; the deep-yellow 2,4-dinitrophenyl hydrazones were extracted from the cuttings by acetonitrile. Acetonitrile was removed on a rotary evaporator; ethylacetate (10 mL) was added and evaporated (to remove traces of water) to yield a dry yellow residue. The residue was dissolved in dry acetonitrile (1.5 mL) and applied on a silica gel 60 plate (20 × 20 cm; thickness 1 mm) in a single line; the plate was developed with a hexane – ethyl acetate solution (4:1). The yellow band at R_f 0.37 containing 2,4-dinitrophenylhydrazones was cut out and extracted with 10% MeOH in CH_2Cl_2; the solvents were evaporated to give a deeply yellow solid, which was subsequently analyzed by MS. Two major ions were [M+H]$^+$ (*m/z* = 421) and [M+H]$^+$ (*m/z* = 449). ^{1}H NMR (CDCl$_3$) confirmed the presence of 2,4-dinitrophenyl derivatives of long chain aldehydes: 0.88 (t, 3H, CH$_3$, *J* = 6.84 and 7.08 Hz), 1.25–1.42 (m, CH$_2$), 6.96 (t, CH=N), 7.53 (t, CH=N), 7.93 (d, H-6 (arom), *J* = 9.52 Hz), 7.96 (d, H-6 (arom), *J* = 9.52 Hz), 8.29 (dd, H-5 (arom), *J* = 3.18 and 9.76 Hz), 8.33 (dd, H-5 (arom), *J* = 3.17 and 9.52 Hz), 9.12 (d, H-3 (arom), *J* = 2.45 Hz), 9.14 (d, H-3 (arom), *J* = 2.45 Hz), 11.00 (s, NH), 11.18 (s, NH).

Two controls were applied: (1) the above procedure up to the chromatography was repeated with blank polyester sheets (no mucous deposited) — no reaction with 2,4-dinitrophenylhydrazine was detectable; and (2) the above procedure was repeated using mucus from colectomies that did not give a colour reaction with Schiff reagent — no reaction with 2,4-dinitrophenylhydrazine was detectable.

2,4-Dinitrophenylhydrazone of palmitic aldehyde from a plasmalogen

A mixture of PE plasmalogen (from brain extract; 10 mg in 2 mL CHCl$_3$), a solution of 2,4-dinitrophenylhydrazine hydrochloride (25 mL, prepared as above), and isooctane (20 mL) was stirred for 1 h at room temperature. The aqueous phase was separated and washed with isooctane; organic phases were combined and evaporated to dryness. The yellow residue was dissolved in dry acetonitrile (0.4 mL) and applied on a silica gel 60 plate (20 × 20 cm; thickness 0.2 mm) in a single line, and the plate was developed with

hexane – ethyl acetate (4:1). The yellow band containing 2,4-dinitrophenylhydrazone was cut out and extracted with 10% MeOH in CH_2Cl_2. Solvents were removed from the extract by evaporation to give a yellow amorphous solid, which was examined by MS. The major ion was $[M+H]^+$ (m/z = 421). ^{1}H NMR ($CDCl_3$; major isomer is E (*syn*); minor isomer is Z (*anti*)): 0.88 (t, 3H, CH_3, J = 6.84 and 7.08 Hz), 1.25–1.42 (m, 24H, CH_2), 1.61 (q, 2H, CH_2 β to CH, J = 7.33 Hz and J = 14.65 Hz, E isomer), 1.67 (q, 2H, CH_2 β to CH, J = 7.06 Hz and J = 15.38 Hz, Z isomer), 2.38 (ddd, 2H, CH_2 α to CH, J = 5.44, 7.33, and 12.94 Hz, Z isomer), 2.43 (ddd, 2H, CH_2 α to CH, J = 5.70, 7.57 Hz and J = 12.94 Hz, E isomer), 6.96 (t, 1H, CH=N, J = 5.37 and 5.62 Hz, Z isomer), 7.53 (t, 1H, CH=N, J = 5.37 and 5.13 Hz, E isomer), 7.93 (d, 1H, H-6 (arom), J = 9.52 Hz, E isomer), 7.96 (d, 1H, H-6 (arom), J = 9.52 Hz, Z isomer), 8.29 (dd, 1H, H-5 (arom), J = 3.18 and 9.76 Hz, E isomer), 8.33 (dd, 1H, H-5 (arom), J = 3.17 and 9.52 Hz, Z isomer), 9.12 (d, 1H, H-3 (arom), J = 2.45 Hz, E isomer), 9.14 (d, 1H, H-3 (arom), J = 2.46 Hz, Z isomer), 11.00 (s, 1H, NH, E isomer), 11.18 (s, 1H, NH, Z isomer).

Preparation of palmitic aldehyde (13)

A solution of diisobutylaluminum hydride (DIBAL-H) in toluene (1 M, 2.95 mL, 2 eq) was added dropwise over 5 min to a solution of methyl palmitate (0.4 g, 1.48 eq) in dry toluene (10 mL) cooled to –70°C. The reaction mixture was stirred for an additional 15 min, and excess reagent was decomposed by 2 N HCl (10 mL); the mixture was allowed to warm up to 0°C, and the aqueous layer was separated and extracted with ethyl acetate (2 × 10 mL). The combined organic extracts were washed with water (3 × 5 mL), dried over Na_2SO_4, and evaporated to dryness to give an amorphous solid containing both the aldehyde (60%) and starting ester (40%). ^{1}H NMR ($CDCl_3$) (aldehyde): 9.77 (d, $J_{1,2}$ = 1.95 Hz, CH_2CH=O), 2.42 (m, $J_{1,2}$ = 1.95 Hz, CH_2CH=O); (unreacted ester): 3.7 (s, CH_3OC[=O]-).

Preparation of 2,4-dinitrophenylhydrazone of palmitic aldehyde

The crude aldehyde (50 mg) dissolved in isooctane (25 mL) and a solution of 2,4-dinitrophenylhydrazine hydrochloride (25 mL, prepared as above) was stirred at room temperature for 1 h. After work-up (analogous to the work-up described for 2,4-dinitrophenylhydrazones of aldehydes from plasmalogens) and ensuing chromatography, a yellow amorphous solid was obtained. MS: $[M+H]^+$ m/z = 421. The chemical shifts in the ^{1}H NMR spectrum were identical with the shifts in the ^{1}H NMR spectrum of 2,4-dinitrophenyl hydrazone of stearic aldehyde (cf. below).

Preparation of stearic aldehyde

A 1 M solution of diisobutylaluminum hydride (DIBAL-H) in toluene (2.95 mL, 2 eq) was added dropwise over 5 min to a solution of methyl stearate (0.44 g, 1.48 eq) in dry toluene (10 mL) cooled to –70°C. The reaction mixture was stirred for an additional 15 min, and excess reagent was decomposed by 2 N HCl (10 mL); the mixture was allowed to warm up to 0°C, and the aqueous layer was separated and extracted with ethyl acetate (2 × 10 mL). The combined organic extracts were washed with water (3 × 5 mL), dried

over Na_2SO_4, and evaporated to dryness to give an amorphous solid containing both the aldehyde (30%) and starting ester (70%). ^{1}H NMR ($CDCl_3$) (aldehyde): 9.77 (d, $J_{1,2}$ = 1.95 Hz, CH_2CH=O); 2.42 (m, $J_{1,2}$ = 1.95 Hz, CH_2CH=O); (unreacted ester): 3.7 (s, CH_3OC[=O]-).

Preparation of 2,4-dinitrophenylhydrazone of stearic aldehyde

A solution of the crude aldehyde (50 mg) in CH_2Cl_2 (4 mL) with added solution of 2,4-dinitrophenylhydrazine hydrochloride (26 mL, prepared as above) was stirred at room temperature overnight. After work-up (analogous to the work-up described for 2,4-dinitrophenylhydrazone of palmitic aldehyde) and following thin layer chromatography on silica gel, a yellow amorphous solid was obtained. MS: 449 ($[M+H]^+$). ^{1}H NMR ($CDCl_3$, major isomer: E, minor isomer: Z): 0.88 (t, 3H, CH_3, J = 6.84 and 7.08 Hz), 1.25–1.43 (m, 28H, CH_2), 1.61 (q, 2H, CH_2 β to CH, J = 7.31 Hz and J = 14.89 Hz, E isomer), 1.67 (q, 2H, CH_2 β to CH, J = 7.08 Hz and J = 15.65 Hz, Z isomer), 2.38 (ddd, 2H, CH_2 α to CH, J = 5.44, 7.33, and 12.94 Hz, Z-isomer), 2.43 (ddd, 2H, CH_2 α to CH, J = 5.68, 7.57 Hz and J = 12.94 Hz, E isomer), 6.96 (t, 1H, CH=N, J = 5.38 and 5.37 Hz, Z isomer), 7.53 (t, 1H, CH=N, J = 5.61 and 5.13 Hz, E isomer), 7.93 (d, 1H, H-6 (arom), J = 9.52 Hz, E isomer), 7.96 (d, 1H, H-6 (arom), J = 9.52 Hz, Z isomer), 8.29 (dd, 1H, H-5 (arom), J = 3.17 and 9.52 Hz, E isomer), 8.33 (dd, 1H, H-5 (arom), J = 3.17 and 9.52 Hz, Z isomer), 9.12 (d, 1H, H-3 (arom), J = 2.44 Hz, E isomer), 9.14 (d, 1H, H-3 (arom), J = 2.45 Hz, Z isomer), 11.00 (s, 1H, NH, E isomer), 11.18 (s, 1H, NH, Z isomer).

O-(2,3,4,5,6-Pentafluorobenzyl) oximes of aldehydes (14)

The above compounds were prepared from *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine (250 μL of a 0.05 M solution in sodium acetate buffer, pH 5), added, in separate experiments, to the phospholipid mixtures PL-1 and PL-2 (cf. section "Separation of mucous components") as well as to authentic specimens of palmitic and stearic aldehydes (1 mg in 100 μL of water), vortexed for 1 min, and allowed to react for 30 min. Then 1 N HCl (10 μL) was added, and the reaction mixture was extracted three times with hexane (1 mL). The combined hexane extracts were dried over sodium sulfate and evaporated to dryness under a stream of nitrogen; the residue was redissolved in hexane (50 μL). This solution (1 μL injections) was used for GLC–MS identification of the aldehydes. Negative ion CI-MS (reagent gas: ammonia) was executed on a quadrupole mass spectrometer VG-Trio 2A interfaced with a Hewlett-Packard 6890 Series II GC using a DB-5 capillary column (length: 30 m, diameter: 0.25 μm), employing helium as the carrier gas at a flow rate of 1 mL min^{-1}, and with the temperature increasing from 60 to 310°C while maintaining the injection port temperature at 250°C (15).

Results

Aldehyde identification

Analytical chemists have been using Schiff reagent for decades to demonstrate that the aldehydic group is present in the examined samples. However, although the reagent is

very sensitive, it is extremely difficult to isolate the products of its reaction with aldehydes (6, 7). 2,4-Dinitrophenylhydrazine in a strongly acid solution, on the other hand, produces chemically stable 2,4-dinitrophenylhydrazones, which can be isolated and purified; often they can be obtained in a crystalline form. Employing modern spectroscopic methods, the chemical structure of such pure compounds can be determined with relative ease. As no aldehydic hydrogen H-C=O could be identified in the NMR spectra of the extracts from which 2,4-dinitrophenylhydrazones were prepared, the aldehydes had to be released from precursors during the treatment with Schiff reagent. Since both Schiff reagent and 2,4-dinitrophenylhydrazine operate in strongly acidic environments, it is reasonable to presume that the acidity of the reagents allowed for the release of the aldehydes from their precursors. Therefore, 2,4-dinitrophenylhydrazones (2,4-DNPH) are valuable derivatives for the identification of the structure of markers. Indeed, palmitic and stearic aldehydes were identified via their 2,4-dinitrophenylhydrazones as the aldehydes originating in colorectal mucous from cancer patients by the combination of MS and ^{1}H NMR spectroscopy. First, strong molecular ions were found in FAB-MS, which corresponded to the 2,4-dinitrophenylhydrazones of palmitic ([M+H]$^+$: m/z = 421) and stearic ([M+H]$^+$: m/z = 449) aldehydes. This finding was confirmed by ^{1}H NMR spectroscopy, by comparison of the NMR spectra of the 2,4-DNPH of aldehydes obtained from mucous fractions with synthetic authentic specimens, and by a further comparison with the previously published ^{1}H NMR data. As expected, two geometric isomers were present in all specimens of 2,4-DNPH of aldehydes and assigned as described in reference 16. The ^{1}H NMR chemical shifts of the 2,4-dinitrophenylhydrazones of palmitic and stearic aldehydes were found to be practically identical. These results indicated that the above aldehydes are the markers detected by Schiff reagent in colorectal mucous. The next question to be answered was: From what precursors were the aldehydes released?

During the chromatography of colorectal mucous, we observed that the fractions containing phospholipids produced the strongest colour with Schiff reagent. Since the only phospholipids that could release the long chain aliphatic aldehydes by treatment with acids are the plasmalogens, we therefore attempted to detect plasmalogens in the phospholipid fraction. To purify the plasmalogens, the phospholipid fraction was further rechromatographed on silica gel columns. Two well-separated groups of phospholipids (PL-1 and PL-2) were obtained. The first group contained ethanolamine and the other contained choline classes of phospholipids; both groups gave strong colouration on treatment with Schiff reagent. As these groups could not be further fractionated, we employed ^{1}H NMR spectroscopy to confirm the presence of the plasmalogens in these fractions (and consequently, to confirm the hypothesis that the aldehydes were released from the plasmalogens).

Plasmalogen identification

^{1}H NMR analysis (17) showed that both fractions were phospholipids with long fatty chain acids (*sn*-glycero-3-phosphoryl derivatives) based on ^{1}H resonances characteristic for glycerol and CH$_2$-groups of polar head groups and for

aliphatic chains of fatty acid ester groups. The less polar fraction consisted of a mixture of phospholipids containing ethanolamine (PL-1), while the more polar fraction contained a mixture of phospholipids with choline (PL-2); neither of the two fractions was further separable by chromatography on silica gel. In the fraction PL-1, hydroxyls in the 2-position and partially in the 1-position of *sn*-glycerol were esterified with fatty acids. The ethanolamine (-OCH$_2$CH$_2$NH$_2$) moiety was identified by ^{1}H resonances at δ = 3.13 ppm (triplet) and at δ = 4.03 ppm (overlapping with H-3 of *sn*-glycerol). The presence of a signal of an α,β-unsaturated ether was confirmed through a doublet ($J_{1,2}$ = 6.1 Hz) at δ = 5.90 ppm, which was assigned to the vinylic proton O-CH=CH-. This proton was further coupled to a quartet at δ = 4.38 ppm and a multiplet at δ = 2.02 ppm in a COSY spectrum confirming the presence of the O-CH=CH-CH$_2$ moiety in the molecule. Other allylic CH$_2$ groups giving rise to signals at δ = 2.82–2.88 ppm were probably present in the olefinic chains of aliphatic acids. Two ^{1}H multiplets assigned to H-2 of the glycerol moiety centered at δ = 5.18 ppm and δ = 5.25 ppm suggested that this fraction contained two derivatives of ethanolamine-containing phospholipids. The integrations of the vinylic signal and the H-2 glycerol signal at δ = 5.18 ppm were of the same intensity (1:1). The estimate of the ratio (7:3) between the 1-alk-1′-enyl-2-acyl-*sn*-glycerophospholipids (= plasmalogens) and 1,2-diacyl-*sn*-glycerophospholipids was made on the basis of a comparison of the integration of signals for CH-2 of the glycerol moiety (cf. above).

In the more polar fraction PL-2, OH-2 and, partially, OH-1 in *sn*-glycerol were again esterified with fatty acids. The signals at δ = 3.24 ppm and δ = 3.40 ppm were identified as belonging to two different phospholipids containing a choline moiety (CH$_2$CH$_2$-N(CH$_3$)$_3$). As in the PL-1 fraction, this fraction contained an α,β-unsaturated ether, which was confirmed through a doublet at δ = 5.90 ppm assigned to the vinylic proton O-CH=CH-. Two proton multiplets, centered at δ = 5.16 ppm and δ = 5.25 ppm and assigned to H-2 of the glycerol moiety, suggested that this fraction contained two derivatives of choline-containing phospholipids. The integration of the vinylic signal and the H-2 *sn*-glycerol signal at δ = 5.16 were again of the same intensity (1:1). The ratio between the 1-alk-1′-enyl-2-acyl-*sn*-glycerophospholipids (= plasmalogens) and 1,2-diacyl-*sn*-glycerophospholipids in PL-2 was estimated to be 4:1 by comparison of the integration of signals for CH-2 of the glycerol moiety (cf. above).

Stereochemistry of the glycerol moiety was not determined, although it was assumed that it does not differ from stereochemistry commonly found in natural phospholipids based on comparisons of the ^{1}H NMR spectra. Similarly, the geometry of the vinylic ether double bond in plasmalogens isolated from the colorectal mucus of cancer patients and plasmalogens from other natural sources was found to be identical (based on the identity of the coupling constant of the vinylic signal for ^{1}H at δ = 5.90 ppm).

The aldehydes released by hydrolysis of PL-1 and PL-2 were identified as stearaldehyde and palmitaldehyde by comparison with authentic specimens of O-(2,3,4,5,6-pentafluoro)benzyl oximes of the aldehydes using MS combined with GLC. These derivatives exhibited positive ions at m/z

435 ([M – H]), 415 ([M – 20]), and 350 ([M – 50]) — with [M – 20] predominating owing to the loss of HF (palmit-aldehyde) — and at m/z 463 ([M – H]), 443 ([M – 20]), and 413 ([M – 50]), again with [M – 20] predominating, for stearaldehyde.

Structure of the marker

Thus, we have identified the markers as a mixture of long chain aliphatic aldehydes released from plasmalogens, predominantly palmitic (**III**) and stearic (**IV**) aldehydes (cf. Scheme 1). Plasmalogens are phospholipids of both the ethanolamine **V** and the choline **VI** types (cf. Scheme 1) in which the aldehydes are cryptic in the form of unsaturated ethers (18). A minor contribution from other aldehydes cannot be excluded; similarly, acetal phospholipids in which the aldehydes are bound as acetals to the C1–C2 of glycerol may be minor precursors. Because of the acid lability of unsaturated ether bonds, the aldehydes are released from plasmalogens under very mild acid conditions (19); therefore, it is not surprising that the aldehydes are released upon exposure to the strongly acidic Schiff reagent. The free aldehydes, on reaction with the *leuko* (colorless) form of the dye in Schiff reagent, provide shades of magenta colour considered characteristic of aldehydes (7, 8).

The lack of colour of the Schiff reagent depends critically on the presence, in sufficient concentration, of SO_2 and HCl in the reagent. Should this concentration decrease, the Schiff reagent may be partially restored to the original red colour of *p*-rosaniline. Therefore, depending on the aldehyde concentration, the shade of colour on the solid support may be observed as a mixture of red (20) and magenta (purple). The adduct of *p*-rosaniline–aldehyde (resulting from the reaction of an aldehyde with Schiff reagent) has a typical absorption >560 nm; therefore, the presence of such an absorption band in a reflectance spectrum should resolve the occasional colour identification problems (21). Schiff reagent further resorts to the original colour of *p*-rosaniline on treatment with an excess of basic substances, for instance, basic amino acids such as lysine, histidine, and arginine; nucleosides such as cytidine; or simple bases such as sodium carbonate. Thorough washing with water and a buffer solution ensures that all such result-altering components of mucous are removed from the specimens before treatment with the Schiff reagent.

Potential of the detection of marker aldehydes in a screening test for colorectal cancer

In the course of the marker identification studies it was necessary to use mucous from individuals whose disease status was known (usually determined by colonoscopy). It was also necessary to determine whether the treatment of the collected mucous with Schiff reagent resulted in colour formation (positive reaction). Therefore, rectal mucous was obtained from patients with colorectal cancer, from patients with various other pathological findings, and from individuals who had no complaints and thus were presumed to be disease free. It was also necessary to establish suitable conditions (as described in the Material and methods section) of the treatment of specimens, such as length of time for the reaction with the Schiff reagent, washings with buffers and water, different supports on which the treatment was performed, and the choice of a variant of Schiff reagent. Through these investigations we could confirm that nearly all mucus specimens from patients with colorectal cancer were positive. For instance, the aldehydes were detected in close to 94% of the mucus samples removed from colectomy specimens obtained in several Toronto hospitals from 101 patients diagnosed with colorectal cancer by colonoscopy (cf. Fig. 1). In rectal mucous specimens collected from colorectal cancer patients attending the Endoscopy suite of the Wellesley Hospital (after the lavage of the colon but before the colonoscopy) and in the rectal mucous of patients with polyps a high proportion of positive results was obtained (cf. Fig. 1). Similar results were obtained with mucous from patients before the lavage (data not shown). In symptom-free individuals (47 students of medicine, ages 20–29), the aldehydes were not detectable in mucus from 43 individuals. Mucous specimens were treated with Schiff reagent as described in the Materials and methods section.

Discussion

A number of clinical (8) and population studies on the mucous test employing the sequence galactose oxidase – Schiff reagent have shown (22) that the test has the potential (23) to become an alternative to the fecal occult blood test (FOBT) (24) as an efficaceous, simple, and economical screening tool for colorectal cancer (25). Some of the shortcomings of the galactose oxidase – Schiff reagent test appear to be due to the targeting of the incorrect carbohydrate marker, one which required repeated, extensive washings and treatments with enzymes (galactose oxidase and catalase), leading to the loss of the marker from test plates. Our finding — that the marker of the mucous test for colorectal cancer screening is of a lipid rather than of a carbohydrate character (including the disaccharide T-antigen) — makes it possible to correlate more accurately the presence of the marker with the disease and to develop a more reliable screening test for the disease. Significantly increased quantities of the plasmalogens in neoplasms of the large bowel (26, 27) and some other tissues (28, 29) were independently found by ^{31}P NMR spectroscopy. Since the amounts of both the ethanolamine and choline families of plasmalogens in neoplastic tissues appear to be significantly increased compared with disease-free tissues, it appears likely that it is a biochemical pathway leading to the unsaturated ether formation that has a connection with the neoplastic transformation.

Plasmalogens are a class of ubiquitous membrane phospholipids. Although the highest levels are normally found in tissues such as brain and heart, small concentrations have been reported in most other normal tissues, and small increases in plasmalogen levels in cancer cells have been previously observed (30, 31). Increased concentrations in the colon were ascribed to a combination of an increased level of the synthetic enzyme CTP – phosphocholine cytidyltransferase and a decreased concentration of hydrolytic enzymes, phospholipases C and D (32). However, biosynthesis of the "aldehydic moiety" of plasmalogens is varied (33, 34).

Presently, a connection between colorectal cancer and plasmalogens can only be hypothesized. For instance, plasmalogens, because of their effect on membrane fluidity, may

facilitate the cellular uptake of carcinogenic substances (35), e.g., of dietary (36) or microbial origin (37, 38). It is of interest to note that the majority of strict anaerobes contain detectable plasmalogens, while aerobic and facultative anaerobic bacteria lack plasmalogens (39). However, plasmalogen-like fecal mutagens (fecapentaenes, produced in the human colon by several anaerobes) seem to play no role in the etiology of human colon cancer (19).

An aldehyde-based test for colorectal cancer screening would be expected to have an advantage over fecal occult blood test (FOBT) and colonoscopy (for screening purposes only!). It could, potentially, uncover earlier stages of the neoplastic progression than both FOBT and colonoscopy because the latter two techniques target more developed cancer. Therefore, *the aldehyde test could detect cases not sufficiently developed to be detected by colonoscopy*. For instance, we have found several patients with strongly positive aldehyde mucus tests who were given a clean bill of health by colonoscopy (therefore they were rated as "false" positives). The same patients returned to the clinic within no later than 1–2 years with frank cancer. Given the lengthy progression of colon carcinogenesis, it is not unlikely that these individuals already harbored the disease at the time of the first aldehyde test. Since it is believed that the progression from early neoplastic changes to frank cancer may span decades (40), an earlier detection of the disease may lead to the realization of the hope that drugs could control and perhaps reverse the disease progression. Early results with non-steroid antiinflammatory drugs (e.g., aspirin) (41), inhibitors of cyclooxygenase-2 (COX-2) (42), and identification of molecular targets of these drugs (43) suggest that such hopes are not unrealistic. Equally encouraging is the prospect that the early neoplastic changes could be reverted, for example, through dietary or other lifestyle measures.

In summary, we believe that the identification of aldehydes from plasmalogens — rather than galactose-containing oligosaccharides — as the substances in colonic mucous that seem to correlate with colorectal cancer and that react with Schiff reagent, will make it possible to design meaningful epidemiologic studies that will confirm whether the aldehydes are indeed markers of colorectal cancer suitable for population screening.

A new phenolic metabolite, involutone, isolated from the mushroom *Paxillus involutus*

Róza Antkowiak, Wieslaw Z. Antkowiak, Izabela Banczyk, Lucyna Mikolajczyk

Abstract: A new optically active metabolite, involutone, was found in methanol, ethanol, or *n*-butanol extracts of freshly collected *Paxillus involutus*. The structure of this compound was proved to be 5-(3,4-dihydroxyphenyl)-2-(4-hydroxyphenyl)-2-hydroxy-4-cyclopenten-1,3-dione on the basis of the spectral and chemical properties of involutone and its tetraacetyl derivative. In addition, a number of compounds of known structures such as linoleic and crotonic acids, mannitol, ergosterol, involutin, as well as methyl, ethyl, or *n*-butyl-β-D-glucopyranosides, and methyl, ethyl, or *n*-butyl linoleates, depending in both cases on the alcohol used in the extraction, were also isolated in a pure state from the mushroom.

Key words: Paxillus involutus, Brown Roll-rim, metabolite isolation, structure study, quaternary hydroxycyclopenta-nedione, NMR of mushroom pigments, glucosides and linoleates, enzymic glucosylation and esterification.

Résumé : L'extraction de *Paxillus involutus* par du méthanol, de l'éthanol ou du butanol a permis d'isoler un nouveau métabolite optiquement actif, l'involutone. Sur la base des propriétés spectrales et chimiques de l'involutone et de son dérivé tétraacétylé, on a déterminé sa structure, la 5-(3,4-dihydroxyphényl)-2-(4-hydroxyphényl)-2-hydroxycyclopent-4-ène-1,3-dione. De plus, les extractions du champignon ont permis d'isolé à l'état pur un certain nombre de composés de structures connues, dont les acides linoléique et crotonique, du mannitol, de l'ergostérol, de l'involutine ainsi que des β-D-glucopyranosides de méthyle, d'éthyle ou de butyle et des linoléates de méthyle, éthyle ou butyle suivant, dans chaque cas, la nature de l'alcool utilisé pour les extractions.

Mots clés : Paxillus involutus, chanterelle brune, isolement d'un métabolite, étude de structure, hydroxycyclopentane-dione quaternaire, RMN des pigments, glucosides et linoléates du champignon, glucosylation et estérification enzyma-tique.

[Traduit par la Rédaction]

Introduction

The usefulness of *Paxillus involutus* (Brown Roll-rim) as an edible mushroom has been a matter of controversy for a long time, which is evident both in the literature and especially when comparing the opinions of amateur mushroom gatherers with those of most research reports, and the problem was the subject of a few review articles (1, 2). The hemolytic symptoms caused by *P. involutus* consumption, which are most often reported as being very serious, were found in the cases of both laboratory animals (3–5) and of human beings (6–11), yet the chemical compound responsible for the mortal toxicity is still unknown.

Research on the chemical composition of the mushroom carried out at the end of the 1960s and in the early 1970s of the previous century showed, mainly on the basis of paper chromatography, electrophoresis and TLC pattern, the presence of such metabolites as fatty acids, carbohydrates, and nitrogen-containing compounds (including traces of muscarine and β-acetylcholine) known from their occurrence in other fungi species (12, 13). In another laboratory, involutin, an unknown pigment at that time, was isolated and its structure determined on the grounds of spectral data and chemical properties (14, 15). In subsequent years, the supposed presence in *P. involutus* of two additional compounds, chamonixin (16) and anhydroinvolutin (17), both with closely related structures to involutin, was suggested. More recently, studies on the absolute configuration of involutin and chamonixin were reported (18). Additionally, the content and metabolism of polyamines occurring in *P. involutus* has been of interest in recent years (19).

Results and discussion

Research carried out recently in our laboratory confirmed the occurrence of involutin[2] in *P. involutus*. Moreover, for

Scheme 1. The structural relationship between involutin and involutone.

Involutin   Involutone
the first time ever, we have isolated from this mushroom several metabolites in an homogeneous form, namely D-mannitol, crotonic acid, (–)-ergosterol, and β-methyl, -ethyl, or -n-butyl-D-glucopyranosides,[3] depending on the alcohol (MeOH, EtOH, or n-BuOH) used for the extraction at room temperature. Additionally, the presence in the mushroom of some fatty acids with linoleic acid as the main component was proved, but most of the acid was isolated in the form of methyl, ethyl, or n-butyl linoleate, depending on the alcohol (MeOH, EtOH, or n-BuOH) used for the extraction, respectively; according to GC–MS, the presence of a small amount of palmitic acid and oleic acid was also identified.

The formation of both glucosides and linoleate esters from the original metabolites[4] suggests enzymatically catalyzed reactions and, consequently, the presence of the suitable, active enzymes (glucosidase or glucosyltransferase and lipase, respectively) as the constituents of *P. involutus*.

A number of mushrooms are able to produce metabolites as a response to a mechanical injury of the fruit bodies, but, as a rule, this involves an enzymatically induced oxidation process (20). The syntheses of glycosides and fatty acid esters can also be catalyzed by enzymes of fungal origin but mostly derived from lower fungi (21–23).

The ability of *P. involutus* to produce some artefacts in the isolation procedure and, thereby, changing its original chemical composition (especially if transglucosylation and (or) transesterification takes place), could be responsible for the hitherto difficulties in finding the right metabolite which causes the toxic properties of the mushroom.

Additionally to the compounds of known structure, we found and isolated with a high degree of purity an optically active metabolite of an unknown structure, which melted at 181 to 182°C and showed a specific rotation ($[\alpha]_D$ +96.3°), and was yellow or, when hydrated, orange in colour. The molecular formula of this metabolite was determined to be $C_{17}H_{12}O_6$ on the basis of HR-MS. The trivial name involutone was given to that compound, refering both to the mushroom species as well as to the elemental compositions only differing from that of involutin by two hydrogens (Scheme 1).

In spite of the small difference in elemental composition, the structural analysis showed that the new compound is not

the product of a simple oxidation of the secondary alcohol (involutin) to a corresponding ketone (didehydroinvolutin). Such a transformation would leave the asymmetric benzylic carbon, to which one hydrogen is attached, as the only chiral center. According to the literature data (14, 15, 24), the NMR absorption of a benzylic proton of similar systems was recorded as being somewhere in the range of 3.98–4.32 ppm. In the case of involutone, the absence of an absorption in that region eliminated such a chiral center in the molecule.

Other spectroscopic data recorded for involutone showed the absence of protons attached to sp^3 hybridized carbons (^{1}H NMR, Distortionless enhancement by polarization transfer (DEPT) and the presence in the molecule of two substituted benzene rings, 4-hydroxyphenyl and 3,4-dihydroxyphenyl (the aromatic ring protons gave the AA′XX′ and AMX systems, respectively, in the range 7.59–6.79 ppm). The region of aromatic carbons (158–115 ppm) contained, apart from the 10 signals originating from the 12 carbons composing the two benzene rings, two additional peaks of vinyl carbons. One of these carbon atoms, absorbing at 139.57 ppm (C-4), is bonded to a proton of chemical shift 7.51 ppm (Heteronuclear correlation spectroscopy (HETCOR) experiment), while the other one (C-5) of the vinyl system gave a resonance absorption, together with the signals of the carbon atoms of the sp^2 hybridization bearing the OH groups, in the range of 158.19–145.78 ppm.

The presence of the three phenolic groups and one additional hydroxyl in the molecule was demonstrated by a broad and intense IR absorption with the maximum at 3350 cm^{-1}, and the strong band at 1250 cm^{-1}. Especially important in this respect was, however, the ^{1}H NMR spectrum run in DMSO-d_6 solution, which consisted of three signals of phenolic OH in the region 9.4–10.0 ppm and of one singlet at 6.60 ppm of the fourth hydroxyl proton separated from those of aromatic OH by about 3 ppm. Further evidence, which confirmed the presence of four hydroxyl groups in the molecule, followed from the observations that four protons are easily exchangeable for deuterium (^{1}H NMR) and that the metabolite can be easily transformed into its tetraacetyl derivative.

Besides the carbons of the aromatic rings and the vinyl system, the molecule of involutone contains three additional

---

[3] In the cases of ethyl and n-butyl β-glucosides, the chemical shifts of the diastereotopic protons of the aglycone methylene group attached to the anomeric carbon through oxygen differ by 0.33 ppm (J_{gem} = 9.6 Hz), due to the long range influence of the D-glucose molecule's chirality.

[4] The transformations proceeded in a corresponding alcohol, being diluted with a great deal of water occurring naturally in the mushroom.

carbons, from which two (absorbing at 202.86 and 200.63 ppm) are components of the two carbonyl groups, giving both a weak and a strong absorption at 1740 and 1692 cm^{-1} for C=O and C=C-C=O, respectively. The nonaromatic structural elements, together with the final remaining carbon, which shows a weak resonance signal at 78.30 ppm, compose a cyclopentenedione skeleton, to which the two substituted phenyl rings and a hydroxyl group are attached. This, consequently, gave a system in which the only sp^3 hybridized carbon constitutes a chiral center, binding either both the differently substituted phenyl rings (while the nonphenolic hydroxyl is involved in an enol system) or one of the phenolic rings and the OH group. This problem was solved by an examination of the intramolecular proton interactions through the space and the heteronuclear long-range connectivity through bonds.

First, to avoid autooxidation when treated with acetic anhydride in the presence of pyridine, involutone was transformed quantitatively into a tetraacetyl derivative, the chromatography of which gave bright yellow crystals of mp 68–70°C and $[\alpha]_D$ +44.2°.

A routine analysis of the ^{1}H and ^{13}C NMR spectra of the obtained product[5] showed, as in the case of nonacetylated involutone, the presence in the molecule of tri- (1, 3, 4) and di- (1, 4) substituted phenyl rings, a vinyl system, as well as two keto carbonyls and, additionally, four acetoxy groups.

On the basis of the HMQC and HMBC experiments carried out for the CD$_3$CN solutions of the tetraacetyl involutone, the assignments of all carbons in the molecule were possible. The presence of a five-membered ring was proved by the observed correlation of the vinyl hydrogen H-4, that absorbed at 7.70 ppm then and at 7.51 ppm before acetylation, with the two carbonyl carbons (C-3 and C-1) absorbing at 197.36 and 196.03 ppm, respectively. The differentiation of these carbonyl carbons was based on the different intensities of the cross-peaks from H-4 to C-1 and from H-4 to C-3, the smaller for the former being coupled through three bonds in comparison with the latter, which was more intense because of the coupling through two bonds only. An additional correlation of proton H-4 was found with both the vinyl carbons C-4 (141.12 ppm) and C-5 (153.55 ppm) by HETCOR and HMBC, respectively, and with the sp^3 hybridized carbon (C-2) absorbing at 81.70 ppm.

Apart from the two signals of the ketone function carbons, the ^{13}C NMR spectrum showed the presence of four ester carbonyl carbons. The protons of one of the four acetoxy groups (2.18 ppm) were found to be correlated ($^4J_{C-H}$) with C-2 (81.70 ppm) being the only sp^3 hybridized element of the five-membered ring. The remaining three (169.90, 169.03, and 168.80 ppm) were recognized as the elements of acetoxy substituents attached to phenyl rings on the basis of their carbonyl carbons' coupling with the suitable aromatic ring protons[6] through four bonds, which gave cross-peaks (of weak intensities, but easily recognizable) in the HMBC

spectrum. Already knowing the chemical shifts of aromatic ring protons at that time, we were able to find the position of attachment to the phenyl ring of each of the acetoxy groups. The two-proton signal of H-3″ and H-5″ (7.16 ppm) gave a correlation point with carbonyl carbon absorption at 169.90 ppm, showing on a coupling through C-4″, to which that acetoxy group has to be bound. Similarly, the coupling of H-2′ (7.92 ppm) with the carbonyl carbon giving a signal at 169.03 ppm made it possible to locate the acetoxy group at C-3′, while the correlation of the chemical shift of H-5′ (7.40 ppm) with that at 168.80 ppm showed the position C-4′ as the attachment point for the acetoxy group responsible for that absorption. The assignment of the chemical shift of 146.16 ppm to C-4′ was proved by its correlation with both H-2′ (7.92 ppm) and H-6′ (7.95 ppm) of the trisubstituted phenyl ring, while of the value 152.55 ppm to C-4″, due to its correlation ($^3J_{CH}$) with H-2″ and H-6″ (7.46 ppm). The assignment of the third aromatic ring carbon bearing the acetoxy group resulted from the coupling of H-2′ (7.92 ppm) and H-5′ (7.40 ppm) with C-3′ absorbing at 143.50 ppm through two and three bonds, respectively.

The assignment of the chemical shifts 127.72 and 129.91 ppm to the aromatic ring carbons C-1′ and C-1″, respectively, was based on the observation that the 127.72 ppm value is correlated with the chemical shift of H-5′ and H-4 ($^3J_{CH}$), which proved the C-1′ position for that carbon, while H-3″ and H-5″ is coupled ($^3J_{CH}$) with the carbon absorbing at 129.91 ppm, which has to be C-1″. The other pair of protons of that ring (H-2″ and H-6″ (7.46 ppm)) gave a cross-peak with C-2 (81.70 ppm), which, as an element of the five-membered ring, binds the 4-acetoxyphenyl group.

The protons (H-2′ and H-6′) mentioned above in connection with the phenyl carbon – proton relationship elucidation, are additionally correlated with a sp^2-hybridized carbon of a chemical shift 153.55 ppm, which, in turn, gave a strong cross-peak ($^2J_{C-H}$) with vinyl proton H-4. This observation led us to the conclusion that the carbon of 153.55 ppm is C-5 of the vinyl system and constitutes the position of the attachment of the 3,4-diacetoxyphenyl group to the five-membered ring.

The conclusions concerning the location of both the phenolic substituents and the hydroxyl group in the molecule were confirmed by a NOE difference experiment, which indicated that a significant interproton contact through the space of the vinyl hydrogen (H-4) only exists with H-2′ and H-6′ of the 3,4-diacetoxyphenyl ring (a diagnostic enhancement of signals at δ 7.92 and 7.95 ppm), while the corresponding protons (H-2″ and H-6″) of the monoacetoxyphenyl ring revealed inertness when the vinyl proton was irradiated. These observations indicated the presence of a (AcO)$_2$C$_6$H$_3$-C=C-H fragment in the molecule, thus, ruling out the previously considered possibility of the immediate, geminal vicinity of both phenolic substituents.

Based on the presented arguments, the structure of 5-(3,4-dihydroxyphenyl)-2-(4-hydroxyphenyl)-2-hydroxy-4-

---

[5] The acetylation of involutone to its tetraacetyl derivative caused the chemical shift of the chiral carbinol carbon to be move downfield from 78.30 to 81.85 ppm, and of the four aromatic carbons (C-2′, C-5′, C-3″, and C-5″) being *ortho* to OAc positions to be deshielded by about 8 ppm.

[6] Besides, there is an evident coupling ($^2J_{C-H}$) with the methyl protons, which, however, appeared to be difficult to analyse, due to the small differences between the chemical shifts of the methyl protons.

Scheme 2. Selected HMBC ($\longleftrightarrow$) and NOE ($\leftarrow - \rightarrow$) correlations in the structure of tetraacetylinvolutone.
cyclopenten-1,3-dione for the new pigment involutone was assigned.[7] The most significant observations for structure elucidation concerning the scalar coupling (HMBC) and through-space interactions (1D NOE) are shown in Scheme 2.

Experimental

Melting points were determined on a Büchi 535 capillary apparatus and are uncorrected. Optical rotations were determined with a PerkinElmer 243B digital polarimeter. UV spectra were taken with a JASCO V-550 spectrophotometer in an acetonitrile solution. IR spectra were measured on a FT IR Bruker IFS 113v instrument for KBr discs. ^{1}H and ^{13}C NMR spectra were recorded on Varian Mercury-300 and Bruker DRX-600 spectrometers. A Bruker DRX-600 spectrometer, operating at 600.055 MHz (^{1}H) and 150.898 MHz (^{13}C), was used for 2D spectra. All spectra were acquired with a Bruker 5 mm inverse triple resonance gradient probe (TBI), using standard Bruker pulse sequences for the respective experiments. Proton and carbon assignments were based on COSY, NOE, HETCOR, HMQC, and HMBC experiments. MS spectral data were obtained on an AMD 402 mass spectrometer.

TLC analyses were carried out using Uniplate™ silica gel plates GHLF 250 μ (Analtech, Inc.) and PhH–CHCl$_3$–MeOH (3:6:1) as a developing system. Column chromatography was carried out using Merck Kieselgel 60 (230–400 mesh) and a 2:1 mixture of Whatman cellulose-silica gel (MN-Kieselgel 60, 100–200 mesh) as the stationary phase, while hexane, benzene, AcOEt, CH$_2$Cl$_2$, CHCl$_3$, and 5% MeOH in CHCl$_3$ were successively applied as the eluting solvents.

The fruit bodies of the mushroom *P. involutus* (growing near birch trees) were collected in Rybojedzko, a southern district of Poznan, Poland, every September in recent successive years.

General procedure of the metabolite isolation

Freshly collected fruit bodies of *P. involutus* were, first rinsed with water to remove sand and pieces of grass and leaves, then, either cut into small pieces or ground and, next treated with methanol, ethanol, or *n*-butanol (1.5 mL of the alcohol per 1 g of the mushroom) at room temperature for a few weeks or months.[8] When MeOH or EtOH were used, some foam appeared on the surface in the first hours of digestion. The resulting dark brown alcohol solution, after separation from the insoluble, semi-solid material by decantation and filtration, was concentrated under diminished pressure until all the alcohol was removed. The remaining aqueous residue, containing the naturally occurring mushroom components, including water (or a solid residue in the case of the *n*-butanol extract), was digested successively with *n*-hexane (A), benzene (B), ethyl acetate (C), and a mixture of PhH, AcOEt, and MeCN (1:2:4) (D). When kept for a week, the aqueous residue separated a light-brown solid (E) of a carbohydrate character.

Following this procedure in an experiment taken by way of example, the extraction of 900 g of fresh fruit bodies gave the individual fractions as follows: 0.84 g (A), 0.52 g (B), 0.53 g (C), 1.39 g (D), and 1.75 g (E). In the case of the extracts A–D, the soluble material was recovered by drying the particular solution over Na$_2$SO$_4$, followed by concentrating it under diminished pressure, and, finally, as a rule, subjecting the residue to chromatographic separation on silica gel. The products of the known structure isolated in a homogeneous state, namely methyl, ethyl, or *n*-butyl linoleate (A), linoleic acid, ergosterol (B), methyl, ethyl, or *n*-butyl-β-D-glucoside, involutin (C), crotonic acid, mannitol (D), were identified on the basis of their physical properties, including the comparisons of their EI-MS and NMR spectra with those reported in the literature (the source of consistent data was shown in a reference following the spectral method).

Linoleic acid ((*Z*,*Z*)-9,12-octadecadienoic acid)

The pure acid was obtained from extract B by an elution of the silica gel column with PhH-*n*-hexane (1:1) solution. References: EI-MS (25), ^{1}H NMR (25), ^{13}C NMR (26).

Linoleic acid esters

The A and B extracts, during the chromatography on silica gel, gave a methyl, ethyl, or *n*-butyl ester as a colourless oil when *n*-hexane, benzene, and 10% AcOEt-*n*-hexane were used as the eluents.

Methyl linoleate

References: EI-MS (27), ^{1}H NMR (28), ^{13}C NMR (29).

Ethyl linoleate

References: EI-MS (25), ^{1}H NMR (25), ^{13}C NMR (25).

---

[7] A possible synthetic relationship between involutin and involutone can consist of a process in which the former is subjected both to a water molecule elimination and the benzylic position oxidation, as suggested by the reviewer, to whom we are very grateful. To preserve the optical activity in such a biotransformation, when not assisted by an enzyme, the benzylic oxidation should precede the elimination.

[8] The treatment of the freshly collected mushrooms (being under nitrogen) with ethyl acetate at room temperature led to the formation of acetic acid, most likely due to enzymic hydrolysis of the solvent.

n-Butyl linoleate

^{1}H NMR (600 MHz, CDCl$_3$): δ 5.40–5.31 (4H, *m*, H-9, H-10, H-12 and H-13), 4.07 (2H, *t*, *J* = 6.7 Hz, H-1′), 2.77 (2H, *t*, *J* = 6.8 Hz, H-11), 2.29 (2H, *t*, *J* = 7.5 Hz, H-2), 2.07–2.01 (4H, *m*, H-8 and H-14), 1.63–1.53 (4H, *m*, H-3 and H-2′), 1.42–1.25 (16H, *m*, H-4, H-5, H-6, H-7, H-15, H-16, H-17 and H-3′), 0.93 (3H, *t*, *J* = 7.1 Hz, H-4′), 0.92 (3H, *t*, *J* = 7.1 Hz, H-18). ^{13}C NMR of the alcohol moiety (see ref. (30)). EI-MS *m/z* (%): 336 ([M]$^+$), 279, 263, 220, 209, 196, 185, 164, 150, 137, 129, 123, 109, 79, 67 (100), 57, 41.

Ergosterol

The continuing chromatography of fraction B, after removing linoleic acid and its methyl, ethyl, or *n*-butyl ester, led to obtaining, by elution with benzene, a colourless solid, the rechromatography of which, carried out twice, gave crystals of mp 168 to 169°C and [α]$_D$ –135° (*c* = 1, CHCl$_3$). The spectral data of the product were consistent with those for ergosterol reported elsewhere (EI-MS (31), IR (32*a*), ^{1}H NMR and ^{13}C NMR (33*a*, 34)).

Alkyl-β-D-glucopyranosides

A suitable (methyl, ethyl, or *n*-butyl) β-glucoside was obtained when fraction C was chromatographed on silica gel and the column was washed with CHCl$_3$. With the exception of the OH proton absorptions, the ^{1}H and ^{13}C NMR data obtained for these glucosides dissolved in DMSO-d_6 were close to the corresponding values reported for D$_2$O solutions (35). Each of the glucosides was additionally characterized by the properties of its tetraacetyl derivative obtained when a solution of the corresponding alkyl-β-glucoside in Ac$_2$O (supplied with a catalytic amount of pyridine) was kept at room temperature for 10 h, followed by an ice addition. After 30 min, the product was taken up into AcOEt.

Methyl-β-D-glucopyranoside

A recrystallization from MeOH gave colourless needles of mp 110 to 111°C and [α]$_D$ –33° (*c* = 1, MeOH). References for: EI-MS (36), ^{1}H NMR (35, 37), ^{13}C NMR (35, 37).

2,3,4,6-Tetra-*O*-acetyl-1-methyl-β-D-glucopyranoside

A colourless solid of mp 108 to 109°C and [α]$_D$ –18.89° (*c* = 0.5, MeOH). References for: EI-MS (38), ^{1}H NMR (38, 37), ^{13}C NMR (37).

Ethyl-β-D-glucopyranoside

A colourless semi-solid of [α]$_D$ –35.2° (*c* = 0.565, MeOH). ^{1}H NMR: see refs. (35, 39). ^{13}C NMR: see ref. (35). EI-MS *m/z* (%): 207 ([M – 1]$^+$), 177, 159, 144, 131, 118, 98, 88, 75, 74, 73, 71, 61, 60 (100), 59, 57, 47, 43, 31.

2,3,4,6-Tetra-*O*-acetyl-1-ethyl-β-D-glucopyranoside

A colourless solid of mp 102.5 to 103.5°C and [α]$_D$ –30.6° (*c* = 0.20, MeOH). ^{1}H NMR: see ref. (39). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 170.61 (*C*OCH$_3$), 170.23 (*C*OCH$_3$), 169.31 (*C*OCH$_3$), 169.25 (*C*OCH$_3$), 100.54 (C-1), 72.89 (C-3), 71.75 (C-5), 71.34 (C-2), 68.45 (C-4), 65.66 (C-1′),

62.00 (C-6), 20.79 (CO*C*H$_3$), 20.71 (CO*C*H$_3$), 20.67 (CO*C*H$_3$), 20.65 (CO*C*H$_3$), 15.08 (C-2′). EI-MS *m/z* (%): 375 ([M – 1]$^+$), 331, 303, 256, 243, 214, 200, 183, 169, 157, 145, 141, 127, 115, 112, 102, 98, 81, 70, 69, 43 (100).

n-Butyl-β-D-glucopyranoside

A colourless solid of mp 52–54°C, [α]$_D$ –25.6° (*c* = 0.55, MeOH). ^{1}H NMR: see ref. (35). ^{13}C NMR: see ref. (35). EI-MS *m/z* (%): 237 ([M + 1]$^+$), 205, 187, 163, 145, 144, 116, 103, 98, 97, 87, 85, 74, 73, 60 (100), 57 (95), 44, 42.

2,3,4,6-Tetra-*O*-acetyl-1-*n*-butyl-β-D-glucopyranoside

A colourless solid of mp 54.5 to 55.5°C, [α]$_D$ –9.36° (*c* = 0.435, MeOH). IR (KBr, cm^{-1}): 2967, 2904, 2871, 1759, 1743, 1433, 1378, 1226, 1169, 1099, 1069, 1040, 958, 603.^{1}H NMR (600 MHz, CDCl$_3$) δ: 5.21 (1H, *t*, *J* = 9.6 Hz, H-3), 5.09 (1H, dd, *J* = 9.8 Hz, *J* = 9.6 Hz, H-4), 4.99 (1H, dd, *J* = 9.6 Hz, *J* = 8.0 Hz, H-2), 4.49 (1H, d, *J* = 8.0 Hz, H-1), 4.27 (1H, dd, *J*$_{gem}$ = 12.3 Hz, *J* = 4.8 Hz, H$_A$-6), 4.14 (1H, dd, *J*$_{gem}$ = 12.3 Hz, *J* = 1.9 Hz, H$_B$-6), 3.88 (1H, dq, *J*$_{gem}$ = 9.6 Hz, *J* = 7.1 Hz, H$_A$-1′), 3.69 (1H, ddd, *J* = 9.8 Hz, *J* = 4.8 Hz, *J* = 1.9 Hz, H-5), 3.48 (1H, dq, *J*$_{gem}$ = 9.6 Hz, *J* = 7.1 Hz, H$_B$-1′), 2.09 (3H, s, CO*C*H$_3$), 2.04 (3H, s, CO*C*H$_3$), 2.03 (3H, s, CO*C*H$_3$), 2.01 (3H, s, CO*C*H$_3$), 1.54 (2H, quintet, *J* = 7.0 Hz, H-2′), 1.35 (2H, sextet, *J* = 7.1 Hz, H-3′), 0.90 (3H, t, *J* = 7.1 Hz, H-4′). ^{13}C NMR (150 MHz, CDCl$_3$) δ: 170.55 (*C*OCH$_3$), 170.17 (*C*OCH$_3$), 169.24 (*C*OCH$_3$), 169.14 (*C*OCH$_3$), 100.79 (C-1), 72.84 (C-3), 71.70 (C-5), 71.33 (C-2), 69.93 (C-1′), 68.46 (C-4), 62.00 (C-6), 31.44 (C-2′), 20.84 (CO*C*H$_3$), 20.73 (2 × CO*C*H$_3$), 20.70 (CO*C*H$_3$), 19.03 (C-3′), 13.82 (C-4′). EI-MS *m/z* (%): 403 ([M – 1]$^+$), 345, 331, 284, 243, 211, 200, 157, 115, 81, 43 (100).

Involutin

(5-(3,4-dihydroxyphenyl)-3,4-dihydroxy-2-(4-hydroxyphenyl)-2-cyclopenten-1-one)

After the elution of glucosides from fraction C, the silica gel column was washed with a 3% solution of MeOH in CHCl$_3$, which gave a cream-coloured solid of mp 173–175°C (with decomp.) and [α]$_D$ –24.7° (*c* = 0.4, AcOEt). An addition of 10% aq NaOH to a methanol solution of the product changed its colour to deep purple. IR: see ref. (18). ^{1}H NMR (300 MHz, CD$_3$CN) δ:[9] 7.68 (2H, d of AA′XX′, *J* = 9.0 Hz, H-2″ and H-6″), 6.83 (2H, d of AA′XX′, *J* = 9.0 Hz, H-3″ and H-5″), 6.75 (1H, d, *J* = 8.0 Hz, H-5′), 6.59 (1H, d, *J* = 2.2 Hz, H-2′), 6.52 (1H, dd, *J* = 8.0 Hz, *J* = 2.2 Hz, H-6′), 4.69 (1H, d, *J* = 6.9 Hz, H-4), 3.95 (1H, d, *J* = 6.9 Hz, H-5). ^{13}C NMR (150 MHz, CD$_3$CN) δ: 190.50 (C-1), 174.63 (C-3), 156.91 (C-4″), 145.25 (C-3′), 144.77 (C-4′), 130.48 (C-2″,6″), 128.95 (C-1′), 123.53 (C-1″), 123.02 (C-6′), 117.60 (C-2′), 116.75 (C-2), 116.21 (C-5′), 115.76 (C-3″,5″), 71.88 (C-4), 55.14 (C-5). HMBC (600 MHz, CD$_3$CN): H-2″ ($^3J_{CH}$) and H-6″ ($^3J_{CH}$) ⇒ C-4″; H-3″ ($^2J_{CH}$) and H-5″ ($^2J_{CH}$) ⇒ C-4″; H-5′ ($^3J_{CH}$) ⇒ C-3′; H-2′ ($^3J_{CH}$) and H-6′ ($^3J_{CH}$) ⇒ C-4′; H-5 ($^2J_{CH}$) and H-5′ ($^3J_{CH}$) ⇒ C-1′; H-3″ ($^3J_{CH}$) and H-5″ ($^3J_{CH}$) ⇒ C-1″; H-2″

---

[9]The ^{1}H and ^{13}C NMR data recorded by us for CD$_3$CN and CD$_3$OD solutions were very similar to each other, but differed to some extent from those reported in ref. (18). The use of CD$_3$CN as a solvent made it possible to observe the C-1, C-2, and C-3 signals.

$(^3J_{CH})$ and H-6″ $(^3J_{CH}) \Rightarrow$ C-2; H-2′ $(^3J_{CH})$ and H-6′ $(^3J_{CH}) \Rightarrow$ C-5. EI-MS: see ref. (18).

D-Mannitol

The crude residue obtained after a concentration of the PhH–AcOEt–MeCN extract (fraction D) was dissolved in hot MeOH and the solution allowed to cool. The separated colourless crystals of mannitol, when recrystallized from MeOH, melted at 168 to 168.5°C and showed $[\alpha]_D \pm 0°$ ($c = 1$, H_2O). The spectral data (EI-MS, IR, ^1H NMR, and ^{13}C NMR) were consistent with those reported elsewhere (40, 32b, 33b).

Hexaacetyl-D-mannitol

Mannitol obtained in the above way, when treated with Ac_2O in the presence of pyridine, gave hexaacetylmannitol in a yield of above 80%. A recrystallization from AcOEt furnished colourless needles of mp 124 to 125°C and $[\alpha]_D$ +24.83° ($c = 1$, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.45 (2H, d, $J = 8.8$, H-3 and H-4), 5.08 (2H, ddd, $J = 8.8.$, $J = 5.1$, $J = 2.7$, H-2 and H-5), 4.22 (2H, dd, $J_{gem} = 12.5$, $J = 2.7$, H_A-1 and H_A-6), 4.07 (2H, dd, $J_{gem} = 12.5$, $J = 5.1$, H_B-1 and H_B-6), 2.10 (6H, s, COCH_3), 2.08 (6H, s, COCH_3), 2.06 (6H, s, COCH_3). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 170.37 (2 × COCH$_3$), 169.70 (2 × COCH$_3$), 169.49 (2 × COCH$_3$), 71.47 (C-2 and C-5), 67.38 (C-3 and C-4), 61.84 (C-1 and C-6), 20.94 (2 × COCH_3), 20.76 (2 × COCH_3), 20.68 (2 × COCH_3). EI-MS: see ref. (41).

Involutone

(5-(3,4-dihydroxyphenyl)-2-(4-hydroxyphenyl)-2-hydroxy-4-cyclopenten-1,3-dione)

The soluble in MeOH material of fraction D, after mannitol separation by crystallization, contained crotonic acid in an amount of about 50%, which was sublimed off at 40°C and 0.06 mmHg (1 mmHg = 133.322 Pa); (mp 64 to 65°C. ^1H NMR (300 MHz, $CDCl_3$) δ: 12.20 (1H, s, COOH), 7.10 (1H, dq, $J = 15.5$, $J = 6.9$, H-3), 5.86 (1H, dq, $J = 15.5$, $J = 1.7$, H-2), 1.92 (1H, dd, $J = 6.9$, $J = 1.7$, H-4). A nonvolatile deep orange residue was subjected to column chromatography on silica gel, which allowed, first, the removal from it of the remaining crotonic acid by using hexane–benzene (1:1), and, next, the isolation of a product, the rechromatography of which, when 10% AcOEt in PhH was used as an eluant, afforded a bright yellow, hygroscopic solid (R_f 0.23) melting sharply at 181 to 182°C and showing $[\alpha]_D$ +96.3° ($c = 0.3$, MeOH). Treated with 10% aq NaOH, the compound changed colour to purple-violet.[10] IR (KBr, cm^{-1}): 3350, 1740, 1692, 1609, 1565, 1512, 1443, 1301, 1250, 1177, 1120, 1060, 875, 833. ^1H NMR (300 MHz, CD_3CN) δ: 7.59 (1H, d, $J = 2.2$ Hz, H-2′), 7.56 (1H, dd, $J = 8.2$ Hz, $J = 2.2$ Hz, H-6′), 7.51 (1H, s, H-4), 7.22 (2H, d of AA′XX′, $J = 8.8$ Hz, H-2″ and H-6″), 6.95 (1H, d, $J = 8.2$ Hz, H-5′), 6.79 (2H, d of AA′XX′, $J = 8.8$ Hz, H-3″ and H-5″). ^1H NMR (300 MHz, DMSO-d_6) δ: 10.02 (1H, s, OH), 9.59 (1H, s, OH), 9.43 (1H, s, OH), 7.73

(1H, s, H-4), 7.59 (1H, d, $J = 2.2$ Hz, H-2′), 7.53 (1H, dd, $J = 8.2$ Hz, $J = 2.2$ Hz, H-6′), 7.11 (2H, d of AA′XX′, $J = 8.8$ Hz, H-2″ and H-6″), 6.89 (1H, d, $J = 8.2$ Hz, H-5′), 6.72 (2H, d of AA′XX′, $J = 8.8$ Hz, H-3″ and H-5″), 6.60 (1H, s, OH). ^{13}C NMR (75 MHz, CD_3CN) δ: 202.86 (C=O), 200.63 (C=O), 158.19, 156.87, 149.91, 145.78 (C-5, C-3′, C-4′, C-4″), 139.57 (C-4), 129.27 (C-1′ or C-1″), 128.36 (C-2″ and C-6″), 124.09 (C-6′), 122.13 (C-1′ or C-1″), 117.00 (C-2′), 116.69 (C-5′), 115.52 (C-3″ and C-5″), 78.26 (C-2). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 203.57 (C=O), 201.32 (C=O), 157.61, 155.55, 150.27, 145.92 (C-5, C-3′, C-4′, C-4″), 138.39 (C-4), 128.05 (C-1′ or C-1″), 127.58 (C-2″ and C-6″), 122.96 (C-6′), 120.52 (C-1′ or C-1″), 116.36 (C-2′), 116.11 (C-5′), 77.39 (C-2). EI-MS m/z (%): 312 ([M]$^+$), 296, 284, 239, 189, 181, 163, 134, 121 (100), 93, 91, 77, 65. HR-MS calcd. for $C_{17}H_{12}O_6$: 312.06339; found: 312.06170.

Tetraacetylinvolutone
(5-(3,4-diacetoxyphenyl)-2-(4-acetoxyphenyl)-2-acetoxy-4-cyclo-penten-1,3-dione)

A solution of involutone ($[\alpha]_D$ +96.3°, 6.5 mg) in 1 mL of Ac_2O was supplied with one drop of anhydrous pyridine and stirred at room temperature for 60 h. The reaction mixture was worked up in a usual way and the product taken up into AcOEt. The solution, when washed with aq Na_2CO_3, dried over Na_2SO_4, and concentrated, gave 9.9 mg (99% yield) of a yellow crude tetraacetate. The pure product was eluted from silica gel column by 2% AcOEt in PhH and the resulting solution, when concentrated, afforded an oil (solidifying eventually) of R_f 0.76, mp 68–70°C and $[\alpha]_D$ +44.2° ($c = 0.275$, $CHCl_3$). UV (CH_3CN) λ_{max} (ε): 231 (18 480), 312 (11 720). IR (KBr, cm^{-1}): 3076 (w), 2935 (w), 2853 (w), 1770 (s), 1743 (s), 1714 (s), 1609 (m), 1574 (m), 1505 (s), 1429 (m), 1372 (s), 1265–1165 (s, b with max at 1202), 1118 (m), 1051 (m), 1013 (m), 904 (m), 846 (m). ^1H NMR (600 MHz, CD_3CN) δ: 7.95 (1H, dd, $J = 8.4$ Hz, $J = 2.2$ Hz, H-6′), 7.92 (1H, d, $J = 2.2$ Hz, H-2′), 7.70 (1H, s, H-4), 7.46 (2H, d of AA′XX′, $J = 8.8$ Hz, H-2″ and H-6″), 7.40 (1H, d, $J = 8.4$ Hz, H-5′), 7.16 (2H, d of AA′XX′, $J = 8.8$ Hz, H-3″ and H-5″), 2.29 (3H, s, COCH_3), 2.28 (3H, s, COCH_3), 2.23 (3H, s, COCH_3), 2.18 (3H, s, 2-OCOCH_3). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.92–7.88 (2H, m, H-2′ and H-6′), 7.46 (2H, d of AA′XX′, $J = 9.0$ Hz, H-3″ and H-5″), 7.43 (s, H-5), 7.35 (1H, d, $J = 8.2$ Hz, H-5′), 7.11 (2H, d of AA′XX′, $J = 9.0$ Hz, H-2″ and H-6″), 2.33 (COCH_3), 2.32 (COCH_3), 2.29 (COCH_3), 2.19 (COCH_3). ^{13}C NMR (150 MHz, CD_3CN) δ: 197.36 (C-3), 196.03 (C-1), 170.79 (2-OCOCH$_3$), 169.90 (4″-OCOCH$_3$), 169.03 (3′-OCOCH$_3$), 168.80 (4′-OCOCH$_3$), 153.55 (C-5), 152.55 (C-4″), 146.14 (C-4′), 143.50 (C-3′), 141.12 (C-4), 129.91 (C-1″), 128.65 (C-2″ and C-6″), 128.47 (C-6′), 127.72 (C-1′), 125.25 (C-2′), 125.22 (C-5′), 123.44 (C-3″ and C-5″), 81.70 (C-2), 21.09 (OCOCH$_3$), 20.73 (OCOCH$_3$), 20.65 (OCOCH$_3$), 19.97 (C_2-OCOCH$_3$). HMBC–NMR (600 MHz, CD_3CN): see Scheme 2. ^{13}C NMR (75 MHz, $CDCl_3$) δ: 196.33 and

---

[10]The phenoxide ion, formed as a result of the C(4′)-OH proton abstraction, constitutes a conjugated system, made by 10 π and n electrons and can be responsible for the colour change.

Semiclassical and quantum-mechanical study of the reaction mechanism for the $N_2 + N_2^+$ electron transfer system

Yu-Mei Xing, Lan Chen, Chong Zhang, Zun-Sheng Cai, and Xue-Zhuang Zhao

Abstract: Density functional theory (DFT) calculations, including electron correlation, were carried out on the $N_2 + N_2^+$ electron transfer system. Six geometries of the precursor complex were assumed and their stabilities were calculated and compared. The activation energy, the electronic transmission factor, and the electronic coupling matrix element in the electron transfer process were also calculated. The electronic transmission factor for this system was far less than unity (ca. 0.006~0.09); thus, the electron transfer reaction was considered to be diabatic in nature. Therefore, the electron transfer rate for the selected structures was calculated using semiclassical and quantum-mechanical theories. The calculated values were compared with each other and were in good agreement with the experimental value.

Key words: $N_2 + N_2^+$ electron transfer reaction, semiclassical and quantum-mechanical theories, electronic transmission factor, electronic coupling matrix element, B3LYP.

Résumé : On a effectué des calculs selon la théorie de la densité fonctionnelle (TDF), y compris une corrélation électronique, du système de transfert d'électron $N_2 + N_2^+$. On pris pour acquis les six géométries du complexe précurseur et on a calculé et comparé leurs stabilités. On a aussi calculé l'énergie d'activation, le facteur de transmission électronique et l'élément de matrice du couplage électronique du processus de transfert d'électron. Le facteur de transmission électronique pour ce système est de beaucoup inférieur à l'unité (environ de 0,006 à 0,09); on en a déduit que la réaction de transfert d'électron est de nature diabatique. On a donc calculé la vitesse de transfert d'électron en faisant appel à des calculs selon les théories de mécanique quantique et semiclassique pour des structures choisies. Les valeurs calculées ont été comparées entre elles et elles sont en bon accord avec la valeur expérimentale.

Mots clés : réaction de transfert d'électron $N_2 + N_2^+$, théories de mécanique quantique et semiclassique, facteur de transmission électronique, élément de matrice du couplage électronique, B3LYP.

Introduction

In the last two decades, the simple electron transfer (ET) theory provided by Marcus (1), Hush (2), Sutin (3), and Newton and coworkers (4, 5) has been very actively pursued, both theoretically and experimentally (6–16). This interest is not surprising, considering the ubiquity of the electron transfer process in chemistry, physics, and biology. ET reactions are commonly thought to be embodied by two potential surfaces, one for the reactants and the other for the products, and are well understood within two distinct limits (see Fig. 1) (17–19). First, for a very weak electronic coupling between the two potential surfaces (the so-called "diabatic limit"), the theoretical developments include semiclassical extensions of the classical formalisms, as well as quantum-mechanical treatments in which the ET is treated with a perturbation theory (7, 20), and its lowest order perturbation in

the electronic coupling leads to the Fermi golden rule expression of the ET rate constant. For the opposite limit (the "adiabatic limit"), in which the electronic coupling is large and the ET reaction is actually limited on one potential surface, the rate is well described by classical transition rate theory (7).

In the two diabatic theories, two important quantities — the electronic coupling interaction and the FC factor — depend strongly on the potential energy surfaces of the reactant and product and on the structural properties of the precursor complex. A considerable effort has been focused on understanding how the structural properties, such as the distance and orientation between donors and acceptors, affects the electron transfer rate (12, 13, 16, 21, 22).

$N_2 + N_2^+$ is a gas-phase ion–molecule ET reaction that plays an important role in stratospheric chemistry. Although the N_4^+ dimer cation, which may be identified as the precursor complex of the above ET reaction, has received much attention from both the experimental and theoretical standpoints (23, 24), the kinetics of this ET reaction has not been explicitly investigated. This reaction would involve a collision between the ion and the molecule, followed by the ET step, and detection. The encounter complex must be formed for the collision process to occur. Three methods were adopted to investigate the mechanism and calculate the

Fig. 1. Parabolic energy profiles of two diabatic states along the reaction coordinate.
rate of the ET process. The main purposes of this investigation are: (*i*) to obtain a more complete understanding of the nature of the interaction between the donor (N_2) and the acceptor (N_2^+) at the DFT level; (*ii*) to compare the electronic structural properties and the relative stability of various possible precursor complexes; (*iii*) to obtain relevant ET kinetic parameters and to compare their contributions to the ET rate from various precursor structures; and (*iv*) to compare the applicability of the semiclassical expressions, the quantum-mechanical method, and the golden rule simplification in studying the nonadiabatic ET problem of the $N_2 + N_2^+$ self-exchange system.

Theoretical model and computational details

Simple description of theoretical model

For the following thermal electron transfer process (eq. [1]),

[1] $N_2(r_0) + N_2^+(r_+) \leftrightarrows N_2^+(r_+) + N_2(r_0)$
according to the framework of the outer-sphere self-exchange ET model (1, 2, 6, 8), the electron transfer between the acceptor, $N_2^+(X^2\Sigma_g^+)$, and the donor, $N_2(X^1\Sigma_g^+)$, can be separated into the following three distinct steps:

1. Formation of the precursor complex or the encounter complex

$N_2(r_0) + N_2^+(r_+) \leftrightarrows N_2(r_0') \parallel N_2^+(r_+')$
2. Activation of the precursor complex, electron transferring, and then relaxation into the successor complex

$N_2(r_0') \parallel N_2^+(r_+') \rightarrow N_2^+(r_+') \parallel N_2(r_0')$
3. Dissociation of the successor complex into products

$N_2^+(r_+') \parallel N_2(r_0') \rightarrow N_2^+(r_+) + N_2(r_0)$
In step 2, it is assumed that there is an energy barrier for the precursor complex to surpass. This process conforms to the Marcus model: an electron is transferred between the donor and the acceptor with very little coupling resonance interaction and with an energy barrier largely originating from

Franck–Condon restrictions, i.e., the electron transfer occurs on a time scale in which the positions of all atomic nuclei are frozen. For ease of discussion we may separate step 2 into three detailed steps:

(*i*) Reorganization of the precursor complex

$N_2(r_0') \parallel N_2^+(r_+') \rightarrow N_2(r_0^*) \parallel N_2^+(r_+^*)$
(*ii*) Elementary electron transfer step (according to the Franck–Condon principle)

$N_2(r_0^*) \parallel N_2^+(r_+^*) \rightarrow N_2^+(r_0^*) \parallel N_2(r_+^*)$
(*iii*) Relaxation into the successor complex

$N_2^+(r_0^*) \parallel N_2(r_+^*) \rightarrow N_2^+(r_+') \parallel N_2(r_0')$
Obviously, step 1 is the collision process between the ion and the molecule. Its energy change corresponds to the stabilization energy (E_s), which is the sum of the electrostatic work required to bring the reactants closer with an optimized constant distance of R and the energy associated with the change of geometry from r to r'. The product in step 1 is the precursor complex and may exist in various structural forms.

Using the steady state approximation, assuming the reaction is not diffusion limited, and assuming that dissociation in step 3 is fast, the overall rate (k_{ovr}), which is usually observed, is determined as the product of the equilibrium constant for the formation of the precursor complex (K_{pre}) and the rate of electron transfer (k_{et}), i.e., the overall rate includes the collision and ET processes.

[2] $k_{ovr} = K_{pre}k_{et}$,

where the unimolecular rate constant for the ET (k_{et}) may be determined by either the semiclassical or the quantum-mechanical method.

Semiclassical method

Taking quantum effects into account, the rate of the ET reaction, k_{et}, can be expressed as (4, 5, 9–11, 25, 26)

[3] $k_{et} = \nu_n\Gamma_n\kappa_{el}\exp(-\Delta G^*/RT)$,

where ν_n is the nuclear frequency factor (s^{-1}), Γ_n is the nuclear tunneling factor, κ_{el} is the electronic transmission coefficient, and ΔG^* is the activated free energy of the reaction. If the entropy effects are not taken into account, the activated free energy can be substituted by the activated energy E_{ad} (see below for definition). At room temperature, nuclear tunneling does not typically contribute significantly to the electron transfer rate, so Γ_n is assumed to be equal to unity throughout this study (27, 28).

The electronic transmission factor denotes the diabaticity of the ET reaction and must be treated explicitly. For the weak coupling electron transfer system, as in the outer-sphere mechanism, the Landau–Zener (LZ) model (29, 30) is available. In terms of the LZ model, the electronic transmission coefficient can be expressed as

[4] $\kappa_{el} = 2P_0/(1 + P_0)$,

where the probability (P_0) of hopping from the initial state potential energy surface (*i*) to the final state potential energy

Fig. 2. Geometrical structure of the precursor complex (r'_0 and r'_+ denote the N—N bond distance of N_2 and N_2^+ in the precursor complex; R is the contact distance)
surface (f) on a single passage of the system through the crossing region is given by

$$[5] \qquad P_0 = 1 - \exp(-4\pi^2 H_{if}{}^2/(h v_s |S_2 - S_1|)),$$

where h is the Planck constant and v_s is the velocity (assumed constant) of the reacting system passing through the crossing region along the reaction coordinate. $|S_2 - S_1|$ is the net force exerted on the system, tending to return it to the original and the final state; S_1 and S_2 are the negative slopes of the potential energy surfaces, at the transition state, of the reactant and product, respectively. H_{if} is the electronic coupling matrix element between the initial state and the final state.

Obviously, the main factors influencing the electron transfer rate are the activated energy, the coupling matrix element, and the slopes of the potential energy surfaces, and these quantities depend strongly on the potential energy surface of the reacting system (31). In the following section, some valid schemes are introduced to determine these quantities on the basis of the potential energy surfaces obtained from ab initio calculations, including electron correlation.

Quantum-mechanical method

Instead of using the LZ expression for the electronic transmission coefficient, the quantum-mechanical expression for the ET rate is given as (9, 14, 32–35)

$$[6] \qquad k_{et} = (4\pi^2/h)Z^{-1} \sum_v \sum_w \exp(-\beta E_{rv})$$
$$\times |(\chi_{rv}|\langle \phi_r|H|\phi_p\rangle|\chi_{pw})|^2 \, \delta(E_{rv} - E_{Pw})$$
$$= (4\pi^2/h)H_{if}{}^2 Z^{-1} \sum_v \sum_w \exp(-\beta E_{rv})$$
$$\times |\langle \chi_{rv}|\chi_{pw}\rangle|^2 \, \delta(E_{rv} - E_{Pw})$$
$$= (4\pi^2/h)H_{if}{}^2 \, (DWFC),$$

where Z denotes the vibrational partition function. This expression gives the probability per unit time that a system in an initial vibration state $\phi_r(r,Q)\chi_{rv}(Q,t)$ will pass to a set of final vibration states $\phi_p(r,Q)\chi_{pw}(Q,t)$. DWFC is the density weighted Franck–Condon factor. This formulation is correct for the case of diabatic ET within the Franck–Condon approximation; for adiabatic ET, the ET is processed on one potential energy surface and can be treated using transition state theory. For the $N_2 + N_2^+$ reacting system, we focus on

the treatment of diabatic ET; thus, the application of eq. [6] leads to (7, 10, 11, 32–34)

$$[7] \qquad k_{et} = (4\pi^2/h)H_{if}{}^2 \, (FC),$$

where λ is the reorganization energy. In the classical limit, and when frequency changes in individual vibrational modes are neglected, the FC factor given in eq. [7] reduces to (18, 25)

$$[8] \qquad FC = (4\pi\lambda RT)^{-1/2}\exp(-(\Delta G^\circ + \lambda)^2/(4\lambda RT)),$$

where $(4\pi\lambda RT)^{-1/2}$ is the classical density of states and ΔG° is the standard Gibbs free energy of the reaction and equal to zero for the self-exchange ET reaction.

One can also use other approximations to represent the DWFC factor in eq. [6]. According to the golden rule (9, 10, 14), we can rewrite eq. [6] into the formula of the Fermi golden rule (36)

$$[9] \qquad k_{et} = (4\pi^2/h)H_{if}{}^2\rho(E_f),$$

where $\rho(E_f)$ denotes the density of the final (product) state (see below).

Computational details

Standard ab initio molecular orbital calculations were performed with the GAUSSIAN 94 program package, Revision E.3 (37). The B3LYP procedure was employed in the density functional theory (DFT) (38) calculations, which cover electron correlation in the self-consistent Kohn–Sham procedure through the functions of electron density. It also gives good descriptions for systems that require sophisticated treatments of electron correlation in the conventional ab initio approach. A large basis set of 6–311+G* (39) was used at the B3LYP level. For the precursor complex, six structural forms, i.e., collinear (L), two T-type (T_1 and T_2), parallel (P), Z-type (Z), and crossing (C) (see Fig. 2), were assumed and optimized under the symmetry constraint and by optimizing in turn the contact distance (R) and the N—N distances (r_0 in the N_2 fragments and r_+ in the N_2^+ fragments of the precursor complex). The first five forms were assumed to be coplanar to keep the largest overlap of the orbitals, while the crossing one was assumed to be nonplanar, owing to the rotation of one of the two molecular fragments by 90° about the C_2 principal axis in the P structure.

The stabilization energy (E_s) of the corresponding precursor complex was defined as the difference between the

corresponding precursor complex and the isolated species, $N_2(X^1\Sigma_g^+)$ and $N_2^+(X^2\Sigma_g^+)$, in step 1. The diabatic transition state — which by no means corresponds to a real structure that exists physically — was defined as the "structure" along the seam of crossing between the two diabatic potential energy surfaces, corresponding to the initial and the final states of the ET. On the other hand, the adiabatic transition state was defined at the saddle point on one potential surface, which can be found by transition state theory.

Results and discussion

Optimized structure and properties of the isolated species

Before we start the discussion on the structure of the precursor complex for the ET system, it is useful to test the applicability of ab initio calculation levels to this system. The calculations on the isolated species, $N_2(X^1\Sigma_g^+)$ and $N_2^+(X^2\Sigma_g^+)$, were performed at the Hartree–Fock (HF), B3LYP, and MP2 (full) levels with the 6–311+G* basis set. The optimized structures, energies, and relevant spectroscopic properties are summarized in Table 1.

By comparing the calculated and experimental values for the structure and the force constants, some trends regarding the dependence of the quality of the results on the level of theory can be identified. It can be noted that, even if a larger basis set such as 6–311+G* is used, the calculated equilibrium N—N bond lengths for both species, $N_2(X^1\Sigma_g^+)$ and $N_2^+(X^2\Sigma_g^+)$, possess larger errors at the HF level (about 0.03 Å shorter than the experimental values); even the vibrational frequencies are higher, at about 340~375 cm^{-1} (70~85 cm^{-1} if the scale factor of 0.8929 is considered), than the experimental values. At the MP2 level, full electron correlation correction may decrease the errors, but the calculation still deviates from experimental values. However, the B3LYP calculations are in good agreement with the experimental values. For the bond length, the largest deviation is 0.0077 Å, and 35 cm^{-1} (considering the scale factor of 0.9613) is the largest deviation for the vibrational frequency. Especially for the dissociation energy (D_e) and the force constants (f and g), the result is indeed improved effectively at the electron correlation level. Of course, the deviation trend of the force constants (f and g) from experimental values is the same as that for vibrational frequency. Comparison of the experimental r_e, D_e, and force constants values with HF, B3LYP, and MP2 (full) results indicates that signif-

icant accuracy is achieved at the B3LYP/6–311+G* level for N_2 and N_2^+ systems.

The geometry of the complexes in precursor state

The geometrical configuration of the precursor complex directly influences not only the activated energy of the reaction but also the electron transfer coupling matrix element and, thus, the ET rate. Therefore, it is very important to find all possible geometrical configurations for the precursor complex. For the ET reaction between N_2 and N_2^+, six possible precursor-state structures have been assumed (Fig. 2). The geometrical parameters and relevant energies are displayed in Table 2. However, the Z-type and C-type geometries did not converged at the B3LYP/6–311+G* level, which may be due to the limitation of the method employed or to the extreme instability of these two configurations. So, in the following discussions, only the four remaining geometries are considered. From Table 2, it can be seen that the N—N bond lengths of the fragments have minor changes compared with the isolated $N_2(X^1\Sigma_g^+)$ molecule and $N_2^+(X^2\Sigma_g^+)$ ion. From the viewpoint of energy, the larger is the E_s, the more stable the complex. So, the most stable precursor complex is L (172.52 kJ mol^{-1}), and the order of stabilization energy is L > T2 > T1 > P.

Transition state of the reaction and the activated energies

According to Marcus' outer-sphere or diabatic ET theory, the interaction between the donor and the acceptor in this case should be very weak and can thus be neglected in some calculations (8, 41–43). Thus, the energy of every point on the potential energy curve of the reactant or the product may be estimated as the sum of energies of the donor and the acceptor. We can write $E(q) = E_{N_2}(q) + E_{N_2^+}(q)$ in general terms, where q specifies the location on the potential curves. According to part (*ii*) of step 2, and as presented by Bu et al. (44), the energy of the activated complex $N_2(r_0^*)\|N_2^+(r_+^*)$ before (E_i) and after (E_f) ET can be expressed as

$$[10] \quad E_i = E_{N_2}(r_0^*) + E_{N_2^+}(r_+^*)$$

and

$$[11] \quad E_f = E_{N_2^+}(r_0^*) + E_{N_2}(r_+^*),$$

respectively, and we have the energy conservation principle, $E_f = E_i$. Therefore,

[a]The results of the semiclassical method according to eq. [3].
[b]The results of the quantum-mechanical method according to eq. [7].
[c]The results of Fermi golden rule according to eq. [9].

[12] $E_{N_2}(r_0^*) + E_{N_2^+}(r_+^*) = E_{N_2^+}(r_0^*) + E_{N_2}(r_+^*)$

Or it may simply be written as

[13] $E(r^*) = E_{N_2}(r^*) + E_{N_2^+}(r^*),$

where r^* is r in the activated state, i.e., $r_0^* = r_+^* =$ r*. Evidently, eq. [13] represents the energy curve constructed at the crossing point between the two diabatic potential energy surfaces, and the lowest $E(r)$, with varying r, is the energy of the activated complex ($E(r^*)$) at the crossing point with geometry r^*.

However, to ensure the ET reaction occurs, the two diabatic potential energy curves must be coupled to a certain extent so that the crossing point of the two curves is avoided and a $2H_{if}$ separation between the lower and upper potential curves arises (see Fig. 1). Indeed, $H_{if} = 0$ means no ET happens, which can be indicated by equations of k_{et}. That is, the interaction of the donor and the acceptor should be taken into account when we refer to the activated state of the ET reaction. The activation energy is then defined by subtracting the energy of the precursor complex from the corresponding energy at the activated state; namely,

[14] $E_{ad} = E\ N_2 \parallel N_2^+\ (r^*, r^*) - E\ N_2 \parallel N_2^+\ (r_0', r_+'),$

where the energies on the right hand side are the single point energies calculated at B3LYP of DFT at the same contact distance R, but with the relevant internal coordinates being optimized as before.

The definition of the diabatic activated energy E_d we have adopted here is found in eq. [15] (44)

[15] $E_d = E_{N_2}(r^*) + E_{N_2^+}(r^*) - E_{N_2}(r_0) - E_{N_2^+}(r_+)$

The interaction between acceptor and donor can be quantitatively described by the coupling matrix element (H_{if}). Accurate theoretical calculations on H_{if} have been made by Newton (45), German (46), and German and Kuznetsov (47). The magnitude of H_{if} is a direct parameter, determining the degree of diabatic character in the electron exchange reaction. If the interaction is strong, the values of the electronic transmission factors are high (κ_{el} tend to 1) and the system can remain in the lower potential surface; that is, the reaction is adiabatic and the reaction process can be treated by classical transition state theory. As shown in Fig. 1, because E_{ad} and E_d denote the adiabatic and diabatic activation energy, respectively, the magnitude of the coupling matrix element H_{if} at the crossing point is approximated by (6, 48)

[16] $H_{if} = E_d - E_{ad}$

$= E_{N_2}(r^*) + E_{N_2^+}(r^*) - E_{N_2}(r_0) - E_{N_2^+}(r_+)$

$- E\ N_2 \parallel N_2^+\ (r^*, r^*) + E\ N_2 \parallel N_2^+\ (r_0', r_+')$

For the precursor complex $N_2(r_0') \parallel N_2^+(r_+')$, of the four different geometries, the activated energies (calculated at the B3LYP/6–311+G* level) are 0.33 (T2), 0.26 (T1), 0.12 (L), and 0.0097 (P) kJ mol^{-1}, respectively, and the coupling matrix elements are 0.33 (L), 0.19 (T1), 0.12 (T2), and 0.44 (P) kJ mol^{-1}, respectively. The P-type transition state with C_{2v} symmetry has the largest coupling matrix element and the T2-type transition state with C_{2v} symmetry has the smallest. This phenomenon may be explained in terms of the orbital overlap interaction between the donor and the acceptor (see Fig. 3). Although the contact distance is larger than the other structures, the P-type structure is favorable with both $\pi_=$ and $\pi_\perp$ maximum overlaps and the largest coupling matrix element. For the L-type structure, the smallest contact distance is favorable for the orbital overlap. T1-type and T2-type

Fig. 3. The diagram of the orbital couplings between the donor and the acceptor.
structures have similar geometries that may be presented by a T-type orbital coupling diagram. Due to the symmetry restriction on the orbital overlap, its coupling interaction should be small.

According to the Franck–Condon principle, the definition of the reorganization energy is the energy that is required to reorganize the molecular structure of the reactants and the surrounding solvent to be compatible with ET. In this gas-phase ET reaction, it may be defined by (49, 50)

$$[17] \quad \lambda = E_{N_2}(r_+) - E_{N_2^+}(r_+) + E_{N_2^+}(r_0) - E_{N_2}(r_0)$$

The reorganization energy calculated according to eq. [17] is 2.43 kJ mol^{-1}, which is consistent with the previous study (2.20 kJ mol^{-1}) (50).

The slopes of the potential energy surfaces and the final-state density

For a given potential energy surface, $E(q)$, the value of its slope, S_j, can be obtained from the relationship

$$[18] \quad S_j = -\partial E_j(q)/\partial q,$$

where $j = 1$ corresponds to the reactant and $j = 2$ corresponds to the product. Considering that $E(q)$ can be expressed as the sum of E_r and E_o, where the subscripts r and o stand for the reduced and oxidized fragment of the reaction system at the crossing point, eq. [18] may be further written as

$$[19] \quad S_1 = -\partial E_i(q_r)/\partial q_r = -\partial E_r(q_r)/\partial q_r$$
$$+ \partial E_o(x - q_r)/\partial(x - q_r) = S_r - S_o$$

$$[20] \quad S_2 = -\partial E_i(q_o)/\partial q_o = -\partial E_r(x - q_o)/\partial(x - q_o)$$
$$+ \partial E_o(q_o)/\partial q_o = -S_r + S_o,$$

where it is assumed that $q_r + q_o = x$. Thus, the difference in slope between the reactant state and the product state may be further expressed as

$$[21] \quad |S_2 - S_1| = 2|S_r - S_o|,$$

where S_r and S_o denote the slopes of the diabatic potential energy surfaces of the reduced and the oxidized fragments, respectively, at the crossing point of the two diabatic potential surfaces.

Moreover, the slopes of one dimensional potential curves can be calculated in terms of the Morse potential function

$(E(q) = D_e(1 - \exp(-\alpha q))^2)$. Thus, the calculation formula is expressed as

$$[22] \quad S_j = -2D_e\alpha(1 - \exp(-\alpha q_t))\exp(-\alpha q_t),$$

where j (= r, o) denotes the reduced and the oxidized species, respectively, and q_t denotes the geometry at the crossing point. The calculated results of the slopes are displayed in Table 2 and they are similar to each other.

To define the final-state density, $\rho(E_f)$, one may note that under perturbation there must be three product states, which all come from the same initial state of E_i. These final states have energy $E_i + \Delta E$, E_i, and $E_i - \Delta E$, so that there are three final states per $2\Delta E$ (51, 52). Hence, the maximum value of the final state density is

$$[23] \quad \rho(E_f) = dN/dE = 3/(2\Delta E),$$

where ΔE is the difference between the initial- and the final-state energies and can be taken as the perturbation or uncertainty in the electron energy, $\Delta E = (\Delta p)^2/(2m_e)$. Then, according to the uncertainty principle,

$$[24] \quad \rho(E_f) = 3m_e/(\Delta p)^2 = 3m_e(\Delta x)^2/h^2,$$

where Δx is the uncertainty in the position of an electron at the crossing point and may be approximately equal to the contact distance. This indicates that the longer the distance, the larger the final-state density. The final results of $\rho(E_f)$ are also displayed in Table 2.

Electron transfer rate

The electronic transmission coefficients were calculated in terms of eqs. [4] and [5]. The results were also listed in Table 2. The values were far less than unity (0.006~0.09); thus, the electron transfer reaction was indeed diabatic in nature. Moreover, it shows the validity of using quantum-mechanical theory to calculate this ET rate.

Once the electronic transmission coefficient, the coupling matrix element, and the relevant energies are obtained, the rate of the ET reaction can be found in terms of eqs. [3], [7], and [9], according to the different methods. At the semiclassical theoretical level, considering the role of the collision between the N_2 molecule and N_2^+ ion, the effective collision frequency Z_{eff} (the combination of $K_{pre} \cdot \nu_n \cdot \Gamma_n$) lies between 10^{11}~10^{12} L mol^{-1} s^{-1} (53). All the calculated results are shown in Table 2. It can be seen that the P-type mechanism has the largest rate constant, then the L-type, and the T-type has the smallest at all the calculated levels. The mean values of the overall ET rates are 3.21×10^9~10^{10}, 1.57×10^{12}, and 5.32×10^{12} L mol^{-1} s^{-1} at the semiclassical (eq. [3]), quantum-mechanical (eq. [7]), and golden rule (eq. [9]) levels, respectively. The experimental value for the ET rate of the $N_2 + N_2^+$ system in the gaseous phase was found to be about 3.97×10^{11} L mol^{-1} s^{-1} (54, 55). Our calculated values showed a good agreement with the experimental values, considering the many approximations employed. On comparing the results of the rate constant it can be seen that the values obtained from the quantum-mechanical theory are higher than those from the semiclassical theory, and the rate constant derived from the final-state density also provides a valid treatment for the diabatic ET reaction.

Conclusions

The structures, properties, and electron-transfer reactivity of the $N_2 + N_2^+$ system in the gas phase have been studied using semiclassical and quantum-mechanical methods based on the single point energies calculated at the B3LYP/6–311+G* level. Six possible precursor structures were assumed and the order of their stability was L > T2 > T1 > P. For these precursor complexes, the larger the contact distance, the weaker is the interaction between the donor and the acceptor, and the floppier is the structure. So, neglecting the interaction between the donor and the acceptor is reasonable in the $N_2 + N_2^+$ ET reaction. The electronic transmission factor for this system is generally substantially less than unity (ca. 0.006~0.09), thus this ET reaction is diabatic in nature. The coupling matrix elements were calculated and were found to be a crucial factor in determining ET occurrence and an important factor in determining ET rate. The rate constant was found to be strongly dependent on the slopes of the potential energy surface at the crossing point. The results of ET rates from the semiclassical and quantum-mechanical theories were in good agreement with the experimental values, which indicates that it is reasonable to neglect the entropy effects of the reaction in the semiclassical calculation and take into account the vibrational ground state contribution only on the FC term in the quantum-mechanical calculation. Moreover, it can be concluded that if the interaction is so weak that it can be represented by a perturbation, this reacting system can be treated using the Fermi golden rule (i.e., first-order perturbation theory). Most importantly, it was demonstrated that both theories are successful in interpreting the diabatic electron transfer reaction.

Since the $N_2 + N_2^+$ system is a simple and typical diabatic ET reaction system, demonstrating its reaction mechanism is useful for a forthcoming investigation — the pattern and rule of diabatic character for self-exchange ET in the periodic table.

The influence of competing factors on the endothermic nature of bile salt binding by cationic adsorbent

Celia K. Williams, William C. Galley, and G. Ronald Brown

Abstract: The binding of sodium chenodeoxycholate, a hydrophobic bile salt, by a polyacrylamide resin with *N,N,N*-trimethylammonium dodecyl chloride (QPDA12) pendant groups was studied in the presence of elevated concentrations of competing anions. The equilibrium bile salt concentration was determined from HPLC data for a range of initial bile salt concentrations. Binding constants extracted from the fit of the isotherms to the Langmuir equation were obtained for data for temperatures from 24 to 60°C. A reduction in chenodeoxycholate binding affinity was observed in comparison with that reported previously at lower overall anion concentrations. A van't Hoff analysis of the data revealed that a decrease in the favourable entropy of binding was responsible for this reduced affinity. Decomposition of the binding constants into specific contributions for the competing buffer anions and the chenodeoxycholate anion returned positive values of $\Delta H°$ and $\Delta S°$ for the binding of both the competing ions and bile salt. These findings reveal that the weakening of the bile salt binding that occurs with added salt is not due to Debye screening of an attraction between ions of opposite charge. A binding mechanism consistent with the thermodynamics observed was proposed in which the dominant role of hydration changes that occur on binding provides the principal driving force for the process.

Key words: bile salts, endothermic binding, polymer sorbents, solvent randomization.

Résumé : La liaison d'un sel biliaire hydrophobique, le chénodeoxycholate de sodium, par une résine de polyacrylamide comportant des substituants chlorure de *N,N,N*-trimethyldodecylammonium a été étudiée en présence d'une forte concentration d'ions compétiteurs. Les concentrations en sel biliaire libre à l'équilibre, pour différentes concentrations initiales, ont été obtenues à partir de mesures HPLC. Les constantes de liaison ont été extraites des isothermes ajustés à l'équation de Langmuir pour des températures de 24°C à 60°C. Une analyse van't Hoff des données a révélé qu'une diminution de l'entropie favorable à la liaison était responsable de l'affinité réduite. Des valeurs positives de $\Delta H°$ et $\Delta S°$ pour la liaison des ions compétiteurs ainsi que pour le sel biliare ont été obtenues par la décomposition des constantes de liaison. Ces résultats révèlent que l'affaiblissement de la liaison du sel biliaire n'est pas seulement due à l'effet d'écran de Debye sur l'attraction d'ions de charges opposées. Un mécanisme de liaison incluant les changements d'hydratation a été proposé pour expliquer les caractéristiques du processus de liaison.

Mots clés : sels biliaires, liaison endothermique, sorbents polymères, désorganisation de la cage d'hydratation.

Introduction

The ingestion of insoluble polymeric resins serves to sequester bile acids in the intestines, resulting in their elimination through the gastrointestinal tract. Prevention of their reabsorption stimulates the breakdown of cholesterol to bile acids, which in turn leads to a reduction in plasma cholesterol levels. The resins currently in wide clinical use, cholestyramine (Questran), a styrene–divinylbenzene copolymer developed in 1959 (1), and colestipol (Colestid), a copolymer of tetraethylene-pentamine and epichlorohydrin (2),

are cationic in nature, as are many of the other resins investigated for this purpose. Although the use of these polymeric sequestrants for the removal of bile acids from the gastrointestinal tract is an accepted means of lowering plasma cholesterol levels, little work has been done to elucidate the nature of the binding interactions.

The binding of bile salts with the cationic resins has been considered to be dominated by the attraction between the oppositely charged ions (3–5). Comparisons of the binding affinities of cationic polymeric resins with uncharged resins have been taken as evidence for the contribution of coulombic interactions in the binding process (3–8). In addition, the significant impact of added salt (6, 7, 9) and phosphate buffer in reducing the binding through Debye screening of an ionic interaction has been taken as support (4, 5, 8) for a model in which ion-pair formation provides the driving force for the process. As a consequence, it has been implicitly assumed that the binding of the participating ions is an exothermic process.

However, recent temperature-dependent studies of the binding of bile salts to a quaternized polyacrylamide resin

conjugated with *N,N,N*-trimethylammonium dodecyl chloride (QPDA12) (Fig. 1) demonstrated that the binding affinity was enhanced with increasing temperature (10). This indicated that an increase in entropy was responsible for the binding and that a considerable enthalpic barrier had to be surmounted in the process. The observed endothermic nature of the process is inconsistent with an association dominated by favourable coulombic interactions between the participating bile salt and resin. Calorimetric binding studies of bile salts with human serum albumin and bovine serum albumin have been observed in previous work to be endothermic. This was taken as evidence for a major hydrophobic involvement in the association of bile salts with these plasma proteins (11).

Alternate molecular descriptions to those that involve a simple electrostatic attraction between bile salts and macromolecular assemblies are required to account, at least qualitatively, for the thermodynamic parameters that are associated with binding. These models, however, must also encompass the earlier evidence that supports the role of ionic interactions in the binding process (3–8).

To provide additional data that might assist in reconciling the endothermic nature of the binding with the known dependence on added salt, binding studies were carried out as a function of temperature and electrolyte composition. The adsorption of sodium chenodeoxycholate with QPDA12 was examined in the presence of an elevated buffer ion concentration and with added salt. A van't Hoff analysis was used to obtain a measure of the $\Delta H°$ and $\Delta S°$ associated with the binding. The manner in which the bile salt binding thermodynamics are influenced by the ionic composition of the medium are interpreted in terms of binding of competing anions in the system and of the role of solvation in the overall process.

Experimental

Materials

Sodium chenodeoxycholate (NaCDC) was purchased from Sigma and was used as received. Sodium cacodylate $(CH_3)_2AsO_2Na$ was from Baker. The QPDA12 resin with chloride as counter ions was a previously synthesized and quaternized sample (12). The functionality (*f*) was determined to be 2.00 ± 0.07 mmol of trimethylammonium pendant groups per gram of dry resin, performed by gravimetric analysis. The chloride counter-ions were precipitated in the form of silver chloride by the addition of 1:1 of 16 M nitric acid and 0.103 M silver nitrate. The precipitate was filtered, washed, dried, and weighed to constant weight.

Adsorption studies

The procedures used for the sorption studies were as described previously (13). The bile salt solutions were prepared in aqueous 50 mM sodium cacodylate buffer, a mixture of 5 mM sodium cacodylate and 41 mM sodium chloride, and a mixture of 5 mM and 8 M urea all at a pH of 7.2. A stock bile salt solution (7 mM) was normally diluted with buffer to generate concentrations as low as 0.23 mM. The polymer resin (10 mg) was added to 20 mL of buffer solution containing varying bile salt concentrations. These mixtures were agitated with a mechanical shaker in a con-

Fig. 1. The chemical structure of (*N,N,N*)-trimethylammonium dodecyl chloride (QPDA12) resin.
stant temperature bath at 120 oscillations per minute for more than 18 h at the desired temperature (24–60°C). The density change of the bile salt solutions over this temperature range was less than 1%; therefore the concentrations of the bile salt solutions were not corrected for increase in temperature. Reverse-phased high-performance liquid chromatography (HPLC) was used to follow the binding according to procedures described previously (13). The bile salt concentrations in the solutions at equilibrium (C_{eq}) and the amount of bile salt bound per gram of resin Q (mmol g^{-1}) were calculated, and the binding isotherms were plotted from these results. The isotherms were then analyzed in terms of the Langmuir equation, eq. [14],

$$[1] \qquad Q = \frac{Q_m K C_{eq}}{1 + K C_{eq}}$$

with the use of SigmaPlot Software Version 5.00, which yielded the "best-fit" values for K and Q_m, the equilibrium site binding constant and maximum Q or binding capacity, respectively.

From the thermodynamic relation

$$[2] \qquad \Delta G_T^\circ = -RT \ln K$$

the standard Gibb's free energy change for a process can be related to K, which is unitless in that the concentrations of the species involved are expressed relative to that of the standard state that is chosen. With an experimental binding constant expressed in terms of molarity, the standard state is the state in which the ligand, or binding species, is at a concentration of 1.0 M, assuming ideal behaviour.

Results

The binding isotherms for chenodeoxycholate to QPDA12 in 50 mM cacodylate buffer appear in Fig. 2. The equilibrium bile salt concentration required to produce half saturation of the binding sites can be seen to decrease with rising temperature, reflecting an increasing binding affinity. This enhanced affinity with temperature is accompanied by an increase in concentration of the bile salt required to saturate the resin. The shape of the isotherms within experimental error remains unaltered. The increase with temperature in both the affinity and the available binding sites for the bile salt reflects the pattern of behaviour observed previously at a 10-fold lower cacodylate buffer concentration (10). These observed changes in binding with temperature cannot be

Table 1.

Temperature (K)	Buffer	$K \times 10^{-3}$ (M^{-1})	$\Delta G^\circ = -RT \ln K$ (kJ mol^{-1})	$n = Q_m/f$

	41 mM sodium chloride	10 ± 2	–23.9 ± 0.5	1.0
323	5 mM cacodylate	25 ± 16	–27 ± 2	1.5
	50 mM sodium cacodylate	11 ± 3	–24.9 ± 0.8	1.2
	41 mM sodium chloride	11 ± 3	–25.1 ± 0.6	1.2
333	5 mM cacodylate	103 ± 19	–32.0 ± 0.5	1.2
	50 mM sodium cacodylate	18 ± 4	–27.2 ± 0.6	1.4

Fig. 2. Binding isotherms of sodium chenodeoxycholate by QPDA12 in 50 nM sodium cacodylate buffer.

Fig. 3. Binding isotherms of sodium chenodeoxycholate by QPDA12 in 5 mM sodium cacodylate and 41 mM sodium chloride buffer.
accounted for by a change in pH. In the temperature range studied (24–60°C) only a 0.1 decrease in pH was observed.

The binding isotherms illustrated in Fig. 2 were fitted to the Langmuir equation, eq. [14], with the values of K, the equilibrium site binding constant, the corresponding ΔG°, and the number of available binding sites n being listed in Table 1. The increase in K with rising temperature, characteristic of an endothermic process, is apparent in Table 1. Binding constants for chenodeoxycholate with QPDA12 at 5 mM cacodylate buffer concentration plus 41 mM sodium chloride[3] are also included in Table 1. The particular sodium chloride concentration was chosen to achieve the ionic strength as the 50 mM cacodylate buffer system. The values of K in the presence of added sodium chloride were derived from the isotherms appearing in Fig. 3. The magnitude of the K values is also seen to increase with temperature. The values of K under both conditions are smaller than those obtained with the lower buffer concentration (10), as shown in Table 1 from earlier data (10). This result is in agreement with weakening of the binding observed in the presence of
increased buffer and salt concentrations that has been demonstrated previously with other systems of this type (6, 7, 9).

The van't Hoff plot in Fig. 4 was generated from site binding constants from the isotherms obtained in the presence of 50 mM cacodylate buffer and the buffer mixture of 5 mM cacodylate and 41 mM sodium chloride. The negative slope under both conditions reflects the increase in binding constant K with temperature or the endothermic nature of the process. A linear analysis on the binding data in the 50 mM buffer yielded values of ΔH° and ΔS° of 36 ± 4 kJ mol^{-1} and 190 ± 12 J mol^{-1} K^{-1} from the slope and intercept, respectively.

The ΔH° and ΔS° for the system with the buffer mixture of 5 mM cacodylate and 41 mM sodium chloride are 18 ± 1 kJ mol^{-1} and 134 ± 4 J mol^{-1} K^{-1}. Comparison of data obtained at the lower 5 mM buffer concentration yielded a ΔH° of 53 ± 11 kJ mol^{-1} and ΔS° of 253 ± 34 J mol^{-1} K^{-1} (10). The steeper van't Hoff plot for the binding at the low buffer concentration is included for comparison with the data ob-

---

[3] Refers to an increased chloride concentration greater than the 1 mM of chloride already present from the chloride counter-ion of the resin. This value was calculated by dividing the functionality of the resin by the 20 mL of the bile salt solution used in the binding experiments.

Table 2. The thermodynamic parameters associated with bile salt binding by QPDA12 under three different buffer conditions, 5 mM sodium cacodylate, 50 mM sodium cacodylate buffer and a buffer mixture of 5 mM sodium cacodylate and 41 mM sodium chloride.

Buffer	$\Delta H°$ (kJ mol^{-1})	$\Delta S°$ (J mol^{-1} K^{-1})	$\Delta G°_{313} = \Delta H° - T\Delta S°$ (kJ mol^{-1})
5 mM sodium cacodylate	53 ± 11	253 ± 34	−26.2
50 mM sodium cacodylate	36 ± 4	190 ± 12	−23.5
5 mm sodium cacodylate + 41 mM sodium chloride	18 ± 1	134 ± 4	−23.9

Fig. 4. The van't Hoff Plot for the binding of sodium chenodeoxycholate by QPDA12 in 5 mM (■) and 50 mM (●) sodium cacodylate and 5 mM sodium cacodylate with 41 mM sodium chloride buffer (▲).
tained in the present study. The values of $\Delta H°$, $\Delta S°$, and $\Delta G°$ at 313 K under all three conditions appear in Table 2.

The thermodynamic parameters in Table 2 illustrate the fact that despite the lower unfavourable $\Delta H°$, or enthalpy barrier, observed with the higher buffer or salt concentrations, binding is weaker than at low salt concentrations. The weaker binding reflected in the more positive $\Delta G°_{313}$ values at high salt concentrations derives from the lower $\Delta S°$ values that represent the driving force for the binding under all conditions. The influence of the changes that occurred in the enthalpic and entropic contributions becomes more evident at a specific temperature. Using data from the temperature of 313 K as an example, the increase in buffer concentration from 5 to 50 mM results in a reduction of 17 kJ mol^{-1} in the enthalpic barrier and is offset by a corresponding larger decrease of 19.7 kJ mol^{-1} in $T\Delta S°$. In agreement with the initial observations (10), binding of chenodeoxycholate with the resin does not occur as a consequence of a favourable energetic interaction. It derives rather from an overall randomization that occurs within the system.

Discussion

The van't Hoff enthalpies (ΔH_{vH}) in this work were calculated from a simple equilibrium involving binding of the bile salt to a resin-binding site. In recent years, with the widespread use of isothermal calorimetry discrepancies have been found between van't Hoff binding enthalpies and directly determined calorimetric enthalpies, ΔH_{cal} (15). It has

been suggested that ΔH_{vH} to a first approximation represented values for the intrinsic binding, while ΔH_{cal} included concomitant reactions involving, for example, hydration or conformation changes that do not directly affect the binding (16, 17). However, an analysis of the errors on a recent study of a binding reaction involving protein conformational isomerization (18) revealed that the ΔH_{vH} and ΔH_{cal} within experimental errors were the same. Concomitant processes involving solvent rearrangements such as hydrophobic interactions, which do not appear explicitly in the binding equilibrium, directly influence K and its temperature dependence, and their influence will contribute to the van't Hoff enthalpy.

The thermodynamic parameters associated with the binding of the bile salt with the polymeric resin and the changes in those parameters observed in the presence of higher buffer and added salt concentrations can be accounted for in terms of a binding model. The model emphasizes competition for the binding of the bile salt anion with the buffer or other anions in the system. Changes in hydration on binding, particularly within the resin, feature as a dominant factor in accounting for the sign and magnitude of the thermodynamic parameters that are observed.

Consideration of binding models: A model for the binding of chenodeoxycholate with the hydrophobic cationic resin

Competitive binding

Binding equilibria involving a common binding site are assumed, and an equation for an isotherm for the binding of bile salt in the presence of added competing ions is derived. The Langmuir equation from eq. [1] was rewritten in the form of eq. [3] (19).

$$[3] \qquad Q = \frac{Q_m K_{eff} C_{eq}}{1 + K_{eff} C_{eq}}$$

where

$$K_{eff} = \frac{K_B}{1 + K_s[S]}$$

in which $[S]$ is the equilibrium concentration of the competing anion involved and K_B and K_S are the specific binding constants for the bile salt and competing anion, respectively. With the use of binding isotherms at more than one concentration of competing anion, the experimental values of K_{eff} were decomposed into specific binding constants for the bile salt and competing anion. Decomposition of this kind at several temperatures provided a measure of the temperature dependence of the specific binding constants and, as a result, within the assumptions of the analysis, a measure of the $\Delta H°$ and $\Delta S°$ associated with each process.

Table 3. The resulting standard enthalpy, entropy changes and Gibbs free energy changes (313 K) associated with sodium chenodeoxycholate and cacodylate ion obtained from binding data of sodium chenodeoxycholate by QPDA12 in 50 mM sodium cacodylate buffer.

	$\Delta H°$ (kJ mol^{-1})	$\Delta S°$ (J mol^{-1} K^{-1})	$\Delta G°$ at 313 K (kJ mol^{-1})
Sodium chenodeoxycholate	62	282	−26.8
Cacodylate ion	34	142	−10.9

The values of the bile salt (K_B) and cacodylate ion (K_S) at a given temperature were obtained by solving eq. [3] simultaneously for K_{eff} at two different salt $[S]$ concentrations of 4.5 and 45 mM basic cacodylate anion. The concentrations of the cacodylate anion were obtained from substituting the 5 and 50 mM total buffer concentrations into the Henderson–Hasselbach equation at a pH of 7.2. The resulting values of the specific binding constants for K_B and K_S appear in the form of a van't Hoff plot in Fig. 5. The line was obtained from the linear regression on the data.

The negative slopes in these plots reveal that the cacodylate binding and the bile salt binding for the cationic resin are both endothermic. It is this endothermic nature of the competing anion binding that produces the observed reduction in the magnitude of the slope for the van't Hoff plot for the apparent chenodeoxycholate binding. The decrease arises from the increase in the buffer anion concentration. With increasing temperature, the increasing K_B is in competition with a concomitant increase in the K_S for the cacodylate anion. The $\Delta H°$, $\Delta S°$, and $\Delta G°_{313}$ values for both K_B and K_S appear in Table 3. The $\Delta H°$ values associated with the bile salt and the cacodylate binding are 62 and 34 kJ mol^{-1}, respectively, and the $\Delta S°$ values are 282 and 142 J mol^{-1} K^{-1}. It is clear from the value for $\Delta G°_{313}$ that cacodylate anion binding is considerably weaker than that of the bile salt. Weaker binding for the cacodylate anion relative to that of the bile salt is seen to be due to a significant decrease in the favourable binding entropy and, despite a 45% reduction in the positive, or unfavourable, $\Delta H°$ of binding.

The decomposition of K_{eff} at the two chloride ion concentrations into specific site binding constants for the bile salt (K_B) and chloride ion (K_S) with QPDA12 was performed in the same manner as with the cacodylate buffer. The equilibrium concentrations of chloride were not determined by HPLC analysis, but under weak binding conditions it was assumed that the initial and final concentration of chloride was the same and the initial concentration of chloride was employed. The result of the extraction of K_B and K_S appear in Fig. 6 in the form of a van't Hoff plot.

As with the cacodylate perturbation, the specific binding constant for the added chloride ion is much weaker than that for the bile salt, and the numbers are still within the same range as of the cacodylate anion. The analysis of the temperature dependence of the specific bile salt and chloride binding constants yielded the same pattern of behavior that was observed with the cacodylate ion, which is that $\Delta H°$ and $\Delta S°$ are both positive, as seen in Table 4. The $\Delta H°$ of 115 kJ mol^{-1} and $\Delta S°$ of 403 J mol^{-1} K^{-1} derived for K_S are actually more positive than the corresponding $\Delta H°$ of 88 kJ mol^{-1} and $\Delta S°$ of 368 J mol^{-1} K^{-1} associated with the specific bile salt binding (K_B). This implies that while the binding of the competing chloride ion is also weaker than that of

Fig. 5. Computed van't Hoff plots for competitive binding of sodium chenodeoxycholate and cacodylate anions.
Fig. 6. Computed van't Hoff plots for competative binding of sodium chenodeoxycholate and chloride anions.
the bile salt, in this case it is due to a relatively higher enthalpic barrier rather than a lower $\Delta S°$.

Competition for binding by the resin between bile salt and other anionic counterions or co-ions in the system can account for the endothermic nature of the bile salt binding as well as the impact of higher concentrations of the competing ions. However, as revealed by the decomposition of the observed salt binding isotherms into K_B and K_S, binding of the competing ions must also be endothermic and entropy-driven. It is the endothermic nature of the competitive ion binding that accounts for the large decreases observed in the

Table 4. The resulting standard enthalpy, entropy changes and Gibbs free energy changes (313 K) associated with sodium chenodeoxycholate and chloride ion obtained from binding data of sodium chenodeoxycholate by QPDA12 in 5 mM sodium cacodylate and 41 mM NaC1 buffer.

slope of the van't Hoff plots for bile salt sequestering at the higher salt concentrations. The enhancement in sodium chenodeoxycholate binding observed with increasing temperature becomes significantly reduced in the presence of high salt because there is also an enhancement in the competing process as the temperature rises. The presence of a competing endothermic process appears as a definitive requirement in accounting for the data irrespective of the precision of the site-binding model.

Molecular model involving changes in hydration

An overall molecular description of chenodeoxycholate sequestering by the cationic QPDA12 resin must, within the context of the competitive binding model, account for the endothermic and entropy-driven nature of the binding of the competing ions as well as that of the bile salt. Changes in hydration on binding are proposed as a major feature of the bile salt binding or ion-exchange process.

The molecular model is centered on the existence of an equilibrium between two putative solvated states of an unoccupied pendant-binding site[4] as depicted in Fig. 7. In the process of binding the bile salt or competing anions with state II of the system to form the bound state III, the equilibrium is shifted from state I to the otherwise less favoured state II. The proposed state I to state II transition is accompanied by large positive $\Delta H°_{I \to II}$ and $\Delta S°_{I \to II}$ values that compensate, resulting in smaller positive $\Delta G°_{I \to II}$ values.

The direct associations (state II → III, in Fig. 7) of the chenodeoxycholate or competing anions with the resin are considered to be enthalpically favoured ($\Delta H°_{II \to III}$ = (–)). The $\Delta S°_{II \to III}$ associated with the direct binding to state II of the resin is purported to involve a balance between a positive contribution due to solvent liberation from the ions and a negative contribution from loss in the degrees of freedom possessed by the free ions themselves. The resulting $\Delta G°_{II \to III}$ values for these transitions are negative and sufficiently favourable to shift the equilibrium in the resin in the direction of overall binding.

The large $\Delta H°_{I \to II}$ and $\Delta S°_{I \to II}$ values associated specifically with the state I → II transition within the resin are proposed to involve the hydrophobic pendant groups. The positive $\Delta H°_{I \to II}$ during contraction of the binding area arises from an increased electrostatic repulsion between quaternary ammonium-terminated pendant groups and the disruption of the hydrophobic hydration of the methylene chains.

This relaxation of the extended pendant chains (elastomer contribution) and the liberation of the ordered hydrophobic solvation form the basis of the accompanying positive $\Delta S°_{I \to II}$. The compensating enthalpy and entropy contributions result in a relatively smaller positive $\Delta G°$ that, in the absence of anions, favours the expanded state I.

It is only the addition of state II → III transitions in the presence of anions that shifts the equilibrium resulting in an overall favourable $\Delta G°$ for binding that nonetheless displays large positive $\Delta H°$ and $\Delta S°$ values that in large part reflect the contraction of the resin binding area. It should be noted that these significant positive contributions would appear irrespective of whether the chenodeoxycholate or other competing anions are involved. The thermodynamic parameters for the separate stages in the model and the predicted overall transition are summarized in Table 5.

The changes observed in the enthalpy and entropy of bile salt binding in the presence of higher buffer and sodium chloride concentrations that can be accounted for with the present model cannot be reconciled with other common mechanisms. Debye screening of the attraction between the opposing charges or an ionic strength effect has often been assumed to be responsible for the general weakening of bile salt binding with added salt (4–8). However, such an effect would be manifested as a decrease in the attraction between bile salt and resin or an increase in binding enthalpy, which is clearly inconsistent with the data.

The general endothermic and entropy-driven nature of the bile salt sequestering process could be accounted for in terms of a direct interaction between the bile salt and resin

---

[4]The pendant binding areas of the resin are viewed as fluctuating among the many members within the assembly of states that exist at a given temperature. These states are arbitrarily divided here into two classes: the more extended members (state I) and the more contracted members (state II) that favour binding. A model involving pre-existing states in equilibrium is employed as compared with one in which the final state of the pendant binding area is induced by binding.

Figure 7. Molecular model for bile salt and competitive anion binding consistent with the observed thermodynamic parameters.
that was largely hydrophobic in character. However, such a model does not readily account for the nature of the perturbations introduced at higher buffer or sodium chloride concentrations. An essential element of the proposed model involves the local contraction of the binding area of the resin (state I → II). It should be noted that this step, in association with large positive enthalpy and entropy contributions, occurs with both sodium chloride and buffer ion binding and with the anion of the bile salt. This feature accounts for the

endothermic binding of the competing inorganic anions with the hydrophobic cationic resin that would not be accounted for in a more direct hydrophobic bile salt – resin interaction.

The significance of hydration changes in the process follows not only from the recurring enthalpy–entropy compensation observed in this work. A major perturbation to the temperature dependence of the bile salt binding was observed when 8 M urea, a known solvent structure breaker, was added to 5 mM sodium cacodylate buffer solution. The

large positive entropy and enthalpy contributions that were observed without urea disappeared, and the process appears exothermic with a $\Delta H°$ of -3.4 kJ mol^{-1} and a $\Delta S°$ of 56.4 J mol^{-1} K^{-1}. This dramatic change in the thermodynamic parameters supports the model in which solvent plays a key role in the binding.

Conclusions

The enhancement in the binding of sodium chenodeoxycholate by QPDA12 observed with increasing temperature was significantly reduced in the presence of elevated competing ion concentration. This was entirely due to the positive entropy manifested in the decrease in the slope of the van't Hoff plot. A competing model was used to describe the binding process and the decomposition of the observed binding constants produced positive values for $\Delta H°$ and $\Delta S°$ for binding both the competing ions (K_S) and the bile salt (K_B).

The dominant feature of the model involves equilibrium between an expanded (low energy, low entropy) state of the binding site in the resin and a more contracted (high energy, high entropy) state. In this picture the expanded, more hydrated state is favoured in the absence of bile salt or other anions. These anions, however, preferentially stabilize the contracted state, shifting the equilibrium. The loss of hydration accompanying this transition is primarily responsible for the endothermic and entropy-driven nature of the overall process.

Chemical potential and concentration fluctuation in some aqueous alkane-mono-ols at 25°C

Jianhua Hu, Charles A. Haynes, Amy H.Y. Wu, Candy M.W. Cheung, Mark M. Chen, Eric G.M. Yee, Takehiko Ichioka, Keiko Nishikawa, Peter Westh, and Yoshikata Koga

Abstract: Vapour pressures of binary aqueous solutions of methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, and 1-hexanol were measured at 25.00°C in small compositional increments over the entire compositional range. Without resorting to any fitting function, the partial pressures were calculated numerically by methods based on the Gibbs–Duhem relation. When the system had an azeotrope, near which the numerical methods caused large errors, a graphical readjustment was applied such that the concentration fluctuation, $S_{XX}(0) = RT(1 - x_{AL})/(\partial \mu_{AL}^E / \partial x_{AL})$, connected smoothly across the azeotrope. Values of $S_{XX}(0)$ from scattering experiments were also used as a guide for the readjustment procedure. Hence, we report here chemical potential data free from any model or any fitting function.

Key Words: aqueous mono-ols, partial pressures by the Boissonnas method, concentration fluctuations.

Résumé : Opérant à 25.00°C sur toute la plage de compositions en procédant à de faibles incréments de composition, on a mesuré les tensions de vapeur de mélanges binaires aqueux de méthanol, d'éthanol, de propan-1-ol, de propan-2-ol, de butan-1-ol et d'hexan-1-ol. Sans faire appel à aucune fonction d'ajustement, on a pu calculer d'une façon numérique les tensions de vapeur partielles à l'aide de méthodes basées sur la relation de Gibbs–Duhem. Quand le système comporte un azéotrope près duquel les méthodes numériques peuvent provoquer de graves erreurs, on a appliqué un ajustement graphique de façon à ce que la fluctuation de la concentration $S_{XX}(0) = RT(1 - x_{AL})/\partial \mu_{AL}^E/\partial x_{AL}$ puisse être arrimée pour tout l'azéotrope. Comme guide pour la méthode de réajustement, on a aussi utilisé des valeurs de $S_{XX}(0)$ obtenues à partir d'expériences de diffusion. On rapporte donc ici des données de potentiel chimique qui ne sont pas liées à un modèle ou à une fonction d'ajustement.

Mots clés : monoalcools aqueux, tensions de vapeur partielles par la méthode de Boissonnas, fluctuations de concentration.

[Traduit par la Rédaction]

Introduction

For the last decade or so, we have been studying aqueous solutions of alkane-mono-ols (abbreviated as AL hereinafter) by determining the following partial molar quantities: the excess chemical potential (μ_{AL}^E), the excess partial molar enthalpy (H_{AL}^E), and the entropy (S_{AL}^E) of alcohols. They were all determined accurately and in small increments, so that we were able to graphically take the derivatives with respect to the mole fraction without resorting to any fitting function. The resulting higher-order derivative quantities provided a model-free, experimentally accessible measure for intermolecular interactions. With the aid of these higher-order derivative quantities, we have successfully advanced our understanding of the mixing schemes, or "structures", of aqueous solutions (1–3).

Briefly, there are three distinct compositional regions; in each of these regions, the mixing scheme is qualitatively different from those in other regions. In the most water-rich region, "mixing scheme I" is operative, in which alcohol molecules enhance the hydrogen-bond network of H_2O in their immediate vicinities — the so called "iceberg formation". At the same time, the hydrogen bond probability of bulk H_2O away from solute molecules is reduced. "Mixing scheme II", operative in the intermediate region, is understood to consist of two kinds of clusters, each rich in H_2O

and in AL, respectively. In "mixing scheme III", in the solute-rich region, the solute molecules cluster together and H_2O interacts with the solute cluster as single H_2O molecules, at least for aqueous 2-butoxyethanol (BE) (4, 5) and DMSO (6, 7).

For small alcohols (3), however, mixing scheme III may deviate from what is described for BE–H_2O (5) and DMSO–H_2O (6), above. The excess partial molar enthalpies of AL are not strictly zero, though very small in the AL-rich region (3). For BE–H_2O (5) and DMSO–H_2O (6), they are equal to zero and constant, which signifies a strictly constant value of the excess partial molar enthalpy of H_2O, H_W^E, in the AL-rich region.

In continuation of our effort to advance the understanding of mixing schemes by determining model-free, higher-order derivative quantities, we wish to study the mixing schemes in the AL-rich region in detail for a series of aqueous monools. This compositional region is far less studied than water-rich systems, and its properties may have a bearing on water-stressed biopolymers and the effect of H_2O molecules inside membranes (8) and protein conformations. This work is the first step, in which we determine the excess chemical potentials.

Table 1 lists the references for the excess partial molar quantity data (at 25°C) that we have determined so far. We use the following abbreviations: methanol (ME), ethanol (ET), 1-propanol (1P), 2-propanol (2P), 1-butanol (1B), 1-hexanol (1H), *tert*-butanol (TBA), and 2-*n*-butoxyethanol (BE). In this work we have determined the excess chemical potentials in aqueous ME, ET, 1P, 2P, 1B, and 1H over the entire concentration range.

Data analysis

In a binary system consisting of AL and W (water), the chemical potentials are conveniently determined by measurement of the vapour pressure, p, in small increments of the mole fraction of AL, x_{AL}. From the (x_{AL}, p) data set, the partial pressures p_{AL} and p_W are calculated basically by two techniques. The commonly used method, which originated with Barker (17), is to assume a fitting function for the Gibbs energy, G, and curve-fit to the observed vapour pressure data. The second technique is to analyze the data purely numerically by using the Gibbs–Duhem relation, as per Boissonnas (18), or using the equivalent method by Lam and Benoit (19). With the resulting p_{AL} and p_W data, the excess chemical potential is then calculated as

[1] $\mu_i^E = RT\ln\{p_i/(p_i^* x_i)\}$,

where the subscript $i = $ AL or W, p_i^* is the vapour pressure of pure i at the same temperature, and x_i is the mole fraction of i. Strictly, eq. [1] should also contain the virial correction term owing to nonideality in the gas phase. However, for TBA–H_2O (10) and BE–H_2O (4), the value of the first term on the right of eq. [1] is orders of magnitude larger than the correction term on the left, and thus it was ignored. We assumed that the same situation prevails in other aqueous solutions, and ignored the virial correction. μ_i^E reflects the degree of nonideality in solution, comprising both enthalpy and entropy effects. In aqueous solutions, however, the entropy–enthalpy compensation is prevalent, and the resulting

[d]Up to the two phase boundary, $x_{1H} < 0.001$.

value of excess chemical potential becomes rather small in comparison (20). Thus, in discussing molecular processes in solution, the excess partial molar enthalpy and entropy are together more useful than the resulting excess chemical potential alone, though the net effect is shown in the latter. A more sensitive indication of nonideality than excess chemical potential may be the osmotic coefficient, ϕ, calculated as

[2] $\phi = 1 + (\mu_W^E/RT) / \ln(x_W)$.

Barker's method (17) or its various modifications start off by assuming that an analytic function can be fitted to the excess Gibbs function over the entire compositional range. Since we did not wish to resort to any fitting function, we instead used the second numerical methods, as we have been doing for all the vapour pressure measurements (4, 9, 10, 14, 15). Briefly, the Boissonnas method makes use of the differential form of the Gibbs–Duhem or the Duhem–Margules relations, which are rearranged as

[3] $\Delta p_{AL} = k_{AL}\Delta p$,

[4] $k_{AL} = 1/\{1 - (p_W/p_{AL})(x_{AL}/x_W)\}$

Thus, if the (x_{AL}, p_{AL}, p_W) data are known at a point, then the measured total pressure increment to the next point, Δp, may be converted to Δp_{AL} through eqs. [3] and [4]. To start the procedure, however, the first data point in the H_2O-rich region was assumed to be in the Henry's law region, and the vapour pressure of the major component, p_W, was calculated using Raoult's law. The subsequent data points were then solved successively by eqs. [3] and [4].

This Boissonnas procedure could be initiated from the AL-rich end by interchanging the subscripts in eq. [3] and [4]. Both treatments are identical mathematically, but in practice it is preferential to start from the end that brings the absolute values of k_i ($i = $ AL or W) closer to unity.

The method by Lam and Benoit (19) uses the integral form of the Gibbs–Duhem relation,

[5] $\ln p_W = \ln p_W^0 - \int_{x_{AL}^0}^{x_{AL}} (x_{AL}/x_W)\, d(\ln p_{AL})$,

where the superscript 0 stands for the data for the first, most dilute, solution, which is also assumed to be in the Henry's law region. Equation [5] was used to improve the values of

p_{AL} and p_W, which were initially estimated. The iteration was repeated until the resulting data converged.

As will become evident below, 1P–H_2O and 2P–H_2O systems possess a maximum in the p vs. x_{AL} plots, similarly to TBA–H_2O (5), i.e., $\Delta p = 0$. This is the azeotrope at which the gas phase composition is identical to that of the liquid phase. Hence, the absolute values of k_{AL} and k_W are infinite, and eq. [3] becomes indefinite. The integration method, eq. [5], also results in chaotic behaviour at this point. These problems can be resolved by applying the Boissonnas procedure from both ends, starting separately at the W-rich and the AL-rich sides, respectively, and working towards the azeotrope. This was done for TBA–H_2O (10). The azeotrope occurred at $x_{TBA} = 0.6$ at 25°C, and at data points close to the azeotrope the values of k_W and k_{TBA} were not infinity but were large: $k_{TBA} = 4$ at $x_{TBA} = 0.52$ and $k_W = -6$ at $x_{TBA} = 0.66$ (10). Barker's method was then used, in the range $0.39 < x_{TBA} < 1$, with only marginal success (10). In this work, to keep our principle of not resorting to any fitting function and to circumvent the difficulty associated with the azeotrope, we used data for the concentration fluctuation,

[6] $S_{XX}(0) = RT(1 - x_{AL})/(\partial \mu_{AL}/\partial x_{AL})$,

determined by a scattering technique, to more correctly evaluate partial pressures near the azeotrope.

The determination of the concentration fluctuation in the liquid mixtures and the long-wavelength limit of the structure factor, $S_{XX}(0)$ — and its relationship with the "structure" of aqueous solution — started with pioneering work by T. Fujiyama and co-workers (21–23). A more direct method of obtaining $S_{XX}(0)$ is small angle X-ray scattering (SAXS), as has been used in previous studies of aqueous alcohols (24–29). The forward SAXS intensity is the sum of two terms, proportional to the $S_{XX}(0)$ that we are interested in and the density fluctuation that can be calculated in a standard manner using isothermal compressibility data, respectively (24–29). Thus, as long as the latter data are available, $S_{XX}(0)$ can be evaluated from the forward SAXS intensity. Usually, where the value of $S_{XX}(0)$ is relatively large, its uncertainty is approximately equal to a few %, while the same data calculated as the right hand side of eq. [6] above could have a large uncertainty, since the slope of μ_{AL} is small. Thus, $S_{XX}(0)$ data from the SAXS measurement provides a rigorous test for μ_{AL}^E data from vapour pressure measurements.

Experimental

H_2O was distilled three times (twice in a Pyrex glass immediately before use). Methanol (Aldrich, 99.9+% GLC), ethanol (Aldrich, H_2O < 0.005%), 1-propanol (Aldrich, 99.5% HPLC), 2-propanol (Sigma–Aldrich, 99.5% by HPLC), 1-butanol (Sigma, ACS Reagent, 99.9%), and 1-hexanol (Aldrich, 98%) were handled in a dry nitrogen atmosphere.

Vapour pressures were determined by a static method. Details have been described elsewhere (4, 10). The total vapour

pressures were corrected for a temperature of 25.00°C by the Gibbs–Konovalov method (4, 10). The excess partial molar enthalpy data, H_{AL}^E and H_W^E, necessary for the correction, were taken either from references listed in Table 1 or from our unpublished data. The precision of the vapour pressures is estimated to be ±0.01 Torr (1 Torr = 101 325/760 Pa) or better. SAXS measurements for aqueous methanol were made at 25 ± 1°C using a Kratky camera. Details have been described elsewhere (24). The SAXS intensity curve was detected by a position sensitive proportional counter (PSPC), also described elsewhere (25).

Results and discussion

Table II (ME), III (ET), IV (1P), V (2P), VI (1B), and VII (1H) have been deposited as supplemental material[2] and contain the total vapour pressure, p, of the six AL–H_2O systems at 25.00°C. Figure 1 shows the plots of p against x_{AL}. Where available, the previously reported data, though not exhaustive, have also been plotted for comparison (see Fig. 1).

Methanol(ME) – H_2O and ethanol (ET) – H_2O systems

The Boissonnas method was first applied from the H_2O-rich end, for both the ME–H_2O and ET–H_2O data. The values of k_{AL} for both start at an ideal value of about 1.1. However, k_{ME} increases to about 1.5 at the ME-rich end for ME–H_2O. For ET–H_2O, on the other hand, k_{ET} increases gradually to 1.3 at $x_{ET} = 0.28$ and rapidly to about 8 at $x_{ET} = 0.8$. Thereupon, k_{ET} values fluctuate wildly. This is due to the flatness of the p vs. x_{ET} curve in this range. We therefore used the integral form of the Gibbs–Duhem relation, eq. [6], for data analysis for both ET–H_2O and ME–H_2O. The resulting partial pressures are listed in Table II. The uncertainty in the resulting partial pressure is estimated to be ±0.03 Torr (1 Torr = 101 325/760 Pa) or better. The chemical potentials are calculated using eq. [1] and are listed in Table II and plotted in Figs. 2 and 3. The uncertainty is estimated to be

---

Fig. 3. Excess chemical potentials of H_2O in aqueous alcohols at 25°C.

$$[7] \qquad G_m^E = x_{AL}(1 - x_{AL}) \sum g_n (1 - x_{AL})^n,$$

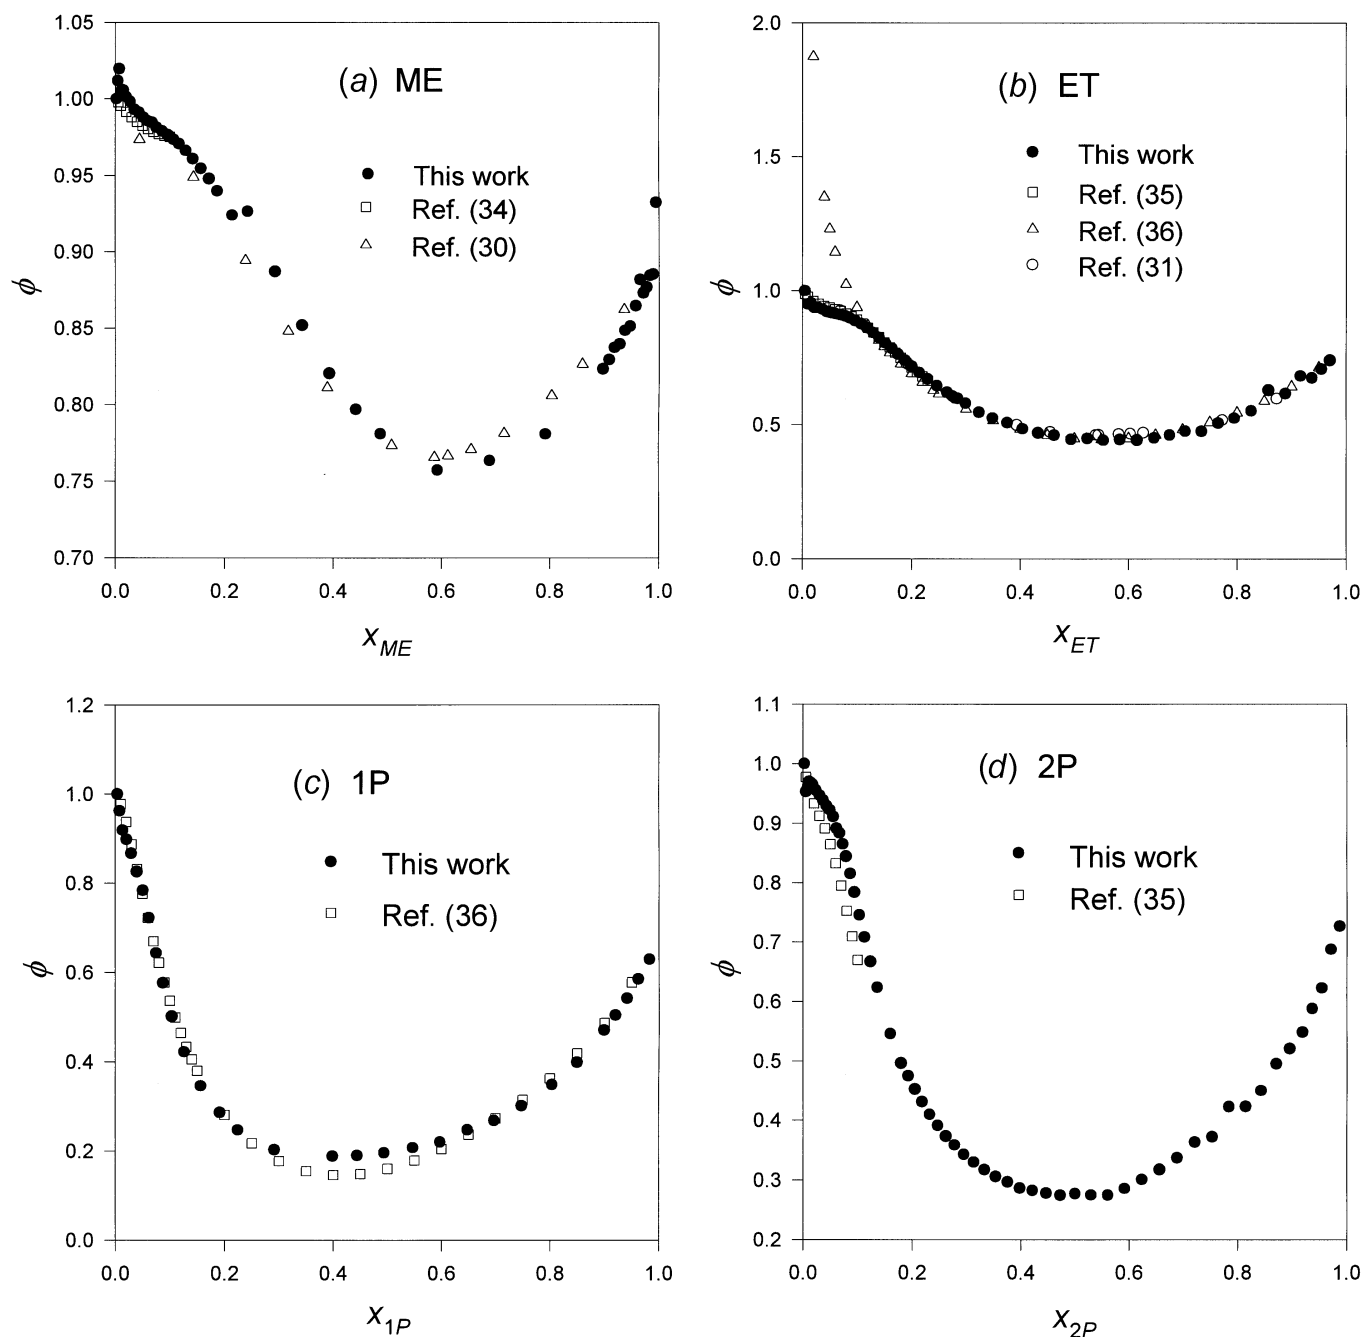
where g_n are the adjustable parameters. For ME–H_2O in the limited H_2O-rich region (34), the first three terms were used. For the entire compositional range, Fenby and co-workers used four terms for ME–H_2O (30) and five for ET–H_2O (31). The resulting data are also plotted in Figs. 2, 3, and 4*a*. As is evident from Figs. 1, 2, 3, 4*a*, and 4*b*, an almost negligible deviation in the *p*-data (Fig. 1) leads to a small but still negligible difference from our numerical results for the chemical potentials (Figs. 2 and 3). Some curve-fitting imperfections, however, appear more conspicuous in ϕ (Fig. 4*a*). In particular, the x_{ME}-dependence of ϕ with a three-term polynomial, as discussed by Christian et al. (34), shows an upwards trend of concavity, towards the upper data limit of the mole fraction. This may be a result of the cut-off effect of the fitted polynomial. Indeed, the authors themselves later cautioned against blindly curve fitting using polynomials (37). Figure 4*a* shows a small but systematic deviation in ϕ between our numerical analysis and a four-term curve fitting (31). This may suggest that the number of terms should be increased.

Hansen and Miller (36) determined the gas phase compositions for about 10 data points by analysis and, hence, determined the partial pressures directly for ET–H_2O and 1P–H_2O, at 25°C, over the entire compositional range. Unfortunately, these partial pressure data were not published. However, they fitted the following function relating to the excess chemical potential of ET, μ_{ET}^E/RT,

$$[8] \qquad \mu_{ET}^E/RT = (1 - x_{ET})^2 \{A + Bx_{ET} + C \exp(-Dx_{ET})\}$$

and the consistent equation for μ_W^E/RT. The resulting plots are shown in Figs. 2*a*, 3, and 4*b*. It is evident that eq. [8] is not satisfactory in the range $x_{ET} < 0.2$ in terms of ϕ (see Fig. 4*b*), while such an imperfection is not conspicuous in

±0.05 kJ mol⁻¹. The osmotic coefficients calculated using eq. [2] are plotted in Fig. 4. Figure 5 shows the concentration fluctuation, calculated using eq. [4], and $S_{XX}(0)$, as determined by SAXS. Since the scattering intensity for ME–H_2O is low, the uncertainty in $S_{XX}(0)$ is substantial, as shown in Fig. 5*a*. The literature vapour pressure data (30, 31, 34, 35) were analyzed using Barker's method. The following polynomial was assumed to represent the excess molar Gibbs energy, G_m^E, as,

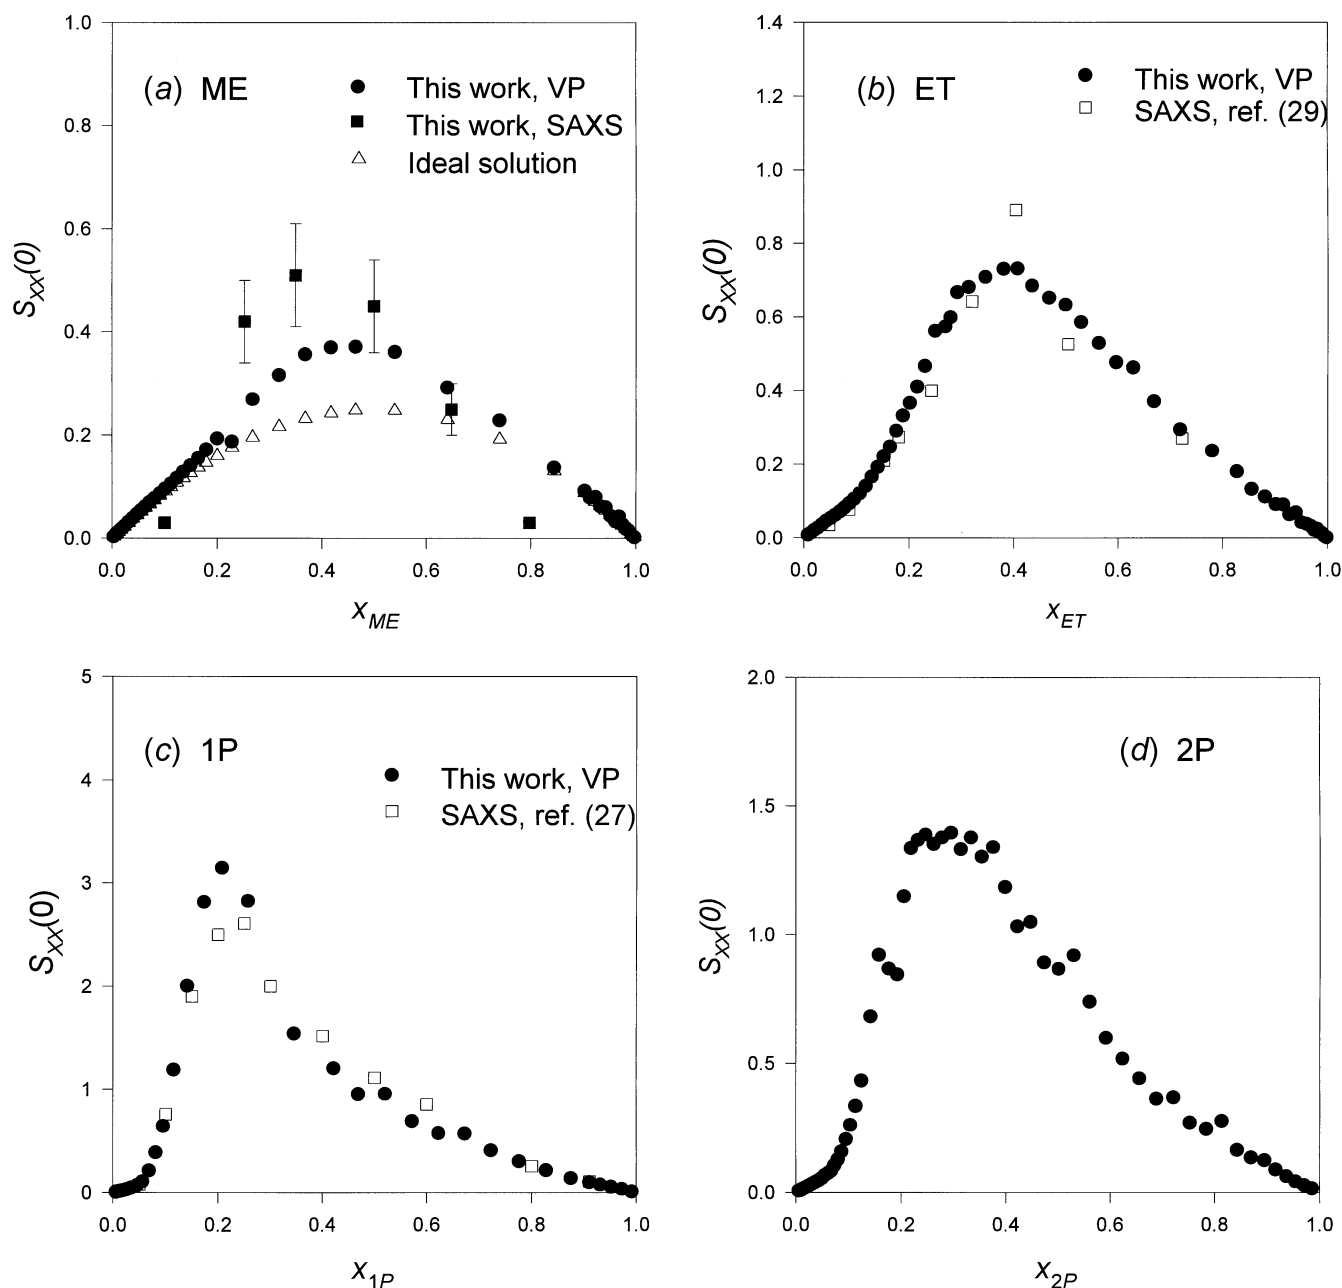
Fig. 4. (*a*) Osmotic coefficient of ME–H_2O at 25°C. Filled symbols, this work, numerically calculated. Hollow symbols, literature data by curve fitting; (*b*) osmotic coefficient of ET–H_2O at 25°C; (*c*) osmotic coefficient of 1P–H_2O at 25°C; (*d*) osmotic coefficient of 2P–H_2O at 25°C.


μ_{ET}^{E} or μ_{W}^{E} (see Figs. 2*a* and 3). The six-term polynomial, eq. [7], used by Nord et al. (35) and the five-term polynomial used by Phutela et al. (31) appear to be reasonable even for φ (see Fig. 4*b*). The general smoothness of $S_{XX}(0)$ calculated from our chemical potential data suggests that the raw data and the subsequent data analysis are reasonable.

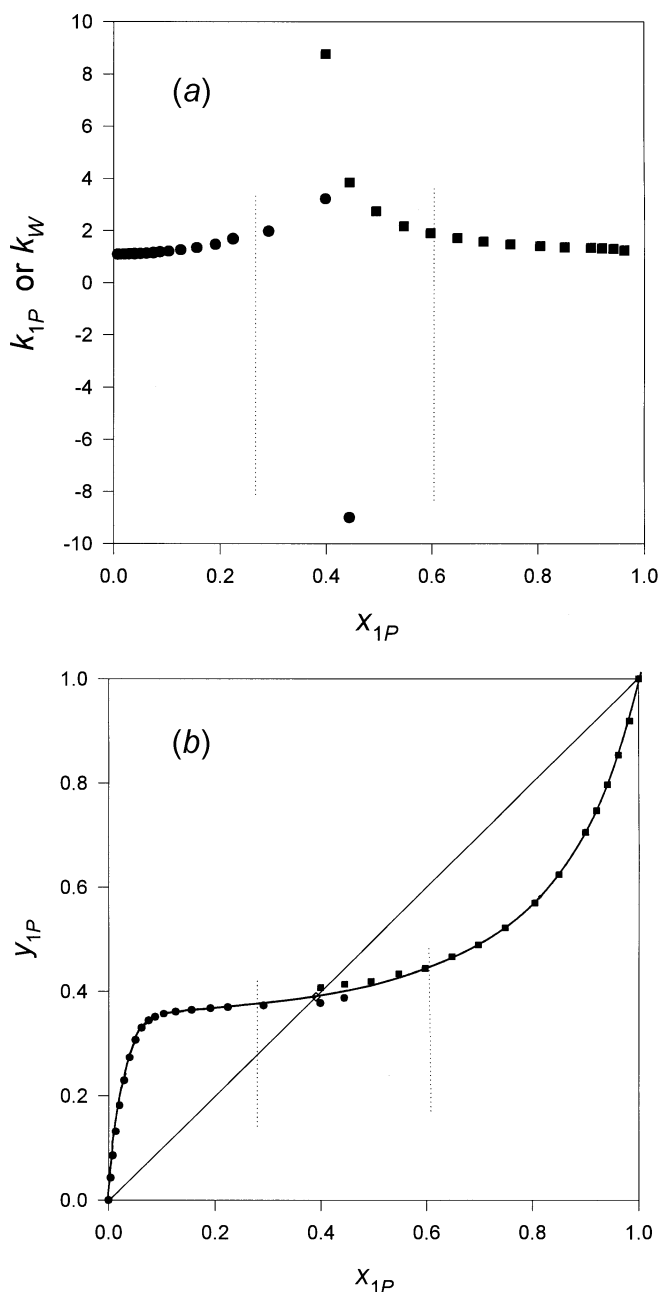
1-Propanol (1P) – H₂O system

The *p* vs. x_{1P} curve, Fig. 1, shows a rather flat plateau, and the position of the azeotrope is not immediately obvious. In

a review of azeotropic data (38), the azeotropic composition at 25°C is quoted as $x_{1P} = 0.3770$. The original data (39) consist of partial pressures determined by the transpiration method at the following compositions: 0.01, 0.02, 0.05, 0.1, 0.2, 0.4, 0.6, 0.8, 0.9, 0.95, and 1. Thus, the azeotropic data quoted above is not measured but is estimated using these rather widely-spaced data points. Here we present closely-spaced data points (Table IV), which indicate that the maximum in *p* appears to be at about $x_{1P} = 0.3987$. We determined the actual value to be 0.390 as described below. The

Fig. 5. (*a*) Concentration fluctuation in ME–H₂O at 25°C, calculated using vapour pressure (VP) and SAXS data; (*b*) concentration fluctuation in ET–H₂O at 25°C, calculated using vapour pressure (VP) and SAXS data; (*c*) concentration fluctuation in 1P–H₂O at 25°C, calculated using vapour pressure (VP) and SAXS data; (*d*) concentration fluctuation in 2P–H₂O at 25°C, calculated using vapour pressure (VP) data.


Boissonnas method was applied from both ends. The values of k_{1P} and k_W are plotted in Fig. 6a. In the range $0.3 < x_{1P} < 0.6$, near the azeotrope, k_{1P} and k_W are significantly larger than unity, and the resulting partial pressures would have some systematic errors. Figure 6b shows the plots of the gas-phase mole fraction, $y_{1P} = p_{1P}/p$, against x_{1P}. The data points in Fig. 6b are reliable except for the above region near the azeotrope. By the aid of a flexible ruler, the reliable portion of the data points were connected smoothly, as shown in the figure. The values of y_{1P} were read off the smooth, drawn curve and the values of p_{1P} were recalculated accordingly. The resulting data are listed in Table IV and plotted in Figs. 2, 3, 4c, and 5c. Comparison with $S_{XX}(0)$ data from the SAXS measurement (27) indicates that our re-adjusted y_{1P} data are acceptable. The uncertainty in this re-adjusted region is estimated to be, at most, twice that of the

Fig. 6. (*a*) Boissonnas coefficients, k_{1P} and k_W, for 1P–H$_2$O. See eq. [4] and text; (*b*) graphical method of solving partial pressure near azeotrope. See text.


normal uncertainty. From the point of intersection of the smooth curve drawn with the line of $y_{1P} = x_{1P}$ in Fig. 6*b*, we conclude that the azeotrope of 1P–H$_2$O at 25°C is at $x_{1P} = 0.390 \pm 0.005$. It is evident that the fitting function devised by Hansen and Miller (36),

[9] $\quad \mu_{1P}^E/RT = (1 - x_{1P})^2 \{Ax_{1P} + B \exp(-Cx_{1P})$

$\qquad\qquad\qquad\qquad + Dx_{1P} \exp(-Ex_{1P})\},$

seems reasonable even for ϕ (Fig. 4*c*).

2-Propanol (2P) – H$_2$O system

For 2P–H$_2$O, the analysis was identical to that for 1P–H$_2$O above. The azeotrope was found to be at $x_{2P} = 0.640 \pm 0.005$. An azeotropic data collection (38) gave $x_{2P} = 0.6650$, and 0.6700 for the azeotropic mole fraction. Both were estimated using data obtained by a dynamic method (33, 40). A dynamic method, while the partial pressures are determined directly, may be less advantageous for locating an azeotrope than the static method we have used here. Furthermore, we have two to three times more data points. The graphical re-adjustment was made in the region $0.58 < x_{2P} < 0.69$. Figure 5*d* shows the plots of $S_{XX}(0)$, and we conclude the connection around the azeotrope, $x_{2P} = 0.640$, is acceptably smooth. It is unfortunate that there are no compressibility data for 2P–H$_2$O in the literature and, hence, $S_{XX}(0)$ data cannot be calculated, although the zero-angle SAXS data are available (27). Small discrepancies (Fig. 1*d*) between Nord et al.'s *p*-data (35) and ours are not conspicuous in the chemical potentials (see Figs. 2*b* and 3), while the ϕ data show clear differences (see Fig. 4*d*).

Both 1B–H$_2$O and 1H–H$_2$O systems were analyzed from the AL-rich end to the respective phase separation boundary, $x_{1B} = 0.50$ and $x_{1H} = 0.54$. For both cases, the values of k_W were found to be from 1.0 to 1.3. The resulting data can be found in the respective tables and plotted in Figs. 2 and 3.

Thus, we have devised a way of circumventing the difficulty associated with the azeotrope when obtaining partial pressures by numerical methods, and we present here the model-free partial pressures data, obtained without resorting to any fitting function for aqueous mono-ols. We point out that various curve fitting attempts in the literature have had mixed success, as shown above, and there is no guarantee that a chosen function can account for the data over the entire compositional range. Instead, we have used a purely numerical method, circumventing the difficulties associated with azeotropes. These partial pressure data, except for the first few points at the dilute end, are correct and model-free. Thus, we now have various indications of nonideality of AL–H$_2$O systems in terms of chemical potentials (first derivatives of G), osmotic coefficients (calculated using μ_W^E), and concentration fluctuations (second derivative of G). The fact that μ_{AL}^E and μ_W^E stay positive and, hence, ϕ is less than 1 indicates that AL–H$_2$O is an unfavorable mixture and tends to separate. Indeed, the fact that the concentration fluctuation, $S_{XX}(0)$, is positive and shows a maximum is a reflection of this tendency. In the event that $S_{XX}(0)$ becomes infinity, phase separation occurs. The positive values of μ_{AL}^E or μ_W^E seem generally to increase in the order of increasing size of the hydrophobic moiety (Figs. 2 and 3). This suggests that the predominant effect of AL on solution properties arises from its hydrophobicity, at least for the alcohols studied here. Table 2 summarizes this evidence. With the additional data relating to TBA (10) and BE (4) in Table 2, the order of the effect of AL on H$_2$O (and particularly the effect of H$_2$O on AL) cannot be rationalized simply with respect to the hydrophobicity of AL (see column ranking in Table 2). As mentioned in the discussion of the data analysis, although the chemical potentials show the net effect, the detailed molecular mechanism is not very apparent in their behaviour, owing to entropy–enthalpy compensation, prevalent particularly in aqueous solutions (20). Thus, an elucidation of these

details requires further data of partial molar enthalpies and entropies and perhaps even higher order derivatives of G.

In a subsequent paper, we will calculate the excess partial molar entropy of AL, S_{AL}^E, using the present μ_{AL}^E data and previously-determined H_{AL}^E data (3). By the aid of S_{AL}^E data, we will make an attempt at confirming or adding to the mixing schemes mentioned above in the Introduction section, particularly for the W-rich region. In the W-rich region, the absolute values of H_{AL}^E and S_{AL}^E are much larger and their changes are much sharper than in the AL-rich region, where they are small, almost zero. Hence, to study the mixing schemes operating in the AL-rich region in more detail, it is advantageous to determine H_W^E and S_W^E data and learn from their compositional dependence. We have just started determining the excess partial molar enthalpies of H_2O, H_W^E, in the AL-rich regions of aqueous mono-ols. In the event of the completion of these determinations, we can then calculate the excess partial molar entropies of H_2O, S_W^E. These, together with other second derivative quantities, excess partial molar volumes, heat capacities, compressibilities, and thermal expansivities, we plan to study the details of for mixing schemes in the AL-rich region.

Excess partial molar entropy of alkane-mono-ols in aqueous solutions at 25°C

Yoshikata Koga, Peter Westh, and Keiko Nishikawa

Abstract: In the preceding paper, we reported the values of model-free chemical potentials for aqueous methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, and 1-hexanol at 25°C over the entire compositional region. Using alcohol excess partial molar enthalpies, H_{AL}^E, determined earlier in this laboratory (Can. J. Chem. **74**, 713 (1996)), we have calculated excess partial molar entropies for the alcohols, S_{AL}^E, where AL stands for an alcohol. We then calculated, numerically, the entropic interaction, $S_{AL-AL}^E = N(\partial S_{AL}^E/\partial n_{AL})_{p,T,n_W}$, where n_{AL} is the amount of AL, n_W is the amount of H_2O, and N is the total amount of solution. S_{AL-AL}^E signifies the effect of addition of AL upon the entropic situation of existing AL in solution. Using these quantities, the mixing schemes in aqueous alcohols have been studied. The earlier conclusions, which used H_{AL}^E and H_{AL-AL}^E alone, are confirmed. Furthermore, the order of the relative hydrophobic nature of alcohols is established from the behaviour of S_{AL-AL}^E and of H_{AL-AL}^E as methanol < ethanol < 2-propanol < 1-propanol.

Key Words: aqueous alcohols, excess partial molar entropies, entropic interaction mixing schemes, hydrophobicity ranking.

Résumé : Dans le travail précédent, on a rapporté des valeurs de potentiels chimiques qui ne dépendant d'aucun modèle pour des mélanges binaires aqueux de méthanol, d'éthanol, de propan-1-ol, de propan-2-ol, de butan-1-ol et d'hexan-1-ol, à 25°C, sur l'ensemble des plages de composition. Utilisant les enthalpies molaires partielles en excès de l'alcool, H_{AL}^E, déterminées antérieurement (Can. J. Chem. **74**, 713 (1996)) dans ce laboratoire, on a calculé les entropies molaires partielles en excès des alcools, S_{AL}^E, où AL représente un alcool. On a par la suite calculé d'une façon numérique l'interaction entropique $S_{AL-AL}^E = N(\partial S_{AL}^E/\partial n_{AL})_{p,T,n_W}$ où n_{AL} = quantité d'alcool, n_W = quantité d'eau et N = quantité totale de solution. La valeur de S_{AL-AL}^E définie plus haut correspond à l'effet d'une addition d'alcool sur la situation entropique réelle d'alcool existant en solution. Utilisant ces quantités, on a étudié les schémas de mélange dans alcools en solutions aqueuses. Les conclusions auxquelles on était arrivé antérieurement en se basant uniquement sur des valeurs de H_{AL}^E et H_{AL-AL}^E sont confirmées. De plus, sur la base des valeurs de S_{AL-AL}^E et de H_{AL-AL}^E, on a établi que l'ordre de l'hydrophobicité relative des alcools est méthanol < éthanol < propan-2-ol < propan-1-ol.

Mots clés : alcools en solutions aqueuses, entropies molaires partielles en excès, entropie d'interaction, schémas de mélange, valeurs relatives d'hydrophobicité.

[Traduit par la Rédaction]

Introduction

In the preceding paper (1), called paper I hereinafter, we have reported the excess chemical potentials of alcohols (abbreviated as AL), μ_{AL}^E, and those of water, μ_W^E, for aqueous solutions at 25°C. They were calculated from total vapour pressure data without resorting to any fitting function. In another earlier paper (2), called paper II, we directly determined alcohol excess partial molar enthalpies, H_{AL}^E, at 25°C. Thus, we can now calculate model-free alcohol excess partial molar entropies, S_{AL}^E, purely experimentally. H_{AL}^E and S_{AL}^E are the second derivatives of G. S_{AL}^E, for example, is

$$[1] \qquad S_{AL}^E = (\partial S^E/\partial n_{AL}) = -\{\partial^2 G/(\partial T\, \partial n_{AL})\},$$

where n_{AL} is the number of moles of AL in the aqueous solution. In this paper, partial differentiation is understood as being performed by keeping other variables constant. Equation [1] implies that S_{AL}^E is the response of the entire system in terms of excess entropy when n_{AL} alone is perturbed. Hence, it signifies the actual contribution of alcohol towards S^E of the system or the actual entropic situation of AL in the solution. If we have accurate S_{AL}^E data in small increments in composition, as is the present case, then the following derivative can be calculated to within an uncertainty of several %:

$$[2] \qquad S_{AL-AL}^E \equiv N(\partial S_{AL}^E/\partial n_{AL})$$
$$= (1 - x_{AL})\, (\partial S_{AL}^E/\partial x_{AL}),$$

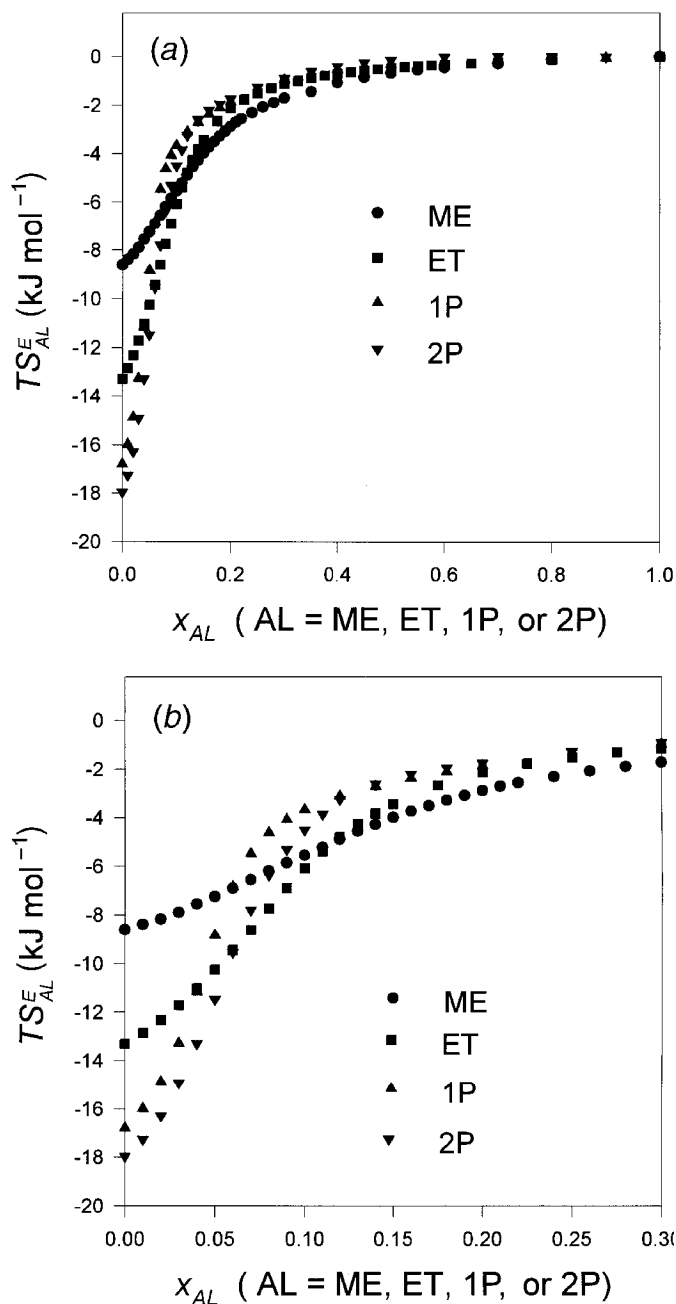
where x_{AL} is the mole fraction of AL and N is the total number of moles of the solution. The last derivative of eq. [2] is, in practice, calculated as $(\delta S^E_{AL}/\delta x_{AL})$, where δ represents the difference in the values of two data points taken from the smooth curve drawn through all the data points by the aid of a flexible ruler. The issue of an appropriate size of δx_{AL} was dealt with earlier in detail (3) and led us to choose $\delta x_{AL} = 0.01$ for this paper. The physical meaning of S^E_{AL-AL}, eq. [2], is the effect of the addition of an infinitesimal amount of AL on the actual entropic situation of alcohol in the solution. Thus, we define S^E_{AL-AL} as the entropic interaction between AL molecules in the system (4, 5). In paper II (2), the enthalpy analogs of eqs. [1] and [2], H^E_{AL} and H^E_{AL-AL}, were used to study the mixing schemes in aqueous alcohol solutions, and some findings were briefly summarized in the Introduction of paper I (1). In this paper, we add information provided by the x_{AL}-dependences of S^E_{AL} and S^E_{AL-AL} and examine if any additional or clearer pictures emerge from them. We direct our attention mainly to methanol (ME), ethanol (ET), 1-propanol (1P), and 2-propanol (2P).

Results and discussion

Table I, deposited at CISTI,[2] lists smoothed values of μ^E_{AL} from paper I (1) and H^E_{AL} values from paper II (2) for AL = ME, ET, 1P, or 2P, from which TS^E_{AL} were calculated and also listed in Table I. Figure 1 shows the plots of TS^E_{AL} thus calculated. As for H^E_{AL}, the plots of TS^E_{AL} exhibit a sharp x_{AL}-dependence in the H_2O-rich region. In the AL-rich region, on the other hand, TS^E_{AL} is almost zero and almost independent of composition. This immediately suggests that there are at least two compositional regions, in each of which the thermodynamic behaviour and, hence, the mixing scheme are different. Whether there is an intermediate region, as for 2-butoxyethanol (BE)–H_2O (4–8), is not so obvious from H^E_{AL} and S^E_{AL} data alone. The existence of the intermediate region for other AL–H_2O systems becomes evident when we calculate S^E_{AL-AL} data, as shown below.

In the alcohol-rich region, the fact that the values of S^E_{AL} and H^E_{AL} (2) are almost zero suggests that the thermodynamic situation of the alcohol in solution is very close to that of the pure alcohol. It is likely that alcohol molecules cluster together in almost the same manner as in the pure state. This is consistent with structural studies conducted using neutron scattering (9–11). Dixit et al. (9) claim that cluster formation occurs over the entire compositional range and, hence, cast doubt on the classical picture of "iceberg formation". Their detailed neutron-scattering study was performed at the ME-rich region, at $x_{ME} = 0.7$. As shown below, this composition falls in the region of mixing scheme III. We stress that Fig. 1 and the H^E_{AL} data in paper II (2) indicate that the mixing scheme operating in the H_2O-rich region, mixing scheme I, must be qualitatively different from that of the alcohol-rich region.

Table 1 lists the values of TS^E_{AL} at infinite dilution together with the values of H^E_{AL} from paper II (2). Thus, an alcohol molecule breaks away from its pure state and is dissolved into pure H_2O with a large enthalpy gain (–7 to

Fig. 1. Excess partial molar entropy of the alcohol multiplied by the temperature at 25°C (TS^E_{AL}).


–17 kJ mol^{-1}) and a larger entropy loss (–9 to –26 kJ mol^{-1}). This is consistent with the enhancement of the hydrogen bond network of H_2O in the vicinity of solute molecules, i.e., "iceberg formation". Figure 1 also indicates that in the H_2O-rich region, the sharpness of the x_{AL}-dependence seems to increase roughly with the increasing order of the alkyl group size. This hints that the predominant cause of thermodynamic behaviour in this range is the effect of the hydrophobic alkyl group. The sharpness of the x_{AL}-dependence is much more accurately represented in the interaction S^E_{AL-AL}.

Table 1. The values of TS_{AL}^E and H_{AL}^E at infinite dilution.

Alcohol	Abbreviation	H_{AL}^E at $x_{AL} = 0$ (kJ mol^{-1})	TS_{AL}^E at $x_{AL} = 0$ (kJ mol^{-1})

Fig. 2. AL–AL entropic interaction multiplied by the temperature at 25°C (TS_{AL-AL}^E).

Fig. 3. ME–ME entropic interaction multiplied by the temperature at 25°C (TS_{ME-ME}^E).
Using the smoothed data in Table I, we have calculated the entropic interaction, TS_{AL-AL}^E (eq. [2]), with $\delta x_{AL} = 0.01$. The results are plotted in Figs. 2–6. It is striking that the x_{AL}-dependences are all similar to each other among the different alcohols, except for the varying scales. This suggests, again, that all the alcohol–water systems studied here share the same thermodynamic behaviour. Furthermore, the x_{AL}-dependences of TS_{AL-AL}^E are also similar to those of H_{AL-AL}^E shown in paper II (2). This is a direct consequence of entropy–enthalpy compensation (14). Following the same argument as in paper II (2), we recognize the regions of mixing schemes I, II, and III, as indicated in the figures. The transition from mixing scheme I to II starts at point X and ends at Y. Table 2 summarizes the loci of these points observed from the behaviour of TS_{AL-AL}^E. In Table 3, corresponding points observed by H_{AL-AL}^E from paper II (2) are shown. The sharpness of the x_{AL}-dependence in the H$_2$O-rich region is reflected in the maximum value of TS_{AL-AL}^E and the loci of points X and Y. The sharper the dependence, the larger the maximum value and the smaller the loci of X

Table 2. The maximum values of TS_{AL-AL}^E and the loci of mixing scheme boundaries.

and Y. In terms of these quantities given in Tables 2 and 3, the strength of the effect of alcohol on H$_2$O is in the order of ME < ET < 2P < 1P < TBA < BE. We suggest that this provides a measure of the hydrophobicity of the mono-ols. It is puzzling, however, that the values of TS_{AL}^E and H_{AL}^E at infinite

dilution (see Table 1) do not follow the same order. In particular, the order of 1-propanol and 2-propanol is reversed, in terms of information given in Table 1. The values of TS^E_{AL} and H^E_{AL} at infinite dilution is associated with the process of an alcohol molecule (or an appropriate cluster thereof) breaking away from its pure environment and mixing into bulk H_2O. The latter process may be broken down into: (*a*) creating a cavity of the size of the alcohol molecule in bulk H_2O and (*b*) allowing the surrounding H_2O molecules to relax into its final form of "iceberg structure" with a concomitant reduction of the hydrogen-bond probability of bulk H_2O away from the solute. Both processes (*a*) and (*b*) are associated with an order-of-magnitude larger absolute value of entropy and enthalpy changes with opposite signs, resulting in the net values of TS^E_{AL} and H^E_{AL} of the order of −7 to −30 kJ mol^{-1}. A subtle alcohol-specific difference in either process could bring about a few kJ mol^{-1} difference in the resulting values of TS^E_{AL} and (or) H^E_{AL}, which is sufficient to change the order of apparent hydrophobicity. Furthermore, we generally note that the thermodynamic information contained in the higher-order derivative of G is more detailed (4, 5). Thus, at this point, the most reliable ranking of the effect of alcohol on H_2O, derived here from TS^E_{AL-AL} and H^E_{AL-AL}, is ME < ET < 2P < 1P < TBA < BE. This seems reasonable considering the amount of nonpolar surface area for these six alcohols.

As mentioned above, S^E_{AL} is the second derivative and S^E_{AL-AL} is the third derivative of G. Another second derivative of G is the excess partial molar volume, V^E_{AL}:

Fig. 7. Excess partial molar volumes of AL and H_2O (V_{AL}^E and V_W^E, respectively) at 25°C, calculated using the density data from refs. (19) and (20).

Fig. 8. AL–AL volumetric interaction (V_{AL-AL}^E) at 25°C, calculated using the data from refs. (19) and (20).
[3] $V_{AL}^E = (\partial V^E/\partial n_{AL}) = \{\partial^2 G/(\partial p \partial n_{AL})\}$

In analogy with eq. [2], we define (4, 5) the volumetric interaction, V_{AL-AL}^E, as

[4] $V_{AL-AL}^E \equiv N(\partial V_{AL}^E/\partial n_{AL})$
$$= (1 - x_{AL})(\partial V_{AL}^E/\partial x_{AL}).$$

Figure 7 shows V_{AL}^E values calculated graphically using literature density data at 25°C (15, 16). The initial decrease in V_{AL}^E, as x_{AL} increases from infinite dilution, was earlier attributed to being one of the signatures of mixing scheme I (4, 5). Equivalently, the excess partial molar volume of H_2O, V_W^E, initially increases, owing to the Gibbs–Duhem relation, as is evident in Fig. 7. This is a reflection of "iceberg formation". Moreover, V_{AL}^E at infinite dilution is determined by the size difference between the alcohol and water molecules (sand-and-pebble analogy) and the characteristic bulkiness of liquid H_2O due to the hydrogen-bond network. The size-difference effect alone gives a negative value of V_{AL}^E, while the latter effect has a positive contribution, resulting in the net value of V_{AL}^E at infinite dilution. As x_{AL} increases, the latter contribution decreases because of the reduction of the hydrogen-bond probability of bulk H_2O away from an "iceberg"-clad solute, while the former is basically independent of x_{AL}. As a result, the value of V_{AL}^E decreases; or, rather, the fact that V_{AL}^E shows the characteristic initial decrease was used as evidence for the reduction of the hydrogen-bond probability of bulk H_2O away from solute. We point out that this initial decrease is also clearly evident for ME–H_2O. Thus, there must be a hydrophobic effect operating in this system that is different from the mixing scheme operating in the AL-rich region.

Figure 8 shows the third derivative quantity, V_{AL-AL}^E (see eqs. [3] and [4]). These quantities also show anomalous be-

haviour near the mixing scheme boundary between I and II. To obtain V_{AL-AL}^E, two consecutive graphical differentiations of the raw density data were required. Hence, the precision of V_{AL-AL}^E data is poorer than that for the S_{AL-AL}^E and H_{AL-AL}^E data. Thus, we did not attempt to locate points X and Y. Nevertheless, Fig. 8 shows that the maximum value of V_{AL-AL}^E evidently increases in the order ME < ET < 2P < 1P, consistent with the order observed for H_{AL-AL}^E and S_{AL-AL}^E. Our earlier measurements of the density of 2-butoxyethanol (BE) – H_2O was performed for the purpose of evaluating V_{AL-AL}^E by two successive graphical differentiations. We therefore determined about 200 densities in the range $0 < x_{BE} < 0.04$. V_{BE-BE}^E thus obtained showed anomalous behaviour at exactly the same locus as H_{AL-AL}^E, S_{AL-AL}^E, and other third derivative quantities (4–8, 17–20). This fact was used as supporting evidence for the existence of the transition between mixing schemes I and II in BE–H_2O mixtures.
Kozak et al. (21) have suggested the same ranking for the first four alcohols, ME < ET < 2P < 1P, using the virial coefficients, B, in the expansion of the logarithm of the activity coefficient of the solvent W, γ_W (see eq. [5]). However, TBA does not follow this trend, even though TBA is more hydrophobic than 1P (See Table 1 in ref. (21)). The logarithm of γ_W is written as

[5] $\ln\gamma_W \equiv \mu_W^E/RT = Bx_{AL}^2 + Cx_{AL}^3 + \ldots$

It follows from the Gibbs–Duhem relation that

[6] $(\partial\mu_W^E/\partial n_{AL}) = -2RTB(1 - x_{AL})^2 + \ldots.$

Thus, the use of B is equivalent to using $(\partial\mu_W^E/\partial n_{AL})$ at infinite dilution rather than the entropic interaction S_{AL-AL}^E (eq. [2]). Due to the entropy–enthalpy compensation (14), sharp changes in the entropic and the enthalpic interactions, S_{AL-AL}^E and H_{AL-AL}^E, are compensated by each other, and as

a result the changes in $(\partial\mu_W^E/\partial n_{AL})$ usually becomes less conspicuous. Thus, it is more advantageous to use S_{AL-AL}^E and H_{AL-AL}^E than $(\partial\mu_W^E/\partial n_{AL})$ or its equivalent B in contrasting the propensities of the hydrophobic moieties.

Determination of the boundary between mixing schemes II and III using H_{AL-AL}^E and S_{AL-AL}^E data is problematic, as is evident in Table 2 and 3 and Figs. 3–6. This is due to shallow intersections between two curves of TS_{AL-AL}^E (and H_{AL-AL}^E) against x_{AL}. Furthermore, the values of H_{AL}^E and S_{AL}^E themselves are small, and subtle changes in curvature are not very conspicuous. To locate the boundary between mixing schemes II and III and, further, to study subtle differences in mixing scheme III among individual alcohols, data are needed for the excess partial molar enthalpy and entropy of H_2O, H_W^E, and S_W^E in the alcohol-rich region. In this region the absolute values of H_W^E and S_W^E are expected to be larger than those of H_{AL}^E and S_{AL}^E and, hence, their x_{AL}-dependences should be more conspicuous.

A new method for the preparation of peroxymonophosphoric acid

Tian Zhu, Hou-min Chang, and John F. Kadla

Abstract: A new method for the preparation of peroxymonophosphoric acid (H_3PO_5) has been developed. It utilizes a biphasic solution to moderate the vigorous reaction between phosphorous pentoxide (P_2O_5) and hydrogen peroxide (H_2O_2). P_2O_5 is suspended in carbon tetrachloride (CCl_4), and concentrated H_2O_2 is slowly added while being vigorously stirred at low temperature. Careful control of the reaction temperature through the slow addition of H_2O_2 is critical. Using typical preparation conditions (P_2O_5:H_2O_2 = 0.5:1, H_2O_2 70 wt %, 2°C, 120–180 min), ~70% of the H_2O_2 is effectively converted to H_3PO_5. Increasing the concentration of H_2O_2, as well as the mole ratio of P_2O_5:H_2O_2, leads to an even higher % conversion of H_2O_2 to H_3PO_5. The addition of glacial acetic acid to the P_2O_5:H_2O_2 suspension at the end of the 120–180 min reaction (P_2O_5:H_2O_2:CH_3COOH = 0.5:1:0.3) leads to the formation of peracetic acid in addition to H_3PO_5, and to an overall increase in the conversion ratio of total peroxy acids based on H_2O_2 (>95%).

Key words: peroxymonophosphoric acid, synthesis, stability, conversion ratio.

Résumé : On a mis au point une nouvelle méthode de préparation de l'acide peroxymonophosphorique (H_3PO_5). Elle fait appel à une solution biphasique pour modérer la réaction vigoureuse du pentoxyde de phosphore (P_2O_5) et du peroxyde d'hydrogène (H_2O_2). Le P_2O_5 est mis en suspension dans le tétrachlorure de carbone (CCl_4) et le H_2O_2 est ajouté lentement à basse température sous agitation vigoureuse. Il est critique de bien contrôlé la température de la réaction par une addition lente du H_2O_2. Utilisant des conditions de préparation typiques (P_2O_5:H_2O_2 = 0,5:1; H_2O_2 à 70% en poids; à 2°C; 120–180 min), environ 70% du H_2O_2 est effectivement converti en H_3PO_5. Une augmentation de la concentration du H_2O_2 ainsi qu'une augmentation du rapport molaire P_2O_5:H_2O_2 conduit à des pourcentages encore plus élevés de conversion du H_2O_2 en H_3PO_5. L'addition d'acide acétique glacial à la suspension de P_2O_5:H_2O_2 à la fin de la réaction de 120 à 180 min ((P_2O_5:H_2O_2:CH_3COOH = 0,5:1:0,3) conduit à la formation d'acide peracétique en plus du H_3PO_5 et à une augmentation globale du rapport de conversion globale en peroxyacides par rapport à la quantité de H_2O_2 utilisée (>95%).

Mots clés : acide peroxymonophosphorique, synthèse, stabilité, rapport de conversion.

[Traduit par la Rédaction]

Introduction

Peroxy acids are widely used, versatile oxidizing agents. The mechanisms of reactions involving peroxy acids have been extensively studied by a variety of techniques and have provided a fundamental understanding of autoxidation and other reactions involving peroxygen compounds (1,2). In spite of their importance as oxidants, the number of peroxy acids available for organic synthesis and oxidation chemistry is rather limited: peroxy formic acid and peroxy trifluoroacetic acid are formed readily in situ from hydrogen peroxide and the corresponding acid, whereas peracetic acid, *m*-chloro-peroxy benzoic acid (MCPBA), and the potassium salt of peroxymonosulfuric acid (OXONE®) are commercially available products.

T. Zhu, H.-m. Chang, and J.F. Kadla.[1] College of Natural Resources, North Carolina State University, Raleigh, NC 27695–8005, U.S.A.

[1]Corresponding author (e-mail: jfkadla@ncsu.edu).

In addition to peroxymonosulfuric acid, several other inorganic peroxy acids have been utilized in oxidation reactions, e.g., pernitric acid (3) and peroxymonophosphoric acid (4–8). Peroxymonophosphoric acid was first prepared in 1910 by Schmidlin and Massini according to the following reaction (eq. [1]) (9):

$$[1] \quad P_2O_5 + 2\ H_2O_2 + H_2O \longrightarrow 2\ H_3PO_5$$
However, the reaction was extremely vigorous, generating a large amount of heat, which rapidly decomposed the peroxy acid. As a result, only a small amount of peroxy acid could be obtained by this method. Subsequently, in 1937, Toennies tried to moderate the vigorous reaction by introducing acetonitrile as an "inert diluent", and claimed to obtain relatively stable solutions containing 51% peroxy acid at –11°C (10). However, problems concerning reproducibility exist, as hydrogen peroxide and peroxy acids are known to hydrolyze acetonitrile (eq. [2]) (11, 12).

$$[2] \quad CH_3CN + H_2O_2 \longrightarrow [(CH_3C(NH)O_2H]$$
$$\longrightarrow CH_3CONH_2 + [O]$$
As a result, the most widely used method for preparing H_3PO_5 is the hydrolysis of potassium or lithium

peroxodiphosphate in a strong acid solution such as $HClO_4$ (eq. [3]) (13).

[3] $P_2O_8^{4-} + H_2O \xrightarrow{HClO_4} H_3PO_5 + H_3PO_4$
Unfortunately, the extreme reagents, combined with the high costs and the low peroxy acid yields have hindered its utilization in large-scale commercial applications. Several other methods for preparing H_3PO_5 have been utilized and include electrolysis of solutions of phosphates (14), as well as the reaction of $H_4P_2O_7$ with hydrogen peroxide (15). However, none of these methods gave reasonable yields of H_3PO_5. In this study we report a novel method for the preparation of H_3PO_5 in high yields.

Experimental

Materials

Phosphorous pentoxide (ACS reagent grade), carbon tetrachloride (ACS reagent grade), ceric sulfate (0.25 N), sodium thiosulfate (0.1 N), potassium iodide (1.0 N), Ferroin (1,10-phenanthroline ferrous sulfate), sulfuric acid (ACS reagent grade), and glacial acetic acid were purchased from Aldrich Chemicals and used as received. Hydrogen peroxide (70% and 90%) was obtained from FMC Corporation (Tonamanda, N.Y.). DTPA (diethylenetriaminepentaacetic acid) and DTMPA (diethylenetriaminepentamethylene phosphonic acid) were gifts from Buchman Chemicals Inc. All solutions were prepared in deionized water.

H_3PO_5 synthesis

In the preparation of H_3PO_5, P_2O_5 (17.0 g, 0.061 mole) was suspended in CCl_4 (10 mL), and the suspension was cooled in an ice bath to a temperature of ~2°C while being vigorously stirred. Aqueous hydrogen peroxide (0.121 mole, 5 mL of 70 wt %) was then added dropwise to the suspension, while the reaction temperature was carefully monitored. CAUTION: the addition rate of H_2O_2 must be carefully controlled to maintain the reaction temperature below 5°C. If the addition of H_2O_2 is too fast, the reaction is too vigorous and a violent exotherm can occur. However, if the addition of H_2O_2 is too slow, the P_2O_5 powder will tend to form larger aggregate particles, which are slow to react with the H_2O_2 and result in the accumulation of H_2O_2, and a potentially violent reaction can occur. Therefore, careful monitoring of the temperature while adding H_2O_2 at a sufficient rate to minimize P_2O_5 aggregation is required. Upon complete addition of H_2O_2 the biphasic reaction system was further stirred, for up to 3 h, to maximize peroxy acid yield (Fig. 1); prolonged mixing can lead to decreased H_3PO_5 yields. The aqueous phase was separated and the CCl_4 layer was extracted 2–3 times with deionized water (5 mL) to extract the H_3PO_5 along with phosphoric acid and hydrogen peroxide. The aqueous solutions were combined and the concentration of H_3PO_5 and H_2O_2 were determined by chemical methods. Accordingly, a sample of the reaction mixture (0.2 mL) was acidified with H_2SO_4 (200 mL, 1 N H_2SO_4) and cooled in an ice bath to permit titration within a temperature range of 0–10°C. Three drops of Ferroin solution was added, and the mixture was titrated with 0.1 N ceric sulfate until the disappearance of the salmon color. KI (5 mL, 1.0 N KI) was added, and the iodine liberated was ti-

Fig. 1. The effect of reaction time on % conversion of H_2O_2 to H_3PO_5 (P_2O_5:H_2O_2 = 0.5:1, 70 wt % H_2O_2, 2°C).
trated with sodium thiosulfate (0.1 N) to a starch end point. The amount (%) of peroxy acid and hydrogen peroxide was calculated according to eqs. [4] and [5], respectively.

[4]   % peroxy acid =

$$\frac{mL\ Na_2S_2O_3 \times 0.1N \times 0.038 \times 100}{sample\ weight}$$

[5]   % hydrogen peroxide =

$$\frac{mL\ Ce(SO_4)_2 \times 0.1N \times 0.017 \times 100}{sample\ weight}$$

Results and discussion

Analogous to the work of Toennies (10), we have focused on moderating the reaction between H_2O_2 and P_2O_5 (eq. [1]). To avoid some of the problems associated with acetonitrile, we have chosen an inert solvent, CCl_4, which unlike acetonitrile is inert to most oxidants, and neither P_2O_5 nor H_2O_2 are soluble in it.

In a typical preparation, the reaction mixture was mixed for no longer than 3 h to maximize peroxy acid yield (Fig. 1). Careful control of the reaction system is required, as longer reaction times result in lower yields of H_3PO_5 because of the slow reaction between H_3PO_5 and H_2O_2 (eq. [6]).

[6] $H_3PO_5 + H_2O_2 \longrightarrow H_3PO_4 + H_2O + O_2$
By controlling the volume of CCl_4, the stirring speed, and the rate of the addition of hydrogen peroxide, approximately 70% of H_2O_2 was converted to H_3PO_5 at a mole ratio P_2O_5:H_2O_2 = 0.5:1. To the best of our knowledge such a high conversion ratio has never been reported.

Effect of P_2O_5:H_2O_2 on the preparation of H_3PO_5

The conversion ratio of H_3PO_5 based on H_2O_2 can be increased by increasing the mole ratio of P_2O_5:H_2O_2 (Fig. 2). When the mole ratio of P_2O_5:H_2O_2 is greater than 0.9, 100% conversion was achieved.

Effect of H_2O_2 concentration

The effect of H_2O_2 concentration on the preparation of H_3PO_5 is shown in Fig. 3. As expected, the concentration of H_2O_2 had a dramatic influence on the generation of H_3PO_5. Increasing the peroxide concentration decreases the amount

Fig. 2. Effect of increasing $P_2O_5:H_2O_2$ on the conversion of H_2O_2 to H_3PO_5 (70 wt % H_2O_2, 2°C, 120 min).
Fig. 3. Effect of H_2O_2 concentration on the conversion of H_2O_2 to H_3PO_5 ($P_2O_5:H_2O_2 = 0.5:1$, 2°C, 120 min).

Fig. 4. Effect of temperature on H_3PO_5 stability: ◆ 50°C, ■ 70°C, ▲ 90°C. Initial $[H_3PO_5] = 0.100$ M, $[H_2O_2] = 0.0$ M, pH = 1.02.
of water available for the hydrolysis of P_2O_5 (eq. [7]). As a result, a higher percent of the H_2O_2 is converted into H_3PO_5. As can be seen from Fig. 3, 90 wt % H_2O_2 gave quantitative conversion. However, concerns exist regarding the safe handling of such highly concentrated H_2O_2 solutions. Therefore, the 70 wt % H_2O_2, which gave satisfactory results (>70% conversion), is a good compromise between H_2O_2 conversion and safe handling.

[7] $P_2O_3 + 3H_2O \longrightarrow 2H_3PO_4$

H_3PO_5 stability

To further characterize the peroxy acid synthesis, the stability of the respective peroxides was determined during the reaction process. Five reactions were conducted ($P_2O_5:H_2O_2$ (0.5:1), 2°C, 180 min), and the total peroxide species present was determined. Analysis of the aqueous solution, which contained H_3PO_5, H_2O_2, and H_3PO_4, showed a total peroxide concentration of 98.2 ± 0.5%. In fact, after 30 days of refrigeration (~5°C), more than 95% of the H_3PO_5 remained. Thus, any decomposition of the peroxide species during the preparation protocol or storage at low temperature is negligible. This remarkable stability provides the possibility that H_3PO_5 may not need to be generated on site when it is utilized in commercial processes.

The thermal stability at higher temperatures was also investigated. Figure 4 shows the effect of increasing temperature on H_3PO_5 stability. As expected, increasing the temperature from 50 to 90°C resulted in a dramatic decrease in H_3PO_5 stability. At 90°C more than 90% of the peroxy acid was decomposed within 120 min.

The decrease in H_3PO_5 concentration may be attributed to several factors, e.g., thermal- and (or) metal-catalyzed decomposition or aqueous hydrolysis. It is known that under acidic conditions in the presence of water peroxy acid hydrolysis takes place according to the equilibrium reaction present in eq. [8] (2).

[8] $H_3PO_5 + H_2O \longrightarrow H_3PO_4 + H_2O_2$
The hydrolysis of H_3PO_5 would result in the corresponding liberation of H_2O_2 and H_3PO_4. During the thermal treatments we monitored the concentration of H_3PO_5 and H_2O_2. Figure 5 shows the results obtained at 90°C.

It can be seen that very little H_2O_2 is generated during the 180 min of thermal treatment. However, this may be because of the thermal decomposition of the generated H_2O_2. To eliminate this possibility, H_2O_2 was thermally treated under the same reaction conditions (pH 1, 90°C), and no decomposition was observed. These results indicate that the rate of H_3PO_5 hydrolysis is extremely slow, and not responsible for the observed decrease in H_3PO_5 concentration under the conditions used. These results are in agreement with those of Battaglia and Edwards who reported that the hydrolysis of H_3PO_5 is negligible unless the pH is much less than 0 (16).

It is well established that peroxides undergo facile decomposition in the presence of transition metal ions. A kinetic chain reaction can be catalyzed by traces (10–20 ppm) of transition metal ions, particularly iron, cobalt, manganese, and copper, and is often referred to as Fenton's chemistry (2, 17). Under such conditions the peroxide acts as both a reducing and an oxidizing reagent with the transition metal ions in the higher and lower valence states, respectively (Scheme 1).

To minimize the effect of transition-metal-induced decomposition reactions, many techniques have been employed, which include the addition of sequestering agents and (or) inorganic salts to remove the majority of these metal ion contaminants (2, 18). To avoid the influence of trace amount of metal ions, which may be introduced during the preparation of H_3PO_5, the effect of DTPA on the reaction system was studied. Increasing concentrations of DTPA were used, and the effect on H_3PO_5 stability measured. There was no observable difference among any of the DTPA-included

Fig. 5. Decomposition of H_3PO_5 at 90°C: ◆ H_2O_2, ○ H_3PO_5, ▲ $H_2O_2 + H_3PO_5$. Initial $[H_3PO_5] = 0.10$ M, $[H_2O_2] = 0.0$ M, pH = 1.02.
Scheme 1.
reactions, and this indicates that metal-induced decomposition is not prevalent in our system.

Thermodynamically, peroxides, particularly peroxy acids, are potentially unstable, decomposing exothermically according to eq. [9].

[9] $ROOH \xrightarrow{\Delta} ROH + 1/2\ O_2$
The facile decomposition is a result of the weak O—O bonds, ~31 kcal mol^{-1} for $CH_3C(O)O$—OH vs. 51 kcal mol^{-1} for HO—OH, which are easily cleaved by light and heat (2). In both peroxy acids and hydroperoxides, heating above a critical temperature (peracetic acid: ~80°C, H_2O_2: ~120°C (19)) initiates homolysis of the O—O bond, leading to the formation of radical species. What ensues is the kinetic decomposition of the peroxide to a variety of radical intermediates (2). Although we did not calculate the critical temperature for H_3PO_5, we are of the opinion that the decreased stability is mainly due to the thermal decomposition of H_3PO_5.

Finally, the effect of pH on the stability of H_3PO_5 (0.10 M) was studied at 70°C (Fig. 6). To avoid the influence of trace amounts of metal ions at high pH conditions where DTPA is not effective, DTMPA (0.1%) was added (20). The reaction was maintained at constant pH and temperature for 120 min, at which time the residual H_3PO_5 was determined. The results are shown in Fig. 6 and reveal that at approximately pH 7, H_3PO_5 has the maximum stability, which rapidly decreases with increasing pH.

Peracetic acid – peroxymonophosphoric acid preparation

To further increase the peroxy acid concentration of the reaction system, we investigated the effect of acetic acid addition. In previous studies, we found that the addition of acetic acid during peroxymonosulfuric acid synthesis results in an increase in peroxy acid concentration through the production of peracetic acid (21). In this system, the unreacted H_2O_2 reacts with the acetic acid to form peracetic acid, CH_3CO_3H, and the conversion ratio of the total peroxy acids

Fig. 6. Effect of pH on the stability of H_3PO_5 at 70°C and 120 min (initial $[H_3PO_5] = 0.10$ M).
based on H_2O_2 is increased. Therefore, glacial acetic acid was added to the P_2O_5–H_2O_2 reaction system prior to working up the reaction system (after approximately 2–3 h of reaction). The system was mixed for a further 30 to 45 min to promote CH_3CO_3H formation (21). The peroxy acids were then extracted from the CCl_4 layer and the concentration of peroxy acids and remaining hydrogen peroxide were determined by chemical methods. In a typical preparation, at a mole ratio of P_2O_2:H_2O_2:CH_3COOH = 0.5:1:0.3, using 70 wt % H_2O_2, the overall conversion ratio of H_2O_2 to peroxy acids was >95%.

Normally, the generation of peracetic acid from acetic acid and hydrogen peroxide requires a strong acid catalyst such as H_2SO_4. The advantage of this method is that no additional strong acid catalyst is needed, as H_3PO_4 and H_3PO_5 are both medium to strong acids. Although both acetic acid and peracetic acid are soluble in the CCl_4, they can be easily extracted by water at the end of the reaction. In fact, after 2–3 extractions (30 mL) with water, there was no acetic acid or peroxy acids left in the CCl_4. Thus, this system enables the CCl_4 to be reused, addressing some of the concerns surrounding its use.

Conclusions

In this paper we describe a new method for the preparation of peroxymonophosphoric acid (H_3PO_5). It utilizes a biphasic solution to moderate the vigorous reaction between phosphorous pentoxide (P_2O_5) and hydrogen peroxide (H_2O_2). Through careful control of the reaction temperature by the slow dropwise addition of H_2O_2, H_2O_2 can be converted to H_3PO_5 with high conversion ratios. Typical preparation conditions involve suspending the P_2O_5 in CCl_4, cooling the reaction system to 2°C, then slowly adding the 70 wt % H_2O_2 (P_2O_5:H_2O_2 = 0.5:1) while vigorously mixing the solution. The preparation is then left mixing at 2°C for between 120–180 min. Increasing the concentration of H_2O_2 as well as the mole ratio of P_2O_5:H_2O_2 leads to a higher % conversion of H_2O_2 to H_3PO_5. The addition of glacial acetic acid to the P_2O_5:H_2O_2 suspension at the end of the 120–180 min reaction (P_2O_5:H_2O_2:CH_3COOH = 0.5:1:0.3) leads to the formation of peracetic acid in addition to H_3PO_5 and an overall increase in the conversion ratio of total peroxy acids based on H_2O_2 (>95%).

The H_3PO_5 solution can be stored for more than 30 days under refrigeration with only minimal loss in H_3PO_5 concen-

tration. Temperature and pH have dramatic effects on the H_3PO_5 stability. At high temperature (70°C), the maximum H_3PO_5 stability was observed at a pH ~7, with both increasing and decreasing pH resulting in a decrease in residual H_3PO_5 after 120 min. Increasing the temperature to 90°C lead to the rapid reduction in H_3PO_5 concentration. Experimental results indicate that aqueous mediated hydrolysis and transition-metal-catalyzed decomposition are not prevalent. The observed decrease in H_3PO_5 can be attributed to the thermal homolysis of the peroxygen bond.

Electrocatalytic oxidation and flow amperometric detection of hydrazine on a dinuclear ruthenium phthalocyanine-modified electrode

Mehrdad Ebadi

Abstract: Electrocatalytic oxidation of hydrazine on a dinuclear ruthenium phthalocyanine ($(RuPc)_2$) modified electrode was studied using cyclic voltammetry (CV) and rotating disc electrode (RDE) techniques. At pH = 13, a four-electron oxidation of hydrazine to N_2 was observed. A suitable mechanism was proposed by analyzing the rate equation and the Tafel slope. The flow injection analysis was performed to characterize the $(RuPc)_2$-modified electrode as an amperometric sensor for the detection of hydrazine. The electrode displays an excellent accuracy and precision in phosphate solution at pH 12 and 13. The linearity range was from 30 nM to 1 mM with a correlation coefficient of 0.9998.

Key words: ruthenium phthalocyanine, electrocatalysis, surface-modified electrode, hydrazine, amperometric sensor.

Résumé : On a étudié l'oxydation électrocatalytique de l'hydrazine sur une électrode modifiée de phtalocyanine de ruthénium dinucléaire $(RuPc)_2$ en faisant appel aux techniques de voltampérométrie cyclique (VC) et d'électrode à disque tournant (EDT). À un pH = 13, on observe une oxydation à quatre électrons de l'hydrazine en N_2. On propose un mécanisme approprié en faisant une analyse de l'équation de vitesse et de la pente de Tafel. On a réalisé une analyse de l'écoulement de l'injection pour caractériser l'électrode modifiée de $(RuPc)_2$ comme détecteur ampérométrique pour la détection de l'hydrazine. L'électrode est à la fois exacte et précise dans une solution de phosphate à des pH de 12 et 13. La plage de linéarité va de 30 nM à 1 mM avec un coefficient de corrélation de 0,9998.

Mots clés : phtalocyanine de ruthénium, électrocatalyse, électrode à surface modifiée, détecteur ampérométrique.

Introduction

Recently (1) we reported the electrochemical properties of the dinuclear ruthenium phthalocyanine $(RuPc)_2$ species and the electroreduction of O_2 and H_2O_2 catalyzed by $(RuPc)_2$-modified graphite electrodes. The solution and surface cyclic voltammetry of $(RuPc)_2$ displays a series of metal-localized processes. Previous studies of ruthenium phthalocyanine complexes have focused on their synthesis and chemical and physical properties (2–9). The exploration of ruthenium phthalocyanine as a catalyst has not been adequately investigated. Most of the work reported in the literature on catalysis by metallophthalocyanine species (MPcs) has been directed toward the study of cobalt and iron phthalocyanine. However, our work indicates that ruthenium phthalocyanine is as versatile a catalyst as CoPc and FePc (10). The modified $(RuPc)_2$ electrode exhibits catalytic activity towards a wide variety of molecules, including hydrazine.

There have been many published reports on the mechanism and kinetics of hydrazine oxidation. Oxidation of hydrazine catalyzed by platinum (11, 12), palladium (13, 14), nickel (15), gold (16), mercury (17), silver (18), vanadium (19), manganese (20, 21), iridium (22), rhodium (23), iron (24), cobalt (25–27), ruthenium (28), and graphite electrodes modified by metallophthalocyanines of VO, Fe, Zn, Co, Cu, Ni, and Mn (29, 30) have been reported. In aqueous

solutions, four-electron oxidation of hydrazine to N_2 was reported, while a two-electron oxidation to N_2H_2 was observed in organic solvents (12, 31).

The electrode materials and solvents have a profound influence on the oxidation mechanism. Fukumoto et al. studied the catalytic activity of metal electrodes in the anodic oxidation of hydrazine by means of the palladium membrane method (32). The experimental results revealed that the initial step in the mechanism occurred either through deprotonation of hydrazine followed by four-electron oxidation to N_2 (mechanism I) or via formation of the N_2H_3 radical followed by three-electron oxidation to N_2 (mechanism II). The oxidation of hydrazine on Pt, Ir, and Co proceeds via mechanism I, whereas on metals such as Pd, Au, and Ni oxidation occurs via mechanism II.

Zagal and co-workers have reported the oxidation of hydrazine catalyzed by MPc, MTSPc, and MP compounds (M = Cu, Cr, Ni, Fe, Co, VO, Zn, or Mn; TSPc = tetrasulphophthalocyanine; P = porphyrin) adsorbed on graphite electrodes (25). They proposed that the initial step in the mechanism involves oxidation of the metal center, followed by catalytic oxidation of coordinated hydrazine.

Many reports have become available on the detection of hydrazine using techniques such as amperometry (33–40), chemiluminescence (41–43), and spectrophotometry (44–48). In the spectrophotometry and chemiluminescence methods,

hydrazine is analyzed through its ability to inhibit or promote a chemical reaction. An example is the kinetic–spectophotometric determination of hydrazine via inhibition of the reaction between bromate and hydrochloric acid (46).

In the amperometric method, hydrazine is detected by oxidation on a working electrode. The oxidation potential of 1.0 V vs. AgCl/Ag is reported (37). To reduce the applied potential and increase the electrode sensitivity, many groups have reported the use of chemically modified electrodes (CME). The choice of the surface modifier is based on its catalytic activity and stability towards hydrazine.

In this article, the catalytic activity of the $(RuPc)_2$-modified electrodes toward the oxidation of hydrazine is described. The main products of the redox reaction are determined using electrochemical methods such as cyclic voltammetry (CV) and rotating disc electrode (RDE). A suitable mechanism is proposed by analyzing the Tafel slopes and the rate equations. The performance of an $(RuPc)_2$-modified electrode for the detection of hydrazine in a flow-through system is reported.

Experimental

Material

Hydrazine sulfate $(NH_2NH_2 \cdot H_2SO_4)$ (Analar), potassium hydrogen phosphate monobasic (KH_2PO_4) (Analar), and sodium hydroxide (NaOH) (Analar) were used without further purification. THF was distilled over sodium wire.

The buffer solutions were prepared using 0.1 M KH_2PO_4. The desired pH was obtained by the addition of a 0.1 M phosphoric acid or a 0.1 M NaOH solution. Nitrogen gas was used to remove dissolved oxygen in the solutions prior to the cyclic voltammetric experiment (CV).

The following parameters were used in all calculations: $D_{N_2H_4} = 1.4 \times 10^{-5}$ cm^2 s^{-1}, and 0.01 cm^2 s^{-1} for the kinematic viscosity of water (49).

Apparatus and electrode preparation

Electrochemical measurements were performed with an RDE3 Pine potentiostat and an X-Y recorder. A pyrolytic graphite disc, sealed to a copper shaft with polyolefin heat-shrinkable tubing, was used as a working electrode in the surface CV experiments. The graphite electrode was mounted on the shaft with the basal plane of the graphite exposed (BPG). The surface of the electrode was polished with 0.05 μm alumina powder, sonicated in doubly distilled water, and rinsed with acetone and water before each experiment. A saturated calomel electrode was used as a reference electrode.

The chromatograms were obtained using an HPLC system consisting of a Waters 590 isocratic pump, a Waters 715 auto sampler, and an HP G1049 electrochemical cell. An AgCl/Ag electrode was used as a reference electrode and glassy carbon (GC) was used as a working electrode. The GC electrode was modified as described below.

Exposing polished GC and BPG electrodes to the THF solution of $(RuPc)_2$ (0.1 mM) modified the graphite electrodes. After 1 min of soaking, the electrode was removed, rinsed with doubly distilled water, and transferred to an electrochemical cell. The $(RuPc)_2$ that was deposited on the electrode was determined to be between 3 to 5 layers thick,

assuming that $(RuPc)_2$ adsorbed flat onto the surface of BPG (1, 10).

Results and discussion

Solution and surface CV of $(RuPc)_2$

In our previous paper (1) we have reported the solution and surface CV of $(RuPc)_2$ in organic and inorganic media. The solution CV of $(RuPc)_2$ in THF displays four reversible redox waves at 0.98 V (wave I), 0.48 V (wave II), –0.13 V (wave III), and –0.55 V (wave IV) vs. SCE and an irreversible wave at –1.38 V (wave V) vs. SCE. The reversible waves are assigned to one-electron redox couples centered at metal centers, and the irreversible wave is assigned to a two-electron redox process centered at the Pc rings (1, 10).

[1]   Wave I: $[(Ru(III)Pc(-2))_2]^{2+}$
$$+ e^- \Leftrightarrow [(Ru(II, III)Pc(-2))_2]^+$$

[2]   Wave II: $[(Ru(II, III)Pc(-2))_2]^+$
$$+ e^- \Leftrightarrow (Ru(II)Pc(-2))_2$$

[3]   Wave III: $(Ru(II)Pc(-2))_2$
$$+ e^- \Leftrightarrow [(Ru(I, II)Pc(-2))_2]^-$$

[4]   Wave IV: $[(Ru(I, II)Pc(-2))_2]^-$
$$+ e^- \Leftrightarrow [(Ru(I)Pc(-2))_2]^{2-}$$

[5]   Wave V: $[(Ru(I)Pc(-2))_2]^{2-}$
$$+ 2e^- \Leftrightarrow [(Ru(I)Pc(-3))_2]^{4-}$$

The surface CV of $(RuPc)_2$ in methylene dichloride displays four quasi-reversible surface waves at 0.85 V (wave A), 0.31 V (wave B), –0.45 V (wave C), and –0.94 V (wave D) vs. AgCl/Ag. They are assigned to the metal localized processes corresponding in assignment to those described above as I, II, III, and IV (1, 10). The surface CV of $(RuPc)_2$ in aqueous medium displays pH-dependent surface waves (Fig. 1). At low pH, two reversible surface waves (waves C and D) are observed, while at high pH two additional waves (waves A and B), positive of wave C, are detected. Wave A is only observed at very high pH values (not shown) (1, 10).

[6]   Wave D: $[(Ru(I, II)Pc(-2))_2H]$
$$+ e^- + H^+ \Leftrightarrow [(Ru(I)Pc(-2))_2 2H]$$

[7]   Wave C: $[(Ru(II)Pc(-2))_2]$
$$+ e^- + H^+ \Leftrightarrow [(Ru(I, II)Pc(-2))_2H]$$

[8]   Wave B: $[OH(Ru(II, III)Pc(-2))_2]$
$$+ e^- \Leftrightarrow [(Ru(II)Pc(-2))_2] + OH^-$$

[9]   Wave A: $[(OHRu(III)Pc(-2))_2]$
$$+ e^- \Leftrightarrow [OH(Ru(II, III)Pc(-2))_2] + OH^-$$

A Pourbaix diagram of waves B, C, and D along with the hydrazine oxidation wave are shown in Fig. 2.

Hydrazine electrocatalytic oxidation

An $(RuPc)_2$-modified electrode shows strong catalytic activity towards the oxidation of hydrazine at pH = 13, while a

Fig. 1. Cyclic voltammetry of surface bound $(RuPc)_2$ on a BPG electrode in phosphate buffer solution; pH = 11.3 (——) and pH = 2.4 (—).
bare BPG electrode shows no activity toward the oxidation of hydrazine (Fig. 3). A plot of the hydrazine oxidation current as a function of the square root of the scan rate yields a straight line ($R = 0.999$, $n = 8$), characteristic of a diffusion-controlled process.

The oxidation current shows a strong dependence on pH (Fig. 2). As the pH decreases, the oxidation peak potential shifts toward a more positive potential and at the same time the oxidation current decreases. At pH values lower than 9, the $(RuPc)_2$-modified electrode loses its activity toward the oxidation of hydrazine. Similar behavior has been reported for hydrazine oxidation catalyzed by polymeric iron tera-aminophthalocyanine (50). The oxidation current is at its highest intensity at pH = 13. As the pH is lowered, the current intensity gradually decreases until pH = 8, where the catalyst loses it activity (50).

To calculate the number of electrons involved in the oxidation at pH = 13, a series of rotating disc electrode CVs was conducted at different spin velocities. In these experiments, the catalytic activity of the $(RuPc)_2$-modified electrode was reduced by 10% after each cycle. The decrease in activity was due to gradual loss of $(RuPc)_2$ from the surface of the electrode. By increasing the number of adsorbed $(RuPc)_2$ layers, the loss of activity was significantly reduced. To eliminate the surface variation and the loss of electrode activity a new surface was used for each spin velocity.

For a rotating-disc electrode, the mass transfer limiting current is described by (51)

[10] $I_d = 0.201 z FAD^{2/3} v^{-1/6} \omega^{1/2} C_o,$

where A (cm^2) is the area of the electrode, v (cm^2 s^{-1}) is the kinematic viscosity, ω (rpm) is the spin rate, C_o (mole cm^{-3}) is the bulk concentration of the redox active species, and z is the number of electrons involved in the redox reaction.

For a first order reaction, the plot of $1/I_{RD}$ vs. $1/\omega^{1/2}$, known as the Koutecky–Levich plot, yields a straight line ($R = 0.99$, $n = 6$). The slopes of the plots obtained in the mass transfer region at pH = 13 (slope = 8.5×10^3) correspond well with a theoretical value for $z = 4$ (slope = 8.3×10^3). The linearity of the plot also indicates that hydrazine oxidation is first order with respect to dissolved N_2H_4.

In a confirmatory experiment, the oxidation of N_2H_4 at pH = 13 was examined during CV at an $(RuPc)_2$-modified electrode. For a totally irreversible redox reaction, the peak current in cyclic voltammetry is expressed as (51):

[11] $I_p = 2.99 \times 10^5 z(\alpha n_\alpha)^{1/2} AC_o D^{1/2} \upsilon^{1/2}$

where υ (V s^{-1}) is the scan rate and αn_a is a parameter reflecting the irreversibility of the reaction. When A, C_o, D, and αn_a are known, the value of z can be calculated from the slope of I_p vs. $\upsilon^{1/2}$.

To determine the value of αn_α, one can use the relation for the peak potential.

[12] $E_p = k - (0.03/\alpha n_\alpha) \log(\upsilon)$

The value of αn_α can then be calculated from the slope of E_p vs. $\log(\upsilon)$. The slope of the line at high over-potential yields a value of $\alpha n_\alpha = 0.22$ ($R = 0.999$, $n = 8$). By substituting this value into eq. [11] along with known values for the other parameters the number of electrons involved in the oxidation of hydrazine is calculated to be $z = 4.2$.

The calculated number of electrons at pH = 13 (i.e., $z = 4$) indicates that the net oxidation of hydrazine occurs as follows (11–32)

[13] $NH_2NH_2 + 4OH^- \rightarrow N_2 + 4H_2O + 4e^-$

Using the procedure described above, a value of $z = 1$ at pH = 9 was observed. A value of $z = 0.7$ has been reported for hydrazine oxidation in organic solvents (12, 31). The experimental data show that the formation in the solution of $N_2H_5^+$, which is not easily oxidizable, resulted in the small z value. Based on the above argument we propose that at pH values lower than 9, the formation of $N_2H_5^+$ in solution and (or) the incapability of the solution to deprotonate the coordinated N_2H_4 prevents the oxidation of hydrazine to nitrogen.

Kinetics of N_2H_4 oxidation at pH = 13

The rate of hydrazine oxidation can be defined as

[14] $I = zFAk [N_2H_4]^p[OH^-]^q,$

where k is the heterogeneous rate constant, z is the total number of electrons involved in the oxidation reaction, and p and q are the reaction orders of hydrazine and hydroxide ion, respectively. The reaction order of hydrazine is determined from a plot of the logarithm of the kinetic current vs. $\log [N_2H_4]$. The slope of the line is close to unity (slope = 0.9, $R = 0.99$, $n = 5$), indicating first-order dependence.

The reaction order of OH^- is determined from a plot of the hydrazine oxidation peak potential as a function of pOH. The slope of the line (slope = 100 mV per pH) is close to the theoretical value of $59 q \alpha n_\alpha^{-1}$ for $q = 1$ and $\alpha n_\alpha = 0.5$, indicating that one OH^- is involved in the rate-determining step of hydrazine oxidation (10, 51, 52). Substituting these values

Fig. 2. A Pourbaix diagram indicating the pH dependence of waves B, C, and D and the hydrazine oxidation peak potential.
Fig. 3. Cyclic voltammetry of N_2H_4 oxidation (2.0×10^{-3} M) on an $(RuPc)_2$-modified and bare BPG electrode in 0.1 M NaOH (pH = 13); scan rate = 25 mV s^{-1}.
into eq. [14], one then derives $k = 1.19 \times 10^{-10}$ cm^4 mole s^{-1} at $E = -0.4$ vs. SCE. We would not attempt to compare the observed k value to published data since the experimental conditions, such as cell design, applied potential, and concentration of electrolytes, will have a profound influence on the value of the rate constant. A quantitative comparison

will require that the studies be performed under similar conditions.

According to these results, the kinetic current of hydrazine oxidation can be written as:

$$[15] \quad I = zFAk \; [\mathrm{N_2H_4}][\mathrm{OH^-}]$$

Mechanism of N_2H_4 oxidation at pH = 13

Oxidation of hydrazine at pH = 13 occurs in the positive waves C and D (Fig. 2). The CVs of $(RuPc)_2$ obtained in the presence and the absence of N_2H_4 show that hydrazine oxidation occurs at the potential where wave B is observed, indicating that the active catalyst on the surface is $[(Ru(III, II)Pc(-2))_2]^+$. By transferring the $(RuPc)_2$ surface into an N_2H_4-free solution following a hydrazine oxidation experiment, the initial surface CV of $(RuPc)_2$ is observed, showing that the ruthenium dimer retains its structure during and after the oxidation process.

Based on our CV data, the calculated electron stoichiometries, and previously published reports, we propose the following mechanism for the oxidation of hydrazine on an $(RuPc)_2$-modified electrode.

$$[16] \quad (\mathrm{Ru(II)Pc(-2)})_2 \Leftrightarrow [(\mathrm{Ru(III, II)Pc(-2)})_2]^+ + \mathrm{e^-}$$

$$[17] \quad [(\mathrm{Ru(III, II)Pc(-2)})_2]^+$$
$$+ \; \mathrm{NH_2NH_2} \Leftrightarrow [\mathrm{N_2H_4(Ru(III,II)Pc(-2))_2}]^+$$

[18] $[N_2H_4(Ru(III,II)Pc(-2))_2]^+$

$\qquad + OH^- \Leftrightarrow [N_2H_3(Ru(II)Pc(-2))_2] + H_2O$

[19] $[N_2H_3(Ru(II)Pc(-2))_2] \rightarrow$ intermediate product $+ e^-$
The steps following eq. [19] are very fast and are not rate-determining steps. These steps would lead to the formation of N_2 as the final oxidation product.

The rate equation for the proposed mechanism for hydrazine oxidation (eq. [16] to [19]) under steady-state conditions is as follows (10, 52):

[20] $$I = \frac{zFA\,k_2\,S[NH_2NH_2][OH^-]}{\begin{aligned}&\{((k_2[N_2H_4][OH^-]/k_1^o)\exp(-(1-\alpha_1)f\eta_1) + (k_2[OH^-][N_2H_4]/k_4^o)\exp(-(1-\alpha_4)f\eta_4) + k_2[N_2H_4]/k_3\\ &+ (k_2[N_2H_4]K_3/k_4^o)\exp(-(1-\alpha_4)f\eta_4) + [OH^-] + k_{-2}/k_3 + (k_{-2}K_3/k_4^o)\exp(-(1-\alpha_4)f\eta_4)\\ &+ (k_{-2}K_3/k_4^o)\exp(-(1-\alpha_4)f\eta_4)\exp(-f\eta_1) + [OH^-]\exp(-f\eta_1) + k_{-2}k_3\exp(-f\eta_1))\}\end{aligned}}$$

where S (mole cm^{-2}) $= (Ru(II)Pc(-2))_2 + [(Ru(III, II)Pc(-2))_2]^+ + [N_2H_4(Ru(III,II)Pc(-2))_2]^+ + [N_2H_3(Ru(II)Pc(-2))_2]$; $[NH_2NH_2]$ and $[OH^-]$ are concentrations with units of mole cm^{-3}; η_i is defined as $(E_{applied} - E_i^{o\prime})$; k_1, k_{-2}, k_{-3}, k_{-1}, and k_4 have units of s^{-1} while k_2 and k_3 have units of cm^3 mole^{-1} sec^{-1}; and $K_3 = k_{-3}/k_3$.[1]

The analysis of the rate equation — to predict experimentally observed data such as the Tafel slope and the rate dependence — has been used as a diagnostic method, to examine the validity of the proposed mechanism (10, 52). The experimental Tafel slopes are obtained from the plot of E_p vs. log (υ), and the rate dependence of hydrazine oxidation towards $[N_2H_4]$ and $[OH^-]$ is described above.

When $k_3 \ll k_1^o$, k_4^o, K_3, k_2, and k_{-2}, eq. [20] simplifies to

[21] $$I = \frac{zFA[NH_2NH_2][OH^-]k_2S}{(k_2[N_2H_4]/k_3 + k_{-2}/k_3\exp(-f\eta_1) + k_{-2}/k_3)}$$

Equation [21] predicts first-order dependency on dissolved hydrazine, $[OH^-]$, and a Tafel slope of 60 mV per decade for $\eta_1 \ll 0$ or infinity for $\eta_1 \gg 0$.

When $k_4^o \ll k_2[NH_2NH_2][OH^-]$, k_1^o, k_{-2}, k_{-3}, and k_3, eq. [20] can be written as

[22] $$I = \frac{zFAk_2S[NH_2NH_2][OH^-]}{(\exp(-(1-\alpha_4)f\eta_4)(k_2[N_2H_4][OH^-]/k_4^o + k_2[N_2H_4]K_3/k_4^o + k_{-2}K_3/k_4^o)\exp(-f\eta_1))}$$

When $\eta_1 \gg 0$, eq. [22] simplifies to

[23] $$I = \frac{zFA[NH_2NH_2][OH^-]k_2S\exp((1-\alpha_4)f\eta_4)}{[k_2[N_2H_4][OH^-]/k_4^o + k_2[N_2H_4]K_3/k_4^o + k_{-2}K_3/k_4^o]}$$

Equation [23] predicts a Tafel slope of $60/(1-\alpha_4)$ at high over-potential. The reaction orders in hydrazine and OH$^-$ are

[24] $$p = \partial \log i / \partial \log[N_2H_4] = 1 - \frac{[k_2[N_2H_4][OH^-] + k_2[N_2H_4]K_3]}{[k_2[N_2H_4][OH^-] + k_2[N_2H_4]K_3 + k_{-2}K_3]}$$

[25] $$q = \partial \log i / \partial \log[OH^-] = 1 - \frac{k_2[N_2H_4][OH^-]}{[k_2[N_2H_4][OH^-] + k_2[N_2H_4]K_3 + k_{-2}K_3]}$$

In a case where $k_{-2} \gg K_3$ and k_2, both eqs. [24] and [25] predict a first-order dependence towards $[N_2H_4]$ and $[OH^-]$.

The experimentally observed Tafel slope of 64 mV ($R = 0.998$, $n = 6$) at low over-potential ($\eta_1 \ll 0$) is consistent with the slope predicted by eq. [21], and the observed slope of 134 mV ($R = 0.998$, $n = 6$) at high over-potential ($\eta_1 \gg 0$) is predicted by eq. [23] using $\alpha_4 = 0.5$. Equation [21] also predicts the correct rate dependence toward $[N_2H_4]$ and

$[OH^-]$. Equation [23] predicts the correct rate dependence under the condition mentioned above.

Detection of hydrazine at (RuPc)$_2$ under flow injection conditions

Figure 4 illustrates the chromatograph of a hydrazine sample (0.1 mM) on an (RuPc)$_2$-modified GC and a bare GC electrode. The intense LC signals are observed only on the

---

[1]k_{-1} and k_1 have the same magnitude and dimension (i.e., $k_{-1}/k_1 = 1$) (10, 52).

[c]Units are (g L^{-1}) for this entry only.

Fig. 4. Chromatogram of hydrazine on an (RuPc)$_2$-modified GC and bare GC electrodes. HPLC parameters: flow rate = 0.5 mL min^{-1}, mobile phase phosphate solution (pH = 12.0), injection volume 5 μL, potential applied = 0.0 V vs. AgCl/Ag.
modified electrode, demonstrating that hydrazine can only be detected by an (RuPc)$_2$ GC electrode at 0.0 V vs. AgCl/Ag. The applied potential of 0.0 V vs. SCE was selected to eliminate interference arising from the reduction of any O$_2$ dissolved in the mobile phase. The precision, accuracy, linearity, and detection limits of the hydrazine detection method, utilizing an (RuPc)$_2$-modified GC electrode, are discussed below.

The precision of the hydrazine detection method, using an (RuPc)$_2$-modified electrode, was examined by multiple injections of 0.1 mM N$_2$H$_4$ in a mobile phase consisting of phosphate solution at pH = 12. After twenty successive injections (5 μL each) of the sample solution, a relative standard deviation of 2.7% (peak height) was observed, which

indicates a good precision and stability of the surface. The precision of the method was further examined using sample solutions containing 0.1 mM to 0.01 M hydrazine. Only at hydrazine concentrations of not more than 1 mM a good precision was observed.

To determine a desirable pH, the response factor of a 0.1 mM sample at 0.0 V vs. AgCl/Ag was examined at different pH. The best response factor was observed in the pH range of 12–13. At lower pH, the signal intensity would significantly decrease until pH = 9 where the surface would lose its catalytic activity.

To determine the optimum injection volume, multiple injections of from 1 to 100 μL of a 0.1 mM N$_2$H$_4$ sample were performed, and the signal precision was examined. The best results were obtained for an injection volume of 5 μL.

Based on the above results, the optimum method parameters are an injection volume of 5 mL, a hydrazine concentration <1 mM, and a mobile phase pH between 12 and 13.

The accuracy of the method was examined by spiking drinking water with known amounts of hydrazine. 100% hydrazine recovery was observed for the samples containing 1 mM hydrazine. The substances present in the drinking water showed no interference with the analysis of hydrazine.

The linearity and detection limits of this method were studied using the parameters selected during the precision study. The detection limits and the linearity data are summarized in Table 1, along with published data for comparison. The linear response for hydrazine is in the range of 30 nM to 1 mM with a correlation coefficient of 0.9998. In comparison with the published work (Table 1), this method displays an acceptable linearity range with an excellent correlation coefficient.

The detection limit of this method is estimated to be 30 nM, based on a signal-to-noise ratio of 3:1 (Fig. 5). The

Fig. 5. Chromatogram of hydrazine at 30 nM concentration on an $(RuPc)_2$-modified GC. HPLC parameters: flow rate = 0.5 mL min^{-1}, mobile phase phosphate solution (pH = 12.0), injection volume 5 μL, potential applied = 0.0 V vs. AgCl/Ag.
Fig. 6.
modified surface has a good detection limit in comparison to published work (Table 1).

In the interference tests, the presence of species such as F$^-$, Cl$^-$, Br$^-$, I$^-$, [SO$_4$]$^{2-}$, [CH$_3$COO]$^-$, [NO$_3$]$^-$, [CO$_3$]$^{2-}$, and [HCO$_3$]$^-$ in the sample solution did not produce any significant interference.

The results presented here illustrate that an $(RuPc)_2$-modified GC is a very sensitive electrode for the detection of hydrazine, and it can accurately and precisely measure hydrazine concentration in water samples. It also has an excellent linearity range.

Conclusion

An $(RuPc)_2$-modified electrode is catalytically active toward the oxidation of hydrazine. Based on the experimentally observed Tafel plot, the analysis of the rate equations, and the calculated electron stoichiometries, a suitable mechanism has been proposed. The pH-dependence experiment shows that the active catalyst on the surface is [(Ru(III, II)Pc(−2))$_2$]$^+$. The initial step is the oxidation of [(Ru(II)Pc(−2))$_2$] to [(Ru(III, II)Pc(−2))$_2$]$^+$, followed by coordination of

hydrazine to the ruthenium metal center. The hydrazine coordinated with Ru^{III} loses first a proton and then an electron in consecutive steps until all the protons are removed and nitrogen is formed on the surface. N$_2$ will then dissociate from $(RuPc)_2$, and the catalytic cycle continues. At low pH values (≤9), the chemical steps involving the removal of protons from the coordinated hydrazine are hindered, and therefore the complete oxidation to nitrogen does not take place.

The $(RuPc)_2$-modified electrode has been shown to be an excellent hydrazine detector with an acceptable linearity range and detection limit.

The relative stabilities of PhE(NH-t-Bu)$_2$ and PhE(μ-N-t-Bu)$_2E$Ph (E = As, Sb, and Bi): X-ray structures of {Li$_2$[PhAs(N-t-Bu)$_2$]}$_2$ and PhE(μ-N-t-Bu)$_2E$Ph (E = Sb, Bi)

Glen G. Briand, Tristram Chivers, and Masood Parvez

Abstract: The reaction of PhECl$_2$ with 2 equiv of LiHN-t-Bu has been studied for the series E = As, Sb, and Bi to determine the effect of the phenyl group on subsequent amine condensation processes. For PhAsCl$_2$, the metathesis product PhAs(NH-t-Bu)$_2$ **4** was obtained as a colourless oil. Similar reactions involving PhECl$_2$, where E = Sb or Bi, yielded the cyclodipnict(III)azanes PhE(μ-N-t-Bu)$_2E$Ph **5** (E = Sb) and **6** (E = Bi), respectively. Treatment of **4** with 2 equiv of n-BuLi produced the dilithium salt Li$_2$[PhAs(N-t-Bu)$_2$] **7a**. Products **4**, **5**, **6**, and **7a** were characterized by ^{1}H, ^{7}Li (**7a**), and ^{13}C NMR spectra, while **5**, **6**, and **7a** were also structurally characterized by X-ray crystallography. Compound **7a** is dimeric in the solid state via intermolecular Li···N and η^6-Li···Ph interactions. The cyclodipnict(III)azanes **5** and **6** have similar structures, with the exocyclic phenyl groups in *trans* positions relative to the E_2N$_2$ ring. This synthetic approach provides a new route to the four-membered rings RE(μ-N-t-Bu)$_2ER$ (E = Sb, Bi) and the first example of a bis(organyl)cyclodibism(III)azane.

Key words: arsenic, antimony, bismuth, amides, imides.

Résumé : Afin de pouvoir déterminer l'effet du groupe phényle sur les processus subséquents de condensation de l'amine, on a étudié la réaction de PhECl$_2$ (E = As, Sb et Bi) avec deux équivalents de LiHN-t-Bu. Dans le cas du PhAsCl$_2$, le produit de dismutation, PhAs(NH-t-Bu)$_2$ (**4**), a été obtenu sous la forme d'huile incolore. Les réactions semblables de PhECl$_2$ dans lesquelles E = Sb ou Bi conduisent respectivement aux cyclodipnict(III)azanes, PhE(μ-N-t-Bu)$_2E$Ph (**5**, E = Sb) et (**6**, E = Bi). Le traitement du composé **4** avec deux équivalents de BuLi conduit à la formation du sel dilithié Li$_2$[PhAs(N-t-Bu)$_2$] (**7a**). Les produits **4**, **5**, **6** et **7a** ont été caractérisés par leurs spectres RMN du ^{1}H et du ^{7}Li (**7a**) et des spectres RMN du ^{13}C alors que les produits **5**, **6** et **7a** ont aussi été caractérisés par diffraction des rayons X. À l'état solide, le composé **7a** existe à l'état trimère par le biais d'interactions Li···N et η^6-Li···Ph. Les cyclodipnict(III)azanes **5** et **6** ont des structures semblables avec des groupes phényles exocycliques en positions *trans* par rapport au cycle E_2N$_2$. Cette approche fournit une nouvelle voie de synthèse vers les cycles à quatre chaînons RE(μ-N-t-Bu)$_2ER$ (E = Sb, Bi) et le premier exemple d'une bis(organyl)cyclodibism(III)azane.

Mots clés : arsenic, antimoine, bismuth, amides, imides.

Introduction

Pnicogen(III) compounds of secondary amines have been employed extensively as reagents for the preparation of compounds containing other functional groups (1). Homoleptic species E(NR_2)$_3$ (E = P, As, Sb, Bi) are synthesized via simple metathesis reactions of a pnicogen(III) halide with the appropriate amine or alkali metal amide. Analogous studies involving primary amines, on the other hand, have proven to be less predictable as a result of the remaining acidic amino

proton after initial E—N bond formation. Reactions involving primary amines and PCl$_3$ do not afford tris(amino)pnictines P(NHR)$_3$; rather, further amine elimination occurs to yield [cyclodiphosph(III)azanes] **1**, **2**, cyclic systems (ClPNR)$_3$, P$_4$(NR)$_6$ cages, or other condensation products, depending on the choice of amine substituent and reaction stoichiometry (2, 3). Although there have been fewer such studies involving ECl$_3$ (E = As, Sb, Bi), similar condensation reactions are observed (4–12).

1   **2**   **3**

In contrast to reactions involving PCl$_3$, metathesis products of H$_2$N-t-Bu and RPCl$_2$ (R = Ph, Me, -t-Bu, C$_5$Me$_5$) yield RP(NH-t-Bu)$_2$ rather than the condensation products **3** (E = P) (6c, 13). The intermediates RP(NH-t-Bu)Cl (R = Me, t-Bu) are also isolable, given the appropriate reaction stoichiometry (14). Similar observations have been made for reactions of H$_2$N-t-Bu and RAsCl$_2$, which yield RAs(NH-t-Bu)$_2$ and RAsCl(NH-t-Bu) with formation of minor amounts of **3** (E = As; R' = t-Bu) (15). To our knowledge, related studies involving RECl$_2$ (E = Sb, Bi) have not been reported. They are of interest in determining the effect of the pnicogen organyl substituent on condensation processes in these systems. We now report the results of an investigation of the reaction between LiNH-t-Bu and PhECl$_2$ for the series E = As, Sb, and Bi, which gives the metathesis product **4** for arsenic and the condensation products **5** and **6** for antimony and bismuth, respectively. Further, we describe the metallation of **4** to give **7a**, and the solid-state structures of **5**, **6**, and **7a**.

Experimental section

Reagents and general procedures

Solvents were dried and distilled over Na/benzophenone prior to use: diethyl ether and n-hexane. Phenylarsonic acid, triphenylantimony, and thionyl chloride were used as received from Aldrich. Antimony(III) chloride, triphenylbismuth, and bismuth(III) chloride were used as received from Strem. PhAsCl$_2$ (16), PhSbCl$_2$ (17), [PhBiCl$_2$(thf)](18), and LiHN-t-Bu (19) were prepared according to literature procedures (thf = tetrahydrofuran). Compound **4** has been reported previously, but was prepared via a different route and characterized by elemental analysis only (15a).

Instrumentation

^{1}H, ^{13}C, ^{31}P, and ^{7}Li NMR spectra were recorded on a Bruker DRX 400 NMR spectrometer at 298 K. Chemical shifts are reported relative to Me$_4$Si in C$_6$D$_6$ (^{1}H and ^{13}C), 85% H$_3$PO$_4$ in D$_2$O (^{31}P), and 1 M LiCl in D$_2$O ([7]Li). Elemental analyses were provided by the Analytical Services Laboratory, Department of Chemistry, University of Calgary.

Preparation of PhAs(NH-t-Bu)$_2$, 4

A slurry of LiHN-t-Bu (4.134 g, 52.29 mmol) in diethyl ether (40 mL) was added dropwise to a solution of PhAsCl$_2$ (5.828 g, 26.14 mmol) in diethyl ether (15 mL) at –90°C to give a cloudy white mixture. The mixture was allowed to warm to 23°C, and after 18 h, the solvent was removed under vacuum. Hexane (30 mL) was added and the mixture was centrifuged. The supernatant was decanted and the solvent removed under vacuum to give **4** as a yellow oil, which was distilled (10^{-3} mm, ~80°C) to give a colourless oil

(5.140 g, 17.35 mmol, 66%). NMR data (thf-d_8): ^{1}H NMR δ: 1.25 (s, 18 H, N-t-Bu), 1.85 (s, 2 H, NH), 7.21–7.25 (m, 1 H, AsPh-p), 7.28–7.32 (m, 2H, AsPh-o), 7.69–7.72 (m, 2 H, AsPh-m). ^{13}C NMR δ: 33.7 (NCMe$_3$), 52.5 (NCMe_3), 128.9 (AsPh), 129.0 (AsPh), 131.6 (AsPh), 150.1 (AsPh).

Preparation of PhSb(μ-N-t-Bu)$_2$SbPh, 5

A slurry of LiHN-t-Bu (2.108 g, 26.67 mmol) in diethyl ether (20 mL) was added dropwise to a solution of PhSbCl$_2$ (3.597 g, 13.33 mmol) in diethyl ether (5 mL) at 0°C to give a cloudy yellow mixture, which was allowed to warm to 23°C. After 18 h, the solvent was removed under vacuum. Hexane (20 mL) was added, and the mixture was centrifuged. The supernatant was decanted, and the solvent was removed under vacuum to give **5** as a yellow-orange oil (3.071 g, 5.69 mmol, 85%). The oily product crystallized on standing at 23°C for 1 day. NMR data (thf-d_8): ^{1}H NMR δ: 1.26 (s, 18 H, N-t-Bu), 7.25–7.31 (m, 6 H, SbPh-p/o), 7.54–7.72 (m, 4 H, SbPh-m). ^{13}C NMR δ: 35.1 (NCMe$_3$), 52.4 (NCMe_3), 128.9 (SbPh), 129.2 (129.3) (SbPh), 134.1 (135.2) (SbPh). Anal. calcd. for C$_{20}$H$_{28}$N$_2$Sb$_2$ (%): C 44.49, H 5.23, N 5.19; found: C 43.95, H 4.81, N 5.42.

Preparation of PhBi(μ-N-t-Bu)$_2$BiPh, 6

A slurry of LiHN-t-Bu (0.100 g, 1.27 mmol) in diethyl ether (5 mL) was added dropwise to a solution of [PhBiCl$_2$(thf)] (0.272 g, 0.633 mmol) in diethyl ether (5 mL) at 0°C to give a cloudy orange mixture, which was allowed to warm to 23°C. After 3 h, the solvent was removed under vacuum. After addition of hexane (5 mL), the mixture was centrifuged, and the supernatant was decanted and concentrated to 1 mL. After 2 days, red crystals of **6** were collected (0.040 g, 0.056 mmol, 18%). NMR data (thf-d_8): ^{1}H NMR δ: 0.66 (s, 18 H, N-t-Bu), 7.33 (m, 2 H, BiPh-p), 7.64 (m, 4 H, BiPh-o), 8.78 (m, 4 H, BiPh-m). ^{13}C NMR δ: 35.5 (NCMe$_3$), 55.1 (NCMe_3), 128.8 (BiPh), 131.3 (BiPh), 136.7 (BiPh). Anal. calcd. for C$_{20}$H$_{28}$Bi$_2$N$_2$ (%): C 33.62, H 3.95, N 3.92; found: C 33.84, H 4.03, N 4.17.

Preparation of Li$_2$[PhAs(N-t-Bu)$_2$], 7a

A solution of 2.5 M n-BuLi in hexanes (8.10 mL, 20.28 mmol) was added dropwise to a solution of PhAs(NH-t-Bu)$_2$ (3.003 g, 10.14 mmol) in diethyl ether (30 mL) at 0°C to give a cloudy yellow mixture, which was allowed to warm to 23°C. After 5 h, the solvent was removed under vacuum. The resulting product was washed with n-hexane (3 × 5 mL) to give **7a** as a white powder (2.002 g, 6.50 mmol, 64%). X-ray quality crystals were grown from diethyl ether – hexane at –15°C. NMR data (thf-d_8): ^{1}H NMR δ: 1.04 (s, 18 H, N-t-Bu), 6.95 (t, 1 H, AsPh-p), 7.06 (t, 2 H, AsPh-o), 7.60 (d, 2 H, AsPh-m). ^{13}C NMR δ: 38.2 (NCMe$_3$), 53.5 (NCMe_3), 126.0, (AsPh), 127.5 (AsPh), 131.1 (AsPh). ^{7}Li NMR δ: 1.92, 2.41. Anal. calcd. for C$_{14}$H$_{23}$AsLi$_2$N$_2$ (%): C 54.57, H 7.52, N 9.09; found: C 55.83, H 7.44, N 8.98.

X-ray structural analyses

Crystals of **5**, **6**, and **7a** were coated with oil (Paratone 8277, Exxon) and mounted on glass fibres. Measurements were made on a Nonius KappaCCD diffractometer using

Table 1. Crystallographic data for **5**, **6**, and **7a**.

monochromated Mo Kα radiation. Crystallographic data are summarized in Table 1.[2]

Data were measured using ω and φ scans. The crystals showed no sign of decay during data collection, and no decay correction was employed. Cell constants were obtained from the refinement (20) of 2330 (**5**), 2208 (**6**), or 3484 (**7a**) reflections in the range $1 < \phi < 27.5°$. The space groups for **5** and **6** were uniquely determined from the systematic absences. The data were corrected for Lorentz and polarization effects and for absorption using the multiscan method (20). The structures were solved using direct methods (21) and expanded using Fourier techniques (22) (SHELXL97) (23). The nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions and were not refined.

The Sb atom in **5** was disordered over two sites, Sb1 and Sb2, with occupancy factors 0.574(1) and 0.426(1), respectively. The *t*-Bu group exhibited rotational disorder wherein the methyl C atoms were located over two sites each with site occupancy factors 0.83(1) and 0.17(1). The disorder in the phenyl ring was also apparent from the large thermal displacement parameters of its carbon atoms.

Results and discussion

Synthetic and NMR studies

The treatment of PhAsCl$_2$ with 2 equiv of LiHN-*t*-Bu in diethyl ether yields PhAs(NH-*t*-Bu)$_2$ **4** in ca. 65% yield, as a colourless oil, after vacuum distillation. ^{1}H and ^{13}C NMR spectra of the unpurified material show that primarily one product is formed in this reaction with very minor amounts

of impurities. The absence of the condensation product **3** (E = As, R = R' = *t*-Bu) represents an improvement on the existing synthesis of **4** (15*a*). The identity of **4** was established by ^{1}H and ^{13}C NMR spectra and by metallation with 2 equiv of *n*-butyllithium to yield the dilithium salt Li$_2$[PhAs(N-*t*-Bu)$_2$] **7a** (R = Ph), cf., the formation of Li$_2$[PhP(N-*t*-Bu)$_2$] **7b** from PhP(NH-*t*-Bu)$_2$ (13*a*). The resulting colourless crystals were of sufficient quality to allow a definitive characterization via X-ray crystallographic analysis (vide infra). Wright and co-workers have recently described extensive studies of the formation of the [As(N-*t*-Bu)$_3$]$^{3-}$ trianion by the reaction of As(NMe$_2$)$_3$ (1 equiv) with a mixture of *t*-BuNH$_2$ and *t*-BuNHLi (3:3 equiv) (24). Although the formation of As(NH-*t*-Bu)$_3$ is implied in this synthesis, this intermediate was not isolated. The authors propose a facile condensation to produce the cyclodiars(III)azane, *t*-BuN(H)As(μ-N-*t*-Bu)$_2$AsN(H)-*t*-Bu (**3**, E = As, R = R' = *t*-Bu) to explain this observation (24).

The reaction of PhSbCl$_2$ with 2 equiv of LiHN-*t*-Bu yields a yellow-orange oil after removal of the solvent. The oil crystallizes after 1 day at 23°C, and it was identified by CHN analyses and NMR spectra as the condensation product PhSb(μ-N-*t*-Bu)$_2$SbPh **5**. Compound **5** was obtained in 85% yield and the ^{1}H and ^{13}C NMR spectra of the unpurified material indicated a single product. For PhBiCl$_2$, the corresponding reaction proceeds in a similar manner but, in this case, the crude product was isolated as a solid. Crystals were obtained from *n*-hexane and characterized as PhBi(μ-N-*t*-Bu)$_2$BiPh **6**. The ^{1}H NMR spectrum of the reaction mixture exhibits three N-*t*-Bu resonances at δ 0.66, 1.01, and 1.07, with approximate relative intensities 1:2:1, in addition to a

complex set of overlapping Ph resonances. The *trans*-isomer of **6** was isolated in ca. 20% yield and shown to be attributable to the resonance at δ 0.66. It is tentatively proposed that one of the other products is the *cis*-isomer of **6**, but attempts to isolate this component by fractional crystallization were unsuccessful. A candidate for the second unidentified product is the monosubstituted derivative PhBi(Cl)(NH-*t*-Bu). However, when the reaction was carried out in a 1:1 stoichiometry, no resonances were observed at δ 0.66, 1.01, or 1.07 in the ^{1}H NMR spectrum. Resonances attributable to the N-*t*-Bu groups of an unidentified product appeared at δ 1.70 and 1.88.

[1] $\text{Ph}E\text{Cl}_2 \xrightarrow[-2\text{LiCl}]{+2\,\text{LiNH-}t\text{-Bu}} \text{Ph}E(\text{NH-}t\text{-Bu})_2$
    ($E = \text{Sb, Bi}$)

    $\xrightarrow{-\,t\text{-BuNH}_2} 1/2\ \text{Ph}E(\mu\text{-N-}t\text{-Bu})_2E\text{Ph}$

    5, $E = \text{Sb}$

    6, $E = \text{Bi}$
For both **5** and **6**, the ^{1}H NMR spectra of the pure products show resonances for N-*t*-Bu and Ph groups in the ratio 1:1, suggesting that a condensation reaction has occurred (eq. [1]). Previous routes to bis(organyl)cyclodistib(III)azanes **3** ($E = \text{Sb}$; $R = \text{Me, }t\text{-Bu}$) involve metathesis reactions between the organolithium reagents and ClSb(μ-N-*t*-Bu)₂SbCl (**2**, $E = \text{Sb}$, $R = t\text{-Bu}$), which is prepared from SbCl₃ and Li(Me₃Si)N-*t*-Bu (24*a*, 24*b*). Bismuth analogues of **3** ($E = \text{Bi}$) have not been reported, nor have the dichloro derivatives **2** ($E = \text{Bi}$). The reaction of organyldihalopnictines and lithiated primary amides thus represents a novel synthetic route to these cyclodipnict(III)azanes.

X-ray structural analyses

ORTEP diagrams of **5** and **6** are shown in Figs. 1 and 2, respectively. The X-ray structure analyses of **5** and **6** confirm the formation of condensation products. In both structures, the exocyclic Ph groups are in a *trans* arrangement with respect to the E_2N_2 ring. In the case of **5**, there is a static disorder in the Sb atom over two positions, giving two unique molecules (Fig. 1). In one molecule, Sb(1) is bound to C(5) of the phenyl ring and N(1) of the N-*t*-Bu group, giving a *trans*-PhSb(μ-N-*t*-Bu)₂SbPh structure, as a result of inversion symmetry. The second molecule shows Sb(2) bound to C(6) of the phenyl ring, as well as N(1) of the N-*t*-Bu group, giving an Sb₂N₂ ring that also has a *trans*-PhSb(μ-N-*t*-Bu)₂SbPh structure. The Sb—N and Sb—N* interactions are quite different in one molecule, but not in the other (Sb(1)—N(1) = 1.988(4) Å, Sb(1)—N(1*) = 2.063(4) Å; Sb(2)—N(1) = 2.019(4) Å, Sb(2)—N(1*) = 2.034(4) Å). However, the average Sb—N bond distances are similar for the two molecules (|Sb(1)—N| = 2.02(4) Å; |Sb(2)—N| = 2.027(8) Å), while the Sb—C$_{phenyl}$ bond distances are significantly different (Sb(1)—C(5) = 2.169(5) Å; Sb(2)—C(6) = 2.234(7) Å). The structural parameters for **5** and **6** are compared in Table 2. As expected, bond lengths to the bismuth centre in **6** are longer than those to the antimony centres (Bi—C = 2.285(4) Å vs. Sb—C = 2.169(5) and 2.234(7) Å; Bi—N = 2.163(3) and 2.167(3) Å vs. Sb—N = 1.988(4)– 2.063(4) Å), and the bond angles at the bismuth centre are

Fig. 1. ORTEP diagram of **5** showing the two disordered molecules (30% probability ellipsoids). Symmetry transformations used to generate equivalent atoms: $-x + 1$, $-y$, $-z + 1$.
Fig. 2. ORTEP diagram of **6** (30% probability ellipsoids). Symmetry transformations used to generate equivalent atoms: $-x$, $-y$, $-z + 1$.

considerably smaller than those at antimony. These observations can be attributed to the larger covalent radius of Bi(III) vs. Sb(III).

Only one example of a bis(organyl)cyclodistib(III)azane has been structurally characterized, i.e., *trans-t*-BuSb(μ-N-*t*-Bu)₂Sb-*t*-Bu **8** (25). Comparison of the bond angles and Sb—N$_{ring}$ bond distances in **5** and **8** show all values to be in the same range. The Sb—C bond distances in **5** are shorter than those of **8** (2.252(6) Å), presumably as a result of sp^2 rather than sp^3 hybridization of carbon. Comparison with other analogues shows that the bond angles at antimony in **5** are greater than those in [(*R*HN)Sb(μ-N*R*)₂(NH*R*)] ($R = 2,6$-Me₂C₆H₃) **9** (8), while the Sb—N$_{ring}$ bond distances are in

[a]Values for one of two unique molecules (13a).

Fig. 3. ORTEP diagram of **7a** (R = Ph; methyl carbon atoms of *t*-Bu groups are removed for clarity; 30% probability ellipsoids). Symmetry transformations used to generate equivalent atoms: $-x + 1$, $-y$, $-z + 2$.
same range. As **6** is the first structurally characterized example of a bis(organyl)cyclodibism(III)azane, RBi(μ-NR')$_2$BiR, no direct structural comparisons can be made. However, comparison with [(RHN)Bi(μ-NR)$_2$(NHR)] (R = 2,6-i-Pr$_2$C$_6$H$_3$) **10**, the only reported analogue (9), shows the bond angles in **6** to be larger, while the Bi—N$_{ring}$ bond distances are similar. The larger bond angles for **5** and **6** are counterintuitive given the steric bulk of the substituted phenyl substituents in **9** and **10**, respectively.

An ORTEP diagram of **7a** is depicted in Fig. 3. The complex **7a** is isostructural with **7b**, reported previously (13a), and the metrical parameters are compared in Table 3. The structure shows the pnicogen atom bound to a phenyl carbon atom and two *tert*-butylamido nitrogen atoms in a pyramidal arrangement. One of the lithium atoms (Li(2)) is symmetrically chelated by the ligand in an N,N' manner (Li(2)—N(1) = 2.015(4) Å; Li(2)—N(1) = 2.011(4) Å), while the second lithium atom (Li(1)) is bound to one nitrogen atom (N(1)) only (1.916(4) Å). The resulting moiety dimerizes via a short Li(1)—N(2*) interaction (1.920(4) Å) and an η^6-Li···Ph* interaction (Li(2)—C$_{phenyl}^*$ = 2.624(4)–2.752(4) Å) to the second molecule. The most significant differences in

the structures of **7a** and **7b** involve the longer E—C and (or) E—N bond distances and the smaller bond angles at the pnicogen center in **7a** (see Table 3), both of which are a result of the larger covalent radius of As(III) vs. P(III). For comparison with the unsolvated structure of **7a**, crystallization of **7a** from THF produces the trisolvated monomer {(THF)$_3$Li$_2$[PhAs(N-t-Bu)$_3$]} in which the [PhAs(N-t-Bu)$_2$]$^{2-}$ ligand is N,N' chelated to both Li$^+$ ions. Each Li$^+$ ion is further coordinated by one terminal and one bridging THF molecule (26).

Conclusions

The reaction of PhECl$_2$ with 2 equiv of LiHN-t-Bu has been studied for comparison with previous work on the analogous phosphorus systems, which yield bis(amido)organylphosphines. These reactions result in the formation of PhAs(NH-t-Bu)$_2$ in the case of arsenic, while a subsequent condensation reaction to afford the *trans*-cyclodipnict(III)azanes PhE(μ-N-t-Bu)$_2$$E$Ph is observed for both the antimony and bismuth systems. This synthetic route represents a novel pathway to RE(μ-NR')$_2$$ER$ (E = Sb, Bi) species, including the first example of a bismuth analogue. The metallation of PhAs(NH-t-Bu)$_2$ with Li-n-Bu produces a dimeric dilithiated derivative that is isostructural with the phosphorus analogue.

Solvent-dependent rate constants of muonium atom reactions

Stefan Karolczak, Hugh A. Gillis, Gerald B. Porter, and David C. Walker

Abstract: The rates of reaction of muonium atoms with solutes, ionic and organic, were studied in solvents of wildly differing polarities (water, methanol, and hexane) and their rate constants were compared, where possible. In these reactions — which are those of a highly reactive atom, an isotope of hydrogen — it transpires that the reaction rates are higher in solvents in which the solute is more soluble and muonium diffuses faster. This study leads to various kinetic-solvent-effect ratios and to the observation of the reaction of muonium with free radicals being among the fastest reactions recorded so far between two neutral species in solution.

Key words: muonium atoms, kinetic isotope effects, solvent-dependent rates, non-aqueous solvents, muon spin rotation technique.

Résumé : Opérant dans des solvants de polarités extrèmement différentes (eau, méthanol et hexane), on a déterminé les vitesses de réaction des atomes de muonium avec des solutés ioniques et organiques et, dans les cas où cela était possible, on a comparé leurs constantes de vitesse. Dans ces réactions — qui sont celles d'un atome très réactif, un isotope de l'hydrogène il est normal que les vitesses de réaction soient plus élevées dans les solvants dans lesquels le soluté est le plus soluble et le muonium diffuse le plus rapidement. Cette étude conduit à divers rapports « d'effet cinétique du solvant » et à l'observation que les vitesses de réactions des muonium avec des radicaux libres sont les plus élevées qui aient pu être mesurées pour des réactions entre des espèces neutres en solution.

Mots clés : atomes de muonium effets isotopiques cinétiques, vitesses de réaction qui varient avec le solvant, solvants non aqueux, technique de la rotation de spin du muon.

[Traduit par la Rédaction]

Introduction

Reactions in solution are expected to have rates that are somewhat influenced by the physicochemical properties of the solvent and its interactions with the reacting solutes. In this paper we explore the potential of using the muonium atom (Mu, μ^+e^-) to study solvent-dependent kinetics and its possible value in determining cross-solvent kinetic isotope effects. Water and *n*-hexane were taken as a pair of solvents at opposite extremes in terms of polarity and solvating power, with methanol squarely in between. Muonium is readily formed in all three solvents and is sufficiently long-lived (>1 μs) in each to allow for the evaluation of muonium-reaction rate constants, k_M In these experiments k_M is evaluated by directly observing the rate-of-disappearance of Mu due to the presence of solutes at known concentrations.

Whereas there is a wealth of data on the reaction of H-atoms with solutes dissolved in water (1), for comparison with Mu (2), there is a dearth of comparable information in organic solvents.

Experimental

These were transverse-field muon spin rotation experiments (TF-μSR). They involved placing deoxygenated solutions in 50 mL round-bottomed glass flasks in the SFUMU cart in the "backward" muon beam of the M9B beamline at TRIUMF. The results are now archived as experiments 15 045 – 15 109 in the μSR Facility. The observed count rates were subjected to on-line analysis; and then computer-fitted to the usual TF-μSR equation, eq. [1] (3).

$$[1] \qquad N_t = N_0 \exp(-t/\tau)\,[1 + A_M \exp(-\lambda t) \cos(\omega_M t + \varphi_M) + A_D \cos(\omega_D t + \varphi_D)] + N_0 B_g$$

In this equation, N (at times t and 0) is the observed count rate, τ is the mean muon lifetime of 2.2 μs, B_g a background factor, $A_M, \omega_M,$ and φ_M are, respectively, the asymmetry, precession frequency, and initial phase of the Mu signal, with $A_D, \omega_D,$ and φ_D the corresponding values for all diamagnetic muon states collectively designated as D. For these experi-

Fig. 1. (*a*) Plot of the TF-μSR asymmetry ($A_M + A_D$) over the first μs in neat *n*-hexane at room temperature with an applied transverse magnetic field of 7.5 G. (The 0.1 μs (10.5 MHz) oscillation corresponds to A_M, which is superposed on the A_D oscillation at 0.1 MHz — where the latter happens to appear as the overall gradual rise because its initial phase is caught in an upward arch in these plots from the UP counter of SFUMU.) (*b*) Analogous plot to that in (*a*), except the hexane contains nitrobenzene at a concentration of 0.15 mM. (The "relaxation" (decay) of the 10.5 MHz Mu signal in (*b*) compared with (*a*) corresponds to λ for the reaction of nitrobenzene with Mu.)
ments the important parameter is λ, a pseudo first-order rate constant representing the decay of Mu by chemical reactions (and by any other Mu-loss processes beyond the spontaneous muon decay accounted for in the $\exp(t/\tau)$ term). On-line computer analysis based on eq. [1] gives "best-fit" values for λ.

A typical plot of "asymmetry" ($A_M + A_D$) versus time is shown in Fig. 1*a* for neat hexane and Fig. 1*b* for a solution of nitrobenzene. Here the computer has plotted asymmetry alone by dividing by the $\exp(t/\tau)$ term, so that the only relaxation of the signal is represented by λ. (It also renormalizes N by subtracting the background factor.) In all the experiments reported here a transverse magnetic field of 7.5 G was applied, so ω_M is about 10.5 MHz (corresponding to the wiggles seen in the asymmetry plot), whereas ω_D is merely 0.1 MHz, and its time variation is seen only as the general upward curvature corresponding to one tenth of one cycle over the first microsecond. The effect of a solute that reacts with Mu appears as a relaxation of the Mu asymmetry signal as can be seen in Fig. 1 by comparing 1*b* with 1*a*. This represents a "direct" method of observing Mu as it reacts with a solute in an analogous manner to many pulse radiolysis studies.

The organic solvents used were the best commercially available to us and were not purified further because they had acceptable Mu background decay constants (λ_0), which arise from a combination of inherent impurities and reaction with the solvent. The hexane was from ACROS Organics and gave $\lambda_0 \sim 0.7$ μs^{-1}, the methanol from Aldrich gave $\lambda_0 \sim 0.5$ μs^{-1}, and the water purified locally had $\lambda_0 < 0.2$ μs^{-1}. These λ_0 values contributed to the overall errors in the values of k_M reported, because $\lambda = \lambda_0 + k_M[S]$, and k_M is evaluated from the slope of plots of λ versus solute concentration [S]. In fact the realistic error-bars on k_M were usually in the ±15–25% range because of different sensitivities of one counter compared with another in the μSR measurement itself due to variations in positioning and thickness of cell walls, etc. For all solutions the "up" and "down" counters on the SFUMU cart were treated as separate detectors to give a pair of readings at each concentration of solute. A typical λ versus [S] plot involved six or eight points covering three or four con-

Table 1. Rate constants (k_M (10^9 M^{-1} s^{-1})) for Mu reactions in three solvents at ~295 K.

Solute	k_M (water)	k_M (methanol)	k_M (hexane)
NO$_2^-$	8.0 (±1.5)	5.3 (±1.5)	—
NO$_3^-$	1.5 (±0.2)[a]	1.1 (±0.3)	—
TEMPO	16 (±3)	48 (±7)	80 (±20)
TEMPO-OH	14 (±3)	50 (±10)	60 (±20)
Nitrobenzene	11 (±3)[b]	—	13 (±1.5)

centrations. When using the TF-μSR technique it is necessary to keep changing the concentration of the solute until the chemical lifetime of Mu falls into the narrow observation window of about 0.3 to 1.5 μs. This can be tedious when k_M is completely unknown.

Results

The values obtained for muonium rate constants (k_M) in water, methanol, and hexane towards six solutes are given in Table 1 (where solubility and reactivity allowed). Of the six solutes studied, two were a related pair of ionic solutes (nitrate and nitrite), two were a related pair of organic free-radicals ("TEMPO", 2,2,6,6-tetramethyl-1-piperidine-*N*-oxyl, and "TEMPO-OH", 4-hydroxy-TEMPO), and two were powerful electron scavengers (nitrobenzene and CCl$_4$). The two values in water referenced in Table 1 (nitrate and nitrobenzene) are data already published.

Various ratios of these values of k_M are collected in Table 2 from the data in Table 1. These include (*i*) the Mu-to-H kinetic isotope effect (KIE, k_M/k_H) in water using published data for k_H(water) and (*ii*) the ratio of k_M in methanol and hexane compared with water, where possible. Unfortunately, KIEs in non-aqueous solvents cannot be determined at present because of the scarcity of H-atom data in solvents other than water.

Table 2. Various ratios of k_M values and kinetic isotope effects (KIE) relative to published data for k_H (water) where available.

Solute	k_H (water)[a]	KIE (water) (k_M/k_H)	k_M (methanol)/k_M (water)	k_M (hexane)/k_M (water)
NO_2^-	1.62 (±0.05)	5 (±1)	0.66 (±0.2)	—
NO_3^-	0.005 (±0.001)	270 (±50)	0.73 (±0.2)	—
TEMPO	4.9	3.7 (±1)	3.0 (±0.5)	5.0 (±1.7)
TEMPO-OH	—	—	3.5 (±0.5)	4.3 (±1.5)
Nitrobenzene	1.6 (±0.6)	7 (±3)	—	1.2 (±0.4)

[a]Reference (1), with k_H in units of 10^9 M^{-1}s^{-1}.

Discussion

Several interesting points emerge from the information reported in Tables 1 and 2.

(1) The water-soluble ions evidently react with Mu marginally faster in water than in methanol, while the TEMPO solutes react faster in hexane than in methanol and faster in methanol than in water. Nitrobenzene, on the other hand, reacts at virtually the same rate in water and hexane. Several solvent-dependent factors must be involved to account for this variety of k_M data.

These factors will undoubtedly include the following: (*i*) the degree-of-solvation of Mu (and solute) in the different solvents; (*ii*) the relative mobility of Mu in the different solvents, including the ratio of inverse-viscosities of the solvents for those values of k_M that are approaching the diffusion-controlled limit; and (*iii*) the relative tunneling probability for Mu in the different solvents, especially for the reactions with the free radicals TEMPO and TEMPO-OH that could alternatively interact by spin-exchange. All these factors have been discussed in various forms previously (see, for example refs. (6), (7), and (8)).

(2) The KIEs for NO_2^- and NO_3^- make an interesting contrast, the first being in the commonly found range of 1 to 5, while the latter is exceptionally large at ~270 (8). This massive KIE shown by NO_3^- ions was noted 25 years ago when Mu was first observed in water and when the first basic reactions of Mu were studied (4). This leads to the idea that k_M might be exceptionally large because of the possibility of a depolarizing spin-exchange involving a particularly long-lived, pre-equilibrium, paramagnetic transition state of Mu–NO_3^-. This would register as a "chemical reaction" in the case of Mu, but not of H.

Here the KIE of NO_2^- is seen to be ~5, and all k_M values with NO_2^- and NO_3^- in methanol are in the same range as in water; therefore a spin-exchange explanation for k_M is an unlikely explanation for KIE being 270 for NO_3^- in water. In fact these results indicate that it is the H+NO_3^- reaction that is the "exception". This H-atom reaction has already been reported (9) to have an unusually high Arrhenius pre-exponential A-factor (2×10^{15} M^{-1} s^{-1}) and a very high activation barrier (49 kJ mol^{-1}) for such a simple interaction. This is in sharp contrast with the Mu + NO_3^- reaction, where particularly small values of both A (2×10^{10} M^{-1} s^{-1}) and E_a (6 kJ mol^{-1} s^{-1}) were obtained (10), together with a shallow convex-upward Arrhenius plot indicative of a dominant tunneling mechanism.

(3) Other implications of the data include the following: (*i*) All these KIEs show Mu to be more reactive than H towards the solutes (by factors of 3.7 to 7). In general it has been found that KIEs are >1 in water for all reaction types except those with high activation barriers (such as "abstraction" reactions) where the zero-point energy effect favours H (8). This suggests that the reaction of Mu with NO_2^- has a "combination" rate-determining step, with subsequent dissociation to OMu$^-$, rather than direct "abstraction" of O$^-$. (*ii*) The similarity of the ratio of values of k_M of TEMPO and TEMPO-OH in the different solvents indicates that the extra –OH group does not affect the relative rates regardless of the polarity of the solvent. Their absolute rates change by factors of about 1 to 3 to 5 with solvent and are probably close to their diffusion-controlled limits. This suggests the reaction rate may be governed by the mobility of Mu in water versus methanol versus hexane. But the ratios of inverse viscosities are only 1 to 1.6 to 3.0, so other factors, such as tunneling propensity in the different solvents, might be involved. (*iii*) The highest absolute rate constant for a Mu reaction seen here is with TEMPO in hexane, which at 8×10^{10} M^{-1} s^{1}, makes it one of the fastest reactions reported so far between a pair of neutral species in the liquid phase, in any solvent.

Aqueous nonelectrolyte solutions. Part XIX. Congruent dissociation melting point and the formula of structure II methane hydrate

David N. Glew

Abstract: Twenty-four equilibrium pressures, $P(h_2l_1g)$, of structure II methane hydrate h_2 with water l_1 between 27.0 and 46.9°C are well represented by a four-parameter equation, which indicates a standard error (SE) of 1.95% on a single pressure measurement. Forty equilibrium constants $K_p(h_2{\rightarrow}l_1g)$ for dissociation of structure II methane hydrate into water and methane between 27.0 and 47.7°C and at pressures up to 784 MPa at 45.0°C are best represented by a three-parameter thermodynamic equation, which indicates an SE 1.25% on a single $K_p(h_2{\rightarrow}l_1g)$ determination. The congruent dissociation melting point $C(h_2l_1gx_m)$ of structure II methane hydrate is at 47.71°C with SE 0.03°C and at pressure 533 MPa with SE 5 MPa. The congruent $K_p(h_2{\rightarrow}l_1g)$ is 102.9 with SE 0.3 MPa, $\Delta H^{ot}(h_2{\rightarrow}l_1g)$ is 61 531 with SE 244 J mol^{-1}, and the congruent formula is CH$_4$·5.670H$_2$O with SE 0.061H$_2$O. At congruent point $\Delta V(h_2{\rightarrow}l_1g) = 0$ and its estimate is 1.0 with SE 1.6 cm^3 mol^{-1}. Stability range of structure II methane hydrate with water extends from quadruple point $Q(h_1h_2l_1g)$ at 26.7°C and 55.5 MPa up to quadruple point $Q(h_2h_3l_1g)$ at 47.3°C and 620 MPa. The metastability range of structure I methane hydrate with water is discussed.

Key words: methane hydrate, clathrate structure II, stability range, dissociation equilibrium constant, formula, congruent melting point, metastability of structure I hydrate.

Résumé : Vingt-quatre pressions d'équilibre, $P(h_2l_1g)$, de la structure II de l'hydrate de méthane, h_2, avec de l'eau, l_1, entre 27,0 et 46,9°C sont bien représentées par une équation à quatre paramètres qui indique que l'erreur standard (ES) est de 1,95% pour chaque mesure individuelle de pression. Quarante constantes d'équilibre, $K_p(h_2{\rightarrow}l_1g)$ pour la dissociation de la structure II de l'hydrate de méthane en eau et en méthane, entre 27,0 et 47,7°C et à des pressions allant jusqu'à 784 MPa, à 45°C, sont bien représentées par une équation thermodynamique à trois paramètres qui indique que l'erreur standard (ES) est de 1,25% pour chaque détermination individuelle de $K_p(h_2{\rightarrow}l_1g)$. Le point de fusion dissociation congruent, $C(h_2l_1gx_m)$, de la structure II de l'hydrate de méthane se situe à 47,71°C, avec une *ES* de 0,03°C, et à une pression de 533 MPa, avec une *ES* de 5 MPa. La valeur congruente de $K_p(h_2{\rightarrow}l_1g)$ est de 102,9 MPa avec une ES de 0,3 MPa, celle de $\Delta H^{ot}(h_2{\rightarrow}l_1g)$ est de 61 531 avec une *ES* de 244 J mol^{-1} et la formule congruente est CH$_4$·5,670H$_2$O avec une ES de 0,061H$_2$O. Au point congruent $\Delta V(h_2{\rightarrow}l_1g) = 0$ et elle est évaluée à 1,0 avec une ES de 1,6 cm^3 mol^{-1}. La plage de stabilité de la structure II de l'hydrate de méthane avec l'eau s'étend du point quadruple, $Q(h_1h_2l_1g)$, à 26,7°C et une pression de 55,5 MPa jusqu'au point quadruple, $Q(h_2h_3l_1g)$, à 47,3°C et une pression de 620 MPa. On discute de la plage de métastabilité de la structure I de l'hydrate de méthane avec l'eau.

Mots clés : hydrate de méthane, clathrate de structure II, plage de stabilité, constante d'équilibre de dissociation, formule, point de fusion congruent, métastabilité de la structure I de l'hydrate.

[Traduit par la Rédaction]

Introduction

The natural abundance of methane hydrate in the permafrost and oceanic regions of the world is enormous (1, 2) and is conservatively estimated within an order of magnitude as 3×10^{15} m^3, making it greater than that estimated for all conventional natural gas reserves. Naturally occurring methane hydrate deposits are formed over millions of years, so that these deposits exist in their thermodynamically stable forms, in temperature, pressure, and composition equilibrium with their environment. The formulae and the stability

ranges of the methane hydrates are clearly important to more accurately assess the methane content stored in the naturally occurring methane hydrate deposits.

Recent work (3) gives formula estimates for two methane hydrates and shows that structure I methane hydrate, phase h_1, is the stable phase in equilibrium with water between the quadruple points $Q(h_1s_1l_1g)$ at –0.29°C and 2.53 MPa and $Q(h_1h_2l_1g)$ at 26.7°C and 55.5 MPa. Structure II methane hydrate, phase h_2, is the stable phase in equilibrium with water from quadruple point $Q(h_1h_2l_1g)$ up to 46.87°C and 397 MPa.

In the present work we evaluate additional measurements at higher pressure for the three-phase (h_2l_1g) equilibrium of structure II methane hydrate with water, from 27.0°C at 56.9 MPa up to 47.7°C at 572 MPa and down to 43.7°C at 816 MPa. The 13 methane hydrate pressure measurements of

data set MSK64 by Marshall et al. (4) serve as the base set with which we compare 27 measurements from Dyadin and Aladko (5): 11 measurements of data set D&A96 lie within the temperature and pressure range of data set MSK64 (4), and 16 measurements are at higher pressure. The level of agreement between these two data sets (4, 5) is good, considering the totally different methods of measurement.

The earlier study MSK64 (4) achieves hydrate equilibrium in a rocked 95 cm³ stainless steel cell, and the methane pressure change is recorded with a slow variation of the temperature of the hydrate cell. Methane pressures are accurate to 0.1%, and temperatures are accurate to 0.004°C (4). In data set D&A96 (5) the equilibrium hydrate decomposition temperature is measured by thermocouple using a high-pressure DTA method on a small sample of compressed methane gas plus water and methane hydrate. Methane pressures are accurate to 1.0% (5), and hydrate temperatures are accurate to 0.1°C.

The present study of methane hydrate extends our earlier work (3) to higher pressure and uses the same numerical methods and thermodynamic equations.

A third data set, NMO99, of 16 hydrate pressures between 31.93 and 47.39°C by Ohgaki et al. (6) deviates systematically with higher pressures than the earlier work (4, 5) because of persistence of the meta-stable structure I methane hydrate.

In the temperature range from quadruple point $Q(h_1h_2l_1g)$ at 26.7°C up to the congruent dissociation melting point $C(h_2l_1gx_m)$ at 47.7°C we reconfirm that, in equilibrium with water and gaseous methane, the stable methane hydrate is phase h_2 (3), the clathrate structure II methane hydrate (7–10) first observed and characterized by Chou et al. (9, 10).

Equilibrium pressure $P(h_2l_1g)$ of structure II methane hydrate with water between 27.0 and 46.9°C

In the temperature range from 27.0 to 46.9°C the equilibrium total pressure $P(h_2l_1g)$ of methane hydrate h_2 with liquid water l_1 is well represented by the unbiased thermodynamic equation,

[1a] $\ln P(h_2l_1g) = b_0 + b_1u_1 + b_2u_2 + b_3u_3.$

This equation is mathematically equivalent (11) to the numerically ill-conditioned unbiased thermodynamic equation,

[1b] $\ln P(h_2l_1g) = A + B/T + C \ln T + DT.$

Temperature variables u_1 to u_3 in [1a] are described briefly in Appendix A and in greater detail in ref. (11).

Table 1 presents 24 estimates of $P(h_2l_1g)$ between 27.0 and 46.9°C, using the 13 measurements of data set MSK64 (4) and 11 measurements from data set D&A96 (5). The arrangement and range of Table 1 is the same as for Table 7 in ref. (3).

The least-squares estimates of the four parameters and their standard errors (SE)s in eq. [1a] are $b_0 = 3.7425$ (0.0269), $b_1 = 43.975$ (3.02), $b_2 = -818.02$ (171), and $b_3 = 10\ 386$ (2070). These parameters give an SE estimate of 0.0193 on ln P, or of 1.95% on a single methane hydrate pressure determination with 20 degrees of freedom. The coefficient of determination R^2 is 0.9992. The 13 measure-

ments of data set MSK64 give a root mean squared (rms) deviation of 0.0167 on ln P or of 1.68% on P. The 11 measurements of data set D&A96 give a larger rms deviation of 0.0188 on ln P or of 1.89% on P and a mean methane hydrate pressure estimate 0.69% larger than data set MSK64.

Equilibrium constant for dissociation of structure II methane hydrate between 27.0 and 47.7°C

The equilibrium constant for dissociation of 1 g molar mass of structure II methane hydrate of formula $CH_4 \cdot nH_2O$ phase h_2 into n mol of pure water l_1 plus 1 mol of gaseous methane is written $K_p(h_2 \rightarrow l_1g)$ and is defined by eq. [2],

[2] $\ln K_p(h_2 \rightarrow l_1g) = \ln f_2(h_2l_1g) + n\ln x_1^{l_1}$

$$+ n(1/RT) \int_{0.1\ \text{MPa}}^{P(h_2l_1g)} (V_1^{l_1} - V_1^{h_2})dP.$$

In eq. [2] $V_1^{l_1}$ is the molar volume of water and $V_1^{h_2}$ is the molar volume of structure II lattice water at pressure $P(h_2l_1g)$ and temperature T. Equilibrium values of $P(h_2l_1g)$ are given in Tables 1 and 3. Equilibrium values of methane fugacity $f_2(h_2l_1g)$ are evaluated from $P(h_2l_1g)$ using the IUPAC fugacity eq. [12] and are given in Table 3. Equilibrium volumes of compressed water are interpolated from tables by Haar et al. (13). Equilibrium values of $x_1^{l_1} = (1 - x_2^{l_1})$ are from $x_2^{l_1}$ values, which are listed in Table 2 and

evaluated using the equation of Rettich et al. (14). Estimates for $V_1^{h_2}$ cm^3 mol^{-1} and its SE at temperature t and at pressure P are 22.63 ± 0.24 at 26.98°C and 56.92 MPa, 22.37 ± 0.24 at 37.15°C and 152.7 MPa, 21.89 ± 0.23 at 45.2°C and 317 MPa, 21.28 ± 0.23 at 47.71°C and 533 MPa, and 20.57 ± 0.22 at 45.0°C and 784 MPa.

The 40 equilibrium constants between 27.0 and 47.7°C from data sets MSK64 and D&A96 are converged as described in ref. (3) and are best (11) represented by the unbiased thermodynamic equation

[3] $\ln K_p(h_2 \rightarrow l_1 g) = d_0 + d_1 u_1 + d_2 u_2.$

Temperature variables u_1 and u_2 and thermodynamic parameters d_0 to d_2 are defined at reference temperature $\Theta =$ 298.15 K (25°C) and are described in Appendix A. The uncertainty of parameter d_2 is such that we are unable to converge and solve the three-parameter equation, eq. [3], directly. Thus the dependent variable is modified to $(\ln K_p(h_2 \rightarrow l_1 g) - d_2 u_2)$ with a pre-defined d_2 and the complementary two-parameter thermodynamic eq. [4],

[4] $(\ln K_p(h_2 \rightarrow l_1 g) - d_2 u_2) = d_0 + d_1 u_1,$

is converged and solved by least-squares for parameters d_0 and d_1.

The parameters of the best converged eq. [4] with their (SE)s are $d_0 = 2.9279$ (0.0056) and $d_1 = 23.421$ (0.099) with the pre-defined $d_2 = 18.4$ and SE estimate of 10.6. The SE estimate on a single determination of unit weight of $\ln K_p(h_2 \rightarrow l_1 g)$ is 0.0124 or 1.25% for $K_p(h_2 \rightarrow l_1 g)$ with 37 degrees of freedom. The number of degrees of freedom is counted from the 40 data minus the two undetermined parameters minus the one weighted datum leaving 37. The coefficient of determination R^2 is 0.9998.

Because we assign unit weight to the 26 measurements of data set D&A96 (5) equal to the unit weight assigned to the less extensive but more accurate 13 measurements of data set MSK64 (4), the best equation for $\ln K_p(h_2 \rightarrow l_1 g)$ in this work is slightly different numerically from that given earlier (3). The present equation is preferred because it represents a greater number and wider range of equilibrium measurements.

The rms of the 13 $K_p(h_2 \rightarrow l_1 g)$ residuals for data set MSK64 is 1.02%, the same as earlier (3). The rms of the 27 residuals, one weighted, for data set D&A96 is 1.31%. The equilibrium constants from data set D&A96 are an average of 0.38% larger than those from data set MSK64.

Table 2 has the same arrangement as Table 8 in ref. (3) and extends the measurements of MSK64 (4) to higher pressure with the measurements of D&A96 (5).

Table 2 shows the 40 converged best estimates of the equilibrium constant $K_p(h_2 \rightarrow l_1 g)$ for dissociation of structure II methane hydrate to liquid water and methane gas with $n = r$. Standard thermodynamic function changes refer to dissociation of 1 g mol of CH$_4 \cdot r$H$_2$O h$_2$ at 0.10 MPa to form r g mol of pure water l$_1$ at 0.10 MPa and 1 g mol of methane gas at 1.0 MPa fugacity. Parameter r is used to indicate the best estimate of n, as described in ref. (3).

The estimates of $K_p(h_2 \rightarrow l_1 g)$ observed in Table 2 are seen to increase monotonously from 22.0 MPa at 26.98°C to 84.7 MPa at 45.2°C, increase more slowly to a maximum between 102.7 and 104.3 MPa at 47.7°C, and then decrease

to 84.4 MPa at 45.0°C. It is noted that the $K_p(h_2 \rightarrow l_1 g)$ observed at 45.2°C and 317 MPa pressure is substantially the same as that observed at 45.0°C and 784 MPa pressure.

The calculated $K_p(h_2 \rightarrow l_1 g)$ estimates in Table 2 properly represent these changes with an SE of 1.25% on a single determination of unit weight. The maximum of $K_p(h_2 \rightarrow l_1 g)$ near 47.7°C and at pressure between 527 and 572 MPa defines the invariant congruent dissociation melting point of h$_2$ methane hydrate, to be discussed fully and located more accurately later.

The measurement at 43.7°C and 816 MPa is an outlier and is assigned weight $w^{1/2} = 0.001$ because its deviation from the best converged eq. [4] is 76 times its estimated standard error.

Standard enthalpy change $\Delta H^{\text{ot}}(h_2 \rightarrow l_1 g)$ and formula number estimate r for structure II methane hydrate with water

The first four columns in Table 3 list the data set, the Celsius temperature (ITS-90), the equilibrium hydrate total pressure $P(h_2 l_1 g)$ MPa, and the equilibrium methane fugacity $f_2(h_2 l_1 g)$ MPa, respectively. Table 3 also presents the converged best estimates of the standard enthalpy change $\Delta H^{\text{ot}}(h_2 \rightarrow l_1 g)$ and the approximate formula number r for standard dissociation of structure II methane hydrate CH$_4 \cdot r$H$_2$O into water and methane gas. The SE on $\Delta H^{\text{ot}}(h_2 \rightarrow l_1 g)$ is 244 J mol^{-1} and on r is 0.061 at all temperatures.

The predefined standard heat capacity change $\Delta C_p^{\text{ot}}(h_2 \rightarrow l_1 g)$ is 153 with SE 88 J mol^{-1} deg^{-1}. The SE is evaluated for eq. [3] with three parameters using the SE $\ln K_p(h_2 \rightarrow l_1 g) = 0.0124$.

At quadruple point $Q(h_1 h_2 l_1 g)$ 26.7°C the estimated formula for structure II methane hydrate h$_2$ is CH$_4 \cdot 5.766$H$_2$O with SE 0.061H$_2$O; this agrees roughly with the earlier estimate CH$_4 \cdot 5.822$H$_2$O with SE 0.064H$_2$O given in (3). The new formula estimate for structure II methane hydrate at 26.7°C is nearer to the equilibrium formula found (3) for the structure I methane hydrate h$_1$ CH$_4 \cdot 5.759$H$_2$O with SE 0.077H$_2$O. These three formula estimates are insignificantly different from each other.

In Table 3 the value of r is shown to decrease with increasing temperature and attains its minimum value 5.670 with SE 0.061 at 47.7°C. This gives the limiting formula CH$_4 \cdot 5.670$H$_2$O with SE 0.061H$_2$O for the congruent structure II methane hydrate (7–10) estimated from the equilibrium pressures (4, 5) and the volumetric properties of methane (12) and of water (13).

The number of methane guest molecules, defined as m per unit cell of 136H$_2$O, increases from 23.59 with SE 0.25 at 26.7°C and 55.5 MPa to 23.95 with SE 0.26 at 45.2°C and 317 MPa to a maximum of 23.99 with SE 0.26 at 47.7°C and 536 MPa, and it decreases to 23.95 with SE 0.26 at 45.0°C and 784 MPa. These values of m between 26.7 and 47.7°C show the increasing number of the 24 lattice sites that must be occupied by methane guests to stabilize the structure II methane hydrate against thermal collapse due to increasing temperature.

Consistent with the observed equilibrium constants, we note that m at 45.2°C and 317 MPa has the same value as at

Table 2. Equilibrium constant for structure II methane hydrate with water.

45.0°C and 784 MPa despite the large difference of methane equilibrium pressure. These externally applied methane pressures remain relatively small, being only 12.4% and 30.7% of the hydrate internal pressure 2551 MPa at 46.87°C (3).

Congruent dissociation melting point of structure II methane hydrate

Eighteen methane hydrate measurements between 317 MPa and 784 MPa from data set D&A96 (5) show that the equilibrium hydrate temperature can be accurately represented by eq. [5] as an empirical quartic function of the equilibrium hydrate pressure,

[5] $\quad t\ (°C) = e_0 + e_1\Delta P + e_2(\Delta P)^2 + e_3(\Delta P)^3$

$$+ e_4(\Delta P)^4.$$

In eq. [5], t (°C) is the equilibrium methane hydrate temperature (ITS-90), ΔP is the equilibrium pressure difference $(P(h_2l_1g) - 532.75)$ MPa, and 532.75 MPa with SE 5.13 MPa is the estimated pressure at maximum hydrate temperature, t_{max}. The estimated maximum congruent dissociation melting temperature of structure II methane hydrate is $t_{max} = e_0 = 47.714$°C with SE 0.032°C. Parameter $e_1 = 2.87 \times 10^{-12}$ with SE 4.2×10^{-4}, parameter $e_2 = -5.80 \times 10^{-5}$ with SE 4.3×10^{-6}, parameter $e_3 = 1.94 \times 10^{-8}$ with SE 1.1×10^{-8}, and parameter $e_4 = 1.63 \times 10^{-10}$ with SE 8.3×10^{-11}. The SE estimate on a single methane hydrate tempera-

[a]The standard errors of $\Delta H^{ot}(h_2{\to}l_1g)$ and r are 244 J mol^{-1} and 0.061, respectively.

ture determination is 0.088°C with 13 degrees of freedom and is in good agreement with the 0.1°C accuracy of temperature measurement indicated by the authors (5). The coefficient of determination R^2 is 0.9934.

The estimate of parameter e_1 is zero. Estimates of parameters $e_0 = t_{max}$ and e_2 are highly significant and could arise by random chance with a probability less than 0.05%. The estimate of parameter e_3 could arise by random chance with a probability ~4.9% and the estimate of parameter e_4 could arise by chance with a probability ~3.8%. This quartic equation gives a flatter maximum and better representation of the methane hydrate temperatures than the best cubic equation.

At the congruent temperature t_{max}, $(dt/dP) = 0$; thus, the volume change for the hydrate dissociation melting reaction is $\Delta V(h_2{\to}l_1g) = (dt/dP)\ \Delta H(h_2{\to}l_1g)/T = 0$, with $\Delta H(h_2{\to}l_1g)/T > 0$.

In the two-component methane–water system, the congruent dissociation melting point of structure II methane hydrate is an invariant three-phase point, denoted $C(h_2l_1gx_m)$, at which the volume and composition x_m of the equilibrium methane hydrate phase h_2 is equal to the volume and composition of its fused reaction products, water and methane.

At the congruent point $C(h_2l_1gx_m)$, 47.71°C, and 533 MPa, the thermodynamic model gives a maximum equilibrium

constant $K_p(h_2{\rightarrow}l_1g)$ of 102.9 MPa with SE 0.3 MPa and a maximum $CH_4{:}H_2O$ mol ratio for the methane hydrate formula $CH_4{\cdot}5.670 \pm 0.061H_2O$ with an h_2 formula volume 120.7 ± 1.3 cm^3 mol^{-1} CH_4 and a cubic hydrate lattice (7–10) spacing 1.688 ± 0.006 nm. The equilibrium volume (12) of methane g is 32.3 ± 0.3 cm^3 mol^{-1} CH_4, and the equilibrium water volume (13) of $5.670H_2O$ l_1 is 89.3 ± 1.0 cm^3 mol^{-1} CH_4. At $C(h_2l_1gx_m)$ the estimated ΔV (products – reactants) = 1.0 ± 1.6 cm^3 mol^{-1} CH_4. Similarly, for the hydrate with formula $CH_4{\cdot}5.678 \pm 0.061H_2O$ at 45.2°C and 317 MPa $\Delta V = 5.1 \pm 1.7$ cm^3 mol^{-1} CH_4 and with formula $CH_4{\cdot}5.679 \pm 0.061H_2O$ at 45.0°C and 784 MPa $\Delta V = -1.2 \pm 1.6$ cm^3 mol^{-1} CH_4.

Between quadruple point $Q(h_1h_2l_1g)$ 55.5 MPa at 26.7°C and up to hydrate pressure 533 MPa at 47.71°C, it is shown that with increasing temperature methane from the gas phase is forced into the equilibrium structure II methane hydrate lattice, enriching its methane content up to its congruent maximum. At methane pressures beyond 533 MPa, increasing up to 816 MPa, the mechanically compressed structure II methane hydrate is forced increasingly to exude guest methane into the gas phase, thereby destabilizing the solid methane hydrate so that it can only exist in equilibrium with water at increasingly lower temperatures.

The quadruple point with a denser hydrate at 620 MPa reported in (5, 15) defines the four measurements between 46.8°C at 658 MPa and 45.0°C at 784 MPa to be in a region of meta-stable equilibrium. Nonetheless these measurements are members of the same (h_2l_1g) equilibrium set as those measurements at pressures less than 527 MPa. This is proved by the accurate representations of the methane hydrate measurements by eqs. [4] and [5] between 317 and 784 MPa.

It is particularly valuable that the high-pressure experimental DTA decomposition technique developed by Dyadin et al. (5) enables the determination of meta-stable (h_2l_1g) equilibria.

There is little doubt that the more stable and denser methane hydrate, indicated by quadruple point $Q(h_2h_3l_1g)$ at 620 MPa and 47.3°C and by its smooth (h_3l_1g) decomposition curve between 48.6°C at 642 MPa and 53.6°C at 1000 MPa (5, 15), is the clathrate structure-H methane hydrate phase h_3 first described and characterized by Chou et al. (10). The growth of single crystals of clathrate structure-H methane hydrate is shown during slow cooling at 33°C and 910 MPa (10). The hexagonal clathrate structure-H methane hydrate is confirmed by a single crystal synchrotron X-ray structure determination at 25°C and 600 MPa, together with a Raman spectrum at 880 MPa (10).

The congruent dissociation melting point of structure II methane hydrate is not unique. Dyadin et al. (16) describe an entirely similar behaviour for structure II argon hydrate with a very gentle maximum congruent dissociation melting point 33.4°C at about 620 MPa going down slightly to 31.5°C at 720 MPa.

Metastability of structure I methane hydrate

The present work and earlier studies (3, 9, 10) show that structure I methane hydrate is metastable between 26.7°C at 55.5 MPa, 47.7°C at 572 MPa, and 45.0°C at 784 MPa and that the structure II methane hydrate clathrate is the stable phase, as demonstrated by Chou et al. (9, 10) at 25°C and at pressures between 100 and 600 MPa.

The initial methane hydrate made at 7°C by Nakano et al. (6) is structure I. The 16 equilibrium pressures reported (6) between 31.93 and 47.39°C are all higher than the pressures estimated for the structure II methane hydrate (4, 5). The positive pressure deviations increase continuously from 1.5 MPa at 31.93°C to 34.7 MPa at 47.39°C and indicate that structure I methane hydrate is meta-stable relative to structure II methane hydrate. The Raman spectrum at 100 MPa pressure (4) confirms the structure I methane hydrate at 31.93°C, and continuity of the spectral shifts confirms the structure I hydrate between 100 MPa at 31.93°C and 500 MPa at 47.39°C. It is remarkable that the single crystal of methane hydrate annealed and aged at 47.85°C and 493 MPa (6) retained its meta-stable structure I form. Over the short experimental time frame of a few days, the metastability of structure I methane hydrate is demonstrated between 32°C at 100 MPa and 47.4°C at 500 MPa (6).

The work of Hirai et al. (17, 18) shows the formation of structure I methane hydrate at room temperature at between 200 and 300 MPa, and with compression up to 700 MPa. The authors provide a powder X-ray diffraction pattern at 400 MPa showing structure I methane hydrate and give unit cell parameters at pressures 260, 300, 380, and 700 MPa, which confirm retention of the structure I hydrate. Structure factor analyses show (17, 18) that within the structure I unit cell both the six tetrakiadecahedral sites and the two pentagonal dodecahedral sites are completely filled by methane at all pressures between 260 and 700 MPa at room temperature. Our estimate of a 99.84% filled structure I methane hydrate at 55.5 MPa and 26.7°C (3) indicates full site occupancy by methane at higher pressures and temperatures. Over the short experimental time frame of days the metastability of structure I methane hydrate at room temperature between 200 and 700 MPa pressure is demonstrated (17, 18).

Chou et al. (9) point out that in some experiments structure I methane hydrate is found to exist metastably at higher pressures. The Raman spectra of metastable structure I methane hydrate are shown at 25°C and at pressures of 125, 649, and 880 MPa (9) and are contrasted with the spectrum of the stable structure II methane hydrate at 25°C and 125 MPa (9, 10). Direct optical observation of single crystals of structure II methane hydrate by Chou et al. (9) shows structure II crystal survival at 41°C and 223 MPa and structure II crystal growth at temperatures down to 35°C and 136 MPa in the presence of metastable structure I methane hydrate. Chou et al. (9, 10) confirm the cubic clathrate structure II methane hydrate by a complete single-crystal synchrotron X-ray structure determination at 25°C and 250 MPa.

The work of Loveday et al. (19) starts with the polycrystalline neutron diffraction pattern of metastable structure I methane D-hydrate at room temperature and 800 MPa pressure and thereby unfortunately misses the entire equilibrium three-phase region for formation of the clathrate structure II methane hydrate (9, 10), from 26.7°C at 55.5 MPa up to 47.7°C at 572 MPa and down to 45.0°C at 784 MPa (3–5).

The metastability of clathrate structure I methane hydrate with water relative to clathrate structure II methane hydrate at room temperature and at pressures between 200 and 880 MPa (6, 9, 17–19) most probably derives from the slow kinetics of reaction [6],

$$[6] \quad 0.9855CH_4 \cdot 5.750H_2O \ (h_1) + 0.0145CH_4 \ (g, l_1)$$
$$= CH_4 \cdot 5.667H_2O \ (h_2)$$
in which additional methane (gaseous or aqueous) is required to drive and balance the reaction at temperatures below $Q(h_1h_2l_1g)$ at 26.7°C.

We consider the slow kinetics at 25°C to be due to (*i*) the lack of excess gaseous and aqueous methane in contact with the methane-full structure I hydrate to force the reaction, (*ii*) the small positive difference of hydrate water molar volume, $\Delta V_1 = V_1^{h_2} - V_1^{h_1} = 0.41 \ cm^3 \ mol^{-1}$, which increases rather than decreases the lattice water Gibbs' energy difference with increasing pressure, and (*iii*) the small negative difference of mean molecular volume of about $-1.0 \ \text{Å}^3$, which decreases the overall Gibbs' energy of the structure II hydrate relative to the structure I hydrate with increasing pressure. Apparently the increased applied pressures of 900 to 1500 MPa at room temperature (17–19) are sufficient to squeeze methane from the gaseous and aqueous phases into faster reaction with the metastable methane-full structure I hydrate lattice to form the more stable methane-full structure II hydrate lattice. This view is supported by the relatively unhindered growth kinetics of single crystals of clathrate structure II methane hydrate (9, 10) in the presence of clathrate structure I methane hydrate at 35.0°C and at low pressures between 130 and 600 MPa.

Appendix A: Definition of thermodynamic parameters at reference Θ *K*

When the dependence of equilibrium constant K_p on temperature T is properly represented by the unbiased, three-variable, four-parameter, thermodynamic equation, eq. [A1]

$$[A1] \quad \ln K_p = A + B/T + C \ln T + DT,$$

then ref. (11) shows that an identical temperature representation of K_p can be obtained using the unbiased, three-variable, four-parameter, thermodynamic equation, eq. [A2]

$$[A2] \quad \ln K_p = b_0 + b_1 u_1 + b_2 u_2 + b_3 u_3.$$

The least-squares fits of K_p data sets by eqs. [A1] and [A2] are identical when the variables u_1, u_2, and u_3 in [A2] are defined as functions of temperature T and a predefined reference temperature Θ, with $u_1 = [(T - \Theta)/T]$, $u_2 = [(\Theta - T)/T] + \ln(T/\Theta)$, and $u_3 = [(T - \Theta)(T + \Theta)/\Theta T - 2\ln(T/\Theta)]$, and then the corresponding thermodynamic parameters b_0 to b_3 are defined at reference Θ, with $b_0 = (\ln K_p)_\Theta = -\Delta G_\Theta^o/R\Theta$, $b_1 = \Delta H_\Theta^o/R$, $b_2 = \Delta C_{p\,\Theta}^o/R$, and $b_3 = \Theta(d\Delta C_p^o/dT)_\Theta/2R$. Reference $\Theta = 298.15$ is used here and in ref. (3).

Outer-sphere electron transfer reactions of aqua(5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1-acetato) nickel(II) and (III).

Robert I. Haines and Dean R. Hutchings

Abstract: The outer-sphere oxidation of the nickel(II) complex of the deprotonated pendant-arm macrocycle, 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1-acetate, $[NiL^1(OH_2)]^+$ by bis-(1,4,7-triazacyclononane)nickel(III), $[Ni(tacn)_2]^{3+}$ has been studied in aqueous perchlorate media. The reaction displays reversible second-order behaviour and the kinetic study reveals the forward and reverse rate constants for the reaction:

$$[Ni(tacn)_2]^{3+} + [NiL^1(OH_2)]^+ \rightleftarrows [Ni(tacn)_2]^{2+} + [NiL^1(OH_2)]^{2+}$$
The kinetics show the forward reaction to be acid dependent, a feature that is attributed to protonation of the acetato group of the nickel(II) complex. Using Marcus theory, the self-exchange rate for the $[NiL^1(OH_2)]^{+/2+}$ couple has been calculated. The nickel(II/III) electron transfer is a reversible one electron process with $E° = 1.04$ V (vs. S.H.E.). The formation of the authentic nickel(III) product has been confirmed by esr spectroscopy. The kinetics of reduction of the $[NiL^1(OH_2)]^{2+}$ species by Fe^{2+}(aq) exhibits a second-order rate law, the reaction being independent of acid. Using the calculated self-exchange rate for the nickel complex, its reaction with Fe^{2+}(aq) has been examined in terms of an inner- versus outer-sphere mechanism.

Key words: nickel(III), pendant-arm macrocycles, hexaaquairon(II), outer sphere, kinetics, Marcus theory.

Résumé : Opérant en solution aqueuse de perchlorate, on a étudié l'oxydation dans la sphère extérieure du complexe de nickel du macrocycle à bras pendant déprotoné 5,5,7,12,12,14-hexaméthyl-1,4,8,11-tétraazacyclotétradécane-1-acétate, $[NiL^1(OH_2)]^+$, par le bis-(1,4,7-triazacyclononane)nickel(III), $[Ni(tacn)_2]^{3+}$. La réaction présente un comportement réversible du deuxième ordre et l'étude cinétique permet de mesurer les constantes de vitesse pour les deux directions de la réaction:

$$[Ni(tacn)_2]^{3+} + [NiL^1(OH_2)]^+ \rightleftarrows [Ni(tacn)_2]^{2+} + [NiLi^1(OH_2)]^{2+}$$
La cinétique montre que la réaction vers la droite dépend de l'acide, une caractéristique qui est attribuée à la protonation du groupe acétato du complexe de nickel(II). Faisant appel à la théorie de Marcus, on a calculé la vitesse d'autoéchange du couple $[NiL^1(OH_2)]^{+/2+}$. Le transfert d'électron nickel(II/III) et un processus réversible à un électron avec $E° = 1,04$ V (vs S.H.E.). La formation du produit authentique nickel(III) a été confirmée par spectroscopie RPE. La cinétique de la réduction d'espèces $[NiL^1(OH_2)]^{2+}$ par le Fe^{2+} (aq) présente une équation de vitesse du deuxième ordre et la réaction est indépendante de l'acide. Utilisant la vitesse d'autoéchange calculée pour le complexe de nickel, on a examiné sa réaction avec le Fe^{2+} (aq) en fonction des mécanismes à l'intérieur ou à l'extérieur de la sphère.

Mots clés : macrocycles à bras pendant, hexaaquafer(II), extérieur de la sphère, théorie de Marcus.

[Traduit par la Rédaction]

Introduction

Pendant-arm macrocyclic complexes, because of their thermodynamic stability and extremely slow acid-dependent dissociation, have important radioimmunotherapeutic value (1, 2). Although many studies examine the properties of amino-, nitro-, and pyridyl-arms, the majority involve car- boxylato-pendant arms (3). The ability of polyazamacro-cycles to stabilize transition metal ions in unusual oxidation states has been well known for many years (4). We are interested in the redox behaviour of transition metal macrocycles that contain pendant carboxylato-arms, since these appendages coordinate to the central metal ion and may provide an inner-sphere pathway for electron transfer to or from other

metal centres. Such behaviour has application, for example, in reductive dissolution of iron(III)-bearing ferrites, which constitute corrosion films found in industrial boilers and nuclear reactors (5). Such complexes also find application as chemical sensors for detection of heavy metals in natural waters (6) and as lanthanide complexing agents for use in magnetic resonance imaging (7). Related work in our laboratory involves the use of platinum(II) and (IV) complexes of these macrocycles as potential anti-tumour agents (8).

This work examines the kinetics of oxidation of the nickel(II) tetraazamacrocyclic complex, 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1-acetate, $[NiL^1-(OH_2)]^+$, which bears one pendant acetato group to the nickel(III) state. The use of the resulting nickel(III) macrocycle as a potential inner-sphere oxidant is also discussed in relation to its reaction with hexaaquairon(II).

L^1H $[NiL^1(OH_2)]^+$
Experimental

Materials

All reagents were of AnalaR grade and were used as received. Sodium perchlorate (Aldrich) solutions were standardized by passing an aliquot through a Dowex ion exchange resin and titrating the liberated acid. Stock solutions of iron(II) perchlorate were prepared by dissolving iron(II) perchlorate (Aldrich) in perchloric acid under a nitrogen atmosphere. The iron(II) concentration was determined spectrophotometrically as $[Fe(phen)_3]^{2+}$ ($\varepsilon_{510} = 11\ 200\ dm^3\ mol^{-1}\ cm^{-1}$) after addition of an excess of 1,10-phenanthroline to the solution. The presence of iron(III) in the solutions, tested for by addition of sulfite and 1,10-phenanthroline, was found to be negligible. Acid concentration was determined by titration with standard NaOH, using phenolphthalein indicator. All solutions were prepared using deionized, double-distilled water.

Solutions of hexaaquacobalt(III) ($\varepsilon_{605} = 35.3\ dm^3\ mol^{-1}\ cm^{-1}$) (9) were prepared by electrochemical oxidation of $Co(ClO_4)_2$ in 5.0 mol dm^{-3} HClO$_4$, under nitrogen at 5°C in the dark. Stock solutions were stored at –12°C and were diluted and standardized freshly each day. Solutions of $[Ni(tacn)_2]^{3+}$, to be used for kinetics studies, were prepared in situ by oxidation of the Ni(II) form with a stoichiometric deficiency of $Co^{3+}(aq)$. The resultant $Co^{2+}(aq)$ is inert with respect to interaction with the nickel macrocycles under study, and so $Co^{3+}(aq)$ can be used safely to generate Ni(III) without interference from the $Co^{2+}(aq)$ formed in situ.

Synthesis of ligands and complexes

1,4,7-Triazacyclononane (tacn) and its nickel(II) perchlorate complex were synthesized by a modified literature method (10). The functionalized macrocycle meso-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1-acetic acid (L^1H) and the nickel(II) complex bromide, $[NiL^1(OH_2)]Br$, were prepared according to the literature (11). The nature of the nickel complex was confirmed by X-ray crystallography. Pink needles (0.04 × 0.15 × 0.80 mm), grown by the vapour diffusion method, crystallized in the $P2_1/n$ (#14) space group. Empirical formula is $C_{18}H_{39}BrN_4NiO_3$. Unit cell dimensions were $a = 9.203(4)$ Å, $b = 19.952(3)$ Å, $c = 12.538(4)$ Å, and $\beta = 106.35(3)$°. Since the crystal structure of this compound has been reported previously (11), the details of the structure, which agree with the literature, will not be repeated here. For kinetic studies, the nickel complex was converted to the perchlorate salt and was recrystallized from water prior to use.

ESR spectroscopy

The ESR spectrum of $[NiL^1(OH_2)]^{2+}$, generated in situ by oxidation of the nickel(II) complex by peroxodisulfate, was run on a Varian E360 spectrometer at 77 K in frozen 0.10 M HClO$_4$. An internal standard of diphenylpicrylhydrazine (DPPH) was used.

Cyclic voltammetry

The cyclic voltammogram for a $1.00 × 10^{-3}$ mol dm^{-3} solution of $[NiL^1(OH_2)]^+$ was measured in 0.50 mol dm^{-3} HClO$_4$ using a platinum disc working electrode, a platinum wire counter electrode, and an aqueous silver – silver chloride reference electrode. An EG &G model 283 potentiostat–galvanostat was used. Solutions were purged for 15 min with argon and voltammograms were collected with the solutions blanketed by argon at 25°C.

Kinetics

Kinetic measurements were made using a Hi Tech SF61-DX2 stopped flow spectrometer, thermostatted to ±0.05°C with a Lauda model RM6 refrigerated recirculating water bath. A constant ionic strength (NaClO$_4$/HClO$_4$) was maintained for all experiments. The reactions were followed by monitoring the increase in absorbance at 440 nm due to formation of the nickel(III) complex. Pseudo-first-order rate constants were determined by non-linear least-squares fitting of absorbance-time data, using Hi Tech's "Kinetasyst" software, on a Dell 466 MHz Pentium III computer.

Ionic strength was kept constant at 0.500 mol dm^{-3} for the oxidation of $[NiL^1(OH_2)]^+$ by $[Ni(tacn)_2]^{3+}$. Pseudo-first-order conditions were maintained using a concentration of $2.00 × 10^{-5}$ mol dm^{-3} of $[NiL^1(OH_2)]^+$ with an excess of both $[Ni(tacn)_2]^{3+}$ (varied between $1.10 × 10^{-3}$ and $2.30 × 10^{-3}$ mol dm^{-3}) and $[Ni(tacn)_2]^{2+}$ (held constant at $2.01 × 10^{-4}$ mol dm^{-3}). The presence of both forms (Ni(II) and Ni(III)) of the tacn complex is explained in the Results and Discussion Section below.

In the oxidation of hexaaquairon(II) by $[NiL^1(OH_2)]^{2+}$, the kinetics were studied under pseudo-first-order conditions using an excess of reductant. The oxidant concentration was kept constant at $5.0 × 10^{-5}$ mol dm^{-3}. The ionic strength was maintained at 0.100 mol dm^{-3} using NaClO$_4$–HClO$_4$. For the study of the acid dependence on this reaction, the ionic strength was 1.00 mol dm^{-3} (to allow a wide range of [H$^+$] to be used).

Results and discussion

ESR spectroscopy and electrochemistry

Figure 1 shows the ESR spectrum of the $[NiL^1(OH_2)]^{2+}$ cation in frozen 0.10 mol dm^{-3} HClO$_4$, at 77 K. The typical spectrum of a low-spin d^7 nickel(III) centre shows distinct $g_{//}$ and g features when the single unpaired electron resides in the d_{z^2} orbital and when the system is tetragonally distorted. In the present case, there appears to be only slight distortion from an octahedral environment, since the ESR signal is almost isotropic. A $g_{//}$ feature is discernable, and values of $g_{//}$ and g were measured at 2.031 and 2.182, respectively. Similarly, slight deviations from octahedral geometry have been seen previously for nickel(III) centres, for the family of tris-bidentate chelate complexes, $[Ni(LL)_3]^{3+}$, where LL is 2,2′-bipy, phen, and their derivatives (12).

The cyclic voltammogram of the $[NiL^1(OH_2)]^{+/2+}$ couple in 0.500 mol dm^{-3} HClO$_4$ is shown in Fig. 2. The peak separation is 75 ± 10 mV, (for sweep rates between 25 and 100 mV s^{-1}), corresponding to a reversible one-electron redox process. This is reasonable because the purple aqueous solution of $[NiL^1(OH_2)]^{+}$ indicates the presence of an octahedrally coordinated high-spin nickel(II) centre that is also present in the solid state (from crystallography). The ESR spectrum also indicated an octahedrally coordinated nickel(III) centre for the complex in its oxidized form. Hence there is expected to be little structural change on electron transfer. The electrode potential for the nickel(II/III) couple was measured at 1.04 V (vs. S.H.E.). The stabilization of tervalent nickel by polyazamacrocycles has been well known for more than 30 years (4). The presence of an acetato pendant arm coordinated to the nickel centre lends further stabilization, resulting in a lower electrode potential for the nickel(II/III) couple. This is seen by comparing the electrode potential for the mono-acetato-complex in the present study (1.04 V) with those of the analogues nickel macrocycles with no (L^2) or two (L^3) acetato arms (1.24 and 0.72 V, respectively) (13, 14). Indeed, there is an almost linear relationship among the electrode potentials of these three nickel macrocycles and the number of pendant acetato arms (incremental drop in $E°$ = 0.26 ± 0.06 V). Busch et al. (13) have shown that there is an additive relationship between electrode potentials of nickel macrocycles and structural features for which a drop of 0.43 V per charge was found for systems with delocalized charges in the macrocyclic ring. Axial anionic ligands such as sulfate are also well known to stabilize nickel(III) macrocycles (4). While the $[Ni(tacn)_2]^{3+}$ cation is not a strong enough oxidant to oxidize $[NiL^2]^{2+}$, it easily oxidizes $[NiL^3]^{2+}$ (14). The electrode potential of $[NiL^1(OH_2)]^{+}$ is close to that of $[Ni(tacn)_2]^{3+}$, allowing for an equilibrium redox reaction to occur. One advantage of such a situation is that the equilibrium constant for the cross reaction may be obtained kinetically and may be used in a Marcus theory analysis of the electron transfer mechanism.

Kinetics

Oxidation of [NiL¹(OH₂)]⁺ by [Ni(tacn)₂]³⁺

The $[Ni(tacn)_2]^{3+}$ cation is a well-known outer-sphere oxidant that is not susceptible to protonation or deprotonation reactions in solution (15). Thus, it provides a useful probe
Fig. 1. ESR spectrum of the $[NiL^1(OH_2)]^{2+}$ cation in frozen 0.10 mol dm^{-3} HClO$_4$, at 77 K.
for the elucidation of the mechanisms of electron transfer reactions of oxidizable substrates. In the present study oxidation of $[NiL^1(OH_2)]^{+}$ occurred smoothly under conditions of excess $[Ni(tacn)_2]^{3+}$, the reaction being first-order in nickel(II) complex, according to the expression:

[1]   rate = d $[NiL(OH_2)^{2+}]/dt$ = k_{obs} $[NiL^1(OH_2)^{+}]$
Preliminary studies using varying concentrations of oxidant at a constant $[H^+]$ showed a linear dependence of rate on oxidant concentration with persistent intercepts in the plots of k_{obs} versus $[Ni(tacn)_2]^{3+}$ concentration. Hence the observed pseudo-first-order rate constant has the form k_{obs} = a + $b[Ni(tacn)_2^{3+}]$. Reaction of $[NiL^1(OH_2)]^{2+}$ with $[Ni(tacn)_2]^{2+}$ using excess oxidant also resulted in an electron transfer reaction producing $[NiL^1(OH_2)]^{+}$ and $[Ni(tacn)_2]^{3+}$. This is the reverse of reaction [1], and so the overall reaction may be described as a second-order reversible redox:

[2] $[Ni(tacn)_2]^{3+}$ + $[NiL^1(OH_2)]^{+}$ $\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}}$ $[Ni(tacn)_2]^{2+}$ + $NiL^1(OH_2)]^{2+}$
Subsequent kinetics measurements were performed under conditions of excesses of both $[Ni(tacn)_2]^{3+}$ and $[Ni(tacn)_2]^{2+}$, according to the method of Pellizzetti and Mentasti (16). This procedure avoids the need to use complex integrated rate laws (17) and yields a pseudo-first-order expression identical to eq. [1], where
[3] k_{obs} = $k_2[Ni(tacn)_2^{3+}]$ + k_{-2} $[Ni(tacn)_2^{2+}]$
Table 1. Observed first-order rate constants, k_{obs} (s^{-1}), for the oxidation of [NiL^1(OH$_2$)]$^+$ by [Ni(tacn)$_2$]$^{3+}$ as a function of acid concentration and temperature.

Fig. 2. Cyclic voltammogram of the [NiL^1(OH$_2$)]$^+$ cation in 0.500 mol dm^{-3} HClO$_4$, at 25°C. Scan rates: (*a*) 25 mV s^{-1}, (*b*) 50 mV s^{-1}, (*c*) 75 mV s^{-1}, and (*d*) 100 mV s^{-1}.
The reaction was found to be dependent on [H$^+$], with the reaction rate decreasing with increasing [H$^+$]. Table 1 gives the raw data for the acid dependence of the oxidation of [NiL^1(OH$_2$)]$^{2+}$ by [Ni(tacn)$_2$]$^{3+}$ at an ionic strength of 1.00 mol dm^{-3} for a range of temperatures. There is a small but real and reproducible dependence of rate on acid concentration. Values for k_2 and k_{-2} reported in Table 2 were derived from k_{obs} vs. [Ni(tacn)$_2$$^{3+}$] at constant [Ni(tacn)$_2$$^{2+}$], according to eq. [3]. Separate kinetic studies on the oxidation of

iron(II) by [NiL^1(OH$_2$)]$^{2+}$, reported later in this paper, were independent of acid. This suggested that, since the [Ni(tacn)$_2$]$^{2/3+}$ system is known to be unaffected by acid (15), the source of the [H$^+$] dependence must be from a protonation equilibrium involving the [NiL^1(OH$_2$)]$^+$ species. The reaction may be described by the mechanism:

[4] $\quad$ [NiL^{1}H(OH$_2$)]$^{2+}$ $\overset{K_a}{\rightleftharpoons}$ [NiL^1(OH$_2$)$^+$] + H$^+$

[5] $\quad$ [NiL^{1}H(OH$_2$)]$^{2+}$ + [Ni(tacn)$_2$]$^{3+}$
$\qquad \overset{k_5}{\longrightarrow}$ [NiL^1(OH$_2$)]$^{2+}$ + [Ni(tacn)$_2$]$^{3+}$ + H$^+$

[6] $\quad$ [NiL^1(OH$_2$)]$^+$ + [Ni(tacn)$_2$]$^{3+}$
$\qquad \overset{k_6}{\longrightarrow}$ [NiL^1(OH$_2$)]$^{2+}$ + [Ni(tacn)$_2$]$^{3+}$

Using the law of mass balance, $k_2 = (k_5 + k_6 K_a [\text{H}^+])/(1 + K_a[\text{H}^+])$, whence the expression for the pseudo-first-order rate constant becomes:

[7] $\quad k_{obs} =$

$$\left[\frac{k_5 + k_6 K_a[\text{H}^+]}{1 + K_a[\text{H}^+]}\right][\text{Ni(tacn}_2)^{3+}] + k_{-2}[\text{Ni(tacn)}_2{}^{2+}]$$

Hence a plot of k_{obs}/[Ni(tacn)$_2$$^{2+}$] versus [Ni(tacn)$_2$$^{3+}$]/[Ni(tacn)$_2$$^{2+}$] is linear, with a slope of $(k_5 + k_6 K_a[\text{H}^+])/(1 + K_a[\text{H}^+])$ and an intercept of k_{-2} (Fig. 3). A consequent plot of $k_2(1 + K_a[\text{H}^+])$ versus [H$^+$] (Fig. 3 inset) yields k_6 as slope/K_a and k_5 as the intercept. Thus, at 25°C, k_5 and k_6 have values of 110 and 2 700 mol^{-1} dm^3 s^{-1}, respectively. A non-linear least-squares curve fit of the k_{obs} versus [H$^+$] gave a value for the protonation constant, K_a for [Ni^{II}L(OH$_2$)]$^+$ of 15 ± 4 mol^{-1} dm^3. Although the value of K_a was estimated at several temperatures, it was found to vary little with temperature. We have not determined activation parameters for pathways k_5 and k_6 because the estimated values of k_5 and k_6 at the various temperatures have large uncertainties due to the limited range of acid concentrations possible. From the k_{-2} data, ΔH and ΔS were estimated for the reverse of reaction [2] to be 30 ± 2 kJ mol^{-1} and −60 ± 5 J K^{-1} mol^{-1}, respectively. Such values for activation parameters are typical of outer sphere electron transfer reactions.

Table 2. Observed first-order rate constants, k_{obs} (s^{-1}) and derived second-order rate constants, k_2, k_{-2} (mol^{-1} dm^3 s^{-1}) for the oxidation of $[NiL^1(OH_2)]^+$ by $[Ni(tacn)_2]^{3+}$; ionic strength maintained at 0.500 mol dm^{-3} ($HClO_4$); $[Ni(tacn)_2^{2+}]$ = 2.01 × 10^{-4} mol dm^{-3}.

Fig. 3. Plot of $k_{obs}/[Ni(tacn)_2^{2+}]$ versus $[Ni(tacn)_2^{3+}]/[Ni(tacn)_2^{2+}]$ at 25.0°C and ionic strength 1.00 mol dm^{-3}. [H^+]: (▲) 0.40 mol^{-1} dm^{-3}, (○) 0.55 mol^{-1} dm^{-3}, (●) 0.70 mol^{-1} dm^{-3}, (□) 0.85 mol^{-1} dm^{-3}, (■) 1.00 mol^{-1} dm^{-3}. Inset Fig. shows acid dependence of k_2 (see text).

The rate of oxidation of the deprotonated nickel macrocycle is approximately 25 times faster than the protonated form. This difference is in keeping with the discussion above and may be attributed to a lower electrode potential of the deprotonated form since the negatively charged acetato group will tend to stabilize the tervalent nickel centre. This is not unusual; for example, in redox reactions involving Co^{3+}(aq), the inverse acid dependence in the rates of its redox reactions is due to the reactivity of the hydrolysed form, $CoOH^{2+}$(aq) (9). Similarly, ascorbate is several orders of magnitude more reactive than ascorbic acid (18).

Owing to the equilibrium nature of this reaction, we may estimate the cross-reaction equilibrium constant for reduction of the deprotonated nickel(III) macrocycle by $[Ni(tacn)_2]^{2+}$ as k_{-2}/k_6. At 25°C, this has a value of 0.77. Since the self-exchange rate for the $[Ni(tacn)_2]^{2/3+}$ couple is known (19), Marcus theory may be used to determine the self-exchange rates for the $[NiL^1(OH_2)]^{+/2+}$ couple.

According to Marcus theory (20), for an outer-sphere electron transfer mechanism, the rate constant for the cross-reaction (k_{12}) is related to the rate constants for the self-exchange rates of the components, k_{11} and k_{22}, and the cross reaction equilibrium constant (K_{12}) by the expression:

[8] $\qquad k_{12} = (k_{11} \, k_{22} \, K_{12}f_{12})^{1/2}W_{12}$

where

$$\ln f_{12} = \frac{[\ln K_{12} + (w_{12} - w_{21})/RT]^2}{4[\ln(k_{11}k_{23}/Z^2) + (w_{11} + w_{22})/RT]}$$

and

$$W_{12} = \exp[-(w_{12} + w_{21} - w_{11} - w_{22})]/2RT$$

where $w_{ij} = 4.225 × 10^3 \, Z_iZ_j/\sigma_{ij} (1 + 0.329\sigma_{ij} (\mu^{1/2}))$. The term w_{ij} is the work required to bring the ions i and j (with charges Z_i and Z_j, respectively) to the separation distance σ_{ij}. This distance is assumed to be equal to the sum of the radii of the ions i and j; and μ is the ionic strength.

The self-exchange rate, k_{11}, for the $[NiL^1(OH_2)]^{+/2+}$ system is calculated from eq. [8] as 870 mol^{-1} dm^3 s^{-1}, where K_{12} has a value of 0.77 (above) and k_{12} (= k_{-2} in our mechanistic scheme) was measured as 2.00 × 10^3 mol^{-1} dm^3 s^{-1}. The estimate of k_{11} is in close agreement with self-exchange rates of other nickel(II/III) macrocyclic systems (21). It is interesting to note that the self-exchange rate for the diacetato complex $[NiL^3]^{0/+}$ has been estimated (14) at 55 mol^{-1} dm^3 s^{-1}, whereas those for nickel complexes of planar tetraazamacrocycles of the type L^2 have self-exchange rates in the region of 1500 mol^{-1} dm^3 s^{-1}. This trend may be explained by an increase in internal reorganizational energies with increasing stricture of the metal ion within the macrocycle. The nickel ion is quite confined in the octahedral complex of L^2. For planar tetraazamacrocyclic complexes, the nickel(III) form, being in a tetragonally distorted octahedral geometry, has axial ligands that are not tethered to the macrocycle and so can "breathe". This lack of tethering allows for bond length changes on electron transfer. A similar situation pertains to the case of
Table 3. Observed first-order rate constants, k_{obs} (s^{-1}), together with the derived second-order rate constants, k_9 (mol^{-1} dm^3 s^{-1}), for the oxidation of Fe^{2+}(aq) by [Ni^{III}L(OH$_2$)]$^{2+}$ in 1 .00 mol dm^{-3} HClO$_4$, for a series of temperatures.

[Fe^{2+}] ($\times 10^4$) (mol dm^{-3})	k_{obs} (s^{-1})				
Temperature (K)	287.9	291.2	294.6	298.1	303
4.58	15.6(1)	18.0(1)	20.7(2)	25.0(2)	30.8(1)
9.16	31.3(3)	36.0(2)	41.8(3)	49.5(2)	61.0(3)
18.3	63.4(5)	73.2(7)	84.0(2)	99.6(8)	122(1)
27.5	96.8(9)	111(1)	128(1)	150(2)	184(2)
36.6	130(3)	149(2)	173(2)	203(2)	248(3)
k_8 (mol^{-1} dm^3 s^{-1})	35 100 ± 100	40 500 ± 300	47 100 ± 400	55 800 ± 400	68 300 ± 500

[Ni(tacn)$_2$]$^{2/3+}$, in which, even though the complex is octahedral, the macrocyclic ligands cap the metal ion and can move in or out with changes in metal-ligand bond length upon change in the metal ion oxidation state. The mono-acetato-macrocycle in the present study is intermediate in that one axial position of the metal ion is confined by the co-ordinated pendant-arm group but the other axial position, co-ordinated to an aqua ligand, can "breathe". Hence it seems reasonable that the self-exchange rate for the last case is intermediate between the previous two.

Oxidation of Fe^{2+}(aq) by [NiL^1(OH$_2$)]$^{2+}$

The pendant-arm macrocyclic complex [NiL^1(OH$_2$)]$^{2+}$ was originally chosen for study because it provides the possibility of an acetato bridging ligand, which might provide a conduit for an inner-sphere electron transfer, from iron(II) to the nickel(III) centre. The reaction was followed by monitoring the disappearance of the strong absorption at 440 nm (ε = 8000 mol^{-1} dm^3 cm^{-1}), typical of UV–visible spectra of nickel(III) macrocycles (4). Spectrophotometric titration showed the reaction to have a 1:1 stoichiometry, within experimental error. The reaction is clearly first order with respect to the oxidant, and the dependence of the rate on [Fe^{2+}] also exhibits excellent first-order behaviour (Table 3). Owing to the high reaction rate, the range of iron(II) concentrations was limited to between 4.7×10^{-4} and 1.3×10^{-3} mol dm^{-3}. The lower limit ensured a sufficient excess of reductant for pseudo-first-order conditions ([NiL^1(OH$_2$)$^{2+}$] = 4.0×10^{-5} mol dm^{-3} for all experiments). The reaction was studied at various acid concentrations between 0.10 and 1.00 M HClO$_4$ (at constant ionic strength) at 14°C for a constant iron(II) concentration of 9.98×10^{-4} mol dm^{-3}. The rate was found to be independent of [H$^+$], with a mean value of k_{obs} of 37.0 ± 0.5 s^{-1} at 14°C. The lack of dependence of the rate on [H$^+$] suggests that there is negligible hydrolysis of either reactant under the experimental conditions. This is not unexpected, since a similar lack of dependence on acid concentration has been observed previously for oxidation of iron(II) by [Ni(oxime)]$^{2+}$ (22) and [Ni(bipy)$_3$]$^{3+}$ (23). While hydrolysis of diaquanickel(III) macrocycles is common, the aquanickel(III) complex in the present study contains a deprotonated pendant acetato group coordinated to the metal centre, resulting in an overall 2+ charge on the complex. Thus, hydrolysis of this species is expected to be minimal. Addition of [NiL^1(OH$_2$)]$^+$ to the system had no effect on rate, indicating that equilibrium conditions do not obtain in this reaction. Hence the reaction equation is

[9]   [NiL^1(OH$_2$)]$^{2+}$ + Fe^{2+}(aq) $\xrightarrow{\,k_9\,}$ [NiL^1(OH$_2$)]$^+$
                                                                            + Fe^{3+}(aq)

and it obeys a simple second-order overall rate law:

[10]   rate = $-\mathrm{d}$[NiL^1(OH$_2$)$^{2+}$]/dt

              = k_9[NiL^1(OH$_2$)$^{2+}$][Fe^{2+}]

The activation enthalpy and entropy were calculated, from the data in Table 3, to be 29.9 ± 0.5 kJ mol^{-1} and –54 ± 2 J K^{-1} mol^{-1}, respectively. The magnitudes of the activation parameters are similar to those for oxidation of iron(II) by other nickel(III) macrocycles (24) and by metal complexes (25, 26). In these systems, an outer-sphere mechanism has been invoked. Since we have evaluated the self-exchange rate for the [NiL^1(OH$_2$)]$^{+/2+}$ couple (vide supra), we can compare the experimental value of the cross-reaction rate constant (k_9) with that calculated from Marcus theory.

The self-exchange rate of the Fe$^{2+/3+}$ couple (k_{22}) has been reported as 1.1 mol^{-1} dm^3 s^{-1} by Sutin and co-workers (27) and by Swaddle and co-workers (28), whereas Jordan (29) suggests that the true rate of self-exchange is 4.2 mol^{-1} dm^3 s^{-1}, after compensation for an inner-sphere pathway via a hydroxo-bridged species. We have used Jordan's value in our calculations. The equilibrium constant, K_{12}, was estimated at 4.0×10^4 from the difference in electrode potentials between the reactants. Using eq. [8], the theoretical cross-reaction rate constant for eq. [9] is calculated to be 1.2×10^4 mol^{-1} dm^3 s^{-1} (using k_{11} = 870 mol^{-1} dm^3 s^{-1}). There is good agreement with the experimentally measured value for k_9 of 5.57×10^4 mol^{-1} dm^3 s^{-1}, lending support to the conclusion that the oxidation of iron(II) by the acetato pendant-arm macrocyclic nickel(III) complex is outer-sphere.

The hexaaquairon(II) species is labile with a solvent exchange rate (30) of 4.4×10^6 M^{-1} s^{-1} at 25°C. Since the cross-reaction rate is significantly slower than this, it is conceivable that an inner-sphere pathway for electron transfer is possible. In this case, rapid dissociation of an aqua-ligand from the iron(II) centre, followed by coordination of the bridging acetato pendant arm to the iron(II) centre is required. Rapid electron transfer from iron(II) to the nickel(III) centre would result in a bridged Ni(II)-OCO-Fe(III) species. Since the acetato group is coordinated to the nickel(II) centre, both in the solid state and in solution, and iron(III) is a hard Lewis acid, it is conceivable that the bridged intermediate may be isolated or, at least, be kinetically observable. We were unable to isolate or kinetically detect such an intermediate. Conversely, since

iron(II) is a soft Lewis acid, it will not have a high affinity for the oxygen donor atom of the acetato group and so the inner-sphere pathway will be less favoured. Additionally, the magnitude and sign of the activation parameters obtained for this reaction are in keeping with those for outer-sphere oxidations of iron(II) (26–28). Thus, while the system has the requisite conditions for an inner-sphere mechanism, viz. a bridging ligand, a labile reductant, and a cross-reaction rate that is slower than the solvent-exchange rate of the reductant, the experimental rate constant is in very good agreement with that calculated for an outer-sphere mechanism from Marcus theory.

XANES of chromium in sludges used as soil ameliorants

R.R. Martin, S.J. Naftel, T.K. Sham, B. Hart, and M.A. Powell

Abstract: Samples of sewage sludges proposed for use as soil ameliorants in an Indo-Canadian project were tested for chromium content. Standard aqua regia extractions found one sludge to have excessive amounts of Cr. X-ray absorption near-edge structure (XANES) spectroscopy, however, indicated that the Cr was present in the relatively benign Cr(III) oxidation state in all the sludge samples.

Key words: soil, chromium, synchrotron, XANES.

Résumé : On a déterminé la teneur en chrome d'échantillons de boues d'égouts dont l'utilisation a été proposée pour l'amélioration de sols dans un projet indo-canadien. Des extractions standards à l'eau régale ont permis de montrer qu'une de ces boues contient des quantités excessives de chrome. Toutefois, la spectroscopie d'absorption des rayons X (XANES) indique que, dans toues les échantillons de boues, le chrome est présent à l'état d'oxydation relativement bénin de Cr(III).

Mots clés : sol, chrome, synchrotron, XANES.

Introduction

Various solid organic wastes can be added to soil, both as an effective means of disposal and for soil amelioration. The practice of adding wastes to soils can improve the soil fertility and the physical and chemical properties of the soil such as organic content and pH. There is some concern, however, that adding wastes to soil may also introduce toxic heavy metals into the soil environment and subsequently into the food chain. Analysis by standard extraction techniques may exaggerate the risk, as metals may be present but may not be bioavailable or may be in a relatively benign form.

Chromium is one of the more abundant trace elements in the lithosphere, ranging in concentration from <1 to 1000s of mg kg^{-1} in soils, with an average near 100 mg kg^{-1} (1, 2), and is most abundant in soils developed on ultramafic–basaltic igneous rocks, which may host Cr at concentrations >10 000 mg kg^{-1}. Anthropogenic sources of Cr are varied and may contribute significantly to soil Cr (3, 4). Both fly ash and sewage sludge have been identified as major sources of soil Cr when used as agricultural amendments (4–8).

Soil Cr has received considerable attention in the literature; much of the interest is related to the potential of the soil as a starting point for Cr in the food chain and, second-

arily, as a reservoir that can release Cr into groundwater under certain conditions. While the abundance of Cr in a soil is closely related to parent material, the addition of soil amendments such as sewage sludge and fly ash (from coal burning power plants) can account for the majority of soil Cr (3, 5, 6, 9).

The role of chromium in plant and animal nutrition is not well understood (6, 9–11). It is, however, well known that Cr can be toxic to both plants and animals (4). The relative toxic, mutagenic, and (or) carcinogenic affects of Cr are a function of the oxidation state present (1, 12). Cr(VI) is acutely toxic to plants and animals at small concentrations and is highly soluble and, hence, mobile. The much more abundant Cr(III), typically found in soil environments, is comparatively harmless and relatively insoluble.

Because Cr is a transition group metal, much of its behaviour in the near-surface environment (soils and groundwater) is controlled by the redox chemistry of chromium and the local pH (12–14), which in turn are affected by the occurrence and form of organic matter (15, 16) in the soils and groundwater. Hence, the factors that control the transition from Cr(VI) to Cr(III) are the most important in determining toxicity and mobility. Cr(VI) is easily reduced by a variety of reductants that are common in soils, including Fe(II) (either aqueous or crystalline), humic and (or) fulvic acids, and sulfides (1, 17). Once Cr has been reduced in a soil, the transition back to the oxidized state is very difficult and requires the presence of dissolved oxygen or compounds such as MnO, under most soil conditions.

The data presented here are derived from samples collected as part of a large Indo-Canadian project designed to test the viability of using municipal sludge mixed with fly ash (from thermal power generation) to regenerate degraded soils in India. The main focus of this paper is to highlight the oxidation state (from X-ray absorption near-edge

structure (XANES) analysis) of Cr in some of the sludges in order to address the potential for Cr toxicity in the amended soil. The selected sludges are from Kanpur, Uttar Pradesh and Jaipur, Rajasthan, India.

Sample locations

Two sample sites were chosen for this study because of their potential for Cr contamination. At the Kanpur, Uttar Pradesh site, samples were collected from domestic sludge drying beds. The distinction of "domestic" is made because this sludge was not supposed to receive any effluent from the extensive tannery operations in the area. However, field observations indicated that there is a partial contribution to this sludge from the tannery industries, a major source of Cr contamination. The Jaipur, Rajasthan site sludge samples were collected from a municipal sludge treatment facility that receives both domestic and industrial effluents. The major sources of Cr in the Jaipur sludge are metal plating and dying industries.

Extraction analysis of chromium in the sludges

Metal speciation studies are typically preceded by the determination of the background concentration of the metal in the material of interest. Data presented here represent the two sludges of interest and the soils receiving them, since Cr concentrations in both must be considered when biosolids are used in agriculture. The concentration of Cr in air-dried sludges worldwide varies significantly, from a few mg kg^{-1} to approximately 10% (3, 4, 18, 19). All samples were air dried, desegregated, passed through a 2 mm sieve, and ground to <150 microns prior to aqua regia extraction and analysis by inductively coupled plasma - optical emission spectrosopy (ICP-OES) according to standard analytical techniques.

The average concentration of Cr in the Kanpur sludge is 6200 mg kg^{-1}. This sludge was planned for application to alkaline–sodic soils around Hardoi, Uttar Pradesh, which contain 32 mg kg^{-1} Cr (n = 71, std. deviation = 8 mg kg^{-1}). The Kanpur sludge was rejected for use based on this high Cr content.

Sludge from Jaipur, Rajasthan contains an average of 126 mg kg^{-1} Cr. The Jaipur sludge was planned for application to a stony soil near Bundi, Rajasthan, where both pit soils and reservoir tank sediments are mixed with the sludge. Unlike the Hardoi soil, both the pit soils and tank sediments at Bundi were highly variable in Cr content, ranging from 37–788 mg kg^{-1} for the tank sediments and 31–2416 mg kg^{-1} for the pit soils. Thus, the soils and sediments at Bundi could be the major source of Cr, rather than the sewage sludge.

In this work, samples of the two sewage sludges were analysed using XANES spectroscopy to determine the oxidation state of Cr. The soil materials were not analysed as part of this study, although this would be important for the Bundi soils. As noted above, the oxidation state of the Cr is essential in assessing the bioavailability of Cr and, hence, the potential risk in using the sludges as ameliorants.

Fig 1. Cr K-edge XANES spectra of CrCl$_3$ [Cr^{3+}] and K$_2$CrO$_4$ [Cr^{6+}].
Methods

Two representative sludge samples were selected for XANES analysis: a Kanpur high-chromium sludge (~5000 ppm) and a relatively low-chromium sludge from Jaipur (~120 ppm). The dried sludge material was spread thinly on clear tape to make the XANES measurements. The Cr K-edge XANES were taken at the PNC-CAT, 20-BM-B beamline at the Advanced photon source (APS) Argonne national laboratory.

The XANES of the sludges were measured in fluorescence yield mode using an Oxford instruments NaI scintillation detector placed at right angles to the incident beam. The Cr standard materials (CrCl$_3$·6H$_2$O and K$_2$CrO$_4$), used to establish the oxidation state(s) of chromium in the sludge material, were obtained from Fisher Scientific Co. and used as received. Standards were spread thinly on tape and the XANES measured in transmission mode.

The spectra shown all represent the average of at least 3 scans and have had a linear pre-edge background removed. The energy scales shown have not been calibrated to a Cr metal standard.

Results and discussion

Synchrotron radiation techniques are becoming important analytical techniques for studying metals in soil (20, 21) and other environmentally important matrices, where the analysis of small volumes containing low concentrations of analyte is required. Naturally the ability of XANES to provide chemical information makes this technique especially attractive.

As the oxidation state of an atom increases, the core electronic states become more tightly bound, producing a measurable shift in the XANES spectra to higher photon energies. The local geometry around the absorbing atom also affects the XANES spectra. The spectra of four-coordinate transition metal ions (such as those of Cr (VI)) exhibit an

Fig 2. Cr K-edge XANES spectra of the Kanpur and Jaipur sludge samples. The spectra have been shifted vertically for clarity.
intense pre-edge peak due to $3d$–$4p$ mixing (22–25). The XANES spectra of Cr (III) compounds do not have this sharp feature; thus, the differences between the two oxidations states of Cr can be clearly seen, as shown in Fig. 1.

The XANES of the two sludge samples are shown in Fig. 2. The spectra have been scaled for clarity. Neither the high-Cr (Kanpur) sludge nor the low-Cr (Jaipur) sludge spectra exhibit a pre-edge peak indicative of the presence of Cr(VI), indicating that only Cr(III) was present in the sludges within the detection limits. A conservative estimate of the detection limits in the present analyses can be obtained by multiplying the concentration of chromium in the sample by the percentage noise level relative to the edge jump. This gives 19 ppm and 50 ppm for the low-Cr sludge and the high-Cr sludge, respectively.

While the XANES data shown here provides an unambiguous identification of the oxidation state of the chromium present in the sludge, the chemical speciation of chromium cannot be identified from the XANES spectrum without matching standards. The spectra may be consistent with organic chromium species and (or) adsorbed chromium. The spectra do suggest that the high chromium levels do not represent a significant environmental hazard in the form in which the samples have been received.

Conclusions

Virtually all the chromium in the sludges studied was present as the relatively benign Cr(III), and, as a result, these sludges might be used as agricultural amendments at proper application rates; however, additional measurements should be carried out to ensure that these results are representative of all the sludge materials. The result has been obtained from both high- and low-chromium samples, providing evidence that XANES is an effective technique for studying the oxidation states of metals in low concentration in real, environmentally relevant samples. It also provides important information for the regulation of metal concentrations in sensitive soil systems.

This result is consistent with measurements of chromium bioavailability in other contaminated soils (26).

Nitroarene reduction using Raney nickel alloy with ammonium chloride in water

Kankan Bhaumik and K.G. Akamanchi

Abstract: Aromatic nitroarenes are reduced in high yields using a user-friendly combination of Raney nickel alloy and ammonium chloride in water at 80–90°C.

Key words: Raney nickel alloy, nitroarenes reduction, ammonium chloride, water.

Résumé : Les nitroarènes aromatiques sont réduits avec des rendements élevés à l'aide d'une combinaison d'un mélange facile à utiliser pour l'utilisateur d'un alliage de nickel de Raney et de chlorure d'ammonium, dans l'eau, à des températures allant de 80 à 90°C.

Mots clés : alliage de nickel de Raney, réductions de nitroarènes, chlorure d'ammonium, eau.

[Traduit par la Rédaction]

Introduction

Nitroarene reduction is one of the fundamental organic transformations and varieties of methods are available (1). The most commonly used reagents (2) are zinc, tin, or iron in the presence of an acid, catalytic hydrogenation (3) with catalysts such as Ni, Pd/C, or PtO_2, and many more. Other reagents include sulfides (4) (sodium sulfhydrate, ammonium sulfide, or polysulfides and others), metal-reducing agents such as Sm (5), In (6), etc., metal-hydride complexes, such as $NaBH_4$–$NiCl_2$ (7). It can also be reduced electrochemically (8) and enzymatically (9). Reduction of nitroarene compounds often generates a mixture of nitroso- and hydroxylamine (10) products, which then couple to form azoxy (11), azo (12), hydrazo, and hydrazine (13) compounds. Raney nickel alloy in alkali (14) solution appears to be a very good reagent for convenient quantitative general reduction of nitroarenes and cleavage of -N—N- and -N—O- bonds and hence practically no formation of by-products. However, a strong basic condition, a vigorous reaction with exothermicity, and a large evolution of hydrogen gas make this system less attractive. To overcome these problems we have developed a new system using Raney nickel alloy and ammonium chloride in water instead of drastic Raney nickel alloy and alkali for the reduction of nitroarenes to aminoarenes. The new system was studied using different substrates and the results are presented in Table 1.

Experimental

All compounds used were purified before use. Solvents were obtained commercially and used without further drying or purification. Each reaction was performed in an efficient fume hood. All reactions were magnetically stirred and monitored by thin layer chromatography (TLC).

Typical procedure for the reduction of 4-nitrocumene to 4-cumidine

4-Nitrocumene (0.5 g, 3.03 mmol) was added to a 100 mL round-bottomed flask and a solution of NH_4Cl (0.40 g, 7.48 mmol) in distilled water (60 mL) was added to it. Then Raney nickel alloy (0.60 g, 1.5 times by wt. of NH_4Cl) was added with a lot of stirring and the reaction mixture was heated to 80–90°C for 1.5 h. Progress of the reaction was monitored by TLC. The reaction mixture was cooled to room temperatue (rt) and ethyl acetate (50 mL) was added and the mixture was stirred for 30 min. The solids (solids contain generated active Raney nickel (to be disposed of carefully)) were then filtered off and the organic layer separated; the aqueous phase was extracted with ethyl acetate (2 × 30 mL). The combined organic layer was concentrated under reduced pressure. The residue obtained was purified by extracting with 15 mL of concd HCl, followed by charcoaling and reextraction with ethyl acetate (2 × 50 mL) after basification. The organic layer was dried over sodium sulphate and concentrated under reduced pressure to yield (0.385 g, 96%) 4-cumidine as a liquid. It was characterized by comparing with a known sample.

Results and discussion

In this work, we investigated the aqueous medium reduction of nitroarenes using Raney nickel (Ni–Al (1:1)) alloy in combination with NH_4Cl. To the best of our knowledge this system is still not reported. The system is good enough for the reduction of nitroarenes (Table 1, entries 1–10). All reac-

[a]All product anilines are known compounds and characterized by comparing with the authentic sample.
[b]Dehaloganated product (20%) was formed.

tions were carried out by refluxing a mixture of substrate, Raney nickel alloy, and ammonium chloride in water. There was no vigorous reaction, nor foaming, and also no vigorous evolution of hydrogen gas and the pH of the medium was neutral. The method is very simple to adopt in the laboratory. However, it has low chemoselectivity towards aldehydes, esters, amides, and halogenated nitroarenes (Table 1, entries 11–15). This lack of chemoselectivity is very similar to that of Raney nickel alloy in an alkali system.

In conclusion, we have demonstrated a mild user-friendly method for reduction of nitroarenes to aminoarenes that can be used for laboratory synthesis. The method is valuable because of its simplicity.

Hot model of muonium formation in liquids

David C. Walker, Stefan Karolczak, Hugh A. Gillis, and Gerald B. Porter

Abstract: The mechanism of formation of muonium atoms from positive muons was studied here through measurements of the yield of diamagnetic muon states in dipolar aprotic solvents and for scavenger solutions in hexane and methanol. The results are compared with published data on common solvents covering a full range of the physico-chemical properties of liquids that affect an ionic formation mechanism, namely their static dielectric constants, electron mobilities, and radiolysis yields of electrons. It is concluded that muonium is not formed by a thermal charge-neutralization reaction in these chemically-active media, though that mechanism does contribute to muonium formation in inert media like liquefied noble gases. It is clear that muonium materializes on a much shorter timescale than the recently proposed "delayed" mechanism (microseconds) and the earlier "spur" model (nanoseconds). In contrast, the data referring to all these liquids are consistent with the intra-track "hot" model. This is the only Mu-formation model proposed so far in which the immediate precursors of Mu ($Mu_{(hot)}$) are neither scavengable nor ionic.

Key words: muonium atoms, formation mechanism, hot model, spur model, delayed-muonium-formation model, diamagnetic yields.

Résumé : On a étudié le mécanisme de formation des atomes de muonium à partir de muons positifs en faisant appel à des mesures de rendement d'états muons diamagnétiques dans des solvants aprotiques dipolaires et pour des solutions de pièges dans l'hexane et le méthanol. On compare les résultats obtenus avec les données publiées pour divers solvants communs couvrant l'ensemble des propriétés physicochimiques des liquides qui affectent un mécanisme de formation ionique, soit les constantes diélectriques statiques, les mobilités électroniques et les rendements en électrons lors de la radiolyse. On en conclut que, dans ces milieux chimiquement actifs, le muonium ne se forme pas par une réaction de neutralisation de charge même si ce mécanisme contribue à la formation du muonium dans des milieux inertes comme les gaz rares liquéfiés. Il est clair que le muonium se forme à une vitesse beaucoup plus rapide que celle proposée récemment sur la base d'un mécanisme « à retardement » (microsecondes) ou du modèle des « spur » (nanosecondes). Par ailleurs, les données se référant à tous ces liquides sont en accord avec le modèle « intra-track chaud ». Ce modèle de formation du Mu est le seul jusqu'à maintenant dans lequel les précurseurs intermédiaires du Mu ($Mu_{(chaud)}$) ne sont ni piégeables ni ioniques.

Mots clés : atomes de muonium, mécanisme de formation, modèle chaud, modèle des « spur », modèle de formation du muonium à retardement, rendements diamagnétiques.

[Traduit par la Rédaction]

Introduction

Whereas the muonium atom (Mu, μ^+e^-) has already yielded about 150 rate constants for kinetic-isotope-effect comparisons with the hydrogen atom (1) and has provided many new free radical structures (2), its formation mechanism (3–5) is still (6–8) in dispute after 25 years. The issue of how Mu is actually formed at the end of the track of a high-energy positive muon remains to be resolved.

When high-energy positive muons (μ^+) reach thermal-energy after impinging on a material they are observed by the muon-spin-rotation technique (μSR) (3) to exist in one of three chemical states — as free muonium atoms (Mu), as muoniated free radicals in which Mu typically has added to a double or triple bond (R), or as "diamagnetic" muon states

(D). The latter includes free μ^+ ions and diamagnetic molecules with Mu substituting for H. All such diamagnetic muon states are recorded collectively as "D" because one cannot distinguish among them with current μSR techniques.

The "yields" of these different muon states are presented as P-values or "fractions" of the total number of incident muons (see Experimental section). Thus P_M, P_R, and P_D represent the fractions of incident muons that are observed as Mu atoms, Mu-radicals, and D, respectively. When P_M, P_R, and P_D sum to less than 1.0, the remainder is known as the missing (lost) fraction, P_L. For liquids with no unsaturated bonds, $P_R = 0$ because free radicals are not formed; for most saturated hydrogenated materials P_L has been found to be similar in magnitude to P_M. This arises after thermalization of Mu because evidently about half of the Mu atoms that are

formed initially are depolarized by paramagnetic species such as electrons, radicals, and H-atoms on the timescale of the "expanding track" (9) either by combination or spin-exchange. Longitudinal-field repolarization studies confirm this (10), since all muon spins are recovered in high fields. For common solvents that do not form Mu-radicals one thus has $P_D = 1 - P_{M(initial)}$ and since $P_{M(init)} \approx P_{M(obs)} + P_L \approx 2P_M$, then $P_D \approx 1 - 2P_M$. Consequently, no change in P_D implies no change in Mu formation. In this paper we look for changes in P_D as a test for changes in the yield of Mu.

There are two fundamentally different models in the literature used to describe the mechanism by which Mu atoms are initially formed at the end of muon tracks:

(1) The "hot" model, in which some of the hot-Mu atoms formed during charge-exchange cycles undergo hot-abstraction or hot-substitution reactions before thermalization to form stable diamagnetic species such as MuH, MuOH, and $C_nH_{2n+1}Mu$. Those that do not undergo such a hot-atom reaction may reach thermal energy as free Mu atoms or occasionally as μ^+ ions. The charge-exchange cycles of $\mu^+_{(hot)}/Mu_{(hot)}$ interchanges from ~10^4 to ~10 eV are represented by the reactions in [1], where S is a solvent molecule.

[1] $\mu^+_{(hot)} + S \rightarrow Mu_{(hot)} + S^+$ and

$$Mu_{(hot)} + S \rightarrow \mu^+_{(hot)} + e^- + S$$
Hot Mu reactions that produce diamagnetic species can be represented by eq. [2], where D may be MuH, MuOH, Mu–R, etc., and the radical does not contain the muon when S has no multiple bonds.

[2] $Mu_{(hot)} + S \rightarrow D + radical$
Hot atom reactions are well known in the gas phase (11) but should be somewhat different from those in a liquid, as here, because of third-body effects and the importance of inter-molecular structures for liquids.

(2) The alternative model calls for Mu atoms to be formed as a consequence of the thermal, post-track, neutralization reaction, represented by [3].

[3] $\mu^+ + e^- \rightarrow Mu$
The presumption here is that all the muons emerge "unattached" from the charge-exchange cycles as thermalized μ^+ ions. They may subsequently encounter an electron from the radiolysis track of the muon to produce Mu (with yield P_M), otherwise they remain as μ^+ and constitute the diamagnetic yield (P_D).

Reaction [3] represents the "spur" model (4) when geminate-electrons are involved and the "delayed-muonium-formation" model (DMF) (6) when free-electrons are involved. In radiation chemistry terms, "geminate" electrons are those still within the Onsager escape distance ($e^2/\varepsilon k_B T$) and doomed to return to geminate cations, whereas "free" electrons are those whose distance exceeds the critical Onsager distance and which first escape from their geminate ion and then from the whole track. Geminate electrons thus have intra-spur lifetimes only on the nanosecond timescale, whereas free electrons can have lifetimes of microseconds or longer. The timescale of the hot model, on the other hand, corresponds to the thermalization time of the charge-

exchange cycles during approximately the last 10^4 eV of the track of the muon, which is less than 10^{-10} s (12).

Formation of Mu by the DMF process (reaction [3]) has been shown by external electric field effects to occur on the microsecond timescale in four chemically inert liquids (superfluid He, Ne, Ar, and N_2) at very low temperatures (13). A DMF model was also developed from the simulation of hydrocarbon data at room temperature and was interpreted in terms of reaction [3] over the 1–10 μs timescale (6). But this microsecond timescale has now been shown to be totally inconsistent with electron scavenger effects at low concentrations in chemically reactive media such as hexane (8).

In this paper we report data obtained for some special liquids at room temperature including the dipolar aprotic solvents that have the distinction of high cation, low anion solvation energies. A fully fluorinated saturated carbon compound was also studied. In addition, we report here results for solutions of *n*-hexane, and one for methanol, containing high concentrations of scavengers for electrons or muons or both. These solutions have high enough scavenging powers ($k[c]$) to completely eliminate one or the other (or both) of the species of a "thermal" reaction such as [3]. However, the solutes are not at sufficiently high concentrations to interfere directly with "hot" reactions as represented by [1] and [2], as already seen in solvent mixtures (14).

Experimental

The experiments conducted in this work were transverse-field muon spin rotation experiments (TF-μSR) and involved placing a sample of deoxygenated liquid (plus additives as indicated) in 50 mL round-bottomed flasks in the SFUMU cart in the "backward" muon beam of the M9B beamline at TRIUMF. The results are now archived as experiments in the range 15000–15109 at the μSR Facility. The observed count rates were subjected to computer-fitting to the familiar TF-μSR equation, eq. [4] (3, 15).

[4] $N_t = N_0 \exp(-t/\tau) [1 + A_M \exp(-\lambda t) \cos(\omega_M t$
$$+ \phi_M) + A_D \cos(\omega_D t + \phi_D)] + N_0 B_g$$

In this equation, N (at times t and 0) is the observed count rate, τ is the mean muon lifetime of 2.2 μs, λ is the Mu decay constant, B_g is a background factor, A_M, ω_M, and ϕ_M are, respectively, the asymmetry, precession frequency, and initial phase of the Mu signal, with A_D, ω_D, and ϕ_D being the corresponding values for all diamagnetic muon states collectively designated as D. The A_M term corresponds to free Mu atoms and A_D to all muon states that are diamagnetic. In the on-line analysis the computer was made to divide out the natural muon decay factor ($\exp(-t/\tau)$), deduct the background (B_g), and display only the asymmetries (A). This enables one to distinguish the "decay" of Mu and D as chemical species from the spontaneous decay of the muon itself.

The computer-fitted A_D values were converted to fractional muon yields, P_D, using $P_{D(x)} = (A_{D(x)}/A_{D(water)}) \times 0.62$, based on the diamagnetic yield in water of 0.62 (3, 4). There is a possible error-bar of ±5% on all reported P_D values. This arises because each beam has an inherent polarization, each liquid has a different density, and each cell has a slightly different glass thickness, shape, and position. All these differ-

Fig. 1. Plot of A_D vs. time from the μSR analysis of muons injected into (*a*) pure hexane and (*b*) hexane containing 0.2 M nitrobenzene (a powerful electron scavenger). (The initial yields are seen to be same and there is no decay evident in either.)
ences alter the mean penetration depth of the muons or the effective stopping-power in the path of the decay positrons on their way to the counters. This causes variations of the positrons' mean polarization, which alters the magnitude of all *A*-values. They have to be referenced to a sample, cell, and liquid of similar density with a known *P*-value. Water was used here.

For these experiments, magnetic fields of 91 G were used (and 500 G merely for confirmation purposes). This made the precession frequencies of Mu too high to observe (ω_M = 123 and 131 MHz), so the only asymmetry seen corresponded to A_D (ω_D = 1.23 MHz). An example of the asymmetry of D is given in Fig. 1 for (*a*) pure hexane and (*b*) a solution of hexane containing a powerful electron scavenger, nitrobenzene, at 0.2 M concentration.

The liquids were used as obtained from commercial sources without further purification, except for deoxygenation by bubbling with pure nitrogen. The hexane and methanol were seen in other experiments (8) to be pure enough for Mu to have a chemical lifetime in excess of 1 μs. The dipolar aprotic solvents were of "reagent grade" quality whereas the perfluoromethylcyclohexane was only of "technical grade" and known to contain ~5% impurities which were probably mainly in the form of other saturated fluorinated compounds. As the results with hexane and methanol show, purity is not an important factor in most P_D measurements. In fact for water, hexane, and formamide, for instance, it was found that the same P_D value was obtained whether the liquid had been deoxygenated or was air-saturated.

Results

The first 16 entries of Table 1 contain the basic results for the observed values of P_D in these liquids and solutions. They are then compared with published data on other common solvents, as given in the lower 7 entries of Table 1.[2] Table 1 also provides values of the physicochemical properties that are expected to be directly related to the efficacy of re-

action [3] in these solvents: ε, the static dielectric constant (relative permittivity); μ_e, the mobility of electrons in the liquid (cm^2 V^{-1} s^{-1}); G(fi), the radiolysis yields of free electrons that escape the track; and G(gi), the radiolysis yields of geminate electrons that do not escape the coulombic field of geminate cations. (There is a possible error of ±0.5 in the values of G(gi) as these were estimated from an assumed total ionization yield of 4.5 ± 0.5 for all the liquids, based on a mean ion yield of $W \approx 22$ eV mol^{-1} (16).)

All the P_D values fall within the small range 0.53 to 0.68, with the majority of saturated H/C/O/N compounds lying within the even narrower range of 0.60 ± 0.03. P_D was also measured in methanol and hexane containing high concentrations of electron scavengers, as reported in Table 1. These additives would be powerful scavengers for the solvated electrons (in methanol) or quasi-free/localized electrons (in hexane) in reaction [3]. In fact, nitrobenzene, benzophenone, styrene, CCl$_4$, and oxygen all have rate constants for electron capture in hexane of the order of 10^{12} M^{-1}s^{-1} (17), yet they do not alter the yield of D. This is displayed directly in Fig. 1, where the initial asymmetry of (*b*) is seen to be essentially the same as (*a*), despite the lifetime of any electrons in hexane having been reduced to <5 ps in (*b*). In addition, one can see that there was no change in A_D over the 5 μs of Figs. 1*a* and 1*b*, which would have been evident had reaction [3] occurred on the DMF timescale.

In the cases of N(C$_2$H$_5$)$_3$ and CH$_3$OH as scavengers, they are expected to capture and hold onto free μ$^+$ ions by virtue of being good proton acceptors. As final confirmation, in two experiments (lines 15 and 16 of Table 1), both an electron and a muon scavenger were present. In these experiments there would be a greatly reduced chance of Mu being formed by reaction [3], even if the "adducts" from e$^-$ and μ$^+$ scavenging eventually encountered each other.

Discussion

Table 1 shows that for all these liquids and solutions, P_D has *no* dependence on any of the physicochemical properties

---

[2] Table 1 (lower part) does not include liquids that are known to have quite different P_D values for other reasons (9, pp. 66–67; 166–168). Thus, unsaturated compounds that form muoniated free radicals during thermalization were not included (benzene having P_D = 0.17 and P_R = 0.83, for instance), nor were chlorinated compounds that evidently undergo pre-thermalization reactions to give P_D values according to the number of halogen atoms (with CH$_2$Cl$_2$ = 0.70, CHCl$_3$ = 0.85, and CCl$_4$ = 1.0, for instance) nor "inert" liquids such as the condensed noble gases.

Table 1. The P_D values obtained in this study; also given are the values, where available, of dielectric constant (ε), electron mobility (μ_e (cm^2 V^{-1} s^{-1})), radiolysis free ion yield ($G(fi)$), and geminate ion yield ($G(gi)$) based on total ion yields of 4.5 ± 0.5; comparisons with literature values of P_D for a range of other saturated, non-chlorinated liquids are also shown (last seven rows).

^{b}Reference (9, pp. 166–168).

that should affect the neutralization reaction [3]. Specifically, P_D changes by <20% (much less in most cases) while: (*i*) ε changes by a factor of 60, from 1.8 to 109; (*ii*) μ_e by a factor of 400 000, from 0.00025 to 100 cm^2 V^{-1} s^{-1}; and (*iii*) $G(fi)$ by a factor of 118, from 0.028 to 3.3. Two of these limits arose from the new liquids studied in this paper. In other words, the yield of D (and hence Mu) is not influenced by the coulombic force between reactants, nor by the mobility of electrons in the medium, nor by the number (local concentration) of electrons available for reaction. Therefore, reaction [3] cannot be a significant source of Mu atoms in these systems.

Equally conclusive is the direct evidence provided by the electron and muon scavengers in hexane and methanol (methanol itself being a μ^+ trap, like water). In those solutions, free electrons and free muons are simply not available to react together in reaction [3]. These electron scavengers react at rate constants of about 10^{12} $M^{-1}s^{-1}$ in hexane, so the lifetime of e^- would be reduced to a few picoseconds in the nitrobenzene, styrene, and benzophenone solutions, thereby almost completely inhibiting reaction [3] on its proposed timescales. Figure 1 shows that the yield of D, and hence Mu, is not affected by capturing electrons by nitrobenzene on the picosecond timescale. P_D would have increased to almost 1.0 in Fig. 1*b* if the yields were governed by reaction [3]. Even at the concentrations used for CCl_4 and oxygen the

lifetime of electrons would be <500 ps. In the solutions that contain both electron and muon scavengers, the probability of both of their "adducts" reacting at the same rate as the free species is negligible. Thus it must be concluded that Mu is not formed to any measurable extent in a thermalized ionic reaction in this range of solvents, even on the timescale of intraspur reactions.

The literature already contains considerable evidence that has been interpreted in this way. The most obvious examples are data for solvent mixtures covering the whole composition range: for c-hexane, CCl_4, and CH_3OH versus benzene, and $CHCl_3$ versus CH_3OH, none of which showed the curvature to be expected if scavenging occurred (9, pp. 68–70). In the case of water, there is overwhelming scavenger evidence against reaction [3] in addition to the expectation that μ^+ would be solvated like H^+ and thus assimilated into the water structure as MuHO within picoseconds (9, p. 79).

All of these factors prove that reaction [3] is not the source of Mu. They are not in conflict with reactions [1] and [2], however, and in fact conform to what one would expect from a hot model in which the precursors (hot Mu) are neither scavengable electrons nor scavengable muons. The hot model wins by default! This conclusion corroborates, using a new range of media, the arguments presented earlier against reaction [3] as the source of Mu atoms in water (9, pp. 77–92).

Kinetics of oxidation of α,β-unsaturated aldehydes by quinolinium dichromate

Girija S. Chaubey, Simi Das, and Mahendra K. Mahanti

Abstract: A series of α,β-unsaturated aldehydes (crotonaldehyde, cinnamaldehyde, acrylaldehyde, and methacrylaldehyde) were oxidized by quinolinium dichromate in sulfuric acid to the corresponding acids in 50% (v/v) acetic acid – water medium. The kinetic data have been discussed with reference to the aldehyde hydration equilibria. The kinetic results support a mechanistic pathway proceeding via a rate-determining oxidative decomposition of the chromate ester of the aldehyde hydrate.

Key words: kinetics, oxidation, unsaturated aldehydes, quinolinium dichromate.

Résumé : Le dichromate de quinolinium dans l'acide sulfurique utilisé en solution d'acide acétique aqueux à 50% (v/v) permet d'oxyder une série d'aldéhydes α,β-insaturés (crotonaldéhyde; cinnamaldéhyde; acrylaldéhyde; méthacrylaldéhyde) en acides correspondants. On discute des données cinétiques en fonction de l'équilibre d'hydratation de l'aldéhyde. Les données cinétiques sont en accord avec un mécanisme réactionnel impliquant une décomposition oxydante de l'ester chromique de l'hydrate d'aldéhyde qui serait cinétiquement limitante.

Mots clés : cinétique, oxydation, aldéhydes insaturés, dichromate de quinolinium.

[Traduit par la Rédaction]

Introduction

In the oxidation of α,β-unsaturated aldehydes, it has been suggested that the reaction could proceed by way of (*a*) enolization being the rate-determining step (1, 2); (*b*) hydration of the double bond to form a β-hydroxyaldehyde (3); or (*c*) oxidation of the aldehyde hydrate (4).

With a view to establishing the mechanistic pathway for this oxidation process, we have carried out a kinetic study of the oxidation of α,β-unsaturated aldehydes (crotonaldehyde, cinnamaldehyde, acrylaldehyde, and methacrylaldehyde) by quinolinium dichromate (QDC, $(C_9H_7N^+H)_2Cr_2O_7^{2-}$) in 50% acetic acid – water medium under a nitrogen atmosphere. This study forms part of our continuing efforts, concerning the quinolinium dichromate oxidation of organic substrates in general (5) and aldehydes in particular (6).

Experimental

Materials and methods

Acrylaldehyde and methacrylaldehyde (Aldrich) and crotonaldehyde and cinnamaldehyde (Merck-Schuchardt) were used without further purification. The oxidant, quinolinium dichromate (QDC, $(C_9H_7N^+H)_2Cr_2O_7^{2-}$) was prepared by the reported method (7), and its purity was checked by spectral analysis. The IR spectrum (KBr) exhibited bands at 930, 875, 765, and 730 cm^{-1}, characteristic of

the dichromate ion. Acetic acid (SD, AR grade) was distilled before use. Sulfuric acid (E. Merck) was used after a check of its physical constants. The deuterated compounds were prepared by the reported method (8). The IR spectra were recorded on a Bomem DA-8 FT-IR spectrophotometer.

The method used for the kinetic determinations has been described previously (5). All the reactions were performed under nitrogen. The rate constants have been evaluated from the linear ($r > 0.995$) plots of log[QDC] against time, and the values reported are the mean of two or more runs (reproducibility ±3%). The solvent was 50% aqueous acetic acid, and the dielectric constant was varied using acetic acid – water mixtures. The reaction mixtures remained homogeneous in the solvent systems used.

Product analysis

Thirty mL of water was taken and cooled in ice. Concentrated H_2SO_4 (7.9 g, 0.08 M) was added slowly with constant cooling. When the acid solution had cooled to room temperature, quinolinium dichromate (QDC 9.52 g, 0.02 M) was added and the mixture was warmed to 313 K for complete dissolution of the QDC. To this mixture, 0.01 M of substrate (0.71 g of methacrylaldehyde, 0.57 g of acrylaldehyde, 0.71 g of crotonaldehyde, and 1.33 g of cinnamaldehyde) taken up in 25 mL of a 50% acetic acid – water solution was added. The reaction mixture was stirred at 313 K for 48 h under nitrogen. The organic layer was extracted thrice with ether (25 mL each time) and the combined organic extracts were washed with water and dried over anhydrous Na_2SO_4. The oxidized products (methacrylic acid from methacrylaldehyde, acrylic acid from acrylaldehyde, crotonic acid from crotonaldehyde, and cinnamic acid from cinnamaldehyde) were obtained after the complete removal of ether (boiling and melting points were

in agreement with literature values; yields ≈ 85–90%). Each reaction product was characterized by IR analysis.

Results and discussion

The oxidation of α,β-unsaturated aldehydes (crotonaldehyde, cinnamaldehyde, acrylaldehyde, and methacrylaldehyde) by QDC results in the formation of the corresponding acids. Under the present experimental conditions, there is no further oxidation of the acids.

The stoichiometry of the reaction was determined (5). Stoichiometric ratios, Δ[QDC]/Δ[substrate], in the range 0.66 to 0.69 conform to the following overall equation (representative):

$$[1] \quad 3C_3H_4O + 2Cr(VI) + 3H_2O \rightarrow 3C_3H_4O_2$$
$$+ 2Cr(III) + 6H^+ \text{ (acrylaldehyde)}$$
Using pseudo-first-order conditions, individual kinetic runs are first order in QDC. The pseudo-first-order rate constants (k) are independent of the initial concentration of the oxidant (Table 1). The order of the reaction with respect to substrate concentration has been obtained by varying the aldehyde concentration and observing the effect on the rate at constant [QDC] and [H$^+$]. The order with respect to the concentration of acid, at constant [aldehyde] and [QDC], is unity. The kinetic results are shown in Table 1. In the range of acid concentrations used, the protonation of the aldehydes would be less significant, though it cannot be ruled out. At present, it may not be possible to decide whether protonation of the aldehyde or protonation of the dichromate results in the observed acid catalysis, since these two processes cannot be distinguished on the basis of the data obtained. Since the acid concentrations used were in the range 0.5 to 1.5 M, it would be justified to suggest that the dichromate ion would be the predominant species in these oxidation reactions.

The oxidation of the substrates by QDC has been studied over the temperature range 303–323 K. The rate data and activation parameters are shown in Table 2. The negative values of ΔS^* provide support for a polar bimolecular reaction.

The effect of a change in the solvent composition (water – acetic acid, %, v/v) on the rate of oxidation has been deter-

mined. The dielectric constants (D) of water – acetic acid mixtures have been calculated (at 313 K: water = 73.28, acetic acid = 6.29) (9). The data in Table 3 shows that a decrease in D of the medium results in an increase in the rate of the reaction (Table 3). The magnitude of this effect could be analyzed by suggesting that, for the equilibrium $2HCrO_4 \rightleftharpoons Cr_2O_7^{2-} + H_2O$, a decrease in D of the medium (increase in the acetic acid content) favors the dichromate form over the chromate form. If ion pairs are formed in this medium, they would have a higher ion-pair association constant for the dichromate ion, and this would again favor the dichromate ion. Although the range of D used for these reactions is not large, plots of log k versus $1/D$ are linear, with positive slopes, suggesting an ion–dipole type of interaction (10).

There is no induced polymerization of acrylonitrile (11), which indicates that a one-electron oxidation is quite unlikely. Control experiments, performed in the absence of the substrate, did not show any appreciable change in the concentration of QDC.

Variations in the ionic strength of the medium, using sodium perchlorate (μ = 0.01–0.25 M), did not influence the rates of these reactions.

Aldehydes are extensively hydrated in aqueous solutions and many oxidation reactions have been reported to proceed via the hydrated form (12–17). Table 4 records the experimental rate constants (k) for the oxidation of the aldehydes by QDC. The aldehyde hydrate dissociation constants (K_d) pertaining to the reaction:

$$[2] \quad RCH(OH)_2 \overset{K_d}{\rightleftharpoons} RCHO + H_2O$$
are also given (12). From k and K_d, two sets of rate constants for the oxidation of the aldehyde in only one of the forms present in solution are computed. The values of k_{Hy} (**Hy** = hydrated form of the substrate) are obtained by assuming that only the hydrate form appears in the rate law:

$$[3] \quad v = k_{Hy} [QDC] [RCH(OH)_2].$$

Similarly, the values of k_A (**A** = substrate) are calculated using the concentration of free aldehyde according to the rate law:

[4] $\qquad v = k_A$ [QDC] [RCHO].

The values of k_{Hy} and k_A have been shown in Table 4. Using the σ values as reported by Taft and co-workers (18), a plot of log k_{Hy} against σ is found to be linear, with a slope of ρ = –0.92 (r = 0.993). On the other hand, the correlation of σ with k_A gave a value of ρ = –0.56 (r = 0.997). This might suggest the involvement of the aldehyde hydrate in the oxidation process. Hence, a mechanism involving a direct hydrogen transfer reaction between a free aldehyde and QDC is very unlikely. In the chromic acid oxidation of benzaldehyde, it has been shown that the reaction proceeds via the chromic acid ester of hydrated benzaldehyde as the intermediate (19). This similarity provides additional support for the mechanistic pathway suggested in the present investigation: that the rate-determining step involves the oxidative decomposition of the chromate ester of an aldehyde hydrate.

Since aldehyde hydrates very closely resemble alcohols both in structure and in many aspects of oxidation, a similarity in the nature of the two oxidation reactions is expected. In the oxidation of alcohols by chromic acid, the rate-determining step has been shown to be the decomposition of the protonated acid chromate ester (20). By analogy, the oxidation of aldehydes would proceed via the formation of a similar intermediate (an ester of the aldehyde hydrate),

which would undergo decomposition in the rate-determining step (21). The ester of the aldehyde hydrate would be in equilibrium with the free aldehyde and the aldehyde hydrate and could be formed either by a carbonyl addition reaction to the free aldehyde or by the esterification of the hydrate (22). It may be added that the esterification reaction has more utility, since it helps one to understand and predict aldehyde oxidation reactions and their relationship to the closely related oxidation of alcohols.

The rate data shows that both acrylaldehyde and methacrylaldehyde are oxidized at approximately equal rates, with methacrylaldehyde reacting marginally faster than acrylaldehyde (Table 1), which suggests that the α-CH$_3$ group has little influence on the rates. It is justified to assume that the oxidation process does not involve an enolization step. The enolization of acrylaldehyde would have yielded hydroxyallene, which would be improbable. Further, the oxidation of methacrylaldehyde is a rapid reaction even though there is no enolizable hydrogen atom. The argument that unsaturated aldehydes could undergo a reaction involving the hydration of the double bond to form a β-hydroxyaldehyde can be ruled out, since no such intermediate could be isolated from the reaction. The order of reactivity is: methacrylaldehyde > acrylaldehyde > crotonaldehyde > cinnamaldehyde (Table 1). The presence of the methyl group (in methacrylaldehyde) accelerates the reaction by increasing the electron availability at the oxygen of the aldehydic carbonyl group. In crotonaldehyde, the methyl group at the β-position is far removed from the site of reaction, suggesting that β-substitution influences the rate of the reaction to a much lesser extent. Hence, the reactivity of crotonaldehyde is much less than that of methacrylaldehyde. The presence of the phenyl group in cinnamaldehyde exerts a deactivating influence on the rate of the reaction and hence its reactivity is the lowest in the series.

Scheme 1.
The mechanistic pathway involves the formation of the ester of the aldehyde hydrate (step 1), followed by the slow oxidative decomposition of this ester (step 2). A cyclic structure for the reaction intermediate would explain all the features of the oxidation reaction. The manner of electron transfer must be established. Electron flow in a cyclic transition state has been considered (23) and can be rationalized by assuming that if the chromium is coordinated through the -OH group (of the aldehyde hydrate), then the process of electron transfer could take place through the carbon—oxygen—chromium bonds, enabling the formation of the chromate ester and enhancing the ease of conversion to the product.

The slow step of the reaction involves the participation of the aldehyde hydrate, protonated QDC, and two electrons in a cyclic system. Removal of the hydrogen (on the carbon) is part of this step, as seen from the kinetic isotope effect for the oxidation of the respective aldehyde-d_1 compounds (Table 5), which indicates a cleavage of the carbon—hydrogen bond in the rate-determining step of the reaction.

This step allows one to envisage a reaction via an electrocyclic mechanism involving six electrons; being a Hückel-type system ($4n+2$), this is an allowed process (24). The kinetic isotope effect could be interpreted to indicate that the reaction proceeds via the formation of the chromate ester of the aldehyde hydrate as an intermediate, and that this is converted to the product in the rate-determining step.

Table 5. Kinetic isotope effect at 313 K.[a]

Substrate	$10^3 k_H$ (s^{-1})	$10^3 k_D$ (s^{-1})	k_H/k_D
Crotonaldehyde-d_1	0.51	0.084	6.25
Cinnamaldehyde-d_1	0.080	0.013	6.15

[a][Substrate] = 0.03 M; [QDC] = 0.003 M; [H$_2$SO$_4$] = 0.5 M.

The last step would be rate-determining, in accord with the observation of the deuterium kinetic isotope effect. Further, the oxidation rate for the aldehydes is not increased as rapidly by a decrease in the water concentration in acetic acid – water mixtures (Table 3), which suggests that a molecule of water is involved in a kinetically important stage in the oxidation of the aldehydes.

The sequence of reactions for the oxidation of α,β-unsaturated aldehydes by QDC is shown in Scheme 1. In acidic medium, the oxidant QDC is converted to the protonated dimetallic chromium(VI) species (**PQ**) (in the acid range used for the present investigation, the Cr(VI) in the protonated QDC would exist mainly as Cr$_2$O$_7^{2-}$). The substrate (**A**) is converted to the hydrated form (**Hy**). The reaction of the hydrated form (**Hy**) with the protonated QDC (**PQ**) results in the formation of the monochromate ester (**E**) and a Cr(VI) monomer. The monochromate ester (**E**) undergoes decomposition in the rate-determining step to give the product (the corresponding acid), along with the Cr(IV) species. The conversion of Cr(IV) to Cr(III) is a dispropor-

tionation reaction. It has been shown that for the reaction $Cr(IV) + Cr(VI) \rightarrow 2Cr(V)$, the standard potential for the Cr(VI)–Cr(V) couple is extremely favourable ($E° = 0.62$ V) (25), and this reaction proceeds rapidly. The Cr(V)–Cr(III) couple has a potential of 1.75 V, which enables the rapid conversion of Cr(V) to Cr(III) after the reaction of Cr(V) with the substrate (25, 26).

If the mechanism shown in Scheme 1 is correct, then the attack of the protonated QDC (**PQ**) on the aldehyde hydrate (**Hy**) is crucial and would be favored by the formation of the cyclic chromate ester (**E**). The rate law has been derived as follows:

[5] $\qquad -d[QDC]/dt = k_3[E] = k_3[Hy][PQ],$

where $[PQ] = K_1[QDC][H^+]$ and $[Hy] = K_2[A][H_2O]$.

Hence, $-d[QDC]/dt = K_1K_2\ k_3[A][QDC][H^+]$, which shows a first-order dependence on each of the concentrations (substrate, oxidant, and acid). Hence, $-2.303d(log[QDC])/dt = k = K_1K_2\ k_3[A][QDC][H^+]$. This rate law explains all the experimentally observed results.

The data collected demonstrates that the QDC oxidation of α,β-unsaturated aldehydes results in the formation of carboxylic acids, substantiating the mechanism wherein there is an attack of the oxidant on the aldehyde hydrate. There is no cleavage of the carbon—carbon bond, thus ruling out the possibility of any enolization. This study emphasizes the efficiency of QDC reacting with α,β-unsaturated aldehydes, suggesting a regioselective route for the synthesis of carboxylic acids.

One-pot synthesis of terpyridines and macrocyclization to C_3-symmetric cyclosexipyridines

Lucie Masciello and Pierre G. Potvin

Abstract: Four examples of 2,6-dicinnamoylpyridines were obtained in 60–65% yields in condensations of commercially available 2,6-diacetylpyridine and benzaldehydes in 1:2 stoichiometry. At 2:1 ratios, four related 6,6″-diacetylated-4′-arylterpyridines were isolated in 70–73% yields in one-pot condensations in the presence of NH_3. 4,4′-Azobenzaldehyde, prepared from nitrobenzaldehyde in three steps and 40% overall yield was similarly converted to a novel azo-linked bis(terpyridine) in 50% yield in a reaction that assembles seven molecules in one step. The 6,6″-diacetylated-4′-arylterpyridines and the correspondingly substituted 2,6-dicinnamoylpyridines were condensed in 1:1 ratio together with NH_3 to form 4,4″,4^{IV}-triarylcyclosexipyridines in 22–26% yields. These were obtained as mixed Na^+ and K^+ complexes and were insoluble amorphous solids, except for one example bearing 4-neopentoxyphenyl substituents. ^1H NMR showed that the 4,4″,4^{IV}-tri(4-neopentoxyphenyl)cyclosexipyridine complexes form aggregates in solution and at low concentrations show twofold symmetry arising from a loss of planarity.

Key words: terpyridines, 4′-aryl-6,6″-diacetylterpyridines, azo-bisterpyridine, cyclosexipyridines, macrocyclization.

Résumé : La condensation de la 2,6-diacétylpyridine avec des benzaldéhydes commercialement disponibles, à une stoechiométrie de1:2, a permis d'obtenir quatre 2,6-dicinnamoylpyridines avec des rendements de 60 à 65 %. Lors de condensations monotopes, à des rapports de 2:1, en présence d'ammoniac, les quatre 6,6″-diacétyl-4′-arylterpyridines apparentées peuvent être isolées avec des rendements de 70 à 73 %. Le 4,4′-azobenzaldéhyde qui a été préparé en trois étapes et avec un rendement global de 40 % à partir du nitrobenzaldéhyde a été converti, avec un rendement de 50 %, en une nouvelle bis(terpyridine) liée par une fonction azo qui permet d'assembler sept molécules en une seule étape. Les 6,6″-diacétyl-4′-arylterpyridines et les 2,6-dicinnamoylpyridines substituées de la même façon peuvent être condensées l'une à l'autre dans un rapport de 1:1 en présence d'ammoniac, pour former de 4,4″,4^{IV}-triarylcyclosexipyridines avec des rendements allant de 22 à 26 %. Celles-ci sont obtenues sous la forme de complexes avec des ions Na^+ et K^+ et il s'agit de solides amorphes insolubles, à l'exception de celle portant des subtituants 4-néopentoxyphényles. Les spectres RMN du ^1H montrent que les complexes de 4,4″,4^{IV}-tri(4-néopentoxyphényl)cyclosexipyridines forment des agrégats en solution et que, à faibles concentrations, ils présentent une symétrie binaire qui découle d'une perte de planéité.

Mots clés : terpyridines, 4′-aryl-6,6″-diacétylterpyridines, azo-bisterpyridine, cyclosexipyridines, macrocyclisation.

[Traduit par la Rédaction]

Introduction

The parent, C_6-symmetric cyclosexipyridine **1** (Scheme 1) was first reported by Newkome and Lee in 1983 (1) as the insoluble and uncharacterized product of a seven-step synthesis. Kelly et al. (2) prepared the curious, inverted cyclosexipyridine **2**, a highly insoluble and partly characterized C_3-symmetric *tris*(bipyridine), after a lengthy synthetic sequence. Bell and Firestone (3) used Friedlander reactions to assemble torand **3**, a C_3-symmetric hexaazakekulene derivative with rigidifying ethylene bridges and solubilizing butyl side-chains, isolated in 3% yield after 11 steps as a Ca^{2+} complex in which the Ca^{2+} apparently originated as a minute

L. Masciello and P.G. Potvin.[1] Department of Chemistry, York University, 4700 Keele Street, Toronto, ON M3J 1P3, Canada.

[1]Corresponding author (e-mail: pgpotvin@yorku.ca).

impurity in a reagent. Toner (4) reported C_2-symmetrical cyclosexipyridines (e.g., **4**) prepared from bipyridines as insoluble and only partly characterized Na^+ complexes, in which the Na^+ was apparently abstracted from the glassware.

Macrocyclic polypyridines such as cyclosexipyridine constitute interesting, rigid supramolecular hosts for cations and H-bond donors, and this was the motivation for the earlier work. With competition experiments, Bell et al. showed that the related torands, with stronger imino dipoles and a more rigid architecture than in crown ethers, are extremely strong complexing agents (5). We anticipated that cyclosexipyridines would also be interesting ligands for transition metals in that they would provide a planar, conjugated π system occupying the equatorial plane of the metal, as do the porphyrins and phthalocyanines. However, unlike those ligands, the cyclopolypyridines are neutral and do not form a contiguous aromatic system. The macroligand LUMO would thus remain relatively high energy, as would any MLCT transition and photochemistry therefrom, and the reduction potentials would remain relatively more negative. The binding geome-

Scheme 1.

try could be trigonal or (distorted) square planar and the binding may be fluxional.

For studies of cyclosexipyridine coordination, one would need a short, high-yield synthesis of material. In the course of our work with Ru(II) complexes of nonmacrocyclic polypyridines, we developed a one-step route from commercially available materials to symmetrical dipyrazinylpyridines (6) and recently applied it to the synthesis of two phenylene-linked *bis*terpyridines (7, 8). This provided an opening to an expedient synthesis of novel C_3-symmetric cyclosexipyridines (e.g., **5**), which, we reasoned, should be more soluble than Toner's C_2-symmetric varieties yet much easier to prepare than were the torands. Furthermore, our ability to prepare *bis*terpyridines provides an entry to an unprecedented *bis*(cyclosexipyridine). In this paper, we report the preparation of a number of diacetylated terpyridines and an azo-linked *bis*terpyridine that are of distinct interest and on macrocyclization reactions to form C_3-symmetric cyclosexipyridines.

Experimental section

General

NMR spectra were acquired on a Bruker AMX 400 MHz spectrometer in CDCl$_3$ unless otherwise indicated. A Kratos Profile mass spectrometer was used for EI-MS acquisitions. MALDI-MS spectra were acquired on a Voyager-DE STR instrument. High resolution mass spectroscopy was performed by the McMaster Regional Centre for Mass Spectrometry in Hamilton, Ont. Mass peaks are presented as mass-to-charge ratios (*m/z*) with, in brackets, peak assign-

ments and % relative intensities. UV–visible spectra were obtained at room temperature on a Hewlett-Packard 8452A diode array spectrophotometer. IR spectra were obtained on a Genesis II FT-IR spectrometer. Elemental analyses were preformed by Guelph Chemical Laboratories Ltd. in Guelph, Ont.

DMF and CH$_2$Cl$_2$ were made anhydrous by distillation of reagent grade material over MgSO$_4$ or P$_2$O$_5$, respectively, and stored over 4 Å molecular sieves. All other materials were used as received, except for *p*-tolualdehyde and 4-*tert*-butylbenzaldehyde, which were washed with 5% aq. NaOH, dried (MgSO$_4$), and then stored under Ar. Thin layer chromatography used Macherey–Nagel Alugram silica gel plates. Preparative thin layer chromatography used EM Science silica gel 60F glass plates. The petroleum ether (PE) used had a bp range of 60–80°C.

2,6-Di-(3-*p*-tolylpropenoyl)pyridine (7a)

A solution of 2,6-diacetylpyridine (3.08 g, 1.9 mmol) in MeOH (40 mL) was added to a solution of *p*-tolualdehyde (4.99 g, 42 mmol) in a 1:2 mixture of MeOH and 5% aq. KOH (60 mL), and the resulting mixture was stirred vigorously at room temperature for 48 h. The precipitate was isolated by vacuum filtration. A second crop was obtained by adding 30 mL of H$_2$O to the filtrate, allowing it to stir for 8 h, and collecting the precipitate by vacuum filtration. The combined crops were dissolved in CHCl$_3$ and extracted with H$_2$O (3 × 25 mL), 5% aq. NaHSO$_3$ (2 × 25 mL), and brine (2 × 25 mL). The combined organic fractions were dried with MgSO$_4$, filtered, and freed of solvent in vacuo. The

resulting yellow residue was recrystallized (CHCl$_3$:MeOH) to afford yellow needles (4.51 g, 65%). mp 198–200°C. ^{1}H NMR (ppm) δ: 8.43 (d, J = 16 Hz, 2H, H-3′), 8.39 (d, J = 7.5 Hz, 2H, H-3), 8.10 (t, J = 7.9 Hz, 1H, H-4), 8.03 (d, J = 16 Hz, 2H, H-2′), 7.69 (d, J = 8.0 Hz, 4H, Ar H-3), 7.29 (d, J = 7.1 Hz, 4H, Ar H-2), 2.46 (s, 6H, CH$_3$). ^{13}C NMR (ppm) δ: 188.7, 153.3, 145.1, 141.4, 138.3, 132.5, 129.8, 128.8, 125.8, 119.8, 21.7; EI-MS: 367 ([M$^+$], 100). Elemental analysis calcd. for C$_{25}$H$_{21}$NO$_2$: C 81.72, H 5.76, N 3.81; found: C 81.79, H 5.36, N 3.89.

2,6-Di-(3-(4-chlorophenyl)propenoyl)pyridine (7b)

A mixture of 2,6-diacetylpyridine (1.28 g, 7.82 mmol) in MeOH (20 mL) and 4-chlorobenzaldehyde (2.39 g, 17.2 mmol) in 1:2 MeOH:15% aq. KOH (60 mL) reacted at room temperature for 2 d and the product mixture was worked up as with **7a** to provide a yellow residue that recrystallized (cold CHCl$_3$) as a pale yellow powder (1.97 g, 62%). mp 210–212°C. ^{1}H NMR (warm CDCl$_3$) (ppm) δ: 8.41 (d, J = 8.8 Hz, 2H, H-3), 8.38 (d, J = 16 Hz, 2H, H-3), 8.12 (t, J = 8.6 Hz, 1H, H-4), 7.99 (d, J = 16 Hz, 2H, H-2′), 7.69 (d, J = 9.1 Hz, 4H, Ar H-3), 7.45 (d, J = 8.9 Hz, 4H, Ar H-2). EI-MS: 407 ([M$^+$], 100). Elemental analysis calcd. for C$_{23}$H$_{15}$NO$_2$Cl$_2$: C 67.66, H 3.70, N 3.43; found: C 67.37, H 3.62, N 3.44.

2,6-Di-(3-(4-*tert*-butylphenyl)propenoyl)pyridine (7c)

By an entirely analogous process, 2,6-diacetylpyridine (1.02 g, 6.25 mmol) in MeOH (25 mL) and 4-*tert*-butylbenzaldehyde (2.51 g, 15.5 mmol) in 1:2 MeOH:5% aq. KOH (75 mL) reacted for 2 d at room temperature, and the product mixture was worked up as with **7a** to provide a yellow residue that was converted to a yellow powder by sonication in MeOH (25 mL) and then recrystallized (CHCl$_3$:MeOH) to afford yellow needles (1.69 g, 60%). mp 169–171°C. ^{1}H NMR (ppm) δ: 8.4 (d, J = 16 Hz, 2H, H-3′), 8.40 (d, J = 7.8 Hz, 2H, H-3), 8.10 (t, J = 7.7 Hz, 1H, H-4), 8.05 (d, J = 16 Hz, 2H, H-2′), 7.76 (d, J = 8.5 Hz, 4H, Ar H-3), 7.52 (d, J = 8.3 Hz, 4H, Ar H-2), 1.40 (s, 18H). ^{13}C NMR (ppm) δ: 188.5, 154.5, 153.2, 144.9, 138.4, 132.6, 128.6, 126.0, 125.7, 120.2, 35.0, 31.2. EI-MS: 451 ([M$^+$], 100). Elemental analysis calcd. for C$_{31}$H$_{33}$NO$_2$: C 82.44, H 7.37, N 3.10; found: C 82.48, H 7.81, N 3.16.

4-Neopentoxybenzaldehyde

A suspension of NaH (1.25 g, 52.1 mmol) in anhydrous DMF (15 mL) was vigorously stirred in a three-neck round-bottom flask fitted with a condenser and an Ar inlet. A dropwise solution of 4-hydroxybenzaldehyde (1.05 g, 8.59 mmol) in anhydrous DMF (4 mL) was added to this suspension. After 10 min, a solution of neopentyl tosylate (9) (3.93 g, 16.4 mmol) and tetrabutylammonium iodide (0.34 g) in anhydrous DMF (5 mL) was added by syringe pump at a rate of 1 drop per 10 s. The solution was heated to reflux for 2 d, poured into H$_2$O (100 mL), and extracted with diethyl ether (4 × 100 mL). The combined ether layers were concentrated and then washed with 5% aq. NaOH (2 × 50 mL) and brine (2 × 50 mL). The organic fraction was dried with MgSO$_4$, filtered, and freed of solvent in vacuo. The residue was dissolved in a small amount of CHCl$_3$ and separated from contaminants (starting materials, identified by ^{1}H NMR) by preparative TLC (5:95 EtOAc:PE). The major UV-active band was scraped off and extracted by sonicating in 30:70 MeOH:CH$_2$Cl$_2$. The extract was filtered, reduced in vacuo, and dried to afford a colourless oil (0.70 g, 42%). The ^{1}H NMR, EI-MS, IR, and elemental analysis data were in agreement with the literature data (10).

2,6-Di-(3-(4-neopentoxyphenyl)propenoyl)pyridine (7d)

By analogy to the preparation of **7a**, a mixture of 2,6-diacetylpyridine (56.2 mg, 0.345 mmol) in MeOH (5 mL) and 4-neopentoxybenzaldehyde (130.5 mg, 0.680 mmol) reacted at room temperature for 48 h. As with **7a**, working up provided a yellow residue that recrystallized (MeOH:H$_2$O) as a bright yellow powder (111 mg, 63%). mp 143–145°C. ^{1}H NMR (ppm) δ: 8.39 (d, J = 7.9 Hz, 2H, H-3), 8.35 (d, J = 16 Hz, 2H, H-3′), 8.08 (t, J = 7.9 Hz, 1H, H-4), 7.9 (d, J = 16 Hz, 2H, H-2′), 7.73 (d, J = 8.3 Hz, 4H, Ar H-3), 6.70 (d, J = 8.5 Hz, 4H, Ar H-2), 3.70 (s, 4H, CH$_2$), 1.09 (s, 18H, CH$_3$). EI-MS: 511 ([M$^+$], 100). Elemental analysis calcd. for C$_{33}$H$_{37}$NO$_4$: C 77.47, H 7.29, N 2.74; found: C 77.21, H 7.52, N 2.73.

3-(*p*-Tolyl)-1-(2-(6-acetylpyridyl))-2-propenone (8a)

A solution of 2,6-diacetylpyridine (3.08 g, 18.9 mmol) in MeOH (50 mL) was added to a vigorously stirring solution of *p*-tolualdehyde (2.23 g, 18.6 mmol) in a 1:4 mixture (50 mL) of MeOH and 2.5% aq. KOH with a syringe pump at a rate of one drop per 10 s. The resulting mixture was stirred vigorously at room temperature for 24 h. The precipitate was isolated by vacuum filtration. A second crop was obtained by adding 30 mL of H$_2$O to the filtrate, allowing it to stir for 8 h, and collecting the precipitate by vacuum filtration. The combined crops were dissolved in CHCl$_3$ and extracted with H$_2$O (3 × 25 mL), 5% aq. NaHSO$_3$ (2 × 25 mL), and brine (2 × 25 mL). The organic fraction was dried with MgSO$_4$, filtered, and freed of solvent in vacuo. The residue was sonicated in MeOH to precipitate the contaminating bispropenone **7a** as a yellow powder (0.58 g) from the mixture. The yellow filtrate was freed of solvent in vacuo and the remaining yellow residue recrystallized (MeOH:H$_2$O) as yellow flakes (3.31 g, 67%). mp 114–116°C. ^{1}H NMR (ppm) δ: 8.37 (d, J = 7.7 Hz, 1H, H-3/5), 8.30 (d, J = 16 Hz, 1H, H-3′), 8.24 (d, J = 7.8 Hz, 1H, H-5/3), 8.04 (t, J = 7.8 Hz, 1H, H-4), 7.98 (d, J = 16 Hz, 1H, H-2′), 7.63 (d, J = 8.1 Hz, 2H, Ar H-3), 7.28 (d, J = 8.0 Hz, 2H, Ar H-2), 2.89 (s, 3H, COCH$_3$), 2.44 (s, 3H, Ar CH$_3$). ^{13}C NMR (ppm) δ: 199.4, 188.6, 153.7, 152.6, 145.7, 141.4, 137.9, 132.7, 129.3, 128.8, 126.1, 124.5, 119.4, 25.8, 22.2. EI-MS: 265 ([M$^+$], 100). Elemental analysis calcd. for C$_{17}$H$_{15}$NO$_2$: C 76.96, H 5.70, N 5.28; found: C 76.55, H 5.51, N 5.27.

Alternatively, the residue containing the two products can be separated by column chromatography (silica, gradient eluent beginning with 3:95 EtOAc:PE and adding 5:95 EtOAc:PE) to afford each as pure yellow products.

3-(4-*tert*-Butylphenyl)-1-(2-(6-acetylpyridyl))-2-propenone (8c)

As for **8a**, 2,6-diacetylpyridine (1.25 g, 7.7 mmol) in MeOH (30 mL) and *p*-*tert*-butylbenzaldehyde (1.25 g, 7.7 mmol) in 1:2 MeOH:2.5% aq. KOH (90 mL) reacted for

24 h, and the reaction mixture was worked up as before. The residue was dissolved in a minimal amount of EtOAc and passed down a short column (silica, 10:90 EtOAc:PE). The major yellow fore-fraction was collected, freed of solvent in vacuo, and sonicated in MeOH (25 mL) to precipitate the bispropenone **7c** in pure form (0.18 g). The filtrate was freed of solvent and the yellow residue recrystallized (MeOH:H_2O) as yellow needles (0.44 g, 19%). mp 83–85°C. ^{1}H NMR (ppm) δ: 8.39 (d, J = 7.8 Hz, 1H, H-3/5), 8.35 (d, J = 16 Hz, 1H, H-3′), 8.26 (d, J = 7.7 Hz, 1H, H-5/3), 8.05 (t, J = 8.0 Hz, 1H, H-4), 8.02 (d, J = 16 Hz, 1H, H-2′), 7.70 (d, J = 8.4 Hz, 2H, Ar H-3), 7.51 (d, J = 8.4 Hz, 2H, Ar H-2), 2.90 (s, 3H, COCH$_3$), 1.38 (s, 9H, C(CH$_3$)$_3$). EI-MS: 307 ([M$^+$], 100). Elemental analysis calcd. for $C_{20}H_{21}NO_2$: C 78.15, H 6.88, N 4.55; found: C 78.29, H 7.00, N 4.49.

6,6″-Diacetyl-4′-(*p*-tolyl)-2,2′:6′,2″-terpyridine (9a)

One-pot method A

A solution of 2,6-diacetylpyridine (1.51 g, 9.27 mmol) in MeOH (35 mL) was quickly added to a vigorously stirring solution of *p*-tolualdehyde (0.56 g, 4.64 mmol) in MeOH (10 mL), 30% aq. KOH (7.5 mL), and concd. NH$_4$OH (7.5 mL). An additional 30 mL of NH$_4$OH was added and the mixture was allowed to stir at room temperature for 4–5 d. The precipitate was filtered by vacuum filtration, washed with H$_2$O, and dissolved in CHCl$_3$. The solution was washed sequentially with H$_2$O (2 × 25 mL) and brine (2 × 25 mL). The organic fraction was dried with MgSO$_4$ and freed of solvent in vacuo. The residue was sonicated in MeOH (30 mL) to afford a golden yellow powder that was filtered and recrystallized (CHCl$_3$:MeOH) as a brown-yellow powder (0.76 g, 70%). mp 191–193°C (dec.). ^{1}H NMR (ppm) δ: 8.89 (d, J = 7.6 Hz, 2H, H-5), 8.85 (s, 2H, H-3′), 8.14 (d, J = 7.7 Hz, 2H, H-3), 8.03 (t, J = 7.7 Hz, 2H, H-4), 7.81 (d, J = 7.8 Hz, 2H, Ar H-3), 7.43 (d, J = 8.0, 2H, Ar H-2), 2.91 (s, 6H, COCH$_3$), 2.50 (s, 3H, Ar CH$_3$). EI-MS: 407 ([M$^+$], 68). 365 ([M$^+$-COCH$_3$], 45), 43 ([COCH$_3$], 100). Elemental analysis calcd. for $C_{26}H_{21}N_3O_2$: C 76.64, H 5.19, N 10.31; found: C 76.26, H 5.05, N 10.65.

Two-step method B

A solution of 2,6-diacetylpyridine (409 mg, 2.51 mmol) in MeOH (20 mL) was quickly added to a vigorously stirring solution of the propenone **8a** (664 mg, 2.51 mmol) in MeOH (62.5 mL) and 15% aq. KOH (22 mL). Concentrated NH$_4$OH (60 mL) was added in portions and the mixture was allowed to stir at room temperature for 4–5 d. The precipitate was filtered by vacuum filtration, dissolved in CHCl$_3$, and washed sequentially with H$_2$O (2 × 25 mL) and brine (2 × 25 mL). The organic fraction was dried with MgSO$_4$ and freed of solvent in vacuo. The residue was triturated with MeOH (20 mL) to afford a golden yellow powder that was filtered and recrystallized (CHCl$_3$:MeOH) as a brown-yellow powder (358 mg, 35%). The mp and ^{1}H NMR data were identical to those from material obtained by Method A.

6,6″-Diacetyl-4′-(4-chlorophenyl)-2,2′:6′,2″-terpyridine (9b)

By analogy to the preparation of **9a** by Method A, 2,6-diacetylpyridine (1.960 g, 12.0 mmol) in MeOH (40 mL) reacted with 4-chlorobenzaldehyde (819 mg, 5.85 mmol) in MeOH (20 mL), 15% aq. KOH (7 mL) and concd. NH$_4$OH (10 mL) at room temperature for 3 days, and the reaction mixture was worked up as before. The yellow solid crude product was passed down a short column (silica, 20:80 EtOAc:PE) with slow elution of the major yellow band and 10:90 MeOH:CH$_2$Cl$_2$ for elution of the baseline fraction. Both fractions were combined and recrystallized (CHCl$_3$:MeOH) to afford a pure brown-yellow powder (1.80 g, 72%). mp 166–168°C. ^{1}H NMR (ppm) δ: 8.89 (d, J = 7.8 Hz, 2H, H-5), 8.82 (s, 2H, H-3′), 8.15 (d, J = 7.4 Hz, 2H, H-3), 8.06 (t, J = 7.8 Hz, 2H, H-4), 7.83 (d, J = 8.5 Hz, 2H, Ar H-3), 7.57 (d, J = 8.41 Hz, 2H, Ar H-2), 2.91 (s, 6H, CH$_3$). EI-MS: 427 ([M$^+$], 100). Elemental analysis calcd. for $C_{25}H_{18}N_3O_2Cl$: C 70.18, H 4.24, N 9.82; found: C 69.70, H 4.24, N 9.57.

6,6″-Diacetyl-4′-(4-*tert*-butylphenyl)-2,2′:6′,2″-terpyridine (9c)

By analogy to the preparation of **9a** by Method A, 2,6-diacetylpyridine (1.503 g, 9.22 mmol) in MeOH (35 mL) reacted with 4-*tert*-butylbenzaldehyde (0.742 g, 4.58 mmol) in MeOH (10 mL), 30% aq. KOH (7.5 mL) and concd. NH$_4$OH (7.5 mL) at room temperature for 3–4 days, and the reaction mixture was worked up as before. The yellow solid crude product was dissolved in a small amount of CHCl$_3$ and separated from contaminants by preparative TLC (silica, 1:9 EtOAc:hexane). The major UV-active band was extracted from the silica with 30:70 MeOH:CH$_2$Cl$_2$, filtered, and reduced in vacuo to afford a white residue. Sonicating in MeOH (30 min,100 mL) and recrystallization (CHCl$_3$:Et$_2$O) afforded a white powder (1.51 g, 73%). mp 185–187°C (dec.). ^{1}H NMR (ppm) δ: 8.88 (d, J = 7.8 Hz, 2H, H-5), 8.85 (s, 2H, H-3), 8.12 (d, J = 7.6 Hz, 2H, H-3), 8.04 (t, J = 7.7 Hz, 2H, H-4), 7.86 (d, J = 8.1 Hz, 2H, Ar H-3), 7.64 (d, J = 8.2 Hz, 2H, Ar H-2), 2.93 (s, 6H, COCH$_3$), 1.74 (s, 9H, C(CH$_3$)$_3$). EI-MS: 449 ([M$^+$], 100). Elemental analysis calcd. for $C_{29}H_{27}N_3O_2$: C 77.48, H 6.05, N 9.35; found: C 77.82, H 6.34, N 8.89.

6,6″-Diacetyl-4′-(4-neopentoxyphenyl)-2,2′:6′,2″-terpyridine (9d)

By analogy to the preparation of **9a** by Method A, 2,6-diacetylpyridine (335 mg, 2.05 mmol) in MeOH (5 mL) reacted with 4-neopentoxybenzaldehyde (191 mg, 0.99 mmol) in MeOH (10 mL), 30% aq. KOH (2.5 mL), and concd. NH$_4$OH (2.5 mL) at room temperature for 4 days, and the reaction mixture was worked up as before. Purification of the yellow solid crude product by preparative TLC (1:3 EtOAc:hexane) gave a major yellow band that was extracted from the silica with 30:70 MeOH:CH$_2$Cl$_2$, filtered, and reduced in vacuo. The yellow solid proved difficult to recrystallize and was isolated as a golden-yellow powder by drying under vacuum (334 mg, 70%). mp 167–170°C. ^{1}H NMR (ppm) δ: 8.88 (d, J = 7.8 Hz, 2H, H-5), 8.83 (s, 2H, H-3′), 8.13 (d, J = 7.7 Hz, 2H, H-3), 8.05 (t, J = 7.6 Hz, 2H, H-4), 7.85 (d, J = 8.2 Hz, 2H, Ar H-3), 7.15 (d, J = 8.1 Hz, 2H, Ar H-2), 3.75 (s, 2H, CH$_2$), 2.92 (s, 6H, COCH$_3$), 1.10 (s, 9H, C(CH$_3$)$_3$). EI-MS: 479 ([M$^+$], 87). Elemental analysis calcd. for $C_{30}H_{29}N_3O_3$: C 75.16, H 6.10, N 8.79; found: C 74.80, 6.49, 8.48.

4′,4‴,4ᵛ-Tri-(p-tolyl)-[(2,6)-pyridyl-6-corand-6] (5a)

Method A

A mixture of **9a** (40.1 mg, 0.098 mmol) and bispropenone **7a** (37.9 mg, 0.103 mmol) were heated at reflux in glacial acetic acid (25 mL) and excess concd. NH_4OAc (1.3 g) for 24 h. The precipitate was filtered hot and washed with $CHCl_3$, MeOH, and Et_2O to give a dark black solid (16.5 mg, 22%). This solid was found to be insoluble in all common organic solvents examined. mp 207–210°C (dec.). MALDI-MS: 755.1 ($[M^+ + Na^+]$, 100). 771.0 ($[M^+ + K^+]$, 7). HRMS calcd. for $C_{51}H_{36}N_6K$: 771.264; found: 771.262 ± 0.005.

Method B

A mixture of bispropenone **10** (5.0 mg, 8.17 µmol) and 2,6-di[2-(N-pyridyl)-1-oxoethyl]pyridine diiodide **11** (11) (4.6 mg, 8.23 µmol) were heated to reflux in glacial acetic acid (25 mL) containing NH_4OAc (0.72 g) for 24 h. The precipitate was filtered hot and washed with $CHCl_3$, MeOH, and Et_2O to give a dark black solid (1.23 mg, 20%), identical in all respects to material obtained by Method A.

4′,4″,4ᵛ-Tri-(4-chlorophenyl)-[(2,6)-pyridyl-6-corand-6] (5b)

The preparation of **5a** by Method A was followed by using **9b** (43.4 mg, 0.102 mmol) and bispropenone **7b** (38.5 mg, 0.0946 mmol) to obtain a dark brown, insoluble solid (16.7 mg, 22%). mp 198–200°C (dec.). MALDI-MS: 815.2 ($[M^+ + Na^+]$, 100). 831.2 ($[M^+ + K^+]$, 7). HRMS calcd. for $C_{48}H_{27}N_6Cl_3Na$: 815.125; found: 815.126 ± 0.005.

4′,4″,4ᵛ-Tri-(4-tert-butylphenyl)-[(2,6)-pyridyl-6-corand-6] (5c)

A solution of **9c** (24.3 mg, 0.054 mmol) in 4:1 n-butanol:MeOH (25 mL) was added to a stirring solution of bispropenone **7c** (17.0 mg, 0.0377 mmol) in 2:1 n-butanol:MeOH (15 mL), 30% aq. KOH (10 mL) and concd. NH_4OH (30 mL). The mixture was heated at reflux for 24 h. The precipitate was filtered hot and washed with H_2O, $CHCl_3$, and MeOH to give a tan solid (9.0 mg, 26%) that was insoluble in all common organic solvents examined. mp 204–207°C (dec.). MALDI-MS: 881.4 ($[M^+ + Na^+]$, 25), 897.4 ($[M^+ + K^+]$, 37). HRMS calcd. for $C_{60}H_{54}N_6Na$ and $C_{60}H_{54}N_6K$: 881.431 and 897.405; found: 881.427 ± 0.005 and 897.408 ± 0.005.

4′,4″,4ᵛ-Tri-(4-neopentoxyphenyl)-[(2,6)-pyridyl-6-corand-6] (5d)

In analogy to the preparation of **5a** by Method A, **9d** (42.3 mg, 0.0885 mmol) and bispropenone **7d** (45.4 mg, 0.0888 mmol) were used to provide a fine precipitate, which was filtered hot, dissolved in $CHCl_3$, and washed with H_2O (3 × 15 mL). The organic layer was freed of solvent in vacuo and dried under vacuum to give a yellow solid (18.5 mg, 22%). mp 173–175°C (dec.). UV–vis ($CHCl_3$) λ_{max} (nm) (ε (10^3 M^{-1} cm^{-1})): 264 (45), 316 (49). ^{1}H NMR (ppm) (0.64 µM, refer to Fig. 1 for assignments) δ: 9.04 (2H, s, H-3B), 8.95 (2H, d, H-3/5C), 8.83 (2H, s, H-3/5D), 8.83 (1H, t, H-4F), 8.76 (2H, d, H-5/3C), 8.14 (2H, d, H-3F), 8.07 (2H, t, H-4C), 7.97 (2H, d, H-2A or H-2/6E), 7.92 (2H, d, H-2A or H-2/6E), 7.92 (2H, s, H-5/3D), 7.14 (8H, d, H-3A, H-

4′-(p-Tolyl)-6,6″-di-(3-(p-tolyl)propenoyl)-2,2′:6′,2″-terpyridine (10)

A solution of **9a** (100.3 mg, 0.25 mmol) in THF (20 mL) was added, dropwise, to a vigorously stirring solution of p-tolualdehyde (208.4 mg, 1.74 mmol), MeOH (23 mL), and 15% aq. KOH (25 mL), and the mixture was stirred for 3 d. The precipitate was filtered, dissolved in $CHCl_3$, and washed sequentially with 5% aq. $NaHSO_3$, (2 × 15 mL), H_2O (2 × 15 mL), and brine (2 × 15 mL). The product was contaminated with a small quantity of unreacted **9a** that was partially removed by seven cycles of preparative TLC (silica, 10:90 EtOAc:PE). The baseline fraction was removed from the silica (30:70 MeOH:CH_2Cl_2), freed of solvent, and recrystallized ($CHCl_3$:MeOH) to afford a tan powder (30.1 mg, 20%). ^{1}H NMR (ppm) δ: 8.89 (d, J = 8.0 Hz, 2H, H-5), 8.85 (s, 2H, H-3′), 8.53 (d, J = 16 Hz, 2H, H-3), 8.14 (d, J = 7.2 Hz, 2H, H-3), 8.05 (t, J = 7.6 Hz, 2H, H-4), 8.04 (d, J = 16 Hz, 2H, H-2), 7.81 (d, J = 8.0 Hz, 2H, Ar H-3), 7.70 (d, J = 7.9 Hz, 2H, Ar H-3), 7.43 (d, J = 7.9 Hz, 6H, Ar H-2), 2.50, (s, 6H, Ar CH_3), 2.46 (s, 3H, Ar CH_3). MALDI-MS: 611 ($[M^+]$, 87).

2-(4-Nitrophenyl)-1,3-dioxolane (12)

A mixture of 4-nitrobenzaldehyde (1.508 g, 9.9 mmol), ethylene glycol (1.21 mL, 21.7 mmol), and chlorotrimethylsilane (5.61 mL, 44.2 mmol) in anhydrous CH_2Cl_2 (55 mL) was stirred at reflux under Ar for 48 h. A 5% aq. solution of $NaHCO_3$ (100 mL) was added and the mixture was extracted with Et_2O (4 × 75 mL). The ether layer was extracted with brine (4 × 75 mL), dried with $MgSO_4$, filtered, and reduced in vacuo. The yellow residue was recrystallized ($CHCl_3$) as cream flakes (1.523 g, 79%). ^{1}H NMR, EI-MS, and mp data were in agreement with those reported in the literature (12, 13).

4,4′-Di-(1,3-dioxolanyl)azobenzene (13)

A suspension of $LiAlH_4$ (1.510 g, 3.98 mmol) in Et_2O (50 mL) was vigorously stirred at –78°C in a three-neck round-bottom flask fitted with a mechanical stirrer, dropping funnel, and an Ar inlet. To this suspension, a solution of 2-(4-nitrophenyl)-1,3-dioxolane **12** (0.6954 g, 3.58 mmol) in Et_2O (40 mL) was added, dropwise. The mixture was allowed to slowly warm to room temperature (3 h) and stirred for an additional 30 min. The reaction was quenched slowly and successively with EtOAc, MeOH, and H_2O with vigorous stirring. The addition of a 5% aq. H_2SO_4 solution produced two brightly coloured (orange and yellow) layers. The orange layer was extracted into Et_2O (40 mL), and the ether layer was washed with H_2O (1 × 25 mL), $NaHCO_3$ (2 × 25 mL), and brine (2 × 25 mL). The ether-borne extract was concentrated and purified by preparative TLC (silica, 1:3 EtOAc:hexane). The major orange band was extracted from the silica with 30:70 MeOH:CH_2Cl_2. The extract was filtered, concentrated in vacuo, and recrystallized (cold MeOH) to afford a bright orange powder (0.7236 g, 62%). mp 140–142°C. ^{1}H NMR (ppm) δ: 7.96 (d, J = 7.9 Hz, 4H, H-2), 7.66 (d, J = 8.0 Hz, 4H, H-3), 5.92 (s, 2H, Ar-CH),

Fig. 1. Cyclosexipyridine **5d**, showing twisting of rings A and F out of plane. The ^{1}H NMR assignments used the position numbers given.
4.20–4.08 (m, 8H, CH$_2$). EI-MS: 326 ([M$^+$], 48). 149 ([M$^+$ – C$_9$H$_9$O$_2$], 100). Elemental analysis calcd. for C$_{18}$H$_{18}$N$_2$O$_4$: C 66.25, H 5.56, N 8.58; found: C 66.77, H 5.69, N 8.31.

4,4′-Azobenzaldehyde (14)

A 10% aq. H$_2$SO$_4$ solution (100 mL) was added to a vigorously stirring solution of 4,4′-di-(1,3-dioxolanyl)azobenzene **13** (0.700 g, 2.15 mmol) in MeOH (60 mL) at room temperature. The mixture was allowed to stir for 20 h, filtered, dissolved in CHCl$_3$, and washed sequentially with 5% aq. NaHCO$_3$ (1 × 75 mL), H$_2$O (1 × 75 mL), and brine (2 × 50 mL). The organic fraction was dried with MgSO$_4$, freed of solvent in vacuo, and recrystallized (MeOH) to afford red leaflets (0.420 g, 82%). ^{1}H NMR, EI-MS, and mp data were in agreement with those reported in the literature (14–16). UV–vis (CHCl$_3$) λ$_{max}$ (nm) (ε (M^{-1} cm^{-1})): 336 (53 500), 478 (1 240).

4,4′-Di-(4′-(6,6″-diacetyl-2,2′:6′,2″-terpyridinyl))azobenzene (15)

A solution of 2,6-diacetylpyridine (0.4890 g, 3.0 mmol) in MeOH (10 mL) was added slowly to a vigorously stirring mixture of 4,4′-azobenzaldehyde **14** (0.1017 g, 0.49 mmol), MeOH (90 mL), 15% aq. KOH (2.5 mL), and concd. NH$_4$OH (23 mL). The mixture was heated to reflux for 20 h. The orange precipitate was filtered and washed with H$_2$O. Trituration with CHCl$_3$ afforded an orange filtrate and an insoluble orange precipitate. The filtrate was washed with NaHCO$_3$ (2 × 25 mL), NaOH (1 × 25 mL), and brine (2 × 25 mL), dried with MgSO$_4$, and freed of solvent in vacuo. The residue was purified by preparative TLC (silica, 31:2:1 MeCN: saturated KNO$_3$:H$_2$O). The baseline fraction was extracted from the silica with 30:70 MeOH:CH$_2$Cl$_2$. The extract was filtered and concentrated in vacuo. The orange solid recrystallized (CHCl$_3$:MeOH) as an orange powder (175.0 mg, 50%). mp 207–209°C. UV–vis (CHCl$_3$) λ$_{max}$ (nm) (ε (M^{-1} cm^{-1})): 356 (12 400), 274 (31 400). IR (neat) (cm^{-1}): 1698 (s, C=O). ^{1}H NMR (ppm) δ: 8.94 (d, J = 7.6 Hz, 4H, H-5), 8.91 (s, 4H, H-3′), 8.23 (d, J = 7.6 Hz, 4H, H-3), 8.15 (d+d, J = 7.8 Hz, 8H, Ar H-2 & H-3), 8.10 (t, J = 7.5 Hz, 4H, H-4), 2.94 (s, 12H, CH$_3$). MALDI-MS: 812 ([M$^+$], 100). HRMS calcd. for C$_{50}$H$_{37}$N$_8$O$_4$: 813.294. found: 813.295 ± 0.005.

Results and discussion

As illustrated in Scheme 2, we explored two approaches to the synthesis of C_3-symmetrical cyclosexipyridines: (*i*) coupling a diacetylterpyridine **9** with a bispropenone **7** in the presence of a source of NH$_3$ via a dihydropyridine intermediate and (*ii*) coupling a more elaborate bispropenone **10** with the salt **11** under Kröhnke's conditions (17). Both approaches required diacetylated terpyridines **9** whose synthesis was to make use of our one-pot preparation of dipyrazinylpyridines (6), essentially a modified Chichibabin synthesis (18). This would start from commercial 2,6-diacetylpyridine **6**, which would be the only source of premanufactured pyridine rings and would require a differential reactivity of the two acetyl groups.

The substituents on the macroring, originating from aromatic aldehydes, could presumably be varied at will. In principle, this approach can also lead to less symmetrical products with one macroring substituent different from the other two, but this possibility was not explored here. Our initial goal was to prepare three examples of cyclosexipyridines, one with electron-releasing substituents, another with electron-withdrawing substitution, and the first example of a *bis*(cyclosexipyridine) with an azo linkage. The latter necessitated the preparation of a novel azo-linked *bis*terpyridine.

Diacetylpyridine **6** was treated with 2 equiv of *p*-tolualdehyde under basic conditions to afford a 65% isolated yield of recrystallized bispropenone **7a** (Scheme 2). Similarly, 4-chlorobenzaldehyde afforded **7b** in 62% isolated yield. Their NMR and EI-MS spectra and their elemental analyses were consistent with the proposed structures. According to ^{1}H NMR, they appeared to be exclusively *trans,trans* isomers. When only 1 equiv of *p*-tolualdehyde and weaker base were used, a 67% isolated yield of monopropenone **8a** was isolated, again as the *trans* isomer according to ^{1}H NMR, along with some **7a**. Hence, the two acetyl groups of **6** seem to react fairly independently, and the reaction of one apparently reduces the reactivity of the other, thereby making our approach promising.

When **6** and propenone **8a** were combined in 1:1 ratio under basic conditions in the presence of NH$_3$ at room temperature, a precipitate formed over the course of several days. After collection, washing, and recrystallization, a 35% yield of diacetylterpyridine **9a** was obtained. If, instead, *p*-tolualdehyde or 4-chlorobenzaldehyde were combined with 2 equiv of **6** in the presence of NH$_3$, terpyridines **9a** and **9b** precipitated in essentially pure form over a few days at room temperature. These terpyridines were isolated in 70% and 72% yields, respectively, after recrystallization. Given the number of intermediates involved in the assembly of the central pyridine ring, such yields are remarkable. Both of these terpyridines were fully characterized by NMR, EI-MS, and elemental analyses. A distinctive feature of these materials was the appearance of a new aromatic singlet in their ^{1}H NMR spectra, signalling the creation of the symmetrical, central pyridine ring.

By an analogous process, 4,4′-azobenzaldehyde (**14**) and 4 equiv of **6** were converted to the novel azo-linked *bis*(terpyridine) **15**, an orange solid, in 50% yield after preparative TLC and recrystallization (Scheme 3). Considering

Scheme 2. Conditions: (*a*) ≥2 equiv Ar-CHO, 5–15% aq. KOH, MeOH, 2 d; (*b*) 1 equiv Ar-CHO, 2.5% aq. KOH, MeOH, 24 h; (*c*) 1 equiv **6**, 15% aq. KOH, concd. NH$_4$OH, MeOH, 4–5 d; (*d*) 0.5 equiv **6**, 15–30% aq. KOH, concd. NH$_4$OH, MeOH, 3–5 d; (*e*) 1 equiv **7a,b**, or **d**, NH$_4$OAc, HOAc, reflux, 24 h, or 1 equiv **7c**, 30% aq. KOH, concd. NH$_4$OH, MeOH:*n*-BuOH, reflux, 24 h; (*f*) 7 equiv CH$_3$C$_6$H$_4$-4-CHO, 15% aq. KOH, MeOH, 3 d; (*g*) 1 equiv **11**, NH$_4$OAc, HOAc, reflux, 24 h. The ^{1}H NMR assignments used the position numbers given.

a Ar = C$_6$H$_4$-4-CH$_3$ b Ar = C$_6$H$_4$-4-Cl
c Ar = C$_6$H$_4$-4-C(CH$_3$)$_3$ d Ar = C$_6$H$_4$-4-OCH$_2$C(CH$_3$)$_3$
that this transformation assembled a total of seven molecules (including NH$_3$) and eliminated a total of six molecules of H$_2$O (as well as 2 equiv of H$_2$), the 50% yield is quite remarkable. For this synthesis, the known dialdehyde **14** (14–16) was prepared from 4-nitrobenzaldehyde involving its TMSCl-catalyzed (19) protection to nitroacetal **12** (12, 13) (79% yield), reductive coupling with cold LiAlH$_4$ (20) to the previously unknown azo-acetal intermediate, the bright orange **13** (62% yield), followed by deprotection (82% yield). The nitro–azo transformation caused an upfield migration of the aromatic signals and the structure of **13** was otherwise supported by MS and elemental analysis as well as its transformation to **14**. In the ^{1}H NMR spectrum of **15**, the azophenyl doublets (identified by COSY) were overlapping. This had been also observed with the aromatic doublets from **14** where the aldehyde group is conjugated with the azo group but not in **12** or **13** where the aldehyde is masked.

The overlap with **15** is therefore consistent with conjugation of the terpyridine unit with the azo group and hence π-overlap among the terpyridines. The high degree of conjugation present was also evident from the energy of the π→π* band for **15** (356 nm), which is at a lower energy than had been found with a phenylene-linked *bis*(terpyridine) (280 nm) (7) or with azobenzene itself (320 nm) (21, 22).

These terpyridine compounds are also of evident interest in transition metal complexation. The synthesis provides for variation of the 4′ substituent, and the products may be further elaborated at the acetyl groups, for instance, to prepare macrocyclic Schiff bases with diamines.

To effect macrocyclization, **7a** and **9a** were combined in 1:1 ratio and heated to reflux in acetic acid in the presence of excess NH$_4$OAc. This produced a black powder in 22% yield that was insoluble in all solvents tested and appeared to decompose on the melting point apparatus. NMR analysis

Scheme 3. Conditions: (*a*) LiAlH$_4$, Et$_2$O, –78°C → RT, 30 min; (*b*) 10% aq. H$_2$SO$_4$, MeOH, 20 h; (*c*) 6 equiv **6**, 15% aq. KOH, concd. NH$_4$OH, MeOH, reflux, 20 h. The ^{1}H NMR assignments used the position numbers given.
of the mother liquor was not informative. MALDI-MS analysis of the insoluble material revealed two principal signals consistent with the presence of both Na$^+$ (M + 23) and K$^+$ (M + 39) complexes of cyclosexipyridine **5a**, in roughly 15:1 ratio, with no sign of metal-free macrocycle. This result is consistent with Toner's obtention of his cyclosexipyridine as a NaOAc complex. It seems that the presence of a third substituent on our macroring failed to produce a more soluble product. Essentially the same result was obtained by the analogous combination of the chlorophenyl-bearing terpyridine **9b** with chlorophenyl–bispropenone **7b**; a 22% yield of an insoluble black powder analyzing as Na$^+$ and K$^+$ complexes of macrocycle **5b** in *ca.* 15:1 ratio.

The condensation reactions forming the last two pyridine rings of the macrocycle actually produce dihydropyridines that require aerial oxidation. In case this might be rate-limiting and contribute to the low yields of macrocycles **5**, an alternative synthesis was performed using Krönhke methodology (17) such as was applied by Toner (4) and by Kelly et al. (2). This leads to fully formed pyridines without need for aerial oxidation but requires extra steps in substrate preparation. Diacetylterpyridine **9a** was converted to the *trans,trans*-bispropenone **10** by base-catalyzed condensation with excess *p*-tolualdehyde. This gave a disappointing, though unoptimized, yield of 20% of material that was, moreover, contaminated with some unreacted **9a** that proved to be very tedious to remove. Compound **10** was not fully characterized, but its structure was proven by MALDI-MS and ^{1}H NMR, which showed the absence of acetyl CH$_3$ signals, the appearance of *trans*-alkenyl signals, and the presence of two benzylic CH$_3$ signals in 2:1 integration ratio. *Bis*propenone **10** was subsequently treated with the known dipyridinium salt **11** and excess NH$_4$OAc in acetic acid at reflux, according to the Krönhke method (17). This afforded the Na$^+$ and K$^+$ complexes of **5a** identical in all respects to

material prepared earlier and in a similar yield (20%). There was, therefore, no apparent advantage to applying the Krönhke method and aerial oxidation was evidently not a limiting factor. We also attempted the direct, one-pot approach that was successful in our terpyridine synthesis using a 1:1 ratio of **6** and *p*-tolualdehyde in the presence of NH$_3$. However, the major product was the monopropenone **8a**. It appears that, once the first acetyl group of **6** has reacted to give **8a**, the reaction of the second is too slow in Michael addition to the propenone moiety of **8a**.

By analogy to other flat, extended π-conjugated systems such as phthalocyanines (23, 24), the insolubility of these cyclosexipyridines was likely due to aggregation. To discourage this, we turned to the commercially available 4-*tert*-butylbenzaldehyde to deliver bulkier substituents. We were able to prepare the *tert*-butylated bispropenone **7c** and terpyridine **9c** in yields very similar to those obtained previously (60 and 73%, respectively), but the monopropenone **8c** was obtained in just 19% yield, in part because of difficulty encountered in separating it from the **7c** that accompanies it, and **8c** was not used further. The macrocyclization was performed this time under basic conditions analogous to those used in our terpyridine synthesis, as opposed to the acidic conditions used earlier for **5a** and **5b**, to control the cation content of the reaction mixture. Thus, terpyridine **9c** and bispropenone **7c** were treated with aqueous KOH and concentrated NH$_4$OH in a butanol–MeOH mixture to produce a tan deposit in 26% yield that again analyzed as a mix of Na$^+$ and K$^+$ complexes of cyclosexipyridine **5c**, this time in a K-rich ratio of ca. 2:3 Na:K, with OH$^-$ as the likely counterion. The Na$^+$ probably again originated from the glass reaction vessel, and the failure of the large excess of K$^+$ in solution to prevent the incorporation of Na$^+$ suggests that the latter forms the stronger complexes. Indeed, Bell et al. measured equilibrium binding constants for torand **2** and found a ca. 2.5-fold preference for Na$^+$ over K$^+$ (5). This contrasts with the usual preference for K$^+$ by crowns (25) and discounts the primacy of cavity size in cation selection, i.e., the "hole-size concept", by which the cyclosexipyridine cavity size, estimated at 1.3 Å (26), better fits the hexacoordinate ionic radius of K$^+$ (1.38 Å) than that of Na$^+$ (1.02 Å) and is therefore expected to better bind K$^+$.

In any case, macrocycle **5c** was just as insoluble as the previous two examples. We then turned to neopentoxy groups to provide solubilizing power, as had been used with success to prepare soluble phthalocyanines (27). There is a two-step published preparation of 4-neopentoxybenzaldehyde (10), but we prepared it by alkylation of 4-hydroxybenzaldehyde using neopentyl tosylate (9) in 42% isolated yield. Conversions to bispropenone **7d** and terpyridine **9d** proceeded in the same fashion and in similar yields (63% **7d**, 70% **9d**) as for their analogues. Also, the macrocyclization proceeded as well as the previous examples (22% isolated yield) but this time the precipitated product was soluble in a variety of solvents, though not aromatic ones. This material defied all attempts at crystallization. TLC with various eluents showed that it was chromatographically homogeneous and free of impurities. MALDI-MS identified the material as **5d**, again obtained as a mix of Na$^+$ and K$^+$ complexes in ca. 5:2 ratio.

^{1}H NMR showed broad aliphatic singlets for this material, one for C(CH$_3$)$_3$ and one for OCH$_2$ in 9:2 ratio, in accord

with the structure, as well as one attributable to the OAc counterion, but the aromatic region contained broad and overlapping signals, indicating a pronounced tendency to aggregate in spite of being well dissolved. Heating the sample to 62°C failed to affect the spectrum, but dilution caused a sharpening of the signals. Progressively sharper signals were obtained with progressive dilution, confirming that **5d**, as a Na$^+$:K$^+$ complex, was subject to aggregation. Even at its sharpest, at sub-micromolar concentrations, the NMR spectrum was not readily interpretable, and it became evident that the symmetry was lower than threefold. Since COSY could not be performed at such high dilutions, homo-decoupling experiments were carried out to help assign the signals, and a total of 11 aromatic signals were thereby located. Their number, multiplicities, and integration values were consistent with twofold symmetry, allowing for some accidental overlap, compared with the five signals expected with the threefold symmetry. Twofold symmetry may result from an out-of-plane twist of any one of the six pyridine rings or of any transannularly opposed pair of rings, as depicted in Fig. 1. Such out-of-plane twisting was indeed present in the crystal structures of the torand alkali metal complexes (26) and was predicted by computation to occur with the Na$^+$ and Li$^+$ complexes of the parent cyclosexipyridine (28), but those structures were of D_3-symmetry, with the pyridine rings twisting "up" then "down" in alternation, a reduction from the sixfold symmetry of the flat ligands. The D_3 conformation probably minimizes lone pair – lone pair repulsions and contacts between pyridine H-3/5. The same conformation with the less symmetrical complexes of **5d** would place all three neopentoxy groups on the same face of the macroring, which may be destabilizing.

Twofold symmetry would give rise to a maximum 14 aromatic signals, 12 with free rotation of the side-chains. Our analysis of the 11 signals observed implies that one of the H-2/6 2H doublets has suffered an *upfield* shift of about 0.8 ppm, consistent with an out-of-plane twist of one phenylene ring such that its H-2 and H-6 are thereby less deshielded by the neighbouring pyridines. This analysis also implies that the two equivalent side-chains (rings E), if not all three, are not freely rotating owing to conjugation and (or) aggregation.

Metal-free torand **3** was isolated after macrocyclization catalyzed by triflic acid (3). We attempted to prepare **5d** in the same manner from **9d** and **7d** using excess NH$_4$OAc in glacial acetic acid spiked with 4% triflic acid. However, heating this to reflux for 3 d failed to cause any precipitation, and NMR indicated the presence of only the starting materials. Triflic acid apparently inhibited the macrocyclization, likely because of its stronger acidity and the favourable protonation of the pyridine rings in the starting materials.

Interestingly, sonicating a CDCl$_3$ solution of **5d** with a solution of potassium picrate in D$_2$O for 24 h failed to cause any detectable anion or cation exchange according to NMR and MALDI-MS. Encapsulating hosts also showed slow ion exchanges (5).

Azo-*bis*(terpyridine) **15** was also subjected to our macrocyclization conditions with 2.2 equiv of **7d** for 48 h and a precipitate formed as before. Though four neopentoxy groups were intended to be present, this material proved to

be insoluble in all solvents tested, as was true with **5a–c**. MALDI-MS revealed numerous high-mass species, but none at or near *m/z* 1798, the molecular weight expected for the desired *bis*(cyclosexipyridine). No further cyclization attempts were made.

Conclusion

We have extended our one-pot synthesis of dipyrazinyl-pyridines and phenylene-linked *bis*terpyridines to four examples of terpyridines and one example of an azo-linked *bis*terpyridine. The simple terpyridines were converted to novel C_3-symmetrical triarylated cyclosexipyridines without resorting to the Kröhnke method, but this was only soluble with neopentoxy substitution. Aggregation and demetalation remain issues to be resolved.

Photobehavior of aqueous uranyl ion and photo-oxygenation of isobutane using light from the visible region

Trevor M. Bergfeldt, William L. Waltz, Xiangrong Xu, Petr Sedlák, Uwe Dreyer, Hermann Möckel, Jochen Lilie, and John W. Stephenson

Abstract: The photochemical and photophysical behavior of the aqueous uranyl ion $[UO_2(H_2O)_5]^{2+}$ has been studied under the influence of visible light and with added perchloric acid over the range of 0.01–4 M. In the presence of 2-methylpropane (isobutane), photo-oxygenation of isobutane occurs to yield, as the major product, 2-methyl-2-propanol (*tert*-butyl alcohol) along with lesser amounts of 2-methyl-2-propene (isobutene) and other C1–C8 products. The quantum yield for formation of *tert*-butyl alcohol is independent of light intensity at the irradiation wavelength of 415 nm and of uranyl concentration, but it increases from 0.016 ± 0.001 at 0.01 M $HClO_4$ (pH 2) to 0.13 ± 0.01 at 4 M $HClO_4$. The emission spectrum from the electronically excited uranyl ion and the associated quantum yields have been measured in the presence and absence of isobutane, as a function of added perchloric acid. While in both cases the shape of the spectrum remains invariant, the quantum yields increase with increasing perchloric acid concentration. The strong dependence on added perchloric acid is interpreted within the context of the presence and interconversion of two electronically excited species, an acid form, $*[UO_2(H_2O)_5]^{2+}$, and a base form, $*[UO_2(H_2O)_n(OH)]^+$. It is proposed that both forms react with isobutane to give a *tert*-butyl radical, and that oxidation of coordinated aqua ligands occur, the latter generating a hydroxyl radical whose reaction with isobutane rapidly leads also to a *tert*-butyl radical. The reaction of this alkyl radical with ground-state $[UO_2(H_2O)_5]^{2+}$ then gives rise to the stable *tert*-butyl alcohol product and reduced forms of uranyl ion. Based upon the values of the quantum yields and of excited-state lifetime measurements reported in the literature, a comprehensive mechanism has been developed in a quantitative manner to provide calculated values of the rate constants for the individual mechanistic steps. The calculated rate constants provide a basis to calculate the values of quantum yields for emission and chemical reaction, as well as for lifetimes, that agree very satisfactorily with the experimental values over a 400-fold concentration change in added perchloric acid.

Key words: photo-oxidation, photo-oxygenation, uranyl ion, isobutane, *tert*-butyl alcohol, lifetime, quantum yield, acid–base dissociation.

Résumé : On a étudié les comportements photochimique et photophysique de l'ion uranyle aqueux $[UO_2(H_2O)_5]^{2+}$ sous l'influence de la lumière visible, en présence d'acide perchlorique ajouté à des concentrations allant de 0,01 M à 4 M. En présence de 2-méthylpropane (isobutane), il se produit une photooxygénation de l'isobutane qui conduit à la formation de 2-méthylpropan-2-ol (*tert*-butanol) comme produit principal aux côtés de quantités plus faibles de 2-méthylprop-2-ène (isobutène) ainsi que d'autres produits comportant de un à huit atomes de carbone. À une longueur d'onde d'irradiation de 415 nm, le rendement quantique pour la formation du *tert*-butanol est indépendant de l'intensité de la lumière et de la concentration en uranyle, mais il augmente de 0,016 ± 0,001 à une concentration de $HClO_4$ de 0,01 M (pH = 2) jusqu'à 0,13 ± 0,01 à une concentration de $HClO_4$ de 4 M. On a mesuré le spectre d'émission de l'ion uranyle électroniquement excité et les rendements quantiques associés, en présence et en l'absence d'isobutane et en fonction de la quantité d'acide perchlorique ajouté. Même si dans les deux cas la forme des spectres ne varie pas, les rendements quantiques augmentent avec une augmentation de la concentration d'acide perchlorique. Cette forte dépendance sur l'acide perchlorique ajouté est interprétée dans le contexte de la présence et de l'interconversion de deux espèces électroniquement excitées, une forme acide $*[UO_2(H_2O)_5]^{2+}$ et une forme basique $*[UO_2(H_2O)_n(OH)]^+$. Il est

suggéré que les deux formes réagissent avec l'isobutane pour produire le radical *tert*-butyle et qu'il se produit une oxydation des ligands aqua coordinés qui génèrent la formation du radical hydroxyle qui, par réaction avec l'isobutane, conduit aussi rapidement à la formation du radical *tert*-butyle. La réaction de ce radical avec du $[UO_2(H_2O)_5]^{2+}$ à l'état fondamental conduit alors à la formation du *tert*-butanol, le produit stable, ainsi qu'aux formes réduites de l'ion uranyle. Sur la base des valeurs des rendements quantiques et des mesures de temps de vie rapportées dans la littérature, on a développé un mécanisme global de manière quantitative qui permet d'obtenir des valeurs calculées pour les constantes de vitesse de chacune des étapes mécanistiques individuelles. Les constantes de vitesse calculées ont permis de calculer des valeurs des rendements quantiques de l'émission et de la réaction chimique ainsi que des temps de vie qui sont en bon accord avec les valeurs expérimentales pour des changements de concentration en acide perchlorique ajouté qui varient par un facteur allant jusqu'à quatre cents.

Mots clés : photooxydation, photooxygénation, ion uranyle, isobutane, *tert*-butanol, temps de vie, rendement quantique, dissociation acide-base.

[Traduit par la Rédaction]

Introduction

This investigation was undertaken with two complementary objectives in mind: namely, to investigate in a quantitative manner the photochemical and photophysical features of the electronically excited uranyl ion, $*[UO_2(H_2O)_5]^{2+}$, and at the same time to study the use of this species as a quantitative means to convert 2-methylpropane (isobutane) into 2-methyl-2-propanol (*tert*-butyl alcohol). Baird and Kemp have recently provided an in-depth review of the many facets of the intriguing yet complicated photobehavior of the uranyl ion and other related forms found in aqueous media (1). Uranyl ion absorbs in the 350–500 nm region to yield a long-lived excited state (μs timescale); however, its behavior is sensitive to pH, temperature, and the nature and concentration of the counter anion. Under our conditions, where we have used the perchlorate salt and added amounts of perchloric acid (0.01–4 M) to vary the pH, the ground state species is the monomeric form $[UO_2(H_2O)_5]^{2+}$. At the higher concentrations of added $HClO_4$, ion pairing between $*[UO_2(H_2O)_5]^{2+}$ and ClO_4^- is likely to occur to some extent in the excited-state species (2); however, our results can be satisfactorily interpreted without invoking this facet.

Electronically excited uranyl ion is a powerful oxidant ($E° \sim 2.6$ V) and is well known to engage in electron-transfer processes and to participate in hydrogen-abstraction reactions with many organic compounds (1, 3–16). Thus one anticipates that in the presence of isobutane, the excited state will abstract a hydrogen atom to generate an alkyl radical and the uranoyl ion, $[UO_2]^+$, leading to subsequent free radical reactions to form the organic products. Mao and Bakac have found with related alkanes and alcohols that the logarithm of the quenching constant for excited uranyl ion increases with decreasing C—H bond energy, which is supportive of hydrogen-abstraction mechanisms (17). The extension of this observation to isobutane implies that hydrogen abstraction will occur preferentially at the tertiary hydrogen rather than at the primary positions, and our findings that the tertiary alcohol is the major product in deaerated media — whereas acetone occurs in the presence of dioxygen — is commensurate with the major occurrence of the *tert*-butyl radical (18).

[1] $*[UO_2(H_2O)_5]^{2+} + (CH_3)_3CH \rightarrow [UO_2(H_2O)_5]^+$

$+ H^+ + (CH_3)_3C\cdot$
However, two additional features need to be considered in evaluating our results. There is now substantial evidence that because of the powerful oxidizing nature of $*[UO_2(H_2O)_5]^{2+}$, water can be oxidized to form a hydroxyl radical that will readily react with isobutane to form further amounts of *tert*-butyl radical (1, 10, 19–21).

[2] $*[UO_2(H_2O)_5]^{2+} \rightarrow [UO_2(H_2O)_4]^+ + H^+ + \cdot OH$

[3] $\cdot OH + (CH_3)_3CH \rightarrow H_2O + (CH_3)_3C\cdot$
Above, we have portrayed that the oxidation of water is of coordinated water because Xu (21) finds that when the coordinated waters are replaced by a fluoride ion, the oxidation of isobutane is not detectable. The observations by many researchers that the excited-state reactivity and emission lifetime are strongly dependent on the acidity of the media has given rise to different mechanistic interpretations. Marcantontos proposed, at relatively high concentrations of uranyl ion, the additional formation of an exciplex complex, $*[U_2O_4H]^{2+}$, to account for bi-exponential lifetimes, multiple emission spectra, and dependence of such on concentrations of acid and uranyl ion (1, 12). Under our conditions we do not observe bi-exponential behavior or multiple emission, and thus we conclude that exciplex formation is not a significant factor in our study. Burrows and co-workers initially offered a mechanism focusing on the interconversion between two closely spaced excited states of the uranyl ion (1, 22). More recently they have adopted the proposal made by Darmanyan, Khudyakov, and co-workers of an electronically excited acid–base mechanism in competition with other reactivity modes (22, 23); the number of waters of hydration for the base form, $*[UO_2(H_2O)_n(OH)]^+$, are unknown.

[4] $*[UO_2(H_2O)_5]^{2+} \rightarrow *[UO_2(H_2O)_n(OH)]^+ + H^+ \quad k_{12}$

[5] $*[UO_2(H_2O)_n(OH)]^+ + H^+ \rightarrow *[UO^2(H_2O)_5]^{2+} \quad k_{21}$
Our findings are consistent with these acid–base steps, as shown in more detail in the Discussion section (see Fig. 1). In this report, we present a comprehensive mechanism incorporating acid–base behavior, radiative and nonradiative processes, and quenching by water and isobutane; specific values are provided for the rate constants associated with the individual steps of the mechanism. A comprehensive and self-consistent set of values has not been available, to our knowledge, until now. The estimates of the rate constant val-

ues have been achieved by using an integrated package of information obtained from both time-resolved and steady-state experiments. Specifically we have measured the integrated emission intensities that lead to emission quantum yields and chemical quantum yields for *tert*-butyl alcohol as a function of acidity. We have used and analyzed in detail the lifetime measurements reported by Moriyasu et al. after we first confirmed that their findings are appropriate to our conditions (13).

The choice of isobutane used here in the quenching and photo-oxygenation processes warrants comment because it has associated with it several useful and advantageous features. Nizova and Shul'pin appear to have been the first to report on the photo-oxygenation of alkanes (cyclohexane and methane) with uranyl ion, although such was performed in acetic acid and acetonitrile solvents (24). Subsequently Mao and Bakac extended such studies to aqueous 0.1 M H_3PO_4 for alkyl aromatic compounds (17). Of concern in such studies is that the products of the reactions are known or expected to be highly reactive in their own right. To minimize such secondary reactions is difficult; however, our observed major product *tert*-butyl alcohol is considerably less reactive as a quenching agent and in its reaction with hydroxyl radical than is isobutane. Even to a much higher conversion (ca. 65%) than normally done here (ca. 10%), we find no evidence for complications arising from the reactivity of the alcohol product. As a further precaution, we have in general carried out the experiments with continuous bubbling of the isobutane gas through the liquid phase before and during photolysis.

Experimental

Apparatus

For steady-state measurements of quantum yields and product analysis, a 1000 W Hg–Xe arc lamp (Oriel 6293) was used with the collimated light beam being passed through an 11-cm water cell and a 9.6-cm cell of 0.1 M $CuSO_4(aq)$ (310 nm < band pass < 640 nm) to filter out IR and UV light. In addition, either a cut-off filter (Schott Glass Technologies Inc., GG400) or, for quantum-yield determinations, an interference filter (Edmund Scientific Co.,

Fig. 2. Variable pathlength cell.
CWL415, $\lambda_{max} = 415$ nm, fwhm = 12 nm) was placed in the light beam prior to the reaction cell. Two types of reaction cells (water-cooled, 25.0 ± 0.15°C) were used: one of fixed path length (8.7 cm) and the second of variable path length (ca. 5 cm to 10 cm). The latter was constructed from a 100 mL syringe (J. Young Scientific, GTS/100/GS) with the end of the barrel having — affixed to it by optical adhesive (Norland 61) — a borosilicate window. A schematic diagram of this cell is shown in Fig. 2. A major advantage of this arrangement is that periodic sampling of the liquid solution can be done during the course of irradiation without the development of a separate gas phase. For ease of carrying out the actinometry, both the actinometric solution and the uranyl solutions have been irradiated under optically dense conditions (absorbance = 2–2.5). Because of this procedure and because of the longer light path, a more dilute concentration of the ferrioxalate actinometry solution (3.9 mM) was used than is generally employed (25); however, all such measurements have been carried out using linear calibration plots. Spectroscopic data were obtained using a Cary 2315 or HP 8451A PhotoDiode Array spectrophotometer for UV–vis spectra; Spex Fluorolog-2 for emission spectra; Bio-Rad FTS-40 FT-IR and FT-NMR, Bruker AM-300 MHz (^{1}H). Mass spectrometry was done with a Fisions GC 8000 (in splitless mode) interfaced with a VG70-VSE mass spectrometer with a Dec Vax 4000 model 60 workstation; authentic

samples and the NIST library were used to identify products. Gamma radiolysis experiments of saturated isobutane without the presence of uranyl ion were performed with a Gammcell ^{60}Co source (Serial #260, Atomic Energy of Canada Limited (AECL)) using either Millipore or triply distilled water, and acidified with $HClO_4$ (Ultrapure, BDH). These radiolysis results allow us to compare the nature of the organic products arising from the reaction of the hydroxyl radical with isobutane to those products formed in the photolysis of the uranyl–isobutane solutions.

Chromatography

A Hewlett-Packard 5890 GC was employed in conjunction with a PC286 computer with Baseline 810 software. The injection port and FI-detector temperatures were 200°C. For aqueous solutions, injections were either 1 mL samples taken directly from the photolysis cell, 1 mL tetrahydrofuran (THF) extractions, or an injection of solid phase micro-extraction fibres. THF extractions were prepared as follows: a sample was withdrawn from the photolysis cell with a 5-mL syringe and passed through a Sep-Pak cartridge (Millipore, Sep-Pak Plus, t-C18) using a syringe pump (rate 1 mL min^{-1}, Sage Instruments 341B). The retained organic material was then eluted at the same rate with 1.2 mL of THF solution containing isopropanol as the GC internal standard followed by 1.5 mL of THF. Extraction using solid phase micro-extraction (SPME) involved the following procedure: a sample was withdrawn from the photolysis cell with a 5 mL syringe and transferred to a 2 dram vial containing 2 g NaCl and a magnetic stirring bar; 0.5 mL 1,4-dioxane was added as the GC internal standard. The SPME fibre (100 mm polydimethyl-siloxane, Supelco) was introduced into the headspace of the sealed vial and the solution magnetically stirred for a period of 10 min in a thermostated water jacket set at 50°C. The fibre was then introduced into the injection port of the GC and left to desorb for 5 min. There was found to be no difference between results obtained by Sep-Pak and SPME methods (±10%). The use of these two different procedures gives considerable confidence as to the validity of the results in the context of our desire to keep the percent product formation as low as possible (normally <10%). The use of the SPME technique also permitted us to carry out reactions at much higher concentrations of $HClO_4$ (>0.1 M) than was possible with the Sep-Pak cartridge approach. To circumvent the degradation of the SPME fibres in the headspace at extreme acid conditions, appropriate amounts of aqueous NaOH were added to bring the pH of the solutions up to approximately one. For gaseous samples, 5–100 mL gas-tight syringes were used to draw samples from the reaction vessel. For hydrocarbon substances of a carbon number less than 5, a GSQ column (J&W Scientific, 30 m × 0.546 mm) was used, while a DB-210 column (J&W Scientific, 30 m × 0.53 mm) was employed for all other analyses. Calibration of the GC for isobutane was done by injection of weighted amounts of isobutane dissolved in isopropanol. For our typical irradiated solution (ca. 35 mM aqueous uranyl solution at pH = 1 ($HClO_4$)), the solubility of isobutane was found to be 0.91 ± 0.02 mM at 22°C and 95.33 kPa partial pressure of isobutane; this compares very favorably with that of 0.94 mM isobutane in pure water at 25°C and 101.325 kPa (26).

Materials and solutions

Aqueous solutions were prepared from water purified by a Millipore Super-Q system, and where compared with those of triply distilled water, the results were found to be the same. The chemicals employed were: isobutane (Linde, instruments grade; Aldrich, 99.9%); isobutene (Matheson, 99.0% min); 2,2,3,3-tetramethylbutane (Aldrich, 99%); *tert*-butyl and *iso*-butyl alcohols (BDH, reagent); and tetrahydrofuran (BDH, AnalaR grade). Identifications by GC retention times of C_1–C_4 alkanes and alkenes were made using a Matheson standard gas mixture. Uranium solutions were prepared from $UO_2(ClO_4)_2 \cdot 6H_2O$ (ROC/RIC, reagent; reclaimed uranium) or more generally from UO_3 (Cameco, 99.4%, natural abundance). As these two sources gave the same results, the background radioactivity of the uranium was not a detectable factor. Uranyl stock solutions were typically prepared by dissolving 178 g UO_3 in 102 mL of 70% perchloric acid (BDH, analytical grade) and 150 mL water, heating at 80°C until dissolution followed by filtering, and allowing the solution to stand for 1 day before use. The concentration of uranyl ion was determined spectrophotometrically using a calibration curve based on dissolved UO_3 in perchloric acid, and this was verified by using U_3O_8 as an alternate source. The latter was prepared from heating, at 800°C for 4 h, uranyl acetate (Fisher, ACS grade), and the uranium content was measured by laser phosphorescence and delayed neutron counting (Saskatchewan Research Council). The molar absorption coefficients, at 414 nm, of $[UO_2(aq)]^{2+}$ in aqueous perchloric acid media were 7.8 ± 0.2 M^{-1} cm^{-1} (pH 1.1), 8.0 ± 0.2 M^{-1} cm^{-1} (pH 2.0), and 8.3 ± 0.2 M^{-1} cm^{-1} (pH 3.0); Bell et al. (27) reported 7.7 M^{-1} cm^{-1} at pH 0.95 ($HClO_4$).

Uranium(V) was measured spectrophotometrically, in the presence of $[UO_2(aq)]^{2+}$, where a complex $[U_2O_4]^{3+}$ occurs with an absorption peak at 740 nm (ε = 24.3 M^{-1} cm^{-1}) (28, 29). Uranium(IV) in aqueous perchloric acid media (pH ~ 1) was prepared by photoreduction of uranyl ion in the presence of ethanol, and its concentration was determined by using potassium dichromate oxidation – titration (30). From this procedure, the molar absorption coefficient at 652 nm was determined to be 43.2 ± 0.9 M^{-1} cm^{-1} (pH 1.0, 22°C), which agrees with that reported by Betts (31).

Results

Our most frequently used condition was a pH of 1 and 35 mM $[UO_2(aq)]^{2+}$ with the solutions being deaerated and saturated with isobutane by continuously bubbling with isobutane gas during and prior to irradiation (30 min or more at room pressure before irradiation to achieve saturation). For specific cases, the concentration of uranyl ion was varied from 25–148 mM, the light was changed from 2.1 × 10^{-7} – 1.2 × 10^{-6} ein L^{-1} s^{-1} (1 ein = 1 mol of light photons), and the concentration of $HClO_4$ ranged from 0.01–4 M. At pHs of about 2 and higher, polyuranium species occur, leading in part to bi-exponential decay of the electronically excited uranyl ion. To confirm the mono-exponential decay behavior reported by Moriyasu and co-workers (13, 14) for conditions very similar to our perchloric acid media, lifetime measurements were performed using laser excitation at 347 nm with a pH of 1 for both argon-saturated and aerated solutions. We

Fig. 3. Plot of the experimental (●) and calculated (△) values of the emission quantum yield of the electronically excited uranyl ion $[UO_2(aq)]^{2+}$ in the absence of isobutane, as a function of the concentration of $HClO_4$ at 34.8 mM $[UO_2(aq)]^{2+}$. Average root-mean-square difference between experimental and calculated values is ±8%.

Fig. 4. Plot of the experimental (●) and calculated (△) values of the emission quantum yield of the electronically excited uranyl ion in the presence of isobutane, as a function of the concentration of $HClO_4$ at 34.8 mM $[UO_2(aq)]^{2+}$. Average percent difference between experimental and calculated values is ±21%.
find the emission decay (510 nm), as well as the excited-state absorption decay (590 nm), to exhibit a single exponential decay with a lifetime of 2.2 ± 0.1 μs. This single-decay behavior and the value of the associated lifetime are in agreement with the findings of Moriyasu and co-workers, as well as those of other reports (1, 7, 13–16). Results presented earlier by us indicate that quenching by isobutane is about 3×10^7 M^{-1} s^{-1} (20). In our modeling studies, as put forward in the Discussion section, this value has proven useful as a guide; however, the value is, from our current findings, indicative of the quenching by isobutane of two excited-state species coupled through acid–base processes (see below).

As one would anticipate from the presence of acid–base processes, the emission quantum yields are strongly dependent on the acidity of the medium, as shown in Figs. 3 and 4 (solid circles). These quantum yields and emission spectra were determined as follows. The emission spectrum, centered at the 506 nm peak, is broad and overlaid with a vibrational structure (1, 32); maxima or estimated maxima for shoulders occurred at 470, 484, 506, 530, and 546 nm. The positions of the maxima and their relative intensities did not change whether the solutions were aerated or saturated with either oxygen or argon, and thus, in general the data was obtained for aerated media. The emission spectrum was recorded two to four times at each concentration of perchloric acid (0.01–4 M), and then for each recording the emission intensities from 430–600 nm were integrated with reference to a Rhodamine B quantum counter (Spex Fluorolog-2 Spectrofluorometer) and averaged for each set of perchloric acid concentrations. The reproducibility of the integrated emission values was good, being within several percent. To minimize the possibility of systematic error, the measurements for different acid concentrations were done in a random manner. The emission spectra were recorded for 35 and 10 mM uranyl ion; the latter concentration was used by Moriyasu et al. in their lifetime studies (0.01–10 M $HClO_4$) (13). While the integrated emission intensities were, for
10 mM, lower than for 35 mM uranyl ion, the calculated quantum yields for emission were the same within experimental error. Of particular note is that while the emission intensities increased with perchloric acid concentration, the spectral features for the peak maxima and minima and their relative intensities were invariant. Thus we conclude that under our conditions, the emission is predominantly from one species, and because the emission intensities are greatest at high concentrations of $HClO_4$, the emission can be ascribed to $*[UO_2(H_2O)_5]^{2+}$, the acid form. Baird and Kemp in their review (1) have proposed that the absolute emission quantum yield value of 0.0055 for 1.0 M $HClO_4$, found by Katsumura et al. (33), was the most reliable measurement, and we have used this value to convert our integrated emission intensities into the quantum yields shown in Figs. 3 and 4.

Aqueous uranyl solutions saturated with isobutane and kept in the dark are found to be thermally unreactive. Upon exposure to steady-state irradiation at 415 nm radiation, the major products are *tert*-butyl alcohol (*t*-BuOH) and the inorganic products $[UO_2(aq)]^+$ and $[U(aq)]^{4+}$, accompanied by minor amounts of isobutene and other organic products. The U(IV) observed is likely due to the disproportionation of uranoyl $[UO_2(aq)]^+$ (28, 34):

[6] $2[UO_2(aq)]^+ + 4H^+ \rightarrow [UO_2(aq)]^{2+}$
$$+ [U(aq)]^{4+} + 2H_2O$$
At pH 3, where the disproportionation of uranoyl to U(IV) is slow, the visible spectrum clearly shows the characteristic peaks of $[U(aq)]^{4+}$ at 652 nm and of the U(V)–U(VI) complex $[U_2O_4]^{3+}$ at 400 and 740 nm, whereas only $[U(aq)]^{4+}$ is seen at pH 1 (28, 34). The results of our mass-balance experiments at pH 1 show the ratios of d[U(VI)]/d[U(IV)] and d[isobutane]/d[U(IV)] to be (1.0 ± 0.1)/1 and (0.9 ± 0.1)/1, respectively.

The organic products are indicative of C—H bond activation. The *tertiary* alcohol accounts for 85 ± 5% of the loss of isobutane, along with isobutene (ca. 5%) and, to a lesser amount, other C1–C8 products. Although isobutene can un-

dergo hydrolysis to yield t-BuOH, we find that the thermal rate is approximately two to three times slower than the photoproduction of t-BuOH. This is in accord with the results of a previous study (35), and therefore, it seems unlikely that the observed t-BuOH is the result of the hydrolysis of isobutene. The possible bimolecular self-recombination products arising from *tert*-butyl and (or) *iso*-butyl radicals (i.e., 2,2,3,3-tetramethylbutane, 2,2,4-trimethylpentane, and 2,5-dimethylhexane) are found only in trace amounts. Gamma radiolysis of aqueous solutions at pH 2, saturated with isobutane but without uranyl ion, results in the major products (>80%) being the aforementioned bimolecular self-recombination products, while t-BuOH is a minor product (~20%). Additionally, when an aqueous acidic uranyl ion solution containing both oxygen and isobutane is irradiated, the major products are acetone and *tert*-butyl alcohol (18). These results all point to the *tert*-butyl radical as the common reactive intermediate resulting from hydrogen abstraction. The overall major chemical reaction at pH 1 can therefore best be described as

[7] $[UO_2(aq)]^{2+} + (CH_3)_3CH + 2H^+ \rightarrow [U(aq)]^{4+}$

$$+ (CH_3)_3COH + H_2O$$
The chemical quantum yield measurements were constrained to t-BuOH, owing to the low concentrations of the other products. The quantum yield (Φ) for formation of t-BuOH was determined from the slope of plots of the quotient (alcohol concentration) × (irradiation volume)/(absorbed light intensity) vs. time. Where the conversion of isobutane was high (upwards of 65%, as in the mass-balance experiments), curvature in the plots occurred. Linear plots were obtained, however, when isobutane was bubbled through the reaction solution during the entire irradiation period. At pH 1, the average observed quantum yield of t-BuOH was 0.022 ± 0.002, as determined from the slopes. In the mass-balance experiments, the curvature was well described by a second order polynomial. The average coefficient for the linear term gave the same average Φ value as that previously cited for the continuous bubbling experiments. This comparison indicates that continuous bubbling of isobutane did not give rise to detectable loss of t-BuOH from the liquid phase. The chemical quantum yield is independent of light intensity ($2.1 \times 10^{-7} - 1.2 \times 10^{-6}$ ein L^{-1} s^{-1}) and of uranyl concentration (25–148 mM) but is dependent on the concentration of added HClO$_4$, as shown in Fig. 5 (solid circles).

Discussion

Results from numerous studies have established that the electronically excited uranyl ion in aqueous media can abstract a hydrogen atom from the C—H bonds of hydrocarbon materials, and, in some instances, products also arise from C—C bond cleavage (1, 4, 6, 17). Our results are in agreement with these features, as we observe *tert*-butyl alcohol as the major product arising from activation of the weaker tertiary C—H bond (85 ± 5%). Activation of the primary C—H bonds and C—C bonds also occurs, as evidenced by formation of isobutene (ca. 5%) along with much lesser amounts of methane, propane, and radical recombina-

Fig. 5. Plot of the experimental (●) and calculated (△) quantum yields of t-BuOH as a function of the concentration of HClO$_4$ at 34.8 mM [UO$_2$(aq)]$^{2+}$. Average root-mean-square difference between experimental and calculated values is ±8%.
tion products. Our earlier report on the photo-oxidation of water in aqueous uranyl solutions using conductivity detection shows the formation of a hydroxyl radical (eq. [2]). Thus, one recognizes that both hydrogen abstraction (eq. [1]) and hydroxyl radical reaction with isobutane (eq. [3]) lead to generation of the *tert*-butyl radical, designated as B·, and its subsequent conversion to *tert*-butyl alcohol (t-BuOH).

The emission and lifetimes of the uranyl ion in aqueous acidic solutions are well documented to be dependent on pH (1, 2, 13, 14, 16, 22, 23, 36–39). Our results for the emission quantum yield and quantum yields for formation of t-BuOH show that the yields increase with increasing HClO$_4$ (Figs. 3–5). The yields of t-BuOH range from 0.016 at 0.01 M HClO$_4$ to 0.13 at 4 M HClO$_4$ (±10%).

We have interpreted our results in terms of the presence of acid–base processes for two electronically excited species, to account for this strong dependence on acid concentration. The electronically excited "acid" form is denoted as *[UO$_2$(H$_2$O)$_5$]$^{2+}$, and it is the nascent species formed upon absorption of visible light by the ground-state species [UO$_2$(H$_2$O)$_5$]$^{2+}$, according to the Franck–Condon Principle. Subsequent and rapid loss of a proton from one of the coordinated aqua ligands (eq. [4]) can then lead to the formation of the "base" form *[UO$_2$(H$_2$O)$_n$(OH)]$^+$; however, reprotonation of this conjugate base must occur to some extent, to account for the observed dependence on acid concentration. The important roles played by coordinated water both in these acid–base steps and in the nonradiative events is underscored by the fact that the replacement of aqua ligands by fluoride and phosphate anions, which are not easily oxidized, leads to much longer lifetimes (1, 14).

The excited-state portion of our mechanism is given in Fig. 1. We have assumed that both the acid and base forms undergo reactions with isobutane to form the *tert*-butyl radical (CH$_3$)$_3$C·, and that both excited-state species can oxidize coordinated water to give rise to a hydroxyl radical; the results of our modeling studies, given below, support this interpretation. The second-order rate constants k_{q1} and k_{q2}

pertain to the hydrogen-abstraction processes for the quenching by isobutane of the acid and base entities, respectively. Correspondingly, the first-order constants k_{OH1} and k_{OH2} pertain to the formation of hydroxyl radical, which reacts rapidly under our conditions to yield additional amounts of *tert*-butyl radical, eq. [3]. Consequently, two competitive modes are envisioned in the formation of the *tert*-butyl radical. Nonradiative decays of the excited states are designated by k_{nr1} (acid form) and k_{nr2} (base form) and those for emission by k_{em1} and k_{em2}. The invariant shape of the emission spectrum with changes in acid concentration, however, implies that k_{em2} is of little consequence under our conditions, and the outcomes of our modeling investigation are supportive of this.

The *tert*-butyl radical formed via the foregoing excited-state events and via eq. [3] is proposed to react primarily — and nearly quantitatively — with ground state $[UO_2(H_2O)_5]^{2+}$ to yield *t*-BuOH and, initially, uranoyl ion, which can then undergo disproportionation (eq. [6]).

[8] $(CH_3)_3C\cdot + [UO_2(H_2O)_5]^{2+} + H_2O$

$\rightarrow [UO_2(aq)]^+ + H^+ + (CH_3)_3OH$
The basis for this proposal rests, in part, on the fact that *t*-BuOH is the major product (85 ± 5%) and on the mass-balance ratios given in the Results section, although the actual source of oxygen in *t*-BuOH is not known. Furthermore, the products of bimolecular self-reactions of *tert*-butyl and *iso*-butyl radicals such as isobutene (disproportionation), 2,2,3,3-tetramethylbutane, 2,2,4-trimethylpentane, and 2,5-dimethylhexane (recombination), which are major products in steady-state gamma radiolysis in the absence of uranyl ion, are found to be minor products of photolysis in the presence of uranyl ion.

Both the *tert*-butyl radical and the α-ethyl alcohol radical react readily with the mild oxidant $[Fe(CN)_6]^{3-}$ ($E° = 0.36$ V), and the latter also reacts with $[UO_2(aq)]^{2+}$ ($E° = 0.16$ V) (7, 40–42). The electrochemistry of the *tert*-butyl radical in acetonitrile also indicates it is a mild reducing agent (43). These comparisons point towards a reaction of $[UO_2(aq)]^{2+}$ with *tert*-butyl radical (eq. [8]). Attempts to measure the rate constant for the reaction of $[UO_2(aq)]^{2+}$ with *tert*-butyl radical were undertaken using our pulse-radiolysis conductivity and optical techniques at low dose (0.5 μM radical concentration, pH 2.7), to try to minimize the self-reaction of the *tert*-butyl radical. This pulse radiolysis approach was only partially successful because even at low dose, the bimolecular self-reactions of the *tert*-butyl radical dominated. An estimate to the upper limit for the rate constant in eq. [8] is 1×10^6 M^{-1} s^{-1}. In the context of our steady-state photolysis experiments where the radical concentration will be very low ($<< 10^{-8}$ M), the situation is likely to be quite different. Even if the rate constant was many powers of ten below 10^6 M^{-1} s^{-1}, the rate of eq. [8] would prevail over other processes, particularly second-order events such as the self-reaction of *tert*-butyl radical, which has, therefore, not been included in our treatment.

To fit our model and thus obtain values of the rate constants, both time-resolved measurements of lifetimes and quantum yields are required. The mathematical development for the lifetimes is given elsewhere (32, 38), and two time

Fig. 6. Comparison of the data of Moriyasu et al. (●) and the fitted values based on our model (△) for the inverse lifetime of the electronically excited uranyl ion as a function of the concentration of HClO$_4$. Average root-mean-square difference between experimental (Moriyasu et al. (13)) and calculated values is ±6%.
constants (lifetimes) occur where the entry into the excited-state scheme (Fig. 1) takes place by a short pulse of light absorbed by $[UO_2(H_2O)_5]^{2+}$ to give the electronically excited *$[UO_2(H_2O)_5]^{2+}$. The values of the rate constants given below indicate that the shorter of the two time constants is less than 100 ns, so it is not observed on the μs time scale either by us or by Moriyasu et al. (13). The longer time constant gives rise, on the μs scale, to mono-exponential decay in emission and excited-state absorption under both our and Moriyasu's conditions, and the reciprocal lifetime (τ^{-1}) that equals the observed first-order rate constant in the absence of isobutane is given by

[9] $\tau^{-1} = 1/2\{(k_1 + k_{(2)} + k_{21}[H^+])$
$- ((k_1 - k_{(2)} - k_{21}[H^+])^2 + 4k_{12}k_{21}[H^+])\}^{1/2}$

where:

[10] $k_1 = k_{nr1} + k_{em1} + k_{12} + k_{OH1}$

[11] $k_{(2)} = k_{nr2} + k_{em2} + k_{OH2}$

[12] $k_2 = k_{(2)} + k_{21}[H^+]$

We have used the lifetimes measured by Moriyasu et al. over the range of 0.01–5 M HClO$_4$ (13) for 10 mM uranyl perchlorate at 25°C. The software program SigmaPlot for Windows 4.00, SPSS Inc. was then employed to fit the lifetime data, to obtain values of the parameters k_1, $k_{(2)}$, k_{12}, and k_{21}. The SigmaPlot program employs a convergence routine, and as a confirmation of the SigmaPlot results, an Excel spreadsheet (Microsoft Office 2000) was used to allow for the input of a range of values for the individual rate constants. The two approaches were in agreement. This procedure has been used in the other cases of the fitting of data, as described below. For the lifetimes, the resulting best fit of the experimental points and the calculated curve is shown in Fig. 6. The fit is very "rigid" in the sense that changes as small as ±10% to the individual rate constants give rise to clearly discernable differences in lifetimes between the cal-

Table 1. Summary of values of the rate constants and efficiencies.

Reaction	k_i	k value	Efficiency[a] (η_i)
$*[UO_2(H_2O)_5]^{2+} \rightarrow [UO_2(H_2O)_5]^{2+} + h\nu'$	k_{em1}	$900\ s^{-1}$	0.00083
$*[UO_2(H_2O)_5]^{2+} \rightarrow [UO_2(H_2O)_5]^{2+} + \Delta$	k_{nr1}	$1.8 \times 10^4\ s^{-1}$	0.017
$*[UO_2(H_2O)_5]^{2+} \rightarrow *[UO_2(H_2O)_n(OH)]^+ + H^+$	k_{12}	$1.1 \times 10^6\ s^{-1}$	0.97
$*[UO_2(H_2O)_n(OH)]^+ + H^+ \rightarrow *[UO_2(H_2O)_5]^{2+}$	k_{21}	$2.2 \times 10^7\ M^{-1}\ s^{-1}$	0.39[b]
$*[UO_2(H_2O)_n(OH)]^+ \rightarrow [UO_2(H_2O)_n(OH)]^+ + h\nu''$	k_{em2}	$0\ s^{-1}$	0
$*[UO_2(H_2O)_n(OH)]^+ \rightarrow [UO_2(H_2O)_n(OH)]^+ + \Delta$	k_{nr2}	$3.5 \times 10^6\ s^{-1}$	0.61[b]
$*[UO_2(H_2O)_5]^{2+} + BH \rightarrow [UO_2(H_2O)_5]^+ + B\cdot + H^+$	k_{q1}	$1.0 \times 10^7\ M^{-1}\ s^{-1}$	0.0088[c]
$*[UO_2(H_2O)_5]^{2+} + H_2O \rightarrow [UO_2(H_2O)_5]^+ + \cdot OH + H^+$	k_{OH1}	$1500\ s^{-1}$	0.0014
$*[UO_2(H_2O)_n(OH)]^+ + BH \rightarrow [UO_2(H_2O)_5]^+ + B\cdot$	k_{q2}	$2.0 \times 10^7\ M^{-1}\ s^{-1}$	0.0033[b,c]
$*[UO_2(H_2O)_n(OH)]^+ + H_2O \rightarrow [UO_2(H_2O)_5]^+ + \cdot OH$	k_{OH2}	$2500\ s^{-1}$	0.00044[c]

[a]Efficiency is defined as $\eta_{1i} = k_{1i} / \sum k_{1i}$ and $\eta_{2i} = k_{2i} / \sum k_{2i}$, where subscripts 1 and 2 refer to acid and base forms, respectively (e.g., the efficiency of the dissociation of the acid form to the base form is given by η_{12}; the efficiency of the reverse reaction is given by η_{21}).

[b][HClO$_4$] = 0.1 M.

[c][isobutane] = [BH] = 0.9 mM.

culated and experimental values. The "best" fit has been determined from the minimization of the value of the root-mean-square difference between the calculated points and experimental ones; the average difference is small (±6%). Furthermore, the differences show no readily apparent systematic trend over the 500-fold change in perchloric acid concentration. Thus the fit is considered to be satisfactory, and the values of the calculated parameters are: $k_1 = 1.1 \times 10^6\ s^{-1}$, $k_{(2)} = 3.5 \times 10^6\ s^{-1}$, $k_{12} = 1.1 \times 10^6\ s^{-1}$, and $k_{21} = 2.2 \times 10^7\ M^{-1}\ s^{-1}$. The ratio of k_{12}/k_{21} leads to a pK_a of 1.3. A range of values from 1.7 to >3.6 have been reported by others (1, 32). However, some caution should be exercised in comparing the different pK_a values. Different methods have been used to obtain the values and, frequently, for systems having different counter anions, so ion pairing may play a subtle but notable role. From the viewpoint of the dependence of the behaviors of the excited states on the acid concentration, the pK_a value is not the critical facet; rather, it is the values of k_{12} and k_{21} in relation to the rate constants of the competing processes that determines the course of events. The rate constants given above, in conjunction with the quantum yields for emission and for formation of the *tert*-butyl alcohol, now provide the basis to evaluate the chemical and nonchemical rate constants for the reactions in competition with the acid and base processes.

The expression for the total quantum yield for the production of *t*-BuOH alcohol arising from the hydrogen-abstraction reactions (k_{q1} and k_{q2}) and from generation of the $\cdot$OH radical (k_{OH1} and k_{OH2}), followed by eqs. [3] and [8], is

$$[13] \quad \Phi_{Total} = \{1/(1 - \eta_{12}^{BH}\eta_{21}^{BH})\}(k_{Rx}^A/k_1 + k_{Rx}^B/k_2)$$

The derivation is given in Appendix 1, and it is based on the assumption that multiple passes between $*[UO_2(H_2O)_5]^{2+}$ and $*[UO_2(H_2O)_n(OH)]^+$ via eqs. [4] and [5] occur in the decay of these excited-state species. The symbols η_{12}^{BH} and η_{21}^{BH} designate the efficiencies of loss of a proton from the acid $*[UO_2(H_2O)_5]^{2+}$ to form the base $*[UO_2(H_2O)_n(OH)]^+$ (eq. [4]) and the re-protonation of the latter (eq. [5]) in the presence of saturated isobutane solutions, respectively. The value, k_{Rx}^A, represents the sum, $k_{q1}[BH] + k_{OH1}$, that leads to the formation of *tert*-butyl al-

cohol via the hydrogen abstraction and the formation of $\cdot$OH from the acid excited-state species. Correspondingly, k_{Rx}^B equals $k_{q2}[BH] + k_{OH2}$ for the base where [BH] is the concentration of isobutane (0.91 mM). Thus, the ratios k_{Rx}^A/k_1 and k_{Rx}^B/k_2 pertain to the total efficiencies for the chemical reactions from $*[UO_2(H_2O)_5]^{2+}$ and $*[UO_2(H_2O)_n(OH)]^+$, respectively.

Values for k_{q1}, k_{q2}, k_{OH1}, and k_{OH2} were obtained by "best fitting" the calculated quantum yields to the experimental ones. The fits were judged on the basis of the minimization of root-mean-square differences, and they are very sensitive to changes in the inputted values of the k_qs and k_{OH}s (±10%). The comparison between the calculated and experimental values for the best fit is shown in Fig. 5 with the two sets agreeing very well within experimental error (±8% average root-mean-square difference), and the deviations appear to be random. The error bars shown for the experimental points (filled circles) are the estimated standard deviations (1 σ), and the calculated points are shown with a deviation of ±10%. (The same procedure has been used for the emission results presented in Figs. 3 and 4). The rate constants obtained from the fit in Fig. 5 are $k_{q1} = 1.0 \times 10^7\ s^{-1}$, $k_{q2} = 2.0 \times 10^7\ s^{-1}$, $k_{OH1} = 1500\ s^{-1}$, and $k_{OH2} = 2500\ s^{-1}$. Gaziev et al. (10) provided an estimate of k_{OH} from the photo-stimulated ^{18}O exchange of $4.4 \times 10^4\ s^{-1}$, and that obtained from time-resolved lifetime measurements by Waltz et al. (20) is $5.4 \times 10^4\ s^{-1}$; the latter studies also yielded a value of $3.3 \times 10^7\ M^{-1}\ s^{-1}$ for quenching by isobutane. Our values of k_{OH1} and k_{OH2} are lower by a factor of about ten, whereas the values of k_{q1} and k_{q2} are of the same magnitude as that report previously (20). The comparison of our present results and those reported previously is perhaps somewhat tenuous because the previous studies were modeled on the presence of only one excited-state species (i.e., the acid form).

In the absence of isobutane, our model gives rise (Appendix 2) to the following expression for the quantum yield of emission, where the efficiencies are,

$$[14] \quad \phi_{em}^{Total} = (\eta_{em1} + \eta_{em2}\eta_{12}^\circ)\{1/(1 - \eta_{12}^\circ\eta_{21}^\circ)\}$$

as previously, symbolized by ηs. The comparison between the experimental results and the calculated ones is shown in

Fig. 3. The average root-mean-square difference for all points is ±8% with no apparent systematic deviations. Although we initially assumed that both excited-state species could emit, the best fit as shown here was obtained for a k_{em1} of 900 s^{-1} and for k_{em2} being zero, i.e., $k_{em2} \ll k_{em1}$. This situation implies that the emission arises predominantly from *$[UO_2(H_2O)_5]^{2+}$, and this is consistent with the emission spectral features remaining stationary as the perchloric acid concentration was varied, as described in the Results section. Using the aforementioned rate constants derived from the model, we extended the fitting procedure to the situation where isobutane was now present. The expression for Φ_{em}^{Total} is given in Appendix 2, and it is analogous to that of eq. [14]. The results are shown in Fig. 4. The average root-mean-square difference between the calculated and experimental yields is somewhat larger, at ±21%, than that in the absence of isobutane (±8%) with deviations being more apparent at low concentrations of perchloric acid. This less satisfactory situation seems to derive, in part, from the low signal levels for integrated emission encountered at low acid concentrations (coupled perhaps with scattered light) and from the further lowering of emission in the presence of isobutane relative to that in its absence.

The information given in Table 1 summarizes the values of the rate constants calculated from the excited-state model. To provide perspective on the relative influence of the different excited-state processes, the efficiencies (η_i) of the individual steps are presented based upon calculations for the condition of 0.1 M HClO$_4$ and 0.9 mM isobutane. For the acid form *$[UO_2(H_2O)_5]^{2+}$, the dominant event for all of our conditions is the deprotonation reaction (eq. [4]) with a η_{12} of ca. 0.97. Furthermore, the efficiency of hydrogen-abstraction reactions is greater for the acid form than for the base species, whereas the reverse prevails in the generation of hydroxyl radical. The efficiency of protonation of *$[UO_2(H_2O)_n(OH)]^+$ is 0.39 at 0.1 M HClO$_4$; however, this value rapidly increases on going to higher acid concentrations. Consequently, the calculated percentage of *tert*-butyl alcohol, which has its origins in the hydrogen-abstraction and ·OH-formation reactions of the acid form *$[UO_2(H_2O)_5]^{2+}$, accounts for greater than 90% (0.8–4 M HClO$_4$) of the product formation. Even at our lowest perchoric acid concentration, the acid form is the dominant reacting species (64%).

The mechanism that is provided here, involving the acid–base processes of the electronically excited uranyl ion, provides a comprehensive framework in which to interpret the experimental results. For over a 400-fold change in perchloric acid concentration (0.01–4 M HClO$_4$), this model predicts well the lifetimes of the excited uranyl ion, the quantum yields of emission in both the absence and presence of a quencher (i.e., isobutane), as well as the quantum yields for the production of *tert*-butyl alcohol.

This study clearly brings into focus the fact that organic products can arise from both hydrogen-abstraction processes and the competitive occurrence of the oxidation of coordinated water to generate hydroxyl radical, which is, in general, highly reactive towards a large variety of organic substances (19). The apparent quantum yields for organic products derived from alkanes reported here and elsewhere (17) tend to be low, partly owing to solubility limitations.

For a saturated isobutane solution, the percent quenching is, in total, about 7%. Because isobutane is a condensable gas at room temperature, it was not feasible to increase the pressure and thus its concentration. However, with less condensable, low molar mass alkanes such as methane, which is known to quench excited uranyl (24), the solubility factor should prove less restrictive through the use of increased pressure and lower temperatures. As a further approach to increasing the apparent quantum yields, the free radicals generated can be used to initiate chain processes. In this context, we report elsewhere (21, 32) that the addition of millimolar amounts of potassium peroxydisulphate gives a 75-fold increase in the apparent quantum yield for *tert*-butyl alcohol formation ($\Phi_{observed} \sim 1.5$) with the additional advantage that there is no net consumption of $[UO_2(aq)]^{2+}$ (i.e., the $[U(aq)]^{4+}$ product is oxidized back to $[UO_2]^{2+}$ during photolysis). The use of visible light coupled with the broad absorption spectrum of uranyl ion provides a strategy to explore further the conversion of alkanes, in particular ones with low molecular mass where product selectivity is of lesser concern, into useful oxygenated products.

Appendix 1: Derivation of the expression for the total chemical quantum yield by species A (acid form) and B (base form)

The quantum yield for the reaction of the A species is given by

[A1] $\phi_{Rx}^{A} = \eta'_{q1} + \eta'_{q1}\eta_{12}^{BH}\eta_{21}^{BH} + \eta'_{q1}(\eta_{12}^{BH}\eta_{21}^{BH})^2 + ...$

For multiple passes through the excited states via protonation and deprotonation and for ηs less than one, this series converges to the limit of

[A2] $\phi_{Rx}^{A} = \dfrac{\eta'_{q1}}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}$

where

[A3] $\eta'_{q1} = \dfrac{k_{q1}[BH]}{k_1 + k_{q1}[BH]}$

[A4] $\eta_{12}^{BH} = \dfrac{k_{12}}{k_1 + k_{q1}[BH]}$

[A5] $\eta_{21}^{BH} = \dfrac{k_{21}}{k_2 + k_{q2}[BH]}$

Accounting for hydrogen abstraction of isobutane by hydroxyl radical produced by species A

[A6] $\phi_{OH1} = \dfrac{\eta_{OH1}}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}$

where

[A7] $\eta_{OH1} = \dfrac{k_{OH1}}{k_1 - k_{q1}[BH]}$

Similarly, the quantum yield for the reaction from species B, along with hydrogen abstraction from isobutane by hydroxyl radical produced by species B are given by

[A8] $\phi_{Rx}^{B} = \dfrac{\eta_{12}^{BH}\eta'_{q2}}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}$

[A9] $\phi_{OH2} = \dfrac{\eta_{12}^{BH}\eta_{OH2}}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}$

The total quantum yield is

[A10] $\phi_{Total} = \phi_{Rx}^{A} + \phi_{OH1} + \phi_{Rx}^{B} + \phi_{OH2}$

or

[A11] $\phi_{Total} = \dfrac{\eta'_{q1} + \eta_{OH1} + \eta_{12}^{BH}(\eta'_{q2} + \eta_{OH2})}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}$

Using the rate constants from the fitting of Moriyasu et al.'s data (A1), $\eta_{12}^{BH} = 0.973$. Let η_Q represent the total efficiency of quenching of both species by isobutane; then

[A12] $\eta_Q = \eta'_{q1} + \eta_{12}^{BH}\eta'_{q2} \cong \eta'_{q1} + \eta'_{q2}$

and

[A13] $\eta_{OH} = \eta_{OH1} + \eta_{12}^{BH}\eta_{OH2} \cong \eta_{OH1} + \eta_{OH2}$

Equation [A1.11] can be written as

[A14] $\phi_{Total} = \left(\dfrac{1}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}\right)\left(\dfrac{k_{Rx}^{A}}{k_1} + \dfrac{k_{Rx}^{B}}{k_2}\right)$

where

[A15] $\dfrac{k_{Rx}^{A}}{k_1} = \dfrac{k'_{q1} + k_{OH1}}{k_1} = \eta'_{q1} + \eta_{OH1}$

and

[A16] $\dfrac{k_{Rx}^{B}}{k_2} = \dfrac{k'_{q2} + k_{OH2}}{k_2} = \eta'_{q2} + \eta_{OH2}$

where

[A17] $k_1 = k_{nr1} + k_{em1} + k_{12} + k_{OH1}$

[A18] $k_2 = k_{nr2} + k_{em2} + k_{OH2} + k_{21}[H^+]$

References

A1. M. Moriyasu, Y. Yokoyama, and S. Ikeda. J. Inorg. Nucl. Chem. **39**, 2211 (1977).

Appendix 2. Derivation of expression for emission quantum yields

The efficiencies of emission by the acid (A) species (η_{em1}) and the base (B) species (η_{em2}) can be expressed as:

[B1] $\eta_{em1} = \dfrac{k_{em1}}{k_1}$

[B2] $\eta_{em2} = \dfrac{k_{em2}}{k_2}$

where

[B3] $k_1 = k_{nr1} + k_{em1} + k_{12} + k_{OH1}$

[B4] $k_2 = k_{nr2} + k_{em2} + k_{OH2} + k_{21}[H^+]$

The quantum yield of emission by the A species in the absence of isobutane can be expressed as

[B5] $\phi_{em1} = \eta_{em1} + \eta_{12}^{\circ}\eta_{21}^{\circ}\eta_{em1} + (\eta_{12}^{\circ}\eta_{21}^{\circ})^2\eta_{em1} + \dots$

where

[B6] $\eta_{12}^{\circ} = \dfrac{k_{12}}{k_1}$

[B7] $\eta_{21}^{\circ} = \dfrac{k_{21}[H^+]}{k_2}$

For $\eta_{12}^{\circ}\eta_{21}^{\circ} < 1$, eq. [A2.5] converges to

[B8] $\phi_{em1} = \dfrac{\eta_{em1}}{1 - \eta_{12}^{\circ}\eta_{21}^{\circ}}$

Similarly, the quantum yield of emission of the B species in the absence of isobutane can be shown to be

[B9] $\phi_{em2} = \dfrac{\eta_{em2}\eta_{12}^{\circ}}{1 - \eta_{12}^{\circ}\eta_{21}^{\circ}}$

The total emission quantum yield from both species in the absence of isobutane is

[B10] $\phi_{em}^{Total} = (\eta_{em1} + \eta_{em2}\eta_{12}^{\circ})\left(\dfrac{1}{1 - \eta_{12}^{\circ}\eta_{21}^{\circ}}\right)$

In the presence of isobutane, the total emission quantum yield from both species is

[B11] $\phi_{em}^{Total} = (\eta_{em1} + \eta_{em2}\eta_{12}^{BH})\left(\dfrac{1}{1 - \eta_{12}^{BH}\eta_{21}^{BH}}\right)$

where

[B12] $\eta_{12}^{BH} = \dfrac{k_{12}}{k_1 + k_{q1}[BH]}$

[B13] $\eta_{21}^{BH} = \dfrac{k_{21}[H^+]}{k_2 + k_{q2}[BH]}$

and k_{q1} and k_{q2} are the quenching constants of the A species and the B species by isobutane, respectively.

Aqueous–gas phase partitioning and hydrolysis of organic iodides

G.A. Glowa and J.C. Wren

Abstract: The volatility and decomposition of organic iodides in a reactor containment building are important parameters to consider when assessing the potential consequences of a nuclear reactor accident. However, there are few experimental data available for the volatilities (often reported as partition coefficients) or few rate constants regarding the decomposition (via hydrolysis) of organic iodides. The partition coefficients and hydrolysis rate constants of eight organic iodides, having a range of molecular structures, have been measured in the current studies. This data, and data accumulated in the literature, have been reviewed and discussed to provide guidelines for appropriate organization of organic iodides for the purpose of modelling iodine behaviour under postulated nuclear reactor accident conditions. After assessment of the partition coefficients and their temperature dependences of many classes of organic compounds, it was found that organic iodides could be divided into two categories based upon their volatility relative to molecular iodine. Similarly, hydrolysis rates and their temperature dependences are assigned to the two categories of organic iodides.

Key words: organic iodide, hydrolysis, partition coefficient, iodine behaviour model, nuclear reactor safety.

Résumé : La volatilité et la décomposition d'iodures organiques dans un bâtiment contenant un réacteur sont des paramètres importants à considérer lorsqu'on évalue les conséquences potentielles d'un accident à un réacteur nucléaire. Toutefois, il y a peu de données expérimentales relatives aux volatilités (souvent rapportées sous la forme de coefficient de partage) ou de constantes de vitesse concernant la décomposition (par voie d'hydrolyse) des iodures organiques. Dans le présent travail, on a mesuré les coefficients de partage et les constantes d'hydrolyse de huit iodures organiques représentatifs de diverses structures moléculaires. On a fait une revue de ces données et de celles recueillies dans la littérature et on en discute dans le but de fournir des indications claires pour l'organisation appropriée des iodures organiques dans le but d'établir un modèle du comportement de l'iode dans les conditions postulées lors d'un accident dans un réacteur nucléaire. Après une évaluation des coefficients de partage de plusieurs classes de composés organiques et de leurs dépendances sur la température, on a trouvé que les composés organiques peuvent être divisés en deux catégories suivant leur volatilité relative en iode organique. Les vitesses d'hydrolyse et leurs dépendances sur la température ont aussi été divisées de la même manière.

Mots clés : iodure organique, hydrolyse, coefficient de partage, modèle de comportement de l'iode, sécurité d'un réacteur nucléaire.

[Traduit par la Rédaction]

1. Introduction

The production and decomposition of volatile forms of radioiodine in, and their release from, a reactor containment building are important processes to consider when assessing the potential consequences of a nuclear reactor accident. A considerable number of studies on these processes have been carried out with the objective of developing a model that can predict iodine volatility in containment during the course of an accident (1–6). Recent critical reviews on iodine behaviour in containment (7, 8, and refs. therein) provide a comprehensive technical background on this subject.

Iodine would be released into the containment atmosphere from fuel via the reactor coolant system, mainly as nonvolatile species (e.g., CsI under most accident conditions) (8).

The initial fraction of volatile iodine species (i.e., molecular iodine and organic iodides) in containment would be very small. However, although CsI is water soluble and would initially be dissolved in containment water, a small fraction of the nonvolatile I^- initially dissolved in water would be continuously oxidized to volatile molecular iodine (I_2) in the presence of the high radiation field following an accident. Molecular iodine reacts easily with organic compounds in the presence of radiation to form organic iodides. Therefore, a significant portion of the gaseous iodine in containment would be in the form of organic iodides. Measurements at the TMI (Three Mile Island) 2-reactor following the 1979 accident showed that organic iodides were a major component of the small amount of iodine that became airborne (9). Studies on total iodine volatility under containment accident

conditions in an intermediate-scale facility have also shown that the organic iodide fraction in the gas phase could be as high as 90% in the presence of painted surfaces (7). Organic iodides are thus very important in the assessment of the radiological consequences of a nuclear reactor accident.

Early studies on organic iodide formation and decomposition under potential nuclear reactor accident conditions focused mainly on CH_3I because it is the simplest organic iodide with a high volatility. Recent studies have shown, however, that organic iodides are formed mainly from the reaction of I_2 with organic impurities in the aqueous phase, which then become airborne, and that a large fraction of the organic iodides formed in the aqueous phase under containment conditions would be less volatile than CH_3I (7, 10, 11). A wide range of organic radicals may be formed by the radiolytic degradation (10) of a wide range of organic impurities dissolved in the containment sump water from containment paints (7, 11). This, in turn, leads to formation of a wide range of organic iodides, whose volatility and decomposition rates differ considerably. The contribution of each of these species to the overall iodine gas-phase concentration will therefore vary considerably from one species to another. Therefore, the partition coefficients and hydrolysis rate constants of eight organic iodides, having a range of molecular structures, have been measured in the current studies.

2. Background

Although the possibility of formation of various organic iodides in containment had been recognized, early studies on organic iodide formation focused mainly on CH_3I. As mentioned above, this was because it is the simplest organic iodide, and it has a high volatility. Radioiodine Test Facility (RTF)[2] experiments performed in painted vessels have found, however, that a large fraction of the organic iodides formed from containment paint impurities are less volatile than CH_3I (7). Formation of low volatility compounds has been further supported by bench-scale studies on the dissolution of organic solvents from painted surfaces into water (11, 12) and on the radiolytic decomposition of organic impurities in water (10, 13–18). Studies on the dissolution of organic solvents from painted surfaces have shown that the molecular structure of compounds released varies (e.g., aromatics, alcohols, and ketones), and that commonly used paint solvents contain from one to 10 carbons (Table 1). Calculations suggest that the amount of organic solvents released from painted surfaces into the sump could result in concentrations of up to 1×10^{-2} mol dm^{-3} (11, 12). (Note that this concentration is subject to many parameters that would be accident scenario and reactor specific such as paint thickness, paint age, compound solubility, water volume, and paint area in contact with water, etc.).

Once released into the sump water, these organic solvents would undergo radiolytic decomposition. Studies on methyl ethyl ketone (MEK) in the absence of iodine species (10,13,14) have shown that the radiolytic decomposition of MEK in the aqueous phase under aerated conditions results

Table 1. Some commonly used paint solvents.

No. of carbons	Organic solvent constituents
1	Methanol
2	Ethanol
3	Propanol, propanone
4	2-Butanone, butanol
5	Furfuryl alcohol
6	4-Methyl-2-pentanone
7	2-Heptanone, methylbenzene
8	Xylene, ethylbenzene
9	Trimethyl benzene

in the sequential formation of smaller and more oxidized organic compounds, and eventually complete conversion to CO_2:

[1] $RH(aq) + \cdot OH(aq) \rightarrow R\cdot(aq) + H_2O$

[2] $R\cdot(aq) + O_2(aq) \rightarrow RO_2\cdot(aq) \rightarrow\rightarrow R'\cdot,$
           alcohols, aldehydes, acids, and CO_2

where RH and R· (or R'·) represent an organic compound and organic radical, respectively. Among the intermediate decomposition products observed during the radiolysis of MEK were 3-hydroxy-2-butanone, 2,3-butanedione, ethanoic acid, ethanal, and methanal (13).

The dissolution and MEK radiolysis studies imply that the range of organic compounds present in the sump could be considerable, with a large proportion of them being highly soluble oxygen-containing compounds (i.e., alcohols, ketones, and carboxylic acids). Various organic radicals would be formed from these organic compounds and, in the presence of I_2, which is known as a very good radical scavenger, a small fraction of the radicals would react with I_2 to form organic iodides:

[3] $R\cdot(aq)$ (or $R'\cdot(aq)$) $+ I_2(aq)$

           $\rightarrow RI(aq)$ (or $R'I$) $+ I(aq)$
where RI (or R'I) represents an organic iodide. Consequently, the range of organic iodides formed under containment accident conditions could be large and could include alkyl iodides, iodoketones, -alcohols, -phenols, and -acids. With the exception of the alkyl iodides, these species would have low volatility (discussed in Section 5.2), and would be very difficult to detect in the gas phase. Generally, only alkyl iodides are detected during RTF tests, or bench-scale experiments (15) by gas chromatographic methods.

Organic iodides, which can be formed in irradiated solutions of iodide and organic compounds (7, 15, 16), will partition between the aqueous and gas phases (rxn. [4]) according to Henry's Law (see Section 3.2). Meanwhile, organic iodides in the aqueous phase will undergo decomposition via hydrolysis (rxn. [5]) and radiolysis (rxn. [6]).
[4] $RI(aq) \leftrightarrow RI(g)$

[5] $RI(aq) + H_2O \rightarrow ROH(aq) + I^- + H^+$

[6] $RI(aq) + e^-_{aq} \rightarrow R{\cdot}(aq) + I^-$
Therefore, to determine the overall behaviour of organic iodides, and their contributions to the gaseous iodine concentration under containment accident conditions, the formation and the decomposition of organic iodides must be adequately quantified. The rate of the hydrated electron reaction (rxn. [6]) is diffusion-controlled and is therefore nearly independent of the type of organic iodide. Therefore, the current study focuses on the partitioning and the hydrolysis of organic iodides. The partition coefficients (see Section 3.2 for its definition) and the hydrolysis rate constants of a range of organic iodides have been measured, and compared with the literature data of organic iodides, if available, and also with compounds of similar structure that do not contain iodine. These values were reviewed for the purpose of providing guidelines to appropriately group organic iodides so that modelling of organic iodide behaviour under radiolytic conditions can be more easily managed.

3. Experimental

A small set of compounds was chosen to cover the major structural possibilities (methyl, primary, secondary, tertiary, benzyl, aryl) of organic compounds that may be present in reactor containment. For example, a primary alcohol (iodoethanol) and a carboxylic acid (iodoethanoic acid) were chosen to explore the effect of neighbouring oxygen-containing functional groups on hydrolysis rate and partition coefficients. All compounds studied were purchased from Aldrich Chemical Co., except (iodomethyl)benzene, which was from Alfa-Aesar (a Johnson Matthey company), and 2-iodobenzenol, which was from ICN Biomedicals Inc. Compounds were of the highest purity available and were used as received without further purification.

3.1 Measurement of hydrolysis rates

Two methods were used to study the hydrolysis rates of these compounds. The first method used a solid-state ion selective electrode (ISE) designed for iodide measurements (Orion 9553) with a double junction reference electrode (Orion 900200) to measure the concentration of iodide produced by hydrolysis. These probes were connected to a Fisher Accumet 950 pH meter. The electrode was calibrated for each temperature of interest using NaI solutions of known concentration. The plot of mV vs. $\log_{10}$ [I^-] was found to be linear over the concentration range studied. This method was successfully used for the hydrolysis of 2-iodobutane. Due to baseline drift however, this method was found to be unsuitable for the time periods required to measure the hydrolysis rates of the other compounds.

For the majority of the studies, the hydrolysis rates were determined from the growth of the absorbance of I^- (ε = 12 980 dm^3 mol^{-1} cm^{-1} at 225 nm) monitored using a HP 8450A spectrophotometer. In some cases there was minor absorbance at 225 nm attributed to the starting material and (or) the resulting alcohol, in addition to the absorbance by I^-. But because the change in concentration of the three components (organic iodide, alcohol, and I^-) occurs at the same rate, the first-order hydrolysis rate constant of the organic

compound can still be obtained from the change in absorbance at 225 nm (see Section 4.1 for the relationship between the absorbance and the first-order rate constant).

In general, the measurements were repeated at least once. The reproducibility of the measurements was better (<5%) when measuring fast hydrolysis rates (i.e., for 2-iodobutane and (iodomethyl)benzene). During the measurement of slow hydrolysis rates (i.e., iodomethane and iodoethane), reproducibility was generally in the 20% range. Measurements lasted between 3–5 half-lives during experiments using the electrode method. For each spectrometer measurement, the absorbance at 225 nm was then monitored until a limiting absorbance was approached (generally > 3 half-lives).

Solutions were prepared by adding the pure compound (as received) to purified (distilled and deionized) water (Millipore Milli-Q Plus) in a temperature-controlled cell. After dissolution of the compound, the electrodes were introduced, and the I^- signal was monitored until completion. For the spectrophotometric method, an aliquot of the solution was removed and placed in a temperature-controlled optical cell (10 cm path length). Starting concentrations of all species for these measurements were approximately 1×10^{-4} mol dm^{-3}. This concentration is below the saturation level of the compounds studied, but high enough to ensure an adequate increase in absorbance as the reaction progresses. To avoid loss of the compound to the gas phase, the cell was completely filled to eliminate any headspace. The water pH was slightly acidic (~pH 6) at the start of a test, but was not controlled or buffered and generally decreased to ~4 during the hydrolysis.

3.2 Partition coefficient determination

In this report, the partition coefficient (^HK) is defined as the ratio of the aqueous phase concentration to the gas phase concentration at equilibrium.

[7] $$^HK = \frac{[\text{Compound(aq)}]_{eq}}{[\text{Compound(g)}]_{eq}}$$

Partition coefficients were determined in ~400 mL temperature-controlled cells at ambient pressure. Prior to being added to the temperature-controlled cell, 200 mL of purified water was purged with high purity air for 20–30 min. The vessel and water was conditioned at a given temperature for several hours before the pure compound, or an aliquot of a concentrated stock solution, was added to the aqueous phase of the vessel. A concentration of approximately 1×10^{-4} mol dm^{-3} was typically used for the partition coefficient measurement. For iodoethanol and iodoethanoic acid, a higher concentration (~1×10^{-3} mol dm^{-3}), which is still below saturation concentration, was used because of their low volatility.

Aqueous samples (400–1000 µL) were analyzed using a Waters high performance liquid chromatography system (LC-18 DB column, detection by UV at 254 nm). Gas samples (200–500 µL) were analyzed by gas chromatography (GC). The volatile species (iodomethane, iodoethane, and 2-iodobutane) were detected using a Varian GC system fitted with a photoionization detector, and an Altec polymethyl siloxane column (30 m, 0.53 mm i.d., 5 µm film thickness). The less volatile species required thinner phase capillary

Fig. 1. Growth of absorbance at 225 nm during the hydrolysis of iodoethane at 80°C. Inset shows the log plot of $A_{225nm}^{INF} - A_{225}$.
columns more suitable for polar compounds (which was on our HP Model 5972 GC–MS system). For iodophenol and iodoethanol, a J&W Scientific DB-1 column (30 m, 0.32 mm i.d., 3.0 μm film thickness) was used, and a HP-5 column (25 m, 0.32 mm i.d., 0.17 μm film thickness) was used for iodoacetic acid. Iodoethanoic acid, the least volatile of the compounds studied, required a solid phase micro extraction (SPME) technique (acrylate fibre) to concentrate material from the gas phase (17). This SPME fibre was calibrated with solutions of known concentration of iodoethanoic acid.

Equilibrium of the organic iodides between the gas and aqueous phase was generally reached within an hour, but sampling continued for several hours (every 30–60 min). Experiments were performed in duplicate.

4. Results

4.1 Hydrolysis rates

A typical absorbance growth curve at 225 nm observed during the hydrolysis of organic iodides is shown in Fig. 1.

The first-order rate constant for the hydrolysis of an organic compound was obtained from the growth curve of the absorbance at 225 nm as a function of time. The absorbance is related to the rate constant of the hydrolysis of the organic compound as follows.

Assuming that the rate of the hydrolysis reaction (rxn. [5]) has a first-order rate dependence[3] (more discussion in Section 5.1), the following expressions can be written:

$$[8] \quad -\frac{d[RI(aq)]_t}{dt} = \frac{d[I^-]_t}{dt} = k \cdot [RI(aq)]_t$$

$$[9] \quad [RI(aq)]_t = [RI(aq)]_0 \cdot e^{-kt}$$

$$[10] \quad [I^-]_t = [I^-]_0 + [RI(aq)]_0(1 - e^{-kt})$$

$$[11] \quad [ROH(aq)]_t = [ROH(aq)]_0 + [RI(aq)]_0(1 - e^{-kt})$$

where k is the rate constant for the hydrolysis reaction of organic iodide, $[RI(aq)]_t$, $[I^-]_t$, and $[ROH(aq)]_t$ are the concentrations of reactant, organic iodide, and products, iodide and alcohol, at time t, and $[RI(aq)]_0$ and $[I^-]_0$ are the initial concentrations of organic iodide and iodide.

The main contributor to the absorbance at 225 nm is I^-, but alcohols and organic iodides also absorb at this wavelength:

$$[12] \quad A_{225nm}(t) = \varepsilon_{I^-}[I^-]_t + \varepsilon_{ROH}[ROH(aq)]_t$$
$$+ \varepsilon_{RI}[RI(aq)]_t$$

where A_{225nm} is the observed absorbance at 225 nm, and ε_{I^-}, ε_{RI}, ε_{ROH} are the molar absorptivities of iodide, the organic iodide, and the corresponding alcohol, at 225 nm, respectively. Therefore, the observed absorbance as a function of time, $A_{225nm}(t)$ has the following relationship:

$$[13a] \quad A_{225nm}(t) = \varepsilon_{I^-}([I^-]_0 + [RI(aq)]_0(1 - e^{-kt}))$$
$$+ \varepsilon_{ROH}([ROH(aq)]_0 + [RI(aq)]_0(1 - e^{-kt}))$$
$$+ \varepsilon_{RI}[RI(aq)]_0 \cdot e^{-kt} = (\varepsilon_{I^-}[I^-]_0$$
$$+ \varepsilon_{ROH}[ROH(aq)]_0 + \varepsilon_{RI}[RI(aq)]_0)$$
$$+ (\varepsilon_{I^-} + \varepsilon_{ROH} - \varepsilon_{RI})[RI(aq)]_0(1 - e^{-kt})$$
$$= A_{225nm}(t = 0) + (\varepsilon_{I^-} + \varepsilon ROH$$
$$- \varepsilon_{RI})[RI(aq)]_0(1 - e^{-kt}) = A_{225nm}^{INF}$$
$$- (\varepsilon_{I^-} + \varepsilon_{ROH} - \varepsilon_{RI})[RI(aq)]e^{-kt}$$

where $A_{225nm}(t = 0)$ is the absorbance at 225 nm at time zero (see eq. [12]) and A_{225nm}^{INF} is the absorbance at 225 nm at time infinity (i.e., when the reaction is completed);

$$[13b] \quad A_{225nm}^{INF} = A_{225nm}(t = \infty) = A_{225nm}(t = 0)$$
$$+ (\varepsilon_{I^-} + \varepsilon_{ROH} - \varepsilon_{RI})[RI(aq)]_0$$

---

[3] The hydrolysis of organic iodides occurs via either an S_N1 or S_N2 mechanism (see section 5.1). For a given constant pH, both mechanisms yield a first-order dependent rate equation.

Fig. 2. Plot of electrode response during the hydrolysis of 2-iodobutane at 60°C. Inset shows the log plot of [I⁻].
Equation [13a] can be rewritten as:

[13c] $\ln A^{INF}_{225nm} (-A_{225nm}(t)) = \ln ((\varepsilon_{I^-} + \varepsilon_{ROH}$

$$- \varepsilon_{RI})[RI(aq)]_o) - kt = const - kt$$

The plot of $\ln A^{INF}_{225nm}$ ($- A_{225nm}(t)$) vs. time therefore provides the rate constant for hydrolysis of RI. The absorbance growth curve is replotted in the semi-log scale in the inset of Fig. 1 and shows first-order behaviour.

A sample electrode response observed of the hydrolysis of 2-iodobutane is shown in Fig. 2. The signal was first converted into I⁻ concentration according to the probe calibration. The $[I^-]_\infty - [I^-]_t$ is plotted on a log scale in the inset of Fig. 2, because the slope yields the rate constant.

[14] $\ln ([I^-]_\infty - [I^-]_t) = const - kt$

Because the response is nonlinear, there is greater uncertainty at the beginning of the experiment. The uncertainty becomes larger again later when the electrode response is very small. This was considered when extracting a *pseudo*-first-order rate constant from the log plot, i.e., more weight was given to the data points in the middle of the test. As mentioned in Section 3.1, the iodide electrode method was used only for the hydrolysis of 2-iodobutane.

The hydrolysis of all the organic iodides studied in this work exhibited a first-order dependence on organic iodide concentration. Furthermore, the rate constant (k) for the organic iodide hydrolysis was, in general, observed to have a simple Arrhenius temperature dependence (Figs. 3–5), suggesting that the main hydrolysis mechanism did not change over the temperature range studied.

Repeat measurements agreed to within 10%, except for iodomethane and iodoethanoic acid. For these cases, the longer duration required for each measurement made reproducibility more difficult to achieve. The rate constants at 70°C (or at a specified temperature if 70°C data were not obtained) and the activation energies are summarized in Table 2. Also given in the table are the values of the preexponential factors that provide the best fits to the data

over the studied temperature ranges. Individual data are discussed in more detail below.

Iodoalkanes

The hydrolysis rate for alkyl iodides was observed to increase from primary (iodomethane and iodoethane) to secondary (2-iodobutane) to tertiary (2-iodo-2-methylpropane) compounds. Because of the low rate, measurements for iodomethane were made only at higher temperatures. The rate constants obtained at 50 and 60°C have higher uncertainty because only a small portion of the organic iodide had hydrolysed over the test period. The reproducibility improved at 70°C, where the standard error was ~20%, based on the standard deviation of the measurements made at each temperature. The iodomethane data obtained in this work were compared to data available in the literature (Fig. 3), showing reasonable agreement with data taken from Laughton and Robertson (18), Moelwyn-Hughes (19), and Adachi et al. (20). Adachi et al. (20) presented formulas to generate both the S_N1 and the S_N2 rate constants at each temperature. The line in Fig. 3 attributed to Adachi et al. (20) was generated from the formula for the S_N1 rate constant.

The activation energy measured in the current work is (104 ± 10) kJ mol⁻¹ and is slightly lower than the value (115 kJ mol⁻¹) reported by Adachi et al. (20). A fit to Moelwyn-Hughes' data provides an activation energy of 106 kJ mol⁻¹. The uncertainty quoted for the activation energies measured in the current work is the statistical standard error of the regression analysis.

The hydrolysis rate of iodoethane (a primary alkyl iodide) was only marginally faster than that of iodomethane at a given temperature (Fig. 4). An activation energy of (100 ± 6) kJ mol⁻¹ was determined for the hydrolysis of iodoethane. For the determination of the activation energy, less emphasis was placed on the lower temperature data points due to the uncertainty in the measurements. Also shown in Fig. 4 is the value measured by Laughton and Robertson (18) at 99°C, which falls on the linear extrapolation of the Arrhenius dependence of our 60–90°C data.

Fig. 3. Arrhenius plot for the hydrolysis of iodomethane.
Fig. 4. Arrhenius plot for the hydrolysis of iodoethane, 2-iodobutane, and 2-iodo-2-methylpropane. Laughton and Robertson's (18) values for iodoethane and 2-iodopropane (another secondary iodide) are also included. Note that the "hydrolysis" of 2-iodo-2-methylpropane was performed in a 70% methanol:30% water solution.
The hydrolysis rates of the secondary alkyl iodide (2-iodobutane) were obtained using the iodide specific electrode method. The observed rates are in line with other data in the literature on hydrolysis of secondary iodides (Fig. 4). Extrapolating the 2-iodobutane results to 80°C yields a hydrolysis rate of about 3.3×10^{-3} s^{-1}, which is comparable to Laughton and Robertsons's (18) 2-iodopropane value of $(2.75 \pm 0.004) \times 10^{-3}$ s^{-1} at this temperature. An activation energy of (97 ± 5) kJ mol^{-1} was determined for 2-iodobutane.

The hydrolysis rate for the tertiary alkyl iodide (2-iodo-2-methylpropane) was very fast, and could not be measured in pure water using the chosen method. Instead, a lower limit for the hydrolysis rate for the compound was determined in a 30% water, 70% methanol solution at only two temperatures (15 and 25°C) (Fig. 4). This slowed the reaction down

to the point where it could be measured ($t_{1/2} \sim 60$ s), however, there may be a mixture of reactions occurring (i.e., the methanol may be reacting with the 2-iodo-2-methylpropane to form an ether). Therefore, the measurement is considered to be a lower limit for the hydrolysis reaction. An activation energy of ~106 kJ mol^{-1} was determined from the data assuming a simple Arrhenius dependence.

Organic iodides with functional groups

The hydrolysis rates for (iodomethyl)benzene (benzyl iodide) were measured using the spectrophotometric method. Difficulties encountered due to the low solubility of this compound were circumvented by decanting an aliquot of homogeneous solution from a dissolution vessel to avoid undissolved globules of (iodomethyl)benzene at the bottom of the reaction vessel.

Fig. 5. Arrhenius plot for the hydrolysis of (iodomethyl)benzene and iodoacetic acid.
Table 2. Hydrolysis rates and temperature dependencies.

Compound	Hydrolysis rate at 70°C $(s^{-1})^a$	Temperature dependence $(Ae^{-E_a/RT})$	
		$\ln (A)^b$	E_a (kJ mol^{-1})^b
Iodomethane	$(3.2 \pm 0.7) \times 10^{-5}$	26.0 ± 4.0	104 ± 10
Iodoethane	$(7.4 \pm 0.3) \times 10^{-5}$	25.4 ± 2.0	100 ± 6
2-Iodobutane	$(1.04 \pm 0.06) \times 10^{-3}$	27.1 ± 1.2	97 ± 5
Iodoethanoic acid	$(2.92 \pm 0.08) \times 10^{-6}$	33.6 ± 3.2	122 ± 10
(Iodomethyl)benzene	$(4.4 \pm 0.3) \times 10^{-3}$	27.1 ± 0.8	95 ± 5
Iodoethanol^c	$(1.8 \pm 0.1) \times 10^{-5}$ (at 90°C)	Not determined	Not determined
2-Iodobenzenol	$<6 \times 10^{-8}$ (at 80°C)^d	Not determined	Not determined
2-Iodo-2-methylpropane	$>1.2 \times 10^{-2}$ (at 25°C)^e	38.2 ± 0.9^f	106 ± 2^f

^{a}Uncertainty given is the statistical standard error in the duplicate measurements at a given temperature. The error given for the rate is the standard deviation among the measured values.
^{b}Uncertainty is the statistical standard error of the Arrhenius fit to the data.
^{c}Only two measurements were made, both at 90°C.
^{d}Estimated upper limit.
^{e}Lower limit estimated in a 70% methanol/30% water solution. It is not known if methanol is reacting with the 2-iodo-2-methylpropane as well.
^{f}Estimate based on data from a 70% methanol/30% water solution.

The Arrhenius plot (Fig. 5) appears linear over the range of temperatures measured (30–70°C), and extrapolation to the entire aqueous range (0–100°C, at a total pressure of 1 bar) should be acceptable. The rates of this reaction can be compared to those of other benzyl halides measured by Laughton and Robertson (18) (2.7×10^{-4} s^{-1} at 30°C for (bromomethyl)benzene and 5.8×10^{-4} s^{-1} at 60°C for (chloromethyl)benzene). The rate of (iodomethyl)benzene hydrolysis seems to fall in between the rates of (bromomethyl)benzene and (chloromethyl)benzene hydrolysis, a trend that has been noted in the past for alkyl halides (18, 19). An activation energy of 95 ± 5 kJ mol^{-1} was extracted from the data.

The hydrolysis rate of iodoethanoic acid was slower than that of iodoethane (and therefore only high temperature measurements were made), even though the basic carbon chain is the same. Iodoethanoic acid has a pK_a of 3.12 (21); therefore, most of it would have been dissociated at the start-

ing pH of the solution (measured at approximately 4.5). One can speculate that perhaps the hydrolysis occurs with primarily the neutral form, the concentration of which, under these conditions, is effectively reduced. The larger field and steric effects of the carboxylic acid group in iodothanoic acid, compared to the effects of alkyl group in iodoethane, may also contribute to the slower hydrolysis rate (22). An activation energy of 122 ± 5 kJ mol^{-1} was extracted from the Arrhenius plot.

Iodoethanol has a very slow hydrolysis rate. Due to the length of time required for the measurements, the rate constant was measured only at 90°C, and was found to be (1.8 ± 0.1) $\times 10^{-5}$ s^{-1} (average of two values).

The rate of hydrolysis for 2-iodobenzenol (2-iodophenol) was too slow to measure directly. The rate was estimated to be less than 6×10^{-8} s^{-1}, based upon the minor increase in absorbance observed after 85 h at 80°C.

Fig. 6. Ratio of the aqueous to gas phase concentration of 2-iodobutane as a function of time after the pure compound is introduced into the aqueous phase of the vessel (60°C).
4.2 Partition coefficients

Henry's Law states that at equilibrium, the solubility of a gas is proportional to the partial pressure of the gas ($P_{Compound}$) above the liquid phase:[4]

$$[15] \quad \text{Henry's Constant} = \left(\frac{[\text{Compound(aq)}]}{P_{\text{Compound}}} \right)_{eq}$$

There are many units available to describe this ratio because there are many different units of pressure and concentration (e.g., mol dm^{-3} atm^{-1}). In this document, we use the term "partition coefficient" and the symbol "^{H}K" to signify a unitless form of Henry's Law constants as it is a more commonly adopted definition in the nuclear industry (see eq. [7]).

Henry's Law constants depend upon temperature, and are independent of the volume of gas or volume of liquid phase. The partition coefficients of the organic iodides were observed to follow a simple exponential temperature dependence over the studied temperature range:

$$[16] \quad \ln{}^{H}K^{T} = \ln{}^{H}K^{298} + \left(\frac{-\Delta_r H^o}{R} \left(\frac{1}{T} - \frac{1}{298} \right) \right)$$

where T is absolute temperature, R is the gas constant, $\Delta_r H°$ is the enthalpy of reaction (i.e., gas–aqueous phase partitioning) and $^{H}K^{T}$ and $^{H}K^{298}$ are the partition coefficients of a given compound at temperature T and 25°C (298 K).[5]

In this work, the aqueous and gas samples were analyzed simultaneously as a function of time until the system reached equilibrium between the aqueous and gas phases. The equilibrium was generally reached within an hour, but sampling continued for several hours (every 30–60 min). An example of the ratio of the aqueous phase concentration to the gas phase concentration observed as a function of time is shown in Fig. 6. Shown in the figure are data for 2-iodobutane at 60°C. The limiting value provides the partition coefficient (^{H}K).

The results are summarized in Tables 3 and 4 along with the literature values of similar organic iodides. The examples of the scatter in the data for the partition coefficient and its temperature dependence are presented in Figs. 7 and 8 for iodomethane and iodoethanol. Individual data are discussed below.

Iodoalkanes

The partition coefficient of iodomethane determined in this study showed an exponential relationship of $\ln{}^{H}K = (3430 \pm 60)/T - (9.9 \pm 0.2)$ (Fig. 7). Our results agree with the partition coefficient measured by Hunter-Smith et al.

---

[4] This law holds for solutions dilute enough that the environment of the solute remains constant. Mackay and Shiu (23) suggest a mol fraction of 0.01 as an upper limit.

[5] The partition coefficient is an equilibrium constant, and has the following relationship at a given temperature:

$$\Delta_r G° = -RT \ln ({}^{H}K/RT) = \Delta_r H_T^o - T\Delta_r S°$$

$$\text{or} \quad \ln ({}^{H}K) - \ln (RT) = -(\Delta_r H_T^o/RT) + \Delta_r S°/R$$

where ^{H}K is the Henry's constant as defined in eq. [15]. The use of eq. [16] to determine the exponential temperature dependence of the partition coefficient thus implies that the $\Delta_r H°$ value reported in this document is the average enthalpy of the gas–liquid partitioning over a temperature range of the aqueous phase. Over the studied temperature range, the enthalpy of the partitioning of the organic iodides appears to be nearly temperature-independent. The use of eq. [16] also implies that the second term of the left hand side of the above thermodynamic relationship ($\ln (RT)$) is ignored in obtaining the slope (the contribution of the term to the slope is very small). Thus, the $\Delta_r H°$ value reported here is the enthalpy of reaction to a first-order approximation.

Table 3. Effect of iodine atoms on partition coefficients.

Compound	^HK (25°C)	Reference	Iodine-substituted compound	^HK (25°C)	Reference	Rel. ratio
Methane	0.04	27	Iodomethane	4.82 ± 0.01	This work	120
			Diiodomethane	56	23	1400
			Triiodomethane	88	28	2200

[a]See footnote 5.

Fig. 7. Temperature dependence of the partition coefficient of iodomethane.

$$\ln{}^HK = (3430 ± 60)/T - (9.9 ± 0.2)$$
(24), and to within 20–60% of those obtained by Hasty (25), and Moore et al. (26). The partition coefficients of Iodoethane and 2-iodobutane and their temperature dependences are very similar to those of iodomethane (Tables 3 and 4).

Organic iodides with functional groups

For the remaining compounds, the partition coefficients of only iodoethanol and iodoethanoic acid were obtained.[6] These compounds are highly soluble in water and have very high partition coefficients and steep temperature

---

[6]The partition coefficients of (iodomethyl)bezene and 2-iodo-2-methylpropane could not be determined because they hydrolysed too quickly to obtain any meaningful results.

Table 5. Literature hydrolysis rates.

Compound	Temperature (°C)	Rate constant (s^{-1})	Reference
Iodomethane	60	8.72×10^{-6}	19
Iodomethane	60	2.3×10^{-5}	20
Iodomethane	70	2.49×10^{-5}	19
Iodomethane	80	2.34×10^{-4}	20
Iodomethane	80	8.19×10^{-5}	18
Iodomethane	90	1.8×10^{-4}	19
Iodoethane	99	8.78×10^{-4}	18
2-Iodopropane	80	2.75×10^{-3}	18
1-Iodopropane	100	5.49×10^{-4}	18
1-Iodo-2-methylpropane	100	3.55×10^{-4}	18

Fig. 8. Temperature dependence of the partition coefficient of iodoethanol.

$$\ln {}^{H}K = (7900 \pm 600)/T - (15.3 \pm 1.9)$$
dependences (Tables 3 and 4, see also Fig. 8). Because of the high partition coefficients, a higher aqueous concentration (~1×10^{-3} mol dm^{-3}) was used for these compounds to ensure a detectable amount in the gas phase. Furthermore, for iodoethanoic acid, a microextraction technique was used for the gas phase detection, in which small amount of iodoethanoic acid was adsorbed and concentrated onto a micro-extraction fibre before injection into the GC.

5. Discussion

5.1 Hydrolysis rates

Hydrolysis of halogenated aliphatic compounds (rxn. [5]) occurs via well-known nucleophilic substitution mechanisms (S_N1 and S_N2). Because the relative contribution of these two mechanisms to the overall hydrolysis of organic iodides impacts on the dependence of its rate on the OH$^-$ concentration, the nucleophilic substitute mechanisms are reviewed briefly below, prior to the discussion on the hydrolysis rate of organic iodides.

The S_N2 hydrolysis reaction of iodo-compounds is a second-order process, with a rate dependent upon the concentration of both OH$^-$ and the organic iodide. Because of the dependence on [OH$^-$], the hydrolysis rate of organic iodides would depend strongly on pH. Because the S_N2 mechanism

involves the hydroxide ion approaching the reactive carbon, steric hindrance affects the rate. Therefore, the relative S_N2 hydrolysis rate at a given pH and temperature, is as follows (21, 29):

methyl > primary > benzylic > secondary > tertiary

The S_N1 reaction rate depends only on the concentration of iodo-alkane because the rate-determining step is the unimolecular dissociation of the carbon—halogen bond. Thus, for S_N1, the hydrolysis rate depends on the stability (and therefore, the structure) of the intermediate carbocation, and the relative S_N1 rates are (21, 29):

tertiary > secondary, benzylic > primary, methyl

The structure of the iodo-compound and the OH$^-$ concentration governs which one of the two nucleophilic substitution mechanisms is dominant. The primary alkyl-iodides should be the most sensitive to pH, as they can hydrolyse faster than other iodo-compounds via the S_N2 reaction, where the nucleophile is OH$^-$. Thus, if there were any significant pH dependence of hydrolysis rate, it would be most pronounced for iodomethane. Adachi et al. (20) have measured both the S_N1 and S_N2 rates of iodomethane hydrolysis

separately, over a temperature range of 25–65°C. Their measurements show that, at a given temperature, the S_N2 contribution to the overall hydrolysis of iodomethane is negligible at pH 6, and does not become significant until about pH 11. Therefore, the S_N2 portion of the reaction can be ignored for the pH range studied in this work. Furthermore, since methyl iodide represents the structure which undergoes S_N2 hydrolysis the fastest, it follows that the S_N2 portion of the hydrolysis rates of all other iodinated compounds can be ignored as well, for the pH range used in this work, and for the pH range (pH 4–10) expected in containment.

Table 5 lists the hydrolysis rates of various alkyl iodides reported by other groups (18–20). (The hydrolysis rates measured in the current study are summarized in Table 2). A hydrolysis rate of $(3.2 \pm 0.7) \times 10^{-5}$ s^{-1} at 70°C and an activation energy of (104 ± 10) kJ mol^{-1} obtained for iodomethane in this study are in good agreement with the values observed by Molewyn-Hughes (19): a hydrolysis rate of 2.49×10^{-5} s^{-1} at 70°C and an activation energy of 106 kJ mol^{-1}. Adachi et al. (20) obtained an activation energy of 113 kJ mol^{-1} for the S_N1 portion of the reaction, and also provided an expression for the temperature dependence for the S_N2 contribution.

Since the main mechanism for the hydrolysis of organic iodides under the experimental conditions (and also expected under accident conditions) is S_N1, the hydrolysis can be expressed as a simple first-order process. The first-order rate constant (k) for the hydrolysis of organic iodides (given in Tables 2 and 5) varies widely at a given temperature. The observed trend is in good agreement with the relative rates expected for S_N1 reactions previously discussed: slow for primary alkyl iodides (e.g., $(3.2 \pm 0.7) \times 10^{-5}$ s^{-1} at 70°C for iodomethane) and aromatic iodides (e.g., less than 6×10^{-8} s^{-1} for 2-iodobenzenol) and faster for benzylic and secondary alkyl iodides (e.g., $(4.4 \pm 0.3) \times 10^{-3}$ s^{-1} for (iodomethyl)benzene and $(1.04 \pm 0.05) \times 10^{-3}$ s^{-1} for 2-iodobutane) and fastest for tertiary alkyl iodides (e.g., very fast even at 25°C for 2-iodo-2-methylpropane). As could be predicted by its nucleophilic substitution mechanism, the most important factor affecting hydrolysis rate is the position of the iodine atom on the carbon structure, rather than the number of carbons in the molecule. For example, 1-iodobutane would be expected to have a hydrolysis rate comparable to that of iodoethane (another primary iodide).

Functional groups adjacent to the iodide atom appear to modify the rates slightly as well (e.g., the hydrolysis rates of iodoethanoic acid and iodoethanol are lower than that of iodoethane). More data would be required to fully assess the effect of functional groups.

The rate constants of the organic iodides studied were observed to have a simple Arrhenius temperature dependence, indicating that for a given compound, the main hydrolysis mechanism (i.e., S_N1 for all the compounds studied) did not change over the temperature range studied. The observed trend for the activation energy also follows that expected from the S_N1 mechanism, lower for (iodomethyl)benzene and 2-iodobutane than for primary alkyl iodides or iodoethanoic acid.

5.2 Partition coefficients

Partition coefficients reported in the literature, along with our data, are listed in Tables 3 and 6. Also shown in these

Table 6. Selected partition coefficients (25°C) for various classes of compounds.

Compound class	Examples	^HK (approx.)[a]
Alkanes	Hexane	0.02
Alcohols	Methanol	5300
	Ethanol	4900
	Butanol	2900
	Hexanol	1500
	Phenylmethanol	220 000
Diols	1,2-Ethanediol	9.8×10^7

[a]Values taken from refs. 23 and 27.

tables are the partition coefficients of non-iodine substituted organic compounds. Comparison of the partition coefficients of these organic iodides with their non-iodine-substituted counterparts provides a reasonable approach to estimate the partition coefficients of other organic iodides. The partition coefficients of organic compounds at 25°C are reviewed first, followed by their temperature dependencies.

Table 3 compares the partition coefficients at 25°C of the few measured organic iodides to those of their non-iodine-substituted counterpart. An examination of Table 3 shows that substituting an iodine atom into a molecule makes the compound less volatile, but the impact of the change decreases as the partition coefficient increases.

Studies on Henry's Law constants have found relationships between the partition coefficient and structural components of a molecule, such as bonds and functional groups (30–33). In general, hydrophilic components such as halogen, oxygen, nitrogen, and sulphur containing functional groups increase the partition coefficient, whereas hydrophobic components such as long chains of carbon—carbon bonds and carbon—hydrogen bonds, decrease the partition coefficient. Some of these trends are apparent by examining the values listed in Tables 3 and 6. Several methods of estimating partition coefficients by empirically correlating partition coefficients with structural parameters have been devised (30–33). These methods provide ways to predict Henry's Law constants for molecules with different functional groups to within a factor of two or three, based upon

Table 7. Range of temperature dependencies of ^HK for various classes of organic compounds.

Compound Class	Range of $-\Delta_r H°/R^a$ (K)	Examples	$-\Delta_r H°/R^a$ (K)
Alkanes	1500–8000	Methane	1800
		Butane	3100
Alcohols	5000–8000	Methanol	5400
		Butanol	7300

^{a}Ranges and approximate values taken from ref. 27.

sets of compounds for which the constant has been experimentally determined. These structure-based calculation methods predict the trend observed in Table 3 that the substitution of an iodine atom for a hydrogen atom within a molecule generally increases the partition coefficient. This increase ranges from two orders of magnitude for low solubility alkane organic compounds (i.e., methane to butane in Table 3), to a factor of 5–10 for highly soluble organic compounds containing a carbonyl, alcohol, or carboxylic acid group.

Table 6 lists the partition coefficients of non-iodinated compounds, from which the partition coefficients of the counterpart organic iodides can be estimated. In general, the partition coefficient increases with the number of oxygen atoms, and decreases with length of the carbon chain. Not all functional groups containing one oxygen atom are equal though; for example, alcohols have much higher partition coefficients than ketones.

The temperature dependences for the partition coefficients of organic iodides reported in the literature and from this work are compared with the temperature dependence of corresponding non-iodine-substituted (parent) organic compounds in Tables 4 and 7.

The value of $-\Delta_r H°/R$ of an organic iodide is consistently higher than that of the corresponding non-iodine-substituted organic compound for the small number of comparisons available (Table 4). However, the increase is small enough that the temperature dependencies of the partition coefficient of an organic iodide may be approximated from that of non-iodine-substituted counterpart. Table 7 lists the range of $-\Delta_r H°/R$ for various classes of organic compounds. The value of $-\Delta_r H°/R$ ranges from about 500–10 000 K. Organic iodides and corresponding non-iodine-substituted organic compounds that are more volatile than I_2 at 25°C (i.e., alkane and aromatic compounds), have $-\Delta_r H°/R$, of the order

of 3400 K, whereas the other more soluble compounds have a $-\Delta_r H°/R$ of the order of 6500 K. Note that the partition coefficient of I_2 has a temperature dependence ($-\Delta_r H°/R$) of ~4000 K (34–36).

The pH is not likely to affect the partitioning of a compound, unless the solubility of a compound is affected, which is not expected to occur at the pH range expected in containment (pH < 11). However, for the compounds that have pKa values within the pH range being considered, the distribution between the acid and base forms must be considered.

5.3 Proposed grouping of organic iodides for reactor safety analysis applications

The wide range of organic iodides expected to be formed in containment following an accident presents several problems for models of iodine behaviour. The precise nature of the important organic iodides to be modelled cannot be predicted because of the number of different sources of organic material within containment, and the variety of organic species that may be derived from these sources. Detailed physical modelling of all of the possible organic species would be computationally intensive and fraught with uncertainty because precise rate information is lacking for many of the potential species. The review of the partition coefficients and hydrolysis rates provides a basis for reasonable and defensible grouping of organic iodide species, and the assignment of common rate constants. This would greatly simplify the challenge facing those who model iodine behaviour. The suggested grouping is presented below.

Recommended hydrolysis rates

If the division of organic iodides based on hydrolysis rates is required, it is recommended that the division be done on the basis of molecular structure because the hydrolysis rates

of organic iodides are sensitive to the structure. Based on the hydrolysis rates listed in Tables 2 and 8, it is proposed that organic iodides be divided into two groups, primary alkyl iodides (PRI) and nonprimary organic iodides (NRI). The NRI group would include secondary, tertiary, and benzylic iodides, as well as any other carbon structure that would enhance hydrolysis rate.

The hydrolysis rates of primary alkyl iodides range from $(2.92 \pm 0.08) \times 10^{-6}$ s^{-1} (iodoethanoic acid) to $(7.4 \pm 0.3) \times 10^{-5}$ s^{-1} (iodoethane) at 70°C. Iodomethane appears to adequately represent the average behaviour of the primary alkyl group. After conversion to 25°C (using the activation energy measured in this work), the iodomethane values can be used to represent the primary alkyl iodides:

$$[17] \quad \ln k_{PRI} = \ln k_{PRI}^{298} + \frac{\Delta E_a}{8.3145} \cdot \left(\frac{1}{298} - \frac{1}{T} \right)$$

where $k_{PRI}^{298} = (1.3 \pm 0.9) \times 10^{-7}$ s^{-1}) and $\Delta E_a = 104 \pm 10$ kJ mol.

For the second group, the hydrolysis rate constants are larger than 1×10^{-4} s^{-1} at 70°C. For this group, 2-iodobutane is recommended to represent the average of the NRI organic iodides (after conversion to 25°C):

$$[18] \quad \ln k_{NRI} = \ln k_{NRI}^{298} + \frac{\Delta E_a}{8.3145} \cdot \left(\frac{1}{298} - \frac{1}{T} \right)$$

where $k_{NRI}^{298} = (7.7 \pm 0.3) \times 10^{-6}$ s^{-1}) and $\Delta E_a = 97 \pm 5$ kJ mol.

Recommended partition coefficients

Examination of Tables 3 to 7 reveals that the range of volatility of organic iodides can be enormous. However, under accident conditions, organic iodides would be formed from the reaction between organic radicals and molecular iodine (rxn. [3]). The fraction of molecular iodine converted to organic iodides is nearly independent of the type of organic impurities present in the containment sump. Hence, the most logical organization of organic iodides for modelling the volatility of organic iodides in containment following an accident is based on their partition coefficient with respect to that of molecular iodine, i.e., whether the compound is more or less volatile than molecular iodine. The partition coefficient of iodine (~79 at 25°C) (27, 34–36) is such that the division essentially corresponds to whether the compound contains oxygen or not. Except in rare cases, the presence of a single oxygen atom within a molecule raises the partition coefficient at a given temperature to above 100, whereas multiple oxygen atoms within a molecule generally raise the partition coefficient to well above 1000. Thus, the proposed strategy for managing the wide range of partition coefficients in containment under accident conditions is to divide organic iodides into two groups, which are based on their volatility relative to the volatility of I$_2$: (i) "high" volatility organic iodides (HVRI) such as alkyl iodides (e.g., methyl-, ethyl-, and butyl-iodides) and aromatic iodides (e.g., iodobenzene); and (ii) "low" volatility organic iodides (LVRI) containing oxygen such as alcohol and acid (e.g., iodoethanol and iodoethanoic acid).

Since iodomethane exhibits the average behaviour of HVRI, the partition coefficient of iodomethane and its tem-

perature dependence are recommended to represent the HVRI compounds:

$$[19] \quad \ln{}^H K_{HVRI} = \ln{}^H K_{HVRI}^{298} + \left((3430 \pm 60) \cdot \left(\frac{1}{T} - \frac{1}{298} \right) \right)$$

The LVRI compounds encompass a much broader range of compounds containing oxygen. A partition coefficient of (1000 ± 250), which is a conservatively averaged (i.e., a low value that provides a conservatively large gas phase concentration) value of alcohols, aldehydes, ketones, and acids from Table 6, is recommended to represent the partition coefficient of LVRI at 25°C. The temperature dependence of the partition coefficients of the LVRI compounds is also somewhat steeper than those of the HVRI compounds, with $-\Delta H/R$ generally ranging from 5000 to 7500 K. An intermediate value of (6500 ± 1000) K for $-\Delta H/R$ is therefore recommended to represent the temperature dependence of LVRI:

$$[20] \quad \ln{}^H K_{LVRI} =$$

$$\ln{}^H K_{LVRI}^{298} + \left((6500 \pm 1000) \cdot \left(\frac{1}{T} - \frac{1}{298} \right) \right)$$

where ${}^H K_{LVRI}^{298} = (1000 \pm 250)$.

The proposed organization and the assignment of the average partition coefficients should be evaluated with the proposed strategies for handling the other aspects of organic reactions. For example, the overall rate of organic iodide formation (via rxns. [1]–[3]) and the relative ratio of HVRI and LVRI formation are also crucial in determining organic iodide volatility in containment. The organization should be also consistent with the organic iodide decomposition processes, such as hydrolysis and radiolysis.

Conclusions

Experiments have been performed to obtain the partition coefficients and hydrolysis rates of various organic iodides. These data, and data accumulated in the literature, have been reviewed to provide guidelines for appropriate organization of organic iodides for the purpose of modelling iodine behaviour under postulated nuclear reactor accident conditions.

If the grouping of organic iodides based on hydrolysis rates is required, it could be done on the basis of molecular structure because the hydrolysis rates of organic iodides are sensitive to the structure. Thus, organic iodides could be divided into two groups, primary alkyl iodides (PRI) and nonprimary organic iodides (NRI). The NRI group would include secondary, tertiary, and benzylic iodides, as well as any other carbon structure that would enhance hydrolysis rate.

Based on the partition coefficients, organic iodides could be divided into two groups based upon their volatility relative to molecular iodine: (i) HVRI (high volatility organic iodides), which is comprised of alkyl iodides having a partition coefficient smaller than I$_2$; and (ii) LVRI (low volatility organic iodides), which is comprised of compounds generally containing at least one oxygen atom, and having a partition coefficient higher than that of I$_2$.

Medium-sized cyclophanes. Part 62:[1] Formylation of *anti*-[*n*.2]metacyclophanes — Through-space electronic interactions between two benzene rings

Takehiko Yamato, Tsuyoshi Furukawa, Kan Tanaka, Tsutomu Ishi-i, and Masashi Tashiro

Abstract: Formylation of *anti*-[*n*.2]metacyclophanes (**1**) (*n* = 2, 3, 4) with dichloromethyl methyl ether in the presence of $TiCl_4$ occurred selectively at *para*-position to the internal methyl substituents of *anti*-[*n*.2]metacyclophanes. Similar reaction of *anti*-5,13-di-*tert*-butyl-8,16-dimethyl[2.2]metacyclophane (**6a**) with dichloromethyl methyl ether in the presence of $TiCl_4$ led to *ipso*-formylation at the *tert*-butyl group to give *anti*-5-*tert*-butyl-13-formyl-8,16-dimethyl[2.2]-metacyclophane (**7a**) as well as the corresponding 2,7-di-*tert*-butyl-*trans*-10b,10c-dimethyl-10b,10c-dihydropyrene (**10**), *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]metacyclophane (**8**), and *anti*-5,13-di-*tert*-butyl-*exo*-1-hydroxy-8,16-dimethyl[2.2]metacyclophane (**9**) depending on the reaction conditions. The higher yield of *ipso*-formylated product is obtained in the presence of $AlCl_3$ $MeNO_2$ in 80% yield along with *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]metacyclophane (**13**). Thus, the yield of *ipso*-formylation at the *tert*-butyl group of **6a** was strongly affected by the activity of the formylation catalyst. Interestingly, in the formylation of *anti*-6,14-di-*tert*-butyl-9,17-dimethyl[3.2]metacyclophane (**6b**) under the same reaction conditions, *syn*-6,14-di-*tert*-butyl-7-formyl-9,17-dimethyl[3.2]metacyclophane (**14b**) was obtained in 40% yield arising from the *anti-syn*-ring inversion of the formylation intermediate along with *ipso*-formylation product **7b** in 42% yield. In the formylation of *anti*-[4.2]metacyclophane (**6c**) only the mono-*ipso*-formylated product **7c** was obtained in 92% yield. The formation of a two-fold *ipso*-formation product, i.e., *anti*-5,13-diformyl-8,16-dimethyl[2.2]metacyclophane (**3a**), was not observed under the reaction conditions used. The mechanism of the *ipso*-formation as well as the formation of the present novel reaction products **8** and **9** is also discussed.

Key words: cyclophanes, strained molecules, electrophilic aromatic substitution, *ipso*-formylation, σ-complex intermediates, through-space electronic interactions.

Résumé : La formylation des *anti*-[*n*.2]métacyclophanes (**1**) (*n* = 2, 3, 4) à l'aide d'oxyde de méthyle et de dichlorométhyle, en présence de $TiCl_4$, se produit d'une façon sélective en position *para* par rapport aux substituants méthyles internes des *anti*-[*n*.2]métacyclophanes. Une réaction semblable de l'*anti*-5,13-di-*tert*-butyl-8,16-diméthyl[2.2]métacyclophane (**6a**) avec de l'oxyde de méthyle et de dichlorométhyle, en présence de $TiCl_4$, conduit à une formylation en position *ipso* par rapport au groupe *tert*-butyle et, suivant les conditions réactionnelles à la formation de l'*anti*-5-*tert*-butyl-13-formyl-8,16-diméthyl[2.2]métacyclophane (**7a**) ainsi que du 2,7-di-*tert*-butyl-*trans*-10b,10c-diméthyl-10b,10c-dihy-dropyrène (**10**), de l'*anti*-5-*tert*-butyl-8,16-diméthyl-13-(3-méthylbut-1-én-2-yl)[2.2]métacyclophane (**8**) et de l'*anti*-5,13-di-*tert*-butyl-*exo*-1-hydroxy-8,16-diméthyl[2.2]métacyclophane (**9**). Le rendement le plus élevé de produit formylé en position *ipso* (80%) est obtenu en présence de $AlCl_3$, dans le $MeNO_2$; à ses côtés, il se forme aussi de l'*anti*-5-*tert*-bu-tyl-8,16-diméthyl-13-(3-méthylbut-1-én-2-yl)[2.2]métacyclophane (**13**). Le rendement en formylation en position *ipso* par rapport au groupe *tert*-butyle du produit **6a** est donc fortement affecté par l'activité du catalyseur de formylation. Il est intéressant de noter que la formylation de l'*anti*-6,14-di-*tert*-butyl-9,17-diméthyl[3.2]métacyclophane (**6b**) dans les mêmes conditions expérimentales conduit à la formation, avec un rendement de 40%, du *syn*-6,14-di-*tert*-butyl-7-formyl-9,17-diméthyl[3.2]métacyclophane (**14b**) qui résulte d'une inversion de cycle *anti-syn* de l'intermédiaire de formylation; ce produit se forme aux côtés du produit de formylation *ipso* (**7b**) obtenu avec un rendement de 42%. Lors

de la formylation de l'*anti*-[4.2]métacyclophane (**6c**), on n'obtient que le produit de formylation *ipso* (**7c**) avec un rendement de 92%. Dans les conditions réactionnelles utilisées, on n'a pas observé de formation de double formylation *ipso*, l'*anti*-5,13-diformyl-8,16-diméthyl[2.2]métacyclophane (**3a**). On discute du mécanisme de formation des produits de formylation *ipso* ainsi que de la formation des nouveaux produits **8** et **9**.

Mots clés : cyclophanes, molécules tendues, substitution aromatique électrophile, formylation *ipso*, complexes-σ comme intermédiaires, interactions électroniques à travers l'espace.

[Traduit par la Rédaction]

Introduction

Because of electronic interaction between two benzene rings, the proximity of 8,16-positions, and the considerable strain energy, [2.2]metacyclophane (MCP = metacyclophane) is prone to giving transannular reaction products under the electrophilic, radical, and photolytic reaction conditions together with other transformation products derived from tetrahydropyrene (2,3). These products have usually been rationalized as involving initial dehydrogenation to 4,5,9,10-tetrahydropyrene.

Maquestiau et al. (4) reported formylation of [2.2]MCP with dichloromethyl *n*-butyl ether in the presence of TiCl$_4$ according to the Rieche procedure (5) to give 4-formyl[2.2]MCP, as shown in Scheme 1. This result was different from other electrophilic aromatic substitution of [2.2]MCP; e.g., bromination, iodination, and nitration, which afforded the corresponding 2-substituted 4,5,9,10-tetrahydropyrenes via addition-elimination mechanism (2). The relatively late transition state in the formylation of [2.2]MCP compared with other electrophilic aromatic substitution might be proposed.

However, there is no report concerning the formylation of internally substituted [2.2]MCPs. We undertook the present work to obtain further information about the chemical behaviour of [2.2]MCPs as well as [3.2]- and [4.2]MCPs, which are less strained than [2.2]MCPs.

Results and discussion

When formylation of *anti*-8,16-dimethyl[2.2]MCP (**1a**) (6) with dichloromethyl methyl ether in the presence of TiCl$_4$ as a catalyst was carried out at 0°C for 1 h, *anti*-5-formyl-8,16-dimethyl[2.2]MCP (**2a**) and *anti*-5,13-diformyl-8,16-dimethyl[2.2]MCP (**3a**) were obtained in 20 and 80% yield, respectively. Treatment of **1a** with dichloromethyl methyl ether at room temperature for 3 h increased the yield of the diformyl compound (**3a**) to 95% (Scheme 2).

Formylation of *anti*-9,17-dimethyl[3.2]- (**1b**) (7) and *anti*-10,18-dimethyl[4.2]MCP (**1c**) (7) at 0°C for 1 h under the same conditions used with **1a**, afforded diformyl derivatives (**3b**) and (**3c**) in 93 and 91% yield, respectively. In the [3.2]- and [4.2]MCP systems the diformylations were both completed within 1 h, which is different from the result that the complete diformylation required at least 3 h in the [2.2]MCP system. The different formylation behaviors of [*n*.2]MCPs can be explained by the stability of the cationic intermediates, which could arise from the through-space electronic interaction with the benzene ring located on the opposite side. Thus, in the case of the [2.2]MCP system, the second electrophilic substitition with dichloromethyl methyl ether

Scheme 1.
can be more strongly suppressed because of deactivation of the second aromatic ring by CH(OMe)Cl group-like nitration of 8,16-dimethyl[2.2]MCP, which only afforded mononitration product even in the drastic nitration conditions (8).

It should be noted that formyl groups of **2a** and **3a** are introduced at positions 5 and 13 of the MCP ring with formylation occurring selectively *para* to the methyl substituents of [2.2]MCP. Similar orientations are observed in the [3.2]- and [4.2]MCP systems. In contrast, treatment of 1,2,3-trimethylbenzene (**4**) with dichloromethyl methyl ether under the same conditions used with **1** afforded a 90% yield of 2,3,4-trimethylbenzaldehyde (**5**). The above results suggest that the orientation of the formylation of **1** is determined by the internal methyl substituents in place of methylene groups of the bridges and quite different from the orientation that can be expected from the result of formylation of 1,2,3-trimethylbenzene (**4**). The deviation of the benzyl carbon atom of methylene groups from the plane of the benzene ring (9) might decrease the degree of stabilization of the σ-complex intermediate by hyperconjugation compared with that of the internal methyl groups.

Attempted formylation of *anti*-5,13-di-*tert*-butyl-8,16-dimethyl[2.2]MCP (**6a**) (6) with dichloromethyl methyl ether (Table 1) in the presence of TiCl$_4$ at room temperature for 0.5 h gave mono-*ipso*-formylated product *anti*-5-formyl-13-*tert*-butyl-8,16-dimethoxy[2.2]MCP (**7a**) in 25% yield as a major product along with *anti*-5,13-di-*tert*-butyl-*exo*-1-hydroxy-8,16-dimethyl[2.2]MCP (**9**), *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]MCP (**8**), and the corresponding 2,7-di-*tert*-butyl-*trans*-10b,10c-dimethyl-10b,10c-dihydropyrene (**10**), depending on the reaction conditions. Thus, decreasing the reaction temperature from 25°C to 0°C or to –20°C decreases the yield of *ipso*-formylated product **7a** but increases the yield of **8** and **9**. In contrast, prolonging the reaction time to 3 h or increasing the reaction temperature to 40°C leads to a slight increase of the yield of *ipso*-formylated product **7a**. Therefore, the present *ipso*-formylation at the *tert*-butyl group of **6a** was found to be strongly affected by the reaction time and temperature.

Scheme 2.
Table 1. Treatment of [2.2]MCP **6a** with dichloromethyl methyl ether in the presence of titanium tetrachloride.

Run	Temp (°C)	Time (h)	Products (%)[a]			
			6a	**7a**	**8**	**9**
1[b]	0	0.5	9	15	25	27
2[b]	−20	0.5	6	13	31	27
3[b]	25	0.5	4	25	16	20
4	25	3	3	35	6	15
5	40	0.5	<1	30	<1	<1

[a]Isolated yields are shown.
[b]Small amount of 2,7-di-*tert*-butyl-*trans*-10b,10c-dimethyl-10b,10c-dihydropyrene (**10**) was obtained.

However, in spite of the prolonged reaction time, di-*ipso*-formylated compound **3a** was not obtained. Furthermore, formation of the corresponding *syn*-8,16-dimethyl[2.2]MCP arising from the *anti-syn*-ring inversion like the nitration of *anti*-5,13-di-*tert*-butyl-8,16-dimethoxy[2.2]MCP was also not observed (10).

Formylation of *anti*-6,14-di-*tert*-butyl-9,17-dimethyl[3.2]-MCP (**6b**) and *anti*-7,15-di-*tert*-butyl-10,18-dimethyl[4.2]-MCP (**6c**), carried out under the same conditions, afforded *anti*-6-formyl-14-*tert*-butyl-9,17-dimethyl[3.2]MCP (**7b**) in 95% yield but the latter MCP (**6c**) afforded only recovered. From this finding, the order of reactivity of *anti*-[*n*.2]MCPs for formylation is estimated to be [2.2]- > [3.2]- > [4.2]MCP. This finding also suggests that the degree of the stability of the cation intermediate, which may be due to a through-space electronic interaction with the opposing benzene ring, decreases as the size of the polymethylene bridge increases.

On the other hand, Reinhoudt and co-workers (11) reported the high-yield four-fold *ipso*-nitration of *tert*-butylcalix[4]arenes. To the best of our knowledge, none of the *ipso*-formylation reactions have been reported in the normal aromatic systems (12). In the MCP system, a first σ-complex intermediate would be stabilized by a through-space electronic interaction with the opposing benzene ring, thus accelerating the reaction. However, only one *tert*-butyl group is *ipso*-formylated because of deactivation of the second aromatic ring by the CH(OMe)Cl group.

The structures of products **7a** and **8** were determined on the basis of their elemental analyses and spectral data. The IR (NaCl) spectrum of **7a** shows $\upsilon_{C=O}$ at 1670 cm^{-1}, typical of an aromatic aldehyde. The ^{1}H NMR (CDCl$_3$) spectrum of **7a** shows two methyl protons at 0.49 and 0.64 ppm, a *tert*-butyl proton at 1.30 ppm, two aromatic protons at 7.14 and 7.64 ppm, and a formyl proton at 9.84 ppm, respectively. The ^{1}H NMR spectrum of **8** shows internal methyl protons as singlets at δ 0.58 and 0.69 and three methyl protons as singlets at δ 1.65, 1.80, and 1.93 (relative intensity 1:1:1). Two aromatic protons are observed at δ 6.89 and 7.12 as singlets that are clearly associated with the protons at C-12 and C-14, and C-4 and C-6, respectively. Structure **8** can also be determined by the fact that there are five nonequivalent methyl groups at 14.38, 14.70, 20.70, 20.75, and 22.16 and two olefinic carbons at 126.25 and 129.86 in ^{13}C NMR spectrum. Furthermore, when **8** was treated with cetyltrimethylpermanganate in methylene dichloride (13), the corresponding oxidation product *anti*-5-acetyl-13-*tert*-butyl-8,16-dimethyl[2.2]MCP (**11**) was obtained in 87% yield (Scheme 4). On the basis of this chemical conversion and spectral data, **8** is assigned the structure *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-2-butene-2-yl)[2.2]MCP. It was also found that the formylation of **8** in methylene dichloride under the same reaction conditions did not afford *ipso* substitution product **7a**. Only the recovery of the starting compound **8** resulted. This finding suggests that the intermediate for the formation of **7a** is not **8**.

The structures of products **9** and **10** were also determined on the basis of their elemental analyses and spectral data. The assignment of **10** was carried out by the comparison with physical properties and spectral data of the authentic sample (14). We previously assigned (15) the ^{1}H NMR signals of *anti*-1-*exo*-5,13-trichloro-8,16-dimethyl[2.2]MCP and have assigned the ^{1}H NMR signals of **9** in a similar fashion. Thus, the ^{1}H NMR spectrum of **9** shows two internal methyl resonances as singlets at δ 0.52 and 0.86 and a bridge methine signal as double doublets at δ 5.34 (*J* = 2.2/4.6 Hz). One of the two methyl protons is in a strongly deshielding region of oxygen atoms of *exo*-OH on the ethylene bridge resulting in a much larger downfield shift (δ 0.86) than that of the other methyl proton (δ 0.52). In contrast, the

Scheme 3.

8 →(Cl$_2$CHOMe-TiCl$_4$ in CH$_2$Cl$_2$ room temp. for 1 h) **7a**
aromatic protons were observed as a multiplet around δ 7.18–7.21 that is almost same as that for the *exo*-Cl arrangement of *anti*-1-*exo*-5,13-trichloro-8,16-dimethyl[2.2]-MCP (δ 7.0–7.3). A deshielded aromatic proton due to the *endo*-OH oxygen atom on the ethylene bridge was not observed. On the basis of the spectral data, compound **9** is assigned the structure *anti*-5,13-di-*tert*-butyl-*exo*-1-hydroxy-8,16-dimethyl[2.2]MCP.

Although the detailed mechanism of formation of **8** is not clear, a reaction pathway for the formation of **8** from **6a** is tentatively proposed in Scheme 5. The *ipso*-electrophilic attack at the *tert*-butyl group could afford the cation intermediate **A,** which could eliminate the isobutene to afford intermediate **B** following hydrolysis by the quenched with water to give *ipso*-formylation product **7a**. On the other hand, Brüggen et al. (16) reported that isobutene reacts with dichloromethyl methyl ether to afford the addition product **12**. In fact, generated isobutene was trapped by the reaction with toluene in the presence of AlCl$_3$ under the Ar gas flow condition to afford *tert*-butyltoluene. Thus, the addition product generated in the present system can react with **6a** on

the *ipso*-position at the *tert*-butyl group to afford the intermediate **C** from which the elimination of formaldehyde and HCl form the cyclopropane ring (intermediate **D**) following the ring opening reaction that occurs to afford **8**.

The formation of alcohol **9** during the formylation of **6a** with dichloromethyl methyl ether leads to the first direct introduction of hydroxy group into the methylene group of [2.2]MCP **6a**. However, the detailed mechanism of formation of **9** is not clear in the present stage.

It was also found that dehydration of alcohol **9** with TiCl$_4$ or concd. HCl in benzene at room temperature for 80 h afforded *trans*-10b,10c-dimethyl-10b,10c-dihydropyrene **10** in 10% and 32% along with recovery of the starting compound. Therefore, the reaction pathway for the formation of *trans*-10b,10c-dimethyl-10b,10c-dihydropyrene **10** in the present formylation reaction via the elimination of H$_2$O from the alcohol **9** itself to afford the corresponding [2.2]MCP-1-ene can be proposed. From [2.2]MCP-1-ene, **10** might be produced via intermediate [2.2]MCP-1,9-diene, as expected on the basis of earlier reported observations that [2.2]MCP-1,9-dienes gave the tautomerization product 10b,10c-dihydropyrenes (17).

Interestingly, the higher yield of *ipso*-formylated product is obtained in the presence of AlCl$_3$–MeNO$_2$ in 80% yield along with *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]MCP (**13a**). Thus, the yield of *ipso*-formylation at the *tert*-butyl group of **6a** was strongly affected by the activity of the formylation catalyst. In contrast, in the formylation of *anti*-6,14-di-*tert*-butyl-9,17-dimethyl-[3.2]MCP (**6b**) under the same reaction conditions, *syn*-6,14-di-*tert*-butyl-7-formyl-9,17-dimethyl[3.2]MCP (**14b**) was obtained in 40% yield arising from the *anti-syn*-ring inversion of the formylation intermediate along with *ipso*-formylation product **7b** in 42% yield. In the formylation of *anti*-[4.2]MCP (**6c**) only the mono *ipso*-formylated product **7c** was obtained in 92% yield. The formation of a two-fold *ipso*-formation product, i.e., *anti*-5,13-diformyl-8,16-di-

^{c}Isolated yields are shown in square brackets.

Scheme 7.
methyl[2.2]MCP (**3a**), was not observed under the reaction conditions used (Scheme 6, Table 2).

Previously we reported (7b) that *anti*-**6b** is thermally stable and does not interconvert at 150°C in DMSO solution or at 400°C in the solid state. Although the detailed mechanistic conclusion to rationalize the present observation of *anti*-to-*syn*-conversion is not clear, one might assume similar behavior to that of the nitration or protic acid induced intramolecular condensation of *anti*-8,16-dimethoxy[2.2]MCP to afford the corresponding 17-oxa[2.2.1](1,3,2)cyclophane via *anti*-to-*syn*-ring inversion (9).

The structures of products **13a** and **14b** were determined on the basis of their elemental analyses and spectral data. The ^{1}H NMR spectrum of **13a** shows internal methyl protons as singlets at δ 0.59 and 0.65 and two methyl protons as a doublet at δ 1.11. Two *exo*-methylenes are observed at δ 4.92 and 5.08 as doublets (*J* = 1.3 Hz). Furthermore, **13a** was alternatively prepared by the *ipso*-acylation of **6a** with isobutanoyl chloride in the presence of TiCl$_4$ followed by Wittig reaction of **15** with methyltriphenylphosphonium iodide in the presence of butyllithium (Scheme 7). On the basis of the spectral data and the comparison of the authentic sample synthesized, **13a** is assigned the structure *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]MCP.

The IR (NaCl) spectrum of **14b** shows $\upsilon_{C=O}$ at 1683 cm^{-1}, typical of an aromatic aldehyde. Especially, the mass spectral data for **14b** (M$^+$ = 390) strongly support the mono formylated product for **6b**. Interestingly, the ^{1}H NMR spectra of **14b** showed the methyl protons at δ 1.73 and 1.96 ppm, respectively, quite a different chemical shift from that of **6a** (δ 0.68 ppm) because of the ring current of the opposite aromatic ring (2,18). The aromatic protons were observed at δ 6.71 and 7.12 ppm (relative intensity 2:1). The former protons are observed at much higher field position than that of *anti*-**6a** (7.04 ppm) because of the face-to-face

overlapping between the two benzene rings. These findings strongly support the theory that the structure of **14a** adopts *syn*-conformation. It was also found that one of the ethano-bridge protons has been observed in a deshielded region (δ 3.45–3.50) owing to the formyl group at position seven (the ortho position for the ethano-bridge). Consequently, **14b** is assigned the structure *syn*-6,14-di-*tert*-butyl-7-formyl-9,17-dimethyl[3.2]MCP.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me$_4$Si. Mass spectra were obtained on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV using a direct-inlet system through GLC; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. Gas–liquid chromatograph (GLC) analyses were performed using a Shimadzu gas chromatograph (GC-14A); silicone OV-1, 2 m; programmed temperature rise, 12°C min^{-1}; carrier gas nitrogen, 25 mL min^{-1}.

Materials

The preparation of *anti*-5,13-di-*tert*-butyl-8,16-dimethyl-[2.2]metacyclophane (**6a**), *anti*-6,14-di-*tert*-butyl-9,17-dimethyl[3.2]MCP (**6b**), and *anti*-7,15-di-*tert*-butyl-10,18-dimethyl[4.2]MCP (**6c**) was carried out as previously reported (6,7).

Formylation of dimethyl[2.2]MCP (1) with Cl$_2$CHOCH$_3$. Typical procedure

To a solution of *anti*-8,16-dimethyl[2.2]MCP (6) (**1a**) (236 mg, 1.0 mmol) and Cl$_2$CHOCH$_3$ (0.56 mL, 6.2 mmol) in CH$_2$Cl$_2$ (10 mL) was added a solution of TiCl$_4$ (0.45 mL, 4.1 mmol) in CH$_2$Cl$_2$ (4 mL). After the reaction mixture was stirred at 0°C for 1 h, it was poured into a large amount of ice-water and extracted with CH$_2$Cl$_2$. The CH$_2$Cl$_2$ extract was washed with water, dried over Na$_2$SO$_4$, and evaporated in vacuo to leave a residue that was chromatographed on silica gel (CHCl$_3$ as an eluent) to give **2a** (52.8 mg, 20%) and **3a** (232.4 mg, 80%), respectively.

anti-5-*Formyl*-8,16-dimethyl[2.2]MCP (2a)

Colorless prisms (hexane), mp 182–185°C. IR (KBr) υ_{max}: 3050, 2940, 2860, 2810, 1685 (C=O), 1580, 1375, 1265,

1180, 1110, 780, 745, 720. ^{1}H NMR (CDCl$_3$) δ: 0.52 (s, 3 H), 0.65 (s, 3H), 2.60–3.20 (m, 8H), 6.84–7.23 (m, 3H), 7.64 (s, 2H), 9.85 (s, 1H). MS m/z: 264 ([M]$^+$). Anal. calcd. for C$_{19}$H$_{20}$O: C 86.32, H 7.62; found: C 86.33, H 7.65.

anti-5,13-Diformyl-8,16-dimethyl[2.2]MCP (3a)

Colorless prisms (hexane), mp 280–282°C. IR (KBr) υ$_{max}$: 2960, 2825, 2790, 2725, 1670 (C=O), 1585, 1550, 1450, 1375, 1330, 1315, 1260, 1245, 1200, 1190, 1145, 1115, 970, 910, 755, 725, 685. ^{1}H NMR (CDCl$_3$) δ: 0.58 (s, 6H), 2.60–3.30 (m, 8H), 7.64 (s, 4H), 9.86 (s, 2H). MS m/z: 292 ([M]$^+$). Anal. calcd. for C$_{20}$H$_{20}$O$_2$: C 82.16, H 6.89; found: C 82.20, H 6.93.

Formylation of *anti*-9,17-dimethyl[3.2]MCP (1b) (7) and *anti*-10,18-dimethyl[4.2]MCP (1c) (7) was carried out as a same procedure as described above to afford (3b) and (3c) in 93 and 91% yield, respectively.

anti-6,14-Diformyl-9,17-dimethyl[3.2]MCP (3b)

Colorless prisms (hexane), mp > 300°C. IR (KBr) υ$_{max}$: 2950, 1680 (C=O), 1590, 1570, 1550, 1445, 1387, 1265, 1255, 1137, 1123, 1111, 1025, 965, 907, 885, 753, 732, 678. ^{1}H NMR (CDCl$_3$) δ: 0.77 (s, 6H), 1.62 (s, 4H), 2.65–3.20 (m, 6H), 7.60 (s, 4H), 9.91 (s, 2H). MS m/z: 306 ([M]$^+$). Anal. calcd. for C$_{21}$H$_{22}$O$_2$: C 82.31, H 7.23; found: C 82.24, H 7.30.

anti-7,15-Diformyl-10,18-dimethyl[4.2]MCP (3c)

Colorless prisms (hexane), mp 202–205°C. IR (KBr) υ$_{max}$: 2950, 2810, 1672 (C=O), 1582, 1560, 1425, 1378, 1258, 1184, 1138, 1103, 1015, 956, 876, 745, 772. ^{1}H NMR (CDCl$_3$) δ: 0.97 (s, 6H), 1.32 (m, 2H), 1.50–1.70 (m, 4H), 2.30–2.47 (m, 2H), 2.79–3.19 (m, 4H), 7.44 (d, J = 1.5 Hz, 2H), 7.69 (d, J = 1.5 Hz, 2 H), 9.93 (s, 2H). MS m/z: 320 ([M]$^+$). Anal. calcd. for C$_{22}$H$_{24}$O$_2$: C 82.46, H 7.55; found: C 82.62, H 7.71.

Formylation of 1,2,3-trimethylbenzene (4) with Cl$_2$CHOCH$_3$

To a solution of 1,2,3-trimethylbenzene (4) (240 mg, 2.0 mmol) and Cl$_2$CHOCH$_3$ (0.56 mL, 6.2 mmol) in CH$_2$Cl$_2$ (10 mL) was added a solution of TiCl$_4$ (0.45 mL, 4.1 mmol) in CH$_2$Cl$_2$ (4 mL). After the reaction mixture was stirred at 0°C for 1 h and at room temperature for 3 h, it was treated as described above to give 2,3,4-trimethylbenzaldehyde (5) as a pale yellow oil (266.4 mg, 90%); IR (NaCl) υ$_{max}$: 1670 (C=O). ^{1}H NMR (CDCl$_3$) δ: 2.20 (s, 3H), 2.33 (s, 3H), 2.57 (s, 3H), 7.13 (d, J = 8.1 Hz, 1H), 7.53 (d, J = 8.1 Hz, 1H), 9.80 (s, 1H). MS m/z: 148 ([M]$^+$). Anal. calcd. for C$_{10}$H$_{12}$O: C 81.04, H 8.16; found: C 81.30, H 8.10.

General procedure for treatment of anti-5,13-di-tert-butyl-8,16-dimethyl[2.2]MCP (6a) with Cl$_2$CHOCH$_3$ in the presence of TiCl$_4$

To a solution of 6a (348 mg, 1.0 mmol) and Cl$_2$CHOCH$_3$ (0.54 mL, 6.0 mmol) in CH$_2$Cl$_2$ (10 mL) was added, dropwise, titanium tetrachloride (0.44 mL, 4.0 mmol) in CH$_2$Cl$_2$ (4 mL) at 0°C under an argon. After the reaction mixture was stirred under several reaction conditions, it was poured into ice-water and extracted with CH$_2$Cl$_2$ (30 mL × 3). The extracts were washed with water, dried over Na$_2$SO$_4$,

and concentrated. The residue was chromatographed over silica gel (Wako, C-300; 100 g) with hexane–ether (1:1) as eluent to give 7a, 8, 9, and 10. The reaction conditions and product yields are compiled in Table 1.

The isobutene, which was generated in the reaction system, was passed through a mixture of toluene (10 mL) containing aluminium chloride (5 mg, 0.037 mmol) with argon gas at room temperature. The reaction mixture was poured into ice-water and extracted with CH$_2$Cl$_2$ (10 mL × 3). The extracts were washed with brine, dried over Na$_2$SO$_4$, and evaporated in vacuo (30°C 20 torr^{-1}) (1 torr = 133.322 Pa). The residue was analyzed by ^{1}H NMR spectroscopy and gas chromatography from which the formation of *tert*-butyltoluene was qualitatively confirmed.

anti-5-tert-Butyl-13-formyl-8,16 dimethyl[2.2]metacyclophane (7a)

Pale yellow oil. IR (NaCl) υ$_{max}$: 1670 (C=O). ^{1}H NMR (CDCl$_3$) δ: 0.49 (s, 3H), 0.64 (s, 3H), 1.30 (s, 9H), 2.70–3.10 (m, 8H), 7.14 (s, 2H), 7.64 (s, 2H), 9.84 (s, 1H). MS m/z: 320 ([M]$^+$). Anal. calcd. for C$_{23}$H$_{28}$O (320.48): C 86.20, H 8.81; found: C 86.45, H 8.65.

2,7-Di-tert-butyl-trans-10b,10c-dimethyl-10b,10c-dihydropyrene (10)

Colorless prisms (hexane); mp 203–204°C (lit. (14) value mp 203–204°C).

anti-5-tert-Butyl-8,16-dimethyl-13-(3-methyl-2-butene-2-yl)[2.2]metacyclophane (8)

Colorless needles (hexane), mp 141–142°C. IR (KBr) υ$_{max}$: 2990, 2960, 2890, 1465, 1360, 1290, 1280, 1190, 890, 860, 740, 710. ^{1}H NMR (CDCl$_3$) δ: 0.58 (s, 3H, Me-8), 0.69 (s, 3H, Me-16), 1.29 (s, 9H, t-Bu), 1.65 (s, 3H, Me), 1.80 (s, 3H, Me), 1.93 (s, 3H, Me), 2.57–2.99 (m, 8H, CH$_2$), 6.89 (s, 2H, ArH-4,6), 7.12 (s, 2H, ArH-12,14). ^{13}C NMR (CDCl$_3$) δ: 14.38 (q, CH$_3$-8), 14.70 (q, CH$_3$-16), 20.70, 20.75, 22.16 (q, CH$_3$), 31.39 (q, C(CH$_3$)$_3$), 33.93 (s, C(CH$_3$)$_3$), 36.46, 36.60 (t, CH$_2$), 124.10 (d, ArCH), 126.25 (s, β-olefin), 127.10 (d, ArCH), 129.86 (s, α-olefin), 136.17, 136.58, 139.48, 140.41, 140.61, 146.77 (s, ArC). MS m/z: 360 ([M]$^+$). Anal. calcd. for C$_{27}$H$_{36}$ (360.59): C 89.94, H 10.06; found: C 89.81, H 10.20.

anti-5,13-Di-tert-butyl-exo-1-hydroxy-8,16-dimethyl-[2.2]metacyclophane (9)

Colorless needles (hexane), mp 258–259°C. IR (KBr) υ$_{max}$: 3580 (OH), 2980, 2880, 1475, 1460, 1360, 1280, 1190, 1020, 880, 770. ^{1}H NMR (CDCl$_3$) δ: 0.52 (s, 3H, Me), 0.86 (s, 3H, Me), 1.27 (s, 9H, t-Bu), 1.30 (s, 9H, t-Bu), 2.01 (broad s, 1H, OH, exchange with D$_2$O), 2.73–3.13 (m, 6H, CH$_2$ and CH_2CH(OH)), 5.34 (dd, 1H, J = 2.2/4.6 Hz, CHOH), 7.01 (d, 1H, J= 2.0 Hz, ArH), 7.18–7.21 (m, 3H, ArH). ^{13}C NMR (CDCl$_3$) δ: 14.03, 14.34 (q, CH$_3$), 31.30, 31.34 (q, C(CH$_3$)$_3$), 33.84, 33.89 (s, C(CH$_3$)$_3$), 35.83, 36.34 (t, CH$_2$CH$_2$), 44.56 (t, CH$_2$CH(OH)), 80.66 (d, CH(OH)), 122.73, 124.98, 125.21, 125.80 (d, ArCH), 133.65, 135.22, 136.71, 136.94, 139.66, 140.77, 146.23, 146.34 (s, ArC)). MS m/z: 364 ([M]$^+$). Anal. calcd. for C$_{26}$H$_{36}$O (360.59): C 85.66, H 9.95; found: C 85.35, H 9.78.

Oxidation of 8 with cetyltrimethylpermanganate affording *anti*-5-acetyl-13-*tert*-butyl-8,16-dimethyl-[2.2]MCP (11)

To a solution of **8** (36 mg, 0.1 mmol) in CH_2Cl_2 (1 mL) was added, dropwise, CTAP (40 mg, 0.1 mmol) in CH_2Cl_2 (1 mL) within 1 min at room temperature. After being stirred for 2.5 h, the reaction mixture was filtered over celite and Na_2SO_4. The filtrate was evaporated in vacuo to give **11** (29 mg, 87%) as a colourless solid. Recrystallization from hexane gave the *title compound* **11** as colorless prisms; mp 155–157°C; IR (KBr) υ_{max}: 1665 (C=O). ^{1}H NMR (CDCl$_3$) δ: 0.50 (s, 3H), 0.63 (s, 3H), 1.30 (s, 9H), 2.55 (s, 3H), 2.73–3.04 (m, 8H), 7.13 (s, 2H), 7.73 (s, 2H). MS *m/z*: 334 ([M]$^+$). Anal. calcd. for $C_{24}H_{30}O$: C 86.18, H 9.04; found: C 86.65, H 8.98.

Conversion of 9 to 10: Typical procedure

A solution of **9** (182 mg, 0.5 mmol) in CH_2Cl_2 (5 mL) or benzene (5 mL) was stirred at room temperature for several times. The reaction mixture was evaporated in vacuo. The residue was purified through silica gel column by eluting with hexane–ether (1:1) to give **10**. When titanium tetrachloride (379 mg, 0.22 mL, 2.0 mmol) or concd. HCl (1 drop) was used as an additive the reaction mixture was poured into ice-water and extracted with CH_2Cl_2. The extracts were washed with brine, dried over Na_2SO_4, and evaporated in vacuo. The residue was purified according to the same manner described above.

General procedure for treatment of 6 with Cl₂CHOCH₃ in the presence of AlCl₃ MeNO₂

To a solution of **6b** (207 mg, 0.572 mmol) and Cl_2CHOCH_3 (0.72 mL, 7.9 mmol) in CH_2Cl_2 (12 mL) was added, dropwise, a solution of $AlCl_3$ (458 mg, 3.4 mmol) in $MeNO_2$ (1.0 mL) at 0°C under argon. After the reaction mixture was stirred at 0°C for 1 h and at room temperature for 5 h it was poured into ice-water and extracted with CH_2Cl_2 (30 mL × 3). The extracts were washed with water, dried over Na_2SO_4, and concentrated to give, as an oil, a mixture of (161 mg, 82%), in the ratio 50:50 (GLC analysis). The residue was chromatographed over silica gel (Wako, C-300; 100 g) with benzene and benzene–CHCl$_3$ (1:1) as eluent to give **7b** (77 mg, 35%) and **14b** (42 mg, 22%) as an oil, respectively.

syn-6,14-Di-tert-butyl-7-formyl-9,17-dimethyl[3.2]meta-cyclophane (14b)

Pale yellow oil. IR (NaCl) υ_{max}: 1683 (C=O). ^{1}H NMR (CDCl$_3$) δ: 1.28 (9 H, s), 1.46 (s, 9H), 1.73 (s, 3H), 1.96 (s, 3H), 2.25–2.35 (m, 2H), 2.15–3.20 (m, 7H), 3.45–3.50 (m, 1H), 6.71 (broad s, 2H), 7.12 (s, 1H), 10.09 (s, 1H). MS *m/z*: 390 ([M]$^+$). Anal. calcd. for $C_{28}H_{38}O$ (390.61): C 86.10, H 9.81; found: C 86.24, H 9.52.

anti-14-tert-Butyl-6-formyl-9,17-dimethyl[3.2]MCP (7b)

Pale yellow oil. IR (NaCl) υ_{max}: 1680 (C=O). ^{1}H NMR (CDCl$_3$) δ: 0.64 (s, 3H), 0.78 (s, 3H), 1.30 (s, 9H), 2.00–2.20 (m, 2H), 2.50–3.20 (m, 8H), 7.04 (d, 1H, *J* = 2.0 Hz), 7.08 (d, 1H, *J* = 2.0 Hz), 7.56 (s, 2H), 9.87 (s, 1H). MS *m/z*: 334 ([M]$^+$). Anal. calcd. for $C_{24}H_{30}O$ (334.51): C 86.18, H 9.04; found: C 86.40, H 9.25.

Similarly, compounds **7a**, **13a**, and **7c** were prepared in the same manner as described above in 60, 15, and 72% yields, respectively.

anti-5-tert-*Butyl*-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]metacyclo-phane (13a)

Colorless needles (hexane), mp 154–155°C. IR (KBr) υ_{max}: 2970, 2930, 2860, 1615, 1470, 1455, 1350, 1270, 1180, 890, 880, 850. ^{1}H NMR (CDCl$_3$) δ: 0.59 (s, 3H), 0.65 (s, 3H), 1.11 (d, 6H, *J* = 6.6 Hz), 1.29 (s, 9H), 2.70–3.03 (m, 9H, CH$_2$ and CH), 4.92, 5.08 (d, each 1H, *J* = 1.3 Hz, olefinic proton), 7.12 (s, 4H). MS *m/z*: 360 ([M]$^+$, 57), 303 ([M$^+$– *t*-Bu]). Anal. calcd. for $C_{27}H_{36}$ (360.59): C 89.93, H 10.07; found: C 89.65, H 10.01.

anti-15-tert-*Butyl*-7-formyl-10,18-dimethyl[4.2]MCP (7c)

Pale yellow prisms (hexane), mp 86–89°C. IR (KBr) υ_{max}: 1693 (C=O). ^{1}H NMR (CDCl$_3$) δ: 0.85 (s, 3H), 0.99 (s, 3H), 1.31 (s, 9H), 1.05–1.20 (m, 4H), 2.16–2.42 (m, 2H), 2.71–3.11 (m, 6H), 6.87 (d, 1H, *J* = 1.8 Hz), 7.15 (d, 1H, *J* = 1.8 Hz), 7.36 (d, 1H, *J* = 1.8 Hz), 7.65 (d, 1H, *J* = 1.8 Hz), 9.91 (s, 1H, CHO). MS *m/z*: 348 ([M]$^+$). Anal. calcd. for $C_{25}H_{32}O$ (348.53): C 86.15, H 9.19; found: C 86.37, H 9.25.

Acylation of 6a with isobutanoyl chloride in the presence of TiCl₄

To a solution of **6a** (299.1 mg, 0.858 mmol) and isobutanoyl chloride (365.3 mg, 3.43 mmol) in CH_2Cl_2 (6.6 mL) was added, dropwise, a solution of $TiCl_4$ (1.21 mL, 11.03 mmol) in CH_2Cl_2 (1.5 mL) at 0°C under an argon. After the reaction mixture was stirred at 0°C for 1 h and at room temperature for 1 h, it was poured into ice-water and extracted with CH_2Cl_2 (30 mL × 3). The extracts were washed with water, dried over Na_2SO_4, and concentrated. The residue was chromatographed over silica gel (Wako, C-300; 100 g) with CHCl$_3$ as an eluent to give **15** as prisms. Recrystallization from hexane gave *anti*-13-*tert*-butyl-5-iso-butanoyl-8,16-dimethyl[2.2]metacyclophane (**15**) (223 mg, 71.8%) as colorless prisms (hexane), mp 114–116°C. IR (KBr) υ_{max}: 1672 (C=O). ^{1}H NMR (CDCl$_3$) δ: 0.52 (s, 3H), 0.63 (s, 3H), 1.30 (s, 9H), 1.20 (d, 6H, *J* = 6.7 Hz), 2.70–3.10 (m, 8H), 3.50–3.60 (m, 1H), 7.13 (s, 2H), 7.75 (s, 2H). MS *m/z*: 362 ([M]$^+$). Anal. calcd. for $C_{26}H_{34}O$ (360.59): C 86.13, H 9.45; found: C 86.08, H 9.51.

Wittig reaction of 15 with methyltriphenylphosphonium iodide affording *anti*-5-*tert*-butyl-8,16-dimethyl-13-(3-methyl-1-butene-2-yl)[2.2]MCP (13a)

To a suspension of methyltriphenylphosphonium iodide (121 mg, 0.3 mmol) in dry THF (10 mL) was added, dropwise, 1.6 N butyllithium hexane solution (0.19 mL, 0.30 mmol) within 1 min at room temperature under an argon. After the reaction mixture was stirred for 0.5 h, a solution of **15** (54 mg, 0.15 mmol) in dry THF (1 mL) was added, dropwise, within 1 min. After being stirred for 1 h, the reaction mixture was poured into ice-water and extracted with ether. The extracts were washed with water, dried over Na_2SO_4, and evaporated in vacuo. The residue was purified through silica gel column (Wako, C-300; 100 g) by eluting with hexane to give **13a** (25 mg, 46%) and unchanged **15**

(21 mg, 38%) as colourless solid. Recrystallization from hexane gave **13a** as colorless prisms.

Conclusions

We conclude that the selective *ipso*-formylation reactions of *anti*-di-*tert*-butyl[*n*.2]MCPs **6** led to the first-reported direct introduction of one formyl group because of a through-space electronic interaction with the opposing benzene ring, similar to the electrophilic aromatic substitution of MCPs. The yield of *ipso*-formylation of **6** was controlled by the activity of the catalyst used. Especially, the present *ipso*-formylation with dichloromethyl methyl ether in the presence of AlCl$_3$ MeNO$_2$ provides excellent yields and easy isolation of the products. The presently developed procedure was further applied to the direct removal of a *tert*-butyl group by electrophilic substitution of *anti*-di-*tert*-butyl-8,16-dimethyl[2.2]MCP **6a**, which are prone to give transannular reaction products under the electrophilic reaction conditions. The chemical behaviours of [*n*.2]MCPs for other electrophilic reagents are now under study.

A pentanortriterpenoid with a novel carbon skeleton and a new pregnane from *Trichilia connaroides*

Hua-Ping Zhang, Shao-Hua Wu, Yue-Mao Shen, Yun-Bao Ma, Da-Gang Wu, Shu-Hua Qi, and Xiao-Dong Luo

Abstract: A new rearranged pentanortriterpenoid (trijugin C) and a new pregnane (3β,4α-dihydroxypregnan-16-one) were isolated from the EtOH extract of *Trichilia connaroides* (Meliaceae). Trijugin C has been shown to be a derivative of methyl angolensate with a novel carbon skeleton. The structures were elucidated on the basis of spectral analysis including ^{1}H-^{1}H COSY, HMQC, HMBC, and NOESY experiments. The possible biogenetic pathway of trijugin C is discussed.

Key words: *Trichilia connaroides*, Meliaceae, pentanortriterpenoid, trijugin C, pregnane.

Résumé : On a isolé un nouveau pentanortriterpénoïde réarrangé, la trijucine C, et un nouveau dérivé du prégnane, la 3β,4α-dihydroxyprégnan-16-one, à partir des solutions éthanoliques d'extraction du *Trichilia connaroides* (Meliaceae). On a montré que la trijucine C est un dérivé de l'angolensate de méthyle à base d'un nouveau squelette carboné. On a élucidé les structures à l'aides d'analyses spectrales, y compris des expériences de « COSY », « HMQC », « HMBC » et « NEOSY » ^{1}H-^{1}H. On discute des voies de formations biogénétiques possibles de la trijucine C.

Mots clés : *Trichillia connaroides*, Meliaceae, pentanortriterpénoïde, trijucine C, prégnane.

[Traduit par la Rédaction]

Introduction

The roots of *Trichilia connaroides* Wight. & Arn. (syn: *Heynea trijuga* Roxb.) (Meliaceae) are used as a Chinese crude drug to treat arthritis, pharyngitis, tonsillitis, and other ailments (1). Four tetranortriterpenoids (trijugin A, trijugin B, trijugin B acetate, and 2-hydroxy-3-*O*-tigloyl-6-*O*-acetylswietenolide) have been isolated from the leaves and pericarps of this plant previously (2–4). Our investigation of the EtOH extract of the roots of *T. connaroides* resulted in the isolation of a rearranged pentanortriterpenoid (trijugin C (**1**)) with a new carbon skeleton, and a new pregnane (3β,4α-dihydroxypregnan-16-one (**2**)) (Fig. 1).

Results and discussion

Trijugin C (**1**) showed a [M]$^{+}$ ion at *m/z* 502.1837 in the HR-EI-MS spectrum, indicating a molecular formula of $C_{26}H_{30}O_{10}$. Twenty-six carbon signals were observed in the ^{13}C NMR spectrum. The multiplicities of the carbons determined by DEPT led to the attribution: 5 CH$_3$, 3 CH$_2$, 8 CH, 10 C, including one ketone (δ 217.2), three ester carbonyls

Fig. 1. Structures of **1** and **2**.
(δ 174.9, 169.9, 168.9), a β-substituted furan (δ 143.2, 139.9, 121.5, 108.6), one methoxyl group (δ 52.9), three oxymethines (δ 80.8, 79.0, 74.1), and two oxyquaternary carbons (δ 92.3, 87.6). The absorption band at 3491 cm^{-1} in the IR spectrum showed the presence of the hydroxyl group. Based on the molecular formula and ^{13}C DEPT spectrum, only one hydroxyl was present in the structure. The ^{1}H and ^{13}C NMR spectra of **1** showed similarities to those of trijugin A (2). The signals of the β-substituted furan ring in the ^{1}H NMR spectrum occurred at δ 7.39 (H-21), 7.37 (H-23), and 6.25 (H-22) and the corresponding carbon signals at δ 139.9, 143.2 and 108.6, respectively, in the HMQC spectrum. Ring D was oxidized to a C-16 lactone, with H-17 oc-

^{a}In ppm relative to the internal TMS run at 500 MHz. Multiplicities and splittings (Hz) are given in brackets.

Scheme 1. Proposed biogenetic pathway of trijugin C (**1**).
Fig. 2. Selected NOESY correlations of **2**.
curring as a singlet at δ 5.62 and H₂-15 occurring as a pair of doublets at δ 2.88 and 2.09 (*J* = 17.0 Hz). Four shielded methyl singlets at δ 1.56, 1.41, 1.11, and 0.97 were attributed to H₃-19, H₃-28, H₃-29, and H₃-18, respectively. The signal at δ 3.85 (3H, s) showed an HMBC correlation with an ester carbonyl carbon at δ 169.9 (Table 1), indicating the presence of a carbomethoxy group at C-7. H₂-11 (δ 2.34 (1H, m), 2.07 (1H, m)) and H₂-12 (δ 1.73 (1H, m), 1.50 (1H, m)) were assigned from their ¹H-¹H COSY correlations as well as an HMBC correlation to C-18. In addition, HMBC correlations were observed for H-15α (δ 2.88) to C-8 (δ 87.6) and C-14 (δ 92.3), and for H-11β (δ 2.07) to C-8 and C-14, supporting a contracted ring C formed by C-11, 12, 13, 14, 8. This was also confirmed by the absence of other coupling to the H₂-11 in the ¹H-¹H COSY spectrum.

In the HMBC spectrum, correlations were observed for H-6 (δ 5.03) to two ester carbonyl carbons C-7 (δ 169.9) and C-9 (δ 174.9), and for H₃-19 (δ 1.56) and H-5 (δ 3.28) to C-9. The presence of two C-11 protons and the absence of an HMBC correlation between H-11 and C-9 suggested that the C-9—11 bond had been cleaved. Thus, C-5, C-6, O, C-9, and C-10 formed a five-membered lactone ring.

The exchangeable sharp singlet at δ 5.87 (1H) in the ¹H NMR spectrum (removed on addition of D₂O) was ascribed to the proton of the hydroxyl group attached to C-8 supported by HMBC correlations between the hydroxyl proton and C-2 (δ 52.9), C-8 (δ 87.6), and C-11 (δ 42.4). Cross peaks observed from H-2 (δ 2.81) to C-3 (δ 217.2), C-8 (δ 87.6), C-11 (δ 42.4), and C-14 (δ 92.3), and from H₂-11 (δ 2.34, 2.07) to C-2, C-8, and C-14 suggested the linkage of ring A and ring C by the C-2—8 bond. Finally, a 1,14-ether linkage (as found in trijugin A) was proposed to satisfy the molecular formula and the deshielded nature of C-1 (δ 79.0) and C-14 (δ 92.3).

The relative stereochemistry at the chiral centers is suggested by the NOESY correlations summarized in Table 1. The NOESY plot showed a correlation between H₃-18 and H-22, suggesting the α-orientation of the furan ring at C-17, and correlations among H-2 and H-1, H-11β, H-12β, H₃-29 and H₃-19, revealing the β-orientation of H-2 and H-1 further supported by the small coupling constant (*J* = 4.2 Hz) of H-1 to H-2. Furthermore, the hydroxyl proton showed a correlation with H-2 but no correlation with H-1, H₂-11, and H₂-12, thus the hydroxyl group attached to C-8 was in the α orientation. Based on the above spectral data, the structure of trijugin C was determined to be as shown for **1**.

Usually tetranortriterpenoids with an open ring B have an 8,30 double bond. Trijugin class compounds have a rare contracted ring C and Connolly and co-workers (2) postulated

that the trijugins may be formed by ring C contraction occurring by a pinacol–pinacolone rearrangement of a 9,11-dihydroxy precursor and anticipated more detailed examination of such compounds would be necessary. Up to now, 11 other analogues, E.P.4, E.P.5 (5), capensolactones 1, 2*a*, 2*b*, 3*a*, and 3*b* (6), voamatin A, B (7), and voamatin C, D (8) have been reported. These 14 compounds have either an 8,30 double bond or an 8,30-epoxide by oxidation, and either an exocyclic carbonyl or a hemi-ketal carbon atom at C-9. In pentanortriterpenoid **1**, C-30 has been removed by further oxidation of the 8,30 double bond. Retro-aldol cleavage of the C-9 (11) bond was followed by an aldol condensation between C-2 and C-8 to form a new ring. The cleavage and the formation of these C—C bonds have not been described before. A suggested biogenesis for **1**, starting with methyl angolensate (9), is given in Scheme 1. The oxidation of C-6 of tetranortriterpenoids with a lactone ring D and an opened ring B had been reported (10, 11).

Compound **2** had a molecular formula of C₂₁H₃₄O₃, as confirmed by HR-EI-MS (*m/z* 334.2511 [M]⁺, calcd. 334.2508) and the ¹³C NMR spectrum showing 21 carbon signals (3 C, 7 CH, 8 CH₂, 3 CH₃, including two oxymethines at δ 76.3, 75.3 and a ketonic carbonyl at δ 219.6). The absorption bands at 3564, 3271, and 1741 cm⁻¹ in the IR spectrum were attributable to two hydroxyl groups and a five-membered ring ketone. The skeleton of **2** was similar to those of 2α,3β-dihydroxypregnan-16-one and 2β,3β-dihydroxypregnan-16-one (12, 13) by comparison of the NMR spectral data, as confirmed by ¹H-¹H COSY, HMQC, and HMBC spectra. The A/B ring junction was deduced as *trans* by the chemical shift value δ 13.5 of the C-19 methyl carbon (14). The two hydroxyl groups were concluded to be adjacent to each other, since the correlation was observed between the two oxymethine protons at δ 3.34 (1H, m) and 3.23 (1H, dd, *J* = 8.9, 11.2 Hz) in the ¹H-¹H COSY spectrum. Moreover, the correlations between the proton at δ 3.34 with a methylene group and the proton at δ 3.23 with a methine group indicated the only possibility for the positions of these two hydroxyl groups on the tetracyclic skeleton to be at C-3 and C-4. The large coupling constants (8.9 and 11.2 Hz) of H-4 indicated that H-3, H-4, and H-5 were axial. This result was also substantiated by H-5 and H-3, H-2α and H-3 showing spatial proximity in the NOESY experiment (Fig. 2). Thus, the structure of compound **2** was determined as 3β,4α-dihydroxypregnan-16-one.

Experimental

General procedure

The melting point was uncorrected. Instrumentation used for: [α]_D: Horiba-300; NMR spectra: Bruker DRX-500; IR: Bio-Rab FTS-135; MS: VG Autospec-3000.

Plant material

The roots of *T. connaroides* were collected at Xishuangbanna, Yunnan Province, the People's Republic of China in August 1997 and identified by Professor Guoda Tao, Xishuangbanna Botany Garden, Chinese Academy of Sciences. A voucher specimen (No. 0620834) was deposited at the Herbarium of the Kunming Institute of Botany, Chinese Academy of Sciences.

Extraction and isolation

Dried and powdered roots (3.5 kg) of *T. connaroides* were extracted with 95% ethanol three times at room temperature. After removal of the solvent by evaporation, the residues (250 g) were suspended in H$_2$O, and then extracted with CHCl$_3$. The CHCl$_3$ extract was evaporated to give a red extract (40 g), which was subjected to a Si gel column, eluting with a CHCl$_3$–Me$_2$CO mixture containing increasing amounts of Me$_2$CO to afford seven fractions. Fraction 6 was purified further on a Si gel column, eluted with CHCl$_3$–Me$_2$CO (4:1) to yield compound **1** (12 mg). Fraction 5 was rechromatographed on a Si gel column and eluted with CHCl$_3$–Me$_2$CO (10:1) to give compound **2** (32 mg).

Considerations about phenol electrohydrogenation on electrodes made with reticulated vitreous carbon cathode

François Laplante, Louis Brossard, and Hugues Ménard

Abstract: The electrocatalytic hydrogenation (ECH) of phenol was carried out in aqueous media with catalytic powders. The catalytic powders were composed of palladium nanoaggregates deposited on various substrates such as Al_2O_3, $BaSO_4$, and $BaCO_3$. Composite powders are trapped (upon stirring) into a reticulated vitreous carbon (RVC) matrix, allowing a rapid in situ build-up of the electrode and alleviating the use of a binder, since the latter may have a detrimental effect on the ECH. For a given amount of noble metal (5% palladium by weight), it is observed that the ECH of phenol to cyclohexanol increases in the following order: $Pd/BaCO_3 < Pd/BaSO_4 < Pd/Al_2O_3$. It is deduced that the ECH rate is largely dependent on the adsorption of organic molecules on the nonmetallic substrate, and a model is considered to explain such a behavior. The ECH of phenol is also feasible at a reasonable rate with composite Pd/Al_2O_3 (0.25% Pd by weight) powders fabricated by physical vapor deposition because the peripheral distribution of Pd nanoaggregates is favorable towards the ECH.

Key words: electrocatalytic hydrogenation (ECH) of phenol, reticulated vitreous carbon (RVC), alumina-based catalyst, agglomeration process, adlineation point, adsorption.

Résumé : On a effectué l'hydrogénation électrocatalytique (HEC) du phénol, en milieu aqueux, en présence de diverses poudres catalytiques. Ces poudres étaient formées de nanoaggrégats de palladium déposés sur divers substrats, tels que Al_2O_3, $BaSO_4$ et $BaCO_3$. Les poudres composites sont piégées (par agitation) sur une matrice de carbone vitreux réticulé (CVR) qui permet d'obtenir une accumulation rapide in situ de l'électrode, ce qui permet d'éviter d'avoir à utiliser un agglomérant puisque ceux-ci peuvent avoir un effet néfaste sur l'HEC. Pour une quantité donnée de métal noble (5 % de palladium en poids), on a observé que l'HEC du phénol en cyclohexanol augmente dans l'ordre suivant: $Pd/BaCO_3 < Pd/BaSO_4 < Pd/Al_2O_3$. On en déduit que la vitesse d'HEC dépend grandement sur l'adsorption des molécules organiques sur le substrat non métallique et on considère un modèle pour expliquer un tel comportement. L'HEC du phénol peut se faire à une vitesse raisonnable avec des poudres composites de Pd/Al_2O_3 (0,25 % de Pd en poids) préparées par déposition physique de vapeur parce que la distribution périphérique des nanoaggrégats de Pd est favorable à l'HEC.

Mots clés : hydrogénation électrocatalytique (HEC) du phénol, carbone vitreux réticulé (CVR), catalyseur à base d'alumine, processus d'agglomération, point d'adlinéation, adsorption.

[Traduit par la Rédaction]

Introduction

The electrode materials used for the electrocatalytic hydrogenation (ECH) of organic molecules are of paramount importance, since the kinetics of the electrohydrogenation process is quite dependent on the nature of the electrode materials (1). As far as the electrodes made with pressed metallic powder particles are concerned (1–3), their mechanical

F. Laplante, L. Brossard,[1,2] and H. Ménard. Centre de recherche en électrochimie et électrocatalyse, Département de chimie, Université de Sherbrooke, 2500 boul. Université, Sherbrooke, Québec, QC 1K 2R1, Canada.

[2]Present address: Institut de recherche d'Hydro-Québec (IREQ), 1800 boul. Lionel-Boulet, Varennes, QC J3X 1S1, Canada.

strength is generally weak without the use of a binding material (4). The electrohydrogenation process may also be carried out in the presence of composite metallic powder particles by an alternate method: the powder particles are trapped inside the pores of a porous electrode possessing a very high hydrogen (molecular or adsorbed) overpotential. Such electrodes are made by the entrapment of composite powder particles with nano-deposits of a metal at their surface, and thus the use of a binding material is not necessary (2, 5, 6). It is an attractive way to discriminate the ability of new powders for use in the electrohydrogenation process without changing their chemical and (or) physical characteristics.

Reticulated vitreous carbon (RVC) is particularly suitable, since this excellent electronic conductor is generally electrochemically stable and has a well-developed tridimensional network of large pores (7–11) (Fig. 1). The specific RVC surface is 66 cm^2 per cm^3 for a 100 pore-per-inch (1 inch = 25.4 mm) matrix with a void volume of 97% (7). The high

Fig. 1. Electron scanning micrograph of a piece of reticulated vitreous carbon foam of 80 pores per inch (ppi).
porosity of the RVC offers a great number of large pores accessible to the composite powder particles. The electrolyte penetrates through the RVC by forced convection, and the electrocatalytic particles in suspension in the electrolyte are trapped inside the pores. Recently, papers dealing with the use of agglomerated electrodes in the dechlorination of polychlorophenol and the electrocatalytic hydrogenation of lignin showed the successful use of Pd–alumina and Rh–alumina electrocatalysts (2, 5, 6).

The rate of the electrohydrogenation process is largely dependant on several experimental parameters, particularly those connected to the electrode fabrication. The present paper deals with the key parameters for the successful entrapment of the electrocatalytic particles by the RVC, that is: the size of the particles, the applied current density during the agglomeration process, and the appropriate design of the electrochemical cell used for the agglomeration process. The reaction under consideration is phenol electrohydrogenation. In addition, different palladium powders supported on various adsorbents (substrates) were considered, to show that the adsorption of the phenol molecule may be the rate-determining step of the ECH process for a given amount of palladium (5% w/w).

Experimental

The electrodes

The electrode was a piece of RVC foam (25 mm × 20 mm × 6 mm, 100 pores per inch (ppi), Electrosynthesis Co.). The electrode was mounted by inserting a glass rod (OD 5~6 mm, ID 3.5 mm) in the horizontal axis of a piece of RVC (20 mm × 40 mm × 6 mm). The excess of RVC was then removed and a copper wire was inserted into the RVC to be further cemented with silver epoxy (Epoxy Technology). Finally, the electrical contact zone on the RVC matrix was glued to the glass rod with epoxy, to isolate the electrical contact from the electro-active part of the electrode. The use of a nickel strip, as a contact with the RVC electrode, should be avoided because the activity of the nickel towards the electrocatalytic hydrogenation of ketone (12) may affect the data.

The physical embodiment of the composite material into the RVC occurred under moderate stirring of the catholyte

(~450 rpm), and the catalyst powder particles were trapped into the RVC matrix pores spontaneously (provided that no sudden perturbation occurred); the RVC electrode was under cathodic polarization during the agglomeration process. The catalytic powder remained in the pores of the RVC electrode (without any apparent loss during polarization); it also remained cathodically polarized ($J = 100$ mA dm^{-2}) for the electrohydrogenation process and was in electrical contact with the matrix (Fig. 2). With this type of RVC, the diameter of the particle size should be between 15 and 43 µm. The entrapment process is completed within 2 h, up to a charge of 50 C. The dimensions of the H-cell and those related to the other parts are given in Fig. 3. We observed that the agglomeration process was successful with this specific cell, since the process is closely dependent on the fluid dynamics. The powder characteristics are summarized in Table 1. Note that the average particle size refers to composite Pd – support-particles when Pd is present.

Electrolysis

The electrolysis was carried out in a two-compartment, jacketed glass H-cell (Fig. 3), having a Nafion-324 (E.I. Dupont de Nemours & Co) membrane as a separator. The cell temperature was fixed at 21°C during the electrohydrogenation process by a circulating thermostated bath (VWR 1160A); to prevent analyte evaporation, a water-cooled condenser was added to the top of the cell. Afterwards, the cathodic compartment was filled with a phosphate buffer (29 mL, 1 M KH$_2$PO$_4$ + 1 M NaOH) previously adjusted to pH 7, and 200 mg of the composite powder was added to the catholyte. The electrode was built-up in situ, using the previously described technique. The anodic compartment was filled with a 1 M NaOH solution (Fisher); the counter-electrode was a platinum mesh. Prior to the electrohydrogenation process, 1 mL of a phenol solution in water (25 mg mL^{-1}) was added to the catholyte, giving a total volume of 30 mL and a phenol concentration of 8.8 mMol L^{-1}. Further, the electrocatalytic hydrogenation was performed under galvanostatic control ($J = 100$ mA dm^{-2}) using an EG&G PAR model 273. All of the commercial powder particles considered in the present paper (Pd/Al$_2$O$_3$, Pd/BaCO$_3$, Pd/BaSO$_4$ 5 or 10 w/w %) were bought from Aldrich and used as received.

During the electrocatalytic hydrogenation process (ECH), 500 µL aliquots were withdrawn from the catholyte, further saturated with NaCl, acidified to pH 1 with HCl (HCl concn. 10 N), and then extracted with 1 mL ethyl acetate, to be further dried under sodium sulfate. After the completion of ECH, both the RVC electrode and the whole cell were rinsed with pure water. Internal standard (ISTD, 2-cyclohexen-1-one) was added to the cell solution; further, the extraction was carried out twice (2 × 20 mL) with distilled ethyl acetate. The organic layer was dried on sodium sulfate and filtered. The filtrate was collected in a 50 mL volumetric flask containing an external standard (ESTD, 3-methylcyclohexanol). The GC analyses were carried out on a Hewlett-Packard 5890 chromatograph equipped with an FID detector on a 30-m-long HP-5 column. The products were then identified by comparison with the retention time of the authentic compound, and the mass balance was obtained from the ISTD:ESTD ratio of the corrected peak surface area.

Fig. 2. SEM micrograph of Pd–alumina (5%) entrapped in RVC pores (I_{app} = 5 mA, T = 25°C, pH 7).
RVC electrode plated with mercury

Mercury depositions on RVC were achieved in accordance with the method described by Armalis and Kubiliene (13).

Catalyst synthesis

Noncommercial catalyst synthesis was carried out according to the technique described by Fournier et al. (14).

Galvanostatic measurements

The potentials were recorded vs. standard calomel electrode (SCE). Reagents (NaOH 99.999% and KH_2PO_4 99.99%) used for the galvanostatic measurements were provided by Aldrich, and high purity water from a Milli-Q unit was used for the preparation of solutions. A constant applied current (from 250 to 0.02 mA dm^{-2}) with an applied current time of 10 s was used to record the galvanostatic traces.

Results and discussion

Catalyst characterization

Despite the presence of a small amount of metal deposited onto the surface of the powder particles, a disk made with pressed composite powder particles (commercially available) is characterized by a very high electrical resistance. However, those powder particles, when agglomerated inside the RVC pores, show an electrocatalytic activity. The beneficial effect of the composite powder particles entrapped in an RVC electrode on the evolution of hydrogen is illustrated in Fig. 4 (curve A and B). At a current density of 100 mA cm^{-2}, the hydrogen overpotential is ~50 mV lower when Pd/Al$_2$O$_3$ is present, as compared with the absence of any catalyst. To show that the current may circulate through the agglomerated composite powder particles — the latter being in electrical contact with the RVC electrode surface — mercury was electrodeposited on a bare RVC electrode. As anticipated, the overpotential for water reduction is very high on an Hg–RVC cathode (Fig. 4, curve C). The picture is completely different with Pd/Al$_2$O$_3$ particles agglomerated on the Hg–RVC cathode (Fig. 4, curve D): the hydrogen overpotential is considerably lower. From the curves of Fig. 4, it

is deduced that the agglomerated powder particles are in electrical contact with the RVC electrode.

Composite Pd/Al$_2$O$_3$ powders were fabricated by physical vapor deposition (PVD) of Pd on alumina powder particles according to the method described in ref. 14. Palladium nano-aggregates are randomly distributed over the entire alumina particle surfaces (Fig. 5). In Fig. 6, galvanostatic traces show the influence of both powders (that is, commercially available or obtained through PVD) on the electrocatalytic activity towards the hydrogen evolution reaction. A tremendous beneficial effect is observed for the hydrogen-evolution reaction with the catalyst obtained by PVD (Pd/Al$_2$O$_3$ 0.1% w/w) relative to the commercial catalyst (Pd/Al$_2$O$_3$ 5% w/w). The overpotential shift of +410 mV at 100 mA dm^{-2} is related to peripheral distribution of the palladium nanoaggregate (Fig. 5). Palladium deposited onto alumina by PVD favors an efficient electrical contact between the powder particles and the RVC matrix, since the preferential location of nano-aggregates is in the "skin" of the powder particles. Moreover, the electrolyte may easily reach the Pd nanoaggregates. On the other hand, the particles of the commercial Pd/Al$_2$O$_3$ powder, which are obtained by an impregnation method, are most likely characterized by a large amount of Pd deposited deeply inside the pores of the alumina and in such a way that the contact with the Pd–RVC matrix is hindered.

Kinetics

The ECH process of phenol in the presence of commercially available Pd/Al$_2$O$_3$ (5% w/w) results in the formation of cyclohexanone and, further, cyclohexanol (Fig. 7). The amount of cyclohexanone is at its maximum for a charge of ~200 C, with the phenol being almost completely exhausted. For a charge (Q) larger than 200 C, the larger the Q, the larger the amount of cyclohexanol and the lower the amount of cyclohexanone. If the amount of palladium is 10% w/w rather than 5% w/w, the current efficiency of the cyclohexanol production remains practically unchanged (Table 2).

The ECH of phenol, made with the catalytic powder produced by PVD (0.25% of Pd w/w), shows a significant activity despite the low amount of metal present at the surface. However, the rate of ECH is lower compared with that for the commercials powders (Fig. 8). The higher ECH yield observed with the commercial powder is attributed to lower hydrogen flow rate, the hydrogen evolution reaction being in competition with the ECH reaction.

Since alumina is slightly soluble in alkaline solution and BaSO$_4$ is not, the effect of pH over a range of 4.1 to 14.0 on the kinetics of phenol ECH was investigated with BaSO$_4$ as the adsorbent (Fig. 9). The rate of the reaction is considerably lower at pH 14.0 — by a factor of 25 — in comparison with the rates at pH 7.0 and 4.1. The adsorption ability of the matrix is linked to the nature of the molecules (ionized or not) present in the solution. In a basic media, phenol is in the phenolate form, which has a strong affinity for polar solvents, and the adsorption of phenol is sluggish; hence phenol adsorption becomes the rate-limiting step for the ECH process. The picture is different at pH 7.0 and below since phenol is principally in its molecular form (pK_a 9.9), and the adsorption is greatly promoted. In addition, the phenolate form most likely induces the enhancement of the resonance, which in return renders the ECH of phenol more difficult.

[c]No agglomeration. Those powders were not further used for the ECH process.

[d]The agglomeration was not complete in the sense that some particles were remaining in the solution. Those powders were not further used for the ECH process.

[e]The particles were completely agglomerated in the electrode, i.e., the solution was becoming very clear.

[f]Catalyst synthesized by PVD.

[g]Specific surface calculated in cm^2 per cm^3.

In acidic media, the rate of the phenol ECH is unchanged in comparison with the rate in neutral media. The difference recorded between the production of cyclohexanol and cyclohexanone can be explained by the hydrogen evolution reaction (HER), which is favoured in acidic media. Hence, the cyclohexanol production is retarded because the Heyrovsky and (or) the Tafel steps (eqs. [5] and [6] below) for the hydrogen evolution are easier.

In Table 2, the remaining concentration of phenol during its electrohydrogenation is expressed against Q for different electrode materials. The main features are: (*i*) in the presence of the bare RVC matrix, the rate of the ECH process is marginal; (*ii*) in the presence of an RVC electrode entirely covered with Pd metal, the rate of ECH is very slightly improved; (*iii*) the activity towards the ECH increases in the following order: $Pd/BaCO_3$ (5%) < $Pd/BaSO_4$ (5%) < Pd/Al_2O_3 (5–10%). Alumina is recognized as an efficient adsorbent for organic molecules; this is ascribed to the presence of aluminum sites (15), which become the Lewis sites. For a given amount of palladium, it is deduced that the adsorption of organic compounds is lower for $BaSO_4$ and $BaCO_3$ in comparison with Al_2O_3.

It is generally admitted that the noble metals possess the ability to generate hydrogen and to adsorb unsaturated mole-

Fig. 4. Galvanostatic traces of agglomerated electrodes without any catalyst (curve A, ▲ and C, ●) and with Pd/Al$_2$O$_3$ 5%[*] (curve B, ▲ and D, ●). Both curve C and D are RVC mercury plated. Solution T = 21°C, pH 7, applied current time = 10 s. [*]Commercially available.

cules (16). Since the phenol electrohydrogenation may not be carried out on a Pd foil, it is tentatively deduced that the adsorption of the unsaturated organic molecule on Pd is marginal.

Assuming that Pd deposited onto the oxide surface possesses marginal specific adsorptive properties, the choice of the adsorbent becomes of prime importance. The existence of such a discrimination between the adsorbent and the metal (adlineation point) in catalytic hydrogenation was previously suggested by Maxted and Ali (17). Later, Chou and Vannice (18) refer to the adlineation point to explain their

results on the gas-phase hydrogenation of benzene. Similarly, in HEC, a discrimination between the adsorption sites (A) and the metallic sites (M) was proposed to explain the ECH process on composite materials, i.e., a metal deposited onto an oxide. The mechanism proposed for the electrohydrogenation of unsaturated bonds is described by eqs. [1]–[4]. First, electrosorbed hydrogen is formed on the metallic aggregates by reduction of water (eq. [1], where (H)$_{ads}$M is the electrosorbed hydrogen).

Hydrogenation of the C=C bond then proceeds as in catalytic hydrogenation, i.e., by the reaction of the adsorbed substrate with the electrosorbed hydrogen (eq. [3], adsorption step shown in eq. [2]) at the adlineation point followed by the desorption of the product (eq. [4]). The adlineation point can be defined as the junction between the adsorbent and the metal; it is the site of the ECH process. For a given adsorbent, the larger the area related to the adlineation point, the higher the rate of the ECH reaction. It is relevant to point out that the efficiency of the ECH of a given organic compound depends also on the relative rates of the adsorption step, the hydrogenation step (eq. [3]), and the hydrogen desorption (eqs. [5] and [6]).

$$[5] \quad (H)_{ads}M + H_2O + M + e^- \rightarrow H_2 + 2OH^-$$

$$[6] \quad (H)_{ads}M + (H)_{ads}M \leftrightarrow H_2$$
The hydrogen desorption can be controlled by adjusting the current density at the electrode to optimize the current efficiency.

The effect of the adsorption process on the kinetics of the ECH is illustrated in Fig. 10. From the suggested ECH mechanisms, eq. [2], and the curves of Fig. 10, barium carbonate is considered a less efficient support for the adsorption of phenol than is barium sulphate. Both catalysts have the same amount of metal on the surface and have approximately the same specific surface area.

The use of a bare RVC matrix (Table 2, entry 1) shows no catalytic properties. The absence of metallic sites (M) and weak adsorptive properties between the RVC and phenol explain the poor yield of hydrogenation. We suspect that the phenol is practically not adsorbed onto vitreous carbon unless it is modified with an organic functional group (19–21).

By controlling the chemical nature of the adsorption sites and the metallic nanoaggregates, our goal is to tailor a cata-

pH 7.
lyst that has some selectivity for targeted molecules. Adsorption sites determine catalyst selectivity and influence the chemical nature of the collected organic products; this is in agreement with the views of Neri et al. (22). Neri uses the idea that the catalytic support plays a predominant role in phenol hydrogenation. Moreover, it was stated that hydrogenation occurs through the phenol adsorption onto the adsorption sites followed by transfer of the chemisorbed hydrogen.

However, the catalyst performance remains highly influenced by the kinetics of hydrogenation, which is highly influenced by the nature of the metal used. In this case, the adsorption is not the limiting step; the rate-determining step is the hydrogen transfer itself from the metal surface to the unsaturated molecule (eq. [6]).

Conclusion

The key parameters for the agglomeration process of catalytic powders are the catalyst particle size and the applied cathodic current. Composite electrode material powders of Pd nanoaggregates deposited onto oxide particles, which were different in nature, were characterized for the electrocatalytic hydrogenation of phenol. A model is proposed to explain the kinetics of the ECH, in which the sites for the adsorption of generated atomic hydrogen are the metallic sites (M) and the sites for the adsorption of the organic molecules to be hydrogenated are the oxide sites (A).

A novel synthesis of *N*-fluoroalkanesulfonyl-amidines using a three-component reaction

Shizheng Zhu, Yong Xu, and Guifang Jin

Abstract: A novel, general, and efficient multicomponent reaction of fluoroalkanesulfonyl azides, secondary amines, and carbonyl compounds for the synthesis of *N*-fluoroalkanesulfonylamidines is presented. This reaction gave a good yield of products under very mild reaction conditions.

Key words: multicomponent reactions, synthetic methods, *N*-fluoroalkanesulfonyl azide, *N*-fluoroalkanesulfonylamidine.

Résumé : On présente une nouvelle réaction générale, efficace et à plusieurs composants des azotures de fluoroalcane-sulfonyles avec une amine primaire et des composés carbonylés qui permet de faire la synthèse de *N*-fluoroalcanesulfo-nylamidines. Cette réaction s'effectue avec de bons rendements, dans des conditions réactionnelles très douces.

Mots clés : réactions à plusieurs composants, méthodes synthétiques, azoture de *N*-fluoroalcanesulfonyles, *N*-fluoroalca-nesulfonylamidine.

[Traduit par la Rédaction]

Introduction

Multicomponent reactions (MCRs), by virtue of their convergence, productivity, facile execution, and generally high yields of products, have attracted much attention from the vantage point of combinatorial chemistry (1). Of pivotal importance in this area are the isocyanide-based MCRs such as the versatile Ugi reactions (2–3).

In the context of our ongoing studies on the reaction of fluoroalkanesulfonylazide with the electron-rich olefines such as vinyl ether, enamines appeared attractive from the viewpoint of devising a novel MCR (4–5).

Prompted by the recent successful preparation of *N*-fluoroalkanesulfonylamidines from the reaction of fluoro-alkanesulfonyl azides **1** with the β-ketoester enamines or 1,2-dihydro-pyridines (6–8) (see Scheme 1), we reasoned that a three-component reaction (3-CR, i.e., the azide, amine, and the carbonyl substrate) would be workable.

It is well known that enamine compounds are formed by treatment of the carbonyl compound with a secondary amine; in this reaction, the equilibrium between the enamine and the carbonyl compound should go forward if the added azide **1** could react fast enough with the enamine.

Experiment section

Typical procedure for the preparation of 4 and 6

N′-Perfluorobutanesulfonyl-N,N-cyclo(ethyleneoxyethylene)-cyclopentanamidine (4a)

To a solution of cyclohexanone **2a** (0.118 g, 1.2 mmol) and morpholine (0.113 g, 1.3 mmol) in absolute Et$_2$O (5 ml),

fluoroalkanesulfonyl azide **1a** (0.325 g, 1.0 mmol) was added dropwise with magnetic stirring at room temperature. The reaction was completed after 5 h (monitored by TLC). After removal of solvent, the residue obtained was purified by column chromatography (petroleum ether:EtOAc, 6:1, R_f = 0.42) to give the pure product **4a** (colorless oil) (0.357 g, 77%).

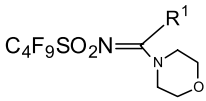
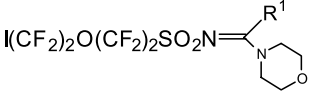
Results and discussion

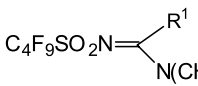
The result of our investigations are presented here.

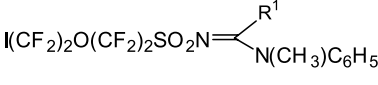
Initially, fluoroalkanesulfonyl azide **1a** was added slowly to a solution of morpholine **2a** and cyclohexanone **3a** in dry toluene at room temperature; TLC analysis showed that the reaction was finished in 5 h. The one-carbon ring contraction condensation product **4a** was obtained in 66% yield (see Scheme 2). Its structure was fully characterized by spectral methods and elemental analysis. Other solvents such as ben-

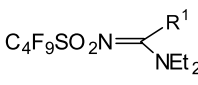
zene, THF, and ether were also suitable for this reaction, and it was found that the reaction gave the best yield in diethyl ether. For example, when the reaction of **1a** with **2a** and **3a** were carried out in Et$_2$O, the yield could be increased to 77%.

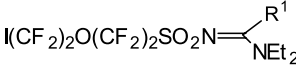
The three component reactions were found to be general and efficient. The amine used could be cyclic, such as morpholine and pyrrolidine, or acyclic, such as *N*-methyl aniline or diethylamine, etc. It should be noted that the less reactive tosyl azide **1c** can also react with **2** and **3** to give the corresponding *N*-tosyl-substituted amidine in the presence of actived 4 Å molecular sieves (see Scheme 2).


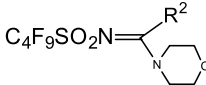


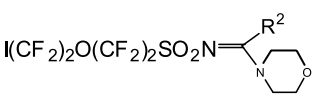


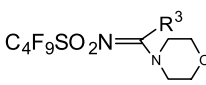


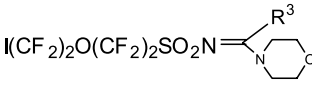


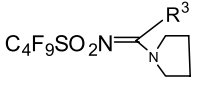


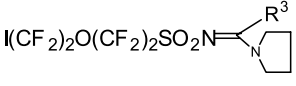


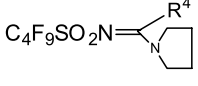


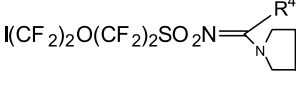


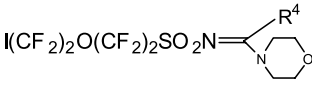


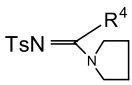


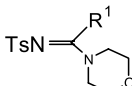












To further explore the scope of this reaction, we have extended it to other carbonyl substrates. We found that the acyclic ketone and aldehydes such as 3-pentanone and isobutylaldehyde were readily present in this reaction; in the case of the aldehyde, the reaction occurred more rapidly: it finished in 1 h (Scheme 3).

A possible reaction pathway is shown in Scheme 4.

All the reaction results are summarized in Table 1.

[a] Isolated yield

[b] 0.4 g of activated 4 Å MS is added for 1 mmol azides **1**.

In conclusion, we uncovered a novel and efficient multi-component reaction of fluoroalkanesulfonyl azides, secondary amines, and carbonyl compounds for the synthesis of *N*-fluoroalkanesulfonylamidines. This reaction also conforms to the principle of green chemistry and atom economics, as the by-products are water and nitrogen gas and, also, the solvent can be reused.

Synthesis and in vitro reactivity of *cis*-dichloro-(pyridin-2-ylcarboxaldimine)platinum(II) complexes with DNA

Liliya G. Nikolcheva, Christopher M. Vogels, R. Alexandra Stefan, Hanni A. Darwish, Stephen J. Duffy, Robert J. Ireland, Andreas Decken, Robert H.E. Hudson, and Stephen A. Westcott

Abstract: Five platinum pyridin-2-ylcarboxaldimine complexes of the type *cis*-[PtCl$_2$(2-C$_5$H$_4$NCH=NR)] (R = CH$_2$CH$_2$OH (**1**); R = N(CH$_2$CH$_2$)$_2$O (**2**); R = C$_6$H$_5$ (**3**); R = 1-C$_{10}$H$_7$ (**4**); R = (CH$_2$)$_8$CH=CH(CH$_2$)$_7$CH$_3$ (**5**)) were prepared and their in vitro reactivity towards a 20-base pair (single- and double-stranded) DNA determined using nuclease digest studies and RP-HPLC. Variation of the imine functionality allowed for the design of compounds with different physical and chemical properties. Complexes **1** and **3** showed binding to both single- and double-stranded DNA comparable to that of cisplatin (*cis*-[PtCl$_2$(NH$_3$)$_2$]). Crystals of **1** were monoclinic, space group *P*2(1)/*n*, *a* = 9.6612 (15), *b* = 12.9678 (19), *c* = 9.7004(13) Å, β = 117.73(3)°, *Z* = 4.

Key words: platinum, pyridin-2-ylcarboxaldimines, DNA binding studies.

Résumé : On a préparé cinq complexes de pyridin-2-carboxaldimine et de platine du type *cis*-[PtCl$_2$(2-C$_5$H$_4$NCH=NR)] (R = CH$_2$CH$_2$OH (**1**); R = N(CH$_2$CH$_2$)$_2$O (**2**); R = C$_6$H$_5$ (**3**); R = 1-C$_{10}$H$_7$ (**4**); R = (CH$_2$)$_8$CH=CH(CH$_2$)$_7$CH$_3$ (**5**)) et, faisant appel à des études de « RP-HPLC » et de digestion par une nucléase, on a évalué leur réactivité in vitro une molécule d'ADN à vingt paires de bases (à simple et à double brin). La variation de la fonction imine a permis de mettre au point des composés ayant des propriétés physiques et chimiques différentes. La fixation des complexes **1** et **3** à l'ADN à simple et à double brin semble être comparable à celle du cisplatine, *cis*-[PtCl$_2$(NH$_3$)$_2$]. Les cristaux du composé **1** sont monocliniques, groupe d'espace *P*2(1)/*n*, avec *a* = 9,6612(15), *b* = 12,9678(19) et *c* = 9,7004(13) Å, β = 117,73(3)° et *Z* = 4.

Mots clés : platine, pyridin-2-ylcarboxaldimines, études de fixation à l'ADN.

Introduction

Cisplatin (*cis*-[PtCl$_2$(NH$_3$)$_2$]) and a few related platinum-based complexes such as carboplatin and oxaliplatin are currently used as cancer therapeutic agents and exhibit particular effectiveness against testicular and ovarian malignancies (1–15). The mechanism of action of this family of drugs is believed to arise primarily from their interactions with DNA. The platinum center reacts with the N-7 position of purine bases, especially guanine, commonly resulting in the formation of 1,2-intrastrand adducts. This interaction can severely distort the DNA duplex geometry and it is believed that these structural distortions are responsible for altered DNA – protein interactions, which ultimately cause programmed cell death (13). There are several limitations to cisplatin therapy, however, such as neural and kidney toxicity as well as intrinsic and acquired resistance of tumor cells to the drug (14). These complications have spurred further research in the development of platinum-based complexes that are less toxic than cisplatin and show enhanced specificity towards cancer cells.

Since structural analogues of cisplatin react with DNA in a way similar to the parent drug, a new platinum drug candidate should demonstrate unique biological activity that eliminates multifactorial drug resistance. Therefore, considerable research has focused on designing platinum complexes that do not follow the classical structure–activity relationships for cisplatin analogues. Indeed, recent studies have shown that *cis*-amminedichloro(2-methylpyridine)platinum(II) (AMD473 or ZD0473, Fig. 1) shows considerable cytotoxicity in cisplatin-resistant cell lines (15, 16). Steric crowding from the methyl group is believed to decrease the rates of hydrolysis and substitution reactions of AMD473 thereby permitting high selectivity in binding with DNA (17). Toward this goal, we have begun to develop AMD473

Fig. 1. AMD473 (ZD0473).

analogues by replacing the NH_3 group with a pendant imine group. Varying the imine functionality allows us to design compounds with a wide range of physical and chemical properties that may provide steric congestion around the platinum atom (18). As well, the use of didentate ligands prevents trans-labilization and undesired displacement of the ligands by sulfur and nitrogen donors in biomolecules, interactions believed responsible for some of the adverse side effects associated with cisplatin (12). We report herein our initial results on the synthesis and in vitro testing of the DNA-binding properties of five *cis*-dichloro(pyridin-2-ylcarboxaldimine)platinum(II) compounds with various physical properties.

Experimental

Reagents and solvents used were obtained from Aldrich Chemicals. Platinum salts were obtained from Precious Metals Online Ltd. NMR spectra were recorded on a JEOL JNM-GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 270 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis II FT-IR spectrometer and reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Desert Analytics (Tucson, AZ). All reactions were carried out in the air and products are stable indefinitely under such conditions.

General procedure for the preparation of complexes 1–5

The pyridin-2-ylcarboxaldimines were prepared by the addition of equimolar amounts of the primary amine and 2-pyridinecarboxaldehyde in CH_2Cl_2 containing 4 Å molecular sieves. Filtration and removal of the solvent under vacuum afforded the desired ligand. The corresponding pyridin-2-ylcarboxaldimine (0.55 mmol) was then dissolved in 5 mL of CH_2Cl_2 and added drop-wise to a stirred solution of $[PtCl_2(coe)]_2$ (0.25 mmol, coe = *cis*-cyclooctene) in 10 mL of CH_2Cl_2 at 0°C. The resulting precipitate was collected by suction filtration and washed with CH_2Cl_2 (2 mL), hexane (3 × 5 mL), and Et_2O (3 × 5 mL) and dried under vacuum. Complex **3** was prepared as described previously (18). Complex **5** was isolated by removing solvent followed by an Et_2O (3 × 5 mL) trituration.

corrected for absorption (20). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (21). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically.

Nuclease digest studies

Binding of the platinum complexes to DNA was investigated using enzymatic degradation of the DNA to nucleosides. The sequence of the model 20-base pair DNA strand used in this study (eq. [1]) has two predominant cisplatin-binding sites, TGGT on one strand and AGGA on the complementary strand. Both the single and the double DNA strands were incubated with each platinum complex in a 1:3 DNA:Pt molar ratio at 37°C for 24 h in the dark. Samples (2.0 nmol of single-stranded and 1.0 nmol of double-stranded DNA) were digested in series with DNAse I (Amersham Biosciences, 36 U for 4 h), nuclease P1 (Sigma, 12.5 U for 18 h), and alkaline phosphatase (Promega, 20 U for 4 h) at 37°C to convert the DNA strand into mononucleosides. The samples were heated to 90°C for 2 min, centrifuged at 10 000 g for 30 s and the protein pellet discarded. The nucleoside composition in each sample was analyzed at 254 nm on a C_{18} column on a Pro-Star RP-HPLC (Varian). The isocratic solvent system used was 93% [Et$_3$NH][OAc] (20 mM, pH 6.5) and 7% CH$_3$CN at 1 mL min^{-1}. The areas under the nucleoside peaks were inte-

Results and discussion

Addition of a primary amine to commercially available 2-pyridinecarboxaldehyde affords the corresponding pyridin-2-ylcarboxaldimine ligand in high yield (11–18, 22–31). Variation of the amine allows for the facile design of ligands and platinum complexes with different physical and chemical properties. In this study, the metal complexes **1**–**5** (Fig. 2) were prepared by the addition of the pyridin-2-ylcarboxaldimine ligands to CH_2Cl_2 solutions of $[PtCl_2(coe)]_2$ (coe = *cis*-cyclooctene) (32). The ethanol and morpholine derivatives, **1** and **2**, respectively, were prepared in an attempt to

increase the hydrophilicity of the metal complexes as compared to cisplatin. The low solubility of cisplatin in water results in the administration of relatively high doses of the drug and accounts for many of the toxic side effects. Conversely, **3**–**5** were designed to increase the lipophilic nature of the complexes (6). Indeed, the oleyl compound **5** is soluble in common organic solvents such as $CHCl_3$. Compounds **3** and **4** are of special interest as recent studies have shown that structurally similar planar or semiplanar chromophores, such as acridine derivatives, play an important role in the class of DNA-intercalating anticancer drugs (33). In fact, the platinum complex derived from aniline (**3**) has been previously shown to display considerable activity against the hormone-independent human mammary carcinoma cell line MDA-MB 231 (18).

Complexes **1**–**5** have been characterized by a number of physical methods, including multinuclear NMR spectroscopy. A significant downfield shift in the ^{1}H NMR is observed for the imine sp^2 proton upon coordination of the ligand to the metal center. For instance, the singlet at δ 8.37 ppm for the free oleyl amine derived ligand shifts to 8.74 ppm in complex **5**. Platinum satellites are also observed for this resonance (J_{H-Pt} = 97 Hz) upon complexation of the

Fig. 5. G:C ratios from the nuclease digests of single-stranded (A) and double stranded DNA (B). Mean values are ±95% CI (n = 10). ns = not significantly different from non-platinum control (p > 0.0001).
ligand to the metal. Similar trends are observed for the pyridine hydrogen α to the nitrogen atom as the chemical shift changes from δ 8.64 to 9.49 ppm ($J_{\text{H-Pt}}$ = 38 Hz).

Complex **1** has also been characterized by an X-ray diffraction study (Fig. 3). Crystallographic data are given in Table 1[3] and selected bond distances and angles shown in Table 2. The nitrogen—platinum bonds of 1.996(3) Å (pyridine) and 1.985(3) Å (imine) are similar to those reported in other iminopyridine platinum systems (34–36). Slightly longer Pt—N bond distances are observed in related five-coordinate Pt(II) (37, 38) and Pt(IV) complexes (39). The C(7)—N(8) distance is 1.282(4) Å which is in the range of accepted carbon–nitrogen double bonds (40). Although there is no considerable interaction of the hydroxy group with the metal center, as observed with AMD473, a network of hydrogen bonding is observed in the solid state with the OH group interacting with the Cl of an adjacent molecule (OH⋯Cl(1′) = 2.329 Å and O⋯Cl(1′) = 3.145 Å). Molecules are also linked by weak Pt(1)⋯N(8′) (3.561 Å) and Cl(1)⋯Pt(1′) (3.794 Å) interactions. Hydrogen bonding has been used recently to self-assemble related organometallic platinum complexes (41).

The efficacy of platinum complexes as anticancer agents is believed to arise, at least in part, from the ability of the metal center to coordinate to DNA. We therefore decided to examine the in vitro activity of complexes **1**–**5** with a well-studied 20-base pair DNA strand (42). This DNA model strand contains one preferential binding site in the single strand, a TGGT motif, and a second binding site (AGGA) on the complementary strand. The degree of platination can be quantified by enzymatically degrading the DNA strand and separating the mononucleosides and Pt-containing dinucleotides using RP-HPLC (43–45). A typical chromatogram of nuclease digests derived from the double-stranded DNA treated with cisplatin is shown in Fig. 4. Cytosine is not affected by platination and is used as an internal standard so a decrease in the G:C ratio indicates a decrease in the amount of free guanosine. The amount of free guanosine can therefore be inversely correlated to the degree of platination, as binding will result in the formation of cis-$[\text{Pt}(\text{NH}_3)_2\{\text{d}(\text{GpG})\}]$ (1).

Complexes **1**–**5** were examined for their activity against both single- and double-stranded DNA, the results of the nuclease digest studies are shown in Fig. 5. Although the long-chain oleyl derivative **5** did not show significant binding to either type of strand, complexes **2** and **4** showed a small degree of binding specific to single-strand DNA. This selectivity is interesting as highly proliferating populations of cancer cells replicate their DNA continuously and are often in the single-stranded form, whereas in a normal healthy cell the usual state of DNA is the double-stranded form. As expected (18), complex **3** showed binding similar to that observed for cisplatin. More remarkable, however, is the observation that ethanol complex **1** also showed significant binding to both single- and double-stranded DNA, comparable to that observed for the control cisplatin. It is plausible that hydrogen bonding plays a role in how this complex interacts with DNA. These results show that complexes **1**–**5** show various degrees of binding to DNA. Future studies in this area will therefore relate the biochemical activities of these complexes to their cytotoxicities against cisplatin-sensitive and cisplatin-resistant cells. We are also investigating other iminopyridine analogues of AMD473, the results of which will be published in due course.

Solid-state ^{25}Mg NMR, X-ray crystallographic, and quantum mechanical study of bis(pyridine)-(5,10,15,20-tetraphenylporphyrinato)magnesium(II)

Gang Wu, Alan Wong, and Suning Wang

Abstract: We report solid-state ^{25}Mg NMR, X-ray crystallographic, and quantum-mechanical calculation results for bis(pyridine)(5,10,15,20-tetraphenylporphyrinato)magnesium(II), Mg(TPP)·Py$_2$. Mg(TPP)·Py$_2$ crystallizes in the triclinic form, in the space group $P\bar{1}$. The unit cell parameters are: $a = 9.6139(13)$ Å, $b = 11.0096(16)$ Å, $c = 11.8656(15)$ Å; $\alpha = 102.063(3)°$, $\beta = 103.785(3)°$, $\gamma = 114.043(2)°$; $Z = 1$. The Mg(II) ion is coordinated to four nitrogen atoms from the porphyrin ring and two nitrogen atoms from the axial pyridine ligands, forming a regular octahedron. The ^{25}Mg quadrupole coupling constant (C_Q) is 15.32 ± 0.02 MHz, which represents the largest value so far observed for ^{25}Mg nuclei. The electric field gradient tensor at the Mg site is axially symmetric, $\eta_Q = 0.00 ± 0.05$. The ^{25}Mg chemical shielding anisotropy is too small to be accurately determined. Quantum-mechanical calculations using a 6–31G(d) basis set reproduce reasonably well the observed ^{25}Mg NMR data for Mg(TPP)·Py$_2$. The calculations also suggest that the span of the ^{25}Mg chemical shift tensor is less than 50 ppm. Using a theoretical approach, we also investigate the dependence of the ^{25}Mg quadrupole coupling constant on the Mg—N$_{ax}$ bond distance. The calculation suggests that the ^{25}Mg quadrupole coupling constant for an Mg(II) ion at the center of a porphyrin ring without axial ligands is approximately 22 MHz, which may be treated as an upper limit of the ^{25}Mg quadrupole coupling constant for all Mg–porphyrin complexes.

Key words: ^{25}Mg NMR, crystal structure, quantum chemical calculation, quadrupole parameter, tetraphenylporphyrin.

Résumé : Dans ce travail, on rapporte les résultats d'études RMN du ^{25}Mg, de diffraction des rayons X et de calculs théoriques de mécanique quantique sur la bis(pyridine)(5,10,15,20-tétraphénylporphinato)magnésium(II), Mg(TPP)·Py$_2$. Le Mg(TPP)·Py$_2$ cristallise dans la forme triclinique, groupe d'espace $P\bar{1}$, avec $a = 9,6139(13)$ Å, $b = 11,0096(16)$ Å et $c = 11,8656(15)$ Å; $\alpha = 102,063(3)°$, $\beta = 103,785(3)°$ et $\gamma = 114,043(2)°$ et $Z = 1$. L'ion Mg(II) est coordiné à quatre atomes d'azote du noyau porphyrine et à deux atomes d'azote des ligands pyridine axiaux et il forme un octaèdre régulier. La constante de couplage quadripolaire du ^{25}Mg (C_Q) est de 15,32 ± 0,02 MHz, ce qui correspond à la valeur la plus élevée jusqu'à maintenant pour le noyau ^{25}Mg. Le tenseur du gradient du champ électrique au niveau du site Mg présente une symétrie axiale avec $\eta_Q = 0,00 ± 0,05$. L'anisotropie de blindage chimique du ^{25}Mg est trop faible pour être mesurée de façon fiable. Des calculs de mécanique quantique effectués à l'aide d'un ensemble de base 6-31G(d) permettent de reproduire raisonnablement les données observées par RMN du ^{25}Mg pour le Mg(TPP)·Py$_2$. Les calculs suggèrent aussi que la plage du tenseur du déplacement chimique du ^{25}Mg est inférieure à 50 ppm. Faisant appel à une approche théorique, on a aussi étudié la dépendance de la constante de couplage quadripolaire du ^{25}Mg sur la longueur de la liaison Mg—N$_{ax}$. Les calculs suggèrent que la constante de couplage quadripolaire du ^{25}Mg pour l'ion Mg(II) au centre d'un noyau porphyrine sans ligands axiaux est d'environ 22 MHz, ce qui peut être considéré comme une limite supérieure pour la constante de couplage quadripolaire du ^{25}Mg pour tous les complexes Mg–porphyrine.

Mots clés : RMN du ^{25}Mg, structure cristalline, calculs de mécanique quantique chimique, paramètre quadripolaire, tétraphénylporphyrine.

Introduction

Metalloporphyrins have been extensively studied for many years because of their biological and catalytic functions (1–3). Several spectroscopic techniques such as EPR (4), NMR (5), and Mössbauer spectroscopy (6) have been used to di-rectly probe the metal centers in metalloporphyrin systems. Magnesium porphyrins represent an important class of metalloporphyrin compounds because of their relevance to chlorophyll (7). Until now it has not been possible to di-rectly study the Mg(II) ion in Mg–porphyrin complexes by ^{25}Mg (spin: –5/2) NMR. The ^{25}Mg nucleus is among a group

of low-γ quadrupolar nuclides that are known to be notoriously difficult to study by NMR. Although solution ^{25}Mg NMR techniques have been applied to many chemical and biological systems, including proteins and nucleic acids (8), the scope of applications is severely restricted to cases where either the cation exchange is fast or the Mg(II) ion is at a symmetrical site, avoiding the unfavorable consequence of rapid ^{25}Mg quadrupolar relaxation. When an Mg(II) ion is tightly bound to a biological macromolecule, the molecular rotational correlation time of the complex is determined by the macromolecule and may be on the order of tens of nanoseconds. Under such a circumstance, the quadrupolar relaxation is so efficient that ^{25}Mg NMR signals may become too broad to be detected.

With recent advances in NMR methodology and high-field magnet technology, solid-state NMR has been recognized as a viable technique for studying half-integer quadrupolar nuclei. Previous solid-state ^{25}Mg NMR studies have almost exclusively focused on inorganic systems (9). In addition, all reported ^{25}Mg nuclear quadrupole coupling constants are relatively small (ca. <9 MHz). Recently, two research groups have extended solid-state ^{25}Mg NMR to organic systems. More specifically, Sham and Wu reported a solid-state ^{25}Mg NMR study of several Mg(II) coordination complexes (10). These compounds were used as models for inner-sphere Mg binding often found in nucleic acids. Frydman and co-workers obtained solid-state ^{25}Mg NMR spectra for an Mg(II) adenosine 5′-triphosphate (ATP) complex (11). These two studies demonstrate the great potential of solid-state ^{25}Mg NMR in probing the Mg(II) binding environment in biomolecular systems. In this paper we report the first set of solid-state ^{25}Mg NMR data for an Mg(II)–porphyrin system. To make the solid-state ^{25}Mg NMR experiment feasible, we prepared ^{25}Mg isotopically enriched bis(pyridine)(5,10,15,20-tetraphenylporphyrinato)magnesium(II), ^{25}Mg(TPP)·Py$_2$. We also determined the molecular and crystal structures of Mg(TPP)·Py$_2$ by single crystal X-ray crystallography. To better understand the ^{25}Mg NMR properties and to examine their relationship to molecular structure, we carried out extensive quantum mechanical calculations for the electric field gradient and chemical shielding tensors in two Mg–porphyrin systems.

Experimental details

Sample preparation

Labeled ^{25}Mg(ClO$_4$)$_2$ (272 mg) was prepared by dissolving 50 mg of ^{25}MgO (^{25}Mg 99.1%, purchased from Trace Science International, Toronto, Canada) in HClO$_4$(aq) and evaporating to dryness. The labeled ^{25}Mg(TPP)·Py$_2$ complex was prepared following the method described in the literature (12, 13). To a pyridine solution containing 310 mg of 5,10,15,20-tetraphenyl-21H, 23H-porphine (99+% obtained from Aldrich Chemicals Co., Canada) was added 225 mg of ^{25}Mg(ClO$_4$)$_2$. The solution was gently refluxed for 12 h in

Scheme 1.
darkness and then evaporated to dryness in a rotary evaporator. The resulting purple precipitate was then washed three times with cold distilled water. ^{1}H NMR (400.13 MHz, CDCl$_3$, 298 K) (ppm) δ: 8.92 (s, 8H, pyrrole), 8.26 (d, 8H, o-phenyl), 7.75 (m, 12H, m,p-phenyl), 7.07 (t, 2H, γ-pyridine), 6.49 (t, 4H, β-pyridine), 5.92 (d, 4H, α-pyridine). ^{13}C NMR (100.61 MHz, CDCl$_3$, 298 K) (ppm) δ: 150.25 (q, α-pyrrole), 146.93 (t, α-pyridine), 143.84 (q, i-phenyl), 135.87 (t, γ-pyridine), 134.68 (t, o-phenyl), 131.80 (t, β-pyrrole), 126.20 (t, m-phenyl), 127.03 (t, p-phenyl), 122.96 (t, β-pyridine), 121.65 (q, meso). The atomic labeling scheme is shown in Scheme 1.

Solid-state NMR

Solid-state ^{25}Mg NMR spectra were recorded on a Bruker Avance-500 (11.75 T) digital NMR spectrometer operating at 30.6 MHz for ^{25}Mg nuclei. The radio frequency (RF) field strength at the ^{25}Mg frequency was approximately 50 kHz. A single-channel wideline probe (5 mm insert) was used. A Hahn echo sequence (14) was employed to acquire static ^{25}Mg NMR spectra: $P_1(\phi 1) - \tau_1 - P_2(\phi 2) - \tau_2 - \text{Acq}(\phi 3)$, where $\phi 1$ = x, x, x, x, y, y, y, y, –x, –x, –x, –x, –y, –y, –y, –y; $\phi 2 = 4 \times$ (x, y, –x, –y); $\phi 3$ = –y, y, –y, y, –x, x, –x, x, y, –y, y, –y, x, –x, x, –x. The radio-frequency (RF) pulse widths were $P_1 = 1.50$ μs and $P_2 = 3.20$ μs. The delay between the two RF pulses, τ_1, was 400 μs. A much shorter delay was chosen between P_2 and acquisition ($\tau_2 = 30$ μs) so that a whole echo signal could be obtained. Recycle delays of 1 and 2 s were used. To record the very short-lived free induction decay (FID) signals, a 12-bit fast digitizer was used with a dwell time of 0.5 μs, corresponding to a spectral window of 1 MHz. A sample of MgO(s) was used as a secondary chemical-shift reference, δ = 26 ppm (15).

X-ray crystallography

Crystallographic data for Mg(TPP)·Py$_2$ were collected from a shiny red-purple, hexagonal-shaped crystal (0.1 mm × 0.2 mm × 0.4 mm) obtained by slow recrystallization from pyridine.[2] The X-ray diffraction data were col-

[2] Two tables containing hydrogen atom coordinates and anisotropic displacement parameters for Mg(TPP)·Py$_2$ have been deposited as supplementary data. Supplementary data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 205592 contain the supplementary data for this paper. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

lected on a Siemens P4 single-crystal diffractometer with graphite-monochromated Mo Kα radiation, operating at 50 kV and 40 mA at 296 K. Data were corrected for Lorentz and polarization effects and analyzed using the Siemens SHELXTL software package (16). The structure was solved by direct methods. Neutral atom scattering factors were taken from Cromer and Waber (17).

Quantum mechanical calculations

All quantum mechanical calculations were performed on a SunFire 6800 symmetric multiprocessor system (24 × 900 MHz processors and 24 GB of memory) using the Gaussian98 suite of programs (18). For each calculation, 4 or 8 processors were allocated. For ^{25}Mg EFG calculations, the following convention was used for the nuclear quadrupole coupling constant (C_Q) and the asymmetry parameter (η_Q):

$$[1] \qquad C_Q[\text{MHz}] = \frac{eQV_{ZZ}}{h} = -46.85 \times V_{ZZ} \text{ [au]}$$

$$[2] \qquad \eta_Q = \frac{V_{XX} - V_{YY}}{V_{ZZ}}$$

where V_{ZZ}, V_{YY}, and V_{XX} are the principal components of the EFG tensor ($|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$ and $V_{ZZ} + V_{YY} + V_{XX} = 0$). The coefficient in eq. [1] is obtained using the ^{25}Mg quadrupole moment value recommended by Pyykkö, $Q(^{25}Mg) = 19.94 \times 10^{-30}$ m^2 (19). The computed EFG tensor components are reported in atomic units (1 au = 9.717365 × 10^{21} V m^{-2}).

To calculate ^{25}Mg magnetic shielding tensors, the Gauge including atomic orbital (GIAO) method (20), as implemented in Gaussian98, was used. Because GIAO magnetic shielding calculations are in general more time consuming than EFG calculations, we employed a simplified molecular model to reduce computational time. In particular, the four phenyl groups in TPP were replaced by hydrogen atoms, resulting in a 59-atom model, which is significantly smaller than the total number of atoms in Mg(TPP)·Py$_2$, 99. To confirm the validity of the 59-atom model, we performed several tests in which calculations were done for both the complete molecule and the simplified model. The shielding tensor results are essentially the same for both clusters, while the computational cost for the 59-atom model was significantly smaller than that for the 99-atom cluster. For example, the HF/6–311G(2d,p) calculation gave σ_{11} = 571, σ_{22} = 578, and σ_{33} = 616 ppm for the 59-atom model with a CPU time of 23 h. In comparison, the CPU time for the complete 99-atom molecule at the same level of theory was 84 h and the ^{25}Mg magnetic shielding tensor components were: σ_{11} = 571, σ_{22} = 578, and σ_{33} = 613 ppm. Therefore, we have assumed that the 59-atom model can be safely used for all shielding calculations.

Results and discussion

Crystal structure

Mg(TPP)·Py$_2$ crystallizes in triclinic form (space group, $P\bar{1}$). The Mg(II) ion is located at the origin (0, 0, 0), which is also the center of inversion. The Mg(II) ion, lying in the approximate porphyrin plane, is coordinated to six nitrogen

atoms in a distorted octahedral fashion. Detailed crystallographic data, atomic coordinates, and selected structural parameters are reported in Tables 1, 2, and 3, respectively. As shown in Fig. 1, the four equatorial nitrogen atoms are from the porphyrin moiety and the two remaining axial nitrogen ligands are pyridine molecules. The most important structural feature in Mg(TPP)·Py$_2$ is that the Mg—N$_{eq}$ bond lengths, 2.062 and 2.065 Å, are significantly shorter than that for the Mg—N$_{ax}$ bond, 2.369 Å. Several precedents exist in the literature for long Mg—N$_{ax}$ bonds in Mg–porphyrin systems. For example, the Mg—N$_{ax}$ bond length in Mg(TPP)·(piperdine)$_2$ is 2.419 Å (21). For Mg(octaethylporphyrin)·Py$_2$ and Mg(TPP)·(4-picoline)$_2$, the Mg—N$_{ax}$ bonds are 2.389 and 2.386 Å, respectively (21, 22), which are both very similar to that in Mg(TPP)·Py$_2$. In contrast, the Mg—N$_{ax}$ distance for Mg(TPP)·(1-methylimidazole)$_2$ is much shorter, 2.297 Å (21). Because in all these systems the Mg(II) ion is at the center of the porphyrin ring, not surprisingly, the Mg—N$_{eq}$ bond distances are essentially the same. The porphyrin core is slightly non-planar. The dihedral angle between the mean pyridine plane and the mean porphyrin plane is 70°. As seen from Fig. 1, the four phenyl groups exhibit two unique orientations with respect to the mean plane of the porphyrin core, 60 and 80°. Clearly, the two different orientations of the phenyl groups are related to the orientation of the pyridine ring. Other structural features regarding the TPP moiety are expected from previous examples.

Solid-state NMR

Figure 2a shows the time-domain ^{25}Mg free induction decay (FID) signal for a stationary powder sample of Mg(TPP)·Py$_2$. The whole echo can be clearly seen. As explained by Massiot et al. (23), the whole-echo approach leads to a signal-to-noise enhancement by a factor of $\sqrt{2}$. Figure 2b shows the direct FT of the whole echo. As expected, because of the long time delay used for obtaining the whole echo signal, a large phase distortion is present in the spectrum. This distortion can be readily corrected by a linear phase correction, as shown in Fig. 2c. The ^{25}Mg NMR central-transition spectrum observed for Mg(TPP)·Py$_2$ exhibits an extremely large line width, ca. 260 kHz at 11.75 T. Because the width of the NMR line shape is much larger than the strength of the B$_1$ field (50 kHz), line shape distortions are observed. To obtain accurate values of C_Q and η_Q, it is important to determine the precise positions of the spectral singularities in a powder pattern. To overcome the so-called "rolling off" effect from a relatively weak RF field, we obtained several spectra with the RF transmitter being set to different frequency positions. As shown in Fig. 3, the entire ^{25}Mg NMR line shape depends strongly on the position of the RF transmitter. For example, when the RF transmitter

was set close to one edge of the powder line shape, the other edge shows very low intensity, as a result of low RF excitation efficiency. Using the NMR spectra shown in Figs. 3a and 3c, we obtained $C_Q = 15.32 \pm 0.02$ MHz and $\eta_Q = 0.00 \pm 0.05$. These values were confirmed by analyzing an ^{25}Mg QCPMG NMR spectrum obtained at 9.40 T (data not shown). It is important to point out that the above ^{25}Mg quadrupole parameters were extracted from the static ^{25}Mg NMR spectra by considering the second-order quadrupole interaction alone. By comparing the spectra obtained at 11.75 and 9.40 T, we have estimated that the span of the ^{25}Mg chemical shielding tensor ($\Omega = \sigma_{33} - \sigma_{11}$) is less than 100 ppm for ^{25}Mg(TPP)·Py$_2$. This estimate is confirmed by quantum mechanical calculations, as described in the next section.

The ^{25}Mg quadrupole coupling constant observed for Mg(TPP)·Py$_2$ is significantly larger than all previously reported C_Q values for ^{25}Mg nuclei (9). Such a large C_Q value made it very challenging to record a satisfactory solid-state ^{25}Mg NMR spectrum for Mg(TPP)·Py$_2$. The observed axial symmetry for the EFG tensor is expected from the crystal structure where an approximate axial symmetry is present at the Mg site. Because of the extremely large line width of the static ^{25}Mg NMR spectrum, it is not possible to obtain a reliable value for the isotropic ^{25}Mg chemical shift. It is also worth noting that our attempt to record ^{25}Mg NMR spectra for Mg(TPP)·Py$_2$ in CDCl$_3$ solution was unsuccessful. This may be attributed to either the rapid relaxation due to a large ^{25}Mg quadrupole coupling constant or the fast ligand exchange in solution. It is also possible that both of these factors are operative. Assuming that the molecular rotational correlation for the complex is approximately 200 ps, the value of T_1 and T_2 was estimated to be 5.6 µs under the extreme narrowing condition. This was much shorter than the typical probe deadtime at low frequencies. This example further illustrates the advantage of solid-state NMR over traditional solution NMR for studying low-γ quadrupolar nuclei.

Quantum mechanical calculations

Because we have obtained both NMR and structural information for Mg(TPP)·Py$_2$, we decided to test whether quantum mechanical calculations can reproduce the experimental NMR parameters in this Mg–porphyrin system. This attempt is of particular interest because there has been no previous theoretical work on ^{25}Mg NMR parameters in organic systems. The paucity of theoretical studies on ^{25}Mg NMR parameters arises primarily from the fact that very little experimental ^{25}Mg NMR data are available because of the practical difficulties mentioned earlier. For comparison, we also studied a closely related Mg–porphyrin compound, Mg(TPP)·(1-MeIm)$_2$. Mg(TPP)·(1-MeIm)$_2$ crystallizes in the tetragonal space group $P4_2/n$ with $Z = 4$ (21). In this compound, the Mg(II) ion is also six-coordinated to nitrogen atoms. The Mg—N$_{eq}$ bonds, 2.082 and 2.074 Å, are very similar to those found in Mg(TPP)·Py$_2$. However, the Mg—N$_{ax}$ bond length in Mg(TPP)·(1-MeIm)$_2$, 2.297 Å, is much shorter than that in Mg(TPP)·Py$_2$, 2.369 Å. The calculated results for the ^{25}Mg quadrupole parameters and chemical shielding tensors in Mg(TPP)·Py$_2$ and Mg(TPP)·(1-MeIm)$_2$ are summarized in Tables 4 and 5. The data shown in Table 4 indicate that, for a given basis set, the EFG calcula-

tions at the Hartree–Fock (HF), B3LYP, and MP2 levels of theory show very similar results. The calculations using the 6–31G(d) basis set seems to give the best agreement between the calculated and observed ^{25}Mg quadrupole parameters. The C_Q values for Mg(TPP)·(1-MeIm)$_2$ are consistently smaller than those for Mg(TPP)·Py$_2$ by approximately 3–4 MHz. This is attributed to the shorter Mg—N$_{ax}$ bond length in Mg(TPP)·(1-MeIm)$_2$ (vide infra). Because no abso-

Fig. 3. Experimental (*a*, *b*, *c*) and simulated (*d*) ^{25}Mg NMR spectra for ^{25}Mg(TPP)·Py$_2$. The spectral widow for each of the above spectra was 1 MHz. The arrows indicate the positions to which the RF transmitter was set. The dashed lines indicate the singularities of the powder line shape. Detailed experimental parameters are: (*a*) transmitter offset = 2700 ppm, 1 s recycle delay, 237 788 transients; (*b*) transmitter offset = –3000 ppm, 1 s recycle delay, 425 216 transients; (*c*) transmitter offset = –5000 ppm, 1 s recycle delay, 339 773 transients.

lute shielding scale for ^{25}Mg is available in the literature, we decided to compute the chemical shielding constant for the referencing species, $[Mg(H_2O)_6]^{2+}$. Using the shielding constant for $[Mg(H_2O)_6]^{2+}$, σ_{ref}, we were able to convert the calculated shielding values for Mg(TPP)·Py$_2$ and Mg(TPP)·(1-MeIm)$_2$ into the "chemical shifts", $\delta_{iso} = \sigma_{ref} - \sigma_{iso}$. The geometry of $[Mg(H_2O)_6]^{2+}$ was obtained by a full geometry optimization at the MP2/6–311G(d,p) level. The Mg—O distance is 2.105 Å and the O—H bond is 0.963 Å. The H-O-H angle for the water molecule is 105.3°. The $[Mg(H_2O)_6]^{2+}$ species has an O_h point group symmetry. To avoid the ap-

parent basis set dependence, we obtained σ_{ref} for each basis set. As seen from Table 5, the GIAO shielding calculations indicate that the span of the ^{25}Mg chemical shielding tensor, $\Omega = \sigma_{33} - \sigma_{11}$, can be safely estimated to be less than 50 ppm for Mg(TPP)·Py$_2$. At 11.75 T, the line width contribution from a chemical shielding anisotropy of this magnitude would be expected to be less than 1.5 kHz in ^{25}Mg NMR spectra. Since the experimental ^{25}Mg NMR spectrum for Mg(TPP)·Py$_2$ is 260 kHz wide at 11.75 T, it is not surprising that the ^{25}Mg chemical shielding anisotropy can be ignored in our spectral analysis. For the same reason, it was also impossible to obtain experimentally a meaningful estimate for the isotropic ^{25}Mg chemical shift for Mg(TPP)·Py$_2$. The GIAO shielding calculations suggest that the isotropic ^{25}Mg chemical shift for an Mg(II) ion coordinated to six nitrogen ligands is approximately 10–20 ppm. We believe that this estimate is reasonably accurate; however, to our knowledge, no experimental ^{25}Mg NMR data are available for six-coordinate MgN$_6$ species.

Another piece of useful information obtained from the quantum mechanical calculations is the orientation of the

NMR tensors in the molecular frame of reference. Figure 4 shows the orientations of both EFG and chemical shielding tensors for the ^{25}Mg nucleus in Mg(TPP)·Py$_2$. The largest EFG tensor component, V_{ZZ}, is 5.3° off the Mg—N$_{ax}$ bond direction. The smallest EFG component, V_{XX}, lies approximately in the porphyrin plane, making an angle of 58.6° with respect to one of the Mg—N$_{eq}$ bonds. The chemical shielding tensor exhibits essentially the same orientation as the EFG tensor. In particular, the tensor component with the most shielding, σ_{33}, is approximately 7.5° off the Mg—N$_{ax}$ direction, while the tensor component with the least shielding, σ_{11}, lies in the porphyrin plane and makes an angle of 45.6° relative to the same Mg—N$_{eq}$ bond described for the EFG tensor.

As mentioned earlier, one obvious structural feature that might be responsible for the observation of a large C_Q value at the Mg center in Mg(TPP)·Py$_2$ is the large difference between Mg—N$_{eq}$ and Mg—N$_{ax}$ distances. To further explore the influence of the Mg—N$_{ax}$ bond on the EFG at the Mg center, we performed a series of EFG calculations for a model where the position of the axial pyridine ligands is systematically varied. The geometry of the porphyrin core in

the model is identical to that in Mg(TPP)·Py$_2$. The results are shown in Table 6 and depicted in Fig. 5. It is interesting to see that the value of C_Q increases monotonically with the increase of Mg—N$_{ax}$ bond distance. As shown in Table 6, the calculation also gave an estimate for an Mg(II) ion in a square-planar binding geometry, $C_Q \approx 22$ MHz. At 11.75 T, this C_Q value would correspond to a central-transition ^{25}Mg NMR spectrum two times wider than the one shown in Fig. 2c. On the basis of these results, we believe that many Mg–porphyrin complexes should be accessible by solid-state ^{25}Mg NMR at currently available high magnetic fields (from 11.75 to 21.15 T).

It is also of interest to compare the EFG tensor observed for Mg(TPP)·Py$_2$ with those reported for two isostructural TPP complexes, Fe^{II}(TPP)·Py$_2$ and Co^{III}(TPP)·Py$_2$. From a Mössbauer experiment, Kobayashi et al. (24) reported an ^{57}Fe quadrupole splitting for Fe^{II}(TPP)·Py$_2$ (low spin) at 300 K, $\Delta E_Q = 1.22$ mm s^{-1}. This quadrupole splitting corresponds to $V_{ZZ} = 0.75$ au, assuming $Q(^{57}$Fe$) = 16.0 \times 10^{-30}$ m^2. This EFG value is much larger than the corresponding value found at the Mg nucleus in Mg(TPP)·Py$_2$, $V_{ZZ} = 0.3202$ au. As illustrated in Fig. 5, the V_{ZZ} value is a function of the

Fig. 4. Orientations of the ^{25}Mg EFG tensor (top) and the chemical shielding tensor (bottom) in the molecular frame of Mg(TPP)·Py$_2$. Quantum mechanical calculations were done at the HF/6–31G(d) level.

^{a}Calculated without axial ligands.

Fig. 5. Calculated dependence of $C_Q(^{25}$Mg) on the Mg—N$_{ax}$ bond length in Mg(TPP)·Py$_2$. The dashed line indicates the $C_Q(^{25}$Mg) value for an Mg–(TPP) complex without axial ligands.
Conclusion

We have reported solid-state ^{25}Mg NMR, crystallographic, and computational results for an Mg(II)–porphyrin complex, Mg(TPP)·Py$_2$. The ^{25}Mg quadrupole coupling constant observed for Mg(TPP)·Py$_2$, C_Q = 15.32 ± 0.02 MHz, is the largest so far reported for ^{25}Mg nuclei. The ^{25}Mg chemical shielding anisotropy is, however, too small to be measured reliably. We have performed quantum mechanical calculations for the ^{25}Mg NMR tensors in two related Mg–porphyrin complexes: Mg(TPP)·Py$_2$ and Mg(TPP)·(1-MeIm)$_2$. Quantum mechanical calculations were carried out at various levels of theory including restricted Hartree–Fock, density functional theory, and MP2 with different basis sets. The calculations with a 6–31G(d) basis set have reproduced reasonably well the observed ^{25}Mg NMR data for Mg(TPP)·Py$_2$. The calculations also suggest that the span of the ^{25}Mg chemical shift tensor is less than 50 ppm for Mg(TPP)·Py$_2$.

To obtain an upper limit for the ^{25}Mg quadrupole coupling constant in Mg–porphyrin systems, we have performed quantum mechanical calculations for an Mg(II) ion at the center of a porphyrin moiety without axial ligands, which represents the most asymmetrical environment for the Mg cation. For such a model, the ^{25}Mg quadrupole coupling

M—N$_{ax}$ distance. In Fe^{II}(TPP)·Py$_2$, however, the Fe—N$_{ax}$ bond length, 2.039 Å, is similar to the Fe—N$_{eq}$ bonds, 1.989 and 1.997 Å (25). This immediately suggests that the d^6 metal TPP complexes behave differently as the Mg—TPP compounds. In Co^{III}(TPP)·Py$_2$, the V_{ZZ} value at the metal center is 0.167 au, as reported by Medek et al. from a solid-state ^{59}Co NMR study (5g). This value is much smaller than that in Fe^{II}(TPP)·Py$_2$. This may be explained by a general trend, in which the M—N$_{ax}$ distance is usually smaller in Co^{III}–TPP complexes than in Fe^{II}–TPP complexes (21). In this regard, the d^6 metal–TPP compounds exhibit a similar M—N$_{ax}$ dependence to that observed for Mg–TPP complexes.

constant is approximately 22 MHz. This may suggest that most of Mg(II)–porphyrin complexes should be accessible by high-field ^{25}Mg NMR. The present work represents the first solid-state ^{25}Mg NMR study for an Mg(II)–porphyrin system. Extension of this research to chlorophyll models is under way in this laboratory.

Insect toxins from spruce endophytes

John A. Findlay, Guoqiang Li, J. David Miller, and Taiwo O. Womiloju

Abstract: Extracts of fermentation cultures of a fungal endophyte (DAOM 221611) from spruce needles have afforded the known macrocyclic antibiotic vermiculin (**1**), 7α,8β,11-trihydroxydrimane (**2**), and eight novel 13-carbon γ-lactones, namely *trans*-3-methyldodec-*cis*-6-en-4-olide (**3**), *trans*-8-hydroxy-3-methyldodec-*cis*-6-en-4-olide (**4**), *trans*-8-acetoxy-3-methyldodec-*cis*-6-en-4-olide (**5**), *trans*-9-hydroxy-3-methyl-8-oxo-dodec-*trans*-6-en-4-olide (**6**), *trans*-8,9-dihydroxy-3-methyldodec-*ci*s-6-en-4-olide (**7**), *trans*-9-hydroxy-8-oxo-3-methyldodecan-4-olide (**8**), *trans*-7,9-dihydroxy-3-methyl-8-oxo-dodecan-4-olide (**9**), and *trans*-6-hydroxymethyl-3-methyl-7-oxo-undecan-4-olide (**10**). A known JH III metabolism product, 10,11-dihydroxyfarnesenic acid (**11**), was also isolated and synthesized from farnesol. Other endophyte cultures from black spruce and white spruce afforded the novel 6,7-dihydroxy-2-propyl-2,4-octadien-4-olide (**16**), 5,6,8-trihydroxy-4-(1′-hydroxyethyl) isocoumarin (**17**) plus the known sescandelin (**18**), sescandelin B (**19**), and 4-hydroxy-2-methoxyacetanilide (**20**). Several of the γ-lactones showed toxicity to spruce budworm (*Choristoneura fumiferana* Clem.) larvae and vermiculin **1** and compound **16** were toxic to spruce budworm cells.

Key words: toxigenic endophytes, insect toxins, γ-lactones, isocoumarins.

Résumé : L'extraction des milieux de cultures de fermentation d'un champignon endophyte (DAOM 221611) des aiguilles d'épinette a permis d'isoler la vermiculine (**1**), un antibiotique macrocyclique connu, le 7α,8β,11-trihydroxy-drimane (**2**) ainsi que huit nouvelles γ-lactones à 13 atomes de carbone, soit les *trans*-3-méthyldodéc-*cis*-6-én-4-olide (**3**), *trans*-8-hydroxy-3-méthyldodéc-*cis*-6-én-4-olide (**4**), *trans*-8-acétoxy-3-méthyldodéc-*cis*-6-én-4-olide (**5**), *trans*-9-hydroxy-3-méthyl-8-oxododéc-*cis*-6-én-4-olide (**6**), *trans*-8,9-dihydroxy-3-méthyldodéc-*cis*-6-én-4-olide (**7**), *trans*-9-hydroxy-8-oxo-3-méthyldodécan-4-olide (**8**), *trans*-7,9-dihydroxy-3-méthyl-8-oxododécan-4-olide (**9**) et *trans*-6-hydroxy-méthyl-3-méthyl-7-oxoundécan-4-olide (**10**). On a aussi isolé un produit connu de métabolisme JH III, l'acide 10,11-dihydroxyfarnésique (**11**) qu'on a synthétisé à partir du farnésol. D'autres milieux de cultures d'endophytes provenant d'épinettes noire ou blanche ont permis d'isoler de nouveaux produits, dont le 6,7-dihydroxy-2-propylocta-2,4-dién-4-olide (**16**) ainsi que la 5,6,8-trihydroxy-4-(1′-hydroxyéthyl)isocoumarine (**17**) en plus de produits connus comme la sescandéline (**18**), la sescandéline B (**19**) et le 4-hydroxy-2-méthoxyacétanilide (**20**). Plusieurs γ-lactones présentent de la toxicité pour les larves de la tordeuse des bourgeons d'épinette (*Choristoneura fumiferana* Clem.) alors que la vermiculine **1** et le composé **16** sont toxiques pour les cellules de la tordeuse des bourgeons d'épinette.

Mots clés : endophytes toxigènes, toxines d'insectes, γ-lactones, isocoumarines.

[Traduit par la Rédaction]

Recently, we reported that inoculation of white spruce, *Picea glauca* (Moench voss.), seedlings with a rugulosin-producing endophyte resulted in a significant reduction in larval growth rate of the destructive forest pest, the spruce budworm *Choristoneura fumiferana* Clem., in feeding experiments (1). This latter study followed from our pioneering discovery that some conifer needles are inhabited by insect-toxin-producing endophytes (2), consistent with the proposal of Carroll and Carroll that fungal endophytes recovered from conifer needles might be mutualistic symbionts (3). In our continuing studies in search of additional toxin-producing endophytic fungi from spruce needles we have encountered

cultures capable of producing an interesting array of novel γ-lactones (**3**–**10**), as well as 10,11-dihydroxyfarnesenic acid **11**, the macrocyclic antibiotic, vermiculin **1** (4), and the known sesquiterpene, 7α,8β,11-trihydroxydrimane **2** (5). Other spruce-needle-derived endophyte cultures gave the novel 2,4-dien-4-olide **16**, the novel isocoumarin **17**, plus the known sescandelin **18** (6), sescandelin B **19** (7), and 4-hydroxy-2-methoxyacetanilide **20** (Scheme 1). Both **18** and **19** have been previously isolated from the fungus *Sesquillium candelabrum*, and sescandelin **18** is reported to be a root-promoting agent (6). Compound **20** has recently been reported as a metabolite of a soil fungus (8).

The endophyte strain **5WS11I**, obtained from needles of a white spruce (*P. glauca* (Moench voss)), was cultured according to established protocols (9) using two different kinds of vessels. In the first case the fermentation was conducted in 250-mL Erlenmeyer flasks (2 L total), and in the second case Glaxo bottles (10 L total) were employed but no other changes in culturing procedures were made, and the fermentations proceeded simultaneously. The fermentation-medium filtrates were extracted with EtOAc, and crude extracts **E** (from Erlenmeyer flask culture) and **G** (from Glaxo bottle culture) were obtained by removal of solvent under vacuum

at room temperature. From the crude extract **G**, a number of γ-lactones **3–10** and the sesquiterpenes **11** and 7α,8β,11-trihydroxydrimane have been isolated and their structures elucidated by spectral data analyses. From the crude extract **E**, only the 16-membered ring dilactone, vermiculin, and 7α,8β,11-trihydroxydrimane were isolated. The antibiotic vermiculin was previously reported from *Penicillium vermiculatum* (4) and a soil fungus *Talaromyces wortmannii* (10) while the γ-lactones **3–10** are closely related to a γ-decalactone (11) and *cis*-6-dodecen-4-olide (12), fungal metabolites previously reported from the cultures of *Sporobolomyces odorus*. Sesquiterpene **11** was previously reported as a biotransformation product of the corresponding 10,11-epoxide, an insect juvenile hormone (JHIII) homologue (13),

and 7α,8β,11-trihydroxydrimane was isolated previously from the fungus, *Fomes annosus*, a destructive forest pathogen (5). Compounds **4**, **6–8**, **11** and 7α,8β,11-trihydroxydrimane **2** were toxic to spruce budworm in a larval feeding bioassay, and vermiculin **1** and **16** were toxic to budworm cells.

Compound **3** was isolated as an optically active, oily substance from a nonpolar fraction of the crude extract **G**. Its molecular formula, $C_{13}H_{22}O_2$, was determined by HR-EI-MS. The IR spectrum is consistent with the presence of a lactone carbonyl group (1780 cm^{-1}) and a vinyl group (1640 cm^{-1}), and the ^{13}C NMR and DEPT spectra (Table 1) indicate the presence of one carbonyl, four methines, six methylenes, and two methyls. A total of four downfield car-

bon signals are assigned to an ester carbonyl, a double bond, and an oxygenated methine carbon. The proton and carbon chemical shifts were assigned on the basis of analysis of ^{1}H NMR, ^{13}C NMR, DEPT, HMQC, ^{1}H-^{1}H COSY, and HMBC spectra and NOE data, as were those of the other compounds reported here. The ^{1}H-^{1}H COSY spectrum displays a coupled spin system, which fully supports the sequence of protons from C-2 to C-8 and the methyl at C-3. The location of the γ-lactone is apparent from the chemical shifts of H-2 and H-4 and confirmed by HMBC correlations from the protons at C-2 to the C-1 carbonyl. The *trans* relationship of the two substituents on the γ-lactone ring is concluded on the basis of NOE enhancements between H-4 and methyl-13. The double bond is assigned the *cis* geometry based on the coupling constant ($J = 11.0$ Hz) between H-6 and H-7 and the large NOE enhancements between them. We therefore assign the structure *trans*-3-methyldodec-*cis*-6-en-4-olide to **3**.

The optically active, oily γ-lactone alcohol **4** was the major metabolite isolated from the extract **G**. Its IR spectrum supports the presence of hydroxyl (3443 cm^{-1}) and lactone (1777 cm^{-1}) functional groups. The ^{13}C NMR and DEPT spectra are very similar to those of γ-lactone **3** but feature one additional oxygenated methine in place of one methylene carbon. The molecular formula, $C_{13}H_{22}O_3$, was deduced on the basis of NMR spectral data and supported by an HR-EI-MS (found: $m/z = 226.1584$; calculated for $C_{13}H_{22}O_3$: 226.1569, [M$^+$]) The ^{1}H-^{1}H COSY spectrum shows an extended coupled spin system, similar to that of compound **3**, supporting the C-2 to C-8 substitution pattern. The γ-lactone ring is established by comparing the ^{13}C chemical shifts with those of compound **3** and confirmed in detail by HMBC correlations. The relative stereochemistry of the five-membered ring lactone was resolved by the NOE enhancements between the methine proton at H-4 and methyl-13. The *cis* geometry of the double bond was apparent from the NOE enhancements between the homo-allylic protons H-8 and H-5, and thus we conclude **4** is *trans*-8-hydroxy-3-methyl-dodec-*cis*-6-en-4-olide.

The IR spectrum of optically active oil **5** shows the presence of vinyl (1641 cm^{-1}), ester (1729 cm^{-1}), and lactone (1781 cm^{-1}) functional groups. The ^{1}H NMR spectrum is nearly identical to that of γ-lactone alcohol **4** except for the presence of an additional methyl singlet at δ 2.01 and the downfield shift of H-8, indicating the presence of an acetate group. The mass spectral data support a molecular formula of $C_{15}H_{24}O_4$ and show a major fragment corresponding to [M$^+$ − C_2H_2O], typical for acetates. The ^{1}H-^{1}H COSY spectrum displays an extended coupling sequence, attesting to the C-2 to C-8 substitution pattern, and the stereochemistry of the double bond and lactone ring substituents were resolved by NOE and coupling constant data as in the case of **3**. We therefore conclude that **5** is *trans*-8-acetoxy-3-methyl-dodec-*cis*-6-en-4-olide.

The IR spectrum of the optically active oil **6** indicates the presence of hydroxyl (3459 cm^{-1}), vinyl (1632 cm^{-1}), ketone (1713 cm^{-1}), and lactone (1777 cm^{-1}) functional groups. Its ^{13}C NMR spectrum and DEPT spectra are similar to those of compound **3** but feature one more carbonyl in place of a methylene carbon. The molecular formula, $C_{13}H_{20}O_4$, was determined on the basis of NMR data. The HR-EI-MS spectrum did not show a molecular ion, but major fragments of

[M$^+$ − C_4H_8O] and [M$^+$ − C_4H_9O] correspond to cleavage at the C-8 — C-9 bond. The ^{1}H-^{1}H COSY spectrum displays two distinct coupled spin systems, $CH_3CH_2CH_2CHO$- and -CH=CHCH$_2$CHCH(Me)CH$_2$-, establishing the connectivity and substitution pattern in **6**. The coupling constant ($J = 15.6$ Hz) for H-6/H-7 indicates a *trans* double bond, and HMBC correlations of H-6 and H-9 to C-8 and of H-2 and H-4 to C-1 complete the structural analysis, and we conclude that **6** is *trans*-9-hydroxy-3-methyl-8-oxo-dodec-*trans*-6-en-4-olide.

Compound **7** was isolated as an optically active, oily substance whose IR spectrum is nearly identical to that of γ-lactone **4** and indicates the presence of hydroxyl (3430 cm^{-1}), vinyl (1630 cm^{-1}), and lactone (1775 cm^{-1}) functions. The ^{13}C NMR and DEPT spectra display one additional oxygenated methine relative to **4**. The molecular formula was determined as $C_{13}H_{22}O_4$ on the basis of MS and NMR data. The ^{1}H-^{1}H COSY spectrum revealed an extended spin-coupling system containing the sequence -CH$_2$CHCHCH=CHCH$_2$CH-CH(Me)CH$_2$-, and the coupling constant ($J = 11.2$Hz) for H-6/H-7 established the *cis* geometry of the double bond. Thus lactone **7** is *trans*-8,9-dihydroxy-3-methyldodec-*cis*-6-en-4-olide.

Compound **8** was isolated as an optically active, oily substance whose IR spectrum indicates the presence of hydroxyl (3474 cm^{-1}), lactone (1777 cm^{-1}), and carbonyl (1711 cm^{-1}) functionalities. Its molecular formula was determined as $C_{13}H_{22}O_4$ on the basis of NMR and HR-EI-MS data (Table 2). The ^{1}H-^{1}H COSY spectrum shows the two independent spin coupling systems $CH_3CH_2CH_2CHO$- and -CH$_2$CH$_2$CH$_2$CHCH(Me)CH$_2$- in agreement with formulation **8**. The HMBC correlations of H-7 and H-9 with C-8 and H-2 and H-4 with C-1 and NOE enhancements between H-4 and Me-13 support the conclusion that **8** is *trans*-9-hydroxy-3-methyl-8-oxo-dodecan-4-olide.

The minor compound **9** was isolated as an optically active oil and its IR spectrum indicates the presence of hydroxyl (3417 cm^{-1}) and carbonyl (1777 and 1757 cm^{-1}) functional groups. The ^{13}C NMR and DEPT spectra are similar to those of γ-lactone **8** but feature an additional oxygenated methine in place of a methylene. The molecular formula, $C_{13}H_{22}O_5$, is assigned based on spectral data, including an EI-MS fragmentation pattern paralleling that of **6** with loss of C_4H_9O from the molecular ion due to cleavage at the C-8 — C-9 bond. The placement of the second oxygenated methine at C-7 follows from the ^{1}H-^{1}H COSY spectrum, which affirms the presence of the -CH(O)CH$_2$CH$_2$CH(O)CH(Me)CH$_2$- moiety. HMBC correlations and NOE data confirm our conclusion that **9** is *trans*-7,9-dihydroxy-3-methyl-8-oxo-dodecan-4-olide.

The IR spectrum of the optically active, oily γ-lactone **10** indicates the presence of hydroxyl (3471 cm^{-1}) and carbonyl (1778, 1723 cm^{-1}) groups. The ^{13}C NMR and DEPT spectra show a total of 13 carbons, comprising two methyls, six methylenes, three methines, and two quaternary carbons. The composition, $C_{13}H_{22}O_4$, was ascertained from EI-MS and NMR data. The two discreet spin coupling systems, $CH_3CH_2CH_2CH_2$- and $CH_2(O)CHCH_2CHCH(Me)CH_2$-, are apparent from the ^{1}H-^{1}H COSY spectrum. Comparison of spectral data with those for the similar compounds **8** and **9** led us to conclude that **10** is *trans*-6-hydroxymethyl-3-

Table 2. NMR data (CDCl₃) for lactones **8–10**.

methyl-8-oxo-undecane-4-olide. This conclusion is fully consistent with HMBC and NOE experiments.

Compound **11** was isolated as an optically active oil whose IR spectrum supports the presence of hydroxyl, α,β-unsaturated carboxyl (3500–2500, 1694 cm⁻¹), and vinyl (1647 cm⁻¹) groups. The composition, $C_{15}H_{26}O_4$, follows from NMR spectral data and an HR-EI-MS that lacks a molecular ion but features prominent ions corresponding to $[M^+ - C_3H_7O]$ and $[M^+ - C_3H_7O - H_2O]$. The ¹³C NMR and DEPT data attest to the presence of four methyls, four methylenes, two sp^2 methines and one sp^3 methine, three fully substituted sp^2 carbons, and one quaternary carbon. The ¹H-¹H COSY spectrum shows the two separate coupling spin systems =CHCH₂CH₂- and -CH(O)CH₂CH₂-. The connection of these and the remaining structural units is readily achieved by an examination of the HMBC correlations (Fig. 1). The strong NOE correlations of H-2 with H-4 and H-6 with H-8 indicate the *trans* stereochemistry of the double bonds, and we conclude that **11** is *trans,trans*-10,11-dihydroxyfarnesenic acid.

It should be noted that **11** is closely related to a *Cecropia* juvenile hormone (JHIII), methyl 10,11-epoxy-3,7,11-trimethyldodecanoate **15**, which profoundly affects metamorphoses of many insects and that **11** has been found to be a metabolic product of JHIII (13). The structure of this sesquiterpene was confirmed via synthesis. Farnesol was converted to farnesenic acid via a two-step oxidation by MnO₂ followed by NaClO₂–NaH₂PO₄. The resulting acid was treated with *N*-bromosuccinimide, producing the corresponding 10,11-bromohydrin **12** in 74% isolated yield, which was then converted to the corresponding 10,11-epoxide **13**. Opening the epoxide ring under acidic conditions produced the racemic diol **11** in 46% yield from **12** plus the 11-membered lactone **14** in 36% yield from **12**. This lactone can be converted to the racemic diol **11** upon treatment with base.

The ¹³C NMR data (Table 3) of compound **16** support the presence of five sp^2 carbons, two of which are protonated, together with two methyl, two methylene, and two oxygen-substituted methines. The ¹H-¹H COSY spectrum attests to

the presence of an *n*-propyl group and the sequence CH₃CH-CHCH- assigned to the side chains H-3′, H-2′, H-1′ and H-8, H-7, H-6, H-5, respectively, in structure **16**. Furthermore, the signal for H-5 (5.34 ppm) shows a long-range coupling to the other vinylic proton H-3 (δ 7.37), while both of these show further couplings to the signal for H-1′ (δ 2.31) consistent with their relationships in structure **16**. The placement of the lactone carbonyl follows from the HMBC correlations from H-1′ and H-3 to C-1. The NOE difference spectrum displays significant correlations from H-3 to H-1′ and H-5. The UV spectrum (λ$_{max}$ = 272) is close to the calculated value (λ$_{max}$ = 268) for this dienone chromophore. The HR-EI-MS showed an $[M^+ - H_2O]$ ion at m/z 194.0962 (calcd. 194.0943 for $C_{11}H_{14}O_3$), which supports formulation **16**. Thus, we conclude compound **16** is 6,7-dihydroxy-2-propyl-octa-2,4-dien-4-olide. A conformational search of **16** (in acetone) revealed that four out of five of the lowest-energy conformations for the *threo* isomer displayed an H-6/H-7 dihedral angle near to 180°, whereas the *erythro* lowest-energy conformations favoured an H-5/H-6 dihedral angle near 70°, consistent with the observed coupling constant of 4.3 Hz. 2,4-Dien-4-olides have been reported from the gorgonians *Plexaura flava* (14) and *Euplexaura flava* (15) and from the liverwort *Marchantia paleacea* subsp. *diptera* (16) but not previously from a fungal source.

Compound **17** was isolated as an optically active, yellowish solid, and its molecular formula $C_{11}H_{10}O_6$ was determined by its HR-EI-MS molecular ion at m/z 238.0467 (calcd. 238.0477). The ¹H NMR spectrum of **17** (Table 4) closely resembles that of sescandelin **18** except for a signal corresponding to H-5. The ¹³C NMR data attest to the presence of nine sp^2 carbons, two of which are protonated, plus a methine and a methyl group. There is a close correspondence in the chemical shift of signals for **17** assigned to C-1, C-3, C-4, C-8a, C-1′, and C-2′ and those of sescandelin **18** (6). The HMBC correlations of the signal at δ 11.47 with signals assigned to C-7, C-8, and C-8a establish the 5,6,8-substitution pattern of the aromatic ring, and correlations between the aromatic proton signal at δ 6.56 with signals assigned to C-5, C-6, C-8, and C-8a confirm this conclusion.

Fig. 1. Selected HMBC correlations for **11**.
Table 3. NMR data (acetone-d_6) for compound **16**.

Carbon	δ	Proton (J Hz)	HMBC (H to C)	NOE diff. (%)

[a]Measured in DMSO-d_6.

The ^{13}C NMR chemical shifts of C-4a, C-6, and C-8 in **17** are significantly downfield relative to the corresponding signals of sescandelin **18**, consistent with the presence of an hydroxyl at C-5. The absolute configuration of **17** is implied from the co-occurrence of S-(–)-6,8-dihydroxy-4-(1′-hydroxyethyl) isocoumarin **18** with the same sign of optical rotation. Isocoumarin derivatives are fairly common metabolites of plants, fungi, and insects and show a wide range of bioactivities (14). While 6,8-dihydroxylated variations are quite common, compound **17** is the first example of a 5,6,8-trihydroxyisocoumarin. Two 6,8-dihydroxy-5-methoxyisocoumarin derivatives have been reported from both *Aspergillus ustus* (17) and *Paecilmyces victoriae* (18).

Crude extracts and compounds **16**–**19** were tested for cytotoxicity against the spruce budworm (*C. fumiferana* Clem.) cell line CF-1 (9). Compound **16** was found to be 20–30% as toxic as the control, deoxynivalenol, while **17**, **18**, and **19** were individually weakly toxic. These findings may provide additional options for our ongoing development of insect resistance in conifers via inoculation of seedlings with toxin-producing endophytes (1).

Experimental section

General

High-resolution mass spectra (HR-EI-MS) were recorded on a Kratos MS-50 instrument. Optical rotations were measured on a PerkinElmer 241 polarimeter. Melting points were taken with a Kofler hot-stage apparatus and are uncorrected. The IR spectra were recorded as films on a Bruker IF-S25 spectrometer. UV spectra were determined on a PerkinElmer 330 spectrometer. Preparative thin layer chro-

matography (ptlc) was performed with precoated silica gel F_{254} (1 mm) plates unless otherwise indicated. NMR data were recorded at room temperature in $CDCl_3$ (unless otherwise specified) on a Varian Unity 400 spectrometer operating at 399.944 MHz for ^1H and 100.575 MHz for ^{13}C. All 2D NMR were recorded non-spinning at 25°C using standard Varian software (VNMR 4.3).

Fungal strain 5WS11I1 (DAOM 221611)

The first fungal strain **5WS11I1** was isolated from a white spruce (*P. glauca* (Moench voss)). This fungus was grown on 2% malt extract agar (MEA) in 250 mL Erlenmeyer flasks (2 L total) and Glaxo bottles (10 L total) according to the established protocols (6). There were no other changes in culturing procedures, and the fermentations proceeded simultaneously.

Isolation of compounds 1–11

The culture filtrate, fermented in 250 mL Erlenmeyer flasks, was extracted with EtOAc (3 × 600 mL). The crude extract **E** (64.7 mg), obtained by removal of solvents under vacuum at room temperature, was purified on Kieselgel 60 F254 plates (1 mm) using $CHCl_3$–MeOH (9:1). The fraction (23 mg, R_f = 0.2–0.8) was further purified by ptlc using $CHCl_3$–acetone (4:1) and yielded vermiculin **1** (1.7 mg) (Kieselgel 60 F254, 0.5 mm, R_f = 0.70) and 7α,8β,11-trihydroxydrimane **2** (3.4 mg) (Kieselgel 60 F254, 0.5 mm, R_f = 0.11). The culture filtrate from the Glaxo bottles was extracted with EtOAc (3 × 3 L), and the total extract was evaporated to dryness at room temperature in vacuum to yield crude extract **G** (0.972 g). A portion of the crude extracts (0.800 g) was chromatographed on a silica column (Kieselgel 60G, 2.8 × 3.0 cm) and eluted with a discontinuous gradient of $CHCl_3$–MeOH (1:0–0:1). The fractions (40 mL each) were combined on the basis of tlc scrutiny and further purified by repeated ptlc, yielding **3** (1.5 mg) (Baker Si-C18F, 0.20 mm, MeOH–H_2O (4:1), R_f = 0.22), **4** (40.0 mg) (Baker Si-C18F, 0.20 mm, acetone–H_2O (3:2), R_f = 0.43), **5** (2.5 mg) (0.25 mm, hexane–EtOAc (3:2), R_f = 0.56), **6** (6.2 mg) (Baker Si-C18F, 0.20 mm, MeOH–H_2O (7:3), R_f = 0.62), **7** (6.3 mg) (Baker Si-C18F, 0.20 mm, MeOH–H_2O (13:7), R_f = 0.56), **8** (11.1 mg) (0.25 mm, $CHCl_3$–acetone (17:3), R_f = 0.62), **9** (5.7 mg) (Baker Si-C18F, 0.20 mm, acetone–H_2O (3:2), R_f = 0.69), and **10** (1.1 mg) (Baker Si-C18F, 0.20 mm, acetone–H_2O (3:2), R_f = 0.54), as well as sequiterpenes **11** (12.0 mg), (0.25 mm, $CHCl_3$–MeOH (9:1), R_f = 0.47) and 7α,8β,11-trihydroxydrimane **2** (4.0 mg) (Baker Si-C18F, 0.20 mm, MeOH–H_2O (13:7), R_f = 0.25).

Sesquiterpene 11

An oil, $[\alpha]_D$ = +11.8° (CHCl$_3$, 0.0039). IR (film, cm^{-1}): 3391 (br, s), 2927 (s), 1694 (s), 1647 (s), 1381 (m), 1077 (m). HR-EI-MS m/z (%): 234.1636 ([M$^+$ – 2H$_2$O], 3.5) (calcd. for C$_{15}$H$_{22}$O$_2$: 234.1612), 211.1359 ([M$^+$ – C$_3$H$_7$O], 19.5) (calcd. for C$_{12}$H$_{19}$O$_3$: 211.1334), 206 (2.1), 194 (9.5), 193 (42.1), 163 (21.9), 143(58.1), 123 (28.9), 100 (40.3), 93 (33.5), 81 (76.2), 59 (100).

Synthesis of sesquiterpene 11

To a solution of 10-bromo-11-hydroxy-farnesylic acid **12** (0.220 g, 0.660 mmole) in DMF–H$_2$O (3:1) (12.5 mL), NaOH (0.055 g, 1.38 mmole) was added, and the solution was stirred at room temperature for 1.5 h before quenching with 0.01 M HCl. The mixture was extracted with CHCl$_3$ (3 × 10.0 mL) and combined extracts washed with brine (15 mL) and evaporated at room temperature under vacuum to yield the crude epoxide **13** (0.197 g), which was dissolved in DMF–H$_2$O (3:1) (12.5 mL), and p-toluenesulfonic acid (0.006 g, 0.003 mmole) was added. The solution was stirred for 2 h before addition of brine (10.0 mL). The mixture was extracted with CHCl$_3$ (3 × 10.0 mL), and the combined extracts were washed with brine and evaporated under vacuum to give a crude mixture, which was purified by column to give sesquiterpene **11** (0.083 g, 46% from **12**) and the lactone **14** (0.060 g, 36% from **12**).

Lactone 14

An oil. Larval bioassays

Compounds **4**, **6**, **7**, **8**, **11**, and 7α,8β,11-trihydroxydrimane **2** were subjected to a budworm larval feeding bioassay according to established protocol (2) at a concentration of 0.0004 g g^{-1} of diet, resulting in mortalities of 60, 76, 68, 72, 52, and 72% relative to control (42% mortality).

Fungal strain 5WS26H1 (DAOM 229664)

Strains were transferred to slants containing 2% malt extract agar (Difco) and incubated at 20°C for at least one month. For each fermentation, the slant was macerated in sterile water (30 mL). An aliquot (2.5 mL) was used to inoculate each of six Erlenmeyer flasks (250 mL) containing 50 mL of medium (CZ Met) made from glucose (20 g), NH$_4$Cl (3 g), KH$_2$PO$_4$ (2 g), MgSO$_4$ (2g), FeSO$_4$·7H$_2$O (0.2 g), yeast extract (2 g), malt extract (2 g), and peptone (2 g) per L of water. The flasks were put on a rotary shaker (3.81 cm throw) at 220 rpm at 20°C for 48 h in the dark.

The culture was then macerated, and 50 mL was used to inoculate three Glaxo bottles containing CZ Met medium (1 L) and three Glaxo bottles containing 2% malt extract medium (1 L). These were incubated at 20°C for 6 weeks. After incubation, each Glaxo bottle was filtered under vacuum though Whatman #1 filter paper and extracted with three portions of ethyl acetate (200 mL). The combined extract was dried with anhydrous sodium sulfate, filtered, and concentrated under vacuum at room temperature. The extracts were transferred into a pre-weighed vial using a small amount of ethyl acetate, which was then evaporated under nitrogen. Compounds **16–20** were variably isolated from a series of white spruce and black spruce strains, but all were produced by DAOM 229664 in CZ met medium incubated under the conditions described. This isolate and DAOM 221611 have been deposited in the Canadian Collection of Fungal Cultures (DAOM, Agriculture Agri-food Canada, Ottawa, ON K1A 0C6). They are preserved in liquid nitrogen.

Isolation of compounds 16–20

Endophyte crude extract 5WS19B2-AMSF OCT 22/98 (73.8 mg) was fractionated by ptlc (two plates) using CHCl$_3$–C$_6$H$_{12}$–CH$_3$OH (7:2:1). Seven fractions A–G (in order of increasing polarity) were collected. Fraction E (20.8 mg, R_f 0.34 to 0.40) was purified by ptlc using C$_6$H$_6$–CH$_3$COCH$_3$ (4:1) to afford pure compound **16** (0.65 mg, R_f 0.51) and pure compound **17** (7.1 mg, R_f 0.56). Fraction F (21.2 mg, R_f 0.32) was purified by ptlc using C$_6$H$_6$–CH$_3$COCH$_3$ to afford compound **19** (5.5 mg, R_f 0.20). Endophyte crude extracts 5BS21B1-ACZGF, 5BS21B1-BCZGF, and 5BS21B1-CCZGF NOV 30/98 were combined (257.3 mg) and fractionated by ptlc (six plates) using CHCl$_3$–C$_6$H$_{12}$–CH$_3$OH (7:2:1). Five fractions A–E (in order of increasing polarity) were collected. Fraction D (58.1 mg) was purified by ptlc with CH$_3$COOC$_2$H$_5$–C$_6$H$_{12}$ (4:1) to give two major fractions, one containing **18** (8.8 mg) and the other a mixture of **19** and **16** (8.4 mg). Compound **18** was further purified by ptlc with CH$_3$COOC$_2$H$_5$–C$_6$H$_{12}$ (3:2), (5.5 mg, R_f 0.52). Further purification of the mixture by ptlc with CHCl$_3$–C$_6$H$_{12}$–CH$_3$OH (15:5:1) gave **19** (1.6 mg, R_f 0.38) and **16** (2.7 mg, R_f 0.42). Crude extract 5WS14G1-ACZGF NOV 10/98 (34.7 mg) was fractionated by ptlc (0.5 mm, two plates) using CHCl$_3$–C$_6$H$_{12}$–CH$_3$OH (7:2:1). The major fraction (8.1 mg) was further purified by ptlc using CH$_3$COOC$_2$H$_5$–C$_6$H$_{12}$ (4:1) to give pure compound **20** (3.1 mg, R_f 0.30)

6,7-Dihydroxy-2-propyl-2,4-octadien-4-olide 16

A pale yellow oil; $[\alpha]_D$ = +17.1° (c 0.0021, MeOH). UV (EtOH) λ_{max} (nm) (ε): 272 (8600). HR-EI-MS m/z (%): 194.0962 ([M$^+$ – H$_2$O], 1.6) (calcd. for C$_{11}$H$_{14}$O$_3$: 194.0943), 168 (100), 152 (11.6), 43 (29.8). See Table 3 for spectral data.

5,6,8-Trihydroxy-4-(1′-hydroxyethyl) isocoumarin 17

A yellow solid; mp 150–155°C; $[\alpha]_D$ = –13.1° (c 0.007, CH$_3$COCH$_3$). UV (EtOH) λ_{max} (nm)(ε): 204 (8320), 238 (12 500), 252 (10 730), 272 (9820), 348 (9120). HR-EI-MS m/z (%): 238.0467 ([M$^+$], 10.8) (calcd. for C$_{11}$H$_{10}$O$_6$: 238.0477), 220 ([M$^+$ – H$_2$O], 100), 205 (36.9), 43 (16). See Table 4 for spectral data.

4-Hydroxy-2-methoxyacetanilide 20

A yellow amorphous solid; mp 166–169°C (synthetic (synth.) 169–171°C). ^{1}H NMR (CD$_3$OD, 400 MHz) δ: 8.57, 7.53 (1H, br s, 4-OH and 1H, s, NH measured in CDCl$_3$ + 5 drops of DMSO-d_6), 7.48 (1H, d, J = 8.0 Hz, H-6), 6.45 (1H, d, J = 2.4, 9.6, H-5), 3.81 (1H, s, OCH$_3$), 2.1 (1H, s, CH3). ^{13}C NMR (CD$_3$OD, MHz) δ: 170.4 (C=O), 155.6 (C-4), 152.4 (C-2), 124.5 (C-6), 118.3 (C-1), 105.9 (C-5), 98.7 (C-3), 54.6 (OCH$_3$), 21.9 (CH$_3$). HR-EI-MS m/z (%): 181.0740 ([M$^+$], 60) (calcd. for C$_9$H$_{11}$NO$_3$: 181.0739), 139 (70), 124 (100).

Cell line assays

The spruce budworm cell line CF-1 was used according to the method of Clark et al. (9) to screen extracts and purified compounds for cytotoxicity. Deoyxnivalenol (2 µg mL^{-1}, cell culture medium) was used as the positive control and ethanol (2 µL mL^{-1}) as the negative control; no effect of ethanol on the CF-1 cells was detected at this concentration. Crude extracts were dissolved in ethanol and tested at 1, 2, and 4 µL mL^{-1} culture medium. The crude extract arising from the non-sporulating strain 5WS26H1 (DAOM 229664) was as cytotoxic as the positive control solution. Compounds **16**–**19** were individually dissolved in ethanol and tested at 2 µg mL^{-1} culture medium as above. Compound **17**, sescandelin **18**, and sescandelin B **19** were individually weakly cytotoxic. Compound **16** was ca. 20–30% as cytotoxic to CF-1 as deoxynivalenol at 2 µL mL^{-1} culture medium.

Convenient, tandem and one-reaction vessel synthesis of mixed dialkylated 2-naphthols from 2-tetralone

Amitabh Jha and Jonathan R. Dimmock

Abstract: A convenient acid-catalyzed method for the synthesis of 1-alkyl-2-alkoxynaphthalenes by one-reaction vessel mixed alkylation of 2-tetralone, using aryl or alkyl aldehydes and alcohols followed by aromatization, is described.

Key words: ethers, aromatization, rearrangement, alkylation, 2-alkoxynaphthalenes.

Résumé : On décrit une méthode pratique de synthèse acidocatalysée des 1-alkyl-2-alkoxynaphtalènes impliquant une réaction monotope d'alkylation mixte de la 2-tétralone à l'aide d'alcools et d'aldéhydes aliphatiques ou aromatiques suivie d'une aromatisation.

Mots clés : éthers, aromatisation, réarrangement, alkylation, 2-alkoxynaphtalènes.

Introduction

A variety of methods are known for the synthesis of 2-alkoxy-1-arylmethylnaphthalenes (**1**, R = aryl), including the reduction of 1-(2-alkoxynaphthyl) aryl ketones (1) or the reduction of 1-(2-alkoxynaphthyl) aryl carbinols (2), Pd(II)-catalyzed C—C bond formation among 2-alkoxy-1-halonaphthalenes and substituted toluenes (3), and other procedures that are cumbersome (4, 5). The C-1 alkylation and etherification of 2-naphthol using dialkyl sulfates leading to 2-alkoxy-1-alkylnaphthalenes (**1**, R = H, R′ = CH$_3$; R = CH$_3$, R′ = C$_2$H$_5$) is known (6). This procedure has at least two limitations: (*i*) the synthesis of the corresponding mixed dialkyl derivatives is not possible; and (*ii*) the unavailability of dialkyl sulfates limits the wider utility of this procedure. Another compound belonging to this class, namely 1-butyl-2-methoxynaphthlene (**1**, R = *n*-C$_3$H$_7$, R′ = CH$_3$), was made by a very lengthy and unwieldy procedure (7).

2-Alkoxy-1-arylmethylnaphthalenes (**1**, R = aryl, R′= alkyl) may also be obtained by the etherification of the corresponding 1-arylmethyl-2-naphthols (**1**, R = aryl, R′ = H), for which a number of methods are known. These include a Fries-type rearrangement of 2-benzyloxynaphthalene (8), a base-catalyzed reaction between benzyl chloride or benzyl alcohol and 2-naphthol (9–12), as well as Zn-catalyzed transfer of a benzyl group from various benzyl aryl ethers to 2-naphthol (8). Some of these reactions yield side products (5, 8, 9, 11).

Recently this research group reported a novel synthetic route to this class of compounds, which involved two simple reaction steps (13). 1-Arylmethylene-2-tetralones (**A**, R = aryl) (14) were converted to 2-alkoxy-1-arylmethylnaphthalenes (**1**, R = aryl, R′ = alkyl) under anhydrous acidic conditions in common alcohols and the yields were generally satisfactory (13). As the synthesis of 1-arylmethylene-2-tetralones (**A**, R = aryl) can be carried out under anhydrous acidic conditions (13–15) and the subsequent reactions yielding the title compounds were also carried out under anhydrous acidic conditions (13), we thought that it should be possible to carry out these two reactions in the same pot, without isolating the corresponding intermediate 1-arylmethylene-2-tetralones (**A**, R = aryl). It was also realized that the success of this three-component reaction would depend on the sequence of occurrence of the two competing reactions, viz. condensation of the aldehyde group with the active methylene of 2-tetralone and the vinyl ether formation between the alcohol and the enolic form of 2-tetralone based on the reaction mechanism described previously (13) (and later in this paper). This could easily be verified by performing the reactions.

The formation of 2-alkoxy-1-alkylnaphthalenes **1a–1i** (Fig. 1) from a mixture of 2-tetralone, aryl or alkyl aldehydes, and an absolute alcohol under anhydrous acidic conditions (Scheme 1) is reported herein.

Experimental section

General

2-Tetralone and the substituted aldehydes were obtained from Aldrich Chemical Co. Column chromatography purifications were undertaken using silica gel (60–230 mesh) obtained from Aldrich Chemical Co. Hydrogen chloride gas was freshly generated in the laboratory by the action of con-

centrated sulfuric acid on the mixture of sodium chloride in concentrated hydrochloric acid in an appropriate apparatus. ^{1}H NMR spectra were recorded on a Bruker AMX 300 NMR spectrometer at 300 MHz and HR-MS spectra were obtained on VG-Analytical (Manchester, U.K.) VG-70 SEQ spectrometer. Melting points were recorded on an electro-thermal apparatus and are uncorrected.

Syntheses of 2-alkoxy-1-alkylnaphthalenes (1a–1i)

General procedure

A mixture of 2-tetralone (3 mmol) and an appropriate aldehyde (3 mmol) in absolute alcohol (10 mL) was cooled by an ice bath to 0–5°C. Under anhydrous conditions, freshly generated dry hydrogen chloride gas was passed briskly through the solution for 20 min. The reaction mixture was stirred at room temperature for 24 h. Thin layer chromatography using precoated fluorescent silica gel and a developing solvent of hexane:chloroform (1:4) showed the formation of a faster moving product. The reaction mixture was evaporated to dryness under vacuum. Products (**1a–1c**, **1e**, **1f**, **1h**, **1i**) were purified using a silica gel (230–400 mesh) column with hexane as the eluent. Compounds **1d** and **1g** were obtained as solid powders from the reaction and were quite pure after filtration as viewed on TLC.

2-Methoxy-1-phenylmethylnaphthalene (1a)

White crystalline solid (yield: 76%). R_f = 0.59 (10% EtOAc – hexane), mp 91 to 92°C (Lit. value (1) 81 to 82°C). ^{1}H NMR (300 MHz, CDCl3) δ: 3.95 (3H, s, -OCH_3), 4.50 (2H, s, Ar-CH_2-Ar′), 7.10–7.22 (5H, m, Ar′-Hs), 7.30–7.36 (2H, m, H-3, 6), 7.38–7.42 (1H, m, H-7), 7.79–7.82 (2H, m, H-4, 5), 7.91 (1H, d, J = 8.6 Hz, H-8). HR-MS calcd. for C$_{18}$H$_{16}$O: 248.1201; found: 248.1196. EI-MS (70 eV) *m/z* (% int.): 248 (100), 233 (16), 215 (39), 202 (24), 171 (21), 141 (17), 91 (14).

2-Ethoxy-1-phenylmethylnaphthalene (1b)

White crystalline solid (yield: 71%). R_f = 0.67 (10% EtOAc – hexane), mp 74–76°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 1.40 (3H, t, J = 7.0 Hz, CH_3), 4.17 (2H, q, J = 7.0 Hz, OCH_2), 4.49 (2H, s, Ar-CH_2-Ar′), 7.10–7.21 (5H, m, Ar′-Hs), 7.29–7.34 (2H, m, H-3, 6), 7.38–7.41 (1H, m, H-7), 7.75–7.80 (2H, m, H-4, 5), 7.92 (1H, d, J = 8.4 Hz, H-8). HR-MS calcd. for C$_{19}$H$_{18}$O: 262.1357; found: 262.1354. EI-MS (70 eV) *m/z* (% int.): 262 (100), 233 (44), 215 (34), 156 (19), 128 (21), 91 (31).

2-Butoxy-1-phenylmethylnaphthalene (1c)

White crystalline solid (yield: 76%). R_f = 0.78 (10% EtOAc – hexane), mp 30–32°C. ^{1}H NMR (300 MHz,

Scheme 1.

R = Aryl, Alkyl; R' = Alkyl
CDCl$_3$) δ: 0.95 (3H, t, J = 7.4 Hz, CH$_2$CH_3), 1.44–1.54 (2H, m, CH_2), 1.73–1.82 (2H, m, CH_2), 4.11 (2H, t, J = 6.4 Hz, OCH_2), 4.50 (2H, s, Ar-CH_2-Ar′), 7.10–7.22 (5H, m, Ar′-Hs), 7.30–7.34 (2H, m, H-3, 6), 7.38–7.42 (1H, m, H-7), 7.76–7.80 (2H, m, H-4, 5), 7.93 (1H, d, J = 8.5 Hz, H-8). HR-MS calcd. for C$_{21}$H$_{22}$O: 290.1670; found: 290.1677. EI-MS (70 eV) *m/z* (% int.): 290 (100), 234 (89), 215 (36), 202 (30), 156 (29), 128 (24), 91 (47).

2-Methoxy-1-(4-nitrophenylmethyl)naphthalene (1d)

White solid (yield: 87%). R_f = 0.41 (10% EtOAc – hexane), mp 103–105°C (Lit. value (3) 106–108°C). ^{1}H NMR data was found to be identical to that of the literature report (3). HR-MS calcd. for C$_{18}$H$_{15}$NO$_3$: 293.1052; found: 293.1058. EI-MS (70 eV) *m/z* (% int.): 293 (100), 278 (6), 262 (7), 231 (18), 215 (29), 202 (28), 171 (24), 141 (21), 128 (12), 101 (9).

1-(4-Chlorophenylmethyl)-2-methoxynaphthalene (1e)

White crystalline solid (yield: 92%). R_f = 0.49 (10% EtOAc – hexane), mp 51 to 52°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 3.94 (3H, s, OCH_3), 4.44 (2H, s, Ar-CH_2-Ar′), 7.10 (2H, d, J = 8.6 Hz, H-2′, 6′), 7.16 (2H, d, J = 8.6 Hz, H-3′, 5′), 7.32–7.36 (2H, m, H-3, 6), 7.39–7.47 (1H, m, H-7), 7.79–7.87 (3H, m, H-4, 5, 8). HR-MS calcd. for C$_{18}$H$_{15}$ClO: 282.0811; found: 282.0820. EI-MS (70 eV) *m/z* (% int.): 282 (100), 267 (13), 251 (20), 231 (26), 215 (49), 202 (31), 171 (29), 141 (20), 125 (18), 115 (14), 101 (17).

2-Methoxy-1-(4-methylphenylmethyl)naphthalene (1f)

White crystalline solid (yield: 84%). R_f = 0.47 (10% EtOAc – hexane), mp 58 to 59°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 2.27 (3H, s, Ar-CH_3), 3.95 (3H, s, OCH_3), 4.46 (2H, s, Ar-CH_2-Ar′), 7.02 (2H, d, J = 8.0 Hz, H-2′, 6′), 7.09 (2H, d, J = 8.2 Hz, H-3′, 5′) 7.30–7.37 (2H, m, H-3, 6), 7.38–7.43 (1H, m, H-7), 7.78–7.82 (2H, m, H-4, 5), 7.93 (1H, d, J = 8.6, H-8). HR-MS calcd. for C$_{19}$H$_{18}$O: 262.1357; found: 262.1363. EI-MS (70 eV) *m/z* (% int.): 262 (100), 247 (25), 231 (34), 215 (34), 202 (19), 189 (8), 171 (15), 158 (10), 141 (14), 115 (13), 105 (16).

1-(4-Carbomethoxyphenylmethyl)-2-methoxynaphthalene (1g)

White solid (yield: 90%). R_f = 0.28 (10% EtOAc – hexane), mp 88 to 89°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 3.86 (3H, s, CO$_2$CH_3), 3.94 (3H, s, OCH_3), 4.52 (2H, s, Ar-CH_2-Ar′), 7.21–7.25 (2H, d, J = 8.5 Hz, H-2′, 6′), 7.32–7.44 (3H, m, H-3′, 5′, 6), 7.78–7.89 (5H, m, Ar-Hs). HR-MS calcd. for C$_{20}$H$_{18}$O: 306.1256; found: 306.1266. EI-MS (70 eV) *m/z* (% int.): 306 (100), 291 (4), 275 (14), 231 (15), 215 (27), 202 (14), 171 (13), 141 (12), 101 (7), 83 (27).

Scheme 2.
2-Methoxy-1-propylnaphthalene (1h)

Light brown viscous oil (yield: 30%). R_f = 0.61 (10% EtOAc – hexane). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 1.02 (3H, t, J = 7.3 Hz, CH$_2$CH_3), 1.63–1.70 (2H, m, CH$_2$CH_2CH$_3$), 3.07 (2H, t, J = 7.9 Hz, ArCH_2), 3.95 (3H, s, OCH_3), 7.25–7.37 (2H, m, H-3, 6), 7.44–7.51 (1H, m, H-7), 7.70–7.81 (2H, m, H-4, 5), 7.97 (1H, d, J = 8.6, H-8). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 14.70, 23.57, 27.20, 56.82, 113.75, 123.31, 123.64, 124.46, 126.26, 127.55, 128.70, 129.48, 133.28, 154.55. HR-MS calcd. for C$_{14}$H$_{16}$O: 200.1201; found: 200.1208. EI-MS (70 eV) m/z (% int.): 200 (44), 183 (26), 171 (100), 157 (96), 141 (66), 128 (56), 115 (24).

1-Heptyl-2-methoxynaphthalene (1i)

Colorless viscous oil (yield: 78%). R_f = 0.65 (10% EtOAc – hexane). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.93 (3H, t, J = 6.8 Hz, CH$_2$CH_3), 1.30–1.53 (8H, m, ArCH$_2$CH$_2$(CH_2)$_4$CH$_3$), 1.63–1.69 (2H, m, ArCH$_2$CH_2CH$_2$), 3.11 (2H, t, J = 7.7 Hz, ArCH_2), 3.96 (3H, s, OCH_3), 7.29 (1H, d, J = 9.0 Hz, H-3), 7.33–7.39 (1H, m, H-6), 7.47–7.52 (1H, m, H-7), 7.73 (1H, d, J = 9.0 Hz, H-4), 7.81 (1H, d, J = 8.1, H-5), 8.0 (1H, d, J = 8.5, H-8). HR-MS calcd. for C$_{18}$H$_{24}$O: 256.1827; found: 256.1825. EI-MS (70 eV) m/z (% int.): 256 (51), 171 (100), 141 (31), 115 (7).

Results and discussion

It was found that when dry hydrogen gas was passed through a solution of 2-tetralone and benzaldehyde in absolute methanol for 20 min, and the reaction stirred at room temperature for 24 h, the TLC showed the formation of a faster moving spot. This product upon workup was characterized as 2-methoxy-1-phenylmethylnaphthalene (**1a**) in good yield.

The initial reactions in the present study were carried out in methyl alcohol (**1a**, **1d**–**1g**), but to confirm the generality of this procedure, one reaction in each of ethyl alcohol and *n*-butyl alcohol were also carried out under similar conditions. These attempts with 2-tetralone and benzaldehyde successfully yielded the compounds **1b** and **1c**. In the case of the reaction of 2-tetralone with 4-carboxybenzaldehyde in methanol, the obtained product (**1g**) had the carbomethoxy group as expected. We also found that this reaction worked for aliphatic aldehydes also and using propionaldehyde and heptaldehyde in methanol, we were able to make 2-meth-

oxy-1-propylnapthalene **1h** and 1-heptyl-2-methoxynapthalene **1i** in 30 and 78% yield, respectively.

The likely mechanism of formation of these compounds seems similar to what was proposed in our previous paper (13) except that 1-arylidene-2-tetralone (**A**, R = Ar) or 1-alkylidene-2-tetralone (**A**, R = alkyl) are intermediates here. The formation of the enol ether **B** and subsequent rearrangement to **C** makes use of the extended conjugation (Scheme 2). Formation of an α,β-unsaturated species from the corresponding active methylene compound and aldehyde is very common in anhydrous acidic conditions (14, 15). Enol ethers are also easily formed under similar conditions especially when the ketone has an α-hydrogen atom (16), while hydronaphthalenes are quite amenable to aromatization (13, 17). Aromatization reactions usually require catalysts and harsh conditions (17), though highly facile aromatizations in different structural moieties are known (18). It was demonstrated by isotopic labeling studies in our previous work (13) that the rearrangement of protons does not take place by the less likely concerted 1,5-sigmatropic type rearrangement (for which a *cisoid* conformation is a prerequisite (19)) but follows the more favorable dissociation mechanism.

Based on these results, it can also be concluded that the condensation of the aldehyde group with the active methylene of 2-tetralone leading to the formation of **A** was favored over the formation of vinyl ether **D** as the highly predominant (or exclusive) intermediate. No efforts were made to detect the formation of **D** in the reaction mixture.

Conclusions

In conclusion, we have devised an exceptionally simple method to perform efficient and selective mixed *C*- and *O*-alkylation leading to 2-alkoxy-1-alkylnaphthalenes from 2-tetralone using an aldehyde and an alcohol under anhydrous acidic conditions. This transformation could be of importance to synthetic and combinatorial chemists. We are working towards widening the scope of this procedure.

Corrosion et passivation de l'étain dans un milieu simulé à une eau industrielle

El Habib Ait Addi, Lahcen Bazzi, Mostafa Hilali, El Alami Zine, Rachid Salghi et Souad El Issami

Résumé : Le comportement à la corrosion de l'étain dans un milieu simulé à une eau industrielle a été étudié par emploi des méthodes électrochimiques (tracé des courbes potentiodynamiques et mesure de la résistance de polarisation). L'effet de la variation du pH, de la température et de la concentration des anions en solution a été étudié. Les résultats obtenus montrent que la variation du pH (autour de la valeur 8,2 du milieu synthétique) n'a pas d'effet sur la sensibilité à la piqûration de l'étain. Cependant, l'augmentation de la température de 20 à 70 °C accélère le processus de corrosion. La présence des anions Cl⁻ et SO₄²⁻ favorise le processus de piqûration de l'étain. Les ions Cl⁻ sont plus agressifs que les ions SO₄²⁻ alors que les ions HCO₃⁻ ont une action inhibitrice vis-à-vis de la corrosion par piqûre de l'étain dans le milieu étudié.

Mots clés : étain, corrosion, piqûration, eau industrielle.

Abstract: The corrosion behaviour of tin in a synthetic medium similar to an industrial water has been studied by using electrochemical methods (plotted potentiodynamic curves and polarization resistance measurement). The effect of pH variation, temperature and concentration of anions in solution has been investigated. The results obtained show that pH variation (around the value 8.2 of the synthetic medium) has no effect on the pitting sensitivity of tin. However, the increasing of temperature in the range of 20–70°C accelerates the corrosion process. The presence of anions Cl⁻ and SO₄²⁻ leads to pitting corrosion of tin. Cl⁻ ions are more aggressive than SO₄²⁻ ions, whereas HCO₃⁻ ions acted as an inhibitor for pitting corrosion of tin in the studied medium.

Key words: tin, corrosion, pitting, industrial water.

Introduction

L'étain est un métal qui est largement utilisé dans l'industrie agro-alimentaire. Il permet le recouvrement superficiel des matériaux tel que l'acier pour les rendre plus résistants à la corrosion dans les eaux industrielles. Cependant, ce matériau est susceptible d'être attaqué par le milieu environnant. L'examen du diagramme potentiel–pH de l'étain (1) montre que ce métal peut être dans un état actif ou passif. Ainsi, l'étain réagit dans les milieux acides et basiques et il est relativement stable et résistant dans les milieux neutres. Sa dissolution est minimale pour une valeur de pH voisine de 8,5.

Plusieurs travaux ont été entrepris sur la corrosion de l'étain en milieux neutres ou légèrement alcalins (2–11).

[1]Auteur correspondant (courriel : lbazzi@caramail.com).

Parmi ces travaux, nous citons ceux de Drogowska et al. (2) et de Brossard et al. (3) en milieu bicarbonate. Ces auteurs ont montré que l'étain présente dans ce milieu un phénomène de passivation sans rupture de passivité. Ils ont attribué ce phénomène à la formation d'un film passif constitué essentiellement par l'oxyde SnO₂. En présence des ions Cl⁻, l'étain devient sensible à la piqûration. La valeur du potentiel de piqûration dépend à la fois de la teneur des ions Cl⁻ et des ions HCO₃⁻ en solution (3). Les travaux de Refaey (4) sur la corrosion de l'étain ont été entrepris dans une solution de borate de sodium (pH = 8,35). Il a montré que l'addition des ions Cl⁻ ou Br⁻ dans ce milieu provoque la corrosion par piqûre de ce matériau et que les ions Cl⁻ sont plus agressifs que les ions Br⁻. Alvarez et al. (5) ont réalisé une étude sur le comportement anodique de l'étain dans une solution contenant soit les ions HCO₃⁻–CO₃²⁻ ou bien les ions B₄O₇²⁻. Ces auteurs ont suggéré que l'oxydation successive de Sn en Sn(II) et de Sn(II) en Sn(IV) stabilise le film passif par le processus de déshydratation. Les mêmes auteurs ont étudié l'effet de la variation du pH entre 7,6 et 11,9 sur la dissolution de l'étain dans la solution de borate. Ils ont montré que la meilleure résistance à la corrosion est obtenue pour une valeur de pH égale à 11,9. Ils ont alors attribué ce phénomène à la formation d'un film compact et résistant.

Le but de ce travail est d'étudier le comportement à la corrosion de l'étain dans une solution simulée à une eau industrielle qui est utilisée dans l'industrie agroalimentaire à Agadir (sud du Maroc). Cette eau industrielle est caracté-

risée par des teneurs en ions Cl^-, HCO_3^- et SO_4^{2-} variables d'une unité de conserve à une autre. Nous évoquerons l'effet de la variation du pH, de la température et de la concentration des ions Cl^-, HCO_3^- et SO_4^{2-} en solution. Notons l'absence à notre connaissance de travaux antérieurs dans de tels milieux contenant simultanément les trois anions précités.

Conditions expérimentales

Au cours de ce travail, nous avons fait appel à deux méthodes électrochimiques. Il s'agit du tracé des courbes potentiodynamiques et la mesure de la résistance de polarisation.

Les essais électrochimiques ont été réalisés dans une cellule étanche thermostatée munie d'orifices permettant l'introduction de trois électrodes. L'électrode de référence est une électrode au calomel saturée (ECS). La contre électrode est en platine. L'électrode de travail est sous forme d'un disque de surface $S = 0,5$ cm^2 en étain enrobé dans une résine et fixé verticalement sur un porte-échantillon. Avant chaque essai, les échantillons subissent un polissage mécanique à l'aide de papier abrasif de granulométrie décroissante allant jusqu'à 1200, un dégraissage à l'acétone, un rinçage à l'eau bidistillée et un séchage à l'air comprimé. L'étude électrochimique est réalisée à l'aide d'un potentiostat–galvanostat PGP 201 piloté par ordinateur à l'aide du logiciel (VoltaMaster). La vitesse de balayage choisie est de 60 mV/min pour avoir des conditions quasi stationnaires (12,13). Avant chaque tracé de la courbe de polarisation, l'électrode de travail est maintenue à son potentiel libre pendant 30 min. La mesure de la résistance de polarisation R_p est réalisée dans les mêmes conditions que le tracé des courbes de polarisation. Une surtension de –10 mV/ECS est imposée à l'électrode de travail. La valeur de R_p est alors déterminée à partir de la pente de droite obtenue. La solution électrolytique est préalablement désaérée par un barbotage continu d'azote et elle est soumise à une agitation constante. Le milieu synthétique (milieu témoin) contenant 0,01 M Cl^-, 0,008 M $SO_4^=$ et 0,003 M HCO_3^-, est préparé par dissolution dans l'eau bi-distillée de NaCl, Na_2SO_4 et Na_2HCO_3 de grade pour analyse. La valeur du pH mesurée dans ces conditions est égale à 8,2.

Résultats

Effet du pH

La variation du pH du milieu synthétique est assurée par ajout dans le milieu témoin (pH = 8,2) de quelques gouttes d'une solution de NaOH ou d'une solution de H_2SO_4. La variation de la concentration anionique provoquée par cet ajout reste négligeable. La température de la solution est fixée à 20 °C.

Les courbes de polarisation de l'étain enregistrées pour différentes valeurs de pH du milieu sont représentées à la figure 1. Nous constatons que l'allure générale de la courbe potentiodynamique est similaire pour les trois valeurs de pH. La branche cathodique est caractérisée par un domaine linéaire indiquant la réduction de l'eau selon un mécanisme d'activation pure (14) :

[1] $2\ H_2O + 4\ e^- \rightarrow 4\ OH^-$

Pour des surtensions plus cathodiques, il y a apparition d'un palier de courant qui pourrait être attribué à la réduction des ions Sn^{2+} en solution.

[2] $Sn^{2+} + 2\ e^- \rightarrow Sn$
L'examen de la branche anodique permet de conclure que l'étain présente un phénomène de passivation avec rupture de passivité par attaque localisée. En effet partant du potentiel de corrosion, la densité de courant anodique augmente avec le potentiel d'électrode pour atteindre un palier de courant appelé palier de passivation. La densité de courant de passivation I_p est alors déterminée par la mesure de la hauteur du palier de courant. Lorsqu'on atteint la valeur du potentiel de piqûration E_{piq}, la densité de courant anodique augmente brusquement. Il y a alors piqûration de l'étain.

L'examen de la figure 1 montre que lorsque la valeur du pH passe de 6,2 à 9,2, le potentiel de corrosion se déplace vers les valeurs plus actives; alors que la valeur du potentiel de piqûration reste sensiblement constante. Les densités de courant de corrosion I_{cor} et de passivation I_p subissent une légère augmentation. Ce résultat est corroboré par la décroissance subie par la résistance de polarisation lorsque le pH croît et traduit la faible tendance à la corrosion uniforme de l'étain.

Effet de la concentration des ions sulfates

La variation de la teneur en ions SO_4^{2-} est réalisée par dissolution de la quantité correspondante de Na_2SO_4 dans la solution contenant 0,01 M Cl^- et 0,003 M HCO_3^-. Le pH de la solution ainsi préparée reste voisin de la valeur 8,2 et la température est fixée à 20 °C.

Les courbes de polarisation de l'étain dans le milieu contenant les ions SO_4^{2-} à différentes concentrations sont représentées sur la figure 2. L'examen des résultats obtenus montre que l'augmentation de la concentration des ions sulfates de 0,0002 à 0,08 M a pour effet un déplacement du potentiel de piqûration vers des valeurs plus actives et du potentiel de corrosion vers des valeurs plus nobles. Ce résultat traduit la tendance de l'étain à la corrosion par piqûre en présence de ces ions. Notons que les densités de courant de corrosion I_{cor} et de passivation I_p ne subissent qu'une légère augmentation lorsque la teneur de ces ions croît en solution.
Effet de la concentration des ions chlorures

Les essais concernant l'effet de la variation de la teneur en ions Cl^- sont réalisés dans une solution contenant 0,008 M SO_4^{2-} et 0,003 M HCO_3^- et x M de Cl^-. La valeur de x désirée (entre 0,002 et 1 M) est obtenue par dissolution de cristaux de NaCl dans la solution contenant les ions SO_4^{2-} et HCO_3^-. Le pH de la solution obtenue est voisin de la valeur 8,2 et la température est maintenue à 20 °C.

La figure 3 représente les courbes de polarisation de l'étain enregistrées dans le milieu contenant différentes concentrations en ions chlorures.

Dans la branche cathodique, nous constatons l'existence de la portion linéaire au voisinage du potentiel de corrosion. Ce qui traduit un comportement Tafelien pour la réduction de l'eau (réaction 1). Néanmoins, le palier de courant observé pour des surtensions plus cathodiques a tendance à s'élargir lorsque la teneur en ions Cl^- en solution croît. Dans la branche anodique, on assiste à un déplacement remar-

Fig. 1. Courbes de polarisation de l'étain dans le milieu témoin pour différentes valeurs de pH à 20 °C.

Fig. 2. Courbes de polarisation de l'étain dans le milieu témoin pour différentes concentrations en ions sulfates à 20 °C.

Fig. 3. Courbes de polarisation de l'étain dans le milieu témoin pour différentes concentrations en ions chlorures à 20 °C.
quable du potentiel de piqûration vers des valeurs plus actives au fur et à mesure que la teneur des ions Cl⁻ en solution augmente. L'étain devient donc plus sensible à la piqûration à forte concentration en ions Cl⁻. L'évolution du potentiel de piqûration E_{piq} en fonction du logarithme de la concentration des ions Cl⁻ ($\log[Cl^-]$) est représentée à la figure 4. À titre de comparaison nous avons également représenté l'évolution de E_{piq} en fonction de $\log[SO_4^{2-}]$. Nous constatons que les deux variations sont sous forme de droites d'équations :

$$E_{piq1} = a_1 \log[Cl^-] + b_1$$

$$E_{piq2} = a_2 \log[SO_4^{2-}] + b_2$$

Où a_1 et a_2 représentent les pentes des deux droites, $a_1 = -99$ et $a_2 = -67$; b_1 et b_2 sont des constantes.

Ce résultat traduit le caractère agressif des ions Cl⁻ et SO_4^{2-} vis-à-vis de la corrosion par piqûre de l'étain dans le milieu étudié.

Notons que les valeurs des autres paramètres électrochimiques (tableau 1) ne subissent qu'une légère variation en présence des ions chlorures. Ces derniers n'ont pratiquement pas d'effet sur la valeur I_p de la densité de courant de passivation.

Effet de la concentration des ions hydrogénocarbonates

Les solutions contenants les ions HCO_3^- à différentes concentrations sont obtenues par dissolution de $NaHCO_3$ dans le milieu contenant 0,008 M SO_4^{2-} et 0,01 M de Cl⁻. Le pH de la solution est ensuite ramené à la valeur 8,2 par ajout de quelques gouttes de NaOH ou H_2SO_4. La température est fixée à 20 °C.

La figure 5 illustre l'effet de la variation de la teneur en ions hydrogénocarbonates sur les courbes de polarisation de l'étain dans le milieu synthétique. L'examen de cette figure révèle un changement remarquable dans la branche anodique. En effet, lorsque la teneur en ions hydrogénocarbonates augmente en solution, il y a apparition d'un domaine

d'activité au voisinage du potentiel de corrosion. Ce domaine est caractérisé par l'existence de deux pics I et II. Drogowska et al. (2), Brossard et al. (3) et Alvares et al. (5) ont observé le même phénomène dans des solutions contenant les ions HCO_3^-. Ces auteurs ont attribué les pics I et II à la formation de Sn (II) et Sn (IV) respectivement. Pour des surtensions plus anodiques, nous assistons à un large domaine de passivation avant d'atteindre la rupture de passivité par attaque localisée. Signalons que la position du potentiel de piqûration a tendance à se déplacer vers des valeurs plus nobles lorsque la concentration en ions hydrogénocarbonates augmente. Ce résultat traduit le caractère inhibiteur de ces ions vis-à-vis de la corrosion par piqûre de l'étain dans le milieu étudié (fig. 6). Cependant, l'examen des résultats présentés dans le tableau 2 révèle la tendance de l'étain à la corrosion uniforme lorsque la concentration des ions hydrogénocarbonates croît en solution. En effet, les densités de courant de corrosion I_{cor} et de passivation I_p augmentent avec la teneur de ces ions en solution. Ces résultats sont corroborés par les valeurs de R_p qui subissent une décroissance monotone.

Pour étudier l'effet des ions hydrogénocarbonates en présence des ions Cl⁻ à forte concentration, nous avons réalisé des essais avec une teneur en ions Cl⁻ égale à 1 M. La figure 7 représente les courbes de polarisation enregistrées dans le milieu contenant 1 M Cl⁻ à différentes concentrations en ions hydrogénocarbonates. Nous constatons que ces derniers ont un effet moins marqué sur l'inhibition de la corrosion par piqûre de l'étain. Le potentiel de piqûration n'est déplacé que de 230 mV vers des valeurs plus nobles pour une augmentation de la teneur en ions hydrogénocarbonates de 0,003 M. Signalons que pour le même intervalle, E_{piq} est déplacé de plus de 2434 mV lorsque la concentration des ions chlorures est égale à 0,01 M.

Les densités de courant de corrosion I_{cor} et de passivation I_p subissent quant à elles une nette augmentation (tableau 2) lorsque la teneur en ions HCO_3^- croît en solution. Ce résul-

Fig. 4. Variation du potentiel de piqûration E_{piq} en fonction de la concentration des ions chlorures et sulfates.
Tableau 1. Effet de la concentration des ions chlorures sur les paramètres électrochimiques de l'étain dans le milieu synthétique à 20 °C.

[Cl⁻] (mol/L)	E_{cor} (mV/ECS)	E_{piq} (mV/ECS)	I_{cor} (μA/cm²)	I_p (μA/cm²)	R_p (kΩ·cm²)
0,002	–777	–145	1,5	3,3	16,10
0,01	–769	–234	1,4	3,1	16,94
0,1	–735	–284	1,3	3,4	17,61
1	–740	–430	1,0	3,4	28,11

tat traduit la tendance de l'étain à la corrosion généralisée en présence de ces ions.

Effet de la température

Du fait que la température est l'un des facteurs susceptibles de modifier le comportement des matériaux dans un milieu corrosif, nous avons mené une étude potentiodynamique de l'étain dans le milieu synthétique (milieu témoin) à différentes températures comprises entre 20 et 70 °C. Les courbes de polarisation correspondantes sont représentées à la figure 8. Les paramètres électrochimiques sont regroupés dans le tableau 3. L'examen de ces résultats permet de faire les constatations suivantes :

L'allure générale des courbes de polarisation n'est pas modifiée par l'élévation de la température. En effet dans la branche cathodique et partant du potentiel de corrosion, nous constatons l'existence du domaine linéaire Tafelien qui traduit la réduction de l'eau selon un mécanisme d'activation pure (réaction 1). Pour des surtensions plus cathodiques, nous retrouvons le palier de courant attribué à la réduction des ions Sn^{2+} en solution (réaction 2) (15). L'élévation de la température a cependant pour effet un accroissement des densités de courant de corrosion et de passivation (tableau 3). Les potentiels de corrosion E_{cor} et de piqûration E_{piq} subissent un déplacement vers des valeurs plus actives. Les ré-

sultats présentés dans le tableau 3 montrent que la corrosion uniforme de l'étain dans le milieu étudié s'accentue avec l'augmentation de la température.

Discussion

Dans ce travail, nous avons étudié le comportement à la corrosion de l'étain dans une eau synthétique simulée à une eau industrielle (pH = 8,2). Les résultats obtenus montrent que l'étain présente un phénomène de passivation avec rupture de passivité par attaque localisée. Le phénomène de passivation est probablement dû à la formation d'une couche passive protectrice qui limite la mise en solution de l'étain. En effet, les densités de courant de corrosion I_{cor} et de passivation I_p ne dépassent pas quelques micro-ampères ($\approx$3 μA/cm²). Selon certains auteurs (2, 5), dans les milieux ayant des pH voisins du pH du milieu neutre, la formation de la couche passive suit le mécanisme réactionnel :

$$Sn + 2\ OH^- \rightarrow Sn(OH)_2 + 2\ e^-$$

$$Sn(OH)_2 \rightarrow SnO + H_2O$$

$$SnO + H_2O + 2\ OH^- \rightarrow Sn(OH)_4 + 2\ e^-$$

$$Sn(OH)_4 \rightarrow SnO_2 + 2\ H_2O$$

Tableau 2. Effet de la concentration des ions hydrogénocarbonates sur les paramètres électrochimiques de l'étain, à différentes concentrations en ions chlorures, dans le milieu synthétique à 20 °C.

$[Cl^-]$ (mol/L)	$[HCO_3^-]$ (mol/L)	E_{cor} (mV/ECS)	E_{piq} (mV/ECS)	I_{cor} (μA/cm^2)	I_p (μA/cm^2)	R_p (k$\Omega \cdot$cm^2)
	3	−765	−271	1,2	2,3	21,41
	0,003	−769	−234	1,4	3,1	16,94
0,01	0,03	−763	500	1,8	3	14,21
	0,1	−771	1300	4	12	4,12
	0,3	−797	2200	13	66	0,90
	0,003	−740	−430	1	3,4	28,10
1	0,1	−747	−285	4,4	7,5	3,72
	0,3	−776	−200	17	90	1,12

Ces auteurs ont également évoqué la possibilité de l'oxydation directe de Sn (0) en Sn (IV) :

$$Sn + 4\ OH^- \rightarrow Sn(OH)_4 + 4\ e^-$$

$$Sn(OH)_4 \rightarrow SnO_2 + 2\ H_2O$$
Dans le cas de notre milieu synthétique, la variation du pH autour de la valeur 8,2 n'affecte pas la sensibilité à la piqûration de l'étain. Le potentiel de piqûration demeure constant. Cependant, une légère augmentation des valeurs de I_{cor} et de I_p et un déplacement de E_{cor} vers des valeurs plus actives se produit lorsque le pH devient plus alcalin (pH = 9,2). Ce phénomène pourrait être attribué à la solubilité des oxydes et des hydroxydes de Sn (II) et Sn (IV) qui croît avec la teneur des ions OH⁻ en solution (4).

L'effet de la variation de la concentration des anions SO₄²⁻, HCO₃⁻ et Cl⁻ sur la résistance à la corrosion de l'étain dans le milieu synthétique a été étudié. Ainsi les ions SO₄²⁻ et Cl⁻ sont des stimulateurs de la corrosion par piqûre de l'étain. En effet, lorsque la concentration de ces ions croît

en solution, le potentiel de piqûration E_{piq} a tendance à se déplacer vers des valeurs plus actives. Les variations de E_{piq} en fonction de $\log[Cl^-]$ et $\log[SO_4^{2-}]$ sont des droites de pentes négatives a_1 et a_2. Nous remarquons que la valeur de a_1 est supérieure à celle de a_2; ce qui montre que les ions Cl⁻ sont plus agressifs que les ions SO₄²⁻ vis-à-vis de la corrosion par piqûre de l'étain dans le milieu synthétique. Ce résultat pourrait être attribué à la taille des ions Cl⁻ plus petite que celle des ions SO₄²⁻; ce qui facilite leur adsorption à la surface du film passif puis leur pénétration à travers les défauts ponctuels et les pores. Il y a alors rupture de passivité (4). Notons que la densité de courant de corrosion est pratiquement indépendante de la concentration des ions Cl⁻ et SO₄²⁻; résultats en accord avec les travaux de Drogowska et al. (16).

Dans le cas des ions HCO₃⁻, deux phénomènes antagonistes se produisent. Le premier est relatif au caractère inhibiteur de ces ions vis-à-vis de la corrosion par piqûre de l'étain dans le milieu étudié. Ce phénomène est clairement

démontré par l'évolution du potentiel de piqûration E_{piq} en fonction de log [HCO_3^-] et qui présente une pente positive (fig. 6, tracé *a*). Cependant, la valeur de la pente de la droite décroît sans devenir négative lorsque la teneur des ions Cl⁻ en solution passe de 0,01 à 1 M (fig. 6, tracé *b*). Ce résultat montre que les ions HCO_3^- ont un caractère inhibiteur moins marqué vis-à-vis de la corrosion par piqûre à forte concentration en ions Cl⁻.

Le deuxième phénomène traduit le caractère agressif des ions HCO_3^- vis-à-vis de la corrosion uniforme de l'étain. En effet, les valeurs de I_{cor}, estimées par extrapolation des pentes de Tafel cathodiques au potentiel de corrosion, ont tendance à augmenter avec la concentration des ions HCO_3^-. Ce résultat est corroboré par la décroissance subie par la valeur de la résistance de polarisation R_p et pourrait être attribué à la stabilisation des cations Sn^{2+} et Sn^{4+} par leur complexation avec les anions HCO_3^-–CO_3^{2-} en solution (3).

Pour des concentrations en ions HCO_3^- supérieures à 0,03 M, il y a apparition dans la branche anodique d'un domaine d'activité caractérisé par l'existence de deux pics d'oxydation I et II attribué à la formation de Sn (II) et Sn(IV) respectivement (2–5). La hauteur de ces deux pics a tendance à croître avec la concentration en ions HCO_3^- en solution. Ce

phénomène pourrait être expliqué par la participation directe de ces ions dans le processus de dissolution et la formation de certains complexes solubles en solution (2, 3, 4).

L'influence de la température sur la résistance à la corrosion de l'étain dans le milieu synthétique a été étudiée. L'intervalle de température choisi est compris entre 20 et 70 °C. Les résultats obtenus (fig. 8; tableau 5) montrent clairement l'effet défavorable de l'augmentation de la température sur la corrosion et la passivation de l'étain. Ceci se traduit par une croissance monotone des densités de courant de corrosion I_{cor} et de passivation I_p. Ce résultat est en accord avec la décroissance des valeurs de la résistance de polarisation R_p. Nous assistons également à un déplacement des potentiels de corrosion E_{cor} et de piqûration E_{piq} vers des valeurs plus actives lorsque la température augmente. L'évolution du logarithme des densités de courant de corrosion I_{cor} et de passivation I_p en fonction de l'inverse de la température absolue est représentée sur la figure 9. Nous constatons que la loi d'Arhénius est vérifiée pour chacune des variations log I_{cor} en fonction de ($1/T$) et log I_p en fonction de ($1/T$). Nous pouvons ainsi calculer les valeurs des énergies d'activation apparentes en utilisant les relations suivantes :

Fig. 9. Droites d'Arhénius pour l'étain dans le milieu témoin.
$$I_{cor} = A \exp(-E/RT)$$

$$I_p = A' \exp(-E'/RT)$$

Où E et E' représentent les énergies d'activation apparentes, R la constante des gaz parfaits et A et A' sont des constantes.

Les valeurs des énergies d'activation apparentes trouvées sont : $E = 14$ KJ/mole et $E' = 20$ KJ/mole.

Nous remarquons que l'énergie d'activation E calculée à partir de la densité de courant de corrosion I_{cor} est inférieure à celle calculée à partir de la densité de courant de passivation I_p. Selon certains auteurs (3), les valeurs de E caractérisent le processus de dissolution de l'étain. Ainsi, lorsque le métal est au potentiel libre de corrosion, il y a probablement formation d'un film mince et poreux. Le processus de corrosion se fait alors à travers ce film. En appliquant une surtension anodique dans le domaine de passivation, le film passif devient compact et protecteur probablement à travers un mécanisme de dissolution–précipitation (3). La mise en solution de l'étain serait plus difficile; ce qui explique la valeur de E' plus importante par rapport à celle de E.

Conclusion

Dans ce travail, nous avons étudié le comportement à la corrosion de l'étain dans une eau synthétique simulée à une eau industrielle. L'effet de la variation du pH du milieu, de la concentration des anions en solution et de la température a été évoqué. Ainsi :

L'étain présente dans le milieu synthétique un phénomène de passivation avec rupture de passivité par attaque localisée.

La variation du pH autour du pH du milieu synthétique (8,2) n'a pas d'effet sur la sensibilité à la piqûration de l'étain.

L'augmentation de la température provoque une accélération du processus de corrosion.

L'étain s'annonce très sensible aux variations de la concentration des anions en solution. En effet, les ions Cl^- et SO_4^{2-} stimulent la corrosion par piqûre mais restent sans effet notable sur la corrosion uniforme de l'étain. Par contre, les ions HCO_3^- réduisent la sensibilité à la piqûration de l'étain dans le milieu étudié.

Volumetric studies of ion solvation in propylene carbonate + *N,N*-dimethylformamide electrolyte solutions

Yang Zhao, Jianji Wang, Xiaopeng Xuan, and Ruisen Lin

Abstract: Apparent molar volumes $V_{2,\phi}$ and standard partial molar volumes $V_{2,\phi}^{\circ}$ for tetraethylammonium bromide (Et$_4$NBr), tetrapropylammonium bromide (Pr$_4$NBr), tetrabutylammonium bromide (Bu$_4$NBr), and tetrahexylammonium bromide (Hex$_4$NBr) have been determined at 298.15 K from precise density measurements in solvent mixtures of propylene carbonate (PC) with *N,N*-dimethylformamide (DMF). Combined with our previous data for LiClO$_4$ and LiBr in the same solvents, ionic molar volumes of Li$^+$, Et$_4$N$^+$, Pr$_4$N$^+$, Bu$_4$N$^+$, Hex$_4$N$^+$, and related anions have been deduced from the extrapolation method suggested by Conway and co-workers. It is shown that the molar volumes of these cations are quite independent of the nature of the solvent and the composition of the solvent mixtures, in contrast to those of ClO$_4^-$ and Br$^-$ anions. This suggests that the Lewis-base-type solvents with similar molecular volumes have similar interactions with Li$^+$. The constancy in partial molar volume for tetraalkylammonium ions provides helpful evidence for the lack of solvation of large tetraalkylammonium cations in organic solvents. These findings have been interpreted using scaled-particle theory. The results are discussed in terms of ion solvation, packing effects of solvent molecules in the solvation shell, and the electrostriction of solvents.

Key words: ionic volumes, propylene carbonate, *N,N*-dimethylformamide, solvent mixtures, solvation, lithium batteries.

Résumé : Faisant appel à des mesures précises de densité faites à 298,15 K dans des mélanges de carbonate de propylène (CP) et de *N,N*-diméthylformamide (DMF) comme solvant, on a déterminé les volumes molaires apparents, $V_{2,\phi}$, et les volumes molaires partiels standards, $V_{2,\phi}^{\circ}$, du bromure de tétraéthylammonium (Et$_4$NBr), du bromure de tétrapropylammonium (Pr$_4$NBr), du bromure de tétrabutylammonium (Bu$_4$NBr) et du bromure de tétrahexylammonium (Hex$_4$NBr). Faisant appel à la méthode d'extrapolation suggérée par Conway et ses collaborateurs, on a combiné ces données avec celles obtenues antérieurement pour le LiClO$_4$ et le LiBr dans les mêmes solvants pour en déduire les volumes molaires ioniques de Li$^+$, Et$_4$N$^+$, Pr$_4$N$^+$, Bu$_4$N$^+$, Hex$_4$N$^+$ et des anions apparentés. Il est démontré que les volumes molaires de ces cations sont assez indépendants de la nature du solvant et de la composition des mélanges de solvants; ce comportement est en opposition à celui des anions ClO$_4^-$ et Br$^-$. Ceci suggère que les solvants de type base de Lewis de volumes moléculaires semblables ont des interactions semblables avec le Li$^+$. La constance du volume molaire partiel des ions tétraalkylammonium fournit des indications utiles pour le manque de solvatation des cations tétraalkylammonium volumineux dans les solvants organiques. Ces observations ont été interprétées à l'aide de la théorie de la particule scalaire. Les résultats sont discutés en fonction de la solvatation des ions, des effets d'entassement des molécules de solvant dans la couche de solvatation et de l'électrostriction des solvants.

Mots clés : volumes ioniques, carbonate de propylène, *N,N*-diméthylformamide, mélanges de solvants, solvatation, batteries au lithium.

[Traduit par la Rédaction]

Introduction

Molar volumes of electrolytes affect the properties of lithium-battery electrolyte solutions such as conductivity and viscosity, etc. (1). They also influence the behavior of the electrodes during cycling. Therefore, studies of volumetric properties are important for developing an understanding of

ion–solvent and ion–ion interactions in lithium-battery electrolyte solutions.

Literature surveys reveal that there have been numerous studies of conductivity, viscosity, and other properties for lithium-battery electrolyte solutions. However, very little investigation has been carried out on the related volumetric properties. Zana et al. (2) obtained the ionic volume of several electrolytes in PC from densities, ultrasonic vibration potentials, and transference numbers of electrolytes measured at 298.15 K. They compared their results with those deduced by other ionic scales and found that the electrostriction in PC is close to that for water, ethylene glycol, ethanol, and dimethyl sulfoxide. The apparent molar volumes of several electrolytes in solvent mixtures of PC with acetonitrile (AN), dimethoxyethane (DME), and tetrahydrofuran (THF) have been determined by Atkins et al. (3), but the

volumes were measured at an electrolyte concentration of 0.05 mol dm^{-3}. No standard partial molar volumes were reported for these systems. Couture et al. (4) reported the volumes, heat capacities, and specific conductivities of LiClO$_4$ and LiBr in mixtures of γ-butyrolactone (BL) with DME or PC. The properties of water in DME, BL, and their mixtures have been compared in the presence of LiClO$_4$ and LiBr. Recently, Naejus et al. (5) determined the standard partial molar volumes of LiClO$_4$, LiCF$_3$SO$_3$, and LiPF$_6$ in PC, ethylene carbonate (EC), and DMC, and of LiClO$_4$ in mixtures of EC with dimethyl carbonate (DMC) or PC. Partial molar volumes of Li$^+$ and related anions in these solvents have been deduced and the effects are discussed in terms of ion–solvent interactions. The solvation of LiAsF$_6$ in PC has been discussed by Afanas'ev et al. (6) on the basis of the dissolution heat, conductivity, and solution density and viscosity. It was shown that the donor–acceptor interaction between Li$^+$ ions and the oxygen atoms of the carbonyl groups of PC makes the main contribution to the enthalpy. In a preliminary study (7), the standard partial molar volumes of LiClO$_4$ and LiBr in solvent mixtures of PC with DMF, AN, THF, and methyl formate (MF) as a function of the mole fraction of the co-solvent have been reported by us. It was shown that these standard partial molar volumes are strongly dependent on the nature of the solvents and that the trends in $V_{2,\phi}^{\circ}$ with changes in composition of the solvent mixtures are determined by the interaction volumes of electrolytes with solvents.

To study the solvation of Li$^+$ and related anions in PC + DMF mixed solvents, which show potential as battery solvents (8), the partial molar volumes of tetraethylammonium bromide, tetrapropylammonium bromide, tetrabutylammonium bromide, and tetrahexylammonium bromide are reported here. The Conway extrapolation method (9) is used to separate the contribution of the anion and cation. The results are discussed in terms of ion–solvent interactions.

Experimental

Materials

Et$_4$NBr (Shanghai Chem. Co., A.R.) was recrystallized from ethanol and dried at 333–353 K under vacuum for 2 days. Pr$_4$NBr (Fluka, A.T.) was recrystallized from acetone or methanol and dried at 383 K under vacuum for 2 days. Bu$_4$NBr (Shanghai Chem. Co., A.R.) was recrystallized from acetone or ethyl ether and dried at 333–353 K under vacuum for 2 days. Hex$_4$NBr (ACROS Organic, New Jersey, U.S.A.) was dried at room temperature under vacuum for 2 days before use.

Propylene carbonate (Luoyang Chemical Factory, A.R.) was dried over 4 Å molecular sieves for several days, refluxed for 5 h in the presence of sodium, and then distilled at reduced pressure. The middle fraction of the distillate was collected. N,N-Dimethylformamide (Tianjin Chemical Factory, A.R.) was mixed with 10% (by volume) of benzene (Beijing Chemical Factory, A.R.). The azeotrope was removed by distillation under atmosphere pressure at about 353 K. The product was dried over silica gel and distilled at reduced pressure.

Both solvents are highly hygroscopic, so the purified solvents were stored over P$_2$O$_5$ in desiccators before use. The water content, determined by the Karl Fischer method, was less than 100 ppm.

Measurements

All solutions were prepared by weight, and the concentrations of the electrolytes are expressed as molalities (mol kg^{-1}). Every precaution was taken to minimize contamination by water. The composition of the binary solvents is always represented by mole fraction (x) of DMF in the solvent mixtures.

Solution densities accurate to ±1.5 × 10^{-5} g cm^{-3} were determined with an Anton Paar DMA 60/602 vibrating-tube densimeter. The temperature around the density meter cell was controlled to 298.15 ± 0.005 K using a CT-1450 temperature controller and a CK-100 ultracryostat. The densimeter was calibrated with pure water and dry air every day. Other experimental details have been described previously (7, 10).

Results and discussion

Molar volume of electrolytes

Apparent molar volumes of tetraalkylammonium bromides in a given solvent were calculated from solution densities by

$$[1] \qquad V_{2,\phi} = \frac{M}{\rho} - \frac{10^3(\rho - \rho_0)}{m\rho\rho_0}$$

where M and m are, respectively, molar mass and molality of the electrolytes; ρ and ρ_0 are densities of the ternary solutions and the binary solvents, respectively, in units of g cm^{-3}. Apparent molar volumes of tetraalkylammonium bromides in PC + DMF solvent mixtures are given in Table 1.

It was found that $V_{2,\phi}$ varied linearly with the square root of molalities of the salts in the studied concentration range (0.01 mol kg^{-1} < m < 0.11 mol kg^{-1}).

$$[2] \qquad V_{2,\phi} = V_{2,\phi}^{\circ} + S_v m^{1/2}$$

where $V_{2,\phi}^{\circ}$ is the infinite-dilution apparent molar volume and S_V is the slope. Values of $V_{2,\phi}^{\circ}$ obtained by least-squares fitting are listed in Table 2, along with their standard deviations. Our standard partial molar volumes for Et$_4$NBr, Pr$_4$NBr, and Bu$_4$NBr in PC are, respectively, 166.16, 235.65, and 304.09 cm^3 mol^{-1}, in excellent agreement with those reported by Zana et al. (2) (166.15, 235.64, and 304.17 cm^3 mol^{-1}, respectively). No literature data can be found in regards to the mixed solvents.

It can be seen from Table 2 that the standard partial molar volumes of the tetraalkylammonium bromides in a given solvent increase with increasing number of carbon atoms (n_C) in the alkyl chains of the cation of the electrolyte and decrease with increasing mole fraction of DMF in the mixtures. The dependence of $V_{2,\phi}^{\circ}$ on n_C in every mixed solvent can be accurately fitted with the following series of linear equations:

$$[3] \qquad x_{DMF} = 0.0000, \qquad V_{R_4NBr}^{\circ} = 28.43 + 17.24\, n_C$$

$$[4] \qquad x_{DMF} = 0.2500, \qquad V_{R_4NBr}^{\circ} = 26.88 + 17.22\, n_C$$

$$[5] \qquad x_{DMF} = 0.5000, \qquad V_{R_4NBr}^{\circ} = 23.65 + 17.23\, n_C$$

$$[6] \qquad x_{DMF} = 0.7500, \qquad V_{R_4NBr}^{\circ} = 18.89 + 17.29\, n_C$$

Table 1. Solution density (ρ) and apparent molar volume ($V_{2,\phi}$) for tetraalkylammonium salts in $(1 - x)$PC $+ x$DMF mixtures at 298.15 K as a function of molality of the salts.

[7] $\quad x_{\text{DMF}} = 1.0000, \qquad V_{\text{R}_4\text{NBr}}^{\circ} = 11.74 + 17.30\,n_{\text{C}},$

with correlation coefficient $r \geq 0.9999$. Values of the slopes in these equations, which represent the contribution of -CH₂- groups to the partial molar volumes of tetraalkylammonium salts, are almost identical. However, the intercepts of the above equations, which represent the contribution of N⁺Br⁻, decrease with increasing mole fraction of DMF. The trend in the partial molar volume for N⁺Br⁻ with changes in the composition of the solvent mixtures is the same as that for the tetraalkylammonium bromides. This indicates that it is the interactions of N⁺Br⁻ with solvent molecules that play an important role in the molar volumes of the salts. It should be pointed out that the above equations can be used to predict the partial molar volumes of other tetraalkylammonium salts in PC + DMF mixed solvents. For example, $V_{\text{Pen}_4\text{NBr}}^{\circ} = 373.21$ cm³ mol⁻¹ has been calculated for Pen₄NBr in PC by eq. [3]. It is in excellent agreement with the value (373.49 cm³ mol⁻¹) reported in literature (2).

On the other hand, the standard partial molar volumes of LiClO₄ and LiBr are also found to be dependent on the nature of the solvents and the composition of the solvent mixtures. To understand these experimental results, it is essential to divide the standard partial molar volumes of the electrolytes into individual ionic contributions.

Molar volume of ions

The major methods for obtaining individual ionic standard partial molar volumes from whole electrolyte data in both aqueous and nonaqueous solutions were critically reviewed by Hefter and Marcus (11). Of the proposed methods, only the "direct" methods such as the ultrasonic vibration potential method, reference electrolyte methods, extrapolation methods, and the method involving crystal ionic radii of alkali metal and halide ions have either been widely used or may be considered to present relatively few theoretical difficulties. However, the reference electrolyte approach, using an electrolyte such as tertraphenylarsonium tetraphenylborate (TATB), appears to be the least objectionable of those available methods. On the other hand, the extrapolating method for the division of the standard partial molar volumes of the electrolyte into ionic contributions has been demonstrated to be more reliable (5), especially when organic solvents are used. Following the latter suggestion, the approach proposed by Conway et al. (9) has been employed in the present work. This approach was based on the assumption of the lack of solvation of large tetraalkylammonium ions in organic solvents. In the last few years, this method has been used more frequently. For example,

Fig. 1. Linear plots of $V_{2,\phi}^{\circ}$ vs. the molar mass of R₄N⁺ ions in $(1 - x)$PC + xDMF mixtures as a function of the mole fraction of DMF.
Saha and Das (12) used this method to separate the partial molar volumes of six symmetric tetraalkylammonium bromides in methanol + acetonitrile binary mixtures into ionic contributions. It has been found that $V_{2,\phi}^{\circ}$ values for R₄N-halides (R₄NX) are linear functions of the molar mass for the cation ($M_{\text{R}_4N^+}$):

[8] $\qquad V_{\text{R}_4\text{NX}}^{\circ} = V_{\text{X}^-}^{\circ} + bM_{\text{R}_4N^+}$

The intercept represents the standard partial molar volume of X⁻, such as Cl⁻, Br⁻, and I⁻.

Figure 1 shows the linear plots between the partial molar volume for tetraalkylammonium bromides in PC + DMF mixtures and the molar mass of the corresponding tetraalkylammonium ions. From the standard partial molar volumes of Br⁻ in the mixtures obtained by least-squares analysis, the ionic molar volumes of Li⁺, ClO₄⁻, and the tetraalkylammonium ions have been inferred based on the additivity law for electrolyte molar volumes and are reported in Table 3. It can be seen that $V_{\text{Li}^+}^{\circ}$ is quite independent of the nature of the solvents under investigation. The mean value of 9.5 cm³ mol⁻¹ is different from that obtained in previous studies (3) using the TATB assumption ($V_{\text{TA}^+}^{\circ} / V_{\text{TB}^-}^{\circ} = 1.000$): $V_{\text{Li}^+}^{\circ} = –9$ cm³ mol⁻¹. As the ratio $V_{\text{TA}^+}^{\circ} / V_{\text{TB}^-}^{\circ}$ has been found to be solvent dependent, the TATB method may therefore sharply affect the volume of cation relative to those of anions. However, our result is in approximate agreement

with the value of 5.2 cm^3 mol^{-1} obtained at 313.15 K using the King method (5). This is attributed to the fact that both the King and Conway methods have the same theoretical base.

It is interesting to find from Table 3 that the partial molar volumes for a given quaternary ammonium ion R$_4$N$^+$ are almost constant in value from one solvent to another. Similar behavior has also been reported for tetraalkylammonium ions in other pure organic solvents (12, 13). The average values for the partial molar volumes of the tetraalkylammonium ions in PC + DMF mixtures at 298.15 K obtained are as follows: $V_{\mathrm{Et_4N^+}}^{\circ} = 160.0 \pm 0.9$ cm^3 mol^{-1}, $V_{\mathrm{Pr_4N^+}}^{\circ} = 229.7 \pm 0.9$ cm^3 mol^{-1}, $V_{\mathrm{Bu_4N^+}}^{\circ} = 298.3 \pm 0.9$ cm^3 mol^{-1}, and $V_{\mathrm{Hex_4N^+}}^{\circ} = 436.4 \pm 0.9$ cm^3 mol^{-1}. These values are in fair agreement with $V_{\mathrm{Et_4N^+}}^{\circ} = 160.8 \pm 1.0$ cm^3 mol^{-1}, $V_{\mathrm{Pr_4N^+}}^{\circ} = 230.8 \pm 0.1$ cm^3 mol^{-1}, $V_{\mathrm{Bu_4N^+}}^{\circ} = 298.6 \pm 1.3$ cm^3 mol^{-1}, and $V_{\mathrm{Hex_4N^+}}^{\circ}$ (at 313.15 K) $= 442.2 \pm 4.8$ cm^3 mol^{-1} reported by Krumgalz (14) with PC, EC, dimethylsulfoxide, formamide, and N-methyl acetamide as solvents at 298.15 K. This constancy in different solvents and solvent mixtures is evidence for the lack of solvation of large tetraalkylammonium cations in organic solvents. Furthermore, the proportionality of the partial molar volumes of tetraalkylammonium cations to the number of alkyl carbon atoms n_C (see Fig. 2) means that the contribution of -CH$_2$- to the partial molar volumes of these cations is constant. This contribution can be expressed by

$$[9] \qquad V_{\mathrm{R_4N^+}}^{\circ} = a + V_{\mathrm{CH_2}}^{\circ} n_c$$

with correlation coefficient $r \geq 0.9999$. An average value for $V_{\mathrm{CH_2}}^{\circ}$ has been calculated to be 17.26 ± 0.04 cm^3 mol^{-1}, which is in good agreement with the value of 17.33 ± 0.09 cm^3 mol^{-1} reported for a series of organic solvents (14) at 298.15 K. Therefore, the contribution of the -CH$_2$- group to the volumes of tetraalkylammonium cation apparently has little to do with the nature of solvent and the composition of the solvent mixtures. The most likely explanation is that the -CH$_2$- group and, accordingly, the hydrocarbon chain for the cations are not solvated by the solvent molecules. The central meaning of the Conway method is fully embodied in these results. Moreover, it is surprising to note that the intercepts of the five straight lines, which are the contributions from N$^+$, are almost identical. An average value of 22.22 cm^3 mol^{-1} was obtained. This suggests that the contribution of N$^+$ is also unrelated to the solvent properties. Therefore, it can be concluded that the contribution of N$^+$Br$^-$ to the molar volumes of the electrolytes is mainly owing to the interaction of Br$^-$ with the solvent molecules.

Fig. 2. Dependence of partial molar volumes of R$_4$N$^+$ on the number of carbon atoms in $(1 - x)$PC + xDMF mixtures as a function of the mole fraction of DMF.
Interactions of ion with the solvents

At infinite dilution, where ion–ion interactions are absent, the partial molar volumes of ions are particularly appropriate for the study of ion–solvent interactions. IR and Raman spectra for PC + DMF mixtures investigated by us (15) indicated that PC and DMF molecules interact very weakly. Density and viscosity measurements (16) confirmed this observation. It can be concluded that the weak interaction between PC and DMF molecules would not affect the interaction of ions with solvents.

IR, Raman, and ^{7}Li NMR data (15, 17) suggest that the interactions of Li$^+$ with PC or DMF are strong in PC + DMF electrolyte solutions and that anions do not influence solvation of the Li$^+$ ions. A coordination number of 4 has been reported for Li$^+$ in PC (15) and DMF (17), reflecting the extent of ion solvation. Therefore, a similar solvation mechanism is operative in PC and DMF. Since no great difference in molecular size (molar volumes for PC and DMF at 298.15 K are 85.2 and 77.4 cm^3 mol^{-1}, respectively) and solvation properties toward Li$^+$ was observed between PC and DMF, it is not surprising that the partial molar volume of Li$^+$ is independent of the nature of the pure solvents and the composition of the solvent mixtures.

In a partial molar volume study of ions in carbonate solvents such as EC, DMC, and their mixtures, Naejus et al. (5) pointed out that the independence of Li$^+$ volumes on the nature of these solvents could be attributed to the fact that Li$^+$

is strongly coordinated by Lewis-base-type solvents. In our opinion, the solvent molar volumes are also an important factor for ion solvation in solvent mixtures. For example, Li^+ is also solvated strongly by AN, as reported by Atkins et al. (3). However, the molar volume of AN (52.9 cm^3 mol^{-1}) is significantly different from that of PC (85.2 cm^3 mol^{-1}). It is expected that the standard partial molar volumes of Li^+ in PC + AN mixtures should decrease with increasing mole fraction of AN. This expectation is supported by the results of Atkins et al. (3). Of course, this point should be confirmed by more experimental work.

Because the molar volume of Li^+ is almost constant in the solvents studied, the dependence of the molar volumes for Br^- and ClO_4^- on the composition of the solvent mixtures is similar to those for LiBr and $LiClO_4$ (see Fig. 3), showing a trend that decreases with increasing mole fraction of DMF in the mixtures. According to the Drude–Nernst equation, the electrostatic field of an ion can penetrate much deeper into a low-dielectric-constant solvent such as DMF than into PC, leading to the increased electrostriction of the solvents and the decreased partial molar volumes of ions. This is also responsible for the decreased intercept in eqs. [3–7], which is mainly the contribution of Br^-, with the addition of DMF in PC.

Since both PC and DMF have weak acceptor properties (acceptor number (A_N) for PC and DMF is 18.3 and 13.6, respectively), anions are usually considered as non-coordinated in these solvents. Steric crowding of solvent molecules around anions will not occur to the same extent as with the cations because of the much larger size of the anions and the weaker interactions with the solvents. Thus, solvent molecules tend to collapse around the anion. It can be expected that the larger the anion, the less steric hindrance there would be to the packing of the solvent molecules, but this effect would be weakened by the decreased charge field around the larger anion (ClO_4^-). Moreover, taking into account the structural differences between the tetrahedral ClO_4^- and linear Br^-, steric hindrance for the penetration of the solvent will occur for ClO_4^- in the bulky solvent molecules, and a higher molar volume than Br^- is expected.

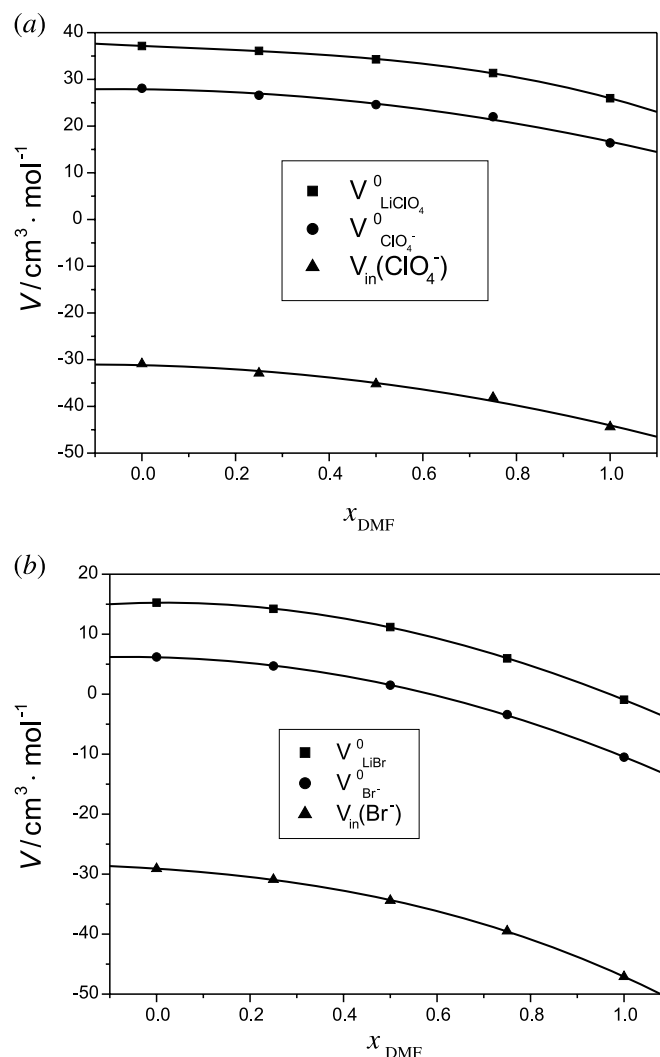
Interpretation by scaled particle theory

Volumetric properties are quite informative regarding solute–solvent interactions. Changes in the molar volumes of ions reflect the relative electrostriction (negative contribution) of solvent in the presence of a given ion. To see if the above experimental findings can be interpreted theoretically, scaled-particle theory (SPT) (18, 19) was used to evaluate the measured particle volume as a sum of the geometric volume of the ion and the change in the solvent due to its interaction with the ion. That is,

[10] $V_{2,\phi}^{\circ} = V_c + V_{in} + \beta RT,$

where V_c is the partial molar volume of cavity formation and V_{in} is the interaction volume; β is the isothermal compressibility of the solvent. The term βRT describes the volume effect of the ideal part of the solute dissolution and is often neglected. Cavity volumes for Li^+, Br^-, and ClO_4^- were calculated from

[11] $V_c = (4\pi N_0 / 3)(r_1 + \Delta)^3$

Fig. 3. Dependence of the partial molar volume for $LiClO_4$, ClO_4^-, LiBr, and Br^- and the interaction volume for ClO_4^- and Br^- on the mole fraction of DMF in the mixtures.


[12] $\Delta = (3V_1 / 4\pi N_0)^{1/3} - r_2$

on the basis of the small spherical ions in the study. Paulings crystal radii (20) are used as ionic radii (r_1) in the calculations, and the radii of the solvents (r_2) were calculated from the van der Waals volume using the method proposed by Bondi (21). Other details of the calculations can be found elsewhere (7).

The cavity volume of organic cations can be estimated by (22):

[13] V_c° (R_4N^+) $= -33 + 1.42M_{R_4N^+}$

The interaction volumes of these ions with solvent mixtures were then calculated by eq. [10] and reported in Table 4, along with the partial molar volumes of cavity formation.

It can be seen from Table 4 that values of V_c for Li^+, Br^-, and ClO_4^- vary slightly with the mole fraction of DMF, whereas those for the tetraalkylammonium ions are constant in the studied mixtures. In fact, V_c consists of two terms:

[14] $V_c = V_g + V_v,$

Table 4. Values of V_c (cm^3 mol^{-1}) and V_{in} (cm^3 mol^{-1}) for the ions in $(1 - x)$PC + xDMF mixed solvents calculated from SPT at 298.15 K.

where V_g is the geometric volume occupied by the solute molecule itself and V_v is the "empty" volume, namely the volume of the void space surrounding the solute molecules (23), which is of the greatest importance for highly structured solvents such as water but is negligible in the case of unstructured solvents such as alkyl carbonates. As a first approximation for low-molecular-weight substances, the value of V_g can be taken as the van der Waals volume V_w, which is considered to be independent of the nature of the solvent and the composition of solvent mixtures. Therefore, it is understandable that no significant differences were observed in the V_c of the ions.

The most interesting result obtained from Table 4 is that the interaction volumes of Li$^+$, Et$_4$N$^+$, Pr$_4$N$^+$, Bu$_4$N$^+$, and Hex$_4$N$^+$ with the solvents are not sensitive to the nature of solvent and composition of the solvent mixtures, in contrast to the interaction volumes of Br$^-$ and ClO$_4^-$. Because the standard partial volumes of ions can be viewed as the sum of the intrinsic volume of the ion (which is independent of the nature of solvents) and the volume resulting from the interaction of the ion with the solvents, the experimental findings for the ionic volumes represented in Table 3 have been interpreted qualitatively by scaled-particle theory.

In Fig. 4, V_{in} values for tetraalkylammonium ions have been plotted vs. the number of carbon atoms in the alkyl chains (n_C). Good linear relations are observed. The slopes of the straight lines, which denote the contribution of the CH$_2$ groups to the interaction volumes of tetraalkylammonium cations, are nearly the same within experimental uncertainty. The increment per CH$_2$ groups is approximately -2.6 cm^3 mol^{-1}. The same increment value has been inferred by Naejus et al. (5) in a study of the volumetric properties of electrolytes in mixed-carbonate solvents. The low magnitude of V_{in} shows that the electrostriction interaction of these solvents by the larger cations is very small. This is in accordance with the conclusion of the lack of solvation of tetraalkylammonium ions in the solvents investigated.

The mean value for V_{in} (Li$^+$) is 6.3 cm^3 mol^{-1} in the investigated solvents. In the solvation shell, solvent molecules that are coordinated have only restricted motions and do not allow for tight packing of uncoordinated solvent molecules by electrostriction. The excluded volume owing to coordinated molecules tends to attenuate the electrostriction effect. Other solvent molecules belonging to the primary or secondary solvation shell of the ion are oriented by the field in a manner that is incompatible with the normal, mutual orientation in the bulk, producing a region of disorder around the ion. Therefore, the constancy in V_{in} (Li$^+$) values results from a compensation between the negative contribution of the electrostriction term and the positive contribution owing to the excluded volume of the coordinated molecules and the disordered volume around the ion.

Finally, the dependence of the interaction volume between the solvents and ClO$_4^-$ or Br$^-$ on the mole fraction of DMF in the mixtures is also included in Fig. 3 for the sake of comparison. It is clear that the interaction volumes of these anions determine the trends in the partial molar volume of the ions and even those of LiClO$_4$, LiBr, and the tetraalkylammonium bromides with the changing composition of solvent mixtures. This suggests that anion–solvent interactions are important and interesting.

Fig. 4. The relation between the interaction volume V_{in}° (R_4N^+) and the number of carbon atoms of tetraalkylammonium ions in $(1 - x)$PC + xDMF mixtures as a function of the mole fraction of DMF.
Conclusions

The ionic molar volumes of Li^+, tetraalkylammonium cations, and related anions in PC + DMF mixed solvents have been deduced by the extrapolation method of Conway. It was found that the partial molar volumes of the cations are not sensitive to the nature of solvents and the composition of the solvent mixtures, whereas those of Br^- and ClO_4^- are. These findings have been interpreted qualitatively by scaled-particle theory.

The constancy in the partial molar volumes of Li^+ in the mixtures suggests that Lewis-base-type solvents with similar molecular sizes have similar and strong interactions with Li^+. The independence of the partial molar volumes of Et_4N^+, Pr_4N^+, Bu_4N^+, and Hex_4N^+ on the composition of the solvent mixtures provides indirect evidence that these tetra-alkylammonium cations are not associated and not solvated in the studied solvents. The central meaning of the Conway extrapolating method is embodied adequately in these results.

The trends in the partial molar volumes of LiBr, $LiClO_4$, and the tetraalkylammonium bromides associated with changes in composition of the solvent mixtures are determined by the interaction volumes of ClO_4^- and Br^- with the solvents, suggesting that anion solvation cannot be neglected in the ternary solutions investigated.

Huperzines S, T, and U: New *Lycopodium* alkaloids from *Huperzia serrata*

Chang-Heng Tan, Xiao-Qiang Ma, Guo-Fu Chen, and Da-Yuan Zhu

Abstract: Three new *Lycopodium* alkaloids, huperzines S (**1**), T (**2**), and U (**3**), along with eight known compounds, were isolated from the total alkaloids of the whole plant of *Huperzia serrata* (Thunb) Trev. (Huperziaceae). Those novel alkaloids were identified as 2β,13β-epoxyalopecuridine (**1**), 5α-hydroxy-6-oxodihydrophlegmariurine A (**2**), and 2,3-dihydro-12-hydroxyhuperzine B (**3**), respectively, by means of spectral techniques including NMR studies.

Key words: Huperzia serrata, Lycopodium alkaloids, huperzines S, T, U.

Résumé : À partir des alcaloïdes totaux obtenus de toute la plante *Huperzia serrata* (Thumb) Trev., Huperziaceae, on a isolé trois nouveaux alcaloïdes du *Lycopodium*, les hupérzines S (**1**), T (**2**) et U (**3**) ainsi que huit composés connus. Sur la base de techniques spectrales impliquant des études de RMN, on a établi les structures des nouveaux alcaloïdes qui sont respectivement le 2β,13β-époxyalopécuridine (**1**), la 5α-hydroxy-6-oxodihydrophlégmariurine A (**2**) et la 2,3-dihydro-12-hydroxyhuperzine B (**3**).

Mots clés : Huperzia serrata, alcaloïdes du *Lycopodium*, huperzines S, T et U.

[Traduit par la Rédaction]

Introduction

The genus *Lycopodium*, which produces a potential therapeutic agent, huperzine A, for treatment of Alzheimer's disease (1, 2), has been extensively studied in recent years (3). This work resulted in the isolation of several new *Lycopodium* alkaloids (4). Recently, we have reported the isolation of new alkaloids with novel frameworks, such as huperzines P (5), Q and its *N*-oxide (6), R (7), and W (8) from *Huperzia serrata* (Thunb.) Trev. (= *Lycopodium serratum* Thunb.). In the continuing search for new chemical constituents on this plant, we examined the low-polarity fraction of the crude alkaloids and isolated huperzines S (**1**), T (**2**), and U (**3**), three new alkaloids with fawcettimine-type, phlegmariurine B-type, and lycodine-type skeletons, respectively, along with eight known compounds, alopecuridine (**4**) (9), 4α-hydroxyphlegmariurine A (lycoposerramine-E, **5**) (10), des-*N*-methyl-α-obscurine (**6**) (11), phlegmariurine B (**7**) (12), lycodine (**8**) (13), fawcettimine (**9**) (14), huperzine B (**10**) (1), and huperzinine (**11**) (15). Like most *Lycopodium* alkaloids, the above compounds exhibited far lower activity against AChE than huperzine A in biological tests. In this paper we report the isolation and structure elucidation of the above alkaloids.

Results and discussion

Huperzine S (**1**) was obtained as white needles and showed a positive response with Dragendorff's reagent. Its HR-EI-MS spectrum gave the empirical molecular formula as $C_{16}H_{23}NO_3$ (found: $[M^+]$ 277.1674; $C_{16}H_{23}NO_3$ requires 277.1678) with six double bond equivalents. IR bands pointed to the presence of a five-membered ring ketone (1747 cm^{-1}) and a hydroxyl (3361 cm^{-1}) group. In the ^{13}C NMR (Table 1) spectrum, two sp^3 quaternary carbons signals at δ 91.7 (C-13) and 46.9 (C-12) and a five-membered ring ketone signal at δ 217.8 (C-5), diagnostic of fawcettimine-type *Lycopodium* alkaloids (3), demonstrated that **1** was a fawcettimine analogue. Since no IR bands and ^{13}C NMR signals indicated a double bond, **1** must be pentacyclic, which suggested the possibility that a new ring was formed through an ether bond between two of the three oxygen-bearing carbons (δ 91.7, 76.6, and 70.0). Its ^{1}H-^{1}H COSY and HMQC spectra displayed three isolated spin systems, -CH$_2$CH$_2$CH$_2$- (C9-C10-C11), -CH$_2$CH(OH)CH$_2$- (C1-C2-C3), and -CH$_2$CH(Me)CH$_2$CHCH$_2$- (C14-C15(C16)-C8-C7-C6). The fawcettimine-type skeleton and the presence of an O-atom connected with C-2 and C-13 were deduced by HMBC analysis, as shown in Fig. 1, which illustrated the long-range correlations for C-12/H$_2$-11 and H-7, C-13/H$_2$-14 and H$_2$-11, C-4/H$_2$-3, H-2 and H$_2$-6, as well as C-5/H$_2$-3 and H$_2$-6. With the exception that the 4-OH group was assigned as α-configuration on the basis of biogenetic consideration (from **4**), the relative configuration of huperzine S was elucidated as **1** by NOESY experiments (Fig. 1). Consequently, **1** was formulated as 2β,13β-epoxyalopecuridine.

The molecular formula $C_{16}H_{23}NO_3$ for compound **2** was deduced from the HR-EI-MS spectrum. IR bands revealed a hydroxyl (3413 cm^{-1}), a lactam (1622 cm^{-1}), and an α,β-un-

saturated carbonyl (1712, 1689, 1456 cm^{-1}) group. Its ^{13}C NMR and DEPT (Table 1) spectra displayed signals for one methyl (δ 22.7, C-16), two N-bearing methylene (δ 49.8 and 50.5, C-1 and C-9), six high-field methylene (δ 21.1, 26.9, 30.2, 30.3, 31.9, and 40.0), three methine (δ 29.2, 50.6, and 73.6), and four sp^2 quaternary carbons (δ 137.9, 172.7, 173.9, and 206.8), indicating a phlegmariurine B-type framework (12). By comparison with the ^{13}C NMR data of phlegmariurine B (**7**) (12), **2** could be assigned a phlegmariurine B carbon skeleton with a rearranged five-membered ring either >C12=C4-C5(=O)-C6(OH)-C7(H)< or >C12=C7-C6(=O)-C5(OH)-C4<. The latter structure was supported by 2D NMR (^{1}H-^{1}H COSY, TOCSY, HMQC, and HMBC) analysis (Fig. 2). The 5-OH group was positioned as α-orientated based on the inspection of H-5 (d, J = 1.5 Hz) and H-4 (br.s) combined with molecular modeling studies. Thus, the relative stereochemistry of huperzine T (**2**) was proved to be 5α-hydroxy-6-oxodihydrophlegmariurine A.

Huperzine U (**3**) was isolated from the mother liquor that yielded huperzine B (**10**). Its EI-MS peaks at m/z 274 ([M$^+$]),

257 ([M$^+$ – 17]), 219 ([M$^+$ – 55]), and 203 ([M$^+$ – 71]) indicated a hydroxylated lycodine-type *Lycopodium* alkaloid with a dedihydrogen bridge ring (16). An olefinic signal at δ 5.36 (br.d, J = 5.5 Hz, H-8) and a methyl signal at δ 1.66 (s, 16-Me) in the ^{1}H NMR spectrum indicated the double bond of the bridge ring was localized between C-8 and C-15. In a comparison of the ^{13}C NMR data of **3** with those of **10**, the main differences were the absence of two sp^2 methines (C-2 and C-3) and an sp^3 methine (C-12) and the presence of two additional methylenes (δ 31.3 and 20.5) and an O-bearing

^{a}Overlapped signals.

quaternary carbon (δ 68.6), respectively, in **3**. These data demonstrated that **3** is 2,3-dihydro-12-hydroxyhuperzine B. The postulated structure was further confirmed by HMBC (Fig. 2). Since its optical rotation was zero (*c* 0.675, MeOH), **3** was considered to be a racemic compound.

As a corollary, we note that the ^{13}C NMR assignments of C-9 and C-14 of **10** in the literature (1) need to be reversed. Carbon signals at δ 41.7 and 48.0 could easily be assigned to C-9 and C-14, respectively, via correlation with the distinguishable proton signals (δ 2.29 and 2.74, H$_2$-9; δ 2.02 and 1.83, H$_2$-14) in the HMQC spectrum of **10**. This result is in agreement with the γ-gauche effect exerted by the 12-OH of **3** (Δδ(**3**–**10**)$_{C-14}$: –9.4; Δδ(**3**–**10**)$_{C-10}$: –4.5) (17).

Experimental

General

All melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The optical rotations were measured using a PerkinElmer 241 MC polarimeter in CHCl$_3$ or MeOH. CD spectra were taken on a JASCO J-715 spectropolarimeter. IR spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer. All NMR spectra were recorded on a Bruker AM-400 instrument (400 MHz for ^{1}H and 100 MHz for ^{13}C) in CDCl$_3$ or CD$_3$OD with TMS as internal standard. EI-MS and HR-EI-MS data were obtained with a MAT-95 mass spectrometer. Silica gel (200–300, 400 mesh) and precoated plates of silica gel (HSGF$_{254}$) (Qingdao Haiyang Chemical Group Co. Ltd., Qingdao, P.R. China) were used for column chromatography (CC) and TLC, respectively.

Plant material

Fresh whole plants of *H. serrata* (Thunb) Trev. (Huperziaceae) were collected in Zhejiang Province, China, in August 2000, and identified by Dr. X-Q. Ma. A voucher sample was deposited in the herbarium of this institute.

Extraction and isolation

A large-scale isolation of huperzine A (HA) from 50 kg of dry *H. serrata*, as described in ref. 1, separated the total alkaloids into pre-HA, HA, and post-HA fractions in polar order. A part (86 g) of the pre-HA fraction was subjected to silica gel (1.5 kg) CC with petroleum ether, petroleum ether – CHCl$_3$ (1:1), and a gradient CHCl$_3$–MeOH (1:0, 50:1, 25:1, 15:1, 10:1, 0:1) and gave 8 fractions in sequence. Fraction (fr.) 2 was chromatographed on silica gel to afford needle-shaped crystals of **1** (24 mg); fr. 3 gave **7** (1.2 g), **5** (560 mg), and **2** (8 mg), respectively, after CC on silica gel with EtOAc–Me$_2$CO (2:1) as eluent and recrystallization (Me$_2$CO). Further purification of fr. 4 on a silica gel column (CHCl$_3$–MeOH, 30:1) yielded needle-shaped crystals of **11** (210 mg). Fraction 6 yielded **8** (15 mg), **9** (34 mg), and **4** (5 mg) by repeated silica gel CC (CHCl$_3$–MeOH, 15:1). Compound **10** (1.0 g) was obtained as a powdery precipitate; the mother liquor gave **6** (24 mg) and **3** (18 mg) after repeated purification by silica gel CC (CHCl$_3$–MeOH, 10:1 and 5:1) and recrystallizations.

Thermodynamics of mixtures containing alkoxyethanols: Part XVII — ERAS characterization of alkoxyethanol + alkane systems

Juan Antonio González, Susana Villa, Nicolás Riesco, Isaías García de la Fuente, and José Carlos Cobos

Abstract: Alkoxyethanol + alkane systems have been examined in the framework of the ERAS model. An exact expression for the molar excess heat capacity at constant pressure, C_P^E, of solutions formed by a self-associated compound and an inert solvent has been derived. The C_P^E and the molar excess enthalpies (H^E) and excess volumes (V^E), as well as the molar enthalpies of vaporization of the pure alkoxyethanols, are represented accurately by ERAS. The calculated curves for H^E and V^E are skewed towards high mole fractions of the alkane. The experimental curves are more symmetrical. The opposite behaviour is observed for C_P^E in solutions with 2-ethoxyethanol, 2-propoxyethanol, or 2-butoxyethanol. The differences between the experimental and theoretical values arise because ERAS does not properly take into account the enhanced dipole–dipole interactions due to the formation of intramolecular H-bonds in alkoxyethanols. As in previous applications, ERAS cannot simultaneously represent molar excess Gibbs energies and liquid–liquid equilibria. DISQUAC, a purely physical theory, improves ERAS predictions for H^E (except at high temperatures and pressures) and for C_P^E. Liquid–liquid equilibria are also described more consistently. The self-association of alkoxyethanols via intramolecular H-bonds and the strong dipole–dipole interactions lead to values of the self-association enthalpy and of the adjustable parameter of the physical contribution to H^E and V^E that are higher than those of the homomorphic 1-alkanols. In contrast, the equilibrium constants are lower. There is good agreement between the partial molar excess enthalpies at 298.15 K and infinite dilution of 2-alkoxyethanol in 2-alkoxyethanol(1) + n-heptane(2) mixtures and the values of the self-association enthalpies.

Key words: alkoxyethanol, intermolecular, intramolecular, H-bond, dipole–dipole interactions.

Résumé : On a étudié les systèmes alkoxyéthanol + alcane dans le cadre du modèle ERAS. On a développé une expression exacte de la capacité calorifique molaire en excès à pression constante, C_P^E, des solutions formées par un composé autoassocié et un solvant inerte. Le modèle ERAS permet de faire une représentation exacte de C_P^E, des enthalpies molaires en excès (H^E), des volumes molaires en excès (V^E) ainsi que les enthalpies molaires de vaporisation d'alkoxy-éthanols purs. Les courbes calculées pour H^E et V^E sont biaisées vers les fractions molaires élevées de l'alcane. Les courbes expérimentales sont plus symétriques. Le comportement opposé est observé pour les valeurs de C_P^E en solutions avec le 2-éthoxyéthanol, le 2-propoxyéthanol et le 2-butoxyéthanol. Les différences entre les valeurs expérimentales et théoriques découlent du fait que la méthode ERAS ne tient pas correctement compte des interactions dipôle–dipôle dont l'importance est augmentée en raison de la formation de liaisons hydrogènes intramoléculaires dans les alkoxyéthanols. Comme il a été observé dans des applications antérieures, ERAS ne permet pas de représenter simultanément les énergies molaires de Gibbs en excès et les équilibres liquide–liquide. DISQUAC, une théorie purement physique, améliore les prédictions d'ERAS pour H^E (excepté pour les pressions et les températures élevées) et pour C_P^E. Les équilibres liquide–liquide sont aussi décrits de façon plus cohérente. L'autoassociation des alkoxyéthanols par le biais de liaisons hydrogènes intramoléculaires et les fortes interactions dipôle–dipôle conduisent aux valeurs de l'enthalpie d'autoassociation et du paramètre ajustable de la contribution physique à H^E et V^E qui sont plus élevées que celles des 1-alcanols homomorphes. Par ailleurs, les constantes d'équilibre sont plus faibles. Il existe un bon accord entre les valeurs des enthalpies d'autoassociation et les enthalpies molaires partielles en excès à 298,15 K et à dilution infinie d'un 2-alkoxyéthanol dans des mélanges de 2-alkoxyéthanol(1) + n-heptane(2).

Mots clés : alkoxyéthanol, intermoléculaires, intramoléculaires, liaison hydrogène, interactions dipôle–dipôle.

Introduction

The extended real associated solution (ERAS) model (1) combines the real association solution model (2–5) with Flory's equation of state (6). The excess functions are split into two additive terms that arise from hydrogen-bonding effects (the so-called chemical contribution) and non-polar van der Waals interactions, including free-volume effects (the so-called physical interactions). Moreover, it is assumed that only consecutive linear association occurs, which is described by a chemical equilibrium constant K_A independent of the chain length i of the associated species. Under these basic assumptions, ERAS has been applied successfully to the characterization of the following types of systems: self-associated component + inert solvent (alkanol + alkane (7–9), linear primary amine + alkane (10)); self-associated component + polar solvent (alkanol + linear or branched monoether (11–13) or + triethylamine (14)); or to solutions containing two self-associated compounds (1-alkanol + primary or secondary linear amine (15–16)).

Alkoxyethanols, $CH_3-(CH_2)_n-O-(CH_2-CH_2O)_m-OH$, are a very interesting class of substances, owing to the presence of the O and OH groups in the same molecule, which allow self-association via inter- and intramolecular hydrogen bonds. The existence of intramolecular hydrogen bonds has been investigated using different spectroscopic techniques (17–22). For molecules of the type $CH_3-(CH_2)_n-O-(CH_2-CH_2)_p-OH$, 5-, 6-, and 7-membered rings are formed for $p = 2$, 3, and 4, respectively. The formation of intramolecular H-bonds is more favourable when the molecules are in gauche conformations. The stability of these conformations decreases with increasing p, resulting in a smaller number of rotational conformations favourable for intramolecular H-bonds. On the other hand, the increasing ring size of the intramolecularly H-bonded monomers results in greater restriction to internal rotation and is responsible for increasing the entropy changes involved in the interconversion of the mentioned species into free monomers. Alkoxyethanols with two ether groups and $m = 1$ form 5-membered rings similar to those previously cited but can also form 8-membered rings of quite different properties. This can be ascribed to the replacement of a methylene group by a less bulky oxygen atom, which increases the stability of the ring system by decreasing the ring strain caused by crowding repulsions (20).

The formation of the intramolecular H-bonds leads to enhanced dipole–dipole interactions in solutions containing alkoxyethanols relative to those present in mixtures with homomorphic alkanols (23). This is supported by the following evidence: (*i*) The effective dipole moment (24) of alkoxyethanols is higher than that of the homomorphic 1-alkanol (23), and consequently, for a given alkane, the upper critical solution temperature (UCST) of the system including an alkoxyethanol is higher than that of the solution with the homomorphic 1-alkanol (23, 25, 26); (*ii*) The Trouton's constant of hydroxyethers (27), 99.58 J mol^{-1} K^{-1}, is closer to the value of non-self-associated compounds (27), 92.05 J mol^{-1} K^{-1}, than the value for 1-alkanols (27), 110.88 J mol^{-1} K^{-1}; (*iii*) $H_1^{E,\infty}$(2-alkoxyethanol(1) + alkane(2)) < $H_1^{E,\infty}$(1-alkanol(1) + alkane(2)) (23, 28), where $H_i^{E,\infty}$ is the excess partial enthalpy at infinite dilution of component i. This has been interpreted by assuming that the

hydroxyether molecules become free via the destruction of the intermolecular H-bonds on addition of the solvent molecules and that each alkoxyethanol molecule forms an intramolecular H-bond between the O and the OH group of the same molecule and thus stabilizes itself (28); (*iv*) The H^E curves for alkoxyethanol + alkane mixtures are more symmetrical than those for alcoholic solutions, which are skewed towards low concentration of the self-associated compound. This also demonstrates that the contribution to the thermodynamic properties from the dipole–dipole interactions is higher in solutions with alkoxyethanols than in the corresponding mixtures with the homomorphic 1-alkanols (23).

All these features make the theoretical study of mixtures with alkoxyethanols very interesting. We have presented a complete treatment of hydroxyether + alkane systems (23) in terms of DISQUAC (dispersive-quasichemical) (29–30), a purely physical model based on the rigid lattice model developed by Guggenheim (31). In that work, we showed that the proximity effects between the O and OH groups of alkoxyethanols substantially change the interaction parameters of 1-alkanol + $CH_3(CH_2)_uO(CH_2)_vCH_3$ systems (32).

The purpose of this work is to examine the ability of the ERAS model to represent the thermodynamic properties of alkoxyethanol + alkane mixtures. This is useful to gain insight into the interactions present in such solutions. 2-Methoxyethanol + alkane systems have been previously studied in terms of the MUNIQUAC-RAS model (33), which combines a modification (34) of the UNIQUAC equation (35) with the real-associated solution model (3).

ERAS model

In this model, only consecutive, linear self-association of the alkoxyethanol is assumed, which can be described by a chemical equilibrium constant K_A independent of the chain length i of the associated species.

$$[1] \quad A_i + A_1 \xrightleftharpoons{K_A} A_{i+1}$$
The dependence of K_A on temperature is given by the van't Hoff relation

$$[2] \quad K_A = K_{Ao} \exp\left[-\frac{\Delta h_A^*}{R}\left(\frac{1}{T} - \frac{1}{T_o}\right)\right],$$

where Δh_A^* is the molar association enthalpy related to the intermolecular hydrogen bond formation. K_{Ao} is the association constant at temperature T_o. Values of the parameters Δh_A^* and K_A are required for calculating the chemical contribution to the excess properties. A further molecular parameter used in the ERAS model is the hydrogen bonding volume Δv_A^*, which is assumed to be a negative value, indicating that hydrogen bonding between alkoxyethanol molecules leads to a contraction of the hard-core volume of the molecules. K_A is a property of the individual alkoxyethanol. The chemical contributions to H^E and V^E are given by

$$[3] \quad H_{chem}^E = x_A K_A \Delta h_A^*(\varphi_{1A} - \varphi_{1A}^*)$$
$$- \left[\frac{P_M^* x_A \Delta v_A^* K_A(\varphi_1 - \varphi_{1A}^\bullet)}{\overline{V}_M}\right]$$

$$[4] \quad V_{chem}^E = x_A \overline{V}_M K_A \Delta v_A^*(\varphi_{1A} - \varphi_{1A}^\bullet)$$

where φ_{1A} and $\varphi_{1A}^{\bullet}$ are the hard-core volume fractions of the monomeric species in the mixture and in the pure component, respectively. These volume fractions are related to the hard-core volume fraction Φ_A ($= 1 - \Phi_B = x_A V_A^*/(x_A V_A^* + x_B V_B^*)$) and K_A

[5] $$\varphi_{1A} = \frac{2K_A\Phi_A + 1 - \sqrt{4K_A\Phi_A + 1}}{2K_A^2\Phi_A}$$

with $\varphi_{1A} \rightarrow \varphi_{1A}^{\bullet}$ as $\varphi_A \rightarrow 1$.

The physical contribution is derived from Flory's equation of state, which holds not only for pure components (index A or B) but also for the mixture (M)

[6] $$\frac{\overline{P_i}\overline{V_i}}{\overline{T_i}} = \frac{\overline{V_i}^{1/3}}{\overline{V_i}^{1/3} - 1} - \frac{1}{\overline{V_i}\overline{T_i}}$$

with $\overline{P_i} = P_i / P_i^*$; $\overline{V_i} = V_i / V_i^*$, and $\overline{T_i} = T_i / T_i^*$ being the reduced pressure, volume, and temperature, respectively. P_i^*, V_i^*, and T_i^* are the corresponding reduction parameters. For associating molecules, the procedure to obtain reduction parameters is somewhat different from the original one applied in Flory's model. In the ERAS model, the reduction parameters are calculated from $P–V–T$ data (density, thermal expansion, α_P, and isothermal compressibility, κ_T), but they also depend on K_A, Δh_A^*, and Δv_A^*. The method is explained elsewhere (36–38). The physical contribution is given by

$$[7] \quad H_{\text{phys}}^E = (x_A V_A^* + x_B V_B^*)\left(\frac{\Phi_A P_A^*}{\overline{V}_A} + \frac{\Phi_B P_B^*}{\overline{V}_B} - \frac{P_M^*}{\overline{V}_M}\right)$$

$$[8] \quad V_{\text{phys}}^E = (x_A V_A^* + x_B V_B^*)(\overline{V}_M - \Phi_A \overline{V}_A - \Phi_B \overline{V}_B)$$

The reduction parameters for the binary mixtures are calculated using the mixing rules

$$[9] \quad P_M^* = P_A^* \Phi_A + P_B^* \Phi_B - \Phi_A \theta_B X_{AB}$$

$$[10] \quad T_M^* = \frac{P_M^*}{\dfrac{P_A^* \Phi_A}{T_A^*} + \dfrac{P_B^* \Phi_B}{T_B^*}}$$

In eq. [9], $\theta_B \left(= 1 - \theta_A = \dfrac{(s_B / s_A)\Phi_B}{\Phi_A + (s_B / s_A)\Phi_B}\right)$ is the surface

fraction of compound B calculated using the surface to volume ratios of molecules B and A, s_B and s_A, which are determined from the Bondi method (39) of molecular group contributions. X_{AB} is the only adjustable parameter of the physical contribution. It characterizes the differences in dispersive intermolecular interactions of molecules A and B in the mixture and in the pure liquids.

On the other hand, for the application of eqs. [3–4] and [7–8], $\overline{V}_M$ must be determined. This is done using eq. [6] together with eqs. [9–10].

The chemical and physical contributions for C_P^E are represented by

$$[11] \quad C_{P,\text{chem}}^E = \frac{x_A K_A \Delta h_A^*}{RT^2}\left(\Delta h_A^* - \frac{P_M^* \Delta v_A^*}{\overline{V}_M}\right)$$

$$\left[\frac{\varphi_{1A}(1 - K_A \varphi_{1A})}{1 + K_A \varphi_{1A}} - \frac{\varphi_{1A}^\bullet(1 - K_A \varphi_{1A}^\bullet)}{1 + K_A \varphi_{1A}^\bullet}\right]$$

$$+ x_A K_A (\varphi_{1A} - \varphi_{1A}^\bullet)\Delta v_A^*\left(\frac{\Phi_A \theta_B \dfrac{dX_{AB}}{dt} + P_M^* \overline{\alpha}_M}{\overline{V}_M}\right),$$

$$[12] \quad C_{P,\text{phys}}^E = (x_A V_A^* + x_B V_B^*)\left(-\frac{\Phi_A P_A^* \overline{\alpha}_A}{\overline{V}_A} - \frac{\Phi_B P_B^* \overline{\alpha}_B}{\overline{V}_B}\right.$$

$$\left. + \frac{P_M^* \overline{\alpha}_M + \Phi_A \theta_B \dfrac{dX_{AB}}{dT}}{\overline{V}_M}\right)$$

The expression usually employed for $C_{P,\text{chem}}^E$ is (7, 11)

$$[13] \quad C_{P,\text{chem}}^E = \frac{x_A K_A \Delta h_A^{*2}}{RT^2}\left[\frac{\varphi_{1A}(1 - K_A \varphi_{1A})}{1 + K_A \varphi_{1A}}\right.$$

$$\left. - \frac{\varphi_{1A}^\bullet(1 - K_A \varphi_{1A}^\bullet)}{1 + K_A \varphi_{1A}^\bullet}\right],$$

which is obtained from eq. [11] when $\Delta h_A^* \gg \Delta v_A^* P_M^* / \overline{V}_M$, as in the case of 1-alkanols (7, 11), and it is recognized that $\varphi_A - \varphi_{1A}^\bullet$ is negligible.

In eqs. [11–12], $\overline{\alpha}_A$, $\overline{\alpha}_B$, and $\overline{\alpha}_M$ are calculated from the equation of state

$$[14] \quad \overline{\alpha}_i = \frac{3(\overline{V}_i^{1/3} - 1)}{T(4 - 3\overline{V}_i^{1/3})}$$

For the activity coefficients, the chemical contribution is written for each component as

$$[15] \quad \ln\gamma_{A,\text{chem}} = \ln\left(\frac{\varphi_{1A}}{x_A \varphi_{1A}^\bullet}\right) - \frac{\varphi_{1A}}{1 - K_A \varphi_{1A}}$$

$$- \frac{V_A^* \Phi_B}{V_B^*} + \frac{\varphi_{1A}^\bullet}{1 - K_A \varphi_{1A}^\bullet}$$

$$[16] \quad \ln\gamma_{B,\text{chem}} = \ln\left(\frac{\Phi_B}{x_B}\right) + \Phi_A - \frac{V_B^* \varphi_{1A}}{V_A^*(1 - K_A \varphi_{1A})},$$

while the physical contributions are given by the following expressions

$$[17] \quad \ln\gamma_{A,\text{phys}} = \frac{P_A^* V_A^*}{RT} 3\overline{T}_A\left[\ln\left(\frac{\overline{V}_A^{1/3} - 1}{\overline{V}_M^{1/3} - 1}\right) + \frac{1}{\overline{V}_A} - \frac{1}{\overline{V}_M}\right]$$

$$+ V_A^* \theta_B^2 \frac{\dfrac{X_{AB}}{\overline{V}_M} - TQ_{AB}}{RT}$$

$$[18] \quad \ln\gamma_{B,\text{phys}} = \frac{P_B^* V_B^*}{RT} 3\overline{T}_B\left[\ln\left(\frac{\overline{V}_B^{1/3} - 1}{\overline{V}_M^{1/3} - 1}\right) + \frac{1}{\overline{V}_B} - \frac{1}{\overline{V}_M}\right]$$

$$+ V_B^*(1 - \theta_B)^2(s_B / s_A) \frac{\dfrac{X_{AB}}{\overline{V}_M} - TQ_{AB}}{RT},$$

where Q_{AB} characterizes the entropic contribution to the different intermolecular interactions.

Finally, using the ERAS model, it is possible to evaluate the enthalpy of vaporization (7, 38) of the pure compounds

$$[19] \quad \Delta_m H_\nu = \frac{P_i^* V_i^*}{\overline{V}_i} - \frac{\Delta h_i^*}{2K_i}(2K_i + 1 - \sqrt{4K_i + 1}) + RT$$

Here, the first term arises from the van der Waals interactions and free volume effects, while the second term is owing to the intermolecular association due to hydrogen bonding.

Estimation of the ERAS parameters

The reduction parameters P_i^* and V_i^* ($i = A$) of the n-alkoxyethanols are listed in Table 1. For the alkanes, the reduction parameters were calculated from α_P and κ_T data available in the literature (40, 47, 48) (Table A1 of Appendix A). The adjustable parameters are K_A, Δh_A^*, Δv_A^*, X_{AB}, Q_{AB}, and dX_{AB}/dT. K_A, Δh_A^*, Δv_A^*, and X_{AB} are fitted to H^E and V^E data at 298.15 K for n-alkoxyethanol + alkane mixtures. For the C_P^E calculations, it is necessary to evaluate dX_{AB}/dT. This was done by taking into account the available C_P^E and H^E data at $T \neq 298.15$ K and assuming a linear dependence with T for X_{AB} (7). The entropic parameter Q_{AB} was obtained from G^E data (see below) (7, 9).

Discussion

ERAS results

The results of the calculations from the ERAS model for H^E, V^E, C_P^E, and G^E are presented in Tables 4–7 (see also Figs 1–6). For H^E, C_P^E, and G^E, these values are compared with those obtained using DISQUAC with the interaction parameters previously determined (23).

The composition dependence of H^E is better represented by DISQUAC than by ERAS except when the measurements were carried out at very high temperatures and (or) pressures. See, for example, the results for the 2-methoxyethanol + n-heptane system at 373.15 K and 15 MPa (Table 4). In this case, the term $\overline{P_i V_i} / \overline{T_i}$ in the equation of

state (eq. [6]), only negligible at atmospheric pressure, was included in the ERAS calculations.

ERAS provides V^E curves skewed towards high mole fractions of the alkane (Figs 3–4). Note that the predicted H^E curves are also slightly shifted towards that region (Fig. 2). The experimental curves are more symmetrical. Such behaviour may be interpreted, assuming that, for the solutions studied here, the model overestimates the chemical contribution to these thermodynamic properties. It should be noted that typically the experimental H^E, V^E, and C_P^E curves are also shifted toward the region of high alkane mole fraction in solutions with 1-alkanols (24).

At 303.15 K, the experimental C_P^E curve for the 2-methoxyethanol(1) + cyclohexane(2) system is rather symmetrical (40) (Fig. 5). In contrast, the C_P^E curve is skewed towards low mole fractions of 2-alkoxyethanol in solutions of 2-ethoxyethanol, 2-propoxyethanol, or 2-butoxyethanol with

n-octane (64) (Fig. 6). In the case of the 2-methoxyethanol mixture, the different shape of the C_P^E curve may be ascribed to the existence of large fluctuations in concentration due to the proximity of the UCST (294.58 K (65)). Consequently, the importance of the self-association of 2-methoxyethanol becomes less relevant, and the model properly describes the C_P^E curve with $C_{P,\text{phys}}^E > C_{P,\text{chem}}^E$. For the same reason, H^E for 2-methoxyethanol + n-alkane mixtures is well represented at high temperatures and pressures. The inequality $C_{P,\text{phys}}^E > C_{P,\text{chem}}^E$ is still valid for the 2-ethoxyethanol, 2-propoxyethanol, or 2-butoxyethanol + n-octane systems and leads to more symmetrical curves than the experimental ones (Fig. 6). That is, at room temperature the experimental data indicate that the more important contribution to C_P^E comes from the structure of the solution. ERAS cannot represent this behaviour because $C_{P,\text{phys}}^E > C_{P,\text{chem}}^E$. So, for the systems including 2-ethoxyethanol, 2-propoxyethanol, or 2-butoxy-

[b]DISQUAC calculations using the interaction parameters given in ref. 23.

ethanol, the model cannot simultaneously describe their rather symmetrical H^E curves and the corresponding asymmetric C_P^E curves.

The composition dependence of C_P^E is also usually better represented by DISQUAC (Table 6, Figs. 5–6), although $V^E = 0$ in terms of this rigid lattice theory. ERAS yields a quite satisfactory description for V^E (Table 5, Figs. 3–4)

Table 7 lists results for G^E using the entropic parameters Q_{AB} collected in Table 3. These parameters were determined from G^E data available in the literature. As in the case of 1-alkanol + alkane mixtures (7), the same Q_{AB} parameter cannot be used to simultaneously represent vapor–liquid equilibria and liquid–liquid equilibria. So, for 2-methoxyethanol + cyclohexane, the calculated UCST is 305 K using $Q_{AB} = 0.07$ (DISQUAC gives 304 K for the UCST; the measured UCST (65) is 294.58 K). With this Q_{AB} value, ERAS predicts for the cited system $G^E(x = 0.5, 305 \text{ K}) = 1339$ J mol^{-1}, which is quite different from the values given in Table 7 at 303.15 K and 323.15 K. This is one of the most important limitations of the ERAS model and of any association theory, as the type of association normally observed is not sufficient by itself to produce phase separation (66). Nevertheless, at temperatures far from the UCST, both models give similar results. This is the case for the 2-butoxyethanol + n-hexane system at 303.15 K (Table 7).

The ERAS parameters

It is interesting to compare K_A, Δh_A^*, and Δv_A^* for alkoxyethanols and homomorphic 1-alkanols. We note that Δh_A^* increases when passing from 1-alkanol (-25.1 kJ mol^{-1}) to

alkoxyethanol (see Table 2). These increases in Δh_A^* indicate that the intermolecular H-bonds between 1-alkanol molecules are stronger than between alkoxyethanol molecules. In terms of the ERAS model, only consecutive linear self-association is assumed, while ring formation is neglected. That is, the model does not take into account the self-association via intramolecular hydrogen bonding characteristic of the alkoxyethanols. This means that ERAS probably overestimates the magnitude of Δh_A^*. In contrast, K_A(1-alkanol) > K_A(alkoxyethanol). So, at 298.15 K, K_A(1-butanol) = 175 (37, 67) while K_A(2-methoxyethanol) = 75 (Table 2) and K_A(1-decanol) = 88 (37, 67); K_A(2-(2-butoxyethoxyethanol)) = 20 (Table 2). The more relevant contribution of dipole–dipole interactions to the thermodynamic properties of alkoxyethanol + alkane mixtures is represented by the large values of the X_{AB} parameter. For example, at 298.15 K, $X_{AB} = 5.42$ J cm^{-3} for 1-hexanol + n-hexane (7); for 2-propoxyethanol + n-heptane, $X_{AB} = 23$ J cm^{-3}. Similar behaviour is observed in 1-alkanol + linear organic carbonate systems (67).

The value $\Delta v_A^* = -5.6$ cm^3 mol^{-1}, widely used for 1-alkanol + alkane mixtures (37, 67), differs from those listed in Table 2. A comparison of Δv_A^* values becomes difficult because other values of Δv_A^* have been used for 1-alkanols in order to provide a more accurate representation of the V^E.

Fig. 1. H^E for the 2-methoxyethanol(1) + n-heptane(2) system. Symbols, experimental data: (●) T = 298.15 K (51); (■) T = 373.15 K and 15 bar (1 bar = 10^5 Pa) (50). Solid lines, ERAS calculations. Dashed lines, chemical and physical contributions at 373.15 K and 15 bar.

Fig. 2. H^E for the 2-ethoxyethanol(1) + n-heptane(2) system at 298.15 K. Symbols, experimental data (53). Solid lines, ERAS calculations. Dashed lines, chemical and physical contributions or DISQUAC (DQ) results (23).
So, $\Delta v_A^* = -9$ cm^3 mol^{-1} for ethanol when mixed with n-hexane (7); or -5.6 cm^3 mol^{-1} when mixed with n-hexadecane (7); or $\Delta v_A^* = -6.9$ cm^3 mol^{-1} for 1-hexanol when mixed with n-hexane (7). The Δv_A^* values determined in this work provide a reasonable description of the corresponding V^E curves.

Fig. 3. V^E for the 2-ethoxyethanol(1) + n-heptane(2) system at 298.15 K. Symbols, experimental data (59). Solid lines, ERAS calculations. Dashed lines, chemical and physical contributions.
Fig. 4. V^E for the 2-propoxyethanol(1) + n-octane(2)system at 298.15 K. Symbols, experimental data (42). Solid lines, ERAS calculations. Dashed lines, chemical and physical contributions.
The K_A, Δh_A^*, and Δv_A^* parameters for alkoxyethanols reported in this article are supported by the ERAS predictions for the molar enthalpy of vaporization (Table 2). In addition, the experimental $H_1^{E,\infty}$ values (28) at 298.15 K for CH$_3$-(CH$_2$)$_n$-O-CH$_2$-CH$_2$-OH(1) + n-heptane(2) are in good agreement with our Δh_A^* values ($H_1^{E,\infty}$ (kJ mol^{-1}) = 17.6, 15.5, 15.5, and 14.4, respectively, for n = 0, 1, 2, and 3)

Finally, it should be emphasized that the relative variation of the K_A and Δh_A^* parameters is consistent with the variation encountered previously for the enthalpic interchange coeffi-

Fig. 6. C_P^E for the 2-ethoxyethanol(1) + n-octane(2) system at 298.15 K. Symbols, experimental data (64). Solid lines, ERAS calculations. Dashed lines, chemical and physical contributions or DISQUAC (DQ) results (23).

Fig. 7. Parameters in the ERAS and DISQUAC models vs. n, the number of C atoms in 2-alkoxyethanol.
ethanol, or 2-(2-alkoxyethoxyethanol) with alkane are characterized by the same quasichemical enthalpic parameter (23).

Conclusions

Alkoxyethanol + alkane systems have been examined in the framework of the ERAS model. The thermodynamic properties H^E, V^E, and C_P^E are represented accurately. However, DISQUAC, a purely physical theory, improves the H^E (except at high temperatures and pressures) and C_P^E results from ERAS. The observed differences between experimental and theoretical values that can be ascribed to ERAS do not properly take into account the enhanced dipole–dipole interactions due to the intramolecular H-bonds of the alkoxyethanols. As in previous applications, ERAS cannot simultaneously represent G^E and liquid–liquid equilibria. There is good agreement between the partial molar excess enthalpies at 298.15 K and infinite dilution of 2-alkoxyethanol in 2-alkoxyethanol(1) + n-heptane(2) mixtures and Δh_A^*. The variation of K_A and of Δh_A^* with the molecular structure of alkoxyethanol is supported by that of the enthalpic interchange coefficients in DISQUAC.

cients in the DISQUAC model (Fig. 7). For instance, the excellent results obtained for H^E for the 2-(2-butoxyethoxy)ethanol + heptane system (Table 4) using $\Delta h_A^* = -13.5$ kJ mol^{-1} (the same value for 2-propoxyethanol or 2-butoxyethanol) are remarkable. Similarly, in the DISQUAC model, mixtures of 2-propoxyethanol, 2-butoxy-

AWARD LECTURE / CONFÉRÉNCE D'HONNEUR

Catalysis by organotransition metal compounds: Synergism between the pure and the applied[1]

Michael C. Baird

Abstract: The modern era of transition-metal-catalyzed polymerization of alkenes began with the Nobel Prize winning work of Ziegler and Natta in the 1950s, but the field has exploded since the mid-1980s and anticipated applications of organometallic catalysts are being spectacularly realized. Our research in metal-catalyzed alkene polymerization began about ten years ago with an investigation of the catalytic applications of half-sandwich complexes of the Group 4 metals, and this lecture will describe our efforts to find both better initiators to make known commercial polymers and new initiators to make novel polymeric materials. Good luck, bad luck, blind alleys, and serendipity have all played key roles in our research, resulting ultimately in a very satisfying convergence of the motives for pure, and the needs of applied, research.

Key words: alkene, polymerization, Ziegler, catalysis, carbocationic, titanium.

Résumé : L'ère moderne de la polymérisation des alcènes à l'aide de catalyseurs à base de métaux de transition a débuté dans les années 1950 avec les travaux qui ont valu un prix Nobel à Ziegler et à Natta; toutefois, le champ a explosé depuis le milieu des années 1980 et des applications anticipées de catalyse par des organométalliques sont maintenant réalisées de façon spectaculaire. Nos travaux de recherches dans le domaine de la polymérisation des alcènes à l'aide de catalyseurs à base de métaux de transition ont débuté il y a une dizaine d'années avec une étude sur les applications catalytiques de complexes à demi-sandwich de métaux du groupe 4 et cette conférence décrira les efforts que nous avons déployés dans le but de trouver de meilleurs initiateurs pour faire des polymères commerciaux connus et de nouveaux initiateurs pour faire de nouveaux matériaux polymères. La chance, bonne et mauvaise, les voies sans issue et la sérendipité ont joué des rôles clés dans nos recherches qui ont permis éventuellement de conduire à une convergence satisfaisante des motifs de la recherche pure et des besoins de la recherche appliquée.

Mots clés : alcène, polymérisation, Ziegler, catalyse, carbocationique, titane.

[Traduit par la Rédaction]

Transition-metal-based catalysts for alkene polymerization are — given the importance of plastics such as polyethylene and polypropylene — among the keystones of western civilization. For instance, current world production of polyethylene (PE) and polypropylene (PP) are $>42 \times 10^6$ and $>24 \times 10^6$ tonnes per annum (p.a.), respectively (1). The most important type (isomer) of PE is linear, i.e., $Me(CH_2)_nMe$ ($n \geq \sim 400$), and may be considered a long molecular strand, as in **A**.

A
This type of polymer was discovered serendipitously by Ziegler in the early 1950s and led quickly to the Nobel Prize in chemistry in 1955. The long chains of linear PE pack very effectively in the solid, resulting in a tough, high-melting ($\sim 140°C$), semi-crystalline material with a relatively high density (0.94–0.97 g mL^{-1}); thus it is oft referred to as high-density PE or HDPE (1). Degrees of branching can also be induced in various ways to give products with a range of properties. For instance, the usual manufacturing processes can produce semi-crystalline material containing the occasional short methyl (or longer) branch, as in the cartoon drawing **B**.

B
The resulting materials exhibit slightly lower melting points (130–135°C), and hence offer greater ease of processability (1).

Isomeric with HDPE are highly branched forms of PE, which may be represented by **C**.

C
This type of material packs much less efficiently as a solid and thus is amorphous, low melting (106–112°C), and of relatively low density (0.915–0.935 g mL^{-1}); hence LDPE (1). Not strictly isomeric but generally regarded as a third major classification of PE is a type of polymer obtained by copolymerizing ethylene with monomers such as propylene or 1-butene. The resulting material contains a random distribution of identical branches (**D**) and exhibits an intermediate melting temperature (~125°C) but low density (0.915–0.935 g mL^{-1}). This material is referred to as linear low density PE or LLDPE (1).

D
The major commercial catalysts used for the manufacture of both PE and PP are generated by combining TiCl$_3$ with aluminum alkyls such as AlEt$_3$, although Cr$_2$O$_3$ is also an important catalyst for PE (1). These catalysts are heterogeneous, but there is currently a growing interest in applications of homogeneous catalysts based on metallocenes of titanium, zirconium, and hafnium (2). The most important class of homogeneous alkene polymerization initiators is of the type [Cp$'_2$ZrMeL]$^+$ (**E**).

E
These contain a labile ligand L, *cis* to the alkyl ligand, important if a vacant site is to be made available for alkene coordination as shown in Scheme 1. The reactivity is also enhanced by the positive charge on the complex (2).

A very important sub-class of metallocene catalysts contains a dicyclopentadienyl ligand, which has local C_2 symmetry (**F**).

The strap between the Cp rings, which may be, e.g., a -(CH$_2$)$_2$- or an -SiMe$_2$- group, maintains a chiral structure that induces molecules of a prochiral monomer such as propylene to coordinate via the same face almost every time. This has major implications for the stereochemistry of the polymer propagation process (2) (see discussion below concerning polypropylene).

The mechanism of polymerization initiation and chain propagation for PP and most types of PE involves coordination of an alkene such as ethylene followed by repeated mi-

F
gratory insertion steps, as illustrated in Scheme 1 for a metallocene catalyst. Here (and below) the letter P is used to indicate a growing polymer chain.

As the HDPE originally discovered by Ziegler was the first example established as an application of this mechanism, the process is often referred to as Ziegler polymerization, although it is often known as coordination polymerization. Chain-termination and chain-transfer steps generally involve very similar chemistry, as in Scheme 2.

Polypropylene can also be obtained in isomeric forms, as regio- and stereoisomers rather than as structural isomers with varying degrees of branching. As a polymer chain grows, whether initiation and propagation involve 1,2- (**G**) or 2,1-insertion (**H**), incorporation of a molecule of monomer generates a new chiral centre (M = catalytic centre; ~P = growing polymer chain).

G   **H**
If the sense of handedness is decided purely randomly (mixture of *R*- and *S*-), the product is "atactic" polypropylene (**I**) (1).

I
With chiral, C_2-symmetric catalysts of type **F**, the stereochemistry of insertion is often highly controlled (asymmetric induction) (1, 2). Each molecule of monomer inserts in the same way to give a stereoregular polymer, as in, e.g., **J**.

J
Chiral catalysts can therefore produce polymers with very high degrees of handedness at each step, i.e., for polypropy-

Scheme 1.

Scheme 2.

lene, semi-crystalline isotactic (**K**) and syndiotactic forms (**L**) are known.

K

L

Atactic (random stereochemistry), isotactic (each chiral centre has the same configuration), and syndiotactic (alternate chiral centres have the same configuration) polymers bear diastereomeric relationships with respect to each other, and thus have different chemical, physical, and mechanical

properties. For instance, *a*-PP is soft (unimportant), while *i*-PP (mp ~176°C) and *s*-PP (mp ~148°C) are high-melting, hard plastics. *i*-PP was discovered by Natta in the 1950s (shared the Nobel Prize of 1955) and is the commercially important variety (1).

There is an extremely extensive literature on metallocene-based catalytic systems (2), but homogeneous catalysts may also be based on monocyclopentadienyl compounds, little studied when we began in early 1991. We have worked largely with the "piano-stool compound" $Cp*TiMe_3$ ($Cp*$ = η^5-C_5Me_5) (**M**).

M

This is a catalyst precursor that can be activated in many ways, as in eq. [1] (3–5).

[1] $Cp^*TiMe_3 + B(C_6F_5)_3 \rightarrow [Cp^*TiMe_2]^+$
$+ [MeB(C_6F_5)_3]^-$

The resulting cationic complex has coordinated alkyl groups, vacant site(s), and a positive charge, as is important for metallocene catalysts (see above). However, it could be more active than metallocenes for both steric and electronic reasons. The structure of "$[Cp^*TiMe_2][MeB(C_6F_5)_3]$" actually involves a non-classical mode of coordination of the borate anion, as in **N**.

N
The chemistry of $Cp^*TiMe_2(\mu\text{-Me})B(C_6F_5)_3$ proved to be very interesting. For instance, the borate anion is readily substituted in solution (eq. [2]) (4–6).

[2] $Cp^*TiMe_2(\mu\text{-Me})B(C_6F_5)_3 + L \rightarrow$
$[Cp^*TiMe_2(L)]^+ + [MeB(C_6F_5)_3]^-$
$L = \text{amines, phosphines}$
Similarly, arene complexes are formed in aromatic solvents (3, 6), e.g., in toluene:

[3] $Cp^*TiMe_3 + B(C_6F_5)_3 \rightarrow$
$[Cp^*TiMe_2(\text{toluene})][MeB(C_6F_5)_3]$
The products, which have been characterized for Ti, Zr, and Hf complexes, contain η^6-bonded arene rings and thus are isoelectronic with the corresponding neutral dimethylmetallocenes. The anticipated structure (**O**), has been demonstrated by an X-ray structure of a hafnium analogue (6).

The cationic moiety $[Cp^*TiMe_2]^+$ also behaves as a Lewis acid towards Cp^*TiMe_3, giving the dititanium species $[Cp^*TiMe_2(\mu\text{-Me})TiMe_2Cp^*]^+$ (**P**), as in eq. [4] (5).

[4] $Cp^*TiMe_2(\mu\text{-Me})B(C_6F_5)_3 + Cp^*TiMe_3 \rightarrow$
$[Cp^*TiMe_2(\mu\text{-Me})TiMe_2Cp^*]^+$ (**P**)
$+ [MeB(C_6F_5)_3]^-$
Thus the neutral Cp^*TiMe_3 is a better ligand than the anionic $[MeB(C_6F_5)_3]^-$!

We have found that $Cp^*TiMe_2(\mu\text{-Me})B(C_6F_5)_3$ is an excellent alkene polymerization catalyst. Polymerizations of ethylene (4), propylene (7), and 1-hexene (8, 9) occur readily over a range of temperatures, and we obtain high-molecular-weight, linear polyethylene (HDPE), as well as high-molecular-weight, atactic polypropylene and poly-1-hexene. We can also make copolymers of ethylene with propylene (10) and 1-hexene (11) and commercially important terpolymers of ethylene, propylene, and 5-ethylidene-2-norbornene,

O

P
known as EPDM (10). These reactions undoubtedly involve Ziegler mechanisms and η^2-alkene complexes of the type shown as **Q**.

Q
Initiation and the dominant mode of propagation involve 1,2-insertions, as shown in Scheme 3.

This was demonstrated using ^{13}C NMR spectroscopy and a labeled catalyst, as in Scheme 4 for 1-hexene ([Ti] = Cp^*TiMe_2) (9).

In situ ^{13}C NMR experiments of the reaction of $Cp^*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)B(C_6F_5)_3$ with 1-hexene in CD_2Cl_2 at −50°C also give interesting mechanistic information. The resonance of the free borate $[B(^{13}CH_3)(C_6F_5)_3]^-$ appeared, and thus the anion had clearly been displaced, as expected. Interestingly, the Ti–Me resonance also disappeared and no new ones appeared. Thus both methyl groups must become involved and polymerization must occur at two sites on the titanium, as expected although not previously demonstrated for any Ziegler-catalyst system. New resonances did appear at δ ~20 (methyl branch) and 10.5 (ethyl branch), and the latter implies an initial 2,1-insertion in CD_2Cl_2 (Scheme 5).

Scheme 3.

Scheme 4.

$$[Ti]\text{-}^{13}CH_3 + CH_2=CHBu \longrightarrow [Ti]\text{—}CH_2CH(^{13}CH_3)Bu$$
NMR analyses of end groups of low-molecular-weight polypropylene indicate two major modes of chain transfer for this olefin, as shown in Scheme 6. Following 2,1-insertion of 1-hexene, β-H elimination in the opposite direction also occurs (Scheme 7).

Very different chemistry was observed with styrene using $Cp*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$. For instance, we obtain only atactic polystyrene (PS) in toluene at temperatures below ~–15°C but highly (>98%) syndiotactic PS (*s*-PS) in neat styrene or in toluene above room temperature (reaction very rapid and exothermic) (4). Atactic PS is familiar as styrofoam, but *s*-PS is a hard solid (mp ~270°C), insoluble in all solvents at 20°C. It is therefore of great interest as a new plastic. That polymerization by $Cp*Ti(CH_3)_2(\mu\text{-}CH_3)B$-$(C_6F_5)_3$ is initiated and proceeds via a Ziegler process involving 2,1-insertions is shown by NMR studies utilizing $Cp*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)B(C_6F_5)_3$ (Scheme 8) (4).

Chain propagation thus proceeds with an extremely high degree of stereoselectivity despite occurring at an achiral (!!) metal centre. As it happens, the stereochemistry of insertion is under chain-end control, as the handedness at C_1 (Scheme 8) controls the mode of insertion of the next monomer (12). There follow conventional termination – chain transfer processes (β-eliminations, migratory insertions). The nature of the catalytic species, possibly of Ti(III), is not known, although we and others have carried out considerable research on what is, at the time of writing, a very controversial issue (13).

It was during the early days of our research on the utilization of $Cp*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$ to polymerize styrene that we carried out our initial experiments with propylene, a line of experimentation that through bad luck resulted in data misinterpretation. The consequences were at the time somewhat embarrassing, but resulted serendipitously in an avenue of exploration that we would not have otherwise taken but that led quickly to the development of a series of novel, quite unanticipated but very useful findings. During our earliest experiments, we had found that $Cp*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$ was seemingly an excellent catalyst for the polymerization of ethylene and styrene to HDPE and *s*-PS, respectively, but a poor catalyst for the polymerization of propylene. This trend did not make sense for a Ziegler cata-

Scheme 5.

$$[Ti]\text{-}^{13}CH_3 + CH_2=CHBu \longrightarrow [Ti]\text{—}CH(Bu)CH_2{}^{13}CH_3$$

$$P\sim CH(Bu)CH_2{}^{13}CH_3 \ (\delta \ 10.5)$$

Scheme 6.

Scheme 7.

$$[Ti]\sim P + CH_2=CHBu \longrightarrow [Ti]\,CH(Bu)CH_2\sim P$$

$$[Ti]\text{-}H + BuCH=CH\sim P$$

Scheme 8.

$$[Ti]\text{-}^{13}CH_3 + PhCH=CH_2 \longrightarrow [Ti]CHPh^{13}CH_3$$

$$[Ti](CHPhCH_2)_nCHPh^{13}CH_3 \ (\delta \ 11.7)$$
lyst, for which one would anticipate an order of activity ethylene > propylene > styrene, and we wondered if some other mechanism might be applicable in the formation of *s*-PS. A radical chain mechanism was clearly inappropriate as it is known to give *a*-PS (1), and we mistakenly gave serious consideration (14) to the possible role of carbocationic initiation (15).

Carbocationic polymerization of alkenes involves activation of the monomer (initiation) by a good electrophile, as shown in Scheme 9 (E^+ = electrophilic reagent) for styrene. The mechanism clearly requires a monomer that can form a stable cation (15).

When the electrophilic activator is $[Cp*Ti(CH_3)_2]^+$, the process would involve η^1-coordination, as in Scheme 10.

While we eventually found that this mode of activation does occur under certain circumstances (see below), we were soon disabused of the appropriateness of the mechanism for the synthesis of *s*-PS. We found that the propylene being used had not been dried appropriately and was killing the catalyst (4); indeed propylene is in fact polymerized quite effectively by $Cp*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$ (7, 16). The results of the labeling experiment described above require a Ziegler mechanism, but, before we realized just what was going on, we investigated monomers that *prefer* to be polymerized via a carbocationic mechanism. In view of the undeniable novelty of an established Ziegler–Natta catalyst behaving preferentially as a carbocationic initiator, we

Scheme 9.
Scheme 10.
thought we would ascertain its possibly wider applicability. Obvious candidates were vinyl ethers, *N*-vinylcarbazole, and isobutene (15), shown in Scheme 11.

These are known to be polymerized only via a carbocationic mechanism, much as in Schemes 9 and 10, because their carbocationic centres are readily stabilized by the adjacent functionalities but never via a Ziegler mechanism (15).

Much to our delight, polymers of vinyl ethers and *N*-vinylcarbazole are readily prepared using Cp*TiMe$_2$(μ-Me)B(C$_6$F$_5$)$_3$ (17). Low temperatures (–78°C) are required for high molecular weights to be achieved, as with conventional initiators, and in most cases the poly(vinyl ether) products exhibit tacticities very similar to those obtained with conventional Lewis-acid initiators and molecular weights comparable with the better literature results. Also in agreement with the postulated carbocationic mechanism, there is no reaction with 2,5-dihydrofuran (**R**), for which a carbocationic intermediate cannot be stabilized by a free electron pair on an adjacent oxygen atom.

While not in the commercial league of high-volume polymers such as PE and PP, polyvinyl ethers are important and are used as adhesives, plasticizers, hair spray, etc. Poly(*N*-vinylcarbazole) is also obtained with very high molecular

R

weights and is a material that forms interesting semiconductors when doped appropriately.

Polymerization by Cp*TiMe$_2$(μ-Me)B(C$_6$F$_5$)$_3$ presumably involves an η^1 metal–alkene interaction, stabilized by a secondary interaction with the counteranion, as in **S**.
S

Scheme 11.
This is an unusual mode of metal—alkene bonding, but it resembles the transition state involved in nucleophilic attack on alkenes activated by coordination to electrophilic metals (18). Near-η^1 structures have precedent in a variety of known complexes of vinyl ethers, vinyl alcohol, and vinyl amine (19). By way of evidence that poly(vinyl ethers) are indeed formed via the carbocationic process, we found that the ^{1}H NMR spectrum of poly(ethyl vinyl ether) formed exhibits a weak resonance at δ 9.88 attributable to an aldehyde end group, arising from hydrolysis of the acetal end group, -CH(OMe)(OEt), formed by methanolysis (eqs. [5], [6]) (17).

[5] $Cp^*TiMe_2[\{CH_2CH(OEt)\}_n(CH_2C^+HOEt)]$

    $+ MeOH \rightarrow$

    $Cp^*TiMe_2[\{CH_2CH(OEt)\}_n(CH_2CHOEtOMe)] + H^+$

[6] $Cp^*TiMe_2[\{CH_2CH(OEt)\}_n(CH_2CHOEtOMe)]$

    $+ H^+ + H_2O \rightarrow$

    $CH_3CH(OEt)\{CH_2CH(OEt)\}_{(n-1)}CH_2CHO$

        $+ EtOH + MeOH$
While carbocationic initiation is not a factor in the polymerization of styrene to *s*-PS, we did demonstrate its applicability to the formation of atactic PS in, e.g., toluene at temperatures below ~–15°C. ^{1}H NMR monitoring of the polymerization reaction of styrene-d_8 to atactic polymer in CD_2Cl_2 by $Cp^*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)B(C_6F_5)_3$ at –50°C showed quite clearly that this process results in no measurable loss of initiator, consistent with a carbocationic mechanism. The ^{1}H NMR spectrum of $Cp^*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)$-$B(C_6F_5)_3$ before addition of styrene-d_8 and after polymerization of the latter was unchanged (4).

The remaining monomer of Scheme 11, which is known to insist on being polymerized only via carbocationic initiation, is isobutylene. We quickly found that this monomer is indeed polymerized by $Cp^*Ti(CH_3)_2(\mu\text{-}CH_3)B$-$(C_6F_5)_3$ in toluene and methylene chloride at temperatures in the range –78°C to 20°C with conversions often >95% (20, 21). The polymer forms as a high-molecular-weight (>700 000), rubbery solid at lowest temperatures and a viscous, oily liquid at room temperature, as with conventional Lewis-acid initiators. The ^{1}H and ^{13}C NMR spectra are also consistent with polymers (**T**) synthesized using conventional initiators. Polyisobutylene is useful in a large range of applications, depending on molecular weight (bicycle inner tubes, chewing gum, engine oil additives).

A related, very interesting, and useful material is isobutylene–isoprene copolymer (butyl rubber). We obtain a copolymer containing ~1% isoprene at –78°C if the monomer ratio is 99:1. Molecular weights are lower if polymerization is carried out at higher temperatures and (or) with higher isoprene:isobutylene ratios. The ^{1}H and ^{13}C NMR spectra
suggest primarily trans-1,4-addition across the isoprene (**U**). This polymer is used primarily as inner lining for tubeless tires.
Virtually all production of this material worldwide is by Bayer and Exxon. Both use essentially the same technology; polymerization is carried out at cryogenic temperatures, ~–100°C, and chloromethane is the solvent of choice. Clearly higher temperatures and a more environmentally benign solvent are desirable for commercial processes, and we are currently focused on the development of initiators that form high-molecular-weight polyisobutylene and polyisobutylene–co-isoprene in hydrocarbon solvents at temperatures significantly higher than –100°C.

Summary

The 2002 Catalysis Award Lecture and this resulting article outline the early days and some of the resulting developments of our research into the utilization of $Cp^*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$ as an initiator of olefin polymerization. As has been shown, $Cp^*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$ is probably the most versatile of all olefin polymerization initiators in its effectiveness as both a very highly active Ziegler catalyst and as a very highly active carbocationic initiator. We have, of course, extended the above discussed research, including a variety of modifications of $Cp^*Ti(CH_3)_2(\mu\text{-}CH_3)B(C_6F_5)_3$, and some of these have resulted in more active species (22–29). Having succumbed to the thrills that can result from the convergence of organometallic chemistry and polymers, we have also explored a variety of other catalytic systems, in part to find better catalysts for known processes and new catalysts for new polymers, in part to better understand the mechanisms applicable to the various systems studied (30–36). However, while time restrictions required omission of these facets of our research from the Award Lecture, the reader is invited to peruse the publications cited.

AWARD LECTURE / CONFÉRÉNCE D'HONNEUR

A fibre-optic biosensor for detection of microbial contamination[1]

Amer Almadidy, James Watterson, Paul A.E. Piunno, Inge V. Foulds, Paul A. Horgen, and Ulrich Krull

Abstract: A fibre-optic biosensor is described for detection of genomic target sequences from *Escherichia coli*. A small portion of the LacZ DNA sequence is the basis for selection of DNA probe molecules that are produced by automated nucleic acid synthesis on the surface of optical fibres. Fluorescent intercalating agents are used to report the presence of hybridization events with target strands. This work reviews the fundamental design criteria for development of nucleic acid biosensors and reports a preliminary exploration of the use of the biosensor for detection of sequences that mark the presence of *E. coli*. The research work includes consideration of the length of the strands and non-selective binding interactions that can potentially block the selective chemistry or create background signals. The biosensors were able to detect genomic targets from *E. coli* at a picomole level in a time of a few minutes, and dozens of cycles of use have been demonstrated. In a step towards the preparation of a completely self-contained sensor technology, a new intercalating dye known as SYBR 101 (Molecular Probes, Inc.) has been end-labelled to the LacZ nucleic acid probe, to examine whether dye tethered onto an oligonucleotide terminus could fluorimetrically transduce the formation of hybrids. The results obtained from experiments in solution indicate that the use of tethered dye provides fluorescence signals that are due to hybridization, and that this process is functional even in the presence of a high concentration of non-selective background DNA obtained from sonicated salmon sperm.

Key words: biosensor, DNA, fibre optic, hybridization, fluorescence, pathogen, *E. coli*.

Résumé : On décrit une fibre optique servant de biosenseur pour la détection du génome cible dans la séquence du *Escherichia coli*. Une petite portion de la séquence du LacZ-ADN sert de base pour la sélection des molécules sondes d'ADN obtenues par la synthèse automatique d'acides nucléiques à la surface des fibres optiques. On a utilisé des agents intercalants fluorescents pour mettre en évidence la présence de phénomènes d'hybridation avec la fibre cible. Ce travail passe en revue le critère de conception fondamental de développement de biosenseurs d'acides nucléiques, et rapporte également une exploration préliminaire de l'utilisation des biosenseurs pour détecter les séquences qui témoignent de la présence du *E.coli*. Les travaux de recherche tiennent compte de la longueur de la fibre et des interactions liantes non sélectives qui peuvent potentiellement bloquer la sélectivité chimique ou créer un bruit de fond. Les biosenseurs ont été capables de détecter le génome cible à partir du *E. coli* au niveau de la picomole et en quelques minutes, on a ainsi pu effectuer des douzaines de cycles d'études. Dans une étape en vue de la préparation de la technologie du senseur auto-contenu, on a marqué un nouveau colorant intercalaire connue sous le nom de SYBR 101 (Molecular Probes, Inc.) à l'extrémité de la sonde d'acide nucléique LacZ, pour voir si le colorant attaché dans l'oligonucléotide terminal peut fluorométriquement induire la formation d'hybrides. Les résultats obtenus à partir des expériences en solution indiquent que l'utilisation de colorant attaché fournit des signaux fluorescents qui sont dus à l'hybridation, et que ce processus est fonctionnel même en présence d'une forte concentration d'ADN d'arrière plan non sélectif obtenue à partir du sperme de saumon traité à l'ultrason.

Mots clés : biosenseur, ADN, fibre optique, hybridation, fluorescence, pathogène, *E. coli*.

Introduction

Design of a nucleic acid biosensor

Methods that are suitable for the routine determination of the presence of bacterial species are of obvious importance in the quality control of foodstuff and water resources everywhere. Classical methods of nucleic acid hybridization assay are often time consuming and so may be inappropriate for laboratories that require rapid turnover of results and high sample throughput (1–6). As a result, significant research has been devoted to the development of biosensors in an attempt to generate assays that are reversible, reusable, sensitive, selective, and relatively simple to use. Methods of signal transduction to detect nucleic acid hybridization on biosensor surfaces include electrochemical, piezoelectric, and optical approaches (7–11) and compete favourably with the recent developments in wet-chemical methods such as those based on the polymerase chain reaction (12, 13).

The development of biosensors must take into consideration the effects of the local environment on the binding capacity of the immobilized selective molecular recognition elements. This involves careful consideration of the nature of the solid substrate used, the method of immobilization, solution conditions under which experiments will generally be done, and probe density and length. Each of these parameters has direct consequences on the reproducibility and sensitivity of signal generation (14–17).

To examine the effects of immobilization on nucleic acid hybridization, thermal denaturation experiments were done at the surface of fibre-optic nucleic acid biosensors to determine whether trends in hybridization observed in bulk solution could be extrapolated to describe nucleic acid hybridization in an interfacial environment (17).

The immobilization of oligonucleotide probes onto the surface of fused-silica optical fibre substrates was achieved by means of a modification using a silane reagent (15, 17). The modified optical fibre substrates were then subjected to standard β-cyanoethyl-phosphoramidite oligonucleotide synthesis protocols in order to undergo the stepwise synthesis of oligonucleotides at controlled densities onto the surface of the substrates.

To examine the energetics of interfacial hybridization, the van't Hoff enthalpy changes and temperature-corrected standard enthalpy changes were computed for a series of denaturation experiments, conducted based on the method developed by Piunno and co-workers (17). This model applies to denaturation occurring within a film of immobilized nucleic acids, with the complementary DNA freely able to float in and out of the membrane. The model assumes no interaction between neighbouring strands and that the denaturation is a two-state transition. The enthalpic change accompanying denaturation in an interfacial environment was significantly lower than that observed in experiments conducted in bulk solution. The sensitivities of ΔH_{VH} (T_m) to changes in the characteristic melt temperature (T_m) were a factor of 2–4 smaller for the transitions occurring at the interface of the optical biosensors relative to those observed for the experiments done in bulk solution and were usually opposite in sign. This suggested that the changes in heat capacity that accompanied the denaturation were not the same in an interfacial environment as they were in bulk solution.

This may be owing to local density changes in the nucleic acid films as a result of the denaturation. The results suggested that there may be significant differences in the nature of the base pairing in an interfacial environment compared with that which occurred in bulk solution. There did not appear to be a relationship between the packing density of immobilized oligonucleotides and the reduction in the endothermicity of the denaturation. The observed T_m values were still of comparable magnitude to those that were observed in experiments done in bulk solution, so it is likely that there is a significant difference in entropy changes accompanying hybridization and denaturation in an interfacial environment relative to those observed in experiments done in bulk solution.

The data further suggest that the selectivity of hybridization in an interfacial environment may be substantially different and advantageous in comparison with that observed in a bulk solution environment. Furthermore, the selectivity of hybridization does not necessarily follow the trend of T_m, which is seen as a function of ionic strength and oligonucleotide immobilization density. These results corroborate the notion that there is an ensemble of interactions that will occur, along with the hybridization–denaturation transition, in an interfacial environment. These interactions contribute to the overall stability of the binding of target DNA and therefore play an important role in defining the T_m values of a particular probe–target complex, as well as the shape of the thermal denaturation profile, and therefore ultimately affect the selectivity of hybridization.

The results of such work (15, 17) indicate that the choice of density of immobilized single-stranded DNA (ssDNA) does provide for control of selectivity. The optimization of the analytical function of a fibre-optic biosensor for any particular hybridization assay must consider both the issues of selectivity and the amount of fully complementary double-stranded DNA (dsDNA) that is formed, as this is the source of the analytical signal. A review of the data suggests that it is possible to select a combination of ssDNA density, solution ionic strength, and temperature that provides an improvement in the selectivity coefficient of about two orders of magnitude when comparing the formation of the fully complementary duplex to that which contains one central base-pair mismatch. Bulk solution experiments do not attain the same magnitude of selectivity coefficient. Importantly, only about 30% of the maximum amount of fully matched dsDNA is available under the conditions in bulk solution where the best case of selectivity is achieved. This does not compare favourably with the immobilized ssDNA system, where about 55% of the maximum amount of fully matched dsDNA is available under conditions where selectivity is maximized.

An important consideration in the evaluation of the sensitivity and selectivity of hybridization for a given sensor system is the nature of the sample that is being introduced. Samples may contain various levels of large, non-complementary genomic DNA and RNA molecules, which may interfere with analysis. Also, most nucleic acid sensor systems will be exposed to the target DNA of interest in double-stranded form. This imposes the requirement of denaturing these double-stranded targets so that selective hybridization may subsequently take place at the sensor

surface. In practice, this may result in a competition for hybridization of target strands in bulk solution between immobilized probe oligonucleotides and the complementary DNA in bulk solution. This competition for hybridization may impart some significant limitations on the sensitivity and selectivity of the assay. A balance can be struck between the desired sensitivity and selectivity of a given hybridization assay, and this balance is somewhat tunable by means of controlling the density of ssDNA immobilization. If non-selective adsorption occurs predominantly in regions between the immobilized oligonucleotide probes, then it may be that optimal assay sensitivity and selectivity would be achieved using a sensor with a higher density of probe molecules, where the number of exposed surface sites for non-selective adsorption is decreased.

To more accurately model the effects of interferences as experienced in a real sample, experiments were done to investigate the effects of the presence of large genomic DNA strands (20 kbp average size) on the response of the sensors to labeled oligonucleotides. The experiments were designed such that the relative concentrations of oligonucleotides and genomic DNA were adjusted. Experiments were done using concentration regimes where both fully complementary (cDNA) and non-complementary (ncDNA) oligonucleotide 20mers were introduced at a concentrations of about 10^{15} molecules L^{-1}, while genomic DNA from *E. coli* was introduced at a concentration of 10^{12} to 10^{14} molecules L^{-1} (15). The results suggest that the presence of genomic DNA as a background species does not substantially block hybridization of very short target oligonucleotides or the extent of non-selective adsorption of short non-complementary oligonucleotides. This trend was observed for all concentration regimes used. Additionally, the presence of genomic DNA did not affect the response times of the sensors in the first few minutes of an analysis. Interestingly, the pretreatment of the sensor surface with genomic DNA for 10 min reduced the response time of the sensors to cDNA. It may be that the larger genomic DNA acted to reduce the effective solution volume near the sensor surface and to increase the effective analyte concentration. This effect was more significant at the lower analyte concentration, where response times were more sensitive to changes in analyte concentration. The response time of sensors to the addition of 10^{15} molecules L^{-1} cDNA was 224 ± 5 s, while the response time after pretreatment with genomic DNA was 192 ± 5 s. The response time for addition of 10^{16} molecules L^{-1} cDNA was 28 ± 1 s, while the response time after pretreatment of the surface with genomic DNA was 21 ± 1 s.

These results have ramifications for analyses of real-world samples. The preliminary results suggest that the process of non-selective adsorption by interfering short and long nucleic acid sequences in solution may not occur in such a manner as to substantially inhibit the extent of hybridization of a target sequence when early in an analytical experiment.

A fibre-optic biosensor for *E. coli*

Coliforms are aerobic and facultatively anaerobic, gram-negative, non-spore forming bacilli, encompassing members of *Escherichia*, *Citrobacter*, *Klebsiella*, and *Enterobacter* (1–3). Although several of the coliform bacteria are not usually pathogenic themselves, they serve as an indicator of potential bacterial pathogen contamination. Using such indicators, researchers in the U.S.A. estimate that 40% of private water supplies and 70% of spring-fed supplies contain coliform bacteria (4). Coliform bacteria concentrations are determined using methods specified by the Environmental Protection Agency (EPA) and those found in ref. 5. These methods can be slow, and new biosensor technologies may offer substantial advantages in providing analyses within seconds to minutes.

Currently, several methods are used for the detection or enumeration of *E. coli* cells in water, including microbiological, serological, and immunological procedures. Polymerase chain reaction (PCR) methods have been developed, where LacZ, lamB, and uid genes have been used as targets for the design of primers for coliform detection (6). False positive and negative results can arise when using these techniques, and only a very limited number of strains have been used to test for specificity of the primers. Standard PCR generally only provides information about detection, and even when using quantitative real-time PCR, the analyses still often require hours.

Herein we report the development of a fibre-optic biosensor for the detection of short sequences of oligonucleotides that indicate the presence of *E. coli*. Single-stranded DNA (ssDNA) was immobilized by covalent binding to a fused silica optical fibre. Hybridization on the solid surface was detected by use of the fluorescent intercalating dye, ethidium bromide (EB). Testing to detect coliform contamination of water was demonstrated using selective hybridization of nucleic acid sequences. A 25mer sequence on the LacZ gene of the *E. coli* was targeted using a 25mer ssDNA probe. The investigation has shown that the biosensor was capable of detecting minute amounts of synthetic cDNA and also genomic DNA that was extracted from *E. coli*. The biosensor could provide analytical information in less than 1 min and was regenerable for many cycles of application.

Preliminary work that targets the development of a self-contained biosensor has involved attachment of the intercalating fluorescent reporter dye to the probe by means of a short molecular tether. The intercalating fluorescing dye (SYBR 101) was covalently attached through a short tether to the 25mer ssDNA (labelled DNA, L-DNA), and the fluorescence changes caused by hybridization have been investigated in bulk solution using free L-DNA. In the design of a self-contained biosensor, this approach may help reduce background fluorescence from free dye in solution, will allow internal standardization, and will substantially reduce the risk of exposure of the operator to toxic chemicals by confining the intercalating dye to the surface of the device.

Experimental

Chemicals

SYBR 101, succinimidyl ester, was donated by Molecular Probes, Eugene, Oregon. Biosynthesis-grade solvents were purchased (EM Science, Toronto, ON) and further purified or dried by standard laboratory protocols. Reagents for DNA synthesis were purchased from Dalton Chemical Laboratories Inc. (Toronto, ON) and were used as received or were prepared as below. Anhydrous acetonitrile (EM Science) was pre-dried by distillation from P_2O_5 and redistilled from

calcium hydride under dry argon. Tetrahydrofuran (EM Science) was pre-dried over CaH_2, filtered, and distilled immediately prior to use from sodium metal (Aldrich) / benzophenone (Aldrich). Water was double distilled in glass, treated with diethyl pyrocarbonate (Aldrich), and autoclaved. Molecular-biology-grade polyacrylamide gel electrophoresis reagents and apparatus were obtained through Bio-Rad (Hercules, California). Silica gel (Toronto Research Chemicals, Toronto, ON) had a particle size of 30–70 microns.

Instrumentation

Fluorescence studies of LacZ-target hybridization onto the probe at the surface of the *E. coli* biosensors were done using an optic-fibre spectrofluorimeter operated in an intrinsic-mode configuration (17). The spectrofluorimeter was equipped with a fluid-handling system for stop-flow fluorescence investigations of nucleic acid hybridization. Preliminary fluorescence studies of LacZ target to the dye labelled ssDNA in solution were done using a spectrofluorimeter instrument.

Attachment of SYBR 101 to ssDNA probe

The SYBR 101 – ssDNA probe consisted of three parts: the ssDNA, a C6 aminomodifier as a tether, and the fluorescent dye SYBR 101 (absorption 483 nm, emission 515 nm). The tether was attached to the ssDNA using an ABI 392 DNA/RNA synthesizer. C6 aminomodifier is a phosphoramidite synthon containing a six-carbon atom chain terminated by a protected amine moiety. The reagent was used in analogy to a phosphoroamidite nucleoside. The modifier was activated with tetrazole to form an active intermediate that coupled to the 5′-hydroxyl terminus of the oligonucleotide, which was bound to controlled pore glass (CPG) in the final coupling cycle. Oxidation and ammonium hydroxide cleavage – deprotection yielded the 5′-amine-modified oligonucleotide.

The ssDNA-linker at this stage bore a nucleophilic, unprotected primary amine group, which reacted with the electrophilic *N*-hydroxy succinamide group of the SYBR 101. SYBR 101 succinimidyl ester (reactive dye) was used to label the amine-modified oligonucleotide because it forms a very stable amide bond between the dye and the amine-modified oligonucleotide probe. The reactive dye is a hydrophobic molecule, so it was dissolved in high-purity dimethylsulfoxide before reaction with the amine-modified oligonucleotide probe. The reaction was done in a tetraborate buffer at pH 8.5, so that the reactive dye reacted with the non-protonated amine group on the modified oligonucleotide probe.

In this protocol, 250 μg of the reactive dye was dissolved in 14 μL dimethylsulfoxide. To this vial, 7 μL of deionized, distilled H_2O was added followed by 75 μL of the sodium tetraborate buffer and 4 μL of a 25 μg μL^{-1} of gel-purified 5′-amine-modified oligonucleotide. The vial was placed on an oscillating platform stirrer at low speed to insure that the reaction remained well mixed. The reaction was allowed to continue overnight. The labelled oligonucleotide (L-DNA) was purified from the reaction mixture by use of a Pharmacia NAP-10 column containing Sephadex G-25 medium of DNA Grade, in distilled water containing 0.15% Kathone CG/ICP Biocide as a preservative.

Preparation of optical fibres

The jacket material surrounding the fused silica optical fibres (400 μm core diameter, 3M Power Core™ Series Optical Fibre, FT-400-URT or FP-400-UHT, distributed by Thor Labs Inc., Newton, NJ, U.S.A.) was mechanically removed by use of a fibre-stripping tool (Thor Labs Inc.) to reveal the fused silica core material and cladding layer. Optical fibre pieces 48 mm in length were then made by use of a custom-built, diamond-edged fibre-scoring device. The termini of the fibre pieces were visually inspected at 40 × magnifications to ensure the fibre termini were flat, orthogonal to the length of the fibre, and free of chips and nicks.

The fused silica fibre segments were cleaned prior to surface modification according to the published methods (14). CPG was used to grow ssDNA in tandem with fused silica fibres and was subsequently used for recovery of ssDNA to determine the quality and quantity of synthesis. CPG was treated identically to fused silica fibres. The fibre substrates were first immersed and gently agitated in a 1:1:5 (v/v) solution of 30% ammonium hydroxide – 30% hydrogen peroxide – water at 80°C for 5 min. The substrates were then recovered, washed with copious amounts of water, and then treated with 1:1:5 (v/v) concd. HCl – 30% hydrogen peroxide – water for 5 min at 80°C with gentle agitation. The substrates were recovered and washed with 100 mL portions of water, methanol, chloroform, and diethyl ether, respectively, dried under reduced pressure, and stored in vacuo and over P_2O_5 until required.

Functionalization of fused silica substrates with 3-glycidoxypropyltrimethoxysilane (GOPS)

The cleaned fused silica substrates were suspended in an anhydrous solution of xylene – 3-glycidoxypropyltrimethoxysilane – diisopropylethylamine (100:30:1 v/v/v). The reaction was stirred under argon at 80°C for 24 h. The fibres were then collected and twice washed with 50 mL portions of methanol, chloroform, and diethyl ether, respectively, and then dried and stored in vacuo and over P_2O_5 at room temperature until required.

Synthesis of dimethoxytrityl hexaethylene glycol (DMT-HEG)

A solution of dimethoxytrityl chloride (7.1 g, 21 mmol) in dry pyridine (10 mL) was added dropwise to a stirred solution of hexaethylene glycol (5.6 mL, 21 mmol in 5 mL pyridine) under an argon atmosphere. Stirring was continued overnight, after which time the reaction mixture was combined with dichloromethane (50 mL). The mixture was shaken against 5% aqueous bicarbonate (2 × 900 mL) and then with water (2 × 900 mL) to remove unreacted HEG, pyridine, and salts. The organic layer was dried under reduced pressure to yield the crude product. The product was purified by liquid chromatography using a silica gel column and an eluent of 1:1 dichloromethane – diethyl ether containing 0.1% triethylamine (2.9 g, 24% yield). ^{1}H NMR (200 MHz, CDCl$_3$) δ: 7.47–7.19 (m, 9H), 6.81 (d, 4H, $J = 8.8$ Hz), 3.78 (s, 6H), 3.74–3.51 (m, 22H), 3.22 (t, 2H, $J = 5.8$ Hz). Purity DMT-HEG = 96%.

Fig. 1. HPLC anion-exchange chromatogram of the 25mer mixed-base LacZ probe that was grown on CPG and then quantitatively removed by base cleavage. The chromatogram indicates the synthetic purity of the sample used in this investigation.
Linkage of DMT-HEG onto GOPS-functionalized substrates

DMT-HEG (10 equiv relative to the quantity of surface hydroxyl moieties, 700 mg DMT-HEG – 100 mg CPG) that had been dried by extended storage in vacuo and over P_2O_5 (>72 h) was dissolved in 20 mL of anhydrous pyridine and introduced to an excess of NaH (10 equiv) that had been thrice washed with dry hexane to remove the oil in which it had been suspended. The reaction was permitted to proceed with stirring for 1 h at room temperature under an argon atmosphere. The reaction mixture was filtered through a sintered glass frit under a positive pressure of argon and the filtrate immediately introduced to the reaction vessel containing the GOPS-functionalized substrates. One batch of GOPS-functionalized substrates containing both optical fibres and CPG was created, for which the DMT-HEG coupling reaction was permitted to proceed under a positive pressure of argon gas at room temperature with gentle agitation on an oscillating platform stirrer for durations of 4 h. Following the coupling reaction, the substrates were quickly recovered by filtration over a fritted glass funnel and washed with 150 mL portions of methanol, water, methanol, and diethyl ether, respectively, to quench the coupling reaction and remove non-specifically adsorbed reactants. The DMT-protected polyether-functionalized substrates were dried by placement in vacuo and over P_2O_5 and were maintained under these conditions until further required.

Capping of unreacted silanol and hydroxyl functionalities with chlorotrimethylsilane

Sites on the surfaces of the fused silica fibres and CPG onto which undesired nucleotide synthon coupling could oc-

cur were capped prior to oligonucleotide assembly using chlorotrimethylsilane (TMS-Cl), as per the method of Watterson et al. (17). The substrates that had been dried by storage in vacuo and over P_2O_5 for a minimum duration of 16 h were suspended in a solution of 1:10 (v/v) chloro-trimethylsilane–pyridine for 16 h under an argon atmosphere at room temperature. The fused silica substrates were thrice washed with 20 mL portions of pyridine, methanol, and diethyl ether, respectively, and stored in vacuo and over P_2O_5 at 25°C until required.

Solid-phase phosphoramidite synthesis of oligonucleotides

All oligonucleotide synthesis was done using a PE-ABI 391-EP DNA synthesizer (PerkinElmer Applied Biosystems, Foster City, CA, U.S.A.). The manufacturer-supplied synthesis cycles were employed for oligonucleotide assembly with modifications to the delivery times of the reagents as required to completely fill the synthesis columns that were used. Oligonucleotide synthesis onto optical fibres (400 μm i.d. × 48 mm) was done in a custom-manufactured Teflon® synthesis column (6 mm i.d. × 50 mm) capable of holding 8 fibres in an evenly distributed and non-contacting fashion via cylindrical bores (400 μm i.d. × 2 mm deep) machined into one of the end caps (9).

A nucleic acid oligonucleotide having the sequence (5′)CAGGTAATGTGGCGGATGAGCGGCA(3′) was synthesized onto the sensor surface as the ssDNA probe. The target nucleic acid (cDNA) used to challenge the probe was an oligonucleotide having the sequence (5′)TGCCGC-TCATCCGCCACATATCCTA(3′), which was derived from a portion of the LacZ gene sequence. The 25mer

Fig. 2. *E. coli* biosensor response to serial dilutions of cDNA as a function of cDNA concentration at various times. Maximum response was observed at about 2 min for all concentrations of cDNA.
oligonucleotides were prepared by use of a phosphoramidite synthon (Dalton) and standard protocols for oligonucleotide assembly, purification, and quantitation, as have previously been reported (15).

Determination of the extent of surface coverage of CPG substrates with covalently immobilized oligonucleotide–polyether conjugates was done by anion-exchange HPLC using methods that have been reported elsewhere (16).

E. coli and salmon sperm DNA preparation

A 60 mL culture of *E. coli* was grown overnight at 37°C in LB media. Bacteria were harvested by centrifugation at 3000*g* for 10 min. Cells were lysed using TRIZOL reagent (Life Technologies, Canada) by repetitive pipetting, using 1 mL of the reagent per 1×10^7 cells of the *E. coli*. The homogenized sample was incubated for 5 min at room temperature, and chloroform was then added (0.2 mL chloroform per 1 mL of TRIZOL). Sample tubes were capped and shaken vigorously for 15 s and incubated at room temp for 2–3 min. The sample tubes were then centrifuged at 12 000*g* for 15 min at 2–8°C, to separate the mixture into a lower, red phenol–chloroform phase, an interphase, and a colourless upper aqueous phase. DNA was precipitated from the interphase and the organic phase by the addition of 0.3 mL of 100% ethanol per 1 mL of TRIZOL reagent originally used. Samples were mixed by inversion and permitted to equilibrate at room temperature for a few minutes, followed

by precipitation of DNA by centrifugation at 2000*g* for 5 min at 2–8°C. Phenol–ethanol supernatant was removed and the DNA pellet was washed twice with ethanol and dried under vacuum. DNA was finally reconstituted by adding 1 mL of $1 \times$ PBS and measurement of absorption at 260 nm showed that the DNA concentration of the resultant solution was about 350 µg mL^{-1}. The extracted *E. coli* DNA was sheared by syringe and then by sonication for 5 min with a Vibra cell sonicator (Sonics & Materials, Inc.) equipped with a 5-mm tip and set to 125 W maximum power at 20 kHz. Samples were kept on ice at all times until they were used for examination of hybridization.

Lyophilized salmon sperm genomic DNA was reconstituted in 1 mL of $1 \times$ PBS to a concentration of 350 µg mL^{-1}, as indicated by measurement of absorption at 260 nm. This DNA was sheared by syringe and then by sonication for 5 min, as was done for the DNA from *E. coli*.

Hybridization assays of the *E. coli* biosensor

All sensors were cleaned by sonication in ethanol in a 40 W bath sonicator for 30 min to remove adsorbed contaminants from the sensor surface. In all cases, sensors were activated for hybridization by undergoing three consecutive thermal denaturation – re-annealing cycles, in which the sensors were exposed to a 1×10^{-7} M solution of the complementary 25mer oligonucleotide sequence (cDNA) in phosphate-buffered saline (PBS) hybridization buffer

Fig. 3. Chronofluorimetric response profile of a biosensor for *E. coli* using immobilized 25mer mixed-base probe on a fused silica optical fibre. Biosensor was exposed to 10 pmols of fully complementary LacZ 20mer (cDNA), 35 ng ssDNA from *E. coli* (prepared by treatment of whole genomic DNA by sonication and shearing), 35 ng of dsDNA from *E. coli*, and 35 ng ssDNA from salmon sperm (prepared by treatment of whole genomic DNA with sonication and shearing), in $1 \times$ PBS containing 10^{-7} M ethidium bromide at 40°C with full washing and chemical regeneration with water at 90°C and formamide solution (90% in TE buffer) between samples.
(1.0 mol L^{-1} NaCl, 50 mmol L^{-1} total phosphate ion, pH 7.0) and subsequently subjected to a temperature ramp of 0.3°C per min, over a range from 20 to 80°C. Hybridization assays were done for optical sensors that were exposed to solution-phase cDNA mixed with the staining intercalator ethidium bromide at a final concentration of 0.1 μmol L^{-1}. Each sample solution had a total volume of 26 μL, once in the reaction chamber. The flow was stopped and the signal was recorded over a period of up to 10 min. After reaction, the sensor was washed at a flow rate of 3 mL min^{-1}. Removal of the bound DNA that had associated with the sensor surface from the previous analysis was done prior to each experiment by flushing 15 mL of 90°C water through the flow cell (3 mL min^{-1}, 5 min), followed by 1 mL of 95% ethanol, and final wash with 90% formamide in TE buffer (10 mm L^{-1} Tris HCl, 5 mmol L^{-1} EDTA, pH = 8.3).

Salmon sperm DNA (0.1 μmole L^{-1}) served as a control for genomic non-complementary DNA. Assays were performed using a solution temperature of 40°C. All hybridization assays were done in triplicate.

The L-DNA probe hybridization assays were done in bulk solution, by titrating the tethered SYBR 101-probe with a fully complementary synthetic LacZ sequence. A concentration range, from 0.133 to 6.00 μg mL^{-1} of each sequence, was used in a total volume of 700 μL.

Results and discussion

The rapid detection of microbes in samples of water is becoming more critical as the population of the world increases. Our research group has focused on developing a biosensor that is rapid and sensitive for the detection of

Fig. 4. HPLC anion-exchange chromatogram of the mixed base 5′ amine-modified LacZ probe that was grown on CPG and then quantitatively removed by base cleavage. The chromatogram indicates the high purity of the synthetic samples used in this investigation.

the strand terminus to a linker molecule, which in turn is covalently linked to the substrate. This strategy has proven advantageous in terms of the enhanced nucleotide coupling efficiency realized during solid-phase assembly of the oligonucleotide onto the linker and the rapid kinetics of hybrid formation of the immobilized strand with target sequences.

The single-stranded probe was immobilized via hexaethylene glycol linker (HEG) to functionalized fused silica substrates. This effectively provided an oligonucleotide surface where each molecule covered an approximate area of 400–1300 Å^2 when using linear co-polymer strands of ca. 100 Å lengths (18). This chemistry is highly stable toward water hydrolysis and physical cleavage, which can occur, owing to treatment of the surface by heating, cooling, and detergent washing. The use of HEG also provides advantages based on high solubility and hydrophilicity (19).

All sensors that were used were checked for quality of oligonucleotide immobilization by an indirect method based on concurrent immobilization of DNA on fibres and CPG. The material on the CPG was cleaved quantitatively from the surface with base, and anion exchange HPLC was then used for separation and analysis of recovered material (16). Figure 1 shows the HPLC analysis of the ssDNA LacZ probe that was synthesized on CPG. The chromatogram demonstrates the sequence integrity of the oligonucleotides that were used throughout this investigation.

Prior to hybridization, sensors were thermally activated by multiple cycles of heating (90°C) and cooling (30°C) in the presence of 1×10^{-7} M cDNA. The response of the biosensor to a series of samples introduced sequentially is shown in Fig. 2. The fluorescence signal was a function of the concentration of cDNA. In these experiments, the maximum signal was obtained at about 120 s after the cDNA was

coliforms as an indicator of microbial contamination in surface and ground water. Immobilized oligonucleotides on solid supports for use as molecular recognition elements in bioassays and biosensors are short sequences conjugated at

Fig. 6. Spectrofluorimetric scan of SYBR 101-LacZ probe. The probe was treated with an equivalent amount of synthetic cDNA (LacZ) in the presence of an equivalent number of molecules of salmon sperm ssDNA, in 1 × PBS at 515 nm (room temperature). Salmon sperm ssDNA (SP-DNA) was prepared by treatment of whole genomic DNA with sonication.
introduced to the sensor. Figure 3 provides an indication of the shape of the curves and the speed of response. Quantities as low as about 100 fmole provided signals at the three-standard-deviation level. Fibres were washed and chemically regenerated using water at 90°C and 90% formamide solution in TE buffer between samples. The reproducibility was excellent, and dozens of cycles of use have been demonstrated.

Figure 3 shows that the sensor does respond selectively to the synthetic cDNA LacZ sequence in comparison to the non-complementary genomic sonicated DNA from salmon sperm. The fact that the signal for cDNA was present and reproducible after challenging the biosensor with sonicated genomic salmon sperm DNA provides an indication that, for real environmental samples, the possible co-existence of other non-complementary DNA would not block the biosensor from functioning. Upon challenging the biosensor with sonicated genomic *E. coli* DNA, the time dependence of the signal obtained demonstrates hybridization between the probe and the genomic LacZ.

Further results investigating the use of PCR products with the target sequences located in various positions within a

longer product have demonstrated that signal magnitude is somewhat dependent on the location of the target sequence (20), with the signals of greatest magnitude appearing when the target sequence is farthest removed from the biosensor surface.

Tethered dye

In a preliminary experiment that was designed as a first step towards preparation of tethered dye, a second probe was constructed in which the fluorescent intercalator SYBR 101 was chemically conjugated to the probe via a tether. The dye-conjugated probe was purified and examined by anion exchange HPLC for purity (Fig. 4). The mass spectral analysis confirmed the formation of SYBR 101 labelled LacZ probe (Fig. 5).

The ability of the L-DNA to hybridize with fully complementary DNA was shown by the change in fluorescence when complementary, in comparison to non-complementary, DNA was added. Importantly, the results confirmed that the tethered dye could still bind into double-stranded DNA and achieve a substantial change in quantum yield. A second important observation was that the fully complementary target

Fig. 7. Spectrofluorimetric titration curve of SYBR 101-LacZ probe (5.7 μg mL^{-1}) against concentrations of LacZ cDNA from 0.1 μg mL^{-1} to 7.7 μg mL^{-1} in 1 $\times$ PBS at 515 nm (room temperature).
could still be detected in the presence of a large background of salmon sperm DNA. Figure 6 provides spectral information about the tethered dye and a summary of the fluorescent signal due to binding events of the labelled probe at a concentration of 1×10^{14} molecules in 700 μL PBS solution. When the probe was mixed with an equivalent number of molecules of salmon sperm DNA, the signal remained relatively high.

To observe the response to hybridization at different concentrations of target cDNA of the SYBR 101 labelled probe, a titration curve was generated using 25mer fully complementary target LacZ. In this experiment, a PBS solution of cDNA containing 5.7 μg mL^{-1} (1×10^{14} molecules) was titrated against the SYBR101-LacZ probe. A maximum of hybridization was achieved when a stoichiometrically equivalent amount of the labelled probe was added to the cell. The intensity of fluorescence did not substantially change beyond the 1:1 stoichiometric equivalence point, indicating that hybridization was necessary to bring the tethered dye into close proximity to a duplex for stable intercalation to occur (Fig. 7).

Preliminary work using tethered thiazole orange labels on short mixed nucleotide probes that were immobilized to the biosensor surface confirmed that such tethered dyes can report selective hybridization (21). The results also indicated that adsorption of non-complementary DNA had a significant effect on the environment of the tethered TO. This ap-

peared to be largely an electrostatic phenomenon where the positively charged dye interacted with the relatively concentrated DNA at the solid interface. The non-selective adsorption was largely eliminated by moving to high salt (3 $\times$ PBS), with the concurrent advantage being that the dsDNA stability was improved. The background intensity effect produced by non-complementary DNA could be reduced to less than 10%. Another limitation that was identified was sensitivity to photobleaching (21), which was easily ameliorated by use of gated detection. Further research has now demonstrated that a more complicated time-dependent chemical process, based on availability of intercalant after denaturation and biosensor regeneration, was the main cause of reduction in signal intensity as a series of experiments were done sequentially.

Conclusions

A fibre-optic biosensor for a portion of the LacZ gene was constructed as a diagnostic device to provide a surface for the hybridization with markers from *E. coli*.

The LacZ gene of *E. coli* was selected because conventional coliform monitoring is based on detection of the activity of the gene product (β galactosidase) produced by coliform bacteria. Also, the LacZ sequence was selected as a target because it is specific to total coliforms, while the lamB gene is within *E. coli*, *Salmonella*, and *Shigella spp.*,

and the uid gene is within *E. coli* and *Shigella s*pp. The 25mer length of the probe was shown to be sufficiently selective to hybridize genomic target from *E. coli* bacteria and was further investigated by searching within the GenBank nucleotide sequence data to insure that there were no other homologies with potential non-target sequences (22). The short length of the probe provides advantages in terms of reversibility and high speed of hybridization.

The LacZ probe was covalently attached through a C6 amino-modifier tether to SYBR 101 fluorescent intercalating dye. This labelled probe was used free in solution to investigate whether the dye could still participate in intercalation as hybridization with fully complementary target in the presence of a high concentration of non-complemetary DNA (salmon sperm DNA) proceeded. The results are encouraging, as there was no indication that the fluorescent signal from hybridization was dramatically affected by the presence of the non-complementary material.

Benzotriazolium ylides: Experimental and theoretical study on the tautomeric equilibrium of monosubstituted benzotriazolium ylides

Neculai Doru Miron, Patrice Woisel, Georgiana G. Surpateanu, Gérard Vergoten, Ludovic Depature, and Gheorghe Surpateanu

Abstract: The biphenacyl benzotriazolium salts **12** give a tautomeric equilibrium **13⇌14** in the presence of triethylamine (TEA) or NaOH. The evaluation of this tautomeric equilibrium has been studied using a dynamic NMR analysis and a new synthetic procedure of disubstituted benzotriazolium ylides **15** and **16**, which have in their structures a picryl fragment. This study also includes a theoretical analysis on the reactivity of salts **12a–c** and the thermodynamical stability of tautomeric forms **13** and **14** by AM1 and PM3 procedure methods.

Key words: synthesis, salts, ylides, semiempirical calculations, kinetics.

Résumé : En présence de TEA ou de NaOH, les sels de biphénacylbenzotriazolium (**12**) donnent lieu à un équilibre tautomère. On a évalué cet équilibre tautomère par le biais d'une analyse RMN dynamique et on a mis au point une nouvelle méthode de synthèse des ylures de benzotriazolium disubstitués **15** et **16** comportant, dans leurs structures, un fragment picryle. Cette étude comporte aussi une analyse théorique, à l'aide des méthodes AM1 et PM3, de la réactivité des sels **12a–c** et de la stabilité thermodynamique des formes tautomères **13** et **14**.

Mots clés : synthèse, sels, ylures, calculs semiempiriques, cinétique.

[Traduit par la Rédaction]

Introduction

The presence of the two tautomeric forms **1** and **2** for some triazolium ylides has been revealed by NMR spectroscopy and confirmed by trapping each monosubstituted ylide with picryl chloride (Scheme 1) (1, 2).

The two tautomeric forms **1** and **2** were generated by addition of aqueous potassium carbonate on a suspension of the corresponding triazolium salt in DMSO-d_6. The ratio of concentrations was evaluated at 23°C from the integration curves of the signals corresponding to the 5-H protons in the triazole ring.

Earlier, two different disubstituted carbanion triazolium ylides **3** and **4** (Scheme 2) had been isolated and characterized as stables compounds (3, 4) by the reaction between tautomeric monosubstituted carbanion ylides **1** and **2** and picryl chloride. These two procedures, dynamic NMR spectra and chemical synthesis of the disubstituted ylides from their tautomeric forms and picryl chloride, represent the basic handling of the characterization of ylidic tautomers.

The synthetic utility of ylidic compounds is widely recognised (5, 6). The reaction of this class of compounds with strong electrophiles such as picryl chloride (7) has also been described and used, in particular in the synthesis of a new azaheterocyclic framework as isoindoles (3, 4).

In this paper, for the first time, the synthesis and characterization of tautomeric benzotriazolium ylides are reported. Systematically, molecular modelling has been used to explain the ratio and the chemical behaviour of ylidic tautomeric forms.

Results and discussion

The monosubstituted benzotriazolium ylides reported in this paper are prepared using the well-known "salt method" (8). 1-Benzylbenzotriazole **5** is obtained from the commercially available benzotriazole via the corresponding anion and benzyl bromide. Thus, the 1-benzylbenzotriazole **5** treated with 4-substituted ω-bromoacetophenones **6** in dry boiling acetone furnish, after recrystallization (ethanol), the

Scheme 1. Monosubstituted triazolium ylides.

$$R_1 = R_2 = \text{4-substituted-}C_6H_4C(O)\text{-}$$

corresponding salts **7** in good yields (Scheme 3). Next, these salts **7** in the presence of triethylamine (TEA) form "in situ" monosubstituted carbanion ylides **8**, which with picryl chloride offer directly benzotriazolium trinitrophenylmethylides **9**. However, this reaction must be carried out under 10°C and without light to prevent cleavage of the ^-C —N^+ bond.

By our experimental procedure only disubstituted benzotriazolium ylides **9** have been isolated. That corresponds to a single type of phenacylide structure (**8**). Another potential tautomeric benzylidic structure, **10**, could not be characterized. That is why we extended our synthesis to a new benzotriazolium ylide (Scheme 4) in which two phenacyl fragments are linked to nitrogen atoms 1 and 3 in a triazole ring. The general synthetic procedure is similar to those employed for the preparation of the benzotriazolium ylides **8**. Indeed, in this case two disubstituted benzotriazolium ylides **15** and **16** have been identified, in different ratios, as the final reaction mixture (Table 1).

Quantitative data were obtained by ^1H NMR spectra, taking into account the chemical shifts and the integration of the signals belonging to the protons in the picryl fragments and methylene groups in every pair of corresponding benzotriazolium ylides **15** and **16**.

We supposed that this experimental result could be explained by the existence of a tautomeric equilibrium **13**⇌**14** between two monosubstituted benzotriazolium ylides.

Moreover, the absence of the ylide equilibrium **8**⇌**10** prompted us to develop a theoretical study on the reactivity of salts **7** and **12**, to generate the corresponding monosubstituted benzotriazolium ylides. Also, the reactivity of all tautomeric forms towards picryl chloride has been considered.

First, the semiemperical AM1 and PM3 calculations were performed using the PC-Spartan Plus package (9). For each compound, a multiconformational search has been developed. The employed method, which gave satisfactory results on our structures, has been described in recent papers (10, 11). Briefly, the procedure consists in studying the ΔH (heat of formation variation) according to the variation of the dihedral angle by rotational increments of 15°. The minimum value of ΔH is chosen according to the curve scribing. All constraints are removed and a new geometry optimization is made to obtain the most stable conformation. All single bonds have been taken in consideration.

In Table 2 the electrostatic and Mulliken charges of four methylenic hydrogens are given. Normally, the positive charges have similar values, as in the case of biphenacylide salts **12**. Otherwise, more important differences, especially

for the Mulliken charges, are observed, as in the case of benzylphenacyl salts **7**.

In this last case based on positive atomic charges, e.g., their acidities (12), we consider as more probable the formation of phenacylide system **8** than benzylide system **10**. Qualitatively, the presence of a tautomeric equilibrium **13**⇌**14** and the absence of an equilibrium similar to the case of benzylphenacyl salts **5**⇌**7** seems to be an expected result.

Next, to evaluate the intervention of a possible thermodynamic factor in the generation of monosubstituted benzotriazolium ylides **8**, **10**, **13**, and **14**, we calculated the heats of formation of these monosubstituted ylides.

From the survey data in Table 3, some complementary conclusions could be extracted: (*i*) larger differences in the range of 2.03–2.81 kcal (AM1) and 1.08–1.68 kcal (PM3) in the case of ylide forms **8** and **10** and (*ii*) smaller differences of 0.21–0.65 kcal mol^{-1} (AM1 and PM3) for ylide tautomeric forms **13** and **14**. In the first case, the formation of phenacylide forms **8** is favoured. Otherwise, in the second case the formation of both the tautomeric forms **13** and **14** is effective.

The reaction between a monosubstituted benzotriazolium ylide and picryl chloride could be considered to be proceeding as a donor–acceptor interaction, respectively. Thus, the atomic orbital coefficient of the ylide carbon atom in the HOMO (High occupied molecular orbital) could be taken into consideration as a chemical reactivity parameter (Table 4) (13–15).

By the absolute values of these coefficients, the reactivity of ylide carbon atoms in tautomeric benzotriazolium ylides **13** and **14** are comparable. Moreover, we proved experimentally that the reaction rate of monosubstituted ylides with picryl chloride is very important (the reaction is instantaneous). The visible disappearance of the colour (orange) of monosubstituted benzotriazole ylide **13** or **14** and the appearance of a deep purple colour corresponding to formation of the disubstituted benzotriazolium ylide have also been highlighted by UV–vis spectra and analytical thin layer chromatography.

Briefly, both experimental and theoretical results presented in this paper permit us to point out some conclusions: (*i*) the 1-phenacyl-3-benzyl benzotriazolium salt **7** in the presence of TEA gave a single monosubstituted benzotriazolium ylide **8**. The mobility of the methylenic hydrogens and the heat of formation of the hypothetical two tautomeric forms **8** and **10** reinforce the absence of an equilibrium; (*ii*) otherwise, the same theoretical parameters, e.g., the mobility of methylenic hydrogens in salt **12** and the heat of formation of the corresponding pair of forms **13** and **14** recommend the co-existence of tautomeric equilibrium of these two form; (*iii*) the small difference in the values of the charges of the two pairs of methylenic hydrogens in **12**, the closer heat of formation of **13** and **14**, and their comparable atomic orbital coefficients suggest formation of both these two tautomeric forms. At this stage of our experiments that is not proved. Experimentally, in all three analyzed equilibria, the form of **13** is the dominant one and much more so in the nitrophenacylide structure **13c**. The increasing trend of substituant constants — $\sigma_{Cl}(0.22) < \sigma_{OCH3}(0.22) < \sigma_{NO2}(0.78)$ (12) — is also found from the ratio of concentrations of the tautomeric equilibrium **13**⇌**14**. Nevertheless,

a: $R_1 = Cl$
b: $R_1 = OCH_3$
others factors (e.g., the nature of the solvent, the polarity of the reaction mixture) could influence the final concentrations of the two tautomeric forms. Next, we choose the equilibrium **13c**⇌**14c** (the extreme case) for a more detailed experimental study, monitoring the kinetics of the tautomeric equilibrium using ^{1}H NMR. The analyses were directly performed in the NMR tube with addition of NaOD (2 equiv) – D_2O to the solution of benzotriazolium salt **12c** $(2.10^{-2}$ mol $L^{-1})$ – D_2O. The addition of NaOD was considered the starting time ($t = 0$). The ^{1}H NMR spectra unambig-

uously indicated the completion of the dehydrohalogenation reaction. The concentration of each tautomer was evaluated, as already mentioned, from the integrals of the remaining methylenic and picryl protons. The results are presented in Table 4.

After 15 min, equilibrium was achieved (no significant modification of involved signals was observed), but the degradation of the reaction mixture was growing significantly.

Finally, taking into account the quantitative data in Table 3, we imagined a new kind of synthesis of disubstituted

Scheme 4. Preparation of the disbstituted biphenacyl benzotriazolium ylides.
Table 1. Mixture of ylides **15** and **16**.

Salt	Ylide **15**	Ylide **16**
12a	76	24
12b	75	25
12c	89	11

benzotriazolium ylides **15c** and **16c**. Always, the aim was to highlight the evolution of the equilibrium **13c⇌14c**.

Concretely, this equilibrium was generated by adding TEA in one step to the benzotriazolium salt **12c** in chloroform. Then a solution of picryl chloride in chloroform was added, also in one step, after 10 min. All other aspects concerning this new procedure are described in the experimental section of this paper.

Indeed, as we supposed, the ratio of disubstituted ylides **15c** and **16c** in the final reaction mixture was changed. Taking into account this new ratio, we could indirectly evaluate a corresponding equilibrium mixture of 78% **13c** and 22% **14c**.

Really, these values are slightly different with respect to those performed by dynamic NMR analysis at the same

time, $t = 10$ min, but deeply different (89% **13c** and 11% **14c**) at time $t = 0$ from those for the experiment described in the experimental section. Thus, we consider that the existence of a dynamic equilibrium **13c⇌14c** is undoubtedly proven by this new synthetic procedure. The developed dynamic NMR analysis and the new synthetic procedure involve different experimental conditions; NaOD or TEA as base and DMSO-d_6 or CHCl$_3$ as solvent, respectively, so that the quantitative differences on the concentrations of the tautomeric forms could be easily justified.

Conclusion

The benzylphenacylbenzotriazolium salts **7** in the presence of TEA give exclusively one monosubstituted benzotriazolium ylide **8**.

The 1,3-biphenacylbenzotriazolium salts **12** under the same experimental condition form a tautomeric mixture of **13** and **14**.

The differences in these previous behaviours are proven by theoretical data, e.g., the mobility of methylenic groups and the thermodynamic stabilities of the tautomeric forms.

using a Platform II Micromass Apparatus. IR spectra were recorded using a PerkinElmer instrument. Melting points were obtained with a Reichert Thermopan apparatus and are uncorrected. Chromatographic separations were carried out on SDS silica gel 60 (70–200 µm). All reagents were used as purchased unless otherwise stated. Solvents were dried according to standard procedures. All reactions were performed under dry argon.

General procedure for the synthesis of benzotriazolium salts 7 and 12

The ω-bromoacetophenone compounds **6a–c** are commercially available. A solution of ω-bromoacetophenone **6** in anhydrous acetone (30 mL) was added, at room temperature under argon, to a solution of 1-benzyl-[1,2,3]benzotriazole **5** or 1-phenacyl-[1,2,3]benzotriazole **11** (10 mmol) in dry acetone (80 mL). The mixture was refluxed under stirring for 8 h. The crude product was filtered off and recrystallized from EtOH.

3-Benzyl-1-[2-(4-chlorophenyl)oxoethyl]-3H-benzotriazol-1-ium bromide (7a)

Yield 3.13 g (71%), mp 158–159°C. IR (KBr) (cm^{-1}) $\bar{\nu}$: 3028, 1700, 1588, 1338, 1224, 1091, 986, 775. ^{1}H NMR (DMSO–TMS) δ: 6.44 (s, 2H, CH$_2$), 7.10 (s, 2H, CH$_2$), 7.43–7.50 (m, 3 aromatic H), 7.55–7.63 (m, 2 aromatic H), 7.77 (d, J = 8.2 Hz, 2 aromatic H), 8.00–8.08 (m, 2 aromatic H), 8.16 (d, J = 8.2 Hz, 2 aromatic H), 8.40–8.45 (m, 1 aromatic H), 8.51–8.56 (m, 1 aromatic H). ES$^+$-MS (cone 21) m/z (%): 364 ([M − Br], 32), 362 ([M − Br], 100). $C_{21}H_{17}BrClN_3O$ calcd.: C 57.14, H 3.88, N 9.53; found: C 56.88, H 3.84, N 9.39.

3-Benzyl-1-[2-(4-methoxyphenyl)oxoethyl]-3H-benzotriazol-1-ium bromide (7b)

Yield 3.01 g (69%), mp 164–165°C. IR (KBr) (cm^{-1}) $\bar{\nu}$: 3035, 1684, 1602, 1575, 1184, 1028, 983, 775. ^{1}H NMR (DMSO–TMS) δ: 3.92 (s, 3H, OCH$_3$), 6.43 (s, 2H, CH$_2$),

In the case of tautomeric ylides **13** and **14**, their reactivities with picryl chloride are comparable (see the absolute values of atomic orbital coefficients of the ylide carbon atoms in HOMO).

The existence and the evolution of the equilibrium **13⇌14** was proven by a dynamic NMR analysis and by a new method of synthesis.

The slow rate of ylidic tautomeric equilibrium is due to a migration of a proton between two similar ylidic carbanion atoms.

Experimental section

General remarks

^{1}H and ^{13}C NMR spectra were recorded with a Bruker AM 250 spectrometer with trimethylsilane as the internal standard. The abbreviations used are s (singlet), d (doublet), t (triplet), and m (multiplet). Mass spectra were measured

7.01 (s, 2H, CH$_2$), 7.20 (d, J = 8.8 Hz, 2 aromatic H), 7.43–7.51 (m, 3 aromatic H), 7.54–7.57 (m, 2 aromatic H), 7.98–8.05 (m, 2 aromatic H), 8.16 (d, J = 8.8 Hz, 2 aromatic H), 8.37–8.39 (m, 1 aromatic H), 8.48–8.50 (m, 1 aromatic H). ES$^+$-MS (cone 32) m/z (%): 358 ([M – Br], 100). C$_{22}$H$_{20}$BrN$_3$O2 calcd.: C 60.40, H 4.61, N 9.61; found: C 59.98, H 4.84, N 9.38.

1-[2-(4-Chlorophenyloxoethyl]-3-(2-phenyloxoethyl)-3H-benzotriazol-1-ium bromide (12a)

Yield (80%), mp 158–159°C. IR (KBr) (cm^{-1}) v̄: 3094, 2968, 2830, 1700, 1588, 1233, 1087, 757. ^{1}H NMR (DMSO–TMS) δ: 7.15 (s, 2H, CH$_2$), 7.16 (s, 2H, CH$_2$), 7.71–7.84 (m, 5 aromatic H), 8.04–8.07 (m, 2 aromatic H), 8.18 (m, 4 aromatic H), 8.45–8.49 (m, 2 aromatic H). ES$^+$-MS (cone 31) m/z (%): 392 ([M – Br], 33), 390 ([M – Br], 100). C$_{22}$H$_{17}$BrClN$_3$O$_2$ calcd.: C 56.29, H 3.65, N 8.96; found: C 56.20, H 3.84, N 9.08.

1-[2-(4-Methoxyphenyloxoethyl]-3-(2-phenyloxoethyl)-3H-benzotriazol-1-ium bromide (12b)

Yield 3.47 g (74%), mp 159–160°C. IR (KBr) (cm^{-1}) v̄: 2909, 2836, 1683, 1600, 1356, 1237, 1176, 757. ^{1}H NMR (DMSO–TMS) δ: 3.93 (s, 3H, OCH$_3$), 7.04–7.24 (m, 6H, 2CH$_2$ + 2 aromatic H), 7.70 (t, J = 7.3 Hz, 2 aromatic H), 7.84 (t, J = 7.3 Hz, 1 aromatic H), 8.01–8.19 (m, 6 aromatic H), 8.43–8.50 (m, 2 aromatic H). 1-[2-(4-Nitrophenyloxoethyl]-3-(2-phenyloxoethyl)-3H-benzotriazol-1-ium bromide (12c)

Yield 4.13 g (88%), mp 161–162°C. IR (KBr) (cm^{-1}) v̄: 2884, 1704, 1600, 1527, 1350, 1226, 994, 756. ^{1}H NMR (DMSO–TMS) δ: 7.18 (s, 2H, CH$_2$), 7.23 (s, 2H, CH$_2$), 7.70 (d, J = 7.3 Hz, 2 aromatic H), 7.83 (d, J = 7.3 Hz, 2 aromatic H), 8.04–8.08 (m, 2 aromatic H), 8.18 (d, J = 7.3, 2 aromatic H), 8.38–8.53 (m, 5 aromatic H). ES$^+$-MS (cone 25) m/z (%): 401 ([M – Br], 100). C$_{22}$H$_{17}$BrN$_4$O$_4$ calcd.: C 55.00, H 3.57, N 11.67; found: C 59.94, H 3.62 N 11.71.

General procedure for synthesis of disubstituted benzotriazolium ylides 9, 15, and 16

To a mixture formed of salts **12** (2.8 mmol) in CHCl$_3$ (30 mL) and picryl chloride (2.8 mmol) was added gradually, at 0°C under Ar, a solution of freshly distilled Et$_3$N (5.6 mmol) in dry CHCl$_3$ (10 mL) at 0°C under Ar. Then the mixture was stirred at room temperature for 3 h. Finally, the solvent was evaporated, and the deep purple crude product was chromatographed on SiO$_2$ using acetone–hexane (40:60) as the eluant.

(3-Benzyl-3H-benzotriazol-1-io)(4-chlorobenzoyl)(2,4,6-trinitrophenyl)methanide 9a

Yield 0.98 g (61%), mp 119–120°C. IR (KBr) (cm^{-1}) v̄: 2910, 1665, 1569, 1489, 1275, 1113, 1015, 766. ^{1}H NMR (CDCl$_3$–TMS) δ: 5.85 (s, 2H, CH$_2$), 7.23–7.32 (m, 4 aromatic H), 7.45–7.57 (m, 6 aromatic H), 7.70–7.79 (m, 3 aromatic H), 8.60 (s, 2H, aromatic). ES$^+$-MS (cone 30) m/z (%): 597 ([M + Na], 12), 595 ([M + Na], 40), 575 ([M + H], 31), 573 ([M + H], 100).

(3-Benzyl-3H-benzotriazol-1-io)(4-methoxybenzoyl)(2,4,6-trinitrophenyl)methanide 9b

Yield 0.87 g (55%), mp 139–140°C. IR (KBr) (cm^{-1}) v̄: 3077, 1603, 1558, 1527, 1258, 1252, 1027, 751. ^{1}H NMR (CDCl$_3$–TMS) δ: 3.85 (s, 3H, OCH$_3$), 5.84 (s, 2H, CH$_2$), 6.81 (d, J = 8.8, 2 aromatic H), 7.30–7.34 (m, 2 aromatic H), 7.47–7.49 (m, 3 aromatic H), 7.52–7.58 (m, 3 aromatic H), 7.66–7.76 (m, 3 aromatic H), 8.58 (s, 2H, aromatic). ES$^+$-MS (cone 20) m/z (%): 569 ([M + H], 100).

(3-(2-Phenyl-2-oxoethyl)-3H-benzotriazol-1-io)(4-chlorobenzoyl)(2,4,6-trinitrophenyl)methanide 15a and [(3-(2-(4-nitrophenyl)-2-oxoethyl)-3H-benzotriazol-1-io](benzoyl)-(2,4,6-trinitrophenyl)methanide 16a

Yield 1.21 g (72%). Experimental values and ERAS model calculations for excess molar volumes and enthalpies of the ternary system 2-butanol + 1,3-dioxolane + cyclohexane

Ignacio Gascón, Santiago Martín, Beatriz Giner, Marta Haro, and Carlos Lafuente

Abstract: Densities and heats of mixing for the ternary system 2-butanol + 1,3-dioxolane + cyclohexane have been measured at 298.15 and 313.15 K. Excess molar volumes and excess molar enthalpies have been calculated from experimental data and fitted by the Redlich–Kister equation. The ERAS model has been used to calculate excess molar properties of the ternary mixture from parameters obtained from the constituent binary mixtures.

Key words: excess properties, ERAS model.

Résumé : On a mesuré à 298,15 et à 313,15 K les densités et les chaleurs de mélange du système ternaire : butan-2-ol + 1,3-dioxolane + cyclohexane. On a calculé les volumes molaires en excès, les enthalpies molaires en excès, à partir des données expérimentales et on les a ajustées à l'aide de l'équation de Redlich–Kister. On a utilisé le modèle ERAS pour calculer les propriétés molaires en excès du mélange ternaire à partir des paramètres obtenus des mélanges binaires de constituants.

Mots clés : propriétés en excès, modèle ERAS.

[Traduit par la Rédaction]

Introduction

The study of the thermodynamic properties of binary mixtures containing cyclic polyethers has increased in recent years (1–6) because of industrial applications and theoretical interest in the structure of such solutions. However, experimental data for ternary mixtures of these compounds are scarce.

This work is a continuation of our previous investigations involving thermodynamic and transport properties of binary and ternary mixtures containing 1,3-dioxolane or 1,4-dioxane together with isomeric butanols, cyclohexane, and *n*-hexane (7–11). Here we report experimental excess molar volumes and excess molar enthalpies of the ternary mixture 2-butanol + 1,3-dioxolane + cyclohexane at 298.15 and 313.15 K. Experimental thermodynamic data of the mixtures provide a better understanding of the molecular interactions and can be used to test thermodynamic models. In the present paper the reported excess molar volumes and excess molar enthalpies are used to test the applicability of the ERAS model for describing excess molar properties of the ternary mixture at different temperatures from binary parameters.

Experimental

2-Butanol (>99%), 1,3-dioxolane (>99%), and cyclohexane (>99.9%) were obtained from Aldrich. The purities of these compounds were checked by comparing the measured densities with those reported in the literature and also by a chromatographic method. This confirmed the absence of significant impurities. No further purification was considered necessary, but the 2-butanol was dried with 0.3 nm molecular sieves from Merck.

Properties of the pure compounds at 298.15 and 313.15 K, along with literature density values at 298.15 K (2, 12), are given in Table 1.

Densities, ρ, of the pure compounds and their mixtures were determined with an Anton Paar DMA-58 vibrating tube densimeter whose temperature was controlled within ± 0.01 K. The accuracy of the densimeter after proper calibration is $\pm 1 \times 10^{-5}$ g cm^{-3} and the precision of the density measurements was $\pm 5 \times 10^{-6}$ kg m^{-3}.

Mixtures were prepared by mass using a Mettler H20T balance. The uncertainty of mole fraction of the mixtures is estimated to be less than $\pm 1 \times 10^{-4}$.

Excess molar enthalpies were determined using a Thermometric 2277 thermal activity monitor with a combination measuring cylinder (LKB 2277–204) running under constant flow conditions (total flow rate = 5×10^{-3} mL s^{-1}). During the experiments the temperature is kept constant within $\pm 2 \times 10^{-4}$ K. Two Shimadzu LC-10ADVP HPLC pumps were used to drive the liquids. One of the pumps delivered pure 2-butanol while the other pump delivered a liquid mixture of 1,3-dioxolane and cyclohexane of known composition. Each pump was calibrated with pure 2-butanol or the binary mix-

ture, respectively, before calorimetric measurements were registered. The uncertainty in the mole fractions of the ternary mixture, calculated from the uncertainty in the flow delivered by the pumps, is ±0.001. The accuracy in the determination of the excess molar enthalpies could be expected to be ±1%. More details about procedure and calibration can be found in a previous paper (18).

Results and discussion

The experimental densities of the ternary system 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) at 298.15 and 313.15 K are shown in Table 2 along with calculated excess molar volumes. The excess molar enthalpies are presented in Table 3. H^E was determined according to the following relation:

$$[1] \quad H^E = \frac{\dot{Q} + (\dot{n}_2 + \dot{n}_3)H_{23}^E}{\dot{n}_1 + \dot{n}_2 + \dot{n}_3}$$

where $\dot{Q}$ is the measured heat effect upon mixing, $\dot{n}_1$ is the molar flow of the components ($i = 1, 2, 3$), and H_{23}^E is the excess molar enthalpy of the binary mixture 1,3-dioxolane + cyclohexane delivered by one of the pumps. The H^E values for this binary mixture are given in Table 4.

The Redlich–Kister equation for ternary mixtures (19) was fitted to the measured excess molar volumes and enthalpies

$$[2] \quad Y^E = Y_{\text{bin}}^E + x_1 x_2 (1 - x_1 - x_2)[C + D_1 x_1 + D_2 x_2]$$

Y^E is the excess molar property (V^E or H^E) of the ternary mixture, x_i is the mole fraction of component i in the mixture, C and D_i are adjustable parameters obtained by the least-squares method, and Y_{bin}^E is the contribution to the excess molar property of the constituent binary mixtures given by

$$[3] \quad Y_{\text{bin}}^E = Y_{12}^E + Y_{13}^E + Y_{23}^E$$

Each binary contribution, Y_{ij}^E, is obtained by means of a Redlich–Kister polynomial equation for binary mixtures

$$[4] \quad Y_{ij}^E = x_i x_j \sum_{p=0}^{n} A_{p,ij}(x_i - x_j)^p$$

where x_i is the mole fraction of component i in the ternary mixture and $A_{p,ij}$ are adjustable parameters obtained by least-squares fitting. Table 5 gives the parameters for the constituent binary mixtures obtained either from experimental measurements carried out in our laboratory or taken from previous papers (7, 9, 20). The standard deviations of the fits, σ, are also tabulated.

In Table 5 the parameters obtained for the excess molar enthalpies of the binary mixture 2-butanol + cyclohexane are included; these were fitted with the fractional equation proposed by Treszczanowicz and Benson (21)

$$[5] \quad H_{13}^E = x_1 x_3 \sum_{p=0}^{m} A_p x_1^{p/2}$$

Table 2. Densities and excess molar volumes of ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures at 298.15 and 313.15 K.

where H_{13}^E is the excess molar enthalpy of the binary mixture, x_1 and x_3 are the mole fractions of 2-butanol and cyclohexane, respectively, and A_p are adjustable parameters obtained by the least-squares method.

The C and D_i parameters of the Redlich–Kister equation for ternary mixtures are given in Table 6 along with the standard deviations of the fits.

Isolines at constant values of excess molar volumes and enthalpies of the ternary mixture at 298.15 and 313.15 K are plotted in Figs. 1 and 2, respectively. The mixtures have relatively large positive excess molar volumes and enthalpies throughout the entire composition range. Both excess molar properties increase slightly with increasing temperature.

The observed behaviour of the excess molar properties can be interpreted in terms of molecular interactions. In particular, the mixtures show positive excess molar volumes

Table 3. Excess molar enthalpies of ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures at 298.15 and 313.15 K.

ken in 2-butanol + 1,3-dioxolane mixtures than in ternary 2-butanol + 1,3-dioxolane + cyclohexane mixtures. Maximum values of V^E appear at small mole fractions of 2-butanol where dissociation of the alcohol agglomerates is more extensive.

Comparing our results with those previously reported (7) for the ternary system 1-butanol + 1,3-dioxolane + cyclohexane, we observe that the composition dependence of the excess molar functions is very similar for both systems, but the H^E and V^E values are slightly larger in the ternary system containing 2-butanol.

ERAS model calculations

The ERAS theory combines the real-associated solution model (22–25) with Flory's equation of state (26). The version of the ERAS model used here (17, 27) allows a description of the excess molar properties of mixtures containing two associating components, provided one of these shows a weak self-association. In the present work cyclohexane was assumed to be an inert component and 2-butanol presents a strong association, while 1,3-dioxolane is a weak-associated compound. Cross association between alcohol and ether was also considered.

The ERAS parameters of the pure compounds along with their physical properties are collected in Table 1. Molar volumes, V_m, and thermal expansion coefficients, α, were derived from measured densities. Isothermal compressibilities, κ_T, at a given temperature T were calculated from molar volumes, thermal expansion coefficients, isentropic compressibilities, κ_S, and molar heat capacities, $C_{p,m}$, using the thermodynamic equation

$$[6] \qquad \kappa_T = \kappa_S + \frac{T V_m \alpha^2}{C_{p,m}}$$

Values of κ_S were evaluated from experimental densities, ρ, and ultrasonic velocities, u (through the relation $\kappa_S = (\rho u^2)^{-1}$). An Anton Paar DSA-48 density and sound analyzer was used to determine ρ and u. $C_{p,m}$ values for 1,3-dioxolane were determined with a programmable, differential-scanning microcalorimeter (Setaram DSC II), while molar heat capacities of 2-butanol and cyclohexane were taken from literature

and enthalpies, which result from the breaking up of alcohol agglomerates and ether–ether interactions that dominate over the negative contributions from heteromolecular interaction.

Although both H^E and V^E are related to molecular interactions, V^E is a better indicator of structural and packing effects. Maximum values of H^E appear for binary 2-butanol + 1,3-dioxolane mixtures, indicating that more bonds are bro-

Table 6. Coefficients of the Redlich–Kister equation (eq. [2]) for V^E and H^E of ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures at 298.15 and 313.15 K.

Property	T (K)	C	D_1	D_2	$\sigma (Y^E)$
V^E (cm^3 mol^{-1})	298.15	4.426	–3.763	–0.957	0.013
	313.15	3.713	–3.299	–1.741	0.013
H^E (J mol^{-1})	298.15	–2920	–26 993	669	31
	313.15	–2098	–27 684	–4707	42

Table 7. ERAS model parameters for the constituent binary mixtures of ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures at 298.15 and 313.15 K.

Mixture	T (K)	X_y (J cm^{-3})	K_{AB}	Δv_{AB}^* (cm^3 mol^{-1})	Δh_{AB}^* (J mol^{-1})
2-Butanol (1) + 1,3-dioxolane (2)	298.15	7.2	3	–15	–3150
	313.15	12	2.8	–15	–3150
2-Butanol (1) + cyclohexane (3)	298.15	21.4	—	—	—
	313.15	26.9	—	—	—
1,3-Dioxolane (2) + cyclohexane (3)	298.15	50.3	—	—	—
	313.15	51.1	—	—	—

data (13–15). Finally, the surface to volume ratios, s, were estimated using Bondi's method (28).

The association parameters for 2-butanol (K_A, Δv_A^*, and Δh_A^*) were obtained from the literature (16, 17). For 1,3-dioxolane, K_B, Δv_E^*, and Δh_E^* were obtained using the ERAS model equations (29) to fit, simultaneously, the experimental excess molar properties (V^E and H^E) of 1,3-dioxolane + n-hexane mixtures (30) and the enthalpy of vaporization of the pure 1,3-dioxolane (13). In the ERAS model, the parameters Δv_i^* and Δh_i^* are considered to be temperature independent and the parameter K_i can be obtained at a given temperature using the van't Hoff equation from the corresponding K_i and Δh_i^* values at 298.15 K.

The adjustable parameters of the ERAS model are: the energetic interaction parameter (X_{ij}) for the three binary mixtures and the cross-association parameters (K_{AB}, Δv_{AB}^*, Δh_{AB}^*) for the 2-butanol + 1,3-dioxolane mixtures. For the 2-

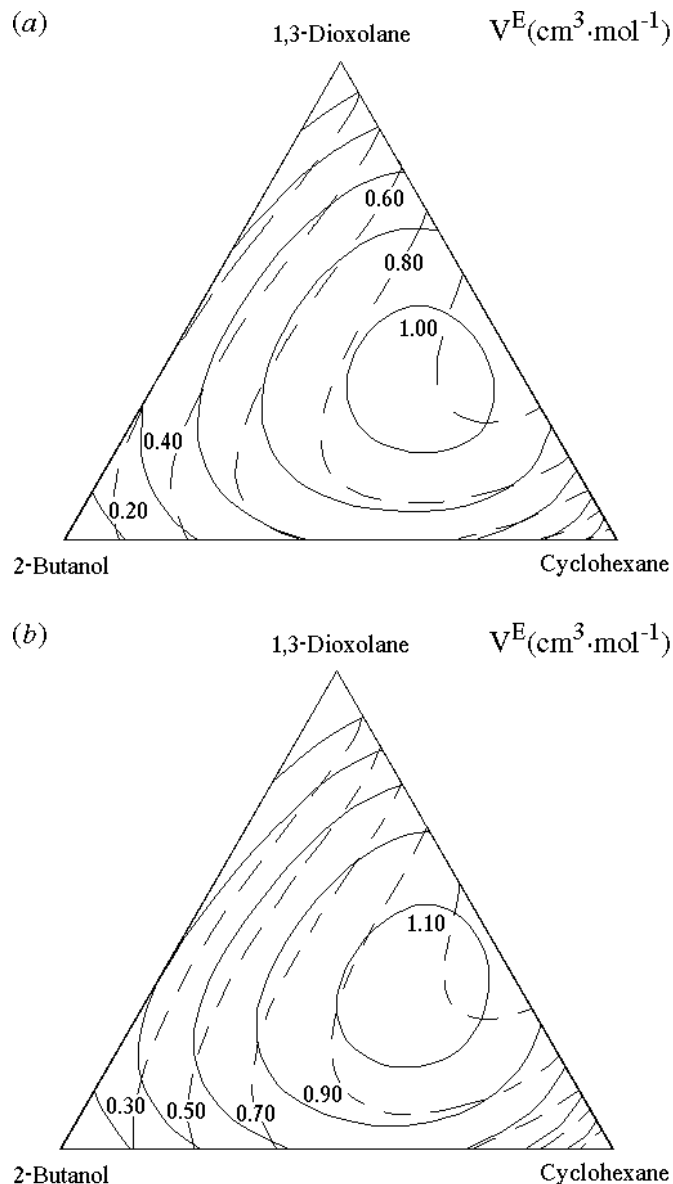
butanol + 1,3-dioxolane mixtures at 313.15 K, it can be pointed out that the only adjustable parameter is X_{AB}, since Δv_{AB}^* and Δh_{AB}^* are temperature independent, and K_{AB} is calculated using the van't Hoff equation from K_{AB} and Δh_{AB}^* values at 298.15 K.

Evaluation of the parameters at each temperature was based on minimization, using the simulated annealing method (31, 32) of an objective function F defined in terms of experimental and calculated V^E and H^E values of the binary mixtures

$$[7] \quad F = \sum_{i=1}^{i=N} \left(\left(\frac{V_{\text{ERAS}}^E - V_{\text{exp}}^E}{V_{\text{exp}}^E} \right) + \left(\frac{H_{\text{ERAS}}^E - H_{\text{exp}}^E}{H_{\text{exp}}^E} \right)^2 \right)$$

where N is the number of experimental data. The parameter values are given in Table 7.

Figure 1. Isolines of constant excess molar volumes for ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures: experimental correlation (continuous lines) and ERAS model predictions (dashed lines). (*a*) 298.15 K; (*b*) 313.15 K.

Figure 2. Isolines of constant excess molar enthalpies for ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures: experimental correlation (continuous lines) and ERAS model predictions (dashed lines). (*a*) 298.15 K; (*b*) 313.15 K.


From these parameters, ERAS model calculations for the ternary system have been made. These calculations are graphically represented in Figs. 1 and 2. We have also obtained the corresponding mean relative standard deviations (MRSD) between experimental and calculated excess molar properties, defined as:

$$[8] \qquad \text{MRSD} \, (\%) = \left[\frac{1}{m} \sum \left(\frac{Y_{\text{ERAS}}^{E} - Y_{\text{exp}}^{E}}{Y_{\text{exp}}^{E}} \right)^{2} \right]^{1/2} \times 100$$

where Y_{exp}^{E} and Y_{ERAS}^{E} are, respectively, the experimental and calculated excess molar properties of the ternary mixture (H^{E} or V^{E}) and m is the number of experimental points. MRSD values are given in Table 8.

Table 8. ERAS model predictions for V^{E} and H^{E} of ternary 2-butanol (1) + 1,3-dioxolane (2) + cyclohexane (3) mixtures at 298.15 and 313.15 K.

Property	T (K)	MRSD (%)
V^{E} (cm^3 mol^{-1})	298.15	22.3
	313.15	24.6
H^{E} (J mol^{-1})	298.15	19.8
	313.15	20.9

In Figs. 1 and 2 we can see that the ERAS model correctly describes the variation with composition of the excess molar volumes and enthalpies of the ternary mixture at 298.15 and 313.15 K. In general, ERAS model predictions

could be considered satisfactory, since the model only uses parameters obtained from the constituent binary mixtures.

Control of disaccharide conformation by π-stacking

Jonathan Watts, Jesús Jiménez-Barbero, Ana Poveda, and T. Bruce Grindley

Abstract: The conformations of a series of derivatives of the disaccharide α-L-fucopyranosyl-(1→3)-2-acetamido-2-deoxy-D-glucopyranoside, part of the Le[x] determinant, were studied by molecular modelling using the MM3* forcefield and by ^{1}H NMR spectroscopy. Unusually shielded *O*-benzyl protons were observed in the ^{1}H NMR spectrum of phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-deoxy-2-phthalimido-1-thio-α-D-glucopyranoside and assigned to the 2-*O*-benzyl group. This observation was explained by a shift in the population of the conformational mixture present about the glycosidic linkage from the positive Ψ region in the unsubstituted disaccharide to the negative Ψ region induced by π-stacking between the phthalimide and the 2-*O*-benzyl phenyl ring. The experimental nuclear Overhauser enhancements confirm the accuracy of the calculations.

Key words: disaccharide, conformation, π-stacking, Le[x] determinant, NOE measurements, MM3 calculations.

Résumé : Faisant appel à la modélisation moléculaire à l'aide du champ de force MM3* et à la spectroscopie RMN du ^{1}H, on a étudié les conformations d'une série de dérivés du disaccharide α-L-fucopyranosyl-(1→3)-2-acétamido-2-désoxy-D-glucopyranoside, une portion du déterminant Le[x]. Dans le spectre RMN du ^{1}H du 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-désoxy-2-phtalimido-1-thio-α-D-glucopyranoside de phényle, on a observé des protons *O*-benzyliques exceptionnellement blindés qui ont été attribués au groupe 2-*O*-benzyle. Cette observation est expliquée par un déplacement dans la population du mélange conformationnel présent autour de la liaison glycosidique par rapport à la région Ψ positive dans le disaccharide non substitué à une région Ψ négative induite par un empilement π entre le phtalimide et le noyau phényle du groupe 2-*O*-benzyle. Des rehaussements expérimentaux d'effet Overhauser nucléaire confirment l'exactitude des calculs.

Mots clés : disaccharide, conformation, empilement π, déterminant Le[x], mesures d'effets Overhauser nucléaire, calculs MM3.

[Traduit par la Rédaction]

Introduction

Recognition of carbohydrate epitopes by protein depends on the conformation adopted by the carbohydrate chains. Normally, the most populated conformations are recognized (1–5), but often less populated conformers are the epitopes (6–8). Therefore, it is important to fully define the factors that influence conformational stability and also to determine the conformational potential energy surface of biologically active oligosaccharides completely.

The sequence α-L-fucopyranosyl-(1→3)-2-acetamido-2-deoxy-D-glucose (**8**) is a principal constituent of Le[x]-bearing glycoconjugates, which mediate protein binding to the selectins and other proteins in several processes: inflammation (9), cancer, and others. As part of a project to synthesize conjugates of

the oligosaccharides present on mamalian zona pellucidas as potential immunocontraceptives, we prepared a disaccharide, phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-deoxy-2-phthalimido-1-thio-α-D-glucopyranoside (**4**). Fucose-containing oligosaccharides were targeted because of a report that the presence of fucose markedly enhanced sperm binding to the murine zona pellucida glycoprotein ZP3 (10). The conformation adopted by this disaccharide (**4**) appeared to be rather unusual because a signal of one of its benzyl protons appeared at 3.38 ppm in its ^{1}H NMR spectrum in chloroform-*d*, far from the normal region for benzyl protons, ~4.4–4.9 ppm (11). This report summarizes our determination of the cause of this unusual observation and provides additional information about the conformational energy surface for the very important disaccharide **8**.

Results and discussion

Synthesis

A summary of the synthetic procedures is shown in Scheme 1. Benzylation of phenyl 1-thio-α-L-fucopyranoside (12) gave the 2,3,4-tri-*O*-benzyl derivative (**1**), whose NMR spectra had not been fully assigned previously. Reaction of phenyl 2-deoxy-2-phthalimido-1-thio-α-D-glucopyranoside with benzaldehyde dimethyl acetal and *p*-toluenesulfonic acid in DMF afforded the 4,6-*O*-benzylidene acetal (**2**) in 80% yield,

Scheme 1.
a compound prepared previously by a different method (13). Oxidation of **1** to a mixture of sulfoxide diastereomers with 3-chloroperbenzoic acid (14, 15) and glycosidation with **2** and triflic acid yielded the de-*O*-benzylidenated disaccharide **4** in 31% yield. Direct reaction of **1** with **2** catalyzed by *N*-iodosuccinimide and triflic acid gave a good yield of the succinimide derivative of the glycosyl donor. Such products have been observed previously when active glycosyl donors were reacted with inactive glycosyl acceptors in the presence of succinimide (16). Catalysis of the reaction of **1** and **2** by dimethyl(methylthio)sulfonium triflate (DMTST) (17, 18), a cationic catalyst with a non-nucleophilic counterion, yielded the expected disaccharide **3** in 73% yield. The *N*-acetyl analogs of **3** and **4**, compounds **5** and **6**, respectively, were obtained by removal of the phthalimide group from **4** with ethylenediamine, *N*-acetylation to give **5**, then de-*O*-benzylidenation with aqueous sulphuric acid to give **6**. Methyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranoside (**7**) was ob-

tained from **1** by reaction with methanol and iodine (19). These latter three compounds were prepared in order to discover which interactions were critical in determining the conformations that caused the unusual chemical shift for the benzyl proton of **4** (Scheme 1).

NMR spectroscopy and conformational analysis

Conformations about glycosidic bonds are discussed in terms of the Φ and Ψ angles, defined as shown in Scheme 2 (20). In the following discussion, protons on the fucosyl residue are indicated by following the ring position by F, e.g., H1F is the fucosyl anomeric proton, while those on the *N*-acetylglucosaminyl residue are indicated by a following G. NMR chemical shifts of the compounds discussed are shown in Table 1, while details of the calculations and the NOE results are listed in Table 2.

Adiabatic potential energy surfaces for α-L-fucopyranosyl-(1→3)-2-acetamido-2-deoxy-D-glucopyranoside (**8**) derivatives

Scheme 2.
$$\Phi = \text{H1'-C1'-O-C3}$$

$$\Psi = \text{C1'-O-C3-H3}$$

have been explored previously using a variety of force fields (21, 22). The major low-energy region is centered in the so-called (23, 24) *syn-*Φ/Ψenergy region, where both Φ and Ψ have absolute values <60°. For **3** and **4**, MM3* calculations indicate that the global minimum is located in the *syn-*Φ/Ψregion and has dihedral angles of ca. $\Phi = 32°$ and $\Psi = –52°$ (see Table 2). A second minimum was also found for **3** and **4** with positive Ψ angles, with Φ ca. 65° and Ψ ca. 40° — about 9 kJ mol^{-1} higher in energy than the global minimum. Obviously, low-amplitude motions around both glycosidic linkages may take place, as commonly found for oligosaccharide molecules. The computed Φ/Ψ values are in agreement with those reported for the natural deprotected disaccharide **8** and its thio-analogue (22). However, for **8**, the Ψ-positive conformer was
calculated (22) to be more stable by about 3 kJ mol^{-1}, the reverse of the preferences calculated for **3** and **4**. Ψ-positive conformers are also calculated (25, 26) and observed (25) to be more stable for the α-L-fucopyranosyl linkage to O-3 of *N*-acetyl-D-glucosamine in Le^x. Both conformers have Φ values in the +*syn* region, in agreement with expectations based on the exo-anomeric effect (20). For **3** and **4**, the calculations indicate that the *anti* minima were, respectively, 24 and 31 kJ mol^{-1} less stable than the global minimum, in contrast to those for **8** (22), where it was only 10 kJ mol^{-1} less stable than the global minimum.

Analysis of the key structural factors present in both minima for **3** and **4** was performed. For the global minimum (Ψ negative), it is evident that the aromatic rings of the phthalimide moiety and the benzyl group at position C-2′ are perfectly stacked (see Fig. 1). Short interresidue proton–proton distances between H1F–H3G (2.3 Å), H5F–H4G (2.5 Å), H6F–OH4G (2.7 Å), and H1F–OH4G (2.7 Å) are predicted for **4** (see Table 2). In addition, for **4**, a short distance was calculated between the hydroxyl hydrogen OH4G and O5F (2.7 Å), which suggests that a hydrogen bond may exist between them.

For the Ψ-positive minimum, the π-stacking between the phthalimide moiety and the benzyl group at position O2F disappears with a concomitant change in the interproton distances. The short interresidue distances from the global minimum conformer are calculated to be longer in this conformer of **4**: H1F–H3G is 3.0 Å; H5F–H4G is 4.0 Å; H6F–OH4G is 4.7 Å; and H1F–OH4G is 4.8 Å; and the two hydrogen atoms in the potentially hydrogen-bonded pair OH4G–O5F are now far apart (4.1 Å). In this conformer, the short interproton distances are H5F–H3G (2.5 Å) and H5F–OH4G (2.6 Å). As mentioned above, the calculated relative energy difference between the minima amounts to 10 kJ mol^{-1}. This difference in stability results in the prediction that the population of the Ψ-positive minimum will be negligible.

NMR spectral data for **4** were recorded and scrutinized to assess the possible existence of both conformers (or conformational families). The most striking feature was the doublet in the spectrum of **4** due to an unusually shielded benzyl proton, which sparked this investigation (see Table 1); it was assigned to the O2F benzyl group through HMBC and NOESY experiments. This shielded position indicated that this benzylic proton is in the vicinity of an aromatic moiety. Obviously, this moiety could correspond to its vicinal OBn moiety at position C3F or to the interresidue phthalimide ring attached to C2G. The observation of normal chemical shifts for the benzyl groups of methyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranoside (**7**) suggests that the vicinal OBn moiety at position C3F is not responsible for the shielding. As will be shown below, by using non-aromatic substituents at C2G, this latter hypothesis is valid.

Relevant interproton NOEs were observed for **4** (see Table 2). Thus, the methyl group of the Fuc residue gives an NOE to OH4G (see Fig. 2), and the H1F gives NOEs to H3G and to OH4G. These NOEs are consistent with the existence of a major conformation in the negative Ψ area, as predicted by the calculations. There was a peak that could also correspond to the fourth expected NOE, according to the short distances explained above, H5F–H4G, but the signal of H5F overlaps with the more deshielded of the benzylic protons at O2F and that of H4G overlaps with that of the other O2F benzylic proton (see Figs. 2 and 3), and the geminal O2F benzylic protons must have a large NOE. No NOEs were observed for H5F–H3G and H5–OH4G, consistent with the predicted negligible contribution from conformers around the positive Ψ area. The presence of the intramolecular O4G—H···O5F hydrogen bond was indirectly deduced from the appearance of the OH signal. This resonance is an unusually deshielded, slightly broadened signal (4.3 ppm) with a vicinal coupling smaller than 1.5 Hz. Therefore, the hydroxyl proton adopts a particular orientation with respect to its vicinal H4G and does not freely rotate in solution. Otherwise, a medium-size coupling of ca. 5–7 Hz would have been expected. This particular orientation may be due to its involvement in an intramolecular hydrogen bond to O5F, as deduced from the calculations.

In the ^{1}H NMR spectrum of the 4,6-*O*-benzylidene derivative of **4**, compound **3**, a single benzyl proton (assigned to the 2-*O*-benzyl group) is again markedly shielded (3.84 ppm). This indicates that **3** also prefers Ψ-negative conformers, although probably not to the same extent as for **4**. The fucose methyl group was also shielded, appearing at 0.87 ppm,

[a]Chemical shift difference too small to measure $J_{A,B}$.

compared to a shift of 1.11 ppm for the methyl of α-L-fucopyranose (**11**), presumably because it is in the shielding cone of the benzylidene phenyl (see Fig. 1). In this case, the MM3* calculations indicate again that the Ψ-negative region contains the global minimum, while the Ψ-positive and *anti* conformers are less stable by 8.6 and 23.9 kJ mol^{-1}, respectively (see Table 2).

As a further step, the existence and importance of the π-stacking interaction between both aromatic rings located at the different GlcN and Fuc moieties was explored. Thus, the GlcNAc-containing analogs of compounds **3** and **4** were studied — disaccharides **5** and **6**, respectively. The molecular mechanics calculations on **5** and **6** also predict the occurrence of conformers with negative and positive Ψ values (see Table 2). However, in contrast with results of the MM3* calculations for **4**, the energy preference for the Ψ-negative conformer is calculated to be much less, ca. 3 kJ mol^{-1} for the unprotected derivative **6** and only 1 kJ mol^{-1} for compound **5**. The *anti* conformers are also destabilized to a lesser extent, 14.1 and 12.8 kJ mol^{-1} for **5** and **6** with respect to the global minima, respectively, but are still too energetic to contribute perceptibly to the conformational mixture. These relatively smaller values, in comparison to those of **3** and **4**, are probably owing to the significant stabilization provided by the Ar–Ar interaction in the phthalimide-containing molecules. Therefore, for both **5** and **6**, significant populations of the Ψ-positive conformers are calculated to be present in equilibrium mixtures in which the Ψ-negative conformers are most populated. The local minimum geometries in this area have Φ/Ψ 62°/43° for the unprotected derivative **6** and slightly different values, Φ/Ψ 45°/17°, for the benzylidene analogue **5**. For both compounds, the Φ/Ψ values and the corresponding geometrical features in the Ψ-negative region are basically identical to those described above for **4** (Φ/Ψ 30°/−50°). In both cases, interactions between the aromatic rings of the 2-*O*-benzyl groups of the Fuc moieties and the methyl groups of the acetamide units of the GlcNAc residues are evident. The H1F–HNAc distance is greater than 4 Å.

The expected distances for the secondary Ψ-positive minimum of the non-benzylidenated derivative **6** are analogous to those described above. One additional interresidue contact does appear: H1F–HNAc (2.5 Å). Some changes in the distances take place for the benzylidene analogue **5**: H1F–H3G (2.4 Å); H5F–H4G (3.6 Å); H5F–H3G (3.4 Å); and H1F–HNAc (2.5 Å).

In the ^{1}H NMR spectrum of the unprotected analogue **6**, the 2-*O*-benzylic protons of the Fuc residue have normal

chemical shifts, similar to those observed for the other CH$_2$ protons of the benzyl groups at positions 3 and 4 and very similar to those of the monosaccharide **7**. However, the methyl group of the acetamide unit is strongly shielded (1.61 ppm), in contrast with the chemical shift of 2.02 ppm for the acetamido methyl of phenyl 2-acetamido-2-deoxy-1-thio-β-D-glucopyranoside, the related monosaccharide (**27**). These features provide evidence about two points, namely that the phthalimide moieties of **3** and **4** are π-stacked with the fucose O2 benzyl groups and that a conformer with an analogous Me–aromatic interaction is present for **6**. The NOESY experiments showed the presence of the short H1F–H3G, H5F–H4G, and H1F–OH4G distances, as expected for the presence of the negative Ψ conformer. However, additional crosspeaks appear in the spectrum that cannot be explained by the exclusive presence of conformers from the negative Ψ area. These are H5F–H3G and H1F–HNG NOEs that can only take place when conformers with positive Ψ values coexist in the conformational mixture.

Similar observations were made for the benzylidene derivative **5**. The acetamide methyl group was shielded (1.66 ppm), as was the methyl group of the fucose moiety (0.83 ppm), indicating the presence of conformers having interactions of these methyl groups with aromatic moieties. H1F–HNG and H1F–H3G NOEs were observed, indicating the presence of conformers in both positive and negative Ψ areas. The analysis of the geometry of the MM3*-derived conformers indicate that the shielding of the methyl group of the fucose moiety is owing to the benzylidene unit of the GlcNAc moiety for both positive and negative Ψ angles, while that of the acetamide methyl group is owing to the 2-*O*-benzyl group of the Fuc unit only when Ψ adopts negative values.

In conclusion, a number of NMR observations assisted by MM3* calculations have shown the importance of stacking interactions for the existence of conformational variations around the glycosidic torsion angles of oligosaccharides. It has been shown that the existence of π-stacking Ar–Ar interaction in the phthalimide derivatives (**3** and **4**) limits the populated conformers to the Ψ-negative region of the complete Φ/Ψ map. In comparison with the unsubstituted disaccharide (**22**), this is a change of about 13 kJ mol^{-1}. The stabilization provided by π-stacking of benzene rings is about 10 ± 5 kJ mol^{-1} (28–31), similar in magnitude to this change. The change of the phthalimide unit to an acetamide shifts the conformational equilibrium in a way that the positive Ψ area starts to be populated. Although an Me–Ar interaction is still evident and stabilizes the negative Ψ area, the removal of the Ar–Ar interaction changes the conform-

[a] Estimated by the MM3* force field and the GB/SA solvent model for water. Values of Φ/Ψ are approximate and may oscillate ±10° between the GB/SA and the ε = 80 values, and the gg and gt rotamers of the hydroxymethyl group of the G moiety of **4** and **6**.

[b] Energy difference values vary less than 4 kJ mol⁻¹ between the GB/SA and the ε = 80 values, and between the gg and gt rotamers of the hydroxymethyl group of the G moiety of **4** and **6**.

[c] The expected distances, which are in agreement with the observed NOEs (given as experimental distances, EXP), are in bold. Experimental NOEs are given as strong (s), medium (m), weak (w), and not observed (no).

Fig. 1. From the left, positive, *anti*, and negative Ψ conformers of compound **3**. The more important stacking interactions take place in the negative Ψ conformer, although the positive Ψ conformer also shows a less energetically relevant 6-Me–benzylidene interaction. The conformers of compound **4** are similar. Torsion angle values and energies are given in Table 2.
ational distribution towards the "natural" one (more positive than negative) (22). The inclusion of a 4,6-*O*-benzylidene group on the GlcNAc moiety further shifts the equilibrium towards the positive Ψ area, possibly attributable to an additional stabilizing Me–Ar interaction, which is stronger for conformations within this region. Although the MM3* force field used in this work only uses van der Waals interactions to model the Me–Ar or the Ar–Ar interactions, it provides models that satisfactorily explain the experimental observations.

The fact that a shift in conformational population to the negative Ψ area occurs on introducing benzyl substituents onto fucose provides experimental support for the conclusion, based on MM3* calculations (22), that the potential energy surface for the natural disaccharide **8** contains a minimum in the negative Ψ area only slightly higher in energy than the global minimum.

Experimental

General methods

NMR spectra for synthetic purposes were recorded on Bruker AC-250 and Bruker AMX-400. The samples were made up in concentrations of approximately 10–15 mM in chloroform-*d* unless otherwise specified. Chemical shifts are given in parts per million (ppm) (±0.01 ppm) relative to TMS (tetramethylsilane) in the case of ^{1}H NMR spectra and to the central line of CDCl$_3$ (δ 77.16) for the ^{13}C NMR spectra. H-1 chemical shifts and coupling constants were obtained by first-order analyses. NMR experiments for conformational studies were recorded on Varian Unity 500 and Bruker DRX-500 spectrometers, using an approximately 5 mg mL^{-1} solution of the disaccharides at different temperatures. Chemical shifts are reported in ppm, using external TMS (0 ppm) as references. CDCl$_3$ and (CD$_3$)$_2$CO were used as solvents. The COSY spectra were performed with a data matrix of 256 * 1K to digitize a spectral width of 4000 Hz. 16 scans were used with a relaxation delay of 1 s. The 2D TOCSY experiments were performed using a data matrix of 256 * 2K to digitize a spectral width of 4000 Hz; 8 scans were used per increment with a relaxation delay of 2 s. MLEV 17 was used for the 70 ms isotropic mixing time. The one-bond proton–carbon correlation experiment was collected in the ^{1}H-detection mode using the HSQC gradient-enhanced sequence and an inverse probe. A data matrix of 256 * 2K was used to digitize a spectral width of 4000 Hz in F$_2$ and 15 000 Hz in F$_1$. Eight scans were used per increment with a relaxation delay of 1 s and a delay corresponding to a *J* value of 145 Hz. ^{13}C decoupling was achieved by the WALTZ scheme. HMBC experiments were recorded using the gradient-enhanced sequence; 16 scans were used per increment (256), adjusting the long-range coupling evolution delay for values of *J* = 3, 4, 6, 8, 10, and 12 Hz. 2D NOESY and 2D-T-ROESY (32) experiments were performed with the standard sequences and with 600 ms of mixing time. Data matrixes of 256 * 2K were employed. The exact masses of compounds **1** and **2** were measured on a CEC 21–110B mass spectrometer using electron ionization (70 eV). The others were measured on a Micromass ZAB mass spectrometer at the University of Alberta using electrospray ionization. Thin layer chromatography was performed on 0.25-mm thick Whatman G/UV and Silicycle silica gel aluminum plates. Components were visualized by spraying with a 2% ceric sulfate solution in 1 M H$_2$SO$_4$, followed by heating on a hot plate until coloured spots formed. They were purified by flash chromatography on TLC standard grade (230–400 mesh) silica gel using mixtures of hexanes and ethyl acetate as eluents unless otherwise specified. Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured on a Digi-Pol model 781 polarimeter.

Pyridine was dried by reflux and distillation over calcium hydride. Dry methanol was obtained by distillation from magnesium turnings activated by iodine. *N*,*N*-Dimethylformamide was dried by distillation under reduced pressure from 4 Å molecular sieves onto fresh 4 Å molecular sieves. Toluene was stored over calcium hydride for 3 h and distilled onto 4 Å molecular sieves. Dichloromethane was distilled from calcium hydride and stored over 4 Å molecular sieves. All organic extracts were dried with anhydrous MgSO$_4$.

Molecular mechanics calculations

Molecular mechanics calculations were performed using the MM3* force field as implemented in MACROMODEL 4.5 (33). The MM3* force field implemented in MACRO-MODEL differs from the original MM3 force field (34) in the treatment of the electrostatic term since it uses charge–charge instead of dipole–dipole interactions. Atoms from the

Fig. 2. Part of the 500 MHz NOESY spectrum of phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2 deoxy-2-phtalimido-1-thio-β-D-glucopyranoside (**4**).
non-reducing monosaccharide are dubbed F and those of the reducing one, G. The torsional angle Φ across the disacchar-ide linkage is defined as H1F-C1F-O-C3G and Ψ as C1F-O–C3F-H3F.

Fig. 3. Part of the 500 MHz HSQC spectrum of phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside (**4**).
MM3* calculations either in vacuo or with the GB/SA solvent model for chloroform were performed. The minimizations were performed using 10 000 conjugate gradient iterations until the rms derivative was better than 0.03 kJ Å^{-1} mol^{-1}. Eighteen different combinations of geometries of **4** and **6**, corresponding to the combination of the nine possible staggered rotamers

around Φ/Ψ with the two major rotamers around C5–C6 (gg and gt) of the reducing end were built and submitted to energy minimizations under both dielectric conditions. For **5**, only the nine possible rotamers around Φ/Ψ were considered. The S-phenyl group was set at a Φ value of –60°, in agreement with an exo-anomeric orientation (H1G-C1G-S-CPh). The phthalimide and the benzyl groups were set at positions where steric interactions with their corresponding rings were minimized and let free during the minimization process, after several trials with the corresponding monosaccharides. In particular, the starting position of the phthalimide group defined as H2G-C2G-N-CO was given an initial value of 30° and H2G-C2G-N-CO′ was started at –150°. For the 2-*O*-benzyl group, the starting orientation H2F-C2F-O-CH$_2$ was given a value of 60° and C2F-O-CH$_2$-CPh was started in an *anti* arrangement. For the 3-*O*-benzyl group, the starting orientation H3F-C3F-O-CH$_2$ was 60° and C3F-O-CH$_2$-CPh was also oriented *anti*. For the 4-*O*-benzyl group, the starting orientation H4F-C4F-O-CH$_2$ was –60° and C4F-O-CH$_2$-CPh was again *anti*. Depending on the compound, displacements of these groups from the original positions were found during the energy minimization steps, particularly for the 2-*O*-benzyl group. The HO-4 hydroxyl group of compounds **4** and **6** was set with a torsion angle (H-C-O-H) of 60°, pointing away from the glycosidic linkage and let free during the minimization process. From the Φ/Ψ viewpoint, and for all of **3**–**6**, three conformers were always the most preferred ones: those with exo-anomeric orientations for the Φ angle of F, combined with the three possible Ψ$_+$, Ψ$_-$, and Ψ$_{anti}$ orientations. In all cases, the Ψ$_{anti}$ conformers displayed the highest energy values, in agreement with the experimental NOE results (see text). The non-anomeric (Φ ca. –60°) starting conformers were not local minima and converged to the exo-anomeric region. The Φ$_{anti}$ conformers were stable, but highly destabilized (more than 50 kJ mol^{-1}) with respect to the global minimum and were not considered for subsequent analysis. Values of Φ/Ψ for the global and local minima oscillated ±10° between the GB/SA and the ε = 80 values, and between the gg and gt rotamers of the hydroxymethyl group of the G moiety of **4** and **6**. Additionally, the relative steric energy values varied less than 4 kJ mol^{-1} between the GB/SA and the ε = 80 values, and between the gg and gt rotamers of the hydroxymethyl group of the G moiety of **4** and **6**. The most stable conformers, which agreed with the experimental NOEs, are depicted in the corresponding figures.

Phenyl 2,3,4-tri-*O*-benzyl-1-thio-β-L-fucopyranoside (1)

A solution of phenyl 1-thio-β-L-fucopyranoside (12) (1.00 g, 3.9 mmol) in DMF (30 mL) was cooled to 0°C. Sodium hydride (60% w/w oil suspension, 30 mmol) was added, and the mixture was allowed to stir for 30 min. Benzyl bromide (2.0 mL, 2.9 g, 17 mmol) was added, and the mixture was allowed to warm to room temperature, then stirred for a further 2 h. Methanol (1 mL) was added, and after 15 min, the mixure was concentrated under reduced pressure, then partitioned between ethyl acetate and water; the water layers were washed with ethyl acetate and discarded, and the combined ethyl acetate layers dried and concentrated. Recrystallization (ether–hexane) yielded colourless prisms (1.26 g, 61%): mp 97–103°C (lit. (12) mp 107–109°C); [α]$_D$ –7.0 (*c* 1.58, CHCl$_3$), (lit. (12) [α]$_D$ –14.0 (*c* 0.7, CHCl$_3$). ^{1}H NMR (400.14 MHz, CDCl$_3$) δ: 1.27 (d, 3H, $J_{5,6}$ = 6.4 Hz, 3 H-6),

3.53 (dq, 1H, $J_{5,6}$ = 6.4 Hz, $J_{4,5}$ = 0.9 Hz, H-5), 3.59 (dd, 1H, $J_{3,4}$ = 2.8 Hz, $J_{2,3}$ = 9.2 Hz, H-3), 3.63 (dd, 1H, $J_{4,5}$ = 0.9 Hz, $J_{3,4}$ = 2.8 Hz, H-4), 4.60 (d, 1H, $J_{1,2}$ = 9.6 Hz, H-1), 4.67 (d, 1H, J = 11.6 Hz, 1 H of -CH$_2$Bn on O-3), 4.73 and 4.79 (2 d (leaning), 2H, J = 10.2 Hz, -CH$_2$Bn on O-2), 4.74 (s with second-order side peaks, 2H, -CH$_2$Bn on O-4), 5.01 (d, 1H, J = 11.5 Hz, 1 H of -CH$_2$Bn on O-3), 7.0–7.7 (m, 20H, 4 Ph). ^{13}C NMR (100.62 MHz, CDCl$_3$) δ: 17.43 (C6), 72.92 (CH$_2$ of 4-O Bn), 74.69 (C5 + CH$_2$ of 3-O Bn), 75.66 (CH$_2$ of 2-O Bn), 76.68 (C4), 77.19 (C2), 84.61 (C3), 87.60 (C1). EI-HR-MS calcd. for C$_{33}$H$_{34}$O$_4$S ([M$^+$]): 526.2178; found: 526.2178.

Phenyl 4,6-*O*-benzylidene-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside (2)

Anhydrous phenyl 2-deoxy-2-phthalimido-1-thio-β-D-gluco-pyranoside (13) (31.1 g, 77.5 mmol) was dissolved in dry DMF (150 mL) in a 500-mL, round-bottomed flask. Benzaldehyde dimethyl acetal (12.3 g, 80.7 mmol) and *para*-toluenesulfonic acid hydrate (0.11 g, 0.58 mmol) were added. The solution was attached to a rotary evaporator, evacuated with a water aspirator, rotated, and lowered into a water bath at 60 ± 5°C. After 140 min, another aliquot of benzaldehyde dimethyl acetal (10.1 g, 66.3 mmol) was added. After 220 min, about half the solvent was removed by reducing the pressure further with an oil pump, then a solution of NaHCO$_3$ (0.43 g) in water (50 mL) was added. A precipitate formed, and the mixture was concentrated to near-dryness. The reaction mixture was partitioned between dichloromethane (500 mL) and water (300 mL). The water layer was extracted with dichloromethane (3 × 100 mL) and discarded. The combined organic layers were washed with water (2 × 100 mL) and dried. These extractions were relatively difficult owing to the recurring formation of an emulsion layer. The organic layers were dried and concentrated, and the residue was purified by flash chromatography (5:2 Hex:EtOAc to 2:1 Hex:EtOAc), yielding **2** (30.2 g, 79.5%) as an amorphous solid: [α]$_D$ 35.0° (*c* 2.04, CHCl$_3$), lit. (13) [α]$_D$ 34.2° (*c* 1.3, CHCl$_3$). ^{1}H NMR (CDCl$_3$) δ: 2.84 (d, 1H, $J_{\text{H-3,OH}}$ = 3.75 Hz, OH), 3.54 (t, 1H, $J_{3,4} \approx J_{4,5}$ = 9.2 Hz, H-4), 3.63 (dt, 1H, $J_{4,5} \approx J_{5,6ax}$ = 9.3 Hz, $J_{5,6eq}$ = 4.6 Hz, H-5), 3.78 (t, 1H, $J_{6ax,6eq} \approx J_{5,6}$ = 9.9 Hz, H-6ax), 4.30 (t, 1H, $J_{2,3} = J_{1,2}$ = 10.3 Hz, H-2), 4.35 (dd, 1H, $J_{5,6eq}$ = 4.5 Hz, $J_{6ax,6eq}$ = 10.2 Hz, H-6eq), 4.59 (ddd, 1H, $J_{H3,OH}$ = 3.8 Hz, $J_{3,4}$ = 8.5 Hz, $J_{2,3}$ = 9.9 Hz, H-3), 5.53 (s, 1H, PhC*H*(O-)$_2$), 5.65 (d, 1H, $J_{1,2}$ = 10.5 Hz), 7.23–7.84 (m, 2 Ph + Phth). ^{13}C NMR (CDCl$_3$) δ: 55.6 (C-2), 68.6 (C-6), 69.7 (C-3), 70.3 (C-5), 81.9 (C-4), 84.3 (C-1), 102.0 (PhCH(OR)$_2$). EI-HR-MS: calcd. for C$_{27}$H$_{23}$O$_6$NS ([M$^+$]): 489.1246; found: 489.1241.

First attempt to prepare phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-4,6-*O*-benzylidene-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside (3)

Anhydrous compounds **1** (175 mg, 0.332 mmol) and **2** (115 mg, 0.236 mmol), along with *N*-iodosuccinimide (NIS, 85 mg, 0.378 mmol) and powdered 4 Å molecular sieves were placed in a 2-necked, round-bottomed flask, which was fitted with a rubber septum and an argon-filled balloon. The mixture was cooled to –40°C, and dichloromethane (8 mL) was added via syringe. The stirred solution was allowed to warm up to –20°C over 35 min, and triflic acid (0.3 μL,

0.5 mg, 0.0035 mmol) was added via syringe at 65 min. The cooling bath was removed after 100 min, and the reaction continued to stir and was monitored by TLC.

After 175 min, the reaction mixture was diluted with dichloromethane (10 mL) and filtered, then washed with saturated aqueous sodium bicarbonate (3 × 50 mL) and brine (50 mL), dried, and concentrated. The residue was purified by flash chromatography (4:1 to 2:1 Hex:EtOAc) to give *N*-(2,3,4-tri-*O*-benzyl-β-L-fucopyranosyl)succinimide as a syrup (132 mg, 77%). ^{1}H NMR (CDCl$_3$) δ: 1.09 (d, $J_{5,6}$ = 6.4 Hz, 3 H-6), 2.55 (s, 2 CH$_2$ of succinimide), 3.71 (bd, $J_{3,4}$ = 2.6 Hz, H-4), 4.28 (bq, $J_{5,6}$ = 6.4 Hz, H-5), 4.49 (dd, $J_{1,2}$ = 7.5 Hz, $J_{2,3}$ = 9.8 Hz, H-2), 4.58 (dd, $J_{2,3}$ = 9.8 Hz, $J_{3,4}$ = 2.9 Hz, H-3), 4.48, 4.67 (2 leaning d, J = 11.7 Hz, C*H*$_2$Bn), 4.66, 4.99 (2 leaning d, J = 11.6 Hz, C*H*$_2$Bn), 4.76, 4.86 (2 leaning d, J = 11.8 Hz, C*H*$_2$Bn), 6.13 (d, $J_{1,2}$ = 7.5 Hz, H-1), 7.25–7.33 (m, 3Ph). ^{13}C NMR (CDCl$_3$) δ: 17.5 (C6), 28.3 (2 CH$_2$ of succinimide), 72.8 (C5), 73.3 (*C*H$_2$Bn), 73.6 (*C*H$_2$Bn), 74.9 (C2 + *C*H$_2$Bn), 76.7 (C1), 77.7 (C4), 80.6 (C3), 127.6, 128.3, 128.4, 138.1, 138.6, 139.1 (aromatic), 178.0 (2 C=O of succinimide).

Phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-4,6-*O*-benzylidene-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside (3)

Anhydrous compounds **1** (670 mg, 1.28 mmol) and **2** (420 mg, 0.851 mmol) were dissolved in dichloromethane (40 mL) in a 2-necked, round-bottomed flask, which was fitted with a rubber septum and an argon-filled balloon. This solution was cooled to 0°C and a solution of dimethyl-(methylthio)sulfonium triflate (0.88 g, 3.4 mmol) in dichloromethane (40 mL) was added via syringe, with stirring. The reaction was monitored by TLC. After 1 h, the reaction was quenched by adding triethylamine (5 mL), then filtered through Celite. Dichloromethane (70 mL) was added, and the solution extracted with saturated aqueous sodium bicarbonate (2 × 100 mL) and water (100 mL), then dried and concentrated. The residue was separated by flash chromatography (5:1 hexanes: ethyl acetate) to give the title compound (0.47 g, 61%) plus a mixed fraction (0.18 g) in which **3** constituted 50%: total yield 0.56 g, 73%; [α]$_D$ 7.1° (*c* 2.04, CHCl$_3$). ^{1}H NMR (400.13 MHz, CDCl$_3$) δ: 0.87 (d, 3H, $J_{5,6}$ = 6.6 Hz, 3 H-6 Fuc), 3.47 (dd, 1H, $J_{3,4}$ = 2.37 Hz, $J_{4,5}$ = 1.27 Hz, H-4 Fuc), 3.66–3.76 (m, 4H, H-4 Glc, H-5 Glc, H-2 Fuc, H-3 Fuc), 3.83 (t, 1H, $J_{5,6ax} ≈ J_{6ax,6eq}$ = 9.5 Hz, H-6ax Glc), 3.84, 4.26 (2 d, 2H, J = 12.6, C*H*$_2$Ph), 4.04 (dq, 1H, $J_{4,5}$ = 1.1 Hz, $J_{5,6}$ = 6.6 Hz, H-5 Fuc), 4.38, 4.43 (2 d, 2H, J = 11.6 Hz, C*H*$_2$Ph), 4.43 (dd, $J_{1,2}$ = 10.6 Hz, $J_{2,3}$ = 9.9 Hz, H-2 Glc), 4.43 (dd, 1H, H-6eq Glc), 4.49, 4.79 (2 d, 2H, J = 11.6 Hz, C*H*$_2$Ph), 4.81 (d, 1H, $J_{1,2}$ = 2.9 Hz, H-1 Fuc), 5.55 (s, 1H, PhC*H*(OR)$_2$), 5.74 (d, 1H, $J_{1,2}$ = 10.7 Hz, H-1 Glc), 7.0–7.8 (m, aromatics). ^{13}C NMR (100.62 MHz, CDCl$_3$) δ: 16.57 (C6 Fuc), 54.98 (C4 Glc), 67.51 (C5 Fuc), 68.77 (C6 Glc), 70.79 (C5 Glc), 72.93 (*C*H$_2$Bn), 73.29 (*C*H$_2$Bn), 74.92 (*C*H$_2$Bn), 75.84 (C4 Glc), 76.72 (C3 Glc), 78.28 (C4 Fuc), 79.83 (C2 Fuc), 82.12 (C3 Fuc), 84.45 (C1 Glc), 99.64 (C1 Fuc), 101.36 (PhCH(OR)$_2$), 123.50, 126.30, 127.61, 127.66, 128.05, 128.28, 128.38, 128.40, 128.48, 128.57, 128.99, 129.15, 133.04, 134.06, 138.55 (aromatics), 167.76, 168.52 (2 C=O of phthalimide). HR-MS calcd. for C$_{54}$H$_{51}$NO$_{10}$S + Na: 928.3131; found: 928.3130.

Phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside (4)

Compound **1** (473 mg, 0.955 mmol) was dissolved in dichloromethane (30 mL) in a 50-mL, round-bottomed flask fitted with a drying tube and a magnetic stirrer. The solution was cooled to –78°C using an ethyl acetate – liquid nitrogen slurry. *m*-Chloroperbenzoic acid (227 mg of 85% reagent, 1.12 mmol) was added to the stirring solution, and the reaction was monitored by TLC (eluent 2.5% acetone in CH$_2$Cl$_2$; R_f sulfide = 0.92, R_f sulfoxide = 0.51, 0.39 (*R* and *S* isomers), R_f sulfone = 0.82). After 3.5 h, the reaction was allowed to warm up somewhat, then saturated aqueous sodium bicarbonate (15 mL) and dichloromethane (20 mL) were added. The aqueous layer was extracted with dichloromethane (2 × 20 mL). The combined organic layers were washed with water (30 mL), dried, and concentrated, yielding a residue that was purified by flash chromatography (2.5% acetone in CH$_2$Cl$_2$). The *R* and *S* isomers of phenyl 2,3,4-tri-*O*-benzyl-1-thio-α-L-fucopyranosyl sulfoxide (**1a**) were collected together and used for the next step.

Compounds **1a** (313 mg, 0.577 mmol) and **2** (200 mg, 0.408 mmol) were combined with 2,6-di-*tert*-butyl-4-methylpyridine (168 mg, 0.812 mmol) in a 2-necked, round-bottomed flask. One neck was stoppered and the mixture was azeotroped with toluene (3 × 10 mL), keeping the temperature low to avoid decomposition of the sulfoxide. The flask was fitted with a rubber septum and an argon-filled balloon. Dichloromethane (25 mL) was added by syringe, and the solution was cooled to –78°C using an ethyl acetate – liquid nitrogen slurry. To the cold, stirred solution was added triflic anhydride (0.08 mL, 130 mg, 0.45 mmol), dropwise, by syringe. Stirring was continued at –78°C, and the reaction was monitored by TLC. When the reaction neared completion, it was removed from the ethyl acetate slurry. The solution was extracted with saturated aqueous sodium bicarbonate (25 mL, 2 × 50 mL) and water (50 mL), then dried and concentrated. The residue was purified using flash chromatography (3:1 to 3:2 Hex:EtOAc). The main product was identified as phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-deoxy-2-phthalimido-1-thio-β-D-glucopyranoside in 31% yield. ^{1}H NMR (500.13 MHz, CDCl$_3$) δ: 1.09 (d, 3H, $J_{5,6}$ = 6.5 Hz, 3 H-6 Fuc), 3.38, 4.13 (2 leaning d, 2H, J = 13.0 Hz, -CH$_2$Bn), 3.53 (dd, 1H, $J_{3,4}$ = 2.5 Hz, $J_{4,5}$ = 1.2 Hz, H-4 Fuc), 3.57 (bt, 1H, $J_{3,4} ≈ J_{4,5}$ = 9.1 Hz, H-4 Glc), 3.64 (ddd, 1H, $J_{5,6}$ = 4.9 Hz, $J_{5,6'}$ = 3.4 Hz, $J_{4,5}$ = 8.3 Hz, H-5 Glc), 3.74 (dd, 1H, $J_{1,2}$ = 3.3 Hz, $J_{2,3}$ = 10.3 Hz, H-2 Fuc), 3.78 (dd, 1H, $J_{2,3}$ = 10.3 Hz, $J_{3,4}$ = 2.5 Hz, H-3 Fuc), 3.87 (dd, 1H, $J_{5,6}$ = 4.9 Hz, $J_{6,6'}$ = 11.8 Hz, H-6 Glc), 4.00 (dd, 1H, $J_{5,6'}$ = 3.4 Hz, $J_{6,6'}$ = 11.8 Hz, H-6′ Glc), 4.07 (dq, 1H, $J_{4,5}$ = 1.0 Hz, $J_{5,6}$ = 6.6 Hz, H-5 Fuc), 4.25 (dd, 1H, $J_{2,3}$ = 10.4 Hz, $J_{3,4}$ = 8.1 Hz, H-3 Glc), 4.33 (t, 1H, $J_{1,2} = J_{2,3}$ = 10.3 Hz, H-2 Glc), 4.55, 4.89 (2 leaning d, 2H, J = 11.4 Hz, -CH$_2$Bn), 4.56, 4.63 (2 leaning d, 2H, J = 11.8 Hz, -CH$_2$Bn), 4.62 (d, 1H, $J_{1,2}$ = 3.3 Hz, H-1 Fuc), 5.78 (d, 1H, $J_{1,2}$ = 10.3 Hz, H-1 Glc), 6.9–7.9 (m, aromatics). ^{13}C NMR (62.9 MHz, CDCl$_3$) δ: 16.58 (C6 Fuc), 53.67 (C2 Glc), 62.77 (C6 Glc), 68.70 (C5 Fuc), 71.66 (C4 Glc), 72.55 (*C*H$_2$Bn), 73.54 (*C*H$_2$Bn), 73.88 (C2 Fuc), 74.86 (*C*H$_2$Bn), 77.92 (C4 Fuc), 79.01 (C3 Fuc), 79.40 (C5 Glc), 83.33 (C1 Glc), 84.03 (C3 Glc), 101.04 (C1 Fuc), 123.15, 123.33, 127.65, 127.74, 128.29, 128.38, 128.49, 128.56, 129.12, 132.88,

133.90, 138.16, 138.36, 138.81 (aromatics), 167.80, 168.76 (2 C=O of phthalimide). HR-MS calcd. for $C_{47}H_{47}NO_{10}S$ + Na: 840.2818; found: 840.2824.

Phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-acetamido-4,6-*O*-benzylidene-2-deoxy-1-thio-β-D-glucopyranoside (5)

To a stirred solution of **3** (0.43 g, 0.47 mmol) in anhydrous 1-butanol (80 mL) was added ethylenediamine (15 mL, 13.5 g, 220 mmol). Argon was bubbled through the solution and stirring continued for 5.5 h, monitoring the reaction by TLC with a ninhydrin spray reagent (0.25% in ethanol). The mixture was then evaporated to dryness. Tolune (2 × 25 mL) and ethanol (25 mL) were in turn added and evaporated. To the residue was added methanol (60 mL), resulting in a heterogeneous mixture, which dissolved upon addition of triethylamine (1 mL, 7.2 mmol) and acetic anhydride (8 mL, 85 mmol) with stirring. After continued stirring for 19 h, the reaction was added to 250 mL ice water, which melted and was extracted with dichloromethane (3 × 100 mL). The organic layers were dried and concentrated. Purification by flash chromatography yielded a white solid (0.22 g, 57%). ^{1}H NMR (400.14 MHz, CDCl$_3$) δ: 0.831 (d, 3H, $J_{5,6}$ = 6.4 Hz, 3 H-6 Fuc), 1.659 (s, 3H, NAc), 3.5–3.65 (complex m, 4H, H-4 Fuc, H-2, H-4, H-5 Glc), 3.774 (t, 1H, $J_{5,6ax}$ = $J_{6ax,6eq}$ = 10.0 Hz, H-6ax Glc), 3.934 (dd, $J_{2,3}$ = 10.1 Hz, $J_{3,4}$ = 2.7 Hz, H-3 Fuc), 4.084 (dd, H-2 Fuc), 4.093 (br q, H-5 Fuc), 4.289 (br t, $J_{2,3}$ = $J_{3,4}$ = 9.0 Hz, H-3 Glc), 4.363 (dd, $J_{5,6eq}$ = 4.5 Hz, $J_{6ax,6eq}$ = 10.5 Hz, H-6eq), 4.562, 4.605 (2 d, 2H, J = 11.5, 2 CH$_2$Ph H), 4.754 (s, 2H, CH$_2$Ph), 4.931 (d, 2H, J = 11.5, 2 CH$_2$Ph H), 5.102 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1 Fuc), 5.193 (broad d, 1H, $J_{1,2}$ = 10.4 Hz, H-1 Glc), 5.518 (s, 1H, O$_2$C*H*Ph), 5.741 (d, 1H, $J_{1,2}$ = 7.7 Hz, NH), 7.2–7.6 (m, Ph H). ^{13}C NMR (62.9 MHz, CDCl$_3$) δ: 16.42 (C-6 Fuc), 23.53 (NCO*C*H$_3$), 56.84 (C-2 Glc), 67.03 (C-5 Fuc), 68.79 (C-6 Glc), 70.64 (C-5 Glc), 72.67, 74.32, 75.04 (3 O*C*H$_2$Ph), 76.65 (C-3 Glc), 77.16 (C-2 Fuc), 77.55 (C-4 Fuc), 79.93 (C-3 Fuc), 80.64 (C-4 Glc), 86.70 (C-1 Glc), 98.39 (C-1 Fuc), 101.61 (O$_2$*C*HPh), 126.3–129.0, 132.5 (PhCH), 137.3, 138.7 (quat C Ph), 170.6 (C=O). Phenyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl-(1→3)-2-acetamido-2-deoxy-1-thio-β-D-glucopyranoside (6)

Compound **5** (0.13 g, 0.16 mmol) was dissolved in a solution of ethanol (150 mL) and water (1 mL). Sulfuric acid (0.18 g, 1.8 mmol) was added with stirring. The resulting solution was heated to reflux for 2 h, then cooled. Solid NaHCO$_3$ (0.31 g, 3.7 mmol) was added and the solvent removed under reduced pressure. The residue was partitioned between water (100 mL) and CH$_2$Cl$_2$ (100 mL) and the aqueous layer extracted with two further portions of CH$_2$Cl$_2$ (100 mL each). Combined organic layers were dried and concentrated, and the product was purified by flash chromatography (2:1 to 1:1 hexanes:ethyl acetate) to yield a white solid (0.10 g, 86%). ^{1}H NMR (250.13 MHz, CDCl$_3$) δ: 1.155 (d, 3H, $J_{5,6}$ = 6.6 Hz, 3 H-6 Fuc), 1.612 (s, 3H, Nac), 3.42 (complex m, H-5 Glc), 3.47 (t, 1H, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H-4 Glc), 3.58–3.73 (complex m, 3H, H-2, H-3 Glc, H-4 Fuc), 3.769 (dd, 1H, $J_{5,6}$ = 4.7 Hz, H-6 Glc), 3.907 (dd, $J_{5,6'}$ = 2.9 Hz, $J_{6,6'}$ = 11.8 Hz, H-6′ Glc), 3.932 (dd, 1H, $J_{3,4}$ =

2.6 Hz, $J_{2,3}$ = 10.2 Hz, H-3 Fuc), H-07–4.17 (complex m, H-2, H-5 Fuc), 4.618, 4.963 (2 d, 2H, J = 11.5 Hz, -CH$_2$Ph), 4.750, 4.779 (AB quartet, 2H, J = 12.6 Hz, -CH$_2$Bn), 4.636, 4.840 (2 d, 2H, J = 11.5, -CH$_2$Ph), 4.946 (d, 1H, $J_{1,2}$ = 3.2 Hz, H-1 Fuc), 5.056 (d, 1H, $J_{1,2}$ = 9.4 Hz, H-1 Glc), 5.530 (d, 1H, $J_{1,2}$ = 7.02 Hz, NH), 7.2–7.5 (m, aromatics). ^{13}C NMR (100.62 MHz, CDCl$_3$) δ: 16.88 (C-6 Fuc), 23.23 (NCO*C*H$_3$), 54.55 (C-2 Glc), 63.00 (C-6 Glc), 68.63 (C-5 Fuc), 71.19 (C-4 Glc) 72.67, 74.32, 75.04 (3 O*C*H$_2$Ph), 76.65 (C-3 Glc), 76.48 (C-2 Fuc), 77.55 (C-4 Fuc), 79.33 (C-5 Glc), 79.39 (C-3 Fuc), 85.96 (C-3 Glc), 86.38 (C-1 Glc), 99.96 (C-1 Fuc), 127.9–129.2, 131.9 (PhCH), 133.66, 138.51, 138.45,138.67 (quat C Ph), 171.16 (C=O). Methyl 2,3,4-tri-*O*-benzyl-α-L-fucopyranoside (7)

To a stirred solution of **1** (250 mg, 0.47 mmol) in dry methanol (2 mL) was added iodine (190 mg, 0.75 mmol). The flask was fitted with a silica gel drying tube and stirred for 4.5 h. Methanol (5 mL) and Rexyn 201 (OH) ion-exchange resin (4 mL) was added to the flask, and stirring was continued until the solution became virtually colorless. Filtration, concentration, and purification by flash chromatography yielded a syrup (150 mg, 70%). ^{1}H NMR (400.14 MHz, CDCl$_3$) δ: 1.114 (d, 3H, $J_{5,6}$ = 6.6 Hz, 3 H-6 Fuc), 3.350 (s, 3H, OMe), 3.630 (dd, 1H, $J_{3,4}$ = 2.8 Hz, $J_{4,5}$ = 1.1 Hz, H-4), 3.828 (qd, 1H, H-5), 3.924 (dd, 1H, $J_{2,3}$ = 10.1 Hz, H-3), 4.035 (dd, 1H, $J_{1,2}$ = 3.7 Hz, H-2), 4.649, 4.978 (2 d, 2H, J = 11.6 Hz, C-4 -O*C*H$_2$Ph), 4.653 (d, 1H, H-1), 4.687, 4.821 (2d, 2H, J = 12.1 Hz, C-2-O*C*H$_2$Ph), 4.730, 4.872 (2d, 2H, J = 11.9 Hz, C-3-O*C*H$_2$Ph), 7.22–7.41(m, Ph H). ^{13}C NMR (62.9 MHz, CDCl$_3$) δ: 16.63 (C-6), 55.31 (OMe), 66.08 (C-5), 73.36 (C3- O*C*H$_2$Ph), 73.48 (C2- O*C*H$_2$Ph), 74.83 (C4-O*C*H$_2$Ph), 76.33 (C-2), 77.83 (C-4), 79.41 (C-3), 98.81 (C-1), 127.5–128.4 (PhC), 138.57 (C-2 quat PhC), 138.62 (C-4 quat PhC), 138.97 (C-3 quat PhC). Derivatives of tetraphenylmethane and tetraphenylsilane: Synthesis of new tetrahedral building blocks for molecular construction

Jean-Hugues Fournier, Xin Wang, and James D. Wuest

Abstract: Useful derivatives of tetraphenylmethane and tetraphenylsilane have been synthesized by efficient methods that give crystalline products without chromatographic purification. New compounds include tetrakis(4-hydroxyphenyl)-methane (**21**), tetrakis(4-formylphenyl)methane (**22**), tetrakis[(4-hydroxymethyl)phenyl]methane (**23**), tetrakis(4-bromo-phenyl)silane (**24**), tetrakis(4-iodophenyl)silane (**25**), tetrakis(4-hydroxyphenyl)silane (**26**), tetrakis[(4-hydroxymethyl)-phenyl]silane (**27**), and tetrakis[(4-chloromethyl)phenyl]silane (**28**). These compounds are valuable precursors for the construction of complex molecules with tetrahedral geometries.

Key words: organic synthesis, molecular and supramolecular design and construction, tetraphenylmethane, tetraphenyl-silane, tetrahedral building blocks.

Résumé : On a réalisé la synthèse de dérivés utiles du tétraphénylméthane et du tétraphénylsilane à l'aide de méthodes efficaces qui conduisent à des produits cristallins sans nécessité de purification chromatographique. Les nouveaux com-posés incluent les tétrakis(4-hydroxyphényl)méthane (**21**), tétrakis(4-formyl)méthane (**22**), tétrakis(4-hydroxyméthyl)mé-thane (**23**), tétrakis(4-bromophényl)silane (**24**), tétrakis(4-iodophényl)silane (**25**), tétrakis(4-hydroxyphényl)silane (**26**), tétrakis(4-hydroxyméthyl)silane (**27**) et tétrakis(4-chlorométhyl)silane (**28**). Ces composés sont des précurseurs précieux pour la construction de molécules complexes à géométries tétraédriques.

Mots clés : synthèse organique, ébauche et construction de molécules et de supramolécules, tétraphénylméthane, tétra-phénylsilane, blocs tétraédriques de construction moléculaire.

[Traduit par la Rédaction]

Introduction

Recent publications have underscored the importance of derivatives of tetraphenylmethane and tetraphenylsilane as subunits in molecular construction (1–39). Such tetrahedral building blocks have been successfully incorporated in supramolecular networks (1–13) and have also found use as precursors of dendrimers and polymers (14–22), nanoscale structures (23–25), optoelectronic materials (26–32), liquid crystals (33), and materials with other applications (34–39). Unfortunately, few syntheses of different functionalized de-rivatives of tetraphenylmethane and tetraphenylsilane have been reported. Currently known simple tetraphenylmethanes that are fully substituted in the *para* positions include com-pounds **1** (12, 21, 40), **2** (6, 19), **3** (41), **4** (42), **5** (42), **6** (12, 40, 41), **7** (40), **8** (40, 41), **9** (21), **10** (31, 43), **11** (43), **12** (19), and **13** (25), and analogous tetraphenylsilanes include compounds **14** (13, 44), **15** (8), **16** (13, 45), **17** (45), **18** (22), **19** (22), and **20** (1). To make a wider range of tetrahedral building blocks readily available for molecular construction, we now report efficient syntheses of a variety of new and previously known *para*-substituted derivatives of tetra-phenylmethane and tetraphenylsilane. Our syntheses use simple reactions and yield crystalline products without chro-matographic purification. Newly characterized derivatives include tetrakis(4-hydroxyphenyl)methane (**21**), tetrakis(4-formylphenyl)methane (**22**), tetrakis[(4-hydroxymethyl)-phenyl]-methane (**23**), tetrakis(4-bromophenyl)silane (**24**), tetrakis(4-iodophenyl)silane (**25**), tetrakis(4-hydroxyphenyl)-silane (**26**), tetrakis[(4-hydroxymethyl)phenyl]silane (**27**), and tetrakis[(4-chloromethyl)phenyl]silane (**28**).

Results and discussion

Our general approach to syntheses of derivatives of tetra-phenylmethane and tetraphenylsilane is based on tetra-lithiation (41) of tetrakis(4-bromophenyl)methane (**1**) (12, 21, 40) or tetrakis(4-bromophenyl)silane (**24**) (4), followed by the addition of an appropriate electrophile. This approach has the advantage of providing a wide variety of derivatives simply by modifying the nature of the electrophile in a com-mon experimental protocol. For example, treatment of tetrakis(4-bromophenyl)methane (**1**) with excess BuLi, fol-lowed by the addition of CH_3I, afforded tetrakis(4-methyl-phenyl)-methane (**3**) (41) in 60% yield after purification by recrystallization. Analogous procedures using $B(OCH_3)_3$–H_2O_2 or *N,N*-dimethylformamide (DMF) provided the corre-sponding tetraphenol **21** and tetraaldehyde **22** in 62% and 46% yields, respectively, again after purification by re-

crystallization. The reduction of tetraaldehyde **22** with NaBH$_4$ gave tetrakis[(4-hydroxymethyl)phenyl]methane (**23**) in 90% yield. Subsequent treatment with SOCl$_2$ gave a 94% yield of tetrakis[(4-chloromethyl)phenyl]methane (**11**), a known compound prepared previously by direct chloromethylation of tetraphenylmethane (43). Compounds **21**–**23** are useful new tetrahedral building blocks that can be subjected to further chemical modifications for use in molecular construction.

The corresponding tetraphenylsilanes were made in a similar way. Tetrakis(4-bromophenyl)silane (**24**) was prepared by the monolithiation of 1,4-dibromobenzene with BuLi, followed by the addition of SiCl$_4$ (4). This procedure provided target **24** in 45% yield after two recrystallizations. Alternatively, tetrakis(4-iodophenyl)silane (**25**) could be synthesized from 1,4-diiodobenzene by an analogous method in 56% yield (4). Tetrakis(4-methylphenyl)silane (**14**) (13, 44) and tetrakis(4-hydroxyphenyl)silane (**26**) could be prepared from tetrakis(4-bromophenyl)silane (**24**) in 65% and 59% yields, respectively, by tetralithiation and addition of appropriate electrophiles, using methods analogous to those used to make the corresponding tetraphenylmethanes. However, attempts to synthesize the aldehyde corresponding to compound **22** by use of DMF as electrophile resulted in complex mixtures that proved to be difficult to purify. Tetrakis(4-bromophenyl)silane (**24**) could be converted into the known tetraacid **16** (13, 45) by adding excess BuLi in THF and bubbling CO$_2$ through the resulting solution. This procedure gave compound **16** in 68% yield after purification by recrystallization. Previous syntheses of tetraacid **16** have been accomplished by oxidizing tetrakis(4-methylphenyl)silane (**14**) (13, 45). The tetraacid was subsequently reduced with LiAlH$_4$ in THF to afford tetrakis[(4-hydroxymethyl)-phenyl]silane (**27**) in 80% yield. The reaction of tetraol **27**

with SOCl$_2$ then yielded tetrakis[(4-chloromethyl)phenyl]sil-ane (**28**) in 76% yield.[2]

Conclusions

The syntheses we describe provide convenient access to a wide variety of functionalized derivatives of tetraphenyl-methane and tetraphenylsilane. The availability of these compounds creates many new opportunities for molecular and supramolecular construction using tetrahedral building blocks.

Experimental

Tetrahydrofuran (THF) and ether were dried by distillation from the sodium ketyl of benzophenone. *N,N*-Dimethyl-formamide (DMF) was purified by distillation under reduced pressure and dried over 4 Å molecular sieves. All other reagents were commercial products that were used without further purification.

Tetrakis(4-methylphenyl)methane (3) (41)
A solution of tetrakis(4-bromophenyl)methane (**1**; 635 mg, 0.998 mmol) (12, 21, 40) in THF (60 mL) was stirred at –78°C under dry N$_2$ and treated dropwise with a solution of butyllithium (3.20 mL, 2.5 M in hexane, 8.0 mmol). The resulting mixture was kept at –78°C for 30 min, and then CH$_3$I (1.00 mL, 16.1 mmol) was added dropwise. The mixture was stirred overnight while the temperature was allowed to rise to 25°C. Saturated aqueous Na$_2$S$_2$O$_3$ was then added, and the resulting mixture was concentrated by partial evaporation under reduced pressure. The remaining aqueous concentrate was extracted with ethyl acetate, and the combined organic extracts were washed with brine and dried over MgSO$_4$. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from ethyl acetate to afford tetrakis(4-methyl-phenyl)methane (41) (**3**; 226 mg, 0.600 mmol, 60%) as a colorless solid: mp 254–256°C (lit. (41) mp 254.5–255.5°C). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 7.12–7.03 (m, 16H), 2.31 (s, 12H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 144.2, 135.0, 130.8, 128.0, 63.5, 20.8. FAB-MS (3-nitrobenzyl alcohol) *m/e*: 376. FAB-HR-MS (3-nitrobenzyl alcohol) calcd. for C$_{29}$H$_{28}$ *m/e*: 376.21912; found: 376.22050. Anal. calcd. for C$_{29}$H$_{28}$: C 92.50, H 7.50; found: C 92.50, H 7.71.

Tetrakis(4-hydroxyphenyl)methane (21)
A solution of tetrakis(4-bromophenyl)methane (**1**; 635 mg, 0.998 mmol) (12, 21, 40) in THF (60 mL) was stirred at –78°C under dry N$_2$ and treated dropwise with a solution of butyllithium (3.20 mL, 2.5 M in hexane, 8.0 mmol). The resulting mixture was kept at –78°C for 30 min, and then B(OCH$_3$)$_3$ (1.80 mL, 16.1 mmol) was added dropwise. The mixture was stirred overnight while the temperature was allowed to rise to 25°C. To the solution was added 3 M aqueous NaOH (3 mL) followed by 30% aqueous H$_2$O$_2$ (2 mL), and then the mixture was heated at reflux for

Tetrakis(4-formylphenyl)methane (22)

A solution of tetrakis(4-bromophenyl)methane (**1**; 1.12 g, 1.76 mmol) (12, 21, 40) in THF (150 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of butyllithium (6.4 mL, 2.5 M in hexane, 16 mmol). The resulting mixture was kept at –78°C for 30 min, and then DMF (2.5 mL, 32 mmol) was added dropwise. The mixture was stirred overnight while the temperature was allowed to rise to 25°C. To the solution was added 1 M aqueous HCl (20 mL), and volatiles were partially removed by evaporation under reduced pressure. The remaining aqueous concentrate was extracted with ethyl acetate, and the combined organic extracts were washed with water and brine, dried over $MgSO_4$, and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from ethyl acetate to provide tetrakis(4-formylphenyl)methane (**22**; 350 mg, 0.809 mmol, 46%) as a light yellow solid: mp > 180°C decomposition (dec). IR (KBr) (cm^{-1}): 1702. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 10.01 (s, 4H), 7.84 (d, 8H, ^3J = 8.7 Hz), 7.44 (d, 8H, ^3J = 8.7 Hz). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 191.6, 151.2, 135.1, 131.4, 129.8, 66.4. FAB-MS (3-nitrobenzyl alcohol) m/e: 433. FAB-HR-MS (3-nitrobenzyl alcohol) calcd. for $C_{29}H_{20}O_4$ + H m/e: 433.14398; found: 433.14540.

Tetrakis([(4-hydroxymethyl)phenyl]methane (23)

A suspension of tetrakis(4-formylphenyl)methane (**22**; 90.3 mg, 0.209 mmol) in CH$_3$OH (10 mL) was stirred at 0°C and treated with NaBH$_4$ (200 mg, 5.29 mmol) added in small portions. The resulting mixture was stirred at 0°C for 30 min and then at 25°C for 1 h. The mixture was poured into cold H_2O (150 mL), and the resulting precipitate was filtered, washed with water, and dried under vacuum. Recrystallization from ethyl acetate – hexane gave tetrakis-[(4-hydroxymethyl)phenyl]methane (**23**; 83.4 mg, 0.189 mmol, 90%) as a colorless solid: mp > 300°C. IR (KBr) (cm^{-1}): 3305. ^{1}H NMR (300 MHz, DMSO-d_6) δ: 7.21 (d, 8H, ^3J = 8.5 Hz), 7.09 (d, 8H, ^3J = 8.5 Hz), 5.12 (t, 4H, ^3J = 5.6 Hz), 4.44 (d, 8H, ^3J = 5.6 Hz). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 145.2, 140.0, 130.2, 125.9, 63.7, 62.6. FAB-MS (3-nitrobenzyl alcohol) m/e: 440. FAB-HR-MS (3-nitrobenzyl alcohol) calcd. for $C_{29}H_{28}O_4$ m/e: 440.19876; found: 440.20030.

Tetrakis[(4-chloromethyl)phenyl]methane (11) (43)

A solution of tetrakis[(4-hydroxymethyl)phenyl]methane (**23**; 440 mg, 0.999 mmol) in dioxane (25 mL) was treated dropwise with SOCl$_2$ (600 µL, 8.2 mmol) under N_2, and the mixture was heated at reflux for 16 h. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from CHCl$_3$–hexane to give tetrakis[(4-chloromethyl)phenyl]methane (43) (**11**; 483 mg, 0.939 mmol, 94%) as light yellow needles: mp > 250°C (lit. (43) mp 279°C). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 7.28 (d, 8H, ^3J = 8.6 Hz), 7.20 (d, 8H, ^3J = 8.6 Hz), 4.57 (s, 8H). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 147.2, 136.3, 131.5, 129.5, 65.0, 46.7. Anal. calcd. for $C_{29}H_{24}Cl_4$: C 67.72, H 4.70; found: C 67.31, H 4.79.

Tetrakis(4-bromophenyl)silane (24)

A solution of 1,4-dibromobenzene (23.6 g, 100 mmol) in ether (250 mL) was stirred at –10°C under dry N_2 and treated dropwise with a solution of butyllithium (40 mL, 2.5 M in hexane, 100 mmol). The resulting mixture was kept at –10°C for 15 min, and then SiCl$_4$ (2.85 mL, 24.9 mmol) was added dropwise. The mixture was stirred at –10°C for 30 min and at 25°C for 1 h. Then 1 M aqueous HCl was added, and the resulting mixture was extracted with ether. The combined extracts were washed with H_2O and brine, dried over $MgSO_4$, and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized twice from CHCl$_3$–ethanol to afford tetrakis(4-bromophenyl)silane (**24**; 7.28 g, 11.2 mmol, 45%) as a colorless solid: mp 240–241°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 7.55 (d, 8H, ^3J = 8.4 Hz), 7.35 (d, 8H, ^3J = 8.4 Hz). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 137.6, 131.4, 131.4, 125.4. FAB-MS (3-nitrobenzyl alcohol) m/e: 652. Anal. calcd. for $C_{29}H_{16}Br_4Si$: C 44.21, H 2.47; found: C 43.83, H 2.45.

Tetrakis(4-iodophenyl)silane (25)

A solution of 1,4-diiodobenzene (13.2 g, 40.0 mmol) in THF (250 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of butyllithium (16 mL, 2.5 M in hexane, 40 mmol). The resulting mixture was kept at –78°C for 20 min, and then SiCl$_4$ (1.15 mL, 10.0 mmol) was added dropwise. The mixture was stirred at –78°C for 30 min and at 25°C for 1 h. Then 1 M aqueous HCl (100 mL) was added, and the phases were separated. The organic phase was washed with saturated aqueous $Na_2S_2O_3$ (100 mL), H_2O (100 mL), and brine (100 mL), and then it was dried over $MgSO_4$ and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized twice from CHCl$_3$–ethanol to afford tetrakis(4-iodophenyl)silane (**25**; 4.70 g, 5.59 mmol, 56%) as a colorless solid: mp > 310°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 7.75 (d, 8H, ^3J = 7.9 Hz), 7.20 (d, 8H, ^3J = 7.9 Hz). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 137.5, 137.2, 131.7, 97.7. Anal. calcd. for $C_{29}H_{16}I_4Si$: C 34.31, H 1.92; found: C 34.17, H 1.78.

Tetrakis(4-methylphenyl)silane (14) (13, 44)

A solution of tetrakis(4-bromophenyl)silane (**24**; 1.31 g, 2.01 mmol) in THF (150 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of butyllithium (6.4 mL, 2.5 M in hexane, 16 mmol). The resulting mixture was kept at –78°C for 30 min, and then CH$_3$I (2.00 mL,

32.1 mmol) was added dropwise. The mixture was stirred overnight while the temperature was allowed to rise to 25°C. Saturated aqueous $Na_2S_2O_3$ was then added, and volatiles were partially removed from the resulting mixture by evaporation under reduced pressure. The aqueous concentrate was extracted with ethyl acetate, and the combined extracts were washed with brine, dried over $MgSO_4$, and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from toluene to afford tetrakis(4-methylphenyl)silane (**14**; 512 mg, 1.30 mmol, 65%) as a colorless solid. The spectroscopic data were identical to those reported in the literature (13, 44).

Tetrakis(4-hydroxyphenyl)silane (26)

A solution of tetrakis(4-bromophenyl)silane (**24**; 652 mg, 1.00 mmol) in THF (60 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of butyllithium (3.20 mL, 2.5 M in hexane, 8.00 mmol). The resulting mixture was kept at –78°C for 30 min, and then $B(OCH_3)_3$ (1.80 mL, 16.1 mmol) was added dropwise. The mixture was stirred overnight while the temperature was allowed to rise to 25°C. To the solution was added 3 M aqueous NaOH (3 mL), followed by 30% aqueous H_2O_2 (2 mL), and then the mixture was heated at reflux for 1 h. The resulting mixture was acidified with 1 M aqueous HCl and concentrated by partial evaporation of volatiles under reduced pressure. The aqueous concentrate was extracted with ethyl acetate, and the combined extracts were washed with water and brine, dried over $MgSO_4$, and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from ethyl acetate – hexane to afford tetrakis(4-hydroxyphenyl)silane (**26**; 238 mg, 0.594 mmol, 59%) as a colorless solid: mp 274–278°C. IR (KBr) (cm^{-1}): 3607, 3300. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 9.59 (s, 4H), 7.22 (d, 8H, ^3J = 8.4 Hz), 6.78 (d, 8H, ^3J = 8.4 Hz). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 158.8, 137.5, 124.3, 115.4. FAB-MS (3-nitrobenzyl alcohol) m/e: 400. Anal. calcd. for $C_{24}H_{20}O_4Si\cdot H_2O$: C 68.88, H 5.30; found: C 69.16, H 5.12.

Tetrakis(4-carboxyphenyl)silane (16) (13, 45)

A solution of tetrakis(4-bromophenyl)silane (**24**; 2.6 g, 4.0 mmol) in THF (250 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of butyllithium (8.0 mL, 2.5 M in hexane, 20 mmol). The resulting mixture was kept at –78°C for 30 min, and then CO_2 was bubbled through it. The mixture was stirred at –78°C for 3 h and was then acidified with 1 M aqueous HCl (125 mL). The organic phase was separated, washed with H_2O (100 mL) and brine (100 mL), dried over $MgSO_4$, and filtered. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from ethyl acetate – hexane to afford tetrakis(4-carboxyphenyl)silane (13, 45) (**16**; 1.40 g, 2.73 mmol, 68%) as a white solid. The physical and spectroscopic data were identical to those reported in the literature (13, 45).

Tetrakis[(4-hydroxymethyl)phenyl]silane (27)

A suspension of tetrakis(4-carboxyphenyl)silane (**16**; 123 mg, 0.240 mmol) in THF (10 mL) was stirred at 0°C under N_2 and treated with LiAlH$_4$ (45 mg, 1.2 mmol) added in small portions. The resulting mixture was heated at reflux

overnight. The mixture was then cooled, treated carefully with 6 M aqueous NaOH and diluted with H_2O. The resulting mixture was filtered, and volatiles were removed by evaporation under reduced pressure. The solid residue was washed with water and dried under vacuum. Recrystallization from ethanol–hexane gave tetrakis[(4-hydroxymethyl)phenyl]silane (**27**; 87.6 mg, 0.192 mmol, 80%) as a colorless solid: mp 298–299°C. IR (KBr) (cm^{-1}): 3339. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 7.42–7.36 (m, 16H), 5.24 (bs, 4H), 4.52 (s, 8H). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 144.4, 135.8, 132.1, 126.3, 63.0. Anal. calcd. for $C_{24}H_{20}O_4Si\cdot0.5H_2O$: C 72.22, H 6.28; found: C 72.45, H 6.25.

Tetrakis[(4-chloromethyl)phenyl]silane (28)

A solution of tetrakis[(4-hydroxymethyl)phenyl]silane (**27**; 205 mg, 0.449 mmol) in dioxane (10 mL) was stirred at 25°C under N_2 and treated dropwise with SOCl$_2$ (260 μL, 3.6 mmol). The resulting mixture was heated at reflux for 16 h. Volatiles were removed by evaporation under reduced pressure, and the residue was recrystallized from ethyl acetate to give tetrakis[(4-chloromethyl)phenyl]silane (**28**; 180 mg, 0.339 mmol, 76%) as a light yellow solid: mp 251–253°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 7.55 (d, 8H, ^3J = 8.1 Hz), 7.42 (d, 8H, ^3J = 8.1 Hz), 4.61 (s, 8H). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 139.1, 136.7, 133.8, 128.1, 46.0.

γ-Irradiation route to photoluminescent CdS–CdSe with core–shell nanostructures under ambient conditions

Fen Xu, Xu Zhang, Jun Lu, Wang Xi, Jie Hong, and Yi Xie

Abstract: Photoluminescent CdS–CdSe nanocomposites with core–shell structures were obtained via a novel two-step γ-irradiation process followed by a simple ion-exchange reaction at room temperature and under ambient pressure. To fully characterize CdS–CdSe nanocomposites, X-ray photoelectron spectroscopy, UV–vis absorption spectra, and photoluminescence spectra were recorded, as well as powder X-ray diffraction, transmission electron microscopy, and high-resolution electron microscopy, to confirm the presence of the core–shell nanostructure.

Key words: core–shell nanostructure, γ-irradiation, ion-exchange reaction.

Résumé : On a obtenu des nanocomposés de CdS–CdSe, à structure conchoïdale avec un noyau central, en utilisant un nouveau processus en deux étapes comportant une irradiation γ suivie d'une réaction d'échange d'ion simple à température et pression ambiantes. Dans le but de caractériser complètement les nanocomposés de CdS–CdSe, on a enregistré les spectres de spectroscopie photoélectronique de rayons X, d'absorption UV–visible et de photoluminescence on a aussi utilisé la diffraction de poudres de rayons X, la microscopie par transmission d'électrons, la microscopie électronique à haute résolution, pour confirmer la présence de la nanostructure conchoïdale avec un noyau central.

Mots clés : nanostructure conchoïdale avec un noyau central, irradiation γ, réaction d'échange d'ion.

[Traduit par la Rédaction]

Introduction

Recently, nanomaterials have become the focus of intensive research because of their numerous applications in diverse fields such as electro-optical and ultramodern electronic devices, super-magnets, photographic suspensions, and catalyst production, etc. (1). Tremendous advances in the preparation and characterization of semiconductor nanoparticles (2–4) have been made in that these materials exhibit strongly size-dependent optical and electrical properties when their dimensions are comparable to the Bohr radius. Because the surface of a nanocrystal is made up of atoms that are not fully coordinated, it is highly active and acts like it possesses defects unless passivated (5). To remove these defects, long-chain organic surfactants have been utilized to passivate these II–VI and III–V nanocrystals. However, it is generally very difficult to simultaneously passivate both anionic and cationic surface sites with the use of organic ligands, and there are always some dangling bonds on the surface. As for the nanocrystals, inorganic epitaxial growth, such as the growth of the shell on the core, can not only eliminate both the anionic and cationic surface dangling bonds but can also generate a new nanocrystal system with novel properties. Furthermore, most of the properties of these "core–shell" systems are dependent on both core and shell materials (6). Hence, inorganic passivation has been explored in such core–shell structures as CdSe–ZnS (7), CdSe–ZnS or ZnS–CdSe (8), CdSe–ZnS (9), CdSe–ZnSe (10), CdS–HgS–CdS (11), CdSe–CdS (6, 12), CdS–CdSe (13), HgTe–CdS (14), CdSe–CdS–ZnS (15), and CdS–ZnO and CdS–Pb$_3$O$_4$ (16). Apparently, the design and preparation of nanocomposites with core–shell structures has been an important, active research direction; these systems show reduced fluorescence lifetimes, exhibit high photoluminescence (PL) quantum yield, higher photoluminescence efficiency and superiority to some existing fluorophores, and other benefits (17) related to tailoring the band-gap positions between the two materials with respect to the uncoated dots due to the elimination of surface non-radiative recombination defects (6, 16, 18, 19).

Among these core–shell systems, the semiconductor pair of CdS and CdSe is the most attractive to focus attention on because of the similarities between the CdS and CdSe lattices (lattice mismatch is 4.26%), which dictated the choice of this semiconductor pair for the present investigation (20). Several synthesis routes (6, 12–13) have been applied to prepare the core–shell nanostructure; however, two limitations seem unavoidable: one is the necessary synthesis temperature (at least 100°C) and the other is the organic precursors. Here, we put forward a novel approach for the preparation of CdS–CdSe nanocomposites (with core–shell structures) at room temperature and under ambient pressure, based on our previous work on the γ-irradiation synthesis of various semiconductor nanoparticles and nanocomposites (21, 22). Using

this approach, a simple ion-exchange reaction followed with γ-irradiation can easily form a heterogeneous semiconductor shell on a certain core. For instance, after γ-irradiating a simple mixture system consisting of the chosen core and a suitable shell precursor solution, the core–shell nanostructure of the semiconductor pair of CdS–CdSe can be obtained easily via an ion-exchange reaction. This method may provide a simple and convenient route to synthesize for various metal chalcogenides with core–shell nanostructures; it is free of the use of complex and expensive organometallic precursors, and all procedures are carried out under ambient condition. Additionally, the chemistry of the core and (or) shell growth is clean — the γ-irradiation can offer a mass of reductive radicals, which are totally clean reductive agents from the point of view of green chemistry, and thus one can avoid the by-products from chemical reducing agents.

Experimental

Materials

All agents were analytically pure and were purchased from Shanghai Chemical Co. Ltd., including cadmium chloride ($CdCl_2$), sodium thiosulfate ($Na_2S_2O_3$), selenium (Se), sodium sulfite (Na_2SO_3), and isopropyl alcohol ($CH_3CHOHCH_3$).

Synthesis of CdS–CdSe core–shell nanocomposites

In a typical process, two stepwise irradiation processes are required, and an ion-exchange reaction follows with the γ-irradiation processes. It is also worth mentioning that all operations were carried out at room temperature and under ambient pressure.

The formation of the CdS core

A typical solution, consisting of 0.05 mol·L^{-1} $CdCl_2$, 0.05 mol·L^{-1} $Na_2S_2O_3$, and 3 mol·L^{-1} $CH_3CHOHCH_3$ (as a scavenger for the hydroxyl radicals), was irradiated in the field of a 2.59×10^{15} Bq ^{60}Co γ-ray source with a radiation dose of 3.0×10^4 Gy (21, 22). The yellow-orange CdS nanoparticles obtained were filtered off and washed with ethanol for the next step.

The growth of the CdSe shell on the CdS core

The prepared CdS nanoparticles, 0.05 mol·L^{-1} sodium selenosulfate (Na_2SeSO_3), and 3 mol·L^{-1} $CH_3CHOHCH_3$ were added to 50 mL distilled water, ultrasonicated for 10 min, and further irradiated for several hours to produce the yellow-red products. Na_2SeSO_3 can be synthesized by refluxing Se powders in an Na_2SO_3 solution, according to the literature (23). The final yellow-red products were filtered off and washed with distilled water and ethanol successively and then dried for 6 h under vacuum at room temperature.

Measurements

Powder X-ray diffraction (XRD) was performed on a Japan Rigaku D/Max rA rotation anode X-ray diffractometer, equipped with a Ni-filter Cu Kα radiation source (λ = 1.54178 Å), 40 kV and 100 mA as the applied voltage and current, a scanning speed of 8.00° min^{-1}, and a 2θ range of 20°–70°. The nanocrystal size and core–shell nanostructure

Fig. 1. XRD patterns of (*a*) CdS nanoparticles, (*b*) CdS–CdSe with core–shell nanostructure, and (*c*) CdSe nanoparticles.
investigations were measured by transmission electron microscopy (TEM) and high-resolution electron microscopy (HRTEM); measurements were taken on an H-800 transmission electron microscope with an accelerating voltage of 200 kV and a JEOL-2010 transmission electron microscope, respectively. Nanocrystals were dispersed in ethanol under ultrasonication, and 1 drop of the solution was deposited onto the grid before evaporating naturally. XPS was recorded on an ESCALab MKII instrument with Mg Kα radiation as the exciting source. The UV–vis absorption spectra were recorded on a JANA Spec200PC UV–vis spectrophotometer using quartz cells, and the PL spectra were obtained using a 970CRT-luminescence spectrophotometer with the excitation wavelength of 220 nm.

Results and discussion

Structural characterization

Powder X-ray diffraction (XRD) patterns of the three samples (shown in Fig. 1) give evidence that the final nanocomposites are CdS–CdSe with core–shell nanostructures. Figure 1*a* shows the XRD pattern for CdS nanoparticles, and Fig. 1*c* is the XRD pattern of CdSe nanoparticles, while Fig. 1*b* is the XRD pattern of the CdS–CdSe core–shell nanocomposites. The reflection peaks of the core–shell nanocomposites shift only a little from those characteristic of pure CdS and pure CdSe. As the shell is grown, the diffraction peaks shift towards a larger *d*-spacing (small 2θ). Some evidence for a superposition of CdS and CdSe peaks forming the broader peaks can be observed in the nanocomposites, especially on their high-angle sides. If, considering the shifts in the peak positions alone, the XRD patterns may be indicative of alloying, however, a homogeneous alloy would show a significant narrowing of XRD peak widths with increasing size. But in this present case, this narrowing phenomenon is not observed (6). So, Fig. 1*b* implies the formation of CdS–CdSe with a core–shell nanostructure rather than that of a CdS_xSe_{1-x} alloy. X-ray photoelectron spectroscopy (XPS) was used to measure the composition of the core–shell nanocomposites, and the signal analysis gave an S:Se ratio of 13:1. To further ascertain the core–shell nano-

Fig. 2. (*a*) TEM image of CdS–CdSe core–shell nanocomposites and (*b*) a typical HRTEM image of CdS–CdSe with core–shell nanostructures.
structure, transmission electron microscopy (TEM) and high-resolution electron microscopy (HRTEM) were employed.

The morphology and particle sizes are determined by transmission electron microscopy (TEM) and high-resolution electron microscopy (HRTEM). The TEM image of CdS–CdSe nanocomposites (shown in Fig. 2*a*) shows the spherical and congregated particles. Figure 2*b* shows a typical HRTEM micrograph of the CdS–CdSe nanoparticles, in which the core–shell structure can clearly be seen in the entire area, with the dark cores being surrounded by a light shell. In addition, the lattice planes of the CdS core are visible, indicating a high degree of crystallinity. It is also observed that the lattice fringes are continuous throughout the core and the shell. Furthermore, CdS nanoparticles have definitely been overcoated with a thick (>3 nm) layer of CdSe. An increase of 4.00~5.00 nm in size testified to the successful growth of the CdSe shell on the CdS core.

Fig. 3. UV–vis absorption spectra of (*a*) CdS nanoparticles and (*b*) CdS–CdSe core–shell nanocomposites.

Optical characterization

The UV–vis absorption spectrum of the bare CdS nanoparticles and the CdS–CdSe core–shell nanocomposites dispersed in the distilled water are shown in Figs. 3*a* and 3*b*, respectively; these were carried out using distilled water as reference. A clear "excitonic" peak is visible for the bare CdS at 455 nm (2.72 eV), which clearly red-shifts 25 nm (0.14 eV) after the capping of CdSe is introduced, and this red shift is indicative of the formation of the core–shell structure. The nanocrystalline nature of the CdS and the CdS–CdSe nanocomposites are also reflected by their photoluminescence (PL) spectra, as shown in Fig. 4. When the excitation energy is 5.65 eV (λ_{ex} = 220 nm), the luminescence spectrum of the pure CdS contains a shoulder peak at ~480 nm (2.59 eV) (Fig. 4*a*) and the luminescence spectrum of the CdS–CdSe core–shell structure contains shoulders at ~456 nm (2.72 eV) and 530 nm (2.36 eV), along with a peak at ≈480 nm (Fig. 4*b*). The peak of ~456 nm and a peak of ~480 nm may result from the CdS excitonic fluorescence. When the emission at ~480 nm (2.59 eV) passes through a thin layer of CdSe, it would be absorbed by CdSe and would excite CdSe to emit luminescence light at ~530 nm. In addi-

tion, the excited energy used (λ_{ex} = 220 nm) can also excite CdSe to emit luminescence. So, for this CdS–CdSe system, the luminescent intensity of CdS would decrease while that of CdSe would increase, as shown in Fig. 4*b*. In a comparison of Fig. 4*a* with Fig. 4*b*, there is little difference in the profile of the two spectra, probably because of the change in surface structure. The optical spectra are somewhat broadened, probably owing to the following two reasons: (*i*) Broadening may be caused by a gradual "ripening" of the nanocrystals with time; the effect of aging the core–shell samples in the experimental process is to red-shift and broaden the absorption spectra, and this effect has been reported in many cases, such as for HgTe–CdS core–shell nanoparticles (14). (*ii*) The shell growth results in a slight broadening while maintaining the optical spectra profile. Similarly, Peng et al. (6) reported the epitaxy growth of CdSe–CdS core–shell nanoparticles in which the absorption spectrum roughly maintains its profile with a slight broadening of feature. Meanwhile, the successful growth of the CdSe shell also causes the fluorescence changes, including the splitting of peaks and the red shift.

Fig. 4. Fluorescence emission spectra (excited at 220 nm) of (*a*) CdS nanoparticles and (*b*) CdS–CdSe core–shell nanocomposites.
Ion-exchange reaction mechanism

In this approach, the fundamental mechanism of the formation of CdS–CdSe core–shell nanostructure is an ion-exchange reaction followed by a two-step γ-irradiation process. It is known that sodium thiosulfate can homogeneously release S^{2-} upon γ-irradiation; thus, it is a good sulfur source to use in the formation of the CdS core. As to the formation of the CdSe shell, the selection of selenium source is critical, since the usual selenium source (selenium element) does not dissolve in distilled water, and this will limit the formation of the CdSe shell. Sodium selenosulfate (Na_2SeSO_3) is a good selenium source, which may well dissolve in distilled water and homogeneously release Se^{2-} under γ-irradiation, owing to the similarity in the structures of the $SeSO_3^{2-}$ and $S_2O_3^{2-}$ (21, 22), which is propitious to the crystallization of the CdS–CdSe core–shell nanoparticles. The formation of CdSe shell on the CdS core can be described as a substitution-type process, considering the substantial difference between the solubility of the CdS ($K_{sp} = 1.4 \times 10^{-19}$) and that of the CdSe ($K_{sp} = 1.4 \times 10^{-35}$) in distilled water. The reactions for the whole process are as follows:

[1] $S_2O_3^{2-} \xrightarrow{\gamma-\text{irradiation}} S^{2-}$

[2] $Cd^{2+} + S^{2-} \rightarrow CdS$

[3] $SeSO_3^{2-} \xrightarrow{\gamma-\text{irradiation}} Se^{2-}$

[4] $CdS + Se^{2-} \rightarrow CdSe + S^{2-}$
Conclusions

In general, γ-irradiation has been successfully used to prepare the CdS–CdSe core–shell nanocomposites for the first time. The keys to the reaction are the selection of the selenium source and the difference between the solubility of CdS and that of CdSe. Both the XRD pattern and the HRTEM image clearly ascertain the core–shell structure of the nanocomposites. In addition, this approach is easily extended to the preparation of various metal chalcogenides by changing the core and shell precursor solution. It is reasonable to expand this method to the synthesis of other core–shell nanocomposites because of its ease, reproducibility, and versatility.

Solubility of carbon dioxide in alkylcarbonates and lactones

F. Blanchard, B. Carré, F. Bonhomme, P. Biensan, and D. Lemordant

Abstract: The solubility of carbon dioxide in γ-butyrolactone (BL), caprolactone (CL), propylene carbonate (PC), ethylene carbonate (EC), dimethylcarbonate (DMC), diethylcarbonate (DEC), and mixtures of these components has been determined at temperatures from 275 to 333 K at atmospheric pressure. The Henry's law constant (k_H) for the dissolution of CO_2 in these solvents has been deduced from the solubility data. The value of k_H increases in the following order: DEC < DMC < PC < CL < BL < EC, which is identical to the order of the Hildebrand parameters (δ) of the corresponding solvents. The accuracy of classical theories for predicting gas solubilities in liquids has been examined. The best results are given by the Vilcu–Perisamu equation, which is derived from the Scatchard–Hildebrand theory but takes into account the polarizability of the solute and the permittivity of the solvent. A modified form of the Prausnitz and Shair equation is proposed to estimate the solubility of nonpolar molecules in strongly dipolar solvents. This equation fits the experimental data with improved precision.

Key words: alkylcarbonate, lactone, carbon dioxide, liquid–gas equilibrium, Henry's law, Hildebrand parameter.

Résumé : La solubilité du dioxyde de carbone dans la γ-butyrolactone (BL), la caprolactone (CL), le carbonate de propylène (PC), le carbonate d'éthylène (EC), le diméthylcarbonate (DMC), le diéthylcarbonate (DEC) et dans des mélanges de ces solvants a été déterminée à des températures comprises entre 275 K et 333 K et à pression atmosphérique. Les constantes de Henry (k_H) relatives à la dissolution de CO_2 dans les précédents milieux augmentent dans l'ordre: DEC < DMC < PC < CL < BL < EC. Les variations de k_H suivent celles du paramètres d'Hildebrand (δ). La validité des théories classiques pour la prévision de la solubilité des gaz dans les liquides a été examinée. Les meilleurs résultats ont été obtenus par application de la relation de Vilcu et Perisamu qui dérive de la théorie de Scatchard–Hildebrand tout en prenant en compte la polarisabilité du soluté et la permittivité du solvant. Une forme modifiée de l'équation de Prausnitz et Shair est proposée pour estimer la solubilité de molécules apolaires dans des solvants très polaires. Cette équation décrit les résultats expérimentaux avec une précision accrue.

Mots clés : alkylcarbonate, lactone, dioxyde de carbone, équilibre liquide–gaz, loi de Henry, paramètre de Hildebrand.

Introduction

Liquid–gas equilibria play an important role in a wide range of natural and industrial processes. In rechargeable lithium cells, oxidation of the electrolyte, mainly composed of alkylcarbonates and lactones, leads to the formation of CO_2 when high potentials are applied to the electrode. The resulting increase in pressure in the sealed cell container can be very large when the cell is overcharged. To estimate the total amount of CO_2 generated at a given pressure, it is necessary to know the solubility of CO_2 in the solvent or solvent mixture. For this reason it is of interest to determine the solubility of CO_2 as a function of temperature in lactones or alkylcarbonates such as γ-butyrolactone (BL), caprolactone (CL), propylene carbonate (PC), ethylene carbonate (EC), dimethylcarbonate (DMC), and diethyl carbonate (DEC) or mixtures of these components.

At low or moderate pressures, the solubility of a gas (*i*) in a liquid solvent (*s*) is given by Henry's law

[1] $$x_i = \frac{P_i}{k_H^s}$$

where x_i represents the mole fraction of dissolved gas in the solvent, P_i its partial pressure, and k_H^s the Henry's law constant for the dissolution of gas *i* in solvent *s*.

If specific interaction effects (e.g., chemical bonds) between the dissolved molecule and the liquid solvent are negligible, cohesion parameters can be used to provide reasonable estimates of gas solubilities. For this reason, many attempts have been made to predict the solubility of gases in liquids using the Hildebrand solubility parameter (δ) (1–3). The Hildebrand solubility parameter is defined by the following equation:

F. Blanchard, B. Carré, and D. Lemordant.[1] Laboratoire de Physicochimie des Interfaces et Milieux Réactionnels (EA2098), Université de Tours, Faculté des Sciences et Techniques, Parc de Grandmont, F 37200 TOURS, France.
F. Bonhomme and P. Biensan. SAFT, Direction de la Recherche, 111 Boulevard A. Daney, 33074 Bordeaux, France.

[1]Corresponding author (e-mail: lemordant@univ-tours.fr).

$$[2] \qquad \delta = c^{1/2} = \left(\frac{\Delta_{vap}U}{V_m}\right)^{1/2}$$

where c is the cohesive energy per unit volume, which can be calculated from the vaporization energy $\Delta_{vap}U$ and the molar volume V_m of the liquid. Hildebrand and others (1–3) have pointed out that a close relationship exists between the logarithm of the gas solubility and the solvent parameter δ. Most of the proposed equations connect the logarithm of the gas solubility to the difference in solubility parameters of the gas (δ_i) and the solvent (δ_s), as

$$[3] \qquad \ln x_i = a - b\,[\delta_s - \delta_i]^2$$

Using relation [3], the numerical values of a and b can be deduced from the physical properties of the solute at a given temperature.

To estimate the solubility of gases in liquids, Lawson and co-workers (4–6) and Gjaldbaeck and co-workers (7–11) proposed the following equation based on the Hildebrand–Scatchard theory:

$$[4] \qquad \ln x_i = -\ln x_i^{id} - \frac{V_i}{RT}[\delta_s - \delta_i]^2 - \ln\left(\frac{V_i}{V_s}\right) - \left(1 - \frac{V_i}{V_s}\right)$$

where x_i^{id} is the ideal solubility of the gas, V_s the molar volume of the solvent, and V_i the partial molar volume of the gas at infinite dilution in the solvent.

Hildebrand, Prausnitz, and Shair (3, 12) considered a two-stage dissolving process, involving, as an intermediate, a hypothetical liquid state for the gas at room temperature. Using this process, the gas solubility is given by

$$[5] \qquad \ln x_i = \ln(f_i / f_{i,l}) - \frac{V_{i,l}}{RT}[\delta_s - \delta_i]^2$$

where $f_i / f_{i,l}$ is the ratio of the fugacities of the gas in its pure gaseous state to its hypothetical liquid state, $V_{i,l}$ is the molar volume of the hypothetical liquid, and δ_i is its solubility parameter. As $V_{i,l}$ and δ_i cannot be determined experimentally at room temperature, their values were obtained by fitting eq. [5] to available solubility data. The hypothetical fugacity $f_{i,l}$ can be deduced from the vapour pressure of the dissolved gas and its critical temperature (3, 12). To the best our knowledge, eq. [5] has never been applied to the dissolution of CO_2 in strongly dipolar solvents such as carbonates or lactones.

Vilcu, Perisamu, and Cucuiat (13–15) applied eq. [4] to systems composed of a nonpolar gas and a polar solvent. To fit experimental data, they introduce a corrected solubility parameter, δ_s^*, which is a function of the dielectric constant of the solvent (ε_s) and the polarizability of the solute (α_i). Using δ_s^* instead of δ_s in eq. [5], deviations between experimental and calculated solubilities do not exceed 20%. Nevertheless, when applied to CO_2 as the dissolved gas, larger deviations are observed owing to the fact that polar solvents dissolve much more CO_2 than predicted. To take into account the quadrupolar interaction of CO_2 molecules with solvent dipoles, an extra term has been added (Q_{CO_2}) in the definition of the corrected solubility parameter δ_s^* (16)

Table 1. Parameters values used in eqs. [4–6] for CO_2.

Parameter	eq. [4]	eq. [5]	eqs. [5], [6]
δ (MPa$^{1/2}$)	6.8(4–6)	12.3(3–12)	10.63*
$10^6\,V_l$ (m^3 mol^{-1})	—	55 (3–12)	35*
f_l (MPa)	—	4.12(17)	4.12 (17)
$\ln x^{id}$	–3.27 (4–6)	—	—
$10^6\,V$ (m^3 mol^{-1})	105 (4–6)	—	—
$10^{24}\,\alpha$ (esu)	—	—	2.65 (14–15)
$10^{26}\,Q$ (esu)	—	—	4.1 (18)

*Values obtained by fitting.

$$[6] \qquad \delta_s^* = \delta_s - (\varepsilon_s - 1)(0.1225 - (8.43 \times 10^{21})\,\alpha_{CO_2} \\ + (2.52 \times 10^{24})Q_{CO_2})$$

In eq. [6], the quadrupole moment of CO_2, Q_{CO_2}, is given in esu and the solubility parameters δ_s^* and δ_s in MPa$^{1/2}$. Numerical factors have been chosen to fit the experimental results. Parameter values for eqs. [4–6] with CO_2 as the solute are reported in Table 1.

The main advantage of using the Hildebrand parameter is that δ values are available for a wide variety of solvents (19). Modern theories (20–22) make use of the Lennard-Jones potential (λ) instead of the cohesive energy density. More precise equations are provided but, for practical reasons, simple empirical equation such as (22)

$$[7] \qquad \ln x_i = a + b\,(\lambda / k)^{1/2}$$

are frequently used. Values of λ differ considerably according to the method used to determine them. Consequently, λ values are known less precisely than δ values. The application of the Lennard-Jones potential to strongly dipolar solvent and molecules having a quadrupolar moment like CO_2 is also questionable. We believe that these theories are better able to predict solubilities of nonpolar gases in nonpolar solvents than polar or nonpolar gases in polar solvents.

Experimental

Materials

Highly pure (99.99%) DMC, DEC, PC, EC, CL, and γ-BL were obtained from Aldrich and used as received. Three mixtures (EC–DMC 1:1 w/w, EC–DEC 1:1 w/w, EC–PC–DMC 1:1:3 w/w/w) were prepared by mixing pure solvent under a dry atmosphere in a glove box. KOH and HCl solutions, used to determine the amount of dissolved CO_2 in the solvents, were prepared with distilled water. HCl solutions were standardized against KOH by potentiometric titration.

Methods

The solubility of CO_2 in each solvent was measured using the apparatus illustrated in Fig. 1. The solvent was first saturated with CO_2 at atmospheric pressure by dissolving the gas in the liquid placed in a temperature-controlled vessel. When saturation was achieved, the dissolved CO_2 was displaced from the saturation vessel by an argon flow. To remove the solvent vapors from the argon stream, the gas mixture was passed through a coil immersed in a cold methanol bath (233 K). The solvent-free gas mixture (CO_2 + Ar) was then introduced into a vessel containing an aqueous KOH solution of known concentration, which was subsequently

Fig. 1. Equipment used for the determination of CO_2 solubilities.

Capillary

Ar

CO₂ saturated solvent Methanol bath at 233 K Aqueous KOH solution
titrated with HCl solution. Each measurement was run in triplicate. Henry's law constants at temperatures from 275 to 333 K were calculated from the CO_2 solubilities at atmospheric pressure using eq. [1]. The dielectric constants of the solvents were determined using an impedance spectrometer (Solartron SI 1260).

Results

CO₂ solubility in pure solvents

Henry's law constants for CO_2 in DMC, DEC, PC, EC, CL, and δ-BL are reported in Table 2 for temperatures from 275 to 333 K. As expected for an exothermic dissolution process, the CO_2 solubility decreases as the temperature is raised. This is in accord with the van't Hoff relation applied to the dissolution of gas in liquids

[8] $\quad \ln x_i = \dfrac{\Delta_{dis}H^{\circ}}{RT} + \dfrac{\Delta_{dis}S^{\circ}}{R}$

In eq. [8], $\Delta_{dis}H^{\circ}$ is the standard enthalpy of dissolution of the gas in the liquid, R is the ideal gas constant, and T is the temperature. $\Delta_{dis}H^{\circ}$ can be determined by plotting $\ln x_{CO_2}$ against $1/T$ (Fig. 2). The linearity variation of $\ln x_{CO_2}$ with $1/T$ indicated that $\Delta_{dis}H^{\circ}$ (and hence the standard entropy of dissolution $\Delta_{dis}S^{\circ}$) can be considered to be independent of temperature in the range of temperatures investigated.

When $\Delta_{dis}H^{\circ}$ is known, the Henry's law constant for CO_2 in each solvent can be calculated at 298 K. The standard entropy and Gibbs energy for the dissolution of CO_2 can be calculated by the following equations

[9] $\quad \Delta_{dis}S^{\circ} = (\Delta_{dis}H^{\circ} - \Delta_{dis}G^{\circ})/T$

[10] $\quad \Delta_{dis}G^{\circ} = RT \ln(k_H)$

The values of k_H, $\Delta_{dis}G^{\circ}$, and $\Delta_{dis}S^{\circ}$ at 298 K are reported in Table 3 together with the boiling temperature of each solvent at atmospheric pressure. The value of k_H for PC at 298 K, obtained in the present study, agrees well with published values: 6.86 MPa (23), 7.98 MPa (24), 8.21 MPa (25), 8.22 MPa (26), 8.39 MPa (27), 10.01 MPa (28). Moreover,

the standard enthalpy of dissolution of CO_2 in PC, deduced from the variations of k_H with temperature (–15.7 kJ mol⁻¹), is in excellent agreement with the value –15.9 kJ mol⁻¹ given by Murrieta-Guevara et al. (25). In the case of BL and EC, respectively, our results, k_H(BL, 298 K) = 11.66 MPa and k_H(EC, 313 K) = 20.47 MPa, are higher than those proposed by Kassim et al. (29): k_H(BL, 303 K) = 6.33 MPa or by Vilcu et al. (13): k_H(EC, 313 K) = 14.41 MPa. The origin of these discrepancies is not known, but one may remark that our values fit eq. [3] better, as seen on the graph in Fig. 3. Among the solvents investigated, DEC dissolves the largest quantity of CO_2 at atmospheric pressure and EC the smallest. It is noticeable that in each homologous series of solvents (acyclic carbonates, cyclic carbonates, and lactones), the solvent having the highest molecular weight dissolves the largest amount of CO_2.

As expected for the dissolution of a gas like CO_2, the dissolution enthalpies are all negative and increase with the boiling temperature of the solvent in all series. Following Hildebrand, Prausnitz, and Shair (3, 12), CO_2 dissolution may be interpreted as a two-step process that involves, as an intermediate, CO_2 in its hypothetical liquid state, as illustrated in Fig. 4. From this scheme, the following relation is easily inferred

Fig. 2. Plot of $\ln x_{CO_2}$ against $1/T$ for CO_2 dissolved in pure solvents.
Table 3. Thermodynamic parameters and Henry's law constant at 298 K for pure solvents.

	EC	PC	DMC	DEC	BL	CL

$$\Delta_{dis}H°$$
$$+ \text{ solvent}$$

CO_2 (g) $\longrightarrow$ $(CO_2)_{sol}$

$\Delta_{liq}H°$ + solvent $\Delta_{mix}H°$

CO_2 (liq)
[11] $\Delta_{dis}H° = \Delta_{liq}H° + \Delta_{mix}H°$

In eq. [11], $\Delta_{liq}H° = -16.90$ kJ mol⁻¹ is the standard enthalpy of liquefaction of CO_2 at 298 K and $\Delta_{mix}H°$ is the enthalpy of mixing of the solvent with CO_2 in its hypothetical liquid state. Calculated values of $\Delta_{dis}H°$ and $\Delta_{mix}H°$ are reported in Table 3.

The enthalpies of mixing are all positive, which clearly indicates a lack of specific interactions of CO_2 with these dipolar solvents. The largest $\Delta_{mix}H°$ value is observed for EC, which is known to be partially self-associated, as indicated by its Kirkwood factor ($g = 1.2$) (30). The $\Delta_{dis}S°$ values are relatively large and negative, owing to the entropy of liquefaction of CO_2 in the first step, which is partially counterbalanced by the entropy of mixing that follows according to the scheme illustrated in Fig. 4.

CO_2 solubility in mixed solvents

Solubilities of CO_2 at 291 K in PC–EC and EC–DMC mixtures are listed in Fig. 5 as a function of the weight fraction in EC (w_{EC}). The variations in solubilities follow a linear relationship when the composition of the solvent is expressed in weight fractions. This result has been used for determining, by a linear extrapolation, the solubility of supercooled CO_2 in EC at 291 K (EC is solid below 311 K).

Henry law constants for the dissolution of CO_2 in EC–DMC (1:1), EC–DEC (1:1), and EC–PC–DMC (1:1:3), at 275, 291, and 316 K, are listed in Table 4. Values of k_H, $\Delta_{dis}H°$, $\Delta_{mix}H°$, $\Delta_{dis}G°$, and $\Delta_{dis}S°$ have been determined at 298 K by use of eqs. [8–11] and are reported in Table 5. The enthalpies of mixing of CO_2 in its hypothetical liquid state with those mixed solvents containing a large amount of DMC (EC–DMC and EC–PC–3DMC) are very weak.

Comparison of measured and calculated CO_2 solubilities

Equation [3] has been used to estimate solubilities for the present CO_2 – dipolar solvent systems. As illustrated in Fig. 3, a linear relationship is obtained when $\ln x_{CO_2}$ is plotted against $(\delta_S - \delta_{CO_2})^2$. For this purpose, the solubility parameters (19) given in Table 6 were used, and for CO_2, $\delta_{CO_2} = 12.3$ MPa$^{1/2}$ has been adopted (3, 12). The solubility parameters of the three solvent mixtures are calculated by:

[12] $\delta = \sum_i^n \Phi_i \delta_i$

eqs. [5, 6]	−1.63	−1.70	−2.12	−1.91	−2.10	−1.92	−1.94	−2.04	−1.79
eqs. [5, 13]	−2.01	−1.96	−1.87	−1.70	−2.27	−2.08	−1.93	−2.07	−1.83

CO_2 solubilities given by eqs. [4–6] are reported in Table 7, together with our experimental results. The Perisamu equation, eqs. [5, 6], gives the best agreement, even though large deviations are observed in the case of PC and EC and to a lesser extent for DMC and DEC. Moreover, for EC and PC, the calculated solubilities are lower than the experimental values, but the reverse is true for DMC and DEC.

To obtain a better fit to the experimental results, the Prausnitz and Shair equation, eq. [5], has been modified by taking into account the quadrupolar interaction of the solute with the solvent. For this purpose a corrected solvent solubility parameter (δ' in MPa$^{1/2}$) has been introduced:

$$[13] \quad \delta' = \delta_s - (0.1\varepsilon_s + 2.41)$$

Equation [13] is in fact identical to eq. [6], but the numerical values have been fitted to experimental data. This equation allows for reasonably good predictions of CO_2 solubilities when polar, as well a nonpolar, solvents are used (refer to eqs. [5] and [13] in Table 7).

Conclusions

The solubilities of carbon dioxide in liquid lactones and alkylcarbonates have been determined at temperatures ranging from 275 to 333 K. In a homologous series of solvents (acyclic carbonate, cyclic carbonate, and lactone), the solubility increases with the molecular weight of the solvent. The standard enthalpies and entropies for the dissolution of CO_2 in these solvents have been deduced from the variations in the Henry's law constant with temperature.

Classical theories using the well-known Hildebrand parameter may be used for predicting CO_2 solubilities in liquids. The present results show that large discrepancies between calculated and experimental values are observed when dipolar aprotic solvents are used as dissolution media. The quadripolar moment of CO_2, interacting with the strong dipolar moment of the solvent molecules, may be invoked to explain these deviations. To take into account this specific intermolecular interaction and to fit experimental data with a better accuracy, a modified version of the Prausnitz and Shair equation has been proposed.

UNIFAC calculation of thermodynamic properties of binary 1-chloroalkane + alkane and α,ω-dichloroalkane + alkane mixtures: Comparison with Nitta–Chao and DISQUAC predictions

J. García, E.R. López, M.J.P. Comuñas, L. Lugo, and J. Fernández

Abstract: Data available in the literature for vapor–liquid equilibria, activity coefficients at infinite dilution, and enthalpies of mixing for binary mixtures of 1-chloroalkanes or dichloroalkanes with alkanes are used to determine interaction parameters for three versions of the UNIFAC model — the Tassios et al., Larsen et al., and Gmehling et al. versions. The interaction parameters for chlorine and methyl or methylene groups are calculated using data for the thermodynamic properties of 1-chloroalkane + alkane mixtures. In the case of the Gmehling version, the geometrical parameters for chlorine are also determined. In addition, structure-dependent interaction parameters for α,ω-dichloroalkane + alkane mixtures are presented, taking into account the proximity effect. When the two chlorine atoms of the dichloroalkane are more separated, they become more independent, and the reported values of the interaction parameters approach those of 1-chloroalkane. For all of the properties studied the mean deviation obtained with the new parameter values is lower than that obtained with older values. The results for the thermodynamic properties obtained using the new parameters of the three versions of UNIFAC are compared with those of DISQUAC and Nitta–Chao models.

Key words: alkanes, chloroalkanes, DISQUAC, excess thermodynamic properties, proximity effect, UNIFAC.

Résumé : Les données publiées dans la littérature de l'équilibre liquide vapeur, des coefficients d'activité à dilution infinie et de l'enthalpie de mélange des systèmes binaires 1-chloroalcane ou dichloroalcane + alcanes, ont été utilisées dans ce travail pour déterminer les paramètres d'interaction pour trois versions du modèle d'UNIFAC, celle de Tassios et al., Larsen et al., et Gmehling et al. Premièrement, les paramètres d'interaction pour les groupes chlorine, méthyle et méthylène ont étés calculés en considérant des données des propriétés thermodynamiques des mélanges 1-chloroalcane + alcane. Pour la version de Gmehling, les paramètres géométriques du groupe chlorine ont été aussi détermines. Secondement, les paramètres d'interaction pour les mélanges α,ω-dichloroalcane + alcane ont été calculés en considérant l'effet de proximité. Si les deux atomes chlorine du dichloroalcane sont de plus en plus écartés, ils sont plus indépendants et les valeurs retrouvées pour les paramètres d'interaction sont très proches a ceux du 1-chloroalcane. Pour toutes les propriétés thermodynamiques étudiées, la déviation moyenne obtenue avec les nouvelles valeurs des paramètres est inférieur a celle trouvée avec les anciennes valeurs. Finalement, les résultats obtenus dans ce travail avec les trois versions du modèle d'UNIFAC, ont été comparés aux résultats des modèles de Nitta–Chao et de DISQUAC.

Mots clés : alcanes, chloroalcanes, DISQUAC, propriété thermodinamique d'excès, effet proximité, UNIFAC.

Introduction

Knowledge of the thermophysical properties of mixtures containing halogenated hydrocarbons is of considerable interest because these systems are widely used as solvents, blowing agents, and working fluids in refrigeration and in

J. García,[1] E.R. López, M.J.P. Comuñas, L. Lugo, and J. Fernández.[2] Laboratorio de Propiedades Termofísicas, Facultade de Física, Universidade de Santiago de Compostela, E-15782 Santiago de Compostela, Spain.

[1]Present address: Dpto. de Física Aplicada, Facultade de Ciencias, Universidade de Vigo, E-36200 Vigo, Spain.
[2]Corresponding author (e-mail: fajferna@usc.es).

air conditioning systems (1). Furthermore, from a theoretical point of view, these mixtures provide very interesting tests of group-contribution models because of the variety of the molecules and the availability of thermodynamic data.

The fundamental assumption of the group-contribution models is that the properties of a group and its interaction energies with other groups are molecule-independent. When a group is postulated, its contributions are estimated by correlating experimental data, and the group identification is tested by comparison with experimental data for other systems. On the basis of this comparison, the group is either accepted or redefined. The group as a whole should have approximately the same net charge, independent of the molecule in which it appears (2). The charge of a group can be affected by neighboring groups, which is known as the intramolecular proximity effect. Proximity effects are especially

important in cases where two or more polarizing atoms such as F, Cl, or Br are present in the same molecule. The proximity effect for molecules containing two identical polarizing groups (such as $X(CH_2)X$) is called the homoproximity effect. The corresponding effect in molecules containing two different polarizing groups (such as $X(CH_2)Y$) is called the heteroproximity effect. In 1989 Wu and Sandler (2) tested proximity effects in the UNIFAC model by analyzing predictions for mixtures of ether compounds. Wu et al. (3) confirmed that the predictions of the UNIFAC model are poor in systems containing morpholine because of important proximity effects.

Subsequently, Wu and Sandler (4, 5) proposed several rules for choosing the definition of groups, specifying that the groups must be approximately electroneutral. This method gives rise to an increase in the number of groups that must be employed and also requires quantum-mechanical analysis to identify the functional groups. However, until now, electronic charge contributions were calculated for only a few halogenated alkanes. Following this line, Storm (6), Kleiber (7, 8), and Jadot and Frère (9), among others, have given different group assignments for fluorocarbons, chlorocarbons, and hydrofluorocarbons. Recently, a new UNIFAC model, to be called KT-UNIFAC, was proposed by Kang et al. (10), to include proximity effects and to distinguish between isomers using contributions from first-order and second-order groups to predict vapor–liquid equilibria. The first-order functional groups are those currently applied in the estimation of mixture properties (i.e., the original UNIFAC), whereas the second-order functional groups involve molecular-structure data. The role of the second-order groups is to consider the proximity effects and to distinguish between isomers.

A solution to the above-mentioned problem has been proposed by Kehiaian and Marongiu (11) using the DISQUAC model. These authors keep the same definition of the groups and allow the interaction parameters to vary regularly with the molecular structure. This method is based on the fact that there is no a priori reason that the force field of an atom or group of atoms should be completely independent of the intramolecular environment. The results obtained by these authors are very good, especially for systems presenting proximity effects.

Following this point of view, in a previous study (12) we determined a set of Nitta–Chao interaction parameters that depend regularly on the chloroalkane length for α,ω-dichloroalkane + n-alkane mixtures. Furthermore, Ortega and Placido (13) have published interaction parameters, which depend on the alkane and dihalogenoalkane chain-lengths, in the framework of the Tassios version of the UNIFAC model for the α,ω-dihalogenoalkane (Cl, Br, I) + n-alkane binary mixtures. It is not clear, however, why the reported parameters can change with the alkane length, because the alkanes do not have polarizing atoms and therefore do not present the proximity effect. Owing to this fact, we prefer not to change the parameters with the alkane length.

For the Larsen et al. (14) and Gmehling et al. (15) UNIFAC versions (also called Lingby and Dortmund UNIFAC), no literature values are avaliable for parameters that change regularly with molecular structure. Taking into account the proximity effect in the present article, we have determined the interaction parameters of the Tassios, Larsen, and Gmehling versions of UNIFAC, as a function of the distance between the chlorine groups, for the α,ω-dichloroalkane + alkane mixtures. We have also determined, for 1-chloroalkane + alkane systems, a unique set of parameters for each version of the UNIFAC model. An updated database of experimental literature values of excess Gibbs energies (16–23), excess enthalpies (24–39), and infinite dilution activity coefficients (40–51) for these kinds of mixtures have been used.

Application of the theoretical model

The UNIFAC versions

The UNIFAC group-contribution model is based on the UNIQUAC equation. The activity coefficient is divided arbitrarily into two parts; the first is a combinatorial term that depends on the volume and surface area of each molecule, and the second, the residual term, is directly related to energy differences. In this sketch we will show only the main differences between the three versions of the UNIFAC model employed here.

The group interaction parameter between m and n groups, Ψ_{mn}, appearing in the residual contribution, is given by

$$[1] \qquad \Psi_{mn} = \exp\left[-\frac{a_{mn}}{T}\right]$$

In the original UNIFAC model, a_{mn} is assumed to be independent of the temperature, whereas in the Tassios version a_{mn} is given by

$$[2] \qquad a_{mn} = \frac{z}{2} a'_{mn}$$

where z is the temperature function

$$[3] \qquad z = 35.2 - 0.1272\,T + 0.00014\,T^2$$

and a'_{mn} are adjustable interaction parameters. This version can predict only excess enthalpies, using two fitting parameters, a'_{mn} and a'_{nm}, for each pair of groups. The Tassios version of the UNIFAC model was developed to predict excess enthalpies and to complement the original UNIFAC model that predicts only excess Gibbs energies (G^E). Then the parameter values for the Tassios version are calculated only from experimental excess enthalpies.

In the Larsen version, a_{mn} depends on the temperature, as:

$$[4] \qquad a_{mn} = a_{mn,1} + a_{mn,2}\,(T - T_0)$$
$$+ a_{mn,3}\,(T \ln\,(T_0/T) + T - T_0)$$

In the Larsen version, G^E at the temperature T_0 depends only on the first interaction parameter coefficient, $a_{mn,1}$, while the excess enthalpy depends on the first and second coefficients, $a_{mn,1}$ and $a_{mn,2}$. The excess heat capacity depends on the three coefficients, $a_{mn,1}$, $a_{mn,2}$, and $a_{mn,3}$.

For the Gmehling version, a_{mn} is expressed as the following function of the temperature

$$[5] \qquad a_{mn} = a_{mn,1} + a_{mn,2}\,T + a_{mn,3}\,T^2$$

The Larsen and Gmehling versions can predict excess enthalpies, excess Gibbs energies, and infinite dilution coef-

ficients with six parameters for each pair of groups, $a_{mn,i}$ and $a_{nm,i}$, with $i = 1$, 2, and 3. In addition, in the Gmehling modification the volume parameter of the group m, R_m, and the surface parameter of the group m, Q_m, are determined by fitting to experimental data.

The combinatorial contribution in the original UNIFAC model is given by the classical Guggenheim (52) approximation for athermal mixtures, whereas in the Larsen version the modification suggested by Kikic et al. (53) has been used. Gmehling et al. (15) changed the original combinatorial part of the UNIFAC model by introducing an empirical 3/4-exponent.

Estimation of the characteristic parameters

Three types of groups form the components in the chloroalkane + alkane mixtures: chlorine groups (defined as Cl in the Tassios version and as $ClCH_2$ for the Larsen and Gmehling versions) and both methyl and methylene groups (defined as CH_3 and CH_2, respectively, for the three versions). As it is standard for the group-contribution models, the energetic parameters of the CH_3 group will be considered here to be the same as those of the CH_2 group. We have determined the interaction parameters for the 1-chloroalkane + alkane mixtures using a Marquardt algorithm. In the case of the Gmehling version, the structural parameters Q_{Cl} and R_{Cl} were also fitted, whereas Q_{CH_2}, Q_{CH_3}, R_{CH_2}, and R_{CH_3} were taken from the literature (15). The geometrical parameters for the other versions are determined, as usual, by the Bondi method. It must be pointed that the values of $(z/2)Q_m$ coincide with that of Q_m for the original and Tassios versions. Tables 1–3 list the calculated parameters for the three versions.

Subsequently, for each dichloroalkane molecule, the energetic parameters were calculated using the database values and also the Marquardt optimization algorithm with the following constraints: (i) all the sets of parameters must present a regular dependence on the number of carbons in the dichloroalkane and (ii) according to the proximity effect, when the chloro groups of the dichloroalkane are more separated they become more independent, and therefore the values of the energetic parameters should approach those of the 1-chloroalkane. The parameters obtained in this manner are shown in Tables 4–6.

The databases employed to fit the parameters contained all of the experimental excess Gibbs energies listed in Table 7 and the enthalpy (H^E) and activity coefficient at infinite dilution ($\ln\gamma^\infty$) values marked with asterisks in Tables 8–10. One of the criteria used to choose a suitable database was the overall coherence of the experimental data. In addition, because the UNIFAC model fails for long-chain components, we have not introduced the activity coefficients at infinite dilution for systems containing compounds with more than 18 carbon atoms.

In Fig. 1 we have plotted the interaction parameters of the Tassios version against the number of carbons of the dichloroalkane. The interaction parameters for 1,8-dichlorooctane were guessed by following the regularity obtained with the dichloroalkane length. For this system, no experimental excess enthalpies — which could have been used to calculate the interaction parameters — were found in the literature. It is worth noting that the shapes of the interaction

parameter curves are similar to those found by Kehiaian and Marongiu (11) for the quasichemical interchange coefficients of the DISQUAC model and by us (12) for the dispersive and chemical-energy parameters of the Nitta–Chao model. For the other versions of UNIFAC, similar trends of energetic parameters in relation to dichloroalkane length also exist.

Results and discussion

The thermodynamic properties at equimolar compositions, calculated using the new and the older UNIFAC parameters, are shown in Tables 7–10. To compare the performance of the different analyzed group-contribution models, two quantities will be used: the absolute average deviation (AAD), defined by

$$[6] \qquad AAD = \frac{100}{N_Y} \sum \frac{\left| Y_{exp} - Y_{cal} \right|}{Y_{exp}}$$

and the root mean square deviation (RMSD) given by

$$[7] \qquad RMSD = \sqrt{\sum \frac{\left(Y_{exp} - Y_{cal} \right)^2}{N_Y}}$$

where Y_{exp} and Y_{cal} are the experimental and the predicted values for each thermodynamic property and N_Y the number of the experimental values for this property. All the deviations were taken for the equimolecular mixtures listed in the relevant table. Owing to the fact that the logarithms of the infinite dilution coefficients are small quantities, their AADs are relatively high. For this reason we prefer to give the RMSD for this property instead of the AAD.

1-Chloroalkane + alkane mixtures

The predictive capacity of the three versions of the UNIFAC model has been increased with the new parameters, especially for the excess Gibbs energies when using the Gmehling version. Actually, for G^E (Table 7) the mean deviations using the new and the older parameters are, respectively: 12%, 14% for the Larsen version and 5% and 44% for the Gmehling version. Figure 2 shows how both sets of parameters for the Gmehling version predict the temperature dependence of G^E for the 1-chlorobutane + heptane system. In Fig. 3 it can be seen that the symmetry and the magnitude are well predicted for 1-chlorobutane + pentane using the new parameters.

Concerning the excess molar enthalpies, the overall AADs (Table 8) using the new and the older parameters are, respectively: 5%, 6% for the Tassios version; 7%, 11% for the Larsen version; and 7% and 12% for the Gmehling version. Again, the best improvements were obtained with the Gmehling version. Figure 4*a* shows H^E for the system 1-chlorodecane + nonane using the Larsen version. The magnitude of H^E is better predicted with the new parameters. The experimental excess enthalpies increase as the alkane length increases and the 1-chloroalkane length decreases. This behavior is well predicted by all the versions of the UNIFAC model, but the experimental dependence is best

Table 10. Logarithm of activity coefficients at infinite dilution ($\ln\gamma_2^\infty$) for 1-chloroalkane + alkane and α,ω-dichloroalkane + alkane mixtures; (I) Experimental data; UNIFAC model: (II) and (IV) Larsen and Gmehling version with parameters of this work; (III) and (V) with older parameters.

reproduced with the new parameters, as can be seen in Fig. 5a for the Tassios and Larsen versions.

For the logarithm of the infinite-dilution activity coefficients, the RMSDs obtained using the new and the older parameters are, respectively: 0.060, 0.091 for the Larsen version and 0.059 and 0.074 for the Gmehling version (Tables 9 and 10). So, the results obtained with the new parameters are similar for both versions.

α,ω-Dichloroalkane + alkane mixtures

These mixtures are very useful for studies of the intramolecular proximity effect. In these cases the intermolecular interactions (and of course their parameters) are affected by the changes in the net charge of the groups due to the proximity of polarizing atoms. This effect decreases when the spacing between the non-alkyl functional groups increases. This is in agreement with the values obtained in Tables 4–6

Fig. 4. (*b*)
for the three versions of UNIFAC, since the interaction parameters for the (Cl(CH$_2$)$_n$Cl) dichloroalkanes with *n* > 6 coincide with those of the 1-chloroalkane + alkane systems.

All of the properties that were considered for the α,ω-dichloroalkane + alkane mixtures are better predicted with the new parameters. The AADs for excess Gibbs energies using the new and the older parameters are, respectively: 10%, 14% for the Larsen version and 5%, 16% for the Gmehling version. As illustrated in Fig. 3, the calculated G^E vs. composition curves, using the Gmehling modification with the new parameters, agree quite well with the experimental data.

Concerning the excess enthalpies, the AADs obtained using the new and the older parameters are, respectively: 9%, 10% for the Tassios version; 11%, 15% for the Larsen version; and 11% and 14% for the Gmehling version. In Fig. 4*b* we compare the predictions of the Larsen and Tassios versions for two examples. The trend of H^E(0.5) with the alkane and dichloroalkane lengths seems to be fairly well reproduced with the Larsen modification, as can be seen in Fig. 5*b*.

In the case of the Tassios version, with the new parameters it is possible to predict the excess enthalpies of dichloromethane + alkane mixtures. Choosing Cl as a group instead of CH$_2$Cl allows the same group definition to be used for all chloroalkanes. The new parameters determined for these systems follow the trend previously obtained for the larger dichloroalkanes, as can be seen in Fig. 1. Figure 6

(*b*)

Chao (12) and DISQUAC (11) models, using molecular-structure-dependent parameters. The conclusion of this comparison was that the different models have similar prediction accuracies. The AADs for the dichloroalkane + alkane mixtures are 6% and 8% for G^E and 10% and 6% for H^E using the DISQUAC and the Nitta–Chao models, respectively. The Gmehling version using the new parameters predicts slightly better excess Gibbs energies, and the DISQUAC model gives the smallest AADs for excess enthalpies. Similar results are obtained for 1-chloroalkane + alkane systems. For the infinite dilution activity coefficients, the best predictions for 1-chloroalkane + alkane mixtures are obtained using the Larsen and Gmehling versions. The corresponding AADs for the DISQUAC model are significantly larger (0.247), whereas for dichloroalkane + alkane mixtures the AADs are similar for the four models.

Based on our experience in fitting length-dependent parameters using several group-contribution models, we conclude that it is generally more difficult to find regular length-dependence with the UNIFAC model. This fact could be owing to the multiple solutions that are found in the minimization process for UNIFAC if there is no imposed limit on the range of the group interaction parameters. In the DISQUAC case the range of dispersive and quasichemical coefficients is small. Similar behavior is observed using the Nitta–Chao model, for which the hard core volumes must be close to their Bondi values, and their temperature-dependence parameter must be positive. The number of degrees of freedom of the groups is always between 0.1 and 1.0, and the dispersive and chemical energies have relatively narrow ranges.

Conclusions and future work

We have determined the interaction parameters between chlorine and methylene groups for three different versions of the UNIFAC model (Tassios et al., Larsen et al., and Gmehling et al.), taking into account the proximity effect. The H^E, G^E, and $\ln\gamma^{\circ}_i$ values of binary 1-chloroalkane + alkane and dichloroalkane + alkane systems are fairly well represented using the parameters proposed in this work. The results are similar to those obtained with the DISQUAC and the Nitta–Chao models.

In previous studies we determined the characteristic parameters representing the interaction of fluorine, bromine, and iodine with methylene groups for the UNIFAC and Nitta–Chao models in 1-fluoroalkane (54), 1-bromoalkane (55), and 1-iodoalkane (56) + alkane systems. We plan to extend this study to binary mixtures of alkanes with difluoroalkanes, dibromoalkanes, or diiodoalkanes to investigate the dependence of the interaction parameters on the distance between the halogen atoms. Furthermore, the halogen–methylene interaction parameters should follow a well-defined trend when the size of the halogen atom is varied.

illustrates how the new parameters improve the predictions. The AAD is reduced from 30% to 6%. It is interesting to point out, however, that Larsen et al. (14) and Gmehling et al. (15) define dichloromethane as an independent group. Using the parameters recommended by these authors, the AADs are 2% and 24%, respectively, for the same systems.

The RMSDs for $\ln\gamma^{\circ}$ using both the new and the older parameters are, respectively: 0.098, 0.334 for the Larsen version and 0.130, 0.184 for the Gmehling version for the dichloroalkane + alkane systems. For this type of system, a better representation of $\ln\gamma^{\circ}_i$ is obtained using the Larsen version.

Comparison with other group-contribution models

Finally, we have compared the above-mentioned results using the UNIFAC model with the predictions of the Nitta–

Canadensenes: Natural and semi-synthetic analogues

Qing-Wen Shi, Anastasia Nikolakakis, Françoise Sauriol, Orval Mamer, and Lolita O. Zamir

Abstract: The first bicyclic taxanes isolated in the needles of the Canadian yew were named canadensene **1** and 5-epi-canadensene **2**. Four additional analogues (**3–6**), isolated previously in *Taxus chinensis* and *Taxus mairei*, and a new natural 5-epi-canadensene analog **7** with a C-20-cinnamoyl group, were characterized for the first time in the needles of *Taxus canadensis*. A bicyclic derivative **8** with a docetaxel side chain on C-20 was synthesized using 5-epi-canadensene **2** as starting material. The lack of bioactivities of these bicyclic analogues (tubulin polymerization and cytotoxicities against human cancer cell lines) is discussed.

Key words: *Taxus canadensis*, Taxaceae, taxanes, natural products, semi-synthesis.

Résumé : Les premiers taxanes bicycliques isolés des aiguilles de l'if Canadien ont été nommés canadensene **1** et 5-epi-candensene **2**. Quatre analogues additionnels (**3–6**) isolés auparavant dans *Taxus chinensis* et *Taxus mairei*, ainsi qu'un nouvel analogue **7** du 5-epi-canadensene avec un groupe cinnamoyl en C-20 ont été caractérisés pour la première fois dans les aiguilles du *Taxus canadensis*. Un dérivatif bicyclique **8** avec la chaîne latérale du docetaxel en C-20 a été synthetisé à partir du 5-épi-canadensene **2**. Le manque d'activité biologique de ces analogues bicycliques (polymérisation de la tubuline ainsi que cytotoxicités envers des cellules humaines cancérigènes) est discuté dans cette publication.

Mots clés : *Taxus canadensis,* Taxaceae, taxanes, produits naturels, semi-synthèse.

Introduction

Taxus canadensis is a low-trailing bush abundant in the province of Quebec, with an unusual composition of taxane analogs (1–4). It is the only yew producing 9-dihydro-13-acetylbaccatin III in abundance in its needles (2, 3). The only other yew where it had been found is in the bark of *Taxus chinensis,* albeit only as *traces* (5). We reported the isolation of two bicyclic oxygenated taxanes in the Canadian yew that we named canadensene **1** and 5-epi-canadensene **2** (Fig. 1) in 1995 and 1998, respectively, to emphasize their origin (6, 7). Simultaneously, taxachitrienes **3–6** were reported in the needles of the Chinese and in the stems of the Japanese yews (8–11).

In the present work, the detailed structures of five 5-epi-canadensene analogs (**3–7**) differing in the substituents on C-2, C-5, C-13, or C-20 are reported from the needles of *T. canadensis*. Taxane **7**, which has a cinnamoyloxy group on C-20, is a new metabolite that has never been found in other

yews. It has been synthesized in our laboratory from cinnamoylation of 5-epi-canadensene (12). We are again reporting the high-resolution 2D NMR data of taxachitriene B (taxane **3**), since some signals had not been assigned. Taxanes **4** and **5** were characterized as 2-deacetyltaxachitriene A and 13,20-dideacetyltaxachitriene A, respectively. They had been previously identified in *Taxus mairei* needles (10, 11). Taxane **6** was identical to 5-deacetyltaxachitriene B previously isolated with taxachitriene B in *T. chinensis* needles (8, 9). In addition, we have semi-synthesized a 5-epi-canadensene analog to which the C-13 side chain of docetaxel was attached to C-20 (docecanadensene **8**, Fig. 1). Our hypothesis was that the canadensene derivative, being flexible because of its bicyclic structure, might allow for a long side chain on C-20 to reach the known active site of paclitaxel: β-tubulin (13–15). The lack of activity of these compounds toward tubulin polymerization and cytotoxicities against human cancer cell lines is discussed.

Results and discussion

The methanolic extracts of *T. canadensis* needles were analyzed, and its taxanes were purified by repetitive chromatography, preparative or semi-preparative HPLC, and preparative TLC.

Characterization of taxanes 3–6 (Fig. 1)

Taxanes **3–6** were identified as taxachitriene B (8), 2-deacetyltaxachitriene A (10), 13,20-dideacetyltaxachitriene A (11), and 5-deacetyltaxachitriene B (9), respectively, on the basis of 1D and (or) 2D spectral analysis and by comparison with the reported spectral data in the literature. Taxanes **3** and **6** have been previously isolated from *T. chinensis* nee-

dles (8, 9). Taxanes **4** and **5** have been previously isolated from *T. mairei* needles (10, 11). This is the first report of compounds **3–6** in the Canadian yew.

Characterization of 20-cinnamoyloxy-5-epi-canadensene 7 (Fig. 1, Table 1)

Compound **7** was obtained as a colorless, amorphous solid in a very small yield (~0.4×10^{-4}%) from dried needles of *T. canadensis*. The composition of **7**, $C_{39}H_{48}O_{13}$, was established from combined analysis of high-resolution FAB-MS at m/z 763.2734 ([M + K]$^+$) and NMR spectral data. In a previous publication, 20-cinnamoyloxy-5-epi-canadensene was prepared from 5-epi-canadensene (12). In this publication, the ^{1}H NMR has been reported. A more comprehensive table of all NMR data for **7** is shown in Table 1. The relatively downfield signals of H-20a and H-20b in **7**, resonating at δ 4.93 and δ 4.55 compared with 5-epi canadensene **2** (7) at δ 4.56 and 3.46 or 5-cinnamoyloxy-epi-canadensene (12) at δ 4.65 and 3.55, implied that the cinnamoyloxy of **7** was positioned on C-20. The ^{1}H NMR data at δ 4.55 revealed that a hydroxy group was attached at C-5. This is in accord with the chemical shift at δ 4.64 for **2**, which has a free C-5-OH, whereas the chemical shift of 5-cinnamoyloxy-epi-canadensene for C-5-OH is further downfield at δ 5.91. The relative stereochemistry of **7** is the same as that of **2**, as confirmed by comparing their NOESY spectra. The structure of **7** is, therefore, (3*E*, 8*E*)-2α,7β,9,10β,13α-pentaacetoxy-5α-hydroxy-20-cinnamoyloxy-3,8-secotaxa-3,8,11-triene (Fig. 1).

Semi-synthesis of docecanadensene 8 (Scheme 1)

The semi-synthesis of docecanadensene (**8**) from **2** afforded a compound with a C-20 side chain. We postulated that the primary C-20 alcohol of **2** would be more reactive than the secondary alcohol at C-5. Direct esterification of **2** was realized with 2-(4-OMe)phenyl-1,3-oxazolidine of *N*-Boc phenylisoserine (**9**) (16); dicyclohexylcarbodiimide and 4-pyrrolidinopyridine in dichloromethane–toluene at 23°C afforded diastereomers **10** (79%). Deprotection of **10** with a stoichiometric amount of *p*-toluenesulfonic acid in MeOH gave **8** (67%). The downfield shift of H-20a/b at δ 4.56/3.46 in **2** (7) to δ 5.06/4.28 in **8** confirmed the attachment of the docetaxel side chain at C-20.

Bioactivity of canadensene analogs

The polymerization of tubulin into stable microtubules is the most characteristic mode of action of paclitaxel (17). According to our original hypothesis, when the configuration of the taxane is substantially altered, a side chain situated elsewhere than on C-13 might lead to bioactivity (13–15). Taxuspine D and taxagifine have a modified A ring. The former has a C12=C13 double bond while the latter has a C16–C12 ether linkage. Both taxuspine D and taxagifine have a cinnamoyl group attached to the C5-OH, and both promoted the polymerization of tubulin but to about 1/3 that of paclitaxel (13–15). Similar results were reported previously by Kobayashi and co-workers (18, 19). In this work, we wanted to test if the core skeleton of the taxane — that is, a 6-membered ring fused to two 8- and 6-membered rings — was essential. We therefore investigated the natural canadensene analogs as well as a synthetic canadensene analog **8**. In the Taxol® series the replacement of the 3′-*N* benzoyl group with a *t*-butoxycarbonyl group substantially increased the tubulin activity and the in vitro cytotoxicity of docetaxel, the 10-deacetyl-3′-*N*-*t*-butoxycarbonyl analog of Taxol® (20). Consequently, we chose to attach a docetaxel side chain to C-20 of 5-epi-canadensene (**8**). We proposed that the bicyclic structure of 5-epi-canadensene, being very flexible, would enable the C-20 side chain to reach the active site of β-tubulin, a known target of paclitaxel. Tubulin polymerization activities were investigated for 5-epicanadensene **2**, 20-cinnamoyloxy-5-epicanadensene **7**, and docecanadensene **8** compared with Taxol® (Fig. 2). Whereas Taxol® induced the initial rate of tubulin polymerization almost twice as much as the control, the analogs only showed comparable activities to the control. We tested the in vitro cytotoxicity of taxanes **2**, **7**, and **8** against breast cancer cell lines MCF7 and MCF7-ADR (adriamycin resistant), as compared with that of Taxol® (Table 2). The IC$_{50}$ (concentration killing 50% of cells) of compounds **2**, **7**, and **8** were comparable around the 700 nM range for the MCF7-wild-type cell line. However, paclitaxel was a more potent compound as its IC$_{50}$ was in the 2 nM range. Similarly for the MCF7-ADR cell line the IC$_{50}$ for compounds **2**, **7**, and **8** were 645 nM, 825 nM, and 882 nM, respectively, compared with the IC$_{50}$ for Taxol® at 5 μM. Unfortunately, these canadensene analogs **2**, **7**, and **8** were inactive in both the tubulin assay as well as the two cytotoxicity assays. We would have liked to prepare two more synthetic analogs from 5-epi-canadensene, one having the side chain attached to C-13 and another analog with the side chain attached to C-5. Unfortunately 5-epi-canadensene can be isolated only in very small quantities, and therefore we were unable to prepare any more synthetic analogs. We cannot conclude, therefore, that the core skeleton (6/8/6 fused membered rings) is essential since we do not have the data pertaining to the compounds having a side chain on the C-13 or C-5 position. It is known, however, that 7,8-secotaxoids have excellent tubulin binding and cytotoxicity activity (21).

Experimental section

General experimental procedures

Optical rotations were recorded on a Jasco DIP-370 digital polarimeter. The NMR and HR-FAB-MS data were

[b] The ^{13}C chemical shifts were extracted from the HMQC experiment (±0.2 ppm). The numbers in bold character represent quaternary carbons whose chemical shifts were obtained from the HMBC experiment (±0.2 ppm).

[c] Italic font means weak HMBC correlations.

[d] NOESY intensities are marked as strong (s), medium (m), or weak (w).

obtained with the instruments and conditions reported previously (4). Flash chromatography was performed on silica gel 60 (230–400 mesh EM Science). Thin layer chromatography was conducted on silica gel 60 F$_{254}$ pre-coated TLC plates (0.25 mm thickness for analytical, 0.25 and 0.5 mm for preparative, EM Science). The components were visualized on TLC plates using a UV illumination lamp (254 and 365 nm). The spraying reagent for TLC plates was 10% sulfuric acid in EtOH followed by heating the plates to visualize the spots. Analytical HPLC was performed on a Waters 600 FHU delivery system coupled to a PDA 996 detector. Preparative and semi-preparative HPLC were carried out on a

Waters Delta Prep 3000 instrument coupled to a UV 486 tunable absorbance detector (Waters). Peaks were detected between 210 and 320 nm, but most chromatograms were plotted at 227 or 278 nm. Analytical HPLC was performed with two Whatman partisil 10 ODS-2 analytical columns (4.6 × 250 mm) in series. Semi-preparative HPLC was performed with two Whatman partisil 10 ODS-2 Mag-9 semi-preparative columns (9.4 × 250 mm) in series. Preparative HPLC was performed with one partisil 10 ODS-2 MAG-20 preparative column (22 × 500 mm). The products were eluted with a 50 min linear gradient of acetonitrile (25–100%) in H$_2$O at a flow rate of 18 mL/min (preparative

Fig. 2. Effect of canadensene analogs on tubulin assembly. Microtubule turbidity was evaluated at 340 nm by incubating tubulin (1 mg/mL) at 37°C in the presence or absence of taxanes. The slope percentage compared with control is depicted. The initial rate of tubulin polymerization was determined by initial slope detected during the first 3 min of tubulin assembly. This data represents mean ± SEM (standard error mean) for separate experiments.
HPLC) and 3 mL/min (semi-preparative HPLC). All the reagents and solvents were of the best available commercial quality and were used without further purification.

Plant material

T. canadensis, Marsh were collected in September 1997 at St-Jean-sur-Richelieu, Quebec, Canada. Several specimens (voucher # lz97–03) have been deposited in the herbarium of the Montreal Botanical Garden.

Extraction, isolation, and purification of taxanes (3–7)

Ground, air-dried needles of *T. canadensis* (4.0 kg) were extracted with 24 L of MeOH for 1 day at room temperature. The ground needles were filtered and extracted again with fresh solvent for another 3 days (8 L MeOH per day). The combined organic extracts were evaporated under reduced pressure. Water (3 L) was added and lipids were removed by stirring the mixture with hexane (3 × 3 L). The hexane layer was removed and then condensed to 1500 mL and extracted with 80% MeOH (4 × 500 mL). The 80% MeOH extract, after being re-extracted with hexane (2 × 300 mL), was evaporated under reduced pressure, diluted with 1 L of H_2O, and extracted with EtOAc (3 × 700 mL). The combined EtOAc extracts were dried, filtered, and evaporated, yielding a dark brown extract (25 g). The aqueous phase was then saturated with 200 g NaCl and extracted with CH_2Cl_2 (4 × 3 L). The combined CH_2Cl_2 extracts were dried, filtered, and evaporated, yielding a dark green extract (115 g).

A portion of the CH_2Cl_2 extract (50 g) was absorbed onto 110 g silica gel. Purification by flash chromatography on 1320 g silica gel and successive elution with a CH_2Cl_2–MeOH gradient, with increasing amounts of MeOH from 5% to 45% (total 15 L), led to 45 fractions (Fr_{D-1} to Fr_{D-45}). Fractions Fr_{D-18} to Fr_{D-24}, after being monitored by TLC, were pooled (3.5 g) and chromatographed over silica gel

Table 2. Cytotoxicity of canadensene analogs.

Compound	Tumor cell cytotoxicity IC$_{50}$ (nM)[a]	
	MCF7-wild type	MCF7-ADR
Taxol®	2 ± 1.52	>5[b]
5-Epicanadensene **2**	750 ± 5.38	645 ± 3.51
20-Cinnamoyloxy-5-epicanadensene **7**	655 ± 1.42	825 ± 2.14
Docecanadensene **8**	740 ± 3.99	882 ± 3.26

[a]Cytotoxicity of taxanes on the breast cancer cell lines MCF7-wild type and MCF7-ADR (adriamycin resistant). Exponentially growing cells were continuously exposed to taxanes at varying concentrations, and cell viability was evaluated by the MTT metabolic assay. Data represents mean ± SEM of three separate experiments. IC$_{50}$ is described as the concentration of agent required to inhibit cell proliferation to 50% vs. untreated cells.
[b]Unit is in µM.

(195 g, 4.2 × 32 cm) while eluting with hexane:EtOAc (1.2:1, 1.1 L; 1:1, 1.2 L; 1:1.2, 1.1 L; and 1:1.75, 1.1 L). Twenty-three fractions (Fr$_{D-18-1}$ to Fr$_{D-18-23}$) were collected. The fraction Fr$_{D-18-19}$ (53 mg) was applied to a preparative TLC plate (hexane:acetone, 3:2) and cut into 5 bands as visualized under a UV lamp. The band with an R_f = 0.30 (29 mg) was further separated by preparative HPLC and yielded **7** (7 mg, t_R = 44.30 min).

The fractions Fr$_{D-38}$ to Fr$_{D-41}$ were combined (24 g) and chromatographed over silica gel (770 g) by eluting with hexane:acetone (3:2, 3 L; 1:1, 3 L; and 2:3, 3 L), affording 28 fractions (Fr$_{D-38-1}$ to Fr$_{D-38-28}$). The fractions Fr$_{D-38-19}$ to Fr$_{D-38-28}$ were combined (2090 mg) and rechromatographed over silica gel (180 g, 4 × 35 cm) by elution with CH$_2$Cl$_2$:CH$_3$CN (3:2, 2 L; 5:4, 1 L; and 1:1, 1 L), yielding 25 fractions (Fr$_{D-38-19-1}$ to Fr$_{D-38-19-25}$). The fraction Fr$_{D-38-19-8}$ (280 mg) was fractionated by preparative HPLC. The peak at t_R = 24.05 min was collected, concentrated (45 mg), and further purified by preparative TLC (hexane:acetone, 1:1) affording **3** (4.0 mg, R_f = 0.32). The peak at t_R = 25.18 min was collected (26 mg) and further purified by preparative TLC (hexane:acetone, 1:1), yielding **4** (3.4 mg, R_f = 0.39). The fraction Fr$_{D-38-19-20}$ (112 mg) was subjected to preparative HPLC. The peak at t_R = 24.08 min was collected (15 mg) and further purified by preparative TLC (CH$_2$Cl$_2$: CH$_3$CN, 5:9), yielding **5** (4.0 mg, R_f = 0.34).

The fractions Fr$_{D-42}$ to Fr$_{D-45}$ were combined (2.5 g), treated with activated charcoal, dissolved in EtOAc, and extracted three times with 10% HCl. The aqueous acid layer was adjusted to pH 9–10 and re-extracted with CH$_2$Cl$_2$. The organic layer was washed with H$_2$O to neutrality, dried, filtered, and evaporated. The residue (200 mg) was fractionated by preparative TLC (hexane:EtOAc, 3:8). The band at R_f = 0.15 was collected, washed with MeOH, and further purified by preparative TLC (hexane:acetone, 30:75), affording **6** (5 mg, R_f = 0.15).

Assignments were achieved on the basis of 2D NMR spectra, including HMBC and HMQC.

(3E,8E)-2α,7β,9,10β,13α-Pentaacetoxy-5α-hydroxy-20-cinnamoyloxy-3,8-secotaxa-3,8,11-triene (7)

Amorphous gum. [α]$_D^{22}$ + 85° (c 0.005, CHCl$_3$). ^{1}H and ^{13}C NMR, HMBC, and NOESY spectral data see Table 1. HR-FAB-MS m/z: 763.2734 ([M + K]$^+$) (calcd. for C$_{39}$H$_{48}$O$_{13}$K: 763.2732).

Docecanadensene (8, Scheme 1)

5-Epi-canadensene **2** (20 mg, 0.034 mmol) in toluene (0.6 mL) was treated with 2-(4-OMe)phenyl-1,3-oxazolidine of N-Boc phenylisoserine (**9**), (27 mg, 0.068 mmol) in 0.3 mL CH$_2$Cl$_2$, 4-pyrrolidinopyridine (4 mg, 0.027 mmol), and DCC (15 mg, 0.073 mmol) at 23°C for 2 h. The reaction mixture was diluted with ethyl acetate, washed with 5% NaHSO$_4$, 5% NaHCO$_3$, and then with brine to neutrality. The organic layer was dried, filtered, and evaporated. The residue was purified by flash chromatography on silica gel with hexane:ethyl acetate, 1:1, as eluent to give compound **10** (26 mg, 79%). The protected 5-epi-canadensene ester (22 mg, 0.023 mmol) in MeOH (4.3 mL) was treated with p-toluenesulfonic acid (4.3 mg, 0.023 mmol) at 23°C for 45 min. The methanol was evaporated, and the residue was diluted with EtOAc and washed with brine to neutrality. The organic layer was dried, filtered, and evaporated. The residue was purified by flash chromatography on silica gel with hexane:ethyl acetate, 35:65, as eluent to give compound **8** (13 mg, 67%). ^{1}H NMR (500 MHz, CDCl$_3$) δ: 7.32 (m, 5H, Ph), 6.92 (br.s, 1H, H-10), 6.50 (d, J = 11.6 Hz, 1H, H-3), 5.73 (dd, J = 11.6, 4.5 Hz, 1H, H-2), 5.36 (br.d, J = 9.3 Hz, 1H, NH-4′), 5.28 (d, J = 9.2 Hz, 1H, H-13), 5.22 (br.d, J = 12.2 Hz, 1H, H-3′), 5.06 (o.br.d, J = 11.7 Hz, 2H, H-7, H-20a), 4.61 (br.s, 1H, H-2′), 4.41 (br.s, 1H, H-5), 4.28 (br.d, J = 11.7 Hz, 1H, H-20b), 3.76 (br.s, 1H, OH-5), 2.65 (m, 1H, H-6a), 2.52 (m, 1H, H-14a), 2.21 (s, 3H, OAc), 2.17 (s, 3H, OAc), 2.07 (s, 3H, OAc), 1.97 (s, 3H, OAc), 1.95 (s, 3H, OAc), 1.94 (s, 3H, H-18), 1.77 (t, J = 5.3 Hz, 1H, H-1), 1.65 (s, 3H, H-19), 1.39 (s, 9H, t-Bu), 1.23 (s, 3H, H-17),

1.12 (s, 3H, H-16). HR-FAB-MS m/z: 896.3467 ([M + K]$^+$) (calcd. for $C_{44}H_{59}N_1O_{16}K$: 896.3471).

Tubulin and bioactivity assay

Tubulin was extracted from cow brain according to a previously published procedure. The in vitro cytotoxicity activity determined on the MCF7 and MCF7-ADR cell lines with the MTT assay followed a previously published procedure (22).

The 30 year anniversary of a seminal paper on radical ions in solution
(Radical ions in photochemistry. I. The 1,1-diphenylethylene cation radical)[1]

J.A. Pincock

Abstract: This article was written to serve as an introduction to this issue of the *Canadian Journal of Chemistry* that honors the contributions to chemistry of Professor D.R. Arnold. It summarizes the observations reported in a communication that appeared in the *Journal of the American Chemical Society* 30 years ago in June 1973. This historically important communication laid the foundation for his program on the photochemical generation and reactivity of radical ions in solution and also served as a guide for a developing area of interest of many other research groups.

Key words: photochemical electron transfer, radical cations, photo NOCAS, benzylic radicals.

Résumé : Cet article se veut une introduction à ce numéro de la *Revue canadienne de chimie* qui souligne les réalisations du professeur D.R. Arnold en chimie. Il résume les observations rapportées dans une communication publiée dans la *Journal of the American Chemical Society* il y a de cela 30 ans, soit en juin 1973. Cette communication est très importante sur le plan historique puisqu'elle a non seulement servi de pierre d'assise au programme du professeur Arnold sur la génération et la réactivité photochimiques des ions radicaux en solution, mais aussi au développement d'un domaine d'intérêt pour de nombreux groupes de recherche.

Mots clés : transfert d'électron photochimique, cations radicaux, photo-NOCAS, radicaux benzyliques.

[Traduit par la Rédaction]

This issue of the *Canadian Journal of Chemistry* honours Professor Donald Arnold's contributions to chemistry. In September of 1972, I joined Don's research group at the University of Western Ontario as a PDF and began a project on cyclopropene photochemistry, vinyl diazo compounds, and the intermediate vinyl carbenes (1). The other PDF in the laboratory, Robert Neunteufel, had just discovered the first clear evidence from the Arnold research group of radical cation involvement in a photochemical reaction. The concise, seminal paper on these results (2) was published exactly 30 years ago in June 1973. Its impact on the larger chemistry community is indicated by its high citation count (over 300). Perhaps more indicative of its long-term importance is the fact that over two-thirds of these citations are from the more recent 15 years of the 30-year-period since its publication. The points[2,3] below summarize and highlight the importance of this paper which proved to be the foundation for Don's program on the generation of radical ions in solution.

Point 1: Introduction

As part of our effort to define the scope and limitations of the photocycloaddition of carbonyl compounds to olefins, our attention was attracted by the recent finding that aromatic esters … can undergo this reaction.

In *benzene* as solvent, *p*-cyanobenzoate **1** had been shown to react by photochemical excitation in a bimolecular reaction with 1,1-diphenylethylene **2** to form the oxetane **3** (Scheme 1). Benzoates with other electron-withdrawing groups also reacted, but methyl benzoate itself did not. Don knew that these esters had lowest energy π,π^* triplet states (3). He had also written a review on oxetane formation (4) and knew that this observation was unusual because oxetanes are normally formed from n,π^* states of carbonyl compounds reacting with alkenes. An exciplex mechanism was therefore proposed.

Point 2: The critical jump in understanding

When we irradiated solutions of **1** and 1,1-diphenylethylene **2**…in acetonitrile-d_3…A new product was isolated in 70% yield and identified as 1,1,4-triphenyl-1,2,3,4-tetrahydronaphthalene (**4**)…

The reaction was performed in *acetonitrile*, a polar solvent that allows separation of the exciplex into solvent separated ion pairs (Scheme 1) making other bimolecular

[2]The text is from the original manuscript.
[3]Structure numbers used here are the same as those in the original manuscript.

Scheme 1. Reactions of the radical cation of 1,1-diphenylethylene **2** in acetonitrile and alcohols, methanol and 2-propanol.
Scheme 2. Carbon–carbon bond cleavage of the radical cation of 1-methoxy-2,2-diphenylethane **7**.
reactions possible. Under these conditions, the tetralin **4** was now the major product. The important intermediates are the distonic radical cation and its precursor, **6** (the radical cation of **2**). These observations led directly to a series of papers on the generation of various distonic radical cations (5), other cycloadditions of radical cations (6), and *Z* to *E* configurational (7) and tautomeric deconjugative (8) isomerization of alkene radical cations.

Point 3: The extension to a new reaction

> Upon irradiation of **1** and **2** in methanol and 2-propanol … we found formation of 2,2-diphenylethyl methyl ether (**7**) and 2,2-diphenylethyl isopropyl ether (**8**), respectively…

Changing the high dielectric constant solvent from acetonitrile to an alcohol, a better nucleophile, completely altered the pathway for the reactivity of the radical cation **6**.

This extension arose from the concept that if **6** reacted with the alkene **2** as a nucleophile, it should react with other nucleophiles. Now *anti*-Markovnikov addition of the alcohol occurred to give **7** and **8** (Scheme 1). This observation initiated a series of publications on additions to radical cations (9) and to the complementary radical anion of 1,1-diphenylethylene (10). More recently, the reactivity of radical cations with nucleophiles in solution (11) and other environments (12) has been directly observed by others using LFP techniques.

Point 4: The importance of minor pathways

> …irradiation in 2-propanol produced appreciable amounts of **3** (**3**:**8** = 1:3.2) besides small quantities of unidentified products.

Don has always taken pride in insisting that even minor products must be characterized because they have often been good predictors of a new pathway which can become the major one by suitable choice of substrate and reaction conditions. The important phrase is "…besides small quantities of unidentified products" (2). These "unindentified products" from **7** were soon identified (13) as diphenylmethane and the dimethylacetal of formaldehyde. The proposed mechanism for their formation (Scheme 2), proceeds by cleavage of the radical cation of **7** to the diphenylmethyl radical and the methoxy methyl cation. This observation resulted in an extensive study of cleavage reactions of arylmethyl radical cations, including other carbon–carbon bond cleavages (14), carbon–oxygen bond cleavages (15), carbon–hydrogen bond

cleavages (16) reflecting the high acidity ($pK_a \sim -11$) of protons on radical cations of benzylic substrates (17). The regiochemistry of the cleavage to the radical and cation fragment was shown to be controlled by the relative stability of the two fragments (oxidation potentials of radicals as a measure of cation stability (18), the $\sigma_\alpha^.$ scale as a measure of radical stability (19), merostabilization of radicals (20)) and by stereoelectronic requirements (21).

The photo NOCAS reaction

Scheme 1 was later extended to studies on the variation in alkene structure. When 1,1-diphenylethylene **2** was replaced by 2,3-dimethyl-2-butene, the product obtained
resulted from *n*ucleophile–*o*lefin, *c*ombination, *a*romatic *s*ubstitution and the photo NOCAS reaction was discovered (22) and developed extensively through the 1990s (23). The ^{1}H NMR spectrum, taken from R. Borg's laboratory note book, of that first photo NOCAS product is reproduced on the cover of this issue of the *Canadian Journal of Chemistry*. The complementary process *e*lectrophile–*o*lefin, *c*ombination, *a*romatic *s*ubstitution (EOCAS) has also been recently explored (24).

Conclusion

My colleagues (including Don) at Dalhousie have for many years taught a graduate class in organic photochemistry. In the section on excited-state electron transfer and radical ion chemistry, I have always used Don's manuscript summarized here as an example of how the right scientist at the right time and with the right background knowledge can make significant changes in our understanding of a research area. Some have called these events paradigm shifts (25). I think the students acquire an appreciation of that possibility from this example. I also think that both those who have contributed to this honorary issue and others have the same appreciation. Thanks Don.

Photocycloaddition of cyclohex-2-enones to acrylonitrile

Lars Meyer, Nacira Alouane, Kerstin Schmidt, and Paul Margaretha

Abstract: The photocycloaddition of cyclohex-2-enones **1a**, **1b**, and **5a**–**5c** to acrylonitrile (**2**) in benzene has been studied. The reactions proceed with moderate regioselectivity and with preferential formation of diastereomeric mixtures of *endo*- and *exo*-5-oxobicyclo[4.2.0]octane-7-carbonitriles **3**, **4**, and **6**–**8**. Very similar relative rates of conversion to products are observed in the photocycloadditions of **1b**, **5a**, and **5b** to **2** and methacrylonitrile (**9**), respectively. In contrast, 5,5-dimethylcyclohex-2-enone (**1b**) forms cycloadducts with 2,3-dimethylbut-2-ene (**12**) as efficiently as with the unsaturated nitriles, but the 2,5,5-trialkylcyclohex-2-enones **5a** and **5b** do not react with this alkene at measurable rates of conversion. A dual path mechanism is presented that involves *either* exciplex formation between triplet-excited cyclohexenones and electron-rich alkenes *or* radical addition of the former to electron-deficient alkenes bearing a substituent, exercising a resonance effect.

Key words: [2+2]-photocycloaddition, cyclobutane, cyclobutanecarbonitrile, radical addition to unsaturated nitriles.

Résumé : On a étudié la photocycloaddition de cyclohex-2-énones (**1a**, **1b**, **5a**–**5c**) sur l'acrylonitrile (**2**) dans le benzène. Les réactions se produisent avec une régiosélectivité modéré impliquant la formation préférentielle de mélanges diastéréomères des *endo*- et *exo*-5-oxobicyclo[4.2.0]octane-7-carbonitriles (**3**, **4**, **6**–**8**). On a observé des vitesses relatives de conversion en produits très semblables pour les photoadditions des composés **1b**, **5a** et **5b** sur respectivement le composé **2** et sur le méthylacrylonitrile (**9**). Par ailleurs, la 5,5-diméthylcyclohex-2-énone (**1b**) forme des cycloadduits avec le 2,3-diméthylbut-2-ène (**12**) d'une façon pratiquement aussi efficace qu'avec les nitriles insaturés, mais les 2,5,5-trialkylcyclohex-2-énones **5a** et **5b** ne réagissent pas avec cet alcène à des vitesses de conversion mesurables. On propose un mécanisme réactionnel double impliquant soit la formation d'un exciplexe entre les cyclohexénones excitées à l'état triplet et les alcènes riches en électrons soit l'addition du radical du premier sur les alcènes déficients en électron portant un substituant qui exerce un effet de résonance.

Mots clés : photocycloadditions [2+2], cyclobutanes, cyclobutanecarbonitriles, additions radicalaires sur des nitriles insaturés.

[Traduit par la Rédaction]

Introduction

In the preparative application of [2+2]-photocyclo-additions of cyclic enones to (substituted) alkenes two factors concerning product formation are of decisive relevance, namely the regioselectivity and the (overall) relative rate of conversion. Regarding the regioselectivity in the addition to mono- and 1,1-disubstituted alkenes, Corey et al. (1) had shown that the preferred addition mode of cyclohex-2-enone to isobutene or dimethoxyethylene was the one leading to both *cis*- and *trans*-fused bicyclo[4.2.0]octan-2-ones with substituents on C(7), while in the reaction with acrylonitrile the alternate orientation of addition, leading preferentially to only *cis*-fused — so-called *head-to-head* — cycloadducts was observed. Similar results were also reported for photo-cycloadditions of 3-methylcyclohex-2-enone to differently substituted alkenes by Cantrell et al. (2). No significant dif-

ferences in the overall relative rates of product formation for the different alkenes were observed in these studies.

To explain these observed regioselectivities it was assumed (1) that an *umpolung* occurs in the charge distribution of the C=C double bond in the triplet-excited cyclohexenone. Shortly thereafter, a mechanistic sequence was proposed by de Mayo (3), involving the formation of an exciplex between triplet-excited cyclohexenone and alkene (which should be the determining factor in the regiochemical outcome), followed by that of triplet 1,4-biradicals, which in turn, after intersystem crossing, afford the final product(s) via 1,4-cyclization. It was also assumed that the triplet-excited cyclohexenone exhibits an electrophilic behaviour and, therefore, reacts faster with electron-rich than with electron-deficient alkenes. This mechanistic description was corroborated by one of us in studies of the photocyclo-addition of 4-oxacyclohex-2-enones to 2-chlorodifluoromethyl-

L. Meyer, N. Alouane, K. Schmidt, and P. Margaretha.[1] Institute of Organic Chemistry, University of Hamburg, M.L.King Platz 6, D-20146 Hamburg, Germany.

[1]Corresponding author (e-mail:Paul.Margaretha@chemie.uni-hamburg.de).

3-chloro-3,3-difluoropropene (4), which led to a very slow but exclusive formation of *head-to-head* cycloadducts, while the corresponding reaction with isobutene or 1,1-dimethoxy-ethylene afforded *head-to-tail* cycloadducts at much higher overall relative rates. It was pointed out (4) that in contrast to acrylonitrile this hexahalogenoalkene is not stabilized by conjugation between the C=C double bond and the substituent.

In a relevant paper describing triplet lifetime measurements using nanosecond flash photolysis, Schuster et al. (5) tackled the problem of describing "relative rates" for such reactions, since product yields in multistep processes depend on overall quantum efficiencies and not on the rate of a single specific step. The results, (*a*) that the rate constants for the quenching of enone triplets are much larger for electron-deficient alkenes than for those bearing electron-donor substituents, and (*b*) that no correlation whatsoever was seen between these quenching rates and the (overall) quantum yield for product formation, were found to be inconsistent with expectations based on the exciplex model described above. The direct formation of triplet biradicals from triplet enones and alkenes was therefore suggested as a plausible reaction step. Slightly later, based on results of photocycloaddition between cyclopent-2-enone and acrylonitrile, Weedon and co-workers (6) concluded that it was unnecessary to introduce an exciplex into the mechanism of the photocycloaddition reaction of cyclic enones with alkenes to explain the reaction regiochemistry.

We have recently (7) presented results on the photocycloaddition of cyclohex-2-enones to 2-alkylprop-2-enenitriles, leading to the exclusive formation of cyclobutanecarbonitriles. The choice of these cyclohexenones came from (*a*) facilitated interpretation of the ^{1}H NMR spectra of the photocycloadducts, owing to the geminal dimethyl group in the six-membered ring, and (*b*) variation of the substituent on C(2), regarding both size and radical stabilization. We now report on the photocycloaddition of these same cyclohex-2-enones to acrylonitrile.

Results and discussion

All the photolyses described were run with benzene as solvent. Irradiation of cyclohexenone (**1a**) in the presence of acrylonitrile (**2**) afforded – as already described (6) – a mixture of six enone + alkene adducts, of which the two major products **3a** (41%) and **4a** (35%) were successfully isolated and analyzed. Similarly, irradiation of 5,5-dimethylcyclohex-2-enone (**1b**) in the presence of **2** gave a mixture of five enone + alkene adducts, of which, again, the two major products **3b** (35%) and **4b** (46%) were isolated and characterized. Irradiation of trialkylcyclohexenones **5a** and **5b** in the presence of **2** afforded almost equal mixtures of four cycloadducts. In both reactions the major components **6a** (50%) and **7a** (20%), and **6b** (40%) and **7b** (25%), respectively, were isolated, while one of the minor components, **8a** (17%) and **8b** (18%), respectively, was analyzed from the product mixture. In contrast, irradiation of **5c** with **2** gave only a 4:1 mixture of **6c** and **8c**. Irradiation of **5b** in the presence of methacrylonitrile (**9**) gave a 3:2 mixture of cycloadducts **10** and **11**, which were separated and fully characterized (Scheme 1).

Scheme 1.

a: R = H
b: R = CH$_3$

a: R = CH$_3$
b: R = CH$_2$Ph
c: R = C≡C· C(CH$_3$)$_3$
Finally, to determine the relative rates of conversion to products, cyclohexenones **1b**, **5a**, and **5b** were irradiated in the presence of either acrylonitrile (**2**), methacrylonitrile (**9**), or 2,3-dimethylbut-2-ene (**12**) in a *merry-go-round* setup. The results of these measurements by GC analysis are summarized in Table 1.

The synthetic utility of cyclohexenone – unsaturated nitrile photocycloadditions definitively seems to be limited, as they proceed with rather moderate regio- and stereoselectivities. The ratio of *HH-* vs. *HT*-photocycloadducts, both for acrylonitrile (**2**) and methacrylonitrile (**9**), is roughly 3:1 for the cyclohexenones bearing no substituents on C(2) (i.e., **1a** and **1b**), about 2:1 for **5a**, 3:2 for **5b**, and, finally, >20:1 for **5c**. Regarding the *exo:endo* selectivity in the formation of these 5-oxobicyclo[4.2.0]octane-7-carbonitriles, cyclohexenones **1a** and **1b** and acrylonitrile (**2**) afford roughly 1:1 mixtures of **3a,b** and **4a,b**, while cyclohexenones **5a–c** give preponderantly (>3:1) the *exo*-nitriles **6a–c**, respectively. In contrast, as observed earlier (7), all these cyclohexenones react with methacrylonitrile (**9**) to give almost exclusively the 7-*endo*-carbonitriles (e.g., **10**).

Table 1. Relative rates for the conversion of cyclohexenones **1b**, **5a**, and **5b** to products[a] upon irradiation in the presence of acrylonitrile (**2**), methacrylonitrile (**9**), or 2,3-dimethylbut-2-ene (**12**).

	Alkene	**2**	**9**	**12**
Cyclohexenone				
1b		*1.00*	1.13	0.67
5a		0.84	0.67	<0.01
5b		0.91	0.66	<0.01

[a]For comparative irradiations of cyclohexenones in the presence of alkenes 2, 9, and 12, Ar-degassed solutions containing 0.1 mmol 1b, 5a, or 5b and 2.0 mmol alkene in 2 mL benzene were irradiated in a merry-go-round setup, and the formation of products was monitored by GC, using dodecane as internal standard, after 15, 30, and 60 min, respectively.

The assignment of the *exo*-nitrile configuration in cyclo-adducts **3** and **6** and that of the *endo*-nitrile in **4** and **8** stems from NOE experiments, as well as from the fact that for all *exo*-nitriles **3** and **6** the chemical shift of H(1), in either $CDCl_3$ or C_6D_6 solvent, is always larger than that of the corresponding H-atom in the *endo*-nitriles **4** and **8**, respectively. This is most probably due to the *cis*-relation between H(1) and the CN group in the former cycloadducts. Similarly, the *cis*-relation between the benzyl and the methyl groups on the cyclobutane ring in **10** is assigned again based on NOE experiments. Another difference between the acrylonitrile and methacrylonitrile cycloadducts is observed in the conformation of the six-membered ring. While in all methacrylonitrile cycloadducts the cyclohexanone ring adopts a twisted-boat conformation, its preferred alignment in cycloadducts **3**, **4**, **6**, and **8** is that of a boat, as reflected by the coupling constants between H(1) and the H-atoms on C(2), as well as by the much smaller chemical shift of one of the H-atoms on C(2) for which the orientation of the C—H bond is almost parallel to that of the carbonyl group.

The fact that the H-atoms of one of the cyclohexanone-methyl groups in **10** resonate at negative δ values (–0.12 ppm in $CDCl_3$, –0.35 ppm in C_6D_6) is also worth mentioning. Apparently, the axial methyl group on C(3), which is *cis* to the benzyl group, experiences a very strong deshielding effect by the aromatic ring. A more striking finding is the results of the measurements of relative rates of photocycloadduct formation between cyclohexenones and unsaturated nitriles, as the overall efficiency in these reactions is affected neither by the change of H vs. alkyl group on C(2) of the cyclohexenone nor by the replacement of H vs. CH_3 on C(2) in the nitrile. This contrasts the results of the cycloadditions of **1** and **5** to 2,3-dimethylbut-2-ene, where cycloadduct formation is totally prevented by the introduction of an alkyl group on the C(2) of the cyclohexenone. It should nevertheless be pointed out that bonding between tertiary C-atoms to afford cyclobutanes is a commonly encountered process for 3-alkylcyclohex-2-enones (2).

Although such overall relative rates have to be looked at with caution (5), qualitative conclusions can certainly be drawn, and the most straightforward one is that the addition of excited cyclohexenones to nitriles proceeds via a different path, which is less sensitive to steric interaction than that of electron-rich alkenes. While for this latter reaction there is substantial evidence for the interference of exciplexes (3, 4,

8, 9), the efficiency of the former can be attributed to the predominant interaction between the SOMO of a (nucleophilic) alkyl radical and the LUMO of the unsaturated nitrile (10). Indeed, it has been shown that alkyl radicals add to styrene about 23 times faster than to ethylene (11), and that cyclohexyl radicals add about 24 times faster to acrylonitrile than to styrene (12), i.e., the addition of C-centered radicals to alkenes experiences a 500-fold acceleration in going from ethylene to acrylonitrile. It seems therefore plausible to define ethylene as a "standard alkene" and to assume that cyclohexenone–alkene photocycloadditions are accelerated by either electron-donating (D) or — mesomerically — electron-withdrawing (A) substituents on the alkene, the former promoting exciplex formation and the latter radical addition (Scheme 2). If one neglects the cleavage of the intermediate biradicals formed by the addition of triplet-excited cyclohexenones, to unsaturated nitriles, back to starting materials, the regiochemical outcome of these reactions should correlate with the relative spin densities on C(2) and C(3) of the "cyclohexenone-1,2-biradical", which should be quite similar for **1b**, **5a**, and **5b**, but significantly altered for **5c**.

This would explain, then, why no *HT*-cycloadduct is formed from **5c**, as the spin density on the propargylic C(2) is negligible.

Experimental

General

NMR spectra were recorded in either $CDCl_3$ or C_6D_6 on a Bruker DRX 500 instrument at 500 and 125.8 MHz, respectively. GC coupled EI-MS was performed on a Varian MAT 311A spectrometer at 70 eV using a 30 m SE-30 capillary column. Photolyses were carried out in pyrex tubes using a Rayonet RPR 100 photochemical reactor equipped with 350 nm lamps (up to 16). The solvent (benzene) used for irradiations was of spectrophotometric grade. Cyclohex-2-enone (**1a**), acrylonitrile (**2**), methacrylonitrile (**9**), and 2,3-dimethylbut-2-ene (**12**) were purchased from Merck (Darmstadt). 5,5-Dimethylcyclohex-2-enone (**1b**) (13), 2,5,5-trimethylcyclohex-2-enone (**5a**) (14), 2-benzyl-5,5-dimethylcyclohex-2-enone (**5b**) (15), and 2-(3,3-dimethyl-but-1-ynyl)-5,5-dimethylcyclohex-2-enone (**5c**) (16) were synthesized according to literature procedures.

Photolyses: General procedures

In the preparative experiments, an Ar-degassed solution of cyclohexenone (1 mmol) and acrylonitrile (20 mmol) in benzene (10 mL) was irradiated for the time indicated and to the degree of conversion indicated (GC monitoring, peak percentages in increasing retention times) until maximum conversion of the enone was achieved. After evaporation, the residue was worked up using chromatography (CC) on SiO_2. For comparative irradiations of cyclohexenones in the presence of alkenes **2**, **9**, and **12**, Ar-degassed solutions containing 0.1 mmol **1b**, **5a**, or **5b** and 2.0 mmol alkene in 2 mL benzene were irradiated in a merry-go-round setup, and the formation of products was monitored by GC, using dodecane as the internal standard, after 15, 30, and 60 min, respectively.

Photolysis of 1a and 2

Irradiation for 2 h with up to 97% conversion led to 6 new product peaks (9% (unidentified (unident.)), 5% (unident.), 43% (**3a**), 7% (unident.), 5% (unident.), and 31% (**4a**)), in accordance with the product distribution reported in ref. (6), although no spectral data of the products are given. CC (Et$_2$O:pentane:toluene:EtOAc = 85:5:5:5) afforded first 50 mg (34%) of **3a** (90% purity), R_f = 0.46, and then 25 mg (17%) of **4a** (95% purity), R_f = 0.32, both as colorless oils.

Stereospecific Grignard reactions of cholesteryl 1-alkenesulfinate esters: Application of the Andersen Protocol to the preparation of non-racemic α,β-unsaturated sulfoxides

Rick R. Strickler, John M. Motto, Craig C. Humber, and Adrian L. Schwan

Abstract: Enantiomerically enriched α,β-unsaturated sulfinate esters of (–)-cholesterol undergo stereospecific substitutions at sulfur when treated in benzene at 6°C with Grignard reagents. Sulfoxides with ees of 85–99.5% are obtained when enantiopure sulfinates are used. The substitution reactions proceed with inversion of sulfur configuration. Enantiomerically pure cholesteryl (*E*)-2-carbomethoxyethenesulfinate is not a suitable reactant under the Grignard reaction conditions. It is suggested that the ester group induces unwanted reactions significantly lowering both the yield and sulfur stereogenicity.

Key words: sulfinate, sulfoxide, Grignard reagents, stereospecific, unsaturated.

Résumé : Lorsqu'on les traite avec des réactifs de Grignard, dans le benzène à 6 °C, les sulfinates α,β-insaturés énantiomériquement enrichis du (–)-chlolestérol subissent des réactions de substitution stéréospécifiques au niveau du soufre. Des sulfoxydes avec des ee de 95 à 99,5 % sont obtenus lorsqu'on utilise des sulfinates énantiomériquement purs. Les réactions de substitution se produisent avec inversion de configuration au niveau du soufre. Le (*E*)-2-carbo-méthoxyéthènesulfinate de cholestéryle énantiomériquement pur n'est pas un réactif approprié dans les conditions utilisées avec les réactifs de Grignard. Il est suggéré que le groupe ester induit des réactions indésirables qui abaissent de façon significative tant le rendement que la stéréogénicité au niveau du soufre.

Mots clés : sulfinate, sulfoxyde, réactifs de Grignard, stéréospécifique, insaturé.

Introduction

Enantioentriched sulfoxides can induce the introduction of carbon chirality into organic molecules by a number of means including carbanionic chemistry, Diels–Alder reactions and chiral ligand complexation (1–4). In these reactions it is the chirality at the sulfur center that plays a pivotal role in controlling the stereochemical outcome of the reaction. As such, a great deal of effort has gone into developing reliable and efficient methods for the synthesis of enantiopure sulfoxides. One mode of preparation of chiral sulfoxides that has enjoyed sustained popularity (4–7) is based on a protocol introduced by Andersen (8*a*). The original Andersen procedure involves treating a sulfinyl chloride with (–)-menthol to generate a diastereomeric mixture of menthyl sulfinate esters which, following a separation step, undergo organometallic substitution to afford enantiomerically pure sulfoxides (Scheme 1, R*OH = menthol). Since the original Andersen method was first introduced several improvements have been advanced. These typically involve the use of other chiral alcohols such

as diacetone-D-glucose (DAG), (5*b*, 9) (1*R*,2*S*)-(–)-*trans*-2-phenyl-cyclohexanol (10), and cholesterol (7, 11). The majority of recent applications of this protocol have tended to employ either DAG (4, 5) or (–)-menthol (6).

To this point, the application of cholesterol to this chemistry has been focused on preparing methanesulfinate esters (11). The propensity of the large cholesteryl auxiliary to crystallize provided the driving force for the sulfinate separation by recrystallization and the eventual formation of enantiopure methanesulfinates and methyl sulfoxides (11). Our group has established a practical method for the synthesis of 1-alkenesulfinyl chlorides (12, 13) and while investigating their conversion to enantiopure α,β-unsaturated sulfinate esters, has found that cholesterol is a preferred chiral alcohol (14). The aptitude for cholesterol derivatives to crystallize provided a benefit no other alcohols could equal. In that investigation the first collection of optically active 1-alkenesulfinate esters was reported (eq. [1]) (14). As part of our continuing interest in this area we investigated the nucleophilic conversion of these α,β-unsaturated sulfinate esters to enantiopure or enriched α,β-

unsaturated sulfoxides, compounds that are well-established as useful sources of a variety of chiral derivatives (1, 15). Most of the existing chiral vinylic sulfoxide preparations either create the double bond after a chiral sulfoxide has been prepared, or treat a chiral arenesulfinate with a vinylic organometallic reagent (15c, 15d). No such syntheses have established the chirality once the C=C-S unit was already intact which is the strategy investigated by us. This paper reports the outcome of our investigation, a portion of which has already been communicated (7).

Results and discussion

A synthetically useful organometallic displacement of the cholesteryl unit requires both high yield and maintenance of the stereogenicity at the sulfur. In work outlined in the preliminary communication (7), it was established using cyclohexyl analogs of the available enantioenriched sulfinate esters (14) that Grignard reagents (2 equiv) were readily found to be favored over organolithiums (16). To find the preferred conditions for maximum enantiomeric excesses, samples of $[R_S]$-(–)-cholesteryl (E)-3,3-dimethyl-1-butenesulfinate (**1**) possessing 88–100% optical purity were treated with n-BuMgCl under various conditions.[2] The results directed us to perform all subsequent substitution reactions in benzene (17) at 6°C where possible, although ethyl ether was the original solvent for such reactions (8b, 18).

Using the reaction conditions found in those preliminary experiments, the reactions of enantiopure or enantioenriched selected $[R_S]$- and $[S_S]$-sulfinates **1–4** with commercial and prepared Grignard reagents were proved to be efficient and chemoselective affording a wide variety of substituted α,β-unsaturated sulfoxides as outlined in Table 1 (eq. [2]). The enantiomeric excesses and the configurational assignments of the sulfoxides were determined using the chiral solvating

agent $[R]$-(–)-2,2,2-trifluoro-1-(9-anthryl)ethanol (19).[3] The sulfoxides possessing the highest ees arose from stereospecific reactions of sulfinates **1**, **3**, and **4**. Simple ethenyl sulfoxides could not be produced with high ee, since the precursor (–)-cholesteryl ethenesulfinate (**2**) could only be formed with des as high as 47% (14). Nevertheless, Grignard reactions of **2** still proceeded with high stereospecificity and yield when aromatic Grignard reagents were employed. Aliphatic Grignard reagents afforded somewhat lower yield and brought on losses of stereogenicity. Utilizing the availability of $[S_S]$-**1** (14) the corresponding Grignard reactions and the obtention of $[R_S]$-sulfoxides confirms the stereospecificity of the substitution pathway and eliminates the possibility of stereoconvergent Grignard reactions.

It was decided that the ^{1}H NMR – solvating agent method (19) of ee determination had a detection limit of 98% for samples that had only one set of peaks evident: the ^{1}H NMR of solvated **6f** shows the minor isomer and the ee of the sample of **6f** was found to be 98%. A closer inspection of the rotation data for **8b** further corroborates the detection limit, and hence the optical purity of the sulfoxides. The literature reports a value of $[\alpha]_D^{25}$ +166.0° (CHCl$_3$) for **8b** with 100% optical purity (20) while we obtained $[\alpha]_D^{25}$ +165.1° (CHCl$_3$) meaning our isolated sample of **8b** possessed an ee of 99.5%.

Successful 2-furyl Grignard reactions were obtained after several attempts and it was found that 2-furylMgBr generated in THF by the reaction of 2-furyllithium with MgBr$_2$-Et$_2$O (6d, 21) reacts with $[R_S]$-**1** in THF at –20°C in 78% yield and with >98% ee. Sulfoxides bearing the furyl group are important in organic synthesis and have been used in the synthesis of naturally occurring compounds (22). Also, noteworthy is that MeMgBr induced a 15% reduction in the measured ees of the sulfoxides obtained. Several repetitions and variations were performed but ees could not be improved and yields consistently ranged from 56 to 67%.

Many of the synthetic protocols for racemic and homo-

mixtures of double bond isomers (6g, 20, 23, 24). At no point were the sulfoxides obtained herein contaminated with any *cis*-isomer. Our protocol establishes the geometry of the double bond at a very early stage of the chemistry, and the double bond configuration is never jeopardized thereafter. In this regard we are demonstrating the stereospecific transfer of selected chiral alkenesulfinyl units, while maintaining the double bond geometry. Hence, the sulfinates represent the first usage of an intact chiral [RCH=CHSO]+ synthon.

Reactions of cholesteryl (*E*)-2-carbomethoxyethene-sulfinate

Grignard reactions of optically pure sulfinate **5** proved troublesome. Under our established conditions little or no sulfoxide was observed. Hence, cyclohexyl (*E*)-2-carbo-methoxyethenesulfinate (**10**) (12) was enlisted as a model compound for **5** to employ in an investigation of the behavior of this unique sulfinate. The reaction of **10** with MeMgBr (eq. [3]) typifies the results of several trials. Sulfoxide **11** could only be obtained in 0–20% yield and the reaction mixture always contained vinyl ether **12**. Changing to other organometallic species such as organolithium and organocerium reagents offered little improvement.

[3]

10 (E = CO₂Me) $\xrightarrow[\text{O C - rt}]{\text{RMgX}}$ E—CH=CH—OcC6H11 + **12** 22%

11 (R = Me) <5%
A mechanism to account for the observed results is offered in Scheme 2. It was felt that the sulfur substitution is indeed occurring, but the product is prone to counterattack by the displaced alkoxide. That attack occurs conjugate to the ester, the stronger electron-withdrawing group, and to conclude what appears to be an addition–elimination mechanism, a sulfenic acid anion (**13**) is released. To test this mechanism, sulfoxide **11** (R = $MeOC_6H_4CH_2$), the precursor of sulfinates **5** (**14**) and **10** (**12**), was treated with lithium cyclohexylate and the mixture was quenched with benzyl bromide to capture any reactive sulfenate (e.g., **13**). The observation of **12** as a reaction constituent and the isolation of **14** (R = $MeOC_6H_4CH_2$) in 47% purified yield from that mixture offer strong support for the proposed mechanism (Scheme 2).

A number of experiments were performed to see if the sulfoxide could be intercepted before the addition–elimination reaction took place. To this end, sulfinate **10** was treated with nucleophiles **15**–**19**. It was hoped that dianions **15** (25), **16**, and **17** (26) would effect sulfoxide formation and rapidly perform an intramolecular Michael addition. As an alternative strategy, it was suggested that **18** (5*d*) and **19** could achieve sulfoxide formation and the presence of a (thio)carbonyl group β to the sulfinyl unit would enhance the acidity of the intervening methylene hydrogens thereby providing the displaced alkoxide the recourse of deprotonation rather than Michael attack. None of these efforts provided significant sulfoxide and vinyl ether **12** was evident in the reaction mixtures.
Not completely discouraged, we pursued several reactions of **5** with Grignard reagents. Equation [4] depicts the best results that could be achieved, and although the low yields of sulfoxide **11** and of vinyl ether **20** were foreseen, the loss of sulfur stereochemistry was unexpected. The loss of sulfur chirality is presumably because of the presence of the conjugating carboxylic ester group. It has recently been shown (27) that the presence of a vinylic ester conjugating to a sulfinyl lone pair and the consequent mesomeric donation of that lone pair toward the ester leads to a reduced inversion barrier for the sulfinyl group. Based on this behavior, it follows that the sulfinyl group in a compound such as **11** exhibits increased electrophilicity at sulfur. Hence, a reasonable explanation for the loss of sulfur stereochemistry entails attack of **11** by excess Grignard agent, a pseudorotation step of the intermediate sulfurane at which time loss of stereogenicity occurs followed by release of one of the two car-

Scheme 2.
bon-based ligands. Alternatively, attack by previously released cholesteryloxy anion on **5** would bring about a similar outcome, as precedented by counterattack and racemization by thiolate on chiral thiosulfinates (28). However, control experiments have shown that racemization of **5** by cholesteryloxy anion is minimal.
Conclusions

Andersen, Mikolazcyk, and co-workers (11) have previously obtained optically pure cholesteryl [R_S]- and [S_S]-methanesulfinates in <5% yield. Although the behavior of cholesteryl ethenesulfinate would appear to be similar to those methanesulfinates, we were able to secure more substituted 1-alkenesulfinates in higher yield through recrystallization chemistry (14) and demonstrate in this paper that they are suitable 1-alkenesulfinyl transfer agents. Based on this observation, diastereomeric mixtures of cholesteryl sulfinate esters bearing large aryl and alkyl groups attached to sulfur may prove readily separable and hence worthy of investigation.

Those sulfinate esters that we have been able to secure undergo stereospecific substitution with inversion at sulfur yielding a range of α,β-unsaturated sulfoxides. The presence of a carbomethoxy group trans to the sulfinate ester creates significant unwanted reactions under Grignard treatment conditions. The method outlined herein is not limited to vinylic sulfoxides bearing only a *p*-tolyl group, the preparations of which have been amply demonstrated in the literature, buts allows for the preparation of a broader array of alkyl or aryl 1-alkenyl sulfoxides. It would appear that the collection of sulfoxides accessible by this protocol is only limited by the number of enantioenriched sulfinates available; we are currently exploring other means of pre-

paring a larger selection of enantiopure 1-alkene-sulfinates.

Experimental

General

Our general experimental methods have been outlined in a previous publication (12). Unless noted below, all Grignard reagents were purchased as stock solutions from Aldrich. Optical rotation measurements were performed on an Autopol III automatic polarimeter.

Typical procedure for the conversion of optically enriched sulfinates 1–4 to sulfoxides

Diastereomerically pure cholesteryl 1-alkenesulfinate ester (**1–4**, 1 equiv) was dissolved in benzene (10 mL) and cooled to 6°C under N_2. After 10 min the Grignard reagent (commercially available stock solution; 1 to 2 equiv) was added dropwise. The reaction mixture was stirred until complete by TLC analysis (1 to 2 h) and then quenched with NH_4Cl (10 mL). The solution was diluted with EtOAc and the organic layer separated, washed with brine, dried with $MgSO_4$, filtered, and concentrated under reduced pressure. The enantioenriched sulfoxides were isolated using silica gel flash chromatography, with EtOAc–hexanes as the eluent. Chemical yields, enantiomeric purities, and optical rotation data (in acetone) are presented in Table 1. All sulfoxides except **6c**, **7c**, **11a**, and **11b** were prepared by this protocol. Structural characterization of the sulfoxides follows.

[R_S]-1-Ethenyl 4-methylphenyl sulfoxide (7b) (23c):

^{1}H NMR (400 MHz) δ: 7.52 (d, J = 8.0 Hz, 2H), 7.32 (d, J = 8.4 Hz, 2H), 6.58 (dd, J = 16.4, 9.6 Hz, 1H), 6.19 (d, J = 16.4 Hz, 1H), 6.18 (d, J = 9.6 Hz, 1H), 2.41 (s, 3H).

[S_S]-1-Ethenyl cyclohexyl sulfoxide (7d):

Mp: 48–50°C. IR (CH_2Cl_2) (cm^{-1}): 3043, 2933, 2856, 1452, 1055. ^{1}H NMR (400 MHz) δ: 6.57 (dd, J = 16.5, 10.0 Hz, 1H), 6.07 (d, J = 16.5 Hz, 1H), 6.00 (d, J = 10.0 Hz, 1H), 2.57 (tt, J = 11.6, 3.6 Hz, 1H), 2.02–1.87 (m, 3H), 1.80–1.60 (m, 2H), 1.50–1.15 (m, 5H). ^{13}C NMR (100.6 MHz) δ: 138.6, 122.9, 60.2, 26.0, 25.5, 25.3, 24.2. MS (CI, NH_3) m/z (%): 159 ([M + 1]$^+$, 21), 108 (24), 91 (100), 90 (35), 74 (28), 73 (14). Anal. calcd. for $C_8H_{14}OS$: C 60.71, H 8.92; found: C 60.92, H 8.70.

[R_S]-4-Fluoro-3-methylphenyl ethenyl sulfoxide (7g):

IR (neat) (cm^{-1}): 3064, 3032, 2928, 1597, 1577, 1485, 1449, 1395, 1384, 1368, 1240, 1183, 1120, 1085, 1055, 1015, 986. ^{1}H NMR (400 MHz) δ: 7.48 (dd, J = 6.8, 1.6 Hz, 1H), 7.42 (m, 1H), 7.14 (t, J = 8.8 Hz, 1H), 6.57 (dd, J = 16.4, 9.6 Hz, 1H), 6.20 (d, J = 16.4 Hz, 1H), 6.91 (d, J = 9.6 Hz, 1H), 2.33 (s, 3H). ^{13}C NMR (100.6 MHz) δ: 162.9 (d, J = 250.6 Hz), 142.8, 138.1, 128.0 (d, J = 6.0 Hz), 126.9 (d, J = 18.5 Hz), 124.3 (d, J = 8.9 Hz), 120.6, 116.1 (d, J = 23.7 Hz), 14.5 (d, J = 3.2 Hz). MS (EI) m/z (%): 184 (M$^+$, 11), 157 (21), 141 (18), 137 (11), 136 (100), 135 (21), 110 (18), 109 (33), 108 (10), 107 (12), 97 (11), 83 (20), 59 (10), 57 (13), 45 (19). Anal. calcd. for C_9H_9FOS: C 58.68, H 4.92; found: C 58.77, H 5.02.

[S_S]-Ethenyl 1-(2-methyl-2-phenylpropyl) sulfoxide (7j):

IR (neat) (cm^{-1}): 3089, 3034, 2967, 2932, 1497, 1444, 1370, 1047. ^{1}H NMR (400 MHz) δ: 7.31–7.24 (m, 3H), 7.17–7.14 (m, 2H), 6.25 (dd, J = 16.4, 9.6 Hz, 1H), 5.92 (d, J = 16.4 Hz, 1H), 5.73 (d, J = 9.6 Hz, 1H), 2.89 (AB$_q$, J = 13.4 Hz, 2H), 1.16 (s, 3H), 0.78 (s, 3H). ^{13}C NMR (100.6 MHz) δ: 146.7, 141.5, 128.5, 126.6, 125.6, 120.7, 70.0, 37.8, 29.9, 27.2. MS (EI) m/z (%): 209, (82), 133 (91), 91(100), 55(20). Anal. calcd. for $C_{12}H_{16}OS$: C 69.19, H 7.74; found: C 69.38, H 7.59.

[S_S]-(E)-3,3-Dimethyl-1-butenyl 1-butyl sulfoxide (6a):

IR (neat) (cm^{-1}): 2959, 2932, 2906, 2870, 1625, 1465, 1364, 1265, 1074, 1039, 971. ^{1}H NMR (400 MHz) δ: 6.45 (d, J = 15.4 Hz, 1H), 6.09 (d, J = 15.4 Hz, 1H), 2.70 (t, J = 7.7 Hz, 2H), 1.68 (m, 2H), 1.48 (m, 2H), 1.11 (s, 9H), 0.96 (t, J = 7.3 Hz, 3H). ^{13}C NMR (100.6 MHz) δ: 151.1, 128.1, 53.8, 34.2, 28.8, 24.1, 22.0, 13.7. MS (EI) m/z (%): 188 (8), 171 (39), 132 (35), 118 (21), 117 (100), 115 (34), 101 (40), 99 (33), 97 (25), 85 (32), 84 (20), 83 (86), 79 (18), 74 (29), 71 (22), 69 (27), 67 (29), 65 (26), 59 (71), 57 (78), 56 (18), 55 (70), 53 (28), 51 (17). Anal. calcd. for $C_{10}H_{20}OS$: C 63.78, H 10.70; found: C 63.83, H 10.45.

[R_S]-(E)-3,3-Dimethyl-1-butenyl 4-methylphenyl sulfoxide (6b) (29):

^{1}H NMR (400 MHz) δ: 7.49 (d, J = 8.0 Hz, 2H), 7.31 (d, J = 8.0 Hz, 2H), 6.59 (d, J = 15.4 Hz, 1H), 6.11 (d, J = 15.4 Hz, 1H), 2.41 (s, 3H), 1.08 (s, 9H).

[S_S]-(E)-3,3-Dimethyl-1-butenyl cyclohexyl sulfoxide (6d):

IR (CH_2Cl_2) (cm^{-1}): 3029, 2935, 2855, 1622, 1474, 1463, 1451, 1365, 1264, 1055, 971. ^{1}H NMR (400 MHz) δ: 6.42 (d, J = 15.6 Hz, 1H), 6.04 (d, J = 15.6 Hz, 1H), 2.54 (m, 1H), 2.04 (m, 1H), 1.88 (m, 3H), 1.67 (m, 1H), 1.31 (m, 5H), 1.11 (s, 9H). ^{13}C NMR (100.6 MHz) δ: 152.2, 126.1, 60.5, 34.3, 28.9, 26.0, 25.6, 25.5, 25.3, 24.8. MS (EI) m/z (%): 214 (M$^+$, 8), 198 (19), 183 (32), 132 (100), 117 (78), 115 (27), 101 (48), 83 (88), 81 (19), 74 (20), 67 (26), 59 (41), 53 (17), 55 (85). Anal. calcd. for $C_{12}H_{22}OS$: C 67.23, H 10.34; found: C 67.08, H 9.93.

[S_S]-(E)-3,3-Dimethyl-1-butenyl methyl sulfoxide (6e) (23d):

^{1}H NMR (400 MHz) δ : 6.47 (d, J = 15.4 Hz, 1H), 6.17 (d, J = 15.4 Hz, 1H), 2.61 (s, 3H), 1.11 (s, 9H). MS (EI) m/z (%): 146 (M$^+$, 20), 131 (28), 130 (32), 117 (12), 115 (100), 83 (47), 81 (21), 71 (20), 58 (21), 57 (62), 53 (29), 51 (22). Anal. calcd. for: $C_7H_{14}OS$: C 57.49, H 9.65; found: C 57.45, H 9.52.

[S_S]-(E)-3,3-Dimethyl-1-butenyl 2-propyl sulfoxide (6f):

IR (neat) (cm^{-1}): 2961, 2932, 2905, 2868, 1628, 1475, 1463, 1365, 1266, 1062, 1024, 973. ^{1}H NMR (400 MHz) δ : 6.43 (d, J = 15.6 Hz, 1H), 6.01 (d, J = 15.6 Hz, 1H), 2.78 (m, J = 6.8 Hz, 1H), 1.24 (d, J = 6.8 Hz, 3H), 1.22 (d, J = 6.8 Hz, 3H), 1.10 (s, 9H). ^{13}C NMR (100 MHz) δ: 152.3, 125.4, 51.7, 34.3, 28.9, 15.2, 14.6. MS (EI) m/z (%): 174 (M$^+$, 15), 158 (20), 143 (38), 132 (90), 117 (100), 115 (42), 101 (59), 99 (39), 83 (81), 74 (30), 67 (35), 65 (31), 59 (85), 57 (27). Anal. calcd. for $C_9H_{18}OS$: C 62.02, H 10.41; found: C 61.82, H 10.25.

[S$_S$]-(E)-3,3-Dimethyl-1-butenyl benzyl sulfoxide (6h) (30):
^{1}H NMR (400 MHz) δ: 7.25–7.23 (m, 3H), 7.16–7.13 (m, 2H), 6.12 (d, J = 15.5 Hz, 1H), 5.89 (d, J = 15.4 Hz, 1H), 3.89 (AB$_q$, J = 12.6 Hz, 2H), 0.90 (s, 9H).

[R$_S$]-(E)-2-Phenylethenyl 1-butyl sulfoxide (8a):
IR (CDCl$_3$) (cm^{-1}): 3084, 3030, 2961, 2933, 2875, 1615, 1494, 1467, 1070, 1039, 965. ^{1}H NMR (400 MHz) δ: 7.45 (m, 2H), 7.35 (m, 3H), 7.21 (d, J = 15.5 Hz, 1H), 6.82 (d, J = 15.5 Hz, 1H), 2.78 (m, 2H), 1.75 (m, 2H), 1.48 (m, 2H), 0.94 (t, J = 8 Hz, 3H). ^{13}C NMR (100.6 MHz) δ: 136.8, 133.8, 130.5, 129.6, 128.9, 127.6, 53.9, 24.0, 22.0, 13.7. [S$_S$]-(Z)-2-Chloro-2-phenylethenyl 4-fluoro-3-methylphenyl sulfoxide (9g):
IR (neat) (cm^{-1}): 3060, 2927, 1580, 1488, 1444, 1239, 1184, 1081, 1060. ^{1}H NMR (400 MHz) δ: 7.35–7.28 (m, 3H), 7.20 (dd, J = 6.8, 1.6 Hz, 1H), 7.11 (s, 1H), 7.10–7.01 (m, 3H), 6.94 (t, J = 8.8 Hz, 1H). ^{13}C NMR (100.6 MHz) δ: 162.9 (d, J = 250.0 Hz), 147.4, 136.7, 129.4, 129.1, 129.0, 128.5, 128.1 (d, J = 6.1 Hz), 126.5 (d, J = 18.5 Hz) 124.6 (d, J = 9.0 Hz), 122.4, 115.7 (d, J = 23.8 Hz), 14.5 (d, J = 3.1 Hz). Anal. calcd. for C$_{15}$H$_{12}$ClFOS: C 61.12, H 4.10; found: C 61.32, H 4.24.

Synthesis of [R$_S$]-2-furyl ethenyl sulfoxide (7c):
n-BuLi (360 µL, 0.73 mmol) was added to a solution of furan (50 µL, 0.65 mmol) in dry ether (5 mL) at –20°C under N$_2$. After stirring for 20 min, MgBr$_2$ (180 mg, 0.98 mmol) dissolved in dry ether (5 mL) was added slowly with vigorous stirring over 20 min and then sulfinate [R$_S$]-**2** (301 mg, 0.65 mmol) in dry ether (5 mL) was added. After 1 h the reaction was quenched with NH$_4$Cl. The organic layer was separated, and the aqueous layer was extracted with EtOAc. The combined organic layers were washed with brine, dried over MgSO$_4$, and concentrated. Following flash chromatography (20% EtOAc – hexanes to elute cholesterol, 80% to elute sulfoxide) enantioenriched sulfoxide **7c** was isolated as an oil (42 mg, 59%). IR (neat) (cm^{-1}): 3117, 3039, 3010, 2952, 1600, 1550, 1456, 1453, 1370, 1220, 1165, 1066, 1051. ^{1}H NMR (400 MHz) δ: 7.64 (m, 1H), 6.95 (dd, J = 3.8, 0.4 Hz, 1H), 6.76 (dd, J = 16.4, 9.6 Hz, 1H), 6.53 (dd, J = 3.8, 2.0 Hz, 1H), 6.34 (d, J = 16.4 Hz,

1H), 6.11 (d, J = 9.6 Hz, 1H). ^{13}C NMR (100.6 MHz) δ: 137.4, 130.5, 130.2, 122.3, 116.4, 111.3. MS (EI) m/z (%): 142 (9), 126 (25), 115 (48), 99 (20), 97 (15), 94 (100), 83(15). Anal. calcd. for $C_6H_6O_2S$: C 50.69, H 4.25; found: C 50.77, H 4.42.

Synthesis of [S_S]-(E)-3,3-dimethyl-1-butenyl 2-furyl sulfoxide (6c):

As described for **7c**, *n*-BuLi (341 μL, 0.68 mmol), furan (40 μL, 0.57 mmol) in dry ether (5 mL), MgBr$_2$ (125.8 mg, 0.68 mmol) in dry ether (5 mL) were all brought together and enantiopure sulfinate [R_S]-**1** (295 mg, 0.57 mmol, 100% [R_S]) in dry ether (5 mL) was added. Work-up as for **7c** and flash chromatography (20% EtOAc – hexanes to elute cholesterol, 80% to elute sulfoxide) afforded enantioenriched sulfoxide **6c** as an oil (114.2 mg, 78%). Data for **6c**: IR (neat) (cm^{-1}): 3114, 2961, 2905, 2868, 1625, 1475, 1366, 1266, 1218, 1128, 1066, 1008, 970. ^{1}H (400 MHz) δ: 7.63 (m, 1H), 6.88 (d, J = 3.6 Hz, 1H), 6.66 (d, J = 15.4 Hz, 1H), 6.51 (dd, J = 3.6, 1.6 Hz, 1H), 6.35 (d, J = 15.4 Hz, 1H), 1.13 (s, 9H). ^{13}C NMR (100.6 MHz) δ: 152.7, 151.7, 146.8, 125.9, 115.2, 111.3, 34.3, 28.7. MS (EI) m/z (%): 199 ([M + 1]$^+$, 6), 150 (51), 135 (69), 107 (11), 99 (15), 91 (10), 83 (17), 81 (16), 79 (15), 71 (14), 67 (11), 59 (22), 57 (57), 55 (82), 53 (17), 45 (32), 43 (37), 41 (100). Anal. calcd. for $C_{10}H_{14}O_2S$: C 60.57, H 7.12; found: C 60.69, H 7.06.

Synthesis of (E)-[S_S]-2-carbomethoxyethenyl 1-butyl sulfoxide (11a):

The reaction of sulfinate **5** (336 mg, 0.65 mmol, 100% [R_S]) with *n*-BuMgCl (388 μL, 0.78 mmol, as a 2 M solution in Et$_2$O) in anhydrous ether at –78°C generated vinyl ether by-product **20** (117 mg, 38%) as a solid after chromatography (20% EtOAc – hexanes). Enantioenriched sulfoxide **11a** was isolated as a solid (37 mg, 30%, 51% [S_S]) after additional chromatography (80% EtOAc – hexanes); mp: 53 to 54°C. $[α]_D^{25}$ +120.6° (*c* 0.73, acetone). IR (cm^{-1}): 3030, 2959, 2932, 1719, 1621, 1292, 1223, 1146, 1041. ^{1}H NMR (400 MHz) δ: 7.58 (d, J = 15.0 Hz, 1H), 6.66 (d, J = 15.0 Hz, 1H), 3.81 (s, 3H), 2.87 (ddd, J = 13.2, 10.0, 5.8 Hz, 1H), 2.74 (ddd, J = 13.2, 10.0, 5.8 Hz, 1H), 1.81 (m, 1H), 1.69 (m, 1H), 1.48 (m, 2H), 0.96 (t, J = 7.2 Hz, 3H). ^{13}C NMR (100.6 MHz) δ: 164.3, 149.7, 126.0, 52.6, 52.3, 24.0, 21.9, 6.6. MS (CI, NH$_3$) m/z (%): 191 ([M + 1]$^+$, 100), 175 (5.6), 151 (12), 141 (9), 135 (8), 121 (16), 107 (18), 57 (33). Anal. calcd. for $C_7H_{14}O_2S$: C 50.66, H 7.42; found: C 50.50, H 7.42.

Synthesis of (E)-[R_S]-2-carbomethoxyethenyl 4-methylphenyl sulfoxide (11b) (23f):

The reaction of sulfinate **5** (471.5 mg, 0.91 mmol, 100% [R_S] with *p*-tolMgBr (1.09 mL, 1.09 mmol, as a 1 M solution in Et$_2$O) in anhydrous ether warming from –78 to –40°C generated vinyl ether by-product **20** (76 mg, 18%) as a solid after chromatography (20% EtOAc – hexanes). Enantioenriched sulfoxide **11b** was isolated as a solid (50.5 mg, 25%, 21% [R_S]) after additional chromatography (80% EtOAc – hexanes). $[α]_D^{25}$ +62.4° (*c* 0.22, acetone) (lit. (23f) value +421°) (acetone, >98% [R_S]). ^{1}H NMR (400 MHz) δ: 7.52 (d, J = 8.0 Hz, 2H), 7.48 (d, J = 15.0 Hz, 1H), 7.33 (d, J = 8.0 Hz, 2H), 6.73 (d, J = 15.0 Hz, 1H), 3.77 (s, 3H), 2.47 (s, 3H).

Characterization data for (–)-cholesteryl (E)-2-carbomethoxyethenyl ether (20):

IR (CH$_2$Cl$_2$) (cm^{-1}): 2946, 2906, 2868, 2851, 1715, 1643, 1133, 959. ^{1}H NMR (400 MHz) δ: 7.55 (d, J = 12.4 Hz, 1H), 5.40–5.39 (m, 1H), 5.26 (d, J = 12.4 Hz, 1H), 3.84–3.76 (m, 1H), 3.69 (s, 3H), 2.38–2.35 (m, 2H), 1.01 (s, 3H), 0.91 (d, J = 6.5, 3H), 0.86 (d, J = 6.6 Hz, 3H), 0.68 (s, 3H), 2.09–0.80 (remaining peaks for cholesteryl skeleton, 26H). ^{13}C NMR (100.6 MHz) δ: 168.6, 161.7, 139.3, 123.1, 97.0, 82.3, 56.7, 56.1, 51.0, 50.0, 42.3, 39.7, 39.5, 38.5, 36.8, 36.6, 36.2, 35.8, 31.9, 31.8, 28.2, 28.1, 28.0, 24.3, 23.8, 22.8, 22.6, 21.0, 19.3, 18.7, 11.8. MS (CI, NH$_3$) m/z (%): 471([M + H]$^+$, 37), 370 (29), 369 (100), 61 (13). Anal. calcd. for $C_{31}H_{50}O_3$: C 79.10, H 10.71; found: C 79.21, H 10.60.

Alkoxy radicals in the gaseous phase: β-scission reactions and formation by radical addition to carbonyl compounds

Arvi Rauk, Russell J. Boyd, Susan L. Boyd, David J. Henry, and Leo Radom

Abstract: The structures and reactivities of the alkoxy radicals methoxy (CH$_3$O·), ethoxy (CH$_3$CH$_2$O·), 1-propoxy (CH$_3$CH$_2$CH$_2$O·), 2-propoxy ((CH$_3$)$_2$CHO·), 2-butoxy (CH$_3$CH$_2$CH(CH$_3$)O·), *tert*-butoxy ((CH$_3$)$_3$CO·), prop-2-enoxy (CH$_2$=CHCH$_2$O·), and but-3-en-2-oxy (CH$_2$=CHCH(CH$_3$)O·) have been investigated at the B3-LYP/6-31G(*d*) and CBS-RAD levels of theory. Enthalpies of formation ($\Delta_f H^\circ_{298}$) were calculated with CBS-RAD for all the alkoxy radicals, the carbonyl and radical products of β-scission reactions, and the transition structures leading to them. The mean absolute deviation between the predicted and available experimental $\Delta_f H^\circ_{298}$ values is 5.4 kJ mol^{-1}. Eyring ($\Delta H^\ddagger_0$, $\Delta H^\ddagger_{298}$, $\Delta G^\ddagger_{298}$) and Arrhenius (log A, E_a) activation parameters for both the forward (β-scission) and reverse (radical addition to carbonyl) pathways were calculated. Agreement with available experimental data is very good, generally within 1–5 kJ mol^{-1} for E_a, and 0.5 for log A. The transition structures are found to be substantially polarized, with the departing radical slightly positive, the O atom negative, and the rest of the molecule positive. The barriers for the β-scission reactions decrease with decreasing endothermicity and with decreasing ionization energy of the departing radical.

Key words: alkoxy, alkoxyl, radical, addition, carbonyl, β-scission, calculaton, electronic structure, B3LYP, CBS-RAD, thermochemistry.

Résumé : Faisant appel à des calculs théoriques aux niveaux B3-LYP/6-31G(*d*) et CBS-RAD de la théorie, on a étudié les structures et les réactivités des radicaux alkoxy, méthoxy (CH$_3$O·), éthoxy (CH$_3$CH$_2$O·), 1-propoxy (CH$_3$CH$_2$CH$_2$O·), 2-propoxy [(CH$_3$)$_2$CHO·], 2-butoxy [CH$_3$CH$_2$CH(CH$_3$)O·], *tert*-butoxy [(CH$_3$)$_3$CO·], prop-2-énoxy (CH$_2$=CHCH$_2$O·) et but-3-én-2-oxy [CH$_2$=CHCH(CH$_3$)O·]. On a calculé les enthalpies de formation, $\Delta_f H^\circ_{298}$, au niveau CBS-RAD de la théorie pour tous les radicaux alkoxy, tous les produits carbonylés et tous les produits radicalaires provenant de réactions de β-scission et toutes les structures de transition qui y conduisent. La déviation absolue moyenne entre les valeurs prédites et les valeurs de $\Delta_f H^\circ_{298}$ expérimentales disponibles est de 5,4 kJ mol^{-1}. On a aussi calculé les paramètres d'activation d'Eyring ($\Delta H^\ddagger_0$, $\Delta H^\ddagger_{298}$, $\Delta G^\ddagger_{298}$) et d'Arrhenius (log A, E_a) pour la réaction vers la droite (β-scission) et pour la réaction inverse (addition d'un radical sur le carbonyle). L'accord entre les valeurs calculées et les valeurs expérimentales disponibles est bon, généralement entre 1 et 5 kJ mol^{-1} pour les valeurs de E_a et de 0,5 pour le log A. On a trouvé que les structures de transition sont assez polarisées alors que le radical qui se détache est légèrement positif, l'atome d'oxygène est négatif et que le reste de la molécule est positif. Les barrières aux réactions de β-scission diminuent avec une augmentation du caractère endothermique et avec une diminution de l'énergie d'ionisation du radical qui se détache.

Mots clés : alkoxy, alkoxyle, radical, addition, carbonyle, scission-β, calculs théoriques, structure électronique, B3LYP, CBS-RAD, thermochimie.

Introduction

Alkoxy radicals ($R_1R_2R_3C$–O·) are important intermediate species in the combustion of hydrocarbons (1, 2), and in atmospheric chemistry (3–5). They can react by intramolecular hydrogen abstraction, or by intermolecular hydrogen abstraction from a suitable donor (R′–H) to yield the corresponding alcohol:

[1] $R_1R_2R_3C\text{-O·} + R'\text{-H} \rightarrow R_1R_2R_3C\text{-OH} + R'·$

Alternatively, alkoxy radicals can undergo β-cleavage to yield an alkyl radical plus a ketone or aldehyde in up to three ways:

[2a] $R_1R_2R_3C\text{-O·} \rightarrow R_1· + R_2R_3C\text{=O}$

[2b] $\rightarrow R_2· + R_1R_3C\text{=O}$

[2c] $\rightarrow R_3· + R_1R_2C\text{=O}$
In proteins, production of such radicals by oxidative processes may lead to protein backbone cleavage (6). In general, the pathway that leads to the most stable radical is found to dominate the endothermic cleavage (7, 8) but exceptions have been noted in polycyclic systems (9) and have been investigated computationally (10).

The reverse reaction, alkyl radical addition to the carbonyl double bond:

[3] $R_1· + R_2R_3C\text{=O} \rightarrow R_1R_2R_3C\text{-O·}$
is hindered by an activation energy ($E_{a(3)}$) which has empirically been found to depend on the ionization energy of the radical ($IE(R_1·)$) and the exothermicity of the reaction ($\Delta H_{(3)}$) (11):

[4] $E_{a(3)} = 8.8[IE(R_1·)] - 0.58|\Delta H_{(3)}| - 26$

where the ionization energy is in units of eV and the enthalpy of the reaction is in kJ mol^{-1}. The relationship with the ionization energy was attributed (11) to a tight transition structure with substantial polarization in the sense:
Additional evidence for charge separation in the TS may be deduced from the observation of a large solvent effect for the β-scission of *tert*-butoxy radical (12). In a similar manner, barriers for the addition of alkyl and related radicals to alkenes have also been found to be dependent on the reaction enthalpy and the ionization energy of the radical but a multiplicative-type relationship is found to better describe this dependence (13).

We investigate here the factors affecting both the decomposition and radical-addition pathways for a systematic series of saturated and unsaturated alkoxy radicals, by using high-level quantum mechanical methods. A number of alkoxy radicals, including some of the systems of interest here, have been previously studied both experimentally, by means of laser flash photolysis – laser-induced fluorescence,

and computationally, by means of ab initio calculations, by Viskolcz and co-workers (14–18), and others (19, 20). Their work is discussed in the present context below.

Theoretical methods

Quantum mechanical calculations

Conventional ab initio (21) and density functional theory (22) calculations were carried out with the Gaussian 94 (23a), Gaussian 98 (23b), and Molpro 2000 (24) suites of electronic structure codes. Geometries and harmonic vibrational frequencies were obtained for all species at the B3-LYP/6-31G(d) level of theory. The vibrational frequencies were used, after appropriate scaling (25), in the calculation of thermodynamic and kinetic parameters including zero-point vibrational energies (ZPVEs), and to characterize each stationary point as a local minimum (no imaginary frequencies), or as a transition structure (one imaginary frequency). Higher-level energies were determined for all structures by the CBS-RAD procedure, which has been developed to provide accurate thermochemistry for radical species (26). The CBS-RAD(B3-LYP) combination employed here has been found to yield good reaction enthalpies and barriers for the addition of C-centered radicals to alkenes (13, 27).

Thermochemical procedures

Gas-phase thermodynamic functions, including thermal enthalpy contributions ($H° - H_0°$) (where $H°$ refers to 298.15 K) and entropies (S) may be accurately calculated by application of standard statistical procedures (28). Values derived experimentally are available in standard sources (29–32).

Theoretical enthalpies of formation at 298.15 K for species C_aH_bO may be calculated from the energies of the atomization reactions:

[5] $aC + bH + O \rightarrow C_aH_bO$

by eqs. [6]–[8]:

[6] $\Delta_f H_{298}°(C_aH_bO) = \Delta H_{(5)} + a\Delta_f H_{298}°(C)$
$$+ b\Delta_f H_{298}°(H) + \Delta_f H_{298}° (O)$$

where

[7] $\Delta H_{(5)}(298.15 \text{ K}) = \Delta H_{(5)}(0 \text{ K})$
$$+ (H° - H_0°)(C_aH_bO) - a(H° - H_0°)(C)$$
$$- b(H° - H_0°)(H) - (H° - H_0°)(O)$$

and

[8] $\Delta H_{(5)}(0 \text{ K}) = E^{CBS}(C_aH_bO) - aE^{CBS}(C)$
$$- bE^{CBS}(H) - E^{CBS}(O)$$

In this procedure, the enthalpies of formation ($\Delta_f H_{298}°$) and the ($H° - H_0°$) values for the gaseous atoms in their lowest electronic states are taken from experiment (29) (kJ mol^{-1}): C (716.7, 6.535), H (218.0, 6.197), O (249.2, 6.724). The CBS-RAD energies ($E^{CBS}(C_aH_bO)$) for all species discussed here are listed in Table 1. For the gaseous atoms in their

lowest electronic states, the CBS-RAD energies are E^{CBS} (hartrees): C (−37.785143), H (−0.499818), O (−74.987034).

Calculated enthalpies of formation are compared with available experimental values in Table 1. We have included for convenience in Table 1 the enthalpies of formation for the transition structures, even though the $\Delta_f H$ would be a somewhat artificial quantity for such species. In cases where a substance exists as an equilibrium mixture of two or more

conformers, the enthalpy of formation listed in Table 1 corresponds to that of the most stable conformer.

The entropy of a pure substance in the gas phase may be expressed as a weighted sum of the entropies of individual conformers, plus an entropy of mixing term (eq. [9]):

[9] $\qquad S^{total} = \Sigma_i x_i S_i - R\Sigma_i x_i \ln x_i \cong S_1 + R \ln n$

where x_i is the mol fraction of conformer i, S_1 is the entropy of the most stable conformation, and n denotes the number of significantly populated conformations (33).

The alkoxy radicals investigated in this study exhibit Jahn–Teller distortions. We have accounted for the near degeneracy of the A′ and A′′ states (C_s symmetry) by the addition of $R \ln 2$ to the electronic entropy. In addition, for the methoxy and *tert*-butoxy radicals we have adopted a rotational symmetry number of 3. Calculated entropies are included in Table 1, together with experimental values where available.

Rates of reaction

In the thermodynamic formulation of transition-state theory (TST) (34), the rate constant (k_T) for a reaction at temperature T is related to the free energy barrier ($\Delta G^\ddagger$) by eq. [10] (35):

[10] $\qquad k_T = (k_B T/h)(c°)^{1-m} \exp(-\Delta G^\ddagger/RT)$

where k_B and h are Boltzmann's and Planck's constants, respectively, R is the ideal gas constant, $c°$ is the standard unit of concentration (mol L^{-1}), and m is the order of the reaction. The factor $((c°)^{1-m})$ provides the correct units for the rate constant of unimolecular ($m = 1$) and bimolecular ($m = 2$) reactions. In the gas-phase standard state (T = 298.15 K) the pressure is 1 atm and $c° = 0.0408$ mol L^{-1}. We apply eq. [10] for the calculation of both the (forward) unimolecular β-scission reaction (eq. [2]) and the (reverse) bimolecular radical-addition reaction (eq. [3]).

In Arrhenius rate theory, the rate constant is given by:

[11] $\qquad k_T = A \exp(-E_a/RT)$

The Arrhenius activation energy (E_a) is given by:

[12] $\qquad E_a = \Delta H^\ddagger + mRT$

The Arrhenius frequency factor (A) contains the entropy of activation ($\Delta S^\ddagger$):

[13] $\qquad A = (k_B T/h)(c°)^{1-m} e^m \exp(\Delta S^\ddagger/R)$

Enthalpy barriers ($\Delta H^\ddagger$ (generally referred to in the course of this paper simply as barriers)) are calculated directly from enthalpies of formation of the appropriate species (or equivalently from the calculated total energies and, if appropriate, the enthalpy temperature corrections). In the present study, we have not considered quantum mechanical tunneling. This could in principle be important in the reactions involving hydrogen-atom scission and (or) addition but preliminary calculations suggest that the effect is not particularly significant.

Results and discussion

The energies of all species considered here are given in Table 1. The variation with the theoretical level of selected

properties of the transition structures are presented in Table 2. Table 3 gives the kinetic parameters ($\Delta H^\ddagger$, $\Delta G^\ddagger$, log A, and E_a) and the reaction enthalpies (ΔH) for β-scission reactions (eq. [2]), while corresponding data for the reverse reaction, radical addition to carbonyl (eq. [3]), are collected in Table 4.

Enthalpies of formation

Enthalpies of formation, calculated from atomization energies as described above, are listed in Table 1. Comparison with experimental values may be made for 17 species. The largest discrepancy occurs for but-3-en-2-one (CH_2=CHC(CH_3)=O) for which the calculated value ($\Delta_f H°_{298} = -108.2$ kJ mol^{-1}) is 29.8 kJ mol^{-1} less negative than the experimental ($\Delta_f H°_{298} = -138.0$ kJ mol^{-1}). For the remaining 16 species, the mean absolute deviation is 3.8 kJ mol^{-1}, consistent with the accuracy expected from CBS-RAD (26). The second-largest discrepancy (+14.1 kJ mol^{-1}) also occurs for an α,β-unsaturated carbonyl compound, acrolein ((E)-CH_2=CHCH=O). The calculated values for the heat of formation of the methoxy, ethoxy, 2-propoxy, and *tert*-butoxy radicals are in close agreement with the recent experimental results of Ramond et al. (36), and support these values over the older results (32) (which are generally less positive or more negative). Larger-than-average differences between theory and experiment occur for two alkoxy radicals 1-propoxy ($CH_3CH_2CH_2O·$, +12.1 kJ mol^{-1}) and 2-butoxy ($CH_3CH_2CH(CH_3)O·$, +6.1 kJ mol^{-1}), and for the ethyl radical ($CH_3CH_2·$, +6.9 kJ mol^{-1}). Experimental reexamination may be warranted in these instances. We are not aware of any experimental enthalpies of formation for the prop-2-en-1-oxy (CH_2=CHCH$_2$O·) or but-3-en-2-oxy (CH_2=CHCH(CH_3)O·) radicals.

Sensitivity of calculated barriers to TS geometry and theoretical level

The barriers for the β-scission (forward, eq. [2]) and radical addition (reverse, eq. [3]) reactions are crucial for determining the kinetic fate of alkoxy radicals in atmospheric chemistry and for understanding the combustion of hydrocarbons. Columns 4 and 5 of Table 2 compare the B3-LYP/6-31G(d) and CBS-RAD barriers ($\Delta H_0^\ddagger$) for β-scission of a number of the alkoxy radicals, in both cases using geometries and ZPVEs obtained at the B3-LYP/6-31G(d) level. It is evident that the B3-LYP values are significantly higher than the CBS-RAD values, by 13–20 kJ mol^{-1} for C-H scission, and by 3–14 kJ mol^{-1} for C-C scission. By either method, methyl-radical loss or ethyl-radical loss has a significantly lower barrier than H-atom loss in species where both channels are available.

The CBS-RAD procedure is expected to produce reasonably reliable estimates of the barriers provided that the geometries of the species derived at the B3-LYP/6-31G(d) level are adequate. The results should be most sensitive to the geometries of the transition structures. We have examined the appropriateness of the B3-LYP/6-31G(d) methodology for determining the transition structures by calculating the CBS-RAD energy at points along the bond-breaking coordinate for most of the β-scission reactions. The breaking C···H or C···C bond is stepped in 0.02 Å increments from the B3-LYP/6-31G(d) transition structure with reoptimization of all the remaining geometric parameters. The zero-point vi-

[a]Bond being broken in TS.
[b]Calculated using B3-LYP/6-31G(d) geometries and (scaled) zero-point vibrational energies.
[c]Calculated using the CBS-RAD–Scanmax procedure (see text); ZPVEs obtained with B3-LYP/6-31G(d) at the B3-LYP/6-31G(d) TS geometry.
[d]CBS-RAD–Scanmax – B3-LYP/6-31G(d).
[e]CBS-RAD–Scanmax – CBS-RAD.

brational energy is held constant at the TS value. The geometry at which the CBS-RAD energy, obtained in this manner, is a maximum, is an approximation to the CBS-RAD transition structure, while the corresponding $\Delta H_0^{\ddagger}$ represents an improved CBS-RAD estimate of the barrier. This procedure has been referred to as Scanmax (37) and is closely related to the IRCMax procedure of Petersson and co-workers (38).

Table 2 lists the length (r) of the bond being broken in the TS as obtained with B3-LYP/6-31G(d), the predicted B3-LYP/6-31G(d), and CBS-RAD values for $\Delta H_0^{\ddagger}$ at the B3-LYP/6-31G(d) optimized geometry, and the values of r and $\Delta H_0^{\ddagger}$ obtained using the CBS-RAD–Scanmax procedure. In each case, the CBS-RAD–Scanmax energy is a maximum at a value of r shorter than the B3-LYP/6-31G(d) optimized value, leading to an increase in the predicted $\Delta H_0^{\ddagger}$. The differences are listed in the last two columns of Table 2. Compared with CBS-RAD–Scanmax, B3-LYP/6-31G(d) overestimates the length of the breaking C—H bonds in the TS by 0.10–0.16 Å, leading to an underestimation of $\Delta H_0^{\ddagger}$ by the standard CBS-RAD procedure by about 1.6–2.4 kJ mol^{-1}. For C—C bond cleavage the corresponding differences in r and $\Delta H_0^{\ddagger}$ are somewhat smaller, 0.04–0.10 Å and 0.4–1.3 kJ mol^{-1}, respectively. Where available, we use the CBS-RAD–Scanmax values of $\Delta H^{\ddagger}$ rather than standard CBS-RAD values in the remainder of this paper.

We note that a detailed analysis of the dependence of the results for some of the alkoxy radicals and their C-C unimolecular decomposition reaction characteristics on theoretical level and basis set, at levels comparable to those employed here, may be found in the study by Somnitz and Zellner (20). Their work is discussed further below. We note also that for most of the alkoxy radicals studied here, the barriers for the β-cleavage reactions have been previously determined at the CASSCF/6-31G(d) level of theory, without

zero-point energy correction (10). The values so obtained are uniformly 30–50 kJ mol^{-1} higher than the values presented in Tables 3 and 4. In another study of β-scission reactions (39), AM1 theory was used to calculate barriers for a number of alkoxy radicals, only one of which is common to the present study. The AM1 barrier for the decomposition of the *tert*-butoxy radical decomposition is 13 kJ mol^{-1} higher than the CBS-RAD value (Table 3).

Individual alkoxy radicals

We discuss some of the individual alkoxy radicals prior to examination of the reactivity trends.

Methoxy radical

The CBS-RAD value of the bond dissociation enthalpy (BDE) of the O—H bond of methanol may be derived from the data in Table 1. The values at 0 and 298 K are 435.4 and 440.8 kJ mol^{-1}, respectively, in good agreement with experimental values 431 ± 4 and 436 ± 4 kJ mol^{-1}, respectively (40). Our calculated enthalpies of formation of the methoxy radical are $\Delta_f H_0^{\circ} = 28.7$ kJ mol^{-1} and $\Delta_f H_{298}^{\circ} = 21.0$ kJ mol^{-1}. Berkowitz et al. (40) reported $\Delta_f H_0^{\circ} = 24.7 \pm 3.8$ kJ mol^{-1} and $\Delta_f H_{298}^{\circ} = 17.2 \pm 3.8$ kJ mol^{-1} while Ramond et al. (36) reported $\Delta_f H_{300}^{\circ} = 21 \pm 4$ kJ mol^{-1}. Osborn et al. (41) reported $\Delta_f H_0^{\circ} = 28.5 \pm 1.7$ kJ mol^{-1}, in close agreement with our calculated value and also with the recent high-level theoretical value of Petraco et al. (19) ($\Delta_f H_0^{\circ} = 27.2$ kJ mol^{-1}).

The methoxy radical is predicted to undergo β-scission of a C—H bond with an Arrhenius activation energy ($E_a = 101.1$ kJ mol^{-1} (Table 3)) in close agreement with the value proposed by Dibble (42) (100 ± 4 kJ mol^{-1}) on the basis of theoretical and experimental results. The length of the breaking C···H bond in the transition structure is 1.80 Å (Table 2), close to that found by Petraco et al. (19) (1.79 Å). The rate

Table 3. [b]Ionization energy of the radical (in eV).
[c]298.15 K.

constant for unimolecular decomposition at 298 K is predicted to be 1.1×10^{-5} s^{-1}.

The β-scission reaction (eq. [3]) is highly endothermic for the methoxy radical and the enthalpy change corresponds to the bond dissociation enthalpy (BDE) of the C—H bond ($\Delta H_0 = 79.0$ kJ mol^{-1} and $\Delta H_{298} = 84.8$ kJ mol^{-1} (Table 3)). Our calculated 0 K value is slightly lower than that deduced experimentally by Osborn et al. (41) (82.8 ± 1.7 kJ mol^{-1}) and that calculated by Petraco et al. (19) (84.1 kJ mol^{-1}).

The reverse reaction, addition of H atom to formaldehyde, has a predicted barrier height at 0 K ($\Delta H_0^{\ddagger}$) of 18.5 kJ mol^{-1}, in good agreement with the recommended theoretical value of Petraco et al. (19) (19.7 kJ mol^{-1}). The reverse barrier is considerably smaller than the forward barrier because of the endothermicity of the β-scission reaction. Our Arrhenius parameters are $\log A = 10.37$ and $E_a = 18.7$ kJ mol^{-1}. The E_a value is somewhat lower than values reported by Walch (43) (22 and 26 kJ mol^{-1}), derived experimentally from rates for deuterium addition at room temperature ($\log A = 10.30$ was assumed) and an RRKM analysis, respectively. Because of the large negative entropy of activation calculated for the addition reaction (–89.6 J mol^{-1} K^{-1}) the free energy barrier ($\Delta G_{298}^{\ddagger} = 40.5$ kJ mol^{-1}) is substantially higher than the enthalpy barrier ($\Delta H_{298}^{\ddagger} = 13.8$ kJ mol^{-1}). Our calculated rate for the addition of H atom to formaldehyde is $k = 1.2 \times 10^7$ L mol^{-1} s^{-1}.

Ethoxy radical

The calculated values for the enthalpy of formation of the ethoxy radical are $\Delta_f H_0^{\circ} = 4.2$ kJ mol^{-1} or $\Delta_f H_{298}^{\circ} = -9.9$ kJ mol^{-1} (Table 1). These are in fair agreement with the values recommended by Berkowitz et al. (40) ($\Delta_f H_0^{\circ} = -1.7 \pm 3.8$ kJ mol^{-1} and $\Delta_f H_{298}^{\circ} = -15.5 \pm 3.8$ kJ mol^{-1}, respectively). We find closer agreement with the experimental value of Ramond et al. (36) ($\Delta_f H_{300}^{\circ} = -12 \pm 7$ kJ mol^{-1}). Viskolcz and co-workers (15) used a variety of high theoretical levels to obtain $\Delta_f H_{298}^{\circ} = 0 \pm 3$ kJ mol^{-1}, significantly higher than our CBS-RAD value and the experimental values.

Our calculated barrier for β-scission of the H atom from the ethoxy radical ($\Delta H_{298}^{\ddagger} = 85.1$ kJ mol^{-1}) is close to that obtained by Viskolcz and co-workers (15) (84.8 kJ mol^{-1}) at the QCISD(T)/6-311+G(3df,2p) level of theory. It is approximately 14 kJ mol^{-1} lower than for H-atom scission from the methoxy radical.

The barrier for the reverse reaction, addition of the H atom to acetaldehyde ($\Delta H_{298}^{\ddagger} = 22.0$ kJ mol^{-1}), is somewhat higher than that for addition to formaldehyde ($\Delta H_{298}^{\ddagger} = 13.8$ kJ mol^{-1}).

An activation energy of 70.4 kJ mol^{-1} is predicted for β-scission of CH$_3^{\cdot}$ from the ethoxy radical, which is in close agreement with a recent experimental determination ($E_a = 70.3$ kJ mol^{-1}) measured by laser flash photolysis – laser-induced fluorescence (15). Our predicted rate constant ($k = 19$ s^{-1}) is higher than the experimental values of Viskolcz and co-workers (14) (5.2 s^{-1}) and Batt and Milne (44) (1.5 s^{-1}). This reaction has also been investigated by Somnitz and Zellner (20) at a modified G2 level of theory, using RRKM theory to derive Arrhenius activation parameters and reaction rate constants. Their E_a value (73.6 kJ mol^{-1}) is slightly higher than ours and their derived $\log A$ value (12.99) is sig-

nificantly lower than ours (13.60). Their predicted rate constant at 300 K (1.46 s^{-1}) is in close agreement with the value of Batt and Milne (44). β-Scission of the ethoxy radical yielding CH$_3^{\cdot}$ + CH$_2$=O is predicted to be endothermic by 40.6 kJ mol^{-1} at 0 K and 47.8 kJ mol^{-1} at 298 K (Table 3).

The experimentally determined activation energy for the addition of the methyl radical to formaldehyde is 31.0 kJ mol^{-1} (11), somewhat higher than that found in the present calculations ($E_a = 25.1$ kJ mol^{-1}) (Table 4).

1-Propoxy radical

The predicted values for the enthalpy of formation of the 1-propoxy radical are $\Delta_f H_0^{\circ} = -8.2$ kJ mol^{-1} and $\Delta_f H_{298}^{\circ} = -29.3$ kJ mol^{-1}, considerably less negative than the experimental value ($\Delta_f H_{298}^{\circ} = -41.4$ kJ mol^{-1}) (Table 1). In the light of the good agreement with recent experimental data (36) observed for other alkoxy radicals, we believe that experimental reexamination for 1-propoxy radical is desirable.

β-Scission of the 1-propoxy radical yielding CH$_3$CH$_2$-CH=O + H$^{\cdot}$ has a predicted barrier ($\Delta H_{298}^{\ddagger}$) of 83.4 kJ mol^{-1} (Table 3). This value is only slightly lower than that predicted for β-scission of the H atom from the ethoxy radical ($\Delta H_{298}^{\ddagger} = 85.1$ kJ mol^{-1}). The 0 K value ($\Delta H_0^{\ddagger} = 82.4$ kJ mol^{-1}, Table 2) is 13.1 kJ mol^{-1} lower than that calculated by Viskolcz and co-workers (14) at the B3-LYP/SVP level of theory. The higher value of Viskolcz is consistent with our observations that the B3-LYP procedure tends to yield higher values for β-scission barriers than CBS-RAD (Table 2). The present results predict that the β-scission reaction of the 1-propoxy radical to give CH$_3$CH$_2$CH=O + H$^{\cdot}$ is strongly endothermic by 62.1 kJ mol^{-1} (ΔH_{298}).

The predicted barrier for addition of the H atom to propanal is 21.3 kJ mol^{-1} (Table 4) which, not surprisingly, is close to the value for the addition to acetaldehyde (22.0 kJ mol^{-1}).

The present calculations predict that β-scission of the 1-propoxy radical yielding CH$_3$CH$_2^{\cdot}$ + CH$_2$=O, is impeded by a barrier ($\Delta H_{298}^{\ddagger}$) of 55.7 kJ mol^{-1} (Table 3) and is endothermic by 44.9 kJ mol^{-1} (ΔH_{298}). This reaction has also been investigated by Somnitz and Zellner (20). Their RRKM-derived E_a of 62.4 kJ mol^{-1} is slightly higher than ours (58.1 kJ mol^{-1}) and, as in the case of ethoxy, their $\log A$ value (13.25) is somewhat lower than ours (13.77).

Our predicted barrier ($\Delta H_{298}^{\ddagger}$) for addition of ethyl radical to formaldehyde is 10.7 kJ mol^{-1} (Table 4), approximately 9 kJ mol^{-1} lower than that for methyl-radical addition ($\Delta H_{298}^{\ddagger} = 20.1$ kJ mol^{-1}) and approximately 3 kJ mol^{-1} lower than that for H-atom addition ($\Delta H_{298}^{\ddagger} = 13.8$ kJ mol^{-1}).

2-Propoxy radical

The predicted values for the enthalpy of formation of 2-propoxy radical are $\Delta_f H_0^{\circ} = -20.9$ kJ mol^{-1} and $\Delta_f H_{298}^{\circ} = -41.9$ kJ mol^{-1}, somewhat less negative than the experimental ($\Delta_f H_{298}^{\circ} = -52.3$ kJ mol^{-1} and $\Delta_f H_{300}^{\circ} = -46 \pm 5$ kJ mol^{-1}) and the value recommended by Sun and Bozzelli (45) ($\Delta_f H_{298}^{\circ} = -49.6$ kJ mol^{-1}).

Loss of the H atom from the 2-propoxy radical by β-scission is predicted to have a barrier ($\Delta H_{298}^{\ddagger}$) of 74.1 kJ mol^{-1}, which is close to the G2(MP2) value of 76.5 kJ mol^{-1} obtained by Devolder et al. (16). It is somewhat lower than the barriers for H-atom loss from the ethoxy and propoxy radicals which have only a single α-alkyl substituent (CH$_3$

and CH_3CH_2, respectively). Conversely, the barrier for addition of the H atom to acetone ($\Delta H^{\ddagger}_{298} = 30.1$ kJ mol^{-1}) is somewhat higher than that for addition to the aldehydes $CH_3CH{=}O$ and $CH_3CH_2CH{=}O$ ($\Delta H^{\ddagger}_{298} = 22.0$ and 21.3 kJ mol^{-1}, respectively).

β-Scission of the 2-propoxy radical yielding $CH_3{\cdot} + CH_3CH{=}O$ is predicted to be endothermic, with $\Delta H_0 = 19.8$ kJ mol^{-1} and $\Delta H_{298} = 27.1$ kJ mol^{-1} (Table 3). The barrier ($\Delta H^{\ddagger}_{298}$) is predicted to be 57.7 kJ mol^{-1}. This value is similar to that found by Viskolcz and co-workers (16) at the G2(MP2) level ($\Delta H^{\ddagger}_{298} = 61.2$ kJ mol^{-1}). Our Arrhenius parameters log $A = 13.96$ and $E_a = 60.1$ kJ mol^{-1}, are in moderate agreement with the experimental values, measured by laser flash photolysis – laser-induced fluorescence (log $A = 14.08$, $E_a = 63.7$ kJ mol^{-1}) (16). Our calculated rate at 298 K is $k = 2.8 \times 10^3$ s^{-1}, somewhat higher than the experimental rate ($k = 8.3 \times 10^2$ s^{-1}). The corresponding theoretical RRKM values of Somnitz and Zellner (20) are $E_a = 62.2$ kJ mol^{-1}, log $A = 13.38$, and $k = 3.53 \times 10^2$ s^{-1} at 300 K, in somewhat better agreement with the experimental values of Viskolcz and co-workers (15).

Addition of the methyl radical to acetaldehyde is predicted to have a significantly higher barrier ($\Delta H^{\ddagger}_{298} = 30.6$ kJ mol^{-1}) than the addition of the H atom to acetaldehyde ($\Delta H^{\ddagger}_{298} = 22.0$ kJ mol^{-1}) or the addition of the methyl radical to formaldehyde ($\Delta H^{\ddagger}_{298} = 20.1$ kJ mol^{-1}).

2-Butoxy radical

β-Scission of the 2-butoxy radical may proceed by three pathways: loss of the H atom, methyl radical, or ethyl radical. Loss of the H atom entails a very similar barrier ($\Delta H^{\ddagger}_{298} = 73.1$ kJ mol^{-1}, Table 3) to that for H-atom loss from the 2-propoxy radical ($\Delta H^{\ddagger}_{298} = 74.1$ kJ mol^{-1}). Likewise the barrier for H atom addition to butan-2-one ($\Delta H^{\ddagger}_{298} = 27.6$ kJ mol^{-1}, Table 4) is similar to that for the addition to acetone ($\Delta H^{\ddagger}_{298} = 30.1$ kJ mol^{-1}).

Loss of either of the two alkyl groups, methyl or ethyl, is hindered by smaller barriers than that for H-atom loss, with $\Delta H^{\ddagger}_{298} = 59.8$ and 46.5 kJ mol^{-1}, respectively. Somnitz and Zellner (20) also investigated the two β-scission pathways involving alkyl group loss. Their theoretical RRKM values (methyl, ethyl) are $E_a = (60.8$ kJ mol^{-1}, 50.0 kJ mol^{-1}), log $A = (12.26, 13.15)$, and $k = (46.0$ s^{-1}, 2.67×10^4 s^{-1}) at 300 K. Our corresponding values from Table 3 are (methyl, ethyl) $E_a = (62.3$ kJ mol^{-1}, 48.9 kJ mol^{-1}), log $A = (13.25, 13.72)$, and $k = (2.2 \times 10^2$ s^{-1}, 1.4×10^5 s^{-1}) at 298 K. The E_a values are in good agreement, but the RRKM log A values are lower than ours and that recommended by Fittschen et al. (17), who suggest a common value (log $A = 14 \pm 0.3$) for β C–C scission in alkoxy radicals. Experimental estimates of the rate constant for the dissociation to the ethyl radical plus acetaldehyde lie in the range 7.5×10^2 to 3×10^4 s^{-1} (see reference (20b) for a review and discussion). An experimental investigation in which both channels were observed found a difference of 11.2 kJ mol^{-1} between E_a values, and that the log A value for the ethyl channel was higher by 0.6 (46). Both features are in reasonable agreement with the theoretical results.

The barrier for methyl-radical addition to propanal ($\Delta H^{\ddagger}_{298} = 31.5$ kJ mol^{-1}) is quite similar to that for the addition to acetaldehyde ($\Delta H^{\ddagger}_{298} = 30.6$ kJ mol^{-1}). However, the barriers for both of these reactions are significantly greater than for ethyl-radical addition to acetaldehyde ($\Delta H^{\ddagger}_{298} = 20.1$ kJ mol^{-1}). The reaction enthalpies for all three processes are generally similar ($\Delta H_{298} = -26.4$ to -28.3 kJ mol^{-1}).

tert-Butoxy radical

The present calculations predict that β-scission of the tert-butoxy radical should occur with a barrier of 54.5 kJ mol^{-1}, only 3.2 kJ mol^{-1} lower than for β-scission of the methyl radical from 2-propoxy radical ($\Delta H^{\ddagger}_{298} = 57.7$ kJ mol^{-1}).

The calculated Arrhenius parameters for the scission reaction are log $A = 14.06$ and $E_a = 56.9$ kJ mol^{-1}. Experimentally determined kinetics of tert-butoxy radical decomposition have been reported by Choo and Benson (11) (log $A = 14.1$, $E_a = 64$ kJ mol^{-1}), Batt et al. (47) (log $A = 14.04 \pm 0.37$, $E_a = 62.5 \pm 0.6$ kJ mol^{-1}), Viskolcz and co-workers (17) (log $A = 14.0$, $E_a = 60.5$ kJ mol^{-1}) and Blitz et al. (48) (log $A = 13.15$, $E_a = 57 \pm 2$ kJ mol^{-1}). While our E_a value is close to that of Blitz et al. (48), their log A value is significantly lower. Our calculations support a value for A close to 1×10^{14}, which is also recommended by Viskolcz and co-workers (17).

As noted earlier for the corresponding H-atom additions to acetone, methyl-radical addition to acetone is hindered by a significantly higher barrier ($\Delta H^{\ddagger}_{298} = 38.1$ kJ mol^{-1}) than for the corresponding additions to acetaldehyde and propanal ($\Delta H^{\ddagger}_{298} = 30.6$ and 31.5 kJ mol^{-1}, respectively).

Prop-2-en-1-oxy and but-3-en-2-oxy radicals

The two unsaturated oxy radicals, prop-2-en-1-oxy and but-3-en-2-oxy, may undergo β-scission by losing a vinyl radical, or by losing a hydrogen atom or a methyl radical, respectively. The structures of the OCCC anticlinal conformers of these radicals, which are linked to the most stable (also OCCC anticlinal) conformations of the transition structures for H loss or CH_3 loss, are shown in Fig. 1. In each case, the <OCCC dihedral angle is such as to orient one of the allylic groups (H and CH_3, respectively) approximately perpendicular to the plane of the vinyl group and well-positioned for π-bond-assisted departure.

The barriers ($\Delta H^{\ddagger}_{298}$) for H-atom loss from prop-2-en-1-oxy (74.7 kJ mol^{-1}) and but-3-en-2-oxy (69.7 kJ mol^{-1}) radicals are lower than those for the equivalent processes in the saturated analogues, 1-propoxy (83.4 kJ mol^{-1}) and 2-butoxy (73.1 kJ mol^{-1}), consistent with π-bond participation in the β-scission process for the unsaturated radicals. The lower barrier for the departure of the methyl radical from but-3-en-2-oxy (48.2 kJ mol^{-1}) as compared to methyl loss from 2-butoxy (59.8 kJ mol^{-1}) provides additional support for the π-bond assistance in the former case.

With the exception of H$\cdot$ loss from methoxy, the loss of vinyl radicals are the most endothermic of those listed in Table 3. The barriers for vinyl group loss from the prop-2-en-1-oxy and but-3-en-2-oxy radicals are $\Delta H^{\ddagger}_{298} = 92.4$ kJ mol^{-1} and 83.1 kJ mol^{-1}, respectively. The higher values for vinyl radical loss partly reflects the greater endothermicity in these cases.

Influence of substituents in β-scission reactions

The data in Table 3 are grouped according to the departing radical (H$\cdot$, $CH_3\cdot$, $CH_3CH_2\cdot$, or $CH_2{=}CH\cdot$). It is apparent

Fig. 1. The unsaturated prop-2-en-1-oxy and but-3-en-2-oxy radicals.

Prop-2-en-1-oxy   But-3-en-2-oxy
that within any of these groupings, increasing alkyl substitution at the site of oxygen attachment promotes β-scission. Thus the barriers ($\Delta H^{\ddagger}$) for β-scission of H· decrease in the sequence: $CH_3O·$ >> $CH_3CH_2O·$ ≈ $CH_3CH_2CH_2O·$ > $(CH_3)_2CHO·$ ≈ $CH_3CH_2CH(CH_3)O·$. Likewise, the $\Delta H^{\ddagger}$ values for β-scission of $CH_3·$ decrease in the sequence: $CH_3CH_2O·$ > $(CH_3)_2CHO·$ ≈ $CH_3CH_2CH(CH_3)O·$ > $(CH_3)_3CO·$. The two examples of loss of ethyl and vinyl groups also follow this pattern. These results are all consistent with a decrease in $\Delta H^{\ddagger}$ accompanying a decrease in the reaction endothermicity ΔH, as expected from the Bell–Evans–Polanyi relationship. The decreased endothermicity may in turn be associated with increased hyperconjugative stabilization of the product carbonyl compounds with increased alkyl substitution.

In addition to the reaction enthalpy effect, the barriers for β-scission (and for the reverse radical addition to carbonyl, see below) decrease as the ionization energy of the departing radical decreases, consistent with the development of positive charge at the incipient radical in the transition structure. Our calculated Mulliken charges indeed indicate that there is a small amount of positive charge of approximately +0.05–0.07 in the incipient radical moiety in the TS. The low net charge on the departing radical (H·, $CH_3·$, $CH_3CH_2·$, or CH_2=CH·) is consistent with a loose (late) TS with more than 80% of the net spin on the radical. Interestingly, there is also a significant polarization of charge in the remainder of the transition structure, with a negative charge of approximately –0.4 on the incipient carbonyl oxygen and a positive charge of approximately +0.3 on the remainder of the molecule. The extent of this polarization increases with increasing alkyl substitution.

Radical addition to the carbonyl group

The addition of radicals to alkenes has been extensively studied by high-level theoretical calculations (for example, see refs. 13 and 49). However, the addition of radicals to carbonyl compounds has received less attention (for example, see refs. 19 and 50). This reaction is the reverse of the β-scission reaction that we have discussed in detail above and we therefore make only a few brief comparative remarks here.

Table 4 contains our computed data for radical additions to carbonyl compounds, grouped according to the radical being added. An initial comment is that, because of the endothermicity of the β-scission reactions, the barriers for the reverse radical addition reactions are considerably smaller than the β-scission barriers.

Transition structures for the addition of hydrogen, methyl, ethyl, and vinyl radicals to acetaldehyde are shown in Fig. 2, along with the calculated Arrhenius activation parameters. A general plot of the calculated activation energies (E_a) against reaction enthalpies (ΔH_{298}) is displayed in Fig. 3. It is clear that E_a generally decreases with increasing exothermicity, as expected from the Bell–Evans–Polanyi relationship. In addition, for a given exothermicity, the barriers tend to be lower for radicals with a lower ionization energy. These observations are qualitatively consistent with the empirical relationship (eq. [4]) of Choo and Benson (11), and with considerations based on a curve-crossing model (13, 51). Lower ionization energies enable greater participation of charge-transfer configurations of the type radical$^+$carbonyl$^-$, which in turn leads to a lowering of the barrier. The barriers follow the pattern $(CH_3)_2C$=O ≈ $CH_3CH_2C(CH_3)$=O > CH_3CH=O ≈ CH_3CH_2CH=O > CH_2=O, in line with the reaction exothermicity. Particularly low barriers are observed for the highly exothermic additions involving the vinyl radical.

An interesting observation, already noted above for the addition of H· to CH_2=O, is that, in contrast to the situation for the β-scission reactions, the $\Delta G_{298}^{\ddagger}$ values for the radical additions are considerably greater than the $\Delta H_{298}^{\ddagger}$ values. This arises because of substantial negative entropies of activation, a result that is not unexpected for a bimolecular reaction. The differences between $\Delta G_{298}^{\ddagger}$ and $\Delta H_{298}^{\ddagger}$ depend on the radical that is added, and increase in the sequence H· (26–31 kJ mol^{-1}) < $CH_3·$ (37–45 kJ mol^{-1}) ≈ CH_2=CH· (37–40 kJ mol^{-1}) < $CH_3CH_2·$ (43–46 kJ mol^{-1}).

Examination of the log A values shows that the frequency factors (A) for H· addition are close to 1×10^{10}, while those for alkyl radical addition are two to three orders of magnitude smaller. Frequency factors for vinyl-radical addition are close to those for methyl-radical addition.

Conclusions

The structures of the alkoxy radicals methoxy ($CH_3O·$), ethoxy ($CH_3CH_2O·$), 1-propoxy ($CH_3CH_2CH_2O·$), 2-propoxy ($(CH_3)_2CHO·$), 2-butoxy ($CH_3CH_2CH(CH_3)O·$), *tert*-butoxy ($(CH_3)_3CO·$), prop-2-en-1-oxy (CH_2=CHCH$_2$O·), and but-3-en-2-oxy (CH_2=CHCH(CH$_3$)O·), and the products of their β-scission reactions, have been determined at the B3-LYP/6-31G(d) level of theory. CBS-RAD has been used to calculate the enthalpies of formation ($\Delta_f H_{298}^{\circ}$). The predicted $\Delta_f H_{298}^{\circ}$

Fig. 2. Calculated transition structures, bond lengths in (Å), and Arrhenius activation parameters (CBS-RAD, kJ mol^{-1}) for the addition of hydrogen, methyl, ethyl, and vinyl radicals to acetaldehyde. Distances for hydrogen, methyl, and ethyl addition are by CBS-RAD–Scanmax; for vinyl group addition, the value is from B3-LYP/6-31G(d) optimization.

values agree well with the available experimental data, with a mean absolute deviation of 5.4 kJ mol^{-1}.

Transition structures (TS) for all the β-scission pathways were located at the B3-LYP/6-31G(d) level and, in most cases, at the CBS-RAD–Scanmax level. The bond being cleaved in the TS tends to be longer with B3-LYP by 0.10–0.16 Å (C—H) or 0.04–0.10 Å (C—C). At the B3-LYP geometry, the predicted B3-LYP barriers ($\Delta H_0^\ddagger$) are 13–20 kJ mol^{-1} higher than the CBS-RAD values for C-H scission, and 3–14 kJ mol^{-1} higher for C—C bond breaking. The consequence of not reoptimizing the bond being broken at the

CBS-RAD level is an underestimation of $\Delta H_0^\ddagger$ by 1.6–2.4 kJ mol^{-1} (C—H) or 0.4–1.3 kJ mol^{-1} (C—C).

Eyring ($\Delta H_0^\ddagger$, $\Delta H_{298}^\ddagger$, $\Delta G_{298}^\ddagger$) and Arrhenius (log A, E_a) activation parameters for both the forward (β-scission) and reverse (radical addition to carbonyl) pathways were calculated within the rigid rotor – harmonic oscillator model and transition-state theory. Most of the available experimental kinetic data refer to the β-scission pathway. Where direct comparison was possible, the agreement with the experimental is very good, generally within 1–5 kJ mol^{-1} for E_a, and 0.5 for log A.

The values of the barriers for either β-scission or radical addition to carbonyl are dominated by the reaction enthalpy: the barrier decreases with decreasing endothermicity (β-scission) or increasing exothermicity (radical addition). As a consequence, for example, alkyl or vinyl substituents in the alkoxy radical lower the barrier for β-scission of H·, CH$_3$·, or CH$_3$CH$_2$· groups. In addition to the enthalpy effect, the barrier depends on the ionization energy of the departing radical in the β-scission reaction (or equivalently, the adding radical in the radical additions). Smaller barriers are associated with lower ionization energies. These results are consistent with expectations based on the curve-crossing model, the smaller ionization energies allowing greater participation of charge-transfer configurations of the type radical$^+$carbonyl$^-$ in the transition structure. We find that in the transition structures, the departing radical carries a small positive charge while there is substantial charge polarization in the nascent carbonyl compound, the oxygen atom becoming negatively charged and the rest of the molecule becoming positively charged.

Regioselectivity of Meisenheimer complexation in reaction of oxygen-centred nucleophiles with picryl aryl ethers: Polar vs. SET mechanisms

Erwin Buncel, Julian M. Dust, Richard A. Manderville, and Richard M. Tarkka

Abstract: Picryl alkyl ethers react with hydroxide and methoxide ions to give regioisomeric Meisenheimer (anionic σ-) adducts; the C-3 adduct is kinetically favoured and the C-1 adduct is thermodynamically favoured (K3T1 behaviour). In the current 400 MHz NMR spectroscopic study of the reactions of two picryl aryl ethers, picryl phenyl ether (PicOPh, **1**) and picryl mesityl ether (PicOMes, **2**), the charge localized nucleophiles OH⁻ and MeO⁻ displayed the same K3 regioselectivity as found with picryl alkyl ethers; attachment at C-1 leads to S_NAr displacement of the aryloxide. In contrast, phenoxide (PhO⁻) and the sterically demanding 2,4,6-trimethylphenoxide (mesitoxide, MesO⁻) react with **1** and **2** to form the C-1 O-adduct as the product of kinetic control (i.e., K1 behaviour). These reactions were studied at low temperature (–40°C in acetonitrile-d_3:dimethoxyethane-d_{10} 1:1) and as a function of increasing temperature (–40°C to ambient). On the thermodynamic side, the C-1 PhO⁻ O-adduct of **1** is also the more stable of the possible phenoxide O-adducts; it shows T1 regioselectivity within the manifold of O-adducts (K1T1), but the C-3 C-adduct (via *para*-attack of PhO⁻) is the ultimate thermodynamic product. The C-1 O-adducts formed by MesO⁻ with **1** or **2** give way with time (or temperature increase) in favour of their C-3 regioisomers or a C-1,3-O-diadduct. Mesitoxide, therefore, displays K1T3 regioselectivity. Stereoelectronic stabilization is discussed as a factor influencing T1 regioselectivity in O-adduct formation. Frontier molecular orbital (FMO) interactions between the HOMO of the nucleophile and the LUMO of the picryl ether may play a role in the K1 preference of aryloxides. An alternative argument is presented based on a single electron (radical) transfer (SET) pathway for the aryloxide nucleophiles rather than the polar (S_NAr) pathway for hydroxide and methoxide. The SET pathway also predicts a kinetic preference for C-1, as the C-1 position is of higher spin density than C-3 in the radical anion of the picryl ether and thus should be the preferred site for coupling by the aryloxide radical.

Key words: anionic Meisenheimer adducts, regioselectivity, kinetic–thermodynamic control, FMO, stereoelectronic stabilization, single electron transfer (SET).

Résumé : Les oxydes de picryle et d'alkyle réagissent avec les ions hydroxydes et méthylates avec formation d'adduits (anioniques σ-) de Meisenheimer régioisomères; l'adduit en C-3 est favorisé d'un point de vue cinétique alors que l'adduit en C-1 est favorisé d'un point de vue thermodynamique (comportement K3T1). Dans l'étude courante, par spectroscopie RMN à 400 MHz, des réactions de deux oxydes de picryles et d'aryles, l'oxyde de picryle et de phényle (PicOPh, **1**) et l'oxyde de picryle et de mésityle (PicOMes, **2**), les nucléophiles à charge localisée, OH⁻ et MeO⁻, présentent la même régiosélectivité K3 que celle observée avec les oxydes de picryle et d'alkyle; la fixation en C-1 conduit à un déplacement S_NAr de l'aryloxyde. Par opposition, le phénolate (PhO⁻) et le 2,4,6-triméthylphénolate (mésitylate, MesO⁻) qui imposent des demandes stériques beaucoup plus importantes réagissent tous les deux avec les composés **1** et **2** pour former, comme produit de contrôle cinétique, un O-adduit en C-1 (comportement K1). On a étudié ces réactions à basse température (–40 °C, dans un mélange acétonitrile-d_3:diméthoxyéthane-d_{10} 1:1) et en fonction d'une augmentation de la température (–40 °C à la température ambiante). D'un point de vue thermodynamique, le O-adduit du PhO⁻ en C-1 du produit **1** est aussi le plus stable des O-adduits possibles pour le phénolate; il présente du régiosélectivé T1 parmi les plusieurs O-adduits (K1T1); toutefois, le C-adduit C-3 (obtenu par une attaque en *para* du

PhO⁻) est le produit thermodynamique ultime. Les O-adduits C-1 qui se forment initialement entre le MeSO⁻ et les produits **1** et **2** laissent la place, avec le temps ou une augmentation de la température, à leurs régioisomères C-3 ou à un C-1,3-O-diadduit. Le mésitylate présente donc une régiosélectivité K1T3. On discute de la stabilisation électronique comme facteur influençant la régiosélectivité T1 dans la formation des O-adduits. Les interactions des orbitales moléculaires frontières (OMF) entre l'OM haute occupée et la basse vacante de l'oxyde de picryle pourrait jouer un rôle dans la préférence K1 des aryloxydes. On présente un argument alternatif, basé sur une voie réactionnelle impliquant le transfert d'un seul (radical) électron (SET) pour les nucléophiles aryloxydes plutôt qu'une voie polaire (S$_N$Ar) pour l'hydroxyde et le méthanolate. La voie SET permet aussi de prédire une préférence cinétique pour C-1 parce que cette position possède une densité de spin plus élevée que celle en C-3 dans l'anion radical de l'oxyde de picryle et qu'elle devrait donc être le site favorisé pour le couplage avec le radical aryloxyde.

Mots clés : adduits anioniques de Meisenheimer, régiosélectivité, contrôles cinétique et thermodynamique, OMF, stabilisation stéréoélectronique, transfert d'un seul électron (SET).

Introduction

Reaction of a base (nucleophile) with an electron-deficient aromatic may give rise to diverse products, namely π-complexes (1), radical anions (2), aryl carbanions (3), and anionic σ-adducts (termed Meisenheimer complexes) (1–4). With 1-X-2,4,6-trinitrobenzenes, nucleophiles react to form Meisenheimer complexes according to an accepted general pattern of the initial formation of a C-3 adduct that gives way over time to a thermodynamically favoured C-1 adduct (5). This regioselectivity has been elaborated in a number of 1-X-2,4,6-trinitrobenzene-nucleophile reaction systems, notably with alkoxides and hydroxide as nucleophiles (5), and has been labelled K3T1 (6, 7) (cf. Fig. 1).

In a series of articles (6, 7), we have delineated a full range of regioselectivities in Meisenheimer complexation. Thus, while 2,4,6-trinitroanisole (TNA) reacts with methoxide according to the K3T1 pattern (cf. Fig. 1) (5a–d, 6b), TNA reacts with the oxygen centre of a phenoxide ion (PhO⁻) with K1T1 regioselectivity. In the latter case, a C-1 TNA·OPh⁻ adduct was the first (and only) phenoxide O-adduct detected by 400 MHz ¹H NMR spectroscopy at –40°C in acetonitrile–dimethoxyethane (MeCN-d_3:DME-d_{10} 1:1) solvent (6b). The regioisomeric C-3 TNA·OPh⁻ adduct was not observed, in accord with a previous stopped-flow UV–vis kinetic study in which the initially observed adduct was identified as the C-1 species (8). Furthermore, the structurally similar phenoxide O-adduct of 1,3,5-trinitrobenzene (i.e., TNB·OPh⁻) can be observed by ¹H NMR spectroscopy under the same conditions used in the TNA·PhO⁻ study (9a). On this basis, the regioselectivity exhibited by the TNA–PhO⁻ system was classified as K1T1, i.e., a system in which the C-1 adduct is favoured by both kinetics and thermodynamics (Fig. 1). However, the ultimate phenoxide product was the C-3 TNA·PhO(H)⁻ *para* C-bonded adduct, consistent with the ambident (O- and C-) nucleophilic nature of PhO⁻ (6b) and in agreement with results gleaned from related systems (9). The behaviour of phenoxide as a C-nucleophile corresponds to K3T3 regioselectivity wherein the C-3 C-adduct is the product of both kinetic and thermodynamic control. Our AM1 calculations on the regioisomeric adducts formed by TNA with OH⁻ and CH$_3$⁻ as prototypical O- and C-nucleophiles, respectively, confirm the thermodynamic preference for C-3 attack by carbon nucleophiles (6d). This K3T3 behaviour (Fig. 1) of C-nucleophiles is also im-

plicit in the synthetic results found in vicarious nucleophilic substitution (VNS) reactions, as documented by Makosza and co-workers (10). Finally, we have reported the results of the reaction of TNA with the bulky aryloxide nucleophile 2,4,6-trimethylphenoxide (mesitoxide, MesO⁻) (6c). In this system, attack at C-1 to yield a C-1 TNA·OMes⁻ Meisenheimer complex is kinetically favoured at –40°C, but as the NMR probe temperature was raised, the C-1 adduct rapidly declined in concentration and was supplanted by the C-3 TNA·OMes⁻ adduct, in accord with K1T3 behaviour (Fig. 1). This reactivity pattern is the inverse of the "normal" K3T1 isomerization pathway displayed by alkoxides and hydroxide.

Although a wide range of kinetic and thermodynamic factors have been advanced (4, 5, 11, 12) to account for the regioselectivity found in picryl ether – base Meisenheimer complexation, our analysis has focused primarily on thermodynamics and has highlighted the contribution made by stereoelectronic stabilization of the relevant C-1 adducts (6b–d, 7, 9a). In this approach, C-1 adducts, as acetal analogues, can be stabilized by $n \rightarrow \sigma^*$ donation from an oxygen lone pair of one RO group into the anti-bonding orbital of the C—OR bond (and vice versa); the interaction is maximized if the relevant lone pairs and C—OR fragment bonds can be arranged antiperiplanar to one another. Where stereoelectronic stabilization is negligible, the C-3 adduct may become the thermodynamic product (7).

The arguments concerning kinetic factors have either relied on assumptions made about the position of the transition state for adduct formation (5d, 6b) or have consisted of assessments of steric hindrance to attack at C-1 (F-strain) (11, 12d, 12e, 13, 14). In light of the K1T3 behaviour exhibited in the reaction of TNA with mesitoxide, a bulky nucleophile, the importance of F-strain in determining the regioselectivity of Meisenheimer complexation warrants re-examination.

The present article extends the study of picryl ether – nucleophile interactions to the picryl *aryl* ethers picryl phenyl ether (PicOPh, **1**) and picryl mesityl ether (PicOMes, **2**). The reactions of these ethers, **1** and **2**, with the aryloxide nucleophiles, phenoxide ion (PhO⁻) and mesitoxide (MesO⁻), were monitored in acetonitrile–dimethoxyethane (MeCN-d_3:DME-d_{10} 1:1 v/v) as a function of temperature (–40° to ambient), and the PicOPh–PhO⁻ system was studied in dimethyl sulfoxide (DMSO-d_6) at room temperature. Thus, the current study

Fig. 1. Qualitative comparative energy-reaction coordinate profiles for the four general patterns of regioselectivity. Barrier heights and relative stabilities are exaggerated for clarity. K3T1 describes those systems in which formation of the C-3 adduct is the product of *kinetic* control, but the C-1 adduct is the *thermodynamic* product. In the K1T1 profile the C-1 adduct is favoured by both kinetics and thermodynamics. The profile designated K3T3 represents the situation where the C-3 adduct is doubly preferred; that is by kinetics and by thermodynamics. The K1T3 profile describes the inverse behaviour from that indicated by K3T1; now the C-1 adduct is favoured kinetically but the C-3 adduct is the most stable product.
further probes the effect of steric hindrance at C-1 on the kinetics of these systems, particularly in the case of the highly hindered PicOMes reacting with the bulky MesO$^-$ anion.

The results are compared with those obtained in the related TNA–Nu$^-$ systems and are discussed with regard to possible frontier molecular orbital (FMO) interactions between the highest occupied molecular orbital (HOMO) of the aryloxide nucleophiles and the lowest unoccupied molecular orbital (LUMO) of the polynitroaromatic substrate. To model a 1-X-2,4,6-trinitrobenzene, we have carried out a semi-empirical (AM1) (15) molecular orbital calculation on TNA, and these results are included in this article. Finally, more recent suggestions that related reactions proceed through transition states having varying degrees of radical character (16) or via single electron transfer (SET) to give a radical–radical anion pair (2) are considered.

Results

Reactions of the aryloxides PhO$^-$ and MesO$^-$ with the electrophiles PicOPh, **1**, and PicOMes **2**, were monitored by 400 MHz ^{1}H NMR in acetonitrile–dimethoxyethane (MeCN-d_3-DME-d_{10} 1:1 v/v), a solvent system that has proven useful in NMR studies down to temperatures of –50°C (6*b*, 6*c*, 9*a*). Reactions of **1** and **2** with OH$^-$ and MeO$^-$ were conducted in DMSO-d_6 at ambient temperature. Spectroscopic characteristics of the species (including coupling constants, *J*, in Hz) shown in Schemes 1 and 2 are listed in Table 1. In general, resonances are located at positions farther downfield

in the MeCN-d_3:DME-d_{10} medium than in DMSO-d_6. ^{13}C NMR peak positions for some relevant σ-adducts measured in MeCN–DME and substrates measured in DMSO-d_6 are given in Table 2.

As in previous studies of the reaction of aryloxides with picryl systems (6*b*, 6*c*, 9), C-3 hydroxide adducts of **1** (i.e., **6**) and **2** (i.e., **15**) were observed also. The assignment of the signals of these adducts (**6** and **15**) was confirmed by control experiments that involved the electron-deficient substrates and tetramethylammonium hydroxide (Me$_4$NOH) in DMSO. In general, these C-3 hydroxide adducts gave way over time to picrate anion (PicO$^-$, **8**) following a pattern seen previously (6*b*, 6*c*, 9). Methoxide reacted with **1** and **2** to yield the respective C-3 adducts **9** and **17**, as the products of kinetic control; the corresponding C-1 adducts **10** and **18** were not observed. Relevant spectroscopic data for the observed adducts are given in Table 1.

Reaction of 1 with excess PhOK in MeCN–DME

To an NMR tube that contained a solution of PicOPh (**1**) in MeCN-d_3:DME-d_{10} (1:1, v/v), cooled to –50°C, was injected 1.5 equiv of a similarly cooled MeCN-d_3:DME-d_{10} solution of phenoxide ion (PhOK; final concentrations of **1**:PhOK were 0.06:0.09 M). The first ^{1}H NMR spectrum recorded at –40°C contained a singlet at δ 8.63 that is consistent with the resonance for two equivalent ring protons (H$_{3,5}$) of a C-1 O-adduct. Other signals in the spectrum are similarly attributable to the C-1 PicOPh·OPh$^-$ O-adduct, **3** (Scheme 1). The initial low-temperature spectrum was re-

Scheme 1.
markably free from signals that would arise from formation of other adducts at this temperature. Therefore, a full assignment could be made for **3**: 8.63 (2H, s, H$_{3,5}$), 7.15 (4H, m, H$_m$), 6.95 (2H, m, H$_p$), and 6.69 (2H, m, H$_o$).[4] It is pertinent to note that the signals assigned to the ring protons of the attached phenoxyl group are equivalent, indicating that the adduct is symmetrical. The ^{13}C NMR spectrum of **3** was also recorded (Table 2).

As the temperature was gradually raised, resonances of **3** began to broaden, and after ca. 1 h at 10°C a new set of doublets could be seen at 8.57 (1H, *J* = 1.9) and 6.42 (1H, *J* = 1.9). These peaks are assignable to H$_5$ and H$_3$, respectively, of the C-3 PicOPh·OH$^-$ adduct, **6** (Scheme 1), that arises from equilibration of PhO$^-$ and adventitious water present in the solvent (cf. ref. 6b, 6c, 17). The OH resonance of **6** was not observed and its state of ionization is, therefore, uncertain.

As the temperature was further raised to ambient, a singlet was noted at 8.65. Comparison with related systems (6) shows that this singlet represents the two equivalent ring protons of picrate anion, i.e., PicO$^-$, **8**. Eventually (>5 h) peaks appear that are ascribable to the C-3 *para*-bonded adduct, **5** (Scheme 1); resonances belonging to **5** are given in Table 1. The OH of the attached phenoxyl group was not observed, so the state of ionization of this OH is uncertain. Moreover, the *para* proton (H$_p$) of the C-1 phenoxyl moiety of the C-3 PicOPh·PhO(H)$^-$ adduct, **5**, was apparently obscured by resonances of free PhOH (i.e., H$_{m'}$, H$_{o'}$, H$_{p'}$).

In summary, as an O-nucleophile, PhO$^-$ reacts at C-1 of PicOPh, **1**, to yield the C-1 O-adduct, **3**, as the first phen-

oxide adduct. More significantly, at no time were peaks observed that could be attributed to a C-3 phenoxide O-adduct (i.e., **4**, Scheme 1). We have previously shown (9a) that the chemical shift of the diagnostic proton bonded to the sp^3-hybridized ring carbon in the phenoxide O-adduct of 1,3,5-trinitrobenzene, TNB·OPh$^-$, is located 0.5–0.8 ppm downfield from the signal for the comparable proton in analogous TNB·OR$^-$ adducts. On this basis, the signal for the similar sp^3-bound proton in the putative C-3 PicOPh·OPh$^-$ adduct, **4**, should appear in a region of the spectrum well separated from the signals of the C-3 hydroxide adduct, **6**, and so should be readily identifiable. In fact, no such signal was seen before the appearance of the peaks assigned to the C-1 O-adduct, **3**, nor did it appear later in response to increasing temperature. As the temperature was raised, **6** and PicO$^-$, **8**, were observed in the spectrum. Slowly, **6** gave way to **8** and free phenol, presumably through the intermediacy of a transient C-1 PicOPh·OH$^-$ adduct, **7**, that is not observed. Such adducts have been postulated in analogous reaction systems (6b–d). In accord with the ambident nature of phenoxide ion, the eventual product of phenoxide attack is the C-3 *para* C-bonded adduct, **5**.

Reaction of 1 with equimolar MesOK in MeCN–DME

Upon addition of 1 equiv of potassium 2,4,6-trimethylphenoxide ion (potassium mesitoxide, MesOK) in MeCN-d_3:DME-d_{10} to the NMR tube that contained a cooled (–50°C) solution of **1** (final concentration 0.06 M), the sample turned a deep orange colour. Interestingly, the initial ^{1}H NMR spec-

---

[4] Signals assigned to the *para*, *meta*, and *ortho* (H$_p$, H$_m$, and H$_o$) protons typically appear as somewhat broadened triplets, and triplets and doublets, respectively. The broadening found is indicative of further unresolved coupling and so throughout this article the signals ascribed to attached phenoxyl groups and to phenoxide ion or phenol will be listed as multiplets.

Scheme 2.
trum, recorded at –40°C, showed the presence of *two* σ-complexes, the C-1 PicOPh·OMes⁻ O-adduct, **11** (Scheme 2), and the C-1 PicOPh·OPh⁻ adduct, **3** (Scheme 1). At this stage, peaks of **11** were found at δ 8.69 (2H, s, H$_{3,5}$), 7.08 (2H, m, H$_m$), 6.80 (1H, m, H$_p$), 6.68 (2H, s, H$_{3',5'}$ mesitoxyl), 6.60 (2H, m, H$_o$), 2.16 (3H, s, *p*-Me, mesitoxyl), and 1.97 (6H, s, *o*-Me) and were clearly distinguishable from the signals assigned to **3** (Table 1). The resonances of **11** were predominant in this initial spectrum: **11**:**3** = 2:1.

As the temperature of the system was slowly raised to –20°C, broad resonances appeared, a set at ca. 8.60 and 6.80 and a signal at ca. 6.67; these resonances were ascribable to PicOMes, **2**, and mesitol (MesOH), respectively. Coincident with the appearance of the new signals, the resonances assigned to **11** declined in favour of those of **3.** With the increase to –10°C and the passage of time (ca. 2 h), new resonances appeared that were assigned to C-3 aryloxide O-adducts. The *sp*³-bound protons (H$_3$) of the O-adducts were doublets at 6.90 (*J* = 2.2) and 6.87 (*J* = 2.2), whereas the *sp*²-bound protons (H$_5$) appeared as a single triplet that arises from overlapping doublets centred at 8.43. The downfield shift of the H$_3$ protons (at 6.90 and 6.87) of these species relative to the shift of the corresponding proton established for the C-3 PicOPh·OH⁻ adduct, **6**, was consistent with attachment of the O-centre of an aryloxide (6, 9*a*). Although additional signals that would be expected for these C-3 aryloxide O-adducts were obscured by the peaks of **2**, **3**, **11**, and MesOH, the signals at 6.90, 6.87, and 8.43 (as well as those for **3**, **6,** and **11**) do not survive acidification (trifluoroacetic acid, TFA; 5 μL); it is a characteristic of O-adducts that they are acid labile (4*b*, 6, 9). Tentative assignment of the structures of the C-3 O-adducts corresponding to the 6.90, 6.87, and 8.43 set of signals will be made below.

Subsequent monitoring of the reaction as a function of increasing temperature (from –10 to 0°C in ca. 30 min) showed that the peaks due to **11** vanished while signals attributed to **3** and the C-3 aryloxide O-adducts remained in the spectrum. Furthermore, peaks assigned to the PicOPh·OH⁻ adduct, **6**, were joined by those of the C-3 PicOMes·OH⁻ adduct, **15** (Table 1, Scheme 2). At ambient temperature the signals attributed to **3** and the C-3 aryloxide O-adducts were no longer present; those of the OH⁻ adducts, **6** and **11**, dominated the spectrum. Peaks for **2**, MesOH, and **8** were also found and a spectrum acquired after 2 days at ambient still contained peaks for **8** and mesitol as well as PhOH.

Thus, the results suggest that in the reaction of MesO⁻ with **1**, initial attack gives the C-1 PicOPh·OMes⁻ O-adduct, **11**. Breakdown of **11** via an S$_N$Ar pathway (18–20) leads to formation of PicOMes and PhO⁻ and, therefore, to a system that contains two substrates (**1** and **2**) as well as two nucleophiles (PhO⁻ and MesO⁻). The liberated PhO⁻ ion reacts at C-1 of **1** to give **3**. As the reaction proceeds, peaks due to **11** decrease in intensity in tandem with growth of the resonances of **2**, MesOH and **3**. At no time are peaks of **1** and free PhOH observed at this early stage of the reaction.

The next observable σ-adducts appeared at –10°C and were identifiable as C-3 aryloxide O-adducts (6, 9*a*). Although the exact assignment of these adducts is tentative, the spectroscopic evidence supports the assignment of the signals to C-3-type aryloxide O-adducts. Moreoover, the C-3 adducts arise from attack of MesO⁻ on **2** and are not C-3 adducts formed by attack of either PhO⁻ or MesO⁻ on **1**. First, the previous experiment (vide supra) confirmed PhO⁻ attack at C-1 of **1** to give **3** as the only process that involves **1** and phenoxide as an O-nucleophile. Thus, none of the C-3 arylo-

xide O-adducts can arise from interaction of **1** and PhO⁻. Secondly, decomposition of the initially formed C-1 PicO-Ph·OMes⁻ adduct, **11**, releases PicOMes, **2**, which could undergo further attack by mesitoxide. Note that **2** and MesOH are both observed in spectra acquired at this temperature. Further justification for the assignments was obtained from study of the PicOMes–MesO⁻ system (vide infra). By the reasoning outlined, the peaks of the C-3 aryloxide O-adducts in the present system are ascribed to the C-3 PicOMes·OMes⁻ adduct, **12**, and the C-1,3 PicOMes·(OMes)₂²⁻ diadduct, **13**. The H₃ resonance at 6.90 (d, J = 2.2) is attributed to **12**; that of **13** appears at 6.87 (d, J = 2.2).

The final σ-adducts found in the system are the C-3 hydroxide complexes **6** and **15** that result from equilibration of PhO⁻ and MesO⁻ with residual water in the medium that, in turn, generates OH⁻. Ultimately, these too give way to picrate ion, **8**, PhOH, and MesOH.

Reaction of 2 with equimolar PhOK in MeCN–DME

The interaction of PicOMes, **2**, with PhOK in MeCN-d_3:DME-d_{10} (1:1 v/v) was found to give results similar to those for the PicOPh–MesO⁻ reaction system described above. Consequently, after the addition of equimolar PhOK in MeCN-d_3:DME-d_{10} to a solution of **2** in the same medium (final concentrations: 0.06 M), cooled to −50°C, the first spectrum (recorded at −40°C) includes resonances of the C-1 PicOMes·OPh⁻ O-adduct, **11** (Scheme 2) as well as the C-1 PicOPh·OPh⁻ O-adduct, **3** (Scheme 1). As the temperature is raised, peaks reappear for **2** and appear for MesOH, but at −10°C, signals are observed that correspond to the C-3 mesitoxide adducts, **12** and **13**. Observation of the peaks for these species validates their observation and assignment in the PicOPh–MesO⁻ reaction system.

Peaks due to **11** disappear from the spectrum at 0°C and resonances attributable to the C-3 hydroxide adducts, **6** and **15**, appear. At ambient temperature the signals for these hydroxide adducts, **6** and **15**, and for PicO⁻ were dominant, whereas the peaks of **3**, **12**, and **13** diminish. Eventually (>12 h), the spectrum obtained at room temperature consists mainly of **8**, PhOH, and MesOH, although small extraneous, unidentified signals were also present.

Reaction of 2 with equimolar MesOK in MeCN–DME

To a solution of **2**, cooled to −50°C, was added a similarly cooled solution of MesOK in MeCN-d_3:DME-d_{10} (final concentration: 0.06 M). The major peaks in the initial ¹H NMR spectrum measured at −40°C (acquired within 5 min of mixing) were identified as belonging to unmodified **2** and MesOK. However, two equivalent broad singlets were also noted at δ 8.62 and 7.17. The 8.62 resonance could correspond to the H₃,₅ protons of a C-1 MesO⁻ adduct; comparison of the chemical shift with those for the H₃,₅ protons of the related C-1 TNA·OMes⁻ adduct, **18**, (i.e., 8.62 (6c)) and the C-1 PicOPh·OPh⁻ adduct, **3** (i.e., 8.63) favours this assignment. However, in the present system the relative integrals link the 8.62 peak to the broad signal at 7.17 (i.e., 1:1 integral ratio). Moreover, peaks, albeit poorly resolved ones, are observed in the 6.5–6.8 and 1.9–2.2 ppm regions (other than those for **2** and MesOK) and are taken to represent the mesitoxyl protons of this initially formed species.

Table 2. ^{13}C NMR spectral characteristics[a] of the C-1 PicOPh phenoxide adduct, **3**, and the C-1 TNA phenoxide adduct **10**,[b] in MeCN–glyme,[c] as well as the substrates, PicOMe (TNA), PicOPh (**1**), and PicOMes (**2**) in DMSO.[d]

Combination of these observations with the kinetic preference shown by aryloxides for attack at the C-1 position of picryl alkyl ethers (6, 7) leads to assignment of the resonances at 8.62 and 7.17 to the ring protons of the C-1 PicOMes·OMes$^-$ adduct, **14** (Scheme 2). In this case, the H$_3$ and H$_5$ protons are non-equivalent as a result of steric interactions between the C-1 mesitoxy substituents and the flanking C-2,6 nitro groups. For example, if one of the C-2,6 NO$_2$ groups in **14** is twisted from the plane of the cyclohexadienate ring to relieve the proposed steric strain, then the negative charge of **14** could only be delocalized to the C-4 and one of the C-2,6 NO$_2$ groups. Thus, assuming that the C-4 and C-6 nitro groups form part of the conjugated anionic system, the C-2 nitro group and the moiety to which it is bonded would resemble an isolated nitroalkene, and H$_3$, in this example, would approximate a proton at the 2-position of a 1-nitroalkene (**14a**, Scheme 2). In this regard, it is noteworthy that the resonance for the olefinic proton at the 2-position of 1-nitrocyclohexene appears at 7.20 in DMSO-d_6 (21). Twisting of NO$_2$ groups out of the aromatic plane has been noted in numerous X-ray crystallographic studies of neutral nitroaromatic compounds that possess an alkoxy group adjacent to the nitro group (22).

As the temperature was gradually raised, the spectra obtained showed a sequential decline in the signals that represent **14** (Scheme 2). The spectrum acquired at $-30°$C (recorded ca. 30 min after the initial spectrum acquired at $-40°$C) lacked peaks of **14**; signals of **2** were notably broad. Upon further warming, peaks sharpened, and at $-10°$C the spectrum contained signals assigned to two C-3 MesO$^-$ adducts as follows: **12** at 8.44 (1H, d, J = 2.2, H$_5$) and 6.90 (1H, d, J = 2.2, H$_3$) and **13** at 8.44 (1H, d, J = 2.2, H$_5$ overlapped with H$_5$ of **12**) and 6.87 (1H, d, J = 2.2, H$_3$). Observation of signals of these Meisenheimer complexes in this system was in accord with their previous identification in the PicOPh–MesO$^-$ and PicOMes–PhO$^-$ reactions and confirmed their assignment as adducts arising from attack of MesO$^-$ on PicOMes in all three studies.

At ambient temperature the peaks of **12** and **13** are replaced by those due to the C-3 PicOMes·OH$^-$ adduct, **15** (Scheme 2). After monitoring the reaction for 12 h at room temperature, the singlet for **8** at 8.65 is also seen.

Discussion

Reaction pathways and classification of regioselectivity

The interactions of the series of O-nucleophiles, phenoxide (PhO$^-$), 2,4,6-trimethylphenoxide (mesitoxide, MesO$^-$), hydroxide (OH$^-$), and methoxide (MeO$^-$) ions with the picryl aryl ethers PicOPh, **1**, and PicOMes, **2**, provide interesting insights into the variable regioselectivity of Meisenheimer complex formation. On the basis of comparison of the pK_a values of the parent phenols (23) in water and with the assumption that nucleophilicity follows basicity (24), MesO$^-$ as the more basic aryloxide of the two would be expected to be a more reactive nucleophile than PhO$^-$ (i.e., pK_a (PhOH) = 9.95; pK_a (MesOH) = 10.88, see also ref. 25). However, PhO$^-$ may act as an ambient (C- and O-) nucleophile, whereas MesO$^-$ is restricted to O-attack. The $ortho$-Me groups in MesO$^-$ make it a sterically hindered nucleophile. This steric bulk would introduce further F-strain to attack at C-1, which would partly offset the higher nucleophilicity of MesO$^-$ compared with PhO$^-$. Therefore, the two aryloxides could display similar kinetic activity overall. Conversely, the steric factor may also render the resultant C-1 MesO$^-$ adduct significantly less stable than its C-1 PhO$^-$ oxygen-centred counterpart. Consequently, these nucleophiles would show different thermodynamic preferences while displaying the same kinetic preference for C-1 attachment.

The ambient nature of PhO$^-$ also results in the formation and observation of C-centred adducts as the final, stable Meisenheimer complexes observed in the reaction systems involving phenoxide as nucleophile. In each case, C-adducts were identified as the C-3 regioisomers bonded via the $para$ site of phenoxide.

In all of the aryloxide systems examined, hydroxide adducts also formed during the period of study as a result of reaction with adventitious H$_2$O in the solvent systems. The assignments of these adducts was confirmed in separate control experiments that included reaction of **1** and **2** with tetramethylammonium hydroxide in DMSO and with potassium methoxide (in MeOH) in DMSO. As in other studies of picryl ether – alkoxide and picryl ether – hydroxide reactions (5), these localized O-nucleophiles reacted according to K3 classification in which attack at C-3 is kinetically pre-

ferred. On the other hand, the C-1 O-adducts **7** and (or) **10** (Scheme 1) and **16** and (or) **18** (Scheme 2) are not detected and represent metastable intermediates in the S_NAr displacement reaction to yield picrate (**8**), TNA, and phenol or mesitol.

The situation in the picryl aryl ether – methoxide systems is particularly informative. Although the C-1 adducts PicOPh·OMe⁻ (**10**) and PicOMes·OMe⁻ (**18**) are observed in the TNA–PhO⁻ (**6b**) and TNA–MesO⁻ (**6c**) systems, respectively, these species are not observed in the present studies where the corresponding picryl aryl ethers react with methoxide to yield the C-3 adducts **9** and **17** as the only observable Meisenheimer complexes. It is important to note that in the TNA systems, **10** and **18** are the first and only adducts detected at –40°C in 1:1 MeCN–DME. Both adducts decompose to yield the C-3 hydroxide adduct of TNA via the thermodynamically unfavourable equilibrium between the aryloxide and adventitious water in the MeCN–DME medium (**6b–6d, 9a**). This observation suggests that the C-3 TNA·OH⁻ adduct is more stable than **10** and **18** and by extension the C-3 TNA·OMe⁻ adduct should also be more stable. These arguments suggest strongly that the inability to detect **10** and **18** in reactions of **1** and **2** with MeO⁻ stems from the fact that they are not as stable as the C-3 adducts **9** and **17**, respectively. The very slow rate of conversion of the C-3 PicOPh·OMe⁻ adduct **9** and C-3 PicOMes·OMe⁻ adduct **17** into the S_NAr products of TNA, PhO⁻, MesO⁻, and picrate (**8**) is consistent with this hypothesis. These arguments are summarized in the reaction coordinate diagram depicted in Fig. 2 for the reaction of PicOPh (**1**) with MeO⁻. Here the C-1 O-adduct **10** is shown to be less stable than the C-3 adduct **9**. However, the S_NAr product from decomposition of **10** (TNA, PhO⁻, and eventually picrate (**8**)) are the final products formed following irreversible processes. *Thus, even though the products from C-1 attack are thermodynamically favoured, the reactions of **1** and **2** with methoxide (and by extension hydroxide) can be designated as K3T3 on the basis of the kinetic and thermodynamic preferences in the initial reactions of **1** and **2** with the alkoxide (hydroxide) nucleophiles.*

Focusing on the aryloxide systems, PicOPh(**1**)–PhO⁻ and PicOMes(**2**)–MesO⁻ are regarded as symmetrical systems, as the nucleophile and leaving group in the S_NAr process are the same; conversely, PicOPh(**1**)–MesO⁻ and PicOMes(**2**)–PhO⁻ are regarded as nonsymmetric systems. In the symmetrical PicOPh(**1**)–PhO⁻ system, it is clear that reaction of PhO⁻ with **1** yields the C-1 PicOPh·OPh⁻ adduct, **3**, as the first observable phenoxide O-adduct (at –40°C). No C-3 phenoxide O-adduct (i.e., **4**, Scheme 1) is detected either prior to observation of **3** or later in the reaction. In our previous study of the TNA–PhO⁻ system we were able to demonstrate that a similar observation at low temperature indicated K1T1 regioselectivity (Fig. 1) in which formation of the corresponding C-1 TNA·OPh⁻ Meisenheimer complex was favoured by both kinetics and thermodynamics (**6b**). However, the TNA–PhO⁻ system had been previously examined by fast kinetic techniques that supported the assignment of the first formed O-adduct to the C-1 TNA·OPh⁻ species (8). Further, it had been established that the related TNB·OPh⁻ adduct could be identified and fully characterized by ¹H NMR spectroscopy under the same experimental conditions

Fig. 2. Qualitative reaction coordinate diagram for reaction of PicOPh (**1**) with MeO⁻.
(**9a**). Since the TNB·OPh⁻ O-adduct is a reasonable model for a hypothetical C-3 TNA·OPh⁻ O-complex, it follows that any C-3 phenoxide O-adduct would have been observed if it had formed. It is, therefore, important in following this train of logic to note that the TNB·OPh⁻ adduct is also a structural analogue of the C-3 PicOPh·OPh⁻ Meisenheimer complex, **4**, and that **4** would be expected to be observed if it formed during the course of the reaction. *Thus, in the symmetrical PicOPh–PhO⁻ system, PhO⁻ (as an O-nucleophile) follows K1T1 regioselectivity.*

The next observable species, as a function of increasing temperature, is **6**, the C-3 PicOPh·OH⁻ complex. The necessary hydroxide is formed in low concentration via the thermodynamically unfavourable equilibrium between PhO⁻ and adventitious water in the MeCN–DME medium (**6b–d, 9a**). The timing of the appearance of the hydroxide adduct in these systems does not parallel the nucleophilicity of OH⁻ relative to PhO⁻ because of the expected significant difference in concentration of the two nucleophiles in these reaction systems. As the reaction proceeds, PicO⁻ (picrate anion, **8**) and PhOH appear, presumably as decomposition products that arise from the transient C-1 PicOPh·OH⁻ adduct, **7** (Scheme 1), whose existence has been postulated in a number of related systems (**6b–6d**).

The ultimate product of thermodynamic control is the C-3 *para*-bonded C-adduct, **5**. Formation of this C-3 PicOPh·PhO(H)⁻ Meisenheimer complex further illustrates the ambident (O- and C-) nucleophilic nature of phenoxide; compound **5** is formed with effective irreversibility. It is apparent that this C-3 C-adduct is the product of kinetic preference for C-attack at the 3-position. AM1 calculations (**6d**) suggest that the C-3 C-adduct is also the product of thermodynamic control. The thermodynamic preference for C-3 attack by carbon nucleophiles is also implicit in the reaction scheme of the VNS reaction (10). *Thus, in the PicOPh–PhO⁻ system, PhO⁻ (as a C-nucleophile) follows K3T3 regioselectivity.*

In the nonsymmetric systems (PicOPh(**1**)–MesO⁻ and PicOMes(**2**)–PhO⁻), reaction of **1** with MesO⁻ forms the C-1 PicOPh·OMes⁻ Meisenheimer complex, **11**, as the kinetically favoured species (Scheme 2). Although **11** is the dominant adduct observed in the first ¹H NMR spectrum acquired at –40°C, significant amounts of the C-1 PicOPh·OPh⁻ adduct, **3**, were also present. This observation im-

plied that **11** broke down to yield low concentrations of **2** and free PhO⁻, which could then attack **1** to yield **3**. In this sense, two nucleophiles (MesO⁻ and PhO⁻) and two substrates (**1** and **2**) must be simultaneously present here and, by extension, in the other nonsymmetric PicOMes(**2**)–PhO⁻ reaction system.

Importantly, the initially formed C-1 O-adducts of **1** and **2** eventually give way to the C-3 mesitoxide O-centred adducts C-3 PicOMes·OMes⁻, **12**, and the C-3 diadduct PicO-Mes·(OMes)$_2$²⁻, **13**. The assignment of the structures of **12** and **13** as progeny of **2** was confirmed by the separate study of the symmetrical PicOMes(**2**)–MesO⁻ system. Here, the initially formed C-1 PicOMes·OMes⁻ adduct, **14**, decomposes in favour of the C-3 species, **12** and **13**. *Thus, the complexity of the nonsymmetric systems (PicOPh–MesO⁻ and PicOMes–PhO⁻) can render only a tentative classification as K1T3 (Fig. 1); however, as noted above, the simpler symmetrical PicOMes–MesO⁻ system can be definitively classified as following K1T3 regioselectivity.*

Stereoelectronic stabilization of the C-1 adducts

Of the factors that stabilize the respective C-1 picryl ether O-adducts, stereoelectronic $n \rightarrow \sigma^*$ interactions have emerged from our analysis of the TNA–PhO⁻ and TNA–MesO⁻ systems as an important mechanism of stabilization of these adducts (6b–d, 7). In brief, full $n \rightarrow \sigma^*$ stabilization is possible only when one O—R sigma bond is aligned antiperiplanar to one of the nonbonding lone pairs of the other C(1)-OR acetal-like group and vice versa (26), i.e., a "doubly antiperiplanar" conformation. We previously argued that in the C-1 TNA·OPh⁻ adduct (i.e., **10**), rotameric forms that would permit single $n \rightarrow \sigma^*$ interactions would be significantly populated in solution. Thus, as depicted in Fig. 3, Fig. 3a, which represents the most stable rotamer of **10**, will partake in this stereoelectronic stabilization through the antiperiplanar configuration of orbitals and consequently, adduct **10** is more stable than its C-3 counterpart (6b). However, from inspection of molecular models (Fieser or Darling) and on the basis of downfield ^{13}C chemical shifts (6c) that suggested puckering of the cyclohexadienate ring of the TNA⁻ moiety, it became apparent that the rotamer shown in Fig. 3b was preferred for the mesitoxide C-1 adduct of TNA, even though it does not permit stereoelectronic stabilization (6c, 7). Consequently, the C-1 TNA·OMes⁻ adduct is not as stable as its C-3 analogue (6c).

A further factor impinges on the degree of $n \rightarrow \sigma^*$ stabilization provided to a given C-1 adduct that is geminally disubstituted by electronegative groups. Even if suitable doubly antiperiplanar conformers are readily accessible through rotation and even if such forms would be expected to be populated at a given temperature, the efficacy of the $n \rightarrow \sigma^*$ stabilization will depend on the relative energies of the two σ^* fragment orbitals. Thus, n donation from OPh in adduct **10** to the σ^* orbital of the OCH$_3$ fragment may be more or less effective than n donation from OCH$_3$ to the σ^* orbital of OPh. In general then, unsymmetrical C-1 adducts should exhibit less stereoelectronic stabilization than their symmetrical counterparts regardless of whether their most favourable rotameric forms are accessible or not (7, 26, 27). Consequently, the C-1 PicOPh·OMe⁻ adduct, **10**, the C-1 PicO-Mes·OMe⁻ adduct, **18**, the C-1 PicOMes·OPh⁻ adduct, **11**,

Fig. 3. (*a*) Illustration of the stereoelectronic stabilization of the C-1 TNA·OPh⁻ adduct **10** through antiperiplanar interaction between the lone pair on the methoxy oxygen and the C—OPh bond; (*b*) Illustration of the TNA·OMes⁻ adduct, where stereoelectronic stabilization as in (*a*) is not possible; (*c*) Illustration of the C-1 PicOPh·OPh⁻ adduct **3** where, as in (*a*), stereoelectronic stabilization is possible; (*d*) Illustration of the C-1 PicOMes·OMes⁻ adduct **14** where, as in (*b*), stereoelectronic stabilization is not possible.
and the C-1 hydroxide adducts, **7** and **16**, would all be expected to partake of less stereoelectronic stabilization than their symmetrical analogues. This factor, no doubt, partly accounts for the inability to observe the hydroxide adducts, for example.

Focusing on the symmetrical aryloxide systems (PicOPh(**1**)–PhO⁻ and PicOMes(**2**)–MesO⁻), whose regioselectivity could be clearly defined, it would be expected that the C-1 PicOPh·OPh⁻ adduct, **3**, if it could achieve suitable rotameric forms that would permit $n \rightarrow \sigma^*$ donation, would be stabilized relative to its C-3 counterpart, **4**. Therefore, the PicOPh–PhO⁻ system would be expected to display thermodynamic preference for formation of the C-1 adduct, i.e., T1 in the observed K1T1 regioselectivity, and **4** would not be detected. Relating the C-1 PicOPh·OPh⁻ adduct, **3**, to its TNA analogue (**10**, Fig. 3a), inspection of molecular models (Fieser or Darling) predicts that the rotamer represented in Fig. 3c would be the most stable for **3**. This configuration would be stabilized by $n \rightarrow \sigma^*$ donation, and consequently **3** would be more stable than its C-3 analogue **4**. These expectations are borne out by the observation of **3** as the sole O-adduct in this system.

For the PicOMes(**2**)–MesO⁻ system, the rotamer represented in Fig. 3d is favoured for the C-1 PicOMes·OMes⁻ adduct, **14**, on inspection of molecular models. This adduct is even more sterically congested than its TNA analogue (Fig. 3b), and **14** will be unable to derive any stabilization from $n \rightarrow \sigma^*$ donation. In fact, the non-equivalence of the 2,4,6-trinitrocyclohexadienate ring protons of **14** showed that to accommodate the bulky mesitoxyl groups at C-1, the adduct must sacrifice delocalization of negative charge into one of the *ortho* nitro groups as indicated in structure **14a**.

The C-1 PicOMes·OMes⁻ adduct (**14**) has a relatively short lifetime even at low temperatures (i.e., **14** is no longer present in the spectrum taken at –30°C, a temperature at which the analogous C-1 PicOPh·OPh⁻ adduct (**3**) is the only adduct seen in the PicOPh–PhO⁻ system). *The lack of stereoelectronic stabilization and the consequent instability of 14 distinguishes the PicOMes–MesO⁻ system that follows K1T3 regioselectivity from the PicOPh–PhO⁻ system that exhibits K1T1 behaviour.*

Molecular orbital approaches to the kinetic preferences

Frontier molecular orbital analysis

An important question arises from the above considerations. If the PicOMes·OMes⁻ adduct, **14**, is inherently so unstable, why does mesitoxide attack at C-1 occur at all? Moreover, given the steric bulk of the mesitoxide nucleophile, why is C-1 attack by MesO⁻, particularly on the congested C-1 centre in PicOMes, **2**, favoured kinetically?

Molecular orbital theory, and, notably, the frontier molecular orbital (FMO) approach (28, 29), have been invoked to rationalize the regioselectivity in aromatic substitution reactions. As applied to the current systems, the FMO treatment holds that the preferred sites of attack will be those that permit maximum orbital overlap between the incoming (donor) nucleophile and the nitroaromatic (acceptor) substrate. In turn, this implies that the regioselectivity will be determined by the magnitude of the lowest unoccupied molecular orbital (LUMO) lobe at each ring carbon, as indicated by the orbital coefficients at each site, for a given nitroaromatic substrate.

Given the similarity in regioselectivity found for PicOPh, **1**, and PicOMes, **2**, in the current study and the behaviour of TNA with the same nucleophiles, namely PhO⁻ (**6b**), MesO⁻ (**6c**), and MeO⁻ and OH⁻ (**6b**, **6c**, **5a**, **5b**), TNA would appear to be an acceptable general model for all picryl ethers. In this regard, we have undertaken AM1 calculations on TNA (and some related compounds (**6d**)). The two degenerate LUMOs of 1,3,5-trinitrobenzene become split upon introduction of the C-1 methoxyl group to form TNA. The AM1 calculated LUMO and superjacent unoccupied molecular orbital (SUMO) are illustrated in Fig. 4. The energy of the LUMO is –2.50 eV according to the AM1 calculation, while the SUMO is higher in energy at –2.39 eV (a difference of 0.11 eV or 2.5 kcal mol⁻¹).

Examination of the LUMO (Fig. 4) shows that C-1 is the site with the largest orbital coefficient. Interestingly, C-4, which bears a nitro group, is the site with the second highest orbital coefficient. The regioselectivity found should, in the FMO treatment, depend also on the energy of the highest occupied molecular orbital (HOMO) of the attacking nucleophile. The most favourable interaction will then be between nucleophile HOMO and substrate LUMO, when these are similar in energy.

Estimates of the HOMO energies of some of the anions have been made by Pearson (30) using the approximation that the electron affinity of the corresponding radicals (i.e., PhO•, OH•) represents the ionization potential (IP) of the anions that, according to Koopmans' theorem (31), is taken to be equal to the negative value of the HOMO energies. Therefore, the HOMO energy for PhO⁻ and for OH⁻ is estimated to be –2.35 and ca. –1.83 eV, respectively.

On the basis of the energetics, phenoxide (and, by extension, mesitoxide and other nucleophiles with relatively low-lying HOMO energies) may interact most strongly with the LUMO of TNA and, consequently, attack C-1, the site of highest orbital coefficient, preferentially. Conversely, hydroxide and methoxide may interact most strongly with the SUMO of TNA, which has its highest orbital coefficients at C-3 and C-5. Hence, aryloxides would show K1 behaviour while alkoxides and (or) hydroxide display K3 behaviour. However, such an analysis attributes significant changes in regioselectivity to relatively small energy differences; the energy gap between LUMO and SUMO is not large, and in fact, the HOMO of aryloxide nucleophiles would be expected to interact both with the LUMO and SUMO.

An alternative to the FMO approach is the configuration mixing model that is considered in the next section.

Configuration mixing model: Polar vs. SET pathways

The configuration mixing model advanced by Shaik, Pross, and Hoz in a series of articles (32) and reviews (16) defines the full reaction profile for an organic reaction by assuming, in general, that transition states possess varying proportions of covalent-bonding and radical character. This model provides a mechanistic spectrum between a single electron transfer (SET) pathway and a polar one, where the polar process involves synchronous electron shift and bond formation through a radical coupling pathway. In the SET route, SET precedes bond formation. Thus, which particular pathway is followed in any given reaction depends on the feasibility of coupling of the two spin-paired electrons (bond formation) following the electron shift. Factors governing SET vs. polar pathways include effects of donor–acceptor ability, steric interactions, the donor–acceptor bond strength, and radical delocalization (16b). Taking these factors into consideration allows assessment of which donor–acceptor pair is likely to follow the SET pathway.

In the present system, single electron transfer from the nucleophile to the picryl aryl ether would produce the radical anion of the picryl aryl ether and the requisite radical of the nucleophile. Change in nucleophile from an alkoxide-HO⁻ to an aryloxide may cause a shift from a polar to a SET pathway. Electrochemical measurements in acetonitrile show that the one-electron half-peak oxidation potential ($E_{1/2}$) for the conversion of phenoxide into the phenoxyl radical is ~0.30 V vs. NHE. The corresponding value for HO⁻ is ~0.6 V (33). The lower oxidation potential of phenoxide indicates that the phenoxyl radical is more stable than the hydroxyl radical as a consequence of the stabilizing effect exerted by the neighbouring aromatic ring on the radical centre. Further, since methyl substituents on a benzene ring are known to impart further stability to a benzylic (and presumably to an analogous aryloxide) radical, mesitoxyl radical would be expected to be more stable than phenoxyl radical and, therefore, to form even more readily (34, 35). Clearly the SET donor ability of the aryloxide is superior to that of alkoxides-HO⁻. In terms of steric interactions, it is equally clear that mesitoxide is a more sterically hindered nucleophile than methoxide-HO⁻. Steric hindrance favours the SET pathway since the polar pathway is energetically favourable when the reacting species can approach each other to within bonding distance. Steric repulsions will cancel en-

Fig. 4. Orbital coefficients (p_z), according to a semi-empirical calculation (AM1), for the lowest unoccupied molecular orbital (LUMO) and for the superjascent unoccupied molecular orbital (SUMO) of 2,4,6-trinitroanisole (TNA), a model for picryl ethers, generally. (The p_x and p_y coefficients are negligibly small). The LUMO, which is calculated to be lower in energy (–2.50 eV) than the SUMO (–2.39 eV), has its largest ring orbital coefficient at C-1 (i.e., –0.600), whereas the largest ring orbital coefficients in the SUMO are located at C-3 and C-5 (0.512 and –0.529, respectively).

LUMO   **SUMO**
ergy lowering because of bonding changes in the transition state, thus favouring the SET pathway, as SET processes take place at distances significantly greater than those at which incipient bonding takes place (16*b*). Furthermore, alkoxides and HO⁻ form strong bonds to give stable Meisenheimer complexes and generate localized radicals. These factors favour the polar pathway. In contrast, the aryloxides generate relatively unstable O-adducts that are transient in DMSO at room temperature (8, 9*a*) and delocalization of the aryloxide radical inhibits bond formation through radical coupling. These factors favour the SET pathway.

Shown in Fig. 5 is a schematic illustrating the relationship between the polar and SET reaction pathways (16*b*) for the present picryl aryl ether – nucleophile systems. The reactants are in the lower left corner where phenoxide and mesitoxide are represented as ArO⁻. The polar process is indicated by the diagonal arrow, where both electron transfer and bond formation are synchronous.

The SET pathway depicted in Fig. 5 involves first electron transfer to generate the picryl aryl ether radical anion and the aryloxide radical (ArO⁻) shown in the upper left corner. The second step involves bond formation. Now the regioselectivity (C-1 or C-3) of Meisenheimer complex formation would be controlled by the spin density at the C-1 or C-3 positions of the radical anion of the picryl aryl ether, an intermediate on the reaction pathway. The position of higher spin density would be expected to be the site where radical coupling will be most favoured. Calculation of the spin density of the radical anion of TNA, the model for picryl ethers, using the AM1 method shows that C-1 is the site of highest spin density. Thus, subsequent radical combination to form the Meisenheimer complex would be expected to occur at C-1.

The configuration mixing model provides a rationale for the regioselectivity observed in reactions of picryl ethers with O-centred nucleophiles. The regioselectivity depends on the degree of concertedness of electron shift and bond formation. When electron shift and bond formation are concerted, C-3 attachment is kinetically favoured because of steric interactions at C-1. However, if the electron shift precedes bond formation, then the spin density of the picryl ether radical anion dictates C-1 attachment even though C-1 is clearly the more sterically hindered site.

In summary, on the basis of the above argument it can be concluded that *hydroxide and methoxide follow the polar (S$_N$Ar) pathway; this will favour kinetically C-3 attachment due to F-strain at C-1. However, phenoxide and mesitoxide follow the SET pathway. In these cases, C-1 attachment is favoured kinetically due to the higher C-1 spin density in the radical anion of the picryl ether.*

Conclusions

The present results on the course of the reactions between picryl phenyl ether (PicOPh, **1**) and picryl mesityl ether (PicOMes, **2**) with the oxygen-nucleophiles, phenoxide, mesitoxide, hydroxide, and methoxide allow us to make the following conclusions.

The reactions of HO⁻ and MeO⁻ with **1** and **2** carried out in DMSO-d_6 at ambient temperature show K3 behaviour, as documented in numerous picryl ether – alkoxide systems (5*a–d*). In contrast, phenoxide and mesitoxide display kinetic preference for C-1 attachment, i.e., K1 behaviour. This observation is analogous to the reactivity of these aryloxide nucleophiles towards 2,4,6-trinitroanisole (6*b*, 6*c*), and now appears to be a general trend for the reactions of aryloxide nucleophiles with picryl ethers. For the reaction of phenoxide with **1**, the C-1 O-adduct is also thermodynamically favoured for phenoxide acting as an O-nucleophile. Stereoelectronic stabilization of the C-1 PicOPh·OPh⁻ adduct through $n \rightarrow \sigma^*$ donation confers thermodynamic preference on this C-1 adduct relative to its C-3 oxygen-centred regioisomer. With mesitoxide ion, the C-1 adducts of both substrates are less stable than their C-3 counterparts. In these cases the steric congestion in the C-1 adducts associated with the presence of the *ortho* methyl groups of mesitoxyl moiety precludes significant stereoelectronic stabilization. Now the C-3 adducts of mesitoxide are more stable and the

Fig. 5. Schematic of a potential energy surface diagram illustrating the relationship between polar and SET reaction pathways for reaction of **1** and (or) **2** with aryoxide (ArO⁻) nucleophiles to give the C-1 Meisenheimer adducts.
initially formed C-1 adducts decline in favour of their C-3 regioisomers.

Although steric inhibition of stereoelectronic stabilization can account for the changeover in adduct stability (i.e., C-1 PhO⁻ adduct of **1** are more stable than its C-3 counterpart, whereas the C-1 MesO⁻ adducts of **1** and **2** are less stable than their C-3 isomers), there is still kinetic preference to formation of the C-1 adducts of **1** and **2** even when the attacking nucleophile is the bulky mesitoxide ion. Frontier molecular orbital considerations suggest that all nucleophiles would preferentially attack the C-1 site of picryl ethers, based on AM1 calculations of 2,4,6-trinitroanisole (TNA), as a general model for picryl ethers. An alternative explanation, which we propose, is that the reactions involving the aryloxides do not follow the polar S_NAr pathway, but rather proceed according to the SET pathway outlined in Fig 5.

Experimental

Materials and methods

2,4,6-Trinitrophenyl phenyl ether (PicOPh,**1**) was prepared from picryl chloride and potassium phenoxide in ethanol as described by Dyall (36), mp 154–155°C (lit. (36) value mp 153–154°C). 2,4,6-Trinitrophenyl-2′,4′,6′-trimethylphenyl ether (PicOMes, **2**) was prepared from picryl chloride and ethanolic potassium mesitoxide, mp. 157–158°C (lit. (37) value mp 154–155°C). Picryl chloride used in these preparations resulted from the reaction of pyridinium picrate with $POCl_3$ (38), mp. 80–81°C, after recrystallization from CCl_4 (lit. (39) value mp 81°C). Acetonitrile-d_3 and dimethoxyethane-d_{10} (Merck) were dried by sequential treatment with 4 Å molecular sieves as advocated by Burfield et al. (17). 1,4-Dibromobenzene (DBB; Eastman) was recrystallized from ethanol and dried in vacuo prior to use as an internal integration standard in the NMR experiments. Potassium phenoxide and mesitoxide were prepared from the re-

spective phenol and standard MeOK–MeOH in an N_2-filled glovebox as described previously (6b, 6c). 2,4,6-Trimethylphenol (mesitol; Aldrich) was recrystallized from petroleum ether and dried in vacuo before use. Trifluoroacetic acid (TFA; Aldrich) and tetramethylammonium hydroxide (Me$_4$NOH, 25 wt % solution in water; Aldrich) were used without further purification. Melting points were measured on a Thomas Hoover capillary apparatus and are not corrected.

NMR experiments: General

NMR experiments were carried out using a Bruker AM-400 specrometer (¹H: 400.1 MHz, ¹³C: 100.0 MHz) in MeCN-d_3:DME-d_{10} (1:1 v/v) or in dried DMSO-d_6. In the mixed solvent system, CD$_2$HCN served as chemical shift reference (¹H: δ = 1.93 ppm) and lock signal, whereas resonances found in spectra determined in DMSO were referenced to the peak for residual CD$_3$SOCD$_2$-H in the solvent (¹H: δ = 2.50 ppm). Chemical shifts are given in parts per million (ppm) and coupling constants (J) are reported in hertz. Wilmad PP-507 NMR tubes (5 mm) were used in all experiments. All stock solutions were prepared in the appropriate solvents under a nitrogen atmosphere. NMR tubes were capped with rubber septa and swept out with dry N_2 prior to injection of the reactants into the NMR tube with a gas-tight syringe.

Low temperature NMR experiments in MeCN–DME (1:1)

Typically, a weighed quantity of the aryloxide was dissolved in a 1:1 (v/v) mixture of MeCN-d_3:DME-d_{10} under a nitrogen atmosphere such that 300 µL of this stock solution would yield 1–1.5 equiv of the aryloxide relative to the substrate. An aliquot of the stock solution (300 µL) was injected into the NMR tube, and the solution frozen by immersion in liquid N_2. To the frozen solution, 1 equiv of PicOPh or

PicOMes was injected by a gas-tight syringe (200 μL; final concentrations 0.06–0.09 M). The final mixture was placed in a dry ice – acetone bath that had been maintained at –50°C. The contents of the tube were allowed to mingle at this temperature. The tube was inverted several times to promote mixing and was then immersed again in liquid N$_2$. The tube was transferred to the spectrometer probe (at –40°C), the instrument was tuned as previously described (6b), and spectra were recorded at various intervals. A standard collection of FID would be made at 3, 5, 7, and 9 min and then as warranted by observed changes in the spectrum. Simultaneously, the temperature of the probe was gradually raised.

Room temperature experiments in DMSO

A solution of the substrate was prepared in DMSO-d_6 under an N$_2$ atmosphere. An aliquot of this solution was transferred via syringe into an NMR tube and an initial spectrum run to ascertain the purity of the substrate. To this solution 1 equiv of nucleophile was injected through the septum and spectra were recorded as rapidly as possible initially and then at longer times as the reaction proceeded. 1,4-Dibromobenzene was present in the solution of the substrate and in the NMR tube as an internal integration standard.

Molecular orbital calculations

Semi-empirical calculations were performed using AMPAC version 2.10 of AM1 (15a) on an IBM 3081 computer. The structure of 2,4,6-trinitroanisole (TNA) was calculated using the PRECISE option within the restricted Hartree–Fock (RHF; closed shell) scheme. The TNA structure was fully optimized following a Fletcher–Powell minimization (40) to a self-consistent field (SCF) that satisfied Herbert's test. The final structure was characterized as a local minimum when no negative force constants were obtained using the FORCE option.

Singlet-oxygen reactions sensitized on solid surfaces of lignin or titanium dioxide: Product studies from hindered secondary amines and from lipid peroxidation

L.R.C. Barclay, M.-C. Basque, and M.R. Vinqvist

Abstract: Product analyses and kinetic methods were used to determine the role of singlet oxygen in lignin-catalyzed oxidations of organic substrates. Method **A** used the ESR analysis of nitroxide radicals formed by singlet oxygen (Type II) on 2,2,6,6-tetramethylpiperidine, **1**, or tetramethylpiperidone, **2**. Method **B** used HPLC analysis of the 9- and 13-linoleate chain hydroperoxides formed on oxidation of methyl linoleate to distinguish free-radical peroxidation (Type I) from singlet-oxygen oxidation (Type II) on the basis of different *cis,trans* (kinetic) to *trans,trans* (thermodynamic) product ratios. Applications of method **A** to solid dispersions of lignin or titanium dioxide (TiO_2, a known singlet-oxygen sensitizer) indicated singlet-oxygen reactions. In addition to the nitroxide triplet, irradiation of lignin produces a persistent broad signal in the solid attributed to phenoxyl radicals. Benzophenone and 3,5-di-*tert*-butyl-*ortho*-benzoquinone, **5**, coated on silica gel were used as models to compare the effects of irradiating such compounds on the products and kinetics of methyl linoleate oxidation. Benzophenone acted as an initiator, giving free-radical peroxidation, whereas **5** or lignin coated with methyl linoleate acted as singlet-oxygen sensitizers, according to both product studies (method **B**) and the kinetic order in oxygen consumption during UV photolysis. Photolysis of phase-separated sensitizer (TiO_2 or lignin) and substrate (methyl linoleate) resulted in typical singlet-oxygen products. These results indicate that singlet oxygen plays a significant role in the photo-yellowing of high-lignin-content wood pulps.

Key words: lignin, singlet oxygen, mechanism, peroxidation, products.

Résumé : Faisant appel à des analyses de produit et à des méthodes cinétiques, on a déterminer le rôle de l'oxygène singulet dans les réactions d'oxydation catalysées par la lignine de substrats organiques. La méthode d'analyse **A** utilise la RPE des radicaux nitroxydes formés par l'action de l'oxygène singulet (Type II) sur la 2,2,6,6-tétraméthyl-pipéridine (**1**) ou la tétraméthylpipéridone (**2**). La méthode **B** est basée sur l'analyse par CLHP des hydroperoxydes des chaînes 9- et 13-linoléates qui se forment par oxydation du linoléate de méthyle; sur la base des divers rapports de produits (*cis*, *trans* (cinétique)) par rapport à (*trans*, *trans* (thermodynamique)), elle permet de distinguer entre la per-oxydation radicalaire (Type I) et l'oxydation à l'aide d'oxygène singulet (Type II). Les applications de la méthode **A** à des dispersions solides de lignine ou de dioxyde de titane, TiO_2 bien connu comme sensibilisateur d'oxygène singulet, indiquent qu'elles se produisent par des réactions d'oxygène singulet. En plus du triplet nitroxyde, l'irradiation de la lignine produit dans le solide un large signal persistant qui est attribué aux radicaux phénoxyles. Des études modèles ont permis de comparer les effets sur la nature des produits et sur la cinétique de l'oxydation du linoléate de méthyle de l'irradiation de couches sur du gel de silice avec de benzophénone ou avec de la 3,5-di-*tert*-butyl-*ortho*-benzoquinone (**5**). La benzophénone agit comme initiateur d'une peroxydation radicalaire alors que, sur la base des études de produits (méthode **B**) et de l'ordre cinétique de la consommation d'oxygène au cours de la photolyse UV, le composé **5** et la lignine recouverte d'une couche de linoléate de méthyle agissent comme sensibilisateurs d'oxygène. La photolyse de photosensibilisateurs, TiO_2 ou lignine, en phases séparées du substrat, le linoléate de méthyle, conduisent à la formation des produits typiques de l'action d'oxygène singulet. Ces résultats indiquent que l'oxygène singulet joue un rôle significatif dans le photojaunissement des pulpes de bois contenant de fortes proportions de lignine.

Mots clés : lignine, oxygène singulet, mécanisme, peroxydation, produits.

Introduction

Products from Canada's wood-pulping industry are the country's major export. The use of thermal mechanical pulps has provided more than 50% of the fibre for Canadian paper products (1). The high lignin content of these products has resulted in undesirable oxidative photo-yellowing, which can reduce the value of these products. Consequently, the inhibition of such yellowing is of major interest. The excited state of oxygen, singlet oxygen $^1\Delta_g$, is known to rapidly oxidize a wide variety of organic substrates (2 and refs. therein) and may be involved in photo-yellowing of thermal mechanical pulps. Singlet oxygen produced by dye sensitization *separately* from the substrates is known to react readily with lignin model compounds (3–8), lignin (9), high-yield pulps (10–12), and cellulose (13, 14). While these studies seem to implicate singlet oxygen as a possible mechanism for oxidative yellowing of lignin, controversy has continued about its significance in this process (5, 10, 11).

Lignin is a complex polymer of phenylpropyl units cross-linked and highly substituted by ether, carbonyl, hydroxyl, and methoxyl groups, as illustrated schematically in Fig. 1. Consequently, lignin is a paradox, in that the hydroxyl groups provide antioxidant activity against Type I free-radical oxidation, as observed for lignin-type monomers (15) and even in lignin itself (16); however, at the same time, the aromatic carbonyl chromophores could act as singlet-oxygen sensitizers and initiate singlet-oxygen (Type II) oxidations.

Earlier studies were limited by the lack of evidence for singlet-oxygen formation *directly* on lignin itself as its own sensitizer. Some evidence for the *direct* formation of singlet oxygen on lignin was given in our report, which showed that the light-induced, self-initiated oxidation of lignin was quenched by sodium azide, a known singlet-oxygen quencher (2). We now report in more detail on the issue of the role of singlet oxygen in lignin photo-oxidation. The structural complexity of lignin and the fact that lignin chromophores react readily with singlet oxygen (3–9) requires a multifaceted approach to the possible formation of singlet oxygen on lignin. Accordingly, we approached this problem in several ways, as follows. (*a*) Product studies: Two known methods of product analysis were used for gathering evidence of a singlet-oxygen reaction: (*i*) electron spin resonance (ESR) detection of nitroxide radicals formed by singlet-oxygen oxidation of hindered secondary amines and (*ii*) product profiles by high performance liquid chromatography (HPLC) of peroxidation of the lipid (methyl linoleate) by singlet oxygen compared with free-radical peroxidation. (*b*) Solid dispersions: A comparison was made of the products formed using a dispersion of titanium dioxide, a known singlet-oxygen sensitizer, with products formed by photolysis of lignin dispersions. (*c*) Kinetic studies: The kinetic orders in light intensity were determined for oxidation of methyl linoleate on silica gel in water catalyzed by the ketones, benzophenone (BP), and 3,5-di-*tert*-butyl-*ortho*-benzoquinone (DTBQ). The latter was selected as a simple lignin model compound because *ortho*-quinones are formed during the early photochemistry of mechanical pulps (17). These results were compared with the kinetics of oxidation of methyl linoleate "sensitized" by aqueous dispersions of lignin. The kinetic data and product analyses of linoleate peroxidation

provided a means of establishing the pathways; namely, free-radical oxidation (Type I) or singlet-oxygen reaction (Type II). (*d*) Phase-separated oxidation: A phase-separated system was used to mimic the natural lignin–air situation. In this technique, the substrate, methyl linoleate, is separated from the sensitizer by a narrow air gap. Product profiles (HPLC) of linoleate hydroperoxides are compared from irradiation experiments using, as sensitizers, titanium dioxide, benzophenone, and lignin. Structures for the main organic compounds employed are shown in Fig. 2.

Results

Product studies from singlet-oxygen oxidation of hindered secondary amines or methyl linoleate

Product studies of (*i*) oxidation of hindered secondary (sec.) amines and (*ii*) peroxidation of methyl linoleate were carried out initially in solution to evaluate the employed methods and for comparison with the more complex heterogenous systems containing lignin. The conversion by singlet oxygen of the hindered sec. amines, 2,2,6,6-tetramethyl-piperidine (TMP, **1**) and its 4-oxo derivative (TMPO, **2**), to the corresponding nitroxide radicals, **3**, detected by ESR, have been used for many years and under various conditions as evidence of a singlet-oxygen reaction (18–30). The method is simple and very sensitive to ESR detection of the stable nitroxide radical. However, there are conflicting literature reports on its use. For example, there is at least one report that states that the TMP reaction with singlet oxygen "is highly specific" since it does not react with the superoxide anion nor with the hydroxyl radical (29), while others reported that these amines, **1** and **2**, are useful tools "for trapping hydroxyl radicals" (30).

We found that great care must be exercised when using the oxidation of these amines as evidence of singlet oxygen because nitroxide radicals are often present in commercial **1** and **2** (19, 25). For such work, the following precautions should be observed: (*a*) the traces of nitroxide radicals should be removed before commencing the singlet experiment to avoid ambiguous results. We found a convenient method to do this is to vortex stir the amine dissolved in hexane with aqueous hydrazine; (*b*) parallel control experiments should be done with a singlet-oxygen quencher; (*c*) the ESR signals observed should be intense, and the amount of conversion from the amine to nitroxide radical measured by integration of the ESR spectra. A typical example of the oxidation of TMP using a known singlet-oxygen sensitizer, methylene blue, and product studies by ESR is illustrated in Fig. 3*b*. This sample was not pretreated with hydrazine, and a trace of nitroxide radical is observed at higher receiver gain (Fig. 3*a*). However, the conversion on sensitization (approximately 2%) to the typical nitroxide triplet (hyperfine nitrogen coupling $a_N = 16.0$ gauss) in agreement with literature values (23, 29), indicates reaction by singlet oxygen.

Product distribution of the hydroperoxides from peroxidation of the lipid, methyl linoleate (Fig. 2, structure **10**), is a useful method to distinguish between free-radical (Type I) and singlet-oxygen (Type II) reactions. Earlier reports described the separation and identification of the various isomers and related these to the two mechanisms involved (31–34). Type

Fig. 1. Schematic illustration of the lignin polymer.
I reactions proceed by initial H-atom abstraction from position 11 on the linoleate chain, rapid reaction of the derived carbon-centered radical with oxygen, and rearrangement of the peroxyl radicals, giving a distribution between the conjugated 9- and 13-substituted oxidation products, two with the *cis,trans* configuration (kinetic products **6** and **8**) and two with the *trans,trans* configuration (thermodynamic products **7** and **9**). A recent discovery (35) found that the *bis*-allylic 11-hydroperoxide is the kinetic product initially formed in the presence of α-tocopherol, a powerful H-atom donor; however, this product was not detected in our experiments. These products are usually analyzed as their corresponding alcohols (Fig. 2) that are formed on reduction of the hydroperoxides. On the other hand, the singlet-oxygen reaction does not involve free radicals. Whether singlet oxygen reacts with linoleate by a concerted ′ene reaction or its reaction possibly involves other intermediates (36), the reaction is

kinetically controlled, producing an excess of the *cis,trans* over the *trans,trans* isomers (e.g., a high *cis,trans* to *trans,trans* ratio). So, a significantly higher *cis,trans* to *trans,trans* ratio is expected from a Type II reaction on linoleate compared with a Type I for the same linoleate concentration, bearing in mind that this ratio depends on the H-atom donating ability of the medium for Type I reactions (37, 38). In addition, the less selective singlet-oxygen reaction gives products of reaction at the 10 and 12 positions of linoleate, leading to two nonconjugated isomers, a total of 6 hydroperoxides (2, 31–34). These two pathways, Type I and Type II, are outlined in Scheme 1. An example singlet-oxygen product formation from the photolysis of methyl linoleate sensitized by methylene blue is shown in Fig. 4. In this case the *cis,trans* ratio was found to be 14.2 at 2.8% oxidation of linoleate. The HPLC method of separation and detection of the isomers at 234 nm shows the relative

Fig. 2. Structural formulas of the main compounds used.
composition of the conjugated isomers, but the non-conjugated ones will actually be more concentrated than they appear in the chromatogram, since they do not absorb as strongly as the conjugated isomers at 234 nm. Our results focus mainly on the conjugated products and their relative yields (e.g., the *cis,trans* to *trans,trans* ratios).

Sensitizations on solid dispersions: Titanium dioxide and lignin

Photolyses involving excited states and intermediates on solid surfaces are of continuing interest and the subject of several reviews (39–42). Solid titanium dioxide, like lignin (presumably), is classified as a *reactive surface* (40), since it is a known singlet-oxygen sensitizer (although despite that, it is also commonly used in cosmetic sunscreens). Irradiation of TiO$_2$ with 320–400 nm light causes electronic excitation from a valence band to a conduction band, which allows energy transfer to oxygen (27). Because of the expected complexity of the excited state chemistry on the solid lignin polymer, we employed a comparative study of products formed from TMP when titanium dioxide sensitization was

used, contrasting these with the products formed from TMP (if any) when solid lignin was used.

A typical experiment using TiO$_2$ dispersed in methylene chloride for photo-oxidation of TMP is shown in Fig. 5. The triplet, which formed only in the presence of TiO$_2$, is attributed to oxidation via singlet oxygen (Fig. 5b). This procedure was then applied to dispersions of solid lignin in solvents. Figs. 5c and 5d show the results of irradiation of lignin in methylene chloride containing TMP and a parallel experiment in the presence of the singlet-oxygen quencher 1,4-diazabicyclo[2.2.2]octane (Dabco). There was no nitroxide signal in the presence of the quencher (Fig. 5c), whereas the strong triplet appeared in its absence (Fig. 5d). In addition, a quantitative study of the radical concentration showed that it increased with time, as illustrated in Fig. 6. In a similar experiment, we found that extended irradiation of TMP in lignin–hexane dispersions (not shown) gave a 10% conversion to the nitroxide radical.

The ESR spectrum resulting from relatively short irradiation of lignin dispersed in hexane in the presence of 4-OXOTMP (**2**) was more complex, as shown in Fig. 7a, and

Fig. 3. ESR spectra from irradiation in PR–350 of tetramethylpi-peridine (TMP), **1**, 7.7 mM, in methylene chloride for 15 min. (*a*) Without sensitizer, receiver gain (R.G.) of 5.0×10^5; (*b*) with 9.2×10^{-8} mol methylene blue, R.G. $= 1.25 \times 10^5$, [R·] $=$ 0.14 mM. The peak on the high field part of the triplet, which appears here and in other spectra, is due to a permanent cavity signal.

consisted of a very broad signal superimposed on the nitroxide triplet. The Lande *g*-factor for the broad signal was estimated to be $g = 2.004–2.005$ with reference to that of the nitroxide radical, $g = 2.006$ (29). This *g*-factor for the broad signal is in the range of a wide variety of phenoxyl radicals substituted by alkyl, hydroxyl, methoxy, and keto groups, where $g = 2.003–2.005$ (43). The separated solution phase shows the spectrum of the nitroxide radical more clearly (Fig. 7*b*). The broad signal was also very persistent, and it could be observed in the lignin that was separated from TMP by filtration. Separate irradiation of lignin alone in hexane also produced this lignin signal (Fig. 7*c*), which on dissolution of the lignin in dioxane disappeared and did not reappear on further irradiation of the lignin–dioxane solution. It is also interesting to note that with irradiation of lignin, under these conditions but in the presence of Dabco, the broad signal appeared but *not* the nitroxide triplet (not shown).

Kinetic and product studies of methyl linoleate peroxidation sensitized by lignin in water: Comparisons with sensitizations by benzophenone and by 3,5-di-*tert*-butylbenzoquinone, 5

The kinetics of free-radical lipid peroxidation is known to follow the classical rate law for autoxidation (44) represented by the following equation (eq. [1]):

[1] $\quad -d[O_2]/dt = k_p/(2k_t)^{1/2} \times [\text{lipid}] \times R_i^{1/2}$

where k_p and $2k_t$ are the rate constants for chain propagation and termination, respectively, and R_i is the rate of free-radical initiation. For photo-initiated H-atom abstraction by the n,π* triplet state of ketones (Type I mechanism), the kinetic order in oxygen consumption is expected to be half-order in light intensity, since this controls the R_i, and this was observed earlier for benzophenone photo-initiated peroxidation of linoleate in heterogeneous aqueous micelles (44). On the other hand, the kinetic order for the peroxidation of linoleate photo-initiated by the coloured lignin model quinone (**5**) was approximately unity, indicative of a change in mechanism to Type II with this quinone as sensitizer (2). With these earlier results in mind, we determined the kinetic order in light intensity — together with the trends in product profiles — for oxidation of methyl linoleate initiated by benzophenone and by **5** in aqueous dispersions, for comparison with similar data using lignin in water. The ketones and methyl linoleate were used as films on silica gel since this is classed as a *non-reactive* surface (40); moreover, benzophenone is an effective H-atom abstractor when adsorbed on silica gel (45). Therefore, these two compounds, benzophenone and **5**, were expected to provide different kinetic orders of oxygen uptake in the oxidation of methyl linoleate. In an experiment using lignin, the lipid was evaporated directly onto the lignin. The results of typical experiments are shown in Fig. 8. The experiment using benzophenone (Fig. 8*a*) gave a kinetic order of 0.55, indicative of a Type I pathway, while with the quinone (**5**) the kinetic order (Fig. 8*b*) was significantly higher at 0.90. The oxygen uptake in the benzophenone – methyl linoleate experiment was inhibited by the active water-soluble antioxidant Trolox, **11**, which gave a distinct induction period (not shown) similar to that observed earlier for photolysis with this combination in micelles (44). It appears that Trolox can trap chain-propagating peroxyl radicals generated on the methyl linoleate – silica gel surface, much like it does in other media. In contrast, Trolox gave no induction period during the photo-reaction combination of **5** – methyl linoleate. Lignin was also an effective photocatalyst for lipid oxidation and gave a kinetic order of 0.84 (Fig. 8*c*), similar to that observed with the quinone.

Product studies were carried out on oxidations of methyl linoleate under similar conditions to those in the kinetic runs. Typical product profiles from reactions using benzophenone and quinone, 5, are shown in Figs. 9*a* and 9*b*. These product profiles are clearly different: the reaction using benzophenone gave the four conjugated isomers with a *cis,trans* to *trans,trans* isomer ratio of ca. unity (Fig. 9*a*), while six isomers were formed with a *cis,trans* to *trans,trans* ratio of ca. 32 when using quinone in the photolysis (Fig. 9*b*). The different kinetic orders together with different product profiles allow one to distinguish between the two possible mechanisms in these heterogenous systems: a Type I free-radical oxidation initiated by H-atom abstraction by excited benzophenone vs. a Type II singlet-oxygen reaction sensitized by the quinone. Product analysis from oxidation of methyl linoleate on lignin (not shown) also showed an excess of the *cis,trans* isomers, but the chromatograms were very complex in the region where the *trans* isomers appear, preventing reliable calculations of the isomer ratios. However, these qualitative product studies, together with the kinetic order experiment, indicate the par-

Scheme 1. Free radical (Type I) and singlet-oxygen (Type II) pathways for lipid peroxidation.
Fig. 4. HPLC trace of photo-initiated oxidation products in air from methyl linoleate, 0.50 M in chloroform, with methylene blue, 1.11×10^{-2} M, using a 1000 W visible lamp for 10 min. Peaks labeled 6, 7, 8, and 9 are the 13 *cis,trans*, 13 *trans,trans*; 9 *cis,trans*, and 9 *trans,trans* isomers, respectively (see Fig. 2). The sample was 2.8% oxidized, giving a *cis,trans* to *trans,trans* product ratio = 14.2. Peaks marked by vertical arrows are non-conjugated isomers (see text). In this and other HPLC separations, PMA = 4-methoxyacetophenone, used as an internal standard for retention times and total hydroperoxides formed.
ticipation of singlet oxygen in the lignin – methyl linoleate photolysis.

Oxidations by separation of the sensitizer and substrate (phase separation, PS)

Physical separation of the sensitizer from the substrate should eliminate complications that are always present when they are together in solution during singlet-oxygen oxidations, such as competing H-atom abstraction by the sensitizer or electron transfer reactions. In addition, the lifetime of singlet oxygen is much longer in the gas phase than in solution (46), which should make the reaction more efficient.

A simple apparatus was constructed for some experiments with the sensitizer and substrate separated 1 to 2 mm by an air gap (Fig. 10), a space that is expected to allow for diffusion of singlet oxygen across the gap (46, 47). The sensitizer was coated on the bottom of the top filter-petri dish either as a film (e.g., benzophenone) or as a powder on double-sided tape. The sensitizer and substrate were then separated by two microscope slides, and the assembly was mounted on a cold plate and moved into the photoreactor. In practice, our procedure had limitations because the coating of sensitizers often "screened" much of the light, making the process less efficient so that long irradiation times were needed, and this can result in thermal or photo-rearrangements of initially formed hydroperoxides in the products (see Discussion section).

We used benzophenone as a typical photo-initiator to test the effect of the PS procedure as compared with results obtained using a homogeneous solution. In the latter case, the classical free-radical reaction (Type I) is known to predominate (44), and this was confirmed in the present case, since the isomer distribution showed a predominance to *trans,trans* isomers (*cis,trans* to *trans,trans* ratio = 0.44, Fig. 11*a*). The PS experiment required longer irradiation times to obtain comparable product buildup for HPLC analysis, and typically the product profiles (Fig. 11*b*) from these experiments were quite different from reactions in solution, showing all six isomers and an excess of the *cis,trans* isomers (*cis,trans* to *trans,trans* ratio = 9.1).

To evaluate the effect that lignin might have in the PS procedure, experiments were carried out with titanium dioxide

Fig. 5. ESR spectra from irradiation in air by PR–350 of methylene chloride solutions of TMP treated with hydrazine before irradiation. (*a*) With TMP, 0.40 M, and irradiated for 3 h, R.G. = 2.0×10^5; (*b*) TMP, 0.40 M, in the presence of titanium dioxide dispersion, irradiated for 45 min., R.G. = 4.0×10^4; (*c*) with TMP, 7.7 mM, Dabco quencher, 0.34 M, and 20 mg of lignin dispersion, irradiated for 40 min., R.G. = 5.0×10^5; (*d*) TMP and lignin, as in (*c*) but without Dabco, irradiated for 40 min., R.G. = 1.5×10^5. The additional peak on the high field side of the triplet, which appears here and in other spectra, is due to a permanent cavity signal.

Fig. 6. Plot of nitroxide concentration vs. time for irradiation of TMP, **1**, 7.7 mM, with a dispersion of lignin, 15 mg, in methylene chloride in PR–350.

solution = 0.44), reflecting the effect of a higher substrate concentration for essentially neat substrate on silica gel.

Experimental

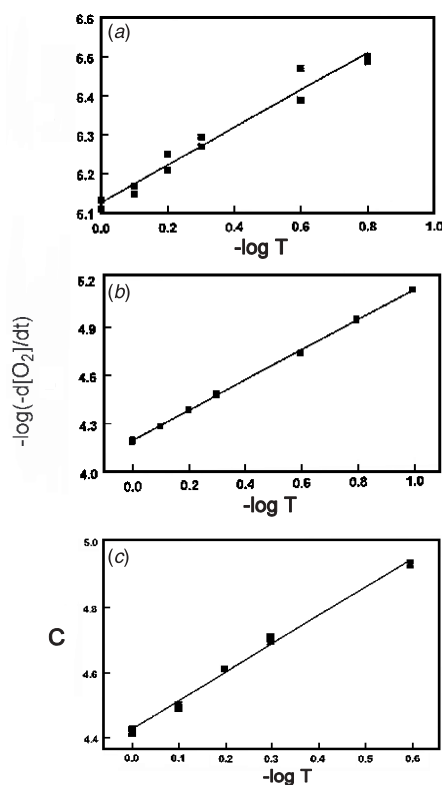
Materials and preparations

The following chemicals used were the purest grade from Aldrich: 2,2,6,6-tetramethylpiperidine (TMP), 2,2,6,6-tetramethyl-4-piperidone (TMPO), 1,4-diazabicyclo[2.2.2]octane (Dabco), 3,5-di-*tert*-butyl-*ortho*-benzoquinone, 4-methoxyacetophenone, benzophenone, titanium dioxide (Anatase- powder), *N*,*N*-dimethyl-*p*-phenylene–2HCl (DMP–HCl), triphenylphosphine, and Trolox. Methyl linoleate (>99%) was obtained from Nu-Chek-Prep and silica gel (100–200 mesh) from Mallinckrodt. The lignin used was milled from unbleached softwood at Paprican, Pointe Claire, Quebec, Canada.

The TMP and TEMPO (sublimed in vacuo) were normally purified to remove nitroxide signals just before use in each experiment (see text). In a typical purification, an equal volume of TMP or TMPO and aqueous hydrazine (35%, Aldrich) in the solvent used (methylene chloride or hexane) were vortex stirred for 2–5 min. The mixture was centrifuged to separate the organic layer, which was dried over sodium sulfate and purged with argon, and the sample was checked for ESR signals before use. Commercial silica gels were washed free of traces of free metal ions before use. For this purpose the material was washed at least three times with distilled water then twice with methanol, and the samples were oven-dried overnight. Traces of hydroperoxides were removed from commercial methyl linoleate by column chromatography on silica gel under argon, and fractions free of hydroperoxides (by TLC analysis, as detected by a DMP–HCl spray) were used in experiments. Alternately, it was convenient to prepare hydroperoxide-free solutions of methyl linoleate by vortex stirring a solution of the ester in distilled hexane with silica gel (nominally: 200 mg of ester in 50 mL hexane and 70 mg of silica gel). The solutions were checked for hydroperoxides by UV absorption at 234 nm (conjugation) and by TLC before use.

powder and with lignin powder for a comparison of the product profiles in the oxidation of methyl linoleate. These results are shown in Fig. 12. For similar relative conversions of the methyl linoleate (ca. 6%), the product profiles of the isomers are quite similar, with *cis,trans* to *trans,trans* ratios of 10.4 and 12.7 for the titanium dioxide sensitizer (Fig. 12*a*) and lignin as sensitizer (Fig. 12*b*), respectively. Both reactions appear to involve significant oxidation by singlet oxygen. This result indicates the specific advantage of phase separation to study a singlet-oxygen reaction. When the benzophenone and methyl linoleate were on separate silica gel surfaces *but irradiated in the same glass vessel* the product distribution (Fig. 9*a*) was similar to that found for a homogeneous solution (Fig. 11*a*). Presumably, this is because benzophenone and methyl linoleate were in close contact on the two silica gel surfaces, resulting in a process similar to a homogeneous system but with formation of a higher *cis,trans* to *trans,trans* ratio (on silica = 0.91 cf. in

Fig. 7. ESR spectra from irradiation with a 200 W Hg arc lamp in air of hexane dispersions of lignin, 10 mg, in the probe of the spectrometer. Samples were purged with argon before recording spectra. (*a*) With TMPO, 6.7 mM, irradiated for 5 min., R.G. = 5.0×10^5; (*b*) the spectrum of the solution after separation of the lignin, R.G. = 2.0×10^5; (*c*) Irradiation of lignin dispersion alone in hexane for 12 min., R.G. = 2.0×10^5.

Fig. 8. Plots of kinetic orders of oxygen uptake vs. light intensity for photo-initiated oxidation of methyl linoleate on silica gel in water at 30°C; comparing the effects of the ketones, benzophenone, DTBQ, **5**, and lignin. (*a*) Methyl linoleate, 54 μm, on 125 mg silica gel with benzophenone, 5.6 μm, on 100 mg silica gel, irradiated with 200 W Hg arc lamp; (*b*) methyl linoleate, 56 μm, on 112 mg silica gel with DTBQ, **5**, 8.7 μm, on 185 mg silica gel irradiated with a 1000 W visible lamp; (*c*) methyl linoleate, 54 μm, evaporated from methylene chloride on lignin, 92 mg, and irradiated with a 200 W Hg arc lamp.


aration (PS) method; it was mixed with silica gel (3 g per 500 mL) to hold the sample in the sample well close to the sensitizer (see Fig. 10 and text). In these cases, the silica gel was washed with methanol to remove the adsorbed oxidation products for reduction and HPLC analyses.

Product analyses

Electron spin resonance (ESR)

ESR spectra were obtained on a Varian E-3 EPR Spectrometer operated generally at a power level of 3 to 3.2 mW and a modulation amplitude of 4 G to optimize signals. Quantitative analysis of nitroxide signals used double integration of the absorption curves and diphenylpicrylhydrazyl as a concentration standard (48). The integrations were corrected for ESR cavity response by the signal of a ruby installed in the probe.

HPLC method

The procedures for reduction of methyl linoleate hydroperoxides by triphenylphosphine and HPLC analysis of the resulting isomeric alcohols and their identification was described previously (2, 37). 4-Methoxyacetophenone was

Photolysis methods

Photolyses were carried out using pyrex filters. Irradiations at 350 nm were done in a photoreactor constructed in the laboratory of J.C. Scaiano, University of Ottawa, Canada, consisting of an air-cooled metal box (30 cm high × 35 cm × 35 cm) fitted with eight 25 W, 350 nm lamps, a prototype of a Luzchem Photoreactor, Inc. A cold plate (Stirr Kool Inc.), fitted into the reactor, permitted samples to be cooled to between 0 and –10°C. This method, used for 350 nm photolysis, is referred to as PR–350 in the figure legends. A 200 W Oriel Hg–Xe lamp was used for photolyses undertaken in the probe of an electron spin resonance spectrometer (ESR); an Oriel 1000 W quartz–tungsten lamp was used for those experiments employing coloured dyes as sensitizers, such as methylene blue or 3,5-di-*tert*-butyl-*ortho*-quinone. A solution of the ester in an inert solvent (e.g., hydrocarbons, heptadecane, or dodecane) was used in the photo-irradiation of methyl linoleate by the phase sep-

Fig. 9. HPLC traces of oxidation products of methyl linoleate on silica gel in water at 30°C; comparing the effects of benzophenone and DTBQ, **5**. The quantities of methyl linoleate, benzophenone, and DTBQ were the same as in Fig. 8. (*a*) Benzophenone and irradiation with a 200 W Hg arc lamp. The *cis*,*trans* to *trans*,*trans* product ratio was 0.91 at 6.6% oxidation; (*b*) DTBQ and irradiation with a 1000 W visible lamp. The *cis*,*trans* to *trans*,*trans* product ratio was 32 at 9.4% oxidation. See Fig. 4 for identification of the HPLC peaks.
Fig. 10. Diagram of apparatus used for the phase separation (PS) method.
used as an internal standard to determine product concentrations, which are reported as "relative concentrations" of the total **6**–**9** isomeric compounds (Fig. 2).

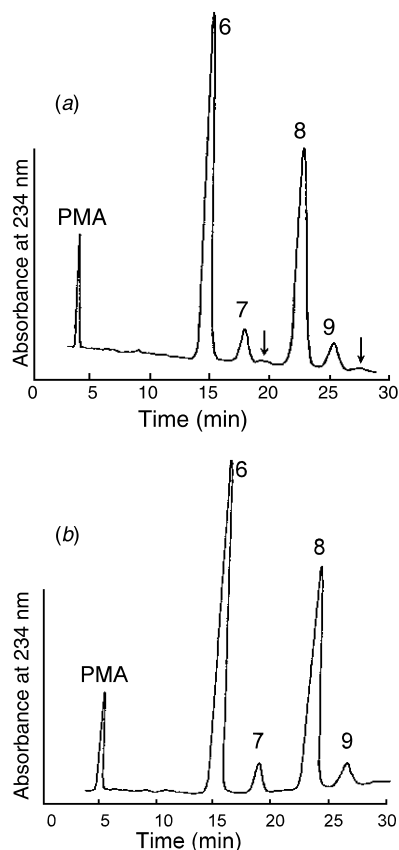
Kinetic methods of oxygen uptake

Kinetic studies of oxidation were carried out at 30°C under 760 torr (1 torr = 133.322 Pa) of oxygen on a dual channel apparatus attached to a pressure transducer, as described previously (2). The kinetic order in oxygen uptake was determined by inserting seven neutral-density filters on a filter wheel into the light beam.

Discussion

The combinations of product studies, kinetic measurements, and phase separations of sensitizer and substrate provide

Fig. 11. HPLC traces of methyl linoleate oxidation products showing the result using "initiation" by benzophenone in solution compared with phase separation of benzophenone as "sensitizer". (*a*) Methyl linoleate, 0.43 M, with benzophenone, 5.5 mM, in dodecane, irradiated in PR–350 for 1 h, giving 1.6% oxidation of methyl linoleate at a *cis*,*trans* to *trans*,*trans* product ratio = 0.44; (*b*) methyl linoleate, 0.69 M, in heptadecane and benzophenone powder, 29 mg, in the PS apparatus (Fig. 10) irradiated for 9 h, giving 2.2% oxidation at a *cis*,*trans* to *trans*,*trans* product ratio = 9.1. The identification of the peaks is given in Fig. 4.
quite conclusive results on the role of lignin in the generation of singlet oxygen. ESR studies of nitroxides from the oxidation of secondary amines **1** and **2** indicate singlet-oxygen generation by the photolysis of dispersions of solid lignin. A singlet-oxygen quencher inhibits the reaction, and in the absence of quencher the reaction products, nitroxides, increase in quantity with time. This ESR method has the advantage of high sensitivity, but the appearance of nitroxide radicals alone does not rule out the possible involvement of Type I reactions occurring simultaneously with singlet-oxygen oxidation. In this regard, the broad ESR signal produced during shorter irradiation times on lignin dispersion together with nitroxide formation is of special interest. Wan and co-workers observed similar broad, persistent signals (*g* = 2.0039) on papers from mechanical pulps, attributed them to phenoxyl radicals formed by H-atom abstraction by excited chromophores (49), and showed their importance in the photo-yellowing of high lignin content pulps and paper (50, 51). Our results show that these radicals are formed from the photo-excited lignin component, presumably by H-atom abstraction by excited carbonyl groups. More importantly, the complex ESR spectrum (Fig. 7*a*) demonstrates that *both* Type I and Type II reactions are initiated from photo-excited lignin: one type by H-atom abstraction forming phenoxyl radicals, which are persistent in the polymer matrix, and the other by energy transfer to oxygen, resulting in nitroxide

Fig. 12. HPLC traces from oxidation of methyl linoleate using the PS method to compare the effect of lignin with that of titanium dioxide as "sensitizers". (*a*) Methyl linoleate, 0.75 M, in heptadecane and titanium dioxide powder, 7.2 mg, irradiated for 8 h in PR–350, resulting in 6.2% oxidation and a *cis,trans* to *trans,trans* product ratio = 10.4; (*b*) methyl linoleate, 0.75 M, in heptadecane and lignin powder, 9.4 mg, irradiated for 1 h in PR–350, resulting in 6.3% oxidation and a *cis,trans* to *trans,trans* product ratio = 12.7. The identification of the peaks is given in Fig. 4.


radical formation by a singlet-oxygen reaction. The lignin–phenoxyl radicals were not observed in dioxane, probably owing to rapid radical–radical recombinations in solution.

The use of both kinetic experiments of oxygen uptake and product studies using methyl linoleate shows that the two mechanisms of peroxidation depend on the initiator or sensitizer used. Thus benzophenone, a known, excellent H-atom abstractor, showed a kinetic order of 0.55 when coated on silica gel, consistent with initiation by H-atom abstraction. The results with an *ortho* quinone were quite different: the higher kinetic order indicates a change in mechanism and the HPLC product profile indicates a singlet-oxygen reaction. As observed before in homogeneous solution (2), kinetic orders for singlet-oxygen oxidation are close to unity, which is expected if one assumes that the oxygen uptake is directly related to the steady-state concentration of singlet oxygen. The somewhat lower kinetic orders, ca. 0.9 — actually observed for oxidations sensitized by the *ortho*-quinone, **5**, a known singlet-oxygen sensitizer, and for dispersions of lignin when coated on silica gel — could be due to some photo-

induced homolysis of the hydroperoxides that accumulate during prolonged irradiation times, resulting in some competing Type I reaction. In any event, lignin is an active "catalyst" for the oxidation of the lipid, methyl linoleate, on its surface (Fig. 8*c*). The reason for the difference in behavior of the two ketones — as shown by product profiles from the reactions on silica gel (Fig. 9*a* and 9*b*), where benzophenone causes initiation of a Type I reaction on methyl linoleate while the *ortho*-quinone acts as a sensitizer — probably lies in the nature and energy of two different excited states of these compounds. The $^3(n,\pi^*)$ of benzophenone is a well-known, very reactive H-atom abstractor. Although the redox properties of **5** have been studied in detail, including reduction by ascorbic acid (52), details on its excited states are not available. However, the triplet states of 2- to 4-ring aromatic *ortho*-quinones exhibit "inversion" between n,π* and π,π* triplets where these were not active H-atom abstractors (53). Similarly, it appears that the excited state of quinone, **5**, is not an H-atom abstractor under our conditions but rather gives energy transfer, forming singlet oxygen.

We are well aware of the limitations of using hydroperoxide product studies as evidence for a singlet-oxygen reaction. In general, secondary photo reactions, especially by UV light, can cause further reactions on sensitive hydroperoxides and complicate the results, as pointed out by others (54–56). Consequently, in our results using geometric product ratios of the *cis,trans* and *trans,trans* isomers, it is not surprising that quite different ratios were observed even in reactions that apparently proceed via singlet oxygen. Most ratios were in the range of 9 to 14 (Figs. 4, 11*b*, 12*a*, and 12*b*), and the high ratio combined with the appearance of six isomers is taken as evidence for a pathway controlled by singlet oxygen, especially when compared with these ratios under conditions recognized to be a Type I reaction (Figs. 9*a* and 11*a*), where the highest ratio was ca. 1. In comparison, the ratio of ca. 33 when the *ortho*-quinone, **5**, was used as sensitizer in the visible region (Fig. 9*a*) is very different and suggests that the other examples may either indicate secondary photo rearrangements or a mixed Type I and Type II pathway. Triphenylphosphine (TPP) is used to rapidly reduce hydroperoxides to alcohols. Since it absorbs only weakly above 300 nm (57), we considered that photolysis experiments in the presence of TPP would reduce hydroperoxides as they form and simplify the product analysis. Unfortunately, other reactions of triphenyl phosphine — including those with excited states of ketones (58, 59) and with singlet oxygen (60) — actually complicate the system, and this procedure was abandoned.

Our experiments using lignin indicate that both Type I and Type II reactions can occur on photolysis. For example, the observation of two radicals following irradiation of **2** in the ESR cavity after a comparatively short irradiation time indicates that H-atom abstraction from phenolic hydroxyls (possibly by excited carbonyl groups) and singlet-oxygen reactions to generate nitroxide radicals occur simultaneously. The phase separation method does definitely show that singlet oxygen can be generated by the lignin surface (Fig. 12*b*). Overall we conclude that singlet oxygen plays an important role in the photo-yellowing of high-lignin-content materials, and consequently, this must be taken into consid-

eration in strategies for inhibition of photo-yellowing of high-lignin-content mechanical pulps.

The synthesis and structural characterization of linear and macrocyclic bis(dinitrosyliron) complexes supported by bis(phosphine) bridging ligands

Lijuan Li, Nada Reginato, Michael Urschey, Mark Stradiotto, and John D. Liarakos

Abstract: Reactions involving $Fe(NO)_2(CO)_2$ and the bis(phosphine) ligands bis(diphenylphosphino)methane (DPPM), bis(diphenylphosphino)acetylene (DPPA), 1,6-bis(diphenylphosphino)hexane (DPPH), and 1,4-bis(diphenylphosphino)-benzene (DPPB) have been examined. From these reactions, the mononuclear complex, $Fe(\kappa^1\text{-DPPM})(NO)_2(CO)$ **3**, linear dinuclear species of the type $Fe_2(\mu\text{-}L)(NO)_4(CO)_2$ ($L = Ph_2PCH_2PPh_2$ **4**, $Ph_2PC\equiv CPPh_2$ **5**, $Ph_2PCH_2(CH_3)_4CH_2PPh_2$ **6**, and $Ph_2P(p\text{-}C_6H_4)PPh_2$ **7**), and macrocyclic dinuclear species of the type $Fe_2(\mu\text{-}L)_2(NO)_4$ ($L = Ph_2PCH_2PPh_2$ **8** and $Ph_2PC\equiv CPPh_2$ **9**) were isolated and spectroscopically characterized. For **4**, **5**, **8**, and **9**, the solid-state molecular structures of the products were determined by use of single-crystal X-ray diffraction techniques.

Key words: dinitrosyliron, iron nitrosyls, dinuclear macrocycles, bis(phosphine) complexes.

Résumé : On a étudié des réactions impliquant le $Fe(NO)_2(CO)_2$ et les ligands bis(phosphines), bis(diphénylphosphino)méthane (DPPM), bis(diphénylphosphino)acétylène (DPPA), 1,6-bis(diphénylphosphino)hexane (DPPH), et 1,4-bis(diphénylphosphino)benzène (DPPB). À partir de ces réactions on a isolé le complexe mononucléaire $Fe(\kappa^1\text{-DPPM})$-$(NO)_2(CO)$ (**3**), les espèces dinucléaires linéaires du type $Fe_2(\mu\text{-}L)(NO)_4(CO)_2$ ($L = Ph_2PCH_2PPh_2$ (**4**); $Ph_2PC\equiv CPPh_2$ (**5**); $Ph_2PCH_2(CH_3)_4CH_2PPh_2$ (**6**) et $Ph_2P(p\text{-}C_6H_4)PPh_2$ (**7**)) et les espèces dinucléaires macrocycliques de type $Fe_2(\mu\text{-}L)_2(NO)_4$ ($L = Ph_2PCH_2PPh_2$ (**8**); $Ph_2PC\equiv CPPh_2$ (**9**)) et on les a caractérisés par spectroscopie. Les structures moléculaires à l'état solide des produits **4**, **5**, **8** et **9** ont été déterminées par la technique de diffraction des rayons X par un cristal unique.

Mots clés : dinitrosylfer, nitrosyles de fer, macrocycles dinucléaires, complexes de bis(phosphine).

Introduction

Dinitrosyliron-based compounds are known to participate in a variety of important chemical processes ranging from the transfer of molecular oxygen to alkenes or phosphines (1, 2) to the polymerization of olefins (3–6). Some non-heme iron nitrosyl complexes have also been identified as nitric oxide storage substances within biological systems; these have been detected by EPR studies, both as products

after the biosynthetic evolution of NO in vitro and from the addition of NO to iron-centered proteins (7). As part of our ongoing study of this class of chemically and biologically important complexes, we reported on the synthesis, structural characterization, and electrochemical behavior of compounds such as **1** that are derived from the reaction of $Fe(NO)_2(CO)(PR_3)$ with tetracyanoethylene (8–10). These molecules represent the first crystallographically characterized examples of dinitrosyliron-based complexes containing π-bound olefinic ligands. Subsequently, we have prepared and studied the non-heme iron complex, **2**, which comprises imidazole and nitrosyl ligands (Scheme 1) (11, 12).
