The penicillin pharmacophore consists of a reactive β-lactam ring with an ionizable acidic group located near the azetidinone nitrogen (24, 39, 40) and, unless the β-lactam ring is exceptionally reactive (41), a hydrogen-bond donor located near the azetidinone carbonyl group (42). In penicillins and cephalosporins (**23**), the hydrogen-bond donor is the N–H of the acylamino side chain, geminal to the carbonyl carbon. In the carbapenems (**24**) (43), the hydrogen-bond donor is the exocyclic hydroxyl group of the side chain, two atoms removed from the carbonyl carbon. A possible five-membered cyclic hydroxamate surrogate of a carbapenem could have an exocyclic beta hydroxyl group, as in **25**, or an endocyclic beta hydroxyl group, as in the hemiacetal **26**. The corresponding six-membered cyclic hydroxamates are **27** and **28**.

Figure 4 shows the PM3-optimized (44) global minimum of penicillin G and a PM3-optimized conformation of the β-lactam and carbapenem surrogate 2R-(5R-hydroxy-3-oxo-[1,2]oxazinan-2-yl)-propionic acid (**29**, R = Me). This compound is an amino acid (D-alanine) whose nitrogen atom is enclosed in the [1,2]oxazinan-3-one ring. Despite the (as yet unexplained) absence of activity in **16**–**18**, we decided to pursue syntheses related to **29**. This paper reports non-stereospecific routes to **29**, R = H (glycine) and R = Me
(alanine), and evidence of antibacterial activity in these compounds, with significantly greater activity in the alanine derivative.

Results and discussion

Syntheses in the glycine series

The O-benzyl ethyl ester of *N*-hydroxyglycine (**30**, R_1 = Et, R_2 = Bn) was synthesized by reaction of O-benzylhy-

Fig. 4. Left: Carboxyl carbon to side chain nitrogen and carboxyl carbon to β-lactam oxygen distances in PM3-optimized penicillin G. Right: Carboxyl carbon to side chain oxygen and carboxyl carbon to C3 carbonyl oxygen distances in one of the conformations of 2*R*-(5*R*-hydroxy-3-oxo-[1,2]oxazinan-2-yl)-propionic acid.
droxylamine hydrochloride with glyoxylic acid in refluxing ethanol (45) and reduction of the oxime with pyridine–borane (46).

Benzoylation yielded **31**, which was debenzylated with aluminium chloride and anisole in nitromethane (47). Since the same compound (**32**) was obtained by direct benzoylation of *N*-hydroxyglycine ethyl ester (**30**, R$_1$ = Et, R$_2$ = H), it was concluded that this ester undergoes N- and not O-acylation. This permitted an approach to **29**, R = H, based on *N*-hydroxyglycine or one of its esters and a four-carbon synthon. A large number of these were examined, including vinylacetic acid, cyclic anhydrides, 3,4-dihydroxybutanoic acid, γ-butyrolactone, diketene, and the diketene–acetone adduct 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one (**33**).
Scheme 1 (48–50) summarizes the syntheses of the ethyl, benzyl, and *tert*-butyl esters of *N*-hydroxyglycine (**30**, R$_1$ = Et, Bn, *t*-Bu, R$_2$ = H). *E*-Benzaldoxime was isomerized to the *Z*-isomer **34** with hydrogen chloride in refluxing toluene. Reaction of the sodium salt with ethyl bromoacetate in ethanol afforded *N*-benzylideneglycine *N*-oxide ethyl ester **35**, and **30** (R$_1$ = Et, R$_2$ = H) was obtained in 80% yield when **35** was treated with hydroxylamine. The benzyl ester (**30**, R$_1$ = Bn, R$_2$ = H) was synthesized from the sodium salt of **34** by

reaction with bromoacetic acid in ethanol, esterification with benzyl bromide in dimethylformamide, and treatment with hydroxylamine. The *tert*-butyl ester (**30**, R$_1$= *t*-Bu, R$_2$ = H) was obtained by sequential treatment of the sodium salt of **34** with *tert*-butyl bromoacetate in 2-propanol and hydroxylamine.

Vinylacetic acid as a synthon

Dicyclohexylcarbodiimide coupling of vinylacetic acid with **30** (R$_1$ = Et, R$_2$ = H) gave **36**, which, like **32**, exhibited infrared absorption at 1625 cm^{-1}. Bromination of **36** in chloroform at room temperature afforded a dibromide, which, upon exposure to sodium bicarbonate, yielded a colourless oil whose elemental analysis and mass, infrared, and proton NMR spectra were consistent with the isoxazolidinone structure **37**, X = Br. The infrared absorptions at 1710 and 1755 cm^{-1} were assigned to the carbonyl groups of the ester and isoxazolidinone ring. The proton NMR spectrum showed a downfield shift of the tertiary hydrogen from 4.55 ppm in the dibromide to 4.80 ppm in **37**. The EI mass spectrum exhibited peaks at *m/z* 85, 93, and 95, which were assigned to **38** and the bromomethyl side chain of **37**. The presence of a peak at *m/z* 85 was used subsequently to recognize the presence of a 5-substituted isoxazolidinone ring.

The bromide **37** (X = Br) was stable to the action of silver acetate in refluxing acetic acid, sodium formate in dimethylformamide (51), potassium phthalimide in refluxing toluene (52), sodium azide and tetrabutylammonium bromide in refluxing benzene (53), and triethylamine and formic acid in acetonitrile (54). The preference for cyclization to a five-membered ring (55) and the stability of the Br-C-C-ON moiety to nucleophilic displacement (56) suggested a synthesis of **39**, a structural isomer of the target compound **29** (R = H). Coupling of **30**, R$_1$ = Bn, R$_2$ = H, with vinylacetic acid and iodination with iodine and sodium bicarbonate in acetonitrile (57) gave **37** (X = I) as the benzyl ester. Peracid oxidation (58), followed by hydrogenolysis, yielded **39**.

Reaction of the alkene **36** with *N*-bromosuccinimide or *N*-bromoacetamide in methanol, followed by a bicarbonate wash, afforded three products, the bromide **37** and a 1:1 mixture of **40** and **41**. The GC–MS of this mixture exhibited

Scheme 1. Reagents and conditions: (*a*) HCl, toluene; then NaOH, NH$_4$Cl, Et$_2$O; (*b*) ROH, Na; then BrCH$_2$CO$_2$Et; (*c*) NH$_2$OH; (*d*) BrCH$_2$CO$_2$H; (*e*) BnBr, Et$_3$N, DMF.
peaks at 8.07 min, with an EI-MS fragmentation at *m/z* 99, assigned to **42**, and at 8.43 min, with the EI-MS fragmentation at *m/z* 85 previously assigned to **38**. The ^{1}H NMR spectra of **40** and **41** and related compounds are summarized in Tables 2 and 3.

Cyclic anhydrides as synthons

Following Procter et al. (59), reaction of the benzyl ester **30** (R$_1$ = Bn, R$_2$ = H) with a cyclic anhydride, followed by cyclization with carbodiimide, afforded the 3,6-diones **43**–**45** from, respectively, succinic anhydride, acetoxysuccinic anhydride, and maleic anhydride.

3,4-Dihydroxybutanoic acid as a synthon

Reaction of methyl 3,4-dihydroxybutanoate (**46**) (60, 61) with benzaldehyde dimethyl acetal and a catalytic amount of *p*-toluenesulfonic acid monohydrate in dimethylformamide (62), followed by alkaline hydrolysis, yielded the acid **47**. This was coupled to the *tert*-butyl ester of *N*-hydroxyglycine to give **48**, and hydrogenolysis yielded **49**. The reaction of **49** with triphenylphosphine and diethyl azodicarboxylate in refluxing tetrahydrofuran (63) gave the isoxazolidinone **50**. Deprotection with trifluoroacetic acid produced the hydroxyacid **39**. Alternative cyclization – Mitsunobu conditions (63) did not give promising results.

Butyrolactone as a synthon

Attempts to prepare compounds of type **51** by a direct reaction of *N*-hydroxyglycine esters with butyrolactone, using trimethylaluminium (**64**) or aluminium trichloride (**65**) as catalysts, were not successful. Therefore, using the method of Larcheveque and Henrot (**66**), butyrolactone was converted to the iodo acid **51**, X = I, with trimethylsilyl iodide

in refluxing dichloromethane, and this acid was coupled to the *tert*-butyl ester of *N*-hydroxyglycine to give **52**. Cyclization to **53** was accomplished using 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU).

51 **52**

53
2,2,6-Trimethyl-4H-1,3-dioxin-4-one and diketene as synthons

The reaction of the O-benzyl ethyl ester **30** (R$_1$ = Et, R$_2$ = Bn) with the diketene–acetone adduct **33** in refluxing toluene (67), followed by hydrogenolysis, yielded the hemiketal **54**, which, in chloroform-*d*, exists as an 85:15 tautomeric mixture of esters **54** and **55**.

54 **55**

^{a}In D$_2$O.
^{b}In CDCl$_3$.

The preparation of the acid **56** (which, like **39**, is a structural isomer of the target compound **29**, R = H) was accomplished using diketene in place of the diketene–acetone adduct (68). Reaction with the benzyl ester of *N*-hydroxyglycine afforded a product, which, in chloroform-*d*, exists as an 83:17 tautomeric mixture of benzyl esters **58** and **59**. Hydrogenolysis produced **56** and **57** as a 2:1 tautomeric mixture in water solvent. Table 4 summarizes the ^{1}H NMR spectra of **54**, **56**, and **58**.

56 **57**

58 **59**
The synthesis of **29**, R = H, is summarized in Scheme 2. Bromination of diketene at –25 °C in the presence of benzyl alcohol afforded benzyl bromoacetoacetate **60** in quantitative yield via the acyl bromide. Reduction with sodium boro-

65 → **66**

67 **68**

69

70
hydride in tetrahydrofuran–methanol produced the bromohydrin ester **61** in 80% yield. Protection of the hydroxyl group with dihydropyran and one crystal of para-toluenesulfonic acid in dichloromethane (69) yielded the tetrahydropyranyl derivative **62** as a mixture of diastereomers in an overall yield of 64% from diketene. The benzyl ester **62** was deprotected by hydrogenolysis to give **63**, and this was coupled to the *tert*-butyl ester of *N*-hydroxyglycine. Cyclization with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and removal of both protecting groups with trifluoroacetic acid produced the target compound.

The sodium salt, which is chemically stable, was isolated by successive treatment of **64** with trifluoroacetic acid and sodium bicarbonate. The ^{1}H NMR spectrum is summarized in Table 3.

Synthesis of 29, R = Me

For the synthesis of *N*-hydroxy-α-alanine, the nitrone **65** was prepared in 40% yield by the reaction of the sodium salt of **34** with *tert*-butyl α-bromopropionate in isopropanol. Hydrolysis with hydroxylamine hydrochloride in the presence of sodium methoxide then gave the racemic *N*-hydroxyalanine ester **66** in 71% yield. Coupling of **66** to **63** using dicyclohexylcarbodiimide produced a mixture of *N*-acylated

diastereomers **67** in 54% yield and also, in contrast to the observations made previously with *N*-hydroxyglycine esters, the O-acylated compounds **68**. Cyclization of **67** using DBU yielded the oxazinone **69** in 65% yield. Deprotection with trifluoroacetic acid or formic acid, followed by extraction with sodium bicarbonate and lyophilization produced the sodium salt as a mixture of diastereomers.

Bioassay results

Bioassays were performed on agar plates seeded with *M. luteus* (see Experimental). Figure 5 shows the zones of inhibition obtained with **29**, R = H, and its two structural isomers **39** and **56** compared with the results for penicillin G and desacetoxycephalosporin G. It can be seen that the racemate **29** exhibits some activity but **39** and **56** are inactive at 1000 μg. Table 5 summarizes semiquantitative test data relative to penicillin G and desacetoxycephalosporin G, expressed as (diameter of the zone in mm)/(μM of test material) for **29**, R = H, and **29**, R = Me. Although both compounds are only weakly active, the alanine surrogate, as a mixture of stereoisomers, is ca. 50 times more active than the glycine surrogate. These findings have encouraged us to continue with this programme and to attempt to devise stereospecific routes to compounds having the general structure **70**. These studies are reported elsewhere (38).

Experimental

All solvents were dried and distilled before use according to standard literature procedures (70). Except where indicated, chemicals were of the highest available purity from Aldrich. All reactions were performed under dry nitrogen using oven-dried (140 °C, 24 h) glassware. The glassware was allowed to cool in a desiccator under vacuum and assembled cold, capped with rubber septa, and evacuated with dry nitrogen gas. Both ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Model AMX 400 Spectrometer operating at 400.1 and 100.6 MHz, respectively. Chemical shifts (δ) are reported in parts per million (ppm) relative to tetramethylsilane (TMS) in an appropriate deuterated solvent. ^{1}H NMR data are reported in the following manner: chemical shift, integration, peak multiplicity, coupling constants, and identification. The peak multiplicities are abbreviated as s (singlet), d (doublet), t (triplet), q (quartet), dd (doublet of doublets), ddd (doublet of doublets of doublets), m (multiplet), etc. ^{13}CMR data are reported as δ values in ppm downfield from tetramethylsilane. Infrared (IR) spectra were recorded on a Bomen–Hartmann–Braun spectrometer (1% KBr or 1% solution). High-resolution mass spectra refer to either direct inlet electron impact (EI) measurements or chemical ionization (CI) measurements, using isobutane, and were provided by Dr. G. Eigendorf at the University of British Columbia. Low-resolution mass spectra refer to direct inlet EI measurements or CI measurements, using isobutane, or fast-atom bombardment (FAB), employing xenon gas, on a Kratos MS50 Spectrometer operated at 70 eV by G. Owens at Simon Fraser University. Melting points (mp) were determined on a Fisher-Johns apparatus and are uncorrected. Analytical thin-layer chromatography was carried out on precoated Merck Silica Gel 60 F-254 plates with aluminium backing. Spots

were observed under short-wavelength ultraviolet light or were visualized with iodine vapour, ninhydrin, or ceric sulfate. Flash column chromatography was carried out on Merck Silica Gel 60 (230–400 Mesh), according to the method of Still et al. (71) unless stated otherwise, using only distilled solvents under dry nitrogen gas. Elemental analyses were performed by M.K. Yang on a Carlo Erba model 1106 elemental analyzer at Simon Fraser University.

Z-Benzaldoxime

Benzaldehyde (5.3 g, 0.05 mol) (Fisher) and hydroxylamine hydrochloride (3.6 g, 0.052 mol) (Mallinckrodt) were added successively at room temperature to a stirred solution of sodium hydroxide (5 g, 0.125 mol). Stirring was continued until a clear solution was obtained and the temperature had increased to 70 °C. The reaction mixture was cooled to 35 °C, and carbon dioxide was passed in until the pH had decreased from 14 to 10. The two layers were then separated. The aqueous layer was extracted with toluene (4 × 25 mL), and the combined organic phase was dried over anhydrous magnesium sulfate, filtered, and poured into a 250 mL three-necked flask equipped with a large-bore gas inlet tube, stirrer, thermometer, and condenser. The flask was heated on an oil bath, and 20 mL of toluene was removed by distillation. The remaining solution was reheated to boiling, the oil bath was removed, and a strong flow of anhydrous hydrogen chloride was sparged through the vigorously stirred solution. Addition of the gas was continued until the oil that first separated had solidified and the temperature had fallen to 50 °C. The resulting white slurry was cooled to 10 °C in an ice-water bath and filtered. The white crystalline solid was washed with toluene (2 × 25 mL) and hexane and stored in a desiccator over potassium hydroxide pellets. Diethyl ether (50 mL) was added to a stirred solution of sodium hydroxide (4 g, 0.1 mol) in water (40 mL). The mixture was cooled to 10 °C and the crude Z-benzaldoxime hydrochloride was added rapidly with stirring until all of the solid had dissolved. A solution of ammonium chloride (10 g, 0.187 mol) (Fisher) in water (40 mL) was added, and the mixture was stirred until a clear solution was obtained (1 min). The two layers were separated, and the aqueous layer was extracted with ether (2 × 25 mL). The combined ethereal extracts were dried over anhydrous magnesium sulfate and concentrated. Hexane (40 mL) was added to the white slurry and the mixture concentrated again. Another 40 mL of hexane were added, the mixture was filtered, and the solid was air dried until a constant weight was obtained. The Z-benzaldoxime was obtained as white needles (4.26 g, 70%); mp 131 °C (lit. (45) mp 130 °C). ^{1}H NMR (CDCl$_3$) δ: 8.19 (1H, s, CH=N), 7.60 (2H, m, ArH), 7.45 (3H, m, ArH).

4.71 (2H, s), 4.26 (2H, q) 1.29 (3H, t). EI-MS (*m/z*): 121 ([M]$^+$). Anal. calcd. for C$_7$H$_7$NO: C 69.42, H 5.79, N 11.57; found: C 69.44, H 5.96, N 10.99.

N-Benzylideneglycine *N*-oxide ethyl ester (35)

Ethyl bromoacetate (0.244 mL, 0.367 g, 2.2 mmol) was added to a stirred solution of sodium (0.46 g, 0.02 g-atom) and *Z*-benzaldoxime (0.242 g, 2.0 mmol) in ethanol (15 mL). Stirring was continued until a wet pH 7 was reached. The reaction mixture was poured into water (20 mL), extracted with ether (2 × 20 mL), dried, and concentrated under reduced pressure. The golden yellow oil was purified by flash chromatography on silica gel (4.5 g) (40% ethyl acetate – hexane) and subsequently crystallized from ethyl acetate – hexane. The pale yellow crystals weighed 0.298 g (73%); mp 53 °C. IR (film, cm^{-1}): 1743 (C=O), 1584 (C=N). ^{1}H NMR (CDCl$_3$) δ: 8.19 (1H, s, (CH=N), 7.60 (2H, m, ArH), 7.45 (3H, m, ArH), 4.71 (2H, s), 4.26 (2H, q), 1.29 (3H, t). EI-MS (*m/z*): 207 ([M]$^+$). Anal. calcd. for C$_{11}$H$_{13}$NO$_3$: C 63.76, H 6.32, N 6.76; found: C 64.04, H 6.41, N 6.60.

N-Hydroxyglycine ethyl ester

Method A

The nitrone **35** (180 mg, 0.87 mmol) was added to a stirred suspension of sodium methoxide (64.8 mg, 1.2 mmol) (Anachemia) and hydroxylamine hydrochloride (83.4 mg, 1.2 mmol) (Mallinckrodt) in methanol (3 mL). The reaction mixture was heated on a water bath (40 °C) with stirring until the wet pH was slightly acidic (2 min) and then concentrated under reduced pressure. The residue was triturated with toluene (2 × 10 mL), concentrated, and purified by flash chromatography (5 g silica gel and 40% ethyl acetate – hexane) to give a pale yellow oil (82.7 mg, 80%). IR (film, cm^{-1}): 3319 (O-H, br), 3267 (N-H, m), 1735 (C=O). ^{1}H NMR (CDCl$_3$) δ: 5.89 (2H, br, NH-OH), 4.23 (2H, q, OCH$_2$CH$_3$), 3.67 (2H, s), 1.29 (3H, t, OCH$_2$CH$_3$).

Method B

A mixture of glyoxylic acid (1.094 g, 0.014 mol) (Eastman), hydroxylamine hydrochloride (1.00 g, 14 mmol) (Mallinckrodt), and *p*-toluenesulfonic acid (0.273 g, 1 mmol) (Fisher) in dry ethanol (8 mL) was heated under reflux for 5 h with removal of water using a Dean-Stark trap. The reaction mixture was concentrated, ether (100 mL) and saturated sodium bicarbonate (100 mL) were added, and the mixture was stirred until the phases became clear. The organic layer was separated, washed with saturated ammonium chloride, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to yield ethyl glyoxylate oxime (1.11 g, 66%). IR (film, cm^{-1}): 3347 (OH, br), 1725 (C=O, s), 1623 (C=N, m). ^{1}H NMR (CDCl$_3$) δ: 9.55 (1H, b, =NOH), 7.56 (1H, s, *HC*=NOH), 4.31 (2H, q, CO$_2$CH$_2$CH$_3$), 1.33 (3H, t, CO$_2$CH$_2$CH$_3$). CI-MS (*m/z*): 118 ([M + 1]). Anal. calcd. for C$_4$H$_7$NO$_3$: C 41.03, H 5.98, N 11.96; found: C 41.41, H 6.12, N 11.43.

Ethanolic hydrogen chloride (6.76 mL of a 7 N solution prepared by diluting 30 mL of 36% HCl to 50 mL with ethanol) was added to a stirred solution of the oxime ethyl ester (1.0 g, 8.5 mmol), and pyridine–borane complex (2.16 mL

of 8 mol/L, 17.28 mmol) in ethanol (10 mL) was added at such a rate that the reaction temperature remained below 40 °C. Stirring was continued for 8 h, while the reaction was monitored by thin layer chromatography (TLC). The reaction mixture was then concentrated, and the pale yellow syrupy residue was dissolved in dichloromethane (50 mL). Sodium carbonate (4 g) was added, and the mixture was stirred at room temperature for 30 h, filtered, and the filtrate concentrated under reduced pressure. The crude oil was purified by flash chromatography (60% ethyl acetate – hexane) to give a pale yellow oil (0.673 g, 67%). CI-MS (m/z): 120 ([M + 1]). Anal. calcd. for $C_4H_9NO_3$: C 40.34, H 7.56, N 11.76; found: C 40.21, H 7.55, N 11.54.

N-Benzyloxyoxime of ethyl glyoxylate

A mixture of glyoxylic acid (0.476 g, 6.26 mmol) (Eastman), O-benzylhydroxylamine hydrochloride (1.00 g, 6.26 mmol), and p-toluenesulfonic acid (0.12 g, 0.626 mmol) (Fisher) in dry ethanol (8 mL) was refluxed for 6 h with removal of water using a Dean-Stark trap. The reaction mixture was concentrated and dichloromethane (50 mL) was added to the yellow oily residue. The solution was washed successively with water (30 mL), saturated sodium bicarbonate (30 mL), and saturated sodium chloride (30 mL), dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to give a pale yellow oil (1.08 g, 83%). IR (CDCl$_3$, cm^{-1}): 1727 (C=O), 1600 (C=N). ^{1}H NMR (CDCl$_3$) δ: 7.57 (1H, s, N=CH), 7.39 (5H, s, OCH$_2$Ph), 5.32 (2H, s, OCH$_2$Ph), 4.33 (2H, q, OCH$_2$CH$_3$), 1.36 (3H, t, OCH$_2$CH$_3$). CI-MS (m/z): 208 ([M + 1]). Anal. calcd. for $C_{11}H_{13}NO_3$: C 63.77, H 6.28, N 6.76; found: C 63.06, H 6.33, N 7.34.

N-Benzyloxyglycine ethyl ester (30, R$_1$ = Et, R$_2$ = Bn)

Ethanolic hydrogen chloride (6.76 mL of a 7 N solution prepared by diluting 30 mL of 36% HCl to 50 mL with ethanol) was added to a stirred solution of the oxime (3.5 g, 16.91 mmol), and pyridine–borane (8.54 mL of 8 mol/L, 68.32 mmol) in ethanol (10 mL) was added at such a rate that the reaction temperature did not exceed 40 °C. Stirring was continued for 13.5 h with monitoring by TLC, and the solvent was then removed. The pale yellow syrup was dissolved in dichloromethane (50 mL), and the solution was washed with N-sodium hydroxide, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The crude oil was purified by flash chromatography using 2% ethanol in dichloromethane as the eluent. The pale yellow oil thereby obtained weighed 3.0 g (85%). IR (CDCl$_3$, cm^{-1}): 3273 (N-H, w), 1739 (C=O, s). ^{1}H NMR (CDCl$_3$) δ: 7.36 (5H, s, OCH$_2$Ph), 6.13 (1H, t, N-H), 4.75 (2H, s, OCH$_2$Ph), 4.24 (2H, q, OCH$_2$CH$_3$), 3.62 (2H, d, NCH$_2$C(O)), 1.30 (3H, t, OCH$_2$CH$_3$). CI-MS (m/z): 210 ([M + 1]). Anal. calcd. for $C_{11}H_{15}NO_3N$: C 63.16, H 7.18, N 6.70; found: C 63.37, H 7.01, N 7.50.

N-Benzylidene glycine N-oxide

Sodium (0.46 g, 0.02 g-atom) and Z-benzaldoxime (1.21 g, 10 mmol) in ethanol (40 mL) were stirred until the sodium dissolved. Then bromoacetic acid (1.53 g, 11 mmol) (Lancaster) was added in one portion, with stirring. Stirring was continued for 1 h at 70 °C, and the solvent was removed. A suspension of the residue in water (10 mL) was cooled, acidified with 0.1 N hydrochloric acid (9.5 mL), and filtered. The white crystals were collected and dried at 1 torr (1 torr = 133.322 Pa) to give 1.21 g (66%) of product; mp 175–177 °C (lit. (47) mp 178–179 °C). IR (KBr, cm^{-1}): 3069, 1724, 1617. EI-MS (m/z): 179 ([M]$^+$).

N-Benzylidene-glycine N-oxide benzyl ester

To a cloudy solution of N-benzylideneglycine N-oxide (0.181 g, 1.01 mmol) in dimethylformamide (2 mL) was added triethylamine (0.141 mL, 103 mg, 1.01 mmol), followed by dropwise addition of benzyl bromide (0.120 mL, 0.173 g, 1.01 mmol) (Sigma). The reaction mixture was stirred for 13 h, poured into water (10 mL), and extracted with chloroform (2 × 10 mL). The chloroform extract was dried over anhydrous sodium sulfate, concentrated, and the residue was purified by column chromatography (60% ethyl acetate – hexanes) to give 0.191 g (70%) of product. IR (CH$_2$Cl$_2$, cm^{-1}): 3054, 1753, 1587. ^{1}H NMR (CDCl$_3$) δ: 8.25 (2H, m, Ar + =CH), 7.45–7.34 (9H, m, Ar), 5.27 (2H, s, CH$_2$Ph), 4.76 (2H, s, CH$_2$). EI-MS (m/z): 269 ([M]$^+$). Anal. calcd. for $C_{16}H_{15}NO_3$: C 71.37, H 5.58, N 5.20; found: C 71.13, H 5.80, N 5.40.

N-Hydroxyglycine benzyl ester

A suspension of N-benzylideneglycine N-oxide benzyl ester (1.35 g, 5.02 mmol) and hydroxylamine hydrochloride (352 mg, 5.02 mmol) (Mallinckrodt) in ethanol (10 mL) was brought into solution by heating. The solution was concentrated, and the residue was taken up in ether (50 mL) and washed with saturated sodium bicarbonate (20 mL). The ether layer was separated, dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The product was purified by flash chromatography (60% ethyl acetate – hexanes) to give 772 mg (85%) of white solid. IR (CH$_2$Cl$_2$, cm^{-1}): 3290, 3055, 1741. ^{1}H NMR (CDCl$_3$) δ: 7.36 (5H, s, Ar), 5.22 (2H, s, PhCH$_2$), 3.73 (2H, s, NCH$_2$). EI-MS (m/z): 181 ([M]$^+$). Anal. calcd. for $C_8H_{11}NO_3$: C 59.67, H 6.08, N 7.73; found: C 59.74, H 6.07, N 7.11.

tert-Butyl bromoacetate

A solution of oxalyl chloride (6.18 mL, 8.99 g, 0.071 mol) in dichloromethane (10 mL) was added to a cooled (0 °C) solution of bromoacetic acid (8.21 g, 0.059 mol) (Lancaster) and dimethylformamide (3 drops) in dichloromethane (40 mL). The pale yellow solution was stirred for 1 h at 0 °C, then at room temperature for 3 h, concentrated to about 10 mL, and slowly added to a cooled solution of tert-butanol (5.255 g, 0.071 mol) and triethylamine (10.71 mL, 7.78 g, 0.077 mol) in dichloromethane (45 mL). The dark brown suspension was stirred for 45 min at 0 °C, then for 3 h at room temperature, and poured into water (60 mL). The organic layer was separated and the aqueous layer extracted with dichloromethane (2 × 15 mL). The organic extract was washed with saturated sodium bicarbonate (50 mL), dried over anhydrous magnesium sulfate, and concentrated to give 4.48 g (39%) of product. ^{1}H NMR (CDCl$_3$) δ: 3.74 (2H, s), 1.47 (9H, s). CI-MS (m/z): 197:195 (1:1).

N-Benzylidene glycine N-oxide tert-butyl ester

Z-Benzaldoxime (5.64 g, 46.61 mmol) and *tert*-butyl bromoacetate (7.58 mL, 10 g, 51.27 mmol) were added successively to a solution prepared by dissolving 1.07 g (0.047 g-atom) of sodium metal in 2-propanol (120 mL). The dark brown suspension was stirred for 2 h at room temperature, poured into water (100 mL), and extracted with dichloromethane (5 × 20 mL). The combined organic extracts were dried over anhydrous magnesium sulfate and concentrated. The crude product was purified by flash chromatography (60% ethyl acetate – hexanes) to give 8.74 g (80%) of an oil. IR (CH_2Cl_2, cm^{-1}): 3054, 1746, 1580, 1260. ^1H NMR ($CDCl_3$) δ: 8.24 (2H, m, Ar + =CH), 7.42 (4H, m, Ar), 4.62 (2H, s, CH_2), 1.51 (9H, s, *t*-Bu). CI-MS (*m/z*): 236 ([M + 1]). Anal. calcd. for $C_{13}H_{17}NO_3$: C 66.38, H 7.23, N 5.96; found: C 66.78, H 7.10, N 6.01.

N-Hydroxyglycine tert-butyl ester

The nitrone (1.3 g, 5.53 mmol) was added to a stirred suspension of sodium methoxide (0.418 g, 7.74 mmol) (Anachemia) and hydroxylamine hydrochloride (0.538 g, 7.74 mmol) (Mallinckrodt) in methanol (6 mL). The reaction mixture was placed in a water bath (50 °C), stirred until all of the nitrone had dissolved, and was then concentrated. The residue was dissolved in dichloromethane (50 mL), filtered, and concentrated. The resultant oil was purified by flash chromatography (60% ethyl acetate – hexanes) to give 0.650 g (80%) of the product. IR (film, cm^{-1}): 3279, 1735. ^1H NMR ($CDCl_3$) δ: 5.46 (2H, br, HNOH), 3.62 (2H, s, CH_2), 1.49 (9H, s, *t*-Bu). CI-MS (*m/z*): 148 ([M + 1]). Anal. calcd. for $C_6H_{13}NO_3$: C 48.98, H 8.84, N 9.52; found: C 49.13, H 8.65, N 9.44.

tert-Butyl 2-bromopropionate

Isobutylene (2.4 g, 42.8 mmol) was condensed into a pressure bottle at –15 °C. Dioxane (6 mL) and 2-bromopropionic acid (3.5 mL, 38.9 mmol) were added, and the mixture was stirred for 5 min, warmed to –10 °C, and concentrated sulfuric acid (250 μL) was added. The bottle was sealed, the reaction mixture was stirred overnight at room temperature, and the bottle was then opened and the contents poured into dichloromethane (50 mL). The solution was washed with 20% potassium carbonate (50 mL) and water (50 mL), dried over anhydrous magnesium sulfate, and evaporated to give *tert*-butyl bromopropionate (2.17 g, 27%). ^1H NMR ($CDCl_3$) δ: 4.31 (1H, q, 7.1 Hz), 1.81 (3H, d, 7.1 Hz), 1.52 (9H, s).

tert-Butyl N-benzylidenealanine N-oxide

Z-Benzaldoxime (580 mg, 4.79 mmol) and *tert*-butyl 2-bromopropionate (980 mg, 4.69 mmol) were added successively to a solution of sodium hydride (200 mg of a 60% dispersion in mineral oil, 5.00 mmol) in 2-propanol (20 mL). The suspension was stirred at room temperature for 3 h, then poured into water, and extracted with ethyl acetate (2 × 20 mL). The organic extract was dried over anhydrous magnesium sulfate and evaporated to give a white solid. Trituration with anhydrous ether (8 mL) afforded the nitrone (464 mg, 40%); mp 115–117 °C. IR (KBr, cm^{-1}): 1736, 1582. ^1H NMR ($CDCl_3$) δ: 8.26–8.23 (2H, m, Ar + *H*C=N$^+$), 7.43–7.41 (4H, m, Ar), 4.65 (1H, q, 7.0 Hz, α-C*H*), 1.73 (3H, d, 7.0 Hz, C*H*$_3$), 1.47 (9H, s, CO$_2$C(C*H*$_3$)$_3$). CI-MS

(*m/z*): 250 ([M + 1]). Anal. calcd. for $C_{14}H_{19}NO_3$: C 67.45, H 7.68, N 5.62; found: C 67.10, H 7.59, N 5.90.

tert-Butyl N-hydroxyalanine

The *N*-oxide (460 mg, 185 mmol) was added to a stirred suspension of sodium methoxide (141 mg, 2.61 mmol) and hydroxylamine hydrochloride (182 mg, 2.62 mmol) in dry methanol (5.5 mL). This mixture was stirred at 40 °C until the solid dissolved, and the solution was then concentrated. The residue was shaken with ethyl acetate (10 mL), filtered, and the filtrate was concentrated. The residue was chromatographed on silica gel. Elution with ethyl acetate – hexanes (2:3) afforded 211 mg (71%) of *N*-hydroxyalanine *tert*-butyl ester; mp 73–74 °C. IR (KBr, cm^{-1}): 3158, 1746. ^1H NMR ($CDCl_3$) δ: 5.61 (2H, br s, N*H* + O*H*), 3.60 (1H, q, 7.1 Hz, α-C*H*), 1.48 (9H, s, CO$_2$C(C*H*$_3$)$_3$), 1.22 (3H, d, 7.1 Hz, C*H*$_3$). ^{13}C NMR ($CDCl_3$) δ: 173.37 (ester *C*=O), 81.54 (CO$_2$*C*(CH$_3$)$_3$), 60.97 (α-*C*H), 28.06 (CO$_2$C(*C*H$_3$)$_3$), 14.65 (*C*H$_3$). CI-MS (*m/z*): 162 ([M + 1]). Anal. calcd. for $C_7H_{15}NO_3$: C 52.16, H 9.38, N 8.69; found: C 51.98, H 9.30, N 8.55.

N-Benzoyl, N-benzyloxyglycine ethyl ester (31)

Benzoyl chloride (0.028 mL, 0.034 g, 0.23 mmol) (Fluka) was added dropwise to a cooled (0 °C) solution of *N*-benzyloxyglycine ethyl ester (48 mg, 0.23 mmol) and triethylamine (0.032 mL, 0.023 g, 0.023 mmol) in dichloromethane (0.5 mL). The cloudy solution was stirred for 20 min, diluted with dichloromethane (25 mL), and washed successively with saturated sodium bicarbonate (10 mL) and saturated sodium chloride (10 mL), dried over anhydrous magnesium sulfate, and concentrated to a pale yellow oil (70.7 mg, 98%). IR (film, cm^{-1}): 1746 (C=O, s), 1626. ^1H NMR ($CDCl_3$) δ: 7.71–7.07 (10H, m, Ar), 4.71 (2H, s, OC*H*$_2$Ar), 4.42 (2H, s, CH$_2$), 4.24 (2H, q, CO$_2$C*H*$_2$CH$_3$), 1.29 (3H, t, CO$_2$CH$_2$C*H*$_3$). CI-MS (*m/z*): 314 ([M + 1]).

Synthesis of 32

Method A

A solution of **31** (38.2 mg, 0.12 mmol) and anisole (0.053 mL, 0.49 mmol) (BDH) in dichloromethane (1 mL) was added dropwise at 0 °C to a solution of aluminium trichloride (48.8 mg, 0.37 mmol) (Anachemia) in nitromethane (1 mL). The resultant pink solution was stirred at 0 °C for 90 min and then at room temperature for 10 min. The reaction mixture was diluted with ethyl acetate (30 mL) and washed successively with *N*-hydrochloric acid (10 mL) and 4% sodium bicarbonate (40 mL). The organic layer was dried over anhydrous magnesium sulfate and concentrated to give a bright orange oil, which was purified by preparative layer chromatography (PLC) (40% ethyl acetate – hexane). The product (12.5 mg, 45%) was identical to that obtained from Method B.

Method B

Benzoyl chloride (0.016 mL, 0.019 g, 0.14 mmol) (Fluka) was added dropwise to a cooled (0 °C) solution of *N*-hydroxyglycine ethyl ester (16.4 mg, 0.14 mmol) and triethylamine (0.019 mL, 0.014 g, 0.014 mmol) in dichloromethane (0.5 mL). The suspension was stirred for 1 h, and

the solvent was then removed. The residue was redissolved in ether (10 mL), filtered, and the filtrate was concentrated. The oil was subjected to PLC (60% ethyl acetate – hexanes) to give 14.8 mg (41%) of the product. IR (film, cm^{-1}): 1743 (C=O, s), 1672. ^{1}H NMR (CDCl$_3$) δ: 7.72 (5H, m, Ar), 4.47 (2H, s), 4.25 (2H, q), 1.30 (3H, t). CI-MS (*m/z*): 224 ([M + 1]).

Vinylacetamido *N*-hydroxyglycine ethyl ester (36)

To a stirred solution of *N*-hydroxyglycine ethyl ester (117 mg, 0.98 mmol) in dichloromethane (2 mL) was added vinylacetic acid (0.088 mL, 0.089 g, 1.03 mmol) in one portion. The solution was cooled to 0 °C, and a solution of dicyclohexylcarbodiimide (213 mg, 1.03 mmol) (BDH) in dichloromethane (2 mL) was added dropwise during 10 min. Stirring was continued for 11 h while the mixture warmed to room temperature. The mixture was then concentrated under reduced pressure, and the residue was extracted with ether (2 × 10 mL). The combined organic extracts were dried, concentrated, and the crude product was purified by flash chromatography (30 g silica gel and 40% ethyl acetate – hexane) to give a pale yellow oil (94 mg, 51%). IR (film, cm^{-1}): 3318 (O-H, br), 3083 (C=C, w), 1742 (C=O, s), 1625 (N-C(O), s). ^{1}H NMR (CDCl$_3$) δ: 5.98–5.91 (1H, m, *CH*=CH$_2$), 5.21–5.18 (2H, d, CH=*CH$_2$*), 4.48 (2H, s), 4.22 (2H, q), 3.36 (2H, d), 1.29 (3H, t). EI-MS (*m/z*): 187 ([M]$^+$).

Bromination of 36

A solution of bromine (0.041 mL, 0.128 g, 0.80 mmol) (Fisher) in chloroform (1 mL) was added dropwise, under nitrogen, at room temperature, to a stirred solution of vinylacetamido *N*-hydroxyglycine ethyl ester (0.125 g, 0.66 mmol) in chloroform (0.6 mL). Stirring was continued for 2 h, and the solvent was then removed to give a deep orange oil (0.148 g, 100%). IR (film, cm^{-1}): 3211 (OH, br), 1745 (C=O), 1650 (N-C(O)). ^{1}H NMR (CDCl$_3$) δ: 7.87 (1H, OH, br), 4.55 (1H, m), 4.50 (2H, s), 4.33 (2H, q), 3.86 (2H, dd), 3.38 (2H, dd), 1.30 (3H, t). EI-MS (*m/z*): 345 : 347 : 349 (1:2:1). The oil was dissolved in dichloromethane (2 mL), and saturated sodium bicarbonate (3 mL) was added. The mixture was stirred for 2 h, washed with saturated sodium chloride (5 mL), dried, and concentrated. The crude product was purified by PLC (60% ethyl acetate – hexane) to give a colourless oil (0.077g, 50%). IR (film, cm^{-1}): 1718–1750 (C=O). ^{1}H NMR (CDCl$_3$) δ: 4.80–4.75 (1H, m), 4.29 (1H, d, C*H*H, 17 Hz), 4.28 (1H, d, CH*H*, 17Hz), 3.58 (1H, dd, 10.78, 5.52 Hz), 3.53 (1H, dd, 10.78, 6.76 Hz), 3.02 (1H, dd, 16.84, 8.24 Hz), 2.83 (1H, dd, 16.84, 7.04 Hz), 4.23 (2H, q, CO$_2$*CH$_2$*CH$_3$), 1.29 (3H, t, CO$_2$CH$_2$*CH$_3$*). EI-MS (*m/z*) (relative intensity): 267 (12.1), 265 (12.6), 194 (78.4), 192 (68.3), 149 (58.2), 147 (57.4), 95 (7.4), 93 (8.7), 85 (17.8). Anal. calcd. for C$_8$H$_{12}$NO$_4$Br: C 36.11, H 4.55, N 5.26; found: C 35.75, H 4.58, N 5.25.

Iodination of 36

Iodine (041 g, 1.60 mmol) and sodium bicarbonate (0.27 g, 3.21 mmol) were added to a solution of **36** (0.20 g, 1.07 mmol) in acetonitrile (5 mL). The solution was stirred for 7 h at 0 °C and then diluted with ether (50 mL) and washed successively with saturated sodium thiosulfate (30 mL), water (30 mL), and saturated sodium chloride

(30 mL), dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The product was purified by flash chromatography (60% ethyl acetate – hexanes) to give an oil 93 mg (28%). IR (film, cm^{-1}): 1718, 1750 (C=O). ^{1}H NMR (CDCl$_3$) δ: 4.70–4.63 (1H, m), 4.26 (1H, d, C*H*H, 17.88 Hz), 4.24 (1H, d, CH*H*, 17.88 Hz), 4.22 (2H, q), 3.39 (1H, dd, 10.40, 5.52 Hz), 3.35 (1H, dd, 10.40, 7.44 Hz), 3.0 (1H, dd, 16.78, 8.0 Hz), 2.76 (1H, dd, 16.78, 7.24 Hz), 1.28 (3H, t).

Oxidation of 37, X = I

m-Chloroperbenzoic acid (45 mg of 85%, 0.22 mmol) was added to a solution of the iodide (46 mg, 0.15 mmol) in dichloromethane (2 mL). The purple solution was stirred for 5 h, then diluted with dichloromethane (10 mL), washed with saturated sodium thiosulfate (10 mL), and dried over anhydrous magnesium sulfate. The residue was purified by PLC (80% ethyl acetate – hexanes) to give 8 mg of product (25%). IR (CHCl$_3$, cm^{-1}): 1747, 1703 (C=O). ^{1}H NMR (CDCl$_3$) δ: 4.69–4.63 (1H, m), 4.57 (1H, d, C*H*H, 18 Hz), 4.24 (2H, q), 4.06 (1H, d, CH*H*, 18 Hz), 3.91 (1H, dd, 12.80, 2.40 Hz), 3.67 (1H, dd, 12.80, 4.0 Hz), 2.96 (1H, dd, 16.60, 8.70 Hz), 2.90 (1H, dd, 16.60, 6.20 Hz), 1.30 (3H, t). CI-MS (*m/z*): 204 ([M + 1]). EI-MS (*m/z*): 203 ([M]$^+$).

Coupling of *N*-hydroxyglycine benzyl ester and vinylacetic acid

Dicyclohexylcarbodiimide (1.38 g, 6.68 mmol) (BDH) was added to a cooled solution of *N*-hydroxyglycine benzyl ester (1.15 g, 6.36 mmol) and vinylacetic acid (0.57 mL, 575 mg, 6.68 mmol) in dichloromethane (30 mL). The cloudy mixture was stirred for 0.5 h at 0 °C and then for 3.5 h at room temperature, filtered, and concentrated. The resulting oil was purified by flash chromatography (60% ethyl acetate – hexane) to give 912 mg (58%) of the product. IR (film, cm^{-1}): 3200 (OH, s), 1749 (C=O, s), 1633 (C=O, amide, s). ^{1}H NMR (CDCl$_3$) δ: 7.38–7.33 (5H, m, Ar), 6.02–5.89 (1H, m), 5.21–5.17 (2H, m, =CH$_2$), 5.19 (2H, s, CH$_2$Ph), 4.52 (2H, s), 3.34 (2H, d, CH$_2$C(O)). CI-MS (*m/z*): 250 ([M + 1]). Anal. calcd. for C$_{13}$H$_{15}$NO$_4$: C 62.65, H 6.02; N, 5.62; found: C 62.88, H 6.22, N 6.00.

Iodocyclization of the benzyl ester

Iodine (1.23 g, 4.83 mmol) and sodium bicarbonate (0.41 g, 8.83 mmol) were added to a solution of the benzyl ester (0.40 g, 1.61 mmol) in acetonitrile (10 mL). The solution was stirred for 3 h at 0 °C and then diluted with ether (20 mL) and washed successively with saturated sodium thiosulfate (20 mL) and saturated sodium chloride (20 mL), dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The product was purified by flash chromatography (60% ethyl acetate – hexanes) to give an oil 0.345 g (57%). IR (film, cm^{-1}): 1718, 1750 (C=O). ^{1}H NMR (CDCl$_3$) δ: 7.38–7.33 (5H, m, Ar), 5.21 (1H, d, CH*H*Ph, 12.08 Hz), 5.19 (1H, d, C*H*HPh, 12.08 Hz), 4.61–4.58 (1H, m), 4.33 (1H, d, C*H*H, 17.84 Hz), 4.30 (1H, d, CH*H*, 17.84 Hz), 3.33 (1H, dd, 10.36, 5.52 Hz), 3.28 (1H, dd, 10.36, 7.56 Hz), 2.98 (1H, dd, 16.80, 8.04 Hz), 2.73 (1H, dd, 16.80, 7.24 Hz). EI-MS (*m/z*): 375 ([M]$^+$).

Oxidation of the iodomethyl benzyl ester

m-Chloroperbenzoic acid (68%) (351 mg, 1.38 mmol) was added to a solution of the ester (345 mg, 0.92 mmol) in dichloromethane (6 mL). The purple solution was stirred for 24 h, then diluted with ether (50 mL), washed with saturated sodium thiosulfate (10 mL), and dried over anhydrous magnesium sulfate. The residue was purified by PLC (80% ethyl acetate – hexanes) to give 66 mg of product (27%). IR (CHCl$_3$, cm^{-1}): 1718, 1750 (C=O). ^{1}H NMR (CDCl$_3$) δ: 7.38–7.33 (5H, m, Ar), 5.21 (1H, d, CH*H*Ph, 12.08 Hz), 5.19 (1H, d, C*H*HPh, 12.08 Hz), 4.66–4.60 (1 H, m), 4.57 (1H, d, C*H*H, 18 Hz), 4.13 (1H, d, CH*H*, 18 Hz), 3.87 (1H, dd, 12.80, 2.48 Hz), 3.66 (1H, dd, 12.80, 4.24 Hz), 2.92 (1H, dd, 16.66, 8.56 Hz), 2.87 (1H, dd, 16.66, 6.68 Hz). CI-MS (*m/z*): 266 ([M + 1]).

Synthesis of 39

Palladium (10% on carbon) (250 mg) was added to a solution of the benzyl ester (190.5 mg, 0.72 mmol) in ethanol (10 mL). The resulting suspension was fitted with a balloon, flushed thrice with hydrogen, and then stirred under hydrogen for 1 h at room temperature. After filtration through Celite and evaporation of the filtrate, the oil was redissolved in water (10 mL), filtered, and the filtrate was lyophilized to give a pale green viscous oil 120 mg (95%). ^{1}H NMR (D$_2$O) δ: 4.74 (1H,m), 4.36 (1H, d, 18.16 Hz), 4.34 (1H, d, 18.16 Hz), 3.78 (1H, dd, 12.88, 3.2 Hz), 3.74 (1H, dd, 12.88, 5.64 Hz), 3.02 (1H, dd, 17.04, 8.76 Hz), 2.79 (1H, dd, 17.04, 7.68 Hz). CI-MS (*m/z*): 176 ([M + 1]).

Reaction of 36 with *N*-bromosuccinimide in methanol

A solution of **36** (100 mg, 0.53 mmol) in dry methanol (5 mL) was cooled in an ice-water bath, and *N*-bromosuccinimide (95 mg, 0.53 mmol) (BDH) was added in one portion. Stirring was continued at 0 °C for 15 min and then at room temperature for 45 min. The reaction mixture was concentrated, and the residue was subjected to flash chromatography (60% ethyl acetate -hexanes). Two products were obtained. These were dissolved in dichloromethane (3 mL), washed with saturated sodium bicarbonate (2 mL), dried over anhydrous sodium sulfate, and concentrated to give **37** (**X** = **Br**) (9.6 mg) and a mixture of **40** and **41** (25 mg). IR (film, cm^{-1}): 1793, 1751, 1700. ^{1}H NMR (CDCl$_3$) δ: **41**: 4.51 (1H, d, 17.8 Hz, CH*H*), 4.23 (1H, d, 17.8 Hz, CH*H*), 4.33 (1H, dd, 11.9, 6.0 Hz, C*H*H), 4.23 (2H, q, OC*H*$_2$CH$_3$), 4.07 (1H, dd, 11.9, 3.6 Hz, CH*H*), 4.02–3.98 (1H, m, CH), 2.80 (1H, dd, 16.0 Hz, 5.8 Hz, C*H*H), 2.68 (1H, dd, 16.0 Hz, 4.7 Hz, CH*H*), 1.30 (3H, t, OCH$_2$C*H*$_3$). **40**: 4.75–4.73 (1H, m, CH), 4.28 (1H, d, 17.8 Hz, C*H*H), 4.23 (2H, q, OC*H*$_2$CH$_3$), 4.22 (1H, d, 17.8 Hz, CH*H*), 3.62 (1H, dd, 10.9, 6.2 Hz, C*H*H), 3.54 (H, dd, 10.9, 3.6 Hz, CH*H*), 2.81 (1H, dd, 16.6, 8.2 Hz, C*H*H), 2.75 (1H, dd, 16.6, 8.8 Hz, CH*H*), 1.30 (3H, t, OCH$_2$C*H*$_3$). EI-MS (*m/z*): 217 ([M]$^+$), 144, 112, 99, 85. CI-MS (*m/z*): 218 ([M + 1]). GC–CI-MS (*m/z*): 218 ([M + 1]), 99 (RT = 9.4 min), 218 ([M + 1]), 85 (RT = 9.7 min).

Synthesis of 43

Succinic anhydride (100 mg, 1 mmol) was suspended in dichloromethane (0.5 mL), and a solution of *N*-hydroxy-glycine benzyl ester (181 mg, 1 mmol) in dichloromethane

(0.5 mL) was added with stirring. Stirring was continued for 16 h. The suspension was then filtered, and the white solid was dried at 1 torr to give 183 mg (65%) of the product. ^{1}H NMR ((CD$_3$)$_2$CO) δ: 7.41–7.33 (5H, m, Ar), 5.17 (2H, s, C*H*$_2$Ph), 4.41 (2H, s), 2.82–2.55 (4H. m, (CH$_2$)$_2$). The hydroxysuccinamic acid (175.6 mg, 0.62 mmol) was suspended in dichloromethane (0.65 mL) under nitrogen at 0 °C, and dicyclohexylcarbodiimide (128 mg, 0.62 mmol) was added in one portion. Stirring was continued for 4 h at 0 °C. The mixture was then filtered through Celite and the filtrate concentrated under reduced pressure to afford an oily residue. Purification by PLC (40% ethyl acetate – hexanes) gave 105 mg (64%) of the product as an oil. ^{1}H NMR (CDCl$_3$) δ: 7.41–7.33 (5H, m, Ar), 5.21 (2H, s, C*H*$_2$Ph), 4.49 (2H, s), 2.91–2.87 (2H, m), 2.77–2.74 (2H, m). CI-MS (*m/z*): 264 ([M + 1]).

5-Acetoxy-tetrahydro-1,2-oxazin-3,6-dione (44)

N-Hydroxyglycine benzyl ester (362 mg, 2 mmol) in dichloromethane (1 mL) was added with stirring to a solution of acetoxysuccinic anhydride (4.11 mg, 2.6 mmol) in dichloromethane (1 mL). Stirring was continued for 16 h. The suspension was then filtered, and the white solid was collected and dried at 1 torr to give 518.2 mg (80%) of the product. ^{1}H NMR ((CD$_3$)$_2$CO) δ: 7.41–7.33 (5H, m, Ar), 5.87 (1H, dd, 2.68, 2.76 Hz), 5.20 (2H, s, C*H*$_2$Ph), 4.66 (1H, d, 17.6 Hz), 4.18 (1H, d, 17.6 Hz), 3.10 (1H, dd, 17, 2.72 Hz), 2.59 (1H, dd, 17.10 Hz). CI-MS (*m/z*): 340 ([M + 1]). This product (500 mg, 1.55 mmol) was suspended under nitrogen in dichloromethane (1.5 mL), the suspension was cooled to 0 °C, and dicyclohexylcarbodiimide (319 mg, 1.55 mmol) was added in one portion. Stirring was continued at 0 °C for 4 h, and the slurry was then filtered through Celite and the filtrate concentrated under reduced pressure. The oily residue was purified by PLC (40% ethyl acetate – hexanes) to give 417.3 mg (88%) of the product as an oil. ^{1}H NMR (CDCl$_3$) δ: 7.41–7.32 (5H, m, Ar), 5.61 (1H, dd, 5.28, 11.16 Hz), 5.20 (2H, s, C*H*$_2$Ph), 4.58 (1H, d, 18.12 Hz), 4.49 (1H, d, 18.12 Hz), 3.22 (1H, dd, 16.72, 11.16 Hz), 3.34 (1H, dd, 16.72, 5.28 Hz). CI-MS (*m/z*): 322 ([M + 1]).

Synthesis of 45

Maleic anhydride (98 mg, 1 mmol) was suspended in dichloromethane (0.5 mL), and a solution of *N*-hydroxyglycine benzyl ester (181 mg, 1 mmol) in dichloromethane (0.5 mL) was added with stirring. Stirring was continued for 16 h. The suspension was then filtered, and the white solid was dried at 1 torr to give 178 mg (64%) of a solid. ^{1}H NMR (CDCl$_3$) δ: 7.41–7.32 (5H, m, Ar), 7.11 (1H, d, 12.88 Hz), 6.35 (1H, d, 12.88 Hz), 5.22 (2H, s, C*H*$_2$Ph), 4.59 (2H, s). The solid (171 mg, 0.61 mmol) was suspended in dichloromethane (1 mL) under nitrogen; the suspension was cooled 0 °C, and dicyclohexylcarbodiimide (126.5 mg, 0.61 mmol) was added in one portion. Stirring was continued at 0 °C for 4 h. The slurry was then filtered through Celite and the filtrate concentrated under reduced pressure to afford an oily residue. Purification by PLC (40% ethyl acetate – hexanes) gave 154 mg (96%) of the product as a yellow solid. ^{1}H NMR (CDCl$_3$) δ: 7.39–7.32 (5H, m, Ar), 7.01 (1H, d, 10.2 Hz), 6.78 (1H, d, 10.2 Hz), 5.20 (2H, s, C*H*$_2$Ph), 4.66 (2H, s). CI-MS (*m/z*): 262 ([M + 1]).

Methyl 3,4-dihydroxybutanoate

DL-Malic acid (20 g, 0.15 mol) was dissolved in a solution prepared by addition of acetyl chloride (6.7 mL) (Fisher) to methanol (134 mL). The solution was stirred at room temperature for 13 h and then concentrated. The product was purified by flash chromatography (60% ethyl acetate – hexanes) to give a colourless oil (18.5 g, 77%). IR (film, cm^{-1}): 3470, 1732. ^{1}H NMR (CDCl$_3$) δ: 4.44 (1H, br), 3.75 (3H, s), 3.65 (3H, s), 3.18 (1H, br), 2.81 (1H, dd, 16.48, 4.36 Hz), 2.74 (1H, dd, 16.48, 6.12 Hz). CI-MS (*m/z*):163 ([M + 1]). Anal. calcd. for C$_6$H$_{10}$O$_5$: C44.44, H 6.17; found: C 44.20, H 6.13.

Borane–dimethylsulfide (11 mL of 10 mol/L, 0.11 mol) was added dropwise to a solution of dimethylmalate (17.80 g, 0.11 mol) in tetrahydrofuran (220 mL). The solution was stirred at 20 °C for 30 min, and sodium borohydride (0.208 g, 5.5 mmol) (BDH) was added in one portion. Stirring was continued for 30 min, methanol (70 mL) was added dropwise, and after an additional 30 min the solvent was removed under reduced pressure. The product was purified by flash chromatography (60% ethyl acetate – hexanes) to give a colourless viscous oil (12.27 g, 83%). IR (film, cm^{-1}): 3414, 1738. ^{1}H NMR (CDCl$_3$) δ: 4.07 (1H, m), 3.66 (3H, s), 3.61 (1H, dd, 11.36, 3.52 Hz), 3.46 (1H, dd, 11.36, 6.2 Hz), 2.80 (2H, br), 2.50 (1H, dd, 16.64, 8.52 Hz), 2.44 (1H, dd, 16.64, 4.16 Hz). CI-MS (*m/z*): 135 ([M + 1]). Anal. calcd. for C$_5$H$_{10}$O$_4$: C 44.78, H 7.46; found: C 44.12, H 7.55.

Benzylidene derivative of methyl 3,4-dihydroxybutanoate

A solution of methyl 3,4-dihydroxybutanoate (11.44 g, 85.36 mmol), benzaldehyde dimethyl acetal (11 mL, 11.15 g, 3.16 mmol), and *p*-toluenesulfonic acid monohydrate (812 mg, 4.27 mmol) (Fisher) in dimethylformamide (20 mL) was stirred at room temperature for 24 h and then poured into ice-water (50 mL) and extracted with ethyl acetate (5 × 40 mL). The organic extract was washed with saturated sodium chloride (30 mL), dried over anhydrous sodium sulfate, and concentrated. Purification by column chromatography (60% ethyl acetate – hexanes) gave 18.5 g (77%) of a colourless oil. IR (film, cm^{-1}): 3034, 1737 (C=O). ^{1}H NMR (CDCl$_3$) δ: 7.49–7.35 (5H, m, Ar), 5.96 (1H, s), 5.86 (1H, s), 4.68–4.60 (1H, m), 4.21 (1H, dd, 8.28, 6.72 Hz), 4.12 (1H, dd, 8.44, 6.16 Hz), 3.98 (1H, dd, 8.44, 6.60 Hz), 3.86 (1H, dd, 8.28, 5.68 Hz), 2.85 (1H, dd, 16.06, 6.36 Hz), 2.82 (1H, dd, 16.06, 6.36 Hz), 2.66 (1H, dd, 16.06, 7.20 Hz), 2.65 (1H, dd, 16.06, 7.32 Hz). CI-MS (*m/z*): 223 ([M + 1]).

Preparation of 47

Sodium hydroxide (25 mL of 1 mol/L, 25 mmol) was added to a solution of the benzylidene methyl ester (5.75 g, 25.9 mmol) in methanol (40 mL). The reaction mixture was stirred for 30 min, and the solvent was then removed. The residue was dissolved in ethyl acetate (50 mL) and water (30 mL). The aqueous phase was acidified with N-hydrochloric acid and extracted with dichloromethane (4 × 30 mL). This extract was dried over anhydrous sodium sulfate and concentrated to give 3.16 g (59%) of product. IR (film, cm^{-1}): 3037, 1713 (C=O). ^{1}H NMR (CDCl$_3$) δ: 7.49–7.36 (5H, m, Ar), 5.96 (1H, s), 5.82 (1H, s), 4.68–4.60 (1H, m), 4.37 (1H, dd, 8.50, 6.20 Hz), 4.11 (1H, dd, 8.32,

6.72 Hz), 3.99 (1H, dd, 8.32, 5.48 Hz), 3.75 (1H, dd, 8.50, 6.60 Hz), 2.88 (1H, dd, 16.36, 6.60 Hz), 2.71 (1H, dd, 16.36, 6.96 Hz), 2.68 (1H, dd, 16.36, 6.80 Hz). CI-MS (*m/z*): 209 ([M + 1]).

Coupling of 47 and *N*-hydroxyglycine *tert*-butyl ester

Dicyclohexylcarbodiimide (0.859 g, 4.16 mmol) (BDH) was added to a cooled solution of 47 (0.87 g, 4.16 mmol) and *N*-hydroxyglycine *tert*-butyl ester (0.60 g, 4.09 mmol) in dichloromethane (20 mL). The cloudy mixture was stirred at 0 °C for 0.5 h and at room temperature for 4 h and then filtered and the filtrate concentrated. Purification of the oil by flash chromatography (60% ethyl acetate – hexane) gave 0.650 g (47%) of the product 48. IR (film, cm^{-1}): 3249, 1739, 1641. ^{1}H NMR (CDCl$_3$) δ: 7.49–7.35 (5H, m, Ar), 5.96 (1H, s), 5.86 (1H, s), 4.59–4.62 (1H, m), 4.45 (1H, d, 17.72 Hz), 4.39 (1H, dd, 8.56, 6.08 Hz), 4.38 (1H, d, 17.76 Hz), 4.31 (1H, d, 17.76 Hz), 4.29 (1H, d, 17.72 Hz), 4.25 (1H, dd, 8.20, 6.80 Hz.), 3.89 (1H, dd, 8.20, 5.84 Hz), 3.79 (1H, dd, 8.56, 7.12 Hz), 3.20 (1H, dd, 15.92, 6.12 Hz), 3.02 (1H, dd, 15.54,5.60 Hz), 2.92 (1H, dd, 15.54, 7 Hz), 2.81 (1H, dd, 15.92, 7.16 Hz), 1.48 (9H, s, *tert*-butyl). CI-MS (*m/z*): 338 ([M + 1]). Anal. calcd. for C$_{17}$H$_{23}$NO$_6$: C60.53, H 6.82, N 4.15; found: C 60.84, H 7.07, N 4.36.

Hydrogenolysis of 48

Palladium on carbon (10%) (0.400 g) was added to a solution of 48 (0.400 g, 1.19 mmol) in tetrahydrofuran (15 mL). The suspension was flushed thrice with hydrogen, then stirred under hydrogen for 3 h, filtered through Celite, and the filtrate concentrated. The residue was purified by PLC (80% ethyl acetate – hexanes) to give 49 as a viscous golden oil (0.150 g, 51%). IR (film, cm^{-1}): 3362, 1737, 1635. ^{1}H NMR (D$_2$O) δ: 4.37 (1H, d, 17.72 Hz), 4.30 (1H, d, 17.72 Hz), 4.13 (1H, m), 3.62 (1H, dd, 11.76, 4 Hz), 3.53 (1H, dd, 11.76, 6.88 Hz), 2.78 (1H, dd, 15.15, 8.24 Hz), 2.71 (1H, dd, 15.15, 4.96 Hz), 1.49 (9H, s). CI-MS (*m/z*): 250 ([M + 1]). Anal. calcd. for C$_{10}$H$_{19}$NO$_6$.1.5H$_2$O: C43.47, H 7.37, N 5.07; found: C 43.45, H 7.29, N 5.26.

Cyclization of 49

A mixture of the diol 49 (68.8 mg, 0.28 mmol), triphenylphosphine (78.3 mg, 0.30 mmol), and diethylazodicarboxylate (65 μL, 72 mg, 0.41 mmol) in tetrahydrofuran (9 mL) was stirred for 24 h at room temperature and then concentrated under reduced pressure. The residue was purified by PLC (60% ethyl acetate – hexanes) to give 50 (68 mg). IR (film, cm^{-1}): 3279, 1735. ^{1}H NMR (CDCl$_3$) δ: 4.64–4.59 (1H, m), 4.37 (1H, d, 17.84 Hz), 3.98 (1H, d, 17.84 Hz), 3.86 (1H, dd, 12.64, 2.68 Hz), 3.65 (1H, dd, 12.64, 4.16 Hz), 2.89 (1H, dd, 16.56, 8.52 Hz), 2.85 (1H, dd, 16.56, 6.64 Hz), 1.47 (9H, s). EI-MS (*m/z*): 231 ([M]$^+$). CI-MS (*m/z*): 232. This compound was dissolved in trifluoroacetic acid (0.5 mL) and stirred under a nitrogen atmosphere for 1.5 h. The solution was then freeze-dried to give 28 mg (57%) of 39. ^{1}H NMR (D$_2$O) δ: 4.74 (1H, m), 4.36 (1H, d, 18.16 Hz), 4.34 (1H, d, 18.16 Hz), 3.78 (1H, dd, 12.88, 3.2 Hz), 3.74 (1H, dd, 12.88, 5.64 Hz), 3.02 (1H, dd, 17.0, 8.76 Hz), 2.79 (1H, dd, 17.0, 7.68 Hz). CI-MS (*m/z*): 176 ([M + 1]).

4-Iodobutanoic acid

Trimethylsilyl chloride (5.0 mL, 4.28 g, 33.4 mmol) was added dropwise under nitrogen to a suspension of sodium iodide (5.84 g, 34.0 mmol) in dichloromethane (60 mL). The mixture was stirred for 15 min, and γ-butyrolactone (2.0 mL, 2.24 g, 26.0 mmol) was then added dropwise (15 min). Stirring was continued at room temperature for 1.5 h and then at reflux for 42 h. Water (50 mL) and ether (100 mL) were added, and the organic layer was separated, washed with 10% sodium thiosulfate (50 mL), and then extracted with sodium bicarbonate (50 mL). The bicarbonate extract was acidified to pH 2–3 with 1 mol/L hydrochloric acid and extracted with ether (2 × 25 mL). The ether extract was washed with saturated sodium chloride (50 mL), dried over anhydrous sodium sulfate, and evaporated under reduced pressure to give 814 mg (15%) of a colourless oil. ^{1}H NMR (CDCl$_3$) δ: 3.25 (2H, t, 6.72 Hz), 2.52 (2H, t, 7.28 Hz), 2.13 (2H, q).

Reaction of 4-iodobutanoic acid with *N*-hydroxyglycine *tert*-butyl ester

Dicyclohexylcarbodiimide (51 mg, 0.25 mmol) (BDH) was added under nitrogen to a cooled (0 °C) solution of the acid (65 mg, 0.30 mmol) in dichloromethane (2 mL), and a solution of *N*-hydroxyglycine *tert*-butyl ester (34 mg, 0.23 mmol) in dichloromethane (2 mL) was added dropwise, with stirring. The cloudy mixture was stirred for 12 h at 0 °C – room temperature and was then filtered. The filtrate was evaporated, and the residue was purified by flash chromatography (40% ethyl acetate – hexane) to give 16.8 mg (21%) of **52** as a yellow oil.

Preparation of *tert*-butyl 3-oxo-[1,2]oxazinan-2-yl-acetate

The oil **52** (4 mg, 0.012 mmol) was dissolved in dichloromethane (5 mL); triethylamine (13 μL, 9.44 mg, 0.093 mmol) was added, and the solution was stirred for 3 h. Then DBU (4 μL, 4 1 mg, 0.027 mmol) was added, and stirring was continued for 3.5 h. The solvent was then removed. The residue was dissolved in ethyl acetate (5 mL), washed with saturated sodium chloride, dried over anhydrous sodium sulfate, and concentrated to give 3 mg of **53**. ^{1}H NMR (CDCl$_3$) δ: 4.28 (2H, s, CH$_2$), 4.16 (2H, t, 6.84 Hz, OCH$_2$), 2.55 (2H, t, 7.2 Hz, CH$_2$CO), 2.14 (2H, m), 1.47 (9H, s)

Acetoacetamido *N*-benzyloxyglycine ethyl ester

A solution of *N*-benzyloxyglycine ethyl ester (0.159 g, 0.76 mmol) and 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one (0.1 mL, 0.76 mmol) in toluene (0.76 mL) was immersed in a preheated (110 °C) oil bath and stirred vigorously for 4 h and monitored by TLC. The reaction mixture was then concentrated under reduced pressure and further dried at 1 torr for 2 h to give a viscous orange oil (0.222 g, 100%). IR (CDCl$_3$, cm^{-1}): 1749 (C=O, s), 1670 (NC(O)). ^{1}H NMR (CDCl$_3$) δ: 7.40 (5H, s, OCH$_2$*Ph*), 4.88 (2H, s, O*CH$_2$*Ph), 4.32 (2H, s, (O)C*CH$_2$*C(O)), 4.22 (2H, q, O*CH$_2$*CH$_3$), 3.55 (2H, s, N*CH$_2$*CO$_2$Et), 2.25 (3H, s, CH$_3$C(O)), 1.29 (3H, t, OCH$_2$*CH$_3$*). CI-MS (*m/z*): 294 ([M + 1]). Anal. calcd. for C$_{15}$H$_{19}$NO$_5$: C 61.43, H 6.48, N 4.78; found: C 61.21, H 6.74, N 5.14.

Hydrogenolysis of acetoacetamido *N*-benzyloxyglycine ethyl ester

Palladium on carbon (10%) (97 mg) was added to a solution of acetoacetamido *N*-benzyloxyglycine ethyl ester (104 mg, 0.35 mmol) in ethanol (2 mL). The resulting suspension was fitted with a balloon, flushed thrice with hydrogen, and then stirred under hydrogen for 1 h at room temperature. After filtration through Celite and evaporation of the filtrate, the oil was purified by chromatography through a short column of silica gel using 60% ethyl acetate-hexanes. The colourless oil (65.2 mg, 91%) was identified as an 85:15 mixture of **54** and **55**. IR (film, cm^{-1}): 3390, 1746, 1687. ^{1}H NMR (CDCl$_3$) δ: **54**: 4.52 (1H, d, 18.16 Hz), 4.24 (2H, q), 4.12 (1H, d, 18.16 Hz), 3.03 (1H, d, 16.76 Hz), 2.75 (1H, d, 16.76 Hz), 1.60 (3H, s), 1.29 (3H, t); **55**: 4.54 (2H, s), 4.24 (2H, q), 3.75 (2H, s), 2.29 (3H, s), 1.29 (3H, s). CI-MS (*m/z*): 204 ([M + 1]). Anal. calcd. for C$_8$H$_{13}$NO$_5$: C 47.29, H 6.70, N 6.20; found: C 47.57, H 6.40, N 6.90.

Synthesis of 56

Diketene (0.13 mL, 0.12 g, 1.67 mmol) was added to a solution of *N*-hydroxyglycine benzyl ester (0.303 g, 1.67 mmol) in chloroform (3 mL). The solution was stirred for 3 h at room temperature, concentrated under reduced preesure, and purified by PLC (60% EtOAc–hexanes). The product was a yellow solid (0.16 g, 36%). ^{1}H NMR (CDCl$_3$) δ: 7.37–7.32 (5H, m, Ar), 5.18 (2H, s, CH$_2$Ph), 4.53 (1H, d, 18.12 Hz), 4.19 (1H, d, 18.12 Hz), 3 (1H, d, 16.84 Hz), 2.76 (1H, d, 16.84 Hz), 1.60 (3H, s, CH$_3$). CI-MS (*m/z*): 266 ([M + 1]). The solid (150 mg, 0.57 mmol) was dissolved in ethanol, and palladium on carbon (150 mg, 10%) was added. The suspension was fitted with a balloon, flushed thrice with hydrogen, and then stirred under hydrogen for 1 h at room temperature, filtered through Celite, and evaporated. The oil was redissolved in water (10 mL), filtered, and the filtrate was lyophilized to give a brown solid (0 mg, 81%) identified as a 2:1 mixture of **56** and **57**. ^{1}H NMR (D$_2$O) δ: **56**: 4.39 (1H, d, 17.72 Hz), 4.20 (1H, d, 17.72 Hz), 3.17 (1H, d, 17.16 Hz), 2.77 (1H, d, 17.16 Hz), 1.60 (3H, s); **57**: 4.38 (2H, s), 3.38 (2H, s), 2.29 (3H, s). CI-MS (*m/z*): 176 ([M + 1]).

Benzyl-γ-bromoacetoacetate

Diketene (500 μL, 545 mg, 6.5 mmol) was dissolved in dichloromethane (2 mL), and the solution was cooled to –25 °C and treated dropwise with a solution of bromine (333 μL, 1.02 g, 6.5 mmol) in dichloromethane (2 mL). After the addition was complete, the solution was stirred at –25 °C for 15 min, and benzyl alcohol (700 μL, 732 mg, 6.8 mmol) was added dropwise. Stirring was continued for 15 min, and the solution was warmed to room temperature and evaporated. The residue was dissolved in diethyl ether (20 mL), washed successively with saturated sodium bicarbonate (2 × 20 mL), water (20 mL), and saturated sodium chloride (20 mL), dried over anhydrous magnesium sulfate, and evaporated to give benzyl γ-bromoacetoacetate as a pale yellow oil (1.70 g, 97%). IR (neat, cm^{-1}): 3033, 1734, 1654. ^{1}H NMR (CDCl$_3$) δ: 7.36 (5H, m), 5.19 (2H, s), 4.02 (2H, s), 3.75 (2H, s). CI-MS (*m/z*): 271, 273 ([M + 1], [M +

3]). Anal. calcd. for $C_{11}H_{11}BrO_3$: C 48.69, H 4.05; found: C 48.55, H 3.94.

Benzyl-3-hydroxy-4-bromobutanoate

Benzyl bromoacetoacetate (500 mg, 1.84 mmol) was dissolved in a mixture of tetrahydrofuran (9 mL) and methanol (1 mL), the solution was cooled in an ice-bath, and sodium borohydride (72 mg, 1.90 mmol) was added in one portion. Stirring was continued in the ice-bath for 15 min and ethyl acetate (50 mL) and 1 mol/L hydrochloric acid (1.5 mL) were added. The aqueous layer was separated, extracted with ethyl acetate (20 mL), and the combined organic layers were washed with saturated sodium bicarbonate (40 mL), dried over anhydrous magnesium sulfate, and evaporated to give benzyl 3-hydroxy-4-bromobutanoate 433 mg, 86%). IR (neat, cm^{-1}): 3443, 3064, 1731, 1624. ^{1}H NMR (CDCl$_3$) δ: 7.36 (5H, s), 5.17 (2H, s), 4.26 (1H, m), 3.50 (1H, dd, 5.0, 10.5 Hz), 3.47 (1H, dd, 5.6, 10.5 Hz), 3.06 (1H, d, 5.1 Hz), 2.72 (1H, dd, 5.0, 16.6 Hz), 2.69 (1H, dd, 7.3, 16.6 Hz). CI-MS (*m/z*): 273, 275 ([M + 1], [M + 3]). Anal. calcd. for $C_{11}H_{13}BrO_3 \cdot 0.5H_2O$: C 53.75, H 5.88; found: C 53.65, H 5.60.

Benzyl 3-[2-tetrahydropyranyloxy]-4-bromobutanoate

The bromohydrin (845 mg, 3.09 mmol) was dissolved in dichloromethane (10 mL), and dihydropyran (300 μL, 277 mg, 3.29 mmol) and *p*-toluenesulfonic acid monohydrate (3 crystals) were added. The solution was stirred at room temperature for 1.5 h. Diethyl ether (40 mL) was then added, and the solution was washed with saturated sodium bicarbonate (2 × 40 mL), dried over anhydrous sodium sulfate, and evaporated. Purification by column chromatography using ethyl acetate – hexanes (3:7) gave the product **62** (1.07 g, 97%) as a 1:1 mixture of diastereomers. IR (neat, cm^{-1}): 3033, 1737. CI-MS (*m/z*): 357, 359 ([M + 1], [M + 3]). Calcd. for $C_{16}H_{21}BrO_4$: C 53.75, H 5.88; found: C 53.65, H 5.60.

3-[2-Tetrahydropyranyloxy]-4-bromobutanoic acid

The protected bromohydrin **62** (73 mg, 0.20 mmol) was dissolved in tetrahydrofuran (3 mL) and 10% palladium on charcoal (65 mg) was added. The mixture was flushed thrice with nitrogen, thrice with hydrogen, and then stirred under hydrogen for 45 min. The mixture was filtered through Celite, the Celite was rinsed with ethyl acetate (10 mL), and the combined filtrates were evaporated to give the product **63** as a colourless oil, 54 mg (98%). IR (neat, cm^{-1}): 1715. CI-MS (*m/z*): 267, 269 ([M + 1], [M + 3]).

Coupling of 63 with *tert*-butyl *N*-hydroxyglycine

The acid **63** (85 mg, 0.32 mmol) was dissolved in methylene chloride (3 mL), the solution was cooled in an ice-bath, stirred, and dicyclohexylcarbodiimide (70 mg, 0.34 mmol) was added, followed by a solution of the *tert*-butyl ester (46.8 mg, 0.32 mmol) in methylene chloride (3 mL). The cloudy mixture was stirred, initially at 0 °C, and allowed to warm to room temperature. After 12 h, ether (20mL) was added, the mixture was filtered, and the filtrate was evaporated. The product was purified by chromatography on silica

gel. Elution with 30:70 ethyl acetate:hexane gave 81 mg (64%) of a viscous oil.

Protected 2-carboxymethyl-5-hydroxy-1,2-oxazine-3-one

A portion of the above oil (37 mg, 0.093 mmol) was dissolved in methylene chloride (2 mL), and triethylamine (14 μL, 10.2 mg, 0.10 mmol) was added. The solution was left under nitrogen for 1 h, and DBU (7.0 μL, 0.047 mmol) was added, followed after 2.5 h by an additional 5.0 μL (033 mmol) of DBU. Stirring was continued under nitrogen for 3.2 h, and the reaction mixture was then diluted with methylene chloride (10 mL), washed with water (10 mL), dried over anhydrous sodium sulfate, and evaporated. Chromatography on silica gel and elution with 45:55 ethyl acetate:hexane gave the protected oxazinone as a semisolid and as a 1:1 mixture of diastereomers. ^{1}H NMR (CDCl$_3$) δ: 4.66 (1H, m, THP proton, one isomer), 4.41 (1H, m, THP proton, second isomer), 4.32–4.45 (2H, m, both isomers), 3.83 (1H, m, 5-H of one isomer), 2.94–2.62 (2H, both isomers, two ddd), 1.8 (2H, m), 1.7 (2H, m), 1.55 (2H, m), 1.47 (9H, s).

5-Hydroxy-3-oxo-[1,2]oxazinan-2-yl-acetic acid

The protected oxazinone (11 mg, 0.35 mmol) was dissolved in methylene chloride (1 mL), cooled in an ice-bath, and trifluoroacetic acid (500 μL) was added. Additional trifluoroacetic acid (3 μL) was added after 15 min, after an additional 20 min (500 μL), and after an additional 30 min (300 μL). After an additional 55 min, the solvent was removed. The residue was redissolved in trifluoroacetic acid (500 μL), evaporated after 30 min, and the residue shaken with ethyl acetate (2 mL), water (1 mL), and sodium bicarbonate (3 mg). The aqueous phase was separated, washed with ethyl acetate, and lyophilized to give **29**, R = H, as the sodium salt. ^{1}H NMR (D$_2$O) δ: 4.49 (1H, m), 4.29 (1H, dd, 12.1, 4.6 Hz), 4.28 (1H, d, 18.2 Hz), 4.15 (1H, d, 18.2 Hz), 4.02 (1H, ddd, 12.1, 3.24, 0.8 Hz), 2.92 (1H, dd, 16.8, 5.9 Hz), 2.52 (1H, ddd, 16.8, 3.16 Hz).

Coupling of 63 to the *tert*-butyl ester of *N*-hydroxyalanine

The acid **63** (54 mg, 0.20 mmol) was dissolved in dichloromethane (3 mL), the solution was cooled in an ice-bath, stirred, and dicyclohexylcarbodiimide (41 mg, 0.20 mmol) was added, followed by a solution of the *tert*-butyl ester in dichloromethane (2 mL). The mixture was stirred in the ice-bath for 5 min; the ice-bath was then removed, and stirring was continued for 3 h. The mixture was filtered, and the filtrate was evaporated. The residue was chromatographed on silica gel. Elution with ethyl acetate – hexanes (2:3) gave **67** (74 mg, 54%) and products of O-acylation. IR (CH$_2$Cl$_2$, cm^{-1}): 3432, 1736, 1657. CI-MS (*m/z*): 410, 412 ([M + 1], [M + 3]).

Cyclization of 67

The *N*-acylated compound **67** (36 mg, 0.088 mmol) was dissolved in dichloromethane (10 mL), cooled in an ice-bath, and 1,8-diazabicyclo[5.4.0]undec-7-ene (15 μL, 0.1 mmol) was added. The solvent was removed after 1 h. The residue was dissolved in ethyl acetate (25 mL), and the solution was washed with water (2 × 25 mL), dried over anhydrous mag-

nesium sulfate, and evaporated to give the protected oxazinone **69** (25 mg, 85%). IR (CH$_2$Cl$_2$, cm^{-1}): 1736, 1678. CI-MS (*m/z*): 330 ([M + 1]). HR-MS-CI calcd. for C$_{16}$H$_{27}$NO$_6$: 330.1917 ([M + 1]); found: 330.1916.

2-(5-Hydroxy-3-oxo-[1,2]oxazinan-2-yl-propionic acid (29, R = Me)

The protected oxazinone **69** (10.1 mg, 0.031 mmol) was dissolved in dichloromethane; the solution was cooled in an ice-bath, and trifluoroacetic acid (1 mL, 13.0 mmol) was added. The solution was stirred for 30 min, and the solvent was then removed. The residue was dissolved in trifluoro-acetic acid (500 µL), and the solution was stirred at room temperature for 15 min and evaporated. The residue was shaken with ethyl acetate (3 mL) and a solution of sodium bicarbonate (2.8 mg) in water (2 mL). The aqueous phase was lyophilized to give the sodium salt of **29**, R = Me as an approximately 1:1 mixture of *RR–SS* and *RS–SR* diastereomers. ^{1}H NMR (D$_2$O) δ: 4.89 (1H, q, 7.3 Hz, α-C*H*, one isomer), 4.88 (1H, q, 7.3 Hz, α-C*H*, second isomer), 4.72–4.69 (2H, m, H5, both isomers), 4.54 (1H, d, 10.5 Hz, H6, one isomer), 4.53 (1H, d, 10.5 Hz, H6, second isomer), 4.35 (2H, d, 10.5 Hz, H6, both isomers), 2.97 (1H, d, 18.3 Hz, H4, one isomer), 2.95 (1H, d, 18.3 Hz, H4, second isomer), 2.51 (2H, m, 18.3 Hz, H4, both isomers), 1.45 (3H, d, 7.3 Hz, C*H*$_3$, one isomer, 1.42 (3H, d, 7.3 Hz, C*H*$_3$, second isomer). CI-MS (*m/z*, for the acid): 190 ([M + 1]), 172 ([M + 1 – H$_2$O]). HR-MS-CI calcd. for C$_7$H$_{12}$NO$_5$: 190.0716 ([M + 1]); found: 190.0712.

Bioassays

Materials

Agar medium (1% w/v)

Yeast extract (1.5 g), peptone (2.5 g), glucose (0.5 g), and agar (5.0 g) were dissolved in deionized water; the volume was diluted to 500 mL, and the solution was sterilized by autoclaving at 121 °C for 20 min.

Preparation of agar plates

Under sterile conditions, the agar medium (150 mL) was heated to 100 °C, cooled to 50 °C, and distributed into ten petri dishes. Once the medium had hardened, the plates were inverted and stored at 4 °C.

Liquid medium

Yeast extract (0.3 g), peptone (0.5 g), and glucose (0.1 g) were dissolved in deionized water; the volume was diluted to 100 mL, and the solution was sterilized by autoclaving at 121 °C for 20 min.

Methods

Step 1: Under sterile conditions, freeze-dried *M. luteus* was dissolved in liquid medium (10 mL) and incubated at 250 rpm for 12 h at 30 °C.

Step 2: Liquid bacterial culture from step 1 (0.5 mL) and 40% glycerol in deionized water (0.5 mL) were vortexed under sterile conditions in a tube fitted with a screw cap and an air-tight gasket. The resulting 20% glycerol bacterial stock solution was stored at –80 °C.

Step 3: An inoculating needle was dipped into 20% glycerol bacterial stock solution from Step 2 and, under sterile conditions, streaked onto the surface of an agar plate. The inverted plate was incubated at 30 °C for 12 h and then stored at 4 °C.

Step 4: Under sterile conditions, a bacterial colony of *M. luteus* was lifted from the surface of the agar plate from Step 3 using a toothpick, added to liquid medium (10 mL), and incubated at 250 rpm for 12 h at 30 °C.

Step 5: Under sterile conditions, the agar medium (150 mL) was heated to 100 °C, cooled to 50 °C; liquid bacterial culture from Step 4 (4 mL) was added with swirling, and the medium was distributed into ten petri dishes. Once the medium had hardened, the plates were inverted and stored at 4 °C.

Step 6: A sterile filter disc was treated with an aliquot of a known concentration of the test compound, and the solvent was removed by air drying under sterile conditions. This disc, a solvent control disc, and a disc containing a known weight of a penicillin or cephalosporin were placed on an agar plate seeded with *M. luteus* from Step 5. The plate was inverted and incubated for 12 h at 30 °C.

Cyclic hydroxamates, especially multiply substituted [1,2]oxazinan-3-ones

Saul Wolfe, Marie-Claire Wilson, Ming-Huei Cheng, Gennady V. Shustov, and Christiana I. Akuche

Abstract: Routes to putative *N*-acyl-D-ala-D-ala surrogates, beginning with the conversion of 4-, 5-, and 6-membered lactones into 5-, 6-, and 7-membered cyclic hydroxamates, are reported. The key step of the synthesis is trimethylaluminium-promoted cyclization of an ω-aminooxyester. The 7-membered cyclic hydroxamate crystallizes in a chair conformation. Extension of the reaction sequence to homoserine or homoserine lactone leads to cyclocanaline and *N*-acylated cyclocanalines. The 4-phenylacetamido derivative of cyclocanaline crystallizes in a boat conformation. The attachment of a 2-carboxypropyl substituent to the ring nitrogen of a 4-acylaminocyclocanaline has been effected, prior to cyclization, by coupling of the acyclic aminooxyester precursor to the triflate of benzyl lactate or, after cyclization, by coupling to *tert*-butyl α-bromopropionate in the presence of potassium fluoride – alumina, followed by removal of the protecting group in each case. A six-membered homolog of the antibiotic lactivicin has been synthesized by the reaction of 4-phenylacetamidocyclocanaline with benzyl 2-oxoglutarate in the presence of carbodiimide, followed by hydrogenolysis. Starting with methyl 2,4-dibromo-2,4-dideoxy-L-erythronate, which is available in two steps from L-ascorbic acid, these reaction sequences have been applied to the stereospecific synthesis of a D-alanine derivative whose nitrogen atom is enclosed within a 3,4-disubstituted [1,2]oxazinan-3-one.

Key words: D-ala-D-ala surrogate, cyclocanaline, homolactivicin, peptidoglycan, trimethylaluminium.

Résumé : On a développé des nouvelles voies permettant de préparer des produits de substitutions potentiels de la *N*-acyl-D-ala-D-ala; elles débutent par la conversion des lactones à 4-, 5- et 6-chaînons en hydroxamates cycliques à 5-, 6- et 7-chaînons. L'étape clé de la synthèse est une cyclisation catalysée par le triméthylaluminium d'un ω-aminooxyester. L'hydroxamate cyclique à sept chaînons cristallise dans une conformation chaise. L'extension de la séquence de réaction à l'homosérine ou à la lactone de l'homosérine conduit à la formation de la cyclocanaline et à des cyclocanalines *N*-acétylées. Le dérivé 4-phénylacétamido de la cyclocanaline cristallise dans la conformation bateau. On a effectué la fixation d'un substituant 2-carboxycyclopropyle sur l'azote du cycle d'une 4-acylaminocyclocanaline avant la cyclisation, par le couplage du précurseur aminooxyester acyclique au triflate du lactate de benzyle, ou après la cyclisation, par couplage à l'α-bromopropionate de *t*-butyle en présence de fluorure de potassium et d'alumine, suivi dans chaque cas de l'enlèvement du groupe protecteur. On a réalisé la synthèse d'un homologue à six chaînons de l'antibiotique lactivicine par réaction de la 4-phénylacétamidocyclocanaline avec du 2-oxoglutarate de benzyle en présence de carbodiimide, suivie d'une hydrogénolyse. Utilisant comme produit de départ le 2,4-dibromo-2,4-didésoxy-L-érythronate de méthyle qui est disponible en deux étapes à partir de l'acide L-ascorbique, on a applique cette séquence de réactions à la synthèse stéréospécifique d'un dérivé D-alanine dont l'atome d'azote est inclus dans une [1,2]oxazinan-3-one disubstituée dans les positions 3 et 4.

Mots clés : substitut de D-ala-D-ala, cyclocanaline, homolactivicine, peptidoglycane, triméthylaluminium.

[Traduit par la Rédaction]

Introduction

We have recently given theoretical and experimental reasons for our belief that the six-membered cyclic hydroxamate **1** can function as a β-lactam surrogate (1). Since penicillin (**2**), the quintessential β-lactam compound, is itself a conformationally constrained surrogate of *N*-acyl-D-ala-D-ala (**3**) (the peptide terminus of the growing bacterial cell wall peptidoglycan (2)), the introduction of an acylamino group at

C4 of **1** and the attachment of a 2-carboxypropyl substituent onto the ring nitrogen of the resulting cyclocanaline derivative **4** (3) would lead to **5**, a novel but conformationally flexible surrogate of **3**.

There is precedent for the proposal of **5** as a synthetic target in the structure of the natural product lactivicin (**6**), which exhibits affinity to penicillin-recognizing enzymes (4), and in the claim that homolactivicins (**7**) have antibacterial activity (5). However, as a caveat, it was known at the

[1]Corresponding author (e-mail: swolfe@sfu.ca).
beginning of the present work that cycloserine derivatives such as **8** are inactive (6).
In this paper we describe a reaction sequence leading from lactone precursors to cyclic hydroxamates and the application of this sequence to the synthesis of biologically inactive D-cyclocanaline, to non-stereospecific syntheses of biologically inactive **5** and **7**, and to a stereospecific approach to the more general structure **9**.

Crystal structures of the parent 7-membered cyclic hydroxamate [1,2]oxazepan-3-one and phenylacetylcyclo-canaline **10** are also reported.
Results and discussion

Although earlier workers (7) had found cyclization of unsubstituted γ-halohydroxamic acids (**11**, R = H, X = halogen) to lead mainly to the 5-membered 1-hydroxypyrrolidin-2-one (**12**) and not to the 6-membered **1**, we observed that only the 6-membered ring is produced in the cyclization of **13**, R = H or Me (1). However, in the latter case (R = Me), the N-acylated product **13**, formed by coupling of the *tert*-butyl ester of N-hydroxyalanine to **14**, was accompanied by the O-acylated product.
To avoid this problem in the general case Z ≠ H, we examined the sequence **15** → **16** → **17**, in which ring closure proceeds by N2—C3 bond formation. Previous workers had reported (8) that this strategy produces cyclocanaline in 35% yield by the action of ethanolic KOH on canaline ethyl ester and N-benzoyl cyclocanaline in 75% yield upon treatment of N-benzoyl canaline ethyl ester with methanolic NaOH. We have now found trimethylaluminium (9) cyclization of aminooxy esters to be a general reaction for the production of cyclic hydroxamates of increasing complexity. The work proceeded in five stages.

5-, 6-, 7-, And 8-membered cyclic hydroxamates from 4-, 5-, 6-, and 7-membered lactone precursors

In the first stage, with γ-butyrolactone as the prototype

Scheme 1. Reagents and conditions: (*i*) 45% HBr–HOAc, 75 °C; (*ii*) MeOH; (*iii*) FtOH, Et$_3$N, MeCN, reflux; (*iv*) MeNHNH$_2$, CH$_2$Cl$_2$; (*v*) AlMe$_3$, THF.
(Scheme 1), a four-step synthesis of the parent 5-, 6-, 7-, and 8-membered cyclic hydroxamates from 4-, 5-, 6-, and 7-membered lactones was developed, consisting of conversion to ω-bromo methyl esters, displacement of bromine with *N*-hydroxyphthalimide, removal of the phthalimido (Ft) protecting group with methylhydrazine, and cyclization.

Heating of butyrolactone at 75 °C with a 45% solution of hydrogen bromide in acetic acid, followed by addition of methanol, gave methyl γ-bromobutyrate (**18**) in 86% yield (10). A protected aminooxy group was introduced by displacement of bromine with *N*-hydroxysuccinimide (11) or *N*-hydroxyphthalimide (12). Both products were crystalline, with mp 69–71.5 and 79–81 °C, respectively, but the yield of methyl γ-phthalimidooxybutyrate (**20**) was 78%, and the yield of methyl γ-succinimidooxybutyrate could not be increased above 28%. Removal of the succinimido protecting group required a 12 h treatment with 4 equiv of hydrazine hydrate in methanol at room temperature to give **20** in 45% yield (12). In contrast, **19** gave a quantitative yield of **20** with 1.5 equiv of methylhydrazine in dichloromethane for 1.5 h at –10 to 0 °C (13). The methyl ester was stable to these conditions. The cyclization of **20** was achieved initially using the basic conditions reported by Khomutov et al. (8). Refluxing with potassium hydroxide in methanol for 2 h, followed by stirring at room temperature overnight, produced **21** in 24% yield. The ^{1}H NMR spectrum showed peaks at 8.89 (1H, br s, N*H*), 4.03 (2H, t, 6.5 Hz, C*H$_2$*O), 2.52 (2H, t, 7.2 Hz, COC*H$_2$*), and 2.10 (2H, quintet, 6.9 Hz, COCH$_2$C*H$_2$*) ppm. The ^{13}C NMR spectrum showed peaks at 172.93, 69.04, 27.42, and 21.55 ppm. Infrared absorptions at 3403 and 1667 cm^{-1} were assigned to the N-H and carbonyl groups. The CI mass spectrum showed an [M + 1] peak at *m/z* 102. The EI mass spectrum showed, in addition to the molecular ion, a peak at [M – 32], corresponding to loss of H$_2$NO (**22**). Trimethylaluminium gave better results. With

2 equiv in tetrahydrofuran or toluene and at room temperature or reflux temperature, the yield of **21** was 65–79%.

Following these exploratory experiments, the 5-, 7-, and 8-membered cyclic hydroxamates were prepared, as summarized in Table 1. The EI mass spectra all showed, in addition to the molecular ion, the peak at [M – 32]. In the case of the 8-membered ring, [1,2]oxazocan-3-one, after numerous unsuccessful experiments, cyclization of the aminooxy ester was performed by dropwise treatment of 4 equiv of a 0.18 mol/L solution of trimethylaluminium in heptane (4.96 mL) and toluene (50 mL) with 50 mL of a 0.4% solution of the ester in toluene, followed by stirring at room temperature for six days. After addition of water and concentration to near dryness, the gelatinous residue was dissolved in 1:4 dichloromethane:tetrahydrofuran, filtered through Celite, and evaporated. Preparative layer chromatography yielded three bands, one of which contained 84 mg of material. The GC of this material contained several peaks, one of which, comprising 2% of the total, gave an EI-MS with peaks at *m/z* 129, corresponding to the molecular ion, and 97, corresponding to loss of H$_2$NO. In Yamamoto's trimethylaluminium-promoted lactam synthesis (14), the 8-membered ring was obtained in 7% yield, which was increased to 43% using triethylgallium.

The 7-membered ring [1,2]oxazepan-3-one crystallized as colourless plates, mp 84.5–85.8 °C, and its crystal structure was determined. The compound crystallizes in the $P2_1/a$ space group and is centrosymmetric with four molecules, consisting of two hydrogen-bonded dimers, in the unit cell. Figure 1 shows several views of the crystal structure. As seen in the centre of this figure, the dimer is held together by linear NH⋯O=C hydrogen bonds; this causes the two monomeric units to be offset with respect to each other, unlike the structure drawn at the bottom. The monomeric structure is a chair.

Table 1. Conversion of lactones into cyclic hydroxamates.

n	Yield (%)	Yield (%)	Yield (%)	Yield (%)
1	56	21[a]	50	45
2	86	78	quantitative	79
3	87	74	97	82[b]
4	95	99	98	trace[c]

[a]This reaction was found to proceed via methyl acrylate. The compound was therefore prepared more conveniently by addition of *N*-hydroxyphthalimide to methyl acrylate in refluxing methanol containing triethylamine.

[b]The 7-membered ring ([1,2]oxazepan-3-one) crystallized as colourless plates; mp 84.5–85.8 °C, and its X-ray structure was determined.

[c]See text.

Scheme 2.
Cyclocanaline and *N*-acylcyclocanalines

In the second stage, with trimethylaluminium-promoted cyclization of an ω-aminooxyester established as a viable reaction, syntheses of cyclocanaline and *N*-acylated cyclocanalines from homoserine (**23**) or homoserine lactone (**24**) were undertaken, as shown in Scheme 2, via **26**, the mesylate of the *N*-acylated methyl ester **25**. The conversion of **26** to **27** proceeded in 64% yield with R_1 = *tert*-butoxy, using *N*-hydroxyphthalimide and DBU in dimethylformamide, and in 84% yield with R_1 = benzyl, using *N*-hydroxyphthalimide and triethylamine in acetonitrile. In both cases the removal of the phthalimido group and the subsequent cyclization of **28** to **29** proceeded without incident. Deprotection of **29**, R_1 = *t*-BuO, to the trifluoroacetic acid salt of cyclocanaline took place in 98% yield, and this salt was converted to **29**, R_1 = PhOCH$_2$.

The phenylacetyl derivative **10** crystallized as colourless plates, mp 164–165 °C, of acceptable quality for an X-ray structure determination. The compound crystallizes in the $P2_1/a$ space group and is centrosymmetric with four molecules (two enantiomeric pairs) in the unit cell. Figure 2 shows one of these pairs. The oxazinone ring has a boat con-

formation with O1 and C4 at the apices and an equatorial acylamino substituent.

The reaction sequences just described were carried out from racemic homoserine, from commercially available *S*-homoserine lactone, and from *R*-methionine, which is readily converted to *R*-homoserine lactone (15). D-Cyclocanaline was inactive at a concentration of 125 μg/mL against a panel of gram-positive, gram-negative, and β-lactam-producing organisms.

N2-alkylation of cyclic hydroxamates

In the third stage we examined the attachment of a substituent to the ring nitrogen of a cyclic hydroxamate. The initial experiments were performed under Mitsunobu conditions (16), using *tert*-butoxycarbonyl-protected *R*-cycloserine (**30**) and ethyl *S*-lactate (**31**). With tetrahydrofuran as the solvent, these experiments yielded a mixture of two products whose ^{1}H NMR spectra featured methyl doublets at 1.53 and 1.58 ppm and methine quartets at 4.80 and 4.96 ppm. The CI mass spectrum showed an [M + 1] peak at *m/z* 303 and a prominent peak at 247 corresponding to loss of C$_4$H$_8$. The mixture is assigned structure **32**, formed by nonstereospecific

Fig. 1. Crystal structure of [1,2]oxazepan-3-one.
attachment of the carboxypropyl chain to the ring nitrogen. Loss of stereochemical integrity has been seen previously (17) in Mitsunobu reactions of α-hydroxyesters.

Following these experiments with the five-membered cyclic hydroxamate, the Mitsunobu coupling of **21** with ethyl *S*-lactate was examined. In this case, because of the insolubility of the oxazinone in tetrahydrofuran, dichloromethane was employed as the solvent (18) to yield two isomeric adducts. The major adduct, isolated in 51% yield, is assigned the *N*-alkylated structure **33** on the basis of an [M + 1] peak at 202 in the CI-MS and the presence of a methine quartet at 5.03 ppm in the ^{1}H NMR spectrum. The minor adduct, isolated in 7% yield, is assigned the O-alkylated structure **34** on the basis of a downfield shift of the methine quartet to

33

38

34

39

Scheme 3.

35

36

37
5.20 ppm. O-Alkylation is a known reaction of *N*-acylated hydroxylamines (19).

The loss of stereochemical integrity in the attachment of the carboxypropyl moiety to the ring nitrogen in the case of *tert*-butoxycarbonyl *R*-cycloserine and the competing O-alkylation in the reaction of the oxazinone suggested that the introduction of a carboxypropyl substituent be performed prior to cyclization, i.e., **20** → **35**. However, **20** was unreactive under Mitsunobu conditions.

It was then discovered (Scheme 3) that **35** could be synthesized in 74% yield by alkylation of the amino group of **20** with the triflate of benzyl *S*-lactate. This alkylation reaction is reported to proceed with inversion of configuration (20), a finding confirmed in the present work (vide infra).

The cyclization of **35** using trimethylaluminium proceeded in 84% yield to give the benzyl ester **36**, which was successfully deprotected by hydrogenolysis to the acid **37**.

N2- and N′-functionalized [1,2]oxazinan-3-ones

Alkylation of **28**, R_1 = PhCH$_2$, R_2 = Me, with the triflate of benzyl *S*-lactate afforded **38** in 29% yield as a 1:1 mixture of diastereomers. Cyclization with trimethylaluminium produced one of the isomers of **39** in 36% yield.

More effectively in this case (Scheme 4), treatment of **10** with *tert*-butyl *S*-α-bromopropionate in the presence of potassium fluoride – alumina produced the diastereomeric products **40a** (26%) and **40b** (31%). Deprotection with trifluoroacetic acid gave **5a**, mp 58–60 °C, from **40a** and **5b**, mp 189–190 °C, from **40b**. The ^{1}H NMR spectra of these compounds, *neither of which was active at a concentration of 32 μg/mL against a panel of Gram-positive, Gram-*

negative, and β-lactam-producing organisms, are shown in Figs. 3 and 4.

For the synthesis of homolactivicin (**7**, R = PhCH$_2$) (Scheme 5), racemic **10**, benzyl 2-oxoglutarate, and dicyclohexylcarbodiimide were stirred for three days in acetonitrile to give the diastereomeric products **41a** (31%) and **41b** (21%). Hydrogenolysis of a 1:1 mixture of **41a** and **41b** gave a homolactivicin, mp 150–152 °C, as a mixture of isomers, which was inactive at a concentration of 32 μg/mL against a panel of Gram-positive, Gram-negative, and β-lactam-producing organisms.

Stage 5: Chiral synthesis of 2,4,5-trisubstituted [1,2]oxazinan-3-ones

As summarized in Scheme 6, calcium L-threonate (**42**), prepared in 95% yield by hydrogen peroxide oxidation of L-ascorbic acid (21), was converted in 90% yield to methyl 2,4-dibromo-2,4-dideoxy-L-erythronate (**43**) by the procedure of Bock et al. (22). Methoxymethylation using dimethoxymethane and boron trifluoride, followed by reaction with sodium azide in dimethylformamide, gave the protected azido threonate **44** in 68% yield over the two steps. Hydrogenolysis in the presence of di-*tert*-butyl carbonate yielded the protected threonate methyl ester **45** (74%), and the introduction of the aminooxy function by an *N*-hydroxyphthalimide-methylhydrazine sequence produced **46** in 46% yield from **45**. Reaction of **46** with the triflate of benzyl L-lactate gave a single *N*-hydroxyalanine product, assigned the *R*-configuration **47**, in 66% yield. The cyclizations of **46** and **47** to **48** and **49** were achieved in 90% and 63% yield, respectively.

Fig. 2. Crystal structure of phenylacetylcyclocanaline.
Scheme 4.
Scheme 5.
Experimental

Scheme 7 summarizes the conversion of **49** to **52**, which has the *R*-configuration in the alanine side chain, the *R*-configuration at C4, and the *S*-configuration at C5. This compound exhibited weak activity vs. *Micrococcus luteus* (Table 2).

Nuclear magnetic resonance spectra were recorded on Bruker 100SY (^{1}H at 100 MHz) and Bruker AMX-400 (^{1}H at 400 MHz and ^{13}C at 100 MHz) spectrometers. Chemical shifts are denoted in δ units (ppm) relative to the solvent and converted to the TMS scale using δ (CHCl$_3$) = 7.27 ppm for

[a]Desacetoxycephalosporin G.

performed on a Carlo Erba model 1106 elemental analyzer. Melting points (mp) were obtained on a Fisher-Johns apparatus and are uncorrected. Preparative layer chromatography (PLC) was carried out on precoated Merck Silica Gel 60 F-254 plates with aluminium backing. Spots were observed under short-wavelength ultraviolet light and were visualized with a solution of 1% ceric sulfate or 2% molybdic acid in 10% sulfuric acid. Flash column chromatography was carried out on Merck Silica Gel 60 (230–400 Mesh).

Methyl γ-bromobutyrate (18)

A solution of γ-butyrolactone (25 mL, 28.0 g, 0.325 mol) in a 45% solution of hydrogen bromide in acetic acid (75 mL) was heated for 4 h at 75 °C, cooled to room temperature, treated with methanol (150 mL), and stirred overnight. Evaporation of the solvent gave a dark oil, which was dissolved in ethyl acetate (150 mL) and washed successively with saturated sodium bicarbonate (2 × 150 mL) and saturated sodium chloride (150 mL), dried over anhydrous magnesium sulfate, and evaporated to yield a clear oil (48.8 g, 86%). IR (neat) (cm^{-1}): 1738. ^{1}H NMR (CDCl$_3$) δ: 3.68 (3H, s, OCH_3), 3.44 (2H, t, 6.4 Hz, CH_2γ), 2.51 (2H, t, 7.2 Hz, CH_2α), 2.17 (2H, quintet, 6.8 Hz, CH_2β). ^{13}C NMR (CDCl$_3$) δ: 172.96, 51.70, 32.66, 32.19, 27.70. CI-MS (*m/z*): 181 ([M + 1]), 183 ([M + 3]). Calcd. for C$_5$H$_9$O$_2$Br: C 33.17, H 5.02; found: C 32.62, H 4.85.

Scheme 7. Reagents and conditions: (*i*) TFA, anisole; (*ii*) PhCH$_2$COCl, Et$_3$N, CH$_2$Cl$_2$; (*iii*) H$_2$, 5% Pd–C, EtOAc.
Methyl γ-succinimidooxybutyrate

Method A

Methyl γ-bromobutyrate (0.5 g, 2.9 mmol) was added dropwise to a solution of *N*-hydroxysuccinimide (0.308 g, 2.6 mmol) and triethylamine (0.38 mL, 0.276 g, 2.6 mmol) in tetrahydrofuran (20 mL). The reaction mixture was stirred for 4 h at room temperature and then filtered. The filtrate was evaporated under reduced pressure to give crystals (47 mg, 10%); mp 69–71.5 °C. IR (KBr) (cm^{-1}): 1727, 1710. ^{1}H NMR (CDCl$_3$) δ: 4.15 (2H, t, 6.1 Hz, C*H*$_2$γ), 3.69 (3H, s, OC*H*$_3$), 2.70 (4H, s, succinimido ring), 2.60 (2H, t, 7.3 Hz, C*H*$_2$α), 2.03 (2H, t, t, 7.3 Hz, 6.8 Hz, C*H*$_2$β). ^{13}C NMR (CDCl$_3$) δ: 173.35, 171.10, 76.18, 51.67, 29.87, 25.44, 23.41. CI-MS (*m/z*): 216 ([M + 1]). Calcd. for C$_9$H$_{13}$NO$_5$: C 50.22, H 6.10, N 6.51; found: C 50.24, H 6.14, N 6.52.

Method B

A solution of methyl γ-bromobutyrate (1.01 g, 5.5 mmol), *N*-hydroxysuccinimide (0.576 g, 5.5 mmol), and sodium methoxide (0.282 g, 5.5 mmol) in dimethylformamide (11 mL) was heated at 100 °C for 6 h. The solvent was then removed under reduced pressure, and the residue was dissolved in ethyl acetate (100 mL) and washed successively with water (2 × 100 mL) and saturated sodium chloride (100 mL), dried over anhydrous magnesium sulfate, and evaporated to give a solid, which was crystallized from ethanol to yield 0.331 g (28%) of product, identical to the product of Method A.

Method C

A solution of methyl γ-bromobutyrate (1.01 g, 5.5 mmol), *N*-hydroxysuccinimide (0.587 g, 5.5 mmol), and triethylamine (1.54 mL, 1.12 g, 11.1 mmol) in acetonitrile (10 mL)

was refluxed for 3 h, then cooled and filtered. The precipitate was washed with water and recrystallized from ethanol to give 0.180 g (15%) of the product, identical to the product of Method A.

Method D

A solution of methyl γ-bromobutyrate (1.01 g, 5.5 mmol), *N*-hydroxysuccinimide (0.584 g, 5.5 mmol), and triethylamine (0.77 mL, 0.559 g, 5.5 mmol) in dimethylformamide (11 mL) was stirred at room temperature for 24 h, then poured into water (80 mL) and extracted with ethyl acetate (2 × 60 mL). This extract was washed successively with water (2 × 100 mL) and saturated sodium chloride (100 mL), dried over anhydrous magnesium sulfate, and evaporated to give a solid, which was crystallized from ethanol to yield 0.175 g (15%) of the product, identical to the product of Method A.

Methyl γ-phthalimidooxybutyrate (19)

A mixture of methyl γ-bromobutyrate (14.7 g, 81.5 mmol), *N*-hydroxyphthalimide (13.3 g, 81.5 mmol), and triethylamine (22.7 mL, 16.5 g, 0.163 mol) in acetonitrile (110 mL) was refluxed for 3 h. The insoluble solid was removed by filtration, and the filtrate was evaporated. The residue was diluted with ethyl acetate (100 mL), and this solution was washed successively with water (3 × 100 mL) and saturated sodium chloride (100 mL), dried over anhydrous magnesium sulfate, and evaporated. The solid was recrystallized from hot ethanol to give 16.8 g (78%); mp 79–81 °C. IR (KBr) (cm^{-1}): 1735, 1727. ^{1}H NMR (CDCl$_3$) δ: 7.79 (4H, m, phthalimido ring), 4.26 (2H, t, 6.1 Hz, C*H*$_2$γ), 3.70 (3H, s, OC*H*$_3$), 2.66 (2H, t, 7.3 Hz, C*H*$_2$α), 2.09 (2H, quintet, 6.7 Hz, C*H*$_2$β). ^{13}C NMR (CDCl$_3$) δ: 174.50, 163.63, 134.43, 128.94, 123.48, 78.20, 51.50, 33.85, 25.14.

CI-MS (m/z): 264 ([M + 1]). Calcd. for $C_{13}H_{13}NO_5$: C 59.30, H 4.99, N 5.32; found: C 59.17, H 4.97, N 5.49.

Methyl γ-aminooxybutyrate (20)

Method A

A solution of methyl γ-phthalimidooxybutyrate (2.75 g, 10.45 mmol) in dichloromethane (50 mL) was cooled to –10 °C and treated dropwise, with stirring, with methylhydrazine (0.83 mL, 0.72 g, 15.7 mmol). Stirring was continued for 1.5 h at –10 to 0 °C, and the mixture was then filtered. The filtrate was concentrated, and the residue, in ethyl acetate (50 mL), was washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (22 mL). The aqueous layer was washed with ethyl acetate (50 mL), and the combined organic extracts were dried over anhydrous magnesium sulfate and evaporated to give a yellow oil (1.39 g, 100%). IR (neat) (cm^{-1}): 3322, 1734. ^{1}H NMR (CDCl$_3$) δ: 5.25 (2H, br s, NH_2), 3.68 (2H, t, 6.2 Hz, CH_2γ), 3.68 (3H, s, OCH_3), 2.38 (2H, t, 7.3 Hz, CH_2α), 1.92 (2H, quintet, 6.7 Hz, CH_2β). ^{13}C NMR (CDCl$_3$) δ: 173.95, 74.78, 51.58, 30.71, 23.65. CI-MS (m/z): 134 ([M + 1]). Calcd. for $C_5H_{11}NO_3$: C 45.09, H 8.34, N 10.52; found: C 45.02, H 8.36, N 10.49.

Method B

Hydrazine hydrate (0.07 mL, 74.6 mg, 1.49 mmol) was added, with stirring, to a solution of methyl γ-succinimidooxybutyrate (80 mg, 0.37 mmol) in methanol (3 mL). Stirring was continued at room temperature for 12 h, and the solvent was then removed. The solid residue was triturated with ethyl acetate (2 × 8 mL, 1 × 4 mL), and the ethyl acetate was evaporated to give the product as an oil (22.3 mg, 45%), identical with the product of Method A.

[1,2]Oxazinan-3-one (21)

Method A

A solution of methyl γ-aminooxybutyrate (0.51 g, 3.75 mmol) in toluene (37.5 mL) was treated with a 2.0 mol/L solution of trimethylaluminium in hexanes (3.75 mL, 7.5 mmol). The resulting mixture was refluxed for 2 h, cooled to room temperature, and poured onto a mixture of 5% hydrochloric acid and ice. The aqueous layer was extracted with chloroform and the organic layer was evaporated to dryness. The residue was purified by flash chromatography on silica gel, using 7:1 ethyl acetate:hexanes as the eluent, to yield a colourless oil (0.30 g, 79%). IR (CH$_2$Cl$_2$) (cm^{-1}): 3403, 1667. ^{1}H NMR (CDCl$_3$) δ: 8.89 (1H, br s, NH), 4.03 (2H, t, 6.5 Hz, CH_2O), 2.52 (2H, t, 7.2 Hz, COCH_2), 2.10 (2H, quintet, 6.9 Hz, COCH$_2$CH_2). ^{13}C NMR (CDCl$_3$) δ: 172.93, 69.04, 27.42, 21.55. CI-MS (m/z): 102 ([M + 1]). Anal. calcd. for $C_4H_7NO_2$·0.1H$_2$O: C 46.68, H 6.97, N 13.61; found: C 46.73, H 7.01, N 13.21.

Method B

Potassium hydroxide (0.042 g, 0.75 mmol) in methanol (4 mL) was added to a solution of methyl γ-aminooxybutyrate (0.10 g, 0.75 mmol) in methanol (10 mL), and the mixture was refluxed for 2 h, cooled to room temperature, stirred overnight, neutralized with 5% hydrochloric acid, and evaporated. The residue was purified by preparative layer

chromatography on silica gel using ethyl acetate as the eluent to yield an oil (18 mg, 24%), identical to the product of Method A.

Method C

A solution of methyl γ-aminooxybutyrate (3.03 g, 22.8 mmol) in tetrahydrofuran (40 mL) was cooled to 0 °C, and a 2.0 mol/L solution of trimethylaluminium in hexanes (22.8 mL, 45.6 mmol) was added in portions. The reaction mixture was allowed to warm to room temperature with stirring during 2 h and quenched with acetone (15mL) with stirring for 30 min and then by slow addition of water (50 mL). Most of the solvent was removed under reduced pressure, and 1:4 dichloromethane:tetrahydrofuran (300 mL) was added. Filtration through Celite and evaporation of the filtrate gave an oil (1.51 g, 65%), identical to the product of Method A.

Methyl β-bromopropionate

A solution of β-propiolactone (2 mL, 2.29 g, 30.8 mmol) in 30% hydrogen bromide in acetic acid (10 mL) was stirred at room temperature for 20 h. Then methanol (20 mL) was added, and stirring was continued for an additional 15 h. Evaporation of the solvent gave a dark oil, which was dissolved in ethyl acetate (50 mL) and washed successively with saturated sodium bicarbonate (2 × 50 mL) and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated to yield a clear oil (2.88 g, 56%). IR (neat) (cm^{-1}): 1742. ^{1}H NMR (CDCl$_3$) δ: 3.77 (3H, s, OCH_3), 3.62 (2H, t, 6.8 Hz, CH_2β), 2.96 (2H, t, 6.8 Hz, CH_2α). CI-MS (m/z): 167 ([M + 1]), 169 ([M + 3]).

Methyl β-phthalimidooxypropionate

Method A

A solution of N-hydroxyphthalimide (18.1 g, 0.111 mol) and triethylamine (15.5 mL, 11.3 g, 0.111 mol) in methanol (100 mL) was stirred at room temperature for 10 min. Methyl acrylate (10 mL, 9.56 g, 0.111 mol) was added dropwise, and the solution was heated to reflux for 18 h and then cooled to room temperature. The solvent was removed under reduced pressure and the residue was dissolved in ethyl acetate (150 mL) and washed successively with water (50 mL), saturated sodium bicarbonate (5 × 50 mL), water (50 mL), 5% citric acid (50 mL), water (50 mL), and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated. The solid residue was recrystallized from hot ethanol to give white crystals, 5.88 g (21%). IR (KBr) (cm^{-1}): 1745, 1727, 1657. ^{1}H NMR (CDCl$_3$) δ: 7.81 (4H, m, phthalimido ring), 4.51 (2H, t, 6.5 Hz, CH_2β), 3.71 (3H, s, OCH_3), 2.85 (2H, t, 6.5 Hz, CH_2 α). ^{13}C NMR (CDCl$_3$) δ: 170.58, 163.44, 134.53, 128.90, 123.58, 73.40, 51.95, 33.65. CI-MS (m/z): 250 ([M + 1]). Calcd. for $C_{12}H_{11}N_1O_5$: C 57.82, H 4.46, N 5.62; found: C 57.70, H 4.50, N 5.46.

Method B

A mixture of methyl β-bromopropionate (0.50 g, 2.99 mmol), N-hydroxyphthalimide (0.49 g, 2.99 mmol), and triethylamine (0.64 mL, 0.45 g, 4.49 mmol) in acetonitrile (7 mL) was refluxed for 3 h, cooled, and filtered. The

filtrate was evaporated under reduced pressure, and the residue was dissolved in ethyl acetate (20 mL). This solution was washed successively with water (3 × 20 mL) and saturated sodium chloride (20 mL), dried over anhydrous magnesium sulfate, and evaporated. Recrystallization from hot ethanol gave 48.9 mg (6%) of white crystals, identical to the product of Method A.

Methyl β-aminooxypropionate

A solution of methyl β-phthalimidooxypropionate (1.5 g, 6.02 mmol) in dichloromethane (50 mL) was cooled to –10 °C and methylhydrazine (0.5 mL, 0.433 g, 9.03 mmol) was added dropwise with stirring. Stirring was continued for 1.5 h at –10 to 0 °C. The mixture was then filtered, and the filtrate was concentrated. The residue was dissolved in ethyl acetate (30 mL), and this solution was washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (8 mL). The aqueous layer was washed with ethyl acetate (30 mL), and the combined organic layers were dried over anhydrous magnesium sulfate and evaporated. Purification by short column chromatography on silica gel, using a gradient solvent system (hexanes to ethyl acetate) gave 0.359 g (50%) of an oil. ^{1}H NMR (CDCl$_3$) δ: 5.85 (2H, s, NH_2), 3.73 (3H, s, CH_3), 3.26 (2H, t, 6.2 Hz, CH_2β), 2.67 (2H, t, 6.2 Hz, CH_2α). CI-MS (m/z): 120 ([M + 1]).

Isoxazolidin-3-one

A solution of methyl β-aminooxypropionate (0.251 g, 2.10 mmol) in tetrahydrofuran (25 mL) was cooled to 0 °C and a 2.0 mol/L solution of trimethylaluminium in hexanes (2.1 mL, 4.20 mmol) was added in portions. The reaction mixture was allowed to warm to room temperature with stirring during 4 h and then by slow addition of water (2 mL) with stirring for 30 min. Most of the solvent was removed under reduced pressure, and chloroform (300 mL) was added. Filtration through Celite and evaporation of the filtrate gave a colourless oil (83.0 mg, 45%). ^{1}H NMR (CDCl$_3$) δ: 9.21 (1H, br s, NH), 4.41 (2H, t, 8.2 Hz, CH_2β), 2.79 (2H, t, 8.2 Hz, CH_2α). CI-MS (m/z): 88 ([M + 1]). Calcd. for $C_3H_5NO_2$: C 41.38, H 5.79, N 16.09; found: C 40.89, H 5.84, N 15.55.

Methyl δ-bromopentanoate

A solution of δ-valerolactone (5.0 mL, 5.39 g, 53.8 mmol) in 30% hydrogen bromide in acetic acid (15 mL) was heated at 75 °C for 5 h, cooled to room temperature, and methanol (20 mL) was added. The mixture was stirred overnight, and the solvent was evaporated to give a dark oil, which was dissolved in ethyl acetate (50 mL) and washed successively with saturated sodium bicarbonate (2 × 50 mL) and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated to yield a clear oil (9.16 g, 87%). IR (neat) (cm^{-1}): 1737. ^{1}H NMR (CDCl$_3$) δ: 3.67 (3H, s, OCH_3), 3.41 (2H, t, 6.4 Hz, CH_2δ), 2.35 (2H, t, 7.3 Hz, CH_2α), 1.90 (2H, m, CH_2γ), 1.79 (2H, m, CH_2β). ^{13}C NMR (CDCl$_3$) δ: 173.55, 51.58, 33.00, 31.97, 23.47. CI-MS (m/z): 195 ([M + 1]), 197 ([M + 3]).

Methyl δ-phthalimidooxypentanoate

A mixture of methyl δ-bromopentanoate (6.01 g, 30.8 mmol), N-hydroxyphthalimide (5.03 g, 30.8 mmol),

and triethylamine (8.6 mL, 6.24 g, 61.5 mmol) in acetonitrile (40 mL) was refluxed for 3 h, cooled, and filtered. The filtrate was evaporated under reduced pressure, and the residue was dissolved in ethyl acetate (75 mL). This solution was washed successively with water (3 × 75 mL) and saturated sodium chloride (75 mL), dried over anhydrous magnesium sulfate, and evaporated. Recrystallization from hot ethanol gave 6.33 g (74%) of product. IR (KBr) (cm^{-1}): 1727, 1710. ^{1}H NMR (CDCl$_3$) δ: 7.81 (4H, m, phthalimido ring), 4.21 (2H, t, 6.1 Hz, CH_2δ), 3.68 (3H, s, OCH_3), 2.43 (2H, t, 7.1 Hz, CH_2α), 1.86 (4H, m, CH_2βCH_2γ). ^{13}C NMR (CDCl$_3$) δ: 173.74, 163.60, 134.45, 128.93, 123.49, 77.88, 51.55, 33.45, 27.51, 21.11. CI-MS (m/z): 278 ([M + 1]). Calcd. for $C_{14}H_{15}NO_5$: C 60.63, H 5.46, N 5.05; found: C 60.54, H 5.43, N 5.06.

Methyl δ-aminooxypentanoate

A solution of methyl δ-phthalimidooxypentanoate (2.01 g, 72.4 mmol) in dichloromethane (50 mL) was cooled to –10 °C, and methylhydrazine (0.58 mL, 0.50 g, 10.8 mmol) was added dropwise with stirring. Stirring was continued for 1.5 h, and the mixture was then filtered and the filtrate evaporated. The residue was dissolved in ethyl acetate (50 mL), and this solution was washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (30 mL). The aqueous layer was extracted with ethyl acetate (50 mL), and the combined organic layers were dried over anhydrous magnesium sulfate and evaporated to give an oil (1.03 g, 97%). IR (neat) (cm^{-1}): 3320, 1732. ^{1}H NMR (CDCl$_3$) δ: 4.50 (2H, br s, NH_2), 3.67 (3H, s, OCH_3), 3.66 (2H, t, 6.2 Hz, CH_2δ), 2.34 (2H, t, 7.0 Hz, CH_2α), 1.66 (4H, m, CH_2βCH_2γ). ^{13}C NMR (CDCl$_3$) δ: 173.97, 75.37, 51.50, 33.76, 27.43, 21.49. CI-MS (m/z): 148 ([M + 1]).

[1,2]Oxazepin-3-one

A solution of methyl δ-aminooxypentanoate (96.6 mg, 0.656 mmol) in tetrahydrofuran (3 mL) was cooled to 0 °C, and a 2.0 mol/L solution of trimethylaluminium in hexanes (0.68 mL, 1.36 mmol) was added dropwise. The resulting solution was allowed to warm to room temperature and was stirred for 5.5 h. Acetone (0.8 mL) was added, and after 20 min, water (2 mL) was added dropwise. Most of the solvent was removed under reduced pressure; 1:4 dichloromethane:tetrahydrofuran (50 mL) was added, and the mixture was filtered through Celite. Evaporation of the filtrate gave a white solid, which was recrystallized from hot ethyl acetate (61.7 mg, 82%); mp 84.5–85.8 °C. IR (KBr) (cm^{-1}): 3419, 1642. ^{1}H NMR (CDCl$_3$) δ: 8.27 (1H, br s, NH), 4.07 (2H, m, CH_2δ), 2.63 (2H, m, CH_2α), 1.91 (2H, m, CH_2γ), 1.81 (2H, m, CH_2β). ^{13}C NMR (CDCl$_3$) δ: 179.36, 78.37, 35.79, 30.94, 21.85. CI-MS (m/z): 116 ([M + 1]). Calcd. for $C_5H_9NO_2$: C 52.15, H 7.89, N 12.17; found: C 52.12, H 7.91, N 12.18.

Methyl ε-bromohexanoate

A solution of ε-caprolactone (5.2 mL, 5.36 g, 46.9 mmol) in 30% hydrogen bromide in acetic acid (12.5 mL) was heated for 6 h at 75 °C, cooled to room temperature, treated with methanol (20 mL), and stirred overnight. Evaporation of the solvent gave a dark oil, which was dissolved in ethyl acetate (50 mL) and washed successively with saturated so-

dium bicarbonate (2 × 50 mL) and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated to yield a clear oil (9.31 g, 95%). ^{1}H NMR (CDCl$_3$) δ: 3.67 (3H, s, OCH_3), 3.40 (2H, t, 6.8 Hz, CH_2ε), 2.33 (2H, t, 7.5 Hz, CH_2α), 1.87 (2H, m, CH_2δ), 1.66 (2H, m, CH_2β), 1.47 (2H, m, CH_2γ). CI-MS (*m/z*): 209 ([M + 1]), 211 ([M + 3]).

Methyl ε-phthalimidooxyhexanoate

A mixture of methyl ε-bromohexanoate (6.44 g, 30.8 mmol), *N*-hydroxyphthalimide (5.02 g, 30.8 mmol), and triethylamine (8.6 mL, 6.24 g, 61.5 mmol) in acetonitrile (40 mL) was refluxed for 3 h, cooled, and filtered. The filtrate was concentrated and the residue diluted with ethyl acetate (50 mL). This solution was washed successively with water (3 × 50 mL) and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated. Recrystallization from hot ethanol gave 8.89 g (99%). IR (KBr) (cm^{-1}): 1787, 1731. ^{1}H NMR (CDCl$_3$) δ: 7.80 (4H, m, phthalimido ring), 4.20 (2H, t, 6.6 Hz, CH_2ε), 3.67 (3H, s, OCH_3), 2.35 (2H, t, 7.4 Hz, CH_2α), 1.80 (2H, m, CH_2δ), 1.72 (2H, m, CH_2β), 1.55 (2H, m, CH_2γ). ^{13}C NMR (CDCl$_3$) δ: 173.06, 163.58, 134.49, 128.90, 123.53, 77.28, 5168, 29.96, 23.52. CI-MS (*m/z*): 292 ([M + 1]). Calcd. for C$_{15}$H$_{17}$NO$_5$: C 61.84, H 5.89, N 4.81; found: C 61.49, H 5.92, N 4.75.

Methyl ε-aminooxyhexanoate

A solution of methyl ε-phthalimidooxyhexanoate (1.05 g, 3.60 mmol) in dichloromethane (19 mL) was cooled to –10 °C; methylhydrazine (0.29 mL, 0.251 g, 5.4 mmol) was added dropwise with stirring, and stirring was continued for 1.5 h at –10 to 0 °C. The mixture was then filtered, and the filtrate was evaporated. The residue was dissolved in ethyl acetate (50 mL) and washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (30 mL). The aqueous extract was washed with ethyl acetate (50 mL), and the combined organic layers were dried over anhydrous magnesium sulfate and evaporated to give an oil (0.567 g, 98%). ^{1}H NMR (CDCl$_3$) δ: 5.10 (2H, br s, NH_2), 3.66 (3H, s, OCH_3), 3.64 (2H, t, 6.6 Hz, CH_2ε), 2.30 (2H, t, 7.4 Hz, CH_2α), 1.64 (2H, m, CH_2δ), 1.58 (2H, m, CH_2β), 1.35 (2H, m, CH_2γ).

[1,2]Oxazocan-3-one

A 2.0 mol/L solution of trimethylaluminium in heptane (4.96 mL, 9.92 mmol) was added to toluene (50 mL), cooled to 0 °C, and a solution of methyl-ε-aminooxyhexanoate (0.400 g, 2.48 mmol) in toluene (50 mL) was added dropwise. The resulting solution was allowed to warm to room temperature and was stirred for 6 days. Water (20 mL) was added dropwise, and the mixture was stirred for 30 min. Most of the solvent was removed under reduced pressure, and 1:4 dichloromethane:tetrahydrofuran (50 mL) was added. Filtration through Celite and evaporation of the filtrate gave a trace amount of product. CI-MS (*m/z*): 130 ([M + 1]).

α-Amino-γ-butyrolactone hydrobromide

A solution of DL-homoserine (0.31 g, 2.6 mmol) in 2.4 mol/L hydrobromic acid (5 mL, 12 mmol, 4.6 equiv) was refluxed for 3 h and then stirred overnight. Removal of the solvent afforded a white solid, which was dissolved in ethanol and cooled to give a solid, which was collected by filtration and washed with cold ethanol to yield 0.384 g (81%); mp 117–119 °C. CI-MS (*m/z*): 102 ([M + 1]). Calcd. for C$_4$H$_8$NO$_2$Br: C 26.40, H 4.44, N 7.70; found: C 26.35, H 4.25, N 7.51.

α-Amino-γ-bromobutyric acid hydrobromide

A suspension of α-amino-γ-butyrolactone hydrobromide (97 mg, 0.53 mmol) in 45% hydrogen bromide in acetic acid (3 mL) was stirred for 4 h at 75 °C, cooled to room temperature, and concentrated under reduced pressure to give a white solid (140 mg, 100%), which was used in the next step without further purification. IR (KBr) (cm^{-1}): 3451, 1720. ^{1}H NMR (D$_2$O) δ: 4.10 (1H, t, 6.8 Hz, CHα), 3.59 (2H, t, 7.0 Hz, CH_2γ), 2.50 (1H, m, CHβ), 2.38 (1H, m, CHβ).

BOC-α-amino-γ-bromobutyric acid

α-Amino-γ-bromobutyric acid hydrobromide (130 mg, 0.50 mmol) was dissolved in 50% aqueous acetone (1.8 mL), triethylamine (0.14 mL, 0.102 g, 1.0 mmol) and BOC-ON (141 mg, 0.55 mmol) were added, and the solution was stirred for 3 h at room temperature. The solvent was then removed under reduced pressure, and the residue was dissolved in water (3 mL), washed with ethyl acetate (3 mL), acidified to pH 3 with 5% citric acid, and again extracted with ethyl acetate (3 × 3 mL). The latter extracts were combined, washed successively with water (2 × 3 mL) and saturated sodium chloride (3 mL), dried over anhydrous magnesium sulfate, and evaporated to give 29.5 mg (21%) of the product. ^{1}H NMR (CDCl$_3$) δ: 5.56 (1H, br s, NH), 4.50 (1H, m, CHα), 3.82 (2H, m, CH_2γ), 2.18 (1H, m, CHβ), 1.78 (1H, m, CHβ), 1.48 (9H, s, C(CH_3)$_3$).

BOC-α-amino-γ-butyrolactone

A solution of triethylamine (7.75 mL, 5.63 g, 56.0 mmol) in dichloromethane (10 mL) was added slowly to a suspension of DL-α-amino-γ-butyrolactone hydrobromide (10 g, 55.0 mmol) in dichloromethane (100 mL). The mixture was cooled to 0 °C, and a solution of BOC anhydride (13.19 g, 60.4 mmol) in dichloromethane (25 mL) was added during 5 min. The resulting suspension was allowed to warm to room temperature, stirred for 96 h, and then washed successively with 5% citric acid (50 mL), water (50 mL), and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated to give a white solid. This was recrystallized from toluene to yield 9.93 g (90%); mp 124–126 °C. IR (KBr) (cm^{-1}): 3359, 1787, 1684, 1528. ^{1}H NMR (CDCl$_3$) δ: 5.05 (1H, br s, NH), 4.44 (1H, m, CHγ), 4.34 (1H, m, CHα), 4.24 (1H, m, CHγ), 2.76 (1H, m, CHβ), 2.18 (1H, m, CHβ), 1.47 (9H, s, C(CH_3)$_3$). ^{13}C NMR (CDCl$_3$) δ: 175.68, 155.72, 80.55, 65.83, 50.21, 30.34, 28.30. CI-MS (*m/z*): 202 ([M + 1]). Calcd. for C$_9$H$_{15}$NO$_4$: C 53.71, H 7.53, N 6.96; found: C 53.98, H 7.58, N 7.19.

BOC-homoserine

Method A

To a solution of DL-homoserine (5.00 g, 42.0 mmol) in 50% aqueous acetone (50 mL) were added, with stirring, triethylamine (8.8 mL, 6.34 g, 63.0 mmol) and BOC anhydride (10.1 g, 46.2 mmol). After 14 h, the solvent was removed under reduced pressure, and the residue was

dissolved in water (30 mL). This solution was acidified to pH 3–4 with 5% citric acid (130 mL) and extracted with ethyl acetate (3 × 50 mL). The combined organic extracts were washed with saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated to give a yellow oil (6.79 g, 74%). ^{1}H NMR (CDCl$_3$) δ: 5.49 (1H, br s, N*H*), 4.50 (1H, m, C*H*α), 3.79 (2H, m, C*H$_2$*γ), 2.21 (1H, m, C*H*β), 1.77 (1H, m, C*H*β), 1.41 (9H, s, C(C*H$_3$*)$_3$). ^{13}C NMR (CDCl$_3$) δ: 176.82, 156.40, 80.14, 58.33, 51.50, 35.14, 28.30. CI-MS (*m/z*): 220 ([M + 1]). Calcd. for C$_9$H$_{17}$NO$_5$: C 49.30, H 7.83, N 6.39; found: C 48.72, H 7.67, N 6.04.

Method B

To a solution of BOC-α-amino-γ-butyrolactone (7.00 g, 34.8 mmol) in dry methanol (80 mL) was added in portions a solution of potassium hydroxide (3.44 g, 52.2 mmol) in methanol (20 mL). The mixture was stirred at room temperature for 24 h, and Amberlyst 15 (H$^+$) (14.0 g, 62.6 mmol), presoaked in methanol, was added. The resin was then removed by filtration, and the solution was evaporated under reduced pressure to an oil (7.39 g, 97%), identical with the product of Method A.

Benzhydryl ester of BOC-homoserine

A solution of BOC-homoserine (0.803 g, 3.66 mmol) in a mixture of dichloromethane (20 mL) and acetonitrile (20 mL) was treated dropwise, with stirring, with a solution of diphenyldiazomethane (0.713 g, 3.66 mmol) in dichloromethane (3 mL). Stirring was continued for 2 h after the addition was complete, and the solvent was then removed under reduced pressure to give a yellow oil. This was dissolved in ethyl acetate (50 mL) and washed successively with water (2 × 50 mL) and saturated sodium chloride (50 mL), dried over anhydrous magnesium sulfate, and evaporated. Purification by flash chromatography on silica gel, using ethyl acetate – hexanes (1:1) as the eluent, gave the product as an oil (0.992 g, 70%). IR (neat) (cm^{-1}): 3499, 3321, 1736, 1688. ^{1}H NMR (CDCl$_3$) δ: 7.31 (10H, m, Ar), 6.90 (1H, s, C*H*O), 5.38 (1H, br d, 7.9 Hz, N*H*), 4.62 (1H, m, C*H*α), 3.65 (2H, m, C*H$_2$*γ), 3.80 (1H, br s, O*H*), 2.24 (1H, m, C*H*β), 1.58 (1H, m, C*H*β), 1.44 (9H, s, C(C*H$_3$*)$_3$). CI-MS (*m/z*): 386 ([M + 1]). Calcd. for C$_{22}$H$_{27}$NO$_5$: C 68.54, H 7.04, N 3.63; found: C 68.68, H 7.14, N 3.61.

Benzhydryl ester of BOC-α-amino-γ-succinimidooxybutyric acid

A solution of the benzhydryl ester (1.01 g, 2.62 mmol) and *N*-hydroxysuccinimide (0.313 g, 2.72 mmol) in tetrahydrofuran (12 mL) was cooled to 15 °C, and triphenylphosphine (0.702 g, 2.67 mmol) and diethyl azodicarboxylate (0.45 mL, 0.498 g, 2.86 mmol) were added successively. The reaction mixture was allowed to warm to room temperature, stirred overnight, and the solvent was then removed under reduced pressure. Purification by flash chromatography on silica gel using 3:1 hexanes:ethyl acetate as the eluent gave a white solid (0.589 g, 47%). ^{1}H NMR (CDCl$_3$) δ: 7.33 (10H, m, Ar), 6.92 (1H, s, C*H*O), 5.81 (1H, br d, 8.2 Hz, N*H*), 4.62 (1H, m, C*H*α), 4.13 (2H, m, C*H$_2$*γ), 2.65 (4H, s, succinimido ring), 2.27 (2H, m, C*H$_2$*β), 1.44 (9H, s, C(C*H$_3$*)$_3$). CI-MS (*m/z*): 383 ([M + 1 – BOC]). Calcd. for C$_{26}$H$_{30}$N$_2$O$_7$·H$_2$O: C 62.38, H 6.46; found: C 62.38, H 6.60.

Methyl α-amino-γ-bromobutyrate hydrochloride

Hydrogen chloride was bubbled for 2 h into a suspension of α-amino-γ-bromobutyrate hydrobromide (0.165 g, 0.586 mmol) in methanol (5 mL) at such a rate that the temperature did not exceed 40 °C. The solvent was then removed under reduced pressure, the residue was dissolved in methanol, and the solution was reevaporated. This procedure was repeated once more, and the residual oil was dried in vacuo in a desiccator over sodium hydroxide pellets. The resulting crystals were triturated with ether, collected, and washed with ether to give 89 mg (65%); mp 96–98 °C. ^{1}H NMR (D$_2$O) δ: 4.33 (1H, t, 6.67 Hz, C*H*α), 3.83 (3H, s, OC*H$_3$*), 3.59 (2H, m, C*H$_2$*γ), 2.56 (1H, m, C*H*β), 2.39 (1H, m, C*H*β). CI-MS (*m/z*): 196 ([M + 1]), 198 ([M + 3]).

Methyl ester of BOC-α-amino-γ-bromobutyric acid

To a solution of methyl α-amino-γ-bromobutyrate hydrochloride (29.7 mg, 0.129 mmol) in 50% aqueous acetone (1 mL) were added, with stirring, triethylamine (0.039 mL, 28.3 mg, 0.258 mmol) and BOC anhydride (30.1 mg, 0.142 mmol). Stirring was continued at room temperature for 3 h, and the solvent was then removed under reduced pressure. The residue was purified by preparative layer chromatography on silica gel, using 2:1 hexanes:ethyl acetate as the eluent, to give 28.4 mg (75%) of the product. ^{1}H NMR (CDCl$_3$) δ: 5.05 (1H, br d, 7.5 Hz, N*H*), 4.41 (1H, m, C*H*α), 3.73 (3H, s, OC*H$_3$*), 3.40 (2H, t, 6.8 Hz, C*H$_2$*γ), 2.37 (2H, m, C*H$_2$*β), 1.42 (9H, s, C(C*H$_3$*)$_3$).

Methyl ester of BOC-homoserine

A solution of homoserine (5.00 g, 42.0 mmol) in 50% aqueous acetone (50 mL) was treated with triethylamine (8.8 mL, 6.39 g, 63.0 mmol) and BOC anhydride (10.1 g, 46.2 mmol) and stirred overnight at room temperature. Removal of the solvent gave the triethylamine salt of BOC-homoserine (13.5 g, 100%). IR (CH$_2$Cl$_2$) (cm^{-1}): 3413, 1709, 1693. ^{1}H NMR (D$_2$O) δ: 4.02 (1H, m, C*H*α), 3.64 (2H, m, C*H$_2$*γ), 3.18 (2H, q, 7.3 Hz, C*H$_2$*CH$_3$), 1.98 (1H, m, C*H*β), 1.82 (1H, m, C*H*β), 1.41 (9H, s, C(C*H$_3$*)$_3$), 1.26 (3H, t, 7.3 Hz, C*H$_3$*). ^{13}C NMR (D$_2$O) δ: 181.68, 160.33, 83.76, 61.09, 55.48, 49.30, 36.57, 30.28, 10.85. CI-MS (*m/z*): 164 ([M + 1 – BOC]).

A solution of the salt (7.49 g, 23.4 mmol) in dimethylformamide (50 mL) was cooled to 0–10 °C and stirred; iodomethane (1.6 mL, 3.65 g, 25.7 mmol) was added; the cooling bath was removed, and stirring was continued overnight. Most of the solvent was removed under reduced pressure, and the residue was diluted with ethyl acetate (80 mL) and washed with water (20 mL). The aqueous extract was washed with ethyl acetate (2 × 25 mL), and the combined organic extracts were washed successively with 5% citric acid (2 × 15 mL), water (15 mL), saturated sodium sulfite (15 mL), saturated sodium bicarbonate (2 × 15 mL), and saturated sodium chloride (2 × 15 mL), dried over anhydrous magnesium sulfate, and evaporated to give a colourless oil (5.15 g, 94%). ^{1}H NMR (CDCl$_3$) δ: 5.43 (1H, br s, N*H*), 4.52 (1H, m, C*H*α), 3.80 (3H, s, C*H$_3$*O), 3.73 (2H, m, C*H$_2$*γ), 3.26 (1H, br s, O*H*), 2.11 (1H, m, C*H*β), 1.64 (1H, m, C*H*β), 1.49 (9H, s, C(C*H$_3$*)$_3$). ^{13}C NMR (CDCl$_3$) δ: 173.62, 156.80, 80.16, 58.65, 52.50, 51.04, 36.18, 28.66. CI-MS (*m/z*): 234 ([M + 1]).

Mesylation of the BOC methyl ester (26, $R_1 = t$-BuO, $R_2 = $ Me)

Methanesulfonyl chloride (2.14 mL, 3.16 g, 27.6 mmol) was added dropwise at –15 to –10 °C to a solution of the methyl ester of BOC-homoserine (5.6 g, 24.0 mmol) and triethylamine (4.0 mL, 2.90 g, 28.8 mmol) in dichloromethane (80 mL). The reaction mixture was allowed to warm to 0 °C and was stirred at that temperature for 1 h. Cold 10% potassium bisulfate (25 mL) was added, and the aqueous layer was separated and washed with dichloromethane (2 × 25 mL). The combined organic layers were washed with sodium bicarbonate (2 × 35 mL), dried over anhydrous magnesium sulfate, and evaporated to give a pale yellow oil (7.25 g, 97%). ^{1}H NMR (CDCl$_3$) δ: 5.25 (1H, br s, NH), 4.75 (1H, m, CHα), 4.35 (2H, m, CH_2γ), 3.82 (3H, s, CH_3O), 3.07 (3H, s, SO$_2$CH_3), 2.36 (1H, m, CHβ), 2.15 (1H, m, CHβ), 1.49 (9H, s, C(CH_3)$_3$).

α-Phenylacetamido-γ-butyrolactone

Triethylamine (7.7 mL, 5.6 g, 55.0 mmol) was added slowly to a suspension of α-amino-γ-butyrolactone hydrobromide (5.0 g, 27.5 mmol) in dichloromethane (50 mL). The mixture was stirred for 10 min, cooled to –5 °C, and treated, during 30 min, with a solution of phenylacetyl chloride (3.3 mL, 3.83 g, 24.8 mmol) in dichloromethane (20 mL). The mixture was allowed to warm to room temperature, stirred for 3 h, and then washed successively with water (25 mL), 1 N hydrochloric acid (15 mL), water (15 mL), and 1:1 water:saturated sodium bicarbonate (20 mL), dried over anhydrous magnesium sulfate, and evaporated to give a white solid (5.14 g, 95%); mp 124–126 °C. IR (KBr) (cm^{-1}): 3305, 1779, 1652. ^{1}H NMR (CDCl$_3$) δ: 7.33 (5H, m, Ar), 5.97 (1H, br s, NH), 4.50 (1H, m, CHγ), 4.43 (1H, t, 9.1 Hz, CHα), 4.25 (1H, m, CHγ), 3.63 (2H, s, PhCH_2), 2.79 (1H, m, CHβ), 2.08 (1H, m, CHβ). ^{13}C NMR (CDCl$_3$) δ: 174.98, 171.49, 134.06, 129.39, 129.13, 127.59, 65.95, 49.37, 43.31, 30.32. CI-MS (m/z): 220 ([M + 1]). Calcd. for C$_{12}$H$_{13}$NO$_3$: C 65.73, H 5.99, N 6.39; found: C 65.69, H 5.97, N 6.12.

Phenylacetamido homoserine

A solution of potassium hydroxide (4.51 g, 68.8 mmol) in methanol (20 mL) was added in portions to a suspension of α-phenylacetamido-γ-butyrolactone (10.1 g, 45.9 mmol) in dry methanol (100 mL). The mixture was stirred at room temperature for 24 h, and Amberlyst 15 (H$^+$) (18.5 g, 82.5 mmol), presoaked in methanol, was added. The mixture was filtered, and the filtrate was evaporated to an oil (10.9 g, 96%), which was used directly in the next step.

Methyl ester of phenylacetylamido homoserine (25, $R_1 = $ PhCH$_2$, $R_2 = $ Me)

A solution of phenylacetamido homoserine (3.19 g, 13.5 mmol) in dimethylformamide (30 mL) was treated dropwise with a solution of triethylamine (1.88 mL, 1.36 g, 13.5 mmol) in dimethylformamide (10 mL). Then iodomethane (1.68 mL, 3.82 g, 26.9 mmol) was added in one portion, and stirring was continued overnight. Most of the solvent was removed under reduced pressure, and the residue was diluted with ethyl acetate (100 mL) and water (20 mL). The aqueous layer was washed with ethyl acetate (2 × 25 mL), and the combined organic layers were washed successively with 5% citric acid (2 × 15 mL), water (15 mL), saturated sodium sulfite (15 mL), saturated sodium bicarbonate (2 × 15 mL), and saturated sodium chloride (2 × 15 mL), dried over anhydrous magnesium sulfate, and evaporated to give a pale yellow oil (2.02 g, 60%). IR (CH$_2$Cl$_2$) (cm^{-1}): 3297, 1743, 1658. ^{1}H NMR (CDCl$_3$) δ: 7.32 (5H, m, Ar), 6.38 (1H, br d, 6.8 Hz, NH), 4.73 (1H, m, CHα), 3.73 (3H, s, CH_3), 3.64 (1H, m, CHγ), 3.63 (2H, s, PhCH_2), 3.49 (1H, m, CHγ), 2.33 (1H, br s, OH), 2.13 (1H, m, CHβ), 1.56 (1H, m, CHβ). ^{13}C NMR (CDCl$_3$) δ: 172.94, 172.15, 134.21, 129.32, 129.09, 127.56, 58.09, 52.64, 49.66, 43.45, 35.63. CI-MS (m/z): 252 ([M + 1]).

Mesylation of the methyl ester of phenylacetamido homoserine (26, $R_1 = $ PhCH$_2$, $R_2 = $ Me)

A solution of the methyl ester (1.90 g, 7.56 mmol) and triethylamine (1.26 mL, 0.91 g, 9.07 mmol) in dichloromethane (30 mL) was cooled to –15 to –10 °C and methanesulfonyl chloride (0.67 mL, 1.00 g, 8.70 mmol) was added dropwise. The mixture was allowed to warm to 0 °C and was stirred at that temperature for 1 h. Cold 10% potassium bisulfate (15 mL) was added, and the aqueous layer was separated and washed with dichloromethane (2 × 15 mL). The combined organic layers were washed with sodium bicarbonate (2 × 25 mL), dried over anhydrous magnesium sulfate, and evaporated to give a yellow oil (2.23 g, 90%). ^{1}H NMR (CDCl$_3$) δ: 7.38 (5H, m, Ar), 6.19 (1H, br d, 7.1 Hz, NH), 4.70 (1H, m, CHα), 4.17 (2H, t, 6.2 Hz, CH_2γ), 3.76 (3H, s, COCH_3), 3.64 (2H, s, PhCH_2), 2.90 (3H, s, SO$_2$CH_3), 2.34 (1H, m, CHβ), 2.12 (1H, m, CHβ). ^{13}C NMR (CDCl$_3$) δ: 171.73, 171.02, 134.36, 129.34, 129.12, 127.55, 65.68, 52.77, 49.34, 43.63, 37.16, 31.46. CI-MS (m/z): 330 ([M + 1]).

Synthesis of 27 ($R_1 = t$-BuO, $R_2 = $ Me)

1,8-Diazabicyclo[5.4.0]undec-7-ene (3.2 mL, 3.18 g, 20.9 mmol) was added dropwise to a solution of N-hydroxyphthalimide (3.40 g, 20.9 mmol) in dimethylformamide (30 mL). The solution was stirred for 30 min, cooled to 10–15 °C, and a solution of 26 ($R_1 = t$-BuO, $R_2 = $ Me) (6.5 g, 20.9 mmol) in dimethylformamide (10 mL) was added dropwise. The mixture was then allowed to warm to room temperature and stirred for 48 h. Approximately 30 mL of solvent was removed under reduced pressure, and ethyl acetate (100 mL) and water (30 mL) were added. The layers were separated, and the aqueous layer was washed with ethyl acetate (2 × 50 mL). The combined organic layers were washed successively with saturated sodium bicarbonate (5 × 30 mL), water (30 mL), 5% citric acid (30 mL), water (30 mL), and saturated sodium chloride (30 mL), dried over anhydrous magnesium sulfate, and evaporated to yield 8.58 g of a solid. Recrystallization from hot ethanol gave white crystals, 5.07 g (64%); mp 135–136 °C. IR (KBr) (cm^{-1}): 3365, 1746, 1725, 1680. ^{1}H NMR (CDCl$_3$) δ: 7.81 (4H, m, phthalimido ring), 5.68 (1H, d, 7.6 Hz, NH), 4.55 (1H, m, CHα), 4.31 (2H, t, 6.1 Hz, CH_2γ), 3.76 (3H, s, CH_3), 2.30 (2H, m, CH_2β), 1.45 (9H, s, C(CH_3)$_3$). CI-MS (m/z): 379 ([M + 1]). Calcd. for C$_{18}$H$_{22}$N$_2$O$_7$: C 57.13, H 5.87, N 7.40; found: C 57.21, H 5.93, N 7.33.

Methyl BOC-α-amino-γ-aminooxybutyrate (28, R₁ = *t*-BuO, R₂ = Me)

A solution of **27**, R₁ = *t*-BuO, R₂ = Me (0.50 g, 1.32 mmol), in dichloromethane (20 mL) was cooled to –10 °C and methylhydrazine (0.10 mL, 91.1 mg, 1.98 mmol) was added dropwise with stirring. Stirring was continued for 2 h at –10 to 0 °C, and the mixture was then filtered. The filtrate was concentrated and the residue, in ethyl acetate (15 mL), was washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (10 mL). The aqueous layer was washed with ethyl acetate (15 mL), and the combined organic layers were dried over anhydrous magnesium sulfate and evaporated to give a white solid (0.325 g, 100%). IR (KBr) (cm^{-1}): 3336, 1738, 1698. ^{1}H NMR (CDCl₃) δ: 5.62 (2H, br s, ONH_2), 5.29 (1H, d, 6.0 Hz, N*H*), 4.41 (1H, m, C*H*α), 3.75 (3H, s, CH_3), 3.75 (2H, t, 6.2 Hz, CH_2γ), 2.07 (2H, m, CH_2β), 1.45 (9H, s, C(CH_3)₃). CI-MS (*m/z*): 249 ([M + 1]). Calcd. for C₁₀H₂₀N₂O₅: C 48.37, H 8.13, N 11.28; found: C 48.77, H 7.96, N 11.36.

4-*tert*-Butoxycarbonylamino-[1,2]oxazinan-3-one (29, R = *t*-BuO)

A solution of **28** (R₁ = *t*-BuO, R₂ = Me) (0.150 g, 0.607 mmol) in tetrahydrofuran (15 mL) was cooled to 0 °C and a 2.0 mol/L solution of trimethylaluminium in heptane (0.60 mL, 1.21 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature and was stirred for 4 h. Water (2 mL) was added dropwise, and after 15 min, the solution was concentrated to near dryness, diluted with 1:4 dichloromethane:tetrahydrofuran (50 mL), and filtered through Celite. The filtrate was concentrated to give a white solid (128 mg, 98%); mp 119–120 °C. IR (KBr) (cm^{-1}): 3364, 1696, 1679, 1528. ^{1}H NMR (CDCl₃) δ: 8.65 (1H, br s, ON*H*), 5.43 (1H, br s, N*H*), 4.54 (1H, m, C*H*α), 4.21 (1H, m, C*H*γ), 4.08 (1H, m, C*H*γ), 2.88 (1H, m, C*H*β), 1.74 (1H, m, C*H*β), 1.46 (9H, s, C(CH_3)₃). ^{13}C NMR (CDCl₃) δ: 174.11, 155.35, 80.03, 69.77, 47.78, 29.74, 28.09. CI-MS (*m/z*): 217 ([M + 1]). Calcd. for C₉H₁₆N₂O₄: C 49.98, H 7.47, N 12.96; found: C 50.17, H 7.47, N 12.74.

Methyl α-phenylacetamido-γ-phthalimidooxybutyrate (27, R₁ = PhCH₂, R₂ = Me)

Triethylamine (0.95 mL, 0.69 g, 6.78 mmol) was added slowly to a solution of *N*-hydroxyphthalimide (1.11 g, 6.78 mmol) in acetonitrile (15 mL). The solution was stirred for 20 min, cooled to 10–15 °C, and a solution of **26** (R₁ = PhCH₂, R₂ = Me) (2.23 g, 6.78 mmol) in acetonitrile (5 mL) was added dropwise. The reaction mixture was allowed to warm to room temperature, and stirring was continued for 24 h. The solvent was removed, and the residue was dissolved in ethyl acetate (50 mL). This solution was washed successively with water (2 × 15 mL), saturated sodium bicarbonate (8 × 15 mL), water (15 mL), 5% citric acid (15 mL), water (15 mL), and saturated sodium chloride (15 mL), dried over anhydrous magnesium sulfate, and evaporated. The resulting solid was recrystallized from hot ethanol to give 2.25 g (84%); mp 138–139 °C. IR (KBr) (cm^{-1}): 3348, 1792, 1735, 1664. ^{1}H NMR (CDCl₃) δ: 7.81 (4H, m, phthalimido ring), 7.24 (5H, m, P*h*), 6.15 (1H, br s, N*H*), 4.87 (1H, m, C*H*α), 4.21 (2H, t, 5.8 Hz, CH_2γ), 3.73 (3H, s, CH_3), 3.67 (2H, s, PhCH_2), 2.30 (2H, m, CH_2β). CI-MS (*m/z*): 397 ([M + 1]). Calcd. for C₂₁H₂₀N₂O₆: C 63.62, H 5.10, N 7.07; found: C 63.97, H 5.19, N 7.12.

Methyl 2-phenylacetamido-4-aminooxybutyrate (28, R₁ = PhCH₂, R₂ = Me)

Methylhydrazine (0.20 mL, 0.174 g, 3.78 mmol) was added dropwise at –10 °C to a solution of **27**, R₁ = PhCH₂, R₂ = Me (1.0 g, 2.52 mmol), in dichloromethane (40 mL). The cooling bath was removed, and stirring was continued for 3 h. The mixture was then filtered, and the filtrate was evaporated. The residue, in ethyl acetate (30 mL), was washed with 1:1 saturated sodium chloride:saturated sodium bicarbonate (6 mL). The aqueous layer was extracted with ethyl acetate (30 mL), and the combined organic extract was dried over anhydrous magnesium sulfate and evaporated to give a pale yellow oil (0.664 g, 99%). ^{1}H NMR (CDCl₃) δ: 7.35 (5H, m, *Ph*), 6.50 (1H, br s, N*H*), 4.68 (1H, m, C*H*α), 3.75 (3H, s, COCH_3), 3.65 (2H, t, 5.8 Hz, CH_2γ), 3.65 (2H, s, PhCH_2), 2.03 (2H, m, CH_2β). CI-MS (*m/z*): 267 ([M + 1]).

4-Phenylacetamido-[1,2]oxazinan-3-one (10)

A 2.0 mol/L solution of trimethylaluminium in hexanes (1.13 mL, 2.25 mmol) was added dropwise at 0 °C to a solution of **28**, R₁ = PhCH₂, R₂ = Me (0.300 g, 1.13 mmol), in toluene (20 mL). The ice bath was removed, and stirring was continued for 4 h. The reaction mixture was then treated dropwise with water (1 mL). After an additional 15 min, the solvent was removed under reduced pressure to neardryness; 1:4 dichloromethane:tetrahydrofuran (150 mL) was added, and the mixture was filtered through Celite. The filtrate was concentrated, and the residue was purified by short column chromatography on silica gel with a gradient solvent system (hexanes to ethyl acetate) to give a white solid (91.2 mg, 35%); mp 164–165 °C. IR (KBr) (cm^{-1}): 3307, 1694, 1660. ^{1}H NMR (CDCl₃) δ: 8.17 (1H, br s, ON*H*), 7.32 (5H, m, Ar), 6.41 (1H, br s, N*H*), 4.72 (1H, m, C*H*α), 4.23 (1H, m, C*H*γ), 4.04 (1H, m, C*H*γ), 3.63 (2H, s, PhCH_2), 2.98 (1H, m, C*H*β), 1.63 (1H, m, C*H*β). ^{13}C NMR (CDCl₃) δ: 173.52, 171.08, 134.45, 129.30, 128.96, 127.37, 69.84, 47.02, 43.56, 28.99. CI-MS (*m/z*): 235 ([M + 1]). Calcd. for C₁₂H₁₄N₂O₃: C 61.52, H 6.04, N 11.96; found: C 61.32, H 6.04, N 11.92.

TFA salt of cyclocanaline

The BOC derivative **27**, R = *t*-BuO (50.9 mg, 0.235 mmol), was added, with stirring, to a cooled (0 to –5 °C) solution of trifluoroacetic acid (0.75 mL). The mixture was allowed to warm to room temperature and was stirred for 1 h. The solvent was then removed under reduced pressure, and the residue was triturated with ether to give a white solid (53.0 mg, 98%). ^{1}H NMR (D₂O) δ: 4.29 (1H, m, C*H*γ), 4.09 (1H, m, C*H*γ), 4.08 (1H, m, C*H*α), 2.77 (1H, m, C*H*β), 2.06 (1H, m, C*H*β).

4-Phenoxyacetamido-[1,2]oxazinan-3-one

Triethylamine (0.2 mL, 0.145 g, 1.43 mmol) was added slowly to a suspension of the trifluoroacetic acid salt of cyclocanaline (0.150 g, 0.63 mmol) in dichloromethane

(5 mL); the mixture was cooled to –10 °C, and a solution of phenoxyacetyl chloride (0.079 mL, 97.2 mg, 0.57 mmol) in dichloromethane (2 mL) was added dropwise. The reaction mixture was allowed to warm to room temperature and was stirred overnight and then washed successively with water (2 mL), 5% citric acid (2 mL), water (2 mL), and 1:1 saturated sodium chloride:saturated sodium bicarbonate (2 mL), dried over anhydrous magnesium sulfate, and evaporated. The residue was purified by short column chromatography on silica gel, using hexanes to ethyl acetate gradient solvent system, to give a white solid (29.8 mg, 38%). IR (KBr) (cm^{-1}): 3314, 1686, 1655. ^{1}H NMR (CDCl$_3$) δ: 7.53 (1H, br s, NH), 7.15 (5H, m, Ar), 4.84 (1H, m, C$H\alpha$), 4.55 (2H, s, PhOCH_2), 4.28 (1H, m, C$H\gamma$), 4.11 (1H, m, C$H\gamma$), 3.03 (1H, m, C$H\beta$), 1.78 (1H, m, C$H\beta$). ^{13}C NMR (CDCl$_3$) δ: 173.06, 168.47, 157.20, 129.75, 122.17, 114.79, 69.89, 67.29, 46.66, 28.94. CI-MS (*m/z*): 251 ([M + 1]).

Carbobenzoxy D-methionine

D-Methionine (29.4 g, 0.20 mol) was added to a solution of 2 N sodium bicarbonate (500 mL). The mixture was cooled in an ice bath, and benzyl chloroformate (37 mL, 0.26 mol) was added dropwise. After the addition, the mixture was allowed to warm to room temperature and was stirred for 22 h. The unreacted benzyl chloroformate was then removed by extraction with ether (4 × 300 mL). The pH of the aqueous solution was adjusted to 2–3 using 6 N HCl (a whitish precipitate formed), and the mixture was extracted with ethyl acetate (5 × 200 mL). These extracts were dried over anhydrous sodium sulfate, and the solvent was removed to give 41.72 g (74%) of a light yellow oil. ^{1}H NMR (100 MHz, CDCl$_3$): 2.10 (s, 3H, -SCH_3), 2.15 (t, 2H, NHCHCH_2), 2.60 (t, 2H, NHCHCH$_2$CH_2), 4.60 (m, 1H, NHCH), 5.20 (s, 2H, CH_2Ph), 5.50 (d, 1H, NH), 7.40 (s, 5H, ArH).

Carbobenzoxy *R*-α-amino-γ-butyrolactone

Carbobenzoxy D-methionine (41.72 g, 0.1474 mol) was dissolved in a mixture of glacial acetic acid (44.5 mL) and 80% HF (89 mL); iodomethane (16.7 mL, 0.268 mol) was added, and the mixture was left in the dark for 15 h, producing a clear, orange solution. This solution was concentrated in vacuo below 40 °C, and the resulting oily residue was triturated with dry ether (3 × 20 mL). The ether-insoluble orange oil was dissolved in 1 N sodium hydroxide (180 mL). The white crystals that appeared after cooling to 0 °C were collected, washed well with water, and maintained at 1 torr (1 torr = 133.322 Pa) for 5 h. The mother liquor from the washings was then acidified to pH 2 with concentrated hydrochloric acid, allowed to stand at room temperature for 1 h, and extracted with ethyl acetate (3 × 200 mL). The combined extracts were washed with 4% sodium bicarbonate (2 × 100 mL), brine (2 × 100 mL), and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a yellow precipitate, which was crystallized from isopropyl alcohol. The total yield of product was 6.62 g (20%). ^{1}H NMR (100 MHz, CDCl$_3$): 2.30 (m, 1H, NHCHCHH), 2.80 (m, 1H, NHCHCHH), 4.20 (m, 3H, NHCH and NHCHCH$_2$CH_2), 5.20 (s, 2H, CH_2Ph), 5.40 (br. s, 1H, NH), 7.40 (s, 5H, ArH).

Methyl ester of *R*-carbobenzoxyhomoserine

A solution of potassium hydroxide (0.716 g, 12.77 mmol) in methanol (8 mL) was added dropwise to a stirred suspension of the carbobenzoxy lactone (2.00 g, 8.51 mmol) in methanol (12 mL). The resulting solution was stirred at room temperature for 18 h, and the reaction was then quenched with a stream of carbon dioxide. Evaporation of the solvent produced a white crystalline solid. This solid was dissolved in dimethylformamide (10 mL), and iodomethane (1.72 mL, 0.028 mmol) was added. The reaction mixture was stirred at room temperature for 66 h, and the solvent was evaporated. The residue was shaken with ethyl acetate (40 mL) and water (10 mL). The aqueous phase was extracted with ethyl acetate (2 × 10 mL), and the combined organic extracts were washed successively with water (10 mL), saturated sodium thiosulfate (10 mL), saturated sodium bicarbonate (10 mL), brine (10 mL), and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 1.73 g (76%) of the product as a pale yellow oil. ^{1}H NMR (100 MHz, CDCl$_3$): 1.60 (m, 1H, NHCHCHH), 2.40 (m, 1H, NHCHCHH), 3.60–3.90 (m, 5H, NHCHCH$_2$CH_2 and CO$_2$CH_3), 4.40–4.70 (m, 1H, NHCH), 5.20 (s, 2H, CH_2Ph), 5.70 (br. s, 1H, NH), 7.40 (s, 5H, ArH).

Mesylation of the methyl ester of *R*-carbobenzoxyhomoserine

The carbobenzoxy methyl ester (1.71 g, 6.40 mmol) was dissolved in methylene chloride (30 mL), and triethylamine (1.2 mL, 8.499 mmol) was added in one portion. After 5 min of stirring, the reaction mixture was cooled (–5 to –10 °C), and methanesulfonyl chloride (0.63 mL, 8.206 mmol) was added dropwise. The reaction mixture was stirred at 0 °C for 2 h, diluted with methylene chloride (20 mL), and washed successively with water (2 × 10 mL), 1 N hydrochloric acid (10 mL), water (10 mL), saturated sodium bicarbonate (10 mL + 10 mL of water), and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 2.10 g (100%) of the mesylate as a yellow oil. ^{1}H NMR (100 MHz, CDCl$_3$): 2.30 (m, 2H, NHCHCH_2), 3.02 (s, 3H, SO2CH_3), 3.82 (s, 3H, CO$_2$CH_3), 4.25–4.55 (m, 3H, NHCH and NHCHCH$_2$CH_2), 5.18 (s, 2H, CH_2Ph), 5.55 (br. d, 1H, NH), 7.45 (d, 5H, ArH).

Methyl ester of *R*-2-carbobenzoxyamido-4-phthalimido-oxybutyric acid

1,8-Diazabicyclo[5.4.0]undec-7-ene (1.74 mL, 11.62 mmol) was added portionwise, with stirring, to a solution of *N*-hydroxyphthalimide (2.08 g, 12.75 mmol) in dimethylformamide (12 mL). After 20 min, the dark red reaction mixture was cooled to 10–15 °C, and a solution of the mesylate (2.10 g, 6.68 mmol) in dimethylformamide (10 mL) was added dropwise with stirring. The reaction mixture was stirred at room temperature for 24 h and then diluted with ethyl acetate (80 mL) and washed with water (6 × 15 mL) until a pale yellow aqueous phase was obtained. The organic layer was washed with saturated sodium bicarbonate (9 × 12 mL) and saturated brine (2 × 12 mL), dried over anhydrous magnesium sulfate, and evaporated. The resulting pale yellow solid (2.32 g) was recrystallized from 85% ethanol to yield 1.81 g (66%) of the mesylate as a white powder; mp

102–104 °C. ^{1}H NMR (100 MHz, CDCl$_3$): 2.30 (q, 2H, NHCHCH_2), 3.80 (s, 3H, CO$_2$CH_3), 4.38 (t, 2H, NHCHCH$_2$CH_2), 4.70 (m, 1H, NHCH), 5.20 (s, 2H, CH_2Ph), 6.20 (br. d, 1H, NH), 7.40 (s, 5H, ArH), 7.85 (m, 4H, ArH from N-hydroxyphthalimide).

Methyl ester of *R*-2-carbobenzoxyamido-4-aminooxy-butyric acid

A solution of methylhydrazine (0.34 mL, 6.305 mmol) in tetrahydrofuran (2 mL) was added dropwise, with cooling at 5 °C and stirring, to a solution of the phthalimidooxy compound (2.00 g, 4.85 mmol) in tetrahydrofuran (15 mL). The reaction mixture was allowed to warm to room temperature, and stirring was continued for 24 h. A white precipitate was then removed by filtration, and the filtrate was evaporated to dryness. The residue was then dissolved in methylene chloride (10 mL) and filtered through a plug of Silica Gel 60H for TLC, with elution by methylene chloride (35 mL). Evaporation of the solvent afforded 1.18 g (86%) of the product as a pale yellow oil. ^{1}H NMR (100 MHz, CDCl$_3$): 2.10 (m, 2H, NHCHCH_2), 3.75 (m, 5H, NHCHCH$_2$CH_2 and CO$_2$CH_3), 4.55 (m, 1H, NHCH), 4.15 (s, 2H, CH_2Ph), 5.65 (br. d, 1H, NH), 7.40 (s, 5H, ArH).

Carbobenzoxy *R*-cyclocanaline

A solution of the carbobenzoxy methyl ester (1.15 g, 4.08 mmol) in tetrahydrofuran (65 mL) was treated dropwise at 0–5 °C with trimethylaluminium (2.45 mL of a 2 mol/L solution in hexane, 4.89 mmol). Stirring of the colourless reaction mixture was continued for 1 h, and the cooling bath was then removed while stirring continued for another 2 h. The slightly yellowish reaction mixture was then cooled to 0 °C, water (7 mL) was added dropwise, and stirring was continued for 1 h. Removal of the solvent afforded a white solid, which was triturated with ethyl acetate (100 mL) and filtered through a plug of Sililca Gel 60H for TLC. Elution with ethyl acetate (100 mL) and evaporation of the solvent yielded 1.17 g of a pale yellow semi-solid, which was further purified by column chromatography on silica gel (30% ethyl acetate – hexanes to 60% ethyl acetate – hexanes) to give 456 mg (44%) of carbobenzoxy D-cyclocanaline as a white solid (mp 126–127 °C). ^{1}H NMR (100 MHz, CD$_3$CN): 1.60–2.10 (m, 1H, NHCHCHH), 2.40–2.80 (m, 1H, NHCHCHH), 3.90–4.70 (m, 3H, NHCH and NHCHCH$_2$CH_2), 5.80–6.20 (br. d, 1H, NHCH), 7.30–7.50 (s, 5H, ArH), 8.60–9.00 (br. s, 1H, ONH). CI-MS (isobutane) *m/z*: 251 ([M$^+$ + 1]). Calcd. for C$_{12}$H$_{14}$N$_2$O$_4$: C 57.65, H 5.64, N 11.20; found: C 57.89, H 5.71, N 11.34.

R-Cyclocanaline

The carbobenzoxy compound (268 mg, 1.071 mmol) was treated in one portion with 30% hydrogen bromide in acetic acid (0.80 mL) in a flask protected with a calcium chloride drying tube. A gas was produced immediately. The mixture was allowed to stand at room temperature for 1 h with occasional shaking, and ether (5 mL) was then added. The supernatant was decanted, and the precipitated solid was triturated with ether, maintained at 1 torr for 2 h, and then dissolved in methanol and treated, with shaking for 5 min, with an ion-exchange resin (CGA-540, OH$^-$ form, 1.15 g). The resin was filtered, rinsed with methanol (10 mL), and

the combined filtrates were evaporated to yield 77.1 mg (62%) of yellow crystals. ^{1}H NMR (100 MHz, D$_2$O): 1.20–2.00 (m, 2H, NH$_2$CHCH_2), 3.00–3.30 (m, 1H, NH$_2$CH), 3.40 (t, 2H, NH$_2$CHCH$_2$CH_2).

BOC-*R*-cycloserine (30)

To a suspension of *R*-cycloserine (2.00 g, 19.6 mmol) in 50% aqueous acetone (25 mL) were added triethylamine (4.1 mL, 2.98 g, 29.4 mmol) and BOC-ON (5.31 g, 21.5 mmol). The reaction mixture was stirred overnight at room temperature; most of the solvent was removed under reduced pressure, and ethyl acetate (70 mL) was added. The aqueous layer was separated, acidified to pH 3–4 with 5% citric acid (75 mL), and extracted with ethyl acetate (90 mL). The latter extract was washed successively with water (3 × 90 mL) and saturated sodium chloride (90 mL), dried over anhydrous magnesium sulfate, and evaporated. Purification by flash chromatography on silica gel, using ethyl acetate – hexanes (2:1) as the eluent, gave 2.41 g (61%) of the product; mp 140–142 °C. IR (CH$_2$Cl$_2$) (cm^{-1}): 1711, 1689. ^{1}H NMR (CDCl$_3$) δ: 9.88 (1H, br s, NH), 5.50 (1H, br s, BOCNH), 4.79 (1H, m, CHβ), 4.58 (1H, m, CHα), 4.10 (1H, m, CHβ), 1.45 (9H, s, C(CH_3)). ^{13}C NMR (CDCl$_3$) δ: 170.81, 155.73, 80.78, 74.80, 52.77, 28.24. CI-MS (*m/z*): 203 ([M + 1]). Calcd. for C$_8$H$_{14}$N$_2$O$_4$: C 47.52, H 6.98, N 13.85; found: C 47.67, H 7.07, N 13.10.

Mitsunobu reaction of 30 with ethyl *S*-lactate

Diethyl azodicarboxylate (0.058 mL, 64.1 mg, 0.371 mmol) was added to a solution of triphenylphosphine (0.103 g, 0.393 mmol) in tetrahydrofuran (3.2 mL) and cooled to –56 to –50 °C. The solution was stirred for 10 min; ethyl *S*-lactate (0.031 mL, 32.3 mg, 0.272 mmol) was added, and stirring was continued for an additional 10 min at –50 °C, at which time BOC-*R*-cycloserine (50.0 mg, 0.247 mmol) was added. Stirring was continued while the resulting mixture was allowed to warm to room temperature during 2.5 h. The solvent was then removed under reduced pressure. Purification of the residue by flash chromatography on silica gel, using 2:1 hexanes:ethyl acetate as the eluent, yielded a 1:1 mixture of diastereomeric products (64.7 mg, 87%). ^{1}H NMR (CDCl$_3$) δ: 5.25 (1H, br s, BOCNH, both isomers), 4.96 (1H, q, 6.9 Hz, CHCH$_3$, one isomer), 4.80 (1H, q, 7.5 Hz, CHCH$_3$, second isomer), 4.71 (1H, m, CHβ, both isomers), 4.57 (1H, m, CHα, both isomers), 4.22 (2H, q, 7.1 Hz, CH_2CH$_3$, one isomer), 4.21 (2H, q, 7.1 Hz, CH_2CH$_3$, second isomer), 4.21 (1H, m, CHβ, both isomers), 1.58 (3H, d, 6.7 Hz, CHCH_3, one isomer), 1.53 (3H, d, 7.4 Hz, CHCH_3, second isomer), 1.45 (9H, s, C(CH_3), one isomer), 1.44 (9H, s, C(CH_3), second isomer), 1.29 (3H, t, 7.1 Hz, CH$_2$CH_3, one isomer), 1.28 (3H, t, 7.1 Hz, CH$_2$CH_3, second isomer). CI-MS (*m/z*): 303 ([M + 1]) (both isomers).

Mitsunobu reaction of 21 with ethyl *S*-lactate

Ethyl *S*-lactate (0.062 mL, 64.6 mg, 0.544 mmol) was added at room temperature to a stirred solution of [1,2]oxazinan-3-one (**21**) (45.4 mg, 0.449 mmol) in dichloromethane (2.8 mL). Triphenylphosphine (0.157 g, 0.597 mmol) was added; stirring was continued for 10 min at room temperature; the reaction mixture was cooled in an ice bath, and diethyl azodicarboxylate (0.093 mL, 0.103 g,

0.593 mmol) was added dropwise. The solution was allowed to warm to room temperature overnight, with stirring. The solvent was removed under reduced pressure, and the residue was purified by preparative layer chromatography on silica gel, using 7:4 hexanes:ethyl acetate as the eluent, to give 46.4 mg (51%) of the *N*-alkylated adduct **33** and 6.7 mg (7%) of the O-alkylated adduct **34**. *N*-Alkylated adduct: ^{1}H NMR (CDCl$_3$) δ: 5.03 (1H, q, 6.9 Hz, C*H*), 4.23 (2H, q, 7.1 Hz, C*H$_2$*CH$_3$), 3.87 (2H, m, C*H$_2$*γ), 2.34 (2H, m, C*H$_2$*α), 2.03 (2H, m, C*H$_2$*β), 1.51 (3H, d, 7.0 Hz, CHC*H$_3$*), 1.31 (3H, t, 7.1 Hz, CH$_2$C*H$_3$*). O-Alkylated adduct: ^{1}H NMR (CDCl$_3$) δ: 5.20 (1H, q, 7.3 Hz, C*H*), 4.24 (2H, q, 7.1 Hz, C*H$_2$*CH$_3$), 4.17 (2H, m, C*H$_2$*γ), 2.56 (2H, m, C*H$_2$*α), 2.14 (2H, m, C*H$_2$*β), 1.50 (3H, d, 7.3 Hz, CHC*H$_3$*), 1.29 (3H, t, 7.2 Hz, CH$_2$C*H$_3$*).

Benzyl (*S*)-lactate

1,8-Diazabicyclo[5.4.0]undec-7-ene (18 mL, 18.3 g, 0.12 mol) was added slowly, with stirring, to a solution of 85% *S*-lactic acid (12.7 g, 0.12 mol) in methanol (50 mL). The solvent was removed under reduced pressure at 70–80 °C, and the resulting oil, in dimethylformamide (50 mL), was cooled to 15 °C. Benzyl bromide (11.9 mL, 17.1 g, 0.10 mol) was added dropwise, and the reaction mixture was stirred at room temperature for 30 h. After removal of approximately 40 mL of solvent by vacuum distillation, ethyl acetate (100 mL) was added, followed by water (30 mL). The aqueous layer was washed with ethyl acetate (2 × 30 mL), and the combined organic extracts were washed successively with water (30 mL), 5% citric acid (30 mL), water (30 mL), saturated sodium bicarbonate (3 × 30 mL), and saturated sodium chloride (2 × 30 mL), dried over anhydrous magnesium sulfate, and evaporated. The crude product was distilled, to give a colourless oil (13.8 g, 76%); bp 119–123 °C at 1 torr. IR (neat) (cm^{-1}): 3483, 1738. ^{1}H NMR (CDCl$_3$) δ: 7.37 (5H, m, Ar), 5.21 (2H, s, PhC*H$_2$*), 4.32 (1H, q, 6.9 Hz, C*H*), 2.38 (1H, br s, O*H*), 1.43 (3H, d, 6.9 Hz, C*H$_3$*). ^{13}C NMR (CDCl$_3$) δ: 175.52, 135.23, 128.66, 128.54, 128.22, 67.31, 66.84, 20.37. CI-MS (*m/z*): 181 ([M + 1]). Calcd. for C$_{10}$H$_{12}$O$_3$: C 66.64, H 6.73; found: C 66.30, H 6.75.

Coupling of 20 with the triflate of benzyl *S*-lactate

A solution of 2,6-lutidine (0.35 mL, 0.32 g, 3.0 mmol) in dichloromethane (3 mL) was added at –78 °C to a solution of benzyl *S*-lactate (0.271 g, 1.5 mmol) in dichloromethane (15 mL). The solution was stirred for 10 min, trifluoromethanesulfonic anhydride (0.25 mL, 0.42 g, 1.5 mmol) was added dropwise, and stirring was continued for 30 min at –78 to –50 °C. A solution of methyl γ-aminooxybutyrate (0.170 g, 1.28 mmol) and 2,6-lutidine (0.175 mL, 0.16 g, 1.5 mmol) in dichloromethane (6 mL) was then added dropwise at –78 °C. The reaction mixture was allowed to warm to room temperature, stirred for 18 h, and then washed with water (2 × 10 mL). The organic phase was further washed with saturated sodium chloride (10 mL), dried over anhydrous magnesium sulfate, and evaporated. Purification by flash chromatography on silica gel using a gradient system, hexanes to ethyl acetate, gave 1.63 g (74%) of **35**. IR (neat) (cm^{-1}): 3264, 1741, 1736. ^{1}H NMR (CDCl$_3$) δ: 7.34 (5H, m, Ar), 5.19 (2H, s, PhC*H$_2$*), 5.14 (1H, br d, ON*H*),

3.75 (1H, q, 7.0 Hz, C*H*), 3.69 (2H, t, 6.3 Hz, C*H$_2$*γ), 3.65 (3H, s, OC*H$_3$*), 2.33 (2H, t, 7.4 Hz, C*H$_2$*α), 1.87 (2H, m, C*H$_2$*β), 1.23 (3H, d, 7.0 Hz, CHC*H$_3$*). ^{13}C NMR (CDCl$_3$) δ: 174.11, 173.89, 135.67, 128.55, 128.28, 128.11, 73.01, 66.55, 58.88, 51.54, 30.68, 23.91, 14.75. CI-MS (*m/z*): 296 ([M + 1]).

Cyclization of 35

A solution of **35** (1.63 g, 5.5 mmol) in toluene (80 mL) was cooled to 0 °C and a 2.0 mol/L solution of trimethylaluminium in toluene (5.4 mL, 10.8 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature, stirred overnight, and then cooled to 0 °C, treated dropwise with methanol (16 mL), and stirred for 20 min. Water (10 mL) was added; the ice bath was removed, and stirring was continued for another 15 min. The solution was then concentrated to near-dryness, 1:4 dichloromethane:tetrahydrofuran (200 mL) was added, and the mixture was filtered through Celite. The filtrate was evaporated to give the crude product, 1.19 g, together with some unreacted starting material. Purification by flash chromatography on silica gel using an ethyl acetate – hexanes gradient solvent system, 10–40%, gave a clear oil (0.99 g, 84%). IR (neat) (cm^{-1}): 1744, 1660. ^{1}H NMR (CDCl$_3$) δ: 7.35 (5H, m, Ar), 5.24 (1H, q, 7.3 Hz, C*H*), 5.20 (1H, d, 13.0 Hz, PhC*H*), 5.14 (1H, d, 13.0 Hz, PhC*H*), 4.14 (1H, m, C*H*γ), 3.98 (1H, m, C*H*γ), 2.51 (2H, m, C*H$_2$*α), 2.08 (2H, m, C*H$_2$*β), 1.50 (3H, d, 7.3 Hz, CHC*H$_3$*). ^{13}C NMR (CDCl$_3$) δ: 170.90, 170.13, 135.45, 128.53, 128.30, 128.07, 69.32, 67.09, 53.17, 28.32, 22.11, 13.76. CI-MS (*m/z*): 264 ([M + 1]).

Hydrogenolysis of 36

To ethyl acetate (15 mL) was added 10% palladium on activated carbon (83.0 mg, 0.078 mmol), and the suspension was stirred in an atmosphere of hydrogen for 1 h. The benzyl ester **36** (0.206 g, 0.78 mmol) in ethyl acetate (15 mL) was then added, and stirring was continued for 24 h. The mixture was filtered through Celite, which was washed with ethyl acetate (2 × 4 mL), and the combined filtrates were evaporated to give **37** as a white solid (0.13 g, 99%). IR (KBr) (cm^{-1}): 1744, 1621. ^{1}H NMR (CDCl$_3$) δ: 5.22 (1H, q, 7.3 Hz, C*H*), 4.23 (1H, m, C*H*γ), 4.05 (1H, m, C*H*γ), 2.56 (2H, m, C*H$_2$*α), 2.13 (2H, m, C*H$_2$*β), 1.52 (3H, d, 7.3 Hz, CHC*H$_3$*). ^{13}C NMR (CDCl$_3$) δ: 173.78, 171.18, 69.61, 53.19, 28.26, 22.09, 13.58. CI-MS (*m/z*): 174 ([M + 1]). Calcd. for C$_7$H$_{11}$NO$_4$: C 49.54, H 6.61, N 8.09; found: C 49.36, H 6.52, N 7.86.

Alkylation of 28, R$_1$ = PhCH$_2$, R$_2$ = Me, with the triflate of benzyl *S*-lactate

A solution of 2,6-lutidine (0.60 mL, 0.54 g, 5.0 mmol) in dichloromethane (3 mL) was added, with stirring, to a cooled (–78 °C) solution of benzyl *S*-lactate (0.450 g, 2.5 mmol) in dichloromethane (15 mL). After 10 min, trifluoromethanesulfonic anhydride (0.42 mL, 0.71 g, 2.5 mmol) was added dropwise, and stirring was continued at –78 to –50 °C for an additional 30 min. A solution of methyl 2-phenylacetamido-4-aminooxybutyrate (**28**) (0.678 g, 2.5 mmol) and 2,6-lutidine (0.30 mL, 0.27 g, 2.5 mmol) in dichloromethane (15 mL) was then added dropwise. When the addition was complete, the reaction mixture was allowed to warm to room

temperature and stirred for 18 h. Water (2×10 mL) was added, and the separated organic phase was washed with saturated sodium chloride (10 mL), dried over anhydrous magnesium sulfate, and evaporated. The residue was purified by flash chromatography on silica gel using a gradient system, hexanes to ethyl acetate, to give an oil (0.304 g, 29%). 4-Phenylacetamido-[1,2]oxazinan-3-one (**10**) was also found as a side product (0.136 g, 23%). IR (CH_2Cl_2) (cm^{-1}): 3286, 1742, 1660. ^{1}H NMR of **38** ($CDCl_3$) δ: 7.34 (10H, m, P*h*CH$_2$CO, P*h*CH$_2$O, both isomers), 6.35 (1H, d, 7.9 Hz, CON*H*, one isomer, exchanges in CD_3OD), 6.32 (1H, d, 7.5 Hz, CON*H*, second isomer, exchanges in CD_3OD), 5.77 (1H, d, 9.5 Hz, ON*H*, one isomer, exchanges in CD_3OD), 5.74 (1H, d, 8.9 Hz, ON*H*, second isomer, exchanges in CD_3OD), 5.16 (2H, d, 4.12 Hz, PhC*H$_2$*O, one isomer), 5.15 (2H, d, 4.12 Hz, PhC*H$_2$*O, second isomer), 4.62 (1H, m, C*H* α, both isomers), 3.69 (2H, t, 6.3 Hz, C*H$_2$*γ, both isomers), 3.68 (3H, s, OC*H$_3$*, one isomer), 3.67 (3H, s, OC*H$_3$*, second isomer), 3.68–3.66 (1H, m, C*H*CH$_3$, both isomers), 3.59 (2H, m, PhC*H$_2$*CO, both isomers), 2.01 (2H, m, C*H$_2$*β, both isomers), 1.19 (3H, d, 7.2 Hz, CHC*H$_3$*, one isomer) 1.18 (3H, d, 7.2 Hz, CHC*H$_3$*, second isomer). ^{13}C NMR ($CDCl_3$) δ:173.56, 172.32, 170.82, 135.55, 134.74, 129.37, 128.90, 128.87, 128.59, 128.21,.127.25, 70.30 (Ph*C*H$_2$O, one isomer), 70.09 (Ph*C*H$_2$O, second isomer), 66.76 (*C*H$_2$γ, both isomers), 58.63(*C*HCH$_3$, one isomer), 58.57 (*C*HCH$_3$, second isomer), 52.36 (Ph*C*H$_2$CO, both isomers), 50.23 (O*C*H$_3$, both isomers), 43.50 (*C*Hα, both isomers), 30.45 (*C*H$_2$β, both isomers), 14.72 (CH*C*H$_3$, one isomer), 14.62 (CH*C*H$_3$, second isomer). CI-MS (*m/z*): 429 ([M + 1]). Calcd. for $C_{23}H_{28}N_2O_6 \cdot 0.75H_2O$: C 62.51, H 6.68, N 6.34; found: C 62.36, H 6.35, N 6.38.

Cyclization of 38

A 2.0 mol/L solution of trimethylaluminium in hexanes (0.20 mL, 0.4 mmol) was added dropwise, at 0 °C, to a solution of **38** (42 mg, 0.10 mmol) in toluene (10 mL). The cooling bath was removed, and the reaction mixture was stirred overnight. Water (1 mL) was then added slowly, and stirring was continued for 15 min. The solvent was evaporated to near-dryness under reduced pressure; 1:4 dichloromethane:tetrahydrofuran (100 mL) was added, and the mixture was filtered through Celite. The filtrate was evaporated to give an oil (18 mg). Purification by short column chromatography, using a hexanes to ethyl acetate gradient solvent system, gave 3.9 mg of one isomer as a white solid; mp 106–107 °C. ^{1}H NMR (CD_3OD): 7.31 (10H, m, P*h*CH$_2$CO, P*h*CH$_2$O), 6.44 (1H, d, 5.6 Hz, CON*H*), 5.14 (2H, q, 8.8 Hz, PhC*H$_2$*O), 5.10 (1H, q, 7.2 Hz, C*H*CH$_3$), 4.66 (1H, m, C*H*a), 4.22 (1H, m, C*H* γ), 4.06 (1H, m, C*H* γ), 3.61 (2H, s, PhC*H$_2$*), 2.85 (1H, m, C*H* β), 1.60 (1H, m, C*H* β), 1.48 (3H, d, 7.3 Hz, C*H$_3$*). ^{13}C NMR (CD_3OD): 170.88, 170.42, 170.03, 135.03, 134.46, 129.35, 129.00, 128.66, 128.30, 127.41, 69.01, 67.43, 53.67, 47.51, 43.68, 29.15.

Synthesis of the *tert*-butyl esters 40a and 40b

To a stirred solution of 4-phenylacetylamido-[1,2]oxazinan-3-one (**10**) (0.447 g, 1.91 mmol) and *tert*-butyl *S*-α-bromopropionate (0.398 g, 1.91 mmol) in dry dimethylformamide (15 mL) was added KF–Al$_2$O$_3$ (40 wt %, 1.94 g) in one portion. Stirring was continued at room temperature for 63 h.

The reaction mixture was then diluted with ethyl acetate (40 mL) and filtered through a pad of Silica Gel 60H (for TLC), which was washed with ethyl acetate (30 mL). The filtrate was washed with water (4×30 mL), 10% potassium bisulfate (15 mL), saturated sodium bicarbonate (15 mL), and brine (30 mL), and dried over anhydrous magnesium sulfate. Removal of the solvent provided 0.621 g of a yellowish oil, which was purified by flash chromatography (Silica Gel 60, 15% ethyl acetate – hexanes → 70% ethyl acetate – hexanes) to afford **40a** (0.183 g, 26%) and **40b** (0.215 g, 31%) as colourless oils.

40a

IR (film) (cm^{-1}): 3319, 2988, 1737, 1658, 1537, 1370. ^{1}H NMR (400 MHz, $CDCl_3$): 1.42 (3H, d, ^3J = 7.4, a-*Me*), 1.44 (9H, C*Me$_3$*), 1.69 (1H, m,^2J = –12.1, ^3J = 10.0, 12.0, C5-*H1*), 2.91 (1H, m, ^2J = –12.1, ^3J = 4.8, 6.9, 7.0, C5-*H2*), 3.60 (2H, C*H$_2$*Ph), 4.14 (1H, m, ^2J = –10.1, ^3J = 7.0, 10.0, C6-*H4*), 4.40 (1H, m, ^2J = –10.1, ^3J = 4.8, 10.0, C6-*H3*), 4.67 (1H, m, ^3J = 6.8, 6.9, 12.0, C4-*H5*), 4.95 (1H, q, ^3J = 7.4, a-C*H*), 6.49 (1H, br. d, ^3J = 6.8, N*H*), 7.26–7.37 (5H, m, *Ph*). ^{13}C NMR (100 MHz, $CDCl_3$): 14.06, 27.93, 29.24, 47.51, 54.33, 69.00, 82.30, 127.34, 128.94, 129.32, 134.51, 169.21, 170.28, 170.86. CI-MS (isobutane), *m/z*: 307 ([M + 1]).

Deprotection of 40b

Repetition of the above experiment with **40b** afforded the acid **5b** in 58% yield as a white solid; mp 189–190 °C. IR

(KBr) (cm^{-1}): 3284, 2935, 1712, 1671, 1645, 1541, 1438. ^{1}H NMR (400 MHz, CD$_3$OD): 1.49 (3H, d, ^3J = 7.3, a-*Me*), 1.93 (1H, m,^2J = –12.7, ^3J = 6.9, 9.0, 11.6, C5-*H1*), 2.54 (1H, m, ^2J = –12.7, ^3J = 5.3, 7.5, 9.0, C5-*H2*), 3.60 (2H, C*H$_2$*Ph), 4.14 (1H, m, ^2J = –10.9, ^3J = 5.3, 9.0, C6-*H4*), 4.26 (1H, m, ^2J = –10.9, ^3J = 6.9, 9.0, C6-*H3*), 4.77 (1H, dd, ^3J = 7.5, 11.6, C4-*H5*), 4.99 (1H, q, ^3J = 7.3, a-C*H*), 7.19–7.40 (5H, m, *Ph*). ^{13}C NMR (CD$_3$OD): 13.80, 29.98, 43.63, 48.36, 55.42, 70.44, 127.91, 129.57, 130.23, 136.66, 172.74, 172.81, 174.01. CI-MS (isobutane), *m/z*: 307 ([M + 1]).

Benzyl ester of homolactivicin

A solution of dicyclohexylcarbodiimide (0.357 g, 1.73 mmol) in acetonitrile (10 mL) was added dropwise to a stirred solution of the oxazinone **10** (0.311 g, 1.33 mmol) and benzyl 2-oxoglutarate (0.408 g, 1.73 mmol) in acetonitrile (20 mL). After three days of stirring, a white precipitate was collected by filtration and washed with methylene chloride. The filtrate was evaporated under reduced pressure to give 0.85 g of a dark semi-solid, which was purified by flash column chromatography (Silica Gel 60, ethyl acetate) to afford diastereomers **41a** (0.189 g) and **41b** (0.126 g) (52% total yield) as white solids.

Homolactivicin

To a 1:1 mixture of **41a** and **41b** (0.217 g, 0.48 mmol) in ethyl acetate (30 mL) was added 5% Pd–C (0.106 g) in one portion. The mixture was stirred at room temperature, under hydrogen, for 7.5 h. The catalyst was then removed by filtration through a pad of Silica Gel 60H (for TLC), followed by washing with ethyl acetate (50 mL) and tetrahydrofuran (50 mL). The combined filtrates were evaporated under reduced pressure, and the white solid residue was triturated with dry ether (3 × 5 mL) and dried in vacuo to afford 0.0945 g (54%) of racemic homolactivicin (a mixture of diastereoisomers) as a white powder; mp 150–152 °C (decomposition temperature (dec)). IR (KBr) (cm^{-1}): 3348, 2942, 1804, 1713, 1542, 1185, 1032. ^{1}H NMR (400 MHz, CD$_3$CN): 1.85 (1H, br.m), 2.45 (1H, br m), 2.56 (2H, br m), 2.72 (1H, br m), 2.90 (2H, br m), 3.52 (2H, C*H$_2$*Ph), 4.13 (1H, br m), 4.26 (2H, br m), 4.71 (1H, br m), 6.71 (br s, N*H*), 7.2–7.4 (5H, m, *Ph*). Calcd for C$_{17}$H$_{18}$N$_2$O$_7$: C 56.35, H 5.01, N 7.73; found: C 56.31, H 5.11, N 7.69.

Calcium ʟ-threonate

Calcium carbonate (60.06 g, 0.6 mol) was added to a solution of ʟ-ascorbic acid (52.8 g, 0.3 mol) in water (410 mL). The slurry was cooled to 0–5 °C and hydrogen peroxide (50% w/w, 61.2 mL, 0.9 mol) was added dropwise during 1 h at 5–20 °C. Stirring was continued at room temperature for 16 h, and the reaction mixture was then heated at 70–75 °C for 1 h until gas was no longer evolved. The suspension was filtered hot, and the filter cake was washed with 50–60 °C hot water (2 × 30 mL). The combined filtrates were concentrated to about 120 mL under reduced pressure at 55 ºC. Methanol (250 mL) was added dropwise to the warm concentrate (50 °C) until the solution became cloudy, and the mixture was then stirred at room temperature for 12 h, filtered, and the precipitate was washed with methanol (3 × 30 mL). The solid was dried to a constant weight at 60 °C (3 h) to give 45.2 g (94.6%) of **42**. IR (KBr) (cm^{-1}):

1600 (s). ^{1}H NMR (D$_2$O, 400 MHz): 4.02 (d, 1H, H$_c$, J_{bc} = 2.3 Hz), 3.94 (ddd, 1H, H$_b$, J_{ab} = 7.7 Hz, $J_{a'b}$ = 5.2 Hz, J_{bc} = 2.2 Hz), 3.65 (ABX, 1H, H$_{a'}$, $J_{aa'}$ = 11.6 Hz, $J_{a'b}$ = 5.2 Hz), 3.58 (ABX, 1H, H$_a$, $J_{aa'}$ = 11.6 Hz, J_{ab} = 7.7 Hz).

Methyl 2,4-dibromo-2,4-dideoxy-ʟ-erythronate (43)

Calcium ʟ-threonate (34.98 g, 0.11 mol) was stirred for 24 h with 30% w/w hydrogen bromide – acetic acid solution (210 mL, 1.05 mol), and methanol (420 mL) was then added. The solution was stirred at room temperature for an additional 12 h, and the mixture was then refluxed for 2 h. The solvent was evaporated under reduced pressure to give an oil, which was dissolved in ethyl acetate (250 mL). This solution was washed with brine (100 mL), dried over sodium sulfate, and evaporated to give **43** (27.38 g, 90.2%) as an oil. IR (film) (cm^{-1}): 3340 (m), 1745 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 4.32 (d, 1H, H$_c$, J_{bc} = 8.8 Hz), 4.24 (m, 1H, H$_b$), 3.81 (s, 3H, CO$_2$*Me*), 3.80 (AB, 2H, H$_a$H$_{a'}$). CI-MS (*m/z*): 277 ([M + 1]).

Methoxymethylation of 43

Boron trifluoride etherate (9.35 mL, 74 mmol) was added dropwise under nitrogen during 10 min at 0–5 °C to a solution of **43** (16.55 g, 60 mmol) in dichloromethane (70 mL) and dimethoxymethane (33 mL). The reaction mixture was stirred at room temperature for 10–12 h, cooled to 0–5 °C, and quenched by dropwise addition of water (50 mL) during 15 min. Dichloromethane (80 mL) was added, and the organic layer was washed with saturated sodium bicarbonate (2 × 50 mL) and brine (100 mL), dried over anhydrous sodium sulfate, and evaporated under reduced pressure to give a pale yellow oil (18.10 g, 92%). IR (film) (cm^{-1}): 1747 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 4.71 (AB, 2H, H$_d$, MeO*CH$_2$*O-), 4.43 (d, 1H, H$_c$, J_{bc} = 9.1 Hz), 4.16 (dt, 1H, H$_b$, J_{ab} ~ $J_{a'b}$ = 2.9 Hz, J_{bc} = 9.1 Hz), 3.86 (ABX, 2H, H$_a$H$_{a'}$, $J_{aa'}$ = 11.5 Hz, J_{ab} = 2.8 Hz, $J_{a'b}$ = 3.1 Hz), 3.79 (s, 3H, CO$_2$*Me*), 3.41 (s, 3H, *Me*OCH$_2$O).

Methyl 2-azido-4-bromo-2,4-dideoxy-3-methoxymethoxy-ʟ-threonate (44)

Sodium azide (2.18 g, 33.5 mmol) was added in one portion at 10–15 °C to a solution of the MOM derivative (10.23 g, 32.0 mmol) in dimethylformamide (40 mL). The mixture was stirred at 10 °C to room temperature for 12 h. Water (35 mL) was then added at 0–5 °C, and the mixture was extracted with ethyl acetate (2 × 80 mL). The combined extracts were washed with water (3 × 20 mL) and brine (20 mL), dried over anhydrous sodium sulfate, and evaporated under reduced pressure to give an oil. Purification by flash chromatography using 5% ethyl acetate as eluent yielded 6.40 g (71%) of **44**. IR (film) (cm^{-1}). 2115 (s), 1744 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 4.67 (AB, 2H, MeO*CH$_2$*O), 4.33 (ddd, 1H, H$_b$, J_{ab} = 9.0 Hz, $J_{a'b}$ = 5.0 Hz, J_{bc} = 2.5 Hz), 4.29 (d, 1H, H$_c$, J_{bc} = 2.5 Hz), 3.85(s, 3H, CO$_2$*Me*), 3.58 (ABX, 1H, H$_{a'}$, $J_{aa'}$ = 10.2 Hz, $J_{a'b}$ = 5.0 Hz), 3.53 (ABX, 1H, H$_a$, $J_{aa'}$ = 10.2Hz, J_{ab} = 9.0 Hz), 3.36 (s, 3H, *Me*OCH$_2$O-). CI-MS (*m/z*) 282 ([M + 1]), 284 ([M + 3]), along with 0.40 g (5.2%) of the diazide-compound. IR (film) (cm^{-1}): 2109 (vs), 1751 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 4.68 (AB, 2H, MeO*CH$_2$*O), 4.18 (ddd, 1H, H$_b$, J_{ab} = 7.3 Hz, $J_{a'b}$ = 6.1 Hz, J_{bc} = 2.9 Hz), 3.95 (d, 1H, H$_c$, J_{bc} = 2.9 Hz),

3.84 (s, 3H, CO$_2$$Me$), 3.62 (ABX, 1H, H$_{a'}$, $J_{aa'}$ = 12.4 Hz, $J_{a'b}$ = 6.1 Hz), 3.49 (ABX, 1H, H$_a$, $J_{aa'}$ = 12.4 Hz, J_{ab} = 7.3 Hz), 3.36 (s, 3H, MeOCH$_2$O-). CI-MS (m/z) 245 ([M + 1]).

Reduction of 44 and protection as the BOC derivative 45

A 5% Pd–C suspension (0.60 g) in ethyl acetate (55 mL) was stirred for 2 h in a hydrogen atmosphere, and a solution of **44** (4.30 g, 15.0 mmol) and di-*tert*-butyl dicarbonate (4.00 g, 18.0 mmol) in ethyl acetate (25 mL) was added. The mixture was stirred under hydrogen until the starting material had disappeared (48 h) and then filtered through Celite. The Celite pad was washed with ethyl acetate (3 × 10 mL), and the filtrate was concentrated under reduced pressure. The crude product was purified by flash chromatography (12% ethyl acetate in hexane) to give 4.03 g (74%) of **45** as a colourless oil. IR (film) (cm^{-1}): 1754 (s), 1721 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 5.19 (d, 1H, NH, J_{NHHc} = 10.0 Hz), 4.72 (d, 1H, H$_c$, J_{NHHc} = 10.3 Hz), 4.64 (AB, 2H, MeOCH_2O-), 4.36 (t, 1H, H$_b$, J_{ab} = 6.4 Hz), 3.77 (s, 3H, CO$_2$$Me$), 3.43 (ABX, 2H, H$_a$, J_{ab} = 6.4 Hz), 3.31 (s, 3H, MeOCH$_2$O-), 1.48 (s, 9H, -CO$_2$CMe_3). CI-MS (m/z): 356([M + 1]), 358 ([M + 3]).

Conversion of 45 to the phthalimidooxy compound

A solution of *N*-hydroxyphthalimide (2.40 g, 14.8 mmol) and DBU (2.20 g, 14.4 mmol) in dimethylformamide (25 mL) was added dropwise with stirring at 10–15 °C to a solution of **45** (4.40 g, 12.4 mmol) in dimethylformamide (10 mL). The mixture was stirred for 60 h and allowed to warm to room temperature. Ethyl acetate (120 mL) was then added, and the organic layer was washed with saturated sodium bicarbonate (5 × 15 mL) and brine (20 mL), dried over anhydrous sodium sulfate, and evaporated to give an oil. Purification by flash chromatography using 30% ethyl acetate in hexane as eluent afforded 2.93 g (54.0%) of the phthalimidooxy compound as a colourless oil. IR (film) (cm^{-1}): 1739 (s), 1732 (s), 1719 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 7.80 (AB, 4H), 5.28 (d, 1H, NH, J_{NHHc} = 9.8 Hz), 4.76 (AB, 2H, MeOCH_2O-), 4.65 (d, 1H, H$_c$, J_{NHHc} = 9.8 Hz), 4.58 (m, 1H, H$_b$, J_{ab} = 7.0 Hz, $J_{a'b}$ = 4.8 Hz, J_{bc} = 1.5 Hz), 4.36 (ABX, 1H, H$_{a'}$, $J_{aa'}$ = 10.6 Hz, $J_{a'b}$ = 4.8 Hz), 4.28 (ABX, 1H, H$_a$, $J_{aa'}$ = 10.6 Hz, J_{ab} = 7.0 Hz), 3.79 (s, 3H, CO$_2$$Me$), 3.31 (s, 3H, MeOCH$_2$O-), 1.43 (s, 9H, -CO$_2$CMe_3). CI-MS (m/z): 439 ([M + 1]).

Formation of the aminooxy compound 46

A solution of the phthalimidooxy compound (2.40 g, 5.48 mmol) in dichloromethane (25 mL) was treated, with stirring at –15 °C, with a solution of methylhydrazine (0.38 g, 8.26 mmol) in dichloromethane (2 mL). The cooling bath was then removed, and stirring was continued for 4 h. The solvent and excess methylhydrazine were evaporated under reduced pressure, and the residue was triturated with ethyl acetate (6 × 3 mL) and filtered through a short silica gel plug. The filtrate was evaporated to give 1.44 g (85.3%) of **46** as a colourless oil. IR (film) (cm^{-1}): 3451 (b), 3323 (m), 1745 (s), 1714 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 5.54 (b, 2H, -ONH_2), 5.25 (d, 1H, NH, J_{NHHc} = 9.6 Hz), 4.61 (AB, 2H, MeOCH_2O-), 4.47 (dd, 1H, H$_c$, J_{bc} = 1.6 Hz, J_{NHHc} = 9.8 Hz), 4.40 (td, 1H, H$_b$, J_{ab}~ $J_{a'b}$ = 6.2 Hz, J_{bc} = 1.6 Hz), 3.76 (s, 3H, CO$_2$$Me$), 3.73 (ABX, 2H, H$_{aa'}$, $J_{aa'}$ =

11.2 Hz, $J_{a'b}$ = J_{ab} = 6.2 Hz), 3.31 (s, 3H, MeOCH$_2$O-), 1.47 (s, 9H, -CO$_2$CMe_3). CI-MS (m/z): 309 ([M + 1]).

Reaction of 46 with the triflate of benzyl L-lactate

Trifluoromethanesulfonic anhydride (0.79 mL, 4.69 mmol) was added dropwise, with stirring at –78 °C, to a solution of benzyl L-lactate (0.84 g, 4.66 mmol) and 2,6-lutidine (0.70 g, 6.53 mmol) in dichloromethane (35 mL). After 20 min a solution of **46** (1.30 g, 4.22 mmol) and 2,6-lutidine (0.46 g, 4.29 mmol) in dichloromethane (20 mL) was added dropwise at –78 to –60 °C. Stirring was continued at –78 to –50 °C for 1 h, and the cooling bath was then removed. After an additional 10 h of stirring the reaction mixture was washed with cold water (2 × 5 mL), dried over anhydrous sodium sulfate, and evaporated to give an oil. Purification by flash chromatography using 25% ethyl acetate in hexane as eluent yielded 1.31 g (66%) of **47**. IR (film) (cm^{-1}): 3445 (b), 3367 (m), 1744 (s), 1719 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 7.37 (m, 5H, PhCH$_2$-), 6.07 (d, 1H, ONH, J_{ONHHd} = 8.8 Hz), 5.23 (d, 1H, NH, J_{NHHc} = 9.9 Hz), 5.18 (AB, 2H, PhCH_2-), 4.56 (AB, 2H, MeOCH_2O), 4.43 (d, 1H, H$_c$, J_{NHHc} = 9.9 Hz), 4.32 (t, 1H, H$_b$, J_{ab} = 6.0 Hz), 3.80 (m, 1H, H$_d$, J_{de} = 7.2Hz,, J_{ONHHd} = 8.8 Hz), 3.77 (d, 2H, H$_a$, J_{ab} = 6.4 Hz), 3.75 (s, 3H, CO$_2$$Me$), 3.27 (s, 3H, MeOCH$_2$O-), 1.45 (s, 9H, -CO$_2$CMe_3), 1.24 (d, 3H, H$_e$, J_{de} = 7.2 Hz). CI-MS (m/z): 471 ([M + 1]).

Cyclization of 46

A 2.0 mol/L solution of trimethylaluminium in hexane (1.68 mL, 3.36 mmol) was added dropwise, with stirring at 0–5 °C, to a solution of **46** (0.86 g, 2.80 mmol) in dry tetrahydrofuran (70 mL). Stirring was continued for 40 min after addition was complete, and for 3.5 h after the cooling bath was removed. Ice-cold water (1 mL) was added, and after 20 min, the solvent was removed under reduced pressure. The residue was triturated with tetrahydrofuran (6 × 5 mL) and dichloromethane (4 × 5 mL) and filtered through a short silica gel – Celite pad. The filtrate was evaporated to give **48**, 0.70 g (90%), as an oil. IR (film) (cm^{-1}): 3342 (m), 3232 (m), 1698 (vs). ^{1}H NMR (CDCl$_3$, 400 MHz): 8.80 (s, 1H, NH_e), 5.19 (d, 1H, NH_d, J_{NHdHc} = 7.0 Hz), 4.69 (AB, 2H, MeOCH_2O-, J = 7.0 Hz), 4.57 (dd, 1H, H$_c$, J_{NHdHc} = 7.1 Hz, J_{bc} = 7.1 Hz), 4.26 (ABM, 1H, H$_{a'}$, $J_{aa'}$ = 12.2 Hz, $J_{a'b}$ = 5.9 Hz), 4.14 (ABM, 1H, H$_a$, $J_{aa'}$ = 12.2 Hz, J_{ab} = 3.3 Hz), 3.99 (ddd, 1H, H$_b$, J_{ab} = 3.3 Hz, $J_{a'b}$ = 5.9 Hz, J_{bc} = 7.8 Hz), 3.37 (s, 3H, MeOCH$_2$O-), 1.45 (s, 9H, -CO$_2$CMe_3). CI-MS (m/z): 277 ([M + 1]).

Cyclization of 47

A 2.0 mol/L solution of trimethylaluminium in hexane (3.40ml, 6.82 mmol) was added dropwise, with stirring at 0–5 °C, to a solution of **47** (0.76 g, 1.62 mmol) in dry toluene (70 mL). Stirring was continued for 40 min at 0–5 °C and then for 4 h after removal of the cooling bath. Ice-cold water (1 mL) was added, the mixture was stirred for 20 min, and the solvent was then removed under reduced pressure. The residue was triturated with tetrahydrofuran (8 × 6 mL) and dichloromethane (3 × 6 mL) and filtered through a short silica gel – Celite pad. Evaporation of the filtrate gave an oil, which was purified by flash chromatography (using ethyl acetate:hexane (20:80) as eluent); this eluted to yield 0.45 g

(62.6%) of **49**. IR (film) (cm^{-1}): 3351 (w), 1745 (s), 1719 (s), 1687 (s). ^{1}H NMR (CDCl$_3$, 400 MHz): 7.37 (m, 5H, PhCH$_2$-), 5.16 (AB, 2H, PhCH_2-), 5.13 (q, 1H, H$_d$, J_{de} = 7.3 Hz), 4.71 (m, 1H, H$_c$), 4.64 (AB, 2H, MeOCH_2O), 4.54 (ABM, 1H, H$_{a'}$, $J_{aa'}$ = 11.9 Hz, $J_{a'b}$ = 6.6 Hz), 4.00 (ABX, 1H, H$_a$, $J_{aa'}$ = 11.9 Hz, J_{ab} = 3.1 Hz), 3.86 (ddd, 1H, H$_b$, J_{ab} = 3.1 Hz, $J_{a'b}$ = 6.6 Hz, J_{bc} = 8.5 Hz), 3.34 (s, 3H, MeOCH$_2$O-), 1.50 (d, 3H, J_{de} = 7.3 Hz), 1.45 (s, 9H, -CO$_2$CMe_3). CI-MS (m/z): 439 ([M + 1]).

Removal of the BOC and MOM groups of 49

Trifluoroacetic acid (1.25 mL, 16.30 mmol) was added dropwise with stirring at 0–5 °C to a solution of **49** (0.25 g, 0.57 mmol) in dichloromethane (1.0 mL) and anisole (0.5 mL). After removal of the cooling bath, stirring was continued for 10 h. The solvent was then removed under reduced pressure, and the residue was washed with ether (2 × 3 mL) to give a solid. The solid that resulted was dried in vacuo to 70 mg (30%) of **50** as an off-white powder. IR (KBr) (cm^{-1}): 3459 (b), 3217 (m), 1731 (s), 1683 (vs). ^{1}H NMR (CD$_3$OD, 400 MHz): 7.36 (m, 5H, Ph-), 5.18 (q, 1H, H$_d$, J_{de} = 7.3 Hz), 5.17 (AB, 2H, PhCH_2OCO-), 4.70 (ddd, 1H, H$_b$, J_{ab} = 2.6 Hz, $J_{a'b}$ = 7.1 Hz, J_{bc} = 4.3 Hz), 4.58 (ABM, 1H, H$_{a'}$, $J_{aa'}$ = 11.8 Hz, $J_{a'b}$ = 7.1 Hz), 4.27 (d, 1H, H$_c$, J_{bc} = 4.3 Hz), 3.98 (ABX, 1H, H$_a$, $J_{aa'}$ = 11.8 Hz, J_{ab} = 2.6 Hz), 1.54 (d, 3H, H$_e$, J_{de} = 7.3 Hz). CI-MS (m/z): 295 ([M]$^+$).

Phenylacetylation of 50

To a solution of the trifluoroacetic acid salt (70 mg, 0.17 mmol) in dichloromethane (6.0 mL) were added dropwise, with stirring at –20 to –10 °C, triethylamine (52.0 mg, 0.51 mmol), followed by a solution of phenylacetyl chloride (31.7 mg, 0.20 mmol) in dichloromethane (1.0 mL). The cooling bath was removed and stirring was continued for 6 h. Dichloromethane (10 mL) was then added, and the reaction mixture was washed successively with 5 °C water (1.5 mL), saturated sodium bicarbonate (3 × 1.5 mL), and brine (1.5 mL), dried over anhydrous sodium sulfate, and evaporated to give an oil. Purification by flash chromatography using ethyl acetate as eluent afforded 37.8 mg (54%) of **49** as an off-white powder. IR (KBr) (cm^{-1}): 3464 (b), 3304 (m), 1736 (s), 1681 (s), 1644 (vs). ^{1}H NMR (CD$_3$CN, 400 MHz): 7.37 (m, 10H, Ph-), 6.71 (d, 1H, NH, J_{NHHc} = 7.4 Hz), 5.11 (AB, 2H, PhCH_2O), 5.07 (q, 1H, H$_d$, J_{de} = 7.2 Hz), 4.67 (dd, 1H, H$_c$, J_{bc} = 3.8 Hz, J_{NHHc} = 7.4 Hz), 4.55 (m, 1H, H$_b$), 4.48 (ABM, 1H, H$_{a'}$, $J_{aa'}$ = 11.6 Hz, $J_{a'b}$ = 7.4 Hz), 3.86 (ABX, 1H, H$_a$, $J_{aa'}$ = 11.6 Hz, J_{ab} = 2.4 Hz), 3.65 (d, 1H, OH, J_{OHHb} = 4.4 Hz), 3.61 (AB, 2H, PhCH_2CONH-), 1.45 (d, 3H, H$_e$, J_{de} = 7.2 Hz). CI-MS (m/z): 413 ([M + 1]).

Hydrogenolysis of 51

A suspension of 5% Pd–C (0.035 g) in ethyl acetate (6 mL) was activated in a hydrogen atmosphere for 2 h. A solution of the benzyl ester **51** (35 mg, 0.085 mmol) in ethyl acetate (10 mL) was added, and the mixture was stirred in a hydrogen atmosphere until the starting material had disappeared (4 h). The mixture was filtered through Celite; the Celite pad was washed with methanol (4 × 5 mL), and the filtrate was evaporated under reduced pressure to give **52**

(25 mg 92%) as a white powder. IR (KBr) (cm^{-1}): 3459 (b), 3283 (w), 1727 (w), 1666 (s), 1644 (vs). ^{1}H NMR (CD$_3$OD, 400 MHz): 7.30 (m, 5H, Ph-), 4.97 (q, 1H, H$_d$, J_{de} = 7.3 Hz), 4.80 (m, 1H, H$_c$), 4.57 (m, 1H, H$_b$, J_{ab} = 1.8 Hz, $J_{a'b}$ = 7.4 Hz, J_{bc} = 3.7 Hz), 4.52 (ABM, 1H, H$_{a'}$, $J_{aa'}$ = 10.9 Hz, $J_{a'b}$ = 7.4 Hz), 3.92 (ABX, 1H, H$_a$, $J_{aa'}$ = 10.9 Hz, J_{ab} = 1.8 Hz), 3.68 (AB, 2H, PhCH_2CONH-), 1.50 (d, 3H, H$_e$, J_{de} = 7.3 Hz). CI-MS (m/z): 323 ([M + 1]).

Bioassays

The data of Table 2 were obtained using seeded agar plates, prepared as described in ref 1. MIC (minimum inhibitory concentration) data were provided by the Health Sciences Centre, Winnipeg, and by NAEJA Pharmaceuticals, Edmonton.

Geometrical and vibrational DFT studies of HOBr·(H₂O)ₙ clusters (*n* = 1–4)

Cristina Maria P. Santos, Roberto B. Faria, Wagner B. De Almeida, Juan O. Machuca-Herrera, and Sérgio P. Machado

Abstract: The geometrical structures and the vibrational spectra of the HOBr·(H₂O)ₙ clusters (*n* = 1–4) have been calculated at the DFT level of theory, using the pBP method and the DN* and DN** numerical basis sets. The results showed that the interaction involving the H of the HOBr and the O of the water molecule represent the preferred arrangements for these hydrated compounds. Both HOBr·H₂O and HOBr·(H₂O)₂ clusters presented stable structures with *syn* and *anti* conformations, the *syn* being the most stable. The HOBr·(H₂O)₃ and the HOBr·(H₂O)₄ clusters have presented stable cyclic structures. In the HOBr·H₂O and HOBr·(H₂O)₂ clusters, low-frequency stretching values could be assigned to hydrogen bonds, but the same could not be done so clearly for the HOBr·(H₂O)₃ and the HOBr·(H₂O)₄ cyclic clusters. The binding energies were also determinated for these HOBr hydrated clusters, showing that the addition of a water molecule to the HOBr·H₂O and HOBr·(H₂O)₂ clusters increases the binding energy by approximately 4 kcal mol⁻¹, while the addition of a water molecule to the HOBr·(H₂O)₃ cluster decreases this value by 4 kcal mol⁻¹.

Key words: DFT, numerical basis, HOBr·(H₂O)ₙ, clusters.

Résumé : On a calculé, théoriquement au niveau DFT, les structures géométriques et les spectres de vibration des agrégats de HOBr·(H₂O)ₙ (*n* = 1–4) en utilisant la méthode pBP et les ensembles de base DN* et DN**. Les résultats montrent que l'interaction impliquant le H du HOBr et le O de la molécule d'eau représente les arrangements privilégiés de ces composé hydratés. Les deux agrégats de HOBr·H₂O et de HOBr·(H₂O)₂ ont des structures stables avec des conformations *syn* et *anti*, la conformation *syn* étant la plus stable. Les agrégats de HOBr·(H₂O)₃ et de HOBr·(H₂O)₄ ont des structures cycliques stables. Dans les agrégats de HOBr·H₂O et de HOBr·(H₂O)₂ on peut attribuer les élongations de faible fréquence aux liaisons hydrogènes mais cette attribution ne peut être faite aussi clairement dans le cas des agrégats de HOBr·(H₂O)₃ de HOBr·(H₂O)₄ et des agrégats cycliques. On a également déterminé les énergies de liaison de ces agrégats de HOBr hydratés, en montrant que l'addition d'une molécule d'eau aux HOBr·H₂O et HOBr·(H₂O)₂ augmente approximativement l'énergie de liaison de 4 kcal mol⁻¹, tandis que l'addition d'une molécule d'eau au HOBr·(H₂O)₃ diminue cette valeur de 4 kcal mol⁻¹.

Mots clés : DFT, base numérique, HOBr·(H₂O)ₙ, agrégats.

Introduction

The water solvation process involving compounds associated with catalytic reactions related to the ozone depletion in the stratosphere (1–3) has been receiving great attention in the past few years. The importance of this process is justified by the higher water concentration in the Earth's atmosphere and the tendency of water to form hydrogen bonds, making possible the association between two or more water molecules (4–7) and between different water clusters and other species present in the atmosphere (8). Among these associations, we have been interested in the HOBr hydrated complexes once the bromine species are directly involved in reactions converting ozone to oxygen, and there is a discus-

sion about the origin of an unexpected higher bromine radical concentration observed on ice surfaces present on the stratospheric clouds and on the Artic snow pack (9). The questioned participation of the ice surfaces in the catalytic reactions and the hydrogen bonds involved in the hydrated clusters have been considered important for the understanding of the properties of weakly bound molecular complexes, for the determination of the hydrated cluster concentration on the troposphere and stratosphere, and for the prediction of catalytic reactions responsible for the chemical atmospheric changes.

In this context, we present theoretical results of equilibrium geometries and vibrational frequencies related to the structures generated by the association of HOBr and water

molecules. These results are compared with other halogen hydrate complexes involving interactions of HOCl with 1–4 water molecules (10–12) and of HOBr with only one water molecule (13).

Methods

DFT equilibrium geometries and vibrational frequencies were performed using PC SPARTAN PRO (Wavefunction Inc., Irvine, CA) and a nonlocal perturbative Becke–Perdew (14, 15) model with a potential comprising a local part and a gradient correction. In this perturbative model the gradient correction is introduced only after the convergence, based on the local potential, has been achieved and not at each self-consistent field interaction, which represent a time calculation reduction. The DN* and DN** numerical basis sets employed describe the inner shell of each atomic orbital by a single function and the valence shell by a pair of functions, together with a set of five d-type polarization functions. The difference between DN** and DN* is that the first includes p-type polarization functions for hydrogen atoms. The calculations were done on Pentium III, 233 MHz, with 10 GB of disk space and 128 MB RAM.

The pBP method, with numerical basis sets, was employed in our previous study involving the equilibrium geometries of $HBrO_x$ ($x = 1$–3) isomers (16) with good results.

The calculated pBP binding energy values are presented without basis set superposition error (BSSE) corrections. This procedure was based on the fact that DFT methods, using basis sets of quality, give low BSSE values.

Results

Three different associations between the HOBr and the H_2O molecules have been studied based on interactions involving the Br and the O of the water molecule, the O of the HOBr and one H of the water molecule, and the H of HOBr and the O of the water molecule. The results pointed to the structures obtained by the last interaction as the most stable configurations.

The atomic charge distribution was obtained from the electrostatic potential, giving qualitative information about the electronic density on the atoms of the hydrated complexes. For all clusters, this charge distribution has presented the bromine atom with a low positive charge and the hydrogen and the oxygen atoms with positive and negative density charges, respectively.

The details for each association of water molecules with HOBr are given below.

HOBr·H₂O

Two C_S structures, with the water molecule oriented in *syn* (dihedral angle of 0.0°) and in *anti* (dihedral angle of 180.0°) positions with respect to the bromine, were submitted to geometry optimization. The optimized *syn* and *anti* conformers have C_S and C_1 symmetry, respectively, and both present a nearly linear hydrogen bond. The HOBr·H₂O optimized structures are presented in Fig. 1, and the corresponding geometrical parameters are listed in Table 1, together with the Ying and Zhao B3LYP/6-311++G(d,p) results (13).

Fig. 1. HOBr·(H₂O) structures: (*a*) symmetric; (*b*) antisymmetric.
As the results obtained using DN* and DN** basis sets have not presented significant geometrical differences, each optimized geometry was submitted to an analytical second derivatives calculation using only the more polarized DN** basis set. The pBP/DN** vibrational frequencies obtained are listed in Table 2, together with the B3LYP/6-311++G(d,p) values (13).

HOBr·(H₂O)₂

The second water molecule was added to the *syn* and *anti* HOBr·H₂O optimized structures, with the hydrogen of the first water molecule interacting with the oxygen of the second water molecule, giving a *syn* and an *anti* HOBr·(H₂O)₂ conformation. These *syn* and *anti* references are also based on the orientation of the first water molecule with respect to the bromine. The *syn* and *anti* HOBr·(H₂O)₂ clusters, which were obtained by a previous conformer search process, were submitted to a geometry optimization, including vibrational frequency determination, and the optimized structures have presented nonlinear hydrogen bonds. These clusters are presented in Fig. 2, and their geometrical parameters can be found in Table 3.

The *anti* and *syn* pBP/DN** HOBr·(H₂O)₂ vibrational frequency values are listed in Table 4. As many vibrational modes have appeared conjugated, it was difficult to assign all of them.

The charge distribution on the HOBr·(H₂O)₂ clusters showed that the proximity between the H_5 and O_1 atoms on the *anti* conformer ($H_5 \cdots O_1 = 1.928$ Å) did not represent a charge transfer from O_1 to the H_5 atom.

HOBr·(H₂O)₃

The most stable structure of this cluster was found considering two initial possibilities. The first was the association of the second and third water molecules to the different hydrogen atoms of the water molecule in the HOBr·H₂O structures presented in Fig. 1. The second possibility was a consecutive association of the water molecules, as considered on water clusters where the free hydrogens are oriented above and below the ring.

In the first case, the optimized geometry conformers and the vibrational frequency results have suggested noncorrespondence to a minimum energy on all tested structures; this possibility was thus refused.

For the second case, the association of the third water molecule was based on *syn* and *anti* HOBr·(H₂O)₂ clusters. All the *anti* HOBr·(H₂O)₃ clusters obtained presented geometrical

and vibrational results with a noncorrespondence to a minimum energy. In this way, based only on the *syn* HOBr·(H$_2$O)$_2$ cluster, three HOBr·(H$_2$O)$_3$ structures were obtained. The less stable optimized structure corresponded to a noncyclic configuration with an energy value of −2879.7652 hartree (1 hartree = 4.359748 × 10^{-18} J). The other two cyclic structures were optimized and the more stable provided a minimum energy of −2879.7772 hartree, corresponding to a closed cyclic chain. This structure is presented in Fig. 3, and the geometrical parameters and vibrational frequencies are listed in Tables 5 and 6, respectively.

The atomic charge distribution shows H$_7$ with a charge lower than the charges of the other hydrogens involved in hydrogen bonding but higher than the atomic charges on the free hydrogens (H$_2$ and H$_6$). The H$_4$ atom, placed in the opposite way to the bromine atom, presents an atomic charge higher than the charges on the other free hydrogen atoms. The vibrational frequency values related to the BrO$_1$ and O$_1$H$_1$ stretch and H$_1$O$_2$H$_3$ bend do not present significant differences when compared with the previous HOBr·(H$_2$O)$_2$ structures, but the OH stretch frequencies related to the water molecules were observed in a characteristic region (above 2900 cm^{-1}), being all conjugated.

HOBr·(H$_2$O)$_4$

In the HOBr·(H$_2$O)$_4$ cluster, one stable cyclic structure has been found, with OH bonds placed above and below the ring made up of five oxygen atoms. This structure can be observed in Fig. 4, and the geometrical parameters are listed in Table 7.

The atomic charge distribution on the HOBr·(H$_2$O)$_4$ cluster was very close to the distribution observed for the HOBr·(H$_2$O)$_3$ cluster, which can be considered as a typical

charge distribution for structures with a ring formed by O—H and H···O bonds.

The vibrational frequencies are presented in Table 8, and we have attributed specific regions for vibrational modes related to the HOBr and HOH molecules. The small vibrational frequency values had been difficult to assign, but the 56.8 cm^{-1} wavenumber could be identified as a BrO$_1$H$_9$ bend.

HOH and (H$_2$O)$_n$ clusters

The optimized geometries of the HOH molecule and the water dimer, trimer, and tetramer were obtained using the pBP/DN** method. This is an initial step necessary to determine the binding energy of the HOBr·(H$_2$O)$_n$ clusters and their energetic stability order. The pBP/DN** vibrational frequencies were also calculated and have presented no imaginary values. The optimization process pointed to a C_S symmetry for the water dimer, with a hydrogen bond close to linearity. The water trimer and tetramer are comprised of cyclic structures, with free hydrogens placed out of the ring formed by the oxygen atoms. The HOH and (H$_2$O)$_n$ geometrical parameters are listed in Table 9.

The reliability of the pBP/DN** calculations for the description of the water–water hydrogen bond could be verified by the equilibrium geometry obtained for the water dimer. The results presented the (H$_2$O)$_2$ structure as possessing C_S symmetry with an OH···O angle of 175.5°, showing a nonlinearity of the hydrogen bonds. Our O···O distance between the water molecules was 2.859 Å; this is smaller than the experimental value of 2.976 Å but close to the MP2/aug-cc-pVTZ value of 2.898 Å and lower than the values of 3.032 Å and 3.084 Å obtained by Xantheas and Dunning (5), using HF and CASSCF methods with aug-cc-pVDZ basis sets. Based on these values, the pBP/DN** method could

be considered a method reliable for the reproduction of hydrogen bonds in small clusters.

Binding energies

The binding energies could be calculated using the pBP/DN** energy values of −2650.3070 hartree — with zero-point vibrational energy correction included — obtained for the isolated HOBr molecule in our previous study (16) and the pBP/DN** energy values of the HOH molecule and the water clusters calculated in this study. The energies of the water monomer, water clusters, HOBr·(H$_2$O)$_n$ clusters (n = 1–4), and the binding energies are presented in Table 10, all including the zero-point vibrational energy correction.

Considering the pBP/DN** energy values for the *syn* and *anti* HOBr·H$_2$O conformers of −2726.7640 hartree and −2726.7631 hartree and including the zero-point vibrational

energy corrections, the *syn* and *anti* binding energy values were 0.0069 hartree (4.3 kcal mol^{-1}) and 0.0056 hartree (3.5 kcal mol^{-1}), respectively. The binding energy values obtained by Ying and Zhao (13) for the *syn* and *anti* conformers were higher than ours, being 5.6 kcal mol^{-1} and 5.5 kcal mol^{-1}, respectively, for B3LYP/6-311++G(*d,p*) calculations. The difference of 0.8 kcal mol^{-1} observed between the *syn* and *anti* binding energy values, which was higher than the difference of 0.1 kcal mol^{-1} observed by Ying and Zhao (13), are probably an effect of the C_s and C_1 symmetries obtained for the *syn* and *anti* pBP/DN** conformers, respectively. Dibble and Francisco (10), using the MP2/6-311++G(*d,p*) method, calculated the binding energy difference between the *syn* and *anti* HOCl·H$_2$O conformers (both with C_S symmetry) to be 0.1 kcal mol^{-1}.

Each water molecule addition in a cluster increases the binding energies by approximately 4 kcal mol^{-1}, except

when the HOBr·$(H_2O)_4$ cluster is generated. This cluster presents almost the same stability as the HOBr·$(H_2O)_2$ cluster; the HOBr·$(H_2O)_3$ is the more energetically favorable cluster among the studied clusters. This change in the binding energy tendency can be attributed to a contribution of the nuclear repulsion energy, which was greater for HOBr·$(H_2O)_4$ than in the other HOBr species. Ortiz-Repiso et al. (12) have studied the HOCl·$(H_2O)_n$ clusters ($n = 1–4$) and found an increase in the binding energy when each water molecule is added to the previous species; HOCl·$(H_2O)_4$ is thus the more energetically favorable cluster. This different behavior can be attributed to the different size of the bromine and chlorine atoms, which affects the repulsion energies.

Discussion

HOBr·H_2O

The pBP/DN** energy values pointed to the *syn* structure as slightly more stable than the *anti* stucture, as obtained by Ying and Zhao (13). Our *syn* conformer was 0.5 kcal mol^{-1} more stable than the *anti* conformer, while the difference observed by Ying and Zhao (13), using the B3LYP/6-311++G(*d*,*p*) method, was only 0.2 kcal mol^{-1}. Generally, the *syn* and *anti* conformers did not present significant bond lengths changes; the *syn* bond length values were slightly longer than the *anti*. The BrO_1H_1, $O_1H_1\cdots O_2$, and $H_2O_2H_3$ angles presented differences of 1.3, 2.0, and 0.5° between the *syn* and *anti* conformers, respectively.

The comparison between the pBP/DN** and B3LYP/6-311++G(*d*,*p*) (13) results showed that the pBP bond lengths were 1% longer, with the exception of $H_1\cdots O_2$, which was approximately 3% shorter. The *syn* pBP/DN** $O_1H_1\cdots O_2$ angle was 4.5° lower than that obtained by the B3LYP/6-311++G(*d*,*p*) method, while the *anti* one was practically coincident. The *syn* and *anti* pBP/DN** BrO_1H_1 angles were, respectively, 2.2° and 1.5° lower than the corresponding B3LYP/6-311++G(*d*,*p*) values, while the *syn* and *anti* pBP/DN** $H_2O_2H_3$ angles did not present significant changes.

The comparison with the corresponding chlorine hydrated complex showed that our *syn* and *anti* $H_1 \cdots O_2$ hydrogen bonds were shorter than the equivalent bonds obtained by Dibble and Francisco (10) and Ortiz-Repiso et al. (12) for the $HOCl \cdot H_2O$ complex (using the MP2/6-311++G(d,p) method), which were, respectively, 1.809 Å and 1.811 Å for the *syn* structure and 1.807 Å and 1.806 Å for the *anti* structure. This would suggest that the hydrogen bond between HOBr and H_2O is stronger than HOCl and H_2O, but, as we are comparing values calculated by different methods, we cannot be sure about this conclusion.

The comparison between the hydrated complexes and the HOBr and H_2O monomers showed that the addition of a water molecule to HOBr decreased the BrO_1 bond length by 0.5% and increased the O_1H_1 bond length by 2%, while the $O_2H_{2,3}$ bond lengths remained the same. Changes in angles were all less than 0.7°. The orientation of the hydrogens of the water molecule related to the bromine on the *syn* conformer has closed the BrO_1H_1 angle.

The vibrational frequency values listed in Table 2 for the *syn* and *anti* conformers showed that, in general, our results did not present any significant discrepancy when compared with the B3LYP/6-311++G(d,p) results (13).

For the *syn* and *anti* conformers, the comparison between pBP/DN** and B3LYP/6-311++G(d,p) vibrational frequencies showed that the pBP/DN** O_1H_1 stretches were 10% and 9% lower than the B3LYP/6-311++G(d,p) values, respectively, while the H_1O_2 stretches were 10% and 8% higher. For the *syn* conformer, our pBP/DN** HOBr and HOH bends were 3% higher than the values obtained by Ying and Zhao (13). For the *anti* conformer, the symmetric and asymmetric pBP/DN** vibrational modes related to the water molecule showed lower frequencies than the values obtained by the B3LYP/6-311++G(d,p) method.

The $HOBr \cdot H_2O$ stretch and bend vibrational modes, when compared with the correspondent HOBr values, showed that the *syn* and *anti* structures gave BrO_1 stretch values that increased by 1.2% and 1.6%, respectively. Both conformers presented HOBr bend frequencies higher than the isolated species; the values for the *syn* and *anti* structures were 14% and 12% higher, respectively. The O_1H_1 stretches were 11% lower than the values observed for the HOBr molecule, suggesting that the hydrogen bond with the water molecule weakens this bond. The $HOBr \cdot H_2O$ modes, when compared with the corresponding values on the H_2O-isolated molecule, showed that the HOH bend and the symmetric $O_2H_{2,3}$ stretch were 6% and 3% higher for the *syn* conformer and only 0.2% and 0.7% lower for the *anti* conformer, respectively. As the *syn* conformer is the most stable, it shows that the *syn* $HOBr \cdot H_2O$ formation disturbs the water molecule more than in the case of the *anti* conformer, as expected.

Table 2 shows that the *syn* and *anti* $HOBr \cdot H_2O$ conformers present the *syn* $H_2O_2H_3$ bend value 6% higher than the *anti*. For the $O_2H_{2,3}$ symmetric stretch, the *syn* conformer value was 3% higher than the value for the *anti* conformer. These differences were not observed in the B3LYP/6-311++G(d,p) results, probably because of the same C_S symmetry found on *syn* and *anti* structures.

The electrostatic potential surface and the calculated pBP/DN** atomic charge distribution pointed to a difference between the H_2 and H_3 atoms in the *anti* conformer as a nat-

ural consequence of the C_1 symmetry obtained for this conformer. The electrostatic potential surface showed a high electronic density located on the atoms of the HOBr molecule, suggesting an electronic-density transfer from the H_2O molecule to the HOBr molecule when the hydrated complex is formed.

HOBr·(H₂O)₂

As compared with the $HOCl \cdot (H_2O)_2$ cluster (12) that presented only one structure with the chlorine atom placed off the planar ring made up of three oxygen, our calculations pointed to two stable structures with a small energy difference for the $HOBr \cdot (H_2O)_2$ cluster. The geometrical parameters listed in Table 3 make some interesting comparisons possible.

For the *anti* conformer, the O_1—H_1 bond length was augmented by 4% and 2%, respectively, when compared with the isolated HOBr and with the $HOBr \cdot H_2O$, while the Br—O_1 length was still practically the same. The H_1O_1Br angle was 2° and 1.5° higher than the values obtained for the isolated HOBr molecule and for the $HOBr \cdot H_2O$ complex, respectively, showing that this angle increases as more water molecules are added. The O_2—H_3 bond length was longer than the other free O_2—H_2, O_3—H_4, and O_3—H_5 bond lengths as a consequence of the interaction of the H_3 atom with the oxygen of the second water molecule. The *anti* O_3—H_5 bond length was larger than the other free O—H bonds and than the *syn* O_3—H_5 bond (see, in Fig. 2, the proximity between the H_5 and O_1 atoms). The $H_2O_2H_3$ angle was slightly higher than that obtained for isolated HOH and for $HOBr \cdot H_2O$, while the $H_4O_3H_5$ angle was very close to the $H_2O_2H_3$ terminal angle in HOBr with one water molecule. The introduction of the second water molecule closed the $H_1 \cdots O_2H_3$ angle by 19%, approximately, showing a first tendency for a cyclic structure formation.

With respect to the *syn* structure, the Br—O_1 bond length was 0.8% and 0.5% lower than the values obtained for the isolated HOBr molecule and for HOBr with one water molecule, respectively, while the O_1—H_1 bond length was increased by 4% and 2%, respectively, as occurred on the *anti* structure. The H_1O_1Br angle was increased 1° and 1.7° when compared with the isolated HOBr molecule and the $HOBr \cdot H_2O$ molecule, respectively. The O_2—H_2, O_2—H_3, O_3—H_4, and O_3—H_5 bond lengths were practically the same as the *anti* conformer.

The *syn* and *anti* $H_1 \cdots O_2$ hydrogen bonds between the HOBr and the first water molecule have shown values shorter than those found for the monohydrated HOBr complex. The $H_3 \cdots O_3$ hydrogen bond between the first and second water molecule presented a value close to the $H_1 \cdots O_2$ value observed in the $HOBr \cdot H_2O$ complex, being smaller than the experimental hydrogen bond (2.03 Å) determinated by Dyke et al. (4) for the water dimer. For the stable $HOCl \cdot (H_2O)_2$ cluster, Ortiz-Repiso et al. (12), using the MP2/6-311++G(d,p) method, calculated the corresponding $H_1 \cdots O_2$ hydrogen bond as 1.933 Å and the $H_3 \cdots O_3$ hydrogen bond as 1.765 Å, just the opposite of our results, with the first hydrogen bond being longer than the second. The $H_3 \cdots O_3$ hydrogen bond values were shorter than the calculated $H \cdots O$ distance obtained for the water dimer: our pBP/DN** $H \cdots O$ distance was 1.874 Å, while the MP2 cal-

culations made by Xantheas and Dunning (5) and Ortiz-Repiso et al. (12) pointed to this distance as 1.95 Å, using aug-cc-pVDZ and 6-311++G(d,p) basis sets. Our *syn* and *anti* $O_2 \cdots O_3$ distances of 2.74 Å and 2.79 Å were, respectively, close to the experimental value of 2.976 Å obtained for the water dimer (5).

The geometrical differences mentioned above for both conformers have shown bond length- and angle-specific behaviors when the atoms are placed in terminal position or in the middle of the molecule chain.

The vibrational frequencies presented in Table 4 show that the BrO_1 and O_1H_1 stretch values are very close for the *anti* and *syn* structures, but 2% higher and 20% lower, respectively, than the values obtained for the isolated HOBr molecule. The comparison of the *anti* and *syn* H_1O_1Br bending values with the corresponding values for the isolated HOBr molecule showed an increase of 15% and 20%, respectively. These differences are in concordance with the geometrical HOBr changes observed when the HOBr is associated with the water molecule. Comparing with the isolated water molecule, the O_2H_3 and O_3H_5 stretch values were close to the symmetric modes, while the O_2H_2 and O_3H_4 stretch values were close to the asymmetric modes, in both *syn* and *anti* conformers. The $O \cdots H$ bond between different water molecules could be verified by the presence of H_1O_2 and H_3O_3 stretch frequencies with low values, being very far from the O–H stretch characteristic region in pure water.

HOBr·$(H_2O)_3$ and HOBr·$(H_2O)_4$

For the HOBr·$(H_2O)_3$ and HOBr·$(H_2O)_4$ clusters, only O—H bonds are located in the ring, contrasting with the Ortiz-Repiso et al. (12) results that have also presented stable structures with O—Cl bonds in the ring. This difference can be attributed to the different sizes between the bromine and the chlorine atoms.

The calculated OH···O angles show that the HOBr·$(H_2O)_3$ cluster is less planar than the HOBr·$(H_2O)_4$ cluster, although the ring that has four water molecules is more distorted than the ring with three water molecules. with three water molecules. The O_4—H_7 and the O_5—H_9 bond lengths are shorter than the other O—H distances on the water cluster, indicating a lower interaction between the H_7 and H_9 atoms and the O_1 atom on the respective clusters.

In the HOBr·$(H_2O)_3$ cluster, the O···H hydrogen bonds were approximately 1.6 Å. This value is shorter than the pBP and MP2 (5, 12) hydrogen bond values of 1.79 Å and 1.9 Å obtained, respectively, for the water trimer. The hydrogen bond of 1.653 Å calculated by Ortiz-Repiso et al. (12) for the HOCl·$(H_2O)_3$ cluster was longer than our $H_1 \cdots O_2$ value of 1.560 Å obtained for the HOBr·$(H_2O)_3$ cluster, which is probably a consequence of the planarity obtained for the cyclic HOCl·$(H_2O)_3$ cluster.

In the HOBr·$(H_2O)_4$ cluster, the O···H hydrogen bonds were practically the same as the corresponding values obtained for the HOBr·$(H_2O)_3$ cluster, with the $H_9 \cdots O_1$ slightly shorter than the $H_7 \cdots O_1$. These $H_9 \cdots O_1$ and $H_7 \cdots O_1$ distances of 1.720 Å and 1.765 Å, respectively, which were longer than the other H···O distances, can justify the atomic charges calculated for the H_9 and H_7 atoms, which were lower than the other hydrogen charges verified on the hydrogen bonds.

The HOBr·$(H_2O)_3$ and HOBr·$(H_2O)_4$ vibrational frequencies did not present significant value differences, making possible the identification of specific ranges for the BrO and OH stretch and BrOH bend frequencies corresponding to the HOBr molecule and the OH stretch regions characteristic to the water molecules. For these clusters we could not identify one specific stretch frequency related to the OH hydrogen bond, as observed on the other small clusters.

Conclusion

In considering several different interactions between HOBr and H_2O molecules, the calculations using the pBP method and DN** basis set showed that the interaction involving the H of the HOBr and the O of the water molecule represents the preferred arrangement for the HOBr·$(H_2O)_n$ clusters (n = 1–4). These pBP/DN** calculations have predicted the existence of the *syn* and *anti* stable conformers for the HOBr·(H_2O) and HOBr·$(H_2O)_2$ clusters. Related to the HOBr·(H_2O) complex, our energy values pointed to the *syn* structure as being slightly more stable than the *anti* one, as obtained by Ying and Zhao (13). The pBP/DN** results have also predicted the formation of two cyclic stable structures corresponding to the HOBr·$(H_2O)_3$ and HOBr·$(H_2O)_4$ clusters. A non-linear hydrogen bond was first observed in the HOBr·$(H_2O)_2$ cluster, showing a tendency to cyclic arrangement, which was satisfied in the cluster with three and four water molecules.

In the HOBr·$(H_2O)_n$ clusters, all free O—H bonds have presented with practically the same bond values that they had in the water molecule, while the other hydrogen bonds that have contributed to the formation and stability of these clusters have presented with their length increased. The H···O distances calculated for the different clusters were shorter than the calculated H···O distances obtained for the water dimer, trimer, and tetramer.

The addition of a water molecule to the HOBr·H_2O and HOBr·$(H_2O)_2$ clusters increases the binding energy by approximately 4 kcal mol^{-1}, while the addition of a water molecule to the HOBr·$(H_2O)_3$ cluster decreases this value by 4 kcal mol^{-1}, the HOBr·$(H_2O)_3$ cluster being the more energetically favorable among the studied clusters.

Looking for the vibrational frequencies, we could observe that the O–H stretches corresponding to the hydrogen bond in the HOBr·(H_2O) and HOBr·$(H_2O)_2$ conformers were in a low frequency region, being very far from the usual O—H bond. The cyclic HOBr·$(H_2O)_3$ and HOBr·$(H_2O)_4$ clusters presented conjugated O–H stretch vibrations that did not permit a specific O–H stretch assignment corresponding to a hydrogen bond. In general, the vibrational frequencies calculated for the HOBr·$(H_2O)_n$ clusters have reflected the geometrical HOBr and HOH changes observed when the hydrated HOBr clusters and the water clusters are generated.

Finally, as a general behavior, we notice that the calculated dipole values decreased with the increasing number of water molecules associated with the HOBr compound, with the higher difference occurring between the HOBr·H_2O and the HOBr·$(H_2O)_2$ clusters.

Determination of phenyl-*N*-methylcarbamates and their hydrolysis products in water, using solid-phase extraction and reversed-phase liquid chromatography with UV and electrospray mass spectrometric detection[1]

Latifa Latrous El Atrache and Sadok Sabbah

Abstract: In this study, eight phenyl-*N*-methylcarbamates (PNMCs) were considered. Reversed-phase LC was set up for UV and mass spectrometry (MS) detection mode. Gradient elution was used, and the mobile phase was composed of acetonitrile and water. UV–vis was performed at 220 nm. The method was tested with different reversed-phase columns. Comparison between chromatographic parameters: retention time (t_R), resolution (R_S), and selectivity (α) was established. Hydrolysis kinetics of three of the PNMCs were reported. The major hydrolysis products were determined by LC–UV, and the effect of pH on hydrolysis was also studied. Also, chromatographic separation of a mixture of PNMCs and four of their hydrolysis products was carried out. The preconcentration of 12 studied solutes was realized by solid-phase extraction. C18 extraction cartridges of 1 g were used to extract solutes from a 100 mL volume of tap and surface water spiked at 10 µg/L. The recoveries were, respectively, between 68–86% and 62–83% with relative a standard deviation of less than 11%. Limits of detection (LODs) and limits of quantitation (LOQs) ranged, respectively, from 1–4 µg/L and from 4–10 µg/L. Since standard UV detection does not provide adequate selectivity for water samples, an electrospray (ES)-MS instrument equipped with a triple quadrupole mass filter was used. MS data acquisition was performed by a time-scheduled, selected-ion monitoring (SIM) program. Limits of quantitation gave values between 0.1–0.5 µg/L.

Key words: phenyl-*N*-methylcarbamates, water analysis, solid-phase extraction, LC–UV–vis, LC–ES-MS.

Résumé : Cette étude concerne le développement d'une méthode d'analyse permettant la détermination à l'état de traces de 8 phényl-*N*-méthylcarbamates (PNMCS) dans les eaux potables et les eaux de surface. Les conditions d'analyse ont été déterminées par chromatographie liquide à polarité de phases inversée, en terme de séparation : choix de la colonne et optimisation de la phase mobile et de détection : spectrométrie d'absorption UV et spectrométrie de masse. Avec un gradient de phase mobile eau–acetonitrile et une colonne octadécyle type XTerra on obtient une séparation convenable. En ce qui concerne la détection le choix de la longueur d'onde λ = 220 nm est un compromis acceptable pour lequel on obtient des réponses voisines pour l'ensemble des composés examinés. L'étude cinétique de trois PNMCs est reportée. La mise en évidence des produits d'hydrolyse est effectuée par LC–UV et les constantes de vitesses sont déterminées en fonction du pH. Par ailleurs, nous avons déterminé les conditions de séparation chromatographique des 8 PNMCs associés à 4 de leurs produits d'hydrolyse. L'étude de l'efficacité de concentration des 12 solutés examinés est réalisée par extraction liquide solide au moyen de silice greffée alkyle. Les préconcentrations ont été menées sur des cartouches de masse 1 g remplies de silice greffée octadécyle sur lesquelles sont percolés 100 mL d'échantillon d'eau de robinet et de surface dopés à 10 µg/L les taux de récupération varient respectivement entre 68–86 % et 62–83 % avec une déviation standard relative inférieure à 11 %. Les limites de détection et de quantification varient respectivement entre 1–4 µg/L et 4–10 µg/L; afin d'améliorer la sensibilité les 12 composés ont été analysés par couplage LC–MS assistée par ionization electrospray en mode positif. En appliquant la méthode de scrutation d'ion spécifique (SIM), nous obtenons des limites de quantification comprises entre 0,1 et 0,5 µg/L.

Introduction

Phenyl-*N*-methylcarbamate (PNMCs) insecticides are aryl esters of phenyl-*N*-methyl-substituted carbamic acids (1). As shown in Fig. 1, the substituents on the phenyl ring can change the characteristic nature of the parent compound in hydrophobic, electronic, and hydrogen bonding and can thus affect the ability of complexation with acetylcholinesterase, a determining factor for its cholinesterase inhibition activity (2).

PNMCs constitute a class of pesticides of growing importance, widely used as substitutes for organochlorine pesticides because of their greater biodegradation ability.

Most PNMCs are degraded into their metabolites shortly after application. In alkaline media PNMCs can be easily hydrolyzed to form methylamine and substituted phenols. For example, carbofuranphenol was the major product from carbofuran in water, whereas 3-hydroxy and 3-keto derivatives were identified as the corresponding degradation products in soil (3). Some papers have dealt with the half-life of carbamates in an aquatic environment with a range of between 4 and 12 weeks (4).

Because of the proven or suspected toxicity of many of these pesticides, it is necessary to monitor them from both a regulatory and a consumer point of view; for example, 0.1–0.5 µg/L of carbofuran was found in ground water from Almeria (Spain) (5).

A large number of analytical methods have been published regarding methods of determination of carbamates, such as supercritical fluid chromatography (SFC) with capillary (6–7) and packed columns (8), thin layer chromatography (TLC) (9), and capillary electrophoresis (10–11), but most analytical methods until now apply to gas chromatography (GC) (12–13) and high pressure liquid chromatography (HPLC) (14–15). In general, carbamates and their transformation products are often quoted as being polar and thermally labile; these properties limit the use of GC, which exhibits derivatization prior to analysis. So LC is an obvious choice for the simultaneous determination of PNMCs.

As regards detection, UV detection is the most widely applied in LC analysis (16).

Fluorescence detection also has good sensitivity, achieved by post-column derivatization; the functional group of the carbamates, with subsequent conversion of methylamine formed with *o*-phthaldehyde (OPA), yields a highly fluorescent isoinolide (17); however, it needs many intermediate steps.

MS detection is very attractive because it offers the possibility of achieving high sensitivity with a high degree of selectivity (18). Several reviews and articles on the different types of interfaces used, including transport systems, direct liquid introduction, thermospray, atmospheric pressure ionization, electrospray, and particle beam, have been published (19–23). During the last few years, atmospheric pressure ionization (API) techniques, high-flow pneumatically assisted electrospray ionization (ESI), and atmospheric pressure chemical ionization (APCI) have become the most popular interface techniques. The main limitation of APCI is that pesticides can undergo thermal degradation (24–26) in comparison with ESI where the sample is ionized directly in the liquid phase at quasi-ambient temperature, thus leaving intact fragile pesticides (27–28).

When carbamate pesticides were correctly applied, their residues could be found in the soil itself and in run-offs from

Fig. 1. Phenyl-*N*-methylcarbamate.

example: carbaryl, R =
the soil, as well as in food, crops, and water. The importance of the presence of the target carbamates and their degradation products in water also must be considered. Degradation leads to compounds more toxic than the parent pesticides; therefore it is of vital importance to be able to determine these pesticides in aquatic media.

The most common preconcentration technique is solid-phase extraction (SPE). The use of SPE and LC techniques to analyze carbamate pesticides and their derivative products in water — focusing on off-line and on-line SPE with different kinds of sorbents — was reviewed (29).

Analytical methods for the determination of a mixture of oxime carbamates and PNMCs are relatively well established in water matrices (30), but simultaneous determination only of PNMC residues and the study of some of their degradation products in water with hydrolysis are not considerably extended.

The purpose of this study was, firstly, to optimize the separation of PNMCs in terms of selectivity, efficiency, and time analysis (for that, various columns were tested using the HPLC–UV–vis method) and, secondly, to determine the kinetics of the hydrolysis of carbaryl, carbofuran, and landrin. The identification of the major hydrolysis products was realized by LC. The rate constants were measured in various buffer solutions ranging from pH 8 to 12.

Therefore, we developed a method for analyzing, simultaneously, PNMCs and their hydrolytic degradation products in water samples. This method is based on combining SPE of water samples with HPLC–UV. The optimization of different parameters affecting the chromatographic separation and the SPE procedures was carried out.

To increase sensitivity and to obtain low detection limits, the LC–ES-MS method was used.

Experimental

Chemicals and materials

PNMCs (aminocarb, baygon, carbofuran, carbaryl, methiocarb, baycarb, landrin, and zectran) and degradation products (2,2-dimethyl-2-dihydrobenzofuran-7-ol, α-naphtol, 2-isopropoxyphenol, 2,3,5-trimethylphenol) were obtained from Supelco.

Fig. 2. Structures and common names of compound used.

Carbaryl   Carbofuran   Baygon

Aminocarb   Landrin   Methiocarb

Zectran   Baycarb   2,3,5-Trimethylphenol

1 Naphtol   Benzofuranol   2 Isopropoxyphenol
The chemical structures of all studied compounds are shown in Fig. 2.

Standard stock solutions were prepared in methanol, which contained each compound at concentrations of 1000 μg/mL, and were stored in glass bottle at 4°C. Standard working solutions of various concentrations were prepared daily by appropriate dilution of aliquots of the stock in the methanol.

The methanol and acetonitrile used are HPLC grade from LAB SCAN (Ireland). HPLC grade water was obtained by purification of demineralized water in a Milli-Q system (Millipore, Elix). Mobile phases were degassed with helium before use.

Silica-based sorbents with octadecyl functional group bond Elut Jr. C18 were acquired from Varian.

Chromatographic conditions

LC–UV analysis

The system consists of a gradient Model 127 LC pump from Beckman, a rehodyne six-port injection valve (Model 7125) with a 20 μL loop. A Model 166 wavelength UV–vis detector from Beckman. Recording of chromatograms and quantitative measurements of peak areas were performed with an HP 3395.

The mobile phases were set at a flow rate of 1 mL/min. Measurement wavelength was 220 nm; in fact, the most common wavelengths are of 210 and 220 nm (31). The solvent employed for the mobile phase was acetonitrile and water, using two gradients. The gradient (*a*) was 30% acetonitrile isocratic, which was increased linearly to 100% over 20 min and held at 100% for 5 min. A return to the initial conditions was carried out over 10 min. The gradient (*b*) was 20% acetonitrile, which was increased to 100% over 40 min and held at 100% for 10 min. The return to the initial conditions was carried out in 10 min. The separation was performed using the following different analytical columns:

(*i*) LC8, 150 × 4.6 mm i.d., 5 μm particulate size

(*ii*) Waters SYMMETRY C18, 150 × 3.9 mm i.d., 5 μm particulate size

(*iii*) XTerra, 250 × 4.6 mm i.d., 5 μm particulate size

Table 1. Retention time of PNMCs obtained for different LC columns.

Peak No.	PNMCs	C8 Supelcosil	C18 Symmetry	XTerra[b]	XTerra[b]
			Retention time (min) RSD[a] (%)		
1	Aminocarb	7.59 (0.04)	10.47 (0.23)	11.96 (0.10)	13.99 (0.41)
2	Baygon	7.84 (0.04)	1078 (0.47)	12.51 (0.23)	14.82 (0.46)
3	Carbofuran	7.84 (0.04)	11.09 (0.47)	12.83 (0.48)	15.18 (0.91)
4	Carbaryl	8.60 (0.10)	12.05 (0.35)	14.32 (0.60)	17.48 (0.35)
5	Landrin	9.47 (0.08)	13.24 (0.41)	14.95 (0.59)	18.40 (0.48)

LC–MS analysis

The system LC–ES-MS consists of PE Sciex API 2000 with an analyst station for recording chromatograms. A gradient model 200 pump from PerkinElmer and a rehodyne injection valve (model 7125) with a 20 µL loop was used. Separation was performed on a 100 × 3 mm i.d. SYMMETRY column packed with C18 bonded silica phase.

The gradient selected for LC–ES-MS, at the flow rate of 0.25 mL/min, was 50% methanol, which was increased linearly to 75% over 5 min. A return to the initial conditions was carried out in 5 min. The MS was operated in the positive-ion mode by application of a voltage of 5000 V to the capillary. The source temperature was maintained at 325°C. Ions were generated using highly pure nitrogen as the drying gas at a flow rate of 10 L/min and nebulizing gas at a pressure of 40 psig.

Full scan LC–MS chromatograms were obtained by scanning for m/z 50 to 500. LC–MS chromatograms were obtained by operating, in the time scheduled, one selected ion monitoring (SIM) acquisition mode.

Sample preparations

Solid-phase extraction was used to preconcentrate selected compound from water. Each sample (100 mL) was extracted onto SPE cartridges packed with 1 g of C18 bonded silica. The solid phase was first conditioned with 6 mL of methanol, then with 7 mL of deionized water. Following sample extraction, the solutes were eluted with 5 mL of methanol. The eluent was collected in a graduated tube and concentrated, under a stream of nitrogen with Kuderna-Danish, to 1 mL.

Results and discussion

Optimization of HPLC–UV parameters

Various workers (17, 32–34) have shown that a multipesticide mixture of nine to 12 oxime carbamates and PNMCs can be separated using a binary gradient of water with methanol or acetonitrile.

Thus, for the separation of eight PNMCs, we have used an acetonitrile–water gradient.

In this present work, three columns were tested at 220 nm. Comparison between the columns was made at the same

Table 2. Resolution and selectivity of eight PNMCs using Xterra column and acetonitrile–water gradient.

PNMCs	Elution program (a) R_s	(a) α	(b) R_s	(b) α
Aminocarb–baygon	1.35	1.05	1.05	1.05
Baygon–carbofuran	0.75	1.03	1.25	1.04
Carbofuran–carbaryl	3.75	1.13	5.50	1.16
Carbaryl–landrin	1.50	1.05	2.50	1.06
Landrin–baycarb	2.75	1.08	6.00	1.014
Baycarb–methiocarb	1.00	1.03	1.75	1.04
Methiocarb–zectran	1.00	1.03	1.75	1.03

chromatographic conditions (solvent programme *a*). The relative retention times and retention factors of all analytes are presented in Table 1.

Two pairs of PNMCs remain unresolved on LC8; on the SYMMETRY C18 we picked up one co-elution as (methiocarb and zectran). But on the XTerra column we obtained good separation and peak resolution with an analysis time shorter than 20 min. So, the XTerra column was the best column for the separation of PNMCs. In Fig. 3, a chromatogram of a standard mixture of PNMCs is shown.

To study the effect of the mobile phase composition on separation, a gradient elution programme (*b*) was tested. According to the chromatogram obtained (in Fig. 4) and the results presented in Table 2, the best separation parameters were given with the latter programme.

Operating conditions of analyses by LC–UV–vis were determined, and our objective in what follows is to separate a mixture of the eight mentioned PNMCs and four of their hydrolytic degradation products, so a kinetic study of three PNMCs such as carbaryl, carbofuran, and landrin was given.

Hydrolysis kinetics of PNMCs

Product analysis of the hydrolysis reaction

An aliquot of each PNMC hydrolysis reaction in a buffer solution (carbamates 20 µg/L) at pH 8.8 was analyzed using high-pressure liquid chromatography, with a reversed phase, in an acetonitrile–water mixture.

Fig. 3. HPLC of a standard solution containing 1 mg/L of carbaryl, 20 mg/L of baycarb, 10 mg/L of aminocarb, baygon, landrin, methiocarb, and zectran, using XTerra in LC-grade water (*a*) registered at λ = 220 nm. Peak numbers correspond to those in Table 1.
The hydrolysis products were identified by comparing their retention times to standard solution ones.

Effect of pH

Carbaryl, landrin, and carbofuran hydrolysis exhibited pseudo-first-order kinetics in aqueous media, and the rate constants were measured in various buffer solutions, varying from pH 8 to 12. The ultraviolet spectra plotted as a function of time show two isosbestic points, indicating no accumulation of intermediates. Table 3 gives the half-life times of carbaryl, carbofuran, and landrin at different pH values. pH has an important effect on the hydrolysis rate of such PNMCs. Shorter hydrolysis half-lives were obtained for higher pH values. At pH 12, half-lives of carbaryl, carbofuran, and landrin were, respectively, 0.18, 0.83, and 866.30 min. Furthermore, it can be pointed out that the order of degradation is carbaryl, carbofuran, and landrin.

We have also determined the half-lives of such PNMCs round about pH 7. It was noted that carbofuran and landrin were practically stable, and the carbaryl half-life time was 15 days.

Table 3. Effect of pH on Hydrolysis.

| | Half-life (min) | | | | | |
| | pH | | | | | |
PNMCs	8.8	9.5	9.8	10.3	11	12
Carbaryl	277.20	700.00	22.30	9.30	1.51	0.18
Carbofuran	1386.00	301.30	—	27.39	8.15	0.83
Landrin	—	—	—	—	—	866.30[a]

[a]pH = 12.2.

Because of the hydrolytic degradation of the studied PNMCs, we were induced to study a mixture of 12 compounds, including PNMCs and their hydrolysis products.

Separation of PNMCs and their hydrolysis products

According to the kinetic study given above, we must consider the presence of PNMCs as well as their hydrolysis products. A mixture of 12 compounds, including α-naphtol, 2,3,5-trimethylphenol, 2-isopropoxyphenol, and benzofuranol, was examined.

Fig. 4. HPLC separation of PNMCs in LC-grade water (*b*). Experimental conditions as in Fig. 3. Peak numbers correspond to those in Table 1.
Table 4. Retention time of eight carbamates and four degradation products using an XTerra column and acetonitrile water gradient.

Peak No.	Carbamates and (or) degradation products	Retention time (RSD%)[a]
1	Aminocarb	13.83 (0.10)
2	Baygon	14.92 (0.15)
3	Carbofuran	15.29 (0.24)
4	Benzofuranol	15.81 (0.24)
5	2-Isopropoxyphenol	17.19 (0.47)
6	Carbaryl	17.61 (0.48)
7	Landrin	18.51 (0.49)
8	2,3,5-Trimethylphenol	20.43 (0.91)
9	α-Naphtol	20.43 (0.91)
10	Baycarb	20.86 (0.28)
11	Methiocarb	21.55 (0.72)
12	Zectran	22.06 (0.62)

[a]Five replicate.

In Fig. 5, the chromatogram of a standard mixture of 12 solutes is shown; the separation is less than 25 min. Despite the short analysis time, one pair of studied compounds remains unresolved (α-naphtol, 2,3,5-trimethylphenol). The retention times and relative standard deviation of all analytes are presented in Table 4. Detection limits calculated for a signal-to-noise ratio of 3:1 are, on average, 1–4 µg/L.

Solid-phase extraction

Liquid-chromatographic determination of PNMCs and their hydrolytic products was examined, and our aim in what follows was to present a method for preconcentrating the mixture of 12 solutes. SPE is presently the most extended method for preconcentrating solutes. Two SPE procedures are used, such as off-line and on-line.

In the present work, we investigated off-line SPE because of its operational flexibility and simplicity. It has been used for the preconcentration of carbaryl (35), carbofuran (36), and their respective metabolites. In addition, this procedure offers the opportunity to apply on-site field sampling and conservation of the analytes on the solid-phase material; this helps in stabilizing the labile carbamates. In fact, complete recovery for desethylatrazine and fenamiphos was observed in precolumns kept at –20°C for 1 month when preconcentrating 2 mL of ground water spiked at 10 µg/L. Degradation of fenamiphos and fenitrothion occurred in precolumns stored at 4°C and at room temperature after 1 month (37). Furthermore, the stability of carbaryl and carbofuran stored on C18 cartridges at three different temperatures

Fig. 5. LC–UV chromatogram of a standard mixture containing 1 mg/L of carbaryl, 20 mg/L of baycarb, 10 mg/L of aminocarb, baygon, landrin, methiocarb, zectran, 2,3,5-trimethylphenol, α-naphtol, 2-isopropoxyphenol, and benzofuranol in LC-grade water (*b*) registered at 220 nm. Peak numbers correspond to those in Table 4.

[a]Three replicate.

(–10, 4, and 20°C) during periods of 1 week to 1 month was examined. At 4°C and after 1 month recoveries were 67.33 and 72.24%, respectively, for carbaryl and carbofuran.

To determine the optimum conditions of the extraction process, several variables were optimized. The first parameter studied was the extraction solvent for the elution of the compounds retained in the C18 cartridges. A 100 mL volume of Milli-Q water spiked with standard pesticides at a level of 2 μg/mL was passed through the cartridges. The cartridges were eluted with different volumes of acetonitrile or methanol. The best recovery was obtained with the second solvent for a volume of 5 mL.

Extraction was done with a blank of cartridges, to check for the presence of interferences, but none were found.

The next parameter was the sample volume preconcentrated onto the cartridges; the extraction process was carried out with 100, 250, 500, and 1000 mL of Milli-Q water spiked at 1 μg/mL. The results of recovery against sample volume are given in Table 5.

There was a significant decrease in the recovery of studied solutes when the sample volume passed from 100 to 1000 mL. So, 100 mL was chosen as the optimum volume.

The performance of the method for real samples was tested in tap and surface water samples; the results obtained

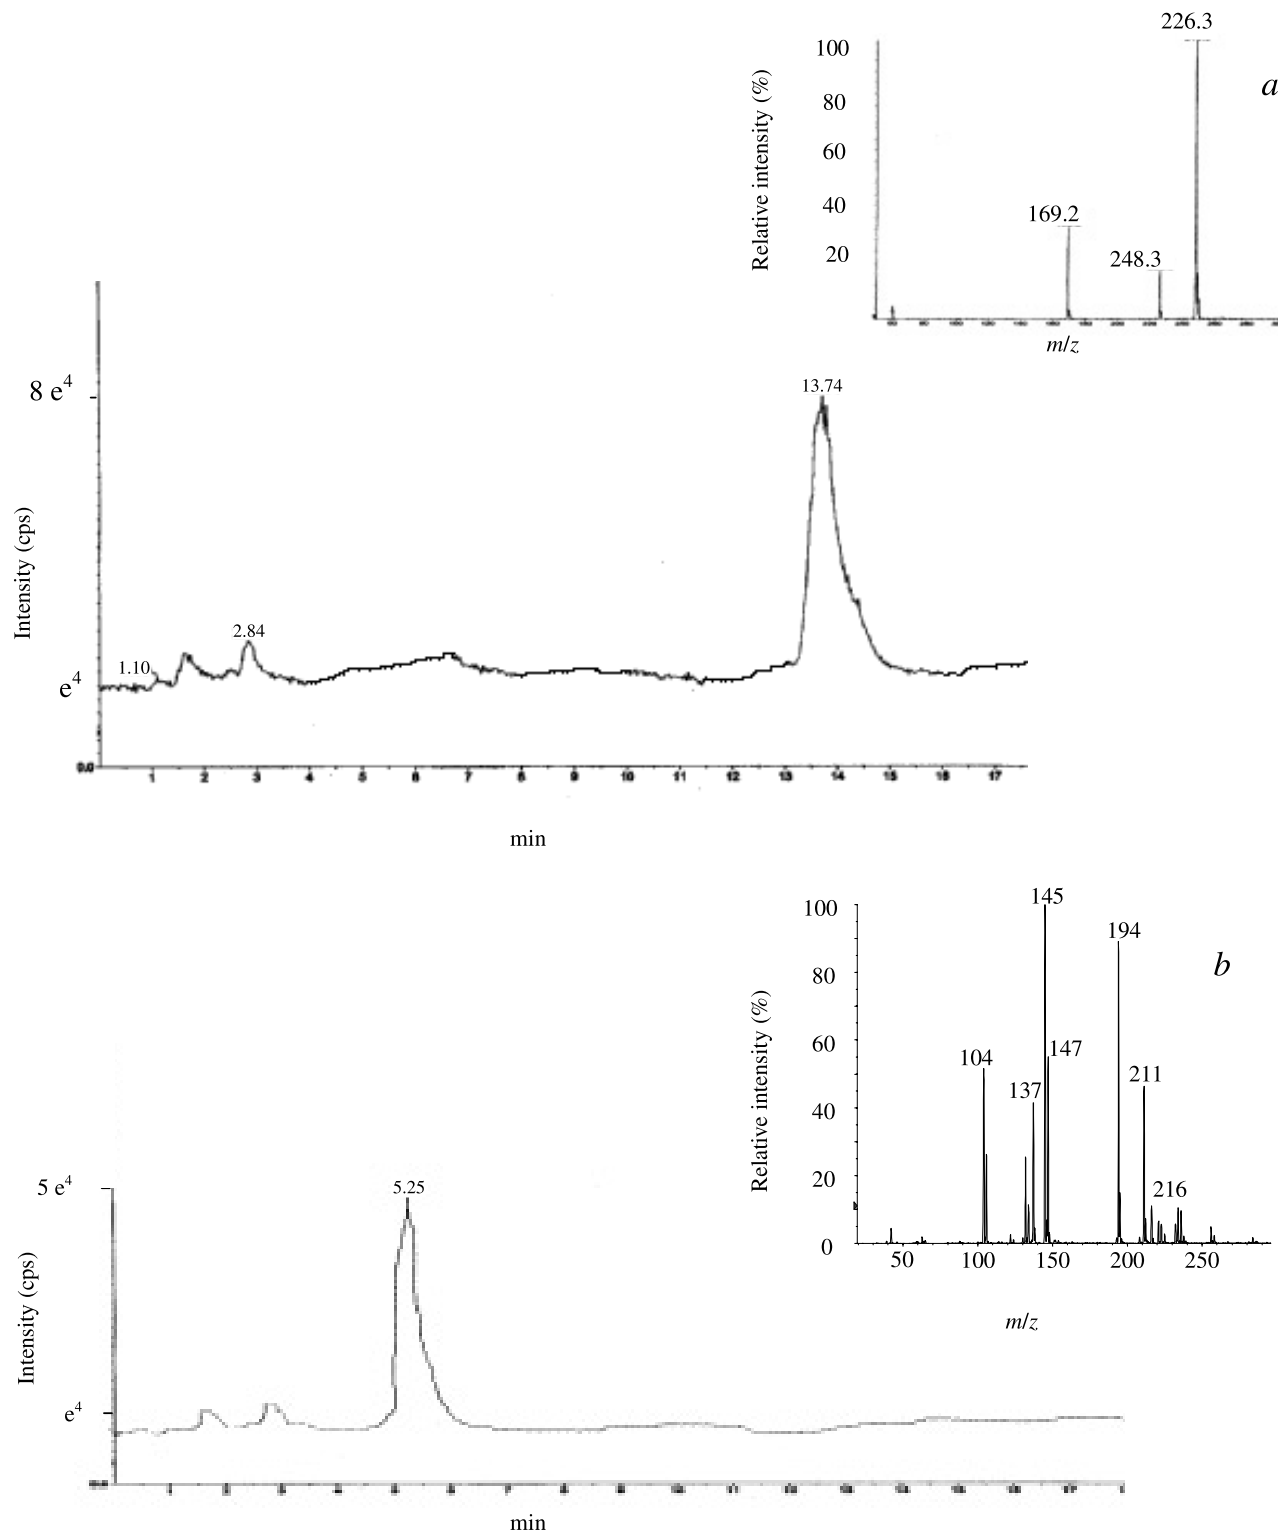
[c]Spiking level 5 µg/L.

Fig. 6. HPLC of surface water samples after 100 mL of a water sample fortified with eight PNMCs and four hydrolytic degradation products at 10 µg/L on 1 g C18 cartridges. Peak numbers correspond to those in Table 4.
Fig. 7. SIM chromatograms and mass spectra of surface sample at 1 µg/L of methiocarb (*a*) *m/z* 248; carbaryl (*b*) *m/z* 224, in LC–ES-MS.


are given in Table 6. The samples were fortified with a standard mixture of eight PNMCs and four hydrolysis products at a fortification level of 10 µg/L. When a sample volume of 100 mL was passed through the SPE cartridges, the recoveries for tap water and surface water were, respectively, in the range of 68–86% (RSD 2–8%) and 62–83% (RSD 3–11%).

We should note that the highest recoveries for all compounds were obtained in tap water. A reduction in the extraction efficacity, as well as the formation of a solute–humic substance complex, can be owed to the presence of humic substances in surface water. The latter formation cannot be retained by adsorption on the solid phase considered.

Table 7. List of compound, molecular weights, and quantitation ions for SIM conditions.

Compound	Molecular weight	Quantitation ion (*m/z*)
Aminocarb	208	231.2
Baygon	209	232.3
Carbofuran	221	244.2
Carbaryl	201	224.2
Landrin	193	216.2
Methiocarb	225	248.3
Baycarb	207	230.2
Zectran	222	223.2

Further experiments carried out with 100 mL samples spiked at 5 and 10 µg/L levels show essentially constant recovery and satisfactory RSD (3–11%).

A chromatogram of a 100 mL surface water sample at pH 7.4, fortified with eight parent PNMCs and four hydrolysis products at a concentration of 10 µg/L and extracted on 1 g C18 bonded silica cartridges, is showed in Fig. 6. The chromatogram is remarkably free from interfering peaks. With the optimized procedure, for the entire listed compound, minimum detectable concentrations (signal-to-noise ratio = 3:1) were in the range of 4–10 µg/L.

Analyses by LC–ES-MS

To improve sensitivity, the results obtained by LC–ES-MS (equipped with a triple quadruple mass filter) were involved. MS data acquisition was performed by a time-scheduled, selected-ion monitoring (SIM) program. The quantitation ions chosen for SIM are listed in Table 7. Under the experimental conditions described in the Experimental section (Chromatographic conditions), no thermal degradation for target compounds was observed. The ion signals for the analytes considered were obtained when LC–ES-MS instrumentation was operated with a mobile phase described in the Experimental section. The LC–ES-MS spectrum of carbaryl and methiocarb in the experimental conditions proposed can be observed in Fig. 7. At 30 V of fragmentor voltage, ES in the positive mode produces three main ions corresponding to $[M + Na]^+$, $[M + H]^+$, and $[M + CH_3NCO]^+$, e.g., for carbaryl, ES in the positive mode produces $[M + Na]^+ = 224$, $[M + H]^+ = 202$, and $[M + CH_3NCO]^+ = 145$, then it can be deduced the soft ionization offered by the electrospray.

Calibrations graphs were obtained for different concentrations of analytes. The regression coefficients were >0.999 in all cases. The values found for the calibration in the graph show good linearity for all PNMCs (Fig. 8). The detection limits calculated for each pesticide range between 0.1 and 0.3 µg/L.

The same analysis was carried out for river water samples, and good linearity was also obtained for the same range. The limit of quantitation for the analytes ranged between 0.1 and 0.5 µg/L injected into the LC column from the extracts of the water river matrices.

Conclusion

A mixture of eight PNMCs and four of their hydrolysis products was studied by LC–UV and LC–ES-MS. Hydroly-

Fig. 8. Calibration graphs of carbaryl (△), carbofuran (○), aminocarb (×), and baygon (◆) obtained from standard solutions using time-scheduled SIM LC–ES-MS.
sis affects the degradation of PNMCs, so hydrolysis kinetics were investigated. In SPE–LC–UV, the analytes were enriched with 100 mL surface water samples on C18 cartridges eluted with methanol and separated by gradient LC on C18 analytical columns and detected by UV. Satisfactory recovery values (62–83%) were given. The quantitation limits of 12 compounds were 4–10 µg/L. LC–MS is highly sensitive (0.1–0.5 µg/L) and specific. Detection limits can be further enhanced using ES-MS-MS.

Cyclic voltammetric studies of tris(alkylisocyanide)-bis(triarylphosphine)cobalt(II) and tris-(alkylisocyanide)bis(triarylphosphine)cobalt(I) complexes exhibiting synthetic interconvertability

Jamil Ahmad, Florence Bothata-Nareetsile, and Clifford A.L. Becker

Abstract: Nine pairs of corresponding $[Co^I(CNR)_3(PR_3')_2]X$, $[Co^{II}(CNR)_3(PR_3')_2]X_2$ complexes — where $X = ClO_4$, BF_4; $CNR = CNCMe_3$, $CNCHMe_2$, CNC_6H_{11}, $CNCH_2Ph$; $PR_3' = PPh_3$, $P(C_6H_4Me-p)_3$, $P(C_6H_4OMe-p)_3$ — have been studied using cyclic voltammetry in CH_3CN solutions. All cycles are reversible, and $E_{1/2}$ for the Co(I) complexes, initially oxidized, are within experimental error identical to $E_{1/2}$ values for the corresponding Co(II) complexes, initially reduced. $E_{1/2}$ values are strongly dependent on the triarylphosphine ligand, decreasing in the order $PPh_3 > >$ $P(C_6H_4Me-p)_3 > P(C_6H_4OMe-p)_3$, and weakly dependent on the alkylisocyanide ligand, decreasing in the order $CNCH_2Ph > CNCMe_3 > CNC_6H_{11} \geq CNCHMe_2$. Solution $v(-N\equiv C)$ IR patterns reveal that the $[Co^I(CNR)_3(PR_3')_2]X$ complexes do not have regular trigonal bipyramidal coordination, their structure being determined by the particular CNR ligand, while the $[Co^{II}(CNR)_3(PR_3')_2]X_2$ complexes, specifically in CF_3CH_2OH, appear to have regular trigonal bipyramidal coordination.

Key words: cyclic voltammetry, cobalt(I) complexes, cobalt(II) complexes, alkylisocyanide ligands, triarylphosphine ligands.

Résumé : Utilisant la voltamétrie cyclique on a étudié neuf paires de complexes de $[Co^I(CNR)_3(PR_3')_2]X$, et de $[Co^{II}(CNR)_3(PR_3')_2]X_2$ dans lesquels $X= ClO_4$, BF_4 ; $CNR = CNCMe_3$, $CNCHMe_2$, CNC_6H_{11}, $CNCH_2Ph$; $PR_3' = PPh_3$, $P(C_6H_4Me-p)_3$, $P(C_6H_4OMe-p)_3$. Tous les cycles sont réversibles et les valeurs de $E_{1/2}$ pour les complexes de Co^I, préa-lablement oxydés sont, à l'intérieur des erreurs expérimentales, identiques aux valeurs de $E_{1/2}$ des complexes correspon-dants de Co^{II} préalablement réduits. Les valeurs de $E_{1/2}$ dépendent fortement du ligand triarylphosphine et décroissent dans l'ordre : $PPh_3 > > P(C_6H_4Me-p)_3 > P(C_6H_4OMe-p)_3$; ces valeurs également dépendent faiblement du ligand alky-lisocyanure et décroissent dans l'ordre : $CNCH_2Ph > CNCMe_3 > CNC_6H_{11} \geq CNCHMe_2$. L'allure des spectres IR $v(-N\equiv C)$ révèle que les complexes $[Co^I(CNR)_3(PR_3')_2]X$ n'ont pas une coordination bipyramidale trigonale régulière, la structure étant déterminée par le ligand particulier CNR, tandis que les complexes $[Co^{II}(CNR)_3(PR_3')_2]X_2$ spécifique-ment dans le CF_3CH_2OH semblent avoir une coordination bipyramidale trigonale régulière.

Mots clés : voltamétrie cyclique, complexes de cobalt (I), complexes de cobalt (II), ligands alkylisocyanures, ligands triarylphosphines.

[Traduit par la Rédaction]

Introduction

Reactions of triarylphosphines with cobalt(II)–alkyliso-cyanide complexes have been characterized by reduction – ligand-substitution, producing disubstituted Co(I) complexes, $[Co^I(CNR)_3(PR_3')_2]X$ ($X = ClO_4$, BF_4) in good yields (1–5). Cyclic voltammograms of some tris(alkylisocyanide)bis-(triarylphosphine)cobalt(I) complexes showed quasi-reversible behavior for oxidative cycles (5), suggesting the existence of stable $[Co^{II}(CNR)_3(PR_3')_2]^{2+}$ species, however, and a number

of tris(alkylisocyanide)bis(triarylphosphine)cobalt(II) com-plexes have since been synthesized (6). The pairs of corre-sponding Co(I) and Co(II) complexes, $[Co^I(CNR)_3(PR_3')_2]X$ and $[Co^{II}(CNR)_3(PR_3')_2]X_2$, having the same alkylisocyanide (CNR) and triarylphosphine (PR_3') ligands show what may be termed "regular behavior" in that mutual interconversion of the two complexes is chemically possible:

$$[Co^I(CNR)_3(PR_3')_2]^+ \underset{N_2H_4}{\overset{Ag^+}{\rightleftarrows}} [Co^{II}(CNR)_3(PR_3')_2]^{2+}$$
This is opposed to "irregular behavior" for cases where only the Co(I) or only the Co(II) complex has been synthesized and where it has not been possible to isolate the correspond-ing Co(II) or Co(I) complex, respectively. Co(I) complexes showing clearly irreversible cyclic voltammograms, for ex-ample, cannot be oxidized to the corresponding Co(II) com-plexes with $AgClO_4$ or $AgBF_4$ (6).

In this paper, corresponding pairs of Co(I) and Co(II) complexes are investigated using cyclic voltammetry; cycles

for the Co(I) complexes were initially scanned oxidatively, and cycles for the Co(II) complexes were initially scanned reductively. If results of these two scans are equivalent, within experimental error, this should confirm that the Co(II) species observed in the voltammograms of the Co(I) species are indeed the recently synthesized $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ complexes. Since there are a limited number of known series of transition metal complexes, differing only in the oxidation state of the metal, this should be a worthwhile study.

Results

The equilibrium cyclic voltammetric data for the $[Co^I(CNR)_3(PR'_3)_2]X$, $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ corresponding pairs of complexes are summarized in Table 1. The equilibrium scans are quite similar in shape to the respective first scans and have quite close E values. A characteristic set of cyclic voltammograms (for $[Co^I(CNC_6H_{11})_3(PPh_3)_2]ClO_4$) at various scan rates is pictured in Fig. 1. The dependence of the peak currents from these voltammograms on the scan rate is shown in Fig. 2. This dependence was used as a diagnostic tool to decide if the electrochemical processes were reversible. The $\nu(-N{\equiv}C)$ IR values for the five-coordinate Co(I) and Co(II) complexes in CF_3CH_2OH, CH_3NO_2, and CH_2Cl_2 are tabulated in Table 2, and the four distinct patterns for the $[Co^I(CNR)_3(PR'_3)_2]X$ complexes are pictured in Fig. 3.

Interpretation of the voltammograms

The plots of the peak current vs. the square root of the scan rate are linear for all of the complexes (see Fig. 2 for compound (cpd) 9). The peak potentials also do not change significantly with the scan rate. According to these criteria, the electrode processes are reversible (7–9). This system has a high solution resistance between the working and the reference electrode because of the non-aqueous nature of the solvent and the low concentration (0.05 M) of the background electrolyte, which is necessitated by its low solubility in CH_3CN. The measured potential is increased by an amount equal to this ohmic (iR) drop. The net result is an increase in the peak separation between the anodic and cathodic peak potential values (8). This "ohmic distortion" contributes to the apparent nonconformity of the system to a third criterion of reversibility, namely the requirement that the peak separation be around 57 mV.

Another source of this discrepancy for high ΔE values is the junction potential created across the ion bridge between the reference electrode and the sample solution. This is caused by the difference in the diffusion coefficients of the cations and the anions of the supporting electrolyte (10). Measurements made on ferrocene–ferrocenium, which is a known reversible couple, under conditions identical to those reported herein gave a peak separation of 110 mV at a 0.1 V s^{-1} scan rate, thereby confirming that the observed peak separation is inherent in the experimental conditions and not characteristic of the redox couple.

Interpretation of the $E_{1/2}$ values

Experimental error of ±10 mV in measurement of the $E_{1/2}$ values was estimated by repetitive scans of the same samples. Within this margin of error, the $E_{1/2}$ values measured

for the Co(I) complexes, initially oxidized, and the $E_{1/2}$ values measured for the Co(II) complexes, initially reduced, are essentially identical (see Table 1). This experimental fact, observed for nine pairs of corresponding Co(I), Co(II) complexes, would seem to confirm that the recently synthesized $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ complexes are indeed the same Co(II) species observed in cyclic voltammetric oxidation of the previously known $[Co^I(CNR)_3(PR'_3)_2]X$ complexes.

Alternately, these Co(II) complexes are reduced by cyclic voltammetry to the same Co(I) complexes that are obtained by chemical reduction with hydrazine or that served as starting materials for synthesis of the Co(II) complexes. Generation of the same chemical species electrolytically and by N_2H_4 reduction – Ag^+ oxidation is thus confirmed.

The $E_{1/2}$ dependence on variation of the PR'_3 ligand with respect to constant CNR ligands for both Co(I) and Co(II) complexes is very pronounced, with the definite trend in decreasing $E_{1/2}$ values, $PPh_3 >> P(C_6H_4Me\text{-}p)_3 > P(C_6H_4OMe\text{-}p)_3$. This is expected since *para*-substituents with increasing electron-donating ability should make the phosphines both stronger σ-donating and less π^*-accepting, favoring stabilization of Co(II) over Co(I). This trend also correlates with the ease or difficulty of synthesizing the Co(II) complexes as opposed to isolating only Co(I). Decreasing Co(II) and (or) increasing Co(I) stability for the species $[Co(CNR)_3(PR'_3)_2]^{n+}$ has been observed to be favored by $P(C_6H_4NMe_2\text{-}p)_3 > P(C_6H_4OMe\text{-}p)_3 > P(C_6H_4Me\text{-}p)_3 > PPh_3 > P(C_6H_4F\text{-}p)_3 \approx P(C_6H_4Cl\text{-}p)_3 > P(C_6H_4CF_3\text{-}p)_3$ (6, 11), this trend running to both extremes. $[Co^I(CNCMe_3)_3\{P(C_6H_4NMe_2\text{-}p)_3\}_2]ClO_4$, prepared by N_2H_4 reduction in CH_2Cl_2 of the initially isolated $[Co^{II}(CNCMe_3)_3\{P(C_6H_4NMe_2\text{-}p)_3\}_2](ClO_4)_2$, for example, spontaneously oxidizes back to the Co(II) complex in CF_3CH_2OH solution (11), while $[Co^I(CNCMe_3)_3(PR'_3)_2]ClO_4$ complexes with $PR'_3 = P(C_6H_4F\text{-}p)_3$, $P(C_6H_4Cl\text{-}p)_3$, and $P(C_6H_4CF_3\text{-}p)_3$ are not oxidized by $AgClO_4$ (6). These latter Co(I) complexes show irreversible voltammograms under oxidation (5). No substantial difference in ease of synthesis for $[Co^{II}(CNR)_3(PPh_3)_2]X_2$ vs. $[Co^{II}(CNR)_3\{P(C_6H_4Me\text{-}p)_3\}_2]X_2$ complexes sufficient to justify these $E_{1/2}$ values has been observed, but the Hammett σ constants do indicate a much larger difference between reactivity involving a $-C_6H_5$ group and the $-C_6H_4Me\text{-}p$ group than between $-C_6H_4Me\text{-}p$ and $-C_6H_4OMe\text{-}p$ groups (12), so this may be reflected in the $E_{1/2}$ values.

The $E_{1/2}$ dependence on variation of the CNR ligand with respect to constant PR'_3 ligands is relatively small but seems to follow the trend in decreasing $E_{1/2}$ values, $CNCH_2Ph > CNCMe_3 > CNC_6H_{11} > CNCHMe_2$. This trend parallels the decreasing ability of the alkylisocyanide substituent to stabilize a δ^+ charge on the C atom adjacent to the isocyanide functional group. Analogous variation of $E_{1/2}$ values with alkylisocyanide ligands was reported by Dart et al. (2) for $[Co(CNR)_3(PPh_3)_2]PF_6$ complexes (measured in CH_2Cl_2 solution), with $E_{1/2}$ values decreasing in the order R = t-Bu (0.29 V) > i-Pr (0.20 V) > Me (0.12 V). $E_{1/2}$ values reported for $[M(CO)_4L_2]$ complexes (where M = Cr, Mo, W; L = $CNCHMe_2$, $CNCMe_3$), however, show very little difference (13). Previous work from this laboratory (5) indicated a narrow range of $E_{1/2}$ values for variation in CNR ligands (i.e., 0.20–0.25 V), but the trend of $CNCMe_3 > CNCHMe_2$ values was detected. For $[PtL_2(CNR)Me]^+$ (L = $PMePh_2$, PMe_2Ph)

Table 1. Cyclic voltammetric results for corresponding pairs of tris(alkylisocyanide)bis(triarylphosphine)cobalt(I) and tris(alkylisocyanide)bis(triarylphosphine)cobalt(II) complexes in acetonitrile solution at 0.1 V s^{-1} scan rate.

Fig. 1. Cyclic voltammograms of $[Co^I(CNC_6H_{11})_3(PPh_3)_2]ClO_4$, cpd 9 (1 mM in CH_3CN), with 0.05 M tetrabutylammonium hexafluorophosphate background electrolyte. The flat (innermost) trace is for the background electrolyte only, at a scan rate of 0.1 V s^{-1}. The other curves are, in order, for scan rates of 0.01, 0.05, 0.1, 0.2, 0.3, 0.4, and 0.5 V s^{-1}.
it is suggested that the σ-donor strength of CNR is essentially independent of the inductive properties of R, making variation in $E_{1/2}$ dependent only on the relatively slight differences in π*-accepting ability of the CNR (14).

Strong $E_{1/2}$ dependence on the triarylphosphine ligands, with relatively little sensitivity to the alkylisocyanide ligands, has been attributed to effective σ-donation from the phosphines in axial positions and ineffective σ-donation by the alkylisocyanides in equatorial positions of trigonal bipyramidal coordination in the Co(I) complexes (5). For diamagnetic d^8 Co(I) complexes in trigonal bipyramidal coordination, the electronic configuration of $(d_{xz})^2(d_{yz})^2(d_{xy})^2$ $(d_{x^2-y^2})^2$ should hinder σ-donation from the equatorial ligands (i.e., the alkylisocyanides) while allowing effective σ-donation

Fig. 2. Plots of anodic and cathodic currents vs. square root of scan rate for cpd 9 (i.e., $[Co^I(CNC_6H_{11})_3(PPh_3)_2]ClO_4$) from the voltammograms in Fig. 1.
from the axial ligands (i.e., the triarylphosphines) by electron donation into the empty $3d_{2z^2-x^2-y^2}$ orbital on the Co(I) (5). Possibly spectral data can provide insight into this question.

Interpretation of solution $\nu(-N\equiv C)$ IR patterns

In previous cyclic voltammetric studies of five-coordinate Co(I) complexes, when quasi-reversible behavior was assigned on the basis of ΔE values exceeding 57 mV, two alternate explanations were offered for quasi-reversibility. One explanation was that Co(I) in a regular trigonal bipyramidal (TBP) coordination is oxidized to Co(II) in a regular TBP structure that rapidly undergoes chemical change to a square pyramidal (SP) solution structure of C_{2v} symmetry (15). The other explanation was that Co(I) in a distorted TBP coordination is oxidized to Co(II) in a regular TBP structure (5). The $\nu(-N\equiv C)$ IR patterns in the solid state (i.e., Nujol mull) are significantly different for the Co(I) (3–5) and Co(II) (6, 16) complexes, but solution structures are more relevant in this study. Solution structures for $[Co^I(CNR)_3(PR'_3)_2]^+$ species in general have been considered only approximately TBP, the strongest evidence for deviation from rigorous (D_{3h}) TBP coordination coming from combined IR and Raman data for the arylisocyanide complexes (17). Spectral data for the Co(I) complexes in this paper were measured over a period of years on different spectrophotometers, so solution IR measurements have now been repeated on superior instrumentation under identical conditions. These data, in Table 2, reveal trends in the $\nu(-N\equiv C)$ IR patterns hitherto unrecognized.

The shape of the $\nu(-N\equiv C)$ IR patterns for these $[Co^I(CNR)_3(PR'_3)_2]X$ complexes in solution is unique for each alkylisocyanide, but independent of the particular triarylphosphine and solvent used. Figure 3 illustrates these four distinct patterns, corresponding to Co(I) complexes with the CNC_6H_{11}, $CNCH_2Ph$, $CNCHMe_2$, and $CNCMe_3$ ligands, respectively (top to bottom). The patterns for $CNCMe_3$ (seen for cpd 5, 11) and $CNCHMe_2$ (cpd 1, 7, 15) are clearly in-

compatible with D_{3h} symmetry (one, E', allowed band), and even CNC_6H_{11} (cpd 3, 9, 17) suggests some distortion in the solution state. Only $CNCH_2Ph$ (represented by one complex, 13) could be assigned D_{3h} symmetry and only if the weak, albeit persistent, higher energy shoulder is ignored. Solution structures of the $[Co^I(CNR)_3(PR'_3)_2]X$ complexes cannot be assumed to be regular TBP.

The shapes of the $\nu(-N\equiv C)$ IR patterns for the $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ complexes in solution are distinctly different from those for the Co(I) complexes and seem to vary mostly depending on solvent. In CF_3CH_2OH almost all spectra exhibit a lone strong band, expected for D_{3h} (regular) TBP structure (see Table 2). Cpds 12 and 14 in CF_3CH_2OH and many Co(II) complexes in CH_2Cl_2 and especially in CH_3NO_2, however, exhibit additional shoulders and (or) weak bands in the energy region appropriate for Co(II). These additional bands are normally accompanied by weak to medium bands attributed to the corresponding $[Co^I(CNR)_3(PR'_3)_2]X$ complex (produced by reduction in solution), except for cpd 14 where reduction is extensive. These data could indicate that a non-TBP structure for Co(II) is more prone to reduction than TBP coordination. These data also suggest that the $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ complexes in CF_3CH_2OH at least tend to be TBP.

Now that the Co(I)–Co(II) couples have been recognized as being reversible, a difference in the solution coordination structures for the two oxidation states is interesting. This would imply that identical coordination structures for oxidized and reduced species is not a requirement for reversibility.

Experimental

Commercially available alkylisocyanides — i.e., $CNCMe_3$, $CNCHMe_2$, CNC_6H_{11}, and $CNCH_2Ph$ (Fluka, Strem, Fluka, and Aldrich Chemicals, respectively) — were used without redistillation. Commercially available triarylphosphines —

Fig. 3. The ν(-N≡C) IR patterns for $[Co^I(CNR)_3(PR'_3)_2]X$ complexes. Top to bottom: $[Co(CNC_6H_{11})_3\{P(C_6H_4Me$-$p)_3\}_2]ClO_4$, $[Co(CNCH_2Ph)_3(PPh_3)_2]BF_4$, $[Co(CNCHMe_2)_3\{P(C_6H_4OMe$-$p)_3\}_2]ClO_4$, and $[Co(CNCMe_3)_3\{P(C_6H_4Me$-$p)_3\}_2]ClO_4$ all in CF_3CH_2OH solution.
i.e., PPh$_3$, P(C$_6$H$_4$Me-p)$_3$, and P(C$_6$H$_4$OMe-p)$_3$ (Aldrich Chemicals) — were used without recrystallization. Anhydrous AgClO$_4$ and AgBF$_4$ were supplied by Strem Chemicals, Inc. 2,2,2-Trifluoroethanol (puriss grade) from Fluka was used for IR spectra. Anhydrous diethyl ether was filtered through an alumina column immediately before use. The $[Co^I(CNR)_3(PR'_3)_2]X$ and $[Co^{II}(CNR)_3(PR'_3)_2]X_2$ (X = ClO$_4$, BF$_4$) complexes were synthesized as previously re-

ported (3–6). Ferrocene, which was used to test the experimental setup, was prepared by standard procedure (18).

For cyclic voltammetry, 1 mM solutions of the compounds were freshly prepared in chromatographic-grade acetonitrile containing 0.05 M tetrabutylammonium hexafluorophosphate (TBAH) as the supporting electrolyte. Cyclic voltammetry measurements were performed using a Metrohm 757 VA Computerace system with a three-electrode compartment cell. The working and auxiliary electrodes were both made of glassy carbon. The reference electrode was a double junction Ag–AgCl system. The voltammograms were recorded in the potential range, –0.2 to +0.6 V vs. Ag–AgCl, at various scan rates ranging from 0.01 V s^{-1} to 0.5 V s^{-1}. Nitrogen gas was bubbled through each solution for 500 s prior to the run. IR spectra were recorded on a PerkinElmer 2000 FT-IR spectrophotometer in spectro-grade CH_2Cl_2, CH_3NO_2, and CF_3CH_2OH.

3,3′-Dipyrrolyl sulfides, useful building blocks for the syntheses of macrocycles containing dipyrromethene units

Qingqi Chen and David Dolphin

Abstract: 5,5′-Dicarboxy-3,3′-dipyrrolyl sulfide was condensed with 5,5′-diformyl-3,3′-dipyrrolyl sulfide or 5,5′-diformyldipyrromethane under acidic conditions to produce, in high yields, macrocycles containing four dipyrromethene units.

Key words: 3,3-dipyrrolyl sulfide, cyclopolypyrrole, dipyrromethene, macrocycle.

Résumé : On a condensé le sulfure de 5,5′-dicarboxy-3,3′-dipyrrolyle avec le sulfure de 5,5′-diformyl-3,3′-dipyrrolyle ou avec le 5,5′-diformyldipyrrométhane en milieu acide pour former, avec des rendements élevés, des macrocycles contenant 4 unités dipyrrométhène.

Mots clés : sulfure de 3,3′-dipyrrolyle, cyclopolypyrrole, dipyrrométhène, macrocycle.

[Traduit par la Rédaction]

Introduction

In recent years expanded porphyrins and macrocycles related to porphyrins have been receiving increasing attention (1–4), and they are being utilized in fields such as photodynamic therapy (PDT), neutral substrate binding, and anion recognition.

Macrocycles containing six (3), eight (4, 5), ten (6), and twelve (7) pyrrolic rings have been reported, and recently *meso*-aryl-substituted expanded porphyrins containing up to 12 pyrrolic rings have been described (8). We report here a new type of macrocycle, which contains dipyrromethene units linked by sulfur atoms prepared via a McDonald synthesis.

Results and discussion

5,5′-Diformyl-2,2′-dipyrrolyl sulfides have been known for many years as intermediates in the synthesis of thiaporphyrins (Scheme 1) (9, 10). We attempted to condense a 5,5′-diformyl-3,3′-dipyrrolyl sulfide **6** with a 5,5′-dicarboxy-3,3′-dipyrroloyl sulfide **3** under acidic conditions and were surprised to find that the product was not the expected compound **7**, but the macrocyclic product **8**, which contained eight pyrrole rings (Schemes 2 and 3) where the dipyrromethene units were linked by sulfur atoms.

The precursor 5,5′-dicarboxy-3,3′-dipyrrolyl sulfide **3** was prepared from 2-ethoxycarbonyl-3,5-dimethylpyrrole **1** via two steps: reacting **1** with sulfur dichloride (11), followed by

Scheme 1.
treatment with sodium hydroxide to give the diacid **3**. Another important intermediate **6** was synthesized from **1** in 3 steps. Thus compound **1** was saponified and decarboxylated under basic condition (sodium hydroxide) at 180 °C using ethylene glycol as solvent to yield 2,4-dimethylpyrrole (**4**), which was converted to 2-formyl-3,5-dimethylpyrrole (**5**) under Vilsmeier formylation conditions. Coupling **5** with sulfur dichloride gave the key intermediate compound **6** in high yield (11).

Compound **8** is formally a dimer of **7** (Scheme 3), which was formed in a [2 + 2 + 2 + 2] condensation from 2 equiv each of **3** and **6**.

To extend our work, we tried to condense **3** with **9** and **6** with **10** under similar acidic conditions. Once again, these reactions did not provide the [2 + 2] product **11**, but the [2 + 2 + 2 + 2] condensation product **12** (Scheme 4). Similar [2 + 2 + 2 + 2] condensations have previously been observed by Sessler, Vogel, and their co-workers (2, 4, 5, 12). In general these reactions occurred with yields usually below 20%, lower than those reported here, which range from 80 to 90%.

The composition of the new macrocycle **8** was established by combustion analysis, UV–vis, and FAB mass spectrometry. As expected, **8** does not possess macrocyclic aromaticity

Scheme 2. Reagents and condition: (*a*) SCl$_2$–CH$_2$Cl$_2$, –50 °C; (*b*) NaOH–EtOH, reflux 3 h, then HOAc, pH = 4; (*c*) NaOH–glycol, 180 °C; (*d*) POCl$_3$–DMF, then NaOH; (*e*) SCl$_2$–CH$_2$Cl$_2$, –60 °C.
Scheme 3.
Scheme 4.
since the conjugated system is interrupted by the sulfur bridges. The molecule has high symmetry, which is consistent with its ^{1}H and ^{13}C NMR spectra; there are two types of CH$_3$ signals, one for α-CH$_3$ and the other for β-CH$_3$ groups, and one -CH= signal at 7.00 ppm. Moreover, the ^{13}C NMR of **8** in TFA-*d* showed 5 *sp*^{2} signals, which correspond to one -CH= and four carbons in each pyrrole ring. Compound **8** has very low solubility in most common solvents such as

dichloromethane, chloroform, methanol, acetone, DMF, DMSO, acetic acid, acetonitrile, THF, dioxane, and pyridine. However, it is soluble in trifluoroacetic acid, in which it displays a beautiful purple color. In other solvents **8** can have a red to yellow color depending on its degree of protonation. Macrocycle **12** was characterized as above, and its optical properties are similar to those of macrocycle **8**; **12** is more soluble than **8** in most solvents.

Experimental section

General

All reagents and solvents were purchased and used as received. Melting points were determined on a Thomas hot stage or Buchi apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC-200 or AMX-300 instrument. The high- and low-resolution mass spectra were obtained by the departmental mass spectroscopy service laboratory. Combustion analyses were performed by the departmental microanalytical laboratory. Optical spectra were recorded on an HP8452A Photo diode array spectrophotometer (instrumental precision ±2 nm).

Bis(5-ethoxycarbonyl-2,4-dimethylpyrrole-3-yl)sulfide **2** and bis(5-formyl-2,4-dimethyl pyrrole-3-yl)sulfide (**6**) were prepared according to literature procedures (11).

Bis(5-carboxy-2,4-dimethylpyrrol-3-yl) sulfide (3)

Bis(5-ethoxylcarbonyl-2,4-dimethylpyrrol-3-yl) sulfide (20 g, 55 mmol) was suspended in ethanol (180 mL). The mixture was stirred, and a solution of sodium hydroxide (8.8 g in 20 mL water) was added all at once. The suspension was then stirred under reflux for 3 h, and the solvent was then removed under vacuum. The residue was stirred with brine (100 mL) at –10 °C; then acetic acid was added dropwise until pH 4. The precipitate was collected by suction filtration and by washing with cold water. After drying under vacuum, the desired product was obtained as a pink solid (16.2 g, 96%).

mp 220 °C (decomposition (dec)). ^1H NMR (200 MHz, DMSO-d_6) (ppm) δ: 2.20 (s, 12H, 4CH$_3$), 11.20 (s, 2H, 2NH), 12.00 (s, 2H, COOH). ^{13}C NMR (75 MHz, DMSO-d_6) (ppm) δ: 11.26, 11.72, 111.57, 119.53, 127.35, 133.68, 163.77 (COOH). $C_{14}H_{16}N_2O_4S$ required: C 54.54, H 5.19, N 9.09; found: C 54.06, H 5.54, N 8.86.

Synthesis of 8·2TFA

5,5′-Dicarboxy-3,3′-dipyrrolyl sulfide **3** (200 mg, 0.66 mmol) was suspended in trifluoroacetic acid (10 mL) and stirred at 40 °C until all the solid had dissolved. The red mixture was cooled to room temperature. To this solution was added 5,5′-diformyl-3,3′-dipyrrolyl sulfide (**6**) (181 mg, 0.66 mmol) under continuous stirring. After 10 min, a mixture of dichloromethane (20 mL), methanol (20 mL), and hydrogen bromide (3 mL, 48% in acetic acid) was added. The red mixture was allowed to stir overnight at room temperature. Anhydrous ether (100 mL) was added. The suspension was allowed to stir for another 2 h. The red solid was collected by suction filtration and washed with anhydrous ether to give **8** (378 mg, 92%). An analytic sample was prepared by repeating the following procedure four times: the crude product was dissolved in a minimum amount of TFA and precipitated by methanol – anhydrous ether (40:60, v/v). The solid was collected by suction filtration and washed with methanol.

mp 320 ºC (dec.). UV–vis (CH$_2$Cl$_2$ + TFA), λ_{max} (nm) (ε): 520 (136 400). FAB-MS m/e: 921 ([M + 1]$^+$). ^1H NMR (TFA-d, 400 MHz) (ppm) δ: 2.51 (s, 24H, 8CH$_3$), 2.57 (s, 24H, 8CH$_3$), 7.50 (s, 4H, 4 -CH=), 11.50 (bs, obscured by TFA signal, NH). ^{13}C NMR (TFA-d, 75 MHz) (ppm) δ: 12.09, 14.54, 122.91, 124.55, 129.69, 152.14, 160.39. MS (LSIMS, thioglycerol), calcd. for ($[C_{52}H_{56}N_8S_4 + 1]$), required: 921.35890; found: 921.35874. $C_{52}H_{56}N_8S_4 \cdot 2TFA \cdot 2H_2O$, required (%): C 56.74, H 5.27, N 9.45; found: C 56.34, H 4.94, N 8.96.

Synthesis of 12·2TFA

Method A, from 3 and 9

5,5′-Dicarboxy-3,3′-dipyrrolyl sulfide (**3**) (200 mg, 0.66 mmol) was suspended in trifluoroacetic acid (10 mL) and stirred at 40 °C until all the solid had dissolved. The red mixture was cooled to room temperature. To this solution was added the 5,5′-diformyldipyrromethane **9** (188 mg, 0.66 mmol) under continuous stirring. After 10 min, a mixture of dichloromethane (20 mL), methanol (20 mL), and hydrogen bromide (3 mL, 48% in acetic acid) was added. The red mixture was allowed to stir overnight at room temperature. Anhydrous ether (100 mL) was added. The suspension was allowed to stir for another 2 h. The red solid was collected by suction filtration and washed by anhydrous ether to give **12** (375 mg, 90%).

Method B, from 6 and 10

The 5,5′-diformyl-3,3′-dipyrrolyl sulfide (**6**) (200 mg, 0.72 mmol) was suspended in trifluoroacetic acid (10 mL) and stirred at 40 °C until all the solid had dissolved. The red mixture was cooled to room temperature. To this solution was added the 5,5′-dicarboxydipyrromethane **10** (230 mg, 0.72 mmol) under continuous stirring. After 10 min, a mixture of dichloromethane (20 mL), methanol (20 mL), and hydrogen bromide (3 mL, 48% in acetic acid) was added. The red mixture was allowed to stir overnight at room temperature. Anhydrous ether (100 mL) was added. The suspension was allowed to stir for another 2 h. The red solid was collected by suction filtration and washed with anhydrous ether to give the product (391 mg) in an 86% yield. An analytic sample was prepared by repeating the following procedure four times: the crude product was dissolved in a minimum amount of TFA and precipitated by methanol – anhydrous ether (40:60, v/v). The solid was collected by suction filtration and washed with methanol.

Conclusion

Vogel (12) has noted that the equimolar MacDonald-type condensation of a diformyl bipyrrole with a dipyrrole dicarboxylic acid gives, in most cases, octaphyrins as the sole products. The present study extends these observations and

shows that related octapyrroles can be produced, in high yield, from 3,3′-dipyrrolyl sulfides via a [2 + 2 + 2 + 2] MacDonald synthesis. Further work on the application of the present method for the synthesis of cyclooctapyrroles and cyclopolypyrroles using 3,3′-dipyrromethanes is in progress.

The extended hyper-Wiener index

X.H. Li

Abstract: According to the definition of molecular connectivity and the definition of a hyper-Wiener index, a novel set of hyper-Wiener indexes (R_n, $^m R_n$) are defined and are named the extended hyper-Wiener indexes. Where $n = 1, 2, 3, 4,\ldots$ represents the type of subgraph units and is the number of endmost atoms of the subgraph unit, m is the number of atoms of the subgraph unit. Here $n = 1$ means the subgraph unit is an atom, $n = 2$ means the subgraph units are straight-line combinations of m atoms ($m = 2, 3, 4, 5, 6,\ldots$), and $n = 3$ means the subgraph units are Y types of combinations of m atoms ($m = 4, 5, 6, 7, 8,\ldots$), and so on. The potential usefulness of the extended hyper-Wiener index in QSAR and (or) QSPR is evaluated by its correlation with a number of C_3–C_8 alkanes and by a favorable comparison with models based on the molecular connectivity index and the overall Wiener index. To verify the robustness and the predictive ability of the models, a cross-validation procedure, leave-one-out, and a random test were also performed. The results show that the extended hyper-Wiener indexes examined demonstrate a good potential for QSAR and QSPR studies. Considerably better statistics are obtained when extending the hyper-Wiener index to the extended hyper-Wiener index. The extended hyper-Wiener indexes provided statistical results as good as the molecular connectivity indexes and the overall Wiener index in all models, and the standard deviations provided by these three sets of indexes are rather close. Moreover, this method may provide a better way to apply the Wiener number and the hyper-Wiener index to the system of unsaturated hydrocarbons and organic compounds, including heteroatoms, according to the method of the molecular connectivity index. This can extend the usefulness of the Wiener number and hyper-Wiener index and can make them a kind of widely used topological index in practice.

Key words: hyper-Wiener index (R), extended hyper-Wiener index, molecular connectivity index.

Résumé : En se basant sur la définition de la connectivité moléculaire et de l'indice hyper-Wiener, on définit de nouveaux indices hyper-Wiener (R_n, $^m R_n$) appelés indices hyper-Wiener élargis. Quand $n = 1, 2, 3, 4,\ldots$, représente le type d'unités du sous-graphe et qu'il correspond au nombre d'atomes d'atomes terminaux de l'unité du sous-graphe, m correspond au nombre d'atomes de l'unité du sous-graphe. Dans ce cas, $n = 1$ signifie que l'unité du sous-graphe est un atome, $n = 2$ signifie que les unités du sous-graphe sont des combinaisons linéaires de m atomes ($m = 2, 3, 4, 5, 6,\ldots$) et $n = 3$ signifie que les unités du sous-graphe sont des combinaisons de type Y de m atomes ($m = 4, 5, 6, 7, 8,\ldots$) et ainsi de suite. On a évalué l'utilité potentielle de l'indice hyper-Wiener élargi dans des études QSAR–QSPR par sa corrélation avec un certain nombre d'alcanes comportant de 3 à 8 atomes de carbones et par une comparaison favorable avec des modèles basés sur l'indice de connectivité et sur l'indice Wiener global. Dans le but de vérifier la solidité des modèles et leur habilité à faire des prédictions, on a aussi effectué un test au hasard ainsi qu'une procédure de validation croisée en ne tenant pas compte d'un atome. Les résultats démontrent que les indices hyper-Wiener étendus examinés présentent un bon potentiel pour des études QSAR et QSPR. On obtient de bien meilleures statistiques en passant de l'indice hyper-Wiener à l'indice hyper-Wiener étendu. Les indices hyper-Wiener étendus conduisent à des résultats statistiques comme les indices de connectivité moléculaire et l'indice Wiener global dans tous les modèles et les déviations standards fournis pas ces trois ensembles d'indices sont assez près. De plus, il peut conduire à une meilleure façon d'appliquer le nombre de Wiener et l'indice hyper-Wiener au système d'hydrocarbures insaturés et de composés organiques comportant des hétéroatomes suivant la méthode de l'indice de connectivité moléculaire. Ceci pourrait étendre l'utilité du nombre de Wiener et de l'indice hyper-Wiener qui pourrait les faire passer au rang d'indice topologique largement utilisé dans la pratique.

Mots clés : indice hyper-Wiener (R), indice hyper-Wiener élargi, indice de connectivité moléculaire.

[Traduit par la Rédaction]

Introduction

The hyper-Wiener index $R(G)$ was proposed by Randić et al. (1); he generalized the Wiener index (W) to the hyper-Wiener index by the much-studied W graph invariant (2–4).

Wiener defined W as the sum of the distances between pairs of vertices of the graph under study (5). For trees, the main difference between W and R is that Randić considered paths p instead of edges e in the Wiener index. In his definition, R is the sum of contributions K_{ij}; here subscripts i and j repre-

sent a pair of vertices. K_{ij} can be obtained (6, 7) using the following two-step algorithm: (*i*) Remove the path (for trees there is only one path) between vertices *i* and *j*; two nonconnected subgraphs will be obtained. (*ii*) Multiply the number of vertices of the first subgraph by the number of vertices of the second one. *R* may be obtained by adding K_{ij} for all pairs of vertices *i* and *j*. There are $N(N-1)/2$ terms altogether, where *N* denotes the number of vertices (i.e., the number of carbons in H-suppressed graphs).

Klein et al. and Hosoya (8, 9) found that the hyper-Wiener index is equal to half of the Wiener index plus half of the sum of squared distances between pairs of vertices:

$$[1] \qquad R = \frac{1}{2}\left[\sum_{i<j} d_{ij}^2 + \sum_{i<j} d_{ij} \right] = \frac{1}{2}\sum_{i<j} d_{ij}^2 + \frac{1}{2}W$$

There have been many studies on the hyper-Wiener index in recent years (10, 11), especially by Tratch and his co-workers, who earlier introduced their index, similar to the hyper-Wiener index (12), and also made the suggestion to extend the Wiener number to sequences of number invariants (13, 14).

But the usefulness of the hyper-Wiener number is not as popular as the molecular connectivity index. Some limits prevent the usefulness of this number; for example, it can only be used for saturated hydrocarbons. There should be a further factor that is not accounted for by the hyper-Wiener number.

Randić introduced the concept of a connectivity (branching) index in 1975 (15). The concept has been further developed and applied extensively by Randić, Kier, Hall, and their co-workers (16, 17). The molecular connectivity index was proved to be one of the most successful and widely used indexes.

According to the definition of molecular connectivity, the first-order connectivity index $^1\chi$ is the sum over all bonds *i*—*j* (eq. [2]), where δ_1 is the valence of carbon atom *i* in the carbon skeleton of a hydrocarbon.

$$[2] \qquad {}^1\chi = \sum_{\text{bonds}} \left(\frac{1}{\delta_i \times \delta_j} \right)^{\frac{1}{2}}$$

And the second-order molecular index $^2\chi$ is a sum over 2-bond paths *i*—*j*—*k* of terms $1/(\delta_i\delta_j\delta_k)^{1/2}$. A hierarchy of additional indexes $^m\chi_t$ of order *m* and type *t* can be obtained by summing analogous terms over substructural units involving path ($t = p$), cluster ($t = c$), path–cluster ($t = pc$), or chain ($t = ch$) combinations of m bonds.

The extended hyper-Wiener index

According to the definition of molecular connectivity and the definition of the hyper-Wiener index, we can define the extended hyper-Wiener index for tree graphs (R_n, ^mR_n, $n \leq m$) as follows.

First, $n = 1, 2, 3, 4,...$ represents the type of subgraph units and is the number of endmost atoms of the subgraph unit. Second, *m* is the number of atoms of the subgraph unit. Here $n = 1$ means the subgraph unit is an atom, $n = 2$ means the subgraph units are straight-line combinations of *m* atoms ($m = 2, 3, 4, 5, 6,...$), and $n = 3$ means the subgraph units are

Y types of combinations of m atoms ($m = 4, 5, 6, 7, 8,...$), and so on.

Definition 1

The 1-type extended hyper-Wiener index R_1 is defined as the sum over all atoms *i*. Here n_i denotes the number of vertices in a tree graph if all the edges and internal vertices of a path are not deleted from the parent graph.

$$[3] \qquad R_1 = \sum_{\text{atoms}} n_i$$

Definition 2

The 2-type extended hyper-Wiener index R_2 is the sum of contributions K_{ij}, where subscripts *i* and *j* denote a pair of vertices. K_{ij} may be obtained by using the following two-step algorithm: (*i*) Remove the path (for trees there is only one path) between vertices *i* and *j* (linear subgraph units); two nonconnected subgraphs will be obtained. (*ii*) Multiply the number of vertices of the first subgraph n_i by the number of vertices of the second one n_j. R_2 may be obtained by adding K_{ij} for all pairs of vertices *i* and *j*.

$$[4] \qquad R_2 = \sum_{\text{all paths}} n_i \times n_j$$

From the definition we can see that the 2-type extended hyper-Wiener index R_2 is equal to the Wiener number.

Definition 3

The *m*th-order ($m \geq 2$) extended hyper-Wiener index of 2-type $^mR_2$ is the sum of contributions K_{ij}, where subscripts *i* and *j* denote a pair of vertices. K_{ij} may be obtained by using the following two-step algorithm: (*i*) Remove the path between vertices *i* and *j* (linear subgraph unit combinations of *m* atoms); two nonconnected subgraphs will be obtained. (*ii*) Multiply the number of vertices of the first subgraph by the number of vertices of the second one. $^mR_2$ may be obtained by adding K_{ij} for all linear subgraph unit combinations of *m* atoms.

From definition 2 and definition 3 we can see that R_2 is the sum of $^mR_2$, where $m = 2, 3, 4,...$.

A hierarchy of additional indexes of type n (R_n) can be obtained by summing analogous terms over substructural units involving 3 types, 4 types, 5 types, 6 types,..., just like definition 2.

A hierarchy of additional indexes of order *m* and type *n* (^mR_n) can be obtained by summing analogous terms over substructural units involving 3 types, 4 types, 5 types,..., combinations of *m* atoms, just like definition 3.

Example: for 2-methylbutane, the extended hyper-Wiener indexes ^mR_n can be calculated as follows:
$n = 1$: 1, 2, 3, 4, 5; $R_1 = 1 + 1 + 1 + 1 + 1 = 5$
$n = 2$: 1–2, 2–3, 3–4, 2–5, 1–5, 1–3, 3–5, 2–4, 1–4, 4–5;
$R_2 = 4 \times 1 + 3 \times 2 + 4 \times 1 + 4 \times 1 + 1 \times 1 + 1 \times 2$
$\qquad + 2 \times 1 + 3 \times 1 + 1 \times 1 + 1 \times 1 = 28$
$m = 2, n = 2$: 1–2, 2–3, 3–4, 2–5; $^2R_2 = 4 \times 1 + 3 \times 2 + 4$
$\qquad \times 1 + 4 \times 1 = 18$
$m = 3, n = 2$: 1–5, 1–3, 3–5, 2–4; $^3R_2 = 1 \times 1 + 1 \times 2 + 2$
$\qquad \times 1 + 3 \times 1 = 8$

$n = 3$: 1–3–5, 1–4–5; $R_3 = 1 \times 1 \times 2 + 1 \times 1 \times 1 = 3$
$m = 4$, $n = 3$: 1–3–5; $^4R_3 = 1 \times 1 \times 2 = 2$
$m = 5$, $n = 3$: 1–4–5; $^5R_3 = 1 \times 1 \times 1 = 1$

Quantitative structure–property relationships with the extended hyper-Wiener index

The potential of the extended hyper-Wiener for structure–property and structure–activity studies can be evaluated by performing comparative modeling of ref. 18 against the molecular connectivity index, the most widely used molecular descriptors in QSAR and (or) QSPR. In this study, we apply multiple regression analysis (MRA) in a QSPR modeling of four physical properties of C_3–C_8 alkanes. The properties are boiling point, bp, in °C; critical temperature, T, in °C; critical pressures, P, in atm; and surface tension, ST, in 0.1 µN/cm (Table 1) (19). The models of molecular connec-

tivity are taken from Bonchev (18); the best models have been selected by the computer program.

The extended hyper-Wiener indexes of the 38 molecules are shown in Table 2, and their physical properties are shown in Table 1. Table 3 summarizes the statistics (correlation coefficient r, standard deviation s, and the Fischer ration F) of the molecular connectivity and the overall Wiener index of the C_3–C_8 alkanes derived with five variables (18).

The best five-parameter, extended hyper-Wiener models obtained for the four examined alkane properties are given below.

[5] $bp = -128.57725 + 47.67585\ ^2R_2$

$- 103.72337\ ^3R_2 + 64.42522\ ^4R_2$

$- 12.5043\ ^5R_2 + 5.3353\ ^6R_2$

$n = 38$, $s = 1.70$, $F = 4394$, $r = 0.9996$

Table 2. The extended hyper-Wiener index of the 38 alkanes.

Discussion

A comparison of the statistical results in Table 3 shows that the extended hyper-Wiener indexes give good statistics for each of the properties, and the standard deviations provided by these three sets of indexes are rather close.

To verify the robustness of the models, a cross-validation procedure, leave-one-out, was performed, and the results are listed in Table 4.

From Table 4 we can see that the maximum, minimum, and mean values of the correlation coefficient r and the standard deviation s are rather close; this indicates that the four five-parameter models are more stable.

A random test was also performed to verify the predictive ability of the four five-parameter models. Five times the tests were performed altogether, each time one third (for the surface tension model, 8 samples were removed, while 13 samples were removed for the other models) of the samples were randomly removed as a test set with the 25 remaining samples as the training set. The statistical results of the training set and test set are listed in Table 5.

The mean values of the correlation coefficient r and standard deviation s of the training sets and test sets are rather close; this also indicates that the four five-parameter models have good predictive ability.

Results and conclusion

Upon summarizing the results, one may conclude that the extended hyper-Wiener indexes examined show a good potential for use in QSAR and QSPR studies. The results show that considerably better statistics are obtained when extending the hyper-Wiener index to the extended Hyper-Wiener Index. The extended hyper-Wiener indexes provided statistical results as the molecular connectivity index and the overall Wiener index in all models, and the standard deviations provided by these three sets of indexes are rather close. Moreover, it may provide a better way to apply the Wiener number and the hyper-Wiener index to the system of unsaturated hydrocarbons and organic compounds, including heteroatoms, according to the method of molecular connectivity index. This can extend the usefulness of the Wiener number and the hyper-Wiener index and can make them a kind of widely used topological index in practice.

It needs to be mentioned that this conclusion is drawn for linear-regression models; the comparison of nonlinear models remains open for later studies.

Preparation of benzocyclobutenols by low temperature reaction of ketone enolates with benzynes

Sasmita Tripathy, Ranga Reddy, and Tony Durst

Abstract: The reaction of benzynes, generated from halobenzenes with lithium tetramethylpipiperide (LTMP) at –40 to –78 °C, with ketone enolates affords benzocyclobutenols in fair to good yields.

Key words: benzyne, ketone enolates, anthracenes, benzocyclobutenol, alkoxides.

Résumé : Les benzynes, obtenues à partir des halobenzènes avec le tétraméyhylpipéridure de lithium (LTMP) dans un intervalle de température de –40 à –78 °C, réagissent avec des énolates de cétone pour conduire à des benzocyclobuténols avec des rendements allant de assez bons à bons.

Mots clés : benzyne, énolates de cétone, anthracènes, benzocyclobuténol, alcoolates.

[Traduit par la Rédaction]

Introduction

Benzocyclobutanols have considerable utility as precursors to *ortho*-quinodimethanes (1) and hence, for the preparation of a variety of polycyclic targets (2), including natural products (3). A number of routes exist for the preparation of these intermediates. These include: (*i*) photolysis of *o*-substituted phenyl alkyl ketones (4); (*ii*) reduction of or addition of organometallic reagents to benzocyclobutenones (5); (*iii*) cyclization of *ortho*- or iodo-substituted benzyl alkyl ketones (5); (*iv*) 2 + 2 cycloaddition of ketene equivalents to benzynes (6); and (*v*) trapping of benzynes with ketone enolates (7).

The latter reaction has been investigated extensively by the Caubere group (7) over a number of years using NaNH$_2$/*t*-BuOK in THF above room temperature to generate both the benzyne and the enolate. Under these conditions only a relatively small group of ketone enolates combine with benzyne to give isolable quantities of benzocyclobutenols. The most successful results were obtained with the enolates of five- to seven-membered ring ketones. We surmise that the explanation for the divergent behaviour is due to the difference in stability of the intermediate alkoxybenzocyclobutenes under the reaction conditions. Typically, the alkali metal alkoxides of benzocyclobutenols such as **1** are unstable at temperatures as low as –78 °C; they open, either by a cycloreversion to an *ortho*-quinodimethane **2** or revert to an aryllithium **3** (8). In the case of **1a**, the initial product of the cycloaddition of the enolate of cyclopentanone or cyclohexanone to benzyne, the concerted conrotatory cycloreversion pathway is very difficult since it results in the generation of a highly strained trans double bond in a seven- or eight-membered ring, respectively, i.e., **4** (Scheme 1).

The tendency for cycloreversion of benzocyclobutene alkoxides has been exploited synthetically (9). Olofson and co-workers (10) described the reaction of benzyne with the enolate of acetaldehyde followed by ring opening of the resultant intermediate **1** (R = R$_1$ = H) to **5**. This step is followed by a second trapping reaction with benzyne thereby yielding a series of symmetrical anthracenes. Unsymmetrical anthracenes were formed starting with the benzocyclobutanol **6**, LTMP, and a halobenzene (10) (Scheme 2).

Choy and Yang (8) showed that the lithium salt of *trans*-2-phenylbenzocyclobutenol undergoes cycloreversion at –78 °C. Trapping of this intermediate with dimethyl maleate or dimethyl fumarate gave the expected tetrahydronaphthalenes mainly with retention of the alkene configuration.

Results and discussion

We have reported that benzyne generation can be carried out at –40 °C to –78 °C with LTMP starting with iodo- and bromobenzene, respectively. When benzyne generation is carried out at these temperatures in the presence of a variety of ketone or enolates, the expected benzocyclobutenols can be isolated, generally in at least fair yield (eq. [1]). Typically, 10–40% of the starting ketone was recovered when equimolar amounts of the ketone enolate and bromobenzene were used (Table 1). The use of chlorobenzene as the benzyne precursor compared with bromo-or iodobenzene improved the yield of the benzocyclobutanol **7a** (R$_1$ = Ph, R$_2$ = H) with yields being 35, 28, and 15%, respectively. In each instance about 40% of the starting ketone was recov-

Scheme 1.
Scheme 2.
Table 1. Synthesis of 1-arylbenzocyclobutenols.
Entry	R	S	Yield (%)	Recovered ketone (%)
7a	H	H	35	39
7b	CH$_3$	H	57	40
7c	C$_2$H$_5$	H	36	16
7d	Ph	H	52	12
7e	H	4-OCH$_3$	41	14
7f	H	3,4-OCH$_3$	42	12

ered. An increase in the benzyne precursor (chlorobenzene) to enolate ratio from 1:1 to 2:1 improved the yield of **7a** from 38 to 55%. In addition to the benzocyclobutanols **7** and some recovered ketones, approximately 5% of the 9-

phenylanthracenes could also be isolated. These compounds (R$_1$ = H, CH$_3$, C$_2$H$_5$) are formed via the same mechanism as is shown for the anthracenes in Scheme 2.

The stereochemistry of the benzocyclobutanol **7b** was assigned as shown on the basis of nOe experiments. Irradiation of the quartet at $\delta = 3.8$ due to the remaining benzylic hydrogen showed enhancement of the signal for the methyl group at $\delta = 1.5$, but had no effect on the O-H group at $\delta = 2.9$. An nOe effect on the nearby aromatic signals was observed. In contrast, irradiation of the methyl signal augmented significantly those of the O-H, the benzylic methine, and the nearby aromatic hydrogens. Finally, irradiation of the O-H peak caused a strong enhancement on the methyl signal but had almost no effect on the benzylic methine hydrogen. The observed stereochemistry is reasonable on mechanistic grounds since the transition state from the intermediate **9** leading to **7b** should be preferred for steric reasons over the alternate possibility commencing with **10**. The stereochemistry of the other benzocyclobutenols carrying two ad-

ditional substituents on the cyclobutene ring is assumed to be the same as **7b** with the non-hydrogen substituent at C-2 being cis to the hydroxyl group.
1-Phenylbenzocyclobutenols, predictably substituted in either or both aromatic rings, were also prepared. Thus, compounds **11a** and **11b** were obtained using 2-methoxy-bromobenzene as the benzyne precursor, together with the appropriate enolate.

Not surprisingly, the yields of the tricyclic benzo-cyclobutenols **12a–12c**, obtained from the trapping of benzynes with the enolates of cyclic ketones, were better than those observed in the above described examples. The best result, an 82% isolated yield of **12c**, was obtained with the enolate of cycloheptanone. The cyclobutenols **12a** and **12b** were obtained in 65 and 55% yield, respectively. In the latter cases, the monosubstitution products **13a** and **13b** were also isolated.

Trapping of benzyne with the enolate **14**, obtained from THP-protected 2-hydroxyacetophenone gave the expected benzocyclobutenol **15** in 94% yield based on 14% recovered starting material; acid-catalyzed hydrolysis afforded the cis

diol **16**. In contrast, the enolates of noncyclic aliphatic ketones such as 3-pentanone gave only 24% yield of the desired product **17**, the minor product being 2-phenyl-3-pentanone **18**, the result of arylation of the enolate.

We were disappointed that the aldehyde enolates reacted much less cleanly with benzynes under our reaction conditions. Examination of the crude products obtained with aldeyhdes such as hexanal and cyclohexanecarboxaldehyde showed the formation of numerous products (NMR peaks in the spectrum of the crude products possibly representing the desired product indicated a yield of less than 15%). These mixtures were not further investigated.

Summary

The method described in this paper constitutes a simple route to benzocyclobutenols, in particular 1-arylbenzocyclobutenols and the tricyclic derivatives **12**. Since treatment of **7a** with NaBH$_4$/TFA–AcOH afforded cleanly the benzoclobutene **19** in 59% yield, the reaction of benzynes with the enolates of aryl alkyl ketones can also lead to 1-arylbenzocyclobutenes.

Experimental

General procedure for the generation of benzynes in the presence of ketone and aldehyde enolates

t-BuLi in hexane (7.95 mmol) was added dropwise to a stirred solution of tetramethylpiperidine (7.95 mmol) in anhyd THF (10 mL) under nitrogen at –40 °C. The mixture was stirred for 10 min and a solution of ketone (3.18 mmol) in THF (5 mL) was added. This was followed by the addition of solution of halobenzene (3.18 mmol) in THF (5 mL). The reaction mixture was stirred at –40 °C for 5 h. An aqueous ammonium chloride solution was added and the resulting solution was extracted with ethyl acetate. The combined organic extracts were washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by chromatography on silica gel with EtOAc–hexanes to give the benzocyclobutenol.

1-Phenylbenzocyclobutenol (7a) (11)

Yield: 32%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 3.38 (s, 1H), 3.60 (ABq, 2H), 7.20–7.58 (m, 9H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 50.4, 82.1, 122.3, 124.8, 126.3, 128.1, 128.3, 128.9, 130.3, 134.4, 142.7, 144.1, 149.7. HR-MS calcd. for $C_{14}H_{12}O$ m/z: 196.0888; found: 196.0861.

cis-2-Methyl-1-phenylbenzocyclobutenol (7b)

Yield: 35%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.51 (d, J = 8.0 Hz, 3H), 2.61 (s, 1H), 3.81 (q, J = 8.0 Hz, 1H), 7.21–7.45 (m, 9H). 6-Methoxy-cis-2-ethyl-1-phenylbenzocyclobutenol (11a)

Yield: 36%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.13 (t, J = 7.4 Hz, 3H), 1.61–1.99 (m, 2H), 2.65 (s, 1H), 3.45 (t, J = 8.0 Hz, 1H), 3.71 (s, 3H), 6.80 (t, J = 8.4 Hz, 1H), 7.21–7.49 (m, 6H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 13.5, 24.1, 58.2, 60.1, 83.5, 115.5, 116.2, 126.1, 128.2, 128.4, 132.2, 146.1, 150.1, 152.1, 156.2. HR-MS calcd. for $C_{17}H_{18}O_2$ m/z: 254.13074; found: 254.13061.

6-Methoxy-1-(3,4-dimethoxyphenyl)benzocyclobutenol (11b)

Yield: 55%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 3.40 (s, 1H), 3.42 (s, 2H), 3.63 (s, 3H), 3.80 (s, 6H), 6.75 (m, 3H), 6.90 (d, J = 8.8 Hz, 1H), 7.08 (s, 1H), 7.22 (t, J = 8.8 Hz, 1H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 50.1, 55.7, 56.6, 80.9, 108.9, 110.6, 113.0, 116.2, 117.6, 131.2, 133.2, 137.1, 143.6, 148.0, 148.6, 157.3. HR-MS calcd. for $C_{17}H_{18}O_4$ m/z: 286.1205; found: 286.1190.

Tricyclo (4,3,0,0) hydroxy-1-nonadecatriene-2,4,6 (12a) (12d)

Yield: 65%, mp 56 to 57 °C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.01–1.29 (m, 1H), 1.56–1.89 (m, 4H), 2.10 (m, 1H), 1.65 (brs, 1H), 3.51 (t, J = 1.6 Hz, 1H), 7.11–7.39 (m, 4H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 25.1, 29.1, 36.3, 57.6, 89.8, 121.4, 123.6, 128.5, 130.2, 144.4, 148.3.

2-Phenylcyclopentanone (13a) (12e)

^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.81–2.61 (m, 6H), 3.51 (t, J = 8.0 Hz, 1H), 7.21–7.49 (m, 5H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 22.1, 32.1, 38.5, 56.1, 128.1, 129.4, 129.9, 140.1.

Tricyclo (4,4,0,0) hydroxy-1-dodecatriene-2,4,6 (12b) (12a–12c)

Yield: 55%, mp 106–108 °C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.11–2.11 (m, 8H), 2.29 (brs, 1H), 3.39 (t, J = 7.6 Hz, 1H), 7.10–7.35 (m, 4H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 18.0, 18.4, 24.3, 32.1, 54.2, 79.6, 121.6, 123.7, 128.1, 129.7, 146.1, 149.9. HR-MS calcd. for $C_{12}H_{14}O$ m/z: 174.1045; found: 174.1071.

2-Phenylcyclohexanone (13b) (12e)

Yield: 20%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.71–2.61 (m, 8H), 3.61 (dd, J = 8.0, 16.0 Hz, 1H), 7.11–7.49 (m, 5H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 25.9, 28.4, 35.7, 42.8, 58.0, 127.5, 128.9, 129.1, 139.3, 210.0. HR-MS calcd. for $C_{12}H_{14}O$ m/z: 174.1045; found: 174.1057.

Tricyclo (4,5,0,0) hydroxy-1-tridecatriene-2,4,6 (12c) (12a–12c)

Yield: 82%. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 1.31–2.21 (m, 10H), 2.70 (s, 1H), 3.41 (dd, J = 4.5, 10.0 Hz, 1H), 7.10–7.31 (m, 4H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 24.8, 28.1, 31.4, 32.6, 36.8, 60.8, 84.2, 121.4, 123.5, 128.0, 129.7, 146.3, 149.8.

Compound 15

t-BuLi in hexane (4.68 mL, 7.96 mmol) was added dropwise to a stirred solution of tetramethylpiperidine (1.34 mL, 7.96 mmol) in anhyd THF (10 mL) under nitrogen at –40 °C. The mixture was stirred for 10 min and a solution of 2-*O*-tetrahydropyranoyl acetophenone (0.70 g, 3.18 mmol) in THF (5 mL) was added. This was followed by the addition of a solution of bromobenzene (0.50 g, 3.18 mmol) in THF (5 mL). After being stirred for 5 h at –40 °C, the reaction mixture was quenched by the addition of NH_4Cl solution and the mixture was allowed to warm to room temperature. The resulting solution was extracted with ethyl acetate, and the combined organic solutions were washed with brine, dried over Na_2SO_4, and evaporated. The residue was purified by chromatography on silica gel with 8% EtOAc–hexanes to afford **15** in 94% yield. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.5–2.0 (m, 6H), 3.52 (m, 1H), 4.0 (m, 1H), 4.55 (s, 1H), 4.70 and 4.90 (2m, 1H), 5.12 and 5.28 (2s, 1H), 7.10–7.50 (m, 9H).

1-Phenyl-cis-benzocyclobuten-1,2-diol (16)

To a stirred solution of **15** (0.27 g, 0.94 mmol) in 5 mL of methanol was added CSA (30 mg) and the reaction mixture was stirred for 30 min. Methanol was evaporated and the residue was extracted with ethyl acetate, washed with satd. $NaHCO_3$ solution, dried over Na_2SO_4, and evaporated. The residue was purified by chromatography on silica gel with 40% EtOAc–hexanes to afford **16** in 91% yield, mp 128–130 °C. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.12, 3.40 (2bs, OH), 5.20 (s, 1H), 7.20–7.40 (m, 9H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 80.8, 83.7, 123.5, 124.7, 126.1, 128.2, 128.9, 130.7, 131.1, 142.8, 146.7, 148.9. HR-MS calcd. for $C_{14}H_{12}O_2$ *m/z*: 212.08376; found: 212.8368.

cis-2-Ethyl-1-methylbenzocyclobutenol (17)

Yield: 24%. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.15 (t, *J* = 7.36 Hz, 3H), 1.30 (d, *J* = 7.22 Hz, 3H), 1.62–1.82 (m, 2H), 2.20 (brs, 1H), 3.44 (q, *J* = 7.19 Hz, 1H), 7.13–7.28 (m, 4H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 8.4, 13.8, 27.6, 53.4, 82.7, 121.5, 122.6, 127.2, 129.2, 146.7, 148.7. HR-MS calcd. for $C_{11}H_{14}O$ *m/z*: 162.1045; found: 162.1036.

1-Phenylbenzocyclobutene (19) (13)

To a solution of glacial acetic acid (6 mL) and trifluoroacetic acid (6 mL) at 0 °C was added sodium borohydride (0.59 g, 10 equiv). The benzocyclobutanol **7a** (0.31 g, 1.58 mmol) in CH_2Cl_2 (10 mL) was immediately added and stirred for 2 min followed by the rapid addition of sidium borohydride (0.30 g, 5 equiv). The solution was stirred for 5–10 min and diluted with H_2O (40 mL) and extracted with CH_2Cl_2 (3 × 25 mL), dried over Na_2SO_4, and evaporated. The residue was purified by chromatography on silica gel with 3% EtOAc–hexanes to afford **19** in 59% yield. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.28 (dd, *J* = 2.85, 13.78 Hz, 1H), 3.90 (dd, *J* = 5.37, 13.78 Hz, 1H), 4.87 (dd, *J* = 2.85, 5.37 Hz, 1H), 7.32–7.54 (m, 9H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 40.1, 47.6, 122.9, 123.4, 126.6, 127.1, 127.3, 127.8, 128.6, 142.9, 144.2, 147.8. HR-MS calcd. for $C_{14}H_{12}$ *m/z*: 180.0939; found: 180.0928.

Novel synthesis of a highly functionalized cyclopropane derivative

Stéphane Trudeau and Pierre Deslongchamps

Abstract: A model study was carried out to explore the feasibility of synthesizing fused tricyclic ring structures containing a C_7—C_8 double bond juncture (steroid numbering) by employing an S_N2' cyclization of a silyl enol ether to displace an allylic acetate as the key step. Instead of the anticipated product, highly functionalized cyclopropanes were obtained. These novel cyclopropane structures are the result of the concomitant 1,2-migration of a dithiane thioether moiety and the eventual displacement of the acetate group, followed by the cyclization of the silyl enol ether.

Key words: tricycles, S_N2' cyclization, inductive effect, cyclopropane.

Résumé : Une étude modèle a été réalisée pour vérifier la possibilité de produire des tricycles possédant une double liaison entre les carbones C_7 et C_8 (numérotation des stéroïdes) par une réaction de cyclisation S_N2' entre un éther d'énol silylé et un acétate allylique comme étape clé. Or, une réaction inattendue s'est produite pour conduire à la synthèse de cyclopropanes hautement fonctionnalisés au lieu du produit attendu. Cela étant le résultat d'une cyclisation entre un éther d'énol silylé sur un groupement dithiane où l'un des thioéthers a subi une migration-1,2 tout en déplaçant le groupement acétate partant.

Mots clés : tricycles, cyclisation S_N2', effet inductif, cyclopropane.

Introduction

More than 25 years ago, Nozaki and co-workers (1) studied cationic cyclization of allylic acetates via nucleophilic participation of silyl enol ether. In light of this study, we recently conducted a model study to investigate the possibility of using an S_N2'-type cyclization of a silyl enol ether to displace an allylic acetate to generate C_7–C_8 (steroid numbering) unsaturated fused tricyclic ring structures (cf. **1**, Fig. 1). In model structures containing a sulfone moiety (X = SO_2Ph, Y = H) or a methylene group (X = Y = H) next to the acetate leaving group no cyclization occurred. In contrast, when the model compound was decorated with a dithiane functionality (X, Y = S-$(CH_2)_3$-S) adjacent to the acetate leaving group, instead of obtaining the anticipated product **1** (Fig. 1), the unexpected formation of a highly functionalized cyclopropane was observed (cf. **2**, Fig. 1). The details of this investigation are disclosed herein.

Results and discussion

The use of a sulfone connector for the coupling of rings A and C was explored initially. The intermediate **7** was synthesized starting from the commercially available (*R*)-(–)-

carvone. Thus, Michael addition of phenylthiomethyl phenyl sulfone (2, 3) and trapping of the attendant enolate with *tert*-butyldimethylsilyl trifluoromethanesulfonate furnished thioether **4** (Scheme 1). It is noteworthy that the presence of the thioether moiety in the nucleophile was necessary to achieve exclusive 1,4-addition. Thioether **4** was then subjected to *n*-Bu$_3$SnH–AIBN reduction in refluxing benzene to obtain sulfone **5**. Deprotonation of sulfone **5** with *n*-BuLi, followed by alkylation with the commercially available reagent, 1-cyclohexene-1-carboxaldehyde, afforded the alcohol **6**. The latter product was then acylated with acetic anhydride and catalytic DMAP in pyridine to yield the acetate **7**. All attempts to procure the ABC-fused tricyclic structure, **8**, using the acetate **7** were in vain. For instance, in protic acidic medium, Lewis acid medium, or under anionic conditions, only deprotection of the silyl enol ether was observed. Even with palladium, the formation of the π-allyl palladium species was not observed, and only starting material was recovered instead. It may therefore be concluded that the inductive effect of the sulfonyl group prohibits the solvolysis of the acetate, thus precluding the formation of the π-allyl cation that would have been trapped by the silyl enol ether.

To circumvent the obstacle encountered with the sulfonyl group, alcohol **6** was oxidized with TPAP–NMO in dichloromethane in the presence of 4 Å molecular sieves to produce the ketosulfone **9** (Scheme 2). Subsequent desulfurization with *n*-Bu$_3$SnH–AIBN in refluxing toluene yielded ketone **10** (4), which was immediately converted to the corresponding alcohol using Luche reduction conditions (NaBH$_4$–CeCl$_3$ in methanol). The alcohol thus obtained was then acylated with acetic anhydride – DMAP (catalytic) in pyridine to obtain the acetate **11**. To our dismay, all efforts directed at effecting cyclization of the precursor acetate **11** to form **12**

S. Trudeau and P. Deslongchamps.[1] Laboratoire de synthèse organique, Département de Chimie, Institut de Pharmacologie de Sherbrooke, Université de Sherbrooke, 3001, 12e Avenue nord, Sherbrooke, QC J1H 5N4, Canada.

were unsuccessful. Exclusive deprotection of the silyl enol ether occurred in most cases (acidic medium as well as anionic conditions). With palladium species, only starting material was recovered. On the basis of the above studies, it can be concluded that even in absence of the inductive effect of the sulfonyl group, the acetate group is reluctant to leave and thereby induce cyclization.

Recently, Saigo and co-workers (5) reported that allylic acetates with a thioether as a neighboring group can undergo

S$_N$2′ coupling with silyl enol ether in the presence of a Lewis acid. Keeping this in mind, the synthesis of acetate **17** was then undertaken, starting from the commercially available 1,3-dithiane **13** (Scheme 3). Deprotonation of the latter with LDA and trapping of the attendant anion with *n*-Bu$_3$SnCl furnished stannane **14** in quantitative yield (6). Deprotonation of intermediate **14** with LDA followed by a 1,4-Michael addition with (*R*)-(–)-carvone and trapping of the resultant enolate with *tert*-butyldimethylsilyl trifluoromethanesulfonate in the presence of triethylamine yielded compound **15**. Transmetallation of the stannyl moiety in **15** with *n*-BuLi, followed by alkylation with 1-cyclohexene-1-carboxaldehyde, afforded alcohol **16** in a 3:1 diastereomeric ratio. The alcohol **16** was then acylated with acetic anhydride – DMAP (catalytic) in pyridine to provide the acetate **17** (3:1 diastereomeric mixture). With acetate **17** in hand, a preliminary attempt was made to induce the S$_N$2′ cyclization using *p*-TSA in benzene. The neighboring group participation induced by the dithiane helped the departure of the acetate group, furnishing compound **18** in 64% yield. Thus,

Scheme 3. (*a*) *i.* LDA, THF; *ii.* n-Bu₃SnCl (quant.); (*b*) *i.* LDA, THF; *ii.* (*R*)-(−)-carvone, HMPA; *iii.* TBS-OTf, Et₃N (88%); (*c*) *i.* n-BuLi, THF *ii.* 1-cyclohexene-1-carboxaldehyde (75%) (ratio of diastereoisomers = 3:1); (*d*) Ac₂O, DMAP, pyridine (79%); (*e*) *p*-TSA, PhH (64%); (*f*) TMS-OTf, CH₂Cl₂ (77%) (ratio **2a**:**2b**:**18**:**19** = 3:1:1.2:1.5); (*g*) LiAlH₄, THF (71%) (ratio of diastereoisomers = 7.5:1); (*h*) 4-nitrobenzoyl chloride, DMAP, pyridine, CH₂Cl₂ (40%).
hydrogen abstraction and formation of a double bond induced a net 1,2-migration of a thioether. The structure of compound **18** was assigned by spectral analysis, including DEPT NMR studies. A similar 1,2-migration of a thioether has also been recently reported by Kutateladze and co-workers (7).

We next explored the possibility of effecting the S_N2' cyclization under Lewis acid conditions. To our great surprise, however, when acetate **17** was treated with trimethylsilyl trifluoromethanesulfonate in dichloromethane at −78 °C, cyclopropane **2** was obtained in 46% yield as a separable 3:1 mixture of two diastereoisomers. Compounds **18** and **19** were also isolated from the reaction mixture (14% and 17%

yield, respectively). Again, it can be surmised that the dithiane facilitated the departure of the acetate group in compounds **17a** and **17b** to form intermediate **21a** and **21b** as sulfonium cations (Fig. 2). These sulfonium cations could then rearrange to intermediates **22a** and **22b** and, thereby, induce a net 1,2-migration of a thioether moiety. Thus, the silyl enol ether participates in a C—C bond formation at C_6 in a Mukaiyama thio-aldol fashion instead of promoting cyclization at C_9 in an S_N2' manner, contrary to our initial expectations. Moreover, it can be presumed that the Mukaiyama thio-aldol process was stereoselective, as the diastereoisomeric composition in cyclopropane products was identical to that in the acetate starting material. The structure

Fig. 2. Proposed mechanism for formation of cyclopropanes **2a** and **2b**.
of the major diastereoisomer **2a** was assigned by single-crystal X-ray diffraction crystallography of the benzoate **20** (Fig. 3).[2] This product was prepared from compound **2a**, which was reduced with LiAlH$_4$ in THF to give two diastereoisomers (7.5:1) that were readily separable by flash chromatography on silica gel. The major diastereoisomer was subsequently acylated, using 4-nitrobenzoyl chloride – DMAP (catalytic) – pyridine in dichloromethane, to provide **20**.

Experimental

General

All reactions were performed under N$_2$ atmosphere with flame-dried glassware. Solvents were distilled and dried according to standard procedures. Analytical TLC were performed on precoated glass plates (0.25 mm) with silica gel 60F-250 (Merck). Flash-chromatography was performed with 230–400 mesh gel 60 (Merck). ^{1}H and ^{13}C NMR spectra were recorded on a Brüker AC-300 and are referenced with respect to the residual signals of the solvent; they are described using standard abbreviations. IR spectra were recorded on a PerkinElmer 1600 FT-IR. Mass spectra were recorded on a ZAB-1F micromass spectrometer.

Thioether (4)

To a solution of phenylthiomethyl phenyl sulfone (2, 3) (0.55 g, 2.1 mmol) in THF (27.0 mL) cooled to –78 °C was added n-butyllithium (1.24 mol·L^{-1} in hexane) (1.7 mL, 2.1 mmol). The solution was stirred for 1 h at –78 °C, then (R)-(–)-carvone (0.26 g, 1.7 mmol) in THF (6.0 mL) was added. The mixture was stirred for 2 h at –78 °C before *tert*-butyldimethylsilyl trifluoromethanesulfonate (1.2 mL, 5.2 mmol) was added. The mixture was stirred for another

0.75 h, and then triethylamine (1.2 mL, 8.7 mmol) was added. The mixture was warmed to room temperature, stirred for 0.15 h, poured into a saturated aqueous solution of NaHCO$_3$ (30 mL), and extracted with ether (3 × 30 mL). The combined organic phases were washed with brine (100 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 8:2) to give the thioether **4** (0.97 g, quantitative) as a pale yellow oil (mixture of diastereoisomers). [α]$_D$ = +63.51° (c 1.71, CHCl$_3$). IR (film, cm^{-1}) ν: 3476, 3063, 2955, 2857, 1710, 1583, 1472, 1448, 1307, 1255, 1148, 1083, 836, 741, 688. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 7.92 (2H, m, H arom. ortho to SO$_2$R), 7.58 (1H, m, H arom. para to SO$_2$R), 7.46 (2H, m, H arom. meta to SO$_2$R), 7.14 (2H, m, H arom. ortho to SR), 7.07 (2H, m, H arom. meta to SR), 6.96 (1H, m, H arom. para to SR), 4.73 and 4.64 (2H, 2d, J = 17.9 and 35.5 Hz, (CH$_3$)C=CH_2), 4.30 (1H, dd, J = 37.0 and 2.0 Hz, PhSO$_2$-CH-SPh), 3.29 (1H, m), 3.00 (1H, m), 2.38–1.78 (4H, m), 1.77 and 1.63 (3H, 2s, (CH_3)C=CH$_2$), 1.60 and 1.42 (3H, 2s, TBSO-C=C-CH_3), 0.95 (9H, m, (CH_3)$_3$-C-Si), 0.13 (6H, m, (CH_3)$_2$-Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 148.1, 147.9, 147.1, 138.4, 137.7, 134.3, 133.7, 133.6, 132.3, 131.8, 129.8, 129.4, 129.1, 129.0, 128.8, 127.9, 112.8, 111.0, 109.5, 109.3, 107.8, 105.2, 80.2, 76.4, 39.9, 38.2, 37.8, 37.7, 36.2, 35.4, 34.4, 28.7, 27.2, 26.0, 25.8, 25.8, 25.6, 22.6, 21.2, 20.2, 18.2, 18.0, 16.6, 14.2, –3.5, –3.6. EI-MS: 528 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{29}$H$_{40}$O$_3$S$_2$Si: 528.2188; found: 528.2184.

Sulfone (5)

To a solution of thioether **4** (1.1 g, 2.0 mmol) in benzene (52.0 mL) was added tributyltin hydride (1.1 mL, 4.3 mmol) and AIBN (0.033 g, 0.20 mmol). N$_2$ was bubbled for 0.1 h

Fig. 3. Single-crystal X-ray structure of cyclopropane **20**.
into the solution to exclude O_2. The solution was then heated at reflux for 2 h, cooled to room temperature, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 9:1) to give the sulfone **5** (0.69 g, 87%) as a clear oil. $[\alpha]_D = +26.56°$ (*c* 1.51, CHCl$_3$). IR (film, cm^{-1}) ν: 2930, 2858, 1683, 1472, 1447, 1306, 1253, 1197, 1150, 1087, 1064, 929, 837. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 7.93 (2H, m, *H* arom. ortho to SO$_2$R), 7.61 (3H, *H* arom. meta and para to SO$_2$R), 4.71 (3H, d, *J* = 17.0 Hz, (CH$_3$)C=C*H*$_2$), 3.10 (2H, m, -C*H*$_2$-SO$_2$Ph), 2.64 (1H, s), 2.21 (1H, m), 2.00 (3H, m), 1.69 (3H, s, (C*H*$_3$)C=CH$_2$), 1.49 (1H, td, *J* = 13.0 and 5.0 Hz), 1.40 (3H, s, TBSO-C=C-C*H*$_3$)), 0.91 (9H, s, (C*H*$_3$)$_3$-C-Si), 0.08 (6H, s, (C*H*$_3$)$_2$-Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 147.9, 145.7, 139.6, 133.6, 129.3, 128.0, 110.9, 109.7, 105.2, 58.1, 37.0, 35.3, 34.7, 31.3, 25.7, 20.8, 18.2, 14.2, –3.7, –3.8. EI-MS: 420 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{23}$H$_{36}$O$_3$SSi: 420.2154; found: 420.2151.

Alcohol (6)

To a solution of sulfone **5** (0.14 g, 0.32 mmol) in THF (2.0 mL) at –78 °C was added *n*-butyllithium (1.24 mol·L^{-1} in hexane) (0.26 mL, 0.32 mmol). The solution was stirred for 1 h at –78 °C and then 1-cyclohexene-1-carboxaldehyde (0.033 mL, 0.29 mmol) was added. The mixture was stirred for 2.5 h and was slowly warmed to –50 °C. It was then poured into a saturated aqueous solution of NH$_4$Cl (4 mL)

and extracted with ether (3 × 5 mL). The combined organic phases were washed with brine (15 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 9:1 to 7:3) to give the alcohol **6** (0.095 g, 61%) as a pale yellow oil (mixture of diastereoisomers). $[\alpha]_D = +34.76°$ (*c* 1.03, CHCl$_3$). IR (film, cm^{-1}) ν: 3491, 2931, 2858, 1682, 1447, 1302, 1176, 1140, 1083, 1056, 913, 834, 731. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 7.89 (2H, m, *H* arom. ortho to SO$_2$R), 7.53 (3H, m, *H* arom. meta and para to SO$_2$R), 5.77 (1H, s, *H*C=C-CH-OH), 4.71 (2H, d, *J* = 33.5 Hz, (CH$_3$)C=C*H*$_2$), 4.66 (1H, d, *J* = 12.5 Hz, C*H*-OH), 3.70 (1H, dd, *J* = 8.5 and 3.0 Hz, C*H*-SO$_2$Ph), 3.00 (1H, d, *J* = 4.5 Hz, CH-O*H*), 2.56 (2H, s), 2.26 (2H, m), 2.00 (4H, m, C*H*$_2$-CH=C-C*H*$_2$), 1.78 (1H, qu, *J* = 6.5 Hz), 1.71 (3H, s, (C*H*$_3$)C=CH$_2$), 1.63 (1H, m), 1.55 (3H, s, TBSO-C=C-C*H*$_3$), 1.46 (4H, m, C*H*$_2$-CH$_2$-CH=C-CH$_2$-C*H*$_2$), 0.94 (9H, s, (C*H*$_3$)$_3$-C-Si), 0.15 (6H, d, *J* = 10 Hz, (C*H*$_3$)$_2$-Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 147.2, 144.5, 142.9, 136.3, 133.0, 128.6, 128.1, 127.7, 109.6, 109.4, 75.9, 67.9, 37.7, 37.7, 34.2, 28.0, 25.8, 25.1, 22.9, 22.2, 22.1, 21.7, 18.1, 14.5, –3.6. EI-MS: 530 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{30}$H$_{46}$O$_4$SSi: 530.2886; found: 530.2894.

Acetate (7)

Acetic anhydride (0.068 mL, 0.72 mmol) and DMAP (0.012 g, 0.10 mmol) were added to a solution of the alcohol

6 (0.26 g, 0.48 mmol) in pyridine (5.0 mL). The solution was stirred for 2 h at room temperature, neutralized with HCl 1 N (5 mL) at 0 °C, and extracted with ethyl acetate (3 × 5 mL). The organic phase was washed with brine (20 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 8:2 to 7:3) to yield acetate **7** (0.25 g, 92%) as a clear oil (mixture of diastereoisomers). [α]$_D$ = +13.98° (*c* 1.18, CHCl$_3$). IR (film, cm^{-1}) ν: 2930, 2858, 1747, 1682, 1447, 1306, 1229, 1177, 1144, 913, 832, 730. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 7.80 (2H, dd, *J* = 8.0 and 1.2 Hz, *H* arom. ortho to SO$_2$R), 7.52 (3 H, m, *H* arom. meta and para to SO$_2$R), 5.91 (1H, s, C*H*=C-(C=O)), 5.74 (1H, d, *J* = 10.1 Hz, C*H*-OAc), 4.72 (2H, d, *J* = 30.5 Hz, (CH$_3$)C=C*H*$_2$), 4.00 (1H, dd, *J* = 10.1 and 2.2 Hz, C*H*-SO$_2$Ph), 2.64 (1H, m), 2.57 (1H, m), 2.42–2.24 (2H, m), 2.00 (4H, m, C*H*$_2$-CH$_2$-CH=C-CH$_2$-C*H*$_2$), 1.85 (1H, m), 1.80 (3H, s, CH-O(C=O)-C*H*$_3$), 1.74 (1H, m), 1.71 (3H, s, (C*H*$_3$)C=CH$_2$), 1.50 (4H, m, C*H*$_2$-CH=C-C*H*$_2$), 1.43 (3H, s, TBSO-C=C-C*H*$_3$), 0.95 (9H, m, (C*H*$_3$)$_3$C-Si), 0.17 (6H, d, *J* = 10.0 Hz, (C*H*$_3$)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 168.6, 147.2, 144.0, 143.8, 132.7, 132.1, 131.5, 128.9, 126.9, 109.9, 109.4, 77.8, 64.1, 37.6, 37.1, 34.4, 26.9, 25.9, 25.1, 22.8, 22.1, 21.9, 20.8, 18.1, 14.2, –3.7, –3.8. EI-MS: 572 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{32}$H$_{48}$O$_5$SSi: 572.2992; found: 572.3000.

Ketosulfone (9)

To a solution of alcohol **6** (0.49 g, 0.92 mmol) in dichloromethane (9.2 mL) was added 4 Å molecular sieves (0.92 g), 4-methylmorpholine *N*-oxide (0.22 g, 1.9 mmol), and tetrapropylammonium perruthenate (0.032 g, 0.090 mmol). The mixture was stirred for 0.5 h at room temperature, and the solvent was then concentrated under reduced pressure. Ether (10 mL) was added, and the mixture was filtered through a silica gel pad. The pad was rinsed with ether (10 mL), and the combined flitrates were concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 9:1 to 7:3) to give the ketosulfone **9** (0.30 g, 60%) as a pale yellow oil. [α]$_D$ = +78.64° (*c* 1.03, CHCl$_3$). IR (film, cm^{-1}) ν: 2931, 2859, 1663, 1633, 1448, 1321, 1255, 1196, 1146, 1083, 921, 840. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 7.89 (2H, m, *H* arom. ortho to SO$_2$R), 7.57 (1H, m, *H* arom. para to SO$_2$R), 7.47 (2H, m, *H* arom. meta to SO$_2$R), 6.70 (1H, t, *J* = 4.0 Hz, C*H*=C-(C=O)), 4.96 (1H, d, *J* = 10.1 Hz, C*H*-SO$_2$Ph), 4.79 (2H, m, (CH$_3$)C=C*H*$_2$), 3.11 (1H, m), 2.69 (1H, m), 2.61 (1H, d, *J* = 13.6 Hz), 2.12 (6H, m), 1.79 (3H, s, (C*H*$_3$)C=CH$_2$), 1.58 (1H, td, *J* = 13.0 and 4.4 Hz), 1.42 (4H, m, C*H*$_2$-CH=C-C*H*$_2$), 1.25 (3H, s, TBSO-C=C-C*H*$_3$), 0.88 (9H, s, (C*H*$_3$)$_3$C-Si), 0.04 (6H, d, *J* = 12.6 Hz, (C*H*$_3$)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 193.2, 148.2, 147.5, 142.6, 140.5, 138.7, 133.6, 129.9, 128.6, 111.6, 109.6, 70.7, 41.2, 37.0, 35.1, 31.1, 26.3, 25.7, 23.2, 21.5, 21.1, 20.5, 18.1, 17.4, –3.7, –3.8. EI-MS: 528 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{30}$H$_{44}$O$_4$SSi: 528.2729; found: 528.2722.

Ketone (10)

To a solution of ketosulfone **9** (0.29 g, 0.54 mmol) in toluene (5.4 mL) was added tributyltin hydride (0.58 mL,

2.16 mmol). N$_2$ was bubbled for 5 min into the solution to exclude O$_2$. The solution was then heated at reflux, and AIBN (0.060 g, 0.37 mmol) was added. The solution was heated at reflux 5 min, and then a second portion of AIBN (0.037 g, 0.12 mmol) was added. The solution was heated at reflux another 10 min, cooled to room temperature, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 10:0 to 8:2) to give the enone **10** (0.23 g, quantitative) as a clear liquid. [α]$_D$ = +19.46° (*c* 1.12, CHCl$_3$). IR (film, cm^{-1}) ν: 2929, 2858, 1661, 1463, 1378, 1252, 1174, 1072, 926, 837. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 6.89 (1H, m, C*H*=C-(C=O)), 4.71 (2H, m, (CH$_3$)C=C*H*$_2$), 2.69 (2H, s, C*H*$_2$-(C=O)), 2.32 (1H, m), 2.24 (4H, m), 2.03 (1H, m), 1.70 (3H, s, (C*H*$_3$)C=CH$_2$), 1.76–1.24 (8H, m), 1.50 (3H, s, TBSO-C=C-C*H*$_3$), 0.95 (9H, m, (C*H*$_3$)$_3$C-Si), 0.13 (6H, s, (C*H*$_3$)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 201.2, 148.9, 143.9, 139.7, 113.7, 109.0, 40.0, 37.4, 35.8, 35.6, 31.9, 27.8, 26.8, 26.1, 25.8, 23.2, 22.0, 21.5, 17.5, 13.6, –3.7, –3.9. EI-MS: 388 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{24}$H$_{40}$O$_2$Si: 388.2797; found: 388.2801.

Acetate (11)

Sodium borohydride (0.012 g, 0.32 mmol) was dissolved in methanol (0.50 mL), and the mixture was cooled to 0 °C. To this mixture was added dropwise a solution of cerium (III) chloride heptahydrate (0.12 g, 0.32 mmol) and ketone **10** (0.11 g, 0.29 mmol) in methanol (0.94 mL). The mixture was stirred for 0.5 h at 0 °C and 0.5 h at room temperature. It was cooled back to 0 °C, and a saturated aqueous solution of NH$_4$Cl (2 mL) was added. The mixture was extracted with dichloromethane (3 × 3 mL). The combined organic phases were washed with brine (10 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 95:5 to 9:1) to give the alcohol (0.089 g, 79%) as a colorless liquid (mixture of diastereoisomers). [α]$_D$ = +14.22° (*c* 1.16, CHCl$_3$). IR (film, cm^{-1}) ν: 3350, 2929, 2858, 1682, 1645, 1448, 1256, 1178, 922, 889, 837, 779, 735. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.65 (1H, d, *J* = 3.5 Hz, C*H*=C-(C=O)), 4.72 (2H, d, *J* = 0.45 Hz, (CH$_3$)C=C*H*$_2$), 4.08–3.97 (1H, m, C*H*-OH), 2.40–1.35 (16H, m), 1.74 (3H, s, (C*H*$_3$)C=CH$_2$), 1.59 (3H, s, TBSO-C=C-CH$_3$), 0.93 (9H, s, (C*H*$_3$)$_3$C-Si), 0.10 (6H, d, *J* = 1.1 Hz, (C*H*$_3$)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 149.2, 143.3, 143.1, 140.7, 139.2, 124.8, 122.1, 114.8, 114.4, 108.9, 108.8, 76.3, 74.5, 38.1, 37.3, 37.2, 36.9, 36.2, 35.7, 35.7, 35.5, 31.6, 31.4, 30.9, 25.9, 25.1, 24.9, 24.0, 22.6, 22.5, 20.7, 18.2, 15.1, 14.9, –3.7, –3.8, –3.8, –3.9. EI-MS: 390 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{24}$H$_{42}$O$_2$Si: 390.2954; found: 390.2951.

Acetic anhydride (0.032 mL, 0.34 mmol) and DMAP (5.5 mg, 0.050 mmol) were added to a solution of the alcohol (0.088 g, 0.23 mmol) of the preceding reaction in pyridine (2.3 mL). The solution was stirred for 3 h at room temperature, neutralized with an aqueous solution of HCl 1 N (5 mL), and extracted with ethyl acetate (3 × 5 mL). The organic phase was washed with brine (15 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 97:3) to yield acetate **11** (0.083 g, 86%) as a colorless liquid (mixture of diastereoisomers). [α]$_D$ =

+10.10° (*c* 1.00, CHCl$_3$). IR (film, cm^{-1}) ν: 2927, 1738, 1682, 1645, 1448, 1371, 1236, 1180, 1017, 922, 838, 780, 734. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.69 (1H, d, *J* = 13.7 Hz, C*H*=C-CH-OAc), 5.15 (1H, m, C*H*-OAc), 4.72 (2H, s, (CH$_3$)C=C*H$_2$*), 2.38–2.28 (1H, m), 2.02 (3H, d, *J* = 11.2 Hz, CH-O-(C=O)-C*H$_3$*), 1.99–1.34 (15H, m), 1.73 (3H, d, *J* = 5.9 Hz, (C*H$_3$*)C=CH$_2$), 1.58 (3H, d, *J* = 5.5 Hz, TBSO-C=C-C*H$_3$*), 0.93 (9H, m, (C*H$_3$*)$_3$C-Si), 0.10 (6H, m, (C*H$_3$*)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 170.5, 170.3, 149.0, 148.9, 143.5, 143.4, 136.4, 135.1, 126.5, 125.9, 124.3, 123.8, 114.2, 114.0, 110.5, 110.4, 109.0, 108.9, 105.2, 78.2, 76.3, 40.0, 39.4, 38.9, 37.3, 37.2, 36.4, 36.1, 35.9, 35.6, 35.6, 34.4, 31.1, 30.9, 25.8, 25.0, 24.9, 24.8, 23.3, 22.4, 21.4, 21.3, 20.8, 20.7, 18.2, 15.0, 14.8, –3.7, –3.9. EI-MS: 432 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{26}$H$_{44}$O$_3$Si: 432.3060; found: 432.3063.

Stannane (15)

Tributyl-[1,3]dithian-2-yl-stannane **14** (1.2 g, 2.9 mmol) was dried via azeotropic removal of water with benzene (3 × 3 mL) and was then dissolved in THF (2.5 mL) and cooled to –30 °C. In another flask, diisopropylamine (0.40 mL, 2.9 mmol) was dissolved in THF (2.5 mL), cooled to 0 °C, and a solution of *n*-butyllithium (1.35 mol·L^{-1} in hexane) (2.0 mL, 2.7 mmol) was added dropwise. The solution was stirred for 0.25 h at 0 °C, cooled down to –30 °C, and transferred via canula to the first solution containing the stannane. The mixture was stirred for 3 h at –30 °C and cooled to –78 °C; HMPA (1.0 mL, 5.7 mmol) was added, and the mixture was stirred for another 0.5 h. A solution of (*R*)-(–)-carvone (0.20 g, 1.3 mmol) in THF (1.5 mL) precooled to –78 °C was transferred via canula to the mixture, which was stirred for 1.25 h at –78 °C before *tert*-butyldimethylsilyl trifluoromethanesulfonate (0.60 mL, 2.6 mmol) was added. The mixture was stirred for 0.25 h at –78 °C, triethylamine (0.55 mL, 3.9 mmol) was added, and the mixture was warmed at room temperature and stirred for 0.5 h. Water (10 mL) was added, and the mixture was extracted with ether (3 × 10 mL). The combined organic phases were washed with brine (25 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane) to give the stananne **15** (0.78 g, 88%) as a colorless oil. [α]$_D$ = +28.14° (*c* 1.13, CHCl$_3$). IR (film, cm^{-1}) ν: 2956, 2856, 1667, 1463, 1252, 1194, 931, 837. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 4.74 (2H, s, (CH$_3$)C=C*H$_2$*), 3.19 (1H, m), 3.13 (1H, m), 2.90 (1H, m), 2.69 (1H, m), 2.35–1.97 (8H, m), 1.94 (3H, s, TBSO-C=C-C*H$_3$*), 1.76 (3H, s, (C*H$_3$*)C=CH$_2$), 1.52 (6H, m, Sn-(C*H$_2$*-CH$_2$-CH$_2$-CH$_3$)$_3$), 1.33 (6H, m, Sn-(CH$_2$-C*H$_2$*-CH$_2$-CH$_3$)$_3$), 1.06 (6H, m, Sn-(CH$_2$-CH$_2$-C*H$_2$*-CH$_3$)$_3$), 0.91 (18H, m, (C*H$_3$*)$_3$C-Si and Sn-(CH$_2$-CH$_2$-CH$_2$-C*H$_3$*)$_3$), 0.14 (6H, s, (C*H$_3$*)$_2$-Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 149.3, 145.4, 114.9, 108.7, 46.8, 36.6, 35.5, 34.0, 29.2, 27.6, 26.5, 25.9, 25.1, 25.0, 20.6, 18.7, 13.7, 10.1, –3.1, –3.3. EI-MS: 617 ([M – C$_4$H$_9$]$^+$). HR-MS ([M – C$_4$H$_9$]$^+$) calcd. for C$_{28}$H$_{53}$OS$_2$SiSn: 617.2329; found: 617.2322.

Alcohol (16)

Stannane **15** (0.61g, 0.91 mmol) was dried via azeotropic removal of water with benzene (3 × 10 mL); it was then dissolved in THF (10.0 mL), cooled to –100 °C, and a solution

of *n*-butyllithium (1.35 mol·L^{-1} in hexane) (1.3 mL, 1.8 mmol) was added dropwise. The solution was stirred for 0.5 h at –100 °C, and a solution of 1-cyclohexene-1-carboxaldehyde (0.33 mL, 2.9 mmol) in THF (15.0 mL) was added via canula. The solution was stirred for 1.25 h at –100 °C, brought to 0 °C, neutralized with a saturated aqueous solution of NH$_4$Cl (20 mL), and extracted with ether (3 × 25 mL). The combined organic phases were washed with brine (50 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 100:0 to 95:5) to give alcohol **16** (0.33 g, 75%) as a clear oil (mixture of diastereoisomers, ratio = 3:1). [α]$_D$ = +10.50° (*c* 1.14, CHCl$_3$). IR (film, cm^{-1}) ν: 3444, 2929, 2857, 1667, 1644, 1252, 1192, 927, 837, 780, 734. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 6.00 (1H, s, C*H*=C-CH-OH), 4.73 (2H, m, (CH$_3$)C=C*H$_2$*), 4.51 (1H, m, C*H*-OH), 3.29–1.34 (15H, m), 1.80 (3H, d, *J* = 9.3 Hz, TBSO-C=C-C*H$_3$*), 1.75 (3H, d, *J* = 4.3 Hz, (C*H$_3$*)C=CH$_2$), 1.61 (4H, m), 1.40 (1H, tt, *J* = 13.1 and 4.8 Hz), 0.95 (9H, d, *J* = 1.7 Hz, (C*H$_3$*)$_3$C-Si), 0.16 (6H, s, (C*H$_3$*)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 149.4, 149.3, 148.8, 136.8, 136.4, 127.4, 127.1, 111.9, 111.5, 108.8, 108.7, 78.1, 76.4, 62.1, 61.9, 45.1, 43.0, 38.2, 37.4, 35.3, 35.1, 31.9, 31.8, 28.8, 28.5, 28.5, 27.8, 27.4, 27.2, 25.9, 25.9, 25.5, 24.4, 24.1, 23.1, 23.1, 22.4, 22.1, 20.5, 20.4, 19.5, 18.9, –3.2, –3.3, –3.4. EI-MS: 476 ([M – H$_2$O]$^+$); 437 ([M – C$_4$H$_9$]$^+$). HR-MS ([M – H$_2$O]$^+$) calcd. for C$_{27}$H$_{44}$OS$_2$Si: 476.2603; found: 476.2596.

Acetate (17)

Acetic anhydride (0.27 mL, 2.9 mmol) and DMAP (71.0 mg, 0.58 mmol) were added to a solution of the alcohol **16** (0.79 g, 0.58 mmol) in pyridine (5.8 mL). The solution was stirred for 4 h at room temperature, neutralized with HCl 1 N (5 mL), and extracted with ethyl acetate (3 × 10 mL). The organic phase was washed with brine (15 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 95:5) to give acetate **17** (0.24 g, 79%) as a colorless oil (mixture of diastereoisomers, ratio = 3:1). [α]$_D$ = +9.56° (*c* 1.13, CHCl$_3$). IR (film, cm^{-1}) ν: 2929, 2857, 1742, 1667, 1438, 1368, 1230, 1170, 1019, 926, 837, 780, 733. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.94 (1H, s, C*H*=C-CH-OAc), 5.76 (1H, d, *J* = 19.2 Hz, C*H*-OAc), 4.74 (2H, m, (CH$_3$)C=C*H$_2$*), 3.30–3.09 (2H,m), 2.98 (1H, m), 2.76 (1H, m), 2.64–2.46 (1H, m), 2.33–2.12 (3H, m), 2.08 (3H, d, *J* = 2.7 Hz, CH-O-(C=O)-C*H$_3$*), 2.03–1.89 (1H, m), 1.84 (3H, d, *J* = 10.5 Hz, TBSO-C=C-C*H$_3$*), 1.75 (3H, d, *J* = 3.8 Hz, (C*H$_3$*)C=CH$_2$), 1.26 (6H, m), 0.95 (9H, d, *J* = 1.0 Hz, (C*H$_3$*)$_3$C-Si), 0.16 (6H, t, *J* = 4.5 Hz, (C*H$_3$*)$_2$Si). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 169.5, 149.5, 149.4, 148.4, 134.9, 134.6, 129.5, 128.5, 111.7, 111.2, 108.8, 108.6, 82.4, 78.5, 59.7, 59.3, 45.7, 43.5, 37.7, 35.3, 35.1, 31.8, 31.7, 31.6, 28.8, 28.0, 27.7, 27.5, 27.4, 25.9, 25.4, 24.3, 24.2, 22.9, 22.6, 22.0, 22.0, 21.4, 20.5, 20.4, 19.8, 19.2, 18.2, 14.1, –3.3, –3.4. CI-MS: 537 ([MH]$^+$). HR-MS ([MH]$^+$) calcd. for C$_{29}$H$_{49}$O$_3$S$_2$Si: 537.2892; found: 537.2887.

Ketone (18)

Acetate **17** (0.026 g, 0.048 mmol) was dried via azeotropic removal of water with benzene (3 × 1 mL) and

then dissolved in benzene (1.0 mL), and *p*-toluenesulfonic acid monohydrate (2.0 mg, 0.010 mmol) was added. The solution was heated at reflux for 16 h, cooled to room temperature, neutralized with a saturated aqueous solution of NaHCO$_3$ (3 mL), and extracted with ether (3 × 5 mL). The organic phase was dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 95:5) to give ketone **18** (8.1 mg, 46%) as a yellow oil. [α]$_D$ = –72.35° (*c* 1.15, CHCl$_3$). IR (film, cm^{-1}) ν: 2929, 1708, 1448, 904, 733. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.39 (1H, m, C*H*=C), 4.84 and 4.61 (2H, 2s, (CH$_3$)C=C*H*$_2$), 3.08–2.51 (9H, m), 2.18 (4H, m), 1.97 (2H, m), 1.77 (1H, dd, *J* = 13.7 and 2.7 Hz), 1.70 (3H, d, *J* = 0.6 Hz, (C*H*$_3$)C=CH$_2$), 1.63–1.47 (5H, m), 0.94 (3H, d, *J* = 6.5 Hz, (C=O)-C-C*H*$_3$). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 212.6, 146.9, 141.0, 138.1, 137.9, 125.9, 112.4, 47.8, 45.9, 44.6, 41.0, 33.0, 32.4, 31.8, 31.4, 28.3, 25.1, 22.6, 22.5, 21.7, 12.5. EI-MS: 362 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{21}$H$_{30}$OS$_2$: 362.1738; found: 362.1729.

Cyclopropanes (2a and 2b)

Acetate **17** (0.35 g, 0.65 mmol) was dried via azeotropic removal of water with benzene (3 × 10 mL) and then dissolved in dichloromethane (33.0 mL) and cooled to –78 °C. Trimethylsilyl trifluoromethanesulfonate (0.12 mL, 0.65 mmol) was added slowly, and the solution was stirred for 5 min before a saturated aqueous solution of NaHCO$_3$ (25 mL) was added. The mixture was extracted with ether (3 × 25 mL). The combined organic phases were washed with brine (50 mL), dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 95:5) to give compound **19** (0.041 g, 17%), compound **18** (0.033 g, 14%), and the cyclopropane **2** (0.11 g, 46%) as a mixture of two diastereoisomers, which were separated by preparative TLC (eluted 2 times with toluene) to give the major product **2a** (0.033 g) and the minor product **2b** (0.011 g). Major product **2a**: [α]$_D$ = –361.07° (*c* 1.40, CHCl$_3$). IR (film, cm^{-1}) ν: 2923, 1693, 1438, 1407, 1376, 1301, 1103, 894, 755. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 6.19 (1H, s, C=C*H*), 4.86 and 4.59 (2H, 2s, (CH$_3$)C=C*H*$_2$), 3.25 (1H, m), 3.05 (1H, m), 2.81 (2H, m), 2.63 (3H, m), 2.38 (3H, m), 2.12 (3H, m), 1.95 (2H, m), 1.79 (3H, s, (C*H*$_3$)C=CH$_2$), 1.62 (5H, m), 1.27 (1H, dd, *J* = 8.1 and 4.0 Hz), 1.17 (3H, s, (C=O)-C-C*H*$_3$). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 208.9, 147.4, 132.2, 128.1, 111.1, 59.9, 45.0, 43.7, 40.4, 39.5, 35.4, 31.5, 30.7, 28.3, 25.8, 25.1, 24.2, 23.2, 22.5, 21.7, 18.2. EI-MS: 362 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{21}$H$_{30}$OS$_2$: 362.1738; found: 362.1743. Minor product **2b**: [α]$_D$ = –96.25° (*c* 0.40, CHCl$_3$). IR (film, cm^{-1}) ν: 2925, 1692, 1448, 1409, 1305, 1101, 894, 730. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.91 (1H, s, C=C*H*), 4.85 and 4.62 (2H, 2s, (CH$_3$)C=C*H*$_2$), 3.30 (1H, m), 3.26 (1H, m), 2.90 (3H, m), 2.76 (1H, dd, *J* = 16.7 and 4.9 Hz), 2.63 (3H, m), 2.46–2.18 (3H, m), 2.12 (3H, m), 1.88 (3H, m), 1.77 (3H, s, (C*H*$_3$)C=CH$_2$), 1.66 (3H, m), 1.35 (3H, s, (C=O)-C-C*H*$_3$), 1.27 (1H, m). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 210.2, 147.5, 133.1, 128.3, 126.7, 111.0, 56.7, 44.2, 40.4, 35.9, 31.6, 30.6, 28.2, 25.8, 25.7, 24.0, 23.1, 22.4, 21.6, 17.4, 14.1. EI-MS: 362 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{21}$H$_{30}$OS$_2$: 362.1738; found: 362.1743. Compound **19**: [α]$_D$ = –41.06° (*c* 2.63, CHCl$_3$). IR (film, cm^{-1}) ν: 2929, 1708, 1438, 1414, 892, 754. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 5.45 (1H, m, C*H*=C), 4.74 (2H, d, *J* = 12.3 Hz, C(CH$_3$) = C*H*$_2$), 3.55 (1H, m), 3.17 (2H, m), 2.92 (1H, m), 2.85 (1H, m), 2.77 (1H, m), 2.60 (1H, dd, *J* = 15.0 and 4.4 Hz), 2.36 (1H, qu, *J* = 6.5 Hz), 2.18 (3H, m), 2.05 (4H, m), 1.90 (2H, m), 1.72 (3H, s, (C*H*$_3$)C=CH$_2$), 1.71–1.54 (4H, m), 1.06 (3H, d, *J* = 6.8 Hz, C*H*$_3$-CH). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 211.8, 147.9, 138.6, 128.3, 125.4, 112.4, 109.8, 47.2, 47.0, 45.3, 41.1, 36.6, 33.3, 32.5, 31.3, 28.4, 25.1, 22.7, 21.8, 20.6, 12.7. EI-MS: 362 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{21}$H$_{30}$OS$_2$: 362.1738; found: 362.1729.

Nitrobenzoate (20)

To a solution of cyclopropane **2a** (0.024 g, 0.066 mmol) in THF (1.3 mL) was added lithium aluminum hydride (3.7 mg, 0.099 mmol). The solution was stirred for 15 min at room temperature, neutralized with a dropwise addition of a saturated aqueous solution of NH$_4$Cl (5 mL), and extracted with ether (3 × 5 mL). The organic phase was dried with MgSO$_4$, filtered, and concentrated under reduced pressure. The crude product was purified by flash chromatography (hexane–ether 100:0 to 98:2) to give the alcohol as the major diastereoisomer (0.015 g, 63%) and the minor diastereoisomer (2.0 mg, 8%). Major diastereoisomer: [α]$_D$ = –173.82° (*c* 1.10, CHCl$_3$). IR (film, cm^{-1}) ν: 3788, 3492, 2921, 1641, 1446, 1403, 1013, 885. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 6.46 (1H, s, C*H*=C), 4.79 (2H, d, *J* = 24.2 Hz, (CH$_3$)C=C*H*$_2$), 3.75 (1H, t, *J* = 9.2 Hz, C*H*-OH), 3.25 (1H, m), 3.10 (1H, m), 2.87 (1H, m), 2.63 (2H, m), 2.40 (2H, m), 2.36–2.11 (3H, m), 2.07 (2H, m), 1.92 (2H, m), 1.78 (1H, m), 1.74 (3H, s, (C*H*$_3$)C=CH$_2$), 1.61 (5H, m), 1.14 (3H, s, (C=O)-C-C*H*$_3$), 1.11 (1H, m). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 147.4, 133.5, 127.3, 110.2, 73.9, 61.5, 46.0, 39.7, 36.9, 34.8, 34.7, 31.7, 30.6, 28.5, 25.8, 25.3, 23.8, 23.3, 23.0, 22.6, 22.3. EI-MS: 364 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{21}$H$_{32}$OS$_2$: 364.1894; found: 364.1888.

The major diastereoisomer of the preceding alcohol (4.5 mg, 0.012 mmol) was dissolved in dichloromethane (0.35 mL) and pyridine (0.35 mL). 4-Nitrobenzoyl chloride (0.023 g, 0.12 mmol) and DMAP (0.7 mg, 6.0 μmol) were added, and the solution was stirred for 16 h at room temperature and concentrated under reduced pressure, and the crude product was purified by flash chromatography (hexane–ether 95:5) to give nitrobenzoate **20** (2.5 mg, 40%) as a yellow solid. IR (film, cm^{-1}) ν: 2928, 1720, 1608, 1529, 1148, 1409, 1348, 1321, 1272, 1117, 1104, 755, 719. ^{1}H NMR (300 MHz, CDCl$_3$, ppm) δ: 8.32 (4H, m, *H* arom.), 6.46 (1H, s, C=C*H*), 5.35 (1H, dd, *J* = 7.7 and 10.9 Hz, C*H*-OAc), 4.91 (2H, d, *J* = 24.3 Hz, (CH$_3$)C=C*H*$_2$), 3.26 (1H, m), 3.13 (1H, m), 2.91 (1H, dt, *J* = 13.9 and 3.1 Hz), 2.67 (2H, m), 2.45 (1H, m), 2.37 (3H, m), 2.25 (1H, m), 1.98 (2H, m), 1.87 (1H, m), 1.83 (3H, s, (C*H*$_3$)C=CH$_2$), 1.65–1.46 (7H, m), 1.26 (1H, m), 1.14 (3H, s, -CO$_2$-C-C-C*H*$_3$). ^{13}C NMR (75 MHz, CDCl$_3$, ppm) δ: 164.5, 146.7, 134.1, 130.8, 126.6, 123.5, 110.8, 85.0, 78.0, 61.0, 46.9, 46.6, 39.8, 37.1, 32.0, 31.2, 30.5, 30.5, 28.3, 25.3, 25.2, 23.3, 23.2, 22.9, 22.4, 22.4. EI-MS: 513 ([M]$^+$). HR-MS ([M]$^+$) calcd. for C$_{28}$H$_{35}$NO$_4$S$_2$: 513.2007; found: 513.1997.

Conclusion

We have studied the plausibility of an S_N2' cyclization using a silyl enol ether onto an allylic acetate by varying the functional groups adjacent to the acetate leaving group. Clearly, the inductive effect of the neighboring group plays a significant role in the departure of the leaving group, as the results with the dithiane neighboring group revealed. Several other alternatives were pursued but without success. Unfortunately, the model studies discussed herein proved that this strategy cannot be employed to access the C_7–C_8 unsaturated tricyclic structures. However, in the case of the substrates containing a dithiane next to the allylic acetate, the synthesis of novel highly functionalized cyclopropanes was observed instead of the desired S_N2' cyclization. This cyclopropanation is due to the cyclization of the silyl enol ether with concomitant 1,2-migration of a thioether and displacement of the acetate.

Alkyl substituent effect on the polarity of phenols–tri-*n*-alkylamine complexes

Zbigniew Pawełka and Therese Zeegers-Huyskens

Abstract: The formation constants and the dipole moments of the H-bonded adducts of 1:1 and 2:1 stoichiometries formed between three different phenols (phenol, 2,4,6-trichlorophenol, and 2,4-dinitrophenol) and different tri-*n*-alkylamines are determined in solvents of weak polarity. The polarity of the 1:1 complexes of 2,4,6-trichlorophenol with tri-*n*-alkylamines markedly increases with increasing degree of amine alkylation, in contrast with the complexes involving the two other phenols. The influence of the basicity and steric hindrance of the tri-*n*-alkylamines on the proton-transfer constant is discussed and quantitative correlations are deduced.

Key words: phenols, tri-*n*-alkylamines, H-bonded complexes, proton transfer, polarity, steric effect.

Résumé : Les constantes de formation et les moments dipolaires de complexes à liaison hydrogène formés entre trois différents phénols (phénol, 2,4,6-trichlorophénol et 2,4-dinitrophénol) et différentes tri-*n*-alkylamines sont déterminés dans des solvants de faible polarité. La polarité des complexes de 1:1 stoechiométrie formés entre le 2,4,6-trichlorophénol et les tri-*n*-alkylamines augmente avec le degré d'alkylation, contrairement aux complexes des deux autres phénols. L'effet de la basicité et de l'encombrement stérique des tri-*n*-alkylamines sur la constante de transfert de proton est discuté et des correlations quantitatives sont présentées.

Mots clés : phénols, tri-*n*-alkylamines, complexes à liaison hydrogène, transfert de proton, polarité, effect stérique.

Introduction

One of the most spectacular manifestations of hydrogen bond (H-bond or HB) interactions (AH···B) is the enhancement of the dipole moment μ_{AHB} in comparison with the vectorial sum of the dipole moments of the isolated molecules, $\vec{\mu}_{AH}$ and $\vec{\mu}_B$. The dependence of the H-bond polarity $\Delta\vec{\mu}$ (= $\vec{\mu}_{AHB} - \vec{\mu}_{AH} - \vec{\mu}_B$) on the aqueous ΔpK_a (= $pK_{BH^+} - pK_{AH}$) of the interacting species AH and B is very characteristic (1–5). For homologous series of complexes, e.g., phenols–triethylamine (1), the $\Delta\vec{\mu}$ vs. ΔpK_a curve presents a sigmoidal shape with a strong increase of $\Delta\vec{\mu}$ in the inversion region. The $\Delta\vec{\mu}/\Delta pK_a$ gradient in that region is so high that an increase of ΔpK_a by two units can lead to a new protonic state of the complex, i.e., to hydrogen-bonded ion pair $A^{\ominus}$···$HB^{\oplus}$. The polarity of the adducts in the inversion region can be explained in terms of the protomeric equilibrium (1–7)

[1]   A—H···B ⇔ A$^{\ominus}$···H—B$^{\oplus}$
governed by the proton transfer (PT) constant K_{PT}. Such H-bonded systems are very sensitive to the intrinsic basicity or acidity of the two partners and also to environmental effects (8–17). Moreover, these complexes show anomalous spectroscopic phenomena, e.g., low isotopic ratio, large shift of the ν_{AH} vibration frequencies, highly downfield proton chemical

shift, etc. Low-barrier, strong hydrogen bonds (LBHBs) were proposed to explain the above particularities (18–20). The H-bonds formed by groups with similar pK_as possess some partial covalent character, as they are the result of orbital overlapping between the matched energy states of AH and B. This covalent character contributes to the strength of the H bond, in addition to the pure electrostatic forces. The dependence of the strength and polarity of the AH···B system on ΔpK_a can be demonstrated by changing the H-bond donating ability of AH in the families of phenols or carboxylic acids complexed with triethylamine or pyridines (1–5, 21–23).

The alkyl substitution effect on the basicity of amines has been discussed for a long time (24–40). There is much less information about this effect on the polarity of the molecular complexes. The sensitivity to N-alkylation is manifested in charge transfer complexes (41–46). For instance, the dipole moment of the triethylamine–I$_2$ complex is higher by about 0.5 D than that of trimethylamine adduct, irrespective of the solvent (45, 46).

To discuss the influence of N-alkylation on the proton acceptor abilities of tri-*n*-alkylamines, we have determined in the present work the dipole moments of hydrogen-bond complexes involving phenols and aliphatic tertiary amines characterized by different degrees of substitution. The studied phenols are unsubstituted phenol, 2,4,6-trichlorophenol,

and 2,4-dinitrophenol, and the tertiary aliphatic amines are diethylmethyl-, triethyl-, tri-*n*-propyl-, tri-*n*-butyl-, tri-*n*-pentyl-, tri-*n*-octyl-, and tri-*n*-dodecylamine. These systems were chosen to cover a broad ΔpK_a range.

It is well recognized that in nonpolar solvents (used in our dielectric measurements), the tertiary amines form both 1:1 (AHB) and 2:1 [(AH)$_2$B] adducts (15, 16, 47, 48). Thus the starting point of the dielectric investigations was the determination of the K_{AHB} and $K_{(AH)_2B}$ formation constants by IR spectrometry. Knowledge of both stability constants allowed us to attribute the dielectric polarization to adducts of a given stoichiometry. In the present work we focused our attention on the H-bond polarities and on the proton transfer degrees in the 1:1 and 2:1 complexes formed between 2,4,6-trichlorophenol and various trialkylamines.

Results and discussion

Dipole moments of the components

The dipole moments of amines and 2,4,6-trichlorophenol in tetrachloroethylene (or carbon tetrachloride) are reported in Table 1. The values obtained for amines are of the expected magnitudes (see values in other solvents (49)) and will not be discussed hereafter. The increase of the dipole moments in CCl$_4$ as compared with tetrachloroethylene may be accounted for by a charge-transfer interaction $\equiv$N$\cdots$Cl-C$\equiv$ (50, 51). In the case of amines with a lower degree of substitution, their photochemical reaction with CCl$_4$ leads, after some time, to a turbidity of the solution. This was the reason for which — in the time-consuming dielectric measurements — CCl$_4$ was replaced by tetrachloroethylene. In the next section, the dielectric polarizations of amines are employed in the calculation of dielectric polarizations of the 1:1 and 2:1 complexes. The dipole moments of amines and 2,4,6-trichlorophenol are also necessary for assessing the dipole moments of the molecular HB (μ_{HB}) and ion pair PT (μ_{PT}) forms of the further discussed 1:1 complexes of 2,4,6-trichlorophenol with trialkylamines.

Dielectric polarizations and dipole moments of the complexes

The formation constants K_{AHB} and $K_{(AH)_2B}$ of the 2,4,6-trichlorophenol–trialkylamine complexes in a given solvent were estimated simultaneously by the method of the appar-

ent constant (K_{app}), based on a model of 1:1 stoichiometry (47)

$$[2] \quad \frac{1}{2C_{AH} + K_{app}C_{AH}^2} =$$

$$\frac{1}{K_{AHB}}\left(\frac{K_{app}}{2C_{AH} + K_{app}C_{AH}^2}\right) - K_{(AH)_2B}$$

The intensity of the ν(OH) absorption at ca. 3600 cm^{-1} was used in the determination of the concentration of the nonbonded phenol derivative. It is worth mentioning that this method gives the total concentration of complexes in their neutral (OH$\cdots$N), as well in their ionic (O$^-\cdots$HN$^+$), forms. At the low concentrations used in this work, secondary interactions such as stacking effects are unlikely to occur.

The equilibrium constants are indicated in Table 2. It may be seen that the formation constants $K_{(AH)_2B}$ are larger than K_{AHB}, which indicates a strong tendency to form 2:1 species.

Both equilibrium constants are used for the simultaneous estimation of the dielectric polarizations of the 1:1 (P_{AHB}) and 1:2 ($P_{(AH)_2B}$) species. It is worth noticing that the K values reported in Table 2 indicate that in an excess of amine larger than 5, the 1:1 complex dominates in the solution. These conditions were therefore taken for the determination of the dipole moment of the 1:1 complexes. In excess of amine the following relation is valid:

$$[3] \quad \frac{P - P_1 x_1}{x_B} = P_B + P_{AHB}\frac{x_{AH}^\circ}{x_B}$$

where P, P_1, P_B, and P_{AHB} are the dielectric polarizations of solution, solvent, amine, and the 1:1 complex, respectively, and x_B ($x_B = x_B^\circ - x_{AH}^\circ$) and x_{AH}° are the molar fractions of the amine and 2,4,6-trichlorophenol; the superscript $^\circ$ indicates the initial molar fractions.

Figure 1 shows the plot of $(P - P_1 x_1)/x_B$ against x_{AH}°/x_B for selected complexes. Similar linear relationships were also observed for other systems. The molar dielectric polarizations and dipole moments obtained in this way are collected in Table 3.

One should note the very good coincidence of the P_B values found from the linear equation, eq. [3] (Fig. 1), and from

independent measurements in binary solutions (indicated in parentheses). The data reported in Table 3 reveal that the dipole moment markedly increases on going from diethylmethyl- to tri-*n*-butylamine and that only smooth changes are observed for longer alkyl chains. This effect was compared with analogous results for much weaker (phenol–trialkylamines) and much stronger (2,4-dinitrophenol–trialkylamines) interactions. The unsubstituted phenol–trialkylamine complex belongs to the typical molecular hydrogen-bonded form OH···N, in which the polarity enhancement of the order of 0.7–1 D is caused by induction and charge transfer effects. In contrast, the 2,4-dinitrophenol–trialkylamine adduct is the hydrogen-bonded ion pair O$^\ominus$···HN$^\oplus$, in which the proton is transferred to the nitrogen atom of the amine. The results obtained from eq. [3] are summarized in Table 4.

A rough inspection of the data in Table 4 shows a moderate increase in the dipole moment when the triethyl group is replaced by the tri-*n*-dodecyl one. Our measurements were carried out at low concentration of phenols. Nevertheless, in the case of 2,4,6-trichlorophenol complexed with long chain amines, one could admit association of the following type: monomer $\Leftrightarrow$ dimer $\Leftrightarrow$ *n*-mer. As a final step, an inverted micelle may be formed with the polar O-H···N group in its interior and the lipophilic alkyl chains directed towards the nonpolar solvent. In principle such an aggregation should enlarge the effective dipole moment resulting from specific dipole orientation. To establish the effect of the proton donor

concentration on μ_{AHB}, we carried out additional measurements in an excess of tri-*n*-dodecylamine ((concentration = *c*) $c_B/c_{AH} \approx 10$) at concentrations of 2,4,6-trichlorophenol ranging from 0.4×10^{-3} to 1×10^{-2} mol dm^{-3}. The dipole moments at $x_{AHB} = 4.23 \times 10^{-4}$ and 1.06×10^{-2} are equal to 6.08 and 6.01 D, respectively. Moreover, the mean deviation from the average value of μ_{AHB} for the whole concentration range is only ± 0.04 D, which indicates the lack of self-association of the complex.

Finally, to estimate the alkylation effect on the polarity of the (AH)$_2$B complex, we have compared the dipole moments of the 2:1 adduct of 2,4,6-trichlorophenol with triethylamine and tri-*n*-dodecylamine. The equilibrium concentrations of all species in the solution were evaluated using the formation constants K_{AHB} and $K_{(AH)_2B}$. In the next step, the dielectric polarizations P_{AHB} and $P_{(AH)_2B}$ were estimated according to the linear equation

$$[4] \qquad P^* = \frac{P - P_1 x_1 - P_{AH} x_{AH} - P_B x_B}{x_{AHB}}$$

$$= P_{AHB} + P_{(AH)_2B} \frac{x_{(AH)_2B}}{x_{AHB}}$$

To allow the 1:1 or 2:1 species to be in excess, the measurements were carried out within a wide range of initial x_{AH}/x_B ratios. For these ratios, the corresponding $x_{(AH)_2B}/x_{AHB}$ values comprise between 0.02 and 2.45.

The μ_{AHB} and $\mu_{(AH)_2B}$ values of the 2,4,6-trichlorophenol–TEA adduct in tetrachloroethylene were obtained by us earlier (16). Equation [4], applied to all investigated complexes of 2,4,6-trichlorophenol, can be expressed as:

$$[4.1] \qquad P^*(TEA, C_2Cl_4)$$

$$= 610 + 1830 \ (x_{(AH)_2B}/x_{AHB}) \begin{pmatrix} N = 7 \\ R = 1 \end{pmatrix}$$

$$[4.2] \qquad P^*(TEA, CCl_4)$$

$$= 610 + 1740 \ (x_{(AH)_2B}/x_{AHB}) \begin{pmatrix} N = 6 \\ R = 0.99 \end{pmatrix}$$

$$[4.3] \qquad P^*(TDA, C_2Cl_4)$$

$$= 770 + 1820 \ (x_{(AH)_2B}/x_{AHB}) \begin{pmatrix} N = 10 \\ R = 0.99 \end{pmatrix}$$

The corresponding dipole moments of the triethylamine adducts are $\mu_{AHB} = 5.42 \pm 0.02$ D and $\mu_{(AH)_2B} = 9.42 \pm 0.05$ D in tetrachloroethylene, and $\mu_{AHB} = 5.43 \pm 0.07$ D and $\mu_{(AH)_2B} = 9.17 \pm 0.14$ D in CCl$_4$. Equation [4.3] gives values of $\mu_{AHB} = 6.10 \pm 0.06$ D and $\mu_{(AH)_2B} = 9.38 \pm 0.14$ D for the tri-*n*-dodecylamine adduct. The good agreement between the μ_{AHB} value determined in excess of amine (see Table 3) and that resulting from eq. [4] is worth noticing. Earlier data based on infrared spectrometry or dipole measurements (15–17, 48) have demonstrated that the adducts of 2:1 stoichiometry between trihalogenophenols and tributylamine are hydrogen-bonded ion pairs. The similar value of the dipole moment of the tridodecylamine complexes indicate that this conclusion can be extended to more hindered amines. The 2:1 complexes are characterized by the struc-

ture OH···O⁻···HN⁺. In this structure, both OH···O⁻ and O⁻···HN⁺ hydrogen bonds become stronger than the OH···O and OH···N hydrogen bonds in the corresponding phenol dimer and in the 1:1 complex. This σ-bond cooperative effect results in a large charge redistribution and proton transfer in the O-H···N bridge. Despite a relatively large error (±0.15 D) in the determination of $\mu_{(AH)_2B}$, the very low sensitivity to the lengthening of the alkyl groups in the amine moiety is worth mentioning. This behaviour is apparently analogous to that found in the 1:1 complexes of 2,4-dinitrophenol with the same tri-*n*-alkylamines (see Table 4).

These results indicate that the effect of N-alkyl substitution on the polarity is weak in complexes characterized by normal OH···N hydrogen bonds and in proton-transfer complexes characterized by O⁻···HN⁺ hydrogen bonds. For both types of complexes, only a very small increase in $\Delta\mu_{AHB}$ with ΔpK_a is observed. This feature is displayed in Fig. 2, which also illustrates the sigmoidal shape found for other systems (1–5).

Proton transfer constant in the 1:1 complexes between 2,4,6-trichlorophenol and tri-*n*-alkylamines

As discussed in the previous section, the polarity of the of 2,4,6-trichlorophenol–trialkylamine complexes increases with increasing extent of alkylation of the amine. This complex lies in the inversion region of the $\Delta\mu_{AHB}$ vs. ΔpK_a curve (Fig. 2). The polarity of such systems can be discussed in terms of the protomeric equilibrium (1). To discuss the alkylation effect more quantitatively, we calculated the H-bond polarity $\Delta\vec{\mu}$, defined as $\Delta\vec{\mu} = \vec{\mu}_{AHB} - (\vec{\mu}_{AH} + \vec{\mu}_B)$, as well as the proton transfer constant K_{PT}. For the calculation of $\Delta\vec{\mu}$, the vectorial scheme proposed in ref. (2) was applied. The degree of proton transfer, x_{PT}, was calculated from the relation

Fig. 2. Dipole moment increment of the 1:1 complexes between phenol, 2,4,6-trichlorophenol, and 2,4-dinitrophenol with tri-*n*-alkylamines as a function of ΔpK_a. The dipole moments of phenol and 2,4-dinitrophenol in carbon tetrachloride are 1.45 and 3.31 D, respectively; their pK_a are 9.95 and 4.10.
$$[5] \qquad x_{PT} = \frac{\mu_{AHB}^2 - \mu_{HB}^2}{\mu_{PT}^2 - \mu_{HB}^2}$$

The proton transfer constant K_{PT} was taken as the ratio x_{PT}/x_{HB}.

The dipole moments of the molecular AH···B (μ_{HB}) and proton-transfered A⁻···HB⁺ (μ_{PT}) forms were estimated assuming $\Delta\vec{\mu} = 0.8$ D (3) in the former and $\Delta\vec{\mu} = 9.3$ D (1) in the latter one. These data are summarized in Table 5.

Table 5. The pK_a and molar volumes of the tri-*n*-alkylamines, polarity of the hydrogen bond ($\Delta\bar{\mu}$), proton transfer degree (% PT), and $\log K_{PT}$ in the 2,4,6-trichlorophenol–tri-*n*-alkylamines complexes.

[a]In carbon tetrachloride.
[b]Obtained from extrapolation of the pK_a values as a function of the number of CH$_2$ groups in the aliphatic chain.

The increase in $\Delta\bar{\mu}$ or K_{PT} may be rationalized in terms of the increasing proton-accepting abilities of amine. The proton affinity is a direct measure of the intrinsic basicity, unaffected by solvation effects. Unfortunately, the proton affinities are known only for the aliphatic tertiary amines characterized by a low degree of substitution, and they increase from 232.3 to 234.8 kcal mol^{-1} on going from triethylamine to tri-*n*-butylamine (52). Therefore, we decided to correlate the K_{PT} values with the basic properties of amines in water (24, 27) (see Table 5). The classical relation

$$[6] \qquad \log K_{PT} = \xi\Delta pK_a + C$$

takes for the present complexes the following form:

$$[7] \qquad \log K_{PT} = -2.67 + 0.42\Delta pK_a \begin{pmatrix} N = 7 \\ R = 0.944 \end{pmatrix}$$

As illustrated in Fig. 3, marked deviations from this linear correlation are observed for tri-*n*-pentyl-, tri-*n*-octyl-, and tri-*n*-dodecylamine, where the bulky substituents restrict the approach of the proton. This steric hindrance must be larger in the 2,4,6-trichlorophenol complexes than in monohydrate B$^\oplus$H···OH$_2$. This comparison is justified since it appears that steric hindrance to ion solvation in bulk water is comparable in magnitude to steric hindrance of solvation by only one H$_2$O molecule (36). To estimate quantitatively the effect of steric hindrances on K_{PT}, we have added to eq. [6] a term dependent on the molar volume of the amine in tetrachloroethylene (V in dm^3 mol^{-1}, see Table 5). The two-parameter linear regression now gives the following relation:

$$[8] \qquad \log K_{PT} = -3.24 - 0.55\Delta pK_a + 0.03(\log V)^{-1}$$
$$\begin{pmatrix} N = 7 \\ R = 0.989 \end{pmatrix}$$

characterized by a better correlation coefficient than that of eq. [7]. It may be concluded that both the C and ξ parameters in eq. [6] are to some degree connected with the steric effects.

A last remark concerns the influence of steric hindrance on the formation constants of the 1:1 complexes. For complexes between phenols and aliphatic tertiary amines characterized by normal OH···N hydrogen bonds, the formation constants have been shown to depend on the polar and steric parameters of Taft (27). Similar correlations could not be de-

Fig. 3. $\log K_{PT}$ as a function of ΔpK_a for the 1:1 complexes between 2,4,6-trichlorophenol and trialkylamine.
duced for the present complexes because, as discussed in this section, both OH···N and O$^-$···HN$^+$ species are present in solution. The O(H)···N distance is considerably shorter (2.50–2.55 Å) than the O$^-$···HN$^+$ one (2.75–2.85 Å) (27), and as a consequence, the normal OH···N hydrogen bonds are expected to be more sensitive to steric interactions than the ionic O$^-$···HN$^+$ ones.

Comparison with the crystal structures

In the solids, the inflection point, where 50% PT is formally reached, occurs with the weaker bases. This is in agreement with expectations since the crystal lattice favors the polar PT state (53). When 2,4-dinitrophenol forms complexes with diamines or tertiary amines, in all the published structures where the hydrogen atoms have been located, the phenol completely transfers the proton to the amine (54–59).

The structure of the (phenol)$_2$-1,4-diazabicyclo[2,2,2]octane (DABCO) complex, determined at −130°, is worth mentioning. In this complex, the hydrogen atoms stay firmly attached to the phenol oxygen atoms. Strong hydrogen bonds are formed, the two O···N distances being 2.694 and 2.681 Å, respectively, and the corresponding OH···N angles

167° and 165°.[2] No PT structure is observed in this case. This may result from the fact that DABCO is less basic than triethylamine; its pK_a is indeed equal to 8.8. A second factor that plays a determinant role is the anticooperativity in the hydrogen bond. The formation of the OH···N hydrogen bond on one of the N atom of DABCO decreases the proton-acceptor ability of the second N atom (60).

Experimental

The dielectric permittivity (ε) was measured on a Dipolemeter DM01 (WTW) at 2 MHz. The dielectric capacity was determined with an accuracy of $\Delta C/C \leq 1 \times 10^{-4}$. The density ($d$) was determined picnometrically with an accuracy of $\pm 1 \times 10^{-4}$ g cm^{-3}, and the refractive index (n) for the D sodium line was measured using an Abbé refractometer with an accuracy of $\pm 1 \times 10^{-4}$. All the measurements were performed at 25 ± 0.02 °C.

The dipole molar polarization (P) of the liquid was calculated according to the Onsager equation (61)

$$[9] \qquad P = \frac{(\varepsilon - n^2)(2\varepsilon + n^2)}{\varepsilon(n^2 + 2)^2} V$$

where V is the molar volume of liquid.

The dipole moments of phenols and amines in binary solution were calculated using the Hedestrand extrapolation procedure (62), in which ε, d, and n^2 were plotted against the molar fraction x_2 of the solute. From the slopes, denoted by α, β, and γ (see Table 1), the molar dipole polarization P_2 of the solute at infinite dilution was obtained by eq. [9], which takes the following form (63):

$$[10] \qquad P_2 = \frac{(\varepsilon_1 - n_1^2)(2\varepsilon_1 + n_1^2)}{\varepsilon_1(n_1^2 + 2)^2}$$

$$\times V_1 \left(\frac{\alpha\varepsilon_1 - \gamma n_1^2}{\varepsilon_1 - n_1^2} + \frac{2\alpha\alpha_1 + \gamma n_1^2}{2\varepsilon_1 + n_1^2} - \frac{2\gamma n_1^2}{n_1^2 + 2} - \alpha - \beta + \frac{M_2}{M_1} \right)$$

where M is the molar mass and the subscripts 1 and 2 refer to the solvent and the solute, respectively. Finally, the μ value of the solute has been obtained from the relation $\mu = [(9kT/4\pi N) \times P_2]^{1/2}$.

The formation constants of the 1:1 (K_{AHB}) and 2:1 ($K_{(AH)_2B}$) complexes between 2,4,6-trichlorophenol and trialkylamines in CCl$_4$ at 25 °C were determined from the absorbance of the ν(OH) stretching vibration of the free phenol. In this determination the infrared spectra were recorded on a PerkinElmer 883 instrument equipped with thermostatic KBr cells with variable path length.

The phenols were crystallized from petroleum ether and the trialkylamines were fractionally distilled and dried over sodium or 4 Å molecular sieves. Carbon tetrachloride and tetrachloroethylene were purified by standard methods (64) and dried over molecular sieves.

Synthesis and molecular recognition of the uridine-containing derivative of *p*-tert-butylcalix[4]arene

Jian Liang, Haiying Fu, Yu Liu, Li Wang, Zhifeng Ye, and Xianfa Shi

Abstract: The new uridine-containing derivative of *p-tert*-butylcalix[4]arene — 5,11,17,23-tetra-*tert*-butyl-25,26,27-trihydroxyl-28-oxyuridinecalix[4]arene (CU) — was synthesized and characterized by ^1H NMR, ^{13}C NMR, IR, EI-MS, and ESI-MS spectra. By the aid of UV–vis spectra, the molecular recognition of CU was studied. The hypochromic effect in UV–vis spectra showed the obvious molecular recognition of CU to ATP. This recognition is actually the hydrogen bond interaction between the uracil group of CU and the base radical of ATP. The association constant between CU and adenine was determined by UV titration at low concentrations.

Key words: calixarene, uridine, molecular recognition, UV–vis spectra.

Résumé : On a réalisé la synthèse d'un nouveau dérivé du *p-tert*-butylcalix[4]arène contenant de l'uridine, le 5,11,17,23-tétra-*tert*-butyl-25,26,27-trihydroxyl-28-oxyuridinecalixa[4]arène (CU), et on l'a caractérisé grâce à la spectroscopie IR, RMN du ^1H et du ^{13}C et à la spectroscopie de masse « EI-MS » et « ESI-MS ». On a étudié les spectres UV–visible comme méthode de reconnaissance moléculaire du CU. L'effet hypochrome dans le spectre UV–visible présente la méthode évidente de reconnaissance du CU avec l'ATP. Cette méthode de reconnaissance correspond à une interaction de liaison hydrogène entre le groupe uracile du CU et le radical de base de l'ATP. La constante d'association entre le CU et l'adénine a été déterminée par titrage UV à faibles concentrations.

Mots clés : calixarène, uridine, reconnaissance moléculaire, spectre UV–visible.

[Traduit par la Rédaction]

Introduction

Calixarenes are cavity-containing macrocyclic compounds made up of substituted phenols with aldehydes (1), which can be used as a basic skeleton in the design of new receptors (2).

We have studied the supramolecular catalysis in the hydrolysis of ATP facilitated by calix[4]arene-5,11,17,23-tetrasulfonate and proved the molecular recognition between calix[4]arene-5,11,17,23-tetrasulfonate and ATP using laser photolysis and pulse radiolysis (3). We also investigated the transport of ATP in an H_2O–CH_2Cl_2 : CCl_4–H_2O liquid membrane system with *p-tert*-butylcalix[4]arene as a carrier (4). The studies showed that *p-tert*-butylcalix[4]arene or calix[4]arene-5,11,17,23-tetrasulfonate could recognize ATP by hydrogen bonds between the phenol hydroxyl group in calixarene and the phosphate group in ATP. But this is not the only kind of molecular recognition model for a nucleotide.

Considering that in the life process, the self-replication of DNA is primarily based on the principle of recognition and pairing of nucleotide bases (A to T, C to G), we want to introduce a nucleoside group (uridine in this paper) into a calixarene molecule as a "recognition factor" or "sensor" for a certain nucleotide (such as ATP) or specific nucleoside. Furthermore, we can develop some applications for these kinds of new calixarene derivatives in recognition of the order of nucleic acid, specific-site cleavage, selective separation, membrane transport, and mimicry of enzymatic catalysis to nucleic acid, etc.

This paper reports the synthesis and characterization of 5,11,17,23-tetra-*tert*-butyl-25,26,27-trihydroxyl-28-oxyuridinecalix[4]arene (CU). The molecular recognition of CU to nucleotide, nucleoside, and base radical was investigated using UV–vis electronic spectroscopy. Furthermore, the association constant between CU and adenine was calculated too.

Experimental

Materials and method

^1H NMR and ^{13}C NMR were recorded at 500 MHz using an AM500 spectrometer in $CDCl_3$. IR spectra were recorded on a Nicolet FT-IR 170SX spectrometer. UV–vis spectra were obtained using a PerkinElmer Lambda Bio40 spectrometer. An LCQ electrospray ionization mass spectrometer (ES-MS Finnigan) was employed for molecular mass determination.

Uridine, adenine, ATP, and GMP were obtained as biochemicals and used without further purification. THF was distilled over sodium pellets. Water used here was deionized (with a conductivity of 1×10^{-6} s^{-1} ~ 1×10^{-7} s). All the other chemicals were of AR grade and were used without further purification.

Synthesis and characterization of CU

The preparation of the compound CU is depicted in Scheme 1. p-tert-Butylcalix[4]arene **I**, 2′,3′-o-isopropylidene-uridine **II**, and 5′-(2′,3′-o-isopropylidene-uridine)-p-methylphenyl-sulfonate **III** were synthesized according to the literature (5, 6) and characterized by ^{1}H NMR, IR spectroscopy, EI and ESI mass spectroscopy, and elemental analysis.

A mixture of 1.51 g p-tert-butylcalix[4]arene **I** (2.33 mmol), 0.47 g 5′-(2′,3′-o-isopropylidene-uridine)-p-methylphenylsulfonate **III** (1.08 mmol), and 0.71 g potassium carbonate (5.17 mmol) in dry THF (40 mL) was stirred under an atmosphere of N$_2$ at 27 °C for 72 h. The resulting solution was filtered to remove potassium carbonate, and the filtrate was concentrated and purified by column chromatography. Then the crude product was recrystallized from methanol to give 0.2 g (21%) as a white powder.

Characterization: mp 146.8–148.8 °C. IR (KBr) (cm^{-1}) ν: 3436 (N–H), 3179 (O–H), 2960 (CH$_3$), 1745 (C=O). ^{1}H NMR (ppm) δ: 1.22 (10H, C(CH$_3$)$_3$), 1.34 (6H, C(CH$_3$)$_3$), 1.56 (6H, C(CH$_3$)$_3$), 2.19 (2H, C(CH$_3$)$_3$), 2.46 (12H, C(CH$_3$)$_3$), 3.45~3.50, 4.26~4.38 (10H, Ar-CH$_2$-Ar and -CH$_2$- in uridine), 4.79~4.81 (2H, in sugar, uridine), 4.92~4.94 (2H, C-OH in sugar, uridine), 5.67 (2H, in sugar, uridine), 5.73~5.75 (1H, uracil), 7.06 (2H, ArH, calixarene), 7.34~7.36 (4H, ArH, calixarene), 7.78~7.79 (2H, ArH, calixarene), 7.78~7.79 (1H, uracil), 10.36 (1H, NH, uracil). ^{13}C NMR (ppm) δ: 25.23 (Ar-CH$_2$-Ar), 27.05 (Ar-CH$_2$-Ar), 31.38 (C(CH$_3$)$_3$), 32.63 (C(CH$_3$)$_3$), 69.25 (5′-C, uridine), 76.69 (3′-C, uridine), 77.33 (2′-C, uridine), 84.97 (4′-C, uridine), 94.79 (1′-C, uridine), 102.74 (5-C, uridine), 114.70 (ArC-CH$_2$-Ar), 125.94 (Ar-CH), 127.96 (Ar-CH), 129.90 (ArC-C(CH$_3$)$_3$), 132.82 (ArC-C(CH$_3$)$_3$), 142.12 (6-C, uridine), 145.23 (ArC-OH), 146.80 (ArC-O-uridine), 149.98 (2-C, uridine), 163.04 (4-C, uridine). EI-MS m/z (%): 648 (M-Uridine (calix[4]arene (Cal)), 31), 592 (Cal – C(CH$_3$)$_3$, 10), 536 (Cal – 2C(CH$_3$)$_3$, 7), 480 (Cal – 3C(CH$_3$)$_3$, 4), 423 (Cal – 4C(CH$_3$)$_3$, 22), 91 (C$_7$H$_7^+$, 100). ESI-MS m/z (%): 898([M + Na]$^+$, 100), 461([M + 2Na]$^{2+}$, 53).

Study on the molecular recognition between CU and ATP, GMP, adenine, and KH$_2$PO$_4$

A series of standard solutions of varying concentrations (1×10^{-3} ~ 1×10^{-6} mol·L^{-1}) of CU was prepared. The absorbance of the standard solutions was determined at 260 nm, and the UV standard curve of CU was taken. The UV standard curves of ATP (260 nm), GMP (252.7 nm and 260 nm), and adenine (260 nm) were determined using the same method. The absorption of KH$_2$PO$_4$ was zero at the UV wave band.

A series of mixed solution samples of CU and ATP were prepared, to maintain the total concentration of the two components constant — about 5×10^{-5} mol·L^{-1} — but varying the concentration ratio of CU and ATP as follows: 5:0,

4.5:0.5, 3.5:1.5, 2.5:2.5, 1.5:3.5, 0.5:4.5, 0:5. Their absorbances were measured at 260 nm, which was the experimental value of absorbance of the sample. For every sample solution, the single absorbance of each component can be calculated by use of their own standard curves, according to the actual concentration in the sample; thus the two single calculated absorbances of the two component were added together, and we got the calculated value of absorbance of the sample. If there is no interaction between the two components in the sample solution, the calculated absorbance value should be the same as its experimental value. So, by comparing the absorbance experimental value to its calculated value, we could find out the information that would enable us to ensure whether there was any interaction between the two components.

A GMP solution, about 1×10^{-4} mol·L^{-1}, was prepared, and its concentration was determined using its standard curve taken at 252.7 nm. But, in the sample solutions, the individual absorbance was calculated using its standard curve taken at 260 nm. The total concentration and the concentration ratio of the two components were the same as in the experiment of the interaction between CU and ATP.

An adenine solution, about 1×10^{-4} mol·L^{-1}, was prepared, and its concentration was determined using its standard curve taken at 260 nm. The total concentration and the concentration ratio of the two components were the same as in the experiment of the interaction between CU and ATP.

A solution of 1.645×10^{-4} mol·L^{-1} KH$_2$PO$_4$ was prepared, and the total concentration and the concentration ratio of the two components were the same as in the experiment of the interaction between CU and ATP.

Determination of the association constant of the supermolecule formed between CU and adenine by UV titration

UV titration has been extensively employed to determine binding constants (7–9). The quantitative determination of the formation constant is based on the absorbance variation of the receptor in the presence of a substrate with certain concentration. Difference absorption spectra were recorded on an Agilent 8453 UV–vis spectrometer. All spectra were obtained in 10 mm cells at 25 ± 1 °C. The added substrate was dissolved in the solution-containing receptor, while the total concentration of the receptor remained constant throughout the titration. The experiments were performed in a concentration range wherein the absorbance of every sample obeyed Beer's law.

The experimental results of the UV titration showed that the association between CU and adenine leads to the formation of only a 1:1 supramolecular complex that has an association constant, K, according to the following equation:

$$R + S \Leftrightarrow C$$

$$[1] \qquad K = \frac{[C]}{[R][S]} = \frac{[C]}{([R]_0 - [C])([S]_0 - [C])}$$

where R, S, and C represent the receptor, the substrate, and the formed supermolecule, respectively, while [R], [S], and [C] are the equilibrium concentration of R, S, and C, respectively; [R]$_0$ and [S]$_0$ are the total concentration of R and S.

Scheme 1. Synthesis of 5,11,17,23-tetra-*tert*-butyl-25,26,27-trihydroxyl-28-oxyuridinecalix[4]arene (CU).
The absorbance, A, measured at a certain wavelength is expressed as:

$$A = l([R]\varepsilon_R + [S]\varepsilon_S + [C]\varepsilon_C)$$

where ε_R, ε_S, and ε_C are the molar extinction coefficients of R, S, and C, respectively, and l is the width of the absorption cell, while the absorbance in the reference cell, A_r, is expressed as:

$$A_r = l[R]_0\varepsilon_R$$

Therefore, the difference in the absorbance, ΔA, is expressed as:

[2] $\Delta A = A - A_r = l([C](\varepsilon_C - \varepsilon_R - \varepsilon_S) + [S]_0\varepsilon_S)$

Using eqs. [1] and [2], the association constant K can be calculated.

Results and discussion

Synthesis and characterization of CU

CU is a new compound whose synthesis, characterization, and properties have not been reported. This paper reports the synthesis and characterization of CU. The characterization methods included IR, ^{1}H NMR, ^{13}C NMR, EI-MS, and ESI-MS — especially the ESI-MS spectrum, which showed, clearly, a strong peak for the molecular ion ($m/z = 898$ ([M + Na]$^+$)) and a strong bivalent ion peak ($m/z = 461$ ([M + 2Na]$^{2+}$)). The characteristic peaks for either calixarene or uridine were found in the ^{1}H NMR and ^{13}C NMR spectra of the synthesized compound CU. The analogous phenomena were observed in the IR or UV spectra of CU too. All these results indicate that the compound synthesized can be identified as the target compound.

UV–vis spectroscopy study of CU

Figure 1 displays the absorption spectra of uridine, 5′-(2′, 3′-o-isopropylidene-uridine)-p-methyl-phonylsulfonate **III**, CU, and p-tert-butylcalix[4]arene **I**. As illustrated in Fig. 1, CU has two obvious absorbance peaks at 260.5 and 226 nm. The two peaks correspond, respectively, to the characteristic absorbance peak of uracil at 261.5 nm (Fig. 1a) (10) and that of p-alkylphenol in the calixarene structure at 227.8 nm (Fig. 1d) (11). This shows that the compound CU is composed of calix[4]arene and uridine.

Using the standard curve of CU taken at 260 nm, the value of the molar absorptivity, ε_{CU260}, can be determined as 1.7955×10^4. For uridine, the value of the molar absorptivity, $\varepsilon_{uridine260}$, can also be determined as 1.028×10^4 (1.01×10^4 in the literature (10)), using the same method. The absorption of p-tert-butylcalix[4]arene **I** is low at around 260 nm, so the corresponding molar absorptivity, ε_{cal260}, is very small. The experimental results showed that CU is a new compound, different from calix[4]arene and uridine.

Molecular recognition study between CU and ATP, GMP, adenine, and KH₂PO₄

CU, ATP, GMP, and adenine all have the characteristic absorbance peak of a nucleotide base group near 260 nm (10). So there is no obvious shift to be found for the charac-

Fig. 1. UV–vis spectra of (a) 1×10^{-5} mol·L^{-1} uridine in water; (b) 1×10^{-5} mol·L^{-1} 5′-(2′,3′-o-isopropylidene-uridine)-p-methyl-phenylsulfonate **III** in THF; (c) 1×10^{-5} mol·L^{-1} CU in water; (d) 1×10^{-5} mol·L^{-1} p-tert-butylcalix[4]arene **I** in CH₂Cl₂.
teristic absorbance peak of every component in the mixed system of CU and ATP, GMP, or adenine, KH₂PO₄, no matter whether they react with each other or not. But an obvious hypochromic effect was indeed found at 260 nm for the mixed system, which shows that there was an interaction between the components in the system.

Interaction between CU and ATP

The experimental data are plotted in Fig. 2a. When there was only CU or ATP in the sample solution, the experimental value was equivalent to the calculated value. For the mixed solutions, the experimental values were always smaller than the corresponding calculated values. Especially when the concentration ratio was 1:1, the difference between the experimental value and the calculated value reached a maximum. This hypochromic effect implies that there is molecular recognition between CU and ATP. Indeed, the molar absorptivity of the formed supermolecule by CU with ATP, $\varepsilon_{CU–ATP}$, can be calculated as 3.1862×10^4 when the component concentration ratio is 1:1.

Interaction between CU and GMP

The experimental data were plotted in Fig. 2b. As illustrated in the figure, the experimental values were almost equivalent to the corresponding calculated values. This did not show a hypochromism or a hyperchromism. This result implies that there is no significant interaction between CU and GMP. The studies reveal that CU can recognize ATP, but not GMP.

Interaction between CU and adenine

The experimental data were plotted in Fig. 2c. As illustrated in the figure, when there was only CU or adenine in the solution, the experimental value was equivalent to the calculated value. For the mixed solutions, the experimental values were always obviously smaller than the corresponding calculated values. Especially when the concentration ratio was 1:1, the difference between the experimental value and the corresponding calculated value reached a maximum.

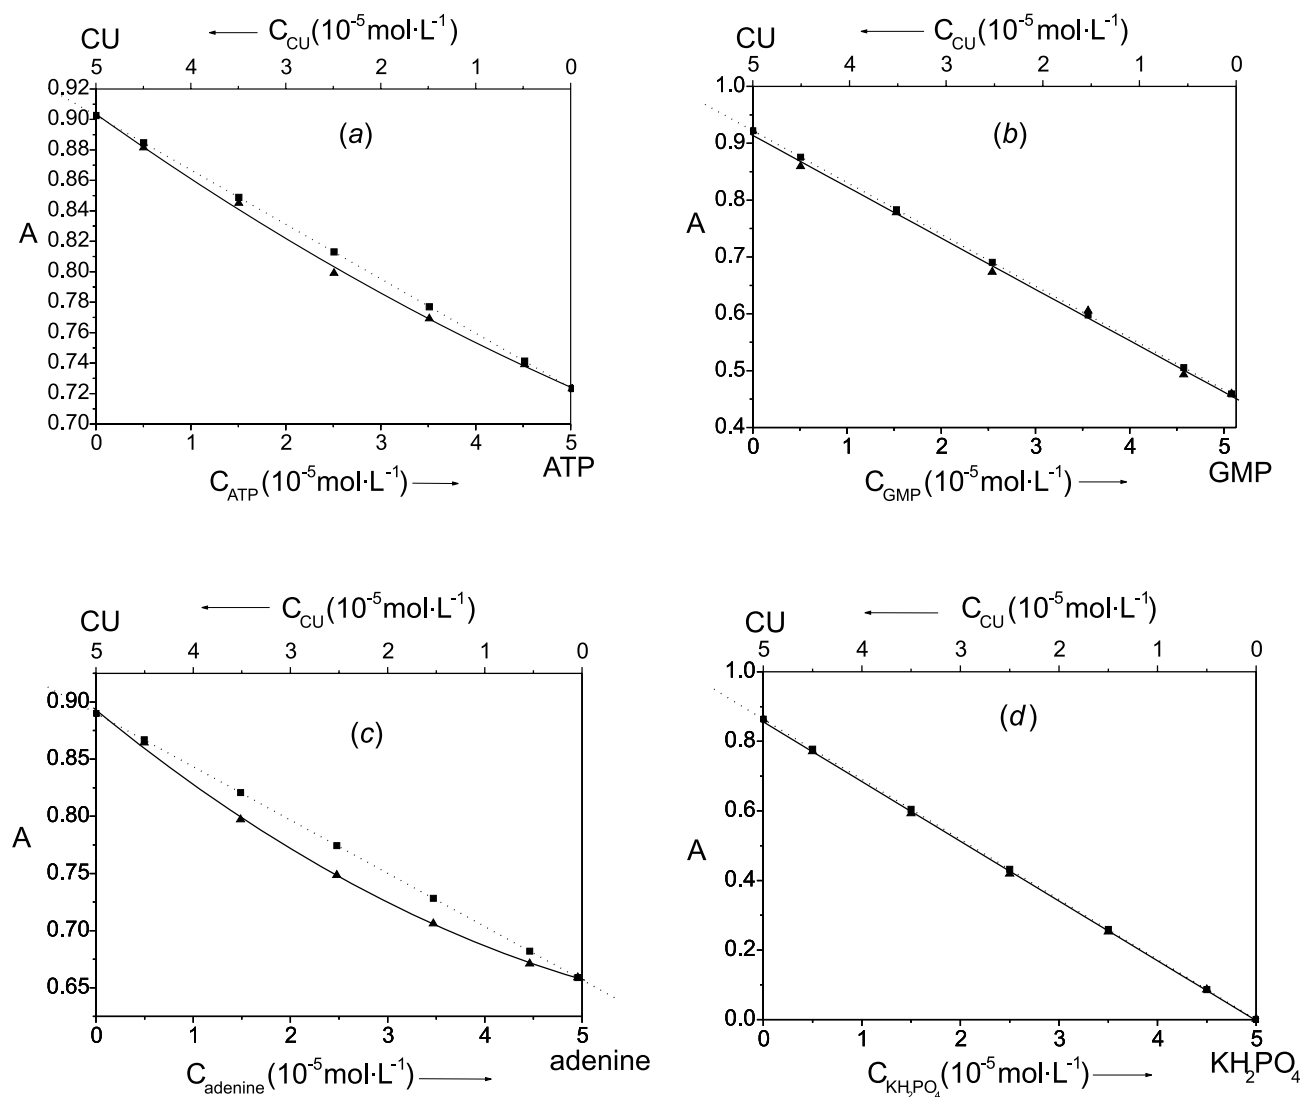
Fig. 2. The absorbance of the sample solutions mixed by CU with ATP (*a*); GMP (*b*); adenine (*c*); KH$_2$PO$_4$ (*d*). Solid line stands for the experimental value; dotted line stands for the calculated value.


Fig. 3. The molecular recognition of CU to adenosine and the formed supermolecule.
This significant hypochromic effect implies that there is obvious molecular recognition between CU and adenine, similar to that between CU and ATP. The base of this molecular recognition may be interpreted as the structural complementarity and hydrogen bonding between the uracil of CU and the adenine in ATP or adenosine.

Interaction between CU and KH₂PO₄

The interaction between CU and KH_2PO_4 was investigated too. The experimental data were plotted in Fig. 2*d*. As illustrated in the figure, the experimental values were almost equivalent to the corresponding calculated values. There is neither a hypochromism nor a hyperchromism. This result shows that CU cannot recognize KH_2PO_4 and implies that the recognition site between CU and ATP is not a phosphate group of ATP.

All the studies suggest that CU can recognize adenosine in the ATP (See Fig. 3), but not the phosphate group. We have studied the molecular recognition between calix[4]arene-5,11,17,23-tetrasulfonate and ATP and found that the basis of recognition was hydrogen bonds formed between hydroxyl group in calix[4]arene-5,11,17,23-tetrasulfonate and the phosphate group in ATP (3). That shows that the recognition mechanisms in these two cases are different.

Determination of the association constant between CU and adenine

In the process of calculation of the association constant between CU and adenine, the self-association of adenine was neglected. The dimerization of CU was not taken into account, as was also the case with adenine. These factors simplify the calculation.

The wavelength of interest was 227 nm, because the difference between the molar extinction coefficients of CU and adenine reaches a maximum at 227 nm.

By using this method, the association constant between CU and adenine was calculated as 2×10^4 mol^{-1}·L.

Conclusion

The experimental results show that the molecular recognition of CU to ATP is based on the recognition of the uridine group in CU to the adenine group in ATP. This recognition function is the same as the one in the process of formation of DNA and RNA, i.e., the base pairing (T to A or U to A).

The experimental result, that CU cannot recognize GMP, also confirms the above recognition function based on U–A pairing. Therefore, according to the idea of molecular design and assembling, by introducing the uridine group (in fact, the uracil group), the target receptor CU can actually work as a "recognition factor" that has the molecular recognition ability for some specific nucleotide, nucleoside, or base (such as ATP, adenosine, or adenine). With this method we can design and synthesize a series of receptors that can have specific molecular recognition ability for given specific nucleotides.

Reactions of dimethoxycarbene with thiocarbonyl compounds

Malgorzata Dawid, Grzegorz Mloston, Darren L. Reid, and John Warkentin

Abstract: A diverse sample of thiocarbonyl compounds were examined to determine what the ultimate stable products are of their reactions with dimethoxycarbene. Those ultimate products can be significantly different for an oxyphosphinyl dithioformate, methyl dithiobenzoate, *O*-methyl thiobenzoate, and dimethyl xanthate.

Key words: dimethoxycarbene, thiocarbonyl compounds, 2,5-dihydro-2,2-dimethoxy-5,5-dimethyl-1,3,4-oxadiazole.

Résumé : On a étudié un large échantillonnage de composés thiocarbonylés pour déterminer la nature de leurs produits ultimes et stables de leurs réactions avec le diméthoxycarbène. Ces produits ultimes varient beaucoup suivant la nature du produit de départ, dithioformiate d'oxyphosphinyle, dithiobenzoate de méthyle, thiobenzoate de *O*-méthyle ou xanthate de diméthyle.

Mots clés : diméthoxycarbène, composés thiocarbonylés, 2,5-dihydro-2,2-diméthoxy-5,5-diméthyl-1,3,4-oxadiazole.

[Traduit par la Rédaction]

Introduction

Carbenes bearing heteroatom substituents (NR$_2$, OR, SR) are nucleophilic, attacking preferentially alkenes with electron-withdrawing substituents. Dimethoxycarbene does not react with cyclohexene (1), but it does add to maleates and fumarates, for example (2). Nucleophilic carbenes react also with carbonyl and thiocarbonyl compounds (3), as do electrophilic carbenes, but the former probably make one bond initially to the electrophilic center (4) or else add in a concerted but asynchronous manner. The latter bond to the carbonyl oxygen (or to thiocarbonyl sulfur) to form ylide intermediates (5). Some of these reactions are illustrated in Scheme 1.

We have examined a diverse sample of thiocarbonyl compounds to determine what the ultimate stable products are, of their reactions with dimethoxycarbene. Surprisingly, those ultimate products can be significantly different for different thiocarbonyl compounds, including *S*-methyl-bis(1-methylethoxy)phosphinecarbothioate-1-oxide (**4**) (also known as *S*-methyl-diisopropyloxyphosphinyl-dithioformate), *S*-methyl benzenecarbodithioate (or methyl dithiobenzoate) (**8**), *O*-methyl benzenecarbothioate (or *O*-methyl thiobenzoate) (**17**), and *O,S*-dimethyl dithiocarbonate (or dimethyl xanthate) (**22**).

The carbene was generated from 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**, also known as 2,5-dihydro-2,2-dimethoxy-5,5-dimethyl-1,3,4-oxadiazole) at 110 °C in a benzene solution containing the thiocarbonyl compound in a sealed tube (Scheme 2). The sequence by which the oxadiazoline undergoes thermolysis is well established (6). The

first step is 1,3-dipolar cycloreversion to N$_2$ and a carbonyl ylide (**2**). The latter is short lived, losing acetone to afford dimethoxycarbene (DMC, **3**).

Results and discussion

Treatment of **4** with DMC gave, in 50% isolated yield, product **7**. It is presumably formed by cycloaddition of DMC to the thiocarbonyl group to generate **5**, which then undergoes desulfurization (typical of such thiiranes) (7) to ketene acetal **6**. Hydrolysis of the sensitive ketene acetal leads to **7**, Scheme 3. The structure of **7** was established by means of spectroscopy and mass spectrometry.

Under similar conditions, dithiobenzoate **8** gave products **11** (not isolable), **12**, **13** (22%), and **16** (28%). The presumed intermediates, **10**, **14**, and **15**, also could not be isolated, and spectroscopic evidence for **12** was based on ^{1}H and ^{13}C NMR spectroscopy only. We assume that **8** reacted with DMC to afford **10**, either via intermediate **9** or directly, by a concerted process, and that thiirane **10** was desulfurized (7) to give ketene acetal **12**. Ketene acetal **12**, like most other ketene acetals, is expected to hydrolyse during workup and to give **13** as the stable end product, Scheme 4. Formation of compound **11** (the probable source of **14**) can be understood in terms of a 1,2-migration of the thiomethyl group in an intermediate like **9**, Scheme 4.

A possible mechanism to **16** is more complicated because it requires two carbene units. The thiocarbonyl group of **11** is expected to be quite reactive toward DMC, and addition would afford **14**. Desulfurization of **14** (7) and hydrolysis, in

(R= CHMe$_2$)
either order, would furnish another ketene acetal (**15**) that would hydrolyze during workup to the end product **16**.

A similar product was formed by reaction of **17** with DMC. Two equivalents of DMC were incorporated, and in this case we were able to identify **21** by means of ^{1}H and ^{13}C NMR spectroscopy, although it too was desulfurized and hydrolyzed to dimethyl phenyl malonate (**16**, 84%). The partial identification of **21** strengthens the analogous mechanism in Scheme 4. Although **19** was not found, it is likely that the first adduct (something like zwitterion **18**) underwent methoxy migration to generate thione **19**, which must be more reactive towards DMC than **17**. We propose, tentatively, that the trimethoxymethyl group of **19** enhances the reactivity of the thiocarbonyl group toward DMC. It might do this by participation of the methoxyl oxygens at the transition state for addition of DMC (**20**) if that transition state were dipolar, as depicted in Scheme 5. A similar suggestion for interaction by a methoxy group was made earlier (3*c*). Alternatively, the reactivity of the thiocarbonyl group might be enhanced by the polar effect of the trimethoxymethyl group. A steric effect, operating in the other direction, would have to be smaller than the polar effect. To support the existence of the polar effect, we compared published values (8, 9) of the IR carbonyl stretching frequencies of the α-methoxyketones (below) with those of corresponding ketones, Fig. 1. It is clear that an α-methoxy group raises the C=O frequency and that the inductive effect of three such groups at a carbon alpha to a carbonyl group could raise its reactivity significantly, although not to the level of acyl

chlorides, which have C=O stretching frequencies near 1800 cm^{-1}.

Compound **22** reacted fairly cleanly with DMC to afford **25** as the major product (40%, isolated). Scheme 6 depicts a possible mechanism for the formation of **25**. In intermediate **24** there is the option of migration of either the methoxy or the methylthio group. The greater polarizability of S and the weaker C—S bond (relative to O and the C—O bond) readily account for the preferential migration of the SMe group.

Experimental

Preparation of starting materials

Compound **1** was prepared according to a published procedure (10); **4** was prepared according to the protocol by D.W. Grisley, Jr. (11); **8** was synthesized by thionation of benzoic acid with the Davy reagent (12); **17** was prepared from methyl benzoate and Lawesson's reagent (13), and **22** was available from methoxide, carbon disulfide, and dimethyl sulfate or methyl iodide (14).

Thermolysis of 1 in the presence of 4

The following thermolysis procedure is typical. A solution of **4** (0.128 g, 0.50 mmol) and **1** (0.080 g, 0.50 mmol) in dry benzene (5 mL) in a thermolysis tube was degassed by means of three freeze–pump–thaw cycles before the tube was sealed under vacuum. It was then placed into an oil bath (110 °C) for a 24 h period. In the case of **4**, evaporation of

Colourless oil. ^1H NMR (200 MHz, CDCl$_3$) δ: 1.37–1.32 (overlapping d, 12H), 2.29 (s) and 2.30 (s) (together 3H), 3.54 (d, $^1J_{P-H}$ = 19.6 Hz, 1H), 3.77 (s, 3H), 4.79 (m, 2H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 23.8, 24.3, 44.7, 47.5, 53.0,

72.7, 72.8, 128.4, 168.0. EI-MS m/z (%): 284 ([M]$^+$, 2), 238 (15), 197 (22), 155 (40), 154 (40), 123 (15), 86 (30), 84 (55), 49 (100). CI-MS m/z (%): 302 ([M + NH$_4$]$^+$, 3), 285 ([M + 1]$^+$, 100).

Thermolysis of 1 in the presence of 8

The standard thermolysis procedure gave, from **8** (0.084 g, 0.50 mmol) and **1** (0.080 g, 0.50 mmol), a residue that was chromatographed on silica (Chromatotron plate, 1 mm, 5% EtOAc in hexane (50 mL) and 10% EtOAc in

hexane (100 mL)) to afford **13** (22%) and **16** (28%) as final, stable products. Small amounts of unstable products **12** and **15** were also isolated.

12

Colourless oil. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 1.98 (s, 3H), 3.52 (s, 3H), 3.77 (s, 3H), 7.18–7.47 (m, 5H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 17.0, 57.5, 97.5, 126.4, 128.1, 129.7, 136.9, 159.2 (from 2d NMR, two of the aromatic carbon signals are coincident). EI-MS m/z (%): 210 ([M]$^+$, 70), 195 (100), 167 (32), 135 (15), 121 (85), 105 (58), 91 (12), 77 (55). Compound **12** hydrolyzed spontaneously to **13**.

13

Colourless oil (15). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 2.08 (s, 3H), 3.74 (s, 3H), 4.52 (s, 1H), 7.26–7.46 (m, 5H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 14.9, 52.6, 53.4, 128.1, 128.4, 128.6, 135.7, 171.1. HR-MS m/z: calcd.: 196.0558, found: 196.0545.

15

Colourless oil. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 3.55 (s, 3H), 3.75 (s, 3H), 3.93 (s, 3H), 7.34–7.20 (m, 5H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 51.6, 57.0, 59.2, 126.7, 127.5, 130.7, 135.2, 166.8, 168.1. Compound **15** hydrolyzed spontaneously to **16**.

16

(16). IR (neat) (cm^{-1}): 2921, 2841, 1740, 1622, 1229, 1152, 1985, 1066, 699. EI-MS m/z (%): 208 ([M]$^+$, 58), 164 (29), 149 (45), 121 (100), 118 (25), 105 (30), 90 (28), 77 (25). The ^{1}H and ^{13}C NMR spectra were in agreement with those of Yang et al. (16) but not with those of Mueller and Tohill (17), which appear to be incorrect.

Thermolysis of 1 in the presence of 17

The standard thermolysis procedure gave, from **17** (0.078 g, 0.52 mmol) and **1** (0.080 g, 0.50 mmol), a residue that was chromatographed on silica (Chromatotron plate, 1 mm, 10% EtOAc in hexane (50 mL), 20% EtOAc in hexane (50 mL), and 40% EtOAc in hexane (100 mL)) to afford **21** (84%).

21

Colourless solid, mp about room temperature. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 3.23 (s, 3H), 3.34 (s, 9H), 3.68 (s, 3H), 7.26–7.32 (m, 3H), 7.53–7.57 (m, 2H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 51.4 (C(OMe)$_3$), 56.0, 57.9, 108.1, 113.1, 127.1, 127.4, 128.8, 130.6, 137.0. EI-MS m/z (%): 269 ([M – S + H]$^+$, 29), 223 (21), 209 (10), 149 (9), 105 (100).

Thermolysis of 1 in the presence of 22

A thermolysis tube (50 mL) was charged with a solution of **22** (3.064 g, 25.1 mmol, 1.0 mol·L^{-1}), and **1** (0.401 g, 2.50 mmol, 0.10 mol·L^{-1}) in dry benzene. Following three freeze–pump–thaw cycles, the thermolysis tube was sealed and placed in a thermolysis bath at 110 ± 0.1 °C for 24 h at which point it was cooled and opened. GC–MS and ^{1}H NMR of the crude indicated that a fairly clean reaction had occurred to give only one product derived from **22**. The product (**25**, 40% isolated yield) was obtained by removing

~90% of the excess **22** by means of bulb-to-bulb distillation (80–90 °C bath temp, 14 mmHg (1 mmHg = 133.322 Pa)) and by centrifugal chromatography of the residue on a 2 mm silica plate with hexanes to elute the remaining **22**, followed by 5% ethyl acetate in hexanes to elute **25**. IR (neat, ν_{max}) (cm^{-1}): 2976, 2942, 2835, 1442, 1266, 1225, 1101, 1067, 1005, 955. ^{1}H NMR (200 MHz, C$_6$D$_6$) δ: 1.87 (s, 3H, SMe), 3.15 (s, 6H, OMe), 3.69 (s, 3H, CO$_2$Me). ^{13}C NMR (50.3 MHz, C$_6$D$_6$) δ: 13.4 (SMe), 50.9 (OMe), 58.8 (C(OMe)$_2$SMe), 111.5 (C(OMe)$_2$SMe), 211.6 (C=S). GC–MS (ei) m/z (relative intensity): 165 ([M – 15]$^+$, 4), 149 (62), 121 (74), 75 (100), 59 (42), 47 (30).

Macroscopically chiral system of three independent orientational effects as a condition for absolute asymmetric synthesis

Roman Bielski and Michal Tencer

Abstract: The paper introduces the concept of using three independent, macroscopic factors affecting mutual orientation of the reactant molecules to accomplish absolute asymmetric synthesis. Unlike with other methodologies of asymmetric synthesis in physical fields, none of the utilized factors is chiral in itself (as, e.g., circularly polarized light would be), but the combination of the three constitutes a macroscopically chiral influence. Examples of applicable directional factors are time-even vector fields (e.g., electric field and the directional effects of surfaces and interfaces) and the time-odd directional transport with encounter control. The directional factors employed may act simultaneously or, if their effect can be preserved, consecutively, thus allowing, e.g., a repeat use of the electric field. The electric field strength needed to achieve a practically useful degree of molecular orientation was estimated to be ca. 3 MV/cm, which is now commonly achieved with organic materials in the area of nonlinear optics. Practical implications are discussed, as well as the implications for the origins of natural homochirality.

Key words: macroscopic chirality, absolute asymmetric synthesis, homochirality, physical fields.

Résumé : Dans ce travail, on propose l'utilisation de trois facteurs macroscopiques indépendants qui affectent l'orientation mutuelle des molécules de réactifs pour faire des synthèses asymétriques absolues. Contrairement aux autres méthodes de synthèses asymétriques dans des champs physiques, aucun des facteurs utilisés n'est chiral en lui-même (comme le serait la lumière polarisée de façon circulaire); toutefois, l'application d'une combinaison des trois constitue une influence chirale macroscopique. Comme exemples de facteurs directionnels applicables, on peut signaler les champs vectoriels appariés en fonction du temps (par exemple, le champ électrique et les effets directionnels de surfaces et d'interfaces) et le transport directionnel non apparié en fonction du temps, mais soumis à un contrôle de rencontre. Les facteurs directionnels utilisés peuvent agir simultanément ou, si leur effet peut être conservé, consécutivement; ce qui permet, par exemple, d'utiliser le champ électrique une autre fois. On a évalué à environ 3 MV/cm la force du champ électrique nécessaire à l'obtention d'un degré d'orientation moléculaire utile d'un point de vue pratique, valeur maintenant fréquemment atteinte dans le domaine de l'optique non linéaire grâce à l'utilisation de composés organiques. Les implications pratiques sont discutées ainsi que les implications pour les origines de l'homochiralité naturelle.

Mots clés : chiralité macroscopique, synthèse asymétrique absolue, homochiralité, champs physiques.

[Traduit par la Rédaction]

Introduction

Absolute asymmetric synthesis has been the object of scientific fascination for several decades; not so much for practical reasons as because of the implications in the important discussion concerning the origin of optically pure compounds in the universe and thus the origin of life itself. The proposed explanations of homochirality derive from two very different directions. One option can be considered a

"random mechanism" and includes such phenomena as preferential enantiomorphic crystallization and stereoselective adsorption on quartz, although the latter mechanism has been disputed (1). The other option, "determinate mechanisms", advocates interaction of non-chiral or racemic chemical systems with chiral physical phenomena (2, 3). However, none of the proposed answers is quite satisfactory (3–5). A recent paper (6) critically reviewed various attempts at asymmetric synthesis in external fields, mostly from the viewpoint of theoretical symmetry considerations of different field types. Also, in the last decade, it was disputed whether or not a very minute but calculable energy difference between enantiomers — caused by the fundamental dissymmetry of weak interactions at the subatomic level — could be responsible for the observed homochirality of the animate world (7, 8).

This paper discusses the possibility of simultaneously using three cooperative macroscopic external factors (such as physical fields) to impart spatial directionality on reacting

molecules, thus creating conditions of macroscopic chirality. In reactions in which a chiral compound is created from either non-chiral or racemic precursors, such macroscopic chirality should result in formation of, preferentially, one enantiomer, provided that the external directional factors are sufficiently strong to give the reacting molecules a predominant orientation. Thus, each of the directional factors confers, onto molecules, orientation along one of three orthogonal directions, which, for simplicity, we shall deem to be identical with the Cartesian axes. While none of these factors is chiral by itself, such a system, as it will be shown below, is chiral. Here, we are interested in the ability of a given field or some other macroscopic factors to hold molecules in a desirable orientation; we do not delve into the theory and intrinsic symmetry properties of individual factors, although those of magnetic fields deserve some comments (see further in the text).

All the methods of enantioselective synthesis and (or) resolution of racemic mixture boil down to formation of a diastereomeric interaction at some stage. For example, enzymes, using this type of interaction, provide spatial directionality on a micro scale, molecule by molecule. We would like to achieve the same effect on a macro scale, directionality being imparted "remotely" on all the reacting pairs at the same time. The question is how to position reacting molecules along the Cartesian axes in such a way that a specific direction of collisions is enforced. If it can be accomplished, a reaction in which a chiral center is formed from non-chiral precursors (or in which the reaction takes place at a chiral center of a racemic compound) will produce a non-racemic mixture. Moreover, based on the relative directions of reacting molecules, one should be able to predict the enantiomer formed in excess. The proposed approach should be valid for reactions at both sp^2 and sp^3 centers.

Let us consider two non-chiral compounds — one of them being prochiral — that react to form a product with one center of chirality. Let the structure of the prochiral compound include functionalities that enable one to define alignment of the molecules with regard to two Cartesian axes using two different physical phenomena. Now, if it were possible to use another physical phenomenon to position the molecules of the other reactant with regard to the prochiral molecules, then optically active products would be formed without introduction of any chiral molecules into the reaction mixture.[3] Of course, by no means are we escaping, here, chirality as the cause of the asymmetry of the product. The novelty of this approach lies in the fact that chirality in this case is macroscopic in nature and is defined by us by the choice of the relative directionality of the three physical phenomena vs. each other. It is different from the proposal by Pierre Curie (see 6 for reference) to introduce asymmetry with electric and magnetic fields, in that Curie's approach proposes two parallel rather than three orthoganol fields and aims to utilize inherent symmetry properties of the fields in what is now considered a false chiral system (6), while we are interested in the orienting effect of the fields. It is also different from the application of magnetochiral dichroism, where unpolarized light parallel to a magnetic field forms a real chiral influence, leading to a small but measurable enantiomeric excess (9).

In reactions performed in the presence of weaker directional factors the resulting enantiomeric excess should depend on the degree of achieved orientation, but even a limited degree of spatial orientation of reacting molecules would be of interest here, since any enrichment of an original non-racemic mixture could shed light on the possible origin of homochirality in nature.

Introducing macroscopic chirality

As an example leading to a further generalization let us have a hypothetical prochiral molecule P (a compound with a carbonyl group attached to substituents M and S, Fig. 1a) with functionalities that enable its unequivocal orientation vs. a plane. Such two functionalities may be, for example, a group enabling covalent or non-covalent attachment to a smooth flat surface and a polar group that confers a dipole moment onto the molecule. In the compound P the carbonyl group is the site of prochirality of the molecule. It may also act as a polar group that imparts a non-zero dipole moment onto the molecule. If the flat surface lies in the xz plane and we turn on electric field **E** along the x direction, the sp^2 prochiral center will be defined within the xy plane (Fig. 1a). The molecule P is reacted with the other reactant, e.g., a nucleophile N. The only reactive site of the reactant N is represented by a group B. Now, if another, yet undefined, directing influence **F** can orient N in the z direction as shown then a specific, predictable, absolute configuration of the reaction product will result.

Since directionality of a flat surface is defined by a vector **G** normal to it, for the situation in Fig. 1a the relationship between the three directional orthogonal vectors **G**, **E**, and **F** is given through cross products, $\mathbf{G} \times \mathbf{E} = k\mathbf{F}$, where k is any scalar proportionality constant. Reversal of the direction of any one vector leads to the formation of a group of vectors that is not identical (i.e., not superimposable) with the original one, $\mathbf{G} \times \mathbf{E} = -k\mathbf{F}$, and a subsequent reversal (reflection) of any of the three vectors leads back to the original cross-product relationship. (However, for limitations operating here, vide infra.)

Considering the stereogenic center of the structure shown in Fig. 1a, let the bond formed by the entering nucleophile in the final product be of the lowest priority (in the Cahn–Ingold–Prelog sense). Let the carbon—oxygen bond be of the highest priority, substituent M be ranked second (medium), and substituent S be ranked third (small). Then the absolute configuration of the formed chiral center will be R. Reflecting this situation in a mirror parallel to the yz plane (which is equivalent to reversing the direction of the electric field **E**) will produce the opposite enantiomer, S (Fig. 1b). Similarly, replacing the flat surface by its mirror image (equivalent to turning the reaction vessel by 180° around the z axis) or reversing the direction of **F** would result in the formation of the S enantiomer. Two such changes would lead, again, to the R product.

---

[3] A similar argument could be made for a racemic mixture reacting at the chiral center. In the presence of macroscopic chirality due to three directional effects, one of the enantiomers would be formed preferentially, provided that the reactants contain appropriate functionalities.

Fig. 1. Macroscopic chirality in the three directional vector system: (*a*) leading to the *R* enantiomer, (*b*) its mirror image leading to the *S* enantiomer.

The challenge of the approach is to transfer the macroscopic chirality of a system of three orthogonal orienting vectors to the molecular level. Possible directional effects are given by the following:

(1) Electric field **E**, which can orient reacting molecules, provided that they have a prominent dipole moment,

(2) Presence of a flat, smooth surface to which a monolayer of reacting molecules is attached (mathematically, the vector **G** normal to the surface defines its directionality),

(3) Directional molecular transport, provided that the reaction is under kinetic conditions and the kinetics is under encounter control, which, for reaction in liquids, would mean diffusion control,

(4) Amphiphilic molecules at interfaces. Molecules containing hydrophobic and hydrophilic groups are oriented at water–oil or liquid–air phase boundaries perpendicularly to the interface.

In this connection, a hypothetical case where **F** = **B** (magnetic field) merits a special distinction. The magnetic field **B** is a time-odd axial (or pseudo) vector (6) that does not reverse by reflection in the **G**,**E** plane but does reverse by reflection in the **G**,**B** and **E**,**B** planes, as can be visualized by **B** being generated by electric current circulating in a coil. However, one could argue that reversing the direction of the magnetic field, no matter how it is brought about, will cause a reversal of orientation of a paramagnetic species equivalent

to a mirror reflection. Unfortunately for our purpose, a paramagnetic molecule does not have a per se defined directionality in terms of the north (N), south (S) poles, and thus, even though in the presence of a strong spin-orbit coupling it can be aligned along the field lines, no directional sense will be preferred. In this sense a paramagnetic molecule is different from a piece of a (ferro) magnet whose orientation in the **B** field can be, in fact, considered an effect of *two* consecutively acting magnetic fields, the first of which was needed to magnetize the material. Perhaps, in the future, progress in molecular magnet research (10) may change our evaluation of the usefulness of magnetic fields as directional physical phenomena.

Thus, since the set of three orthogonal vectors has been shown to be chiral, to achieve an optically active product three such directional effects should be employed, either at the same time or consecutively, although not all of the above factors are compatible with each other. Two of these factors should orient one reactant and the third factor must affect the other reactant. The three vectors should be time-even, polar for thermodynamic control of the reaction, but under kinetic conditions one of them may be time-odd.

Imparting directionality

The proposed macroscopic system can be looked upon from two different points of view. Firstly, it would be of major importance to show experimentally that the application of orienting macroscopic phenomena to an appropriately designed system of reagents can produce a non-negligible enantiomeric excess (ee). It could open a possibility of synthesizing certain optically active compounds without introducing chiral molecules into reaction mixtures. Secondly, it may provide another possible mechanism with which to explain the origin of homochirality.

With the former viewpoint, the directional influences used should be strong enough to lead to a convincing and reproducible ee. Of course, an ee leading to a practical enantioselective synthesis would certainly be convincing. With the latter viewpoint, the formation of even relatively low enantiomeric excesses can be of great interest. A "one-time" event of macrochirality followed by amplification could have eventually led to the L-amino acids and D-sugars we encounter today. Philosophically, this would not differ from other one-time events.

Electric field

Molecules in an external field are subject to two opposing effects: the organizing effect of the field and the randomizing effect of thermal motion. A significant degree of directionality can be achieved if the energy of interaction ε of the molecule with the field is greater than $k_B T$ (k_B, the Boltzmann constant; T, temperature) amounting to ca. 0.025 eV (4×10^{-21} J) at the ambient temperature of 300 K or, in molar terms, RT (ca. 2.5 kJ/mole). The proper merit number showing the effectiveness of the field is, here, the ratio $u \equiv \varepsilon/k_B T$. On top of it, a racemic mixture is entropically preferred by a numerically similar value of free en-

ergy, $k_B T \ln 2$ ($RT \ln 2$ or 1.7 kJ/mole). Thus, to be effective, fields have to supply at least several $k_B T$ worth of energy of interaction per molecule, as will be shown in more detail below.

If the reacting center is separate from the site of the directing center (e.g., dipole moment), the two moieties should be connected with some kind of rigid structure. This condition of rigidity does not exist if these two centers are one and the same, as in Fig. 1, where the carbonyl is both the site of prochirality and of the dipole moment.

"Convincing" E fields

The energy of interaction of the electric field **E** with a molecule having a dipole moment μ is $\varepsilon = \mu E$. Thus, $u = \mu E/k_B T$. For the **E** fields typically encountered in the laboratory (e.g., with dielectric measurements), the degree of orientation[4] is quite small and can be given by the Debye approximation (11) as $\langle \cos\theta \rangle = u/3$. Such a small degree of orientation would have no noticeable chemical effect, and any attempt to utilize it in asymmetric synthesis would be futile. To achieve a significant orientation, a much stronger **E** field has to be applied. The average degree of orientation is then given (11) by the Langevin function [1]

$$[1] \qquad \langle \cos\theta \rangle = \frac{\mu_i}{\mu} = \coth(u) - \frac{1}{u}$$

The effect of **E** on the degree of orientation, as calculated from this function, is shown in Fig. 2. We can see that, to achieve a "convincing" degree of orientation — say 60% — the value of u should amount to 2.5 or more. Strongly conjugated organic molecules can have dipole moment as high as 30 D (12). Assuming a more moderate dipole moment of 10 D (3.34×10^{-29} C·m), we arrive at the field value of $E = 3 \times 10^8$ V/m or 3 MV/cm. This kind of electric field strength is typically close to dielectric breakdown conditions. One way of overcoming dielectric breakdown is to use a large series resistance to prevent any breakdown current. A common way to introduce such resistance is the corona-poling technique in which air is one of the electrodes. It is commonly used in the area of nonlinear optical organic materials (13). Even without resorting to corona poling, a field of 3.7 MV/cm has been achieved before breakdown, and stable reproducible poling was achieved at fields in excess of 3.0 MV/cm (14). Hence, while it is not yet a routine task, it will be possible to orient many organic molecules in an electric field to a significant degree.

Soft matter

Some organized forms of matter, where even moderate field strengths have a strong orienting effect, can decrease the field requirements even further. For example, liquid crystals (LCs) can be easily aligned in electric (and magnetic) fields, owing to the fact that the molecules of a liquid crystal have no choice but to move in unison (15). Therefore, energy of interaction with the field must be multiplied by a value on the order of the Avogadro number (ca. 10^{22}). The orienting property of LCs has been used in the study of or-

---

[4]In dielectric theory, the degree of orientation is defined as the ratio of the effective dipole moment, μ_i, in the direction of the field to the dipole moment of the molecule. It is also the average cosine of the angle between the dipole moment and **E**, $\langle \cos\theta \rangle$.

Fig. 2. Degree of orientation of a dipolar molecule as a function of the applied electric field.

$$\langle \cos \theta \rangle = \frac{\mu_i}{\mu} = \coth u - \frac{1}{u}$$
ganic reaction mechanisms (16). Liquid crystals are so easy to orient that even container walls can impart directionality on them (15, 17).

Effect of temperature

The directional effect of a field can be greatly enhanced by lowering the temperature, as the value of $u = \varepsilon/k_BT$ becomes very large as T approaches 0 K. However, the penalty here would be the kinetics of the process. Since values of ε attainable in relatively weak fields are close to k_BT (2.5 kJ/mole) and activation enthalpies for organic reactions are typically 80–100 kJ/mole, by lowering the temperature we lose much more on reactivity than we gain on selectivity. This is true even for diffusion-controlled reactions, as the activation energy may amount to 20 kJ/mole or more. On the other hand, as far as the origin of natural chirality is concerned, Nature has plenty of time to work at very low temperatures, and thus even moderate fields could have imparted enough directionality to preferentially form one enantiomer over another in the given circumstances.

Freezing of orientation

If the solvent can be either polymerized or cooled below the glass-transition temperature while the **E** field operates, the resulting molecular orientation can be frozen in place. The field will not be needed anymore and thus can be removed before another orienting factor is applied. This would make the system easier experimentally but again, at the expense of reaction kinetics. Another option is to covalently attach molecules equipped with appropriate functionalities to a flat surface (see below), while subjected to the electric

field. After the reaction is completed the **E** field may be removed, its effect being fixed in space. Thus, the **F** field of Fig. 1 could be another **E** field, acting later in time.

Surfaces and interfaces

Directionality of chemical functional groups in a molecule can be accomplished by attaching these molecules to a surface that is genuinely flat and smooth on the molecular level. The attached molecules can then attain directionality in a manner similar to being in the presence of an external field. Availability of appropriate surfaces is limited. Gold, silicon, or cleaved mica (18) may serve as examples. However, gold and other conductive surfaces may be incompatible with the **E** field. Organic monolayers can be prepared at either solid–vacuum (gas), liquid–air, or solid–liquid interfaces (19). Liquid–air interfaces can provide precisely controlled molecular orientation when the Langmuir technique is used to prepare organic films. The films can then be transferred onto solid substrates, forming Langmuir–Blodgett films (20). Monolayers can also be formed directly on solid surfaces in a self-assembly process (21). Of these, the most studied systems are silane compounds on silica (22) and thiols on gold surfaces. Both chemisorbed and physisorbed monolayers can be employed, as long as they are stable in the reaction conditions. It should be possible to detach the molecule from the surface after the reaction without damaging the active center. For rigid molecules, there should be no limitation on the distance of the functional groups from the surface. With flexible molecules (e.g., attached through an alkane chain), the orientation effect may decrease with distance from the surface because of bond rotation, folding, etc. (one can, per-

haps, talk here about a certain "correlation distance" dependent on the structure).

The oil–water (or water–air) interfaces at which an amphiphilic reagent is oriented perpendicularly to the phase border are in many respects similar to monolayers. The energy of the thus imparted orientation is similar to that of a hydrogen bond. In a system employing both the oil–water interface and a monolayer attached to a flat surface, the solid surface must be vertical, as the liquid interface is horizontal. The fact that only molecules at the surface react reduces the amount of available product by a factor of 10^7 when compared with bulk. Ways to partially overcome this difficulty are proposed further in the text.

Directionality of transport — encounter control

Let us imagine molecules of a nucleophile migrating in the z direction and reacting with a prochiral carbonyl compound that has been oriented vs. the x and y directions. Such directionality could be achieved if the source of the nucleophile is in a different phase. If kinetic conditions typical of most organic reactions operate, all sense of directionality will be lost. Let us assume that the reaction in solution between the prochiral molecule P and the nucleophile N consists of two steps: the diffusion-controlled formation of the encounter pair PN, followed by formation of the chiral molecule, C (23). For typical organic reactions, the second step is orders of magnitude slower than the first one. It means that P and N will collide many times within the solvent cage before they react, and when it finally happens, the reaction can proceed from either side with equal probability. The situation that would interest us is when the first step is slower, i.e., when the rate is controlled by diffusion and the reaction takes place on the first encounter. This can happen when the chemical step of the reaction is very fast ($>10^9$ L/ mol·s). Unfortunately, this case is limited to ion neutralization, electron transfer, and certain photochemical processes (e.g., fluorescence quenching), all of which are of limited utility in asymmetric synthesis, with the possible exception of electrochemical reduction of carbonyl, which, it has been claimed, leads to asymmetric synthesis in the presence of a magnetic field (24). At the other extreme, if the viscosity of the solvent was very high (which could be achieved by polymerization), one can imagine that the nucleophile would not be free to move around after collisions and would maintain the sense of directionality. Even if this could be achieved, the distance between the source of the nucleophile and the reactive center should be relatively small because the diffusion process has a "random-walk" character, and the probability of the nucleophile entering the solvent cage from the wrong side increases with distance. Also, the obvious drawback here would be the time penalty we would have to pay — the reaction could be too slow to be of practical value. It may be beneficial for our cause, however, that in supercooled liquids the inverse relationship between translational motion and viscosity breaks down whereas that between rotational motion and viscosity holds. It is found that near glass-transition temperature, molecules translate faster by as much as two orders of magnitude than expected based on their viscosity. In other words, when the temperature is lowered, molecules translate progressively more for every rotation they undergo (25).

Fig. 3. Free energy profiles for formation of R and S enantiomers (*a*) in the presence of 0 to 2 fields, (*b*) in the presence of 3 fields, and (*c*) in the presence of 2 fields and directional transport with encounter control.

(a)

(b)

(c)
In the gas phase, directionality could be maintained with molecular beams of the nucleophile. In this case molecules in the beam with enough energy would react on first encounter; other ones would be scattered away (26).

Thermodynamic vs. kinetic control

The simultaneous or consecutive presence of three physical fields, e.g., two consecutive electric fields and a flat surface that can be represented by the three vectors, **E**, **F**, and **G** in Fig. 1, provides real macroscopic chirality and, as such, can affect the free energy of the chiral products, as well as that of the transition states vs. reactants (6). Thus, the out-

Fig. 4. A possible route to asymmetric synthesis using a surface reaction and two consecutive electric fields, both parallel to the surface and orthogonal to each other. X: electron acceptor or negatively charged substituent, Y: electron donor or positively charged substituent, R–Z: a polar reagent (e.g., alkyllithium or Grignard reagent).
come of a reaction under these conditions can be both thermodynamically and kinetically controlled (see Figs. 3a and 3b). The thermodynamic preference of one enantiomer over the other will disappear when the fields are turned off; thus, we have to be careful that the subsequent work-up of the reaction mixture does not lead to racemization.

If one of the orienting influences is directional transport with encounter control (represented by the velocity vector **v**), R and S products are not differentiated by free energy.

Such a reaction would not lead to an enantiomeric excess if carried out to thermodynamic equilibrium. However, enantiomeric excess can be achieved here through kinetic control (Fig. 3c).[5]

As a relevant example of kinetic control, let us consider nucleophilic substitution at a chiral center. Let us assume here for the sake of simplicity that all three directional effects are very strong and render 100% orientation in each direction. If the reaction goes through the planar transition

---

[5] This could be considered a situation of Barron's "false" chiral conditions, as the vector system **E**, **G**, **v** can be converted into its mirror image **E**, **G**, **–v** by the time reversal; see (6) for references.

state (S_N1), the structure of the product is independent of the configuration of the starting material; both the racemate and the pure enantiomer will produce a single enantiomer. Its configuration depends only on the direction of the effects orienting the nucleophile and the carbocation vs. each other.

The outcome would be different for the S_N2 mechanism, where the attack of the nucleophile takes place from the side opposite to the leaving group. Since only one direction of attack is allowed in the presence of the fields, only one enantiomer of a racemic starting material would enter into reaction, leading to a single enantiomer of the product. Surprisingly, an enantiomeric starting material would produce either the inversed product or would not react at all. Of course, in a real system, 100% alignment would never happen, and we would have enantiomeric enrichment rather than a pure enantiomer.

Practical considerations

Finally, let us look briefly at criteria that should be considered when selecting potential directional factors, potential reactants, and reaction conditions. The choice of the three directional factors from the ones described above depends on their accessibility, the required ee, and the acceptable minimum amount of reaction product. It would be elegant if we were able to take advantage of a simultaneous use of three different (orthogonal) fields, but this does not seem practical at this point. As the high electric field is relatively easy to effectively apply (13, 14), it seems reasonable to employ it twice, if possible. An example of such application is shown in Fig. 4. In this example, a prochiral molecule A with a high dipole moment (due to the electronegative and electropositive substituents X and Y) is reacted with reactive groups on a flat surface (e.g., mica) in the presence of the **E** field. A variety of plausible surface chemistries were described recently (27). Upon completion of this reaction the field can be removed because the orientation of A is frozen. At least two bonds have to be involved for the A attachment to achieve this effect. Next, after unreacted functional groups on the surface are blocked, an electric field perpendicular to the one previously applied is turned on, and a strongly polar reactant B (for example, a metalloorganic compound R–Z; Z represents a metal atom such as lithium) is introduced and allowed to react with the prochiral center of the previously fixed A. After the work-up, an optically active compound will be produced. If R is a methyl group, then the absolute configuration of the product shown in Fig. 4 will be *R*. Possible candidates for this approach include, i.e., nucleophilic (S_N1) substitution (racemate as a starting material), nucleophilic reactions at the carbonyl group or its derivatives, Michael addition, and concerted reactions such as Diels–Alder and the ene syntheses.

As mentioned before, a reaction involving interaction with a surface will lead inevitably to rather miniscule amounts of optically active product, which is the main drawback of the approach. To increase the reacting quantities, one can introduce a large number of parallel sheets of flat surfaces into the reaction vessel, all facing the same direction. Alternatively, it is conceivable to use a constantly moving, closed-loop tape with one reactive side to which a reagent would be attached before entering the consecutive reactors, followed

by removal of the product in the post-vessel. Upon continuous operation, the concentration of the chiral product in the post-vessel would increase gradually until it reaches a usable level. In this connection, with a properly designed system, even small yields of an optically active material can potentially be turned into a very significant ee through autocatalysis, as was convincingly shown recently (28).

The adsorption of cyclohexanone on aluminum oxide – hydroxide powders in relation to its electrocatalytic hydrogenation

François Laplante, Nicolas-Alexandre Bouchard, Patrick Dubé, Hugues Ménard, and Louis Brossard

Abstract: Henry's law constants were determined for cyclohexanone adsorption onto aluminium oxide – hydroxide powders by dynamic isotherm measurements using the HPLC method. The key parameters that control cyclohexanone adsorption were established. Further, it is suggested that the amount of cyclohexanone adsorbed onto aluminium oxide – hydroxide compounds (AOHC) is of paramount importance for its electrocatalytic hydrogenation in the presence of composite nickel–AOCH powders.

Key words: adsorption isotherm, electrocatalytic hydrogenation (ECH), cyclohexanone, aluminum oxide – hydroxide powders.

Résumé : En se basant sur des mesures d'isothermes dynamiques effectuées par le biais de la méthode de la chromatographie liquide à haute performance, on a déterminé les constantes de la loi de Henry pour l'adsorption de la cyclohexanone sur des poudres d'oxyde – hydroxyde d'aluminium. On a établi la nature des paramètres clés qui contrôlent l'adsorption de la cyclohexanone. De plus, il est suggéré que la quantité de cyclohexanone adsorbée sur des composés à base d'oxyde – hydroxyde d'aluminium (COHA) est de prime importance pour son hydrogénation électrocatalytique en présence de poudres composites de nickel–COHA.

Mots clés : isotherme d'adsorption, hydrogénation électrocatalytique (HEC), cyclohexanone, poudres d'oxyde – hydroxyde d'aluminium.

[Traduit par la Rédaction]

Introduction

The electrocatalytic hydrogenation (ECH) of cyclohexanone to cyclohexanol was recently carried out in the presence of composite powder particles suspended in aqueous solution under vigorous stirring conditions (1, 2). The brief contact of the composite powder particles with a porous carbon cathode was sufficient to form adsorbed hydrogen on the metallic nanoaggregates during water electrolysis to initiate the ECH. The yield of the ECH reaction was closely dependent on both the nature of the metallic nanoaggregates deposited on the non-conductive powder (e.g., alumina and activated carbon) and the nature of the latter. Using a very strong adsorbent matrix material, such as activated carbon, for organic molecules is preferable to using a moderate adsorbent, such as γ-alumina, the latter being more active than

Al(OH)$_3$ and AlO(OH). Consequently, the key role of the adsorption–desorption of the organic compounds involved in the ECH reaction was deduced. The same general deduction is also applicable to the ECH of phenol to cyclohexanol, the composite powders being trapped in a reticulated vitreous carbon matrix cathode (3). In both situations, however, the exact nature of the adsorption–desorption processes of the organic molecules on the adsorbent matrix remains unclear, and further investigation is required.

The present study pertains mainly to the adsorption of cyclohexanone under the experimental conditions previously reported (1), using γ-Al$_2$O$_3$, AlO(OH), and Al(OH)$_3$ adsorbent matrices. The adsorption isotherms, through dynamic measurements, allow the determination of Henry's law constants (k_H) for the adsorption of cyclohexanone on the matrix. It is shown that the ECH yield of cyclohexanone is linked to the Henry's law constant value.

Theory

As previously described (4–6), the technique used to calculate the Henry constant (k_H) can be defined as follows:

$$[1] \qquad Q_e = k_H C_e$$

where Q_e is the adsorption capacity at equilibrium, and C_e is the equilibrium concentration of cyclohexanone in the mobile phase.

F. Laplante, N.-A. Bouchard, P. Dubé, H. Ménard,[1] and L. Brossard.[2] Centre de recherche en électrochimie et électrocatalyse, Département de chimie, Université de Sherbrooke, 2500 boul. Université, Sherbrooke, QC J1K 2R1, Canada.

[1]Current address: Institut de recherche d'Hydro-Québec (IREQ), 1800 boul. Lionel-Boulet, Varennes, QC J3X 1S1, Canada.

[2]Corresponding author (e-mail: brossard.louis@ireq.ca).

From the elution profile, based on the chromatogram, Q_e corresponds to:

$$[2] \qquad Q_e = \frac{n_i I_1}{m I_2}$$

and C_e is expressed by

$$[3] \qquad C_e = \frac{n_i h}{I_2}$$

where n_i is the amount (in moles) of cyclohexanone injected into the chromatographic column, m is the mass (in grams) of adsorbent packed in the column, and h is the peak height (arbitrary units).

The I_1 and I_2 parameters are determined from the elution profile of the chromatograms, as shown in Fig. 1. The integral I_1 is given by the area of the prism ABCD. Line CD links the peak maxima. I_1 is expressed by

$$[4] \qquad I_1 = \int_0^h (\tau_r - \tau_0)\,dh$$

where τ_r and τ_o are, respectively, the retention time of cyclohexanone and the dead time (in minutes), with the latter corresponding to the appearance of a non-retained compound. I_2 represents the amount of the compound injected into the column and is proportional to the area under the elution profile. I_2 is given by

$$[5] \qquad I_2 = \int_{\tau_1}^{\tau_2} h\,d\tau$$

where τ_1 and τ_2 are the times delimiting the beginning and the end of the chromatographic peak. From different amounts of cyclohexanone injected in the column, the distribution factor of cyclohexanone between the adsorbed state (Q_e) and the mobile phase (C_e) allows the determination of k_H.

Experimental

The different Al(OH)$_3$ powders with specific BET surfaces of 0.23 and 35 m^2 g^{-1} were supplied by Alcan International. All the powders were sifted to provide particles with a narrow distribution of diameters. The powder with a BET surface of 0.23 m^2 g^{-1} was further heated at 350 °C or 800 °C for 24 h to induce changes in the chemical nature of the compound, namely, AlO(OH) at 350 °C and γ-Al$_2$O$_3$ at 800 °C. The average particle size remained close to a given value between 17 and 52 µm, depending on the set of the experiments carried out. Each powder was individually packed in the chromatographic column for further characterization.

HPLC-grade water (Caledon) was used for the solution preparation. The mobile phase contained KH$_2$PO$_4$ (0.05 mol L^{-1}, Fluka $\geq$ 99.5%) and NaOH (0.05 mol L^{-1}, Aldrich 99.99%). The pH was adjusted to 7.0 by adding NaOH. The buffer was filtered under vacuum with Millipore filters (0.22 µm) prior to the HPLC measurements.

The columns (Supelco, stainless steel column blanks, 4.6 mm i.d. × 6.35 mm o.d. × 100 mm long) and the injector nozzle were filled with an aluminium oxide – hydroxide

powder, according to the slurry packing method in water. Afterwards, to condition the column, a phosphate buffer (KH$_2$PO$_4$, 1 mol L^{-1} and NaOH, 1 mol L^{-1}, adjusted to pH 7.0) was pumped (Beckman, model 100A) through the column for 2 h at a flow rate of 0.15 mL min^{-1}. Martin and Giochon (7) reported a complete review on the packing techniques for the HPLC columns.

Solutions of cyclohexanone were prepared from a 0.5 mol L^{-1} stock solution. Solution (5 µL) containing from 25 to 2500 nmol of cyclohexanone was injected into an HPLC system (Agilent, HPLC 1100 series) equipped with a diode array detector (Agilent, DAD module 1100 series) operating at a wavelength of 278 nm. The temperature was maintained at 25 °C by using a thermostat module (Agilent, 1100 series thermostated column compartment). The buffer (0.05 mol L^{-1}) flow rate was set to 0.5 mL min^{-1}. The determination of the column dead time was made by injecting 5 µL of deuterium oxide into the column. The passage of eluted D$_2$O through the diode array module induced a slight variation of the base line indicating the column void volume (or the dead time, τ_0).

Results

Adsorption vs. specific surface

Al(OH)$_3$ powders with two different specific surface areas (0.95 m^2 g^{-1} and 35 m^2 g^{-1}) were used to determine the adsorption of cyclohexanone under dynamic isotherm conditions. Table 1 summarizes the characteristics of the powders. Despite the large variation of the BET surface, the value of

Table 3. Characteristics of the aluminium oxide – hydroxide powders used to correlate k_H with the type of support.

Entry	Support	Specific surface (BET) (m^2 g^{-1})	Particles diameter (μm)	Geometric surface (m^2 g^{-1})
F	γ-Al_2O_3	203	28.5	0.087[a]
G	$Al(OH)_3$	0.36	30.6	0.081[a]
H	$AlO(OH)$	67.6	29.2	0.085[a]

[a]See footnote *b* in Table 1.

k_H is practically the same (Fig. 2), indicating that the adsorption of cyclohexanone is independent of the BET surface.

Adsorption vs. particle diameter

To establish the relationship between particle diameter and adsorption, $Al(OH)_3$ powder with a specific surface of 0.23 m^2 g^{-1} was sifted and separated into three fractions (Table 2). Since the effect of the BET surface area on cyclohexanone adsorption is marginal and the variation of the BET surface area with particle diameter is small, it was deduced that the smaller the particle diameter, the larger the adsorption (Fig. 3).

Adsorption vs. type of support

The aluminum hydroxide calcinations were carried out according to ref. 1, to obtain $AlO(OH)$ and γ-Al_2O_3. Each powdered aluminum compound, including $Al(OH)_3$, was sifted in such a way that the fraction with a mean particle diameter of 29.4 ± 1.1 μm was collected (Table 3). The adsorption of cyclohexanone was seen to increase in the following order: $AlO(OH) < Al(OH)_3 < \gamma$-$Al_2O_3$ (Fig. 4). The constant k_H is 400 times lower for $AlO(OH)$ compared with γ-Al_2O_3.

Discussion

Cyclohexanone adsorption

As far as the adsorption of cyclohexanone is concerned, it was deduced from Fig. 2 that the adsorption is located near the particle surface and is negligible at depth. The adsorption of cyclohexanone at depth is negligible because the solution does not penetrate inside the pores to reach the core

Fig. 4. Q_e against C_e of cyclohexanone for three different aluminum compounds. Powders in Table 3. Powder F, $k_H = 120 \times 10^{-3}$ mL g^{-1}; powder G, $k_H = 13 \times 10^{-3}$ mL g^{-1}; powder H, $k_H = 0.3 \times 10^{-3}$ mL g^{-1}.

Support	Particle diameter (µm)	Nickel loading (% w/w)	ECH yield (%)
Al(OH)$_3$	25.3	1.10	56
Al(OH)$_3$	20.3	1.10	66
Al(OH)$_3$	5.4	0.70	86
AlO(OH)	25.4	0.15	31
Al(OH)$_3$	25.3	0.37	38
γ-Al$_2$O$_3$	26.4	0.20	69

[a]For a total charge consumption of 1400 C.

[9] $A(YH–ZH)_{ads} \leftrightarrow A + YH–ZH$

[10] $M(H)_{ads} + H_2O + e^- \leftrightarrow M + H_2 + OH^-$

[11] $2\,M(H)_{ads} \leftrightarrow 2\,M + H_2$
The first step, eq. [6], consists of the formation of chemisorbed hydrogen on the metallic sites (M) by the reduction of water, with the chemisorbed hydrogen represented by $M(H)_{ads}$. The adsorption of the organic compound proceeds onto the adsorption sites (A) (step 2, eq. [7]). The adsorption sites are located on the oxide. Two pathways are possible for the adsorbed atomic hydrogen: it may be involved in the ECH reaction (step 3, eq. [8]) or lost through steps 6 or 7 (eqs. [10] and [11]) (12). The greater the fraction of atomic hydrogen involved in eq. [8], the higher the ECH yield. Step 3 (eq. [8]) occurs at the adlineation point, where the metal nanoaggregates (M), the adsorbent (A), and the solution come in contact (2, 3, 13). Consequently, since the rate-determining step of the ECH is a surface reaction, it may be deduced that the greater the number of adsorption sites filled by the reactant (the reactant being the organic compound under consideration, such as cyclohexanone), the easier the pathway for the ECH process (eqs. [8] and [9]). In other words, the greater the adsorption capacity of cyclohexanone at the adsorption sites (A), the higher the ECH yield. In the present study, the smaller the particle diameter, the larger the adsorption capacity (Fig. 3), with the latter increasing in the following order: AlO(OH) < Al(OH)$_3$ < γ-Al$_2$O$_3$. If the adsorption of cyclohexanone is rate-determining, the ECH yield should increase as the particle diameter decreases and from AlO(OH) to γ-Al$_2$O$_3$ as the adsorption materials. This is fully consistent with the ECH yields recently reported, regarding the ECH of cyclohexanone on composite aluminum oxide – hydroxide powders with a small amount of nickel deposited on the particle surfaces (Table 4).

The nature of the adsorption sites of aluminum oxide – hydroxide powders remains to be further investigated. The acid–base properties of the compounds under consideration are of paramount importance for the adsorption capacity of organic molecules and are intimately linked to the crystallization nature of the material, which is hydration-dependent (14). Since orthophosphate is present in the solution and the affinity of phosphate species is considerable for aluminum oxide – hydroxide compounds (15–18), phosphate complexes and (or) aluminum phosphate may be present at the solution-support interface, and the cyclohexanone adsorption may be affected. The theoretical approach (19, 20) developed by

of the particles. On the other hand, the gas used for the BET measurements may easily penetrate the particle to the core. Consequently, as reported in Fig. 2, there is no correlation between the BET surface area and the k_H value. Values of k_H should be related to the characteristics of the "skin" of the particles, as the geometric surface (m^2 g^{-1}) available and the nature of the compound in the particle surface region (8). As observed, the greater the geometric surface or the smaller the particle diameter, the greater the adsorption (Fig. 3). Moreover, the amount of cyclohexanone adsorbed (ACAD) on the particle surface is largely dependent on the chemical nature of the particles (Fig. 4), with the ACAD being greatest in the presence of γ-Al$_2$O$_3$. The features reported in Fig. 4 for cyclohexanone adsorption are consistent with the views of Madsen and Blokhust (9) concerning the adsorption of benzoic acid on α-alumina and boehmite. In addition, it may be pointed out from the latter reference that the finer the particle powder, the greater the adsorption capacity.

It is perhaps relevant to point out that cyclohexanone adsorption is weak on the three aluminum compounds considered in the present paper. This may be ascribed to the hydrophilic character of the aluminum oxide – hydroxide compound under consideration (10, 11). Since water is a polar solvent, the adsorption sites tend to be taken up by water molecules, and few sites remain available for cyclohexanone adsorption. The fact that water comes in contact with the particles prior to the cyclohexanone injection most likely contributes to lowering the cyclohexanone adsorption capacity.

Adsorption vs. ECH yield

For composite materials, such as a metal deposited onto an oxide, the different steps involved in the ECH of an organic compound through water electrolysis are

[6] $2\,M + 2\,H_2O + 2\,e^- \leftrightarrow 2\,M(H)_{ads} + 2\,OH^-$

[7] $A + Y{=}Z \leftrightarrow A(Y{=}Z)_{ads}$

[8] $2\,M(H)_{ads} + A(Y{=}Z)_{ads} \leftrightarrow A(YH\text{-}ZH)_{ads} + 2\,M$

other groups may be useful in shedding light on the adsorption process.

Conclusion

The amount of cyclohexanone adsorbed on aluminum oxide – hydroxide powders increases as the powder particles become smaller, in the following order: $AlO(OH) < Al(OH)_3 < Al_2O_3$, and regardless of the BET surface area. Furthermore, when the cyclohexanone ECH is carried out on the same adsorbent compounds with a small loading of nickel nano-aggregates on the particle surfaces; the larger the amount of cyclohexanone adsorbed onto the aluminum oxide – hydroxide compounds, the higher the ECH yield.

A study of the decomposition behaviour of 12-tungstophosphate heteropolyacid in solution

Zhirong Zhu, Ruan Tain, and Colin Rhodes

Abstract: In this paper, the decomposition of $H_3PW_{12}O_{40}$ in aqueous solution or in mixed solutions of water–ethanol or water–acetone is investigated by potentiometric titration and ^{31}P NMR. Identification of the products from $H_3PW_{12}O_{40}$ decomposition over a pH range of 1–12 was achieved using preparation high performance liquid chromatography (Pre-HPLC) combined with IR, UV–vis spectroscopy, and inductively coupled plasma atomic emission spectroscopy (ICP). It is found that $H_3PW_{12}O_{40}$ in aqueous solution decomposes in a stepwise fashion with increasing pH, with the following solution compositions: $[PW_{12}O_{40}]^{3-}$ (at pH ~ 1) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ (at pH 2.2) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ + $[P_2W_{19}O_{67}]^{10-}$ (at pH 3.5) → $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ (at pH 5.4) → $[PW_9O_{34}]^{9-}$ (at pH 7.3) → PO_4^{3-} + WO_4^{2-} (pH > 8.3). In the first stages at pH < 8, $H_3PW_{12}O_{40}$ decomposes partially with removal of W=O units. In the second stage at pH > 8, tungstophosphoric completely decomposes to PO_4^{3-}. In contrast, the decomposition of $H_3PW_{12}O_{40}$ is reduced, or the stability of the $[PW_{12}O_{40}]^{3-}$ anion is enhanced, in ethanol–water or acetone solution at pH < 8.

Key words: 12-tungstophosphate heteropolyacid, decomposition behaviour, potentiometric titration, ^{31}P NMR, preparation high performance liquid chromatography.

Résumé : Faisant appel à des titrages potentiométriques et à la RMN du ^{31}P, on a étudié la décomposition du $H_3PW_{12}O_{40}$ en solution aqueuse, dans des solutions mixtes d'eau et d'éthanol ou d'eau et d'acétone. L'identification des produits résultants de la décomposition du $H_3PW_{12}O_{40}$ à des pH allant de 1 à 12 a été effectuée par chromatographie liquide à haute performance au niveau préparatif (CLHP-Pré) combinée aux méthodes spectroscopiques IR, UV–visible et d'émission atomique des plasmas à couplage inductif (ICP). On a observé que, en solution aqueuse, le $H_3PW_{12}O_{40}$ se décompose par étape avec une augmentation du pH; la composition de la solution passe de $[PW_{12}O_{40}]^{3-}$ (à un pH d'environ 1) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ (à un pH de 2,2) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ + $[P_2W_{19}O_{67}]^{10-}$ (à un pH de 3,5) → $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ (à un pH de 5,4) → $[PW_9O_{34}]^{9-}$ (à un pH de 7,3) → PO_4^{3-} + WO_4^{2-} (à un pH supérieur à 8,3). Dans les premiers stades, à des pH inférieurs à 8, le $H_3PW_{12}O_{40}$ se décompose partiellement avec l'élimination d'unités W=O. Dans un deuxième stade, à un pH supérieur à 8, l'entité tungstophosphorique se décompose complètement en PO_4^{3-}. Par ailleurs, en solution dans un mélange éthanol–eau ou acétone–eau, à des pH inférieurs à 8,0, le $H_3PW_{12}O_{40}$ est réduit ou la stabilité de l'anion $[PW_{12}O_{40}]^{3-}$ augmentée.

[Traduit par la Rédaction]

Introduction

The study of polyoxometalates, which are unmatched in terms of molecular and electronic structural versatility, is an increasingly important field, having wide applications in analytical and clinical chemistry, biochemistry, catalysis, medicine, and materials science (1). The synthesis of hundreds of polyoxometalate compounds has been described since the first heteropolytungstate compound was discovered by

Marignac in 1862 (2). Most polyoxometalates are synthesized in aqueous solution, and consequently the processes involved in the assembly of polyoxometalates are important in understanding the fundamental processes that give rise to the final compound (3, 4). Recently, Raman spectroscopy, ^{17}O magic angle spin - nuclear magnetic resonance (MAS-NMR), and fast atomic bombardment mass spectroscopy (FAB) have been used to discern the important relationships that exist between structures in aqueous solution and the nature of the resulting solid (5–7). The behaviour of heteropolymolybdates in aqueous solution has been studied in detail using potentiometric titration combined with ^{31}P NMR (8, 9). As a result, the formation of Keggin species was observed in solution at pH < 2, and other polyoxospecies were obtained from decomposition of the Keggin species with increasing pH of solution.

The chemical structure of the heteropolyacid $H_3PW_{12}O_{40}$ was identified by Keggin in 1933 as being a compact, edge-

Z. Zhu[1] and R. Tain. Shanghai Research Institute of Petrochemical Technology, Pudong Beilu 1658, Shanghai 201208, China.

shared polyhedral arrangement (10). Of the Keggin structures, $H_3PW_{12}O_{40}$ is considered to be the most stable and the most acidic of the heteropolyacids and is used as an acid catalyst (11, 12). In the solid form, often, the catalysts are supported to improve surface area. Upon support materials, heteropoly acids are known to exhibit reduced acidic character and are known to undergo varying degrees of decomposition. For example, the decomposition of Keggin $H_3PW_{12}O_{40}$ has been observed to occur when $H_3PW_{12}O_{40}$ is supported on the surface of basic materials, such as Al_2O_3 and MgO (13). However, in such cases the compounds formed by $H_3PW_{12}O_{40}$ decomposition were not identified, although $[PW_{11}O_{39}]^{7-}$ of the lacunary Keggin structure was presumed to exist. It is known that in dilute solutions (1 wt%) with pH ca.2, $H_3PW_{12}O_{40}$ may decompose to form the lacunary $[PW_{11}O_{39}]^{7-}$ anion (14). Similarly, it has been shown that under appropriate conditions, other tungstophosphate anions, such as $[PW_9O_{34}]^{9-}$, $[P_2W_{18}O_{62}]^{6-}$, and $[P_2W_{21}O_{71}]^{6-}$, may be formed (15, 16). It was reported that $H_3PW_{12}O_{40}$ decomposed to PO_4^{3-} and WO_4^{2-} with the addition of NaOH through several intermediates, i.e., $H_3PW_{12}O_{40}$ + OH^- → $[P_2W_{21}O_{71}]^{6-}$ + OH^- → $[PW_{11}O_{39}]^{7-}$ + OH^- → $[P_2W_{19}O_{67}]^{10-}$ + OH^- → $[PW_9O_{34}]^{9-}$ + OH^- → PO_4^{3-} (17). During the decomposition of polyoxometalates, the mechanism of decomposition between $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ was similar, i.e., $H_3PW_{12}O_{40}$ ($H_4SiW_{12}O_{40}$) + OH^- → $[PW_{11}O_{39}]^{7-}$ ($[SiW_{11}O_{39}]^{8-}$) + OH^- → $[PW_9O_{34}]^{9-}$ ($[SiW_9O_{34}]^{10-}$) + OH^- → PO_4^{3-} (SiO_4^{4-}), but this was not investigated over a wide pH range of 1 ~ 12, owing to the difficulty in identifying products (18, 19). Detusheva et al. (20) studied the reaction of $H_3PW_{12}O_{40}$ with NaOH in aqueous solution (neutralized to pH < 7.8) using ^{31}P NMR, IR, and Raman spectroscopy. The products formed during decomposition of $H_3PW_{12}O_{40}$ were identified as $[P_2W_{21}O_{71}]^{6-}$, $[PW_{11}O_{39}]^{7-}$, $[PW_9O_{34}]^{9-}$, $[PW_{12}O_{42}]^{12-}$, and WO_4^{2-}, and a Raman spectroscopic method was developed to analyze some components from the decomposition of $H_3PW_{12}O_{40}$, but only with a very limited range for determination. Maksimovskaya (21) investigated the titration of $H_3PW_{12}O_{40}$ (0.002 ~ 0.1 mol·L^{-1}) with MOH (M = Li, Na, K), Li_2CO_3, and $MgCO_3$ or $CaCO_3$ at pH 1.5 ~ 9 in aqueous solution, using ^{31}P NMR. At the first stage, the $H_3PW_{12}O_{40}$ converted into $[PW_{11}O_{39}]^{7-}$ through some intermediates, and this conversion is reversible at pH 1.5 ~ 4. At the second stage (pH > 7), $[PW_{11}O_{39}]^{7-}$ decomposed to PO_4^{3-} and WO_4^{2-} directly (with Na, Li) or indirectly (with K, Mg) through the intermediates of monomeric heteropoly acids (PWx) with W/P < 11. However, the products formed during decomposition of $H_3PW_{12}O_{40}$ were identified only by NMR, with the result that the identification of some intermediates appears vague.

Therefore, accurate identification of the formed products (i.e., analysis of the components of the $H_3PW_{12}O_{40}$ solution) is a key in the study of the mechanism of $H_3PW_{12}O_{40}$ decomposition, and the combination of multiple methods, especially the method for the separation of mixed heteropoly acids, is an ideal way to solve this problem. On the other hand, heteropoly acids have been widely used in organic–water systems, but the mechanism of $H_3PW_{12}O_{40}$ decomposition has not been studied in detail. Moreover, to identify all the components resulting from the decomposition of solid $H_3PW_{12}O_{40}$ is extremely difficult, and the initial step to understanding the properties of the solid phase is to understand, first, the steps of decomposition in solution.

In this paper, the behaviour of $H_3PW_{12}O_{40}$ decomposition is investigated by potentiometric titration and ^{31}P NMR in aqueous solution, in a mixed solution of water–ethanol, and in water–acetone. The components of the $H_3PW_{12}O_{40}$ solution were separated by preparative high pressure liquid chromatography (Pre-HPLC). Characterization of the components of products from $H_3PW_{12}O_{40}$ decomposition was achieved using IR, UV–vis spectroscopy, and inductively coupled plasma atomic emission spectroscopy (ICP).

Experimental section

Hydrated 12-tungstophosphoric acid ($H_3PW_{12}O_{40}$) (supplied by Aldrich, > 99%) was dried at 393 K for 8 h to obtain $H_3PW_{12}O_{40} \cdot 6H_2O$ (22, 23). Subsequently, the hexahydrate was used to prepare 0.1 mol·L^{-1} $H_3PW_{12}O_{40}$ in water, 0.1 mol·L^{-1} $H_3PW_{12}O_{40}$ solution in water–ethanol (volume fraction 50/50), and 0.1 mol·L^{-1} $H_3PW_{12}O_{40}$ in water–acetone (volume fraction 50/50).

Potentiometric titration

Potentiometric titration was carried out by adding 0.2 N NaOH standard aqueous solution into each of the $H_3PW_{12}O_{40}$ solutions (20 mL, 0.1 mol·L^{-1}) at a rate of 2 drops per second at room temperature, using Fisherbrand AR10 pH equipment with a glass hydrogen electrode that was calibrated before and after every titration. Water was boiled just before being used, and the titration container was isolated from air with the flow of helium.

Component identification

The above samples, obtained with the titration of NaOH and after ageing for 1 day, were analyzed using ^{31}P NMR and HPLC at the same time, and the pH of the solution was determined again. ^{31}P NMR spectra were measured (161.97 MHz) using a Bruker MSL-400 instrument at 298 K, using 5 µs pulses and a relaxation time of 10 s and the resolution of 3.052 Hz per point. Exponential multiplication with 3 Hz line-broadening was applied prior to Fourier transformation. Phosphoric acid (85% in D_2O) was used as an external reference.

The solid material formed from tungstophosphate in water–ethanol or water–acetone was recovered by filtration. A PerkinElmer 2000 FT-IR spectrometer was used to characterize the solids produced, which were combined with KBr to form self-supporting discs.

The components of products from $H_3PW_{12}O_{40}$ decomposition in aqueous solution were separated using a Waters 4000 Pre-HPLC instrument fitted with a reverse-phase C18 preparation column and a photodiode array UV detector (254 nm). HPLC grade H_2O and 90% (volume fraction) methanol solution, both containing 60 mM $BuNH_3$ and 20 mM citrate, were used for the linear gradient elution, according to the following program (time in minutes (H_2O – 90% methanol ~ (volume fraction))): 0 (90/10), 10 (80/20), 10 (50/50), 10 (15/85). The separated components were collected in a flask and recovered by evaporation under vacuum. The P/W elemental ratio of the components obtained above was determined using a BRUKER PS-6 ICP instrument.

Results and discussion

Behaviour of $H_3PW_{12}O_{40}$ decomposition with increasing pH in aqueous solution

Potentiometric titration has been widely used to study the decomposition of 12-tungstophosphate heteropolyacid as the pH of the solution changes (23, 24). Figure 1 shows how the pH of an $H_3PW_{12}O_{40}$ solution changes from pH 1.1 to 12.0 with addition of 0.2 N NaOH solution. As is expected, the pH value of the original solution, pH ~ 1, indicates that $H_3PW_{12}O_{40}$ is more acidic than ordinary mineral acids or the corresponding oxoacids arising from any combination of its constituent elements.

Initially, the pH changes slowly — from pH ~ 1 to pH ~ 4.5 — as NaOH is added. Continued addition of NaOH leads to a rapid increase in the rate of pH change between pH ~ 4.5–8. An indistinct endpoint emerges at pH 5 ~ 8, which indicates that the potentiometric curve for pH < 8 is consistent with the presence of more than one acidic species or single polyprotic species, with narrowly spaced pK values.

At pH ~ 8 further addition of NaOH does not lead to a significant increase in the overall pH of the solution. Rapid addition of NaOH causes only a temporary rise in the measured pH, but after standing, or by reducing the velocity at which NaOH is introduced to the mixture, the pH returns to ca. 8. This effect becomes more pronounced as more NaOH is added. Clearly the ability of the polyoxometalate to maintain the pH of the solution to within 0.5 pH units indicates that tungstophosphoric acid has high buffering capacity. Further addition of NaOH ultimately produces a very obvious endpoint when the molar ratio of OH^-:$H_3PW_{12}O_{40}$ is 27. This feature is similar to those observed for normal acid–base titrations, and a sharp rise in pH from 8.5 to 11.5 is seen to take place.

^{31}P NMR spectra of the solutions produced during the titration of $H_3PW_{12}O_{40}$ with NaOH are shown in Fig. 2. At the pH of the original solution, ca. 1.1, the singlet at –14.7 ppm, characteristic of the P heteroatom of the Keggin 12-series tungstophosphate, is clear. As NaOH is added to the $H_3PW_{12}O_{40}$ solution, however, the spectra become increasingly complex up to pH = 3.5, after which further addition of NaOH leads to the spectra becoming increasingly simpler. At pH = 7.3, a singlet at –8 ppm is visible. When the pH of the solution exceeds 8 an additional peak at 0 ppm, attributable to PO_4^{3-}, can be observed, the intensity of which increases as further NaOH is added. Upon complete decomposition of the heteropolyacid at pH = 12, only the peak attributable to PO_4^{3-} is visible.

In conclusion, the whole process of $H_3PW_{12}O_{40}$ titration with NaOH may be divided into two stages. In the first stage, where the pH of the solution is <8, the behaviour of $H_3PW_{12}O_{40}$ is similar to a mixture of acids or a polyprotic acid. In the second stage, tungstophosphoric acid behaves as the acid salt of a normal weak acid, such as $NaHCO_3$ or Na_2HPO_4.

Determination of the composition of tungstophosphate solution

Identification of the products from $H_3PW_{12}O_{40}$ decomposition has been investigated using HPLC. A few scattered re-

ports of chromatography for certain subclasses of polyoxometalates have appeared (25–27). The reversed-phase HPLC with a methanol–water gradient, using ion-interaction reagents to promote retention and a citrate ion as the competing ion, resulted in excellent and rapid separations of mixed

polyoxometalates, such as $[PW_{11}VO_{40}]^{5-}$, $[PW_{10}V_2O_{40}]^{5-}$, and $[PW_9V_3O_{40}]^{6-}$ (28). Recently, some reversed-phase HPLC methods using ion-interaction reagents and competing ions have also been developed, including separation of tungstophosphate anions (29, 30). Figure 3 presents the chromatograms resulting from the decomposition experiments of $H_3PW_{12}O_{40}$. The chromatograms correlate well with the NMR data in the number of species present in solution as the pH is varied from pH ~ 1 to pH ~ 12.

As each component was eluted from the HPLC instrument, a UV spectrum was collected by the detector, which was fitted with an automatic scanning function. The data collected are presented in Fig. 4. With the aid of a preparation-scale HPLC column, the individual fractions (components) of products from the tungstophosphate decomposition process were collected for further identification. The W/P ratio of the components, corresponding to chromatographic peaks, was determined by ICP analysis, and combined with ^{31}P NMR and UV–vis spectra reported previously (15, 17, 31, 32), each component may be identified accurately (shown in Table 1). In addition, each of the fractions collected was re-injected for HPLC analysis, and

only one peak was observed, which shows that every component is stable under HPLC separation conditions. It is observed in the UV spectrum in Fig. 4 that the wavelength of maximum UV absorption of tungstophosphate anions decreases with decreasing W/P. This results from the fact that the increase of charge density in tungstophosphate anions leads to enhancement in P—O π-bonding as the tungsten–oxygen units surrounding the heteroatom are removed (31).

Effect of organic solvent on the behaviour of $H_3PW_{12}O_{40}$ decomposition

It is seen clearly in Figs. 5 and 6 that the pH-titration curve of $H_3PW_{12}O_{40}$ in water–ethanol is almost the same as that in water–acetone, both of which are different from that in aqueous solution. The apparent pH value of the $H_3PW_{12}O_{40}$ solution (the value indicated by pH equipment) is higher (near 1.7) in water–ethanol or water–acetone solutions than in aqueous solution, which indicates that the acidity of $H_3PW_{12}O_{40}$ solution is decreased by the addition of organic solvents.

As is expected, the endpoint of the acid–base titration emerges at an exact 3 OH^-:$H_3PW_{12}O_{40}$, which indicates that the $H_3PW_{12}O_{40}$ anion is stable at pH < 8 when in a water–ethanol or water–acetone solution. As observed for the aqueous solution, the pH remains 8.5–9.0 when NaOH continues to be added. Eventually a precipitate is formed in solution with further addition of NaOH, and meanwhile, the pH of solution increases rapidly.

If the addition of NaOH is stopped at this stage, the solution pH will fall to about 9 in several minutes, and the precipitate will redissolve. Continued addition of NaOH

Table 1. Characterization data of components of tungstophosphate solution.

Compound	Chemical shift of ^{31}P NMR (min)	Retention time of HPLC (min)	Wavelength at maximum absorption (nm)	W/P ratio by ICP
$[PW_{12}O_{40}]^{3-}$	–14.7	9.9	264	12.08
$[P_2W_{21}O_{71}]^{6-}$	–12.6	15.0	257	10.59

produces a precipitate that will not redissolve readily. IR spectra of the precipitate produced from water–ethanol and water–acetone solutions are presented in Fig. 7, and the solid is positively identified as $[PW_9O_{34}]^{9-}$, according to the report (33). At pH ~12, all the deposit is dissolved, but a period of several hours or days is needed, depending on solution temperature.

Fig. 7. IR spectra of the deposit formed during titration in water–ethanol or water–acetone at pH > 9.0: (1) in water–ethanol, (2) in water–acetone.
^{31}P NMR clearly shows (in Fig. 8) that the decomposition pathway of tungstophosphate upon addition of NaOH is much simpler in water–ethanol and water–acetone than in aqueous solution. The $H_3PW_{12}O_{40}$ anion remains intact in solution to pH ~8 with no peaks due to $[P_2W_{19}O_{67}]^{10-}$ or $[P_2W_{18}O_{62}]^{6-}$ being visible in the ^{31}P NMR spectra. At pH = 8.6, decomposition of the anion is observable with a small amount of precipitate produced, which redissolves readily. At pH = 9.4, all the $[PW_{12}O_{40}]^{3-}$ and $[P_2W_{21}O_{71}]^{6-}$ anions have decomposed to form $[PW_{11}O_{39}]^{7-}$ and $[PW_9O_{34}]^{9-}$, and eventually, when pH = 11.7, only PO_4^{3-} remains.

Mechanism of tungstophosphate variation with increasing pH

Based on the above experimental results, it may be considered that $H_3PW_{12}O_{40}$ in aqueous solution decomposes with the following solution compositions in increasing pH:

$[PW_{12}O_{40}]^{3-}$ (at pH ~ 1) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ (at pH 2.2) → $[PW_{12}O_{40}]^{3-}$ + $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ + $[P_2W_{19}O_{67}]^{10-}$ (at pH 3.5) → $[P_2W_{21}O_{71}]^{6-}$ + $[PW_{11}O_{39}]^{7-}$ + $[P_2W_{18}O_{62}]^{6-}$ (at pH 5.4) → $[PW_9O_{34}]^{9-}$ (at pH 7.3) → PO_4^{3-} + WO_4^{2-} (pH > 8.3).
The above mode for $H_3PW_{12}O_{40}$ decomposition is similar to that proposed previously (17). However, our study clearly shows that although the lacunary $[PW_{11}O_{39}]^{7-}$ anion is the main product of $H_3PW_{12}O_{40}$ decomposition, it exists simultaneously with dimeric anions of tungstophosphate, i.e., $[P_2W_{21}O_{71}]^{6-}$, $[P_2W_{18}O_{62}]^{6-}$, and $[P_2W_{19}O_{67}]^{10-}$, in the region of pH 2–6. The relationship between $[PW_{11}O_{39}]^{7-}$ and $[P_2W_{21}O_{71}]^{6-}$ is not easy to observe or explain because the conversion from $H_3PW_{12}O_{40}$ to $[PW_{11}O_{39}]^{7-}$ and $[P_2W_{21}O_{71}]^{6-}$ anions is too rapid to be studied in detail.

It has been considered in previous reports that $[P_2W_{21}O_{71}]^{6-}$ was directly produced from $[PW_{12}O_{40}]^{3-}$ decomposition. For example, the solute–support interaction between $H_3PW_{12}O_{40}$ with SiO_2 or TiO_2 lead to partial transformation in $[P_2W_{21}O_{71}]^{6-}$, and contact of $H_3PW_{12}O_{40}$ in ethanol–water solution with Al_2O_3 gave rise to the $[P_2W_{21}O_{71}]^{6-}$ species (15). During preparation of supported $H_3PW_{12}O_{40}$ on Al_2O_3, the appearance of the dimeric species of $[P_2W_{21}O_{71}]^{6-}$ was revealed by ^{31}P NMR after a tungstophosphoric acid solution had contacted with basic Al_2O_3, which produced a substantial change of solution pH, from 1.1 to 4.0 (16).

However, in the previous study of $H_3PW_{12}O_{40}$ solution, it was found that $H_3PW_{12}O_{40}$ decomposed initially to $[PW_{11}O_{39}]^{7-}$ at diffusion-controlled rates at pH > 1.5 (21). It was also reported that $H_3PW_{12}O_{40}$ decomposed to $[P_2W_{21}O_{71}]^{6-}$, and there was equilibrium between $H_3PW_{12}O_{40}$ and $[P_2W_{21}O_{71}]^{6-}$ at pH 1.3 ~ 2.3 (34). Besides, a very dilute solution of 1 wt% $H_3PW_{12}O_{40}$ at pH ca. 2 decomposed to form the lacunary $[PW_{11}O_{39}]^{7-}$ anion (14). It was reported that $[P_2W_{18}O_{62}]^{6-}$ and $[P_2W_{21}O_{71}]^{6-}$ were formed from $[PW_{11}O_{39}]^{7-}$ decompositon during contact of $[PW_{11}O_{39}]^{7-}$ with TiO_2, as well (15). Therefore, it is possible that a series of equilibria exists between $[PW_{11}O_{39}]^{7-}$ and dimers in the tungstophosphate solution in the region of pH 2–6. It was reported that a similar equilibrium in the molybdophosphate system depended on solution pH (8), and that the cation in solution affected the rate of tungstophosphate decomposition (19). It may be considered that the ratio of $[PW_{11}O_{39}]^{7-}$:$[P_2W_{21}O_{71}]^{6-}$ in this equilibrium depends on both the pH and other ions in solution. As a result, many different results were obtained for a variety of tungstophosphate solutions. Therefore, during the conversion of the solution components described in the beginning of this paragraph, it may be considered that there are certain equilibria between these components, as follows:

(*a*) An equilibrium between $[PW_{12}O_{40}]^{3-}$ and $[P_2W_{21}O_{71}]^{6-}$ and $[PW_{11}O_{39}]^{7-}$ at pH 2.2 ~ 3.5.

(*b*) An equilibrium between $[P_2W_{21}O_{71}]^{6-}$ and $[PW_{11}O_{39}]^{7-}$ at pH 2.2 ~ 5.4.

(*c*) An equilibrium between $[PW_{11}O_{39}]^{7-}$ and $[P_2W_{18}O_{62}]^{6-}$ at pH 3.5 ~ 5.4.

Fig. 8. ^{31}P NMR spectra of tungstophosphate solution (water–acetone) formed during titration: (1) original $H_3PW_{12}O_{40}$, (2) pH = 8.6, (3) pH = 9.4, (4) pH = 11.7.
(*d*) An equilibrium between $[P_2W_{19}O_{67}]^{10-}$ and $[P_2W_{18}O_{62}]^{6-}$ at about pH 3.5.

The previous study has shown that the conversion of $[PW_{12}O_{40}]^{3-}$ to $[PW_{11}O_{39}]^{7-}$ takes only milliseconds, with $[PW_{11}O_{39}]^{7-}$ to $[PW_9O_{34}]^{9-}$ taking several seconds (18, 23). This conversion from $[PW_{11}O_{39}]^{7-}$ and the dimeric species to $[PW_9O_{34}]^{9-}$ is very rapid, and only a little NaOH leads to a rapid increase of solution pH and completion of the conversion. It was seen from the HPLC chromatogram (Fig. 3) and ^{31}P NMR spectra (Fig. 2) that the $[PW_9O_{34}]^{9-}$ anion alone is formed at about pH 6.8. This is in agreement with the previous investigation of tungstophosphate, which found that in weakly alkaline solutions of pH 7–9, the $[PW_{11}O_{39}]^{7-}$ degradation into $[PW_9O_{34}]^{9-}$ anion takes place rapidly, but the period for the total decomposition to PO_4^{3-} varies from minutes to hours, depending on temperature and pH (23). It is observed in this study that the decomposition of $[PW_9O_{34}]^{9-}$ to PO_4^{3-} is relatively slow, and the velocity of $[PW_9O_{34}]^{9-}$ decomposition increases with increasing pH and temperature. It is easy to understand that the complete destruction of the lacunary Keggin structure needs higher activation energy than the removal of W=O units from the lacunary Keggin structure.

It has been suggested previously that this enhanced stability results from protons being only partially removed by organic solvents. It was found that $H_3PW_{12}O_{40}$ was completely deprotonated in aqueous solution and partially deprotonated in polar organic solvent (35, 36) and that protons may stabilize tungstophosphate anions by decreasing the intramolecular repulsion in the interior structure of the Keggin unit. It is well established that organic molecules in solution can reduce the dissociation of protons from a conjugate base. As a result, the proton activity of $H_3PW_{12}O_{40}$ acid decreases and the stability of the acid increases in organic solvents. On the other hand, the action of water molecules on tungstophosphate anions is weakened by absorption of organic mole-

cules, with the hydration number of tungstophosphoric acids decreasing. Anion repulsion also plays a role with anion–anion repulsion being more intense than that corresponding to aqueous or acidified-with-HCl solutions (37).

Conclusion

$H_3PW_{12}O_{40}$ decomposition with NaOH addition in aqueous solution may be divided into two stages. In the first stages at pH < 8, $H_3PW_{12}O_{40}$ decomposes partially with removal of W=O units. In the second stage at pH > 8, tungstophosphoric acid completely decomposes to PO_4^{3-}. As well, a series of equilibria exists between $[PW_{11}O_{39}]^{7-}$ and tungstophosphate dimers in solution at pH 2–6, depending on the pH and the other ions in solution. It may be considered that $H_3PW_{12}O_{40}$ in aqueous solution decomposes in increasing pH with the following solution compositions:

$$[PW_{12}O_{40}]^{3-} \text{ (at pH} \sim 1) \rightarrow [PW_{12}O_{40}]^{3-} + [P_2W_{21}O_{71}]^{6-} + [PW_{11}O_{39}]^{7-} \text{ (at pH 2.2)} \rightarrow [PW_{12}O_{40}]^{3-} + [P_2W_{21}O_{71}]^{6-} + [PW_{11}O_{39}]^{7-} + [P_2W_{18}O_{62}]^{6-} + [P_2W_{19}O_{67}]^{10-} \text{ (at pH 3.5)} \rightarrow [P_2W_{21}O_{71}]^{6-} + [PW_{11}O_{39}]^{7-} + [P_2W_{18}O_{62}]^{6-} \text{ (at pH 5.4)} \rightarrow [PW_9O_{34}]^{9-} \text{ (at pH 7.3)} \rightarrow PO_4^{3-} + WO_4^{2-} \text{ (pH} > 8.3).$$
A normal endpoint of acid–base titration may be observed at an exact ratio of 3 OH^-:$H_3PW_{12}O_{40}$, which indicates that the $H_3PW_{12}O_{40}$ anion is stable in pH < 8 water–ethanol or acetone solution. The proton activity of $H_3PW_{12}O_{40}$ acid decreases and the stability of the acid increases in the presence of organic solvents. On the other hand, the action of water molecules on tungstophosphate anions is weakened by absorption of organic molecules.

Supercritical argon as a mobile phase for the flame photometric detection of sulfur

Kevin B. Thurbide and Brad W. Cooke

Abstract: The background emission properties of supercritical argon and supercritical carbon dioxide mobile phases in packed column supercritical fluid chromatography (pSFC) with flame photometric detection (FPD) were compared. As column flow rates were increased toward common values used in pSFC, the carbon dioxide background emission grew enormously. The resulting emission spectrum displayed dominant features at wavelengths between 325 and 525 nm, consisting of a complex series of overlapping molecular emission band systems partly attributed to CO* and CH*. By comparison, when using the same flow rates with a supercritical argon mobile phase, the background emission was identical to that of the FPD flame without column effluent. In terms of intensity, when using a column flow rate of 2 mL/min, supercritical carbon dioxide contributes a background emission in the FPD that is about 3×10^5 times larger than that produced by supercritical argon. This difference leads to an improvement of two orders of magnitude in the pSFC-FPD signal-to-noise ratio for sulfur when a supercritical argon mobile phase is used. Results indicate that supercritical argon could also be advantageous for the pSFC-FPD analysis of other elements.

Key words: supercritical fluid chromatography, packed column, flame photometric detection, supercritical argon.

Résumé : On a comparé les propriétés de l'émission ambiante des phases mobiles de l'argon et du dioxyde de carbone supracritiques en chromatographie à fluide supracritique dans une colonne à remplissage (CFSr) avec détection photométrique à flamme (DPF). L'émission ambiante du dioxyde de carbone croît énormément lorsque l'on augmente la vitesse d'écoulement de la colonne vers les valeurs couramment utilisées en CFSr. Le spectre d'émission résultant révèle des caractéristiques importantes à des longueurs d'onde comprises entre 325 et 525 nm, consistant en une série complexes due au recouvrement des systèmes de bandes d'émission moléculaire que l'on attribue partiellement au CO* et au CH*. En comparaison lorsqu'on utilise la même vitesse d'écoulement pour la phase mobile de l'argon supracritique l'émission ambiante est identique à celle de la flamme DPF sans l'effluent de la colonne. En termes d'intensité, lorsque l'on utilise une vitesse d'écoulement de 2 mL/min, la contribution du dioxyde de carbone supracritique à l'émission ambiante dans le DPF est d'environ 3×10^5 fois plus élevé que celle due l'argon supracritique. Cette différence conduit à une amélioration de deux ordres de grandeur du rapport signal : bruit pour le soufre lorsque l'on utilise une phase mobile d'argon supracritique. Les résultats indiquent que l'argon supracritique peut aussi être avantageux pour l'analyse par CFSr-DPF d'autres éléments.

Mots clés : chromatographie à fluide supracritique, colonne à remplissage, détection photométrique à flamme, argon supracritique.

[Traduit par la Rédaction]

Introduction

Packed column supercritical fluid chromatography (pSFC) is being used in an increasing number of applications and provides a complimentary separation method to conventional high performance liquid chromatography (HPLC) and gas chromatography (GC) (1, 2). This is mainly attributed to the increased speed and selectivity that pSFC can offer, compared with HPLC, and the wider range of compounds that can be analyzed by pSFC relative to GC (3, 4). Carbon diox-

ide is the most common mobile phase in pSFC, and since it decompresses to a gas after leaving the separation column, pSFC can also greatly facilitate the union of HPLC-type separations with conventional gas-phase GC detectors. While numerous applications of this method using the universal flame ionization detector have been reported (1, 2, 5), specific GC sensors such as the electron capture and thermionic detectors have also been used in pSFC (6). One of the most common selective GC detectors used for the specific analysis of sulfur is the well-known flame photometric detector (FPD), which is based on chemiluminescence emanating from a low-temperature, fuel-rich, hydrogen–air flame (7).

Previously, a thorough optimization of the use of FPD to monitor sulfur in capillary column supercritical fluid chromatography (cSFC) has been reported (8, 9). The authors achieved very good detection limits for sulfur and demonstrated that cSFC-FPD yields a performance that is similar

to conventional GC-FPD in many respects. A major obstacle noted in that work and others in this area is the large background emission that is observed in the FPD flame when carbon dioxide is used as the mobile phase (8–10). This can interfere with the detection of sulfur emission in the FPD and leads to baseline variations when the column flow is changed. As such, the need to reduce this background emission was cited as being extremely important in regards to the performance of the detector.

In addition to independent control of flow and pressure, modern pSFC instruments also use much larger columns and mobile phase volumes compared with cSFC (6). For instance, the typical column flow rate of 40 µL/min used in previous cSFC-FPD studies generated about 14 mL/min of carbon dioxide gas directed into the FPD. In contrast to this, pSFC commonly uses column flow rates of about 2–3 mL/min, which translates into over 1000 mL/min of carbon dioxide gas upon decompression. As such, the background emission of a typical FPD can be expected to increase dramatically and cause much greater interference with the use of pSFC as compared with cSFC. In relation to this, the FPD literature in this area is dominated by cSFC applications (8–11). While it is possible to operate pSFC-FPD in the split mode, where only a portion of the column effluent and analyte are directed into the detector, this option is often less desirable because of the variable split ratio and detailed design considerations associated with such pSFC interfaces (6, 12, 13).

An interesting, alternative mobile phase used in recent years is supercritical argon (critical point: 48 atm (1 atm = 101.325 kPa) and –122 °C), which can be readily produced by conventional pumping instrumentation and has been shown to provide similar performance to that of supercritical carbon dioxide (critical point: 72 atm and 31 °C) (14). In addition to its low cost, inertness, and available purity, other significant advantages of using supercritical argon as a mobile phase include its optical transparency in infrared analyses and its compatibility with the determination of nonmetals by inductively coupled plasma atomic emission spectroscopy (15). Whereas, in this method, supercritical carbon dioxide can create a very large background signal, the use of supercritical argon eliminates this problem since argon is also the plasma reagent gas. Further, while supercritical xenon can offer some similar benefits, it is much more expensive, and other inert gases such as nitrogen and helium are much less efficient as supercritical mobile phases when compared with carbon dioxide (14, 16). Thus it would be interesting to examine the improvements that might be offered by using this approach in pSFC-FPD. However, no reports comparing the use of supercritical argon and supercritical carbon dioxide as mobile phases in this detector have appeared.

Considering the lack of available information and the potential difficulties regarding the operation of a splitless pSFC-FPD system, it would be useful to acquire more knowledge of the interference presented by high flows of carbon dioxide in the FPD. Particularly beneficial would be more insight into the spectral distribution of the carbon dioxide background emission and how it impacts the performance of this widely used detector (17–19). Such information would be helpful since more than twenty other elements besides sulfur are known to provide useful analyti-

cal emission in the visible wavelength range of the FPD (20). Finally, since it could provide potential improvements in this area, it would be interesting to evaluate how the FPD performance when using supercritical argon compares with that obtained when using supercritical carbon dioxide. This paper presents a comparison of the spectral distribution and relative intensity of the FPD background emission obtained from using a supercritical carbon dioxide and a supercritical argon mobile phase under typical pSFC conditions. To gauge the effects of any differences observed, the performance of the FPD in the detection of sulfur, using each of these mobile phases under optimized conditions, will also be compared.

Experimental

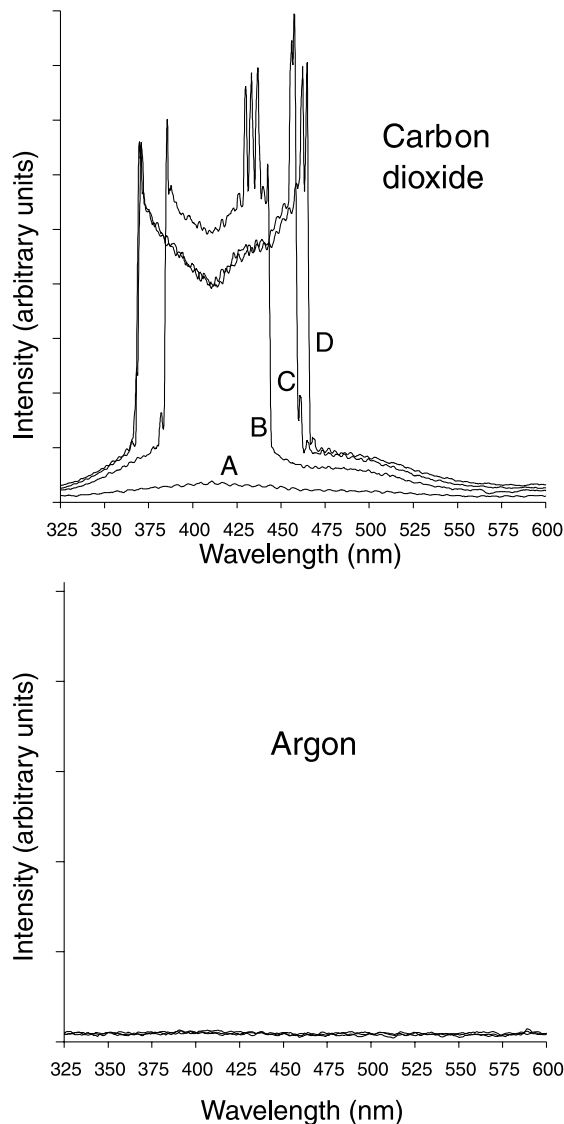
The pSFC system used was a Gilson series SF3 (Gilson, Villiers-le-Bel, France) comprised of a dual reciprocating pump – solvent delivery system (model 308 and 306), a column oven (model 831), a back pressure regulator (model 821), and an evaporative light scattering detector (ELSD; Sedere, CEDEX, France). This system is designed to facilitate delivery of the mobile phase by continually cooling the pump heads with chilled water (typically –5 to 5 °C) from a refrigerated circulating bath. A 250 mm × 4.6 mm i.d. Lichrosorb Diol column (10 µm particles; Alltech, Deerfield, IL, U.S.A.) was used for separations. The GC-FPD system used for adaptation to the pSFC instrument was a Shimadzu model GC-8A (Shimadzu, Kyoto, Japan). Flame emissions were monitored using an R-1104 photomultiplier tube (PMT) (wavelength range of 185–850 nm; Hamamatsu, Bridgewater, NJ). Spectra were acquired using a 1/4 m Jarrell-Ash monochromator (1180 lines/mm grating, 3 nm/mm bandpass). Instrument-grade carbon dioxide and high purity hydrogen, air, and argon were obtained from Praxair (Praxair, Calgary, AB, Canada). Tetrahydrothiophene (99%) and carbon disulfide (99.9%) were used as obtained from Aldrich (Aldrich, Oakville, ON, Canada).

The FPD is connected downstream from the back pressure regulator, where the ELSD is normally attached via a splitless interface (6). With the ELSD disconnected, a 4 foot (1 foot = 0.3048 m) length of 1/16″ (1″ = 25.4 mm) × 0.01″ i.d. stainless steel tubing (Alltech) is instead used to guide the effluent from the pSFC into the GC oven through a side port. Using a stainless steel zero dead volume union (Alltech), this tubing is connected to a 20 cm length of 0.10 mm i.d. deactivated, fused-silica restrictor tubing (Alltech), which extends into the base of the FPD burner. In this way, the pSFC effluent combines with the hydrogen and flows concentrically around the central tube, delivering air to the flame. The restrictor position within this arrangement was not found to critically affect the flame stability or response. However, optimal conditions for this transfer line were realized when the GC oven was maintained above 60 °C and the FPD detector base was maintained at 250 °C. The pSFC oven was normally operated at 60 °C, and the typical FPD flame gas-flow rates used were 300 mL/min of hydrogen and 90 mL/min of air. Variations on these conditions are outlined in the text.

Results and discussion

Given the much larger flow rates in pSFC compared with cSFC, it might be anticipated that flame instability in the FPD could be a problem. However, this was not found to be the case, and the flame remained very stable over a wide range of column flow rates tested — up to 5 mL/min — with no visible signs of flicker or lift off from the burner. The steady interface between the mobile phase and the flame is certainly facilitated by the smooth transition of supercritical carbon dioxide into a gas upon decompression. More importantly, however, this stability in the presence of several liters per minute of carbon dioxide gas flow is a result of the burner configuration, which has the hydrogen and the column effluent enter concentrically about the central tube delivering air to the flame, as is common in GC-FPD (7). Since the FPD flame relies upon a very hydrogen-rich stoichiometry to deliver response, this arrangement prevents solvent peaks and, in this case, large flows of carbon dioxide from diluting and starving the flame of oxygen, causing it to extinguish. Similar attempts to introduce the column effluent through the central air tube caused the flame to extinguish at pSFC flow rates of less than 0.5 mL/min.

Although the flame remained stable at large column flow rates, it was visually clear that, as the flow of carbon dioxide increased in the detector, the flame luminescence grew from barely observable to an intense blue emission. To examine the features of this background emission and how it might be affected by varying amounts of carbon dioxide, spectra of the FPD flame were acquired using several pSFC column flow rates. Figure 1 displays these spectra and indicates that the emission from carbon dioxide in the FPD is predominantly situated between 325 and 525 nm. At a low column flow rate of 0.5 mL/min (trace A), the blue flame emission stems from a distribution of narrowly spaced bands that appear to reside upon an underlying continuum. Although no flame spectra under pSFC-FPD conditions have been reported, this spectrum does agree very well with the "carbon monoxide flame bands" of CO_2 (21), which were also speculated earlier as the background emission source in cSFC-FPD (8). Therefore, at this low pSFC flow rate (which is about ten times larger than those used in cSFC), the FPD background emission features still appear similar for the two methods. However, as the flow rates are increased to more common pSFC values of 1 mL/min and greater, the background emission becomes enormous and assumes a very complex appearance. Gaydon details several molecular emission band systems obtained from excited CO (21) that could possibly be ascribed to the luminescence observed for carbon dioxide in the FPD flame. Owing to the overlapping wavelengths of many of the systems described, an exact identification of some of the spectral features presented in Fig. 1 could not be firmly established; however, certain interesting correlations can be noted. For instance, the bands superimposed on the spectrum obtained at a flow rate of 1 mL/min (trace B) match very well with those assigned for excited CH, which is also commonly found for carbon emission in GC-FPD (20, 21). As the flow rate increases to 1.5 and 2 mL/min (traces C and D, respectively), the spectra broaden and resemble the distribution features of Eméléus's cool-flame formaldehyde spectrum and also those noted for the comet-tail system of excited CO emission (21). Also in-

Fig. 1. Upper trace: the emission spectrum of carbon dioxide in the FPD at pSFC column flow rates of 0.5 (A), 1.0 (B), 1.5 (C), and 2.0 (D) mL/min and a pressure of 15 MPa. Lower trace: the emission spectrum of argon in the FPD at pSFC flow rates of 2.0, 3.0, and 4.0 mL/min (superimposed) and a pressure of 27 MPa. Flame gas flow rates are 300 mL/min of hydrogen and 100 mL/min of air. The bandpass is 1.5 nm.


teresting is that, despite the large flow of carbon as CO_2 in the FPD flame, no evidence of excited C_2 emission was observed, which is another common feature in GC-FPD carbon spectra (20).

The most significant feature realized from the spectra in Fig. 1 is that the carbon dioxide background emission is distributed over exactly the same wavelength range as that produced by sulfur emission in the FPD, which is used for analytical purposes to measure quadratic S_2^* response (7). While some methods add a sulfur compound to the mobile phase in attempts to linearize this response, the same sulfur emission spectrum is produced (7). Therefore, serious interference from this carbon dioxide background emission should be anticipated in the pSFC-FPD analysis of sulfur and other elements that are monitored in this wavelength

range (e.g., manganese atomic lines and tin quartz surface emission) (7, 20). By comparison, other elements emitting outside of this range should be less affected. For example, earlier cSFC-FPD studies in which analyte emissions of phosphorus at 530 nm and of tin (gas-phase emission) at 610 nm (which are more remote to the carbon dioxide emission spectrum shown in Fig. 1) were monitored, less interference from baseline variations was observed when the column flow rate was changed (10, 11). This is understandable considering that the carbon dioxide emission shown in Fig. 1 is reduced by a factor of about ten between the 400 and 530 nm wavelength regions where sulfur and phosphorus are, respectively, monitored.

In this context, it is interesting to note that "pulsed" FPD methods can temporally resolve sulfur and carbon emissions to yield less interference and greater selectivity (22). However, it is unknown if such benefits could be extended to pSFC-FPD since it greatly depends on the emission spectrum of carbon dioxide in that detector and its time dependence relative to other analytical emissions under typical pSFC conditions. Thus, although such investigations are beyond the scope of the current study, this approach could be potentially useful.

Also presented in Fig. 1 is the FPD background emission, generated when a supercritical argon mobile phase is introduced at pSFC flow rates equal to or greater than those examined for supercritical carbon dioxide. As can be seen, even when using substantial flows of 4 mL/min of supercritical argon, no spectral features are observed and the background emission remains steady. In fact, for all of the flows investigated, supercritical argon produced the same spectra and emission intensities as that of the FPD flame without any column effluent. This lack of variation implies that argon provides little or no emission in the FPD and is consistent with visual observations of the flame under these conditions, which showed no change when supercritical argon was introduced into it. This finding, while somewhat expected, agrees with the conditions of the relatively cool, small FPD flame compared with the larger, high-temperature flames and plasmas used as excitation sources in conventional spectroscopy (20). For example, in contrast to the thermal luminescence produced in those methods, emission in the FPD is generated by chemiluminescence, which is favored by cooler flame conditions (7). Further, it has been estimated that the FPD yields a maximum excitation energy of 3.6 eV, which is far lower than the excitation potentials associated with argon emission lines (20, 23). While traces of a molecular emission system due to excited ArO is also known to occur near 558 nm (21), no evidence of this exists in Fig. 1, also possibly as a result of the low-temperature, hydrogen-rich conditions under which the FPD is operated.

The essentially unobstructed background spectrum obtained with supercritical argon in the FPD makes it potentially much more suitable than supercritical carbon dioxide for monitoring the emission of sulfur and other elements by pSFC-FPD. Figure 2 illustrates this with the spectrum of sulfur emission in the FPD using a supercritical argon mobile phase. This spectrum clearly displays the characteristic S_2^* emission bands of sulfur chemiluminescence in the FPD and, compared with Fig. 1, demonstrates that the emissions

Fig. 2. The emission spectrum of sulfur (as carbon disulfide) in the FPD using 2.0 mL/min of supercritical argon as the pSFC mobile phase. Other conditions as for supercritical argon in Fig. 1.
of sulfur and carbon dioxide severely overlap in this detector under pSFC conditions.

To better gauge the relative background emission that each mobile phase generates in the FPD, the flame intensity was monitored at various column flow rates with the two supercritical fluids. Figure 3 shows the background emission of the FPD as a function of supercritical carbon dioxide column flow rates tested up to 4 mL/min. As seen in the figure, even at modest flow rates of supercritical carbon dioxide, the background increases by about 5 orders of magnitude. In comparison to this, similar flows of supercritical argon produce no increase in the observed background emission of the FPD flame. Given the considerable difference between the two, supercritical argon should generate much less interference than supercritical carbon dioxide when emission in the FPD is monitored, particularly for elements such as sulfur that emit in the 400 nm wavelength region.

Figure 4 demonstrates this with the sulfur response obtained for a series of tetrahydrothiophene standard solutions monitored in the FPD under the same optimum flame conditions for both a supercritical argon and a supercritical carbon dioxide mobile phase. The response is measured as the sulfur signal-to-noise (i.e., peak-to-peak fluctuations of the baseline) ratio, and as seen in the figure, it greatly differs between the two mobile phases. When using supercritical carbon dioxide, the sulfur response increases over two orders of magnitude to an upper mass flow limit of about 0.1 μg of sulfur per second. In terms of detectivity (i.e., corresponding to a signal-to-noise ratio of two), the response yields a mass flow detection limit of almost 1 ng of sulfur per second. This value is about 25 times larger than the average value of the sulfur detection limits reported for cSFC-FPD (8), which is reasonable, considering the much greater column flow rate used in the current pSFC experiments. It should be noted that the data in Fig. 4 were obtained in the open

Fig. 3. A comparison of the relative background emission intensity generated in the pSFC-FPD system using a supercritical argon (■) and a supercritical carbon dioxide (●) mobile phase at various column flow rates. Conditions as in Fig. 1.
Fig. 4. The pSFC-FPD system response toward varying amounts of sulfur (as tetrahydrothiophene) using a supercritical argon (■) mobile phase at 2.5 mL/min and 28 MPa and a supercritical carbon dioxide (●) mobile phase at 2.0 mL/min and 15 MPa. Flame gas flow rates are 300 mL/min of hydrogen and 90 mL/min of air.
nonwavelength dispersive mode, which is often employed in GC-FPD to increase sensitivity by monitoring a greater fraction of the analyte emission bands. While narrow-band interference filters can also be employed to increase the selectivity of sulfur response over other flame emissions, this is usually accompanied by a decrease in sensitivity (20). Not surprisingly then, owing to the direct overlap of the sulfur and the carbon dioxide emission bands in the FPD, the

use of such filters in these experiments did not improve the discrimination between the two and only further reduced sensitivity.

By comparison, in Fig. 4, the sulfur response over the same concentration range is much improved when a supercritical argon mobile phase is used. As expected, the resulting curve yields the same slope and upper calibration limit; however, the response is increased by nearly two orders of magnitude. Since the flame conditions were not varied, this finding can be directly attributed to the large decrease in background emission obtained when using supercritical argon in the FPD. Previous GC-FPD studies have verified that the peak-to-peak baseline noise increases as a square-root function of the background emission intensity if the noise is random and increases proportionally if the noise becomes correlated with the signal at higher levels (24). As observed, the difference in the background emission intensity of Fig. 3 (i.e., about 1×10^5) and the corresponding difference in the signal-to-noise ratio of Fig. 4 (i.e., about 1×10^2) is related by greater than a square-root function. This suggests that the high level of carbon dioxide in pSFC-FPD also generates flame noise that is not entirely random in nature, which differs from earlier studies using supercritical carbon dioxide that showed cSFC-FPD to be shot-noise limited (9). In the absence of carbon dioxide, as a result of the nearly quadratic sulfur response in the FPD, the improved signal-to-noise ratio when supercritical argon is used translates into a minimum detectable flow of about 100 pg of sulfur per second. In contrast to the above, this value, obtained from the pSFC-FPD system, compares quite well to those reported for cSFC-FPD (8). Thus, relative to a conventional supercritical carbon dioxide mobile phase, supercritical argon can provide improved sulfur detection limits in pSFC-FPD by greatly reducing the background emission to levels on the same order as the FPD flame itself. This also indicates that supercritical argon may be advantageous for the pSFC-FPD analysis of other elements.

An ionic liquid mediated Friedel–Crafts addition of arenes to isothiocyanates

Prashant U. Naik, Susheel J. Nara, Jitendra R. Harjani, and Manikrao M. Salunkhe

Abstract: A new protocol is developed for the synthesis of *N*-substituted thioamides, employing arenes and isothiocyanates in 1-butyl-3-methylimidazolium chloroaluminate ionic liquid, [bmim]Cl·2AlCl$_3$, as a homogenous Lewis acid catalyst and solvent. The effect of Lewis acidity and the stoichiometry of the ionic liquid on the extent of product formation is studied. Studies reveal that a progressive increase in yields was observed with increasing Lewis acidity, and two equivalents of [bmim]Cl·2AlCl$_3$ was the optimal amount for the reaction. A distinct *para* selectivity for the incoming thioamido group on activated arenes was observed under ambient conditions.

Key words: arenes, isothiocyanates, Friedel–Crafts, ionic liquids, thioamides.

Résumé : On a développé un nouveau protocole pour la synthèse de thioamides *N*-substitués qui fait appel à l'utilisation d'arènes et d'isothiocyanates dans du chloroaluminate de 1-butyl-3-méthylimidazolium, [bmim]Cl·2AlCl$_3$, un liquide ionique qui agit comme catalyseur acide de Lewis homogène et comme solvant. On a étudié l'effet de l'acidité de Lewis et la stoechiométrie du liquide ionique sur le niveau de formation du produit. Les études révèlent qu'une augmentation progressive des rendements peut être observée avec une augmentation de l'acidité de Lewis et que deux équivalents de [bmim]Cl·2AlCl$_3$ correspond à la quantité optimale pour la réaction. Dans les conditions ambiantes, on a observé une sélectivité *para* pour le groupe thioamido qui s'insère sur les arènes activés.

Mots clés : arènes, isothiocyanates, Friedel–Crafts, liquides ioniques, thioamides.

Introduction

Room temperature ionic liquids have attracted considerable attention as novel reaction media, offering cleaner and environmentally benign protocols to a number of chemical processes (1). An appropriate amalgamation of properties possessed by these liquids, such as high thermal stability, reusability, nonvolatility, and excellent solvating ability has undoubtedly made them the most protean and promising solvents of the future (2). The most interesting feature of ionic liquids is the extensive flexibility they offer in terms of alteration of properties such as density, viscosity, Lewis acidity, hydrophobicity, hydrophilicity, etc. (3). This feature of ionic liquids has enabled chemists to design and engineer them so that a proper equilibrium of properties is attained, making them the most suitable and compatible solvents for several chemical processes (4–8).

The significance of thioamides and their polyfunctional derivatives as useful building blocks in organic syntheses has been recently reviewed (9). Thioamides are a class of compounds that comprise a variety of derivatives that possess diverse physiological properties such as antigastric, antiulcer, antidiabetic, antitubercular, fungistatic, etc. (10). Besides, they have been technically applied in a number of commercial applications as vulcanisation promoters, antioxidants, corrosion inhibitors, etc. (10). Activated arenes are known to undergo Lewis acid mediated amidation (11, 12) and thioamidation (13, 14) with isocyanates and isothiocyanates, respectively. In contrast to the Lewis acid mediated amidation of arenes with isocyanates, thioamidation with isothiocyanates has been particularly attractive, as the former procedure often suffers from the disadvantage of low yields of products. The isothiocyanato group is one of the excellent acceptors of nucleophiles, and its reactivity has been aptly utilized in various synthetic procedures (15). With Lewis acids, the isothiocyanato group is known to

form a charged complex containing electrophilic carbon (16), which is believed to be involved as an intermediate in its reaction with arenes.

Results and discussion

Over the last two years, our group has developed considerable interest in investigating the Friedel–Crafts (17–19) and condensation (20, 21) reactions in the Lewis acidic chloroaluminate ionic liquids. As a part of our ongoing venture to exploit chloroaluminate ionic liquids for newer reactions, we present herein an account of the execution of 1-butyl-3-methylimidazolium chloroaluminate, [bmim]Cl·AlCl$_3$ ($0.67 \geq N > 0.50$; N is the apparent mole fraction of AlCl$_3$ in the ionic liquid) mediated addition of activated arenes to isothiocyanates (Scheme 1).

We anticipated an exhortive result in the case of activated arenes such as phenols, and they were therefore an obvious choice for the preliminary investigations. A reaction performed in [bmim]Cl did not fetch any product. The encouraging results obtained in the subsequent investigations carried out in [bmim]Cl·AlCl$_3$, $N = 0.67$, prompted us to plan a systematic study aimed at the optimization of Lewis acidity and stoichiometry of the ionic liquid and time of reaction, to develop an ambient protocol for thioamidation. 2,5-Xylenol, being sufficiently reactive, was preferred as a model substrate for these optimizations.

To study the effect of the Lewis acidity of [bmim]Cl·AlCl$_3$ ($0.67 \geq N \geq 0.50$) on the extent of product formation, a series of ionic liquids with varying Lewis acidities were prepared. The molar proportion of 2,5-xylenol, phenyl isothiocyanate, and ionic liquid was maintained at 1:1:1 at room temperature for 24 h, and the extent of conversion in terms of the percentage yield of the product obtained in each case was compared. The results reflected that an increase in the Lewis acidity resulted in an increase in the percentage yield of product formed, but in all the cases the yields were too low to be quantitative. The yield increased from 0% to 30% as N increased from 0.50 to 0.63, progressively, and only 64% yield was realized for [bmim]Cl·AlCl$_3$, $N = 0.67$.

The [bmim]Cl·AlCl$_3$, $N = 0.67$, was an obvious choice for all further investigations. With a view to obtain an optimal yield of the product, we further planned to study the effect of stoichiometry of [bmim]Cl·AlCl$_3$, $N = 0.67$, on the extent of product formation. A series of experiments were planned in which the molar proportion of 2,5-xylenol and phenyl isothiocyanate was fixed at 1:1 and varying amounts of [bmim]Cl·AlCl$_3$, $N = 0.67$, ranging from 1 to 2.5 mole equivalents, was added. The reaction time was 24 h at room temperature. The results indicated that the optimal product formation calls for the use of at least 2 mole equivalents of [bmim]Cl·AlCl$_3$, $N = 0.67$. No significant increase in yields was observed with a further increase in stoichiometry of the ionic liquid.

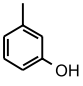
To optimize the time for the thioamidation procedure, a series of experiments were planned in which the molar proportion of 2,5-xylenol, phenyl isothiocyanate, and [bmim]Cl·AlCl$_3$ ($N = 0.67$) was maintained at 1:1:2 at room temperature for different time periods (ranging from 2–12 h). The yields of the product formed at different time in-

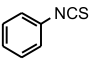
Scheme 1. The [bmim]Cl·AlCl$_3$ ($0.67 = N > 0.50$) catalyzed addition of arenes to isothiocyanates.

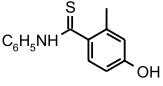
(-R is alkyl or aryl group)
tervals were compared. The results indicated that the optimal time for the reaction is 8 h, beyond which no substantial increase in yield was observed. No improvement in yield was realized, even after a prolonged reaction time of 30 h.

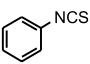
To generalize the procedure and to study the effect of substituents on product formation, a variety of arenes were screened under optimized conditions. The results obtained are indicative of successful thioamidation of activated arenes (Table 1). The reaction of phenyl isothiocyanate did not occur with benzene, but with *m*-xylene 83% yield of the product was obtained. In terms of yields and selectivity, the method is comparable to a nitromethane–AlCl$_3$ system (13). In general, aryl isothiocyanates fetched better yields than alkyl isothiocyanates. In contrast to a number of classical carbonylation procedures, an exquisite *para*-selectivity was observed in reaction even with the arene that has both *ortho* positions unblocked (entry 5). In the case of substrates with the *para* position blocked, such as *p*-xylene and *p*-cresol, no reaction was observed.

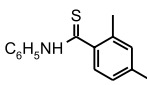
The present methodology can be easily extended to *ortho* carbonylation of benzoic acids, i.e., conversion of benzoic acids to phthalic acids and also for conversion of phthalic acids to homophthalic acids, which are synthetically versatile intermediates (22, 23). In addition, the method can serve as an advantageous alternative to the synthesis of certain benzoic acids and benzyl amines, which cannot be synthesized by other methods.

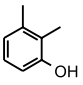
Conclusion


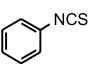


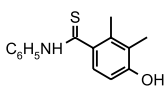


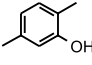


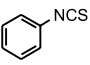


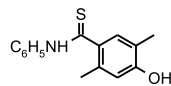


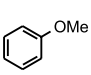


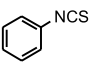


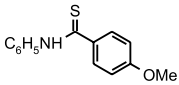


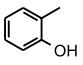


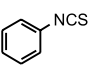


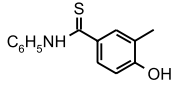


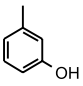


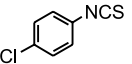


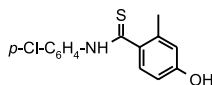


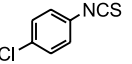


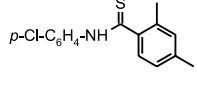


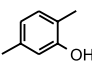


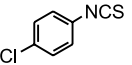


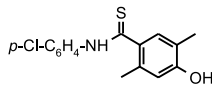


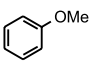


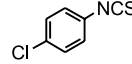


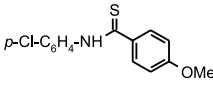


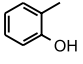


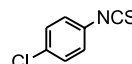


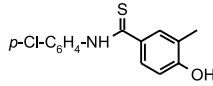


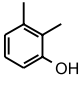


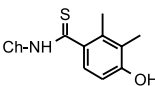


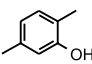


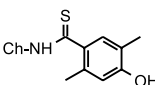


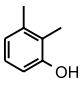


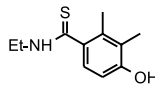












In effect, we found 1-butyl-3-methylimidazolium chloroaluminate, [bmim]Cl·AlCl$_3$ ($N = 0.67$), to be a homogenous Lewis acidic medium for Friedel–Crafts type addition of activated arenes to isothiocyanates, thus eliminating the use of conventional obnoxious or volatile solvents such as halogenated hydrocarbons, nitromethane, and carbon disulphide. Homogenous catalysis, reduced reaction times, ambient conditions, and exquisite *para*-selectivity are some of distinctively notable advantages offered by the novel procedure.

Experimental

The ionic liquids used in the present study were prepared as per the procedures reported earlier (24, 25). In a typical experimental procedure for thioamidation of arene, to the weighed quantity of the arene (5 mmol) and isothiocyanate (5 mmol), the ionic liquid [bmim]Cl·AlCl$_3$ ($N = 0.50$–0.67, 5–15 mmol (as specified in the text)) was added, and the reaction mixture was stirred for a specified time at room temperature. All additions were carried out under a nitrogen atmosphere glove box. The reactions were quenched with 6 mol L^{-1} HCl under cold conditions. The resultant solution

was extracted using ethyl acetate (3 × 10 mL). The combined organic extracts were dried using anhydrous Na$_2$SO$_4$ and evaporated under reduced pressure to obtain the crude product. The crude products were chromatographed using silica gel column chromatography to yield pure thioamides, which were characterized by physical constants, IR, and

NMR. The analytical and spectral data was consistent with that reported in the literature (13).

Comparison of supported liquid membranes and solid-phase extraction for quantitative removal of lead from aqueous solutions

Emily R. Yourd and Julian F. Tyson

Abstract: The selective transport of a target metal ion across a membrane from a donor to an acceptor solution is an attractive concept for preconcentration or separation in a flow injection (FI) system. However, we found that the transport of lead across a supported liquid membrane consisting of dicyclohexano-18-crown-6 in decanol embedded in Celgard 2400 was too slow to be practical for an FI atomic spectrometry system. On the other hand, the same chemistry in an on-line, solid-phase reactor (a mini-column containing Pb-Spec resin) gave a satisfactory performance. In an attempt to understand the kinetics of the system, we have calculated the rate of transport across the membrane. As flux is proportional to concentration on the donor side — which decreases with time — we performed a series of numerical simulations involving fixed time intervals of decreasing values. These calculations show that for the sizes of membranes in a typical FI system, transport is very slow compared with the adsorption of lead by the Pb-Spec resin: it takes about 100 min for the concentration in a 0.06 mL donor solution to decrease by a factor of 1000. The time required for the same decrease in concentration for a membrane having the same surface area and ligand concentration as the Pb-Spec column was calculated as approximately 9 s.

Key words: supported liquid membrane, solid-phase extraction, flow-injection, lead.

Résumé : Le transport sélectif d'un ion métallique cible à travers une membrane à partir d'un donneur vers une solution accepteuse est un concept attrayant pour la préconcentration ou la séparation dans un système à injection continue (IC). Cependant, nous avons trouvé que le transport du plomb à travers une membrane liquide incrustée dans un support, cette membrane est constituée de dicyclohexano-18-couronne-6 dans le décanol incorporé dans du Celgard 2400, est trop lent pour être pratique dans un système de spectrométrie atomique à injection continue (IC). Par ailleurs la même chimie en continu dans un réacteur en phase solide (une mini colonne contenant une résine Pb-Spec), a donné une performance satisfaisante. Dans une tentative pour comprendre la cinétique du système, nous avons calculé la vitesse de transport à travers la membrane. Comme le flux est proportionnel à la concentration du côté du donneur, laquelle diminue avec le temps, nous avons réalisé une série de simulations numériques impliquant des intervalles de temps fixes de valeurs décroissantes. Ces calculs montrent que, compte tenu des dimensions des membranes dans un système typique à injection continue, le transport est très lent comparativement à l'adsorption du plomb par la résine Pb-Spec; il faut environ 100 minutes pour que la concentration dans 0,06 mL d'une solution donneuse décroisse d'un facteur de 1000. Le temps requis pour la même diminution de concentration dans le cas d'une membrane ayant la même superficie et la même concentration de ligand dans une colonne de Pb-Spec est selon les calculs approximativement de 9 s.

Mots clés : membrane liquide supportée, extraction en phase solide, injection continue, plomb.

Introduction

Analytical method development often involves sample pretreatment so that a potentially interfering component of the sample matrix, which may be present in relatively high concentration compared with that of the analyte, is removed. Another common problem is that the analyte concentration is below the detection limit, and thus preconcentration is needed. For example, the determination of trace elements in forensic bullet samples by inductively coupled plasma mass spectrometry (ICP-MS) is inhibited by the presence of the lead matrix, which causes analyte signal suppression. The removal of this element prior to introduction to the instrument is therefore required. On the other hand, the determination of lead in drinking water by flame atomic absorption spectrometry (FAAS) requires preconcentration. Flow injection (FI) analysis is a versatile sample pretreatment technique that can be useful for the automated removal of a

sample matrix or the preconcentration of a sample component (1–3). FI manifolds can be tailored to specific applications by incorporating the appropriate on-line components, such as a packed column for solid-phase extraction (SPE) or a membrane cell.

In developing a method for the analysis of bullets by ICP-MS, we initially chose FI-SPE to remove the lead (4). Most of the previous work on the use of solid-phase reactors in FI systems for the separation of analytes from matrices has been based on a protocol whose primary goal is preconcentration. The analytes are retained from a relatively large volume of solution, while the unwanted matrix components are discarded to waste. Following removal of any unretained matrix materials from the reactor, the analytes are eluted in the direction opposite to that in which the species were loaded and are transported to the detector.

Several design features of such a reactor are desirable. There should be rapid transport from the bulk liquid in the interstices between the solid particles to the surface of the particles. The binding of the analytes to the particle surface should also be rapid, while the reverse reaction should be slow (i.e., the reaction between the analyte and the surface-immobilized reagent should have a high "equilibrium" or binding constant). The surface density of the binding sites should be such that the reactor has sufficient capacity to retain all of the analyte species. As is well known from HPLC theory, important factors include particle size, column dimensions, and flow rate; to get high efficiency (in the chromatographic sense of minimum band broadening) when using HPLC, the particle size should be small: 5 µm or less. Even for the miniature columns that are typically used in FI-SPE applications, the back-pressure generated by using small particles is often sufficiently high that it is difficult to obtain useful flow rates from peristaltic pump delivery.

In the typical FI-SPE preconcentration procedure, such considerations are not of prime importance, as the first part of the experiment is performed under conditions such that the capacity factor is very large (the analyte is retained on the column). All that is necessary is that during the passage of any given solute through the column, there is a high probability that the species will interact with the reagent immobilized at the particle surface and will be retained. For the second part of the experiment, broadening processes are relevant, as the goal is to elute the retained analyte in as small a zone of fluid as possible. This maximizes the instrument response peak height and minimizes the time required for this portion of the experiment. Guidelines, based on these considerations, have been developed by Fang (2) and can be summarized as the optimum conditions for FI-SPE preconcentration for trace element determination by atomic spectrometry. These guidelines involve column volumes between 20 and 250 µL with aspect ratios (5) of 10–15, containing particles of 150–200 µm, and sample loading at 8–9 mL min^{-1}. Elution flow rates depend on the detection mode, as the eluent is delivered directly to the spectrometer.

When FI-SPE is to be used for matrix removal by retention of the matrix and direct determination of the analytes, the guidelines described above no longer apply. Now there are two important considerations: (a) there must be sufficient retention of the matrix element to reduce its concentration to below that which causes problems with the subsequent analyte determinations, and (b) there should be minimum peak broadening of the unretained analytes. The first consideration means that the columns are significantly larger than those typically used for trace element preconcentration and, thus, may be capable of substantial peak broadening. In addition to the purely "chromatographic" features of the experiment, the flow rate is constrained to values at which the detector has suitable signal-to-noise ratio, and factors affecting the throughput have to be considered. Both of these considerations have implications for the sample volume injected, which, as always in flow injection experiments, cannot simultaneously maximize signal and minimize throughput. In addition, the elution characteristics of the system are still relevant, as the retained matrix component must be removed at frequent intervals by a suitable eluent.

It is clear, though, from basic HPLC theory that from the viewpoint of both retaining a matrix component and minimizing the broadening of non-retained components, the particle size should be decreased. A number of beneficial features would be realized by working with particle sizes of 10 µm or less. For these values, not only is the peak broadening very much less than for larger particle sizes, but the broadening is also essentially independent of flow rate, and relatively high flow rates could be used to load samples rapidly. Unfortunately, there is a practical limitation related to the high back-pressure generated by columns of useful dimensions filled with particles of this size, which far exceeds the capabilities of the peristaltic pumps used for fluid handling in such experiments. Because of the additional costs and complexities associated with high-pressure pumping in multi-line manifolds, this option is not considered viable. As the performance of a method based on SPE is clearly limited, we considered other options.

While there are a number of such procedures that might be considered for implementation in an FI format, selective transport across a flat membrane is attractive. The procedure may be implemented in a device with minimum back-pressure and thus, when fluid is delivered by peristaltic pump, could accept much higher fluid flows than can a packed bed solid-phase reactor. The device also allows the facile separation of phases associated with interaction between a liquid sample and an immobilized "reagent"; this is not realized when phase transfer into another mobile phase (either liquid or gas) forms the basis of the separation.

There are numerous recent reports of chemical separations by supported liquid membranes (SLM) (6–13). The pores of a microporous solid support are impregnated with a hydrophobic liquid, forming the membrane that separates the sample (donor) and receiver solutions. The analyte, if it is soluble in the membrane liquid, diffuses from the sample solution, through the membrane, and into the receiver solution. The mass-transport efficiency can be significantly enhanced when the membrane incorporates a carrier molecule that complexes with the analyte and facilitates its transit through the membrane to the receiver solution, where the complex dissociates. The carrier remains within the membrane.

The affinity of macrocyclic crown ethers for specific cations is well known (14–17). Those cations with ionic radii most closely matching the dimensions of the cavity of the macrocycle will be selectively complexed. Cations that are

significantly smaller than the cavity will be too far from the lone pairs of the oxygen to form an appreciable bond, while larger cations will not fit inside the cavity. The selectivity of crown ethers can be used to separate certain cations from a mixture, both for preconcentration purposes and for matrix removal.

We have investigated the feasibility of using an SLM in the flat-sheet configuration with the goal of removing lead from a matrix, as part of the sample pretreatment in the analysis of high-lead materials such as bullets. The membrane was impregnated with the crown ether dicyclohexano-18-crown-6 (DC18C6), which has a cavity size selective for lead (9, 17, 18). The lead-containing solution was introduced to the donor compartment of the membrane cell, and the receiver side was monitored for the appearance of transported lead. The transport process was also modeled mathematically. The experimental results were compared with the behavior predicted on the basis of the calculations. The model was also applied to a rapid FI-SPE procedure (4) based on the almost identical extraction chemistry (0.75 mol L^{-1} di-*tert*-butyldicyclohexano-18-crown-6 in decanol immobilized on Amberchrom CG-71 (19)), to understand why this process is kinetically favorable to FI applications while the SLM procedure is not.

Experimental

Reagents and standards

Celgard 2400 polypropylene membranes (thickness 25 μm, porosity 35%, pore sizes 0.041 μm × 0.12 μm; Celgard Inc., Charlotte, NC) and Pb-Spec (100–150 μm diameter, Eichrom, Inc., Darien, IL) were used as received. Dicyclohexano-18-crown-6, phenylhexane, and decanol (Sigma-Aldrich, Milwaukee, WI) were also used as received. Ten millilitre solutions of 0.05 and 0.10 mol L^{-1} crown ether in decanol and 0.05 mol L^{-1} crown ether in phenylhexane were prepared. A stock solution of 1000 mg L^{-1} Pb was prepared by dissolving the appropriate amount of lead nitrate (Certified ACS grade, Fisher Scientific) in 2% (volume fraction) nitric acid (Mallinckrodt). Solutions of 50 and 250 μg L^{-1} Pb and 20 mg L^{-1} Pb, all in 2% HNO_3, were prepared through the dilution of a 1000 mg L^{-1} atomic absorption standard (Sigma-Aldrich, Milwaukee, WI). Solutions of 3% HNO_3 and 0.1 mol L^{-1} ammonium citrate (Certified ACS grade, Fisher Scientific, pH 5.23) were prepared for use in the membrane cell. A dilute solution of alkaline phenolphthalein (Certified ACS grade, Fisher Scientific) was made by dissolving a sufficient amount of the indicator along with some sodium hydroxide (Mallinckrodt) in water to produce a strongly colored solution. All solutions were prepared using deionized water with a resistivity of 18.0 MΩ (E-Pure, Barnstead) and were stored in acid-washed polyethylene (Nalgene) bottles.

Apparatus

A flame atomic absorption spectrometer model 1100B (PerkinElmer, Shelton, CT, U.S.A.) with deuterium background correction was used. The instrument was operated with a lead hollow cathode lamp according to the manufacturer's recommended conditions. The 10 cm air–acetylene burner head position was optimized in three dimensions while aspirating a 20 mg L^{-1} solution of Pb in 2% HNO_3. The position of the nebulizer capillary in the venturi throat was adjusted such that the nebulizer suction was zero. This positioning ensured that the flow rate of the solution reaching the nebulizer was controlled solely by the peristaltic pump of the flow injection manifold.

A graphite furnace atomic absorption spectrometer model 4100ZL (PerkinElmer, Shelton, CT, U.S.A.) with Zeeman background correction and a lead hollow cathode lamp was operated in accordance with the manufacturer's recommended conditions. An AS-71 autosampler transferred 20 μL of solution to the furnace, and the standard program for lead without matrix modification was used. The autosampler probe was rinsed with deionized water between injections. Peak area was measured.

An Olympus BH-2 transmission microscope was used to visually inspect the Pb-Spec resin. The 40× objective was used with a 10× eyepiece for a total magnification of 400×. A small amount of resin was placed on a glass slide and suspended in a few drops of water. A coverslip was placed over the beads to hold them in place.

The flow injection manifold consisted of one peristaltic pump (Ismatec), one 6-port rotary valve, and a membrane cell. The manifold is shown schematically in Fig. 1.

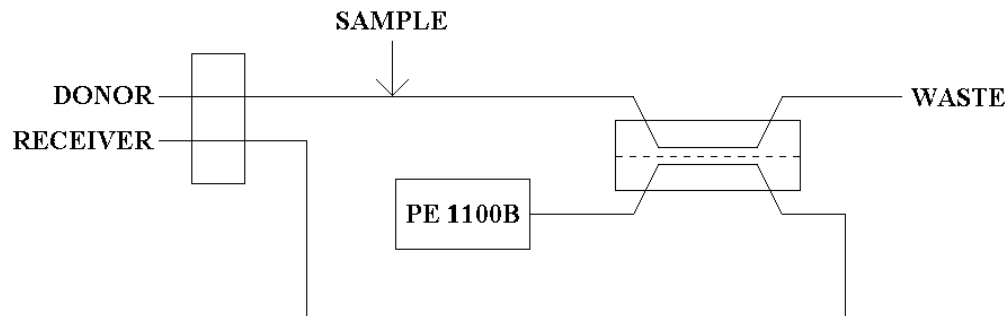
The cell was constructed from two nylon blocks (8 cm × 3 cm × 2 cm), each with a central groove (4 cm × 2 mm × 0.2 mm for receiver, 0.75 mm for donor). The sample volume of 130 μL was propelled through a 20 cm length of tubing into the top block of the cell with a flow rate of 1.3 mL min^{-1}. The receiver solution was pumped in the opposite direction from the donor, creating a counter-current flow. The Celgard 2400 polymeric membrane was soaked in a solution of dicyclohexano-18-crown-6 and either decanol or phenylhexane for a minimum of 15 min, then placed between the blocks, physically separating the two channels. The entire cell was clamped between two aluminum plates. The pump tubing was Tygon 1.52 mm i.d. three-stop tubing (blue-yellow); manifold components were connected via 0.8 mm i.d. PTFE tubing.

The SPE manifold, which provides the basis for the comparison, has been described previously (4). To summarize, a 130 μL sample was injected into a nitric acid carrier that moved the sample through a glass column (5 cm × 4 mm i.d.) packed with 105 mg of Pb-Spec resin. The now lead-free sample passed directly into the ICP-mass spectrometer for the determination of the diagnostic elements in bullets: Ag, As, Bi, Cd, Cu, Sb, and Sn. The resin was rinsed with 0.1 mol L^{-1} ammonium citrate after every third sample injection to remove the accumulated lead.

Characterization of transport

To determine when the injected sample solution completely filled the donor channel, the time required for the sample to travel from the injection valve to the membrane cell was measured. A basic solution of phenolphthalein was injected into a water carrier so that this transport time could be evaluated visually.

Different compositions of receiver solution were investigated. The acceptor stream was 3% HNO_3 or 0.1 mol L^{-1} ammonium citrate. The amount of Pb transported to the re-

Fig. 1. Flow injection manifold for the SLM experiment. The dashed line indicates the position of the membrane.


ceiver was observed for each solution after various stop times.

The contact time between the sample and the membrane was an important experimental parameter. The time required for lead to travel from the donor solution to the receiver was determined through a series of stopped-flow experiments with crown ether concentrations of 0.05 and 0.1 mol L^{-1} in decanol and 0.05 mol L^{-1} in phenylhexane. The 1000 mg L^{-1} Pb sample was injected into the 3% HNO$_3$ carrier stream and transported into the donor channel of the membrane cell. The pump controlling the two streams was stopped for a measured period of time (0, 5, 15, 30, 60, 120, and 1320 min) and then restarted. The absorbance due to lead in the ammonium citrate receiver solution was monitored by FAAS, and the height of the resulting lead peak was recorded.

The number of moles of lead transported across the SLM was quantified by electrothermal atomization atomic absorption spectrometry (ETAAS). The 1000 mg L^{-1} Pb sample solution was placed in contact with the SLM containing 0.1 mol L^{-1} DC18C6 in decanol for a stop time of 15 min. At the end of the stop time, the receiver solution was pumped into a 25 mL volumetric flask and approximately 2 mL were collected. The solution was made to volume with 2% HNO$_3$. This sample was measured ($n = 10$) along with standards of 0, 50, and 250 μg L^{-1} Pb in 2% HNO$_3$. Each standard was measured five times.

Mechanism of transport and calculations

A theory of transport of divalent cations through a crown-ether-containing SLM has been developed (17, 20, 21). The cation flux is strongly dependent on the equilibrium constant (K_{ex}) for the following reaction (20):

[1] $MA_m{}^{aq} + L^{org} = MA_mL^{org}$
In this equation, M represents the metal cation, and A is a counterion present in the stoichiometric quantity m. L represents ligand. The superscripts in the equation refer to the aqueous (donor) and organic (membrane) phases. This reaction is the pertinent one, rather than the expected $M^{m+} + nL = M^{m+}L_n$, because the transport of a cation by a neutral macrocycle requires the simultaneous transport of an anion to maintain electroneutrality. The transported moiety is therefore equivalent to MA_m, a neutral species. Additionally, it is known that the rate-determining step in the mechanism is the diffusion of the complex through the membrane. A more accurate model would also account for the loss of macrocycle from the membrane, since carrier leaching

would diminish the concentration of macrocycle available to move the cation.

The cation flux, J, can be calculated from a single equation containing terms whose values can either be measured or calculated readily (20):

$$[2] \qquad J = \frac{DK_{ex}[L_{total}{}^{org}][MA_m{}^{aq}]}{l(1 + K_{ex}[MA_m{}^{aq}])}$$

The variables are defined as follows: D is the diffusion coefficient of the neutral solute species, MA_mL^{org}, through the membrane solvent; $[L_{total}{}^{org}]$ is the total concentration of crown ether in the organic solvent; $[MA_m{}^{aq}]$ is the concentration of neutral solute species in the source phase; and l is the membrane diffusion path length. The value of D/l is generally calculated, because the l value is difficult to obtain alone, owing to the need to include a term to account for membrane porosity and tortuosity. These values are calculated for each solvent–membrane system, so the value for Celgard 2400 with phenylhexane is used. The K_{ex} value can be measured experimentally, and the concentration of ligand is known from the membrane solutions. The units of J are mol s^{-1} m^{-2}, incorporating time, area, and amount of substance.

This equation was used to predict the permeation behavior of Pb through a Celgard 2400 membrane soaked with DC18C6 in decanol or phenylhexane under stopped-flow conditions. The time required for the Pb concentration to change from 1000 to 1 mg L^{-1} in the donor solution was desired. This corresponded to the removal of a specific quantity of Pb matrix from a sample, which provided a value for the number of moles transported. The area of the SLM in contact with the donor in the flow injection experiments was calculated from measurements of the channel dimensions. These values, when combined with the calculated flux, allowed for the calculation of the transport time. To a first approximation, it was assumed that the behavior of the system with decanol was similar to that with phenylhexane, so the equilibrium constants and other variables for phenylhexane were used.

Before it is possible to calculate the flux of Pb across the membrane, however, the concentration of the neutral species available for transport must be obtained. The remaining variables in the flux equation are known: D/l for the Celgard 2400-phenylhexane system (3.19×10^{-4} L s^{-1} m^{-2}) (20), K_{ex} for the complexation of Pb(NO$_3$)$_2$ with DC18C6 (398.11) (20), and the concentration of DC18C6 in the membrane soaking solution. The only unknown, then, is the concentra-

tion of $Pb(NO_3)_2$ in the donor. This value depends on the initial amount of Pb in the sample (1000 mg L^{-1}) and the concentration of HNO_3 (volume fraction 0.02).

To calculate the amount of Pb in the sample present as $Pb(NO_3)_2$, an iterative approach to the systematic treatment of equilibrium was taken. Using the β (log stepwise formation constant) values (18) for the formation of $PbNO_3^+$ and $Pb(NO_3)_2$ (2.14 and 2.15, respectively) and the sample concentration of 1000 mg L^{-1} for the total amount of Pb, it was possible to compute $[Pb^{2+}]$ from the mass balance equation for lead. This value for $[Pb^{2+}]$ was used, along with the appropriate β value and the concentration of unbound NO_3^- in solution, to obtain the concentration of $Pb(NO_3)_2$. The total amount of nitrate anion bound up in all of the complexes was calculated and subtracted from the initial value. This adjusted initial value was used as the starting condition for the next iteration of the calculation, yielding a new $[Pb(NO_3)_2]$ and [unbound NO_3^-]. This iterative process was performed five times, at which point the calculated concentrations of $Pb(NO_3)_2$ and NO_3^- had each converged. The concentration of the neutral species was substituted into the flux equation, and the flux was calculated, yielding the quantity of Pb that could be transported.

The flux equation only describes an instantaneous condition. Immediately after the transport of Pb begins, the total concentration of Pb on the donor side decreases. This produces a new concentration for the neutral species and, hence, a different value for the flux. To account for this, the flux was assumed to be constant over a specific period of time, after which the concentration of Pb remaining in the donor solution was calculated and a new flux computed. The initial Pb concentration in the sample was 1000 mg L^{-1} and the desired final concentration was 1 mg L^{-1}, which produced a defined end for the process. Time increments of 600, 300, 60, 15, and 1 s were used.

In earlier work (4) we devised an FI-SPE procedure based on Pb-Spec (0.75 mol L^{-1} di-*tert*-butyldicyclohexano-18-crown-6 in decanol immobilized on Amberchrom CG-71 (19)), which successfully removed the lead from digested bullet samples, allowing for accurate analyte determinations by ICP-MS. Although the overall analysis time was rather long for routine use, the rate of the lead removal was compatible with a flow rate of approximately 1 mL min^{-1}. To compare the performance of a column of Pb-Spec with that of the SLM, Pb-Spec was considered to consist of a thin coating of crown ether solution on the surfaces of impermeable spherical particles. Thus, each particle was imagined to function as a miniature, single-sided liquid membrane.

Physical characteristics of the Pb-Spec resin were calculated from information provided by the manufacturer, Eichrom, Inc. The resin bead size ranged from 100 to 150 μm, so for spherical beads the surface area ranged from 0.0314 to 0.0707 mm^2 per bead. Visual inspection through a transmission light microscope showed that the particles appeared uniformly spherical. It was therefore concluded that the surface area calculated on the basis of spherical resin beads was sufficient for use in subsequent calculations. From the dimensions of the resin bed (2.3 cm × 4 mm i.d.) within the glass column, the volume of resin was 0.289 mL. The resin has a free column volume of 0.65 mL per mL resin bed (19), or 0.188 mL in this specific column. Thus the

volume occupied by the resin was 0.101 mL. By considering the volume of spheres with diameters of 100 and 150 μm, the total number of beads in a volume of 0.101 mL was computed: 1.93×10^5 beads if they are all 100 μm and 5.71×10^4 if 150 μm. Factoring in the surface area of an individual bead, the total surface area in a column containing 105 mg of 100 μm beads is 0.00605 m^2 and 0.00403 m^2 for a column of 150 μm beads.

As the flux is calculated per unit area, the effect of membrane surface area is one of direct proportion. Different surface areas were considered. The contact area of the flat sheet membrane in the nylon cell, 8×10^{-5} m^2, was included, as well as the Pb-Spec column areas of 0.00403 and 0.00605 m^2.

The effect of crown ether concentration on rate of transport was examined. Values of 0.05 mol L^{-1} DC18C6 (SLM) and 0.75 mol L^{-1} (Pb-Spec) were substituted into eq. [2].

Results and discussion

Experimental

The membrane polymeric support consisted of a sheet of Celgard 2400 with approximate dimensions 4.5 cm × 3.5 cm. This effectively covered the faces of the membrane cell blocks. The white membrane, made from 25 μm thick polypropylene, was hydrophobic and shed water as droplets. After the membrane was soaked in an organic solvent, however, it was completely wetted and became transparent. Because the membrane was then placed in contact with aqueous donor and receiver solutions, it was vital that the organic solvent be immiscible in water. A comparison (18) of water solubilities of common membrane solvents (chloroform: 7950 mg L^{-1}; toluene: 526 mg L^{-1}; 1,2-dichlorobenzene: 156 mg L^{-1}; decanol (22): 3.70 mg L^{-1}; phenylhexane: 0.902 mg L^{-1}) indicates that phenylhexane is the solvent with the lowest water solubility, followed by decanol.

The time required for the phenolphthalein slug to arrive at the membrane cell and fill the donor channel was 12 s. The dye experiment revealed that the 130 μL sample slug underwent noticeable dispersion, allowing only a relatively small portion of the sample volume to be in contact with the membrane during the stop time.

The better receiver solution was 0.1 mol L^{-1} ammonium citrate. This result, displayed in Fig. 2, was anticipated. The transport of Pb through the membrane was expected to be enhanced when the Pb was actively stripped from the membrane. The acid receiver was more passive, allowing the Pb to diffuse into it from the membrane. The ammonium citrate solution, however, allowed for the formation of a strong lead citrate complex, which provided an additional driving force for the Pb transport.

Figure 3 shows the results for the stopped-flow experiments using the two crown ether concentrations. The concentration of lead in the receiver solution increased with time until a constant value was obtained, which indicated that an equilibrium was reached. That is, the rates of transport of lead across the membrane in each direction were then equal. The results indicate that the membrane that contained 0.05 mol L^{-1} DC18C6 allowed more permeation of Pb than the other membranes. These findings contradict the results

Fig. 2. The effect of different receiver solutions on Pb transport.
Fig. 3. Results for stopped-flow experiments. Each point represents a single measurement.
expected on the basis of eq. [2], from which it would be expected that the presence of more carrier molecules in the membrane would cause more Pb to be transferred. However, the higher concentration of crown ether may decrease the diffusion coefficient term in the numerator of eq. [2], which could account for the slower-than-expected rate of transport. Further investigation of this possibility was considered beyond the scope of the present study.

The Pb content of the 15 min stop flow point (0.1 mol L^{-1} DC18C6 membrane) was measured off-line by ETAAS. The

least-squares calibration equation produced by three standard solutions was $y = 0.0016x - 0.0058$, where y is the absorbance and x the Pb concentration in μg L^{-1}. The correlation coefficient r was 0.9996. The concentration of Pb in the sample was 89.4 μg L^{-1}, corresponding to 1.1 $\times$ 10^{-8} moles Pb in the 25 mL flask. This amount of Pb was transported across the membrane in 15 min. Assuming a linear relation between absorbance and concentration, the FAAS absorbances for each of the other stop times were calculated from this point, as shown in Fig. 4. The 0.05 mol L^{-1}

Fig. 4. The number of moles transported across the membrane at each stopped-flow time. The 15 min point for the 0.1 mol L^{-1} DC18C6 membrane was quantified by ETAAS, from which all other *y*-values are calculated.
DC18C6 membrane absorbances were also calculated from this value.

It is clear from Figs. 3 and 4 that the kinetics of transport for the flat sheet SLM are too slow for the process to be implemented in a flow injection mode. The transfer mechanism relies on the diffusion of the Pb – crown ether complex through the membrane, for which the concentration gradient of Pb is a driving force. Thus, if the receiver solution is not stagnant, this diffusion would continue, and eventually the desired amount of lead could be transported across the membrane. However, in this mode of operation, the transport processes would not produce any preconcentration.

The Pb transport rate is also proportional to the membrane area. As the dispersion of the sample slug allowed only a small portion of the initial volume to be in contact with the membrane during the stop time, the rate of transport was less than would be obtained with either a larger surface area or a smaller sample volume. Although, the additional dispersion incurred with a smaller sample volume would probably offset this benefit, owing to the decreased concentration in the donor phase.

Model calculations

The calculated number of moles of Pb remaining in the donor solution is plotted as a function of the elapsed time in Fig. 5. As the time increments decreased, the system was described more accurately, since chemical processes are rapid. Also, the new plots became more and more similar until they converged. It was therefore assumed that further reducing the increments would not substantially alter the predicted transport time.

The line for the calculations using 5 s increments overlapped that for the 1 min increments so that they are indis-

tinguishable on the figure. Both lines showed a total transport time of 105 min; the 5 s trace was subsequently omitted from the plot for clarity.

In addition to calculating the number of moles of Pb remaining in the donor solution vs. elapsed time, the number of moles appearing in the receiver could be derived. A comparison between the calculated transport and the experimental values for the two membranes containing 0.05 mol L^{-1} crown ether may be made from the plots in Fig. 6. One reason for the low experimental rate compared with the calculated rate may be the leaching of macrocycle from the membrane. Izatt et al. (20) calculated that for a similar crown ether and phenylhexane in Celgard 2400, about 90% of the macrocycle was lost. It should be noted, however, that their calculations modeled transport under conditions in which both the donor and acceptor solutions were constantly stirred.

When the total surface area of the Pb-Spec resin was inserted into the flux equation, the time for the lead concentration to reach 1 mg L^{-1} was significantly diminished for a membrane containing 0.05 mol L^{-1} ligand. For an area of 0.00605 m^2 (100 μm resin), the transport time is 2.5 min for 10 s increments. The time is 4.1 min when the area is 0.00403 m^2 (150 μm resin) for the same increments.

Increasing the ligand concentration in the SLM had a significant effect on the transport time. With 0.75 mol L^{-1} ligand and the membrane area held at the experimental value of 8×10^{-5} m^2, the time was 6.7 min with 10 s increments of constant flux. When the area of the 100 μm resin is combined with the increased ligand concentration, the transfer time calculated from 1 s increments is diminished to 8.7 s. The value obtained for the 150 μm resin corresponds to 15.3 s.

Fig. 5. Calculated number of moles remaining in the sample as a function of time for different time increments used in the flux calculations. Inset is an enlargement of the region where the calculated concentrations go below 1 mg L^{-1} Pb.
Fig. 6. Comparison of calculated and observed transport of Pb across the 0.05 mol L^{-1} DC18C6 membranes. Calculated results based on 1 min increments.
As can be seen from Figs. 3, 4, and 6, decanol is to be preferred over phenylhexane as an SLM solvent, though the reasons for this are not immediately obvious. Decanol has higher viscosity and water solubility than phenylhexane, though information regarding the diffusion coefficients of DC18C6 in these solvents is not immediately available. However, the results confirm that decanol is an appropriate choice for the formulation of the Pb-Spec SPE material.

Conclusions

Separations by SLM systems are not feasible for on-line, dynamic, flow injection applications. Although the advantages of SLMs (i.e., the lack of back-pressure and sample dispersion, as well as the single-step analysis procedure) make these devices attractive for this type of analysis, both experimental results and model calculations indicate that the transport processes are too slow for typical FI systems. On the other hand, the same chemistry conducted in thin films coated on spherical beads is compatible with FI time scales. It is concluded that this is due largely to the increased surface area of the "membrane". This raises the question, to what extent could the SLM performance be improved by using a bundle of hollow fibers instead of a flat sheet? For example, a bundle of 140 Celgard X-30 240 fibers (i.d. 240 μm, o.d. 300 μm) packed into a 5 cm column has a total internal surface area of approximately 0.0045 m^2. This value is comparable to that obtained for the 100 μm Pb-Spec beads, implying that such a bundle might have a feasible rate of transport for use in a flow injection manifold.

Syntheses, characterization, and X-ray crystal structures of diorganotin(IV) derivatives of 2-pyridinethiolato-*N*-oxide

Chunlin Ma, Junhong Zhang, and Rufen Zhang

Abstract: The diorganotin(IV) dichloride reacts with sodium 2-pyridinethiolato-*N*-oxide in a 1:1 ratio to produce [Me$_2$SnCl(2-SpyO)] (**1**), [Et$_2$SnCl(2-SpyO)] (**2**), [Bu$_2$SnCl(2-SpyO)] (**3**), [Ph$_2$SnCl(2-SpyO)] (**4**), and [(PhCH$_2$)$_2$SnCl(2-SpyO)] (**5**). The new complexes have been characterized by elemental analysis and IR and NMR (^{1}H, ^{119}Sn, and ^{13}C) spectroscopy. On the basis of ^{119}Sn NMR data the effective coordination number in solution is five. The structures **1** and **4** have been confirmed by X-ray crystallography. Crystals of **1** are triclinic with space group $P\bar{1}$ and those of **4** are monoclinic, $P21/n$. The tin environment is a distorted trigonal bipyramid with the Cl and oxygen atoms in apical positions. Both complexes exhibit strong π–π stacking interactions.

Key words: diorganotin, π–π stacking interaction, 2-pyridinethiolato-*N*-oxide, crystal structure.

Résumé : Le dichlorure de diorganoétain(IV) réagit avec le 2-pyridinethiolato-*N*-oxyde de sodium dans un rapport de 1:1 pour donner: [Me$_2$SnCl(2-SpyO)] (**1**), [Et$_2$SnCl(2-SpyO)] (**2**), [Bu$_2$SnCl(2-SpyO)] (**3**), [Ph$_2$SnCl(2-SpyO)] (**4**) et [(PHCH$_2$)$_2$SnCl(2-SpyO)] (**5**). On a caractérisé les nouveaux complexes par l'analyse élémentaire, par la spectroscopie IR et RMN (^{1}H, ^{119}Sn, ^{13}C). Les données de la RMN du ^{119}Sn révèlent un indice effectif de coordination de 5 en solution. Les structures **1** et **4** ont été confirmées par cristallographie de rayons X. Les cristaux du composé **1** sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ et ceux du composé **4** sont monocliniques et appartiennent au groupe d'espace $P21/n$. L'environnement de l'atome d'étain est une bipyramide trigonale déformée avec les atomes de Cl et d'oxygène en positions apicales. Les deux complexes exhibent de fortes interactions d'empilement π–π.

Mots clés : diorganoétain, interaction d'empilement π–π, 2-pyridinethiolato-*N*-oxyde, structure cristalline.

Introduction

The synthesis and characterization of organotin(IV) complexes have been a continuing subject of study in recent years (1–6). Organotin(IV) compounds containing electronegative atoms, such as halogen atoms, show Lewis acid character, and the tin atom increases its coordination number from four to five, six, or seven upon addition of neutral, organic donor ligands (7, 8). There have been numerous studies on adduct formation by organotin(IV) halides with a variety of O-, S-, and N-containing ligands (9–11). Owing to widespread applications of organotin (IV) complexes, they have played an important role in medicine, agriculture, and industry. A variety of organotin(IV) complexes are now known to show antitumor activity (12), and some others are well established for use as fungicides, biocides, and pesticides (13–15).

In the past few years, studies on organotin complexes with 2-pyridylthiolato (2-Spy), essentially concerning diorganotin derivatives of the type R$_2$Sn(2-Spy)$_2$ or R$_2$SnCl(2-Spy), have been reported (16–19). Evidence was obtained for tin chelation by thiol sulfur and one heterocyclic nitrogen atom. In our previous work, we have reported some novel macrocycle organotin complexes with sulfur, nitrogen, and oxygen donor ligands (20–22). To continue our research in the field, we herein describe the synthesis and characterization of five diorganotin(IV) complexes R$_2$SnCl(2-SpyO) (R = Mt, Et, *N*-Bu, Ph, or PhCH$_2$), along with the X-ray crystal structures of Me$_2$SnCl(2-SpyO) **1** and Ph$_2$SnCl(2-SpyO) **4**. The reaction equation may be found in Scheme 1.

Experimental

Materials and measurements

Dimethyltin dichloride, diethyltin dichloride, *N*-dibutyltin dichloride, diphenyltin dichloride, and sodium 2-pyridinethiolato-*N*-oxide were purchased from Aldrich Company, and they were used without further purification. Dibenzyltin dichloride was prepared by a standard method reported in the literature (23). The melting points were obtained with a Kofler micro melting point apparatus and were uncorrected. Infrared spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H, ^{13}C, and ^{119}Sn NMR spectra were recorded on a Bruker AMX-300 spectrometer operating at 300, 75.3, and

111.9 MHz, respectively. The spectra were acquired at room temperature (298 K) unless otherwise specified; ^{13}C spectra are broadband proton decoupled. The chemical shifts were reported in ppm with respect to the references and were stated relative to external tetramethylsilane (TMS) for ^{1}H and ^{13}C NMR and to neat tetramethyltin for ^{119}Sn NMR. Elemental analyses were performed with a PE-2400II apparatus.

Syntheses

[Me$_2$SnCl(2-SpyO)] 1

The reaction was carried out under nitrogen atmosphere. The sodium 2-pyridinethiolato-*N*-oxide (0.149 g, 1.0 mmol) was added to a solution of benzene (20 mL) in a Schlenk flask and stirred; then dimethyltin dichloride (0.219 g, 1.0 mmol) was added to the reactor. The reaction mixture was stirred for 12 h at 40 °C and then was filtrated. The filtrate was gradually removed by evaporation under vacuum until a solid product was obtained. The solid was then recrystallized from dichloromethane–hexane. Colorless crystals were formed. Complex **1**: Yield 88%. mp 108–110 °C. IR (KBr, cm^{-1}): 1596 (C = N), 1460 (C-N), 1207 (N-O), 750 (C-S), 350 (Sn-O), 305, 270 v_{as}, v_s(Sn-C), 301 (Sn-S), 238 (Sn-Cl). ^{1}H NMR (CDCl$_3$) δ: 1.02 (s, 6H,Sn-CH$_3$, $^2J_{SnH}$ = 78.1 Hz), 7.35 (1H, 3-CH), 7.65 (1H, 4-CH), 7.05 (1H, 5-CH), 8.15 (1H, 6-CH). ^{13}C NMR (ppm) δ: 7.2 (s, Sn-CH$_3$, $^1J_{SnC}$ = 578Hz); δ (C$_5$H$_4$NS): 118.8, 128.6, 129.1, 137.1, 157.2. ^{119}Sn NMR (CDCl$_3$) (ppm): –52.6. [Bu$_2$SnCl(2-SpyO)] 3

Complex **3** was prepared similarly to **1** by using sodium 2-pyridinethiolato-*N*-oxide (1.0 mmol), benzene (30 mL), and Bu$_2$SnCl$_2$ (1.0 mmol). It was recrystallized from di-

chloromethane–hexane. Yield 79%. mp 123–125 °C. IR (KBr, cm^{-1}): 1604 (C = N), 1467 (C-N), 1215 (N-O), 746 (C-S), 366 (Sn-O), 323, 282 v_{as}, v_s(Sn-C), 306 (Sn-S), 237 (Sn-Cl). ^{1}H NMR (CDCl$_3$) δ: 0.88 (t, 6H, -CH$_3$), 1.28–1.70 (mbr, 12H, -CH$_2$), 7.30 (1H, 3-CH), 7.43 (1H, 4-CH), 6.93 (1H, 5-CH), 8.12 (1H, 6-CH). ^{13}C NMR (ppm) δ: 13.81, 26.02, 27.0, 28.6 (^{n}Bu, $^1J_{SnC}$ = 494 Hz, $^2J_{SnC}$ = 36.6 Hz, $^3J_{SnC}$ = 101.7 Hz); δ (C$_5$H$_4$NS): 118.3, 129.5, 129.9, 138.8, 156.7. ^{119}Sn NMR (CDCl$_3$) (ppm): –78.6.. Anal. calcd. for C$_{13}$H$_{22}$NClOSSn (%): C 39.79, H 5.07, N 3.57, S 8.15; found: C 39.73, H 5.11, N 3.51, S 8.11.

[Ph$_2$SnCl(2-SpyO)] 4

Complex **4** was prepared similarly to **1** by using sodium 2-pyridinethiolato-*N*-oxide (1.0 mmol), benzene (30 mL), and Ph$_2$SnCl$_2$ (1.0 mmol). The solid was then recrystallized from ether–dichloromethane. Colorless crystals were formed. Complex **4**: Yield 80%. mp 154–156 °C. IR (KBr, cm^{-1}): 1606 (C = N), 1470 (C-N), 1215 (N-O), 745 (C-S), 368 (Sn-O), 328, 289 v_{as}, v_s(Sn-C), 310 (Sn-S), 245 (Sn-Cl). ^{1}H NMR (CDCl$_3$) δ: 7.17–7.65 (mbr, 10H, ph-H, $^3J_{SnH}$ = 89 Hz), 7.35–7.40 (m, 1H, 3-CH), 7.37–7.41 (m, 1H, 4-CH), 6.80 (1H, 5-CH), 8.11 (1H, 6-CH). ^{13}C NMR (ppm) δ: (C$_6$H$_5$) 124.7 ($^3J_{SnC}$ = 50 Hz, *m*-C), 129.6 ($^4J_{SnC}$ = 12 Hz, *p*-C), 136.9 ($^2J_{SnC}$ = 36 Hz, *p*-C), 146.5 ($^1J_{SnC}$ = 597 Hz, *i*-C); δ (C$_5$H$_4$NS): 119.7, 128.1, 128.5, 137.0, 154.1. ^{119}Sn NMR (CDCl$_3$) (ppm): –177.6. [(PhCH$_2$)$_2$SnCl(2-SpyO)] 5

Complex **5** was prepared similarly to **1** using sodium 2-pyridinethiolato-*N*-oxide (1.0 mmol), benzene (30 mL), and (PhCH$_2$)$_2$SnCl$_2$ (1.0 mmol). It was recrystallized from dichloromethane–hexane. Yield 85%. mp 168–170 °C. IR (KBr, cm^{-1}): 1608 (C = N), 1467 (C-N), 1215 (N-O), 747 (C-S), 370 (Sn-O), 325, 281 v_{as}, v_s(Sn-C), 309 (Sn-S), 250 (Sn-Cl). ^{1}H NMR (CDCl$_3$) δ: 7.26–7.65 (mbr, 10H, -Ph), 3.26 (4H, CH$_2$-Ph), 7.35 (d, 1H, 3-CH), 7.40 (1H, 4-CH), 6.89 (1H, 5-CH), 8.09 (1H, 6-CH). ^{13}C NMR (CDCl$_3$) (ppm) δ: 38.5 (CH$_2$-Ph, $^1J_{SnC}$ = 546 Hz), 125.4 ($^4J_{SnC}$ = 30 Hz, *m*-C), 127.0 ($^5J_{SnC}$ = 26 Hz, *p*-C), 130.5 ($^3J_{SnC}$ = 44 Hz, *o*-C), 139.0 ($^2J_{SnC}$ = 36 Hz, *i*-C); δ (C$_5$H$_4$NS): 119.9, 128.5, 136.6, 141.5, 153.8. ^{119}Sn NMR (CDCl$_3$) (ppm): –178.9. Anal. calcd. for C$_{19}$H$_{18}$NClOSSn (%): C 49.34, H 3.89, N 3.03, S 6.92; found: C 49.29, H 3.83, N 3.07, S 6.88.

X-ray structure determination

X-ray crystallographic studies of complexes **1** and **4** were done using a Bruker Smart 1000 diffractometer fitted with

graphite-monochromated Mo Kα radiation (λ = 0.71073 Å).[3] The ω/2θ scan technique was employed. Corrections were applied for Lorentz and polarization effects but not for absorption, satisfying $I \geq 2\sigma(I)$. Criterion of observability was used for the solution and refinement. The structures were solved using direct methods and refined by a full-matrix least-squares procedure based on F^2 using the SHELXL-97 program system. All non-H atoms were included in the model at their calculated positions.

In vitro antitumour activity tests of complexes 1, 2, 3, 4, and 5

The in vitro antitumour activity tests of complexes **1**–**5** against the cell lines were performed according to the PIT method described previously (24).

Results and discussion

IR data

In the IR spectra of **1**–**5** we have assigned some bonds in the range 350–370 cm^{-1} to Sn-O, which in our series seems to be little influenced by the type of halogen that is bonded to tin. In the far IR region complexes **1**–**5** show a strong absorption in the 301–310 cm^{-1} range, due to the Sn-S stretching mode of vibration. The Sn-C and Sn-Cl stretching vibrations agree well with the trends previously observed in similar complexes containing N-donor chelating ligands (9). In the spectra of alkyl derivatives **1**, **2**, and **3**, the Sn-Cl stretching bands are observed between 235 and 238 cm^{-1}, while in **4** and **5** these bonds fall in the region 245–250 cm^{-1}, being shifted to lower frequencies with respect to those reported for corresponding Ph$_2$SnCl(Ma) (25).

NMR data

The chemical shift values of the ligand protons in complexes **1**–**5** are in the region 6.80–8.19 ppm. The $^2J(^{119}$Sn-^{1}H) of dimethyltin derivative **1** has a value of 78.1 Hz, typical of five-coordinated tin species. On the basis of Lockarts' equation (26), the Me-Sn-Me angle is estimated to be approximately 128°, which agrees with that found in the crystal structure. Moreover, the ^{1}H NMR spectra of complex **4** shows two multiplets attributable to the H(2,6) and H(3,4,5) of the phenyl protons. The resonance of H(2,6) has tin satellites with $^3J_{SnH}$ (89 Hz) greater than in uncomplexed Ph$_2$SnCl$_2$ (81.3 Hz) (27). The increase in the coupling constant indicates the higher coordination number of tin.

The ^{119}Sn NMR chemical shifts of **1**–**5** are in accordance with those of five-coordinate diorganotin(IV) halide complexes involving halide or phosphine ligands (28), as well as chelating S-donor and O-donor complexes (29, 30). Five-coordinate ClPh$_2$SnXY compounds (X and Y = electronegative groups) in solution have ^{119}Sn NMR values in the region –140 to –180 ppm, depending on the groups present (31, 32). The ^{119}Sn value for **4** at –177.6 ppm in solution suggests that the Sn-O interaction probably survives in solution and that a five-coordinate species is maintained.

Table 1. ID$_{50}$ values in ng mL^{-1} against two human tumour cells, MCF-7 and WiDr, of the complexes and reference compounds.

Complexes	MCF-7	WiDr
1	276	894
2	288	1185
3	96	295
4	295	1143
5	292	1182
CPT	699	967
ETO	2594	150
5FU	18	<3

The ^{13}C NMR spectra show a significant downfield shift of all carbon resonances. The shift is a consequence of an electron density transfer from the ligand to the acceptor. The $^nJ(^{119}$Sn-^{13}C) coupling constants were detected in the case of sufficiently soluble derivatives. In complexes **1**–**5**, the order of magnitude of the coupling constants is the same as those previously reported for analogous five-coordinate derivatives (33, 34). By using the simple linear relationship between $^1J_{SnC}$ and the C-Sn-C bond angles derived by Lockart and Manders (26) and Howard et al. (27) for the dimethyltin species, a value has been found for complex **1** in the range 126–132°, which agrees well with the angles of 125° and 129° found in the crystal structure.

Biologic activity measurement

The in vitro activities of all complexes **1**–**5**, expressed as ID$_{50}$ values against two human tumour cells, MCF-7 and WiDr, are given in Table 1. They are compared with the ID$_{50}$ values obtained for some reference compounds (12). All the activities are rather poor. Complex **3** exhibited the highest activity, slightly better than *cis*-platin (CPT) and comparable or slightly better than etoposide (ETO) against MCF-7 but less than 5-fluorouracil (5FU) against MCF-7 and WiDr (12).

Molecular structures

The crystal data and refinement details of complexes **1** and **4** are given in Table 2. Selected bond distances and angles are shown in Tables 3 and 4. The crystal structures and unit cell packing figures are shown in Figs. 1–4, respectively.

For complex **1**, the molecular structure and the atom numbering scheme is shown in Fig. 1. The asymmetric unit cell contains two crystallographically independent molecules **A** and **B**. Conformations of the two independent molecules are almost the same, with only little differences in bond lengths and bond angles (see Table 3). The coordination geometry about Sn(IV) is a distorted trigonal bipyramid in which the two methyl groups and a sulfur atom form the equatorial plane, while the halogen and the ligand oxygen occupy the apical positions. In this way the ligand behaves as a

bidentate species and chelates the tin atom by means of the oxygen and the thiolato sulfur. The consequence is formation of a five-membered ring with an S-Sn-O bite angle (76.85(16)° for Sn(1), 78.01(15)° for Sn(2)), which is a little

bigger than those found in [Me$_2$Sn(2-SpyO)$_2$] (72.0(1)° and 73.5(1)°) (33, 35). The Sn—C distances (2.075(8)–2.120(8) Å) and the Sn—S distances (2.459(4) and 2.449(4) Å) are similar to those found in [Me$_2$SnCl(TNEE)] (2.110(6) and 2.473(2) Å, respectively) (36), but shorter than those found in other trialkyltin(chelate) systems (37). The Sn—O distances (Sn(1)—O(1) = 2.223(6) Å and Sn(2)—O(2) = 2.212(6) Å) are well within the range observed for pyridine-*N*-oxide adducts of organotins (38). The S—C bond distances (1.717(8) and 1.727(9) Å) are shorter than those found in [R$_2$Sn(Spy)$_2$] (1.751(7) Å) (19) and are consistent with single-bond character. These values suggest that the ability of HSpy to transform its thione to the thiol is higher when compared with HSpyO. The Sn—Cl bond length (Sn(1)—Cl(1), 2.465(4) Å and Sn(2)—Cl(2), 2.467(4) Å),

Fig. 1. Molecular structure of complex **1**.

A   B

Fig. 2. Crystal packing of complex **1**.

Fig. 3. Molecular structure of complex **4**.
Fig. 4. Crystal packing of complex **4**.

lies in the range of the normal covalent radii, 2.37–2.60 Å (39). In molecule **B**, as seen in Fig. 2, the closest intermolecular Sn(1)···Cl(1)$^{\#}$ distance is 3.974 Å, which is just comparable to the sum of the van der Waals radii of Sn and Cl (4.0 Å) (40). It is apparent that the presence or absence of the additional intermolecular Sn···Cl interaction has only a small effect on the molecular geometry of the R$_2$SnCl(2-SpyO) complexes.

For complex **4**, which is similar to complex **1**, the geometry at Sn is also a distorted *cis*-trigonal bipyramidal with Cl and O atoms in axial sites (Cl(1)-Sn(1)-O(1) 165.75(8)°) and one S and two phenyl C atoms occupying the equatorial plane (C(12)-Sn(1)-C(6) 126.65(14)°, C(12)-Sn(1)-S(1)

119.76(11)°, C(6)-Sn(1)-S(1) 112.98(13)°). The Sn—S bond length (Sn(1)—S(2), 2.4402(14) Å) lies in the range of that reported for triphenyltin heteroarenethiolates (2.41 to 2.48 Å) (41) and is shorter than that of Ph$_2$SnCl(MBT) (2.485(22) Å) (24). Finally, the Sn—C bond lengths are approximately equal (2.123(4) and 2.132(4) Å) and similar to the average value, 2.13 Å (41).

Both of the crystal structures of complexes **1** and **4** show ring-stacking interactions; each SpyO group is arranged face-to-face at a distance of 3.588 Å for molecule **A** and 3.625 Å for molecule **B** in complex **1**, and 3.557 Å in complex **4**, which shows significant π–π stacking interactions (42, 43).

Synthesis, characterization, and optical properties of a novel azo-dye bearing an oligo(ethylene glycol) methyl ether side chain in solution and in the solid state

Ernesto Rivera, Michel Belletête, Almeria Natansohn, and Gilles Durocher

Abstract: A novel azobenzene compound bearing a short poly(ethylene glycol) methyl ether side chain, *N*-methyl-*N*-{4-[(*E*)-(4-nitrophenyl)diazenyl]phenyl}-*N*-(3,6,9,12,15,18,21,24-octaoxapentacos-1-yl)amine (RED-PEGM-8) was synthesized and characterized. RED-PEGM-8 exhibits a thermal behavior similar to that of Disperse Red-1; however, its thermal stability, as well as its T_g and T_m values, are lower because of the presence of the PEGM segment. The optical properties of this compound in solution and in the solid state were studied by UV–vis spectroscopy. The appearance of a blue-shifted band in aqueous solutions at high concentrations of the chromophore reveals the existence of H-type aggregates, resulting from π–π intermolecular interactions between the azobenzene units. Strong intermolecular interactions were also confirmed by ^{1}H NMR measurements. Optical properties of RED-PEGM-8 in the solid state (thin film) also suggest the presence of H aggregates. However, a tail is also detected in the red region of the absorption spectrum, which could be because of the formation of J-type aggregates in the thin film.

Key words: aggregation, azo-dye, poly(ethylene glycol) methyl ether.

Résumé : Un nouveau dérivé de type azobenzène, ayant une courte chaîne poly(éthylène)glycol méthyl éther, soit le *N*-méthyl-*N*-{4-[(*E*)-(4-nitrophényl)diazényl]phényl}-*N*-(3,6,9,12,15,18,21,24-octaoxapentacos-1-yl)amine (RED-PEGM-8), a été synthétisé et caractérisé. RED-PEGM-8 montre un comportement thermique similaire à celui du Disperse Red-1. Cependant, sa stabilité thermique de même que les valeurs de T_g et T_m sont inférieures à celles du Disperse Red-1 à cause de la présence du segment PEGM. Les propriétés optiques de ce composé en solution et à l'état solide (film mince) ont été étudiées à l'aide de la spectroscopie UV–visible. En solution aqueuse, à hautes concentrations, ce composé montre l'apparition d'une bande d'absorption dans la région bleue du spectre. Ces résultats révèlent la présence d'aggrégats de type H provenant d'interactions intermoléculaires π–π entre unités azobenzène. L'étude des spectres RMN protoniques a confirmé la présence d'interactions intermoleculaieres fortes. Finalement, les propriétés optiques du RED-PEGM-8 à l'état solide (film mince) suggèrent également la présence d'aggrégats de type-H. Cependant, le spectre d'absorption du film mince montre aussi l'apparition d'une queue aux grandes longueur d'onde, qui pourrait être due à la formation d'aggrégats de type J dans le film.

Mots clés : aggrégation, colorant azo, poly(éthylène)glycol méthyl éther.

Introduction

Poly(ethylene glycol) (PEG) has been widely studied because of its interesting and useful properties, such as solvent-selective combination, owing to its water solubility. These properties make it attractive for the synthesis of new amphiphilic compounds (1*a*). PEG has been widely used for the preparation of nonionic surfactants, which can act as

demulsifiers, dispersing agents, and emulsion stabilizers. For instance, polyhydroxystearic acid – PEG copolymers are used in emulsion polymerization, and PEG-alkyd resins are used for producing water-emulsifiable gloss paints and industrial degreaser concentrates (1*b*). Besides, PEG has been often used in the synthesis of ionic conducting materials (2) because of its ability to complex cations and forms charge-transfer complexes (CT) (3). In a recent study, an end-

capped sample, oligo(ethylene glycol) methyl ether 3,5-dinitrobenzoate (DNB), has been synthesized, and the formation of an intramolecular CT in a water solution has been reported, resulting from the coiling of the highly hydrophilic oligo(ethylene glycol) methyl ether (PEGM) chain around the hydrophobic DNB unit (4).

On the other hand, azobenzenes are very versatile chromophores for incorporation in novel materials, owing to the *trans–cis* photoisomerization of the azobenzene groups. For instance, photoinduced motions at different levels occur when azopolymers are irradiated with laser polarized light (5). Several reviews covering most of the implications of azobenzene photoisomerization in polymer structures have been published (6–10). In the last few years, Natansohn and co-workers have synthesized and characterized various polymers bearing amino-nitro substituted azobenzene units (11–13). In general, they exhibit absorption wavelength maxima close to those observed for similar push–pull azo compounds (14). Some azopolymers have also been studied in Langmuir–Blodgett films (15–17). In these materials, both J- and H-type aggregation have been observed.

Since azopolymers are highly versatile materials and PEG provides water solubility and other interesting properties, we have decided to link a PEGM oligomer chain to donor–acceptor azobenzene chromophores, thus forming new amphiphilic dyes. We believe that these azo-dyes can provide valuable information about optical properties of self-assemblies, Langmuir–Blodgett films, and mono and multilayer systems. In this paper, we report on the synthesis, characterization, and optical properties of *N*-methyl-*N*-{4-[(*E*)-(4-nitrophenyl)diazenyl]phenyl}-*N*-(3,6,9,12,15,18,21,24-octaoxapentacos-1-yl)amine (RED-PEGM-8) in organic and aqueous solutions, as well as in the solid state (casted film). The appearance of new absorption bands in the blue region were found in aqueous solutions and in the solid state and were interpreted in terms of aggregate formation.

Experimental section

All the solvents and reagents employed in the synthesis were purchased from Aldrich and used as received. *N*-methylaniline was freshly distilled under reduced pressure prior to use. Materials were dissolved in spectral quality solvents, purchased from Aldrich, for UV–vis spectroscopy. The ^{1}H and ^{13}C NMR spectra of the compounds were recorded in solution on a Bruker ARX-400 spectrometer. Thermal properties of the compounds such as stability, glass transition temperature (T_g), and melting point (T_m) were determined by thermogravimetric analysis (TGA) from 20 to 800 °C and differential scanning calorimetry (DSC) from –150 to 300 °C. Absorption spectra of RED-PEGM-8 were recorded on a Varian Cary 1 Bio UV–vis (model 8452A) spectrophotometer using 1 cm quartz cells.

Synthesis of RED-PEGM-8

PEGM-Ts (1)

To an ice–salt cooled mixture of poly(ethylene glycol) methyl ether (PEGM), bearing an M_w of 350 (52.5 g, 150 mmol) in 170 mL of pyridine, tosyl chloride (29.6 g, 155 mmol) was added. The mixture was vigorously stirred

until tosyl chloride was completely solubilized. The mixture was put in the refrigerator overnight, then poured into 500 mL of HCl 50%, and extracted with chloroform. The combined organic extracts were washed with a saturated solution of Na_2CO_3 and then with water. The organic phase was dried with Na_2SO_4 and concentrated under vacuum. PEGM-Ts was obtained as a transparent liquid (72.8 g, 135 mmol). Yield 90%.

PEGM-I (2)

To a solution of **1** (43.8 g, 81.2 mmol) in 98 mL of acetone, NaI (26 g, 173 mmol) was added and heated to reflux for 24 h. The solution was filtered to remove the TsONa generated during the reaction and the filtrates concentrated under reduced pressure. PEGM-I crude product (37.9 g, 79.6 mmol) was obtained as a yellowish, viscous oil and used immediately in the next step. Yield 85%.

N-PEGM-N-methylaniline (3)

To a solution of *N*-methylaniline (8.5 g, 79.5 mmol) and Na_2CO_3 (8.6 g, 81 mmol) in DMF (120 mL), **2** (37.9 g, 79.6 mmol) dissolved in 20 mL of DMF was added, and the mixture was heated with vigorous stirring at 70 °C for 24 h. The reaction mixture was poured into water and extracted with chloroform. The organic phase was dried with Na_2SO_4 and concentrated under vacuum. The crude product was purified by flash column chromatography, first eluting with ethyl acetate 100% to remove the remaining starting material and then with a mixture of $CHCl_3$–MeOH, 10:1. *N*-PEGM-*N*-methylaniline **3** (see Scheme 1) was obtained as an orange liquid (20.9 g, 47.7 mmol). Yield 60%. IR (film) (cm^{-1}): 3092 (s, aromatic C-H), 2873 (s, CH_2 and CH_3), 1600, 1507, 1451 (s, aromatic ring C=C), 1350 (s, C-N), 1111 (s, O-CH_2), 750, 694 (out of plane, aromatic =C-H). ^{1}H NMR (CDCl$_3$, 300 MHz) (ppm) δ: 7.17 (t, 2H, H^2), 6.67 (m, 3H, H^1 and H^3), 3.61–3.33 (m, 28.6H, all -CH$_2$-), 3.34 (s, 3H, -OCH$_3$), 2.93 (s, 3H, CH$_3$-N). ^{13}C NMR (CDCl$_3$, 75MHz) (ppm) δ: 149.81 (C^a), 129.76 (2C, C^c), 116.82 (1C, C^d), 112.71 (2C, C^b), 72.56, 71.32, 71.27, 71.21, 71.13, 69.18 (15C, all O-CH$_2$), 59.62 (1C, O-CH$_3$), 52.96 (1C, N-CH$_2$-), 39.52 (1C, CH$_3$-N).

RED-PEGM (4)

To a suspension of *p*-nitrobenzenediazonium tetrafluoroborate (0.85 g, 3.58 mmol) in acetic acid 50% (13 mL), a solution of **3** (1.5 g, 3.41 mmol) in acetic acid 50% (2.5 mL) was added slowly, dropwise, keeping the temperature around 0 °C. After the addition was completed, the reaction mixture was stirred vigorously for 1 h at this temperature and then at room temperature for 4 h. Further, it was neutralized with a saturated solution of Na_2CO_3 and extracted with chloroform. The chloroform extracts were combined and the organic phase was washed with water, dried with Na_2SO_4, and concentrated under reduced pressure. The crude product RED-PEGM was obtained as a dark red viscous liquid (1.74 g, 2.88 mmol). Yield 80%.

Since the crude product is a mixture of compounds with a variety of oligo(ethylene glycol) methyl ether chains with different values of *n*, all these compounds were separated by column chromatography in silica gel using a mixture of hexane–acetone, 1:1, as eluent. RED-PEGM with *n* = 8 or

Scheme 1.

N-methyl-*N*-{4-[(*E*)-(4-nitrophenyl)diazenyl]phenyl}-*N*-(3,6,9, 12,15,18,21,24-octaoxapentacos-1-yl)amine (named here RED-PEGM-8) was isolated and further purified by flash column chromatography in silica gel, using a mixture of hexane–acetone, 1:4, as eluant.

For RED-PEGM-8 (see Scheme 2): IR (KBr) (cm^{-1}): 3102 (s, aromatic C-H), 2923 (s, CH_2 and CH_3), 1606, 1509 (s, NO_2), 1465 (s, aromatic C=C), 1430 (s, N=N), 1383, 1341, 1115 (s, O-CH_2), 958, 827 (out of plane, aromatic C=C-H). ^{1}H NMR (CDCl$_3$, 300 MHz) (ppm) δ: 8.34 (d, J = 8.7 Hz, 2H, H^4), 7.95 (d, J = 6.9 Hz, 2H, H^3), 7.94 (d, 2H, J = 3.6 Hz, H^2), 6.81 (d, 2H, J = 9.3 Hz, H^1), 3.73–3.55 (m, 32H, all CH_2), 3.39 (s, 3H, OCH$_3$) and 3.17 (s, 3H, CH$_3$-N). ^{13}C NMR (CDCl$_3$, 75 MHz) (ppm) δ: 157.40 (1C, C^e), 153.22 (1C, C^a), 147.92 (1C, C^h), 144.34 (1C, C^d), 126.77 (2C, C^c), 125.28 (2C, C^g), 123.22 (2C, C^f), 112.14 (2C, C^b), 72.56, 71.47, 71.28, 71.13, 69.18 (all OCH$_2$), 59.65 (1C, OCH$_3$), 52.84 (1C, N-CH$_2$), 40.02 (1C, CH$_3$-N). Elemental analysis (C$_{30}$H$_{46}$N$_4$O$_{10}$)$_n$ (622)$_n$ calcd.: C 57.86, H 7.44, N 8.99; found: C 57.84, H 7.41, N 9.00.

Results and discussion

Synthesis of RED-PEGM-8

RED-PEGM was prepared from *N*-methylaniline according to the synthetic sequence shown in Fig. 1. Poly(ethylene glycol) methyl ether (with $M_w \cong 350$ g mol^{-1} and n values from 2 to 11) was reacted in the presence of tosyl chloride and pyridine to give the corresponding tosylate PEGM-Ts (**1**). This compound was treated with NaI to give the alkylating agent PEGM-I (**2**) with an overall yield of 76%. Compound **2** was further reacted with *N*-methylaniline in the presence of Na$_2$CO$_3$ to give the *N*-PEGM-*N*-methylaniline (**3**) with 60% yield. A comparison between the ^{1}H NMR spectrum of the PEGM used as the starting material and that of **3** showed that both compounds possessed the same average number of methylenes. Finally, **3** was coupled, according to a procedure described in the literature (18), with *p*-nitrobenzenediazonium tetrafluoroborate at 0 °C, using acetic acid 50% as solvent, to give RED-PEGM (**4**) with 90% yield. Compound **4** contains a distribution of products each having a different number of methylenes (from 2 to 11). The crude RED-PEGM was purified, first by column chromatography using a mixture of MeOH–CHCl$_3$, 9:1, as eluant. The ^{1}H NMR spectrum shows that **4** is a mixture of *para* and

Scheme 2.

4
ortho isomers for each *n* value of the distribution. This was also confirmed by thin layer chromatography (TLC). A well-defined alternated distribution of *para* and *ortho* isomers (with *n* values from 2 to 11) was observed when a mixture of hexane–acetone, 1:1, was used as eluant. Since it was not possible to get the whole distribution of products containing only the desired *para* isomers, only one *para*-compound bearing an exact number of methylenes in the PEGM chain (*n* = 8) was isolated for our study. In a first step, the different products of the distribution were separated by column chromatography, using a mixture of hexane–acetone, 1:1, as eluant. In a second step, the *para* isomer of RED-PEGM with *n* = 8 (RED-PEGM-8) was isolated from the *ortho* by-product by column chromatography, eluting with a mixture of hexane–acetone, 1:4.

Characterization of RED-PEGM-8

^{1}H NMR spectrum of RED-PEGM-8 in CDCl$_3$ solution (Fig. 2A) shows two doublets at 8.43 and 7.95 ppm, belonging to protons H^4 and H^3 present in the nitro-substituted aromatic ring (see Scheme 2), as well as two additional doublets at 7.94 and 6.81 ppm, belonging to protons H^2 and H^1 present in the *N*-PEGM-*N*-methylamino-substituted one. A multiplet at 3.73–3.55 ppm, integrating for 32 protons and two singulets at 3.39 and 3.17 ppm, belonging to methylene groups, methoxy group, and the *N*-methyl group, respectively, were also observed. The ^{13}C NMR spectrum of RED-PEGM-8 displayed 8 signals between 157.4–112.14 ppm, belonging to the aromatic carbons, followed by five signals at 72.56–69.18 ppm, which can be attributed to all the OCH$_2$ groups present in the PEGM side chain and three signals at 59.65, 52.84, and 40 ppm, belonging to the OCH$_3$, N-CH$_2$, and CH$_3$-N, respectively, present in the molecule. The purity of this compound was confirmed by elemental analysis.

Fig. 1. Synthesis of RED-PEGM.
RED-PEGM-8 is an azo-dye totally soluble in chloroform, acetone, ethyl acetate, methanol, and fairly soluble in water. It is very well known that the azobenzene group is hydrophobic while the PEGM chain is highly hydrophilic. The ground state dipole moment of RED-PEGM-8, estimated by AM1 (Austin model 1) semi-empirical calculations (19), is very high (9.63 D) because of the presence of strong donor and acceptor groups in the *para* positions of the azobenzene chromophore.

Thermal properties of RED-PEGM-8

According to TGA measurements recorded from 20 to 800 °C (Fig. 3), RED-PEGM-8 displays a good thermal stability with a T_{10} (10% weight loss temperature) at 268 °C. This thermal stability is lower than that measured for a similar compound, [(4-nitrophenylazo)-N-ethyl-phenylamino] ethanol or Disperse Red-1 ($T_{10} = 273$ °C), and much higher than that measured for the corresponding oligo(ethylene glycol) methyl ether used in the synthesis ($T_{10} = 179$ °C). Moreover, this compound exhibits a fast degradation around 300 °C, reaching 90% of weight loss at 500 °C. Disperse Red-1 behaves similarly and shows, also, fast degradation around this temperature, but for this dye degration takes place in two steps, reaching 90% of weight loss at 749 °C. On the other hand, PEGM degrades rapidly between 200–300 °C, reaching 90% of weight loss at 300 °C and having 1.5% remaining at 400 °C. Consequently, we can affirm that the presence of the PEGM segment decreases the stability of the dye towards decomposition.

On the other hand, DSC measurements were recorded from –150 to 300 °C (Fig. 4), and in this range of temperatures, RED-PEGM-8 displayed a T_g at –18 °C, much lower than that of Disperse Red-1 (142 °C) and higher than that of the corresponding PEGM used as starting material (–87 °C). RED-PEGM-8 also displayed a crystallization temperature, T_c, at 10 °C. A melting point T_m at 45 °C was found, which is much lower than that of Disperse Red-1 ($T_m = 168$ °C) but remarkably higher than that of PEGM (–3.4 °C followed by two additional weaker endothermic T_ms at –28 and –47 °C). Thus, as expected, RED-PEGM-8 possesses a thermal behaviour typical of a liquid crystalline structure. The presence of crystallization can be attributed to the packing of the PEGM oligomer within the azobenzene unit, and the low glass transition temperature and melting point indicate the influence of the PEGM segment over the thermal properties because the presence of the oligomer decreases significantly the T_g and T_m values of this dye compared with our reference dye (Disperse Red-1). Along these lines, it is worth pointing out that PEGM itself and non-end-capped poly(ethylene glycol)s possess low T_g and T_m values (20).

Optical properties of RED-PEGM-8

The azobenzene molecule is characterized spectroscopically by a low-intensity $n \rightarrow \pi^*$ band in the visible region of the spectrum and a high-intensity $\pi \rightarrow \pi^*$ band in the UV. Substitution by a pull and a push substituent like in 4-dimethylamino-4′-nitroazobenzene increases the charge-transfer character (CT) of the $\pi \rightarrow \pi^*$ transition along the

long molecular axis and shifts the corresponding band far to the red, thus overlapping the weak $n \rightarrow \pi^*$ band (14). The CT character of the band causes a strong dependence of the band position on the solvent polarity (21).

The absorption spectrum of RED-PEGM-8 has been recorded in chloroform for various concentrations of the chromophore (Fig. 5). The long wavelength absorption band of this molecule appears around 477 nm. We have measured the same absorption wavelength for RED-PEGM-8 dissolved in tetrahydrofuran (THF). In a previous work, Whitten and co-workers have recorded an absorption peak at 489 nm for 4-diethylamino-4′-nitroazobenzene in THF (21). This clearly indicates that the oligo(ethylene glycol) methyl ether chain reduces the donor effect of the dimethylamino substituent, thus causing a blue shift of the absorption band. No changes in the shape of the absorption spectra is observed by increasing the concentration of the chromophore in chloroform. This shows that this azo-dye is well solubilized in this organic solvent, avoiding significant intermolecular interactions.

Figure 6 shows the absorption spectra of RED-PEGM-8 in water at various concentrations. These spectra exhibit a

Fig. 4. DSC measurements of (A) RED-PEGM-8 and (B) PEGM recorded from –150 to 200 °C (heating rate 10 °C min^{-1}).

Fig. 6. Absorption spectra of RED-PEGM-8 in water at different concentrations of the chromophore (from the top to the bottom: (*a*) 3.12×10^{-4} mol L^{-1}, (*b*) 2.5×10^{-4} mol L^{-1}, (*c*) 1.25×10^{-4} mol L^{-1}, (*d*) 1×10^{-4} mol L^{-1}, (*e*) 7.5×10^{-5} mol L^{-1}, (*f*) 3.75×10^{-5} mol L^{-1}, (*g*) 1.87×10^{-5} mol L^{-1}, (*h*) 9.3×10^{-6} mol L^{-1}, (*i*) 4.6×10^{-6} mol L^{-1}.
Fig. 5. Absorption spectra of RED-PEGM-8 in CHCl$_3$ at different concentrations of the chromophore (from the top to the bottom: (*a*) 1.25×10^{-4} mol L^{-1}, (*b*) 1×10^{-4} mol L^{-1}, (*c*) 7.5×10^{-5} mol L^{-1}, (*d*) 3.75×10^{-5} mol L^{-1}, (*e*) 1.87×10^{-5} mol L^{-1}, (*f*) 9.3×10^{-6} mol L^{-1}, (*g*) 4.6×10^{-6} mol L^{-1}).
broad band around 500 nm, which is red-shifted by about 23 nm compared with the one measured in chloroform. This solvatochromic shift is surely due to the increase in the solvent polarity going from chloroform to water, as mentioned above for push–pull azobenzenes. By increasing the concentration of the chromophore in water, a new band around 415 nm is observed. We believe that this spectral behavior involves an excitonic coupling effect, which causes a band-splitting (22). Thus, the absorption band in the blue region would involve face-to-face molecular arrangements (H-

aggregates) whereas head-to-tail molecular arrangements (J-aggregates) are not detected in the RED-PEGM-8 – water system. Recently, azo-dye aggregates have also been observed on dendrimer surfaces (23) and incorporated in surfactants (24).

The absorption spectrum of RED-PEGM-8 in the solid state (thin film), casted from a chloroform solution at room temperature, is shown in Fig. 7. One can see that this spectrum is similar to the one recorded at high concentrations of the chromophore in water ($\lambda_{max} = 500$ nm). This could imply that H-aggregates are also formed in the thin film of this compound. Moreover, compared with the spectrum obtained in chloroform solution ($\lambda_{max} = 477$ nm), the solid state absorption spectrum is red-shifted and shows a tail in the red region. These spectral observations might be because of the formation of J-aggregates in the thin film, indicating a higher molecular alignment in the solid state. However, physical aggregation could also take place in the solid state and be responsible of this behavior. Since RED-PEGM-8 is a non-emissive dye, we were not able to monitor the aggregation phenomenon via steady-state and time-resolved fluorescence studies.

NMR spectra of RED-PEGM-8

^{1}H NMR spectrum of RED-PEGM-8 in a CDCl$_3$ solution (Fig. 2A) shows well-defined signals at 8.43, 7.95, 7.94, and 6.81, belonging to aromatic protons and at 3.73–3.55, 3.39, and 3.17, belonging to methylene groups, which were previously assigned in the characterization section. The ^{1}H NMR spectrum of the same compound in D$_2$O (Figs. 2A and 2B) shows three broad signals at 7.11 (H^4), 6.69 (protons H^2 and H^3), and 6.0 ppm (H^1) followed by three signals centered at 3.69, 3.63 (all CH$_2$), and 3.47 (OCH$_3$). Besides, the signal corresponding to CH$_3$-N appears at 4.82 ppm, which is downfield shifted compared with that observed in CDCl$_3$

Fig. 7. Absorption spectrum of RED-PEGM-8 in the solid state (thin film) casted from a chloroform solution at room temperature.
(2.93 ppm). This is due to the formation of H-bonds between D_2O and the amino group, which decreases the electron density of the nitrogen atom. By contrast, no significant difference in shift was observed for the methylene signals of the PEGM oligomer segment in both solvents. On the other hand, one can observe a remarkable broadening of the aromatic signals, which are also upfield shifted by 1.21 ppm in D_2O. These results reveal the existence of strong intermolecular interactions (aggregation) in D_2O, which are in agreement with the results obtained by UV–vis spectroscopy. We are currently studying the NMR and optical properties for a series of similar azo-dyes having different donor–acceptor substituents and varied chain length of the PEGM segment. These results should provide valuable information about the aggregation process occurring in these types of oligomers.

Summary

A novel azobenzene compound bearing a short poly(ethylene glycol) methyl ether side chain (RED-PEGM-8) has been synthesized and characterized. RED-PEGM-8 is well solubilized in chloroform and THF, avoiding any significant intermolecular interactions. On the other hand, aqueous solutions of this compound show the appearance of blue-shifted bands at high concentrations, which are interpreted in terms of the formation of H-aggregates. ^1H NMR spectra measured in D_2O also reveal the existence of strong intermolecular interactions (aggregation), which confirm the optical properties measured in water. It is also suggested that H-aggregates are formed for RED-PEGM-8 in the solid state (thin film). Moreover, the observation of a tail in the red region of the solid-state absorption spectrum could imply the formation of J-type aggregates. However, physical aggregation could also explain this spectroscopic behavior.

The photochemistry of indenyl alcohols and esters: Substituent effects on the competition between ion- and radical-derived products

J.A. Pincock and I.S. Young

Abstract: The photochemistry of the indenyl acetates **1** and pivalates **2**, substituted with X = H, 5-CH$_3$O, and 6-CH$_3$O, have been examined in both methanol and cyclohexane. The precursor alcohols **3** were also found to be photoreactive. Although only radical-derived products were obtained in cyclohexane, both ion- and radical-derived products were formed in methanol. The absence of significant fluorescence emission from any of the substrates **1**, **2**, and **3** indicates that the excited singlet states are highly reactive. A mechanism is proposed for the ion-derived products that proceeds through direct heterolytic cleavage to give an indenyl cation – carboxylate anion pair. The indenyl cations generated are anti-aromatic in the ground state and their efficient generation by this photochemical solvolysis is in sharp contrast to the very low reactivity of related ground-state substrates. For the pivalate esters **2**, an excited-state migratory decarboxylation is proposed for the formation of *tert*-butyl derived products.

Key words: ester photochemistry, indenyl cations, indenyl radicals.

Résumé : La photochimie des acétates **1** et des pivalates **2** d'indényle, substitués avec X = H, 5-CH$_3$O et 6-CH$_3$O a été étudiée dans le méthanol et dans le cyclohexane. On a trouvé que les alcools précurseurs **3** sont également photo-réactifs. Dans le cas du cyclohexane on n'obtient que des produits d'origine radicalaire, par contre dans le cas du mé-thanol on obtient des produits d'origine ionique et d'origine radicalaire. L'absence d'émission de fluorescence significative à partir des substrats **1**, **2** et **3** indique que les états singulets excités sont hautement réactifs. On propose un mécanisme qui explique la formation des produits d'origine ionique via le clivage hétérolytique direct pour donner une paire cation indényle – anion carboxylate. Les cations indényles générés sont anti aromatiques dans l'état fonda-mental et leur production efficace par cette solvolyse photochimique est en nette opposition avec la très faible réactivité des substances apparentées à l'état fondamental. Pour les esters pivalates **2**, on propose une décarboxylation migratoire de l'état excité pour expliquer la formation des produits dérivés du *t*-butyle.

Mots clés : photochimie des esters, cations indényles, radicaux indényles.

[Traduit par la Rédaction]

Introduction

The photochemistry of arylmethyl esters (ArCH$_2$O-(CO)-R) in nucleophilic solvents (1) and arylmethyl compounds with leaving groups in general (ArCH$_2$-LG) (2) has recently attracted considerable interest. As outlined in the mechanism in Scheme 1, products are derived from both radical pair and ion pair (photosolvolysis) intermediates and, for esters at least, only from the excited singlet state. Apart from a fundamental interest in the factors (substituents, solvent, leaving group, excited-state multiplicity) that control the partitioning between these two pathways, the potential of applying this process to the design of photolabile protecting groups or phototriggers has been explored (3, 4).

On the basis of extensive studies on a range of functionalized arylmethyl esters, we have proposed a mecha-

nism where the major pathway for reactivity is homolytic cleavage (k_{hom}) of the carbon—oxygen bond to give a radical pair (1, 2). Competition between electron transfer (k_{et}) to form an ion pair and decarboxylation (k_{CO2}) of the acyloxy radical then controls product distribution. This latter process serves as a radical clock with the rate constant differing by many orders of magnitude, depending on the stability of the radical formed. Values range from ~10^6 s^{-1} for ArCO$_2$$^\bullet$ (5) to ~10^9 s^{-1} for RCO$_2$$^\bullet$ with primary alkyl groups (6). For cases that form highly stabilized radicals, such as Ar$_2$C(OH)CO$_2$$^\bullet$, the decarboxylation occurs within a few pi-coseconds; the rate constants approach those for barrier-free unimolecular reactions (7). The rate of electron transfer also ranges over several orders of magnitude and follows Marcus theory in both the normal and the inverted region (8, 9). On the basis of high-level MO calculations, this mechanism has been questioned in favor of one involving direct heterolytic cleavage (k_{het}) from S$_1$, particularly for substrates with *meta*-methoxy substitutents (10, 11).

The high reactivity and the high yield of ion-derived products for the photochemistry of 9-fluorenol in mixed organic–aqueous media has been interpreted as resulting from the formation of a cyclically conjugated 4n π cation (12, 13).

Scheme 1. General mechanistic scheme for the photolysis of benzylic substrates.

Recent picosecond laser flash photolysis (LFP) experiments (14) have shown that in fact 9-fluorenol reacts to form the 9-fluorenol cation very rapidly (<10 ps) in solvents (water, TFE, HFIP) of high polarity (E_T^N). The antiaromatic character of the 9-fluorenyl cation has been discussed in a recent review (15) with the conclusion that it will be attenuated relative to that for cyclopentadienyl and indenyl cations. In fact, on the basis of recent calculations, the fluorenyl cation has been described as nonaromatic by some criteria and antiaromatic by others (16). The possible photochemical generation of indenyl cations, which, from experiment and calculation, have more antiaromatic character than fluorenyl cations, is therefore of interest.

We now report on the photochemistry of six indenyl esters **1a–c** and **2a–c** and three indenyl alcohols **3a–c** in the solvents methanol and cyclohexane. The photochemistry of the alcohols was examined to allow a more direct comparison with the photochemistry of 9-fluorenol. The choice of examining acetate esters **1** vs. pivalates **2** was made because the rate constants of decarboxylation of their corresponding acyloxy radicals differ by an order of magnitude ($\sim 10^9$ s^{-1} for CH$_3$CO$_2$• vs. 1.1×10^{10} s^{-1} for (CH$_3$)$_3$CCO$_2$•) (6), and these radicals are good probes for radical pair chemistry. The choice of 5-methoxy vs. 6-methoxy was made in order to examine the effect of the change in position of the electron-donating group from *para* (5-methoxy) in **1b**, **2b**, and **3b** to *meta* (6-methoxy) in **1c**, **2c**, and **3c** relative to the arylmethyl center with the leaving group. The results will also be compared with those obtained previously for the corresponding indanyl derivatives (17).

Results and discussion

Synthesis of alcohols and esters

The esters were synthesized from the corresponding alcohols **3** by reaction with the appropriate acid chloride in benzene–pyridine, Scheme 2. The alcohols were obtained by reduction of the ketones **4** with NaBH$_4$ with added CeCl$_3$. In the absence of the CeCl$_3$, considerable reduction of the indenone double bond occurred (18). Two of the indenones (**4a**: X = H and **4b**: X = 5-CH$_3$O) were prepared by a procedure developed by Floyd and Allen (19) and used in our laboratory previously (20). The indanone **5** (X = 6-CH$_3$O) could not be prepared by this method because the Friedel–Crafts cyclization was not successful. Instead, the method of Sam and Plampin (21) was used. The indenone **4c** (X = 6-CH$_3$O) was then prepared from **5** by a bromination–dehydrobromination sequence.

Absorption and emission spectra of the esters and alcohols in methanol

In general, indene derivatives have UV absorption spectra with two bands, a weak one ($\epsilon \sim 10^2$ (mol L^{-1})$^{-1}$ cm^{-1}) between 280 and 300 nm, corresponding to the symmetry-forbidden ^1L_b band in benzene, usually partially overlapped by a stronger one ($\epsilon \sim 10^4$ (mol L^{-1})$^{-1}$ cm^{-1}) around 260 nm, corresponding to the symmetry-allowed ^1L_a band in benzene (22). In methanol, the unsubstituted indenyl ester **1a** has two similar bands (λ_{max} = 266 nm, ϵ = 7130 (mol L^{-1})$^{-1}$ cm^{-1} and 306 nm, 391 kJ mol^{-1} (the longest wavelength maximum in the long wavelength band), ϵ = 950 (mol L^{-1})$^{-1}$ cm^{-1}), but

Scheme 2. Synthesis of the esters **1a–c** and **2a–c** and the alcohols **3a–c**.

these are shifted to somewhat longer wavelength than that for 2-methylindene (22) in cyclohexane (λ_{max} = 257 nm, ϵ = 11 700 (mol L^{-1})$^{-1}$ cm^{-1} and 295 nm, ϵ ~ 500 (mol L^{-1})$^{-1}$ cm^{-1}) or *cis*-phenylpropene (23) in hexane (λ_{max} = 256 and 288 nm). The long wavelength band has a series of obvious, but broad, vibrational bands in contrast to the shorter wavelength band, which does not. The methoxy-substituted esters **1b** and **1c** have similar absorption bands (see Experimental section), although the long wavelength band lacks vibrational structure and moves to even lower energy (320 nm, 373 kJ mol^{-1}) for the 6-methoxy isomer **1c**, as expected when compared with a similar shift to longer wavelength for

trans-1-(4-methoxyphenyl)propene (λ_{max} = 298 nm) relative to *trans*-1-phenylpropene itself (λ_{max} = 284 nm) (23).

Fluorescence spectra for the three indenyl esters **1** in methanol revealed only extremely weak, if any, emission. The quantum yields of emission were estimated to be less than 0.001 when compared with that for naphthalene (0.21). The alcohols **3**, precursors for the esters, also did not fluoresce significantly. In contrast, 3-methylindene, which is photochemically unreactive in hexane, has a quantum yield of fluorescence of 0.077 and excited singlet state lifetimes of 13.9 ns (22); the major process competing with fluorescence from the excited singlet state is likely intersystem crossing.

The very inefficient fluorescence for the indenyl compounds studied here strongly suggests that they are undergoing rapid ($k > 10^9$ s^{-1}) excited-state cleavage of the indenyl C1 to oxygen bond. The absence of measurable fluorescence unfortunately prevents the determination of excited-state lifetimes and rate constants for excited-state processes.

Photochemistry of the alcohols 3 in methanol and cyclohexane

The photolysis of the indenyl alcohols in either methanol or cyclohexane gave the products expected from arylmethyl photochemistry, as shown, in a general way, in eq. [1].[2]

1: Y = O(CO)CH$_3$ Z = CH$_2$OH
2: Y = O(CO)C(CH$_3$)$_3$ Z = C$_6$H$_{11}$
3: Y = H

6a: X = H
6b: X = CH$_3$O

7

8   **9**   **12a**: R = CH$_3$
                              12b: R = C(CH$_3$)$_3$

The methyl ethers **6**, formed only in methanol, are of particular interest because they are clearly derived from indenyl cations. The hydrocarbon products **7–9** are radical derived. The reactions are relatively efficient; irradiation of 60 mg of **3a** (X = H) in 100 mL of methanol with 254 nm lamps in a Rayonet reactor resulted in 72% conversion in 15 min. The difficulties in completely characterizing the photoproducts of these reactions can be exemplified by this case. At this extent of conversion, the mass balance (GC peak areas) was only 60%. This is characteristic of the photochemistry of indene derivatives where quantum yields for disappearance of starting material are often considerably higher than those for appearance of volatile products (24), presumably as a consequence of oligomerization processes. Moreover, complete separation by flash or radial chromatography of the non-polar hydrocarbon products was not possible. GC–MS analysis of mixtures of variable composition was invaluable for preliminary structural assignment. For the unsubstituted substrate, **3a**, the hydrocarbons **7** (X = H) (commercial sample, Aldrich) and the dimers **9** (X = H) (*meso* and *dl* diastereomers) are known (25, 26), and literature ^{1}H NMR spectra were helpful in identifying components in the mixtures obtained by chromatography.

The methyl ethers **6** were synthesized from the indenols **3** using trimethyl orthoformate under acidic conditions (aqueous HClO$_4$) (27). An attempt to alkylate **3a** (X = H) using NaH–DMSO followed by CH$_3$I resulted in 2,2-dimethylindanone, confirming that the indenyl hydrogen at C1 is more acidic (pK_a = 20) than an alcohol (pK_a [CH$_3$OH] = 29) in DMSO (28). Using the trimethyl orthoformate procedure for the indenols **3b** (X = 5-OCH$_3$) and **3c** (X = 6-OCH$_3$) resulted in the isolation of only one ether in-

dependent of which alcohol was used as the starting material, eq. [2].

The compound obtained was shown to be the 5-methoxy

[2]

or

3: 6-CH$_3$O

6: 5-CH$_3$O

not

6: 6-CH$_3$O

isomer, **6b**, by NOE difference spectra: irradiation of H1 (δ = 4.82 ppm) gave a strong enhancement for H7, which is assigned by its higher chemical shift (δ = 7.30 ppm) relative to that of H6 (δ = 6.64 ppm) for the two aromatic protons, which are *ortho* to each other and therefore have a coupling constant of 8.0 Hz. This acid-catalyzed reaction, which presumably proceeds through the indenyl cation, raises an interesting point for reactions that generate indenyl cations or radicals at C1 of the 5-methoxy and 6-methoxy substrates. Because of delocalization through C1, C2, and C3 of these intermediates, both substrates will generate the same intermediate for either the cation **10** or the radical **11**, Fig. 1.

This observation prompted us to examine the charge and spin distribution in these species by PM3 calculations.[3] As shown in Fig. 1a, nine resonance forms can be drawn for an indenyl cation with a positive charge on each one of the nine carbons. From the calculations for the indenyl cation (C_{2v} symmetry), the positive charge is mainly on C1 and C3 (+0.34 for each, 0.68 total, with hydrogen charges summed into the carbons), as indicated by the first two resonance forms. This suggests that, to a first approximation, the indenyl cation can be viewed as an allyl cation fused to a benzene ring. For 5-substituted indenyl cations, the C_{2v} symmetry is no longer present. For these preliminary calculations, as shown in Fig. 1b, we chose the substituent as OH to model the OCH$_3$ group in order to minimize conformational complications. For the radical, the spin population at C1 (0.89) and C3 (0.72) is similar and delocalization results in a structure with similar bond lengths in the upper and lower part, i.e., the OH group only slightly perturbs the plane passing through C2 and bisecting the C5—C6 bond. In contrast, the calculations of the atomic charge density for the cation reveal a much higher positive charge at C1 (+0.21) than C3 (–0.03); values for C1 (+0.44) and C3 (+0.25) are obtained with hydrogen charges summed into the carbons. In addition, the bond lengths indicate that the indenyl ring system can be pictured as almost two independent π-systems. The first, a 5-hydroxy pentadienyl cation for the string of carbons from C1 through the ring fusion to C7, C6, and C5, with almost equal bond lengths (1.41 ± 0.02 Å) and the sec-

---

[2] The products **12** in eq. [1] cannot be formed from the alcohols **3** but only from the esters **1** and **2**, as will be discussed later.
[3] We thank Dr. F. Ban, Dalhousie University, Department of Chemistry, Halifax, Nova Scotia, for these calculations.

ond, an isolated butadiene fragment from C2 to C4 with alternating short (~1.35 Å) and long (1.49 Å) bond lengths; i.e., the OH group severely perturbs the structure on either side of the same plane (defined above) for the radical. The high positive charge density at C1 of the cation, which was obtained from these calculations, rationalizes nicely why both indenols **3** (X = 5-OCH$_3$ and X = 6-OCH$_3$) give the same ether **6** (X = 5-OCH$_3$) in the synthesis, eq. [2], and in the photochemistry, eq. [1]. The calculations for the hydroxyindenyl radical **10** will also be relevant to the photolysis results described below. Higher level MO calculations on the charge and spin distribution in substituted indenyl cations and radicals are in progress.

Another issue in the photolysis experiments was that of

secondary photochemistry of several kinds. First, alkyl indenes are well known to photoisomerize (24). For instance, 2-methylindene **7** (X = H) isomerizes to both 1- and 3-methylindene (Φ = 0.13) on photolysis in hexane and even isomerizes to 2-methyleneindane under acidic conditions (29). Similarly, 1,2-dimethylindene **12a** (X = H, R = CH$_3$) isomerizes to the 2,3-isomer (24). We have confirmed these previous observations by the photolysis of 2-methylindene in methanol, which gave three isomers (GC–MS) along with 2-methoxy-2-methylindane by *anti*-Markovnikov addition of methanol, also as reported previously (30). In agreement with these observations, at higher conversions, the initially formed products decreased in yield as the other isomers appeared (GC–MS). Second, photolysis in methanol of the

ether **6a** (X = H), the ion-derived product, resulted in formation of the radical-derived products **7**, **8**, and **9**, eq. [3].

The major product in this photolysis, 2-methylindene **7** (X = H), is probably derived by disproportionation of the indenyl–methoxy radical pair, as proposed previously for the photolysis of 9-methoxyfluorene derivatives (12, 13). Third, as indicated in Table 1, the 6-methoxy alcohol **3c** converts photochemically to the 5-methoxy isomer **3b**. For instance, at 14% conversion in cyclohexane, the ratio of **3c:3b** was 7.8:1. As a consequence of these various secondary photochemistries, only product yields obtained at low conversions (<5%) give values that are useful for mechanistic consideration. These values are given in Table 1. Because the percentage conversion is too small to reliably determine the mass balance, the yields are normalized to 100%.

[3]

$$[3]$$

73% conversion	Z = CH_2OH	35%	5%	8%
49% conversion	Z = C_6H_{11}	36%	3%	3%
The products shown in eq. [1] and Table 1 for the photolysis of the alcohols **3** are easily explained by formation of indenyl radical and cation intermediates. A mechanism is outlined in Scheme 3, a specific example of the general Scheme 1. The most interesting observation is the very high yield in methanol of the ion-derived product, the methyl ester **6**, particularly from the methoxy-substituted substrates **3b** and **3c** (82%). Also, the same product yields are obtained for both substrates **3b** and **3c**, indicating that both the indenyl radical and cation lose, as expected, the memory of the substrate from which they originated. The radical-derived products **7** and **8** from **3b** and **3c** are mixtures (ratio ~ 1.3:1) of two regioisomers, as expected for the unequal spin distribution at C1 and C3 for the methoxy-substituted indenyl radical. The formation of these products is rationalized (Scheme 3) by exothermic hydrogen abstraction (31) by the hydroxyl radical from the solvents methanol (bond dissociation energy (BDE) = 393 kJ mol^{-1}) and cyclohexane (BDE= 401 kJ mol^{-1}) to give water (BDE = 497 kJ mol^{-1}) and the hydroxymethyl and cyclohexyl radical, respectively. The indenyl radical will not abstract a hydrogen atom from these

solvents because the process would not be exothermic (BDE = 351 kJ mol^{-1} for the C1—H bond in indene). Reaction of the two radicals by disproportionation then gives **7**, whereas coupling gives **8**, in a ratio of 1:9 in cyclohexane. In methanol, only disproportionation was observed. The other major products that are radical derived are the two indenyl dimers, **9** (X = H), now diastereomers (*dl* and *meso*) because regioisomers are not possible. For reasons that are not obvious, similar dimers were not observed for the methoxy-substituted substrates.

The major conclusion from these results is that indenyl cations are efficiently formed in the photochemistry of indenyl alcohols. Similar cations have been generated by ground-state solvolysis of the indenyl compounds **13**, and rate retardations of approximately 10^{-5} have been measured relative to the corresponding indanes **14** in 80% aqueous acetone, reflecting the antiaromatic destabilization of the cation derived by solvolysis of **13** (32).

Product studies indicated that two regioisomeric alcohols are formed from both **13** (X = CH$_3$) and **13** (X = CH$_3$O), although the experimental evidence for the latter compound is not conclusive. Moreover, these solvolysis reactions were carried out at high temperature (100 °C for 22 days), conditions where 5- and 6-substituted indene derivatives may be equilibrating thermally by 1,5-hydrogen migrations involving isoindene derivatives (33). The question as to whether

13   **14**
the ion pair is generated by direct heterolytic cleavage (k_{het}, Scheme 1) or by electron transfer from an initially formed radical pair (k_{et}) cannot be answered from these results. However, the clear evidence from LFP experiments for direct heterolytic cleavage to the ion pair for 9-fluorenol in polar protic solvents (14) suggests that the first pathway is possible. Moreover, the very high oxidation potential expected for the indenyl radical makes the latter seem unlikely. Therefore, the efficient photochemical formation of the indenyl cations (Scheme 3) would seem to be another exam-

Scheme 3. Mechanistic pathways for the photolysis of the alcohols **3a**–**c** in methanol and cyclohexane.
ple of the generation of a $4n$ π cation, first proposed by Wan and co-workers for the photodehydroxylation of fluorenol (12, 13).

Photochemistry of the esters 1 and 2 in methanol and cyclohexane

The photolysis of the indenyl esters **1** and **2** in either methanol or cyclohexane again gave the products expected from arylmethyl photochemistry, also shown in eq. [1]. Again, the reactions are relatively efficient; irradiation of 100 mg of **1a** (X = H, R = CH₃) in 100 mL of methanol with 254 nm lamps in a Rayonet reactor resulted in 50% conversion in 15 min. The same difficulties as for the alcohols **3** (lack of separation of non-polar products and secondary photochemistry) were encountered in completely characterizing the photoproducts for the esters. Moreover, an additional secondary photochemical process was revealed, involving the coupling products **12b** (R = C(CH₃)₃). The ratio of these two *tert*-butyl products derived from the 5- and 6-methoxy pivalate esters changed with the percent conversion. Parallel to this process, the yield of the two isomeric 5- and 6-methoxy-2-methylindene derivatives **7** increased. For instance, the yield of **7** for photolysis of the pivalates **2b** and **2c** in methanol was essentially zero at very low conversion (<5%) but reached 20–25% at high conversion (>80%). Finally, the 6-methoxy esters **1c** and **2c** were converted to the corresponding 5-methoxy substrate **1b** and **2b** (see footnotes in Tables 2 and 3). This observation is expected on the basis of the internal return processes (k_{icom} and k_{rcom}, Scheme 1) previously observed for the intermediates in ester photochemistry (34–36). Again as a consequence of these competing processes, only product yields obtained at very low conversions (<5%) are useful for mechanistic consideration. These values are given in Table 2 for reactions in cyclohexane and in Table 3 for those in methanol. Because the percentage conversion is too small to determine reliably, the yields are normalized to 100%.

The photolysis products obtained for the esters **1** and **2** in cyclohexane are easily explained by the radical pair mecha-

Table 2. Product yields for the photolysis of the esters **1** and **2** in cyclohexane.

	X	R	7^a	9^a	12^b
$\mathbf{1a}^c$	H	CH₃	—	15 (1:1.3)	80
2a	H	(CH₃)₃C	20	15 (1:1.3)	65
1b	5-CH₃O	CH₃	—	—	100 (1:2.3)
2b	5-CH₃O	(CH₃)₃C	15 (1:1.1)	—	85 (1:2.5)
$\mathbf{1c}^d$	6-CH₃O	CH₃	—	—	100 (1:1.5)
$\mathbf{2c}^e$	6-CH₃O	(CH₃)₃C	25 (1:1.1)	—	75 (1:2.1)

Note: Yields are for low conversion (<10%) and normalized to 100%. Estimated error ±5%.

^{a}Numbers in brackets refer to the ratio of the two possible diastereomers.

^{b}Numbers in brackets refer to the ratio of the two possible regioisomers.

^{c}For **1a**, 8% of the material was 1-cyclohexyl-2-methylindene **8**, a product not detected for the other five compounds.

^{d}Ratio of **1c:1b** = 5.8:1 at 41% conversion.

^{e}Ratio of **2c:2b** = 3.9:1 at 75% conversion.

nism in Scheme 4, where the radical paired with the indenyl one is now an acyloxy, rather than hydroxyl as it was for the indenols in Scheme 3. For the acetates **1** (R = CH₃), decarboxylation gives the methyl radical leading to the coupling product **12a** (R = CH₃) (two regioisomers for X = 5-CH₃O and 6-CH₃O). For the pivalates **2** (R = C(CH₃)₃), decarboxylation now gives the *tert*-butyl radical, leading to the coupling product **12b** (R = C(CH₃)₃) and disproportionation to 2-methylindene **7** (again, two regioisomers for X = 5- and 6-CH₃O for both **7** and **12b**). As in the photolysis of the indenols **3** (Table 1), the out-of-cage dimers were only obtained for the unsubstituted esters **1a** and **1b**. The very similar yields of **7** and **12** obtained for both the 5- and 6-methoxy substrates, independent of which one is the starting material, indicates that the indenyl radical again loses the memory of its precursor.

The products obtained for the photolysis of the indenyl esters in methanol are given in Table 3. Particularly striking is the very high yield of the ion-derived product, the methyl ether **6**, particularly from the 5- and 6-methoxy acetates, **1b**

Table 3. Product yields for the photolysis of the esters **1** and **2** in methanol.

	X	R	**6**	**7**	**9**[a]	**12**[b]	Ion:radical[c]	Ion:radical[d]

[e]Ratio of **1c:1b** = 8.7:1 at 48% conversion.
[f]Ratio of **2c:2b** = 40:1 at 32% conversion.

Scheme 4. Mechanistic pathways for the photolysis of the esters **1a–c** and **2a–c** in cyclohexane.
and **1c**. The ratio of ion- to radical-derived product is significantly larger for the methoxy-substituted substrates than the corresponding indanyl (Table 3) derivatives **15** and **16** (17). In fact, the ion-derived ether **6b** (X = 5-CH_3O) is the only product observed (at low conversion) for the acetate **1c** (X = 6-CH_3O). The change in product distribution for the change in substrate from acetate esters **1** to pivalate esters **2** has been used effectively in the past by us (1) and others (37) to test for the intervention of acyloxy radicals. Their very different rates of decarboxylation serve as radical clocks for other possible processes of the radical, in particular, the electron transfer process (k_{et}, Scheme 1) that converts the radical pair to the ion pair.

15: R = CH_3
16: R = $C(CH_3)_3$
However, the surprising observation of the absence of the disproportionation products **7** in the photolysis of the 5- and

6-methoxy pivalates esters **2b** and **2c** at low conversion in methanol suggests that free *tert*-butyl radicals are not formed. This observation emphasizes why product yields at low conversion are essential for understanding the photochemistry involved. As mentioned above, the yield of **7** increases with the extent of conversion by a process of secondary photochemistry involving **12b** (X = $C(CH_3)_3$). The parallel change in the ratio of the two regioisomeric coupling products **12** indicates that this secondary photochemistry is homolytic carbon—carbon bond cleavage to generate the indenyl–*tert*-butyl radical pair, allowing for both disproportionation and regioisomeric equilibration to occur.

The question then arises as to the mechanism of formation of the *tert*-butyl coupling products if *tert*-butyl radicals are not involved in the primary photochemistry of the methoxy pivalate esters in methanol. A tentative proposal is an excited-state migratory (from C1 to C2) decarboxylation of the *tert*-butyl group via a five-membered transition state **17** (shown in Scheme 5 for the 6-methoxypivalate **2c**) to form an isoindene derivative **18**. Excited state migrations from C1 to C2 are well known for phenyl-substituted indenes (38). The resulting isoindenes would be thermally unstable and revert to indene. On the basis of migratory aptitudes (CH_3 <

Scheme 5. Proposed mechanism for the formation of the coupling products **12** and **12′** for the photolysis of the ester **2c** in methanol.
CH$_2$CH$_3$ < CH(CH$_3$)$_2$) previously determined (33) for the thermal reversion of isoindenes to indenes, the *tert*-butyl group in **18** will migrate in preference to methyl, giving the two observed regioisomeric products, **12b** and **12b′**. The process described by transition state **17** is not observed and not possible for other benzylic substrates, which lack the required indenyl type conjugation. In those cases, disproportionation always accompanies coupling of *tert*-butyl radicals, as expected (39).

This process is reminiscent of that proposed for the thermal decomposition of peresters, which are concerted (40, 41), where the potential acyloxy radical will fragment very rapidly because of the stability of the radical generated, **19**. These reactions have negative ρ values (approximately –1.1), indicating that the transition states have some positive character on carbon and negative on oxygen (42). The photochemical migration suggested by structure **17** in Scheme 5 might also have a substituent effect, which could potentially explain why the yield of the isomers **12** are slightly different for the 5-methoxy **2b** (80%) vs. the 6-methoxy (70%) pivalate ester **3b**. The substitutent effect could also rationalize why the unsubstituted substrate **2a** seems to undergo normal homolytic bond cleavage and give both coupling (**12**) and disproportionation (**7**) products.

19
The mechanistic proposals for the indenyl esters can then be summarized as follows: In cyclohexane, all three esters react by homolytic cleavage to give radical-derived products as shown in Scheme 4. In methanol, as outlined in Scheme 6, the unsubstituted esters **1a** and **2a** react by the same mechanism for the radical-derived products, but now formation of the ion pair leads to low yields (15%) of the methoxy ether **6** for the acetate **1a**. The decrease in the yield of **6**, as a consequence of the change from acetate **1a** to pivalate **2a**, suggests that the radical clock method is operative and that the ion pair is formed (at least partially) from the radical pair by redox electron transfer (k_{et}, Scheme 1) in competition with the rate of decarboxylation, which is faster by an order of magnitude for the (CH$_3$)$_3$CCO$_2$ radical.

Two other potential photochemically generated intermediates that have not yet been discussed should be mentioned as possible precursors for the ion-derived ether product in methanol. The first, **20**, an isoindene, would result from migration of the acyloxy group from C1 to C2 of the indene.

20
The second, **21**, analogous to the intermediate **22** observed in the photolysis of 3,5-dimethoxybenzyl acetate in methanol and other alcohol solvents (43), would be formed by acyloxy migration from C1 to C7. A similar intermediate has been reported for the photolysis of 9-fluorenol in metha-

Scheme 6. Mechanistic pathways for the photolysis of the esters **1a–c** and **2a–c** in methanol.
nol (44) and non-acidic zeolites (45). Either of these could be very reactive (thermally or photochemically) in methanol as solvent. For instance, the half life for ground-state solvolysis of **22** in methanol is approximately 2 min. We are currently conducting nanosecond laser flash photolysis experiments to examine the reactive intermediates for the photochemistry described above.
Conclusions

For the 5- and 6-methoxy-substituted esters in methanol, the proposed mechanism is that direct heterolytic cleavage from the excited state to form an ion pair (Scheme 6) competes with migratory decarboxylation of the ester to give the isoindene derivative **18** (as shown in Scheme 5). This latter process is less important for the acetates **1b** and **1c** than the pivalates **2b** and **2c**, and therefore, the acetates give very high yields of the ion-derived ether **6**, reaching 100% for the 6-methoxy acetate **1c**! This substrate has the activating group *meta* to the reactive benzylic centre. The photochemical "*meta* effect", as originally proposed by Zimmerman and co-workers (46) for methoxy-substituted benzylic acetates and supported by studies of methoxy-substituted benzylic alcohols by Wan and co-workers (47), predicts enhanced efficiency for heterolytic cleavage reactions for leaving groups

meta (and *ortho*) to electron-donating substituents. It seems to be playing an important role in the photochemistry of these indenyl esters. This suggestion is in marked contrast to our proposal for all previously studied ester substrates where homolytic cleavage followed by electron transfer is considered to be the dominant mechanistic pathway for the formation of ion-derived products. Although the limited data available make these mechanistic conclusions somewhat speculative, the fact that products derived from indenyl cations are formed in these photoreactions is certain. This may well be a consequence of the antiaromatic character of these $4n$ π cations, in agreement with Wan and co-workers' proposal for 9-fluorenyl derivatives (12, 13).

Experimental section

General procedures

Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectra were obtained in CDCl$_3$ on an AC 250 F NMR spectrometer in automation mode. Ultraviolet (UV) spectra were obtained in 1 cm quartz cuvettes on a Varian-Cary Bio 100 spectrometer. Fluorescence measurements were done in methanol, with non-degassed samples, using a PTI spectrometer at 25 °C. Corrected spectra were obtained. GC–MS analyses were performed on a PerkinElmer Autosystem XL instrument with a mass selective detector. The column used was a Supelco 30 m × 0.25 mm MDN-5S 5% phenyl methylsiloxane, film thickness 0.50 µm, temperature programmed: 60 °C for 1 min; 20 °C increase per min to 240 °C; 240 °C for 10 min. GC–FID analyses were done in a similar way except on a Supelco DB200 column. Mass spectral data are reported in units of mass over charge (*m/z*) for all values between 50 and the molecular ion if greater

than 10% of the base peak. Intensities are reported as a percent of the base peak.

Indenone synthesis

2-Methyl-1-indenone 4a and 5-methoxy-2-methyl-1-indenone 4b

These indenones were prepared using the procedure of Floyd and Allen (), outlined in Scheme 2.

6-Methoxy-2-methyl-1-indenone 4c

The precursor to this indenone, 6-methoxy-2-methyl-1-indanone **5** (X = 6-CH$_3$O), was prepared using the procedure of Sam and Plampin (), outlined in Scheme 2. To a solution of 13.9 g (79 mmol) of **5** (X = 6-CH$_3$O) in 170 mL of CCl$_4$ was added 14.4 g (90 mmol) of bromine in 70 mL of CCl$_4$. After the addition was complete, the mixture was stirred at room temperature for 2 h. The solvent and excess bromine were removed under reduced pressure and 20.5 g (79 mmol, 100%) of the crude bromide, as a brown solid, resulted. ^{1}H NMR (CDCl$_3$) δ: 7.22–7.32 (m, 3H), 3.85 (s, 3H), 3.72 (d, 1H, J = 18 Hz), 3.41 (d, 1H, J = 18 Hz), 1.95 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 200.4, 160.0, 141.8, 133.8, 127.1, 125.3, 106.7, 60.3, 55.7, 45.8, 27.0. GC–MS: 256 (19), 254 (18), 176 (58), 175 (100), 174 (22), 161 (96), 148 (20), 147 (41), 146 (10), 133 (29), 132 (23), 131 (41), 117 (16), 115 (32), 105 (10), 104 (11), 103 (42), 102 (14), 91 (36), 89 (14), 79 (19), 78 (29), 77 (77), 76 (18), 75 (17), 74 (20), 65 (13), 64 (10), 63 (45), 62 (15), 51 (34), 50 (13). HR-MS calcd. for C$_{11}$H$_{11}$O$_2$Br: 253.9942; found: 253.9934. A mixture of 20.5 g (79 mmol) of crude bromoindanone, 12.1 g (139 mmol) LiBr, and 10.4 g (140 mmol) Li$_2$CO$_3$ in 175 mL of DMF was heated between 135–140 °C for 3 h under a nitrogen atmosphere. After cooling, the mixture was poured into 300 mL of water and extracted three times with ether. The combined ether layers were washed twice with water and dried with MgSO$_4$. Evaporation of the ether produced 10.4 g of thick red oil that contained crystals. This material was purified by flash chromatography on silica gel producing 3.60 g (21 mmol, 26%) of bright orange needles: mp 82–84 °C. ^{1}H NMR (CDCl$_3$) δ: 7.06 (q, 1H, J = 1.8 Hz), 6.97 (d, 1H, J = 2.4 Hz), 6.78 (d, 1H, J = 7.9), 6.67 (dd, 1H, J_1 = 2.4, J_2 = 7.9 Hz), 3.77 (s, 3H), 1.81 (d, 3H, J = 1.8 Hz). ^{13}C NMR (CDCl$_3$) δ: 198.6, 160.1, 144.1, 136.6, 134.9, 132.7, 121.6, 116.1, 110.9, 55.6, 10.0. GC–MS: 175 (12), 174 (100), 159 (40), 131 (92), 115 (10), 103 (74), 102 (21), 77 (64), 76 (21), 75 (20), 63 (25), 62 (12), 51 (18). HR-MS calcd. for C$_{11}$H$_{10}$O$_2$: 174.0681; found: 174.0675.

Indenol syntheses

Indenols **3** were prepared from the corresponding indenones using Luche's reagent (18). The yields were 60–95%.

2-Methyl-1-indenol 3a

mp 84–86 °C. ^{1}H NMR (CDCl$_3$) δ: 7.09–7.50 (m, 4H), 6.33 (broad s, 1H), 4.84 (broad s, 1H), 2.07 (broad s, 3H), 1.66 (broad s, 1H). ^{13}C NMR (CDCl$_3$) δ: 148.3, 145.2, 143.0, 128.5, 127.0, 124.9, 123.3, 120.1, 78.9, 13.8. GC–MS: 146 (86), 145 (38), 132 (10), 131 (100), 129 (13), 128 (22), 127 (14), 117 (15), 116 (11), 115 (46), 103 (31), 91

(14), 89 (10), 77 (21), 63 (16), 51 (15). HR-MS calcd. for C$_{10}$H$_{10}$O: 146.0731; found: 146.0741.

HR-MS calcd. for C$_{11}$H$_{12}$O$_2$: 176.0837; found: 176.0841.

General method for the preparation of esters 1a–c and 2a–c

The corresponding acid chloride (4 mmol) in 5 mL of dry benzene was added to a solution of the corresponding indenol (2 mmol) and pyridine (4 mmol) in 10 mL of dry benzene. The solution was stirred overnight at room temperature, then 50 mL of water was added, and the two layers were separated. The benzene layer was washed twice with 10% aqueous HCl and once with saturated aqueous sodium bicarbonate and finally with water. The esters were purified by column chromatography on silica gel. The yields were 50–75%. Solid samples were recrystallized and oils were bulb-to-bulb distilled.

Preparation of ethers, 3

The ethers were prepared from the corresponding indenols using the procedure of Freidrich and Taggart (48) and were purified by chromatography on silica gel. The yields of these reactions were not high (<20%), particularly for the methoxy-substituted cases, and the ^{1}H NMR of the crude indicated the appropriate peaks for the ethers superimposed on broad, featureless bands (oligomers?). Only one ether **9** (X = 5-OCH$_3$) was obtained when starting with either 5- or 6-methoxy-2-methyl-1-indenol, although GC analysis indicated that the isomer was formed (<5%). ^{1}H NOE difference spectra demonstrated that this ether was 1-methoxy-5-methoxy-2-methylindene. This ether **3** (X = 5-CH$_3$O) was

also isolated from photolysis of 6-methoxy-2-methyl-1-indenol in methanol.

^{1}H NMR (CDCl$_3$) δ: 7.02–7.42 (m, 4H), 6.42 (broad s, 1H), 4.84 (broad s, 1H), 3.02 (s, 3H), 2.02 (broad s, 3H). ^{13}C NMR (CDCl$_3$) δ: 145.9, 143.9, 141.9, 128.7, 128.4, 124.7, 123.8, 120.2, 84.9, 51.8, 14.1. GC–MS: 160 (82), 159 (11), 145 (100), 130 (14), 129 (23), 128 (45), 127 (20), 117 (40), 116 (12), 115 (60), 102 (17), 91 (22), 77 (12), 63 (18), 51 (16). HR-MS calcd. for $C_{11}H_{12}O$: 160.0888; found: 160.0887.

1-Methoxy-5-methoxy-2-methylindene

^{1}H NMR (CDCl$_3$) δ: 7.30 (d, 1H, J = 8.0 Hz), 6.72 (d, 1H, J = 2.3 Hz), 6.64 (dd, 1H, J_1 = 8.0 Hz, J_2 = 2.3 Hz), 6.39 (broad s, 1H), 4.82 (broad s, 1H), 3.81 (s, 3H), 3.02 (s, 3H), 2.03 (broad s, 3H). ^{13}C NMR (CDCl$_3$) δ: 160.3, 147.3, 145.5, 133.6, 128.4, 124.3, 109.1, 106.9, 84.2, 55.4, 52.6, 14.2. GC–MS: 191 (11), 190 (88), 189 (15), 176 (11), 175 (100), 160 (25), 159 (32), 147 (28), 144 (16), 132 (13), 116 (23), 115 (55), 103 (12), 91 (18), 89 (13), 77 (14), 63 (15), 51 (10).

Quantitative photolyses

A solution of ~100 mg of the appropriate ester **1** and **2** in 100 mL methanol or cyclohexane was purged with nitrogen and then irradiated in a Rayonet photochemical reactor using 4 lamps (75 W, 254 nm). The temperature was controlled at 25 °C by circulating water in an immersion tube. Reaction progress was monitored by GC, and the reaction stopped when the ester was less than 5% consumed. For the alcohols **3** and the ether **6** (X = H), ~50 mg in 100 mL of the appropriate solvent (methanol or cyclohexane) was used.

CuO – activated carbon catalysts for methanol decomposition to hydrogen and carbon monoxide

Tanya Tsoncheva, Radostin Nickolov, Svetoslava Vankova, and Dimitar Mehandjiev

Abstract: A comparison of the abilities of CuO – activated carbon catalysts, prepared by different copper precursors and preparation techniques, in the methanol decomposition reaction to carbon monoxide and hydrogen, was undertaken. Higher catalytic activity and stability are found for the catalysts obtained from an ammonia solution of copper carbonate. The nature of the catalytic active complex in the samples is also discussed.

Key words: methanol decomposition, CuO – activated carbon catalysts, catalytic active complex.

Résumé : On a réalisé une comparaison de la réaction de décomposition du méthanol en monoxyde de carbone et en hydrogènes sous l'action de divers catalyseurs de CuO sur des charbons activés, préparés à partir différents précurseurs de cuivre et par diverses techniques. On a observé que l'activité catalytique et la stabilité des catalyseurs étaient plus élevées pour les catalyseurs obtenus à partir de solutions ammoniacales de carbonate de cuivre. On discute aussi de la nature du complexe catalytique actif dans les échantillons.

Mots clés : décomposition du méthanol, catalyseurs de CuO sur du charbon activé, complexe catalytique actif.

[Traduit par la Rédaction]

Introduction

In view of the application of methanol as an alternative ecological fuel (1–4), its catalytic decomposition to CO and hydrogen is a process of considerable interest. Some copper-containing materials appear to be promising catalysts (5–7) for this purpose. In our previous investigations we considered the favorable effect of activated carbon used as a support for the preparation of efficient catalysts for methanol decomposition (8–13). The role of the copper precursor in the catalytic activity and selectivity of these materials has been also reported (10, 12, 13). In this aspect, we would like to draw attention to some peculiarities in methanol decomposition on copper-oxide-supported catalysts obtained by different preparation techniques and to look for a correlation with the nature of the catalytic active complex (CAC) in them (14).

Experimental

Materials

This investigation encompasses three copper-containing catalysts supported on activated carbon, a commercial product (15). The specific surface area of the support is 1060 m^2 g^{-1}; the pore volume is 0.91 cm^2 g^{-1}. The catalysts were prepared by an incipient wetness method as follows:

Sample Cu-AC-N

The active phase was deposited by four-fold spraying of the support with an aqueous solution of Cu(NO$_3$)$_2$.

Sample Cu-AC-A1

The active phase was deposited by four-fold spraying of the support with 2.4 wt% basic copper carbonate in ammonia water and ammonium carbonate, pH = 9.9.

Sample Cu-AC-A2

The active phase was deposited by single spraying of the support with 2.4 wt% basic copper carbonate in ammonia water and ammonium carbonate, pH = 9.9.

After each deposition, the samples were kept for 24 h in a closed volume and subjected to drying for 1 h under vacuum at 298 K and then for 1 h in air at 313 K. The samples were decomposed at 480 K in air for 1 h.

Methods and apparatus

Copper content in the samples was determined by atomic absorption spectrometry (Pye Unicam SP 90B spectrometer). X-ray diffraction powder patterns were obtained on a Phylips APD-15 diffractometer equipped with a Cu Kα radiation source and graphite monochromator. XP and Auger spectra were registered using an ESCA LAB Mk II (VG Scientific). The ESR spectra were obtained in an ERS-220

spectrometer (Germany) at 298 K. The magnetic measurements were performed with a Faraday-type magnetic balance in a temperature range of 298–473 K.

The catalytic experiments were carried out in a flow reactor with partial pressure of methanol at 1.57 kPa and WHSV at 1.5 h^{-1} in a thermo-programmed regime with a heating rate of 1 K min^{-1}. A standard catalytic test with time on stream (about 200 min) at selected temperatures was also performed. The on-line gas chromatographic analysis was performed.

Results and discussion

In Table 1 data of the copper content and specific surface area for the initial copper-oxide-supported materials are presented. The magnetic susceptibility of the active phase, calculated as CuO at 298 K, is also given. An essential decrease in the BET surface area for all copper-loaded samples in comparison with the parent activated carbon is observed. Therefore, a highly dispersed copper species, located mainly within the pores of the support, seems to be formed.

In Fig. 1 the temperature dependencies of methanol conversion for the copper oxide – activated carbon samples, obtained by different techniques, are presented. The main registered products are CO and H$_2$. Methyl formate (MF) is also found at lower temperatures. A well-defined tendency for increased conversion with increasing temperatures is registered for Cu-AC-A1. In this case the conversion remains unchanged (about 100%) above 530 K. On the contrary, a maximum in the conversion curve at 510 K for Cu-AC-N is observed. Further increase in methanol conversion above 600 K is also found. The catalytic activity for Cu-AC-N is lower compared with that for Cu-AC-A1 in the whole temperature interval that was investigated. The conversion curve for Cu-AC-A2 is close to that for Cu-AC-A1, up to 600 K, but a sharp decrease above this temperature is registered. So, a favourable effect of active phase deposition from ammonia solution is concluded. However, the preparation technique that includes a four-fold spraying of the support with copper solution facilitates the formation of more stable catalysts.

As far as the fact that the activated carbon does not exhibit a catalytic activity in methanol decomposition on its own (not shown), some significant differences in the copper state for the initial catalysts could be assumed. Further changes in the copper state during the catalytic process could also be expected.

To describe the peculiarities of the active-phase state on the investigated catalysts, a complex study by different methods was performed. The XRD spectra for the initial samples are identical, and CuO is the only phase observed (Fig. 2, curve 1). However, two ESR signals are also found in all investigated samples (Fig. 3), in spite of the fact that CuO does not register on ESR spectra. This is also in accordance with the results in ref. 16. A sharp ESR signal, typical of single Cu^{2+} ions, is registered. The presence of Cu^{2+} ions interacting with each other (Cu^{2+}–Cu^{2+}) and characterized with a broader ESR signal are found as well. So, despite the nature of the used copper precursor, the CAC in the initial sample contains predominantly Cu^{2+} ions, differing in coordination and type of interaction. This conclusion is proved by the magnetic measurements as well. The calculated mag-

Table 1. Copper content, specific surface area, and magnetic susceptibility of the initial samples obtained by different preparation techniques.

Samples	Cu content (wt%)	BET (m^2 g^{-1})	χ_g (g ions $\times$ 10^6)
AC	0.0	1060	–0.6
Cu-AC-N	4.0	960	19.0
Cu-AC-A1	5.0	958	7.5
Cu-AC-A2	5.0	657	18.4

Fig. 1. Total conversion vs. temperature on various copper-loaded samples.
netic susceptibilities, per g mol Cu^{2+} ions in the initial samples, are rather different (Table 1). The lower magnetic susceptibility for Cu-AC-A1 could be an indication of the presence of copper species in a lower oxidative state in this sample, since their effective magnetic susceptibility is zero (17). Indeed, only in the case of the initial Cu-AC-A1 does XPS analysis show the presence of Cu^{1+} ions (Table 2). So, the participation of copper species in different oxidative states (Cu^{2+}, Cu^{2+}–Cu^{2+}, and Cu^{1+}) in the CAC Cu-AC-A1 could be assumed. On the contrary, Cu^{2+} and Cu^{2+}–Cu^{2+} ions are exclusively present in the CAC of the initial Cu-AC-N. In this relation, the observed higher activity for Cu-AC-A1 (Fig. 1) could be ascribed to the presence of Cu^{1+} ions in the initial CAC. The favourable role of the ammonia copper precursor for these types of CAC formations in the process of catalyst preparation is considered. This assumption is also proved by the higher turnover frequencies (TOF), calculated on the basis of the initial conversion at different temperatures, for Cu-AC-A1 in comparison with Cu-AC-N (Fig. 4). However, the similarities of TOF values for both samples above 530 K could be evidence for some essential changes in CAC for Cu-AC-N during the reaction. This conclusion is confirmed by the XPS spectra for Cu-AC-N, where Cu^0, together with Cu^{2+} and Cu^{1+}, is found (Table 2). Intensive signals, typical of Cu^0, are also observed in the XRD spectrum for this sample (Fig. 2, curve 2). On the contrary, no Cu^0 is found for the used Cu-AC-A1. Hence, a more stable CAC in Cu-AC-A1 with respect to the reaction medium influence is most probably formed.

The higher stability of CAC in the ammonia-obtained sample compared with that in Cu-AC-N could also be

Table 2. Binding energies of Cu $2p_{3/2}$ and O $1s$ and the kinetic energy of the Cu $L_3M_{4,5}M_{4,5}$ peak (eV) of the initial (I) samples and those used in the catalytic test at 700 K (T).

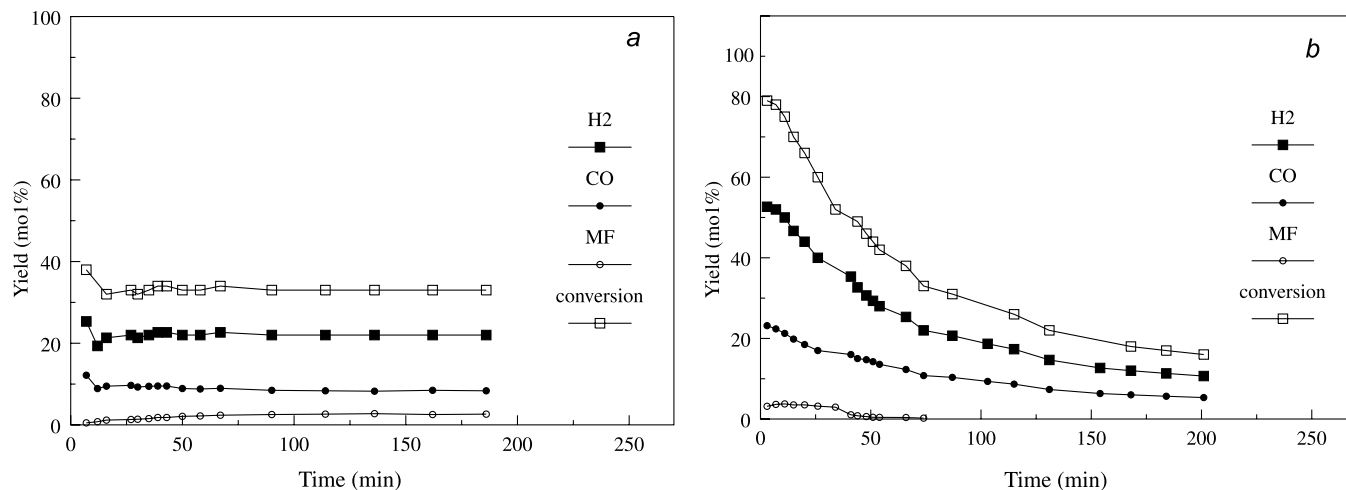
Fig. 4. Temperature dependences of TOF for Cu-AC-A1 and Cu-AC-N.
Fig. 5. Evolution of the conversion and product distribution with time on stream on Cu-AC-N at 473 K (*a*) and 551 K (*b*).


Fig. 6. Evolution of the conversion and product distribution with time on stream on Cu-AC-A1 at 490 K (*a*) and 575 K (*b*).
proved by the catalytic experiments in isothermal conditions (Figs. 5 and 6). For Cu-AC-N, the conversion remains unchanged only at lower temperatures (Fig. 5*a*). However, it gradually decreases at 550 K (Fig. 5*b*), and the catalyst practically loses its catalytic activity after about 5 h. On the contrary, no essential changes with time on stream are registered for Cu-AC-A1 even at 575 K (Fig. 6).

Conclusions

In comparison with the nitrate-obtained, copper-loaded activated carbon materials, the catalysts prepared from the ammonia precursor exhibit higher catalytic activity during methanol decomposition to CO and hydrogen. In this case, the preparation technique that includes four-fold spraying of the support with the precursor is favoured as producing the catalyst with the best stability in this reaction. It results in easier formation and better stabilization of the CAC, containing Cu^{1+} ions on the support in the process of catalyst preparation. Indeed, the nature of the CAC is only one aspect of the complex problem of optimization of catalysts. Higher catalytic activity, selectivity, and stability at low temperatures are needed. In relation to this, further investigations are in progress.

A theoretical analysis of the conformational behaviour of substituted methylenecyclohexanes

Robert C. Mawhinney, Heidi M. Muchall, and Jean Lessard

Abstract: The use of the PBE0 hybrid density functional theory method in conjunction with the COSMO solvation model allowed us to reproduce, both qualitatively and quantitatively, the experimentally observed conformational compositions of 2-substituted and 2,7-disubstituted methylenecyclohexanes. An analysis revealed several different interactions that influence the overall equilibrium. It was found that the endo (general) anomeric effect plays a significant role in the equilibrium and that the "unsaturation effect" possibly comprises two effects.

Key words: conformational analysis, methylenecyclohexanes, anomeric effect, unsaturation effect.

Résumé : L'utilisation de la méthode théorique fonctionnelle de densité hybride PBE0 de concert avec le modèle de solvatation COSMO nous permet de reproduire qualitativement et quantitativement, les compositions conformationnelles, observées expérimentalement, des méthylènecyclohexanes substitués en position 2 et disubstitués en positions 2 et 7. Une analyse révèle plusieurs interactions différentes qui influencent l'équilibre global. On a trouvé que l'effet anomère endo (général) joue un rôle important dans l'équilibre et que l'effet d'insaturation comporte probablement deux effets.

Mots clés : analyse conformationnelle, méthylènecyclohexanes, effet anomère, effet d'insaturation.

[Traduit par la Rédaction]

Introduction

The anomeric effect is invoked to explain the unusual stability of the more sterically unfavoured synclinal (*gauche*) conformer over the sterically favoured antiperiplanar (*anti*) conformer (1). A number of theories have been hypothesized to explain these findings (2). To test these theories, Lessard and co-workers (3–6) assessed the equilibrium composition of a number of systems using ^{13}C NMR spectroscopy, including substituted methylenecyclohexanes.

The first article in the series (3) revealed that the dipole–dipole – dipole–quadrupole and rabbit-ear (or *n–n* interaction) theories for the anomeric effect were negligible (the latter because the chosen system did not have any endocyclic atoms with electron lone pairs), leaving only the double bond – no bond resonance or $\pi_{C=C}-\sigma^*_{C-O}$ orbital overlap as the main interaction. This appeared to explain the finding that the introduction of a methoxy substituent to the methylene group (position 7) in 2-methoxymethylenecyclohexane led to a stabilization of the axial conformer to such an extent that the equatorial conformer was not observed.

In the second paper (4) this was explored further by changing the 2-substituent. It was found that the introduction of a π system had the unexpected result of switching the

conformer preference from axial to equatorial, with the proportion of equatorial orientation on going from methoxy (OMe) to vinyloxy (OVi) to acetoxy (OAc) increasing from 41% to 61% to 80% at 0 °C. Based on double bond – no bond resonance, the increase in anion stability of the 2-substituent along this series should produce the opposite effect. Similarly, the $\pi_{C=C}-\sigma^*_{C-O}$ interaction should become more pronounced, since the σ^*_{C-O} orbital energy should decrease along the series. This counter observation was termed the "unsaturation effect".

Instead of invoking a double bond – no bond resonance or $\pi_{C=C}-\sigma^*_{C-O}$ stabilizing interaction, a number of these results could also have been explained through an $n_O-\pi^*_{C=C}$ stabilizing interaction. To examine the effect of the $n_O-\pi^*_{C=C}$ interaction, Lessard et al. (5) examined a series of 7-substituted 2-methoxymethylenecyclohexanes. The substituent on the methylene carbon was changed from hydrogen to methoxy (OMe), phenyl (Ph), and cyano (CN), and the observed proportion of equatorial orientation changed from 41% (0 °C) to <5% (–113 °C), 12% (–113 °C), and 88% (–60 °C), respectively. These results showed that $n_O-\pi^*_{C=C}$ orbital interactions are not the dominant factor for determining the equilibrium composition.

In the last paper of this series (6), the authors brought together all previous results, as well as those for several similar systems, and concluded that the generalized anomeric effect is operating in these systems along with a contribution from electrostatic (dipole–quadrupole) interactions. Most important, however, is the as yet unexplained "unsaturation effect", which appears to override the generalized anomeric effect in a number of cases.

To understand the "unsaturation effect", we started a computational study of the axial preference for the 2-substituted

methylenecyclohexanes (7). The experimentally observed trend was reproduced qualitatively. While the equilibria for the methoxy- and vinyloxy-substituted compounds were best obtained at single point solvated levels of theory, the large equatorial preference for the acetoxy species could only be reproduced when solvent-optimized geometries and energies were employed. Even then the equilibrium composition could only be estimated, since a minimum for one of the conformers was not located.

In this paper we have undertaken a reexamination of the 2-substituted equilibrium compositions. We report that the use of the COSMO solvation model (8–10) in conjunction with the empirical-parameter-free PBE0 hybrid density functional method (11, 12) not only correctly predicts the compositional preferences in the 2-substituted methylene-cyclohexanes but also those seen for the 2,7-disubstituted systems (Scheme 1). This combination of theory and solvation model has recently been shown to give reliable results for examining the role of stereoelectronic effects in the collagen dipeptide (13).

Computational details

The Gaussian 98 suite of programs was used in all calculations (14). The minimum energy conformations were optimized using the empirical-parameter-free hybrid density functional PBE0 (11, 12) and the Pople split valence 6-31G(d) basis set (15–19), starting from the previously optimized gas phase HF/6-31G(d) structures (7). The COSMO polarizable continuum solvent model (8–10) was used, with dichloromethane as solvent, in all optimizations. All minima were confirmed by harmonic vibrational frequency analyses. Since all relative energies are based on rotational conformers, there is negligible dependence on entropy, and we report zero-point corrected, as opposed to free energy, values.

Results and discussion

As in the previous work (7), rotational isomers for both the axial and equatorial conformers were explored. In all cases, two rotamers are obtained within a 2.5 kcal/mol cut-off criterion. In Fig. 1 the structures for **2-OMe** are given. As one can see, the O—R^1 bond is aligned antiperiplanar with one of two possible C—C bonds, either C—C$_{sp^3}$ or C—C$_{sp^2}$. This general feature is the same in all systems. All species will from here on be labelled by their conformations, axial (a) or equatorial (e), antiperiplanar to C$_{sp^3}$ or C$_{sp^2}$ (i.e., a(sp^3), a(sp^2), e(sp^3), e(sp^2)), as shown in Fig. 1. In the case of the vinyloxy-substituted system there are twice as many conformers because of the *cis* and *trans* orientations in the C-O-CH=CH$_2$ fragment. While also possible for the acetoxy substituent, it was found earlier (7) that the *cis* species lie around 8 kcal/mol higher in energy and therefore are not a factor in the equilibrium composition. Unlike the previous study, we have now been able to locate solvent-optimized minima for all four conformers in the acetoxy system and can therefore concentrate on understanding the causes of the effects that lead to the observed equilibria.

Compositional analysis

The experimentally observed axial:equatorial equilibrium composition for the 2-substituted methylenecyclohexanes is

The relative energy differences for each of the species that make up the equilibrium are given in Table 1. The equilibium composition is derived from these energy differences by combining the Boltzmann distribution relationship with the molar fractions distribution relationship (20, 21). As shown in Table 1, our results are both qualitatively and quantitatively in good agreement with the experimental values. The largest differences are observed for **2-OVi** (Δ = −12%) and **7-Ph** (Δ = +16%). All other results are within at

least 7%, and for three systems (**2-OMe**, **2-OAc**, and **7-OMe**) there is no appreciable error.

In the 2-substituted systems, the major change in equilibrium composition on going from methoxy (**2-OMe**) to vinyloxy (**2-OVi**) is a decrease in a(sp^3) (from 57.5 to 21.6% (9.7(*trans*) + 11.9(*cis*))) and a concomitant increase in e(sp^3) (from 30.3 to 52.8%). In **2-OAc**, the decrease in a(sp^3) is accompanied by an additional major increase in e(sp^2) (from 10.8 to 44.5%). In the 7-substituted series, the introduction of the cyano group (**7-CN**) has a similar effect to that of the acetoxy group (**2-OAc**) in the 2-substituted series. The exchange of the hydrogen atom in **2-OMe** for a phenyl ring (**7-Ph**) in the 7-position has only a small effect on the energy differences, stabilizing a(sp^2) and destabilizing e(sp^3), thereby shifting the equilibrium composition further towards axial. The 7-methoxy substitution (**7-OMe**) dramatically destabilizes both equatorial species so that a(sp^3) now makes up ~98% of the equilibrium.

Geometric evidence

The anomeric effect, aside from energetic considerations, is typically accompanied by certain geometric changes that form the basic reasoning behind a number of its explanations (1). In particular, the C—X bond in the anomeric position is usually observed to be elongated in the axial conformer with respect to the equatorial conformer. This is also the case here, as shown for the C—O bond distances given in Table 2. In all 2-methoxy systems (**2-OMe**, **7-CN**, **7-OMe**, and **7-Ph**) the difference between the axial and equatorial C—O distance is ca. 0.012 Å. This difference increases as the electronegativity of the 2-substituent increases, as expected

for an anomeric effect. This is demonstrated by a difference of 0.015 Å in **2-OVi** and a difference of 0.018 Å in **2-OAc**. These results are consistent with the conclusions of Lessard and co-workers that the generalized anomeric effect is operating in these systems (6).

The C—O bond distances in both axial and equatorial conformers increase as the electronegativity of the 2-substituent increases. This in itself is not surprising. What is surprising is that the C—O bond distance is affected by 7-substitution. For example, the addition of the electron-withdrawing cyano group (**7-CN**) shortens r_{C-O} with respect to the unsubstituted system (**2-OMe**). The addition of an electron-donating group (**7-OMe**) is accompanied by an increase in r_{C-O}, and conjugation (**7-Ph**) elicits no change. An examination of the r_{C-O} differences between axial and equatorial species also shows this trend. The difference of 0.012 Å (as assessed using the raw bond distances from which Table 2 was created) in the unsubstituted **2-OMe** decreases to 0.011 Å with the addition of an electron-withdrawing group (**7-CN**), increases to 0.013 Å with an electron-donating group (**7-OMe**), and is unchanged (0.012 Å) by conjugation (**7-Ph**). This remote effect implies that the methylene π system has an effect on both anomers and is probably part of the reason behind the "unsaturation effect".

The operation of another effect, the exo-anomeric effect, is revealed by the r_{C-C} entries in Table 2. When O–R[1] is antiperiplanar to C_{sp^3} (left hand structures in Fig. 1), the overlap between an oxygen lone pair (n_O) and $\sigma^*_{C-C_{sp^2}}$ is maximized. Consequently, $r_{C-C_{sp^2}}$ is found to be longer in a(sp^3) and e(sp^3) than in a(sp^2) and e(sp^2) (Table 2). Simi-

larly, when O–R^1 is antiperiplanar to C_{sp^2} (right hand structures in Fig. 1), the n_O–$\sigma^*_{C-C_{sp^3}}$ interaction is maximized and $r_{C-C_{sp^3}}$ is longer in these species. These results also demonstrate that the effect on distance is larger in C—C_{sp^3} than in C—C_{sp^2}. For example, in the **2-OMe** case the former changes by 0.006–0.007 Å and the latter by 0.004 Å. This is a reflection of the differing strengths of the C_{sp^3}—C_{sp^3} and C_{sp^3}—C_{sp^2} bonds, as shown by the shorter overall C_{sp^3}—C_{sp^2} distances.

As expected, this effect diminishes as O–R^1 becomes more electronegative. The average $r_{C-C_{sp^2}}$ bond difference decreases from 0.004 Å (**2-OMe**) to 0.003 Å (**2-OVi**) and to 0.002 Å (**2-OAc**). Similarly, the average $r_{C-C_{sp^3}}$ bond difference decreases from 0.007 Å (**2-OMe**) to ~0.004 Å (**2-OVi**) and ~0.003 Å (**2-OAc**). In the $r_{C-C_{sp^2}}$ case, there is virtually no variation in the axial and equatorial differences. The $r_{C-C_{sp^3}}$ case, on the other hand, exhibits some variation between the axial and equatorial differences, which also increases along the series **2-OMe**, **2-OVi**, and **2-OAc**. The effect of 7-substitution is rather small, if present at all, and no discernable pattern can be ascertained in the $r_{C-C_{sp^3}}$ case. The $r_{C-C_{sp^2}}$ bond distances reveal that the addition of an electron withdrawing group increases the sp^3 – sp^2 difference in both anomers (**7-CN**), an electron-donating group decreases it in the axial anomer (**7-OMe**), and conjugation increases it in the equatorial anomer (**7-Ph**).

Aside from the changes due to 7-substitution, the C=C distance is fairly insensitive, owing to the stiffness of the bond (even more so than for the C_{sp^3}—C_{sp^2} bond). This is expected, and the lack of any appreciable change in C=C distance on its own does not imply that $\pi_{C=C}$–σ^*_{C-O} and n_O–$\pi^*_{C=C}$ interactions do not play a significant role in these systems, as has been concluded earlier (3, 5). In fact, the ex-

pected small lengthening of the C=C bond in the axial species can be seen most clearly in **7-OMe** and **7-Ph**.

Decomposition of energy differences

The equilibrium composition depends on the energy differences between the different species, as described earlier. As well, the Edward–Lemieux effect (which incorporates both the endo- and exo-anomeric effects, similar to our case) can be "energetically quantified by the energy difference between the sum of the endo- and exo-anomeric effects for one of the anomers and the sum for the other anomer" (22). Within this context, we have plotted the energy relationships between the different conformers (the *cis* and *trans* components of vinyloxy have been separated) as a function of the % axial composition (all calculated at 0 °C). The overall results, along with the linear trend lines and corresponding correlation coefficients, are presented in Fig. 2.

In most cases there does not seem to be any direct relationship between energy difference and equilibrium composition. The one exception is the e(sp^3) – a(sp^3) energy difference, where there is a strong correlation ($r^2 = 0.97$). This relationship corresponds to the endo- (generalized) anomeric effect, as Lessard and co-workers have concluded (6). However, our results do not show a second overall effect offsetting it; perhaps there are two effects within the subsets that are masking each other on a global scale. To explore this further, we have separated out the two systems, **2-OMe**, **2-OVi(cis)**, **2-OVi(trans)**, and **2-OAc** ("2-substituted") and **2-OMe**, **7-CN**, **7-OMe**, and **7-Ph** ("7-substituted") and again plotted the energy differences between the different conformers as a function of the % axial composition. These are given in Figs. 3 and 4, respectively.

Fig. 2. The overall relationship between energy differences (kcal/mol) and % axial composition: ▲ $E_{a(sp^2)} - E_{a(sp^3)}$; ◆ $E_{e(sp^2)} - E_{e(sp^3)}$; × $E_{e(sp^3)} - E_{a(sp^3)}$; ■ $E_{e(sp^2)} - E_{a(sp^2)}$.
Fig. 3. The relationship between energy differences (kcal/mol) and % axial composition in the 2-substituted systems: ▲ $E_{a(sp^2)} - E_{a(sp^3)}$; ◆ $E_{e(sp^2)} - E_{e(sp^3)}$; × $E_{e(sp^3)} - E_{a(sp^3)}$; ■ $E_{e(sp^2)} - E_{a(sp^2)}$.
The e(sp^3) – a(sp^3) energy difference shows the same strong correlation (r^2 = 0.97 and 0.96) in both 2- and 7-substituted systems. In the 2-substituted systems there is also a considerable correlation (r^2 = 0.90) with the exo-anomeric effect in the axial conformers, a(sp^2) – a(sp^3), as seen in Fig. 3. The 7-substituted systems, where the

Fig. 4. The relationship between energy differences (kcal/mol) and % axial composition in the 7-substituted systems: ▲ $E_{a(sp^2)} - E_{a(sp^3)}$; ◆ $E_{e(sp^2)} - E_{e(sp^3)}$; × $E_{e(sp^3)} - E_{a(sp^3)}$; ■ $E_{e(sp^2)} - E_{a(sp^2)}$.
substituent effect is removed from the exo portion of the ring, do not show any correlation ($r^2 = 0.19$) with the $a(sp^2) - a(sp^3)$ energy difference. They do, however, exhibit a strong correlation ($r^2 = 0.98$) with the other endo-anomeric effect, $e(sp^2) - a(sp^2)$ (Fig. 4).

The fact that there are two main trends to each series and only one of them in common suggests that the "unsaturation effect" is a combined effect. There is no straightforward explanation, and since within each conformer there are three common energy components (steric, electrostatic, and electronic) (23), a full understanding will only come from a complete analysis of all energetic contributions. Also, one must realize that most of the data points in the figures are essentially clustered at one end, as intermediate experimental data are not available at this moment. Further studies, both experimental and computational, are planned to remedy this situation.

Conclusions

In this work we have shown that the combination of PBE0 and COSMO reliably predicts the experimentally observed axial:equatorial equilibrium compositions in 2-substituted and 2,7-disubstituted methylenecyclohexanes. We have analyzed the compositions with respect to both the endo- and exo-anomeric effects, jointly known as the Edward–Lemieux effect.

The geometries of the species that make up the equilibrium composition revealed evidence of three different effects. The r_{C-O} distances exhibit the generalized anomeric effect. The exo-anomeric effect reveals itself as an increase in C—C bond lengths due to $n_O - \sigma^*_{C-C}$ interactions. The rigidity of the C=C bond limits its use as a detector of

$\pi_{C=C} - \sigma^*_{C-O}$ and $n_O - \pi^*_{C=C}$ interactions. However, 7-substitution has an effect on r_{C-O} in both anomers, unlike typical anomeric systems, which implies that the methylene π system might be the source of the "unsaturation effect". This is supported by an analysis of energy differences and their relationship to the observed equilibrium composition in that an overall endo- (generalized) anomeric effect for one of the rotamers ($e(sp^3)$-$a(sp^3)$) is accompanied by two more correlations within the subsets of 2- and 7-substituted systems.

Studies are now underway to examine this further. These include an AIM analysis (24) of the electron density, as has been done previously (25–27); an NBO analysis (28) to examine the role of the suspected orbital interactions (29–34); and a bond energy analysis (35–37), which, to our knowledge, has never been used for the examination of the anomeric effect but should reveal results about steric, electrostatic, and electronic effects similar to other energy decomposition methods (38–40). As well, experiments are underway to examine all possible permutations within the two subsets.

Electroreduction of 1-methyl 5-nitroindole, 5-nitrobenzofurane, and 5-nitrobenzothiophene in acidic and basic hydroorganic media: Generation and trapping of iminoquinone-type intermediates and electrosynthesis of ring-substituted amino derivatives

Luc Bouchard, Ian Marcotte, Jean Marc Chapuzet, and Jean Lessard

Abstract: Preparative electrolysis of 1-methyl-5-nitroindole (**1b**, X = NCH$_3$), 5-nitrobenzofurane (**1c**, X = O), and 5-nitrobenzothiophene (**1d**, X = S) at Hg, in acidic hydromethanolic media, leads to the formation of the corresponding 4-substituted amino derivatives **5**, which result from the 100% regioselective addition to iminoquinone-type intermediate **4** of methanol or of any other good nucleophile present in the electrolytic solution. In acidic medium, the iminoquinonium intermediates **4b** and **4c** were trapped in a cycloaddition reaction with cyclopentadiene added to the electrolysis medium. The regiochemistry of the nucleophilic addition is discussed in light of AM1 calculations.

Key words: 1-methyl-5-nitroindole, 5-nitrobenzofurane, 5-nitrobenzothiophene, iminoquinone, electrosynthesis.

Résumé : L'électrolyse préparative du 1-methyl-5-nitroindole (**1b**, X = NCH$_3$), du 5-nitrobenzofurane (**1c**, X = O) et du 5-nitrobenzothiophene (**1d**, X = S), sur Hg et en milieu hydrométhanolique, mène à la formation des amines correspondantes **5** substituées en position 4, lesquelles proviennent de l'addition, aux intermédiaires de type iminoquinonique **4**, du méthanol ou d'autres bons nucléophiles présents au sein de la solution électrolytique. L'addition du nucléophile est 100% régiosélective. En milieu acide, les intermédiaires diiminoquinonium **4b** et **4c** ont été piégés par une réaction péricyclique avec le cyclopentadiène ajouté à la solution électrolytique. La régiochimie de l'addition du nucléophile est discutée à la lumière des résultats de calculs AM1.

Mots clés : 1-méthyl-5-nitroindole, 5-nitrobenzofurane, 5-nitrobenzothiophène, iminoquinone, électrosynthèse.

Introduction

Recently, we reported the electroreduction at a mercury cathode of 5-nitroindole (**1a**) in acidic, neutral, and basic hydroorganic media (1, 2). As shown in Scheme 1, preparative electrolysis of 5-nitroindole (**1a**) in acidic or basic methanolic solutions gives 4-substituted-5-aminoindoles **5a**. In acidic medium, the latter are formed through dehydration of the protonated hydroxylamine **2a** to the diiminoquinonium intermediate **4a** followed by the regioselective addition of methanol and (or) of any other good nucleophile present in the electrolytic solution. In such acidic medium (0.15 mol L^{-1} in acid, pH = 0.3), two monoprotonated diiminoquinones **4a**

and **6** are potential intermediates, and one could consider the possibility of a diprotonated intermediate **4aH$^+$**, depending on the basicity of the imino nitrogen of **4a** and of the ring nitrogen of **6**. In basic medium, the hydroxylamine and the diiminoquinone are not protonated (see **7a** and **8**, respectively). In the presence of a good nucleophile, such as bromide ion in acidic medium or thiophenolate anion in basic medium, substituted aminoindole **5a** is the sole compound isolated in yields of 71%–86% and 59%, respectively (2).
4H$^+$ **6**   **7**   **8**

a: X = NH; **b**: X = NCH$_3$; **c**: X = O; **d**: X = S

We studied the electroreduction of 1-methyl-5-nitroindole (**1b**), 5-nitrobenzofurane (**1c**), and 5-nitrobenzothiophene (**1d**) at a mercury cathode, in the same acidic (pH = 0.3) and basic (pH = 13.5) aqueous methanolic solutions (MeOH–H$_2$O 95:5 (volume fraction)) as those used for the electro-

Scheme 1.
reduction of **1a** (2). The aim was to get a better understanding of the nature and reactivity towards nucleophiles of cationic iminoquinone intermediates **4** and (or) **4H⁺** (neutral diiminoquinones are not possible intermediates in these cases) and to see if substituted 5-amino derivatives **5** could also be obtained in good yield and high regioselectivity from this family of nitro compounds.

Voltammetric measurements

Cyclic voltammetry was used to determine the reduction potential of 1-methyl-5-nitroindole (**1b**), 5-nitrobenzofurane (**1c**), and 5-nitrobenzothiophene (**1d**) in acidic and basic aqueous methanolic solutions. The data are summarized in Table 1. An increase of the scan rate from 100 to 500 mV s⁻¹ caused the expected increase of current for the diffusion controlled processes. In acidic medium (entries 2–4 and 6–8), the cyclic voltammograms of the three nitro compounds are similar to that of 5-nitroindole (**1a**) (entries 1 and 5) (2) and show only one peak, corresponding to a six-electron reduction to the amine. 5-Nitrobenzofurane (**1c**) has the most negative reduction potential, –0.58 and –0.51 V vs. ECS (entries 3 and 7, respectively), followed by 5-nitrobenzothiophene (**1d**), –0.51 and –0.47 V (entries 4 and 8), then by 1-methyl-5-nitroindole (**1b**), –0.47 and –0.44 V (entries 2 and 6), and finally by 5-nitroindole (**1a**), –0.34 V (entry 1) and –0.35 V (entry 5). In basic medium, the cyclic voltammograms of 1-methyl-5-nitroindole (**1b**) (entry 10: $(E_{pc})_1$ = –1.03 V and $(E_{pc})_2$ = –1.25 V) and of 5-nitrobenzofurane (**1c**) (entry 11: $(E_{pc})_1$ = –1.03 V and $(E_{pc})_2$ = –1.25 V) are also similar to that of 5-nitroindole (**1a**) (entry 9: $(E_{pc})_1$ = –1.06 V and $(E_{pc})_2$ = –1.28 V) (2) in showing two reduction peaks (i_1 + i_2/i_1 of about 2), corresponding, respectively, to the reversible monoelectronic reduction to the radical anion and to the irreversible three-electron reduction of the radical anion to the hydroxylamine. However, the cyclic voltammogram of 5-nitrobenzothiophene (**1d**) shows only one four-electron reduction peak (entry 12: $(E_{pc})_1$ = –1.09 V). The cyclic voltammograms of all four nitro derivatives show the presence, on the second and third half-cycles at a less negative potential, of the hydroxylamine–nitroso reversible redox couple (see peaks $(E_{pc})_3$ and E_{pa} in entries 9 to 12). Thus,

the voltammetric behaviour of these nitro derivatives in basic medium is similar to the well-known voltammetric behaviour of nitroaryl groups (3). The decreasing order of ease of reduction in basic medium (**1c** > **1b** > **1a** > **1d**) differs from that in acidic medium (**1a** > **1b** > **1d** > **1c**), so there seems to be no straightforward relationship between the structure (for instance, the electronegativity of X and its electron-withdrawing or electron-donating ability) and the reduction potential.

Preparative electrolyses of 1-methyl-5-nitroindole (1b)

The results of preparative electroreduction of 1-methyl-5-nitroindole (**1b**) at Hg, in methanol–water (95:5 volume fraction) solutions and under controlled potential conditions (E_W ~ $(E_{pc})_1$ – 100 mV in acidic medium, E_W ~ $(E_{pc})_1$ – 300 mV in basic medium), are presented in Table 2.

In acidic medium (entries 1 to 3), the results are very similar to those reported previously for the electroreduction of the parent 5-nitroindole (**1a**) in the same media (2). With HBr as acid and supporting electrolyte (0.15 mol L⁻¹, pH = 0.3) (entry 1), the electroreduction of **1b** consumed 4.6 F mol⁻¹ (1 F = 96 488 C) and led to 1-methyl-4-bromo-5-aminoindole (**5b**, Nu = Br) as the unique product in 57% yield. With H₂SO₄ as acid and supporting electrolyte (0.15 mol L⁻¹) (entry 2), the electrolysis of **1b** gave a 0.7 ratio of **3b** and **5b** (Nu = MeO) and consumed also 4.6 F mol⁻¹. The mechanistic hypothesis for the formation of **3b** and **5b** (Scheme 1) is the same as that proposed previously for the electroreduction of 5-nitroindole (**1a**) in an acidic medium (2). First, **1b** is reduced to the protonated hydroxylamine **2b** through four successive electron and proton transfers. Then, there could be a competition between path A, the two-electron reduction of **2b** to aminoindole **3b** (protonated in the medium), and path B, acid-catalyzed elimination of water from **2b** to give a diiminoquinonium intermediate (**4b** and (or) **4bH⁺**). Since **3b** was not detected in the products of the electrolysis in the HBr medium (Table 2, entry 1), it is reasonable to assume that reaction A is slower than reaction B and thus may be neglected as proposed for the electroreduction of **1a** (2). 1-Methyl-5-aminoindole (**3b**) would

Table 1. Cyclic voltammetric data of 1-methyl-5-nitroindole (**1b**), 5-nitrobenzofurane (**1c**), and 5-nitrobenzothiophene (**1d**) at Hg in methanol–water (95:5 volume fraction).

[f]A third substitution product, 5-amino-1-methyl-3-thiophenoxyindole (**9b**), was isolated in 20% yield.
[g]The 5,5′-azo derivative **11b** was isolated in 27% yield.

then be formed by a two-electron reduction of the diiminoquinonium intermediates **4b** and (or) **4bH⁺** (path C), and 4-bromo-5-aminoindole (**5b**, Nu = Br) would result from the addition of a bromide ion to these intermediates (path D). The fact that 4-bromo-5-amino-1-methylindole (**5b**, Nu = Br) was the sole product isolated shows that the addition of Br⁻ to **4b** and (or) **4bH⁺** (path D) is faster than their reduction to **3b** (path C). In the absence of bromide ions — methanol being a weaker nucleophile than Br⁻ in such protic medium (hydrogen bonds to Br⁻ are weak) — the reduction of **4b** and (or) **4bH⁺** to **5b** (path C) now competes effectively with the addition of methanol to these intermediates (path D), the rate of the two reactions being similar (rate of reaction D : rate of reaction C ~ 1.5, entry 2). In the presence of thiophenol (entry 3), the electroreduction of 1-methyl-5-nitroindole (**1b**) gave 1-methyl-5-aminoindole (**3b**) (5%), 1-methyl-4-methoxy-5-aminoindole (**5b**, Nu = MeO) (9%), and two substituted 5-amino indoles in equimolar amounts: the 4-thiophenoxy derivative **5b** (Nu = PhS) (20%) and the 3-thiophenoxy derivative **9b** (20%). These results

are again similar to those obtained with 5-nitroindole (**1a**) under the same conditions (formation of **9a** in 14% yield) (2). It is reasonable to assume that both isomers **5b** (Nu = SPh) and **9b** come from the addition of thiophenol to **4b** and (or) **4bH⁺**. The larger proportion of thiophenoxyindoles (**5b** (Nu = SPh) + **9b**: 40%) over 4-methoxy-5-aminoindole (**5b**, Nu = OMe: 9%) shows that thiophenol is a better nucleophile than methanol in the electrolysis medium (protic medium), which is in agreement with the fact that hydrogen bonding to sulphur is weaker than hydrogen bonding to oxygen. That thiophenol is a better nucleophile than methanol in such protic medium is seen also in the relative proportion of substituted-1-methyl-5-aminoindoles (**5b** + **9b**) and 1-methyl-5-aminoindole (**3b**) (proportional to the ratio of the rate of reaction D over the rate of reaction C, Scheme 1), which   is larger in the presence of thiophenol ((**5b**(%) + **9b**(%))/**3b**(%) ~ 10, entry 3) than in its absence (**5b**(%)/**3b**(%) ~ 1.5, entry 2). The material balance based on the weight of crude product after work-up was nearly quantitative for all electrolyses in acidic medium (entries 1 to 3),

Scheme 2.

1a (R = H)
1b (R = CH$_3$)

10a (R = H)
10b (R = CH$_3$)
and both **3b** and **5b** were shown to be stable in the electrolysis medium, as well as during the work-up and chromatographic separation. So (*i*) the low material balances (32% in entry 2, 54% in entry 3, and 57% in entry 1) after chromatographic separation and (*ii*) the fact that the higher the material balance, the better the nucleophile suggests processes giving molecules that are retained on silica gel must be competing with path D and, to a lesser extent, path C (Scheme 1). One probable hypothesis is polymerization and (or) oligomerization of the diiminoquinonic intermediate **4b** (polymerization and (or) oligomerization of the diprotonated form **4bH$^+$** appears less likely). The polymers and (or) oligomers formed would be strongly adsorbed on silica gel, and this would explain why all attempts to isolate any polymeric and (or) oligomeric material failed. In the presence of a good nucleophile (Br$^-$ or PhSH, entries 1 and 2), polymerization and (or) oligomerization would account for about 40% of the products, and in methanol only (entry 2), it would be the main reaction (about 70% of the products).

The formation of **4b** and (or) **4bH$^+$** was confirmed beyond any doubt by the isolation of the tetracyclic compound **10b** (R = CH$_3$) in 31% yield (Scheme 2) when electrolysis of **1b** in acidic medium (H$_2$SO$_4$ 0.15 mol L^{-1}) was carried out in the presence of cyclopentadiene in excess (8 equiv). The formation of **10a** has been previously reported for the electrolysis of **1a** under the same conditions (2). Adducts **10** most probably result from a [$\pi^6s + \pi^4s$] cycloaddition reaction between the fulvene part of the diminoquinonic intermediate(s) and cyclopentadiene, as has already been suggested (2). Fulvenes are known to undergo [$\pi^6s + \pi^4s$] cycloadditions with cyclic 1,3-dienes (4, 5).

9a: R = H
9b: R = CH$_3$

11b: X = NCH$_3$
11c: X = O
11d: X = S
In basic medium (Table 2, entry 4), the electroreduction of 1-methyl-5-nitroindole (**1b**) gave 2% of 1-methyl-5-aminoindole **3b**, 7% of 4-methoxy-5-aminoindole (**5b**, Nu = MeO), and 27% of the 5,5′-azo derivative **11b**. The formation of **3b** and **5b** (Nu = MeO) is again explained by the mechanistic hypothesis of Scheme 1 with the following difference: the intermediate hydroxylamine is not protonated (see structure **7b**). Therefore, (*i*) path A does not occur at all since unprotonated arylhydroxylamines are not reducible (3)

and (*ii*) the dehydration of unprotonated hydroxylamine **7b** to the diiminoquinonium cation **4b** occurs by elimination of OH$^-$. Such elimination would be expected to be slower than in acidic medium (acid-catalyzed elimination of H$_2$O from **2b** (see path B in Scheme 1)). Assuming that the low material balance after chromatographic separation (36%) is due to polymerization and (or) oligomerization of the diiminoquinonium cation **4b**, which occurs also in basic medium (the crude material balance is again close to 100%), the elimination of OH$^-$ from hydroxylamine **7b** would be faster than the condensation between **7b** and its nitroso precursor (structure not shown), a well-documented reaction in the electroreduction of arylnitro groups (3) in basic medium; rate of elimination : rate of condensation ~ 73:27. The hydroxylamine–nitroso coupling gives the azoxy derivative first, which is reduced to the azo compound **11b** at the electrolysis potential (3). Azo compounds are more easily reducible than azoxy compounds (3), and **11b** is immediately reduced to the hydrazo derivative during the electrolysis. The latter is rapidly oxidized back to the azo compound **11b** in the presence of oxygen during the basic work-up (3), and the azo derivative **11b** was isolated in 27% yield. The hydroxylamine–nitroso condensation is much slower in acidic medium (3) and did not occur during the electroreduction of **1b** under acidic conditions discussed above. It was not observed either during the electroreduction of 5-nitroindole (**1a**) in basic medium (2) because the dehydration of the unprotonated hydroxylamine **7a**, being base catalyzed (abstraction of the proton at position 1 by OH$^-$), is much faster than the nitroso–hydroxylamine coupling reaction. Finally, the low yield of 1-methyl-5-aminoindole (**3b**) and of 1-methyl-4-methoxy-5-aminoindole (**5b**) shows that polymerization and (or) oligomerization of the diiminoquinonium cation **4b** (about 64% of the reaction products) is faster than its reaction with nucleophiles (path D of Scheme 1) and its reduction (path C) (9% of reaction products).

Preparative electrolyses of 5-nitrobenzofurane (1c)

The results of preparative electroreduction of 5-nitrobenzofurane (**1c**) at Hg, in MeOH–H$_2$O (95:5 volume fraction) solutions, are presented in Table 3. In acidic medium (entries 1 to 3), the electrochemical reduction of 5-nitrobenzofurane (**1c**) gives 4-substituted-5-aminobenzofuranes (**5c**: Nu = Br, OCH$_3$, SPh) as the major products (Scheme 1). They represent 70%–100% of the isolated products. The other products isolated are 5-aminobenzofurane

Table 3. Electroreduction of 5-nitrobenzofurane (**1c**) (6×10^{-3} mol L^{-1} solution) at Hg in MeOH–H_2O (95:5 volume fraction).

[g]Azo derivative **11c** was isolated in a 69% yield.

Scheme 3.
(**3c**) (6% in entry 1, 18%–27% in entry 3) and *cis*- and *trans*-2,3-dihydro-2,3-dimethoxy-5-aminobenzofurane (see **12** in Scheme 3) (trace amounts of *trans* isomer in entry 2 and 11%–18% of a mixture of *cis* and *trans* isomers (*cis*:*trans* = 0.66) in entry 3). The aminofuranes **3c** and **5c** must be formed through the same mechanistic pathways (Scheme 1, X = O) as those discussed above for the electroreduction of 5-nitroindole (**1a**) (2) and 1-methyl-5-nitroindole (**1b**) (Scheme 1, X = NH and NCH$_3$, respectively). The dimethoxy derivatives **12** could have been formed as described in Scheme 3 — addition of a first molecule of methanol to the dication **4cH$^+$**, followed by the addition of a second methanol molecule on the resulting dication **13** — which would be faster than deprotonation of **13** since 3-methoxy-5-aminobenzofurane (**14**) was not detected. The charge of about 4 F mol^{-1} in the first three entries of Table 2 correlates very well with the fact that the main products isolated are 4-substituted-5-aminobenzofuranes (**5c**), the formation of which involves four electrons (Scheme 1, paths B and D). These results also show that the acid-catalyzed dehydration of the protonated hydroxylamine **2c** (path B) is faster than its reduction to **3c** (path A), as for the electroreduction of **1a** and **1b**. The material balance, after chromatographic separation, is higher with 5-nitrobenzofurane (**1c**) (Table 3: 83%, 79%, and 78% in entries 1, 2, and 3, respectively) than with 1-methyl-5-nitroindole (**1b**) (Table 2:

57%, 32%, and 53% in entries 1, 2, and 3, respectively) (the material balance before separation was 100%, as in the electroreduction of **1b**). This difference in material balance strongly suggests that the cationic intermediate **4c** has a lesser tendency to polymerize and (or) oligomerize and (or) is more reactive towards nucleophiles (paths D of Scheme 1) than the cationic intermediate **4b**. The diprotonated intermediate **4cH$^+$** would also be more reactive towards nucleophiles than the diprotonated intermediate **4bH$^+$**. Moreover, when a nucleophile other than methanol is also present in the reaction medium (is competing with methanol), the relative amount of methoxy derivative (Nu = OCH$_3$) in the 4-substituted-5-amino derivatives **5** is higher in the benzofurane series **c** (17% (MeOH vs. Br$^-$) in entry 1 of Table 3, 96% (MeOH vs. PhSH) in entry 3) than in the indole series **b** (0% (MeOH vs. Br$^-$) in entry 1 of Table 2, 23% (MeOH vs. PhSH) in entry 3). This can be readily explained by the fact that the cation **4c** and dication **4cH$^+$** would be harder electrophiles than cation **4b** and dication **4bH$^+$**, oxygen being more electronegative than nitrogen and MeOH being a harder nucleophile than Br$^-$ and PhSH for electronegativity reasons as well. When the electrolysis of 5-nitrobenzofurane (**1c**) was carried out in acidic medium in the presence of cyclopentadiene in excess (8 equiv), the cycloadduct **15** was isolated in a low yield of 7% (Scheme 4). As seen above, the yield of cycloadduct **10a** was 32% for the electrolysis of 1-methyl-5-nitroindole (**1b**) carried out under the same conditions (Scheme 2). This difference in yield of cycloaddition is readily explained again by the greater reactivity of cationic electrophiles **4c** and (or) **4cH$^+$** towards the hard nucleophile methanol when compared with the reactivity of the softer cationic electrophiles **4b** and (or) **4bH$^+$**. Cyclopentadiene is a much softer nucleophile than methanol. It must be noted that cations **4c** and (or) **4cH$^+$** act as dienophiles (2-electron partner) at the 5,6 positions in a Diels–Alder reaction ([$\pi^4 s + \pi^2 s$] cycloaddition) with cyclopentadiene (Scheme 4), whereas cations **4b** and (or) **4bH$^+$** act as the 6-electron component (fulvene moiety) in a [$\pi^6 s + \pi^4 s$] cycloaddition, as already seen (Scheme 2).

In basic medium (Table 3, entry 4), the electroreduction of 5-nitrobenzofurane (**1c**) gave the azo derivative **11c** as the main product (69%) and some 5-aminobenzofurane (**3c**) (10%). Since unprotonated arylhydroxylamines are not re-

Scheme 4.
ducible in protic medium, as already mentioned (3), 5-aminobenzofurane (**3c**) must have been formed by reduction of the cationic intermediate **4c** (path C of Scheme 1). No methoxy derivative such as **5c** (Nu = OCH$_3$), resulting from the addition of a methoxide anion to **4c** (path D), was observed. This shows that, in basic medium, the reduction of **4c** is faster than its reaction with methoxide ions and (or) methanol. Moreover, elimination of OH$^-$ from hydroxylamine **7c** to give the cationic intermediate **4c** is slower than the hydroxylamine–nitroso coupling reaction, leading ultimately to the isolation of azo derivative **11c**. In the case of hydroxylamine **7b**, the elimination of OH$^-$ to form **4b** was faster than the coupling reaction, as seen above. This difference in reactivity between **7c** and **7b** can be ascribed to the fact that oxygen is more electronegative than nitrogen, the cationic intermediate **4c** being more difficult to form (having a higher enthalpy) than intermediate **4b**.

Preparative electrolyses of 5-nitrobenzothiophene (1d)

The results of preparative electroreduction of 5-nitrobenzothiophene (**1d**) under the same conditions as those used for the electroreduction of the two other nitro compounds, **1b** and **1c**, are presented in Table 4. Those results are similar to those reported in Table 3 for the electroreduction of 5-nitrobenzofurane (**1c**) for both acidic and basic media (charge passed, yields, and relative proportion of 5-amino product **3** and of 4-substituted-5-amino derivative **5**), except that no dimethoxy derivative analogous to **12** was detected in the products of electroreduction of 5-nitrobenzothiophene (**1d**) in acidic medium (compare entries 2 and 3 in Table 4 with entries 2 and 3, respectively, in Table 3). Another slight difference in reactivity was noted when the electroreduction of 5-nitrobenzothiophene (**1d**) in acidic medium was carried out in the presence of cyclopentadiene under the same conditions as those used with 5-nitrobenzofurane (**1c**). No cycloadduct analogous to **15** (or any other possible adduct) was detected (**15** was isolated in a low 7% yield from the electroreduction of **1c**). So the mechanisms must be the same for the three nitro compounds (see Scheme 1), and the reactivities of the various intermediates (**2d**, **4d** and **4dH**$^+$, **7d**) must be comparable to those of the related intermediates involved in the reduction of 5-nitrobenzofurane (**1c**). This close similarity seems surprising since sulphur is less electronegative and is a third-row element.

Regioselectivity of ring substitution

A very interesting aspect of the electroreduction of 5-nitroindoles **1a** and **1b** and of the related 5-nitrobenzofurane

(**1c**) and 5-nitrobenzothiophene (**1d**) is the high regioselectivity of the addition of nucleophiles (*i*) to cationic intermediates **4a**–**4aH**$^+$ (2), **4b**–**4bH**$^+$, **4c**–**4cH**$^+$, and **4d**–**4dH**$^+$ (this work) in acidic medium and (*ii*) to neutral intermediate **8** (2), as well as to cationic intermediates **4b**, **4c**, and **4d** in basic medium (this work). The addition occurs exclusively at carbon 4 and not at the other electrophilic positions (positions 2, 3, 6, and 7) except (*i*) for the addition of methanol to **4c** and (or) **4cH**$^+$ (Table 3, entry 2) in acidic medium with a regioselectivity of about 83%, some addition taking place at carbon 2 of **4cH**$^+$ (see Scheme 3) and (*ii*) for the addition of PhSH to cationic intermediates **4a** and (or) **4aH**$^+$ with a regioselectivity of 62% (38% of 3-thiophenoxy derivative **5a**) (2) and to intermediates **4b** and (or) **4bH**$^+$ with a regioselectivity of 50% (50% of 3-thiophenoxy derivative **5b**) (Table 2, entry 3).

According to frontier molecular orbital theory, the most important frontier orbital interaction in a reaction between an electrophile and a nucleophile (5, 6) is that between the LUMO of the electrophile and the HOMO of the nucleophile. In the case of the addition of a nucleophile to a multivalent electrophile, the reaction would be the fastest at the carbon where the coefficient of the LUMO is the largest (5, 6). The results of theoretical calculations using the AM1 method (7, 8) on intermediates **4** (Scheme 1) and their conjugate acids **4H**$^+$ are gathered in Table 5. They show that the LUMO of unprotonated intermediates **4** and protonated **4H**$^+$ have the largest coefficient on carbon 4, which agrees entirely with the experimental results: the regioselective formation of 4-substitued-5-amino derivatives **5** in acidic media. However, the largest coefficient of the LUMO of the protonated intermediate **6** (reduction of 5-nitroindole (**1a**)) is on carbon 6 (2). Although calculations give a slightly higher gas-phase enthalpy of formation for cationic intermediate **4a** (257.6 kcal mol^{-1}) than for cationic intermediate **6** (255.4 kcal mol^{-1}) (2), the similarity of the experimental results obtained with 5-nitroindole (**1a**) (2) and 1-methyl-5-nitroindole (**1b**) (the cationic intermediate **4b** is the sole possible) and the calculated largest coefficient on carbon 4 strongly suggest the participation of intermediate **4a** and (or) **4aH**$^+$ instead of intermediate **6** in the electroreduction of **1a**. As for the low regioselectivity of substitution observed in the electroreduction of 5-nitroindole (**1a**) (62%) and 1-methyl-5-nitroindole (**1b**) (50%) in acidic medium in the presence of thiophenol, it would be surprising that it would be because of the fact that the addition of thiophenol to **4a**–**4aH**$^+$ and **4b**–**4bH**$^+$ would be much less regioselective than the addition of the other nucleophiles (bromide ion and methanol). One possibility is that the addition of thiophenol would occur regioselectively at position 4 of **4a**–**4aH**$^+$ and **4b**–**4bH**$^+$. Then there would be a competition between deprotonation of the initial adduct **16** to give the 4-thio-

[a]C$_2$, C$_3$, etc. correspond to the numbering of carbons of indole, benzofurane, and benzothiophene (see **1**, Scheme 1).

phenoxy derivative **5** (Nu = SPh) and rearrangement of **16** into adduct **17** as shown in Scheme 5 for the monocationic intermediates **4**. Deprotonation of **17** would give the 3-thiophenoxy derivatives **9**. Interestingly, the electroreduction of 5-nitroindole (**1a**) in the presence of thiophenol in basic medium was reported to give 59% of 4-thiophenoxy-5-aminoindole (**9a**) as the sole substitution product (2), which then means that the addition of a thiophenolate anion to diiminoquinone **8** is 100% regioselective, as with the other nucleophiles, and occurs solely at position 4. The AM1 calculations once more agree with this result; the LUMO of the neutral diiminoquinone **8** has the largest coefficient on carbon 4 (2).

Conclusion

In this paper, we have shown that the electroreduction of 1-methyl-5-nitroindole (**1b**), 5-nitrobenzofurane (**1c**), and 5-nitrobenzothiophene (**1d**) at Hg, in acidic hydromethanolic media, gives the corresponding 4-substituted amino derivatives **5b**, **5c**, and **5d** in good yields and high regioselectivity. The proposed mechanism (Scheme 1) involves first the electroreduction of the nitro substrate **1** to the corresponding protonated hydroxylamine **2**, which is quickly dehydrated to an electrophilic quinonic intermediate **4**–**4H$^+$** (step B). The latter reacts with nucleophiles present in the medium (step D) faster than it is reduced to the corresponding amino compound **3** (step C). The mechanism was confirmed by unequivocal trapping of the intermediates diiminoquinonium cation **4b**–**4bH$^+$** and iminoquinonium cation **4c**–**4cH$^+$**, via a

Scheme 5.

a: R = H
b: R = CH$_3$
pericyclic reaction with cyclopentadiene in the electrolysis of 1-methyl-5-nitroindole (**1b**) (Scheme 2), and 5-nitrobenzofurane (**1c**) (Scheme 4) in acidic medium. The material balance was always lower than 100% after chromatographic separation. This has been attributed to a competition between, on the one hand, reduction of the intermediate quinonium species **4** and its reaction with nucleophiles (steps C and D) and, on the other hand, their polymerization and (or) oligomerization. The electro-

reduction of all of the nitro compounds **1** in basic medium gives the corresponding azo derivative **11** as the major product. In the case of 5-nitrobenzofurane (**1c**) and 5-nitrobenzothiophene (**1d**), the hydroxylamine–nitroso coupling reaction is faster than dehydration of the hydroxylamine in basic medium. It is slower in the case of 1-methyl-5-nitroindole (**1b**), and the main process in basic medium is polymerization and (or) oligomerization of **4b**.

Experimental

General information

All commercially available chemicals were purchased from Aldrich and BDH, and all the solvents were distilled before use. Infrared spectra were recorded in chloroform on a PerkinElmer 1600 FT-IR spectrometer, and nuclear magnetic resonance spectra were recorded in deuterochloroform or deuteroacetone on a Bruker AC-300 spectrometer using the signal from chloroform or acetone as reference (s = singlet, d = doublet, t = triplet, q = quartet, dd = doublet of doublets, m = multiplet). Vapor phase chromatography was performed on a Hewlett-Packard (HP) 5710A chromatograph with an FID detector, an HP 3390A integrator, and a DB-5 fused silica capillary column (30 m). High resolution mass spectra were recorded on a ZAB-2F model VG apparatus. Flash chromatography was carried out on Silicycle Inc. silica gel (70–230 mesh). Solutions for all electrochemical experiments were deoxygenated by bubbling dry argon through them for 15 min, and an argon atmosphere was maintained throughout the experiments. The cyclic voltammetry (CV) experiments were performed using a Princeton Applied Research PAR 273 potentiostat in a single compartment cell with 7 mL of 0.25 mmol L^{-1} solutions of the substrate in methanol–water (95:5 volume fraction) containing the supporting electrolyte (see Table 1). No correction was applied to compensate for the solution resistance. The voltammograms were recorded and processed using EG&G software M270. The working electrode was a mercury hanging drop Metrohm, model E410. A glassy carbon rod was used as the counter electrode and an Ag/AgCl/(Cl$^-$)$_{dil}$ electrode, the potential of which was adjusted to that of an SCE, served as the reference. The controlled potential electrolyses were carried out on a mercury pool, in a vertical glass cell with two concentric compartments separated by a fritted glass, using an Electrosynthesis Company (ESC) 410 potentiostat with an ESC 640 coulometer and an ammeter connected in series within the auxiliary circuit. The volume of the cathodic compartment was 45 mL and that of the anodic compartment 10 mL. The same reference electrode as the one described above was used, and a platinum grid was used as the counter electrode. The other conditions are given in Tables 2–4.

Computational procedure

All calculations were performed at the RHF level using the AM1 method (7, 8). The first input files for MOPAC 6.00 were created by means of SYBIL 6.01 (Tripos Associates, Inc., St-Louis, Mo.) for IBM RS/6000 computers. The gradients of the norm of these draft structures were then fully optimized using the EF subroutine. The AM1 method

was considered more adequate than the PM3 method for calculations on cationic species.

Substrate and authentic sample synthesis

All prepared compounds had spectral and physical characteristics identical to those reported in the literature.

1-Methyl-5-nitroindole (**1b**) was prepared by alkylation of commercially available 5-nitroindole (**1a**) with iodomethane (9). 5-Nitrobenzofurane (**1c**) was synthesized by nitration (10) and decarboxylation (11) of coumarillic acid, previously prepared by the method of Suzuki et al. (12). 5-Nitrobenzothiophene (**1d**) was prepared by the method of Zambias and Hammond (13).

1-Methyl-5-aminoindole (**3b**) was synthesized by reduction of 1-methyl-5-nitroindole (**1b**) by NaBH$_2$S$_3$ (14) and was used as an authentic sample. To a suspension of freshly prepared NaBH$_2$S$_3$ (15) (300 mg, 2.28 mmol) in THF (70 mL), a solution of 1-methyl-5-nitroindole (**1b**) (200 mg, 1.14 mmol) in anhydrous THF was slowly added. The mixture was refluxed for 24 h. The solvent was removed at room temperature under reduced pressure, and a solid residue was obtained. The crude material was hydrolyzed with HCl (1 mol L^{-1}) in the presence of diethyl ether. The solids were filtered and rinsed with diethyl ether. The filtrate was basified to pH 11 with NaOH (1 mol L^{-1}). The aqueous phase was extracted with diethyl ether. The organic phase was washed with brine, and the organic phases were combined, dried (Na$_2$SO$_4$), and filtrated. The solvent was evaporated under vacuum, and a dark oil was obtained. After flash chromatography on silica gel, 67 mg of 1-methyl-5-aminoindole (**3b**) were obtained (40% yield) as a dark oil (lit. (15) mp = 100–101 °C). IR (CHCl$_3$) (cm^{-1}) : 3005 (CH aro), 2930 (CH ali), 1630 (C=C), 1497 (C=C), 1455 (CH$_3$), 1250 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 7.17 (1H, d, J = 8.6, H7), 7.14 (1H, d, J = 2.2, H4), 7.00 (1H, d, J = 3.0, H2), 6.86 (1H, dd, J = 2.2, J = 8.6, H6), 6.34 (1H, d, J = 3.0, H3), 3.73 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 139.1, 131.8, 129.1, 128.0, 112.5, 109.7, 105.7, 99.5, 32.8. HR-MS, m/z: calcd. for C$_9$H$_{10}$N$_2$: 146.0844; found: 146.0849.

Typical electrolysis procedure

Electroreduction of 1-methyl-5-nitroindole (**1b**) in acidic HBr medium (entry 1, Table 2). Argon was bubbled through the cathodic compartment containing the electrolyte for 1 h, and an argon atmosphere was maintained throughout the electrolysis. A pre-electrolysis was performed at –0.54 V vs. SCE until the current was 0.1 mA or less. The circuit was opened, then **1b** (48.9 mg, 0.27 mmol) was added to the catholyte. The potential was applied, and the electrolysis was stopped when the current had dropped to 0.1 mA or less. The electrolysis solution was transferred to a round-bottomed flask, the cell was washed with methanol and water, and methanol was removed on a rotatory evaporator. The pH of the resulting solution was brought to 12 with aqueous NaOH (1 mol L^{-1}); the solution was saturated with NaCl and extracted with ether (4 × 50 mL). The organic phase was washed with brine, dried (Na$_2$SO$_4$), and the solvent removed under vacuum. The crude materiel was purified by flash chromatography on silica gel (elution with 20% volume

fraction AcOEt–hexanes) to give 35.4 mg of **5b** (Nu = Br) (57% yield).

The crude product from the electroreduction of 5-nitrobenzofurane (**1c**) was acetylated by acetic anhydride in ethyl acetate before chromatographic separation, and the amino compounds were isolated as their *N*-acetyl derivative. The acetylation was quantitative.

1-Methyl-4-methoxy-5-aminoindole (5b, Nu = MeO)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 2930 (CH ali.), 1501 (C=C), 1446 (CH$_3$), 1265 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 6.94 (1H, d, J = 3.1, H2), 6.90 (1H, d, J = 8.4, H7 or H6), 6.76 (1H, d, J = 8.4, H6 or H7), 6.45 (1H, d, J = 3.1, H3), 4.02 (3H, s, O-CH$_3$), 3.72 (3H, s, N-CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 135.7, 133.3, 129.9, 128.4, 113.3, 112.1 104.8, 96.8, 58.5, 33.0. HR-MS, *m/z*: calcd. for C$_{10}$H$_{12}$N$_2$O: 176.0950; found: 176.0953.

1-Methyl-4-thiophenoxy-5-aminoindole (5b, Nu = PhS)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3001 (CH aro.), 2946 (CH ali.), 1613 (C=C), 1505 (C=C), 1253 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 7.25 (1H, d, J = 8.6, H6), 7.18–7.14 (2H, m, H phenyl), 7.07–7.03 (3H, m, H phenyl), 6.98 (1H, d, J = 3.0, H2), 6.82 (1H, d, J = 8.6, H7), 6.44 (1H, d, J = 3.0, H3), 3.76 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 142.8, 137.1, 129.6, 128.8, 128.5, 127.9, 127.3, 126.0, 124.8, 112.2, 111.9, 100.0, 33.0 (CH$_3$). HR-MS, *m/z*: calcd. for C$_{15}$H$_{14}$N$_2$S: 254.0878; found: 254.0884.

4-Bromo-5-acetamidobenzofurane (acetylated 5c, Nu = Br)

Beige solid. mp = 160–161 °C. IR (CHCl$_3$) (cm^{-1}): 3416 (NH), 3010 (CH aro.), 1693 (C=O), 1518 (NH), 1432 (CH$_3$), 1252 (C-O), 1211 (C-N). ^{1}H NMR (300 MHz, acetone-d$_6$) (ppm) δ: 8.66 (1H, m, NH), 7.94 (1H, d, J = 2.2, H2), 7.81 (1H, d, J = 8.8, H4), 7.52 (1H, d, J = 8.8, H6), 6.87 (1H, d, J = 2.2, H3), 2.08 (3H, s, CH$_3$). ^{13}C NMR (acetone-d$_6$) (ppm) δ: 168.4 (C=O), 146.1, 119.4, 110.8, 107.2, 151.2, 131.1, 129.0, 105.6, 24.6. HR-MS, *m/z*: calcd. for C$_{10}$H$_8$NO$_2$Br: 252.9738; found: 252.9743.

4-Methoxy-5-acetamidobenzofurane (acetylated 5c, Nu = MeO)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3426 (NH), 3320 (NH), 3006 (CH aro.), 2947 (CH ali.), 2838 (CH$_2$), 1677 (C=O), 1597 (C=C), 1544 (NH), 1254 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.20 (1H, d, J = 8.9, H7), 7.75 (1H, m, NH), 7.52 (1H, d, J = 2.3, H2), 7.15 (1H, d, J = 8.9, H6), 6.87 (1H, d, J = 2.3, H3), 4.08 (3H, s, O-CH$_3$), 2.08 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 168.2, 144.4, 118.0, 115.3, 103.4, 153.0, 141.8, 123.7, 117.1, 59.9, 24.6. HR-MS, *m/z*: calcd. for C$_{11}$H$_{11}$NO$_3$: 205.0739; found: 205.0742.

4-Thiophenoxy-5-acetamidobenzofurane (acetylated 5c, Nu = PhS)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3476 (R$_2$N-H), 3367 (R$_2$N-H), 3009 (C-H arom.), 1679 (C=O amide), 1613, 1582 (C=C), 1215 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.56 (1H, m, NH), 8.24 (1H, d, J = 8.6 Hz, H7), 7.45 (1H, d, J = 8.8 Hz, H6), 7.20 (1H, M, H2), 7.16 (2H, d, J = 7.7 Hz, H phenyl), 7.05 (3H, m, H phenyl), 6.58 (1H, M, H3), 2.09 (3H, s, CH$_3$-). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 168.4 136.0, 133.9, 132.7, 131.6, 129.1, 126.6, 126.0, 125.6, 116.2, 113.2, 102.7, 24.7. HR-MS, *m/z*: calcd. for C$_{16}$H$_{13}$NO$_2$S: 282.0827; found: 282.0833.

4-Bromo-5-aminobenzothiophene (5d, Nu = Br)

Dark oil. IR (acetone) (cm^{-1}): 3464 (NH), 3001 (CH aro.), 1623 (C=C), 1502 (C=C). ^{1}H NMR (300 MHz, CD$_3$OD) (ppm) δ: 7.57 (1H, d, J = 8.7, H7), 7.54 (1H, d, J = 5.7, H2), 7.27 (1H, d, J = 5.5, H3), 6.92 (1H, d, J = 8.6, H6). ^{13}C NMR (75 MHz, CD$_3$OD) (ppm) δ: 143.5, 141.5, 131.0, 128.8, 124.4, 122.8, 116.2, 102.6. HR-MS, *m/z*: calcd. for C$_8$H$_6$NSBr: 226.9404; found: 226.9409.

4-Methoxy-5-aminobenzothiophene (5d, Nu = MeO)

Dark oil. IR (acetone) (cm^{-1}): 3459 (NH), 3005 (CH aro.), 2937 (CH ali.), 1620 (C=C), 1509 (C=C), 1454 (CH$_3$). ^{1}H NMR (300 MHz, CD$_3$OD) (ppm) δ: 7.44 (1H, d, J = 5.5, H2), 7.39 (1H, d, J = 8.5, H7), 7.31 (1H, d, J = 5.5, H3), 6.92 (1H, d, J = 8.6, H6), 4.91 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CD$_3$OD) (ppm) δ: 143.0, 137.0, 135.5, 132.9, 127.5, 120.4, 119.2, 117.4, 60.8. HR-MS, *m/z*: calcd. for C$_9$H$_9$NOS: 179.0405; found: 179.0399.

4-Thiophenoxy-5-aminobenzothiophene (5d, Nu = PhS)

Dark oil. IR (acetone) (cm^{-1}): 3494 (NH), 3004 (CH aro.), 1616 (C=C). ^{1}H NMR (300 MHz, CD$_3$OD) (ppm) δ: 7.71 (1H, d, J = 8.6, H7), 7.46 (1H, d, J = 5.5, H2), 7.34 (1H, d, J = 5.5, H3), 7.17–7.12 (2H, m, H phenyl), 7.07–6.95

(4H, m, H6 and H phenyl). ^{13}C NMR (75 MHz, CD$_3$OD) (ppm) δ: 149.4, 145.9, 138.2, 130.8, 129.9, 128.8, 127.2, 126.2, 125.8, 124.3, 115.8, 106.9. HR-MS, *m/z*: calcd. for C$_{14}$H$_{11}$NS$_2$: 257.0333; found: 257.0339.

1-Methyl-3-thiophenoxy-5-aminoindole (9b)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3004 (CH aro.), 2974 (CH ali.), 1627 (C=C), 1493 (CH$_3$), 1241 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 7.24 (1H, s, H2), 7.19 (1H, d, *J* = 8.6, H7), 7.15–7.09 (2H, m,, H phenyl), 7.07–7.03 (3H, m, H phenyl), 6.93 (1H, d, *J* = 2.2, H4), 6.78 (1H, dd, *J* = 2.2, *J* = 8.6, H6), 3.78 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 140.5, 139.9, 135.4, 132.4, 131.0, 128.6, 125.4, 124.5, 113.2, 110.4, 104.3, 98.5. HR-MS, *m/z*: calcd. for C$_{15}$H$_{14}$N$_2$S: 254.0878; found: 254.0884.

Compound 10b (cyclopentadiene cycloadduct)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3431 (NH), 3359 (NH), 3001 (CH aro.), 2946 (CH ali.), 1506 (C=C), 1456 (CH$_3$), 1256 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 6.92 (1H, d, *J* = 8.4, H7), 6.66 (1H, s, H2), 6.63 (1H, d, *J* = 8.4, H6), 5.95–5.92 (2H, m, H9 and H10), 3.81–3.77 (1H, m, H11 or H8), 3.71–3.69 (1H, m, H8 or H11), 3.65 (3H, s, CH$_3$), 2.48–2.41 (1H, m, H12b), 1.99 (1H, d, *J* = 9.8, H12a). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 130.8, 132.3, 130.5, 124.8, 121.1, 117.1, 113.9, 112.7, 108.2, 39.4, 38.7, 44.1, 32.7. HR-MS, *m/z*: calcd. for C$_{14}$H$_{14}$N$_2$: 210.1157; found: 210.1299.

Azo compound 11b

Yellow solid. mp = 196–198 °C. IR (CHCl$_3$) (cm^{-1}): 3007 (CH aro), 2946 (CH ali), 1613 (C=C), 1490 (C=C), 1449 (CH$_3$), 1237 (C-N). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.25 (2H, d, *J* = 1.7, H4 and H4′), 7.94 (2H, dd, *J* = 8.3, *J* = 1.7, H6 and H6′), 7.40 (2H, d, *J* = 8.8, H7 and H7′), 7.11 (2H, d, *J* = 3.1, H2 and H2′), 6.64 (2H, d, *J* = 3.1, H3 and H3′), 3.85 (6H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 130.0, 118.3, 115.3, 109.5, 102.9, 147.1, 137.9, 128.5, 33.2. HR-MS, *m/z*: calcd. for C$_{18}$H$_{16}$N$_4$: 288.1375; found: 288.1371.

Azo compound 11c

Orange solid. mp = 160–162 °C. IR (CHCl$_3$) (cm^{-1}): 3020 (CH aro), 1454 (C=C), 1269 (C-O), 1095 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.09–7.93 (6H, m, H2, H2′, H4, H4′, H7 and H7′), 7.71 (2H, d, *J* = 8.8, H6 and H6′), 7.09 (2H, d, *J* = 2.2, H3 and H3′). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 146.9, 119.3, 117.2, 112.1, 107.8, 156.7, 149.4, 128.4. HR-MS, *m/z*: calcd. for C$_{16}$H$_{10}$N$_2$O$_2$: 262.0742; found: 262.0747.

Azo compound 11d

Orange solid. mp = 165–166 °C. IR (CHCl$_3$) (cm^{-1}): 3018 (CH aro), 1463 (C=C). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.42 (2H, s, H4 and H4′), 8.10–7.95 (4H, m, H2, H2′, H7 and H7′), 7.58–7.49 (4H, m, H3, H3′, H6 and H6′). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 150.2, 140.2, 131.8, 129.7, 124.9, 123.0, 120.3, 117.4. HR-MS, *m/z*: calcd. for C$_{16}$H$_{10}$N$_2$S$_2$: 294.0285; found: 294.0290.

trans-*2,3-Dimethoxy-2,3-dihydro-5-acetamidobenzofurane* (trans *12*)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3437 (NH), 3011 (CH aro.), 1684 (C=O), 1490 (C=C), 1230 (C-N), 1194 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 7.67 (1H, d, *J* = 2.3, H4), 7.25 (1H, dd, *J* = 2.3, *J* = 8.6, H6), 7.08 (1H, broad peak, NH), 6.83 (1H, d, *J* = 8.6, H7), 5.41 (1H, s, H2), 4.64 (1H, s, H3), 3.54 (3H, s, OCH$_3$), 3.43 (3H, s, OCH$_3$), 2.15 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 168.3, 156.5, 144.8, 131.5, 123.3, 119.2, 111.2, 110.8, 85.1, 56.4, 56.2, 24.4. HR-MS, *m/z*: calcd. for C$_{12}$H$_{15}$NO$_4$: 237.1001; found: 237.1005.

cis-*2,3-Dimethoxy-2,3-dihydro-5-acetamidobenzofurane* (cis *12*)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3437 (NH), 3009 (CH aro.), 1685 (C=O), 1490 (C=C), 1210 (C-N), 1202 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 7.55 (1H, d, *J* = 2.2, H4), 7.00 (1H, dd, *J* = 2.2, *J* = 8.5, H6), 7.12 (1H, broad peak, NH), 6.77 (1H, d, *J* = 8.5, H7), 5.48 (1H, d, *J* = 5.2, H2), 4.87 (1H, d, *J* = 5.2, H3), 3.63 (3H, s, OCH$_3$), 3.52 (3H, s, OCH$_3$), 2.14 (3H, s, CH$_3$). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 168.2, 154.1, 131.5, 126.0, 123.1, 118.9, 110.5, 106.8, 79.9, 58.2, 57.2, 29.7. HR-MS, *m/z*: calcd. for C$_{12}$H$_{15}$NO$_4$: 237.1001; found: 237.1003.

Acetylated compound 15 (acetylated cycloaddition product)

Dark oil. IR (CHCl$_3$) (cm^{-1}): 3001 (CH aro.), 1654 (C=O), 1468 (CH$_2$), 1437 (CH$_3$). ^{1}H NMR (300 MHz, CDCl$_3$) (ppm) δ: 8.25 (1H, m, NH), 7.59 (1H, d, *J* = 2.3, H2), 7.30 (1H, d, *J* = 9.3, H4), 6.82 (1H, d, *J* = 2.3, H3), 5.82 (1H, dd, *J* = 2.4, *J* = 5.5, H6), 5.16 (1H, m, H7), 3.79 (2H, m, H5 and H8), 2.45 (3H, s, CH$_3$), 2.30 (2H, m, H9). ^{13}C NMR (75 MHz, CDCl$_3$) (ppm) δ: 170.3, 150.7, 130.5, 125.2, 124.3, 116.1, 145.2, 139.3, 120.6, 108.9, 104.8, 60.2, 41.0, 37.3, 25.3. HR-MS, *m/z*: calcd. for C$_{15}$H$_{13}$NO$_2$: 239.0946; found: 239.0951.

Orthogonene: A computational study of a strongly twisted alkene

E. Lewars

Abstract: The strongly twisted (calculated dihedral angle 84°) alkene orthogonene (tetracyclo[8,2,2,0^{2,7},0^{3,10}]tetradecene-2(3)) was studied at the DFT (B3LYP/6-31G*) and ab initio (HF/6-31G* and MP2(fc)/6-31G*) levels with a view to exploring the question of how realistic a synthetic objective it is, particularly in view of the fact that an attempt was made to synthesize it. Orthogonene is a relative minimum on the potential energy surface at the B3LYP/6-31G* and MP2(fc)/6-31G* levels, but is predicted to have a very low barrier (1.2 kJ mol^{-1} from the B3LYP calculations) to rearrangement by a 1,2-carbon shift to a carbene, which in turn isomerizes to a cyclopropane and (or) an alkene (the carbene is perhaps not a stationary point on the potential energy surface). Thus, very likely orthogonene could be observed only at temperatures approaching absolute zero, if at all.

Key words: orthogonene, tetracyclo[8,2,2,0^{2,7},0^{3,10}]tetradecene-2(3), twisted double bond, orthogonal double bond, carbene-strained alkene isomerization, ab initio, DFT.

Résumé : Faisant appel à des calculs théoriques aux niveaux DFT (B3LYP/6-31G*) et ab initio (HF/6-31G* et MP2(fc)/6-31G*), on a étudié l'alcène orthogonène {tétracyclo[8.2.2.0^{2,7},0^{3,10}]tétradéc-2(3)-ène} qui est fortement déformé dans le but d'évaluer s'il est réaliste d'espérer réaliser la synthèse de ce composé, surtout en tenant compte du fait qu'un tel essai a déjà été tenté. L'orthogonène est un minimum relatif sur la surface d'énergie potentielle aux niveaux DFT (B3LYP/6-31G*) et MP2(fc)/6-31G*, mais les calculs B3LYP prédisent que la barrière est très faible (1,2 kJ mol^{-1}) pour son réarrangement en carbène (par le biais d'un déplacement 1,2 de carbone) qui subit une isomérisation ultérieure en cyclopropane et/ou en un alcène (le carbène n'est peut-être pas un point stationnaire sur la surface d'énergie potentielle). Sur cette base, on peut en conclure que si cela peut se faire, l'orthogonène ne pourrait vraisemblablement être observé qu'à des températures s'approchant du zéro absolu.

Mots clés : orthogonène, tétracyclo[8.2.2.0^{2,7},0^{3,10}]tétradéc-2(3)-ène, double liaison déformée, double liaison orthogonale, isomérisation carbène–alcène tendu, ab initio, DFT.

[Traduit par la Rédaction]

Introduction

One cornerstone of the structural theory of organic chemistry is that "the carbon—carbon double bond is flat", i.e., that the two carbons and the four attached groups lie in, or nearly in, a plane. Of course, when the molecule as a whole lacks a symmetry plane strict planarity is not expected. In CHF_2–CH=CH$_2$, for instance, in conformer **1a**, an H vs. an F breaks the symmetry of the two faces of the double bond; the calculated (B3LYP/6-31G*) double bond H-C=C-H dihedral angle is 0.4°. More interesting are cases in which nonplanarity, although not dictated by lack of symmetry nor imposed by steric conflict (1), is nonetheless found. Wagner et al. (2) showed, with ab initio calculations, that some strained alkenes, like bicyclo-1(3)butene, should be nonplanar (we find from B3LYP/6-31G* calculations an angle of 44° between the two CCC planes). This nonplanarity was discussed in terms of orbital overlap (2) and was analyzed in detail by Spangett-Larson and Gleiter (3). Pyramidalization of double bond carbons, which is what nonplanarity in bicyclic alkene systems amounts to, is a well-recognized phenomenon (4–7).

1a
Particularly fascinating would be a molecule designed to impose on a carbon—carbon double bond a twist of 90°; in the context of the σ/π model, this represents loss of *p/p* atomic orbital overlap (the σ/π model is not correct in any absolute sense, but it will be convenient to employ it here (8, 9)). Such a molecule was conceived almost two decades ago: orthogonene, **1** (Scheme 1), was explored both experimentally (10) and with semiempirical calculations (11) by Jeffrey and Maier (the synthesis failed some steps short of its goal). Concurring with these workers that this is an "exciting molecule" (11), I report here the results of a reasonably high-level ab initio and DFT study.

E. Lewars.[1] Department of Chemistry, Trent University, Peterborough, ON K9J 7B8, Canada. (e-mail: elewars@trentu.ca).

Scheme 1. Rearrangement pathways of orthogonene, **1**. The symmetry of species that were stationary points at the B3LYP/6-31G* and MP2(fc)/6-31G* levels (C_2 and C_1) is shown; the transition states had C_1 symmetry (at the HF/6-31G* level **1** was a TS with C_2 symmetry).
Computational methods

Calculations were done with Gaussian 98 for Windows (G98W) (12) and visualized with GaussView 2.1 for Windows (13) on a 933 MHz Pentium 3 or a 1.5 GHz Pentium 4 computer equipped with Microsoft Windows NT 4.00, 1 GB of memory, and 15 360 MB of scratch space. Ab initio (14) HF and DFT (15) B3LYP calculations were full geometry optimizations followed by frequency calculations (16), except for the calculation of vertical ionization energies, where a single-point calculation on the radical cation at the geometry of the neutral was done and zero-point energies (ZPEs) were not used. For calculating relative MP2 energies, energies from MP2(fc)/6-31G* optimizations were corrected with B3LYP/6-31G* frequencies because of the long times needed for calculating MP2/6-31G* frequencies on molecules of this size; the similarity of the MP2 and B3LYP ge-

ometries left little doubt that the former structures were relative minima (no attempt was made to locate transition states at the MP2 level). For orthogonene, MP2(fc)/6-31G* frequencies *were* calculated to confirm the curvature of the MP2(fc)/6-31G* potential energy surface at that stationary point (indeed a relative minimum). ZPEs from the frequency jobs were multiplied by the appropriate correction factors (0.9135 for HF/6-31G* and 0.9806 for B3LYP/6-31G*) recommended by Scott and Radom (17) and were added to the raw energies to give the ZPE-corrected energies. The two species connected by a transition state (a stationary point with one imaginary frequency) were identified by animation of the imaginary frequency with GaussView or, in ambiguous cases, by following the intrinsic reaction coordinate (IRC) well toward reactant and product (18). Absolute total energies, ZPEs, and ZPE-corrected energies are given in the supplementary material.[2]

Table 1. Relative energies (kJ mol^{-1}) of species in Scheme 1.

Species	HF/6-31G*	B3LYP/6-31G*	MP2(fc)/6-31G*
1	0	0	0
c1	–796.5	–602.3	Not a stationary point at this level: goes toward **cy1**
c2	–602.6	Not a stationary point at this level: goes toward **a1**	Not a stationary point at this level: goes toward **cy1**
cy1	–1057.7	–885.1	–883.4
a1	–1127.7	–953.2	–925.9
a2	–854.2	–713.5	–695.4
a3	–797.2	–676.1	–666.4
t1–c1	0 (**1** is a TS connecting two **c1** enantiomers)	+1.23	
t1–c2	**1** is a TS connecting two **c1** enantiomers	**c2** is not a stationary point at this level (**c2** goes toward **a1**)	
tc1–cy1	–757.4	–601.4	
tc1–a1	–738.6	–584.5	
tc1–a2	–645.2	–509.6	
tc1–a3	–489.3	–387.8	

Note: The location of transition states at the MP2(fc)/6-31G* level was not attempted.

Table 2. Activation energies (kJ mol^{-1}) for reactions of orthogonene **1** and the carbene **c1** (Scheme 1) based on relative energies in Table 1.

Reaction	HF/6-31G*	B3LYP/6-31G*	MP2(fc)/6-31G*
1 → c1	0 (**1** is a TS connecting two **c1** enantiomers)	1.2	**c1** is not a stationary point at this level: goes toward **cy1**
1 → c2	**1** is a TS, not a relative minimum, at this level	**c2** is not a stationary point at this level: goes toward **a1**	**c2** is not a stationary point at this level: goes toward **a1**
c1 → cy1	39.1	1.6	
c1 → a1	57.9	17.8	
c1 → a2	151.3	92.7	
c1 → a3	307.2	214.5	

Note: The location of transition states at the MP2(fc)/6-31G* level was not attempted.

Results and discussion

Preliminary survey

Intuitively (or from a general knowledge of the chemistry of strained alkenes), one suspects that the likeliest reactions of orthogonene will be isomerization to a carbene. In **1**, shift (migration) of a β-C — C5 moving to C2 (Scheme 1; the numbering pattern here is for convenience and does not reflect a systematic name) — would give the carbene **c1**, and the shift of C3 to C1 would give the carbene **c2**. Such interconversion of carbenes and strained alkenes is well-established (4, 5, 19) and should of course proceed in the direction that releases strain, a consideration that clearly points to conversion of **1** to carbenes. As a heuristic, at least, such alkene → carbene reactions can be viewed as migration of a carbon to the positive end of a double bond with $^+$C–C$^-$ character (C$^+$ and C$^-$ singly-bonded). We return later to the question of polarization of the orthogonene formal double bond.

Focusing on the fate of **c1**, which calculations indicate (below) is much more likely than **c2** to be the favored proximate product from **1**, one envisages the following four possibilities:

(1) Insertion of the carbene carbon into a β-C C—H bond (this can also be viewed as an H atom shift) forming a cyclopropane; **c1** lacks a symmetry plane (it belongs to the C_1 symmetry group) and C4 represents the closest β-C and has the closest C—H bond (C1—C4 = 2.185 Å, C1—H = 2.051 Å). These two atoms are thus within bonding distance of C1. The intramolecular insertion of a carbene into a C—H bond on a β-C has long been known (20). This reaction would generate the cyclopropane **cy1**.

(2) Shift of C4 to C1, giving the alkene **a1**. This is a carbene–alkene interconversion of the kind relating **1** and **c1** (and **1** and **c2**).

(3) Shift of C7 to C1 giving the alkene **a2**. This is another carbene–alkene interconversion.

(4) A 1,2-H shift giving the alkene **a3**. Such shifts are the best known and normally the most facile kind of intramolecular reaction of carbenes (21).

Orthogonene to carbenes c1 and c2

The relative energies, where available, of **1**, **c1**, **c2**, **cy1**, **a1**, **a2**, **a3**, and the transition states (TS) (**t1–c1**, etc.) connecting various species are given in Table 1, and the activation energies based on these relative energies are given in Table 2. The most salient indication from these calculations is that orthogonene is restrained from isomerization by a

Fig. 1. Selected parameters of MP2(fc)/6-31G* geometry, electrostatic potential charges (HF/3-21G//MP2(fc)/6-31G*), and Wiberg bond orders (HF/3-21G//MP2(fc)/6-31G*).

Fig. 2. Orbital hybridizations associated with the orthogonene double bond, from Weinhold natural population analysis (STO-3G///MP2(fc)/6-31G*).

Twisted double bond CCCC dihedral = 83.7⁰
barrier that is either nonexistent (at the HF/6-31G* level it is a transition state linking enantiomeric **c1** molecules) or tiny (at the B3LYP/6-31G* level the barrier to isomerization to **c1** is a mere 1.2 kJ mol⁻¹). The carbene **c1** is itself calculated to readily suffer insertion into the proximate C—H bond (see above), forming the cyclopropane **cy1**, the HF and B3LYP activation energies for this process being 39.1 and 1.6 kJ mol⁻¹, respectively. The likely situation is either (1) **1** is a real molecule with a very low barrier to isomerization to carbene **c1** or perhaps directly to the cyclopropane **cy1** (higher-level calculations may indicate that **c1** is not a stationary point), or (2) **1** is a TS linking enantiomeric **c1** molecules or perhaps linking enantiomeric **cy1** molecules.

Concerning the carbene **c2**, the product of the alternative carbon shift in **1** (C3 → C1 instead of C5 → C2) on the HF/6-31G* potential energy surface **1** is merely a transition state leading to **c1** enantiomers, while on the B3LYP/6-31G* surface, the **1** → **c1** barrier is exceedingly low (1.2 kJ mol⁻¹) *and* **c2** is not a stationary point: attempts to optimize it from lower-level geometries lead to the alkene **a1**.

Besides the cyclopropane **cy1**, the alkenes **a1**, **a2**, and **a3** can reasonably be postulated as products of the carbene **c1**. From the data in Table 2, the only product from **c1** that might compete with **cy1** is the alkene **a1** (barriers to **a1**, **a2**, **a3**, HF/B3LYP: 57.9/17.8; 151.3/92.7; 307.2/214.5 kJ mol⁻¹). Note the good agreement between relative energies calculated at the B3LYP and MP2 levels for **1**, the cyclopropane, and the three alkenes (Table 1). It is known that correlated-level barriers are lower than those calculated at the HF level and closer to experimental values, although the trends predicted by HF-level calculations are usually reliable (22). From these energetic relationships and the curvature of the potential energy surface (viz., minima, transition states, and non-stationary points) indicated by these calculations we may conclude that attempts to synthesize orthogonene will lead to the formation of the cyclopropane **cy1** and possibly the alkene **a1**, but the possibility of detection of **1** and (or) **c1** under matrix-isolation (23) conditions cannot be ruled out.

Structure and electronic properties of orthogonene

Tacitly assuming **1** is actually a relative minimum on the potential energy surface (i.e., that it is a real molecule), a
brief look at its "static" properties is warranted. Selected values for geometry, bond orders, and electrostatic potential atomic charges (24) and the dipole moment are shown in Fig. 1. The length (MP2(fc)/6-31G*) of the formal double bond (1.420 Å) is close to the average of the standard C—C single and double bond lengths: 1/2 (1.54 + 1.33) Å = 1.435 Å. Its Wiberg bond order of 1.64 (from a Weinhold natural population analysis (NPA (25)) is only a little more than the value (1.5) one would intuitively assign to a "one-and-a-half" bond. In comparison, tetramethylethene at the same computational levels has a C=C double bond length of 1.352 Å and a bond order of 1.85 (this molecule has a calculated C-C-C-C dihedral angle of 2.6°). A dramatic indication of the weakness of the double bond of **1** is its calculated stretching frequency: 1348 cm⁻¹, cf. 1765 cm⁻¹ for tetramethylethene. These are MP2(fc)/6-31G* uncorrected frequencies; the frequency- (not the ZPE-) correction factor of Scott and Radom (17), 0.9434, predicts experimental frequencies of 1272 and 1665 cm⁻¹. The calculated formal double bond C=C frequency of **1** is actually somewhat closer to
a calculated C—C *single* bond stretch (e.g., 1050 cm^{-1} for CH$_3$–CH$_3$, MP2(fc)/6-31G*) than to a normal double bond stretch like that in tetramethylethene. This stretch in **1** has a calculated relative intensity (the strongest vibration is a CH stretch) of 8%, but the corresponding vibration in tetramethylethene is undetectable in the IR (26) because of symmetry. The electrostatic potential charges indicate a modest polarization of this bond, in keeping with its modest IR intensity.

Figure 2 shows the NPA hybridization for the bonding orbitals associated with the twisted double bond. C1 and C2 both utilize ca. 40% s : 60% p hybrid orbitals to bond to their adjacent carbons, which overlap these with normal sp^3 orbitals (ca. 25% s : 75% p). The σ bond of the formal C=C double bond is approximately sp^3—sp^3 (20% s : 80% p — 25% s : 75% p) and the (presumably weak) π bond results from twisted p:p overlap. The very wide (155.6°) and extraordinarily wide (175.7°) C-C-C angles at the ends of the double bond can be rationalized in terms of the high s character of the sp hybrids (ca. 40% s : 60% p, approaching the 50% s : 50% p character of the linearly disposed sp hybrids of alkynes) used to bond to the neighboring carbons, but it is unclear why one angle is so much bigger than the other; a referee suggested that the dissimilar angles may indicate it is energetically favorable to distort one carbon more to reduce strain at the other.

As a C=C double bond is twisted toward 90°, the HOMO and LUMO should tend to become degenerate atomic p orbitals, and the closed-shell molecule should approach singlet diradical status (this kind of twisting has been analyzed in detail for ethene and its C–Si and Si–Si analogues (27)). Since the single-determinant molecular orbital wavefunction usually used for normal closed-shell molecules is based on filling molecular orbitals pairwise (28), this approach may not be valid for strongly twisted double bonds (ref. 27 used the GVB method). One test of the validity of normal DFT calculations on such systems is to compare the results of unrestricted and restricted DFT calculations (4, 29). Restricted

and unrestricted B3LYP/6-31G* optimizations + frequencies on **1** gave identical results, and the spin contamination parameter $\langle S^2 \rangle$ before and after spin annihilation was 0.0000. The appearance of the HOMO and LUMO, visualized with GaussView (HF/3-21G wavefunction from the MP2 geometry), was identical (Fig. 3); these orbitals look as one would expect from twisting a normal alkene HOMO. The HOMO : LUMO energies (MP2/6-31G*//MP2/6-31G*) are –4.80 : 3.13 eV, giving a frontier orbital gap of 7.93 eV. From Koopmans' theorem (30) the HOMO gives an approximate vertical ionization energy (IE) for **1** of 4.80 eV. The energy difference between neutral **1** and the radical cation at the geometry of the neutral (no ZPEs used) gives a vertical IE of 5.36 eV (MP2(fc)/6-31G*//MP2/6-31G*). For tetramethylethene the HOMO : LUMO energies are –8.56 : 5.18 eV, giving a frontier orbital gap of 13.74 eV, much bigger than for **1**, as expected. For tetramethylethene the Koopmans and energy-difference IEs are 8.56 and 8.24 eV; experimental values of ca. 8.3–8.8 eV are typical of alkenes (31). Normally, Koopmans' theorem values are about 1.0–1.5 eV too high, and MP2/6-31G* ΔE values tend to be within ca. 0.4 eV (32). For the exotic **1** the Koopmans IE is, however, lower than the energy-difference one. Nevertheless, we can be confident that the IE of **1** (assuming it to be a "real molecule") is ca. 5 eV. This is a remarkably low IE for an alkene; it is essentially the same as the value of 4.6 eV calculated by Radom and Rasmussen for the hypothetical dimethanospirooctaplane, a cycloalkane predicted to have a planar carbon atom, and as these workers point out for their molecule, possibly lower than the IEs of lithium and sodium (5.39 and 5.14 eV) (33). In both hydrocarbons this anomaly arises, of course, from the decoupling of normally bonding orbitals: the HOMO of dimethanospirooctaplane is essentially a carbon p orbital, and that of orthogonalene has high p orbital character by virtue of the weak interaction between the nearly orthogonal carbon p orbitals (Figs. 2 and 3).

These calculations apply to the singlet energy surface; our main purpose here was to investigate the stability and fate of

1 understood as a twisted singlet alkene. However, the unusual double bond of **1** raises the possibility that the normal situation is reversed, and the triplet is the lower-energy state. Comparing the energies (ZPE-corrected) of fully-optimized geometries at different levels we find the following: E(triplet) – E(singlet) = +221.9 kJ mol^{-1} (HF/6-31G*), –72.1 kJ mol^{-1} (UB3LYP/6-31G*), –4.8 kJ mol^{-1} (UMP2(fc)/6-31G*). Thus at the noncorrelated level the triplet is much the higher-energy state, but with UB3LYP the triplet is moderately lower, and with UMP2 it is very marginally lower than the singlet. These results suggest only that the two states may not differ widely in energy; they leave open the possibility that attempts to synthesize **1** by some route involving entry to the singlet potential energy surface will lead to triplet **1** by intersystem crossing.

Conclusions

Orthogonene was calculated to be at best highly unstable toward isomerization to a carbene, the HF/6-31G* barrier being zero and the B3LYP/6-31G* barrier 1.2 kJ mol^{-1}. The carbene itself may in fact not be a stationary point and orthogonene may go directly to a cyclopropane and (or) to an alkene (these latter two arise, formally at least, by carbene insertion into a nearby C—H bond or by 1,2-carbon shift). We note a referee's suggestion that it may be possible to find substituents to stabilize orthogonene.

Synthesis and study of platinum silylene complexes of the type (R_3P)$_2$Pt=SiMes$_2$ (Mes = 2,4,6-trimethylphenyl)[1]

Jay D. Feldman, Gregory P. Mitchell, Jörn-Oliver Nolte, and T. Don Tilley

Abstract: The synthesis and characterization of neutral platinum silylene complexes (R_3P)$_2$Pt=SiMes$_2$ ($R = i$-Pr (**1**) or cyclohexyl (**2**), Mes = 2,4,6-trimethylphenyl) is reported. The dimesitylsilylene ligand in **2** is displaced by a number of ligands including phosphines, alkenes, alkynes, and O$_2$. Complex **2** reacts with ROH substrates (R = H, Me, Et) to give (Cy$_3$P)$_2$Pt and Mes$_2$Si(OR)(H) and with H$_2$ to give *trans*-(Cy$_3$P)$_2$Pt(H)SiHMes$_2$ (**3**). Reaction of H$_2$SiMes$_2$ with (Cy$_3$P)$_2$Pt gave *cis*-(Cy$_3$P)$_2$Pt(H)SiHMes$_2$ (**4**). EXSY NMR experiments of **4** reveal that exchange of silicon and platinum hydrides occurs via reductive elimination – oxidative addition and not via a silylene intermediate.

Key words: silylene, EXSY, platinum, hydride.

Résumé : On a effectué la synthèse et la caractérisation de complexes neutres de silylène de platine, (R_3P)$_2$Pt=SiMes$_2$ (R = isopropyle (**1**) ou cyclohexyle (**2**); Mes = 2,4,6-triméthylphényle). Le ligand diméthylsilylène du composé **2** est déplacé par un grand nombre de ligands, dont les phosphines, les alcènes, les alcynes et le dioxygène. Le complexe **2** réagit avec des substrats de formule ROH (R = H, Me, Et) pour conduire à la formation de (Cy$_3$P)$_2$Pt et de Mes$_2$Si(OR)(H); il réagit aussi avec H$_2$ pour donner le *trans*-(Cy$_3$P)$_2$Pt(H)SiHMes$_2$ (**3**). La réaction du H$_3$SiMes$_2$ avec le (Cy$_3$P)$_2$Pt conduit à la formation du *cis*-(Cy$_3$P)$_2$Pt(H)SiHMes$_3$ (**4**). Des expériences de RMN de type « EXSY » effectuées sur le composé **4** révèlent qu'il se produit un échange des hydrures de silicium et de platine par le biais d'une réaction d'élimination réductrice – addition oxydante et non pas par le biais d'un intermédiaire silylène.

Mots clés : silylène, « EXSY », platine, hydrure.

[Traduit par la Rédaction]

Introduction

Platinum complexes play an important role as catalysts in transformations of organosilanes. These metal species are used to effect olefin hydrosilylation (1), dehydrogenative coupling of silanes to produce oligomers (2), and redistribution of substituents on silicon (3, 4). The latter two transformations occur extensively with low-valent platinum catalysts and are usually observed concurrently. Because these processes occur together it is likely that they involve a common intermediate. One possible mechanism for this redistribution–oligomerization reaction involves an intermediate silylene complex (L_nPt=SiR_2) and migration chemistry (Scheme 1), although a mechanism involving reductive elimination – oxidative addition (Scheme 2) is preferred by some (4). While many of the proposed steps for redistribution via

the latter mechanism have precedent (e.g., Si–H oxidative addition and reductive elimination), there is little evidence to support the direct addition of an Si—C bond to platinum.

In 1971 Kumada and co-workers discovered the first hydrosilane oligomerization and redistribution reactions catalyzed by a platinum complex (3*b*, 5). In the presence of *trans*-(Et$_3$P)$_2$PtCl$_2$ as a precatalyst, Me$_3$SiSiMe$_2$H was transformed into Me$_3$SiH (redistribution product) and Me-(SiMe$_2$)$_n$H (n = 3–6, oligomerization products). The investigators subsequently found that introducing diphenylacetylene into the reaction resulted in formation of a disilacyclohexadiene (eq. [1]), which was proposed to result from the trapping of dimethylsilylene (5).

$$\xrightarrow{\text{[Pt]}}\quad 2\ \text{Me}_3\text{SiH}\quad +$$
More recently, Tanaka suggested that the formation of a platina-sila-cyclohexadiene, by the addition of phenylacetylene to a similar oligomerization–redistribution system, resulted from the trapping of a Pt^0 silylene complex (6) (eq. [2]). Although these results suggested a mechanism involving intermediate platinum silylene species, the goal of isolating and probing the reactivity of such a complex still remained. Additionally, given the utility of carbene com-

Scheme 1.
plexes as catalysts and synthons in organic and polymer chemistry (7), it is likely that development of silylene chemistry will lead to similar advancements in organosilicon chemistry.

[2]
Many synthetic efforts have targeted the isolation of complexes featuring silylene ligands. In recent years, these efforts have culminated in the syntheses of a number of transition metal compounds containing sp^2-hybridized silicon (8). For the most part, these compounds are cationic, having been obtained via an "anion-abstraction" method (8a–e). However, some neutral silylene complexes have been prepared via coordination of a stable free diamidosilylene (of which there are very few) to a transition metal (8k–o). The free silylenes are conjugated, five-membered rings in which the Si atoms are stabilized via heteroatom coordination to nitrogen.

Only two platinum silylene complexes have been previously reported, [$trans$-$(Cy_3P)_2(H)Pt=Si(SEt)_2$][BPh_4] (8c) and [(i-$Pr_2PCH_2CH_2P$-i-$Pr_2)(H)Pt=SiMes_2$][$MeB(C_6F_5)_3$] (8f). Neither of these cationic compounds is a good model for silylenes of the type ($R_3P)_2Pt=SiR_2$, which have been the primary focus of speculation regarding catalytic silylene intermediates (9). In an effort to prepare netural platinum(0) silylene complexes, we have explored reactions of metastable silylenes generated in situ with zero-valent platinum compounds. Some of this work has been communicated (10).

Results and discussion

Survey of reactions and observation of (i-$Pr_3P)_2$-Pt=SiMes_2

Silylenes were generated photolytically from linear or cyclic trisilanes, including Mes_2Si: (Mes = mesityl) from $Mes_2Si(SiMe_3)_2$ (11) or $(Mes_2Si)_3$ (12), Ph_2Si: (13) from $Ph_2Si(SiMe_3)_2$, and Me_2Si: from $(Me_2Si)_6$ (14). The photolyses were carried out using a quartz tube and in hexanes with a 1:1 stoichiometry of silylene precursor to platinum substrate. The first reactions surveyed involved the generation of Mes_2Si: from $(Mes_2Si)_3$ in the presence of $Pt(PEt_3)_3$ (15), $(C_2H_4)Pt(PPh_3)_2$ (15), $Pt(P$-i-$Pr_3)_3$ (15), $Pt(PCy_3)_2$ (15), or $Pd(PCy_3)_2$ (16). While no reaction was observed with $Pt(PEt_3)_3$, $(C_2H_4)Pt(PPh_3)_2$, or $Pd(PCy_3)_2$,

small amounts (<10%) of new products were observed (by ^{31}P NMR spectroscopy) with $Pt(P$-i-$Pr_3)_3$ and $Pt(PCy_3)_2$. It is notable that in these two cases the reacting platinum species is 2-coordinate, since $Pt(P$-i-$Pr_3)_3$, unlike $Pt(PEt_3)_3$, readily dissociates one of its phosphines in solution to give $Pt(P$-i-$Pr_3)_2$ and an equivalent of free phosphine. Thus, further experiments concentrated on the use of these 2-coordinate species. The generation of Me_2Si: or Ph_2Si: in the presence of $Pt(P$-i-$Pr_3)_2$ (+ free phosphine) or $Pt(PCy_3)_2$ gave no new complexes (by ^{31}P NMR spectroscopy). However, Mes_2Si: generated from $Mes_2Si(SiMe_3)_2$ gave >85% of a new, blood-red complex (**1**) as observed by ^{31}P NMR spectroscopy (eq. [3]). Furthermore, use of a slight excess of $Mes_2Si(SiMe_3)_2$ (1.2 equiv) gave **1** as the only platinum phosphine species observed.

1
Although there are many examples of silylene-bridged, dimeric bis(phosphine) platinum complexes (dimeric analogs of **1**) (17), the observation of only a single resonance with [195]Pt satellites in the ^{31}P NMR spectrum (δ: 82.2 $^1J_{PPt}$ = 3119 Hz) is consistent with a monomeric structure for **1**. Apparently, the steric protection provided by the Mes and *i*-Pr substituents is sufficient to prevent the formation of a more thermodynamically stable 4-coordinate silicon species via dimerization. The ^{29}Si NMR data for **1** are also consistent with the characterization of this complex as monomeric, with an sp^2-hybridized silicon atom. Silylene complexes exhibit characteristically large downfield chemical shifts, typically in the range of 250 to 340 ppm (8). Significantly, the resonance for **1** (Fig. 1) was observed at δ: 367 ($^2J_{SiP}$ = 107 Hz; $^1J_{SiPt}$ = 2973 Hz). For comparison, the only other platinum silylene complexes to be reported have [29]Si resonances at δ: 309 for [*trans*-(Cy$_3$P)$_2$(H)Pt=Si(SEt)$_2$][BPh$_4$] (8*c*) and δ: 338 for [(*i*-Pr$_2$PCH$_2$CH$_2$P-*i*-Pr$_2$)(H)Pt=SiMes$_2$][MeB(C$_6$F$_5$)$_3$] (8*f*). Complexes related to **1** include several dimeric analogs of the type [(*R*$_3$P)$_2$Pt(μ-Si*R'*$_2$)]$_2$, which were prepared from reactions of secondary silanes with Pt(PR$_3$)$_n$ complexes (17), as well as the trimer [Pt(μ-SiPh$_2$)(PMe$_3$)]$_3$, which was derived from loss of Ph$_2$SiH$_2$ and PMe$_3$ from *cis*-(Me$_3$P)$_2$Pt(SiHPh$_2$) (18). While the [(*R*$_3$P)$_2$Pt(μ-Si*R'*$_2$)]$_2$ complexes exhibit ^{29}Si NMR shifts that are over 400 ppm upfield of that for **1** (in the range of δ: –65 to –95), [Pt(μ-SiPh$_2$)(PMe$_3$)]$_3$ has a [29]Si chemical shift of 279 ppm, which is uncharacteristically downfield for a 4-coordinate silicon species.

Repeated attempts to isolate **1** were unsuccessful. Removal of the solvent afforded Pt(P-*i*-Pr$_3$)$_3$, along with a variety of unidentified silicon-containing products. When Pt(P-*i*-Pr$_3$)$_2$ (19) (without a third equivalent of P-*i*-Pr$_3$ present) was employed as a trapping reagent, the only platinum product observed upon photolysis was *trans*-H$_2$Pt(P-*i*-Pr$_3$)$_2$ (20) (by ^{1}H and ^{31}P NMR spectroscopy) presumably resulting from C–H activation of the hexanes solvent. When the photolysis reaction was performed in benzene-d_6, neither solvent activation nor efficient formation of **1** were observed.

Synthesis and structure of (Cy$_3$P)$_2$Pt=SiMes$_2$ (2)

Photolysis of a mixture of Mes$_2$Si(SiMe$_3$)$_2$ and Pt(PCy$_3$)$_2$ in hexanes gave a green, supersaturated solution of Me$_3$SiSiMe$_3$ (by ^{1}H and ^{29}Si NMR spectroscopy) and the silylene complex (Cy$_3$P)$_2$Pt=SiMes$_2$ (**2**). Cooling the solution to 0°C, concentrating the solution in vacuo, or allowing the solution to stand for a few hours facilitated precipitation of microcrystalline **2** (54% isolated yield). Complex **2** is completely insoluble in alkane solvents, dichloromethane, fluorobenzene, and tetrahydrofuran (THF) and is only slightly soluble in toluene or benzene. The ^{1}H NMR spectrum of **2** in benzene-d_6 consists of resonances for each of the three types of Mes protons (*o*-Me, *p*-Me, ArH) as well as a group of multiplets for the cyclohexyl protons. Likewise, the ^{31}P NMR spectrum contains a single peak with [195]Pt satellites (δ: 71.7, $^1J_{PPt}$ = 3068). Because of its low solubility, a long accumulation time was required to observe the ^{29}Si NMR resonance for **2** at δ: 358 ($^2J_{SiP}$ = 112 Hz). This large

Fig. 1. [29]Si spectrum of **1**.
Fig. 2. ORTEP diagram of **2**.
downfield chemical shift is evidence for the presence of an sp^2-hybridized silicon atom, confirming the assignment of **2** as a silylene complex.

X-ray quality crystals of **2** were grown from dilute (<0.04 M) reaction solutions over a 3–4 h period.[3] An ORTEP diagram of **2** is shown in Fig. 2. The Pt—Si bond distance of 2.210(2) Å is the shortest yet reported and is about 6% shorter than typical Pt—Si single bonds (2.30–2.40 Å) (1, 21). For comparison, the Pt—Si distance in [*trans*-(Cy$_3$P)$_2$(H)PtSi(SEt)$_2$][BPh$_4$] is 2.270(2) Å, but note that the latter complex was characterized as being somewhat Fischer-like, with both Si—S and Pt—Si π-bonding (8*c*, 22). The summation of angles about Si, 359.8(6)°, confirms the presence of a planar, sp^2-hybridized silicon atom, and the angles about platinum also sum within experimental error to 360°. The least-squares plane of the silylene ligand (including Pt, Si, and the two *ipso* carbons) and the coordination plane of platinum (Si, Pt, P, P) intersect at a dihedral angle of 68.6° (see Fig. 3), which is not optimal for Pt-to-Si π-donation. The ideal dihedral angle for overlap between the HOMO of the *L*$_2$Pt fragment and the empty *p*-orbital on silicon is 90°, which is the

---

Fig. 3. ORTEP view of **2** in which most of the cyclohexyl carbon atoms have been removed for clarity. The dihedral angle between the silicon coordination plane and platinum coordination plane is 68.6°.
observed angle of the related germylene and stannylene complexes $(Et_3P)_2PtGe[N(SiMe_3)_2]_2$ (23) and $(i\text{-}Pr_2PCH_2CH_2P\text{-}i\text{-}Pr_2)PdSn[CH(SiMe_3)_2]_2$ (24), respectively. The deviation from 90° for **2** appears to result from steric interactions between the Mes and Cy substituents.

It is interesting that although complexes of the type $(R_3P)_2PtER'_2$ are known for tin, germanium, and now silicon, no such analogs are known with carbon. The complexes with germanium (23) and tin (24) were prepared by reacting a stable, free germylene or stannylene with a platinum complex of the type $(R_3P)_2PtL$, where L is a leaving group such as an alkene, alkyne, or oxalate (which forms 2 equiv of CO_2). It is noteworthy that while $(Et_3P)_2PtGe[N(SiMe_3)_2]_2$ decomposes in ambient laboratory light (25), silylene complexes **1** and **2** are generated under intense UV–vis irradiation. Also, no mention has been made of the sensitivity of stannylene complexes to light.

Reactivity of 2

Given that **2** is a member of the $(R'_3P)_2Pt=SiR_2$ class of compounds proposed as intermediates in hydrosilane oligomerization and redistribution, we have searched for similarities between the reactivity of **2** and that of the proposed intermediate species. Alkyne coupling with extruded silylenes is the primary evidence supporting such an intermediate species (vide supra); thus we have examined reactions of **2** with substrates containing unsaturated C—C

bonds. Given the high steric congestion surrounding the Pt=Si bond, small substrates, including 2-butyne, propyne, and ethylene, were employed.

Addition of 2-butyne to a benzene-d_6 solution of **2** initially resulted in the formation of an unsymmetrical complex with inequivalent resonances in the ^{31}P NMR spectrum. This is consistent with a complex derived from either alkyne addition across the Pt=Si double bond (eq. [4], structure **B**) or coordination of the alkyne to the silylene complex (structure **C**).

[4]
This species appears to be an intermediate and is only observed in very small concentrations (<5% by ^{31}P NMR spectroscopy), as the silylene complex is converted into the alkyne complex $(Cy_3P)_2Pt(\eta^2\text{-MeCCMe})$.[4] The ^{31}P NMR spectrum of the intermediate consists of two doublets with [195]Pt satellites (δ: 41.6, d $^2J_{PP}$ = 34 Hz, $^1J_{PPt}$ = 3483 Hz; δ: 33.3, d $^1J_{PPt}$ = 2899 Hz). An analogous process is observed when propyne or ethylene (1 atm (1 atm = 101.325 kPa)) is used as the reactant in place of 2-butyne. In this ligand-displacement reaction the dimesitylsilylene is lost as multiple uncharacterized silicon-containing products. The apparent low stability of the intermediate species is likely due to the steric congestion associated with **2** and its derivatives.

Hydrosilanes do not react cleanly with **2**; however, NMR tube reactions indicate that redistribution and, to a small extent, oligomerization processes take place. For example, addition of $PhSiH_3$ (4 equiv) to a green benzene-d_6 solution of **2** resulted in bleaching of the color and formation of Mes_2SiH_2 as the only mesityl-containing product. Redistribution products Ph_2SiH_2, SiH_4, and other Si–H containing products, as well as trace amounts of H_2 (presumably from dehydrocoupling), were also observed (by ^{1}H NMR spectroscopy). The platinum-containing product from this reaction has equivalent phosphines, as well as a hydride ligand (by NMR spectroscopy). These data are consistent with its formulation as $trans\text{-}(Cy_3P)_2Pt(H)(SiHPh_2)$, although this could not be confirmed as it was not isolated. Furthermore, the symmetrical complex $trans\text{-}(Cy_3P)_2PtH_2$ (20) (also consistent with the NMR data) could be ruled out based on comparison of NMR data to an authentic sample.

Complex **2** quantitatively transfers its silylene group to water and alcohols, giving O—H bond insertion products (eq. [5]).

---

[4] The alkyne complex, $(Cy_3P)_2Pt(\eta^2\text{-MeCCMe})$, was generated via the addition of 2-butyne to $(Cy_3P)_2Pt$ in order to compare its ^{31}P spectrum with the product mentioned here. $(Cy_3P)_2Pt(2\text{-butyne})$ ^{31}P NMR (C_6D_6) δ: 36.8, $^1J_{PPt}$ = 3302 Hz.

[5]

$$Cy_3P \cdots Pt=Si \xrightarrow[R = H, Me, Et]{HOR} Mes_2Si\overset{H}{\underset{OR}{}} + Pt(PCy_3)_2$$

2
Thus, addition of ROH (R = H, Me, Et) to **2** resulted in the clean formation of Pt(PCy$_3$)$_2$ and the corresponding siloxane Mes$_2$Si(OR)H. No intermediates were observed in the reaction of **1** with ethanol at –60°C (by ^{1}H and ^{31}P NMR spectroscopy in toluene-d_8). Related reactivity was previously reported for the base-stabilized silylene complex [Cp*(Me$_3$P)$_2$RuSiPh$_2$(NCMe)]$^+$, which was presumed to dissociate acetonitrile prior to reaction with an alcohol (26). This reactivity contrasts with what has been observed for (*i*-Pr$_2$PCH$_2$CH$_2$P-*i*-Pr$_2$)PdSn[CH(SiMe$_3$)$_2$]$_2$, which reversibly adds H$_2$O across the Pd—Sn bond to form a palladium hydride species (27).

Many reactions of **2** result in loss of the silylene ligand. For example, O$_2$ reacts with **2** to give Pt(PCy$_3$)$_2$(η^2-O$_2$) (28), and the displaced silylene ligand is observed to decompose to a number of species (but not to significant amounts of the silylene dimerization product, Mes$_2$Si=SiMes$_2$). This reactivity is unlike that of the related germylene complex, (Et$_3$P)$_2$-PtGe[N(SiMe$_3$)$_2$]$_2$, which cleanly adds O$_2$ across its double bond (29). Reactions of **2** in benzene-d_6 with an excess amount of *i*-Pr$_2$PCH$_2$CH$_2$P-*i*-Pr$_2$, Ph$_2$PCH$_2$CH$_2$PPh$_2$, and PMe$_3$ led to PCy$_3$ and Mes$_2$Si: displacement, with quantitative formation of the corresponding PtL_4 (30) complex (by ^{31}P NMR spectroscopy). Addition of 1 equiv of phosphine resulted in partial conversion to PtL_4, and no other products were observed. These results suggest that the dimesitylsilylene ligand in **2** is rather labile. However, attempts to trap the silylene by reacting **2** with 2 equiv of 2,3-dimethylbutadiene (which is known to react with free dimesitylsilylene) (31) in benzene-d_6 over 3 days at room temperature failed to give the expected cycloaddition product, Mes$_2$Si(CH$_2$CMeCMeCH$_2$). Instead, several unidentified mesityl-containing species were observed by ^{1}H NMR spectroscopy. This suggests that complex decomposition pathways are operative in silylene displacement reactions. Unlike cationic silylene complexes, **2** is stable in the presence of 1 equiv of the nitrogen bases *para*-dimethylaminopyridine and acetonitrile and does not form a base-stabilized silylene complex (32). Formation of the four-coordinate adduct may be disfavored due to the significant steric protection of the electrophilic, *sp^2*-hybridized silylene.

Formation of *trans*-(Cy$_3$P)$_2$Pt(H)(SiHMes$_2$) (3) from 2 and H$_2$

Hydrogen (1 atm) reacted with a benzene solution of **2** over 2 days to form *trans*-(Cy$_3$P)$_2$Pt(H)(SiHMes$_2$) (**3**, Scheme 3). With this slow conversion there was competing decomposition of **2** via loss of the silylene ligand to produce

trans-(Cy$_3$P)$_2$PtH$_2$ (20) (ca. 50%; *without* formation of Mes$_2$SiH$_2$). At higher temperatures (refluxing benzene-d_6), **3** was hydrogenated to give *trans*-(Cy$_3$P)$_2$PtH$_2$ and Mes$_2$SiH$_2$. In contrast to the germylene complex (Et$_3$P)$_2$PtGe[N-(SiMe$_3$)$_2$]$_2$ (33), the addition of hydrogen to **2** is irreversible.

Complex **3** is fluxional in solution, as observed by variable-temperature ^{31}P NMR spectroscopy. At –29°C, two doublets (δ: 26.9, d $^1J_{PtP}$ = 2632 Hz, $^2J_{PP}$ = 346 Hz; δ: 33.6, d $^1J_{PtP}$ = 2715 Hz) are observed, which, upon heating, broaden and coalesce to a singlet (δ: 28.9, $^1J_{PtP}$ = 2707 Hz) at 91°C. This behavior is consistent with restricted rotation about the sterically congested Pt—Si bond; the rotational barrier ($\Delta G^{\ddagger}_{rot}$) was calculated to be 15.8 ± 0.4 kcal mol^{-1}. The mechanism of hydrogen addition to **2** could involve oxidative addition to the platinum center followed by migration of hydride to the silylene ligand, or direct addition of hydrogen to the Pt=Si double bond. At this point the mechanism is unknown, but it is interesting to note that whereas the *trans* silyl hydride is formed by this reaction, the oxidative addition of Mes$_2$SiH$_2$ to Pt(PCy$_3$)$_2$ exclusively gives *cis*-(Cy$_3$P)$_2$-Pt(H)(SiHMes$_2$) (vide infra).

Synthesis and EXSY NMR Studies of *cis*-(Cy$_3$P)$_2$Pt-(H)SiHMes$_2$ (4)

The *cis* isomer of **3** is obtained via the addition of Mes$_2$SiH$_2$ to Pt(PCy$_3$)$_2$ in 48% isolated yield. Competing *cis–trans* isomerization and decomposition took place upon thermolysis (80°C, 6 h) or photolysis (2.5 h) of a benzene solution of **4**.

The Pt–H and Si–H resonances of **4** are broad at room temperature, suggesting that exchange of these protons takes place. Cooling the sample to –70°C (toluene-d_8) only partially resolved the broad peaks. The cyclohexyl resonances prevent observation of the Pt-H–Si-H proton coalescence at high temperatures, and thus exchange NMR spectroscopy (EXSY) was used to study this process. The ^{1}H EXSY experiment confirms the exchange of the platinum and silicon hydrides. The rate constant for exchange was determined to be 23 ± 4 Hz (27°C).[5]

Given the stability of silylene ligands in this system, it seemed possible that this exchange could occur via an α-H migration process to give a 5-coordinate intermediate (eq. [6]).

[6]

$$Pt(PCy_3)_2 + Mes_2SiH_2 \rightleftharpoons \begin{matrix} Cy_3P & & H \\ & Pt & \\ Cy_3P & & SiHMes_2 \end{matrix}$$

$$\xrightarrow{\quad\quad} \left[\begin{matrix} & H & \\ Cy_3P & | & H \\ & Pt & \\ Cy_3P & & SiMes_2 \end{matrix} \right]$$
However, a reductive elimination – oxidative addition couple could also account for this observation. An intermolecular mechanism was suggested upon close examina-

---

[5]EXSY NMR experiments (phase sensitive NOESY) were performed at two different mixing times of 12 and 25 ms, and exchange rate constants were determined using the program D2DNMR.

Scheme 3.
Fig. 4. Pt-H region of ^{1}H EXSY NMR spectrum of **4** showing exchange cross peaks between different Pt isotopes.

Fig. 5. ^{31}P EXSY NMR spectrum of **4**.
tion of the Pt–H region of the EXSY spectrum, Fig. 4, which contains cross-peaks corresponding to the exchange of ^{195}Pt–H hydrides with molecules of complex **4** containing other Pt isotopes. More significantly, EXSY experiments revealed the exchange of Pt–H hydrides with the Si–H hydrides of *free* H$_2$SiMes$_2$ (25 equiv) with a rate constant of 23 ± 4 Hz (27°C). Also, addition of D$_2$SiMes$_2$ to **4** resulted in concurrent incorporation of deuterium into the Pt–H and Si–H positions of **4**. In addition, ^{31}P EXSY NMR experiments provided a similar rate constant (27 ± 4 Hz) for phosphine exchange. This process was shown to be intramolecular, based on the absence of cross peaks between ^{195}Pt–P phosphines with those bound to other isotopes of platinum (Fig. 5), as well as the lack of exchange with free phosphine (5 equiv). Coalescence of the phosphorus resonances of **4** into a broad singlet occurred at 135°C (toluene-d_8), yielding an energy of activation of 16.1 ± 0.5 kcal mol^{-1}. Thus, hydrogen exchange in *cis*-(Cy$_3$P)$_2$Pt(H)(SiHMes$_2$) occurs via the rate-determining reductive elimination of dimesitylsilane, which does not require prior phosphine dissociation. These results are consistent with the recent observation that hydrogen appears not to migrate to platinum in 4-coordinate (*i*-Pr$_2$PCH$_2$CH$_2$P-*i*-Pr$_2$)Pt-(Me)SiHMes$_2$, whereas the 3-coordinate cation [(*i*-Pr$_2$PCH$_2$-CH$_2$P-*i*-Pr$_2$)PtSiHMes$_2$]$^+$ rapidly converts to [(*i*-Pr$_2$PCH$_2$CH$_2$-P-*i*-Pr$_2$)(H)Pt=SiMes$_2$]$^+$(8*f*).

Conclusion

The first examples of neutral, platinum(0) silylene complexes have been synthesized and characterized by ^{29}Si

NMR specroscopy (**1** and **2**) as well as by X-ray crystallography and UV–vis, IR, and Raman spectroscopies (**2**). Their preparation was achieved via a novel route: trapping of a metastable silylene with electron-rich bis(phosphine)platinum compounds. These are the first silylene complexes to closely resemble proposed catalytic intermediates, in that the L_2Pt=SiR$_2$ compounds (**1** and **2**) resemble species proposed in the redistribution and oligomerization of hydrosilanes by platinum catalysts. Steric protection of the reactive Pt=Si double bond not only stabilizes **1** and **2**, thus allowing for their isolation, but apparently also limits their reactivity. Dihydrogen is the only reactant to yield a product with an intact Si—Pt bond (**3**). Other substrates either displace the silylene ligand or fail to react with **2**. Although no direct analogies can be drawn between the reactivity of the isolated and proposed intermediate silylenes, the very existence of **1** and **2** lends some credence to mechanisms which invoke this class of compounds. Studies of the closely related and dynamic molecule *cis*-(Cy$_3$P)$_2$Pt(H)SiMes$_2$H (**4**) point to a Pt-H–Si-H exchange mechanism that does not involve a silylene intermediate, but rather a reductive elimination – oxidative addition couple. This observation is consistent with the notion that a metal center must be unsaturated for

silylene complex formation by α-migration to be favorable (see ref. 8*f*).

Experimental

General information

Unless otherwise noted, all manipulations were performed under an atmosphere of nitrogen using standard Schlenk techniques and (or) in a glovebox. Dry, oxygen-free solvents were employed throughout. Diethyl ether (Et_2O), pentane, hexane, and toluene were distilled from sodium benzophenone ketyl and stored under N_2 prior to use. Benzene-d_6 and toluene-d_8 were purified by vacuum distillation from Na–K alloy. Unless otherwise specified, all reagents were purchased from commercial suppliers and used without further purification. Pyridine was distilled from sodium and stored under N_2. Pt(P-*i*-Pr$_3$)$_3$ (15), Pt(PCy$_3$)$_2$ (15), Mes$_2$Si(SiMe$_3$)$_2$ (11), and Mes$_2$SiH$_2$ (34) were prepared by literature methods. Lithium aluminum hydride was recrystallized from Et_2O and dried in vacuo prior to use. Ethylene (99.9%) was obtained from Airgas, and 2-butyne (Aldrich) was vac-transferred and stored over molecular sieves prior to use. Photolysis reactions were carried out in a Rayonet RPR-100 Hg lamp reactor.

NMR spectra were recorded with a Bruker AMX-400 at 400.1 MHz (^{1}H) and 162.0 MHz (^{31}P) or a DRX-500 at 125.8 MHz (^{13}C) instrument and at room temperature and in benzene-d_6 unless otherwise noted. ^{29}Si NMR spectra were obtained with the Bruker DRX-500 instrument at 99.4 MHz using 10 mg of Cr(acac)$_3$ as a relaxation agent. EXSY NMR experiments (phase sensitive NOESY) were performed at two different mixing times of 12 and 25 ms, and exchange rate constants were determined using the program D2DNMR (35). Melting points were taken under N_2 in sealed capillaries and are uncorrected. Elemental analyses were performed by the UCB Microanalytical Laboratory. Infrared (IR) spectra were obtained on a Mattson Galaxy 3000 FT-IR spectrometer, and all absorptions are reported in cm^{-1}. The UV–vis spectrum of **2** in toluene were recorded on a Hewlett Packard 8452A Diode Array spectrophotometer, respectively.

Pt(P-*i*-Pr$_3$)$_2$

A previous report described the low-yield conversion of Pt(P-*i*-Pr$_3$)$_3$ to Pt(P-*i*-Pr$_3$)$_2$ in vacuo (19). An improved synthesis is reported here. In a PTFE-sealed vessel, (*i*-Pr$_3$P)$_2$PtCl$_2$ (1.94 g, 3.30 mmol) was dissolved in 25 mL of THF, and 1% sodium amalgam (55 g, 30 equiv Na) was added. The pale yellow solution turned red over the reaction time of 3 days. The solution was transferred away from the remaining amalgam–NaCl mixture via cannula. The amalgam was washed with 2 × 5 mL pentane, and the washings were combined with the original supernatant. All solvent was removed in vacuo to give a viscous red oil. To this, 30 mL of pentane were added, giving a red solution and purple precipitate. The solution was filtered and concentrated to dryness to give red crystals of Pt(P-*i*-Pr$_3$)$_3$ (1.62 g, 96%). ^{1}H NMR δ: 1.99 (m, 1H, C*H*), 1.31 (virtual q $^2J_{HP} = ^1J_{HH} = 7$ Hz, 3H, C*H*$_3$). ^{31}P NMR δ: 72.2 (s with ^{195}Pt satellites, $^1J_{PPt} = 4179$ Hz).

(*i*-Pr$_3$P)$_2$Pt=SiMes$_2$ (1)

Complex **1** was prepared by the same method employed for **2** (vide infra), using Pt(P-*i*-Pr$_3$)$_3$. This red compound was observed in solution but was not isolated. ^{31}P NMR δ: 82.2 (s with ^{195}Pt satellites, $^1J_{PPt} = 3119$ Hz). ^{29}Si NMR δ: 367 (t with ^{195}Pt satellites, $^2J_{PSi} = 107$ Hz, $^1J_{SiPt} = 2973$ Hz).

(Cy$_3$P)$_2$Pt=SiMes$_2$ (2)

A fused silica Schlenk tube containing a magnetic stir bar was charged with Pt(PCy$_3$)$_2$ (314 mg, 0.415 mmol), Mes$_2$Si(SiMe$_3$)$_2$ (212 mg, 0.499 mmol), and 12 mL of hexane. The resulting mixture was stirred rapidly until all solids dissolved (10 min). Within minutes of beginning photolysis, the color of the solution changed from colorless to green. This color persisted and darkened over the photolysis period of 120 min at which time a green precipitate was observed on the sides of the tube. The hexane and hexamethyldisilane byproduct were removed under vacuum. The resulting mixture was washed with 2 × 5 mL of hexane to remove tetramesityldisilene (the silylene dimerization byproduct) as well as unreacted Pt(PCy$_3$)$_2$. The remaining green solid was dried in vacuo to give analytically pure **2** (mp 104°C decomposition (dec)). Yield: 231 mg (54%). X-ray quality crystals of **2** were grown from dilute (<0.04 M) reaction solutions over a 3–4 h period during photolysis. UV–vis (ε (M^{-1} cm^{-1})): 282 (14 000), 316 (14 000), 392 (2900). IR: 3033 (w), 1601 (w), 1448 (s), 1265 (w), 1173 (w), 1046 (w), 1002 (w), 850 (m), 738 (w), 723 (w), 613 (w), 512 (w), 464 (m). ^{1}H NMR δ: 6.83 (s, 4H, Ar*H*), 2.72 (s, 12H, *ortho*-Me), 2.19 (s, 6H, *para*-Me), 0.8–2.1 (br m, Cy). ^{31}P NMR δ: 71.7 (s with ^{195}Pt satellites, $^1J_{PPt} = 3068$ Hz). ^{29}Si NMR δ: 358 (t, $^2J_{PSi} = 112$ Hz). Anal. calcd for C$_{54}$H$_{88}$P$_2$PtSi: C 63.44, H 8.68; found: C 63.35, H 8.87.

Reaction of 2 with 2-butyne

In an NMR tube, **2** (11 mg, 0.01 mmol), 2-butyne (1 μL, 0.01 mmol), and benzene-d_6 were combined, and the tube was inverted several times to mix the reactants. The reaction was monitored by ^{31}P NMR spectroscopy and produced (Cy$_3$P)$_2$Pt(η^2-MeCCMe) via an unsymmetrical intermediate over several hours.[4] The ^{31}P NMR spectrum of the intermediate consists of two doublets with ^{195}Pt satellites (δ: 41.6, d $^2J_{PP} = 34$ Hz, $^1J_{PPt} = 3483$ Hz; δ: 33.3, d $^1J_{PPt} = 2899$ Hz).

Reaction of 2 with ethylene

A sealable PTFE-capped NMR tube containing **2** (10 mg, 0.01 mmol) and benzene-d_6 was degassed via three freeze-pump-thaw cycles, and 1 atm of ethylene was introduced. The reaction was monitored by ^{31}P NMR spectroscopy as it was converted to (Cy$_3$P)$_2$Pt(η^2-C$_2$H$_4$) via an unsymmetrical intermediate over several hours.

Reaction of 2 with PhSiH$_3$

Compound **2** (11 mg, 0.01 mmol), PhSiH$_3$ (5 μL, 0.04 mmol), and benzene-d_6 were combined in an NMR tube, which was then inverted several times to mix the reactants. The green color of **2** was rapidly bleached, and ^{1}H NMR spectroscopy revealed the presence of Mes$_2$SiH$_2$, Ph$_2$SiH$_2$, SiH$_4$, and trace H$_2$.

Formation of *trans*-(Cy₃P)₂Pt(H)SiMes₂H (3) from 2 and H₂

$$\text{Formation of } trans\text{-}(Cy_3P)_2Pt(H)SiMes_2H \text{ (3) from 2 and } H_2$$

A sealable PTFE-capped NMR tube containing a solution of **2** (7 mg, 6 µmol) and benzene-d_6 was degassed via two freeze-pump-thaw cycles, and 1 atm of H_2 was introduced. $(Cy_3P)_2Pt{=}SiMes_2$ dissolved slowly over the reaction period of 2 days. During this time, the solution changed color from green to pale yellow. The formation of **3** and $(Cy_3P)_2PtH_2$ (ca. 1:1) was observed by NMR spectroscopy. ^1H NMR (for **3**) δ: 6.66 (s, 4H, ArH), 5.76 (m with ^{195}Pt satellites, $^2J_{HPt}$ = 319 Hz, 1H, SiH), 2.43 (s, 12H, *ortho*-Me), 2.25 (s, 6H, *para*-Me), 1.0–2.5 (br m, Cy), –3.12 (t with ^{195}Pt satellites, $^2J_{HP}$ = 17.6 Hz, $^1J_{HPt}$ = 629 Hz, 1H, PtH). ^{31}P NMR (–29°C, toluene-d_8) δ: 33.58 (d, $^2J_{PP}$ = 346 Hz, $^1J_{PPt}$ = 2715 Hz), 26.94 (d with ^{195}Pt satellites, $^2J_{PP}$ = 346 Hz, $^1J_{PPt}$ = 2632).

cis-(Cy₃P)₂Pt(H)SiMes₂H (4)

A Schlenk tube containing $Pt(PCy_3)_2$ (228 mg, 0.302 mmol), a magnetic stir bar, and 25 mL of hexane was stirred and cooled to 0°C. Simultaneously, another tube containing Mes_2SiH_2 (81 mg, 0.302 mmol) and 10 mL of hexane was likewise cooled and stirred. The dimesitylsilane solution was added to the first vessel dropwise via cannula over 12 min. Stirring at 0°C was continued for another 10 min, and then the solution was allowed to warm to room temperature. After 1.5 h the solvent was removed in vacuo. Recrystallization from diethyl ether afforded 147 mg (48%) of **4** (mp 159°C dec). IR (KBr): 3014 (m), 2932 (m), 2660 (w), 2150 (w), 2064 (m), 1596 (m), 1546 (w), 1446 (s), 1410 (w), 1328 (w), 1260 (m), 1173 (m), 1105 (m), 1011 (m), 928 (w), 887 (m), 846 (s), 737 (m), 710 (w), 599 (w), 519 (m), 496 (m), 432 (w). ^1H NMR δ: 6.89 (s, 4H, ArH), 5.86 (br, 1H, SiH), 2.85 (s, 12H, *ortho*-Me), 2.23 (s, 6H, *para*-Me), 1–2.2 (br m, Cy), –3.98 (br dd with ^{195}Pt satellites, $^2J_{HPcis}$ = 37 Hz, $^2J_{HPtrans}$ = 183 Hz, $^2J_{HPt}$ = 1050 Hz, PtH). ^{31}P NMR δ: 45.1 (s with ^{195}Pt satellites, $^1J_{PPt}$ = 1580 Hz), 31.6 (s with ^{195}Pt satellites, $^1J_{PPt}$ = 2740 Hz). ^{13}C NMR δ: 144.2 (br, *ortho*-C), 143.1 (br, *ipso*-C), 136.0 (br, *para*-C), 129.3 (s, *meta*-C), 39.6, 37.1, 31.1, 28.6, 28.2, 27.4, 27.2 (br, Cy), 25.4 (br, *ortho*-Me), 21.6 (s, *para*-Me). Anal. calcd for $C_{54}H_{90}P_2PtSi$: C 63.31, H 8.85; found: C 63.84, H 9.28.

Reactions of 1 with *R*OH (*R* = H, Me, Et)

In three separate reactions, water (ca. 0.2 µL, 0.01 mmol), methanol (0.3 µL, 0.01 mmol), or ethanol (0.6 µL, 0.01 mmol) was injected into a septum-capped NMR tube containing **1** (10 mg, 0.01 mmol) and benzene-d_6. The tube was then inverted several times to assure mixing. The resulting colorless solutions were then analyzed by ^1H and ^{31}P NMR spectroscopy, which revealed quantitative formation of $Pt(PCy_3)_2$ and $Mes_2Si(OR)H$, which were identified by comparison with independently prepared siloxanes (*R* = H (36), Me (37), Et (38)).

Isocyanide insertion reactions into the Ta—C bonds of cationic and zwitterionic tantalocenes[1]

Kevin S. Cook, Warren E. Piers, Brian O. Patrick, and Robert McDonald

Abstract: The insertion of isonitriles R'NC (R' = t-Bu, C_6H_{11}, $CH_2C_6H_5$) occurs exclusively into the Ta—CH_2 bonds of the zwitterionic compounds $(C_5H_4R)_2Ta[CH_2B(C_6F_5)_3]CH_3$ (R = H, **1a**; R = CH_3, **1b**) at relatively slow rates at room temperature to form ***N-out*** isomers as the sole kinetic products. By comparison, insertion of the same isonitrile substrates into a Ta—CH_3 bond of the non-zwitterionic analogs $[(C_5H_4R)_2Ta(CH_3)_2][A]$ (R = H, A = $B(C_6F_5)_4$, **3a**; R = CH_3, A = BF_4, **3b**) occurs much more rapidly, again to form ***N-out*** isomers exclusively under kinetic conditions. The difference in rate is attributed to the presence of a ground state α-agostic interaction in the zwitterionic compounds, which is not featured in the dimethyl ion pairs. All of the ***N-out*** isomers formed undergo thermal and irreversible conversion to the corresponding ***N-in*** isomers at rates that are conveniently followed by ^{1}H NMR spectroscopy. The rates were studied at different temperatures to obtain activation parameters for each transformation. The rate and activation trends for this isomerization were analyzed as a function of the structural changes in the compounds. It was found that the rate decreased as the steric bulk of the isonitrile substitutent R' increased and that the rates were faster for the series that incorporated the more electron-donating $C_5H_4CH_3$ ancillary ligand. Furthermore, isomerization rates for the zwitterionic ***N-out*** compounds were faster than those found in the non-zwitterionic series. This study represents one of the more extensive kinetic analyses of the rate of ***N-out*** to ***N-in*** isomerization as a function of structural changes. The observations are consistent with the mechanistic picture that has been developed for this process, involving dissociation of the η^2 iminoacyl ligand, rotation about the M—$C_{iminoacyl}$ bond and recoordination to the inside site of the metallocene wedge.

Key words: cationic metallocenes, isocyanide insertion, agostic interactions, tantalum.

Résumé : À la température ambiante, l'insertion d'isonitriles, R'NC (R' = t-Bu, C_6H_{11}, $CH_2C_6H_5$) se produit à des vitesses relativement faibles et uniquement dans les liaisons Ta—CH_2 des composés zwitterioniques $(C_5H_4R)_2Ta[CH_2B(C_6F_5)_3]CH_3$ (R = H, **1a**; R = CH_3, **1b**) pour conduire à la formation d'isomères ***N-out*** comme seuls produits cinétiques. Par comparaison, l'insertion des mêmes substrats isonitriles dans une liaison Ta—CH_3 des analogues non zwitterioniques $[(C_5H_4R)_2Ta(CH_3)_2][A]$ (R = H, A = $B(C_6F_5)_4$, **3a**; R = CH_3, A = BF_4, **3a**) se produit beaucoup plus rapidement, mais dans des conditions cinétiques il ne se forme encore une fois que les isomères ***N-out***. La différence de vitesse est attribuée à la présence, dans l'état fondamental des composés zwitterioniques, d'une interaction α-agostique qu'on n'existe pas dans les paires d'ions diméthylées. Tous les composés ***N-out*** qui se forment subissent une conversion thermique et irréversible vers les isomères correspondants ***N-in***, à des vitesses qui peuvent être facilement suivies par spectroscopie RMN du ^{1}H. On a étudié les vitesses à différentes températures pour déterminer les paramètres d'activation de chacune des transformations. On a analysé les tendances dans les vitesses et les activations en fonction des changements structuraux dans les composés. On a trouvé que la vitesse diminue avec une augmentation de l'encombrement stérique du substituant R' des isonitriles et que les vitesses augmentent pour les séries qui incorporent le ligand ancillaire électrodonneur $C_5H_4CH_3$. De plus, les vitesses d'isomérisation des composés ***N-out*** zwitterioniques sont plus rapides que celles des séries non zwitterioniques. Cette étude représente l'une des analyses cinétiques les plus extensives de la vitesse d'isomérisation ***N-out*** en ***N-in*** en fonction de changements structuraux. Les observations sont en accord avec les idées mécanistiques qui ont été développées pour ce processus et qui impliquent une dissociation du ligand η^2-iminacayle, une rotation autour de la liaison M—$C_{iminoacyle}$ et une recoordination vers le site intérieur de l'extrémité du métallocène.

Mots clés : métallocènes cationiques, insertion d'isocyanure, interactions agostiques, tantale.

Introduction

The migratory insertion of CO or CNR into metal—carbon bonds is a key C—C bond-forming reaction in organometallic chemistry (1). Its mechanism has been investigated in several classic studies (1), and stoichiometric insertions into the metal—carbon bonds of early transition metal, bent metallocenes such as Cp_2ZrMe_2 have figured prominently in this body of research (2). For these electrophilic organometallic substrates, the resulting acyl or iminoacyl products adopt an η^2 bonding mode where an O or N lone pair also contributes electron density to the Lewis acidic metal center. Consequently, the η^2 acyl or iminoacyl complexes can exist as "*O/N-out*" or "*O/N-in*" isomers (Chart 1), and the latter has been shown to be the thermodynamically favored isomer, while the former is the kinetically preferred product. Better orbital overlap between the acyl–iminoacyl ligand frontier orbitals with the available metallocene orbitals in the *N-in* isomer accounts for the greater overall stability of this isomer (3).

O/N-out   **O/N-in**

E = O, NR

I, ref. 5
The *O/N-out* to *O/N-in* isomerization is often quite rapid, and the *O/N-out* isomers are for the most part only fleetingly observed, making detailed study of this process difficult. However, based on both experimental (2) and computational (3, 4) studies, it is accepted that the isomerization probably takes place via dissociation of O or N to form an η^1 acyl–iminoacyl complex that can undergo rotation about the M—$C_{acyl–iminoacyl}$ bond. Much qualitative experimental evidence in support of this picture exists, but few studies have reported quantitative kinetic and thermodynamic data as a function of systematic structural variation to delineate the factors influencing this isomerization process.

While group 4 metal-based metallocenes have played a crucial role in the development of this chemistry, recently the reactions of tantalocene mimics containing dianionic

carborane (5), borollide (6), or imide (7) donors (which are isoelectronic to, for example, Cp_2ZrMe_2) with various isonitriles have also been studied and shown to undergo similar chemistry. In one of these systems — the tantalum(V) carborane system **I** shown in Chart 1 and reported by Finn, Grimes, and co-workers (5) — the *N-out* isomers formed with a variety of isocyanides were observed to be somewhat more stable than those of the group 4 metallocenes, allowing for the direct observation of the interconversion of these isomers. The *N-out* structure thermally converts to the *N-in* isomer, which can in turn be driven back to the *N-out* species photochemically. While no kinetic data were reported, both *N-out* and *N-in* isomers of one particular compound were structurally characterized for direct comparison.

By virtue of their dianionic Cp mimics, these Ta(V) dialkyls are similar to the group 4 dialkyls in that they are neutral. Another family of Ta(V) dialkyls isoelectronic to Cp_2ZrMe_2 are the *cationic* compounds $[Cp_2TaMe_2]^+[A]^-$, formed readily by abstraction of methide anion from the neutral trimethyl precursor Cp_2TaMe_3 (8). A subgroup of this series are the *zwitterionic* analogs of these ion pairs, prepared by the reaction of Schrock's methylidene methyl complex $Cp_2Ta(=CH_2)CH_3$ with the highly electrophilic borane $B(C_6F_5)_3$ (9). We found that the zwitterions react slowly with *tert*-butyl isonitrile to form an *N-out* iminoacyl complex, resulting from regioselective insertion into the Ta—$CH_2B(C_6F_5)_3$ bond. Surprisingly, isonitrile insertions involving ion pairs $[Cp_2TaMe_2]^+[A]^-$ have not been reported, so to compare the characteristics of these reactions with those observed for zwitterions, we have prepared examples of compounds $[Cp_2TaMe_2]^+[A]^-$ and evaluated their reactivity with RNC (R = *t*-Bu, C_6H_{11}, and $CH_2C_6H_5$). In all cases we find the kinetic *N-out* isomers to be isolable and stable towards isomerization under ambient conditions. All, however, undergo clean conversion to their thermodynamic *N-in* isomers under controlled conditions, allowing for determination of the kinetic and thermodynamic parameters of this isomerization for a variety of related compounds.

Results and discussion

As shown in eq. [1], the methylidene methyl tantalocene compounds $Cp_2Ta(=CH_2)CH_3$ and $Cp_2'Ta(=CH_2)CH_3$ (Cp = C_5H_5; Cp' = C_5H_4Me) react rapidly with the perfluoroaryl borane Lewis acids $B(C_6F_5)_3$ (10) and $H_3CB(C_6F_5)_2$ (11) via electrophilic attack on the nucleophilic carbene ligand.

[1]

R = H; R' = C_6F_5, **1a**
R = CH_3; R' = C_6F_5, **1b**
R = H; R' = CH_3, **2a**
The products, as detailed in our earlier communication (9), are the zwitterionic tantalum dialkyl compounds **1a–b** and **2a** and are characterized by a strong ground state α agostic interaction involving one of the C—H bonds of the borate-substituted alkyl ligand. Strong evidence for this

interaction is found in the solid state structure of compound **1a**, and it persists in solution, as evidenced by the low average $^1J_{C-H}$ values of 82–100 Hz found for the CH$_2$ group. In all three compounds, the anionic charge associated with the borate moiety is largely localized on the methylene carbon, rendering the C—H bonds quite electron rich and capable of strong donation to the cationic metal center. In so doing, the agostic interaction utilizes the last available metallocene orbital and perhaps stabilizes the complex with respect to a neutralizing -C$_6$F$_5$ transfer from boron to tantalum, a process that is apparently quite facile in related, titanium-based zwitterions formed upon elimination of methane from ion pairs of the general formula [Cp(L)TiCH$_3$]$^+$[H$_3$CB(C$_6$F$_5$)$_3$]$^-$ (12).

Non-zwitterionic dialkyl tantalocene ion pairs **3a–b** are trivially synthesized via methide abstraction from Cp$_2$TaMe$_3$ and Cp$'_2$TaMe$_3$ using trityl salts (eq. [2]).

[2]

R = H; A = B(C$_6$F$_5$)$_4$, **3a**
R = CH$_3$; A = BF$_4$, **3b**
This reaction has been known for some time and is a key step in the synthesis of Cp$_2$Ta(=CH$_2$)CH$_3$ (8). Note that the counteranions in compounds **3** are different; in **3a**, the counteranion is the tetrakis-perfluoroarylborate [B(C$_6$F$_5$)$_4$], while for the C$_5$H$_4$Me-stabilized metallocene cation **3b**, the [BF$_4$] counteranion is used. The reasons for this discrepancy have to do with the solubility properties of the various ion pairs and the requirements for the kinetic studies described below. The C$_5$H$_5$–BF$_4$ combination gave an ion pair that was sparingly soluble even in donor solvents, while the compound [(C$_5$H$_4$Me)$_2$TaMe$_2$][B(C$_6$F$_5$)$_4$] was too soluble, even in non-donor solvents, for us to isolate in purity sufficient to carry out reliable kinetic studies. The C$_5$H$_5$–B(C$_6$F$_5$)$_4$ and C$_5$H$_4$Me–BF$_4$ combinations, however, had ideal solubility properties. Since the [Cp$_2$TaMe$_2$]$^+$ cation has been shown to be very weakly coordinating towards perfluoroaryl borate counteranions (13), and since even the relatively more coordinating triflate anion shows little interaction with the related [(C$_5$Me$_5$)CpTaMe$_2$]$^+$ cation (14), we feel that any effects due to the change in anion can be largely ignored in the interpretation of the data presented below. Nevertheless, this is an assumption and must be acknowledged as such.

While compound **3b** has been reported previously (8), **3a**, with the [B(C$_6$F$_5$)$_4$]$^-$ counteranion, is a new ion pair. The ^{1}H NMR spectrum of the cation is identical to that reported for the [BF$_4$]$^-$ salt, lending credence to the above assumption that the anion has little effect on the properties of the cation. The ^{19}F NMR data for the [B(C$_6$F$_5$)$_4$]$^-$ anion is typical for this species (15). Analytically pure samples of **3a** were pre-

pared in order to carry out the kinetic studies described below. Unlike the zwitterionic compounds, neither **3a** nor **3b** exhibits any evidence for α agostic interactions in the ground state. No low-frequency IR C–H stretches are observed in the IR spectra, and $^1J_{C-H}$ coupling constants for the Ta-CH$_3$ groups are normal, although admittedly perturbation in this value would not be expected to be large given the six C—H bonds over which the agostic interaction would be averaged.

The zwitterions **1** react slowly with isocyanides to form new **N-out** iminoacyl zwitterions via selective insertion of the isocyanide reagent into the Ta—CH$_2$ bond; no products resulting from insertion into the Ta—CH$_3$ bond are observed (eq. [3]) (16).

[3]

R = H; R' = ^{t}Bu, **N-out 4a**
R = CH$_3$; R' = ^{t}Bu, **N-out 4b**
R = H; R' = C$_6$H$_{11}$, **N-out 5a**
In order for the reaction to proceed cleanly, an excess of the isocyanide reagent is required; with only 1 equiv, the reactions are very slow. Under pseudo-first-order conditions, the reactions are clean and conveniently followed by NMR spectroscopy. The products **4a–b** and **5a** are assigned[3] as the η^2 **N-out** iminoacyl isomers on the basis of ^{13}C NMR spectroscopy, ^{1}H ROESY experiments, and the X-ray structure for **N-out 4b**, which has been discussed in detail elsewhere (9). In sharp contrast to the sluggish pace of the reactions of eq. [3], reaction of ion pairs **3a** and **3b** with 1 equiv of RNC at –78°C results in a rapid reaction and provides the iminoacyl compounds **6a–b** (t-BuNC), **7a–b** (C$_6$H$_{11}$NC), and **8a–b** (C$_6$H$_5$CH$_2$NC) as one isomer (eq. [4]).

[4]

R = H; A = B(C$_6$F$_5$)$_4$; R' = ^{t}Bu, **N-out 6a**
R = CH$_3$; A = BF$_4$; R' = ^{t}Bu, **N-out 6b**
R = H; A = B(C$_6$F$_5$)$_4$; R' = C$_6$H$_{11}$, **N-out 7a**
R = CH$_3$; A = BF$_4$; R' = C$_6$H$_{11}$, **N-out 7b**
R = H; A = B(C$_6$F$_5$)$_4$; R' = C$_6$H$_5$CH$_2$, **N-out 8a**
R = CH$_3$; A = BF$_4$; R' = C$_6$H$_5$CH$_2$, **N-out 8b**
These reactions are essentially complete upon mixing and are quantitative by ^{1}H NMR spectroscopy, as indicated in particular by a downfield shift of one of the Ta-CH$_3$ groups by about 2 ppm upon iminoacyl group formation. The ^{13}C NMR chemical shifts for the iminoacyl carbon all appear

---

[3] Although IR spectroscopy is a valuable analytical tool for iminoacyl compounds because of the C=N chromophore, the stretching frequency does not correlate well with the nature of the bonding, i.e. η^1 vs. η^2 or **N-out** vs. **N-in**. Therefore, since the iminoacyl compounds reported herein have been well characterized by NMR spectroscopy and X-ray crystallography, we have not acquired IR data for the new compounds.

Fig. 1. ORTEP diagram of the cation in **N-out 6a**; the anion has been omitted for clarity. Selected bond distances (Å): Ta(1)—N(1), 2.143(2); Ta(1)—C(1), 2.147(3); Ta(1)—C(7), 2.267(3); C(1)—N(1), 1.259(4); C(1)—C(2), 1.472(4); N(1)—C(3), 1.500(4). Selected bond angles (°): C(7)-Ta(1)-C(1), 78.7(1); C(1)-Ta(1)-N(1), 34.1(1); N(1)-Ta(1)-C(7), 112.9(1); C(2)-C(1)-N(1), 134.4(3); Ta(1)-C(1)-C(2), 152.8(2).
within the narrow range of 210.1–211.7 ppm and are characteristic of η^2-iminoacyl ligands (2a).

As in the reactions involving the zwitterions, the **N-out** isomers were formed exclusively under these conditions and were stable enough to isolate and fully characterize. The X-ray structures of **N-out 6a** and **N-out 7a** were carried out to demonstrate this conclusively; ORTEP diagrams of the cations for these compounds are given in Figs. 1 and 2 along with selected bond distances and angles. Full details on these structure determinations are available in the supporting information.[4] Given the similarity in the ^{13}C NMR data, the other compounds were also assigned to the **N-out** geometry. As can be seen in the figures, the nitrogen of the iminoacyl ligand is coordinated to the Ta center on the outside of the metallocene wedge in both cases. For transition metal iminoacyl complexes, the parameter Δ is defined as d(M—N) – d(M—C) and correlates at least qualitatively with the

electrophilicity of the metal center (2a). That is, the more electrophilic the metal center, the stronger is the dative M—N bond and the lower is the value observed for Δ. For **N-out 6a** and **7a**, the values of Δ are 0.004 Å and 0.000 Å, respectively, which are similar to the value of –0.002 Å reported for the carborane **N-out I** isomer of Chart 1 (5). Given the cationic nature of the Ta centers in **N-out 6a** and **7a**, one might expect a larger difference in Δ compared with the neutral (and relatively electron-rich) dicarbollide complex. It should be noted, however, that the values of Δ for η^2 iminoacyl complexes have been, for the most part, determined only for **N-in** isomers. Since the **N-out** isomers are thermodynamically less stable than the **N-in** isomers, owing to poorer overlap of the nitrogen lone pair with metallocene orbitals in this geometry (3, 4), Δ is likely less affected by electronic changes at the metal center and more prone to steric effects in the **N-out** isomer. Consistent with this

Fig. 2. ORTEP diagram of the cation in **N-out 7a**; the anion has been omitted for clarity. Selected bond distances (Å): Ta—N(1), 2.130(6); Ta—C(3), 2.130(7); Ta—C(1), 2.287(7); C(3)—N(1), 1.245(8); C(2)—C(3), 1.496(10); N(1)—C(4), 1.508(9). Selected bond angles (°): C(1)-Ta-C(3), 79.0(3); C(3)-Ta-N(1), 34.0(12; N(1)-Ta-C(1), 112.6(3); C(2)-C(3)-N(1), 132.0(7); Ta-C(3)-C(2), 154.7(6).
notion is the larger value of Δ of 0.088 Å observed for the **N-in** isomer of **I**, which is more in line with expectations for a neutral and relatively electron-rich d^0 complex (17).

The reason for the marked difference in reaction rates for the insertion of RNC, involving zwitterions **1** vs. ion pairs **3**, has its roots in the different ground-state structures for these compounds. Kinetic studies on the reaction of *t*-BuNC with **1a** under pseudo-first-order conditions pointed to a mechanism for insertion that involves dissociation of the α agostic interaction prior to isocyanide coordination and insertion (9). Most telling was the substantial inverse k_H/k_D of 0.84(4) at 30°C, observed when comparing the rates of insertion for **1a** and d_5-**1a** (prepared from Cp$_2$Ta(=CD$_2$)CD$_3$ and B(C$_6$F$_5$)$_3$). In the deuterated compound, the equilibrium between agostic and non-agostic structures will be perturbed towards the latter, allowing for faster rates of isocyanide coordination (and therefore insertion) in the labeled compound. In comparison to the ion pairs **3**, the necessity for dissociation of the α agostic C—H bond in zwitterions **1**, with its itinerant charge separation, slows the overall rate of the reaction considerably. Since the compounds **3** do not exhibit this interaction, they have an orbital available to accept the isocyanide

donor, allowing for rapid insertion chemistry. The lower steric demands of the dimethyl compounds probably also contribute to the dramatic rate difference observed.

[5]

R = H; R' = ^{t}Bu,   **N-in 4a**
R = CH$_3$; R' = ^{t}Bu,   **N-in 4b**
R = H; R' = C$_6$H$_{11}$,   **N-in 5a**

R = H; A = B(C$_6$F$_5$)$_4$; R' = ^{t}Bu,   **N-in 6a**
R = CH$_3$; A = BF$_4$; R' = ^{t}Bu,   **N-in 6b**
R = H; A = B(C$_6$F$_5$)$_4$; R' = C$_6$H$_{11}$,   **N-in 7a**
R = CH$_3$; A = BF$_4$; R' = C$_6$H$_{11}$,   **N-in 7b**
R = H; A = B(C$_6$F$_5$)$_4$; R' = C$_6$H$_5$CH$_2$,   **N-in 8a**
R = CH$_3$; A = BF$_4$; R' = C$_6$H$_5$CH$_2$,   **N-in 8b**
Iminoacyl compounds **N-out 4**–**8** are unusual in that they are essentially immune to isomerization to **N-in** isomers under ambient conditions. All of them do, however, undergo clean conversion to the thermodynamic **N-in** isomers under thermal duress (60–110°C, eq. [5]).

The isomerization is signaled in the ^{1}H NMR spectrum by a slight upfield shift in the cyclopentadienyl resonances and a downfield shift in the Ta-CH$_3$ and iminoacyl CH$_n$ protons ($n = 2$ for **4** and **5**; $n = 3$ for **6**, **7**, and **8**). In addition, the ^{13}C chemical shift for the iminoacyl carbon shifts downfield 8–9 ppm into the ranges of 221.7–223.6 ppm for the zwitterions and 217.7–220.2 ppm for compounds **6**–**8**. Thus, the two isomers are easily distinguishable on the basis of their ^{13}C NMR spectra.

Baseline separation in the signals for the two isomers in the ^{1}H NMR spectra allows for convenient monitoring of the isomerization and determination of first-order rate constants for the various compounds in the study; this data, along with the thermodynamic activation parameters obtained from Eyring plots, is collected in Table 1. The reactions were all found to be first order in the **N-out** isomer for greater than 3 half lives, and the rate constants given are an average of two separately determined values.

There are few studies measuring the activation parameters for the **N-out** to **N-in** isomerization process and no studies employing a wide range of derivatives. Bullock and coworkers have investigated the isomerization of the zirconocene system prepared through reaction of Cp(PMe$_3$)$_2$RuCH=CHZrClCp$_2$ with *t*-BuNC, the first system studied that showed irreversible rearrangement to the **N-in** isomer (18). Activation parameters reported for this zirconocene system were $\Delta H^{\ddagger} = 19.9(6)$ kcal mol^{-1}, $\Delta S^{\ddagger} = -3.4(22)$ eu, with a $\Delta G^{\ddagger}_{298} = 20.9$ kcal mol^{-1}. Measurement of the barrier to **N-out**/**N-in** interconversion in fluxional systems has also been reported. For example, Adams and Chodosh (19) have investigated the molybdenum system

Table 1. Rate constants and activation parameters for *N-out* to *N-in* isomerization of η^2-iminoacyl complexes.

[a]Reliable kinetic data for compound *N-out* **4a** could not be obtained because of the long reaction times required to effect isomerization. Higher temperatures also gave poor data owing to undesired side reactions.
[b]The range observed in $\Delta S^{\ddagger}$ (e.g., **6a** and **7b**) likely is a reflection of the narrow temperature ranges we were restricted to experimentally.

Cp(CO)$_2$Mo[η^2-C(=NMe)Me] and found activation parameters of $\Delta H^{\ddagger}$ = 14.7(5) kcal mol^{-1}, $\Delta S^{\ddagger}$ = −1.7(15) eu, and $\Delta G^{\ddagger}_{298}$ = 20.9 kcal mol^{-1}. Rothwell and co-workers (20) have reported a Gibbs free energy of activation of $\Delta G^{\ddagger}_{233}$ = 11.4(5) kcal mol^{-1} for the observed rotation in (ArO)$_2$Zr[η^2-C(=N(2,6-Me$_2$C$_6$H$_3$))CH$_2$Ph]$_2$ (Ar = 2,6-C$_6$-*t*-Bu$_2$H$_3$). The less bulky derivative (Ar = 2,6-C$_6$Ph$_2$H$_3$) gave a result of $\Delta G^{\ddagger}_{208}$ = 10.3(5) kcal mol^{-1}. Lappert et al. have also observed the interconversion of the two isomers of Cp$_2$Zr(Cl)-[η^2-C(=N(*p*-C$_6$H$_4$CH$_3$))CH(SiMe$_3$)$_2$] (16*b*). While our values for $\Delta S^{\ddagger}$ are comparable to those found in other systems — the magnitudes consistent with an intramolecular process, as can be seen in Table 1 — the $\Delta H^{\ddagger}$ and $\Delta G^{\ddagger}_{298}$ values are generally substantially larger in the present cationic tantalocene systems than these previously reported examples. This can be attributed to the stronger metal—ligand bonds for third row transition metal complexes, as well as the increased electrophilicity of the cationic tantalum center. Assuming the mechanism of isomerization involves slippage of the η^2-iminoacyl to an η^1-bound species, a stronger tantalum—nitrogen dative bond must be dissociated to form an η^1-iminoacyl ligand.

A trend is apparent in the rate of isomerization based on the steric bulk of the iminoacyl substituent on the nitrogen atom. The C$_5$H$_5$ cationic complexes, *N-out* **6a**, *N-out* **7a**,

and *N-out* **8a**, exhibit isomerization rate constants that increase as the alkyl group on the nitrogen atom changes from *t*-Bu (k_{360} = 1.21 × 10^{-5} s^{-1}) to C$_6$H$_{11}$ (k_{358} = 2.15 × 10^{-4} s^{-1}), which is similar to that found for the C$_6$H$_5$CH$_2$ isomerization (k_{358} = 1.96 × 10^{-4} s^{-1}). The $\Delta G^{\ddagger}$ values parallel the trend in rate constants, and a similar phenomenon is observed for the C$_5$H$_4$Me cations. The origin of this effect likely resides in steric interactions between the N-iminoacyl substituent and the Cp rings upon rotation about the Ta—C$_{\text{iminoacyl}}$ bond in the η^1 structure.

Comparison of the isomerization rates of the unsubstituted cyclopentadienyl cations *N-out* **6a**–**8a** with those of the methylcyclopentadienyl compounds *N-out* **6b**–**8b** provides further insight. In each cation pair the isomerization of the methylcyclopentadienyl derivative proceeds at an elevated rate compared with the Cp derivative. For example, the *t*-BuNC insertion product *N-out* **6a** isomerizes with a rate constant of k_{360} = 1.21 × 10^{-5} s^{-1}, nearly an order of magnitude slower than *N-out* **6b** (k_{358} = 1.05 × 10^{-4} s^{-1}). The presence of more electron-donating cyclopentadienyl rings for the C$_5$H$_4$Me derivatives facilitates the slippage of the iminoacyl from η^2 bonded to the η^1 intermediate.

Interestingly, a comparison of the rates of isomerization between analogous zwitterions and ion pairs (*N-out* **4b** vs. *N-out* **6b** and *N-out* **5a** vs. *N-out* **7a**) reveals that the zwit-

terions undergo more rapid isomerization at comparable temperatures. This seems counterintuitive given that, in the ground state of the *N-out* isomers whose structures have been determined, the bond distances from Ta to the iminoacyl nitrogen are comparable for *N-out* **4b** (2.121(5) Å) to those for the ion pairs *N-out* **6a** (2.143(2) Å) and *N-out* **7a** (2.130(6) Å). Indeed, the Δ parameter for the zwitterion is smaller (–0.061 Å), suggesting a more electrophilic metal center in the zwitterions. It might also be expected that more steric hindrance would exist in the iminoacyl rotation necessary for isomerization in the zwitterionic species. Nevertheless, the rates for zwitterions isomerization are about an order of magnitude higher than the non-zwitterionic counterpart, suggesting that differences in ion pairing in the zwitterionic vs. the non-zwitterionic ion pairs may be important in the transition state.

Conclusions

The results reported herein add to the body of research on the mechanistic aspects of isonitrile insertion into M—C bonds, providing corroborative evidence for the general mechanistic picture of the insertion step and the isomerization of *N-out* isomers to *N-in* structures. In particular, we have shown how ground state α agostic interactions can hamper coordination of the isonitrile substrate, leading to overall lower rates of insertion in comparison to non-agostic reactions. These results also show that kinetic *N-out* isomers are stabilized in highly electrophilic species, and that the barriers to conversion to the thermodynamic *N-in* isomers are influenced by a variety of factors, including the steric bulk of the isonitrile substituent and the electron-donating ability of the Cp ligands on the metallocene. Finally, the rate of isomerization in the zwitterionic *N-out* compounds is somewhat faster than the non-zwitterionic reactions, although the origin of this phenomenon is less clear.

Experimental section

General procedures

General procedures have been described in detail elsewhere (21).

Synthesis of Cp$_2$Ta[CH$_2$B(C$_6$F$_5$)$_3$]CH$_3$, 1a

Toluene (15 mL) was condensed into an evacuated flask containing B(C$_6$F$_5$)$_3$ (214 mg, 0.418 mmol) and a slight excess of Cp$_2$Ta(=CH$_2$)CH$_3$ (156 mg, 0.458 mmol) at –78°C. The solution was warmed to 25°C and stirred for 30 min. The toluene was removed under reduced pressure to leave a yellow residue. Hexane (15 mL) was condensed into the vessel, and the light yellow precipitate was isolated by filtration. The precipitate was washed by back distillation of hexane, and the solvent was removed under reduced pressure. Yield of **1a**: 324 mg, 0.380 mmol, 91%. X-ray quality crystals were grown by cooling a saturated 1,2-dichloroethane solution to –25°C. ^{1}H NMR (C$_6$D$_6$): 5.93 (s, 10H, C$_5$H$_5$), 2.13 (br., 2H, CH$_2$), 0.56 (s, 3H, CH$_3$). ^{13}C NMR (C$_6$D$_6$): 150.3 (CH$_2$, $^1J_{CH}$ = 98.7 Hz), 108.4 (C$_5$H$_5$), 21.4 (CH$_3$, $^1J_{CH}$ = 129.1 Hz). ^{11}B NMR (C$_6$D$_6$): –9.4. ^{19}F NMR (C$_6$D$_6$): –132.0 (2F, *o*-F), –159.7 (1F, *p*-F), –164.4 (2F, *m*-F).

Anal. calcd. for C$_{30}$H$_{15}$BF$_{15}$Ta: C 42.28, H 1.77; found: C 42.42, H 1.50.

Synthesis of Cp$_2'$Ta[CH$_2$B(C$_6$F$_5$)$_3$]CH$_3$, 1b

A procedure analogous to the synthesis of **1a**, using (C$_5$H$_4$Me)$_2$Ta(=CH$_2$)(CH$_3$), was employed. The product was isolated with 0.5 equiv of toluene by ^{1}H NMR after extended exposure to vacuum. Reagent amounts: B(C$_6$F$_5$)$_3$ (690 mg, 1.35 mmol), (C$_5$H$_4$Me)$_2$Ta(=CH$_2$)(CH$_3$) (500 mg, 1.36 mmol). Yield of **1b**, accounting for toluene: 1.183 g, 1.28 mmol, 95%. ^{1}H NMR (THF-d_8): 6.05 (m, 2H, C$_5$H$_4$), 5.83 (m, 2H, C$_5$H$_4$), 5.62 (m, 2H, C$_5$H$_4$), 5.57 (m, 2H, C$_5$H$_4$), 2.24 (s, 6H, C$_5$H$_4$-CH$_3$), 1.91 (br, 2H, CH$_2$), 0.43 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 139.9 (CH$_2$, $^1J_{CH}$ = 100.1 Hz), 126.2 (C$_5$H$_4$-CH$_3$), 114.2 (C$_5$H$_4$), 109.1 (C$_5$H$_4$), 109.0 (C$_5$H$_4$), 102.9 (C$_5$H$_4$), 27.7 (Ta-CH$_3$, $^1J_{CH}$ = 124.9 Hz), 14.8 (C$_5$H$_4$-CH$_3$). ^{11}B NMR (THF-d_8) = –4.4. ^{19}F NMR (THF-d_8): –130.9 (2F, *o*-F), –161.2 (1F, *p*-F), –164.8 (2F, *m*-F). Anal. calcd. for C$_{32}$H$_{19}$BF$_{15}$Ta·1/2C$_7$H$_8$: C 46.03, H 2.50; found: C 45.98, H, 2.42.

Cp$_2$Ta[CH$_2$B(C$_6$F$_5$)$_2$CH$_3$]CH$_3$, 2a

In a dry box, benzene (10 mL) was added to a flask containing H$_3$CB(C$_6$F$_5$)$_2$ (122 mg, 0.338 mmol) and Cp$_2$Ta(=CH$_2$)CH$_3$ (113 mg, 0.332 mmol). The solution was stirred at 25°C for 1 h, and the light yellow precipitate was isolated by filtration. The precipitate was washed with benzene through back distillation, and the solvent was removed under reduced pressure. Yield of **2a**: 183 mg, 0.261 mmol, 79%. ^{1}H NMR (CD$_2$Cl$_2$): 6.07 (s, 10H, C$_5$H$_5$), 2.46 (br. s, 2H, CH$_2$), 0.42 (s, 3H, Ta-CH$_3$), 0.36 (br. s, 3H, B-CH$_3$). ^{13}C NMR (CD$_2$Cl$_2$): 159.6 (C$_5$H$_5$), 108.0 (CH$_2$, $^1J_{CH}$ = 82.7 Hz), 20.6 (Ta-CH$_3$, $^1J_{CH}$ = 112.3 Hz), 14 (B-CH$_3$). ^{11}B NMR (CD$_2$Cl$_2$): –7.0. ^{19}F NMR (CD$_2$Cl$_2$): –133.7 (2F), –163.5 (1F), –166.0 (2F). Anal. calcd. for C$_{25}$H$_{18}$BF$_{10}$Ta: C 42.89, H 2.59; found: C 42.59, H 2.20.

Synthesis of [Cp$_2$TaMe$_2$]$^+$[B(C$_6$F$_5$)$_4$]$^-$, 3a

CH$_2$Cl$_2$ (10 mL) was condensed into an evacuated flask containing Cp$_2$TaMe$_3$ (1.513 g, 4.25 mmol). In separate flask, CH$_2$Cl$_2$ (40 mL) was condensed over [Ph$_3$C]$^+$[B(C$_6$F$_5$)$_4$]$^-$ (3.918 g, 4.25 mmol). The solution of trityl salt was added to the Cp$_2$TaMe$_3$ solution by cannula at 25°C with rapid stirring. An immediate light yellow precipitate formed, and the solution was stirred for an additional 15 min. The precipitate was isolated by filtration and washed once by back distillation of CH$_2$Cl$_2$. The solvent was then removed under reduced pressure. Yield of 5a: 3.917 g, 3.84 mmol, 90%. ^{1}H NMR resonances are identical to those previously reported for the cation (9, 13). ^{13}C NMR (THF-d_8): 114.1 (C$_5$H$_5$), 55.6 (Ta-CH$_3$, $^1J_{CH}$ = 125.6 Hz). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, *o*-F), –163.0 (1F, *p*-F), –166.5 (2F, *m*-F). Anal. calcd. for C$_{26}$H$_{16}$BF$_{20}$Ta: C 42.38, H 1.58; found: C 41.94, H 1.48.

Reaction of 1a with *t*-BuNC: Synthesis of *N-out* 4a

THF (10 mL) was condensed into an evacuated flask containing **1a** (315 mg, 0.370 mmol) at –78°C. Under a flow of argon, an excess of *tert*-butylisocyanide (400 mL, 3.83 mmol) was syringed into the flask. The solution was warmed to 25°C and stirred for 75 min. THF was removed

under reduced pressure to leave a white residue, which was filtered after suspension in hexane (10 mL). The precipitate was washed by back distillation using hexane, and the solvent was removed under reduced pressure. Yield of *N-out* **4a**: 288 mg, 0.308 mmol, 83%. ^{1}H NMR (THF-d_8): 5.67 (s, 10 H, C$_5$H$_5$), 3.75 (br., 2H, CH$_2$), 1.35 (s, 9H, C(CH$_3$)$_3$), 0.39 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 219.8 (*C*=N-*t*-Bu), 107.4 (C$_5$H$_5$), 62.9 (*C*(CH$_3$)$_3$, 34.5 (CH$_2$), 29.2 (C(*C*H$_3$)$_3$, 5.0 (CH$_3$). ^{11}B NMR (THF-d_8): –10.9. ^{19}F NMR: –129.4 (2F, *o*-F), –162.2 (1F, *p*-F), –165.7 (2F, *m*-F). Anal. calcd. for C$_{35}$H$_{24}$NBF$_{15}$Ta: C 44.95, H 2.59, N 1.50; found: C 44.69, H 2.39, N 1.57.

Isomerization of *N-out* **4a** to *N-in* **4a**

N-out **4a** (170 mg, 0.18 mmol) was placed into a 25 mL glass bomb and THF (10 mL) was condensed in. The bomb was heated at 70°C for 10 days. The colourless solution was cannula-transferred into a 25 mL round bottom flask with filtering frit. The THF was removed to leave a sticky, colourless residue. Hexanes (10 mL) were condensed in at –78°C, and the residue sonicated to produce a white powder. The product was filtered off, washed with hexanes by distillation (3 × 5 mL), and volatiles were removed in vacuo. Yield of *N-in* **4a**: 152 mg, 0.16 mmol, 89%. ^{1}H NMR (THF-d_8): 5.46 (s, 10 H, C$_5$H$_5$), 3.85 (br, 2H, CH$_2$), 1.41 (s, 9H, C(CH$_3$)$_3$), 0.78 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 221.7 (*C*=N-*t*-Bu), 106.0 (C$_5$H$_5$), 66.1 (*C*(CH$_3$)$_3$), 35.0 (CH$_2$), 30.0 (C(*C*H$_3$)$_3$), 3.9 (CH$_3$). ^{11}B NMR (THF-d_8): –10.0. ^{19}F NMR: –130.0 (2F, *o*-F), –160.3 (1F, *p*-F), –164.6 (2F, *m*-F).

Reaction of 1b with *t*-BuNC: Synthesis of *N-out* **4b**

THF (10 mL) was condensed into an evacuated flask containing **1b** (325 mg, 0.35 mmol) at –78°C. Under a flow of argon, an excess of *tert*-butylisocyanide (400 mL, 3.83 mmol) was syringed into the flask. The solution was warmed to 25°C and stirred for 2 h. THF was removed under reduced pressure to leave a white residue, which was filtered from hexane (10 mL). The precipitate was washed by back distillation with hexane, and the solvent was removed under reduced pressure. Yield of *N-out* **4b**: 283 mg, 0.29 mmol, 84%. X-ray quality crystals were grown by layering a saturated CH$_2$Cl$_2$ solution with hexanes. ^{1}H NMR (THF-d_8): 5.75 (m, 2H, C$_5$H$_4$), 5.61 (m, 2H, C$_5$H$_4$), 5.35 (m, 2H, C$_5$H$_4$), 5.01 (m, 2H, C$_5$H$_4$), 3.76 (br, 2H, CH$_2$), 2.01 (s, 6H, C$_5$H$_4$(CH$_3$)), 1.35 (s, 9H, C(CH$_3$)$_3$), 0.22 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 220.7 (*C*=N-*t*-Bu), 121.4 (C$_5$H$_4$-CH$_3$), 110.0 (C$_5$H$_4$), 109.7 (C$_5$H$_4$), 108.2 (C$_5$H$_4$), 94.4 (C$_5$H$_4$), 62.9 (*C*(CH$_3$)$_3$), 33.1 (CH$_2$), 29.4 (C(*C*H$_3$)$_3$), 14.2 (C$_5$H$_4$-*C*H$_3$), 9.4 (Ta-CH$_3$). ^{11}B (THF-d_8): –9.0. ^{19}F NMR (THF-d_8): –129.3 (2F, *o*-F), –162.3 (1F, *p*-F), –165.7 (2F, *m*-F). Anal. calcd. for C$_{37}$H$_{28}$NBF$_{15}$Ta·CH$_2$Cl$_2$: C 43.54, H 2.88, N 1.34; found: C 43.63, H 2.78, N 1.34.

Isomerization of *N-out* **4b** to *N-in* **4b**

N-out **4b** (350 mg, 0.360 mmol) was placed into a 25 mL glass bomb and THF (10 mL) was condensed into the vessel. The bomb was heated at 70°C for 2 days. The colourless solution was cannula-transferred into a 25 mL round bottom flask with filtering frit. The THF was removed to leave a colourless, waxy residue. Hexanes (10 mL) were condensed

in at –78°C, and the suspension was sonicated to produce a white powder. The product was isolated by filtration, washed with hexanes by distillation (3 × 5 mL), and dried in vacuo. Yield of *N-in* **4b**: 250 mg, 0.257 mmol, 71%. ^{1}H NMR (THF-d_8): 5.34 (m, 2H, C$_5$H$_4$), 5.10 (m, 2H, C$_5$H$_4$), 5.06 (m, 2H, C$_5$H$_4$), 5.02 (m, 2H, C$_5$H$_4$), 3.85 (br, 2H, CH$_2$), 1.99 (s, 6H, C$_5$H$_4$(CH$_3$)), 1.38 (s, 9H, C(CH$_3$)$_3$), 0.55 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 223.3 (*C*=N-*t*-Bu), 125.5 (C$_5$H$_4$-CH$_3$), 108.1 (C$_5$H$_4$), 103.9 (C$_5$H$_4$), 103.6 (C$_5$H$_4$), 98.4 (C$_5$H$_4$), 66.0 (*C*(CH$_3$)$_3$), 35.2 (CH$_2$), 30.3 (C(*C*H$_3$)$_3$), 14.6 (C$_5$H$_4$-*C*H$_3$), 11.1 (Ta-CH$_3$). ^{11}B NMR (THF-d_8): –9.9. ^{19}F NMR: –129.8 (2F, *o*-F), –160.6 (1F, *p*-F), –164.7 (2F, *m*-F).

Reaction of 1a with C$_6$H$_{11}$NC: Synthesis of *N-out* **5a**

A procedure analogous to that employed for the synthesis of *N-out* **4a** was used to prepare this compound. Reagent amounts: **1a** (300 mg, 0.352 mmol), cyclohexyl isocyanide (500 mL, 4.02 mmol). Yield of *N-out* **5a**: 247 mg, 0.256 mmol, 76%. ^{1}H NMR (THF-d_8): 5.66 (s, 10 H, C$_5$H$_5$), 3.60 (br. s, 3H, CH$_2$ and CH, C$_6$H$_{11}$), 1.05–1.95 (m, 10H, C$_6$H$_{11}$) 0.53 (s, 3H, CH$_3$). ^{11}B NMR (THF-d_8): –9.3. ^{19}F NMR: –129.5 (2F, *o*-F), –161.7 (1F, *p*-F), –165.5 (2F, *m*-F). Anal. calcd. for C$_{37}$H$_{26}$NBF$_{15}$Ta·C$_7$H$_8$: C 50.16, H 3.25, N 1.33; found: C 50.36, H 3.07, N 1.39.

Isomerization of *N-out* **5a** to *N-in* **5a**

N-out **5a** (221 mg, 0.230 mmol) was placed in a 25 mL glass bomb and THF (15 mL) was condensed in at –78°C. The bomb was sealed and placed in an oil bath at 65°C for 24 h. The light yellow solution was then cannula-transferred to a 25 mL round bottom flask equipped with a filtering frit. The THF was removed under reduced pressure to leave a yellow oil. Hexanes (10 mL) were condensed onto the oil at –78°C and the solution sonicated to produce light yellow powder. The powder was filtered off, washed with hexanes (3 × 5 mL) by back distillation, and dried in vacuo. Yield of *N-in* **5a**: 153 mg, 0.159, 61%. ^{1}H NMR (THF-d_8): 5.63 (s, 10 H, C$_5$H$_5$), 3.85 (br. s, 2H, CH$_2$ and *ipso*-CH, C$_6$H$_{11}$), 1.05–1.95 (m, 10H, C$_6$H$_{11}$) 0.75 (s, 3H, CH$_3$). ^{13}C NMR (THF-d_8): 223.6 (*C*=N), 105.9 (C$_5$H$_5$), 60.4 (*ipso*-C, C$_6$H$_{11}$), 32.3 (CH$_2$), 31.6 (C$_6$H$_{11}$), 26.4 (C$_6$H$_{11}$), 25.9 (C$_6$H$_{11}$), 3.2 (Ta-CH$_3$). ^{11}B NMR (THF-d_8): –11.2. ^{19}F NMR: –129.7 (2F, *o*-F), –160.7 (1F, *p*-F), –164.6 (2F, *m*-F).

Reaction of 3a with *t*-BuNC: Synthesis of *N-out* **6a**

THF (20 mL) was condensed into an evacuated flask containing **3a** (454 mg, 0.45 mmol) at –78°C. Under a flow of argon, an excess of *tert*-butylisocyanide (300 mL, 2.87 mmol) was syringed into the flask at –78°C. An immediate colour change from yellow to colourless was noted and the solution was warmed to 25°C. THF was removed under reduced pressure and the white residue filtered after suspension in hexanes. The solid was washed once with hexanes and dried under reduced pressure. Yield of *N-out* **6a**: 450 mg, 0.41 mmol, 92%. X-ray quality crystals were grown by cooling a saturated CH$_2$Cl$_2$ solution to –35°C. ^{1}H NMR (THF-d_8): 5.87 (s, 10H, C$_5$H$_5$), 2.80 (s, 3H, C(=N-*t*-Bu)CH$_3$), 1.49 (s, 9H, C(CH$_3$)$_3$), 0.76 (s, 3H, Ta-CH$_3$). ^{13}C NMR (THF-d_8): 211.1 (*C*=N-*t*-Bu), 107.3 (C$_5$H$_5$), 62.9 (*C*(CH$_3$)$_3$), 28.7 (C(*C*H$_3$)$_3$), 15.3 (C(=N-*t*-Bu)CH$_3$), 5.6 (Ta-

CH_3). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F). Anal. calcd. for C$_{41}$H$_{25}$NBF$_{20}$Ta: C 44.63, H 2.28, N 1.27; found: C 44.28, H 2.26, N 1.25.

Isomerization of *N-out* 6a to *N-in* 6a

N-out **6a** (250 mg, 0.226 mmol) was placed into a 25 mL glass bomb and THF (15 mL) was condensed in at –78°C. The vessel was backfilled with argon and placed in a 110°C oil bath for 24 h. The solution was cooled and then cannula-transferred to a 25 mL round bottom flask with a filtering frit. The THF was removed in vacuo to leave a sticky colourless oil. The oil was broken into a precipitate through sonication with hexanes (15 mL). The hexanes were then removed under reduced pressure to give a white powder. More hexanes (10 mL) were condensed in to make a slurry, from which the precipitate was filtered. The product was washed with hexanes (2 × 5 mL) by back distillation and the volatiles removed in vacuo. Yield of *N-in* **6a**: 228 mg, 0.206 mmol, 91%. ^{1}H NMR (THF-d_8): 5.85 (s, 10H, C$_5H_5$), 3.20 (s, 3H, C(=N-t-Bu)CH_3), 1.37 (s, 9H, C(CH_3)$_3$), 0.82 (s, 3H, Ta-CH_3). ^{13}C NMR (THF-d_8): 217.7 (*C*=N-t-Bu), 106.6 (*C*$_5$H$_5$), 65.2 (*C*(CH$_3$)$_3$), 29.2 (C(*C*H$_3$)$_3$), 23.1 (C(=N-t-Bu)*C*H$_3$), 3.8 (Ta-*C*H$_3$). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F). Anal. calcd. for C$_{41}$H$_{25}$NBF$_{20}$Ta: C 44.63, H 2.28, N 1.27; found: C 44.52, H 2.36, N 1.56.

Reaction of 3b with *t*-BuNC: Synthesis of *N-out* 6b

[Cp$_2$TaMe$_2$]$^+$[BF$_4$]$^-$, **3b** (295 mg, 0.647 mmol), was weighed into a 25 mL two-necked, round bottomed flask with septum, and CH$_2$Cl$_2$ (10 mL) was condensed in at –78°C to dissolve the solid. *tert*-Butylisocyanide (75 mL, 0.663 mmol) was syringed into the solution at –78°C and resulted in an immediate colour change from yellow to colourless. The solution was stirred for 30 min at 25°C and the CH$_2$Cl$_2$ was removed in vacuo to give a colourless oil. Hexane (10 mL) was condensed into the vessel and the solution sonicated to generate a white powder. The hexane was removed under reduced pressure, and a second quantity of hexane (10 mL) was condensed into the flask. The vessel was sonicated to free the white powder from the wall, the powder filtered, and volatiles removed in vacuo. Yield of *N-out* **6b**: 299 mg, 0.555 mmol, 86%. ^{1}H NMR (CD$_2$Cl$_2$): 5.92 (m, 2H, C$_5H_4$), 5.70 (m, 2H, C$_5H_4$), 5.66 (m, 2H, C$_5H_4$), 5.24 (m, 2H, C$_5H_4$), 2.73 (s, 3H, C(=NC(CH$_3$)$_3$)CH_3), 2.04 (s, 6H, C$_5$H$_4$CH_3), 1.49 (s, 9H, C(CH_3)$_3$), 0.62 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_3$CN): 211.7 (*C*=N), 118.3 (*C*-Me, C$_5$H$_4$Me, under solvent resonance), 113.1 (*C*$_5$H$_4$Me), 111.1 (*C*$_5$H$_4$Me), 103.9 (*C*$_5$H$_4$Me), 100.7 (*C*$_5$H$_4$Me), 62.7 (*C*(CH$_3$)$_3$), 29.0 (C(*C*H$_3$)$_3$), 13.8 (C$_5$H$_4$-*C*H$_3$), 13.6 (NC-*C*H$_3$), 7.6 (Ta-*C*H$_3$). ^{11}B NMR (CD$_2$Cl$_2$): –1.0. ^{19}F NMR (CD$_2$Cl$_2$): –152.2 (4F). Isomerization of *N-out* 6b to *N-in* 6b

N-out **6b** (32 mg, 0.060 mmol) was weighed into a J. Young NMR tube, and an NMR amount of CD$_3$CN was added by Pasteur pipette. The tube was placed in a 110°C oil bath for 16 h. ^{1}H NMR (CD$_3$CN): 5.64 (m, 2H, C$_5H_4$), 5.58 (m, 2H, C$_5H_4$), 5.43 (m, 2H, C$_5H_4$), 5.33 (m, 2H, C$_5H_4$), 3.11 (s, 3H, C(=NC(CH$_3$)$_3$)CH_3), 2.02 (s, 6H, C$_5$H$_4$CH_3), 1.33 (s, 9H, C(CH_3)$_3$), 0.62 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_3$CN): 219.6 (*C*=N), 118.3 (*C*-Me, C$_5$H$_4$Me, under solvent resonance), 107.6 (*C*$_5$H$_4$Me), 107.2 (*C*$_5$H$_4$Me), 106.1 (*C*$_5$H$_4$Me), 101.6 (*C*$_5$H$_4$Me), 65.4 (*C*(CH$_3$)$_3$), 29.9 (C(*C*H$_3$)$_3$), 23.7 (NC-*C*H$_3$), 14.7 (C$_5$H$_4$-*C*H$_3$), 8.8(Ta-*C*H$_3$). ^{11}B NMR (CD$_2$Cl$_2$): –1.0. ^{19}F NMR (CD$_2$Cl$_2$): –152.2 (4F).

Reaction of 3a with C$_6$H$_{11}$NC: Synthesis of *N-out* 7a

A procedure analogous to that used to prepare *N-out* **6a** was used to prepare this compound. Reagent amounts: **3a** (366 mg, 0.359 mmol), cyclohexyl isocyanide (60 mL, 0.483 mmol). Yield of *N-out* **7a**: 295 mg, 0.261 mmol, 73%. ^{1}H NMR (THF-d_8): 5.88 (s, 10H, C$_5H_5$), 4.03 (m, 1H, *CH*, C$_6$H$_{11}$), 2.70 (s, 3H, C(=NC$_6$H$_{11}$)CH_3), 2.01 (m, 4H, C$_6$H$_{11}$), 1.58–1.30 (m, 6H, C$_6$H$_{11}$), 0.78 (s, 3H, Ta-CH_3). ^{13}C NMR (THF-d_8): 210.5 (*C*=N), 107.5 (*C*$_5$H$_5$), 63.5 (*C*H, C$_6$H$_{11}$), 32.5 (C$_6$H$_{11}$), 26.0 (C$_6$H$_{11}$), 25.8 (C$_6$H$_{11}$), 14.9 (NC-*C*H$_3$), 5.3 (Ta-*C*H$_3$). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F).

Isomerization of *N-out* 7a to *N-in* 7a

Prepared in the same manner as *N-in* **6a**. Reagent amounts: *N-out* **7a** (276 mg, 0.244 mmol). Yield of *N-in* **7a**: 240 mg, 0.212, 87%. ^{1}H NMR (CD$_3$CN): 5.71 (s, 10H, C$_5H_5$), 4.01(m, 1H, *CH*, C$_6$H$_{11}$), 2.94 (s, 3H, C(=NC$_6$H$_{11}$)CH_3), 1.80–1.10 (m, 10H, C$_6$H$_{11}$), 0.76 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_3$CN): 217.8 (*C*=N), 106.0 (*C*$_5$H$_5$), 68.4 (*ipso-C*, C$_6$H$_{11}$), 31.9 (C$_6$H$_{11}$), 26.1 (C$_6$H$_{11}$), 25.8 (C$_6$H$_{11}$), 21.0 (NC-*C*H$_3$), 3.7 (Ta-*C*H$_3$). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F). Anal. calcd. for C$_{43}$H$_{27}$NBF$_{20}$Ta: C 45.73, H 2.41, N 1.24; found: C 45.47, H 2.45, N 1.37.

Reaction of 3b with C$_6$H$_{11}$NC: Synthesis of *N-out* 7b

A procedure analogous to the synthesis of *N-out* **6b** was used to prepare this compound. Reagent amounts: **3b** (298 mg, 0.653 mmol), cyclohexyl isocyanide (82 mL, 0.659 mmol). Yield of *N-out* **7b**: 332 mg, 0.587 mmol, 89%. ^{1}H NMR (CD$_2$Cl$_2$): 5.91 (m, 2H, C$_5H_4$), 5.68 (m, 4H, C$_5H_4$), 5.34 (m, 2H, C$_5H_4$), 4.05 (m, 1H, *ipso-CH*, C$_6$H$_{11}$), 2.62 (s, 3H, C(=NC$_6$H$_{11}$)CH_3), 1.96 (s, 6H, C$_5$H$_4$CH_3), 1.96 (m, 3H, C$_6$H$_{11}$), 1.51 (m, 7H, C$_6$H$_{11}$), 0.62 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_2$Cl$_2$): 211.0 (*C*=N), 119.6 (*C*-CH$_3$, C$_5$H$_4$CH$_3$), 112.9 (*C*$_5$H$_4$), 110.3 (*C*$_5$H$_4$), 103.9 (*C*$_5$H$_4$), 100.4 (*C*$_5$H$_4$), 63.3 (*ipso-C*H, C$_6$H$_{11}$), 32.4 (C$_6$H$_{11}$), 25.6 (C$_6$H$_{11}$), 25.6 (C$_6$H$_{11}$), 14.0 (C$_5$H$_4$*C*H$_3$), 13.5 (C(=NC$_6$H$_{11}$)*C*H$_3$), 7.3 (Ta-*C*H$_3$). ^{11}B NMR (THF-d_8): –1.0. ^{19}F NMR (CD$_2$Cl$_2$): –152.2 (4F). Anal. calcd. for C$_{21}$H$_{30}$NBF$_4$Ta: C 44.70, H 5.36, N 2.48; found: C 44.14, H 5.85, N 2.46.

Isomerization of *N-out* 7b to *N-in* 7b

N-out **7b** (30 mg, 0.052 mmol) was weighed into a J. Young NMR tube, and an NMR amount of CD$_3$CN was added by Pasteur pipette. The tube was placed in a 100°C oil bath for 16 h. ^{1}H NMR (CD$_3$CN): 5.62 (m, 2H, C$_5H_4$), 5.60 (m, 2H, C$_5H_4$), 5.45 (m, 2H, C$_5H_4$), 5.35 (m, 2H, C$_5H_4$), 4.05 (m, 1H, *ipso-CH*, C$_6$H$_{11}$), 2.97 (s, 3H, C(=NC$_6$H$_{11}$)CH_3), 1.99 (s, 6H, C$_5$H$_4$CH_3), 1.81 (m, 2H,

C_6H_{11}), 1.65 (m, 3H, C_6H_{11}), 1.51 (m, 2H, C_6H_{11}), 1.12–1.40 (m, 3H, C_6H_{11}), 0.62 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_3$CN): 219.1 (C=N), 122.1 (C-CH$_3$, C$_5$H$_4$CH$_3$), 108.7 (C_5H_4), 106.6 (C_5H_4), 105.0 (C_5H_4), 101.7 (C_5H_4), 59.3 (ipso-CH, C_6H_{11}), 32.5 (C_6H_{11}), 26.0 (C_6H_{11}), 25.9 (C_6H_{11}), 21.0 (C(=NC$_6$H$_{11}$)CH$_3$), 14.5 (C$_5$H$_4$$CH_3$), 8.2 (Ta-$CH_3$). ^{11}B NMR (CD$_3$CN): –1.0. ^{19}F NMR (CD$_3$CN): –152.2 (4F).

Reaction of 3a with $C_6H_5CH_2NC$: Synthesis of N-out 8a

Compound **3a** (312 mg, 0.306 mmol) was weighed into a two-necked, round bottom flask fitted with a filtering frit and rubber septum. THF (10 mL) was condensed in at –78°C to produce a yellow solution, and benzyl isocyanide (37 mL, 0.306 mmol) was syringed in under a flow of argon. The resulting white slurry was stirred for 45 min while warming to room temperature and THF removed under reduced pressure to give a clear residue. Hexanes (20 mL) were condensed into the flask and the solution sonicated to break down the residue into a white powder. Solvent was removed in vacuo, and to leave a fine white powder, a second portion of hexanes (10 mL) was added, the resulting white slurry filtered, and solvent removed in vacuo. Yield of *N-out* **8a**: 300 mg, 0.263 mmol, 86%. ^{1}H NMR (THF-d_8): 7.49 (m, 5H, C_6H_5), 5.70 (s, 10H, C_5H_5), 5.05 (s, 2H, CH_2), 2.64 (s, 3H, C(=NCH$_2$C$_6$H$_5$)CH_3), 0.75 (s, 3H, Ta-CH_3). ^{13}C NMR (THF-d_8): 210.1 (C(=NCH$_2$C$_6$H$_5$)), 134.7 (ipso-C, C_6H_5), 130.9 (C_6H_5), 130.6 (C_6H_5), 107.5 (C_5H_5), 57.1 (CH$_2$), 14.2 (C(=NCH$_2$C$_6$H$_5$)CH$_3$), 5.4 (TaCH$_3$). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F). Anal. calcd. for C$_{44}$H$_{23}$NBF$_{20}$Ta: C 46.46, H 2.04, N 1.23; found: C 46.25, H 2.00, N 1.27.

Isomerization of N-out 8a to N-in 8a

N-out **8a** (30 mg, 0.052 mmol) was weighed into a J. Young NMR tube, and an NMR amount of THF-d_8 was added by Pasteur pipette. The tube was placed in an 80°C oil bath for 16 h. ^{1}H NMR (THF-d_8): 7.36 (m, 3H, C_6H_5), 7.24 (m, 2H, C_6H_5), 5.69 (s, 10H, C_5H_5), 4.82 (s, 2H, CH_2), 3.06 (s, 3H, C(=NCH$_2$C$_6$H$_5$)CH_3), 0.73 (s, 3H, Ta-CH_3). ^{13}C NMR (THF-d_8): 218.9 (C(=NCH$_2$C$_6$H$_5$)), 134.9 (ipso-C, C_6H_5), 130.6 (C_6H_5), 130.1 (C_6H_5), 129.7 (C_6H_5), 106.3 (C_5H_5), 49.4 (CH$_2$), 20.7 (C(=NCH$_2$C$_6$H$_5$)CH$_3$), 5.1 (Ta-CH$_3$). ^{11}B NMR (THF-d_8): –13.6. ^{19}F NMR (THF-d_8): –130.9 (2F, o-F), –163.1 (1F, p-F), –166.6 (2F, m-F).

Reaction of 3b with $C_6H_5CH_2NC$: Synthesis of N-out 8b

An analogous procedure to that employed for the synthesis of *N-out* **6b** was employed, except that pentane was used in the isolation of the product rather than hexane. Reagent amounts: **3b** (310 mg, 0.680 mmol); benzylisocyanide (83 mL, 0.681 mmol). Yield of *N-out* **8b**: 306 mg, 0.534 mmol, 79%. ^{1}H NMR (CD$_2$Cl$_2$): 7.45 (m, 5H, C_6H_5), 5.70 (m, 2H, C_5H_4), 5.53 (m, 2H, C_5H_4), 5.47 (m, 2H, C_5H_4), 5.12 (m, 2H, C_5H_4), 5.03 (s, CH_2), 2.55 (s, 3H, C(=NCH$_2$C$_6$H$_5$)CH_3), 1.86 (s, 6H, C$_5$H$_4$CH_3), 0.58 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_2$Cl$_2$): 211.1 (C=N), 133.8 (ipso-C, C_6H_5), 130.7 (C_6H_5), 130.2 (C_6H_5), 129.9 (C_6H_5), 118.8 (C-CH$_3$, C$_5$H$_4$CH$_3$), 112.9 (C_5H_4), 109.2 (C_5H_4), 104.3 (C_5H_4), 100.5 (C_5H_4), 57.3 (CH$_2$), 14.0 (C$_5$H$_4$$CH_3$), 13.0 (C(=NCH$_2C_6H_5$)$CH_3$), 7.5 (Ta-$CH_3$). ^{11}B NMR (THF-$d_8$): –1.0. ^{19}F NMR (CD$_2Cl_2$): –152.2 (4F). Anal. calcd. for

C$_{22}$H$_{27}$NBF$_4$Ta: C 46.10, H 4.75, N 2.44; found: C 45.71, H 4.97, N 2.41.

Isomerization of N-out 8b to N-in 8b

N-out **8b** (30 mg, 0.052 mmol) was weighed into a J. Young NMR tube, and an NMR amount of CD$_3$CN was added by Pasteur pipette. The tube was placed in an 80°C oil bath for 16 h. ^{1}H NMR (CD$_3$CN): 7.38 (m, 3H, C_6H_5), 7.27 (m, 2H, C6H5), 5.66 (m, 2H, C_5H_4), 5.56 (m, 2H, C_5H_4), 5.49 (m, 2H, C_5H_4), 5.22 (m, 2H, C_5H_4), 4.83 (s, CH_2), 2.98 (s, 3H, C(=NCH$_2$C$_6$H$_5$)CH_3), 1.80 (s, 6H, C$_5$H$_4$CH_3), 0.52 (s, 3H, Ta-CH_3). ^{13}C NMR (CD$_2$Cl$_2$): 220.2 (C=N), 135.4 (ipso-C, C_6H_5), 131.5 (C_6H_5), 131.2 (C_6H_5), 129.6 (C_6H_5), 121.6 (C-CH$_3$, C$_5$H$_4$CH$_3$), 110.8 (C_5H_4), 106.1 (C_5H_4), 103.6 (C_5H_4), 101.1 (C_5H_4), 48.6 (CH$_2$), 21.0 (C(=NCH$_2$C$_6$H$_5$)CH$_3$), 13.9 (C$_5$H$_4$$CH_3$), 7.7 (Ta-$CH_3$). ^{11}B NMR (THF-$d_8$): –1.0. ^{19}F NMR (CD$_2Cl_2$): –152.2 (4F).

Kinetic measurements for isocyanide insertion into the Ta—CH$_2$ bond of zwitterions 1

In a glove box, a known amount of zwitterions **1a** or **1b** was dissolved into an NMR amount of THF-d_8 and the NMR tube fitted with a rubber septum. Using a vacuum line in a vented fumehood, dry isocyanide reagent (~10 equiv) was syringed out of the glass bomb under a flow of argon. The isocyanide was added to the zwitterion solution at –78°C through the rubber septum, and the NMR sample was then placed into the NMR probe equilibrated to the desired temperature. Prior to each analysis the temperature of the NMR probe was checked against a standard of methanol. Kinetic data was collected by following the disappearance of the cyclopentadienyl proton resonance for **1a** or the methyl signal in **1b**, as compared with an internal standard of ferrocene. ^{1}H NMR spectra were generated with eight pulses (90°) with a 5 s relaxation delay. At higher temperatures, the reaction remains first order in [**1**] for greater than 3 half-lives, while the reaction remained linear throughout the experiment time for lower temperatures. Typical reagent amounts: **1a** (23 mg, 0.027 mmol), ferrocene (5 mg, 0.027 mmol), THF-d_8 (0.63 mL), and cyclohexyl isocyanide (40 mL, 0.322 mmol).

Kinetic measurements for N-out to N-in isomerization of η²-iminoacyl complexes

In a glove box, the *N-out* isomer was weighed into an NMR tube with a sealable Pyrex neck and secured to a vacuum line with a 180° needle valve. A known amount of CD$_3$CN or THF-d_8 was vacuum-transferred into the tube. The sample was kept at –78°C and sealed under ~0.9 atm of argon. The NMR tube was placed in the NMR probe and equilibrated to the analysis temperature, which was checked using an ethylene glycol standard. Kinetic data were collected by following the disappearance of the cyclopentadienyl proton resonance or the Ta-CH$_3$ signal in the ^{1}H NMR spectrum. For t-BuNC and benzylisocyanide derivatives, ferrocene was used as an internal standard and weighed directly into the NMR tube with analyte. For cyclohexyl derivatives, an internal standard, toluene, was used by spiking CD$_3$CN (61 mg of toluene in 6.223 g of CD$_3$CN). ^{1}H NMR spectra were generated with four pulses (90°) with a 5 s delay. At higher temperatures, the reaction

[a]R_1 (calcd on F, $I > 3\sigma(I)$) = $\Sigma \, ||F_o| - |F_c|| \, / \, \Sigma |F_o|$.
[b]R_1 (calcd on F, $I > 2\sigma(I)$) = $\Sigma \, ||F_o| - |F_c|| \, / \, \Sigma |F_o|$; wR_2 (calcd on F^2, all data) = $[\Sigma \, (w(F_o^2 - F_c^2)^2) \, / \, \Sigma w(F_o^2)^2]^{1/2}$.

remains first order in the *N-out* isomer for greater than 3 half-lives, while the reaction remained linear throughout the experiment time for lower temperatures. Typical reagent amounts: *N-out* **6a** (24 mg, 0.021 mmol), ferrocene (5 mg, 0.027 mmol), and THF-d_8 or CD_3CN (0.599 g). Reaction rates in THF-d_8 and CD_3CN were identical within experimental error.

X-ray crystallography

N-out 6a

See supporting information[4] and Table 2 for full experimental details.

N-out 7a

Data were collected on a Bruker P4/RA/SMART 1000 CCD diffractometer using Mo Kα radiation at −80°C. Unit cell parameters were obtained from a least-squares refinement of the setting angles of the number of reflections from the data collection. An empirical absorption correction was applied to the data through use of the SADABS procedure. The structures were solved using the direct-methods program SHELXS-86 (22) and full-matrix least-squares refinement on F^2 was completed using the program SHELXL-93 (23). Hydrogen atoms were assigned positions based on the geometries of their attached carbon atoms and were given isotropic thermal parameters 20% greater than the equivalent isotropic displacement parameters of the attached carbons.

The formation of mixed metal aminophosphinidene clusters via reactions of terminal chloroaminophosphido complexes with $Co_2(CO)_8$[1]

Javier Sánchez-Nieves, Brian T. Sterenberg, Konstantin A. Udachin, and Arthur J. Carty

Abstract: Reactions of terminal chloroaminophosphido complexes with $Co_2(CO)_8$ have been examined. The ruthenium phosphido complexes $[Cp^*Ru(CO)_2\{P(Cl)TMP\}]$ (**1a**) and $[CpRu(CO)_2\{P(Cl)TMP\}]$ (**1b**) (TMP = 2,2,6,6-tetramethyl-piperidinyl) react with $Co_2(CO)_8$ to form the cobalt cluster $[Co_4(CO)_7(\mu-CO)_3\{\mu_3-P(TMP)\}]$ (**2**) with complete transfer of the phosphinidene unit to cobalt. In contrast, the phosphido complex $[Cp^*Ru(CO)_2\{P(Cl)N-i-Pr_2\}]$ (**1c**) affords the spiked-triangular cluster $[Cp^*RuCo_3(CO)_8(\mu-CO)_2(\mu_3-PN-i-Pr_2)]$ (**3**), which retains the Cp*Ru unit upon reaction with $Co_2(CO)_8$. The molybdenum phosphido complex $[CpMo(CO)_2\{P(Cl)TMP\}]$ (**4**) reacts with $Co_2(CO)_8$ to form cluster **2**, while $[Cp^*Mo(CO)_3\{P(Cl)N-i-Pr_2\}]$ (**5**) generates the mixed metal tetrahedral cluster $[Cp^*MoCo_3(CO)_5(\mu-CO)_4(\mu_3-PN-i-Pr_2)]$ (**6**).

Key words: phosphido, phosphinidene, cobalt, ruthenium, molybdenum, cluster.

Résumé : On a étudié les réactions de complexes du $Co_2(CO)_8$ comportant des groupes chloroaminophosphido termi-naux. Les complexes phosphido du ruthénium $[Cp^*Ru(CO)_2\{P(Cl)TMP\}]$ (**1a**) et $[CpRu(CO)_2\{P(Cl)TMP\}]$ (**1b**) (TMP = 2,2,6,6-tétrapipéridinyl) réagissent avec le $Co_2(CO)_8$ avec formation de l'agrégat de cobalt $[Co_4(CO)_7(\mu-CO)_3\{\mu_3-P(TMP)\}]$ (**2**) et un transfert complet de l'unité phosphinidène au cobalt. Par ailleurs, le complexe phosphido $[Cp^*Ru(CO)_2\{P(Cl)N-i-Pr_2\}]$ (**1c**) fournit l'agrégat à triangle en aiguille $[Cp^*RuCo_3(CO)_8(\mu-CO)_2(\mu_3-PN-i-Pr_2)]$ (**3**) qui retient l'unité Cp*Ru lors de la réaction avec le $Co_2(CO)_8$. Le complexe phosphido du molybdène $[CpMo(CO)_2[P(Cl)TMP]]$ (**4**) réagit avec le $Co_2(CO)_8$ avec formation de l'agrégat **2** alors que le complexe $[Cp^*Mo(CO)_3\{P(Cl)N-i-Pr_2\}]$ (**5**) gé-nère l'agrégat tétraédrique à métal mixte $[Cp^*MoCo_3(CO)_5(\mu-CO)_4(\mu_3-PN-i-Pr_2)]$ (**6**).

Mots clés : phosphido, phosphinidène, cobalt, ruthénium, molybdène, agrégat.

[Traduit par la Rédaction]

Introduction

Phosphido (PR_2) and phosphinidene (PR) groups are im-portant and versatile ligands in organometallic chemistry (1, 2). As a terminal ligand, the phosphido group is analogous to an alkyl fragment, acting as a one-electron donor; how-ever, the phosphorus lone pair also allows it to act as a three-electron donor (3). Terminal phosphinidene complexes are analogous to carbene complexes and show similar reactivity, ranging from nucleophilic to electrophilic behaviour (4). In some cases, the phosphinidene lone pair can form a do-nor interaction with the metal, resulting in a net four-electron donor (5).

In cluster chemistry, both phosphido and phosphinidene ligands have been used extensively to enhance structural in-tegrity and stability (6). In bimetallic and cluster complexes, the phosphido fragment generally acts as a doubly bridging ligand and a net three-electron donor (2), although examples of co-ordination to more than two metals are known (7, 8). The phosphinidene fragment commonly co-ordinates as a μ_2, μ_3, or μ_4 ligand and rarely as a μ_5 ligand (8, 9) and con-tributes two or four electrons.

Over the past several years we have developed an exten-sive chemistry based on the transformation of functionalized phosphido and phosphinidene ligands. For example, we have used chloroaminophosphido complexes as precursors to ter-minal, electrophilic phosphinidene complexes, enabling the isolation and characterization of these elusive compounds for the first time (10–12). We have also exploited the pro-pensity of cluster-bound aminophosphinidene complexes to undergo P—N bond cleavage and substitution at the phosphinidene phosphorus atom, to develop a versatile route to co-ordinated phosphorus monoxide clusters (13) and a va-riety of functionalized phosphinidenes (14, 15).

In a previous paper (16), we described the syntheses of several bimetallic μ_2-aminophosphinidene complexes via reactions of terminal molybdenum chloroaminophosphido complexes with $Co_2(CO)_8$ (see Scheme 1). In this paper, we describe similar reactions of ruthenium and molybdenum phosphido complexes with $Co_2(CO)_8$ that lead to homo- and heterometallic clusters containing μ_3-aminophosphinidene ligands.

Results and discussion

Although a number of complexes of the type $CpM(CO)_2PR_2$ (M = Fe, Ru) containing terminal phosphido groups are known (17), the compounds $[Cp^*Ru(CO)_2\{P(Cl)TMP\}]$ (**1a**) and $[CpRu(CO)_2\{P(Cl)TMP\}]$ (**1b**) are new, and with $[Cp^*Ru(CO)_2\{P(Cl)N\text{-}i\text{-}Pr_2\}]$ (**1c**), briefly described earlier (10), represent the first terminal chloroaminophosphido complexes of the fragments $Cp^*Ru(CO)_2$ and $CpRu(CO)_2$. They were synthesized in good yield (65–68%) via the reaction of the potassium salts of the respective ruthenium anions with the dichloroaminophosphine $Cl_2P(TMP)$ in THF. Both **1a** and **1b** exhibit two $\nu(CO)$ bands in the infrared, indicating that only one conformation of the phosphido ligand is present, likely the conformer in which the bulky TMP ligand points away from the Cp or Cp* ring. This conformation was confirmed in the previously reported X-ray crystal structure of **1c** (10). The $^{31}P\{^1H\}$ NMR spectrum shows singlet resonances at δ 251.3 (**1a**) and δ 303.5 (**1b**), typical of terminal $P(Cl)NR_2$ ligands (10, 11, 18).

Reaction of the ruthenium phosphido complexes $[Cp^*Ru(CO)_2\{P(Cl)TMP\}]$ (**1a**) and $[CpRu(CO)_2\{P(Cl)\text{-}TMP\}]$ (**1b**) with $Co_2(CO)_8$ led to the tetracobalt cluster $[Co_4(CO)_7(\mu\text{-}CO)_3\{\mu_3\text{-}P(TMP)\}]$ (**2**) as the major isolable product (Scheme 2). In these reactions, the aminophosphinidene unit has been transferred completely to cobalt and the Cp or Cp* ruthenium fragment is eliminated. In contrast to the related Mo system, no RuCo bimetallic complexes could be isolated or detected in the reaction, regardless of stoichiometry and reaction conditions. Attempts to isolate or identify ruthenium-containing fragments from the reaction mixture were unsuccessful. Infrared spectroscopy of the mother solution after crystallization of **2** showed a complex mixture of carbonyl complexes.

The cluster **2** has been structurally characterized. An ORTEP diagram is shown in Fig. 1 and selected distances and angles are shown in Table 1. The structure consists of a tetrahedral core of four cobalt centres with one trigonal face capped by the aminophosphinidene ligand, resulting in a trigonal bipyramidal arrangement of the core Co_4P atoms. Each cobalt atom of the phosphinidene-capped face also has two terminal carbonyl ligands. The fourth cobalt centre bears one terminal carbonyl. A carbonyl ligand bridges each of the metal—metal bonds between the equatorial cobalt atoms and the axial cobalt. The cobalt—phosphorus distances of 2.144(1), 2.156(1), and 2.172(1) Å are similar to those of previous cobalt μ_3-phosphinidene complexes (19–23). The cluster electron count is 60, consistent with a tetrahedral M_4 structure if only the metal atoms are considered part of the skeleton. Alternatively, with 6 skeletal electron pairs, **2** has a closo trigonal bipyramidal Co_4P framework. Surprisingly, **2** appears to be the first simple diamagnetic μ_3-phosphinidene
cobalt carbonyl cluster, although several paramagnetic complexes of the type $[Co_3(CO)_9(\mu_3\text{-}PR)]$ have been described (20, 22, 24), as have Co_3 phosphinidene–phosphido (23) and phosphinidene–boride clusters (21). Also of note are the tetracobalt clusters $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ and $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]^+$, which consist of a tetrahedron of cobalt atoms surrounded by four μ_3-phosphinidene ligands (19), and $[Co_4(CO)_{10}(P\text{-}i\text{-}Pr)_3]$, in which two Co_2 units are bridged by three μ_3-PR units (25). Cobalt clusters containing μ_4-phosphinidene ligands are, on the other hand, relatively common (20, 26).

The ^{31}P NMR spectrum of **2** shows a peak for the phosphinidene phosphorus atom at δ 503.5, which is in the typical range for μ_3-phosphinidene ligands. In all of the cobalt clusters described, the phosphorus resonances are broad as a result of quadrupolar coupling to ^{59}Co and ^{14}N. The ^1H NMR spectrum shows the expected peaks for the TMP

group. The IR spectrum shows terminal carbonyl stretching bands at 2038, 2028, and 1906 cm⁻¹ and a bridging carbonyl stretch at 1862 cm⁻¹.

In contrast, reaction of the phosphido complex [Cp*Ru(CO)₂{P(Cl)N-*i*-Pr₂}] (**1c**), which has a less sterically demanding di-isopropylamino group on the phosphido ligand, led to the cluster [Cp*RuCo₃(CO)₈(μ-CO)₂(μ₃-PN-*i*-Pr₂)] (**3**). An ORTEP diagram of **3** is shown in Fig. 2 and selected distances and angles are shown in Table 2. The molecule consists of a triangle of cobalt atoms

capped by a μ₃-phosphinidene ligand with the Cp* ruthenium fragment bound to one of the cobalt atoms, resulting in a spiked-triangular arrangement of the metals. The two cobalt atoms that are not bound to ruthenium each have three terminal carbonyl ligands. The ruthenium-bound cobalt atom has one terminal carbonyl ligand and two carbonyls bridge the cobalt—ruthenium bond. In addition to the bridging carbonyls, the ruthenium atom is attached to the Cp* ligand and one terminal carbonyl. The overall cluster electron count is 64, consistent with the presence of only four metal—metal bonds. The ruthenium atom in **3** is not coplanar with the Co₃ triangle but deviates from the plane by 0.8879 Å on the same side of the plane as the phosphinidene ligand. Compound **3** appears to be a unique example of a ruthenium spiked cobalt triangle, although spiked triangular clusters involving other transition metals are well known (27).

The phosphorus—nitrogen distance of 1.659(3) Å is intermediate between P—N single and P=N double bonds, which is typical of bridging aminophosphinidene ligands in clusters and consistent with partial P—N multiple bonding (15, 28). The geometry at nitrogen is nearly planar.

Scheme 3.

Fig. 3. ORTEP diagram of the X-ray crystal structure of [Cp*MoCo₃(CO)₅(μ-CO)₄(μ₃-PN-*i*-Pr₂)] (**6**). Thermal ellipsoids are shown at the 50% level, and hydrogen atoms have been omitted for clarity.
The phosphinidene phosphorus atom of **3** appears at δ 461.4 in the ^{31}P NMR spectrum. The ^{1}H NMR spectrum exhibits one set of peaks for the isopropyl groups and the Cp* methyl groups, indicating that there is free rotation about the P—N bond and suggesting that the N$p\pi$—P$p\pi$ bonding is weak. Terminal carbonyl stretching bands are observed at 2069, 2031, 2012, 2000, 1985, and 1969 cm^{-1} and the bridging carbonyl stretch appears at 1797 cm^{-1}.

Given the facility of cluster formation by ruthenium phosphido complexes with Co₂(CO)₈ and our inability to isolate any RuCo bimetallic complexes, we re-examined the reactions with the Mo phosphido complexes. In our previous paper, conditions were optimized for the formation of bimetallic complexes. However, by reacting the bimetallic MoCo complexes with further Co₂(CO)₈ or by reacting the starting phosphido complexes with excess Co₂(CO)₈ we anticipated favouring the formation of phosphinidene clusters.

Thus the reaction of [CpMo(CO)₂{P(Cl)TMP}] (**4**) with excess Co₂(CO)₈ led to the formation of [Co₄(CO)₇(μ-CO)₃{μ₃-P(TMP)}] (**2**), the same product that was observed in the reaction with [Cp*Ru(CO)₂{P(Cl)TMP}] (**1a**) and [CpRu(CO)₂{P(Cl)TMP}] (**1b**). Again, we observed a complete transfer of the phosphinidene unit from Mo to Co and loss of the Mo fragment (Scheme 3).

However, in sharp contrast, the reaction of [Cp*Mo(CO)₃{P(Cl)N-*i*-Pr₂}] (**5**) with excess Co₂(CO)₈ did not result in a complete transfer of the phosphinidene unit and instead led to the formation of the heterometallic cluster [Cp*MoCo₃(CO)₅(μ-CO)₄(μ₃-PN-*i*-Pr₂)] (**6**). An ORTEP diagram of **6** is shown in Fig. 3 and selected distances and angles are shown in Table 3. The core structure is similar to that of **2** with a trigonal bipyramidal arrangement of the four metals and the phosphorus atom. The molybdenum atom occupies one of the equatorial positions and is bound to the

phosphinidene phosphorus atom and the Cp* ring, as well as to two carbonyl ligands that bridge the molybdenum and the axial cobalt centre. Each equatorial cobalt atom is bound to phosphorus and to two terminal carbonyls. In addition, there is a carbonyl bridge between each of the equatorial cobalt centres and the axial cobalt centre. The axial cobalt is bound to only one terminal carbonyl ligand in addition to the four bridging carbonyl ligands mentioned.

Bonding to the μ₃-phosphinidene ligand is significantly unsymmetrical, as expected given the smaller atomic radius of Co compared with Mo. The P—Co distances are 2.158(2) and 2.142(2) Å and the Mo—P distance is 2.391(1) Å. Also

Scheme 4.
of note is the distortion of the phosphinidene ligand away from the pseudo threefold axis that would pass through P, N, and the centroid of the three equatorial metal atoms. In most μ_3-phosphinidene complexes, the P—X bond is essentially perpendicular to the metal plane. In complex **6**, the P—N bond forms an angle of 80.5° to the Co_2Mo plane. This deviation may be attributed to the steric interaction between the Cp* and di-isopropyl amine groups. Unfortunately, we were unable to synthesize the Cp analogue for comparison. However, it is clear that an analogous complex to **6** containing the bulkier TMP group on the phosphinidene would suffer from severe steric congestion.

The ^{31}P NMR spectrum of complex **6** shows a peak at δ 514.4, which corresponds to the μ_3-phosphinidene ligand. The ^1H NMR spectrum shows peaks for two equivalent isopropyl groups and the Cp* methyl groups.

One side product was also isolated from this reaction, which was identified as [Cp*MoCo(CO)$_7$] (**7**). It is somewhat surprising that this compound was observed only for this reaction, since the main product still contains the Cp*Mo unit. However, the yield of the main product is moderate, and there are clearly other reactions occurring. While we were unable to identify side products for any of the other reactions, we can speculate on the mechanism of the reactions (Scheme 4). For the molybdenum complexes, the initial products are the bimetallic complexes [(C$_5$R$_5$)MoCo-(CO)$_7$(μ-PNR$_2$)]. The other product of this initial reaction is presumably an unstable cobalt carbonyl chloride. The second step of the reaction is the addition of a second equivalent of $Co_2(CO)_8$ across the Mo—Co bond, leading to a cluster with the formulation [(C$_5$R$_5$)MoCo$_3$(CO)$_9$(μ_3-PNR$_2$)]. With the phosphinidene PN-i-Pr$_2$, this is the final stable product. With the bulkier phosphinidene ligand P(TMP),

steric congestion probably induces the elimination of [Cp*MoCo(CO)$_7$], leading to a phosphinidene-bridged dicobalt cluster, which adds $Co_2(CO)_8$, leading to the final product [Co$_4$(CO)$_7$(μ-CO)$_3${μ_3-P(TMP)}] (**2**). The mechanism of the reactions with the ruthenium phosphido complexes is more difficult to discern. Formation of compound **2** may occur by an analogous mechanism to that above. However, bimetallic CoRu complexes could not be isolated, and the spiked tetrahedral structure [Cp*RuCo$_3$(CO)$_8$(μ-CO)$_2$(μ_3-PN-i-Pr$_2$)] (**3**) clearly does not fit into such a reaction scheme.

In reactions of both the Mo phosphido complexes and the Ru phosphido complexes, the TMP substituent encourages transfer of the phosphinidene ligand and elimination of the metal fragment containing the Cp or Cp* ligand. This reactivity is likely a result of steric interactions between the very bulky TMP group and the other ligands. Thus, some degree of steric control over the reactivity of the terminal phosphido complexes can be achieved. With the bulkier TMP ligand, the phosphido complex acts as a source of phosphinidene (PR). With the smaller di-isopropylamino group, the entire phosphido complex is incorporated into the cluster.

In summary, the results in this paper confirm that readily accessible terminal chloroaminophosphido complexes serve as useful precursors for the synthesis of new phosphinidene-based homo- and heteronuclear clusters.

Experimental section

All procedures were carried out under a nitrogen atmosphere using standard Schlenk techniques or a glovebox. The compounds [Cp*Ru(CO)$_2${P(Cl)N-i-Pr$_2$] (**10**), [CpMo(CO)$_2$-{P(Cl)TMP] (**29**), and [Cp*Mo(CO)$_3${P(Cl)N-i-Pr$_2$] (**18**)

were prepared according to published procedures. All NMR spectra were recorded in CDCl$_3$, and infrared spectra were recorded in hexane solution.

Preparation of compounds

[Cp*Ru(CO)$_2${P(Cl)TMP}] (1a)

[Cp*Ru(CO)$_2$]$_2$ (100 mg, 0.17 mmol) and KC$_8$ (56 mg, 0.41 mmol) were stirred in THF (15 mL) for 12 h. The resulting solution was filtered and added dropwise to a solution of Cl$_2$P(TMP) (83 mg, 0.34 mmol) in THF (10 mL), resulting in the formation of a pale yellow solution. The solvent was removed in vacuo, and the residue was extracted into hexane (5 mL), filtered, and cooled to –25 °C, resulting in the formation of pale yellow crystals of [Cp*Ru(CO)$_2$-{P(Cl)TMP}] (1a). Yield 110 mg, 65%. IR (ν(CO), cm^{-1}): 2007 (s), 1952 (s). ^{1}H NMR δ: 1.87 (s, 5H, C$_5$(CH$_3$)$_5$), 1.53 (b, 18H, CH$_3$ and CH$_2$). ^{31}P{^{1}H} NMR δ: 303.5. Anal. calcd. for C$_{21}$H$_{33}$NO$_2$PClRu: C 50.55, H 6.67, N 2.81; found: C 50.33, H 6.98, N 2.77.

[CpRu(CO)$_2${P(Cl)TMP}] (1b)

[CpRu(CO)$_2$]$_2$ (190 mg, 0.43 mmol) and KC$_8$ (140 mg, 1.0 mmol) were stirred in THF (15 mL) for 12 h. The resulting solution was filtered and added dropwise to a solution of Cl$_2$P(TMP) (208 mg, 0.86 mmol) in THF (10 mL), resulting in the formation of a pale yellow solution. The solvent was removed in vacuo, and the residue was extracted into hexane (5 mL), filtered, and cooled to –25 °C, resulting in the formation of pale yellow crystals of [CpRu(CO)$_2${P(Cl)TMP}] (1a). Yield 250 mg, 68%. IR (ν(CO), cm^{-1}): 2027 (s), 1976 (s). ^{1}H NMR δ: 5.35 (s, 5H, C$_5$H$_5$), 1.64 (b, 12H, CH$_3$), 1.51 (b, 6H, CH$_2$). ^{31}P{^{1}H} NMR δ: 251.3. Anal. calcd. for C$_{16}$H$_{23}$NO$_2$PClRu: C 44.81, H 5.41, N 3.27; found: C 44.75, H 5.70, N 3.15.

Reaction of [Cp*Ru(CO)$_2${P(Cl)TMP}] (1a) with Co$_2$(CO)$_8$

A solution of [Cp*Ru(CO)$_2${P(Cl)TMP}] (1a, 100 mg, 0.200 mmol) and Co$_2$(CO)$_8$ (220 mg, 0.643 mmol) in hexane (10 mL) was stirred for 2 h and then filtered. The solvent volume was reduced to approximately 3 mL, and the resulting solution was cooled to –25 °C, resulting in the gradual formation of black crystals of [Co$_4$(CO)$_7$(μ-CO)$_3${μ$_3$-P(TMP)}] (2). Yield, 75 mg, 47%. IR (ν(CO), cm^{-1}): 2038 (s), 2028 (m), 1906 (w), 1862 (w). ^{1}H NMR δ: 1.89 (6H, CH$_2$), 1.83 (12 H, CH$_3$). ^{31}P{^{1}H} NMR δ: 503.5 (bs). Anal. calcd. for C$_{19}$H$_{18}$NO$_{10}$PCo$_4$: C 33.22, H 2.64, N 2.04; found: C 33.34, H 2.47, N 2.08.

Reaction of [CpRu(CO)$_2${P(Cl)TMP} (1b) with Co$_2$(CO)$_8$

Using the procedure described above, [CpRu(CO)$_2$-{P(Cl)TMP}] (1b, 100 mg, 0.20 mmol) was reacted with Co$_2$(CO)$_8$ (240 mg, 0.70 mmol) to form [Co$_4$(CO)$_7$(μ-CO)$_3${μ$_3$-P(TMP)}] (2). Yield: 0.068 mg, 50%.

Reaction of [Cp*Ru(CO)$_2${P(Cl)N-i-Pr$_2$] (1c) with Co$_2$(CO)$_8$

A solution of [Cp*Ru(CO)$_2${P(Cl)N-i-Pr$_2$}] (1c, 200 mg, 0.44 mmol) and Co$_2$(CO)$_8$ (300 mg, 0.88 mmol) in hexane

(15 mL) was stirred for 2 h and then filtered. The solvent volume was reduced to approximately 5 mL, and the solution was cooled to –25 °C, resulting in the formation of black crystals of [Cp*RuCo$_3$(CO)$_8$(μ-CO)$_2$(μ$_3$-PN-i-Pr$_2$)] (3). Yield: 180 mg, 51%. IR (ν(CO), cm^{-1}): 2069 (s), 2031 (s), 2012 (s), 2000 (m), 1985 (w), 1969 (m), 1797 (w). ^{1}H NMR δ: 4.03 (septet, ^3J(HH) = 6.8 Hz, 2H, CH(CH$_3$)$_2$), 1.92 (s, 15H, C$_5$(CH$_3$)$_5$), 1.34 (d, ^2J(HH) = 6.8 Hz, 12H, CH(CH$_3$)$_2$). ^{31}P{^{1}H} NMR δ: 461.4. Anal. calcd. for C$_{26}$H$_{29}$NO$_{10}$PCo$_3$Ru: C 37.88, H 3.55, N 1.70; found: C 37.46, H 3.52, N 1.90.

Reaction of [CpMo(CO)$_2${P(Cl)TMP] (4) with Co$_2$(CO)$_8$

A solution of [CpMo(CO)$_2${P(Cl)TMP}] (4, 100 mg, 0.24 mmol) and Co$_2$(CO)$_8$ (270 mg, 0.80 mmol) in hexane (10 mL) was stirred for 2 h and then filtered. The solvent volume was reduced to approximately 3 mL, and the resulting solution was cooled to –25 °C, resulting in the gradual formation of black crystals of [Co$_4$(CO)$_7$(μ-CO)$_3${μ$_3$-P(TMP)}] (2). Yield, 160 mg, 53%.

Reaction of [Cp*Mo(CO)$_3${P(Cl)N-i-Pr$_2$] (5) with Co$_2$(CO)$_8$

A solution of [Cp*Mo(CO)$_3${P(Cl)N-i-Pr$_2$}] (5, 100 mg, 0.21 mmol) and Co$_2$(CO)$_8$ (220 mg, 0.64 mmol) in hexane (10 mL) was stirred for 2 h and then filtered. The volume of the filtrate was reduced to approximately 3 mL. The solution was then cooled to –25 °C, resulting in the gradual formation of a mixture of black crystals of [Cp*MoCo$_3$(CO)$_5$(μ-CO)$_4$(μ$_3$-PN-i-Pr$_2$)] (6) and red crystals that were identified as [Cp*MoCo(CO)$_7$] by infrared spectroscopy and X-ray crystallography. Spectral data for 6: ^{1}H NMR δ: 4.37 (septet, 2H, CH(CH$_3$)$_2$, ^3J(HH) = 6.8 Hz), 2.04 (s, 15H, C$_5$(CH$_3$)$_5$), 1.60 (d, 12H, CH(CH$_3$)$_2$, ^3J(HH) = 6.8 Hz). ^{31}P{^{1}H} NMR δ: 514.4 (bs). Accurate elemental analysis for 6 could not be obtained because samples could not be completely separated from [Cp*MoCo(CO)$_7$].

X-ray structure determination

Crystals of compounds 2, 3, and 6 were mounted on glass fibres. Intensity data were collected on a Siemens SMART CCD diffractometer using graphite-monochromated Mo Kα radiation at 173(2) K. Unit cells were determined from randomly selected reflections obtained using the SMART CCD automatic search, centre, index, and least-squares routines. Integration was carried out using SAINT and empirical absorption corrections were applied using SADABS. Structure solution was carried out using the SHELXTL 5.1 suite of programs. Initial solutions were obtained by direct methods and refined by successive least-squares cycles. Full matrix least-squares refinements minimized the function $\Sigma_{hkl}w(|{*}F_o| - |F_c|)^2$, where $w = 1/\sigma(F_o)2$, $\sigma(F_o) = \sigma(F_o{}^2)/2F_o$, and $\sigma(F_o{}^2) = [\sigma(I_{raw})^2 + (0.02I_{net})^2]^{1/2}/Lp$. Crystal data and collection parameters are listed in Table 4. For compound 3, the Cp* ring was disordered over three positions with occupancies of 0.8, 0.2, and 0.2. The major disordered ring was refined with anisotropic thermal parameters, while the minor disordered rings were refined isotropically. For compound 6, the isopropyl groups were disordered over two positions, and the carbon atoms of that group were refined isotropically.

Band-gap tuning by solid-state intercalations of Mg, Ni, and Cu into Mo_3Sb_7[1]

N. Soheilnia, E. Dashjav, and H. Kleinke

Abstract: Mo_3Sb_7 was synthesized by heating the elements in the stoichiometric ratio in a sealed silica tube at 700 °C. The title compounds $A_\delta Mo_3Sb_7$ (A = Mg, Ni, Cu) were prepared by annealing prereacted Mo_3Sb_7 with different amounts of A in powder form between 500 and 750 °C. According to our single-crystal structure studies, the A atoms can be intercalated in small amounts into the cubic voids of the Mo_3Sb_7 structure without noticeable symmetry changes (space group $Im\overline{3}m$). The different cations cause different band-gap decreases that depend on the element as well as its concentration.

Key words: thermoelectrics, band-gap tuning, intercalation, antimonide, electronic structure.

Résumé : On a réalisé la préparation du Mo_3Sb_7 en chauffant les éléments à 700 °C, dans un rapport stoechiométrique, dans un tube de silice scellé. Les composés mentionnés dans le titre, $A_\delta Mo_3Sb_7$ (A = Mg, Ni, Cu) ont été préparés par recuisson à des températures allant de 500 à 750 °C, du Mo_3Sb_7 obtenu antérieurement avec diverses quantités de l'élément A sous la forme de poudre. D'après les études de diffraction des rayons X effectuées sur des mono cristaux, les atomes de l'élément A peuvent s'intercaler dans les vides cubiques de la structure de Mo_3Sb_7 sans changement notable de symétrie (groupe d'espace $Im\overline{3}m$). Les différents cations provoquent des diminutions de la largeur de bande interdite qui dépendent de la nature de l'élément ainsi que de sa concentration.

Mots clés : thermoélectrique, ajustement de la largeur de bande interdite, intercalation, antimoine, structure électronique.

[Traduit par la Rédaction]

Introduction

Our motivation to chemically modify Mo_3Sb_7 (1) stems from our research interests in thermoelectric materials. Thermoelectrics are used to convert electricity into a temperature gradient (e.g., for Peltier cooling) or vice versa (for power generation) (2). The materials commercially used are usually narrow band-gap semiconductors comprising heavy elements. Several new materials are currently under investigation because of their promising thermoelectric properties (3). Among them are bismuth chalcogenides (4–8), germanium- and tin-based clathrates (9–12), and tin- and antimony-based half-Heusler compounds (13–17). In particular, many researchers from different countries concentrate on the filled skutterudites (18–26). The general formula of the filled skutterudites is $Ln_\delta M_4Sb_{12}$ with $0 \le \delta \le 1$, with Ln being a lanthanoid and M a late transition element such as Fe, Co, and Ni. While the parent compound, $LaFe_4Sb_{12}$, is metallic, $LaFe_3CoSb_{12}$ exhibits outstanding thermoelectric properties, for its high thermopower and electrical conduc-

tivity are combined with an extraordinarily low thermal conductivity. The latter stems from the high vibrations of the La atom situated in a large "cage" of Sb atoms, a phenomenon usually referred to as *rattling*. Thus, the filled skutterudites may serve as an ideal for a phonon-glass, electron-crystal material (27, 28).

Mo_3Sb_7, albeit a metallic material, is another interesting candidate for the thermoelectric energy conversion, as we have recently demonstrated that it becomes semiconducting by a partial Sb–Te exchange. The highest Seebeck coefficient in the series $Mo_3Sb_{7-y}Te_y$ is found at y = 2.2 (29). Furthermore, its crystal structure (Ir_3Ge_7 type) comprises large cubic voids, which may be filled with small cations to create the rattling effect discussed above. This article deals with the successful intercalation of Mg, Ni, and Cu, as confirmed via single-crystal X-ray studies and EDS investigations, and its consequences for the electronic structure and, thus, the physical properties.

Experimental

Synthesis

All starting materials were used as acquired in powder form from ALFA AESAR and ALDRICH, with purities of at least 99.5%. Mo_3Sb_7 was prepared first by annealing the elements Mo and Sb in the stoichiometric 3:7 ratio in an evacuated fused silica tube at 700 °C for at least 72 h. In attempts to investigate the possibility of filling the cubic void of the Mo_3Sb_7 structure, the elements A = Mg, Ni, and Cu were added in three different amounts each to Mo_3Sb_7, resulting

N. Soheilnia, E. Dashjav, and H. Kleinke.[2] Department of Chemistry, University of Waterloo, Waterloo, ON N2L 3G1, Canada.

[2]Corresponding author (e-mail: kleinke@uwaterloo.ca).

in nine different reactions, aiming for the product $A_\delta Mo_3Sb_7$ with $\delta = 0.1$, 0.25, and 0.5. The number of A atoms per Mo_3Sb_7 unit required to fill all cubic voids of the structure is 0.5.

These mixtures were annealed at different temperatures between 500 and 750 °C. The most homogeneous samples were obtained at 600 °C. Subsequent attempts, starting from the elements, yielded the same X-ray powder diffractograms, i.e., most likely the same products. As only the reactions with $\delta = 0.1$ gave (seemingly) single phase powder diagrams of $A_\delta Mo_3Sb_7$, it is concluded that less than 0.25 A cations may be intercalated into Mo_3Sb_7.

Analysis

EDS investigations (LEO 1530, with integrated EDAX Pegasus 1200) on selected crystals of the products of the nominal composition "$Cu_{0.10}Mo_3Sb_7$" revealed that no impurities were present. While the peak of the Cu–K line was very small in each case, its presence was obvious, supporting the incorporation of Cu atoms in these crystals. Averaging the integrations over all peaks obtained from the four crystals resulted in a Cu:Mo:Sb ratio of 1:28:71 atomic %. Since the Cu concentration was not a function of the acceleration voltage, it is not a surface effect.

Structure determination

Three different block- to cubic-like single crystals of the nominal composition "$A_{0.25}Mo_3Sb_7$" with A = Mg, Ni, and Cu were selected under an optical microscope and then mounted on glass fibers. This composition was chosen to ensure that the upper limit of the A intercalation was determined. Single-crystal X-ray diffraction data were collected with the use of graphite-monochromatized Mo Kα radiation (λ = 0.71073 Å) at 298(2) K on a Bruker Smart APEX CCD diffractometer. The crystal-to-detector distance was 4.550 cm. Data were collected by a scan of 0.3° in ω in groups of 606 frames. The data were corrected for Lorentz and polarization effects. Absorption corrections were based on fitting a function to the empirical transmission surface, as sampled by multiple equivalent measurements using SADABS (30). Diffraction peaks obtained from all frames of the reciprocal space images were used to determine the unit cell parameters, which were slightly, yet significantly, enlarged, e.g., from a = 9.559(3) Å (Mo_3Sb_7) to a = 9.5829(9) Å ($Cu_{0.041(6)}Mo_3Sb_7$).

First refinements using SHELXTL (31) were done for A = Cu, with the space group and the atomic positions taken from our earlier refinements on Mo_3Sb_7 (29). This resulted in small residual factors (e.g., $R(F)$ = 0.0236), but a high rest electron density of 10.5 e/Å^3 at (0, 0, 0), the location of the cubic void. The other remaining peaks in the difference-Fourier map were below 2.5 e/Å^3. Refining this site, then, as a Cu atom with free occupancy lowered the residual factor to 0.0219 (by changing the data:parameter ratio from 164:10 to 164:12) and resulted in an occupancy factor of 8%. No hints towards ordering of the Cu atoms by a symmetry reduction (formation of an ordered superstructure) were found. Repeating this procedure for A = Mg and Ni yielded similar occupancy factors. The final refined formulas are $Mg_{0.07(2)}Mo_3Sb_7$ and $Ni_{0.04(1)}Mo_3Sb_7$ and $Cu_{0.041(6)}Mo_3Sb_7$,

respectively. Details of the structure determinations are given in the Table 1.

Electronic structure calculations

The self-consistent, tight-binding *first principles* LMTO (LMTO = linear muffin tin orbitals) approach (32, 33) was used for all band structure calculations. In the LMTO approach, the density-functional theory is used with the local density approximation (LDA) (34). The integrations in k space were performed by an improved tetrahedron method (35) on grids of more than 200 independent k points of the first Brillouin zone, depending on its size and symmetry. Several structure models were calculated, namely Mo_3Sb_7 as taken from our single crystal data, hypothetical "$A_{0.125}Mo_3Sb_7$" (with A = Mg, Ni, Cu), and "$Mg_{0.25}Mo_3Sb_7$" and "$Mg_{0.5}Mo_3Sb_7$" using the structure parameters of Mo_3Sb_7. For the last case, the (0, 0, 0) position was filled completely with Mg atoms, retaining the space group. For the other two, the cell had to be enlarged, as it originally contains only one A atom in the primitive unit cell. Then, one A atom out of two and one A atom out of four were filled per cell causing symmetry reduction, modeling "$Mg_{0.25}Mo_3Sb_7$" and "$A_{0.125}Mo_3Sb_7$", respectively. Modeling structures with smaller A content (e.g., corresponding to "$A_{0.0625}Mo_3Sb_7$") was not possible, since that unit cell would become too large, containing too many valence orbitals for our computational facilities.

Results and discussion

Crystal structure

Mo_3Sb_7 was confirmed to crystallize in the cubic Ir_3Ge_7 type. Its structure comprises pairs of face-condensed (distorted) $MoSb_8$ square antiprisms, which are interconnected to form infinite chains by Sb—Sb bonds between neighboring pairs. This connection occurs with the formation of an empty Sb_8 cube, which we were able to partly fill with the cations Mg, Ni, and Cu. As all six faces of each cube are part of a face of an $MoSb_8$ square antiprism, three chains orthogonal to each other are interpenetrating at the Sb_8 cube, thus forming a three-dimensional network of interwoven chains. Parallel chains are interconnected via a short Sb—Sb bond from one cube of one chain to one of the next. Figure 1 shows the whole crystal structure of $A_\delta Mo_3Sb_7$ in a projection onto the a,b plane on the left and two parallel chains on the right.

While there is only one Mo site as well as one A site in this structure, two symmetrically independent Sb atoms are present. The Sb(1) atoms form the face in the center of the pair of $MoSb_8$ square antiprisms, with Sb—Sb distances of 3.38 Å within the face (dashed lines in Fig. 1). On the other hand, the Sb(2) atoms form the cube, with shorter Sb—Sb distances of 3.10 Å within the cube and the shortest Sb—Sb bond of this structure (2.91 Å) between the Sb(2) atoms of the cubes of two parallel chains. The 2.91 Å bond length compares well to the length of Sb—Sb single bonds, as in the Zintl compound KSb (2.83 and 2.85 Å) (36). On the other hand, Sb—Sb bonds around 3.10 Å (the longer Sb(2)—Sb(2) distance) are usually described as half bonds

Fig. 1. Crystal structure of $A_\delta Mo_3Sb_7$ (left) and chains of face-condensed $MoSb_8$ square antiprisms and ASb_8 cubes (right). Small, black circles: A atoms; medium, white: Mo; large, gray: Sb.
(37–40). Weakly bonding interactions of 3.2–3.4 Å occur quite often in transition-metal antimonides (41–43).

As well, the Mo—Sb distances are different for both Sb atoms: 2.82 Å for the four Mo—Sb(1) bonds vs. 2.79 Å for the four Mo—Sb(2) bonds per Mo atom. The Mo—Sb bonds of Mo_3Sb_7, the only known binary Mo antimonide, compare well to those of the recently published Mo antimonide–chalcogenides, namely Mo_2SbS_2 (shortest Mo—Sb bond: 2.83 Å) (44), $MoSb_2S$ (2.82 Å) (45), and $MoSb_2Se$ (2.80 Å) (46). These distances are all longer than the sums of the sin-

gle bond radii, e.g., after Pauling: $r_{Mo} + r_{Sb} = 1.29$ Å + 1.39 Å = 2.68 Å (47).

The $MoSb_8$ antiprisms are face-condensed; an Mo—Mo contact of 3.00 Å is present across the shared face. As we have reported before (29), all these distances have bonding character, albeit of different strength.

In the binary Mo_3Sb_7, the distance between each corner of the Sb_8 cube (i.e., the cubic void) and its center is 2.69 Å, which corresponds to a reasonable A—Sb bond: the shortest Mg—Sb bond in Mg_3Sb_2 is 2.82 Å (48); the Ni—Sb bond in

Fig. 2. Densities of states of Mo_3Sb_7 (left) and "$Mg_\delta Mo_3Sb_7$" (with increasing δ from left to right).
NiSb$_2$ is 2.44 Å (49); and the Cu—Sb bond in Cu$_2$Sb is 2.62 Å (50). Thus, a rattling effect would best be achieved using Ni atoms or, better yet, even smaller ones.

The next nearest neighbors would be six Mo atoms that form A—Mo contacts of 3.28 Å through the centers of the Sb$_8$ cube. It is thus not surprising that intercalating Mg, Ni, or Cu atoms into the cubic voids leads only to small structural changes, the most obvious being a slight enlargement of the unit cell. Other changes are slight shifts in the atomic positions. Both the A atom (located on (0, 0, 0)) and the Sb(1) atom (on (1/4, 0, 1/2)) are on fixed positions, while the Mo atom (on (x, 0, 0)) and the Sb(2) atom (on (x, x, x)) both have one free parameter each. A list of the different lattice dimensions, occupancies, and positional parameters may be found in Table 2. In all the four cases studied, the x parameter of the Mo atom remains the same within its standard deviation, while the x parameter of Sb(2) is constant among the ternary representatives (again within its standard deviation, i.e., between 0.16235(9) and 0.16239(4)) but somewhat smaller in Mo$_3$Sb$_7$ (0.16220(8)).

Along with these partly significant variations in the lattice dimensions and atomic positions come differences in the interatomic distances, which are listed in Table 3. As expected based on the comparable atomic positions and lattice parameters between Mg$_{0.07}$Mo$_3$Sb$_7$ and Ni$_{0.04}$Mo$_3$Sb$_7$, all distances of these two structures are equivalent within their standard deviations. While the fractional coordinates of the third ternary antimonide, Cu$_{0.04}$Mo$_3$Sb$_7$, are not significantly different, its lattice parameter is significantly larger at 9.5829(9) Å, compared with 9.5740(7) and 9.5734(6) Å for A = Mg and Ni, respectively. Thus, all interatomic distances are largest in the case of A = Cu, with differences of a few hundredth of an Å.

Because of the smaller volume of Mo$_3$Sb$_7$, its interatomic distances between the atoms on fixed positions are some hundredth of an Å shorter than in the ternary compounds. However, the shifts of the Mo and the Sb(2) site occur with equivalent Mo—Mo distances (3.00 Å for Mo$_3$Sb$_7$ and Mg$_{0.07}$Mo$_3$Sb$_7$) and equivalent short Sb(2)—Sb(2) distances (2.91 Å in all cases studied).

Electronic structure

Since the electronic structure of Mo$_3$Sb$_7$ was published before (29), we concentrate here on the differences resulting

Table 2. Atomic positions^a and occupancy factors of $A_\delta Mo_3Sb_7$.

^{b}Data from single crystal analysis of the binary Mo$_3$Sb$_7$ (29).

from the additions of the A atoms. The densities of states (DOS) of Mo$_3$Sb$_7$ and of the three models for hypothetical "Mg$_\delta$Mo$_3$Sb$_7$" (with δ = 0.125, 0.25, and 0.5) are shown in Fig. 2. In all cases, a band gap is present slightly above the Fermi level, albeit of different sizes, which would be reached with 55 valence electrons per formula unit (Mo$_3$Sb$_7$: 53; "Mg$_{0.5}$Mo$_3$Sb$_7$": 54). Therefore, adding only Mg atoms to Mo$_3$Sb$_7$ is not sufficient to yield semiconducting properties, as required for thermoelectric materials, for one Mg atom adds two valence electrons and each Sb–Te substitution adds one more; 55 valence electrons are obtained with the general formula "Mg$_\delta$Mo$_3$Sb$_{5 + 2\delta}$Te$_{2 - 2\delta}$".

Increasing the Mg content not only adds valence electrons and thus fills more electronic states, it also leads to a decrease in the size of the band gap, i.e., from 0.9 eV in Mo$_3$Sb$_7$, to 0.5 eV in "Mg$_{0.125}$Mo$_3$Sb$_7$", to less than 0.1 eV in "Mg$_{0.5}$Mo$_3$Sb$_7$". A band-gap decrease from 0.9 eV is advantageous when considering thermoelectric applications, as theory dictates an ideal band gap size of 0.1–0.6 eV (which is temperature dependent) (51). Such a decrease, to 0.5 eV, was already obtained by going from Mo$_3$Sb$_7$ to Mo$_3$Sb$_5$Te$_2$ (29), and the trend to decreasing band gap size will continue while adding Mg atoms. It should be noted that all ternary structure models calculated have more Mg than the maximum Mg content obtain experimentally (0.07(2)). Owing to physical computation limits, we could not calculate the more realistic model "Mg$_{0.0625}$Mo$_3$Sb$_7$", as this requires an unreasonably large unit cell with one out of 16 Mg sites filled and, thus, with 16 × 6 = 96 Mo atoms and 224 Sb atoms.

Using Ni and Cu atoms as the A atoms in the model "$A_{0.125}$Mo$_3$Sb$_7$" also occurs with a band-gap decrease compared with Mo$_3$Sb$_7$ (Fig. 3). Adding Ni instead of Mg to

Fig. 4. First Brillouin zone for cubic body-centered lattices.
Mo_3Sb_7 leads to a very comparable band gap, while the Cu addition yields a significantly narrower band gap of about 0.4 eV.

To answer the question of why the band gap decreases upon A intercalation, we compare the band structures of Mo_3Sb_7 and "$Mg_{0.5}Mo_3Sb_7$" using the notations suggested by Bradley and Cracknell for the cubic body-centered Bravais lattice (52), as indicated in a plot of the first Brillouin zone (Fig. 4) (53).

We used the *fat band* representation (54) to emphasize the Mo d_{z^2} contributions for the Mo_3Sb_7 band structure (left part of Fig. 5). In the "$Mg_{0.5}Mo_3Sb_7$" model, the Mg s contributions are highlighted (right part of Fig. 5). It is evident that the band-gap decrease stems exclusively from lowering the lowest unoccupied band at both the N and H point, for the energies of the highest-filled bands remain virtually unchanged upon Mg intercalation. More important in this context is the band at the H point, as this is where the smallest direct gap occurs. This band has mainly Mo d_{z^2} character, which gets stabilized (i.e., its energy gets lowered) by interacting with the Mg s orbital.

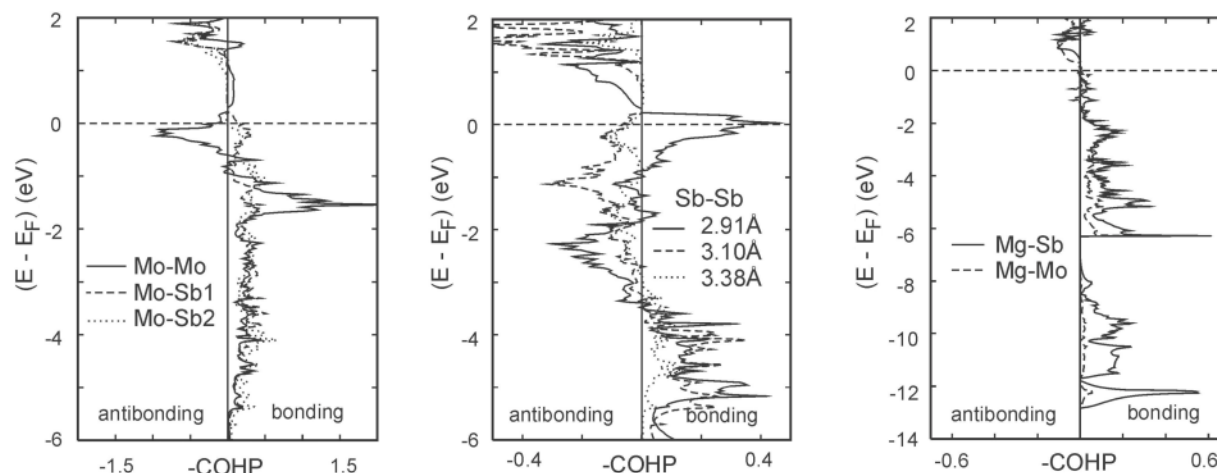
To investigate possible changes in the bonding character of the different interactions arising from the Mg addition, we turn our attention to the crystal orbital Hamilton population (COHP) curves of the model "$Mg_{0.5}Mo_3Sb_7$". The COHP formalism differentiates the states into bonding and antibonding contributions (55), which gives results comparable to the longer-established crystal orbital overlap populations (COOP) (56) used to weigh the DOS obtained via extended Hückel calculations (57, 58). Bonding contribu-

tions are reflected in negative COHPs but positive COOPs. We plotted –COHP vs. energy in order to have the COHP diagrams resemble the COOPs from earlier publications on related topics, i.e., with the bonding part on the right side. Figure 6 shows all interatomic interactions shorter than 3.5 Å, not weighted according to their multiplicity in the unit cell — i.e., simply depicted per bond.

Overall, all of these interactions have bonding character, although in some cases significant amounts of antibonding states are filled as well. The latter is true for all homonuclear interactions, i.e., the Mo—Mo bond, as well as the three different Sb—Sb interactions. On the other hand, almost exclusively bonding states are filled in the cases of the heteronuclear Mg—Mo, Mg—Sb, Mo—Sb(1), and Mo—Sb(2) interactions. The last one shows a few antibonding states that are starting to become filled just under the Fermi level.

It is obvious that adding Mg atoms to Mo_3Sb_7 leads to the formation of bonding Mg—Sb and Mg—Mo bonds. How far the other bonds are influenced must be analyzed in more detail. A suitable procedure is to integrate over all filled states, which results in ICOHP values, in analogy to the Mulliken overlap populations (MOP) (59) obtained from COOP curves. ICOHP values differ from MOP values in their sign (i.e., negative values indicate bonding character) and units (eV per bond vs. electrons per bond). As demonstrated before (60), the absolute ICOHP values are typically higher than the corresponding MOP values (ignoring the different units).

For a detailed investigation, we added two columns of –ICOHP values (i.e., ICOHP multiplied with (–1)) to Table 3, one for Mo_3Sb_7 and one for "$Mg_{0.5}Mo_3Sb_7$". Two interactions are stronger in "$Mg_{0.5}Mo_3Sb_7$", namely the Mo—Mo (–1.21 vs. 1.01 eV/bond) and the Mo—Sb(1) bond (–1.70 vs. 1.62 eV/bond). Reasons for this bond strengthen-

Fig. 5. Band structures of Mo_3Sb_7 (left) and "$Mg_{0.5}Mo_3Sb_7$" (right).
Fig. 6. Selected COHP curves for "$Mg_{0.5}Mo_3Sb_7$".


ing are the increase in the number of valence electrons, thus filling more bonding states, and covalent mixing with the added Mg states. All the other bonds decrease in strength on going from Mo_3Sb_7 to "$Mg_{0.5}Mo_3Sb_7$", in most cases because more antibonding states become filled by adding Mg atoms to Mo_3Sb_7 (with the exception of the short Sb(2)—Sb(2) bond of 2.91 Å).

Summary

This contribution describes the successful intercalation of small cations into Mo_3Sb_7, which was motivated by attempts to create the rattling effect and to tune the band gap, both strategies to enhance the thermoelectric properties. The cubic void of Mo_3Sb_7 may be filled with up to 14% Mg, 8% Ni, or 8% Cu without detectable long-range order. This leads to a small increase of the unit cell, the formation of bonding Mg—Sb and Mg—Mo interactions, and a decrease of the band gap.

The mixed occupancies will likely help in lowering the thermal conductivity, and the decrease of the band gap leads to a narrow gap, as desired for thermoelectrics. To reach the band gap, the Sb atoms have in part to be replaced by Te atoms, as described before for the unfilled Mo_3Sb_7. As 55 valence electrons are necessary to fill all bands below the gap,
the ideal formula for the Mg-containing material is "$Mg_\delta Mo_3Sb_{5+2\delta}Te_{2-2\delta}$". The thermoelectric properties of these quaternary materials are currently under investigation. In particular, we are investigating the possibility of intercalating smaller A cations to create the rattling effect.

Insertion reactions of nitrosobenzene and ketenes into silaaziridines[1]

Adrian G. Brook and Abraha Habtemariam

Abstract: Nitrosobenzene, trimethylsilyl ketene, and diphenylketene insert into the ring of silaaziridines to yield relatively unstable 5-membered heterocyclic ring systems. The new compounds, which have been characterized by ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy, arise from two different modes of insertion into the ring Si—N bond, leading to compounds with an exocyclic C=N bond (from nitrosobenzene) or two exocyclic C=C bonds (from the ketenes).

Key words: silaaziridines, ring insertion, nitrosobenzene, ketenes, heterocyclic rings.

Résumé : Le nitrosobenzène, le triméthylsilylcétène et le diphénylcétène s'insèrent dans le cycle des silaaziridines pour conduire à des systèmes cycliques hétérocycliques à cinq chaînons instables. Les nouveaux composés, qui ont été caractérisés par spectroscopie RMN du ^{1}H, du ^{13}C et du [29]Si, découlent de deux modes différents d'insertion dans la liaison Si—N du cycle conduisant à des composés avec une liaison C=N exocyclique ou deux liaisons C=C exocycliques (à partir des cétènes).

Mots clés : silaaziridines, insertion dans un cycle, nitrosobenzène, cétènes, noyaux hétérocycliques.

[Traduit par la Rédaction]

Introduction

Previously we have described the insertion reactions of aldehydes and isocyanates (1) into the ring of silaaziridines (2) that yielded 5-membered ring heterocycles **4** and **5**, respectively (see Scheme 1).

Also, the insertion of some isocyanides into the silaaziridine ring leading to 4-membered ring heterocycles has been reported (3). It seemed probable that other reagents would also insert into the silaaziridine ring, and this note describes reactions with nitrosobenzene, trimethylsilylketene, and diphenylketene, each of which led to novel heterocyclic compounds.

Results and discussion

By virtue of their similar polarization it seemed probable that silaaziridines would react with nitrosobenzene in the same manner as with an aromatic aldehyde, yielding analogs of **4**. This was found to be the case since the unstable heterocycles **6a** and **6b** were the major products of reaction of nitrosobenzene with the silaaziridines derived from either the adamantylsilene **2a** or the *tert*-butylsilene **2b** in the dark at room temperature (see eq. [1]). Each of these products

(**6a**, **6b**) is characterized by a prominent ^{13}C NMR absorption at 184 ppm, as observed in **4**.

On the other hand, benzonitrile, a much less polar molecule, failed to react over several days with silaaziridines.
In contrast to the behavior of the silaaziridines with aldehydes or nitrosobenzene, their reactions with ketenes gave rise to unstable compounds which did **not** contain C=N groups, based on the ^{13}C NMR data. Instead we believe that the original C=C double bond of the silaaziridine survives as a double bond exocyclic to a five-membered ring, based again on the ^{13}C NMR data for the C=C carbon atoms. Three possible structures, **7**, **8**, and **9** must be considered as discussed below.

Scheme 1.

Scheme 2.

The structure **7**, which could be formed analogously to the reaction of silaaziridines with isocyanates (1) (nominal addition of the Si—N bond of the silaaziridine across the ends of the C=C bond of the ketene), seems unlikely, especially for the trimethylsilylketene adduct where R′ = H, R″ = Me$_3$Si, since the position of the ring CH in the ^{1}H NMR spectrum, observed at approximately 4.1 ppm, is not reasonable for a hydrogen on a carbon attached to two Me$_3$Si groups (expected 1–2 ppm). Also, the IR frequency for an amide C=O in such a structure is expected in the region of 1700 cm^{-1} rather than the observed 1612 cm^{-1}. This data appears to rule out **7** as an appropriate structure.

An isomeric structure[3] — **8**, a cyclic acylsilane — could arise from nominal addition of the Si—N bond of the silaaziridine across the ends of the C=C bond in the ketenes with the alternative regiochemistry. This structure would be expected to have C=O IR absorption in the range 1636–1650 cm^{-1}, as observed for previously described acylsilanes (4), and not at 1612 cm^{-2}, as observed. Also the ^{13}C NMR absorption of the carbon atom of the C=O group would be expected to occur in the range 230–260 ppm (5), whereas we

observed 158–165 ppm. Based on the distinctive differences from expectation we rule this structure out also.

Finally, considering structure **9**, in principle this could arise by addition of the Si—N bond of the silaaziridine across the ends of the C=O group (see Scheme 2). We assign the IR absorption at 1612–1625 to the C=C groups of all four adducts characterized. For the pair of trimethylsilylketene adducts, the signal in the ^{1}H NMR spectrum at about 4.1 ppm for the Me$_3$SiC**H** = hydrogen seems reasonable. There are four signals in the ^{13}C NMR spectra of each compound that can be assigned to the two double bonds, two at about 115 ppm and two at about 161 ppm, due to the carbon atoms of the C=C that bear the OSiMe$_3$ group, and for the trimethylsilylketene adducts **9a** and **9b**, two signals at about 86 ppm and 165 ppm for the residual double bond of the original ketene. The ^{29}Si NMR signals due to the ring silicon atom, found in all compounds in the region –2 to –6 ppm, are completely consistent with a silicon atom bearing two trimethylsilyl groups, a carbon atom, and an oxygen atom (1). For the diphenylketene products **9c** and **9d** the other signals appear at about 120 and 154 ppm. We believe that this

---

[3] We are indebted to one of the referees for suggesting that this structure should be considered.

structure, of all considered, best fits the experimental data. It is regrettable that we could not get stable crystals for an X-ray crystal structure, which would have established the structures unambiguously.

A mechanism related to that proposed earlier (1) for the reaction of benzaldehyde with the silaaziridines, which involves dipolar intermediates derived from ring opening and rearrangement, appears to account adequately for the current results with nitrosobenzene. Thus nucleophilic attack on the ring silicon atom of the silaaziridine ring **3** by nitrosobenzene would result in breaking the ring Si—N bond, leading to the dipolar species **10**, which closes via attack by the resonance carbanion contributor **10′** onto the nitrogen atom, leading to the observed product **6**, as summarized in Scheme 3.

A mechanism accounting for the formation of the products derived from the reactions of the silaaziridines with the two ketenes is shown in Scheme 4. Silaphilic attack by the oxygen of the ketene on the silicon atom of the silaaziridine would result in ring opening and the formation of the intermediate dipolar species **11**, which on ring closure would yield the adducts **9**.

In summary, it is clear that a variety of polar reagents having either simple polar functional groups (e.g., C=O or N=O) or more complex functionality (C=C=O or N=C=O) will insert under very mild conditions into the Si—N ring bond of silaaziridines, yielding in each case 5-membered ring heterocycles. However, the adducts described in this paper were, in general, rather unstable, which precluded further investigation of their behavior.

Experimental

All NMR spectra were run either on a Varian XL400 or Varian XL200 spectrometer in C_6D_6 unless otherwise noted, using TMS as reference. Where appropriate APT (6) or DEPT (7) NMR pulse sequences were employed for ^{13}C NMR spectra. ^{29}Si NMR spectra were run in the DEPT mode or were run NOE suppressed.

Solutions in sealed NMR tubes were photolyzed inside a water-cooled Dewar flask maintained at 10 °C, using three external 100-watt Par 38 mercury spot lamps (BLAK RAY long wavelength ultraviolet lamps, Ultraviolet Products Inc.), having wavelengths ≥ 360 nm.

Reaction of silaaziridine 3a with nitrosobenzene: Formation of 6a

Silaaziridine **3a** was prepared by photolysis of a solution of the adamantylacylsilane **1a** (0.21 g, 0.5 mmol) in 2 mL C_6D_6 with 0.08 mL (4.4 mmol) of t-BuN=C: for 58 h according to the published procedure (1, 2). To the silaaziridine solution was added 0.06 g (0.56 mmol) of nitrosobenzene (8) and the solution was left in the dark overnight. The ^1H NMR spectrum showed that all the silaaziridine had been converted to the new product **6a**. The volatiles were removed under reduced pressure, and the NMR spectra were taken of the residue. Attempts to purify the material by chromatography on silica gel led to serious decomposition. ^1H NMR δ: 0.20, 0.33, 0.50 (each 9 H, s, Me_3Si), 1.25 (9 H, s, Me_3C), 1.6–2.1 (15 H, m, Ad), 6.8–7.3, 7.8–8.3 (5 H, m,

Scheme 3.
Ph). ^{13}C NMR δ: 0.45, 0.63, 4.78 (Me_3Si), 29.20 (CH Ad), 30.15 (Me_3C), 37.28, 37.41 (CH_2 Ad), 40.55 (C quat Ad), 59.48 (Me_3C), 100.32 (ring C sp^3), 117.59, 120.84, 128.21 (CH sp^2 Ph), 150.41 (quat C sp^2 Ph), 184.22 (C=N). ^{29}Si NMR δ: –14.62, –12.98 (Me_3Si), –5.12 (ring Si), 7.88 ($OSiMe_3$).

Reaction of silaaziridine 3b with nitrosobenzene 6b

Following the above procedure but using acylsilane **1b**, the volatiles were removed under reduced pressure and flash chromatography on silica gel eluting with hexane – ethyl acetate (9:1) gave a fraction that contained relatively pure **6b**, based on the NMR spectra. ^1H NMR δ: 0.17, 0.26, 0.45 (each 9 H, s, Me_3Si), 1.10 (9 H, Me_3C-C,), 1.19 (9 H, Me_3C-N), 6.8–7.3, 7.7–8.4 (5 H, m, Ph). ^{13}C NMR δ: 0.42, 0.60, 4.70 (Me_3Si), 28.81, 30.06 (Me_3C), 44.78 (Me_3C-C), 59.34 (Me_3C-N), 100.92 (ring C sp^3), 118.52, 121.55, 128.16 (CH sp^2 Ph), 150.13 (quat C sp^2), 184.28 (C=N). ^{29}Si NMR δ: –14.91, –13.00 (Me_3Si), –4.74 (ring Si), 7.65 ($OSiMe_3$).

Reaction of silaaziridine 3a with trimethylsilylketene 9a

To the silaaziridine **3a** prepared from 0.41 g (1.0 mmol) of the adamantylacylsilane **1a** in 4 mL C_6D_6 was added 0.19 g (1.1 mmol) of trimethylsilylketene (9) with vigorous shaking, and the solution was then left in the dark at room temperature. The ^1H NMR spectrum indicated that the silaaziridine was 40% converted to a single product after 30 min and completely converted after 24 h. The volatile material was removed under reduced pressure, and the residue was redissolved in C_6D_6. Attempts to further purify the material by chromatography on alumina, eluting with hexane – ethyl acetate 9:1, led to much decomposition. **9a**: IR (film) (cm^{-1}): 1612 (C=C). ^1H NMR δ: 0.27 (9 H, s, Me_3Si), 0.32 (18 H, s, two Me_3Si), 0.33 (9 H, s, Me_3Si), 1.34 (9 H, Me_3C), 1.6–2.1 (Ad), 4.08 (1 H, s, ring CH). ^{13}C NMR δ: 0.34, 0.55, 0.66, 2.10 (Me_3Si), 28.79 (CH Ad), 29.19 (Me_3C), 37.00, 40.47 (CH_2 Ad), 39.87 (quat C Ad), 61.38 (Me_3C), 86.81, 117.92, 161.44, 165.11 (C=C). ^{29}Si NMR δ: –16.48, –13.27, –10.24 (Me_3Si), –2.19 (ring Si), 15.13 ($OSiMe_3$).

Scheme 4.

9a, 9b   R' = H, R" = Me$_3$Si
9c, 9d   R' = R" = Ph
Reaction of silaaziridine 3b with trimethylsilylketene 9b

After following the above procedure using acylsilane **lb**, the volatiles were pumped off under reduced pressure, and the residue was dissolved in C$_6$D$_6$. **9b**: IR (film) (cm^{-1}): 1614 (C=C). ^{1}H NMR δ: 0.26 (9 H, s, Me$_3$Si), 0.31 (18 H, s, two Me$_3$Si), 0.34 (9 H, s, Me$_3$Si), 1.12 (9 H, *Me*$_3$C-C), 1.34 (9 H, *Me*$_3$C-N), 4.07 (1 H, s, ring CH). ^{13}C NMR δ: 0.26, 0.33, 0.64, 1.91 (Me$_3$Si), 29.10 (*Me*$_3$C-C and *Me*$_3$C-N overlapped), 37.44 (*Me*$_3$*C*-C), 61.11 (*Me*$_3$*C*-N), 86.74, 117.47, 160.85, 165.17 (C=). ^{29}Si NMR δ: –16.72, –14.13 (Me$_3$Si-Si), –10.26 (Me$_3$Si-C), –2.58 (ring Si), 15.24 (OSiMe$_3$).

Reaction of silaaziridine 3a with diphenylketene 9c

To the silaaziridine **3a** prepared from 0.21 g (0.5 mmol) of the adamantylacylsilane **la** and *t*-BuN=C: (0.085 mL, 0.7 mmol) in 2 mL C$_6$D$_6$ was added 0.11 g (0.6 mmol) of diphenylketene (**10**). The very slow reaction was monitored by ^{1}H NMR spectroscopy for 10 days, by which time the ratio of the adduct **9c** to the silaaziridine **3a** was 3:1. The material remaining after removal of the volatiles was chromatographed on silica gel, being eluted with hexane – ethyl acetate 30:1 to give a relatively pure oily solid **12c**. IR (film) (cm^{-1}): 1625 (C=C). ^{1}H NMR δ: 0.08, 0.29, 0.42 (each 9 H, s, Me$_3$Si), 1.28 (9 H, s, *Me*$_3$C), 1.6–2.1 (15 H, m, Ad), 7.14–7.21, 7.50–7.59 (10 H, m, Ph). ^{13}C NMR δ: –0.83, –0.35, 2.42 (Me$_3$Si), 28.57 (CH Ad), 29.55 (*Me*$_3$C), 36.57, 40.26 (CH$_2$ Ad), 40.11 (quat C Ad), 65.11 (Me$_3$*C*), 112.48, 120.02 (C=) 125.26, 125.41, 128.12, 128.28, 131.41, 132.10 (CH *sp*^{2} Ph), 143.70, 143.79 (quat C *sp*^{2} Ph), 154.25, 159.63 (C=). ^{29}Si NMR δ: 14.93, –13.78 (Me$_3$Si), –6.11 (ring Si), 11.68 (OSiMe$_3$).

Reaction of silaaziridine 3b with diphenylketene 9d

To the silaaziridine prepared in the usual way from 0.5 g (1.5 mmol) of the *tert*-butylacylsilane **lb** and 0.2 mL (2.4 mmol) of *t*-BuN=C: in 4 mL C$_6$D$_6$ was added 0.3 g (1.5 mmol) of diphenylketene. No reaction was observed overnight so the solution was photolyzed for 5 h, after which

time a new compound was observed in a 1:2 ratio with unconsumed silaaziridine. After 21 h further photolysis NMR spectroscopy indicated that all the silaaziridine **3b** had been converted to the product **9d**. Chromatography on silica gel, with elution using hexane – ethyl acetate 9:1 gave purer material. IR (film) (cm^{-1}): 1623 (C=C). ^{1}H NMR δ: 0.08, 0.26, 0.41 (each 9 H, s, Me$_3$Si), 1.15 (9 H, s, Me$_3$C-C), 1.27 (9 H, s, Me$_3$C-N), 6.95–7.60 (10 H, m, Ph). ^{13}C NMR δ: –0.50, 0.03, 2.71 (Me$_3$Si), 29.54, 29.88 (*Me*$_3$C), 38.03 (Me$_3$*C*-C), 65.26 (Me$_3$*C*N), 112.47 (ring C=), 120.00 (C=), 125.22, 125.41, 126.21, 127.52, 131.37, 131.94 (CH *sp*^{2} Ph), 143.52, 143.70 (quat C *sp*^{2} Ph), 154.17 (C=), 158.66 (C=C). ^{29}Si NMR δ: –15.25, –14.35 (Me$_3$Si), –6.28 (ring Si), 11.92 (OSiMe$_3$).

Crystal structures, magnetic properties, and absorption spectra of nickel(II) thiocyanato complexes: a comparison of different coordination geometries[1]

Bruno Larue, Lan-Tâm Tran, Dominique Luneau, and Christian Reber

Abstract: Thiocyanatonickel(II) compounds with composition $\{(AsPh_4)_2[Ni(NCS)_4]\}$ **1**, $\{(Cat)[Ni(NCS)_4]\}$ **2**, $\{(AsPh_4)_4[Ni_2(NCS)_8]\}$ **3**, $\{(Cat)_2[Ni_2(NCS)_8] \cdot 2CH_3NO_2]\}$ **4**, and $\{(Et_4N)_4[Ni(NCS)_6]\}$ **5** $(Cat^{2+} = (p\text{-xylylenebis(tri-} phenyphosphonium}))^{2+})$ were prepared. The crystal structures of compounds **1**, **3**, and **4** were determined. Compound **1** crystallizes in the monoclinic $C2/c$ space group with $a = 22.761(2)$ Å, $b = 15.055(1)$ Å, $c = 15.054(1)$ Å, $\beta = 108.915(1)^\circ$, $V = 4879.9(6)$ Å^3, and $Z = 4$. Compound **3** crystallizes in the triclinic $P\bar{1}$ space group with $a = 11.2183(6)$ Å, $b = 14.2551(8)$ Å, $c = 16.629(1)$ Å, $\alpha = 79.326(1)^\circ$, $\beta = 73.605(1)^\circ$, $\gamma = 75.496(1)^\circ$, $V = 2451.0(2)$ Å^3, $Z = 2$. Compound **4** crystallizes in the monoclinic $P2_1/n$ space group with $a = 13.1148(9)$ Å, $b = 27.128(2)$ Å, $c = 14.882(1)$ Å, $\beta = 114.056(2)^\circ$, $V = 4834.8(6)$ Å^3, $Z = 4$. The magnetic properties of compounds **1–4** were studied over the 2–300 K temperature range. Compounds **1** and **2** with monometallic $[Ni(NCS)_4]^{2-}$ complex units have similar magnetic properties, in agreement with nickel(II) ions in pseudo-tetrahedral environments. Compounds **3** and **4** with bimetallic $[Ni_2(NCS)_8]^{4-}$ complex units exhibit magnetic properties, which are indicative of Ni(II)–Ni(II) ferromagnetic interactions with zero-field splitting effects caused by the pseudo-square-pyramidal or pseudo-trigonal-bipyramidal coordination environments of the nickel(II) ion in compounds **3** and **4**, respectively. The structures and magnetic results for all compounds are correlated with NIR–UV–vis absorption spectra.

Key words: nickel(II) thiocyanato complexes, crystal structures, paramagnetism, molecular magnetism, exchange coupling, absorption spectroscopy.

Résumé : Les composes à base de complexes thiocyanate de nickel(II) de composition $\{(AsPh_4)_2[Ni(NCS)_4]\}$ **1**, $\{(Cat)[Ni(NCS)_4]\}$ **2**, $\{(AsPh_4)_4[Ni_2(NCS)_8]\}$ **3**, $\{(Cat)_2[Ni_2(NCS)_8] \cdot 2CH_3NO_2]\}$ **4** et $\{(Et_4N)_4[Ni(NCS)_6]\}$ **5** $[Cat^{2+} = (p\text{-xylylènebis(triphenyphosphonium}))^{2+}]$ ont été synthétisés. Les structures cristallines des composés **1**, **3** et **4** ont été déterminées. Le composé **1** cristallise dans le groupe d'espace monoclinique $C2/c$ avec $a = 22.761(2)$ Å, $b = 15.055(1)$ Å, $c = 15.054(1)$ Å, $\beta = 108.915(1)^\circ$, $V = 4879.9(6)$ Å^3, $Z = 4$. Le composé **3** cristallise dans le groupe d'espace triclinique $P\bar{1}$ avec $a = 11.2183(6)$ Å, $b = 14.2551(8)$ Å, $c = 16.629(1)$ Å, $\alpha = 79.326(1)^\circ$, $\beta = 73.605(1)^\circ$, $\gamma = 75.496(1)^\circ$, $V = 2451.0(2)$ Å^3, $Z = 2$. Le composé **4** cristallise dans le groupe d'espace monoclinique $P2_1/n$ avec $a = 13.1148(9)$ Å, $b = 27.128(2)$ Å, $c = 14.882(1)$ Å, $\beta = 114.056(2)^\circ$, $V = 4834.8(6)$ Å^3, $Z = 4$. Les propriétés magnétiques des composés **1–4** ont été étudiées dans le domaine de température 2–300 K. Les composés **1** et **2** contiennent l'entité complexe mononucléaire $[Ni(NCS)_4]^{2-}$ et ont des comportements magnétiques identiques caractéristiques d'un ion nickel(II) dans un environnement pseudo tétraédrique. Les composés **3** et **4** contiennent l'entité complexe dinucléaire $[Ni_2(NCS)_8]^{4-}$ et ont des comportements magnétiques qui indiquent l'existence d'interactions ferromagnétiques Ni(II)–Ni(II) associées aux effets de levée de dégénérescence en champ nul dus au nickel(II) dans un environnement pseudo pyramide à base carrée (composé **3**) ou pseudo bipyramide trigonale (composé **4**). Les structures et résultats des mesures magnétiques pour tous les composés sont mis en rapport aux spectres d'absorption.

Introduction

The magnetic properties of coordination compounds have received renewed interest in view of the recent discoveries of molecular magnetic materials (1–4). In some cases, understanding their magnetism still poses a challenge even when simple molecular building blocks, such as the title compounds, are involved. In the vast majority of the published work, the temperature dependence of the magnetic properties is given and explained based on only the crystal structure of the material. It is sometimes difficult, however, to understand even fundamental magnetic properties, such as deviations from spin-only behavior for chemically related compounds, if only structural data is used. More detailed information on the electronic structure and precise energies of electronic states are then needed. In this report we use absorption spectroscopy to provide such information.

The thiocyanato and other isoelectronic bridging ligands have attracted interest from a crystal engineering perspective, as they lead to many different of molecular and extended structures, and a variety of nickel(II) thiocyanato complexes have been reported (5–7). In the following, we reexamine a previously characterized set of nickel(II) complexes with thiocyanato ligands (5). Room-temperature solid-state reflectance spectra and the magnetic susceptibility of the title compounds — also mainly at room temperature — were measured, but neither the absorption spectroscopy nor the magnetic properties have been explored in detail. In the following, we present temperature-dependent magnetic measurements, single-crystal absorption spectra, and crystal structures. Octahedral, distorted tetrahedral, square-pyramidal, and trigonal-bipyramidal coordination geometries are investigated. The absorption spectra obtained from crystals at low temperature depend strongly on the coordination geometry. They are analyzed with a quantitative ligand-field model based on the experimental metal–ligand angular geometry. The ground-state properties obtained from this analysis are then compared with the observed χT values (the product of the molar magnetic susceptibility with temperature) at room temperature. We also show that for bimetallic compounds, complementary information on magnetic exchange interactions can be obtained from temperature-dependent absorption spectra, even if the exchange coupling is relatively weak and the bands are not highly resolved. The combination of experimental techniques and quantitative empirical models gives detailed insight that is valid for high-symmetry complexes with a single nickel(II) center and for bimetallic complexes with lower symmetry. The approach is based on absorption spectra without highly resolved structure and appears to be applicable to larger clusters and higher-dimensional systems with a variety of bridging ligands.

Experimental

Synthesis

All reagents were purchased from commercial sources and used without further purification. Compounds $(AsPh_4)_2$-$[Ni(NCS)_4]$ **1**, $(Cat)[Ni(NCS)_4]$ **2**, $(AsPh_4)_4[Ni_2(NCS)_8]$ **3**, $(Cat)_2[Ni_2(NCS)_8]\cdot 2CH_3NO_2$ **4**, and $(Et_4N)_4[Ni(NCS)_6]$ **5** $(Cat^{2+} = (p$-xylylenebis(triphenyphosphonium)$)^{2+})$ were synthesized according to literature methods (5).

Crystallography

Single crystal diffraction data were collected at room temperature (298 K) with a Bruker SMART CCD diffractometer equipped with a normal monochromatized focus X-ray tube having a molybdenum target. The data were processed through the SAINT reduction software (8a). Empirical absorption corrections were carried out by SADABS (G.B. Sheldricks, 1994) (8b). The structures were solved and refined on F^2 using the SHELXTL software (8c). Scattering factors were taken from the International tables for crystallography (9). All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the final refinement in calculated positions with isotropic thermal parameters. Crystal structure and refinement data are summarized in Table 1. Weighting functions used were $w = 1/[\sigma^2(F_o^2) + (0.0894P)^2]$ for compound **1** and $w = 1/[\sigma^2(F_o^2) + (0.1000P)^2]$ with $P = (F_o^2 + 2\ F_c^2)/3$ for compounds **3** and **4**.

Magnetic susceptibility measurements

The temperature dependence of the magnetic susceptibility was measured on the bulk material between 6 and 300 K with an SHE superconducting SQUID magnetometer operating at a field strength of 0.5 T. The data were corrected for diamagnetism of the constituent atoms using Pascal constants.

Spectroscopy

Absorption spectra were measured with a Varian Cary 5E spectrometer using the photomultiplier tube and the PbS detector for the visible and near-infrared wavelength ranges, respectively. The sample crystals were cooled in an He gas flow cryostat (Oxford Instruments CF-1204), and the temperature was monitored with an RhFe resistor connected to an electronic controller (Oxford Instruments ITC4) to stabilize the temperature to better than ±1 K, by adjusting both a heater for the He gas cooling the sample and the gas flow valve from the He storage Dewar to the cryostat. All spectra presented in the following are unpolarized. Raman spectra of solid samples at low temperature were measured using a Renishaw System 3000 Raman microscope, using 782 or 514.5 nm excitation wavelengths. Selected spectra and frequencies are given in the supplementary material.[4] No evidence for electronic Raman transitions was observed.

Results

Crystal structures

(AsPh$_4$)$_2$[Ni(NCS)$_4$] 1

The crystal structure consists of the anionic [Ni(NCS)$_4$]$^{2-}$ monometallic complex units shown on Fig. 1 with AsPh$_4^+$ cations. Selected bond lengths and angles are given in Tables 2 and 3. In each complex unit, the nickel(II) ion is located on a C_2 axis and has a pseudo-tetrahedral ligand environment. The Ni—N bond lengths are similar (1.929(4) and 1.921(4) Å). The structural features for the [Ni(NCS)$_4$]$^{2-}$ complex unit in compound **1** show slight differences from those previously determined for the same complex unit in Cat[Ni(NCS)$_4$] **2** (10). In compound **2,** three of the Ni—N bonds are shorter (1.906(6)-1.908(7) Å) and one is longer (1.937(7) Å) than in compound **1.** However, the mean values (1.92 Å) are identical for both compounds **1** and **2**, as shown in Table 2. Owing to the (AsPh$_4$)$^+$ cations, the [Ni(NCS)$_4$]$^{2-}$ complex units are well separated from each other. The shortest intermolecular distances in compound **1** are found between the S(thiocyanato) atoms (5.777(3) Å), while the shortest intermolecular distance between two nickel(II) ions is 8.1260(6) Å.

(AsPh$_4$)$_4$[Ni$_2$(NCS)$_8$] 3

The crystal structure consists of the anionic [Ni$_2$(NCS)$_8$]$^{4-}$ bimetallic complex units, shown in Fig. 2, with AsPh$_4^+$ cations. Selected bond lengths and angles are given in Tables 2 and 3. The bimetallic complex units [Ni$_2$(NCS)$_8$]$^{2-}$ are centrosymmetrical and are built from two [Ni(NCS)$_4$]$^{2-}$ moieties, which are double-bridged by two NCS$^-$ ligands in the end-to-end fashion (Ni—S1A = 2.5319(9) Å). The two nickel(II) ions and the two thiocyanato bridges are coplanar with a maximum out-of-plane deviation of 0.03 Å. The Ni···Ni separation in the bimetallic unit is 5.6745(6) Å. The nickel(II) ions are in a pseudo-square-pyramidal environment (Tables 2 and 3) (11). The atoms N1, N2, N3, and S1A, forming the base of the pyramid, are coplanar (Fig. 2) with a maximum out-of-plane deviation of 0.08 Å. The nickel(II) ion is located 0.3 Å above this plane. To measure the degree of distortion of the square pyramidal polyhedron we calculated the geometric parameter, τ, defined by Addison et al. (12) to systematize five-coordinate coordination geometries intermediate between the idealized square-pyramidal and trigonal-bipyramidal structures. The parameter τ is defined as $\tau = (\beta - \alpha)/60$, with β and α the largest ligand-metal-ligand bond angles and $\beta > \alpha$. These angles are schematically illustrated in Fig. S5 of the supporting information.[4] The parameter τ is equal to zero for perfectly square pyramidal structures and is unity for perfectly trigonal-bipyramidal coordination geometries. Table 3 shows that for compound **3** the angle β corresponds to the N1-Ni-N2 bond angle (165.5°) and α is the N3-Ni-S1A angle (160.1°). These angles lead to a τ parameter of 0.09, which is close to the value for a perfect square-pyramidal structure. The NiNCS atoms (N coordination) are found to be almost collinear (Ni-N-C: 165–172°), but for the NiSCN fragment (S coordination), the Ni-S1A-C1A bond angle is 104.36° (Table 2). These values are comparable to those previously found in di-μ-thiocyanato-briged nickel(II) complexes (7, 13). The four Ni—N bond lengths are similar (1.983(3) and 2.025(3) Å) but longer than those in the pseudo-tetrahedral

Note: Data for compound **2** are extracted from ref. 10. Letter A denotes the symmetry related atoms ($-x$, y, $-z + 3/2$) for **1** and ($-x$, $-y$, $-z$) for **3** and **4**.

[Ni(NCS)$_4$]$^{2-}$ complex unit with either AsPh$_4^+$ **1** or Cat^{2+} **2** counterions (Table 2). The Ni—S1A bond length is 2.5319(9) Å. The [Ni$_2$(NCS)$_8$]$^{2-}$ bimetallic units are well separated by the (AsPh$_4$)$^+$ cations. The shortest intermolecular distance between two complex units is found between the S atoms (4.332(3) Å) while the shortest intermolecular distances between two nickel(II) ions is 11.2183(6) Å.

(Cat)$_2$[Ni$_2$(NCS)$_8$]·2CH$_3$NO$_2$ 4

The crystal structure consists of the anionic [Ni$_2$(NCS)$_8$]$^{4-}$ bimetallic complex units, shown in Fig. 3, with Cat^{2+} cations and nitromethane as the crystallization solvent. Selected bond lengths and angles are given in Tables 2 and 3. As for **3**, the bimetallic complex units [Ni$_2$(NCS)$_8$]$^{4-}$ are centrosymmetrical and are built from two [Ni(NCS)$_4$]$^{2-}$ moieties bridged by two NCS$^-$ ligands in the end-to-end fashion. The two nickel(II) ions and the two thiocyanato bridges are again coplanar with a maximum out-of-plane deviation of 0.01 Å. The Ni···Ni distance is 5.715(1) Å. In compound **4**, the nickel(II) ions of the [Ni$_2$(NCS)$_8$]$^{2-}$ bimetallic units are in a pseudo-trigonal-bipyramidal environment (11). Atoms N3, N4, and S1A (Fig. 3) define the base of the bipyramid and the nickel(II) ion is only 0.03 Å out of this plane. As for compound **3**, we calculated the parameter τ (12) to determine the distortion from an ideal trigonal-bipyramidal coordination geometry. Table 3 shows that for compound **4** the angle β again corresponds to the N1-Ni-N2 bond angle (169.8°) and the angle α is again N3-Ni-S1A (136.9°). The τ parameter equals 0.55, a value halfway between the perfectly square-pyramidal and trigonal-bipyramidal coordination geometries. The NiNCS (N coordination) atoms are

Fig. 2. View of the complex unit $[Ni_2(NCS)_8]^{4-}$ for $(AsPh_4)_4[Ni_2(NCS)_8]$ **3**. Ellipsoids are drawn at the 30% probability level. The letter A denotes symmetry related atoms $(-x, -y, -z)$.
Fig. 3. View of the complex unit $[Ni_2(NCS)_8]^{4-}$ for $(Cat)_2[Ni_2(NCS)_8]$ **4** $(Cat^{2+} = (p\text{-xylylenebis(triphenyphophonium)})^{2+})$. Ellipsoids are drawn at the 30% probability level. The letter A denotes symmetry related atoms $(-x, -y, -z)$.
found to be almost collinear (Ni-N-C: 164–170°), but for the NiSCN fragment (S coordination), the Ni-S1A-C1A bond angle is 105.3(2)°. These structural features are similar to those found in compound **3** and in previous di-μ-thiocyanato-bridged nickel(II) complexes (7, 13). The Ni—N bond distances are comparable to those found for compound **3** (1.997(4) and 2.039(5) Å) and are again longer than for the monometallic complex $[Ni(NCS)_4]^{2-}$ either with $AsPh_4^+$ or with Cat^{2+} (10) cations, as summarized in Table 2. The Ni—S1A bond length is 2.485(1) Å. Owing to the

Cat^{2+} cations, the $[Ni_2(NCS)_8]^{4-}$ units are again well separated. The shortest intermolecular distance between two complex units is found between the S(thiocyanato) atoms (3.516(3) Å), and the shortest intermolecular distances between two nickel(II) ions is 11.036(1) Å.

Compounds **3** and **4** both undergo an irreversible color change from olive-green and brown-orange to blue at temperatures above 100 °C, as reported in the literature (5, 14). Powder X-ray diffraction patterns and Raman spectra shown in the supporting material indicate that the blue high-

Fig. 4. Temperature dependence of χT. From top to bottom: $(Cat)_2[Ni_2(NCS)_8]$ **4**, open circles; $(AsPh_4)_4[Ni_2(NCS)_8]$ **3**, solid circles; $(AsPh_4)_2[Ni(NCS)_4]$ **1**, open squares. Solid lines denote fits as described in the text.
temperature product contains pseudo-tetrahedral $[Ni(NCS)_4]^{2-}$ chromophores, as expected from the color, which corresponds to that of the distorted tetrahedral chromophores in **1** and **2**.

Magnetic properties

The magnetic properties of compounds **1**, **3**, and **4** in relation to the temperature dependence of χT, the product of the molar magnetic susceptibility with temperature, are shown in Fig. 4. Magnetic measurements for compound **2** are in good agreement with literature values reported between room temperature and 95 K (5), as shown in the supplementary material.[4]

$(AsPh_4)_2[Ni(NCS)_4]$ 1 and $Cat_2[Ni(NCS)_4]$ 2

The two monometallic compounds exhibit similar magnetic properties, illustrated for compound **1** by the bottom trace in Fig. 4. At room temperature, χT is 1.71 emu K mol^{-1} for **1** and 1.56 emu K mol^{-1} for **2**. χT decreases slowly with temperature down to 50 K, where it reaches 1.59 emu K mol^{-1} for **1** and 1.38 emu K mol^{-1} for **2**. At lower temperatures, χT falls abruptly. The large deviation of χT at room temperature from the spin-only value ($S = 1$, $\chi T = 1$ emu K mol^{-1}) is due to significant angular momentum contributions, as expected for nickel(II) ions in a tetrahedral environment with a $^3T_1$ ground state (6, 15, 16). The deviation from the Curie law behavior at low temperature can be attributed to zero-field splittings. The crystal structure shows that the $[Ni(NCS)_4]^{2-}$ units are well separated

from each other and therefore only extremely weak intermolecular antiferromagnetic interactions are expected. Their contribution to the decrease of χT at low temperature is negligible.

We tentatively tried to fit the magnetic behavior using the expression of the magnetic susceptibility derived by Ginsberg et al. (13), taking into account a single-ion zero-field splitting parameter (D) and assuming g to be isotropic. The experimental behavior is well reproduced with $g = 2.3$ and $D = -8.9$ cm^{-1} for compound **1**, as shown in Fig. 4a, and with $g = 2.2$ and $D = -2.9$ cm^{-1} for compound **2**, as shown in the supplementary material.[4]

$(AsPh_4)_4[Ni_2(NCS)_8]$ 3

At room temperature, χT is 2.87 emu K mol^{-1} per bimetallic molecular unit, and it increases upon cooling to reach the value of 3.00 emu K mol^{-1} at 50 K. At lower temperatures, χT decreases abruptly. As for **1** and **2**, the large deviation from the spin-only value at room temperature has to be ascribed to the ground-state angular momentum in the pseudo-square-pyramidal coordination environment. The value at room temperature is 1.43 emu K mol^{-1} per nickel(II) ion, lower than the value measured for **1** and in agreement with previous reports, which show that generally χT values for square-pyramidal nickel(II) complexes deviate less from the spin-only value than those of tetrahedral or trigonal-bipyramidal nickel(II) complexes (6).

The increase of χT upon cooling below 50 K is the signature of ferromagnetic interactions between the two nickel(II)

ions within the $[Ni_2(NCS)_8]^{4-}$ unit. The zero-field splitting cannot account for such an increase in χT, as is confirmed by comparison with compounds **1** and **2**, which show a clear decrease of χT at the lowest temperatures. In addition, the $[Ni_2(NCS)_8]^{4-}$ units are well separated by the $(AsPh_4)^+$ cations, and intermolecular interactions are unlikely to account for the ferromagnetic behavior. The increase of χT is therefore due to intramolecular Ni–Ni ferromagnetic interactions operating through the $[Ni_2(NCS)_2]$ bridge, as is generally found for end-to-end di-μ-thiocyanato-bridged nickel(II) compounds (7, 13, 17, 18). We simulate the magnetic behavior using the expression of the magnetic susceptibility derived by Ginsberg et al. (13) and taking into account the zero-field splitting parameter (D), an isotropic g factor, and a ferromagnetic intramolecular interaction ($H_{ex} = -2JS_1S_2$). The experimental behavior is well reproduced with $g = 2.06$, $J = 4.5$ cm^{-1}, and $D = -3.9$ cm^{-1}.

$(Cat)_2[Ni_2(NCS)_8]\cdot2CH_3NO_2$ 4

At room temperature, χT is 3.50 emu K mol^{-1} per bimetallic molecular unit. Its value increases slightly upon cooling to reach a maximum of 4.03 emu K mol^{-1} at 50 K. At lower temperatures, it falls abruptly. As for compounds **1** to **3**, the large deviation from spin-only behavior at room temperature is due to the significant contribution of orbital angular momentum in the pseudo-trigonal-bipyramidal environment shown in Fig. 3. The value of 1.71 emu K mol^{-1} per nickel(II) ion at room temperature is comparable to the value for **1** but higher than the value for the bimetallic compound **3**. This is in qualitative agreement with previous reports showing that trigonal-bipyramidal nickel(II) complexes exhibit deviations from spin-only behavior that are intermediate between those for tetrahedral and square-pyramidal nickel(II) complexes (6). As for compound **3**, the increase of χT upon cooling is the signature of ferromagnetic interactions coupling the two nickel(II) ions within the $[Ni_2(NCS)_8]^{2-}$ units. Our attempts to simulate the magnetic behavior using the same approach as for compounds **1** and **3** were unsuccessful, but the qualitative comparison with the results for compound **3** indicates a ferromagnetic intramolecular coupling of comparable magnitude.

Absorption spectroscopy

Figure 5 shows a comparison of the low-temperature solid-state absorption spectra of nickel(II) complexes with tetrahedral (**1**), octahedral (**5**), square-pyramidal (**3**), and trigonal-bipyramidal (**4**) coordination geometries. The complexes in compounds **1** and **5** have a single nickel(II) center with tetrahedral and octahedral coordination geometries, respectively. They show the expected three spin-allowed ligand-field bands, as illustrated by the two lowest traces in Fig. 5. All band maxima from low-temperature solid-state absorption spectra are numbered in Fig. 5, and their energies are given in Table 4. The two lowest-energy bands correspond to transitions between states arising from the ^3F free ion term. Their maxima are lower (by approximately 4000 cm^{-1}) for the tetrahedral complex **1** than for the octahedral complex **5**, indicating the expected weaker ligand-field strength in **1**. A room-temperature reflectance spectrum in the literature (5) shows similar energies, shapes, and relative intensities as given for bands 1, 2, and 4 of **1** in the bot-

tom spectrum of Fig. 5. The weak band 3 is not observed in the literature spectrum. The bimetallic complexes show distinct differences from the compounds with only one nickel(II) center. Their lowest-energy broad absorption band maxima are at intermediate energies between those of tetrahedral and octahedral complexes, as qualitatively expected from ligand-field arguments. A quantitative model based on the crystal structures is essential to assign their bands, as discussed in section 4.1.

Figure 6 shows a detailed view of the band maxima of two spin-allowed absorption bands with resolved vibronic structure at 5 K: band 3 (Fig. 5) for the octahedral complex **5** and band 4 (Fig. 5) for the square-bipyramidal complex **3**. The average energy difference between maxima forming the progression is 204 ± 20 cm^{-1}, an interval in the range expected for metal–ligand stretching modes in the title complexes. This progression interval is similar for the two compounds, indicating that no large differences in bond strength are caused by the change of coordination geometry or by the influence of one sulfur ligator atom. Raman spectra of these compounds are given in the supplementary material[4] and show transitions attributed to ground-state Ni–NCS stretching modes at 211 cm^{-1} and at 201, 224, and 260 cm^{-1} for **5** and **3**, respectively, indicating that offsets along these normal coordinates lead to the vibronic progressions in Fig. 6.

Several weak features are observed in addition to the broad spin-allowed bands. A first peak or shoulder occurs between 12 000 and 14 000 cm^{-1} in all compounds. This is the lowest-energy spin-flip transition to a singlet excited state, and it has been observed and interpreted for many different octahedral complexes of nickel(II) (19). For the octahedral compound **5**, the band is weaker than usual for coordination to six nitrogen ligator atoms because the closest spin-allowed bands are relatively far in energy. In most complexes with nitrogen donor ligands, the lowest-energy spin-allowed band occurs in the same energy range as the transition to the first singlet excited state (19), leading to a strong intensity enhancement of the spin-forbidden transition and a characteristic interference dip observed even in unresolved spectra (20–22). This observation confirms that NCS$^-$ is a relatively weak ligand compared with other nitrogen donors (19). Additional transitions to higher energy singlet states are observed for the two bimetallic complexes at approximately 17 600 cm^{-1} for **3** and 17 950 cm^{-1} for **4**. All energies of singlet bands determined from absorption spectra are given in Table 4.

Discussion

Assignment of absorption bands

A quantitative analysis of the observed absorption spectra, summarized in Fig. 5, is based on the angular overlap model (AOM), a modern implementation of ligand-field theory. The title complexes have only thiocyanato ligands, an attractive situation for this analysis because a single set of AOM parameters can be used for all compounds. We base our calculations (23) on the crystal structures of the anionic complexes shown in Figs. 1–3. The first calculations are carried out for the four- and six-coordinate complexes with a single nickel(II) center shown as the bottom two traces in Fig. 5.

Fig. 5. Overview absorption spectra recorded on single crystals at 5 K. Bottom to top: $(AsPh_4)_2[Ni(NCS)_4]$ **1** (pseudo-tetrahedral coordination geometry, dashed line); $(Et_4N)_4[Ni(NCS)_6]$ **5** (octahedral coordination geometry, solid line); $(AsPh_4)_4[Ni_2(NCS)_8]$ **3** (pseudo-square-pyramidal coordination geometry, solid line); $(Cat)_2[Ni_2(NCS)_8]$ **4** (pseudo-trigonal-bipyramidal coordination geometry, dashed line).
These spectra show three spin-allowed bands, as expected in idealized T_d and O_h point-group symmetries, and the final states of the transitions are easily assigned from literature Tanabe–Sugano diagrams. The traditional ligand-field parameters B, C, Δ_{oct}, and Δ_{tet} can be determined from the band maxima. This analysis reproduces the observed band maxima well, leading to a B value of 825 cm^{-1} (76% of the free-ion value) and a ratio C/B of 4.6, values in the range determined in the literature for a large number of nickel(II) complexes (19). The angular-overlap approach replaces the parameters Δ_{oct} and Δ_{tet} with the point-group symmetry independent parameters e_σ and e_π, assumed to be identical for each NCS$^-$ ligand. The six spin-allowed bands of the two bottom traces in Fig. 5 allow these parameters to be fitted and values of 4720 and 1000 cm^{-1} are obtained for e_σ and e_π, respectively. The resolution of the spectra used to determine these parameter values is not sufficient to reveal spin-orbit splittings, and the spin-orbit coupling constant ζ is set to zero for all calculations described in the following.

The parameter set obtained from the two bottom spectra can be used to calculate absorption band maxima for compounds **1**, **3**, and **4** using the polar coordinates of the ligands determined from the structural data reported in Tables 2 and 3. These θ and ϕ angles are given in Table 4. The calcula-tions assume identical e_σ and e_π values for all ligands, thereby neglecting the variations of Ni—N bond lengths and the different nature of the S ligator atom for one metal—ligand bond in **3** and **4**. These assumptions allow us to calculate energies for all compounds without introducing additional adjustable parameters and lead to a good overall agreement of calculated and observed band maxima, as documented in Table 4.

The calculated splittings of degenerate excited triplet states for **1** due to deviations from perfect tetrahedral coordination geometry are less than 1000 cm^{-1}, as given in Table 4, and cannot be determined from the broad, unresolved bands of the experimental spectrum, shown as the bottom trace in Fig. 5. The lowest-energy singlet state is observed lower (by 800 cm^{-1}) than calculated, a discrepancy most likely because of our choice of C/B ratio and indicating that both independently fitted Racah parameters and a nonzero spin-orbit coupling constant would be needed for a perfect agreement. The band positions for octahedral compound **5** are very well reproduced by the parameters chosen for our calculations.

In contrast to complexes **1** and **5**, the absorption spectra of bimetallic complexes **3** and **4** cannot be analyzed in an idealized high-symmetry point group. The crystal structures and

7					23 600	23 040, 23 830		

Note: The following ligand-field parameters were used for all calculations: e_σ(N) = 4720 cm^{-1}, e_π(N) = 1000 cm^{-1}, C = 3795 cm^{-1} (C/B = 4.6). For the bimetallic complexes, e_σ(S) = e_σ(N) and e_π(S) = e_π(N) were used. The angles θ and φ are determined from the crystal structures. The N4—Ni and N3—Ni bonds were set to θ = 0 for compounds **3** and **4**. The Ni—S1A bonds were set to φ = 0 in the plane perpendicular to the bond defining θ for both **3** and **4**. The angle ψ and the spin-orbit coupling constant ζ were set to zero for all calculations. All calculated triplet states and selected singlet states, denoted as s, are given.

^{a}Calculated ground-state splittings, not observed in the absorption spectra.

Fig. 6. Resolved vibronic structure for octahedral $[Ni(NCS)_6]^{4-}$ molecular units in $(Et_4N)_4[Ni(NCS)_6]$ **5**, bottom trace and bottom wavenumber scale, and pseudo-square-pyramidal $[Ni(NCS)_4(SCN)]^{3-}$ molecular units in $(AsPh_4)_4[Ni_2(NCS)_8]$ **3**, top trace and top wavenumber scale. The bands enlarged here are labeled in Fig. 5 as bands 3 and 4 of the lower and upper solid traces, respectively.
AOM parameter set determined above allow us to calculate absorption maxima without adjusting any parameters. The overall agreement between calculated and observed energies is good, as documented in Table 4. The correct number and energies of spin-allowed transitions are obtained from the calculations. As was the case for **1**, the energies of the singlet states are less reliably reproduced, again most likely a consequence of the C/B ratio that was not treated as an adjustable parameter. Nevertheless, a good interpretation of the absorption spectra is obtained and we conclude that band energies are strongly influenced by the single-ion coordination geometry, with no clear-cut effects of the exchange interaction between the two nickel(II) centers evident in the 5 K spectra of compounds **3** and **4** in Fig. 5. The analysis of exchange effects requires detailed temperature-dependent measurements, as discussed in section 4.2. It is interesting to note that the exact coordination geometries of the nickel(II) centers in **3** and **4** are required for the analysis of the spectrum. This is illustrated by the lowest-energy absorption bands shown in Fig. 5 (labeled 1 on the top two traces). The band maximum for the distorted square-pyramidal complex **3** is lower in energy by approximately 800 cm^{-1} than for the pseudo-trigonal-bipyramidal complex **4**, an energetic order correctly reproduced by our AOM analysis based on the crystal structures. In contrast, AOM calculations for perfect square-pyramidal and trigonal-bipyramidal structures with the parameter values used above lead to band maxima of 7200 and 6200 cm^{-1}, respectively, not only in worse agreement with the experimental maxima but also in the wrong

energetic order. The observed variation of spin-allowed absorption band maxima is quantitatively rationalized by a comparison of the calculated energies for all triplet states as a function of τ, the parameter used to classify the five-coordinate coordination geometries of **3** and **4** in the Results: Crystal structures section. These calculated energies are shown in Fig. S5 of the supporting information.[4] The deviations from idealized symmetry in **3** and **4** have, therefore, a significant effect on the observed absorption bands, and care should be taken when analyzing absorption spectra in an idealized coordination geometry, as was done in a recent study of nickel(II) thiocyanato complexes (7).

The calculated energy differences between the lowest triplet states for **1**, **3**, and **4** (given in Table 4) can be qualitatively related to the χT values measured at room temperature. Compound **1** has the smallest splitting with levels at 0, 1370, and 1800 cm^{-1}, and its χT value per nickel(II) ion is 1.71 emu K mol^{-1}, higher than the value of 1.56 emu K mol^{-1} measured for compound **2**. The same order of χT values at 290 K is reported in the literature (5): 1.68 and 1.64 emu K mol^{-1} for compounds **1** and **2**, respectively. The calculated splitting for **2** indicates levels at 1300 and 2600 cm^{-1} — larger energy differences than for compound **1** — and therefore the lower χT value is justified. The correlation between AOM calculations and χT values remains qualitative because the effects of spin-orbit coupling are neglected, and identical e_σ and e_π values are used for each metal—ligand bond. The latter assumption is justified for compound **1**, where all four nickel(II)—N bond lengths are comparable, but less so for compound **2**, where one bond is longer by 0.3 Å than the other three. This bond-length difference further increases the ground-state splitting of **2** and reduces the χT value; thus, the large difference between compounds **1** and **2** is rationalized. The bimetallic compound **4** has a χT value of 1.75 emu K mol^{-1} per nickel(II) ion, corresponding to a relatively small calculated splitting of 2800 cm^{-1}. The calculated energy difference between the two lowest-energy triplet states for compound **3** is larger than 6000 cm^{-1}, and the strongest quenching of the orbital angular momentum is therefore expected for this compound, in agreement with the smallest room-temperature χT value of 1.43 emu K mol^{-1} per nickel(II) center, as observed in Fig. 4, very similar to the literature value of 1.39 emu K mol^{-1} (5). The AOM analysis of the absorption spectra allows us to qualitatively understand the magnetic properties at high temperature and indicates that the parameter values obtained with a minimum number of adjustable quantities are reasonable.

Exchange interaction in $(AsPh_4)_4[Ni_2(NCS)_8]$ and $(Cat)_2[Ni_2(NCS)_8]$

The magnetic measurements for bimetallic compounds **3** and **4** in Fig. 4 show a ferromagnetic coupling between the nickel(II) centers. The coupling constant, J, of 4.5 cm^{-1} determined for **3** is well within the range of 2.5–6.3 cm^{-1} observed for other thiocyanato-bridged bimetallic complexes and linear chains containing nickel(II) ions, as summarized in Table 3 of ref. 7. Complementary information on exchange interactions is often obtained from temperature-dependent absorption intensities and is used to determine ground-state exchange splittings (24, 25). Figure 7 shows a detailed view of the spin-forbidden band of $(AsPh_4)_4$-

Fig. 7. Temperature dependence of the spin-forbidden, ligand-field transition of $(AsPh_4)_4[Ni_2(NCS)_8]$ **3**, labeled as band 5 on the upper solid line in Fig. 5. Traces are given for temperatures of 5, 10, 20, 30, 40, 50, 80, 110, and 150 K (top to bottom). The inset shows the integrated intensities of this band as a function of temperature. The solid line was obtained with the parameters determined from the fit to the magnetic measurements shown as solid circles in Fig. 4.
$[Ni_2(NCS)_8]$ **3**, labeled 5 in Fig. 5. This weak band has been assigned as a spin-forbidden transition from the AOM analysis in Table 4. Its intensity shows a strong decrease with increasing temperature from 5 to 150 K. In this temperature range, the thermal population of the ground-state levels, split by both the exchange interactions and coordination geometry of each nickel(II) center, changes significantly. The ferromagnetic coupling determined from the magnetic measurements indicates that the lowest energy state of the bimetallic complex has a total spin $S_{total} = 2$, with the $S_{total} = 1$ and $S_{total} = 0$ levels higher in energy. The final state of the transition in Fig. 7 has $S_{total}^* = 1$. The observation of an absorption band with decreasing intensity at higher temperature indicates that the single-ion intensity mechanism (26, 27) dominates the observed band, as its spin selection rule is $\Delta S_{total} = 0 \pm 1$, and a transition from the lowest-energy level is possible. In contrast, the pair mechanism (28, 29) has a strict $\Delta S_{total} = 0$ selection rule, and an intensity increase with temperature, corresponding to the thermal population of the $S_{total} = 1$ ground-state level, would be expected. This mechanism can therefore be excluded for compound **3**. We apply the model derived to fit the magnetic data in Fig. 4 (middle trace, solid line) and calculate the Boltzmann population of the lowest energy level over the temperature range for which absorption spectra are shown in Fig. 7. These populations are then scaled and compared with the temperature-dependent experimental absorption intensities, whose estimated error is on the order of 10% from uncertainties of the

baseline. The inset to Fig. 7 illustrates the good agreement obtained by adjusting only a scaling factor, confirming the validity of our analysis of the magnetic data and showing that the distinct character of absorption transitions can reveal information on exchange coupling, in this case on the magnitude of the ground-state exchange coupling in compound **3**. The band in Fig. 7 is larger by several orders of magnitude than the ground-state splitting caused by the exchange interaction. It is therefore not possible to resolve transitions arising from each ground-state level or to determine exchange splittings in the excited state, as has been reported for other bimetallic complexes with weak exchange coupling (25, 30). The intensity variation of this absorption band supports the assignment of the increase in χT to an intramolecular ferromagnetic coupling, as d–d band intensities are not expected to depend strongly on intermolecular exchange effects. No corresponding temperature effect is observed for the bimetallic compound **4**, possibly because of the higher energy of the corresponding singlet band, which is in closer proximity to the intense transitions at higher energy and therefore more likely to borrow intensity from these allowed transitions. This intensity borrowing can easily mask an intensity change, as illustrated in Fig. 7. Complexes **1**, **2**, and **5** have only a single metal center and do not show any intensity changes comparable to Fig. 7, again indicating that this temperature-dependent absorption band does involve exchange coupling between nickel(II) ions bridged by thiocyanato ligands.

The structural, magnetic, and spectroscopic study of the title compounds shows the influence of coordination geometries on electronic states and energies of absorption maxima in the near-infrared and visible spectral regions. The exact experimental structures have to be used for a quantitative understanding of the spectra and the magnitude of χT at room temperature. Magnetic measurements reveal a ferromagnetic coupling in the bimetallic compounds, confirmed by temperature-dependent absorption spectra.

Ferrocenyl-penta-(β-naphthyl)benzene — Synthesis, structure, and dynamic behaviour[1]

Laura E. Harrington, James F. Britten, and Michael J. McGlinchey

Abstract: 3-Ferrocenyl-2,4,5-tri-(β-naphthyl)cyclopentadienone undergoes a Diels–Alder reaction with di-(β-naphthyl)acetylene to yield, after elimination of carbon monoxide, ferrocenyl-penta-(β-naphthyl)benzene (**4**). [1]H and ^{13}C variable-temperature NMR studies on **4** reveal the existence of multiple diastereoisomers at low temperature. These data are interpreted in terms of slowed rotation of the naphthyl groups, and are supported by the X-ray crystal structure of **4**, which exhibits disorder at three of the naphthyl sites.

Key words: sterically crowded molecules, hindered rotations, crystallography, NMR.

Résumé : La 3-ferrocényl-2,4,5-tri-(β-naphthyl)cyclopentadiénone donne une réaction de Diels–Alder avec le di-(β-naphtyl)acétylène pour donner, après élimination de monoxyde de carbone, au ferrocényl-penta-(β-naphthyl)benzène (**4**). Des études RMN du ^{1}H et du ^{13}C du composé **4** à températures variables démontrent l'existence de nombreux diastéréoisomères à basse température. On interprète ces données en fonction d'un ralentissement de la rotation des groupes naphtyles et ces conclusions sont appuyées par les études de diffraction des rayons X du composé **4** qui montrent l'existence d'un désordre à trois des sites naphtyles.

Mots clés : molécules stériquement encombrées, empêchement à la rotation, cristallographie, RMN.

Introduction

The pioneering work of Gust and Mislow (1) on sterically hindered organic molecules, especially hexa-substituted arenes, prompted a number of subsequent studies on molecular paddle-wheels and propellers (2). Recognition of the novelty and utility of a system that could exhibit correlated rotation of crowded substituents about a central ring (3) stimulated a variety of investigations directed towards their potential application as molecular machines (4).

On the NMR time-scale, the pendant groups in hexaarylbenzenes are perpendicular to the central ring, and substitution is required to invoke observable barriers to rotation. Ortho-substituted derivatives exhibit significantly higher barriers to peripheral ring rotation (~33 kcal mol^{-1}), than do their meta-substituted analogues. In the latter cases, the barriers (~17 kcal mol^{-1}) are more reflective of the buttressing effects of the ortho-hydrogens (5). These $\Delta G^{\neq}$ values have been ascribed to diastereomeric interconversions via the independent rotation of one ring at a time through approximately π radians (5, 6). Ultimately, these successive rotations provide the most favourable pathway for inversion of the propeller helicity; enantiomerization requires the rotation of *all* substituted peripheral rings, and the synchronous, correlated rotation of six rings is entropically and energetically disfavored.

The necessity for increased steric bulk and the presence of a probe to detect restricted rotation has led to the development of organometallic derivatives of hexaarylbenzenes ((C_nAr_n)ML_x) where n = 5, 6, or 7; progress in this area has recently been reviewed (2). Whereas Gust elegantly labeled the peripheral substituents by "painting the edges different colours" (5), our focus has been to "paint the faces" of the rings differently (7).

Towards this goal, we have reported the synthesis and fluxional behaviour of hexaphenylbenzene chromium tricarbonyl (**1**), in which the metal moiety is bonded to one of the peripheral phenyl rings (8). As depicted in Scheme 1, under conditions of rapid rotation of all six peripheral rings, the molecule exhibits time-averaged C_{2v} symmetry, which is lowered to C_s when rotation of the chromium-complexed ring is slowed on the NMR time-scale at –100 °C. Unfortunately, X-ray crystallographic data are not available for **1**, but it is a reasonable assumption that the peripheral phenyls are not all arranged perpendicular to the central ring. The NMR-derived barrier towards rotation of the chromium-complexed ring was 12.2 ± 0.2 kcal mol^{-1}. Although this work represented an advance in the development of

Scheme 1. Fluxional behaviour of $(C_6Ph_6)Cr(CO)_3$.

1
sterically encumbered organometallic derivatives based on molecular propellers, the barrier observed was lower than those observed for Gust's *ortho-* or *meta*-substituted hexaarylbenzenes. This could be interpreted either as lowering the barrier towards peripheral ring rotation, or a consequence of raising the energy of the ground state. Clearly, an increase in the steric bulk of the metal moiety, or an enhancement of its interaction with neighbouring substituents must be achieved.

This concept was further developed by the replacement of a peripheral phenyl ring by a ferrocenyl group, and led to intriguing results, including the possibility of correlated rotation (9). In the solid state, C_6Ph_5Fc (**2**) does not adopt a propeller conformation, but rather exhibits an incremental progression of dihedral angles (51° to 120°) as discussed in more detail below. It is tempting to invoke a "domino effect" (10) such that rotation of the ferrocenyl group would proceed with correlated rotation of the phenyl rings. However, since variable-temperature ^1H and ^{13}C NMR studies on **2** gave no indication of restricted ferrocenyl or phenyl ring rotation on the NMR time-scale, no definitive conclusions could be drawn (9).

With the aim of augmenting the interactions between the organometallic fragment and the peripheral aryl groups, our attention turned toward naphthyl derivatives, which act as phenyl groups with a labelled edge and a greater "wingspan". We have recently reported the syntheses, structures, and dynamic behaviour of several naphthyl-substituted (cyclopentadienone)rhodium acetylacetonate complexes (**3a**, **3b**) for which restricted rotation of the naphthyl groups was clearly detectable via splitting of the ^{31}P NMR signals of the

triphenylphosphine substituent. The barriers to naphthyl rotation were evaluated as 8.2 ± 0.5 kcal mol^{-1} (11).

Although a number of purely organic naphthyl-substituted benzenes have been described (12), and several naphthyl rotation barriers have been determined (13), we are unaware of any analogous organometallic derivatives apart from Rausch's naphthyl-cyclobutadiene cobalt systems (14). With the goal of investigating the dynamic behaviour of an arene possesing both ferrocenyl and naphthyl substituents, we now report the synthesis, structure, and variable-temperature NMR spectra of ferrocenyl-penta-(β-naphthyl)benzene (**4**).

Results and discussion

Synthesis

The synthesis of **4** was achieved by a method similar to that previously reported (9) for C_6Ph_5Fc (**2**) and is summarized in Scheme 2. The sodium-cyanide-catalyzed reaction of ferrocene carboxaldehyde with β-naphthaldehyde, followed by manganese dioxide oxidation yielded the diketone **5**. Base-catalyzed aldol condensation of **5** with 1,3-di-(β-naphthyl)propanone (**6**) furnished 3-ferrocenyl-2,4,5-tri-(β-naphthyl)cyclopentadienone (**7**), which underwent a Diels–Alder addition with di-(β-naphthyl)acetylene (**8**) at 180 °C and, after loss of carbon monoxide, afforded the desired product (**4**).

NMR spectroscopic results

As indicated above, the 500 MHz ^1H and 125 MHz ^{13}C NMR spectra of ferrocenylpentaphenylbenzene (**2**) remained essentially unchanged to temperatures as low as 188 K, thus, offering no evidence for the restricted rotation of the ferrocenyl group or peripheral phenyl substituents. In contrast, although at room temperature the 500 MHz ^1H NMR spectrum of the naphthyl analogue (**4**) exhibits the expected well-resolved aromatic signals attributable to the naphthyl and ferrocenyl protons, as the temperature is decreased, there is marked broadening of all of the signals in the ferrocenyl region. Moreover, the singlet at 3.73 ppm, assigned to the α-CH protons in the C_5H_4 ring, splits into at least three peaks (3.58, 3.66, and 3.69 ppm at 203 K; Fig. 1*a*). These findings are mirrored in the 125 MHz ^{13}C NMR spectra, in which the corresponding peak for the ferrocenyl α-carbon gradually splits into three peaks as the temperature is reduced (72.5, 73.1, and 73.3 ppm at 203 K; Fig. 1*b*). The peaks for the other ferrocenyl carbon and hydrogen atoms appear to broaden, but do not cleanly decoalesce at low temperature. There is similar broadening and decoalescence behaviour in the aromatic region, but severe overlap of the naphthyl signals in both the proton and

carbon regimes at low temperature renders these peak assignments ambiguous, even at 11.74 T.

If the ferrocenyl and naphthyl ring rotations have slowed on the NMR time-scale, and the molecule has adopted a single favoured conformation, one would expect to see four equal intensity ^{1}H and ^{13}C NMR resonances attributable to the C_5H_4 moiety. However, since decoalescence gives rise to three signals of unequal intensity for the ferrocenyl α-carbon, it is unlikely that restricted ferrocenyl rotation is the single explanation for the observed behaviour. An alternative rationale is that restricted rotation of the naphthyl groups gives rise to a number of diastereomers and, as a result, each ferrocenyl environment gives rise to distinct peaks, the intensities of which correspond to the relative stability of each of the rotamers.

Another possibility, but one that would require extensive labelling of the naphthyls (such as by incorporation of ^{19}F nuclei as independent probes) to verify, is that of residual stereoisomerism, a phenomenon originally recognized in maximally labelled Ar$_3$Z and Ar$_3$ZX moieties (1*b*, 3*b*). In those cases, correlated ring rotation gave rise to closed subsets of interconverting isomers separated by substantial barriers. Thus, the interdependent motion of all three rings imposes a constraint on the relationship between torsional angles, and so blocks a number of interconversion pathways among the full set of conformers. If such a phenomenon were to be viable for **4**, it would imply that, on a given time-scale, ferrocenyl rotation is correlated with naphthyl rotation, but that individual naphthyl rings could not undergo independent rotation through π radians.

Such speculation assumes that the naphthyl rings in **4** can adopt a variety of up and (or) down combinations, thus, generating several diastereomers that interconvert slowly on the NMR time-scale at low temperatures. To test this hypothesis, an X-ray crystallographic study on ferrocenyl-penta-(β-naphthyl)benzene (**4**) was initiated.

X-ray crystallographic results

Numerous attempts to grow single crystals of **4** suitable for an X-ray crystallographic study were thwarted, either by the slow decomposition of the sample, or rapid conversion to powder. Finally, slow evaporation of a CH_2Cl_2 solution furnished crystals that were uniformly small and thin, and by no means ideal candidates for a crystallographic investigation. Nevertheless, it was possible to acquire a data set from which one could establish the atom connectivity and unequivocally characterize the molecule. Although the structure could, eventually, be refined to an *R* value of 18%, we clearly cannot claim high accuracy for the bond lengths and angles.

Figure 2 displays the structure of **4**, and the unit cell parameters are summarized in Table 1. The molecule exhibits several interesting features, notably the up and (or) down orientations of the naphthyl substituents. The possibility of two orientations for each naphthyl group often leads to disorder in crystal structures (cf. ref. 11), and in this instance, three of the naphthyl groups exhibit a disorder in which both orientations are represented. In particular, this phenomenon is seen for the naphthyl substituents at central ring carbons C(2) and C(6) (i.e., those adjacent to the ferrocenyl

Fig. 1. Variable-temperature NMR spectra of **4**, showing the decoalescence behaviour of (*a*) the ferrocenyl ^{1}H environments at 500 MHz, and (*b*) the corresponding ^{13}C resonances at 125 MHz.

(*a*)

(*b*)

substituent), as well as for the naphthyl ring bonded to C(3). It is tempting to draw a parallel between the solid state structure, in which these diastereomers are clearly similar in energy, and the solution state dynamic behaviour, in which several naphthyl groups apparently exhibit restricted rotation, and give rise to more than one conformer.

It is also informative to examine the dihedral angles of the peripheral substituents with respect to the central ring. As noted previously, in the crystal structure of **2** (see Fig. 3*a*) there is an incremental progression of angles from 51° to 120°, thus suggesting a "domino effect" that may offer insight into the mechanism for propeller interconversion (9, 10). This may be contrasted with the propeller conformation of the phenyl groups in hexaphenylbenzene, which all adopt interplanar angles of 75° with respect to the central ring (15). In **4** (see Fig. 3*b*), there is a progression of angles similar to that expressed by **2** (esd ~1°): 134° for the ferrocenyl substituent, followed by 106°, 81°, 62°, 65°, and 73° for the naphthyls bonded to central ring carbons C(6) through C(2). The interesting contrast to **2** is that the naphthyl groups bonded to carbons C(2) through C(4) show a decrease in dihedral angle rather than an increase; thus, the angles do not display a clear incremental progression leading to propeller interconversion. This phenomenon is not limited to the groups adjacent to the bulky ferrocenyl group; there is evidently significant interaction among the naphthyl substituents themselves, leading to the expression of more dramatic dihedral angles than in the phenyl analogue. The interplanar angles displayed are not influenced by the disorder in the up and (or) down orientation of the naphthyl groups since these conformations are coplanar.

Although the X-ray crystal structure data are not of sufficient quality to permit the evaluation of bond lengths and angles with very high precision, they do allow a realistic assessment of the relative orientations of the peripheral substituents. In particular, one can draw viable comparisons

with the dihedral angles formed by the peripheral substituents relative to the central ring in ferrocenyl-pentaphenylbenzene (**2**) ferrocenyl-penta-(β-naphthyl)benzene (**4**), and hexaphenylbenzene.

Conclusions

The juxtaposition of ferrocenyl and five β-naphthyl substituents within a benzene ring results in the generation of at least three diastereomers arising from different up and (or) down combinations of naphthyl rings. In the solid state, this is reflected in disorder at three peripheral ring sites; correspondingly, variable-temperature ^{1}H and ^{13}C NMR spectra in solution indicate the presence of multiple rotamers. These observations may be compared with the analogous data for ferrocenylpentaphenylbenzene (**2**), which adopts a similar "non-propeller type" structure in the solid state, but which does not exhibit restricted rotation of the peripheral rings. This manifestation of the enhanced steric requirements of naphthyl substituents suggest that it may be possible to construct a six-bladed molecular propeller exhibiting correlated motion. Future reports will describe the use of other substituents, such as anthracenyl or fluorenyl, which have even larger wingspans.

Experimental section

All reactions were carried out under an atmosphere of dry nitrogen employing conventional benchtop and glovebag techniques. Silica gel (particle size 20–45 µm) was employed for flash column chromatography. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker DRX 500 spectrometer operating at 500.13 MHz and 125.76 MHz, respectively, and were referenced to the residual proton or ^{13}C signal of the solvent. Assignments were based on standard ^{1}H-^{1}H and ^{1}H-^{13}C two-dimensional techniques. Mass spectra were determined using a Finnigan 4500 spectrometer by direct electron impact (DEI) or direct chemical ionization (DCI) with NH$_3$ or on a Micromass GCT TOF instrument, as well as electrospray (ESI). Infrared spectra were recorded on a Bio-Rad FTS-40 spectrometer. Melting points (uncorrected) were determined on a Fisher-Johns melting point apparatus.

Ferrocene carboxaldehyde, β-naphthaldehyde, and benzophenone were obtained from Aldrich Chemical Co. and used as received. Di-(β-naphthylmethyl)ketone (**6**) was synthesized by using the phase-transfer method outlined in ref. (16). Di-β-naphthylacetylene (**8**) was synthesized following the methodology described in ref. (17); however, the oxidation was performed using silver oxide rather than mercuric oxide, as in ref. (18).

Preparation of 2-ferrocenyl-2-hydroxy-1-naphthylethanone

Ferrocene carboxaldehyde (7.135 g, 0.03 mol), β-naphthaldehyde (5.83 g, 0.04 mol), and NaCN (1.16 g, 0.02 mol) were dissolved in 20 mL H$_2$O and 40 mL ethanol, then refluxed for 1 h. The solution was cooled, resulting in the formation of a red precipitate, which was collected by suction filtration to give the desired product (9.05 g, 0.02 mol, 73%), mp 142–145 °C (dec). Preparation of 2,4,5-trinaphthyl-3-ferrocenylcyclopentadienone (7)

1-Ferrocenyl-2-naphthylethanedione (**5**, 0.77 g, 2.1 mmol) and KOH (0.2 g, 3.6 mmol) were dissolved in 50 mL etha-

nol and heated to reflux. A solution of di-(β-naphthyl-methyl)ketone (**6**, 0.68 g, 2.2 mmol) was dissolved in 50 mL ethanol and added dropwise, the mixture was then stirred under reflux for 2 h. The solution was cooled to room temperature, then in ice, and filtered with suction to give **7** as a dark blue powder (0.69 g, 1.1 mmol, 49%), mp 247–250 °C (dec). The powder was purified by column chromatography under nitrogen (50:50, CH_2Cl_2:hexanes) before further use. The sample is indefinitely stable as a solid, however, it decomposes in a wide variety of solvents over time. ^{1}H NMR (500 MHz, CD_2Cl_2) δ: 7.94 (9H, m, naphthyl-H), 7.61 (9H, m, naphthyl-H), 7.39 (2H, m, naphthyl-H), 7.18 (1H, m, naphthyl-H), 4.25 (2H, s, ferrocenyl-$H_{2,5}$), 4.05 (5H, s, ferrocenyl-C_5H_5), 3.98 (2H, s, ferrocenyl-$H_{3,4}$). ^{13}C NMR (125 MHz, CD_2Cl_2) δ: 200.27 (CO), 157.6, 154.0 (cyclopentadienone-C), 134.2, 134.0, 133.8, 133.7, 133.6, 133.4, 133.0, 132.2 (naphthyl-Cs), 130.5, 129.9 (naphthyl-CHs), 129.3 (naphthyl-C), 128.9, 128.8, 128.7, 128.6, 128.5, 128.3, 128.0, 127.8, 127.6, 127.3, 126.8, 126.5 (naphthyl-CHs), 123.8 (cyclopentadienone-C), 77.7 (ferrocenyl-*ipso*-C), 72.1 (ferrocenyl-$C_{2,5}$), 72.0 (ferrocenyl-$C_{3,4}$), 71.0 (C_5H_5). IR (KBr) (cm^{-1}): 1689 (CO). HR-MS (EI) calcd. for $C_{45}H_{30}OFe$: 642.1646; found: 642.1635.

Preparation of ferrocenyl-penta-(β-naphthyl)benzene (4)

Benzophenone (5 g) was melted by heating to 120 °C in a 100 mL round bottom flask. The temperature of the oil bath was increased to 150 °C, then di(β-naphthyl)acetylene (**8**, 0.42 g, 1.50 mmol) and 2,4,5-tri(β-naphthyl)-3-ferrocenyl-cyclopentadienone (**7**, 0.96 g, 1.49 mmol) were added. The mixture was stirred and heated at 180–190 °C for 52 h with a reflux condenser (to prevent loss of benzophenone). The flask was cooled almost to room temperature and benzene

(5 mL) was added to prevent solidification of the benzophenone. The resulting mixture was purified by column chromatography under nitrogen (75:25, CH_2Cl_2:hexanes) to give **4** as a yellow-orange powder (0.30 g, 0.33 mmol, 22%), mp 260 °C (dec). ^1H NMR (500 MHz, CD_2Cl_2) δ: 7.81–7.00 (35H, m, naphthyl-H), 3.75 (2H, s, ferrocenyl-$H_{2,5}$), 3.69 (2H, s, ferrocenyl-$H_{3,4}$), 3.59 (5H, s, C_5H_5). ^{13}C NMR (125 MHz, CD_2Cl_2) δ: 142.6–125.7 (naphthyl-CH, C, cyclopentadienone-C), 87.5 (C_5H_4-C), 73.6 (ferrocenyl-$C_{2,5}$), 69.6 (C_5H_5), 67.5 (ferrocenyl-$C_{3,4}$). MS (ESI): 892.4 (M^+, 100). HR-MS (EI) calcd. for $C_{66}H_{44}Fe$: 892.2792; found: 892.2721.

Crystallographic data for 4

X-ray crystallographic data for **4** were collected on a P4 Bruker diffractometer equipped with a Bruker SMART 1K CCD area detector (employing the program SMART) (19) and a rotating anode utilizing graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). Data processing was carried out by use of the program SAINT (20), while the program SADABS (21) was utilized for the scaling of diffraction data, the application of a decay correction and an empirical absorption correction based on redundant reflections. Structures were solved by using the direct-methods procedure in the Bruker SHELXTL (22) program library and refined by full-matrix least-squares methods on F^2. As a result of the size of the crystal and the absence of diffraction data beyond 1.2 Å, we were unable to refine anisotropically on the carbon atoms. Hydrogen atoms were added as fixed contributors at calculated positions, with isotropic thermal parameters based on the carbon atom to which they are bonded. Three disordered naphthyl groups were located in the course of the refinement process for **4**, which complicated the analysis; rigid naphthyl groups were imposed.

X-ray diffraction and solid-state ^{119}Sn CP-MAS NMR studies of some triaryltin(IV) chlorides[1]

Jordan M. Geller, Ian S. Butler, Denis F.R. Gilson, Frederick G. Morin, Ivor Wharf, and F. Bélanger-Gariépy

Abstract: The solid-state ^{119}Sn cross-polarization (CP) magic angle spinning (MAS) NMR spectra of a series of triaryltin chlorides of the form Ar$_3$SnCl have been acquired. The indirect spin-spin coupling constants ($J(^{119}$Sn-^{35}Cl)), quadrupolar-dipolar shifts ($d(^{119}$Sn-^{35}Cl)), and the ^{119}Sn chemical shift tensors were extracted. For the spectrum of triphenyltin chloride (**I**) the validity of the first-order perturbation approximation was tested by comparing results of both the perturbation and cubic-equation approaches and a variable-temperature NMR study undertaken to investigate the influence of the previously reported molecular motion in the solid. The X-ray crystal structures of the tris(*o*-tolyl)tin chloride (**II**) and tris(*p*-tolyl)tin chloride (**IV**) complexes have been examined. They belong to the monoclinic and triclinic space groups $P2_1/n$ and $P\bar{1}$, respectively, which are different from the previously reported tris(*m*-tolyl)tin chloride (**III**) complex, which crystallizes in the space group $R3$ and has threefold molecular symmetry. The structures and NMR properties of the complexes with meta-substituents are quite different from those with ortho- or para-substituents having axially symmetric shift tensors with small spans and larger J values.

Key words: aryltin chlorides, magic angle spinning NMR, tin-chlorine spin-spin coupling, ^{119}Sn chemical shift tensor, crystal structure.

Résumé : On a déterminé les spectres RMN du ^{119}Sn, à l'état solide et à la polarisation croisée (« CP ») de l'angle magique de rotation (« MAS ») d'une série de chlorures de triarylétain de la forme Ar$_3$SnCl. On en a extrait les constantes de couplage spin-spin indirectes, $J(^{119}$Sn-^{35}Cl), les déplacements quadripolaire-dipolaire, $d(^{119}$Sn-^{35}Cl), et les tenseurs du déplacement chimique du ^{119}Sn. Pour le spectre du chlorure de triphénylétain (**I**), on a testé la validité de l'approximation de la perturbation du premier ordre en comparant les résultats des approches de perturbation et d'équation cubique avec les résultats d'une étude RMN à température variable réalisée dans le but d'étudier l'influence du mouvement moléculaire rapportée antérieurement dans le solide. On a déterminé les structures par diffraction des rayons X des chlorures de tris(*o*-tolyl)étain (**II**) et de tris(*p*-tolyl)étain (**IV**). Elles appartiennent respectivement aux groupes d'espace monoclinique ($P2_1/n$) et triclinique ($P\bar{1}$) qui diffèrent de celle rapportée antérieurement pour le complexe du chlorure de tris(*m*-tolyl)étain (**III**) qui cristallise dans le groupe d'espace $R3$ et qui présente une symétrie moléculaire ternaire. Les structures et les propriétés RMN des complexes portant un substituant en méta- sont très différentes de celles des produits portant des substituants en positions ortho- et para- qui possèdent des tenseurs de déplacement axialement symétriques de faible portée et des valeurs de J plus élevées.

Mots clés : chlorures d'arylétain, RMN à l'angle magique de rotation, couplage spin-spin étain-chlore, tenseur de déplacement chimique du ^{119}Sn, structure cristalline.

[Traduit par la Rédaction]

Introduction

Triaryltin compounds have been studied for many years since the discovery of the biocidal properties of triphenyltin hydroxide and acetate and their subsequent use as agricultural fungicides (1). As part of an investigation of the effect of phenyl ring substituents on the biological and other properties of triaryltin compounds, a wide range of *o*-, *m*-, and *p*-substituted triaryltin hydroxides and acetates was synthesized and tested for bioactivity (2, 3). This required the preparation of the corresponding tetraaryltins and triaryltin halides and the effect of varying the substituients on the aro-

---

matic ring on their vibrational (Raman, IR) spectra (4, 5) has been reported. In addition, ^{119m}Sn Mössbauer spectroscopic studies of various para-substituted aryltin complexes have also appeared (6, 7). More pertinent to this paper are two solution-state ^{119}Sn and ^{13}C NMR studies (8, 9) of various para-, meta- and ortho-substituted tetraaryltins (Ar$_4$Sn) and triaryltin halides (Ar$_3$SnX; X = Cl, Br, I). For both the *p*- and *m*-substituted Ar$_4$Sn and Ar$_3$SnX series, the ^{119}Sn chemical shifts could be correlated with various substituent parameters (σ_I, σ_R, σ_R^0, σ_P, σ_P^0) showing electronic effects due to the ring substituents are sufficient to account for the observed $\delta(^{119}$Sn) trends. We now report solid-state ^{119}Sn studies of a wide range of triaryltin chlorides for comparison with the earlier solution studies.

Solid-state NMR spectra often provide information that is unavailable from solution spectra. Thus, when a probe nucleus such as a ^{119}Sn ($I = 1/2$) nucleus is bonded to a quadrupolar nucleus, line splittings occur in the solid-state NMR spectra, which can be analyzed to give information about the electronic environment and bonding about the tin nucleus. A review of the effects of quadrupolar nuclei on the CP-MAS spinning spectra of spin 1/2 nuclei has been published, which includes the tin-chlorine case (10), and the ^{31}P–$^{35/37}$Cl case has also been reported (11). The spectra are complicated by the presence of two isotopes: ^{35}Cl (75% abundant) and ^{37}Cl (25% abundant). Both nuclei ($I = 3/2$) have similar magnetogyric ratios ($\gamma(^{35}$Cl) = 2.264 × 10^7 rad s^{-1} T^{-1}, $\gamma(^{37}$Cl) = 2.184 × 10^7 rad s^{-1} T^{-1} (12)) and nuclear quadrupole moments ($Q(^{35}$Cl) = –8.165 × 10^{-30} m^2 and $Q(^{37}$Cl) = –6.435 × 10^{-30} m^2 (13)).

Olivieri (14) developed a treatment of the splittings ($\Delta\nu_m$) in the MAS spectrum of a probe nucleus ($I = 1/2$) directly bonded to a quadrupolar nucleus based on first-order perturbation theory, which is valid in the limit $\chi/[4S(2S-1)\nu_s] \ll 1$, where ν_s is the Larmor frequency of the quadrupolar nucleus and χ is the nuclear quadrupolar coupling constant. Thus, with ^{35}Cl and ^{37}Cl, provided that $\chi/12\nu_s \ll 1$, the splittings observed in the solid-state spectra under magic angle spinning are given by eq. [1]:

[1] $\Delta\nu_m = -m_s J_{IS} + (3\chi D'/20\nu_s)(3\cos^2\beta^D - 1 +$
$$\eta \sin^2\beta^D \cos 2\alpha^D)[\{S(S+1)$$
$$- 3m_s^2\}/\{S(2S-1)\}]$$

where J_{IS} is the spin-spin coupling constant, $D' = (D - \Delta\mathbf{J}/3)$, where D is the direct dipolar coupling constant ($D = (\mu_o/4\pi)\gamma_s\gamma_I h^2/(4\pi^2(r_{IS})^3)$, and $\Delta\mathbf{J}$ is the anisotropy in the spin-spin coupling, while α^D and β^D are, respectively, the azimuthal and polar angles relating the internuclear vector to the principal axis of the electric field gradient (EFG), and η is the asymmetry in the field gradient. Equation [1] assumes that the $\mathbf{J}$ tensor is colinear with the internuclear dipole vector. The second-order quadrupolar–dipolar splitting (d) is given by $3\chi D'/20\nu_s$. In most Ar$_3$SnCl compounds in the solid state, the local symmetry about the Sn—Cl bond is approximately C_3 (in some cases exactly so). Thus, it can be assumed that the angle β^D is 0° and with the value of α^D undefined because it is multiplied by $\sin^2\beta^D$, eq. [1] is reduced to a simpler form

[2] $\Delta\nu_m = -m_s J_{IS} + (3\chi D'/10\nu_s)[5/4 - m_s^2]$

with d now given by $3\chi D'/10\nu_s$.

The ^{119}Sn-MAS NMR spectrum of triphenyltin chloride was first reported in 1987 (15) followed soon after by the application of the perturbation theory to describe the multiplet from the (^{119}Sn-$^{35/37}$Cl) spin pair, but only an average value of $|J_{iso}|$ over the two sites was extracted from the spectra (16, 17). Values of the d and ΔJ were reported (14, 18) but these values were based on an average d for the two crystallographically nonequivalent tin sites (19), while a more detailed analysis in terms of the two chlorine isotopes was not attempted. NQR data have been reported for triphenyltin chloride at 77 K (20) and at 303 K (21).

In the present study, the solid-state NMR spectrum of triphenyltin chloride (**I**) has been fully re-examined with extraction of J, d, and δ_{iso} for both tin sites as well as consideration of both (^{119}Sn-^{35}Cl) and (^{119}Sn-^{37}Cl) spin pairs. The validity of the first-order perturbation approximation was tested by comparing results of both the perturbation- (10, 14) and cubic-equation approaches (22), and a variable-temperature NMR study undertaken to investigate the influence of the previously reported molecular motion in the solid (23).

For comparison with (**I**) we also present the ^{119}Sn CP-MAS spectra of a series of triaryltin chloride complexes with various substituents in the ortho-, meta-, and para-positions (**II – IX**); see Table 4 for the numbering scheme. To correlate the NMR parameters (J, d, D') and chemical shift tensor components (δ_{11}, δ_{22}, δ_{33}) with molecular geometries, full-crystal structures are needed. Although the structures of most of the Ar$_3$SnCl complexes studied here have been reported earlier (9, 24–26), in this paper we now add the structures of (*o*-tolyl)$_3$SnCl (**II**) and (*p*-tolyl)$_3$SnCl (**IV**). The solid-state NMR spectra of some triaryltin fluorides have been reported (27) but these complexes differ from the chlorides since, with the exception of tris(mesityl)tin fluoride, they are five-coordinate and form polymeric chains in the solid. The chlorides are all distorted tetrahedral molecules with the shortest nonbonded distance between tin and chlorine occurring in the tris(*m*-anisyl)tin chloride at 4.37 Å (24), much longer than the sum of the van der Waals radii (3.93 Å) (28).

Experimental

The triaryltin chlorides were either from previous preparations or synthesized by literature methods (8, 9). Solid-state ^{119}Sn NMR spectra were recorded at 111.7 MHz using a Chemagnetics CMX-300 (7.05 T) spectrometer under conditions of ^{119}Sn-^{1}H cross-polarization, high-power proton decoupling, and magic-angle spinning. The CP-MAS spectra were obtained for approximately 250–300 mg of sample packed into zirconia pencil-type rotors (7.5 mm diameter), using pulse delays of 10–60 s, depending on the proton T_1 value, and contact times of 2 or 3 ms. The number of transients ranged from 240–1992 depending upon the compound in question. Line broadening of 0–10 Hz was applied and the FIDs were zero filled to 8 K and 16 K points before transformation. Different spinning rates, from 1600–4000 Hz, were used to identify the centre band. Chemical shifts are given with respect to external tetramethyltin ((CH$_3$)$_4$Sn) using the chemical shift of solid tetracyclohexyl-

tin (–97.0 ppm) as an external secondary reference. The line positions of the centre band and spinning sidebands were extracted using the program Peakfit (Jandel Scientific). Calculations of the shielding tensors were performed using the method developed by Herzfeld and Berger (29) and the computational program HBA version 1.4 (30).

X-ray crystallography

Both (**II**) and (**IV**) were recrystallized by dissolving in ethanol, hot filtering through Celite, followed by slow evaporation over several days at room temperature. Crystal data and structural refinement details are given in Table 1. For both compounds (**II**) and (**IV**), data were processed by XPREP (31) and the structures were solved by direct methods using SHELXS-97 (33) and refined using SHELXL-96 (34). Non-hydrogen atoms were refined with anisotropic thermal parameters with H-atoms in calculated positions. Scattering factors were from the usual source (35). Compound (**IV**) was run with Mo Kα radiation since the crystals were large and could not easily be cut.[4]

[4] Data for (**II**) and (**IV**) may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 188728 and 188729 contain the crystallographic data for (**II**) and (**IV**). These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Results and discussion

X-ray crystallography

Tris(*o*-tolyl)tin chloride (**II**) and tris(*p*-tolyl)tin chloride (**IV**) crystallize in monoclinic ($P2_1/n$) and triclinic ($P\bar{1}$) space groups, respectively. In both cases there is only one molecule in the asymmetric unit and the geometry about tin is distorted tetrahedral. ORTEP diagrams of (**II**) and (**IV**) are shown in Figs. 1 and 2, respectively, and selected bond lengths and angles are given in Table 2. In (**II**), the geometry around tin closely resembles that found earlier for (*o*-tolyl)$_3$SnNCS (36) with two ortho-methyl groups (C-17 and C-27) cis- to chlorine while the third (C-37) is trans, with the phenyl ring close to coplanar with the Cl-Sn-C(31) plane at a dihedral angle Cl-Sn-C(31)-C(36) of 19.9(3)°. For (*o*-tolyl)$_3$SnNCS, with two molecules in the asymmetric unit, the corresponding angles are 10.1(3)° and 17.6(3)°. Compound (**IV**) also has one phenyl ring nearly coplanar with the Cl-Sn-C(31) plane, the dihedral angle Cl-Sn-C(31)-C(32) being 17.9(2)°. Table 2 also includes data for tris(*m*-tolyl)tin chloride (**III**), which belongs to the trigonal space group *R*3, with the threefold rotation axis containing the Sn—Cl bond (9). Two other meta-substituted complexes (tris(*m*-anisyl)tin chloride (**VI**) (24) and tris(3,5-dimethylphenyl)tin chloride (**VIII**) (9)) also crystallize in trigonal space groups and possess axial molecular symmetry. In contrast, the ortho-substituted complexes tris(*o*-anisyl)tin chloride (**V**) (26) and tris(mesityl)tin chloride(**IX**) (25) are monoclinic ($P2_1/n$).

Solid-state ^{119}Sn CP MAS NMR spectra

Triphenyltin chloride

With two molecules in its asymmetric unit, the ^{119}Sn MAS centre band of (**I**) consists of two asymmetric overlapping quartets, from the (^{119}Sn-^{35}Cl) and (^{119}Sn-^{37}Cl) spin pairs, with intensities in the ratio of 3:1, for each of the tin sites, for a total of 16 lines. Alarcón et al. (22) derived cubic equations for both the spin-spin coupling and the quadrupolar-dipolar splitting for *I*-*S* spin pairs, with *S* = 3/2, which are valid when $1 < |\chi/\nu_s| < 3$. As the $|\chi/\nu_s|$ ratio becomes greater than 0.8, the observed splittings are smaller than would be predicted by first-order theory. The nuclear quadrupolar coupling constants (χ) have been reported as 33.50 and 33.97 MHz at 303 K (21). At 7.05 T the ^{35}Cl and ^{37}Cl resonance frequencies (ν_s) are 29.39 and 24.47 MHz, thus, the calculated $|\chi^{35}/\nu_s^{35}|$ ratios are 1.16 and 1.14 and $|\chi^{37}/\nu_s^{37}|$ ratios are 1.10 and 1.08 for the two tin sites, respectively. To consider the validity of using first-order perturbation theory, the NMR parameters were extracted from the line positions in the ^{119}Sn MAS spectrum of triphenyltin chloride using both the first-order and the cubic-equation approaches and are given in Table 3. The differences are small, with the largest deviations being in the spin-spin coupling constant for one of the tin sites, which is underestimated by 8 Hz or a 3% difference. From this comparison we assume that the underestimation of these couplings is small enough to justify using the first-order perturbation equation to analyze the spectra of the complexes (**II**)–(**XI**), which also requires that that their quadrupolar coupling constants are not substantially different from that of triphenyltin chloride (**I**).

Fig. 1. ORTEP diagram of tris(*o*-tolyl)tin chloride (**XI**) viewed along the tin–chlorine bond with the chlorine atom in front showing 30% thermal probability ellipsoids.
Fig. 2. ORTEP diagram of tris(*p*-tolyl)tin chloride (**VII**) viewed along the tin–chlorine bond with the chlorine atom in front showing 30% thermal probability ellipsoids.
For comparison,the experimental and simulated spectra of triphenyltin chloride are shown in Fig. 3. The simulated spectrum is the sum of 16 lines broadened by Lorentzian functions, eight from the coupling of ^{119}Sn with ^{35}Cl; the line positions given by eq. [2] with the values for $J(^{119}$Sn-^{35}Cl), $d(^{119}$Sn-^{35}Cl), and $\delta_{iso}(^{119}$Sn-^{35}Cl) given in Table 3. The other eight lines are one-third of the intensity from coupling of ^{119}Sn with ^{37}Cl and their positions were calculated assuming that the ^{119}Sn isotropic shifts are the same and by using the ratios $J(^{119}$Sn-^{35}Cl)/$J(^{119}$Sn-^{37}Cl) = $\gamma(^{35}$Cl)/$\gamma(^{37}$Cl) and $d(^{119}$Sn-^{35}Cl)/$d(^{119}$Sn-^{37}Cl) = $Q(^{35}$Cl)/$Q(^{37}$Cl). The experimental spectra represent the centre band with all side-

bands folded in, i.e., the spectrum that would be obtained at infinite spinning speed.

Chemical shifts

Chemical shift data for all Ar$_3$SnCl complexes are given in Table 4. Solid-state ^{119}Sn MAS spectra of compounds (**II**)–(**VIII**) and (**XI**) show a single centre band consistent with one molecule in the asymmetric unit as found in the crystal structures of (**II**)–(**VI**) and (**VIII**). For (**IX**) and (**X**), as with (**I**), more complex spectra are observed that correspond to two isotropic shifts and thus, two chemically inequivalent sites. The intensities of the resonances for the two sites are equal, suggesting the presence of two different molecules in the asymmetric unit, which is consistent with the crystal structures of complexes (**I**) (19) and (**IX**) (25).

All isotropic solid-state ^{119}Sn chemical shifts, except that for (**VIII**), show a shift to higher frequency when compared with the corresponding solution data but still follow the same general trend. The differences, which range from 0.4 to 17 ppm, are moderate and reflect slight changes in geometry about tin rather than a change in coordination on going from solution to the solid state (37). The differences between solid and solution shifts ($\delta_{solid} - \delta_{solution}$) are smallest for compounds containing meta-substituents, where the shifts' differences range from +2.4 to +3.5 ppm in (**III**) and (**VI**), while for (**VIII**) the difference is –2.3 ppm. Tris(mesityl)tin chloride (**XI**) also has a small ($\delta_{solid} - \delta_{solution}$) difference but for most other compounds with ortho- or para-substituents, the ($\delta_{solid} - \delta_{solution}$) differences are larger, the largest being 17 ppm for tris(*p*-anisyl)tin chloride (**VII**). The exception is (*p*-FC$_6$H$_4$)$_3$SnCl for which the chemical shifts in solution and solid states are effectively the same.

The orientations of the chemical shift tensor components can by assigned by the known molecular symmetries of these tin complexes. Thus, the meta-substituted compounds (**III**), (**VI**), (**VII**) have axially symmetric chemical shift ten-

Table 3. NMR parameters for triphenyltin chloride (**I**) by perturbation and cubic-equation methods.

Parameter	Perturbation theory (eq. [1])	Cubic equation (ref. 22)
^{35}J Site 1, site 2 (Hz)	265(2), 258(1)	273(1), 267(1)
^{35}d Site 1, site 2 (Hz)	−76(2), −68(4)	−78(4), −71(2)
$^{35}D'$ Site1, site 2 (Hz)	440(10), 400(20)	450(20), 410(10)
$\Delta\mathbf{J}$ Site1, site 2 (Hz)	−300(40), −180(70)	−330(70), −230(40)
δ_{iso} Site 1 (ppm)	−34.5	−34.4
δ_{iso} Site 2 (ppm)	−32.3	−32.4

Note: Standard deviations in the average values in parentheses. For $\Delta\mathbf{J}$, the errors were propagated from the standard deviations in D and d.

[b]From the static spectrum.

sors with the more shielded component ($\delta_{//}$ (δ_{33})) assigned to the unique direction along the threefold rotation axis containing the Sn—Cl bond, leaving $\delta_\perp$ (δ_{11}, δ_{22}) to the trigonally symmetric plane perpendicular to the Sn-Cl axis. The symmetry of the shift tensor is consistent with the axial molecular symmetry found in the solid state. Systems with ortho- or para-substituents have non-axially symmetric shift tensors, hence the assignment of δ_{33} is less clear. Tris(mesityl)tin chloride, although it has both ortho- and para-substituents, has $\delta_{11} = \delta_{22}$, suggesting a quasi-trigonal molecular symmetry, which is consistent with the crystal structure of (mesityl)$_3$SnCl (25).

The ^{119}Sn CP-MAS full NMR spectra of tris(o-anisyl)tin chloride (**V**), tris(m-anisyl)tin chloride (**VI**), and tris(p-anisyl)tin chloride (**VII**) complexes are shown in Fig. 4. Similar spectra are also observed when the substituent is a methyl group. Extensive sideband manifolds are seen for (**II**), (**IV**), (**V**), (**VII**), (**X**), and (**XI**), indicating spans ($\delta_{11}-\delta_{33}$) in the range of 129–147 ppm, consistent with these compounds not being axially symmetric. In contrast, the spectra of (**III**), (**VI**), and (**VIII**) have few sidebands due to their much smaller spans (24–38 ppm). It is noteworthy that, while there are large differences in the spans, the isotropic chemical shifts show much smaller differences, particularly for the ortho- and meta-anisyl complexes. This demonstrates

the utility of chemical shift tensor measurements in providing additional information unavailable from solution spectra. For the archetype Ph$_3$SnCl, the span of 92 ppm lies between the two ranges given above.

Spin-spin coupling (*J*) and quadrupolar-dipolar (*d*) constants

For complexes with a single chemical shift, there should be two overlapping asymmetric quartets, with intensity ratios of 3:1, arising from the ^{119}Sn-^{35}Cl and ^{119}Sn-^{37}Cl pairs, respectively. In typical spectra, between three and five line positions can be extracted, e.g., the spectrum of tris(m-tolyl)tin chloride (Fig. 5). In cases where there are two isotropic chemical shifts, these numbers are doubled. Experimental and simulated spectra for complexes (**V**), (**VI**), and (**VII**) are shown in Fig. 6; once again the experimental spectra represent the centre band with all sidebands folded in. Values of $J(^{119}$Sn-^{35}Cl) and $d(^{119}$Sn-^{35}Cl) are given in Table 5. In general, the compounds with meta-substituents, (**III**), (**VI**), and (**VIII**), have slightly larger coupling constants, which range from 263 to 279 Hz, while compounds with ortho- and para-substituents, (**V**)–(**XI**), range from 230 to 262 Hz. These values can be compared with the previously reported coupling constants for tribenzyltin chloride of 226 Hz and bis(acetylacetonato)tin chloride, of 276 Hz (17).

Fig. 4. ¹¹⁹Sn CP-MAS spectra of the isomers of trianisyltin chloride at 7.05 T and 298 K: *o*-anisyl (**V**) 2000 Hz spinning speed (top), *p*-anisyl (**VIII**) 2000 Hz spinning speed (middle), and *m*-anisyl(**III**) 4000 Hz spinning speed (bottom).

Fig. 5. ¹¹⁹Sn CP-MAS centre band spectrum of tris(*m*-tolyl)tin chloride at 7.05 T and 298 K. The spectrum contains one tin chemical shift from which there are two overlapping quartets shown in the top and second rows. The sum of the two quartets gives the calculated spectrum (3rd row), which is similar to the experimental spectrum (bottom).
Tris(mesityl)tin chloride (**IX**) exhibits the largest $^1J(^{119}\text{Sn-}^{35}\text{Cl})$ coupling constants, 332 and 328 Hz for the two sites. Assuming that the Fermi contact mechanism is the dominant contribution for tin–chlorine spin-spin coupling, then the *s*-character of the Sn—Cl bond in (**IX**) should be higher than in the other Ar_3SnCl complexes. Solution $^1J(^{119}\text{Sn-}^{13}\text{C})$ data for complexes (**I**)–(**XI**) have been reported (8, 9); these range from 603 to 644 Hz except for $(o\text{-anisyl})_3\text{SnCl}$ (**V**) with a value of 685 Hz. However, the mesityl system (**IX**) has a significantly smaller coupling of 596 Hz. A smaller $^{119}\text{Sn-}^{13}\text{C}$ coupling is consistent with less *s*-character in the Sn—C bonds and thus, more *s*-character in the Sn—Cl bond.

The quadrupolar-dipolar splittings ($d(^{119}\text{Sn-}^{35}\text{Cl})$) range from –72 to –83 Hz with no apparent trend. The significantly smaller value of –21 Hz for (**IX**) may be the result of a larger $\Delta\mathbf{J}$ value, which would reduce the effective dipolar splitting D' and hence the value of d. A larger $\Delta\mathbf{J}$ value is consistent with the larger J observed and seems reasonable, as it is unlikely that the nuclear quadrupole coupling constant for this complex is four times smaller than those of the other members of the series.

Calculation of the direct dipolar coupling constants (D) requires the exact values of $r(\text{Sn-Cl})$, which are known for all systems studied here except for (**VII**), (**X**), and (**XI**). With $D' = (D - \Delta\mathbf{J}/3)$, the determination of $\Delta\mathbf{J}$ requires that

Fig. 6. ¹¹⁹Sn CP-MAS centre band spectra of the trianisyltin chloride isomers at 7.05 T and 298 K. (*a*) *o*-Anisyl (**V**), (*b*) *m*-anisyl (**III**), (*c*) *p*-anisyl (**VIII**) lower (experimental), upper (calculated).
D' be obtained from $d = 3\chi D'/10\nu_s$. However, values of $\chi(^{35}\text{Cl})$ and $\chi(^{37}\text{Cl})$ data are available only for (**I**) and only in this case is a direct calculation of D', and then $\Delta\mathbf{J}$, possi-

ble. Harris and co-workers (38) have shown that the effective dipolar coupling constant (D') can be obtained from an analysis of the chemical shift anisotropy for each of the spin states of the quadrupolar nucleus, but this method gave results with large errors, presumably because of incorrect intensities resulting from the overlap of the (^{119}Sn- ^{35}Cl) and (^{119}Sn-^{37}Cl) lines.

The effect of temperature on the spectrum of triphenyltin chloride (I)

An earlier solid-state proton magnetic resonance second moment study on (**I**) provided evidence for motion in the solid state at about 300 K (23). This motion was considered to be a C_3 reorientation of the whole molecule along the Sn—Cl bond axis. To investigate further the effect of this motion on the spectrum of triphenyltin chloride, the solid-state ^{119}Sn CP-MAS spectra of (**I**) were obtained at three temperatures (Fig. 7). The low-temperature spectrum at 248 K was taken to investigate the rigid phase, where no change in the second moment of the proton resonance occurs; that at room temperature represents the situation where motion has just begun, while at high temperature (333 K) the second moment transition is complete. The NMR parameters are given in Table 6. The isotropic chemical shifts move to lower frequency (more shielded) with increasing temperature for both tin sites and the difference between the two tin sites decreases with increased temperature, suggesting an averaging of the two shifts at higher temperatures. After heating, the room temperature spectrum was acquired again and was identical to the unheated sample except that the line widths had decreased. This suggests that an annealing process occurs. The quadrupolar-dipolar splitting is expected to change with temperature as the nuclear quadrupolar coupling con-

Fig. 7. ^{119}Sn CP-MAS centre band spectra of Ph$_3$SnCl (**I**) at 7.05 T and different temperatures.
stant is temperature dependent, however, this temperature dependence is a very small effect in comparison to the large changes in isotropic chemical shift.

The mechanism of protonolysis of phenylplatinum(II) bonds in complexes with phenyl trans to nitrogen or carbon donors[1]

Christopher M. Ong, Michael C. Jennings, and Richard J. Puddephatt

Abstract: Addition of acids of the form HX (X = Cl, BF_4, CF_3SO_3, CF_3CO_2) to complexes [$PtPh_2(NN)$] (NN = bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) and [$PtPh(NCN)$] (NCN = 2,6-$C_6H_3(CH_2NMe_2)_2$) at –78 °C gave the corresponding phenyl(hydrido)platinum(IV) complexes [$PtX(H)Ph_2(NN)$] and [$PtX(H)Ph(NCN)$], which decomposed by reductive elimination of benzene at about –20 °C to give the platinum(II) complexes [$PtXPh(NN)$] and [$PtX(NCN)$]. Further addition of HCl to [$PtClPh(NN)$] at low temperature gave [$PtHCl_2Ph(NN)$], which decomposed above –10 °C, to give benzene and [$PtCl_2(NN)$]. The reaction of DBF_4 in the presence of excess CD_3OD with [$PtPh_2(NN)$] led to formation of C_6H_5D and $C_6H_4D_2$ but with [$PtPh(NCN)$] no multiple deuterium incorporation was observed in the product benzene. The mechanisms of these reactions are discussed.

Key words: platinum, phenyl, benzene, protonolysis.

Résumé : L'addition, à –78 °C, d'acides de la forme HX (X = Cl, BF_4, CF_3SO_3, CF_3CO_2) à des complexes [$PtPh_2(NN)$] (NN = bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) et [$PtPh(NCN)$] (NCN = 2,6-$C_6H_3(CH_2NMe_2)_2$) conduit aux complexes correspondants phényl(hydrido)platine(IV) [$PtX(H)Ph_2(NN)$] et [$PtX(H)Ph(NCN)$] qui se décomposent par élimination réductrice du benzène, à environ –20 °C, pour conduire aux complexes de platine(II) [$PtXPh(NN)$] et [$PtX(NCN)$]. L'addition subséquente de HCl au complexe [$PtClPh(NN)$], à basse température, conduit au [$PtHCl_2Ph(NN)$] qui se décompose au-dessus de –10 °C pour donner du benzène et du [$PtCl_2(NN)$]. La réaction du DBF_4 avec du [$PtPh_2(NN)$], en présence d'un excès de CD_3OD, conduit à la formation de C_6H_5D et de $C_6H_4D_2$; toutefois, avec le [$PtPh(NCN)$], on n'observe aucune incorporation multiple de deutérium dans le benzène obtenu comme produit. On discute des mécanismes de ces réactions.

Mots clés : platine, phényle, benzène, protonolyse.

[Traduit par la Rédaction]

Introduction

The activation of alkanes or arenes by platinum(II) complexes is thought to involve the intermediacy of alkyl(hydrido)platinum(IV) or aryl(hydrido)platinum(IV) complexes, and so there has been much interest in such complexes (1–13). A useful synthetic route to platinum(IV) complexes [$PtX(H)R_2(NN)$] (NN = bidentate nitrogen-donor ligand, X = halide, R = alkyl or aryl) is by addition of acid HX to a platinum(II) complex [$PtR_2(NN)$] and the decomposition of these platinum(IV) complexes by reductive elimination of RH to give [$PtXR(NN)$], which leads to overall protonolysis of the alkyl–platinum or aryl–platinum bond, can then be studied (3–5). Hydrido(alkyl)-, hydrido(aryl)-, and hydrido(silyl)platinum complexes are proposed in several other important catalytic reactions, including the hydrosilation reactions catalyzed by platinum complexes (14). Most of the recent studies of protonolysis of platinum–carbon bonds have involved complexes [$PtR_2(NN)$], in which the alkyl or aryl groups are trans to nitrogen donor ligands (3–5), and it was of interest to compare complexes with mutually trans Pt—C bonded groups. This paper reports a study of the reactions of acids with the complexes *cis*-[$PtPh_2(NN)$](NN = bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine, **1**) and [$PtPh(NCN)$] (NCN = 2,6-$C_6H_3(CH_2NMe_2)_2$, **2**) in which the NCN pincer ligand forces the two aryl groups to be mutually trans (15) (Chart 1).

Results

The phenylplatinum complexes 1 and 2

Complex **1** was prepared by reaction of the ligand bu_2bpy with the precursor [$PtPh_2(\mu-SMe_2)$]$_n$, n = 2 or 3 (16–18), in

Chart 1.

diethyl ether solution, while complex **2** was prepared by a
modified literature method (15).

The structures of complexes **1** and **2** are shown in Figs. 1
and 2, with selected bond distances and angles listed in Ta-
bles 1 and 2. Each complex contains a roughly square-planar
platinum(II) center, but with *cis-* and *trans-*PtC_2N_2 coordina-
tion, respectively, and in each case the phenyl group lies
roughly orthogonal to the square plane (79° in **1**, in which
the two phenyl groups are crystallographically equivalent;
84° in **2**, Figs. 1 and 2). This conformation allows platinum–
phenyl $d\pi$-$p\pi$ bonding and minimizes steric effects. The Pt—
C(phenyl) bond distance is shorter in **1** (2.023(2) Å, trans to
N) than in **2** (2.111(6) Å, trans to C), as expected since ni-
trogen has the lower trans-influence. However, the distance
Pt(1)—C(1) = 1.956(6) Å in **2** is shorter than either of these
Pt—C(phenyl) distances, as a result of the chelate effect.
Other bond distances and angles are comparable to those re-
ported for related complexes $[PtR_2(bu_2bpy)]$ (5, 16) or
$[PtX\{2,6-C_6H_3(CH_2NMe_2)_2\}]$ (15).

Reactions with acids

Complex **1** reacted with 1 equiv. of acid HX (X = Cl,
CF_3CO_2, CF_3SO_3, BF_4) at room temperature to give benzene
and the corresponding product $[PtXPh(bu_2bpy)]$ (**3a**, X = Cl;
3b, X = CF_3CO_2; **3c**, X = CF_3SO_3; **3d**, X = BF_4)
(Scheme 1). The complexes were characterized by elemental
analysis and by their ^{1}H NMR spectra, which showed the
presence of nonequivalent t-BuC_4H_3N units and only a sin-
gle phenylplatinum group.

The reaction of complex **1** in $CDCl_3$ solution with HCl at
–78 °C gave an intermediate hydridoplatinum(IV) complex
4a (Scheme 1) that was identified by its ^{1}H NMR spectrum.
The hydride resonance was observed at δ = –20.15 with
^1J(PtH) = 1613 Hz (Table 3). The trans oxidative addition of
HCl was shown by the observation of equivalent t-BuC_4H_3N
and phenyl groups. Complex **4a** decomposed at –20 °C by
reductive elimination of benzene to yield the product
$[PtClPh(bu_2bpy)]$ (**3a**) and no other intermediates were ob-
served. The similar reaction of **1** in $CDCl_3$ with the other ac-
ids failed to give detectable hydride intermediates, but the
reaction with HBF_4 or CF_3SO_3H in $CDCl_3$–CD_3CN gave a
hydride intermediate (**5**) characterized by δ(PtH) = –21.84,
^1J(PtH) = 1619 Hz. This is presumed to be a cationic
acetonitrile complex, since the spectral properties were the
same in each case and acetonitrile is a stronger ligand than
either triflate or tetrafluoroborate. Complex **5** decomposed
on warming the solution to –20 °C to give complex **3d**.

The complex $[PtClPh(bu_2bpy)]$ (**3a**) reacted with HCl at
room temperature to give benzene and $[PtCl_2(bu_2bpy)]$ (5).
When the reaction was carried out at –78 °C, the intermedi-
ate hydridoplatinum(IV) complex $[PtHCl_2Ph(bu_2bpy)]$ (**6**)

Scheme 2.

Scheme 3.

was detected. The ^1H NMR spectrum contained a hydride resonance at δ = –25.94 with ^1J(PtH) = 1540 Hz, in the range expected for a hydride trans to chloride (Table 3) (5). The aromatic region of the spectrum contained six resonances for the bu$_2$bpy ligand and three for the phenyl group, consistent with the proposed structure that arises from trans oxidative addition. The hydride complex decomposed at –20 °C to give benzene and [PtCl$_2$(bu$_2$bpy)] (Scheme 2).

Reaction of [PtPh{2,6-C$_6$H$_3$(CH$_2$NMe$_2$)$_2$}] (**2**) with acids HX gave benzene and the corresponding complexes [PtX{2,6-C$_6$H$_3$(CH$_2$NMe$_2$)$_2$}] (**7a**, X = Cl; **7b**, X = CF$_3$CO$_2$; **7c**, X = CF$_3$SO$_3$; **7d**, X = BF$_4$) (Scheme 3) (15). Reaction of complex **2** with HCl in CDCl$_3$ at –78 °C gave the hydridoplatinum(IV) complex [PtHClPh{2,6-C$_6$H$_3$(CH$_2$NMe$_2$)$_2$}] (**8**) which was characterized by a hydride resonance at δ = –21.36 with ^1J(PtH) = 1622 Hz. The hydride resonance de-

cayed at –20 °C as reductive elimination of benzene occurred to give **7a**. Similarly, reaction of **2** in CDCl$_3$–CD$_3$CN at –78 °C with triflic acid or tetrafluoroboric acid gave [PtHPh(NCCD$_3$){2,6-C$_6$H$_3$(CH$_2$NMe$_2$)$_2$}]$^+$ (**9**) identified by its ^1H NMR spectrum (δ(PtH) = –20.47, ^1J(PtH) = 1644 Hz) and it decomposed at –20 °C to give benzene and complex **7c** or **7d**. The complexes **7** were inert to protonolysis under

Scheme 4.
mild conditions, and there was no evidence for the addition of protons to the aryl group, though several electrophiles are known to add easily to the ipso carbon atom (15).

Studies of H-D exchange

The reaction of **1** and **2** with DBF_4 in $CDCl_3$–CD_3OD was studied to observe H-D exchange and hence, to investigate reversibility of the protonation and C-H reductive elimination steps. In each case, the benzene was analyzed by GC–MS. In the reaction with **1**, the ratio of C_6H_6:C_6H_5D:$C_6H_4D_2$ was 0.1:1.0:0.2, indicating significant formation of $C_6H_4D_2$, but in the reaction of **2** the ratio was 0.1:1.0:0.01, indicating very little if any deuterium enrichment beyond C_6H_5D. Integration of the phenylplatinum resonances in the product **3a** from reaction with complex **1** indicated that there was about 10% D-incorporation, distributed equally in the ortho, meta, and para positions. In the reaction with **2** there was no detectable D-incorporation in the C_6H_3 group of the NCN ligand. It has been shown previously that electrophilic attack at the ipso carbon atom of the C_6H_3 group of the NCN ligand is easy, but of course the chelate ligand prevents scrambling if reversible addition of D occurs at this point and no direct evidence of such reactivity was found (15).

Discussion

The intermediacy of hydridoplatinum(IV) complexes in the protonolysis of metal–carbon bonds in electron-rich alkyl or aryl complexes of platinum(II) or in C-H activation by electrophilic platinum complexes, is now accepted as the general rule, though other mechanisms are possible (1–12).

It is easier to detect these hydridoplatinum(IV) complex intermediates when they are generated by protonation of alkyl or aryl platinum(II) complexes and many details of their structures and energetics have been determined over recent years (1–10). Strong dependence on the nature of the hydrocarbyl group, the supporting ligands, the acid used, and the solvent medium has been demonstrated (3–5). The phenylplatinum complexes **1** and **2** are constrained to have the phenyl group(s) trans to nitrogen or carbon, respectively, and so a study of the dependence of protonolysis mechanism on stereochemistry is possible.

The chemistry shown in Schemes 1–3 illustrates that the mechanism of protonolysis of the phenylplatinum groups in **1**, **2**, and **3a** is similar in each case. Intermediate hydridoplatinum(IV) complexes are detected by low-temperature ^1H NMR in all cases. These intermediates are formed essentially quantitatively at –78 °C and they survive for several hours at this temperature, but they decompose on warming to –10 to –20 °C by reductive elimination of benzene. No other intermediates were detectable during reactions that were monitored by NMR, and there were no very dramatic differences in reactivity.

The chief difference between **1** and **2** was observed when the deuterolysis of the phenylplatinum groups was carried out in $CDCl_3$–CD_3OD solvent medium, in which there is a very large excess of exchangeable deuterium. The cleavage of the phenylplatinum groups from **1** or **2** under these conditions gave mostly C_6H_5D, as expected for simple cleavage. However, complex **1** also gave $C_6H_4D_2$ in significant yield and moderate deuterium enrichment in the residual phenylplatinum group of the product **3a**. Free benzene did

Fig. 3. Proposed reaction coordinate diagram for the protonolysis of a phenyl group from either complex **1** or **2** in CDCl$_3$–CD$_3$OD.

not undergo H-D exchange under the experimental conditions, so the deuterium enrichment occurred during cleavage of the phenylplatinum group to give **3**. A proposed sequence of reactions leading to H-D exchange is shown in Scheme 4. The five-coordinate complex **10*** is proposed as a key intermediate based on earlier work (4, 5); it can be formed by addition of D$^+$ to complex **1** or by chloride dissociation from the resting state complex [PtDClPh$_2$(bu$_2$bpy)] (**4a***), which is not shown in Scheme 4. Reductive elimination with C—D bond formation then leads naturally to the benzene-d_1 complex **11***, for which there are now several known precedents (4, 7, 10). Deuterium enrichment in the phenylplatinum groups requires that this reductive elimination reaction be reversible to form a hydrido(deuteriophenyl)platinum(IV) cation **10**** (Scheme 4). The complex **11*** is expected to be fluxional and to undergo rapid edge-to-edge migration of the benzene group, and so the position of the deuterium label will naturally scramble among all possible positions in **11*** and **10**** (though only one is shown in Scheme 4). Formation of C$_6$H$_4$D$_2$ requires further deuterium incorporation, likely by deprotonation of **10**** to give **1*** followed by addition of D$^+$ to give **10***** and C-H reductive elimination to give **11****. Dissociation or displacement of the coordinated benzene from **11** is irreversible, so free benzene cannot coordinate and hence, cannot undergo H-D exchange. In principle, the reactions of Scheme 4 can continue and give complete H-D exchange but only modest enrichment is observed. Hence, the benzene dissociation or displacement step from **11** to give **3** is competitive with the C-H oxidative addition and PtH–PtD exchange steps. Since the addition of D$^+$ to complex **2** gives no significant amount of C$_6$H$_4$D$_2$, in this case the C-H reductive elimination is probably irreversible.

The difference between the chemistry of complexes **1** and **2** can be understood in terms of the qualitative reaction coordinate diagram shown in Fig. 3. There is a destabilizing effect of two strong donor ligands (antisymbiosis) in organoplatinum chemistry, and so the trans-diaryl arrangement in **2** is less stable than the cis-diaryl arrangement in **1**. This relative stability is maintained through the various intermediates through to the proposed benzene complex, but is most pronounced in the trans-diaryl complexes. The six-coordinate hydridoplatinum(IV) complex is the most stable of the intermediates and so the only one that is directly observable in either case. The difference comes at the benzene loss step. The trans-ligand controls the rate of ligand loss through the trans-effect, and so the activation energy for benzene loss is

much lower for **2** than for **1**. For **1** the activation energy for benzene loss from the benzene complex cation (Fig. 3) is similar to that for the reverse reactions leading to H-D exchange, whereas for **2** the benzene loss is much faster and so the back reactions are not competitive.

The relevance to C—H bond activation is also clear from Fig. 3. The trans-aryl group in [PtX(NCN)] will labilise the group X$^-$ and so facilitate benzene coordination, but the overall energetics for oxidative addition of the C—H bond will be less favorable than in the case of [PtXPh(NN)]. It is interesting that a platinum(II) complex with a pincer ligand, which has a nitrogen-donor amide rather than a carbon-donor aryl group at the center, is capable of activating benzene to give a phenylplatinum(II) derivative (17).

The mechanism by which the five-coordinate hydrido(phenyl)platinum(IV) intermediate might be transformed to the benzene complex was examined by using density functional theory (DFT) on the model complex [PtHMePh(NH$_3$)$_2$]$^+$, chosen so as to give a reasonable model for the complex [PtHPh$_2$(bu$_2$bpy)]$^+$ (**10**). This model is also useful since it allows a comparison of the Me···H and Ph···H reductive elimination pathways. Some data are given in Table 4 and summarized in Fig. 4, while the proposed mechanism is summarized in Scheme 5. The five-coordinate complex **B** (Fig. 4, Scheme 5) has square-pyramidal stereochemistry. The hydride is slightly displaced towards the methyl group (HPtC = 85°) and the phenyl group rotates away from the position in which it is orthogonal to the C$_2$PtN$_2$ plane to avoid steric effects between the hydride and the ortho hydrogen atom of the phenyl group (Fig. 4). Complex **B** can decompose by C-H reductive elimination to give either a phenyl(methane)platinum(II) complex **D** or a methyl(benzene)platinum(II) complex **G** (Scheme 5). The formation of **D** (Scheme 5) occurs in a very similar way to that found earlier for methane reductive elimination from methyl(hydrido)platinum(IV) complexes (9), with a late transition state **C** (Scheme 5) and the activation energy was calculated as 3.1 kcal mol^{-1} (Table 4). The reductive elimination from **B** by coupling of the hydride and phenyl groups proved more difficult to define by DFT. The final state is predicted to be **G** (Scheme 5, Fig. 4) in which the benzene ligand is η^2-bonded, with the C-C axis perpendicular to the plane of the platinum(II) and with the benzene oriented towards the methyl group. The orientation of the benzene in **G**

Fig. 4. The predicted structures of the complexes [PtHMePh(NH$_3$)$_2$]$^+$ (**B**) and [PtMe(C$_6$H$_6$)(NH$_3$)$_2$]$^+$ (**F** and **G**) and below the calculated energies (kcal mol^{-1}) of the complexes **B**–**G**.
Scheme 5.
is very similar to that found experimentally in the hydrido(benzene)platinum(II) complex [PtH(C$_6$H$_6$){κ^2-(Hpz*)BHpz*$_2$}]$^+$, in which benzene is oriented towards the

hydride (10). There is a conformer of **G** in which the benzene is oriented towards the ammine (**H**) and it is very close in energy, presumably because the steric effects of CH$_3$ and

NH_3 are essentially the same (Table 4), but **H** will certainly be less favored in complexes with bulkier amine or imine ligands. The hydrogen atoms C^1H^1 and C^2H^2 in **G** and **H** are bent away from the platinum by about 10° but otherwise the benzene molecule is like free benzene. The transition state was expected to resemble **E** (Scheme 5), with the hydride bridging between platinum and the ipso carbon in an analogous way as in **C**, but no such transition state could be located. The only transition state found was **F** in which the Pt—H bond is completely broken (PtH^1 = 2.91 Å) and the C—H bond completely formed (C^1H^1 = 1.09 Å) (Scheme 5, Fig. 4). Complex **F** is another η^2-bonded benzene complex of platinum(II) but with atom H^1 still oriented roughly perpendicular to the plane of platinum(II) and so with the coordinated C-C axis in a less favorable orientation than in **G** or **H** for binding to platinum. The benzene is oriented towards the ammine ligand in **F** (Fig. 4). It is possible that the reaction proceeds in two steps, with a first transition state on the way to C-H reductive elimination (**E**) but this could not be defined and is probably close in energy to **F**; the transition from **F** to **G** just requires rocking about the Pt-C^1 axis. The benzene complex **G** is more stable than the methane complex **C**, as expected from the relative ligating abilities of benzene and methane. Since the transition state for C-H reductive elimination was not found, the relative energies of the transition states **C** and **E** are not known. Complex **E** is placed slightly higher than **C** or **F** in Fig. 4, based on the known selectivity for methane elimination in methyl(phenyl)platinum(II) complexes with nitrogen-donor ligands (4). The activation energy for the benzene C-H oxidative addition step, as measured by the energy difference between **G** and **F**, is calculated as 19 kcal mol^{-1}, which can be compared to experimental activation energies of ΔG = 13 to 14 kcal mol^{-1} for transformation of the benzene complex $[PtH(C_6H_6)\{\kappa^2\text{-}(Hpz^*)BHpz^*_2\}]^+$ and similar arene complexes, to the corresponding hydrido(phenyl)platinum(IV) complexes, such as $[PtH_2Ph\{\kappa^2\text{-}(Hpz^*)BHpz^*_2\}]^+$ (10).

Although there are still some questions about the detailed mechanism of the reductive elimination step to form benzene from complex **B**, it seems that the initial C⋯H bond formation occurs by movement of the hydride parallel to the Pt-C axis, but then a major sideways motion of the phenyl group occurs so as to allow side-on η^2-coordination of the forming benzene group. The activation of benzene by oxidative addition (4, 7, 10, 17) is then expected to follow the microscopic reverse of this sequence.

Experimental section

Syntheses were carried out using a nitrogen atmosphere, employing either Schlenk or glovebox techniques. Solvents were dried and distilled under N_2 prior to use. ^1H and ^{13}C NMR spectra were recorded using Varian Inova 400 and 600 MHz spectrometers. Chemical shifts are reported relative to $SiMe_4$. GC–MS experiments were carried out using a Finnigan Mat 8200 spectrometer; samples were prepared using CD_2Cl_2–CD_3OD solutions followed by direct injection to the GC coupled to the MS and isotopic composition of benzene was determined by simulation, based on spectra of authentic samples. The phenylplatinum(II) complexes were

stable in CD_2Cl_2–CD_3OD solution in the absence of added acid, as shown by NMR. The complexes $[\{PtPh_2(\mu\text{-}SMe_2)\}_n]$, bu_2bpy, and $[PtCl\{2,6\text{-}C_6H_3(CH_2NMe_2)_2\}]$ were prepared according to literature methods (15, 18). Solutions containing HCl or DCl were prepared by reaction of a known amount of acetyl chloride with MeOH or CD_3OD, respectively. The DFT calculations were carried out at the B3LYP level employing a LANL2DZ basis set, which uses a relativistic effective core potential for platinum. The program used was the Gaussian-94 software package (19) and the methods used were as described and justified previously (9).

$[PtPh_2(bu_2bpy)]$ (1)

To a solution of $[\{PtPh_2(\mu\text{-}SMe_2)\}_n]$ (0.494 g, 1.04 mmol) in Et_2O was added bu_2bpy (0.280 g, 1.04 mmol). The solution immediately turned orange in color. After 12 h, the orange precipitate that formed was filtered off, washed with Et_2O, and dried under vacuum. Yield: 54%. ^1H NMR ($CDCl_3$) δ: 8.45 (d, 2H, J_{HH} = 6Hz), 7.94 (s, 2H), 7.45 (d, 4H, J_{HH} = 8Hz, $H_o(Ph)$), 7.35 (d, 2H, J_{HH} = 7 Hz), 7.01 (t, 4H, J_{HH} = 7 Hz, $H_m(Ph)$), 6.88 (t, 2H, J_{HH} = 7 Hz, $H_p(Ph)$), 1.37 (s, 18H, t-Bu). Anal. calcd. for $C_{30}H_{34}N_2Pt$ (%): C 58.33, H 5.55; found: C 58.11, H 5.56.

$[PtClPh(bu_2bpy)]$ (3a)

To a solution of **1** (0.062 g, 0.099 mmol) in CH_2Cl_2 (0.5 mL) was added HCl (0.099 mmol). The orange precipitate of the product was filtered off, washed with Et_2O, and dried under vacuum. Yield: 73%. ^1H NMR (acetone-d_6) δ: 9.31 (d, 1H, J_{HH} = 6 Hz), 8.40 (s, 1H), 8.38 (d, 1H, J_{HH} = 6 Hz), 8.33 (s, 1H), 7.79 (d, 1H, J_{HH} = 6 Hz), 7.42 (d, 1H, J_{HH} = 6 Hz), 7.32 (m, 2H, $H_o(Ph)$), 6.98 (t, 2H, J_{HH} = 7 Hz, $H_m(Ph)$), 6.87 (t, 1H, J_{HH} = 7 Hz, $H_p(Ph)$), 1.44 (s, 9H, t-Bu), 1.38 (s, 9H, t-Bu). Anal. calcd. for $C_{24}H_{29}ClN_2Pt$ (%): C 50.04, H 5.07; found: C 49.56, H 4.94.

$[PtPh(O_2CCF_3)(bu_2bpy)]$ (3b)

To a solution of **1** (0.068 g, 0.11 mmol) in CH_2Cl_2 was added CF_3CO_2H (9 µL, 0.11 mmol). The reaction mixture was stirred for 12 h and the solvent was removed under vacuum to yield the product as an orange powder. Yield: 56%. ^1H NMR (acetone-d_6) δ: 8.85 (d, 1H, J_{HH} = 6 Hz), 8.53 (s, 1H), 8.46 (s, 1H), 8.17 (d, 1H, J_{PtH} = 60 Hz, J_{HH} = 6Hz), 7.82 (d, 1H, J_{HH} = 6 Hz), 7.53 (d, 1H, J_{HH} = 6 Hz), 7.37 (d, 2H, J_{HH} = 7 Hz, $H_o(Ph)$), 7.13 (t, 2H, J_{HH} = 7 Hz, $H_m(Ph)$), 7.08 (t, 1H, J_{HH} = 7 Hz, $H_p(Ph)$), 1.46 (s, 9H, t-Bu), 1.39 (s, 9H, t-Bu). Anal. calcd. for $C_{26}H_{29}F_3N_2O_2Pt_1$ (%): C 47.78, H 4.47; found: C 47.49, H 4.41.

$[PtPh(CF_3SO_3)(bu_2bpy)]$ (3c)

This was prepared similarly by using CF_3SO_3H. Yield: 64%. ^1H NMR (acetone-d_6) δ: 8.88 (d, 1H, J_{HH} = 6 Hz), 8.53 (s, 1H), 8.46 (s, 1H), 8.16 (d, 1H, J_{PtH} = 58 Hz, J_{HH} = 6 Hz), 7.84 (d, 1H, J_{HH} = 6 Hz), 7.54 (d, 1H, J_{HH} = 6 Hz), 7.35 (d, 2H, J_{HH} = 7 Hz, $H_o(Ph)$), 6.98 (t, 2H, J_{HH} = 7 Hz, $H_m(Ph)$), 6.87 (t, 1H, J_{HH} = 7 Hz, $H_p(Ph)$), 1.46 (s, 9H, t-Bu), 1.40 (s, 9H, t-Bu). Anal. calcd. for $C_{25}H_{29}F_3N_2O_3SPt$ (%): C 43.54, H 4.24; found: C 43.56, H 4.31.

[PtPh(BF₄)(bu₂bpy)] (3d)

This was prepared similarly by using HBF₄. Yield: 48%. ¹H NMR (acetone-d_6) δ: 8.89 (d, 1H, J_{HH} = 6 Hz), 8.55 (s, 1H), 8.47 (s, 1H), 8.19 (d, 1H, J_{HH} = 6 Hz), 7.85 (d, 1H, J_{HH} = 6 Hz), 7.55 (d, 1H, J_{HH} = 6 Hz), 7.37 (d, 2H, J_{HH} = 7 Hz, H$_o$(Ph)), 7.13 (m, 2H, H$_m$(Ph)), 7.05 (m, 1H, H$_p$(Ph)), 1.46 (s, 9H, t-Bu), 1.40 (s, 9H, t-Bu). Anal. calcd. for C₂₄H₂₉BF₄N₂Pt (%): C 45.95, H 4.66; found: C 45.47, H 4.80.

[PtHClPh₂(bu₂bpy)] (4a)

To an NMR tube charged with a solution of **1** (0.052 g, 0.085 mmol) in CDCl₃ (0.5 mL) at –78 °C was added HCl (0.085 mmol). ¹H NMR in CDCl₃ at –80 °C δ: 8.18 (s, 2H), 8.06 (d, 2H, J_{HH} = 6 Hz), 7.86 (d, 2H, J_{HH} = 7 Hz), 7.29 (d, 4H, J_{HH} = 7 Hz, H$_o$(Ph)), 6.76 (t, 4H, J_{HH} = 7 Hz, H$_m$(Ph)), 6.67 (t, 2H, J_{HH} = 7 Hz, H$_p$(Ph)), 1.19 (s, 18H, t-Bu), –20.15 (s, 1H, J_{PtH} = 1613 Hz, Pt-H). Compound **2** was indefinitely stable at –78 °C but decomposed rapidly at –20 °C to give C₆H₆ and [PtClPh(bu₂bpy)] (**3a**) as monitored by NMR.

[PtH(NCCD₃)Ph₂(bu₂bpy)][BF₄] (7)

This was prepared similarly in CDCl₃–CD₃CN (1.0 mL) by using HBF₄. ¹H NMR (CDCl₃–CD₃CN) δ: 8.45 (s, 2H), 8.10 (d, 2H, J_{HH} = 6 Hz), 7.52 (d, 2H, J_{HH} = 6 Hz), 7.18 (d, 4H, J_{HH} = 7 Hz, H$_o$(Ph)), 6.99 (t, 4H, J_{HH} = 7 Hz, H$_m$(Ph)), 6.89 (t, 2H, J_{HH} = 7 Hz, H$_p$(Ph)), 1.36 (s, 18H, t-Bu), –21.84 (s, 1H, J_{PtH} = 1619 Hz, Pt-H). Compound **7** was indefinitely stable at –78 °C but decomposed rapidly at –20 °C to give C₆H₆ and [Pt(BF₄)(C₆H₅)(tbu₂bpy)] (**3d**).

[PtHCl₂Ph(bu₂bpy)] (6)

To an NMR tube charged with a solution of **3a** (0.016 g, 0.028 mmol) in CDCl₃ (0.6 mL) at –78 °C was added HCl (0.028 mmol). ¹H NMR (CDCl₃) δ: 9.17 (s, 1H), 8.25 (s, 1H), 7.99 (s, 1H), 7.94 (s, 1H), 7.52 (s, 1H), 7.22 (d, 2H, J_{HH} = 6.8Hz, H$_o$(Ph)), 7.15 (s, 1H), 6.89 (t, 2H, J_{HH} = 7 Hz, H$_m$(Ph)), 6.76 (t, 1H, J_{HH} = 7 Hz, H$_p$(Ph)), 1.28 (s, 9H, t-Bu), 1.22 (s, 9H, t-Bu), –25.94 (s, 1H, J_{PtH} = 1540 Hz, Pt-H). Compound **6** was indefinitely stable at –78 °C but decomposed rapidly at –10 °C to give C₆H₆ and [PtCl₂(bu₂bpy)].

[PtPh{2,6-C₆H₃(CH₂NMe₂)₂}] (2)

To a solution of [PtCl(C₆H₃(CH₂NMe₂)₂)] (0.357 g, 0.78 mmol) in ether (10 mL) at 0 °C was added PhLi (0.43 mL, 0.78 mmol). The mixture was stirred at 0 °C for 5 min, then for 1 h at room temperature. The beige precipitate that had formed was filtered off, washed with pentane, and recrystallized from CH₂Cl₂–pentane to yield colorless crystals of the product (15). Yield: 56%. ¹H NMR (CDCl₃) δ: 7.67 (d, 2H, J_{HH} = 6 Hz), 7.11 (t, 1H, J_{HH} = 7 Hz), 6.97 (d, 2H, J_{HH} = 7 Hz), 6.92 (m, 2H), 6.87 (t, 1H, J_{HH} = 7 Hz), 4.11 (s, 4H, J_{PtH} = 42 Hz, N-CH₂), 2.89 (s, 12H, J_{PtH} = 44 Hz, NMe₂). ¹³C NMR (CDCl₃) δ: 145.54, 139.59, 126.84, 123.19, 122.63, 119.25, 81.22, 54.36.

[PtCl{2,6-C₆H₃(CH₂NMe₂)₂}] (7a)

To a solution of **2** (0.052 g, 0.105 mmol) in a THF:Et₂O (50:50) mixture was added HCl (0.105 mmol). The reaction mixture was stirred for 2 h at which time the beige precipitate was filtered off and washed with ether. Yield: 61%. ¹H NMR (CDCl₃) δ: 6.97 (t, 1H, J_{HH} = 7 Hz), 6.79 (d, 2H, J_{HH} = 7 Hz), 4.00 (s, 4H, J_{PtH} = 45 Hz, N-CH₂), 3.06 (s, 12H, J_{PtH} = 36 Hz, NMe₂). Anal. calcd. for C₁₂H₁₉ClN₂Pt (%): C 34.17, H 4.54; found: C 34.01, H 4.62.

[Pt(CF₃CO₂){2,6-C₆H₃(CH₂NMe₂)₂}] (7b)

This was prepared similarly using CF₃CO₂H. Yield: 48%. ¹H NMR (CD₂Cl₂) δ: 6.81 (t, 1H, J_{HH} = 6 Hz), 6.79 (d, 2H, J_{HH} = 4 Hz), 4.01 (s, 4H, J_{PtH} = 48 Hz, N-CH₂), 2.95 (s, 12H, J_{PtH} = 36 Hz, NMe₂). Anal. calcd. for C₁₄H₁₉F₃O₂N₂Pt (%): C 33.67, H 3.83; found: C 33.59, H 3.72.

[Pt(CF₃SO₃){2,6-C₆H₃(CH₂NMe₂)₂}] (7c)

This was prepared similarly using CF₃SO₃H. Yield: 36%. ¹H NMR (CD₂Cl₂) δ: 6.92 (t, 1H, J_{HH} = 7 Hz), 6.76 (d, 2H, J_{HH} = 7 Hz), 3.98 (s, 4H, J_{PtH} = 41 Hz, N-CH₂), 2.99 (s, 12H, J_{PtH} = 37 Hz, NMe₂). Anal. calcd. for C₁₃H₁₉F₃N₂O₃PtS (%): C 29.16, H 3.58; found: C 29.42, H 3.73.

[Pt(BF₄){2,6-C₆H₃(CH₂NMe₂)₂}] (7d)

This was prepared similarly using HBF₄. Yield: 57%. ¹H NMR (acetone-d_6) δ: 6.72 (t, 1H, J_{HH} = 7 Hz), 6.55 (d, 2H, J_{HH} = 7 Hz), 3.78 (s, 4H, J_{PtH} = 48 Hz, N-CH₂), 2.76 (s, 12H, J_{PtH} = 38 Hz, NMe₂). Anal. calcd. for C₁₂H₁₉BF₄N₂Pt (%): C 30.46, H 4.05; found: C 30.42, H 4.11.

[PtHClPh{2,6-C₆H₃(CH₂NMe₂)₂}] (8)

To an NMR tube charged with a solution of **2** (0.046 g, 0.091 mmol) in CDCl₃ at –78 °C was added HCl (0.091 mmol). ¹H NMR (CDCl₃) δ: 7.70 (d, 2H, J_{HH} = 6 Hz), 7.16 (t, 1H, J_{HH} = 7 Hz), 6.98 (d, 2H, J_{HH} = 7 Hz, H$_o$(Ph)), 6.96 (m, 2H, H$_m$(Ph)), 6.94 (t, 1H, J_{HH} = 7 Hz, H$_p$(Ph)), 4.15 (s, 4H, N-CH₂), 2.89 (s, 12H, NMe₂), –21.36 (s, 1H, J_{PtH} = 1622 Hz, Pt-H). Compound **8** was indefinitely stable at –78 °C but decomposed rapidly at –20 °C to give C₆H₆ and [PtCl{C₆H₃(CH₂NMe₂)₂}] (**7a**).

[PtHPh(NCCD₃){2,6-C₆H₃(CH₂NMe₂)₂}][CF₃SO₃] (9)

This was prepared similarly in CDCl₃–CD₃CN solution at –78 °C by using CF₃SO₃H. ¹H NMR (CDCl₃–CD₃CN) δ: 7.92 (t, 1H, J_{HH} = 8 Hz), 7.46 (d, 2H, J_{HH} = 8 Hz), 6.98 (m, 2H, H$_o$(Ph)), 6.87 (t, 2H, J_{HH} = 7 Hz, H$_m$(Ph)), 6.75 (t, 1H, J_{HH} = 7 Hz, H$_p$(Ph)), 4.10 (s, 4H, N-CH₂), 2.86 (s, 12H, NMe₂), –20.47 (s, 1H, J_{PtH} = 1644 Hz, Pt-H). Compound **9** was indefinitely stable at –78 °C but decomposed rapidly at –20 °C to give C₆H₆ and [Pt(CF₃SO₃){C₆H₃(CH₂NMe₂)₂}] (**7c**).

X-ray structure determinations

Crystals of **1** and **2** were grown from acetone and chloroform solution, respectively. Crystals were mounted on glass fibres. Data were collected by using a Nonius Kappa-CCD diffractometer with COLLECT (20) software. Crystal data and refinement parameters are listed in Table 5. Data were scaled using SCALEPACK (21), and empirical absorption corrections were applied using redundant data and XPREP (SHELXTL 5.03). Full-matrix least-squares refinement on

Allylation of aldehydes catalyzed by chiral *N,N′*-bis(*N*-methyl-2-methylene-4,5-bisphenyl-imidazole)-1,2-cyclohexane diamine rhodium(III) complexes[1]

Frank J. LaRonde and Michael A. Brook

Abstract: Chiral bis-imidazole rhodium(III) complexes catalyze the allylation of aldehydes by allyltributyltin. The pre-catalyst was readily prepared from chiral N,N′-bis(N-methyl-2-methylene-4,5-bisphenylimidazole)-1,2-cyclohexanedi-amine, potassium carbonate, and rhodium(III) chloride trihydrate. The rhodium(III) complex produced showed no activity in an allyl transfer process in the presence of the allyltin reagent. However, when silver tetrafluoroborate was added to the pre-catalyst and stirred for 1 h, the resulting system became an efficient catalyst for the allyl transfer process. The reductions produced homo-allyl alcohols with good to excellent yield, although generally with poor facial selectivity (8–10% ee, aryl aldehydes, 4 examples; 99% ee, aliphatic aldehyde, 1 example).

Key words: allylation, aldehydes, enantioselectivity, rhodium(III) tetramine complex.

Resumé : Les complexes chiraux du bis-imidazole rhodium catalysent l'allylation des aldéhydes par l'allyltributylétain. On a préparé facilement le précatalyseur par réaction du N,N′-bis(N-méthyl-2-méthylène-4,5-bisphénylimidazole)cyclo-hexane-1,2-diamine avec le carbonate de potassium et le trihydrate du chlorure de rhodium(III). Le complexe de rho-dium(III) qui est produit ne présente aucune activité vis-à-vis du processus de transfert de l'allyle en présence du réactif allylétain. Toutefois, quand on ajoute du tétrafluoroborate d'argent au précatalyseur et qu'on agite pendant une heure, le système qui en résulte devient un catalyseur efficace pour le transfert de l'allyle. Les réductions conduisent à la formation d'alcools homoallyliques avec des rendements allant de bons à excellents même si la sélectivité faciale est généralement faible (8 à 10% d'excès énantiomérique avec quatre exemples d'aldéhydes aromatiques et un ee de 99% pour un exemple d'aldéhyde aliphatique).

Mots clés : allylation, aldéhydes, énantiosélectivité, complexe tétrammine du rhodium(III).

Introduction

The efficient control of stereochemical induction during bond formation remains one of the hallmarks of synthetic organic chemistry. The utilization of enantiopure metal complexes to induce chirality and, simultaneously, promote bond formation is one of the most effective strategies for stereo-induction, particularly when the bond to be formed results from nucleophilic addition to a carbonyl group. One such example is the metal-complex-promoted addition of non-polar allyl nucleophiles, based on group 14 elements, to aldehydes. The asymmetric version of this reaction is a valuable means of constructing chiral functionalized structures (Scheme 1). Two classes of metal complexes are generally used to catalyze these reactions: oxyphilic Lewis acid catalysts and late transition metal complexes.

The majority of Lewis acid "catalysts" are developed from oxophilic metals including aluminum, boron, tin, and titanium. These are broadly applicable for the allylation of aldehydes, but suffer from extreme moisture sensitivity and a propensity to form oligomers in solution. In addition, chiral complexes based on these metals are usually generated in situ, so that a variety of species with varying Lewis acid strengths and enantioselection may be present in the reaction medium. This makes it difficult to develop selective processes and to understand the actual species participating in the reaction.

Scheme 1. Enantioselective allylation of aldehydes.

Fig. 1. Rh(III) catalysts used for the allylation of aldehydes.
Fig. 2. Bis-imidazole ligands.
The optimization of chiral Lewis acid catalysts remains challenging (1). With some notable exceptions, the most convenient metal ligands based on heteroatoms (N, P, O) significantly reduce the Lewis acidity and, thus, the catalytic activity. It should be noted that most of the reactions that are promoted by Lewis acid "catalysts" actually need stoichiometric quantities; those that require only catalytic quantities are much rarer.

A number of chiral allylmetal reagents that are generally used with stoichiometric amounts of Lewis acid catalysts (2) have been designed and synthesized (3). Some chiral Lewis acids that operate as true catalysts include chiral (acyloxy)borane (CAB) complexes with allylsilanes (4) or allylstannanes (5), binaphthol-derived chiral titanium complexes with allylstannanes (6) or allylsilanes (7), and BINAP-derived chiral silver complexes with allylstannanes (8).

Several groups have turned to late transition metal catalysts in the hope of avoiding some of the deficits of highly oxophilic Lewis acids: transition metal complexes can form single, well-defined species that are generally not moisture sensitive (9). For example, Nishiyama and co-workers (10) have described the synthesis and use of aryl-substituted oxazolines **1**, and Masaki and co-workers (11) have prepared pyrrolidine derivatives **2** (Fig. 1). Both classes of compounds activate aldehydes to attack by allyltin derivatives. They differ in the number of heteroatom ligands tethered to the central metal.

We recently reported the convenient synthesis and characterization of bis-imidazoles **3–7** (Fig. 2) (12). These compounds were examined for their ability to provide a chiral environment for the reduction of ketones by hydrosilanes. Compound **4** was found to be a more efficacious catalyst than **6** and **7** for the reduction of aryl methyl ketones by $HSi(OMe)_3$, its use leading to good yields (70–75%) of phenylethanol and related compounds, albeit with low degrees of enantioselectivity (25–30% ee).

Tetraamino compounds are well-known ligands in transition metal chemistry (13), particularly the chemistry of rhodium. It was of interest to bind these readily available ligands **4–7** to rhodium and establish if acceptable enantioselectivities would accrue in C—C bond-forming reactions. We present an examination of the enantioselective allylation of aldehydes with allyltributylstannane catalyzed by a new air-stable rhodium(III) complex **8** derived from ligand **7** (14).

Results and discussion

Complex **9** was directly synthesized by the mixing of equimolar amounts of commercially available rhodium(III) chloride hydrate, **7**, and 2.2 equiv of potassium carbonate in ethanol. The complex thus formed is sufficiently air stable that purification by silica gel chromatography is possible (Scheme 2*a*). Although no crystallographic structure data are yet available on this compound, we propose structure **9** for the precatalyst on the basis of crystal structures obtained for the analogous copper chloride salt of **6** and its achiral ethylenediamine-derived parent **5** (Scheme 2*b*). NMR, IR, and mass spectral data are also consistent with the proposed structure.

Scheme 2. (*a*) Bis-imidazole rhodium complexes; (*b*) Cu(II) complex of **5**.

A   R = Ph, H   **9**   **8**

B
The NMR data (see experimental section) indicate that the symmetry of the ligand is lost upon complexation–deprotonation.

The allylation reaction was attempted with benzaldehyde and allyltributylstannane in the presence of 5 mol% of the (*S*,*S*)-**9** as the chiral catalyst. No reaction was observed during the course of 7 days at room temperature. The electrophilicity of the catalyst was then increased, following the precedent of Nishiyama et al. (15). Compound **9** was treated with silver tetrafluoroborate for 1 h to give **8** with accompanying precipitation of AgCl. Allylations mediated by this catalyst at room temperature were efficient, but not rapid: complete conversion took about 4 days. Low enantioselectivity was noted in all solvents tested. The absolute configurations of the allylated aromatic products were determined to be *S* by comparison of their optical rotations with literature values (16). The selectivities in methylene chloride were somewhat worse than in THF: enantiomeric excesses were determined by ^{1}H NMR integration of the corresponding Mosher esters. Although the reaction was accelerated in the presence of 4 Å molecular sieves, the enantiomeric excess of the product did not appreciably change (Table 1, entries 3 and 4). This improvement in conversion may result from

fewer unproductive ligand-exchange reactions at rhodium with water.

Table 2 summarizes the results obtained from the allylation reaction using allyltributylstanane and catalyst **8** with a variety of aldehydes. It is evident that the enantioselectivity is dependent on the nature of the aldehyde, generally showing a low level of induction with aromatic aldehydes but a much higher selectivity with the one aliphatic example examined. Further work is underway to establish if the improved efficiency with aliphatic aldehydes is general.

The main distinction between **8** and the ligands of Nishiyama or Masaki is the number of available binding sites and the size of the chiral steering groups. The rhodium in **8** is tetradentate, rather than tridentate as in the other two complexes. Normally, this larger number of binding sites would auger well for stereoinduction: fewer degrees of freedom are available to an Rh-bound aldehyde and to the approach of the allylstannane. However, mitigating against this is the relatively small steric footprint of cyclohexanediamine.

Models of the likely rhodium complexes of benzaldehyde derived from the X-ray structures of **1** and the copper chloride salt **7**,[3] respectively, illuminate the differences in stereoselectivity induced by the two complexes. The larger

[a]Isolated yield after chromatography. The conversions are only slightly higher than these values.
[b]Determined by synthesis of Mosher esters; see experimental section.

Table 2. Asymmetric allylation of aldehydes catalyzed by **8**.

Entry	Aldehyde	Product	Yield (%)[a]	ee (%)[b]	Configuration[c]
1			97	10	*S*
2			78	10	*S*
3			67	6	*S*
4			85	8	
5			82	99	*R*

[a]Determined after purification by column chromatography on silica gel.
[b]Determined by synthesis of Mosher esters and comparison with known compounds (16); see experimental section.
[c]Note that the same mechanism and same facial selectivities are implicated in all these reactions. The changeover from *S* to *R* is a consequence of different Cahn–Ingold–Prelog priorities.

stereodirecting groups of the Nishiyama or Masaki ligands — for example, benzyl derived from **1** — are perfectly located in the complexes to direct facial attack at the carbonyl group. By contrast, the chiral cyclohexyldiamino groups in complexes derived from **7** are essentially flat (Fig. 3, R = H). It is apparent that generic stereochemical induction using complexes of this type will require larger groups (R = large).

Conclusion

Enantiopure, tetraamine ligands bind effectively to Rh(III). Cationic complexes derived from the ligand are suf-

ficiently electrophilic to act as Lewis acids that catalyze the enantioselective addition of allyltributylstannane to aldehydes.

Experimental

Reagents and physical methods

The following materials were obtained from Aldrich and were used without further purification: acetophenone, benzophenone, benzaldehyde, 4-trifluorotolualdehyde, 4-methoxybenzaldehyde, *trans*-4-phenyl-2-methyl-2-butenal, dodecanal, (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride

Fig. 3. Modelled structures of benzaldehyde adducts of rhodium derivatives of **1** and **8**, respectively.

Derived from **1**

Derived from **8**

no steric bulk for stereodiscrimination when R = H
(MTPA-Cl (+)), pyridine, silver tetrafluoroborate, rhodium(III) chloride trihydrate, potassium carbonate, and 4 Å molecular sieves. Compound **7** was prepared following the literature procedure (13).

^{1}H NMR spectra were recorded on a Bruker AC-200 (at 200 MHz for protons) Fourier transform spectrometer. ^{13}C NMR was performed on a Bruker AC-200 (at 50.32 MHz) or a Bruker AC-300 (at 75.44 MHz) Fourier transform spectrometer. [1]H chemical shifts are reported either with respect to tetramethylsilane as an external standard (set to 0 ppm) or CDCl$_3$ as an internal standard (set at 7.24 ppm). [13]C chemical shifts are reported with respect to CDCl$_3$ as an internal standard (set at 77 ppm.). Coupling constants (J) are recorded in Hertz (Hz). The abbreviations s = singlet, d = doublet, t = triplet, q = quartet, dd = doublet of doublets, dt = doublet of triplets, and m = multiplet are used to report spectra.

Electron impact (EI) and chemical ionization (CI, NH$_3$) mass spectra were recorded at 70 eV with a source temperature of 200 °C on a VG analytical ZAB-R mass spectrometer equipped with a VG 11–250 data system. High resolution mass spectral (HR-MS) data were obtained using the EI method. Infrared spectra were run as KBr pellets or as liquid films on NaCl discs (as indicated) on a PerkinElmer 283 spectrometer or on a BIORAD FTS-40 spectrometer as a neat film. Models shown in Fig. 3 were calculated with the Hyper-Chem 5 modelling package, using molecular mechanics methods (MM+). The starting geometries used came from the respective crystal structure data. Absolute configurations of the product homoallylic alcohols were assigned based on the rotations reported in the literature (16).

All solvents were thoroughly dried before use: acetonitrile was dried over P$_2$O$_5$; THF was dried from Na–benzophenone. All reactions were carried out in dry apparatus under a nitrogen atmosphere with the use of septa and syringes for the transfer of reagents.

Preparation of 9

To a dry 25 mL round-bottomed flask flushed with nitrogen was added **7** (0.12 g, 0.20 mmol), potassium carbonate (0.06 g, 0.42 mmol), and absolute EtOH (15 mL). The system was stirred under nitrogen, under reflux, for 2 h. The resulting mixture was filtered and was washed with THF

(10 mL). The solvent was removed in vacuo. The crude product was purified using column chromatography, eluting with CHCl$_3$:MeOH (9:1, R_f = 0.85) to produce 0.12 g (80%) of an orange powder.

FT-IR (neat, KBr disc) (cm^{-1}) ν: 3424.6, 3056, 2935, 2854, 1640, 1602, 1505, 1445, 1426, 1027, 785, 700. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 7.89 (bs, 1H, N-H), 7.43–7.08 (m, 20H, Ph-H), 4.06 (d, J = 13.5 Hz, 2H, 2 × NCH_aH_b), 3.60 (d, J = 13.5 Hz, 2H, 2 × NCH$_aH_b$), 3.52 (s, 6H, NCH$_3$), 2.32 (m, 2H, Cy-H), 1.95 (m, 2H, Cy-H), 1.77 (m, 2H, Cy-H), 1.28 (m, 4H, Cy-H). ^{13}C NMR (CDCl$_3$, 200 MHz) δ: 23.95, 24.33, 28.63, 30.75, 33.00, 45.71, 51.12, 58.14, 68.55, 70.57, 126.10, 126.86, 127.51, 127.59, 127.67, 127.81, 128.27, 128.33, 128.42, 128.68, 129.20, 130.40, 130.57, 131.01, 131.21, 132.09, 139.12, 148.99, 149.49. ES-MS (positive) m/z (%): 779.2 ([M + 1]$^+$, 100).

Typical experimental for allylation (example benzaldehyde)

To a dry 25 mL round-bottomed flask flushed with nitrogen was added **9** (0.02 g, 0.025 mmol), silver tetrafluoroborate (0.01g, 0.05 mmol), molecular sieves (250 mg), and THF (15 mL). The system was stirred for 1 h at room temperature. To this stirring mixture was added benzaldehyde (0.05 g, 0.5 mmol) and allyltributyltin (0.23 mL, 0.77 mmol). The resulting system was stirred at ambient temperature for 4 days. The system was quenched with an aqueous solution of sodium bicarbonate (1 mol/L, 5 mL) and filtered. The aqueous layer was extracted with ether (3 × 10 mL). The combined organic fractions were washed with sodium bicarbonate (1 mol/L, 3 × 10 mL), HCl (1 mol/L, 3 × 10 mL), and water (3 × 10 mL). The solvent was removed under reduced pressure. The crude product was purified by silica gel chromatography, eluting with pentane:ether (9:1). FT-IR (neat, KBr disc) (cm^{-1}) ν: 3388, 3078, 3032, 2927, 1642, 1494, 1454, 1048, 916, 758, 700. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 7.26–7.12 (m, 5H, Ph-H), 5.81–5.60 (m, 1H, CH=CH$_2$), 5.10–5.00 (m, 2H, CH=CH_2), 4.60 (t, J = 6.5 Hz, 1H, CH (OH)), 2.41(t, J = 6.5 Hz, 2H, CH_2CH=CH$_2$), 2.32 (bs, 1H, OH). ^{13}C NMR (CDCl$_3$, 200 MHz) δ: 26.69, 65.66, 117.97, 125.72, 127.33, 128.22, 134.39, 143.84. EI-MS m/z (%):148 ([M]$^+$, 1), 131 ([M – 17]$^+$, 5), 107 (100), 79 (75), 41 (33). CI-MS m/z (%): 166

([M + 18]$^+$, 27), 148 ([M]$^+$, 70), 131 ([M]$^+$ – 17, 100), 94 (5), 77 (2), 41 (1). HR-CI-MS *m/z*: Anal. calcd. for C$_{10}$H$_{12}$O: 131.0846; found: 131.0861.

General experimental procedure for preparation of Mosher esters (shown for (S)-1-phenyl-3-buten-1-ol)

1-Phenyl-3-buten-1-ol (3.0 mg, 0.02 mmol) and MTPA-Cl (+) (4 μL, 0.02 mmol) were mixed with carbon tetrachloride (3 drops) and dry pyridine (3 drops). The reaction mixture was allowed to stand in a stoppered flask for 12 h at ambient temperature. Water (1 mL) was added, and the reaction mixture transferred to a separatory funnel and extracted with ether (20 mL). The ether solution, after successive washing with HCl (1 mol/L, 20 mL), saturated sodium carbonate solution (20 mL), and water (20 mL), was dried with sodium sulfate and filtered, and the solvent was removed in vacuo. The residue was dissolved in deuterated chloroform for NMR analysis. The integration(s) of the hydrogen on the carbon bearing the hydroxyl group was used as a measure to assess the enantioselection. The data was compared with that found in ref. 16.

Synthesis, characterization, and polycondensation of new stable α,ω-organo(bis-silanediols)[1]

Geneviève Cerveau, Sabrina Chappellet, Robert J.P. Corriu, and Bertrand Dabiens

Abstract: The synthesis and characterization of stable bis(dihydroxymethylsilyl) derivatives are described. These compounds were obtained as microcrystalline powders by controlled hydrolysis in a biphasic medium (ethyl ether – water) of the corresponding bis(dimethoxymethylsilyl) organic precursors containing phenyl, biphenyl, stilbenyl, diphenylacetylene, and diphenylbut-1,3-diyne groups. All the solids obtained exhibited a layered structure. Condensation of the bis-silanediols could be effected by fluoride catalysis in solution at ambient temperature or simply by heating in solid state. The polysiloxanes obtained from the bis-silanediols have been compared with those obtained by hydrolysis–polycondensation of the corresponding bis-dimethoxysilanes. The thermal route led to highly polycondensed solids arranged into thin plates as evidenced by TEM analysis; furthermore, in the case of the longer spacer, the organization was controlled by the arrangement of the Si-O-Si layers instead of the spacer. The X-ray study of these materials clearly evidenced the drastic influence of the length of the organic spacer, the polycondensation route and the nature of the leaving group (hydroxy or methoxy) on the short-range organization of the solids.

Key words: silanols, hybrid materials, polycondensation, polysiloxanes.

Résumé : La synthèse et la caractérisation de dérivés bis(dihydroxymethyl)sililés stables est décrite. Ces composés sont obtenus sous forme de poudres microcristallines par hydrolyse contrôlée en milieu biphasique (éther éthylique – eau) des dérivés bis(diméthoxyméthyl)sililés correspondants. Ces précurseurs contiennent des groupements phenyl, biphenyl, stilbenyl, diphenylacetylène et diphenylbut-1,3-diyne. Tous les bis-silanediols obtenus présentent une structure en feuillets. La polycondensation des ces composés par traitement thermique du solide et par voie catalytique en solution a été étudiée. Les polysiloxanes obtenus à partir des bis-silanediols ont été comparés à ceux obtenus par hydrolyse–polycondensation des bis-diméthoxysilanes correspondants. La voie thermique conduit à des solides très polycondensés se présentant sous forme de plaquettes ; de plus dans le cas du plus long groupement organique, l'organisation est controlée par l'arrangement des couches Si-O-Si au lieu de l'espaceur organique. Une étude aux rayons X de ces polysiloxanes montre clairement l'influence fondamentale de la longueur de l'espaceur organique, du mode de polycondensation et de la nature du groupement partant (hydroxy ou méthoxy) sur l'organisation à courte distance de ces solides.

Mots clés : silanols, matériaux hybrides, polycondensation, polysiloxanes.

Introduction

During the past few years there has been considerable interest in the chemistry of compounds containing Si-OH functional groups (1–9). Indeed the isolation of pure silanetriols $RSi(OH)_3$ or silanediols $RR'Si(HO)_2$ is more difficult than that of silanols $RR'R''SiOH$ because of the easier polycondensation with the increasing number of OH groups at silicon (3, 4). However, until now only a few silanetriols or silanediols have been isolated (2–4). Most of the compounds synthesized and structurally characterized contain bulky substituents at silicon and most of the studies have been carried out on diphenyl or di-*tert*-butylsilanediol (10–14). Only recently have more complex silanediols been isolated (15–19). The case of molecules containing two silanediol groups is more difficult because of the faster polycondensation reaction. Only a few of them have been synthesized (20, 21). The ones that have been reported are tetrahydoxydisiloxanes (20, 22) or a disilane (23).

We have recently shown that it is possible to isolate stable bis-silanetriols where the presence of hydrophilic interactions is the driving force in the formation of an ordered structure (24, 25). At the same time we also reported the synthesis and the X-ray crystal structure of a stable organo-bis(alkylsilanediol), 1,4-bis(dihydroxymethylsilyl)benzene (26). The crystal structure shows a remarkable hydrogen-bonded network leading to three-dimensional packing. Each $MeSi(OH)_2$ moiety is linked to four oxygen atoms belonging to three different molecules and is cross-linked through the aromatic ring with the second $MeSi(OH)_2$, thus, achieving a

rigid three-dimensional structure. The structure of such a compound has been presented and provides evidence for the importance of the hydrogen bonding between neighboring silanol groups (26) as illustrated in Scheme 1.

We report here an extension of the synthesis and characterization of bis-silanediols containing two MeSi(OH)$_2$ groups in the same molecule shown in Scheme 2.

They constitute precursors for the preparation of hybrid organic–inorganic silicon-based solids (27, 28). The synthesis of polysiloxanes formed by thermal (**DHt**, Scheme 3a) and catalytic polycondensation (**DHa**, Scheme 3b) of these silanediols is also reported as well as the comparison of the solids obtained with those prepared by hydrolysis–polycondensation of the corresponding bis-dialkoxysilanes (**DMa**, Scheme 4).

Results and discussion

Synthesis and characterization of bis-silanediols DH1–DH6

Most silanediols reported in the literature have been prepared by controlled hydrolysis of dichlorosilanes (15, 29, 30) i.e., hydrolysis at low temperature of the corresponding polychlorosilylated compounds by a stoechiometric amount of water in the presence of a weak base as a catalyst (triethylamine or aniline). We investigated an alternative

route consisting of the hydrolysis of the corresponding dialkoxysilanes (31, 32); this route originally reported by Tyler (32) for the preparation of phenylsilanetriol was modified for the synthesis of bis-silanetriols (24, 25) by using biphasic conditions which allowed a slower rate of polycondensation and favored the formation of hydrogen bonding between the silanol groups in the aqueous phase. The bis-silanediols reported here (**DH**) (Scheme 2) were prepared by controlled hydrolysis of the corresponding bis-(dimethoxymethylsilyl) precursors (**DM**) (33) in a biphasic medium (ethyl ether – water) in the presence of acetic acid as the catalyst at room temperature (Scheme 2).

The reaction mixture was stirred vigorously for various reaction times depending on the precursor **DM1**–**DM6**, until the resulting organo-bis-silanediol precipitated out in the aqueous phase. The progress of the reaction was followed by ^{1}H NMR in DMSO-d_6 and it was stopped when the singlet at 3.60 ppm owing to OMe groups had totally disappeared. In all cases a new singlet at ≈6.4 ppm revealed the presence of hydrogens of hydroxy groups. After filtration and drying at 25 °C under vacuum during 12 h, the bis-silanediols **DH1**–**DH6** were isolated. The experimental conditions and the yields for **DH1**–**DH6** are reported in Table 1.

However, it is interesting to point out the importance of the ratio (np/na) between the numbers of mol of precursor (np) and the number of mol of acetic acid (na) which must

be adjusted case by case: in the case of **DM2**, **DM4**, and **DM5**, using the same experimental conditions as for **DM1** ($np/na = 25$), only 32% of **DH2** was obtained after 32 days, whereas no reaction occurred after 20 days for **DM4** and 60 days for **DM5**, even when the ratio was $np/na = 6$.

To shorten the very long reaction times required, we investigated liquid–liquid phase transfer catalysis (34) using tetraethylammonium *para*-toluenesulfonate (TEApTS) as the catalyst, which was shown to be very efficient in the case of the formation of bis-silanetriols (25). The results are reported in Table 2. It appears that in every case the reaction times were significantly shortened and the yields increased, with the exception of **DM6** which gave a mixture of **DH6** and polycondensation product.

The bis-silanediols **DH1**–**DH6** were soluble in the usual organic solvents such as methanol, ethanol, THF, and DMSO. In this case, it was possible to recover the bis-silanediols after removal of the solvent. They were identified by IR, ^{1}H, ^{13}C, ^{29}Si NMR spectroscopies. For all samples, the FT IR spectra exhibited a broad absorption band centered at ≈ 3125 cm^{-1} owing to hydrogen-bonded hydroxy groups and an intense band at ≈ 900 cm^{-1} attributed to the Si-O(H) bond vibrations. No free ν OH vibrations were detected. The ^{1}H and ^{13}C NMR spectra were recorded in DMSO-d_6 solution. They exhibited the expected resonances for the organic moiety in all cases (see *Experimental*). The OH groups displayed a sharp singlet at ≈ 6.32–6.49 ppm. The ^{29}Si NMR spectrum in DMSO-d_6 solution exhibited in all cases a sharp resonance at ≈ -21 ppm in agreement with chemical shifts already reported for silanediols (26, 30). Interestingly, the ^{29}Si CP-MAS NMR spectra of the solid bis-silanediols exhibited two sharp signals in some cases (see *Experimental*). In contrast to the bis-silanetriols containing the same organic groups, the ^{29}Si NMR spectra showed only one singlet attributable to the OH groups (25).

The compound **DH1** exhibited two singlets of the same intensity at –15.9 and –17.2 ppm, respectively, whereas **DH4** and **DH5** presented two signals of different intensity at –14.7 and –16.8 ppm and –13.7 and –16.7 ppm, respectively. It is noteworthy that the chemical shifts were slightly different in DMSO-d_6 solution and in the solid state. This could be explained by a difference in the hydrogen bonding inter-

Table 2. Experimental conditions and yields of bis-silanediols in the presence of TEApTS (10%).

[b]Mixture of bis-silanediol and polysiloxane.

actions: in the solid state, the hydrogen bonds involved only silanediol molecules, whereas in solution the crystalline structure is broken and the DMSO, which is a strong hydrogen bond acceptor, might certainly be more strongly associated to the hydroxy groups, thus, shifting the signal towards higher fields (–21 ppm).

A ^{29}Si CP-MAS NMR study was performed varying the temperature from 20 to 100 °C. No changes occurred as the two signals at –15.9 and –17.2 ppm were always present at the same chemical shifts and neither coalescence nor polycondensation were observed. Thus, the presence of two signals of the same intensity in the case of **DH1** could be indicative of a slight difference in the environment of the two silicon atoms in the solid state at the NMR timescale. The presence of the two signals was not indicative of a mixture of two different crystalline structures. This was confirmed by the thermal analysis of **DH1**, which did not reveal any phase transition.

The thermal stability of the bis-silanediols **DH1**–**DH6** was studied by differential scanning calorimetry (DSC). The analysis were performed under an inert atmosphere. The curves displayed broad asymmetric endothermic peaks at ≈ 200 °C (see *Experimental*), which corresponded to the polycondensation reaction as evidenced by IR spectroscopy.

These bis-silanediols appeared to be relatively stable despite the presence of four OH groups. The length of the organic group seemed to have almost no influence on the thermal stability of the different compounds in contrast with the behavior observed in the case of bis-silanetriols for

which the thermal stability decreased when the length on the organic group increased (25).

Structural study

The X-ray diffraction patterns of the solids **DH1–DH6** (Fig. 1) revealed that all the bis-silanediols were not crystals. However, they exhibited some organization in the solid state. A short-range order was evidenced by the observation of narrow X-ray diffusion signals. Moreover, a micrometric scale organization was suggested by the TEM images (Fig. 2), which always showed the presence of the superposition of thin plates as illustrated in the case of **DH1**.

The presence of strong hydrogen bonds appeared to be the driving force for the stabilization of the bis-silanediols. The use of a biphasic medium allowed their isolation by slowing down the polycondensation and favoring the formation of a hydrogen bonding network in the aqueous phase. The presence of an aromatic group bonded to silicon was found to be unavoidable for the formation of bis-silanediols. The same results have been observed with the bis-silanetriols (25). In this case also, the use of a rigid and linear precursor was found to be much more favourable for hydrogen bond formation than a flexible or angular one.

Polycondensation reaction of bis-silanediols DH1, DH3, and DH5

Thermal polycondensation

The thermal polycondensation of **DH1** was studied under air at different temperatures (Scheme 3*a*) varying the length of heating. White solids were obtained. The experimental conditions and the main results are reported in Table 3.

The ^{29}Si CP-MAS NMR spectra showed the presence of the D^0 (C_2-Si(OH)$_2$, δ –15.9, –17.2 ppm), D^1 (C_2-Si(OH)(OSi), δ –24 ppm), and D^2 (C_2-Si(OSi)$_2$, δ –33 ppm) substructures in the case of the solids (entries 1, 2, 3, and 4 in Table 3), whereas the solid entry 5 was totally polycondensed since only D^2 units were detected. The deconvolution of the spectra (35, 36) led to levels of condensation ranging between 48% (entry 1) and 100% (entry 5). No cleavage of Si—C bonds occurred under the thermal treatment since no signals in the range δ –50 to –80 ppm (T^n units) and δ –90 to –110 ppm (Q^n units) were observed (37–39). Furthermore, the ^{13}C CP-MAS NMR spectra showed the integrity of the organic group since signals at δ 138, 132, and –1.7 ppm (aromatic carbons and CH$_3$) were present in each case.

Fig. 1. X-ray powder diffraction patterns of **DH1–DH6**.
Fig. 2. TEM image of **DH1**.
The TG analysis of these different solids performed between 30 and 400 °C allowed observation of the progress of the polycondensation reaction. A weight loss of 15.3% was observed for **DH1** which corresponded to a level of condensation of 98%. The weight losses observed in the case of the solids (entries 1, 4, and 5 in Table 3) corresponded to levels of condensation of 50%, 66%, and 98%, respectively, in

good agreement with the results deduced from the ^{29}Si CP-MAS NMR spectra.

The X-ray powder diffraction diagram of the solid **DH1t** (Table 3, entry 5) did not exhibit any thin peaks of Bragg. Only two broad signals centered at 7.4 and 3.8 Å were observed (Fig. 3), which were indicative of a short-range order in the solid (40, 41).

Taking into account the results obtained in the case of **DH1**, the thermal polycondensations of **DH3** and **DH5** were investigated (Scheme 3*a*). The bis-silanediols were heated at 250 °C for 3 days, since the maximum temperatures for the endothermic peaks were in the same range for all the starting bis-silanediols. The reaction was performed under an inert atmosphere of argon to avoid any degradation of the organic group (42). The ^{29}Si NMR data for the resulting solids are given in Table 4.

The solids **DH3t** and **DH5t** were highly polycondensed. The ^{29}Si CP-MAS NMR spectra displayed D^1 and D^2 units at δ –24 and δ –33 ppm, respectively. The levels of condensation ranged between 93% and 95%. These materials presented no significant specific surface area.

The X-ray powder diffraction diagrams of **DH3t** and **DH5t** presented signals at 11.9 Å (sharp peak) and 4.8 Å (broad peak) and at 7.5 Å (broad signal) and 4.8 Å (sharp signal), respectively (Figs. 4 and 5).

The TEM images of the solids **DH1t**, **DHt3**, and **DH5t** showed plate-like morphologies similar to those observed with the diols. They suggested a lamellar type organization at the micrometric scale.

Catalytic polycondensation of DH1, DH3, DH5 and DM1, DM3, DM5

The catalytic polycondensation of the bis-silanediols and the hydrolysis–polycondensation of the corresponding bis-(dimethoxymethyl)silanes were performed in THF in the presence of 1 mol% of TBAF as the catalyst at room temperature (Schemes 3*b* and 4). Monolithic gels were obtained in all cases. The solids obtained from the bis-silanediols **DH** had a high level of condensation (77%–100%) (Table 5). They exhibited high specific surface areas (Table 5, entries 1–4 and 6) or moderate ones (Table 5, entry 5). They were mainly mesoporous without narrow pore size distribution (pore size <100 Å); the microporous contribution ranged between 3% and 15%.

In contrast, the corresponding bis-dimethoxysilanes **DM** led to less polycondensed solids for **DM1** with D^0 units (Table 5, entry 2). However, highly polycondensed solids were obtained from **DM3** and **DM5** (Table 5, entries 5 and 6). The solid **DM1a**, **DM3a**, and **DM5a** presented high specific surface areas. The microporous contribution was weak in all cases (Table 5, entries 2, 4, 6).

Fig. 3. X-ray powder diffraction diagram of **DH1t**, **DH1a**, and **DM1a**.
The X-ray powder diffraction diagrams of the different solids are shown in Figs. 3–5. In the case of **DH1** and **DM1**, two broad signals were observed (Fig. 3). In contrast, the X-ray patterns of **DH3a** and **DH5a** were different from those of **DM3a** and **DM5a** (Figs. 4 and 5). The TEM images of all the solids obtained by the catalytic route showed the presence of particles irregular in size and geometry in all cases.

Comparison of the three polycondensation routes

A comparison of the properties of the polysiloxanes obtained using the three different routes (Schemes 3 and 4) is of great interest. Although highly polycondensed solids were always obtained, their textural properties and macroscopic geometry were highly dependent on the route employed. The thermal treatment always led to nonporous solids, which exhibited a lamellar type organization at the micrometric scale as evidenced by TEM. In contrast, the route in solution from **DH** or **DM** gave mainly mesoporous materials with high specific surface areas, which do not exhibit any lamellar property by TEM experiments.

Moreover, all the X-ray studies clearly demonstrated that the short-range organization of the solids was drastically influenced by the following factors: length and nature of the organic spacer, polycondensation route, and nature of the leaving group (hydroxy or methoxy). The influence of the precursor was very important since the three spacers selected showed a drastically different behaviour.

For **1** the thermal and solution routes (Schemes 3 and 4) led to solids presenting similar X-ray diffraction diagrams. The halo centered at 3.8 Å, observed on all the diffraction diagrams, corresponded to the contribution of the Si-O-Si

Table 5. Experimental conditions, ^{29}Si CP-MAS NMR data, and textural properties of solids obtained by polycondensation of bis-silanediols and hydrolysis–polycondensation of bis-dimethoxysilanes.

Fig. 5. X-ray powder diffraction diagram of **DH5t**, **DH5a**, and **DM5a**.
units as reported for organopolysilsesquioxanes (40). The other signals are connected with the length of the organic spacer (6.8 or 7.4 Å) (40, 41). The different locations of the signals observed among the three polycondensation routes cannot be discussed in greater depth. They show that the short-range organization is related to the size of the organic spacer, but that it also depends on the type of polycondensation, which is different in each case as confirmed by the different texture and polycondensation levels (Schemes 3 and 4).

The longer spacer **3** shows a more regular arrangement depending on the route of polycondensation. The three routes led to solids presenting X-ray signals at roughly the same distances. However, the signal widths were different. Thermal treatment induced an organization, which was controlled by the spacer, with the presence of a sharp peak of Bragg for a distance close to the length of the spacer. The second characteristic was the shift of the halo corresponding to the Si-O-Si layers which appeared between 4.5 and 4.8 Å instead of 3.8 Å, as observed for **1**. This signal was of interest since it could be probably connected with the formation of wider and almost homogeneous -Si(Me)O- layers. These layers were different from those obtained in the case of **1**, which were similar to those observed in the case of silsesquioxanes (40). Another interesting feature was the pres-

ence of a more narrow signal connected with the length of the spacer when the thermal treatment was used (**DHt3**). A better organisation in this case could be explained by the fact that the polycondensation occured in the solid state, partially preserving the organization of the starting diol. All these observations suggest that in the case of **3**, the polycondensation is controlled by the length of the spacer with formation of -Si(Me)O- layers.

The case of **5** was different from the previous ones since the three routes led to solids exhibiting different X-ray diffraction patterns. The two main features were the absence of any signal that could be directly related to the length of the spacer (d_{Si-Si} ~15 Å); all the diffraction signals were for lower distances. The second one concerned the thermal treatment. Its X-ray diagram exhibited a sharp signal at 4.8 Å that can be attributed to -Si(Me)O- layers. Finally, the signals observed in the case of the polycondensation performed in solution from MeO groups (**DM5a**) were completely different from those observed with **DH5a**. One possible explanation could originate from the fact that polycondensation occurs in two different media: for **DH5a**, the polycondensation occurs in hydrophilic conditions and implies only homocondensation of OH groups, whereas for **DM5a**, there is hydrolysis in a hydrophobic medium followed by competition between homo- and heterocondensa-

tion of OH and OMe groups, the medium becoming more and more hydrophilic. Further studies are in progress to clarify these observations.

Conclusion

In conclusion, we have reported for the first time the synthesis of stable bis(alkylsilanediols), stabilized by a hydrogen bonding network. Polysiloxanes have been prepared by thermal polycondensation from the bis-silanediols **DH** and by a catalytic route in solution from the bis-silanediols and the corresponding bis-dimethoxysilanes **DM**. The solids obtained presented some similarities in all cases: the level of condensation was higher and the X-ray scattering exhibited better organization in the case of longer spacers. However, several differences have been evidenced: (*i*) the solids obtained by the thermal route (**DHt**) were always nonporous, whereas the catalytic route gave mainly mesoporous solids with a high specific surface area; (*ii*) moreover, the thermal route led to a better organization at the nanometric scale as evidenced by X-ray scattering and at the micrometric distances as evidenced by TEM (thin plates in all cases); (*iii*) in contrast, the catalytic routes from **DH** or **DM** always led to grains irregular in size and geometry. Furthermore, the X-ray scattering does not exhibit any reasonably sharp signals.

Experimental

All reactions were carried out under argon using a vacuum line and Schlenk techniques. Solvents were dried and distilled just before use. IR data were obtained on a Perkin-Elmer 1600 FT IR spectrophotometer using KBr pellets. The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DPX-200 spectrometer and the ^{29}Si NMR spectra were recorded on a Bruker WP-200 SY spectrometer. The ^{29}Si CP-MAS NMR spectra were recorded on a Bruker Avance 300 spectrometer operating at 59.6 MHz using a recycling delay of 10 s and a contact time of 5 ms. The spinning rate was 5 kHz. Chemical shifts are given relative to tetramethylsilane. The nitrogen adsorption–desorption isotherms at 77.35 K were recorded on a Micromeritics Gemini III 2375 apparatus. The specific surface area was determined using the BET equation. The pore size distribution was calculated using the BJH method, and the microporous volume was estimated by the t-plot method using the Harkins and Jura standard isotherm. The differential scanning calorimetry were obtained on a Mettler DSC 30. The X-ray experiments were performed on several apparatus, either on a classical θ-2θ goniometer (Seifert MZ4) or an imaging plate two-dimensional detector (Marresearch 2D Image-Plate) with a rotating anode apparatus (Rigaku RU 200). The radiation is Cu Kα (λ = 1.5418 Å) for both. The microscopy electronic transmission was realized on a Cambridge Stereoscan 360. Elemental analyses were carried out by the Service Central de Micro-Analyse du CNRS. The percentages of oxygen were calculated by difference. The bis-(dialkoxymethylsilyl) precursors **DM1**–**DM5** were prepared according to literature procedures (33). The synthesis of 1,4-bis(dihydroxymethylsilyl)benzene **DH1** has been previously reported (26).

4,4′-Bis(methyldihydroxysilyl)biphenyl DH2

A suspension of 4,4′-bis-(methyldimethoxysilyl)biphenyl **DM2** (0.950 g, 2.62 mmol) in 4.5 mL of ether was stirred vigorously with 5 mL of 0.5% acetic acid solution in water for 3 days. The resulting white suspension was filtered and the solid was washed three times with acetone and ether. The fine white solid was dried for 1 day under vacuum at room temperature and gave 4,4′-bis(methyldihydroxysilyl)biphenyl **DH2** in 58% yield (0.465 g, 1.52 mmol). ^{1}H NMR (DMSO-d_6) δ (ppm): 7.66 (8H, s), 6.40 (4H, s), 0.19 (6H, s). ^{13}C NMR (DMSO-d_6) δ (ppm): 144.7, 139.3, 134.9, 126.6, 0.38. ^{29}Si NMR (DMSO-d_6) δ (ppm): –21.2. ^{29}Si CP-MAS NMR δ (ppm): –16.5. Anal. calcd. for $C_{14}H_{18}O_4Si_2$ (%): C 54.87, H 5.92, Si 18.33; found (%): C 54.82, H 5.79, Si 18.80. DSC: endothermic peak 210 °C.

Phase transfer catalysis route: **DM2** (1 g, 2.76 mmol); 4 mL Et$_2$O; 3.2 mL AcOH 0.5% in water; TEApTS (0.083 g, 0.276 mmol); stirring 1 day; **DH2** yield 68% (0.575 g, 1.88 mmol).

4,4′-Bis(dihydroxymethylsilyl)stilbene DH3

A suspension of 4,4′-bis(methoxymethylsilyl)stilbene **DM3** (0.630 g, 1.62 mmol) in 10 mL of ether was stirred vigorously with 10.3 mL of 0.5% acetic acid solution in water for 10 days. The same work up led to 4,4′-bis(dihydroxymethylsilyl)stilbene **DH3** as a white solid in 40% yield (0.215 g, 0.65 mmol). ^{1}H NMR (DMSO-d_6) δ (ppm): 7.68 (4H, d), 7.59 (4H, d), 7.29 (2H, s), 6.37 (4H, s), 0.39 (6H, s). ^{13}C NMR (DMSO-d_6) δ (ppm): 139.7, 138.1, 134.7, 129.5, 126.4, 0.02. ^{29}Si NMR (DMSO-d_6) δ (ppm): –21.4. ^{29}Si CP-MAS NMR δ (ppm): –11.0. Anal. calcd. for $C_{16}H_{20}O_4Si_2$ (%): C 57.80, H 6.06, Si 16.90; found (%): C 57.58, H 5.92, Si 17.15. DSC: endothermic peak 205 °C.

Phase transfer catalysis route: **DM3** (0.6 g, 1.55 mmol); 5 mL Et$_2$O; 4.7 mL AcOH 0.5% in water; TEApTS (0.047 g, 0.155 mmol); stirring 7 days; **DH3** yield 50% (0.257 g, 0.775 mmol).

4,4′-Bis(dihydroxymethylsilyl)diphenylacetylene DH4

A suspension of 4,4′-bis(dimethoxymethylsilyl)diphenylacetylene **DM4** (1.62 g, 4.2 mmol) in 8 mL of ether was stirred vigorously with 6.65 mL of 0.5% acetic acid solution in water for 55 days. 4,4′-Bis(dihydroxymethylsilyl)diphenylacetylene **DH4** was isolated as a beige solid in 35% yield (410 mg, 1.26 mmol). ^{1}H NMR (DMSO-d_6) δ (ppm): 7.63 (4H, s), 7.54 (4H, s), 6.49 (4H, s), 0.19 (6H, s). ^{13}C NMR (DMSO-d_6) δ (ppm): 141.2, 134.5, 131.2, 123.7, 90.8, 0.18. ^{29}Si NMR (DMSO-d_6) δ (ppm): –21.7. ^{29}Si CP-MAS NMR δ (ppm): –14.7, –16.8. Anal. calcd. for $C_{16}H_{18}O_4Si_2$ (%): C 58.16, H 5.49, Si 17.00; found (%): C 58.42, H 5.89, Si 17.51. DSC: endothermic peak 211 °C.

4,4′-Bis(dihydroxymethylsilyl)diphenylbut-1,4-diyne DH5

A suspension of 4,4′-bis(dimethoxymethylsilyl)diphenyl-but-1,4-diyne **DM5** (1.22 g, 2.98 mmol) in 10 mL of ether was stirred vigorously with 3.5 mL of 0.5% acetic acid solution in water for 30 days. Similarly, 4,4′-bis(dihydroxymethylsilyl)diphenylbut-1,4-diyne **DH5** was obtained as a beige solid in 8% yield (0.084 g, 0.238 mmol). ^{1}H NMR (DMSO-d_6) δ (ppm): 7.60 (8H, s), 6.54 (4H, s), 0.19 (6H, s).

^{13}C NMR (DMSO-d_6) δ (ppm): 141.2, 134.5, 132.06, 122.7, 85.8, 75.1, 0.11. ^{29}Si NMR (DMSO-d_6) δ (ppm): –21.7. ^{29}Si CP-MAS NMR δ (ppm): –13.7, –16.7. Anal. calcd. for $C_{18}H_{18}O_4Si_2$ (%): C 60.99, H 5.12, Si 15.85; found (%): C 60.82, H 5.48, Si 16.07. DSC: endothermic peak 185 °C.

Phase transfer catalysis route: **DM5** (0.410 g, 1 mmol); 3.4 mL Et$_2$O; 1.2 mL AcOH 0.5% in water; TEApTS (0.30 g, 0.1 mmol); stirring 12 days; **DH5** yield 25% (0.089 g, 0.25 mmol).

1,2-Bis(dimethoxyphenylsilyl)ethane DM6

1,2-Bis(dichlorophenylsilyl)ethane was prepared from dichlorovinylsilane (4.06 g, 20 mmol) dissolved in 20 mL dry hexane, phenyldichlorosilane (15.6 g, 90 mmol), and 0.01% of H$_2$PtCl$_6$ in 20 mL of dry hexane as described in the literature (43). The methanolysis was then performed by addition of 5.54 mL of Et$_3$N and 1.7 mL of MeOH. The mixture was stirred for 2 h and the solution was then filtered. The organic solvent was pumped off and the corresponding crude yellow oil was distilled under vacuum (bp 90–100 °C, 5×10^{-2} mbar) to afford 1,2-bis(dimethoxyphenylsilyl)ethane **DM6** in 55% yield (3.98 g, 11 mmol). ^{1}H NMR (CDCl$_3$) δ (ppm): 7.60 (2H, m), 7.61 (4H, d), 7.40 (8H, m), 3.60 (12H, s), 0.86 (4H, s). ^{13}C NMR (CDCl$_3$) δ (ppm): 134.8, 130.5, 128.3, 51.1, 3.35. ^{29}Si NMR (CDCl$_3$) δ (ppm): –16.15. Anal. calcd. for $C_{18}H_{26}O_4Si_2$ (%): C 59.63, H 7.23, Si 15.49; found (%): C 59.52, H 7.19, Si 15.81.

1,2-Bis(dihydroxyphenylsilyl)ethane DH6

A suspension of 1,2-bis(dimethoxyphenylsilyl)ethane **DM6** (1.08 g, 2.98 mmol) in 6 mL of ether was stirred vigorously with 6 mL of 0.5% acetic acid solution in water for 6 days. The same treatment led to 1,2-bis(dihydroxyphenylsilyl)ethane as a white solid in 20% yield (182 mg, 0.6 mmol). ^{1}H NMR (DMSO-d_6) δ (ppm): 7.56 (2H, m), 7.34 (8H, d), 6.28 (4H, s), 0.56 (4H, s). ^{13}C NMR (DMSO-d_6) δ (ppm): 134.8, 128.3, 4.8. ^{29}Si NMR (DMSO-d_6) δ (ppm): –18.9. Anal. calcd. for $C_{14}H_{18}O_4Si_2$ (%): C 54.87, H 5.92, Si 18.33; found (%): C 54.52, H 5.71, Si 18.12.

Thermal polycondensation of DH1 (solids Table 3, entries 1–5)

General procedure

A sample of **DH1** grounded and deposited into a cupel was heated in an oven under air at a given temperature (the increase of temperature was 10 °C/min). The final temperature was maintained for various lengths of time. In all cases a white powder was obtained. ^{13}C CP-MAS NMR data were the same for all the solids: δ (ppm): 138, 132, –1.7. ^{29}Si CP-MAS NMR data were the same for solids entries 1–4: δ (ppm): –15.9, –17.2, –24, –33. The specific surface area (S_{BET}) was <10 m^2 g^{-1} in all cases.

Solid Table 3, entry 1:

Temperature 165 °C for 5 h. FT IR (KBr) ν (cm^{-1}): 1050, 1147, 1265, 3180.

Solid Table 3, entry 2:

Temperature 170 °C for 5 h. FT IR (KBr) ν (cm^{-1}): 1050, 1147, 1259, 3145, 3615. Anal. calcd. for $C_8H_{10}O_2Si_2$ (%): C

39.48, H 5.15, Si 28.87; found (%): C 43.87, H 5.73, Si 24.09; this corresponds to $C_{8.5}H_{13.4}O_{3.8}Si_2$.

Solid Table 3, entry 3:

Temperature 180 °C for 0.75 h. FT IR (KBr) ν (cm^{-1}): 1050, 1147, 1259, 3250, 3620. Anal. calcd. for $C_8H_{10}O_2Si_2$ (%): C 39.48, H 5.15, Si 28.87; found (%): C 43.33, H 6.12, Si 28.08; this corresponds to $C_{7.2}H_{12.2}O_{2.8}Si_2$.

Solid Table 3, entry 4:

Temperature 190 °C for 24 h. FT IR (KBr) ν (cm^{-1}): 1050, 1147, 1259, 3350, 3620. Anal. calcd. for $C_8H_{10}O_2Si_2$ (%): C 39.48, H 5.15, Si 28.87; found (%): C 44.79, H 5.44, Si 29.03; this corresponds to $C_{7.2}H_{10.5}O_{2.5}Si_2$.

Solid Table 3, entry 5 (DH1t):

Temperature 250 °C for 72 h. FT IR (KBr) ν (cm^{-1}): 1050, 1147, 1265, 3664. ^{29}Si CP-MAS NMR δ (ppm): –33. Anal. calcd. for $C_8H_{10}O_2Si_2$ (%): C 39.48, H 5.15, Si 28.87; found (%): C 39.48, H 2.76, Si 28.40; this corresponds to $C_8H_{10}O_{2.2}Si_2$.

Thermal polycondensation of DH3 and DH5

The procedure was the same as above, the compound **DH** was heated at 250 °C for 72 h under argon (**DH3** and **DH5**). S_{BET} was <10 m^2 g^{-1} in all cases.

DH3t

White powder. FT IR (KBr) ν (cm^{-1}): 1080, 1152, 1265, 3620. ^{13}C CP-MAS NMR δ (ppm): 142, 133, 128, 125, –0.2. ^{29}Si CP-MAS NMR δ (ppm): –25, –31.

DH5t

Orange powder. FT IR (KBr) ν (cm^{-1}): 1080, 1152, 1265, 3620. ^{13}C CP-MAS NMR δ (ppm): 133, 126, 125, 124, 82, 78, –2. ^{29}Si CP-MAS NMR δ (ppm): –25, –31.

Catalytic polycondensation of DH1, DH3, and DH5

General procedure

The precursor **DH** was dissolved in MeOH or THF containing 1 mol% of the catalyst TBAF at room temperature. After various reaction times a gel or a precipitate formed, which was aged for 5 days. It was then ground in a mortar and washed with ethanol, acetone, and ether. The resulting powder was dried under vacuum (10^{-1} mbar) for 12 h at room temperature. The ^{13}C CP-MAS NMR data were the same as those of the corresponding solids obtained by the thermal route.

DH1a:

1.15 g (5 mmol) of **DH1**, 10 mL of THF (conc. 0.5 M), 50 μL of a 1 M solution of TBAF, gel after 24 h, white powder, 1.00 g (103%). FT IR (KBr) ν (cm^{-1}): 1060, 1147, 1265 3450. ^{29}Si CP-MAS NMR δ (ppm): –24, –33. S_{BET} (m^2 g^{-1}): 850.

DH3a:

0.28 g (0.84 mmol) of **DH3**, 2.8 mL of THF (conc. 0.3 M), 8 μL of a 1 M solution of TBAF, gel after 15 min, white powder, 0.25 g (100%). FT IR (KBr) ν (cm^{-1}): 1080, 1152, 1265 3620. ^{29}Si CP-MAS NMR δ (ppm): –31. S_{BET} (m^2 g^{-1}): 910.

DH5a:

0.50 g (1.41 mmol) of **DH5**, 4.7 mL of THF (conc. 0.3 M), 14 μL of a 1 M solution of TBAF, gel after 15 min, orange powder, 0.45 g (100%). FT IR (KBr) ν (cm^{-1}): 1080, 1152, 1265 3620. ^{29}Si CP-MAS NMR δ (ppm): –25, –31. S_{BET} (m^2 g^{-1}): 157.

Catalytic polycondensation of DM1, DM3, and DM5 (sol–gel route)

General procedure

A solution in THF of 1 mol% of the catalyst TBAF and water was added to a solution of the precursor **DM** in THF at room temperature. After various reaction times a gel or a precipitate formed, which was treated as above leading to a powder. The FT IR and ^{13}C CP-MAS NMR data were the same as those of the corresponding solids obtained by the thermal route, an additional signal at δ = 50 ppm owing to residual methoxy groups was present in all cases.

DM1a:

2.13 g (7.44 mmol) of **DM1**, 7.10 mL of THF (conc. 1 M), 74.4 μL of a 1 M solution of TBAF, 270 μL of water, gel after 5 min, white powder (1.48 g, 103%). ^{29}Si CP-MAS NMR δ (ppm): –15, –24, –33. S_{BET} (m^2 g^{-1}): 1000.

DM3a:

0.54 g (1.39 mmol) of **DM3**, 4.7 mL of THF (conc. 0.3 M), 14 μL of a 1 M solution of TBAF, 50 μL of water, gel after 15 min, white powder (0.45 g, 109%). ^{29}Si CP-MAS NMR δ (ppm): –25, –31. S_{BET} (m^2 g^{-1}): 450.

DM5a:

0.75 g (1.83 mmol) of **DM5**, 6.1 mL of THF (conc. 0.5 M), 18 μL of a 1 M solution of TBAF, 66 μL of water, gel after 5 min, orange powder (0.58 g, 100%). ^{29}Si CP-MAS NMR δ (ppm): –25, –31. S_{BET} (m^2 g^{-1}): 500.

A metal-free catalytic intramolecular hydrosilylation[1]

Hans-Uwe Steinberger, Christian Bauch, Thomas Müller, and Norbert Auner

Abstract: A metal-free catalytic intramolecular hydrosilylation reaction is reported. The key intermediates in the catalytic cycle are silyl cationic species. The reaction is used to produce 2-silanorbornanes **2** from 3-cyclopentenemethylsilanes **1** under mild conditions and in high isolated yields.

Key words: hydrosilylation, catalysis, silaheterocycles, silyl cations.

Résumé : On a effectué une réaction d'hydrosilylation intramoléculaire catalytique n'impliquant aucun métal. Les intermédiaires clés dans le cycle catalytique sont des espèces cationiques silylées. On utilise la réaction pour préparer des 2-silanobornanes (**2**) avec des rendements élevés à partir de cyclopent-3-èneméthylsilanes (**1**), dans des conditions douces.

Mots clés : hydrosilylation, catalyse, silahétérocycles, cations silyles.

[Traduit par la Rédaction]

Introduction

The hydrosilylation reaction, the formal addition of a Si-H functionality across a C—C multiple bond, is one of the most widely used methods for the formation of Si—C bonds, with a strong impact on laboratory work as well as on commercial processes (1). Since Speier's original finding (2) that chloroplatinic acid efficiently catalyzes this reaction, platinum catalysts are the standard reagents in this type of chemistry. Due to Chalk and Harrods' mechanistic investigations in 1965 (3), the course of the catalytic cycle is quite well understood and therefore, stereo- and regiochemistry in the products can be reasonably well predicted. There is, however, a recent interest in transition metal-free processes with possible applications in polymer chemistry. Free-radical-induced hydrosilylation reactions (1a, 1c), a plausible alternative to the metal-catalyzed reaction, are severely hampered by possible side reactions as for example, radical polymerization of the unsaturated organic compound (4). A catalytic hydrosilylation reaction based on silyl cationic intermediates was first suggested by Lambert and Zhao (5) in 1996. Their finding that trityl cation efficiently catalyzes the hydrosilylation reaction between triethylsilane and diphenylethene in toluene solution suggests that the chain propagators in this process are silylated arenium ions and β-silyl substituted carbocations (5). Similarly, we report here a convenient procedure for a catalytic intramolecular hydrosilylation reaction giving silaheterocycles under mild conditions and in high isolated yields. The key intermediates in this process are silanorbornyl cations, intramolecularly π-stabilized silyl cations (6).

Results and discussion

Treatment of cyclopentenemethyl silanes **1** with catalytic amounts of trityl tetrakispentafluorophenyl borate (TPFPB) (typical molar ratio **1**:TPFPB = 600–100:1) in toluene at room temperature resulted in the clean formation of 2-silanorbornanes **2** in high isolated yields (85–94%, see Scheme 1).

The silanorbornanes **2** were isolated as mixtures of exo and endo diastereomers with exo to endo ratios of about 2.7–1.8:1 (see also Table 1). Silanorbornanes **2** were characterized by standard NMR methods and analytical procedures. In the case of **2a**, the exo and endo diastereomers were separated by preparative gas chromatography; this allowed the unequivocal assignment of the complex ¹H and ¹³C NMR spectra of the silanorbornanes **2**.

The intramolecular hydrosilylation of the cyclopentenemethylsilanes **1** was thought to proceed via silyl cationic

Scheme 2. Proposed catalytic cycle for the intramolecular hydrosilylation of **1**.
species (see Scheme 2, eq. [1]). In the first step, the catalytic active species was formed by a hydride transfer reaction from silanes **1** to trityl cation (7). The by-product triphenylmethane was identified by NMR analysis.[3] The silylium ions **3** were only transient species and underwent fast intramolecular reactions to the more stable silanorbornyl cations **4** (Scheme 2, eq. [2]). In stoichiometric reactions, the silanorbornyl cations **4** can be synthesized and are persistent at ambient conditions (6). In the presence of excess silanes **1**, however, a second hydride transfer took place, which resulted in the finite generation of the silanorbornanes **2** with newly formed Si—C and C—H bonds and the silylium ions **3**, which started new catalytic cycles. Thus, both silyl cationic species, the trivalent silyl cation **3** and the silanorbornyl cation **4**, were propagators in the catalytic process.

This mechanistic proposal is supported by deuterium labeling experiments. The catalytic reaction of [D]-**1a** with trityl cation produced exclusively the exo and endo 3-neopentyl mixture of the *exo*-6-deutero norbornane **2a** (Table 1, entry 4 and Scheme 3). The exclusive exo-orientation of the deuterium atom in 6-[D]-**2a** is verified by one- and

Scheme 3.

[D]1a, R^1 = *neo*-C$_5$H$_{11}$

***exo* 6-[D]2a,** R^1 = *neo*-C$_5$H$_{11}$
two-dimensional ^{1}H NMR spectroscopy and by comparison with the ^{1}H NMR spectra of the separated 3-exo- and 3-endo-isomers of **2a**. The selective formation of *exo*-6-[D]-**2a** is reminiscent of the preferred formation of exo products in the solvolysis of 2-norbornanes (8) and is best explained by an exclusive exo addition of a deuteride equivalent at the C=C double bond in the intermediate silanorbornyl cation **4** (see Scheme 4). The endo attack on the C=C double bond was efficiently blocked by the bridging SiMe$_2$ group. Previous studies (6) definitely ruled out the possibility of an achievable fast degenerate equilibrium between two β-silyl-

^{3}Triphenylmethane: ^{1}H NMR (400 MHz, 300 K, C$_6$D$_6$) δ: 7.09 (br, 15H), 5.41 (s, 1H). ^{13}C NMR (100 MHz, 300 K, C$_6$D$_6$) δ: 57.1, 126.5, 128.5, 129.6, 144.2.

endo 6-[D]2a, $R^1 = neo$-C_5H_{11}

exo 6-[D]2a, $R^1 = neo$-C_5H_{11}
substituted carbocations. Therefore, the labeling experiments give additional evidence for the silanorbornyl cations **4** as intermediates in this catalytic process.

Density functional calculations (9) at the B3LYP/6-311G(2d,p)//B3LYP/6-31G(d) + ΔZPVE level of theory (10, 11) indicated that the suggested catalytic process was an overall exothermic process. Thus, for R^1 = H the intramolecular reaction **3a → 4a** (eq. [2], Scheme 2) was exothermic by 19.8 kcal mol^{-1}. The second reaction (eq. [3]) of the catalytic process was predicted to be endothermic by 9.0 kcal mol^{-1}. This resulted in an overall exothermic catalytic cycle (by 10.8 kcal mol^{-1}).[4] Addition of thermal energies and entropic factors suggested that the process was also exergonic at 298 K (Δ*G*(calcd.) = –9.4 kcal mol^{-1}, at B3LYP/6-31G(d)).

The catalytic intramolecular hydrosilylation reaction (shown in Scheme 3) was more efficient than the traditional hydrosilylation reaction using platinum catalysts. Thus, reaction of **1a** with hexachloroplatinic acid in toluene at room temperature proceeded only sluggishly and heating to reflux for several hours was needed for complete transformation into **2a** (see Table 1, entry 5) (12). This is in agreement with observations by Cremer and Blankenship (13) and Sakurai and co-workers (14), who reported that the intramolecular hydrosilylation reaction forming silanorbornanes using platinum catalysts needed more vigorous reaction conditions (i.e., for the reaction **1a → 2a** (R^1 = H): 100 h, 130 °C, neat substance).

Conclusion

In summary, we report a metal-free catalytic reaction for the intramolecular hydrosilylation of C=C double bonds giving silanorbornanes **2** in high yields under mild reaction conditions. The process advances via silylcationic species with silanorbornyl cations **4**, as the key intermediates. Similar intramolecular reactions can be envisaged for other intramolecular stabilized silylcations (15, 16) and the scope of

Chart 1.

[D]-1a
this reaction is currently under investigation in our laboratory.

Experimental

General

All reagents were obtained from commercial suppliers and were used without further purification. THF was distilled from sodium – potassium alloy – benzophenone; benzene and toluene were distilled from sodium. All reactions were carried out in oven-dried glassware under an inert atmosphere of argon. 3-(3-Cyclopentenyl)-1-chloro-1,5,5-trimethyl-2-silahexane (12) and TPFPB (17) were prepared as described in the literature. NMR spectra were recorded on Bruker AM 600 and DPX 300 instruments. ^{1}H NMR spectra were calibrated using residual non-deuterated solvents as internal reference, ^{13}C NMR spectra using the central line of the solvent signal. ^{29}Si NMR spectra were recorded using the INEPT pulse sequence and were calibrated using external TMS (δ^{29}Si = 0.0).

exo- and *endo-*2,2-Dimethyl-3-neopentyl-2-silabicyclo[2.2.1]heptane (2a)

Silane (1.3 g, 6.19 mmol) **1a** (12) was added slowly to a solution of 10 mg TPFBP in 20 mL toluene. After 1 h,

Molecular modelling of self-assembled alkynyl monolayer structures — Unnatural symmetry units, surface bonding, and topochemical polymerization[1]

Adam J. Dickie, Ashok K. Kakkar, and Michael A. Whitehead

Abstract: Geometric modelling techniques are used to map the potential energies of packing for self-assembled alkyl- and phenyl-backboned monolayers across a range of intermolecular separations. Natural packing distances of 4.2–4.4 Å produce less stable, more isotropic monolayers because of repulsive interchain contacts. Optimizations at unnatural surface densities found thin films of lower energy and higher symmetry existed at increased chain–chain separations. Head-group bonding is therefore identified as a force for controlling monolayer order. Analysis of the natural monolayer structures on a silicon dioxide surface determined the favourable head-group structures, and allowed the topochemical polymerization of *p*-bis(butadiynyl)benzene monolayers to be rationalized.

Key words: self-assembled monolayers, molecular modelling studies, repeating symmetry units, thin-film order, topochemical polymerization.

Résumé : On a utilisé des techniques de modélisation géométrique pour établir une carte des énergies potentielles d'empilement des monocouches autoassemblées à squelette d'alkyle ou de phényle sur toute une plage de distances intermoléculaires. Les distances normales d'empilement de 4,2 à 4,4 Å produisent des monocouches plus isotropes et moins stables en raison des contacts répulsifs entre les chaînes. Des optimisations à des densités de surface non naturelles ont permis de montrer que, à des distances interchaînes plus élevées, il existe des films minces d'énergie plus faible et de symétrie plus élevée. La liaison du groupe de tête a donc été identifiée comme la force qui contrôle l'ordre de la monocouche. L'analyse des structures de la monocouche naturelle sur une surface de bioxyde de silice permet de déterminer les structures favorables du groupe de tête et de rationaliser la polymérisation topochimique de monocouches de *p*-bis(butadiynyl)benzène.

Mots clés : monocouches autoassemblées, études de modélisation moléculaire, unités de symétrie qui se répètent, ordre d'un film mince, polymérisation topochimique.

Introduction

The creation of ordered organic materials on solid-state interfaces is critically dependant upon molecular geometry. The phenomenon of interfacial self-assembly was first realized (1) when long, hydrophobic alkyl chains were observed to spontaneously create close-packed, nearly crystalline structures at the water surface. The key to formation of these

ordered Langmuir monolayers was identified as the favourable packing interactions among the long alkyl chains. The geometry of all trans -CH_2- molecules allows close-packing of alkyl chains, with the "bumps" of one methylene projection (the van der Waals radius of the carbon–hydrogen plane) fitting neatly into the "hollows" (the backside of the carbon atom, with no hydrogen bonds) of a neighbouring unit (2). The packing forces among the -CH_2- groups involve attractive van der Waals interactions. These nonbonded forces are additive, meaning increased stability for longer chains and larger assemblies, and are thermodynamically weak, meaning structural defects can eventually be removed and geometries optimized to construct the lowest-energy supramolecular configuration.

The same geometric packing forces between alkyl chains were used to develop the original self-assembled monolayers (SAMs) at liquid and (or) solid interfaces, such as alkanethiolates on Au or organosilanes on SiO_2 (3, 4). Although the solid surface drives the adsorption of molecules out of solution, and provides a stable geometric space for weak organic intermolecular interactions, the resulting structure and order of the self-assembled thin film is determined primarily

by molecular packing forces. In fact, during self-assembly of alkylsilanes on inorganic oxide substrates, the organic chains are essentially detached from the underlying surface (5), existing as a Langmuir-type monolayer upon a thin layer of surface-adsorbed H_2O. The alkylsilane chains are free to diffuse laterally across the surface, packing into ordered assemblies before surface bonding or cross-linking of the silanol headgroups (6, 7). Geometric differences between optimal chain packing separations and Si—O—Si bond distances (8) gives rise to competitive forces in alkylsilane SAMs, with head-group bonding disrupting the order established by chain–chain interactions.

Geometric modelling will therefore provide unique theoretical insight into the order and structure of self-assembled monolayers. Organic monolayers with functional device properties, such as π-conductivity, can be easily self-assembled on Si(100)–SiO$_2$ surfaces, using acid–base hydrolytic chemistry (9). The hydrolysis of surface-bound [Sn]-NEt$_2$ groups with alkyne-terminated organic molecules, such as 1,9-decadiyne or p-diethynylbenzene, creates thin films of good structural quality on oxide substrates. The use of these chromophoric thin films as molecular electronic devices is dependent on the interfacial monolayer order, and on the ability to manipulate and optimize surface geometries. Modelling techniques have recently been introduced (10) that allow the monolayer surface to be reduced and described as natural symmetry units, natural because they effectively reproduce the density and packing structure of an infinite thin film. In this article, the rigid-rod scanning method (RRSM) (10, 11) and the periodic optimizations of chains (PGO-C) and surfaces (PGO-S) (10), are used to calculate monolayer structures away from the natural packing densities, creating *unnatural* symmetry units. Such calculations, on alkyl-backboned Sn-(C≡C)$_m$-(CH$_2$)$_n$-(C≡C)$_m$-H (m = 0 to 1, n = 2–10) and phenyl-backboned Sn-(C≡C)$_m$-p-C$_6$H$_4$-(C≡C)$_m$-H (m = 0–2) molecules, provide information on the intermolecular interaction forces, and allow new theoretical symmetry patterns, based upon new geometric arrangements, to be identified.

The modelling methods are extended to two structural problems involving the chromophoric thin films. In the first study, surface bonding of Sn headgroups is investigated by calculating the stability of monolayers at full coverage, with zero, one, or two neighbouring cross-links. These calculations not only determine the most favourable surface conformations, they highlight how the order established by organic chain packing influences the underlying surface structure.

In the second study, the topochemical polymerization in Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayers is considered. By exposing a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H thin film to UV radiation, photopolymerization of the diacetylene units occurs, as evidenced visually by the appearance of a blue film, and spectroscopically by FT-IR, UV–vis, and ellipsometric methods (9a). Because surface polymerization of diacetylene is subject to strict geometric constraints (12, 13) molecular

modelling calculations prove to be very successful in describing the structure and mechanism of thin film photopolymerization.

Theoretical methods

The rigid-rod scanning method (RRSM)

Optimized models of Sn-(C≡C)$_m$-(CH$_2$)$_n$-(C≡C)$_m$-H (m = 0 to 1, n = 2–10) and Sn-(C≡C)$_m$-p-C$_6$H$_4$-(C≡C)$_m$-H (m = 0–2) were oriented so that the primary inertial axis of each molecule was aligned with the z-axis, the carbon atoms were situated within the yz plane, and the Sn atom was at the origin (Fig. 1). Hexagonal 6 × 6 arrays of identical Sn-R chromophores were then constructed in the xy plane, with intermolecular separations ranging from d = 4.0 to d = 5.0 Å, in 0.1 Å increments. Intramolecular geometries were fixed, and the van der Waals energy (E_{vdW}) of the array was evaluated as a function of the intermolecular conformation angles θ (inertial axis twist), φ (in-plane axis tilt), and ψ (out-of-plane axis tilt) to find angle combinations that yielded low energy packing modes (11). The inertial axis (z-axis) twist (0° ≤ θ ≤ 360°) is defined as the rotation from the initial orientation, relative to the y-axis; calculations were performed along 5° increments. The in-plane (y-axis) tilt (–60° ≤ φ ≤ 60°) is defined as the displacement of the inertial axis from the z-axis normal, in the y-axis direction; calculations were performed at 1° increments. The out-of-plane (x-axis) tilt (–60° ≤ ψ ≤ 60°) is defined as the displacement of the inertial axis from the z-axis normal, in the x-axis direction, with 1° increments. Molecules located in odd-numbered in-plane rows were restricted to the vertical axis orientation θ$_1$, while molecules within even-numbered in-plane rows were restricted to θ$_2$; once the low-energy modes of (θ$_1$, θ$_2$) were identified, the angles φ and ψ were minimized. Single-point E_{vdW} calculations, parameterized (14) from similar molecular crystals, were performed with the MM$^+$ force field of HyperChem v5.1 (15).

Periodic geometry optimization of chains (PGO-C)

Hexagonal arrays of Sn-R chromophores, with orientations taken from RRSM intrinsic symmetry cells, were optimized under 6 × 6 boundary conditions: $a = b = (6 \times d$ Å), c = 30 Å, α = β = 90°, and γ = 120°, where d is the RRSM intermolecular separation. Sn atoms were fixed in space at a hexagonal separation of 4.4 Å throughout the optimization. Optimizations were performed with the Universal Force Field (UFF) force field (16) of Cerius2 version 3.5 (17). Global minimum structures were calculated with the Cerius2 Smart Minimizer[4] under high convergence[5] conditions. Charges were calculated with the charge equilibration method (18), a point charge interaction at variable distances r_{ij}, and were recalculated every 500 iterations until convergence criteria were met. Local minimum structures used a conjugate gradient algorithm, and recalculated charges every 100 iterations until standard convergence[6] criteria were met.

---

[4] The Cerius2 Smart Minimizer is a combination of Steepest Descent, Adopted Basis Newton–Raphson, Quasi-Newton, and Newton–Raphson gradient techniques.

[5] High convergence criteria: atom root mean square force = 1.0×10^{-3} kcal mol^{-1} Å^{-1}; atom maximum force = 5.0×10^{-3} kcal mol^{-1} Å^{-1}; energy difference = 1.0×10^{-4} kcal mol^{-1}; root mean square displacement = 1.0×10^{-5} Å; maximum displacement = 5.0×10^{-5} Å.

[6] Standard convergence criteria: atom root mean square force = 0.1 kcal mol^{-1} Å^{-1}; atom maximum force = 0.5 kcal mol^{-1} Å^{-1}; energy difference = 1.0×10^{-3} kcal mol^{-1}; root mean square displacement = 3.0×10^{-3} Å; maximum displacement = 1.5×10^{-2} Å.

Fig. 2. RRSM plot of E_{vdW} as a function of (θ_1, θ_2) for H-C≡C-(CH$_2$)$_6$-C≡C-Sn molecules, at a hexagonal separation of 4.4 Å.
A spline switching function is used for calculation of nonbonded interactions. Nonbonded energies are calculated up to 8.0 Å and smoothed off by 8.5 Å. Symmetries of packing were subsequently determined on the optimized 6 × 6 surfaces using the Cerius2 Symmetry calculator, with a tolerance set to 0.1 Å.

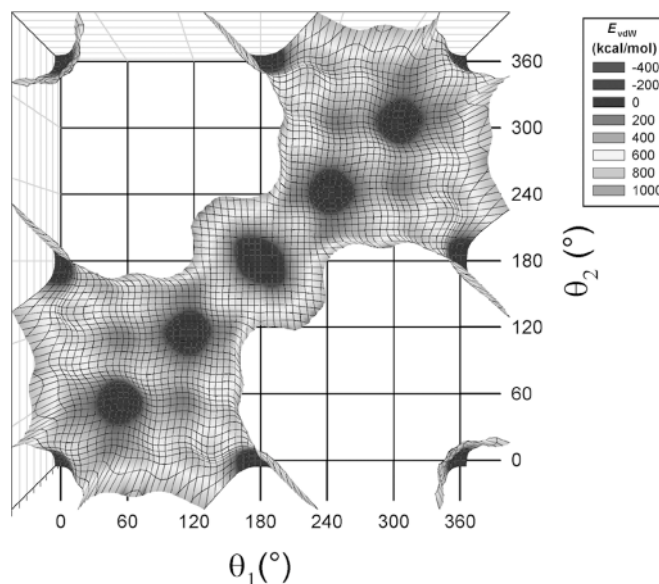
Periodic geometry optimization of surfaces (PGO-S)

Hexagonal arrays of Sn-R chromophores, with orientations taken from RRSM intrinsic symmetry cells, were attached to each oxygen binding site of a scaled tridymite SiO$_2$ surface (8), with intermolecular separation d = 4.4 Å. Symmetric monomer [R-Sn(OH)$_2$(OSi)], dimer [R-Sn(OH)(OSi)O], or trimer [R-Sn(OSi)O$_2$] structures were constructed across the entire surface to model Sn-O-Sn headgroup cross-linking. Periodic boundaries (6 × 6) were imposed on the surface models ($a = b$ = 26.56 Å, c = 35 Å, $\alpha = \beta$ = 90°, γ = 120°), and optimizations were performed with the silica surface fixed in space. Optimizations were performed with the UFF force field (16) of Cerius2 version 3.5 (17). Geometries were optimized with the Cerius2 Smart Minimizer[4] under high convergence[5] conditions. Charges were calculated with the charge equilibration method (18), a point charge interaction at variable distances r_{ij}, and were recalculated every 500 iterations until convergence criteria were met. A spline switching function is used for the calculation of nonbonded interactions. Nonbonded energies are calculated up to 8.0 Å and smoothed off by 8.5 Å. Symmetries of packing were subsequently determined on the optimized 6 × 6 surfaces using the Cerius2 Symmetry calculator, with a tolerance set to 0.1 Å.

Results and discussion: Unnatural symmetry units

Analysis of alkyl-backboned monolayers by RRSM calculations

Because hydrolytic SAMs are formed through a lateral diffusion process, rigid scans were performed on Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers across a sample distance range (d = 4.0–5.0 Å) to calculate structures and nonbonding ener-

gies at various theoretical stages of the self-assembly process. These calculations were repeated using different -(CH$_2$)$_n$- chain lengths (n = 2–10) to determine how the alkyl backbone influences the energy and geometry of the assembly. The scans of E_{vdW}, using the RRSM, found that all Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers were consistently minimized at hexagonal face-packing orientations, regardless of separation d or chain length: (θ_1, θ_2) = (0°, 0°), (60°, 60°), (120°, 120°), (180°, 180°) etc. The packing of alkyl-backboned monolayers is isotropic, producing plots of E_{vdW} vs. (θ_1, θ_2) with multiple energy minima (Fig. 2). A summary of the minimized E_{vdW} energies for Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers at distances between 4.0–5.0 Å is presented in Fig. 3, and Table 1 lists the calculated monolayer orientation angles across this distance range.


The alkyl-backboned monolayers reach a general E_{vdW} packing minimum at d = 4.5 Å, corresponding to the van der Waals radius of an alkyl chain (19*a*), and show a near-linear relation between E_{vdW} stabilization energy and increasing chain length, proof of the additive nature of -CH$_2$- packing forces. The tilt values calculated at d = 4.5 Å are optimal for in-plane -CH$_2$- packing, and correspond well with the tilts measured by X-ray diffraction for octadecyltrichlorosilane SAMs (20). No out-of-plane tilts are observed at this distance because (*i*) ψ values >0° will diminish the favourable in-plane packing forces, and (*ii*) no excess free volume exists in the hexagonal array. Compression of the monolayer (to d = 4.0–4.4 Å) produces tilt orientations identical to values observed at d = 4.5 Å, but at less favourable energies because of repulsive van der Waals overlap of the alkyl chains. As free volume is decreased in the monolayer, the chains are forced into in-plane packing conformations, and other orientations become extremely unfavourable. This phenomenon was previously observed in the natural symmetry descriptions of monolayer surfaces (10), where headgroup cross-linking compressed the ordered alkyl-chain surface, but in-plane symmetry was retained.

Table 1. Calculated in-plane (φ) and out-of-plane (ψ) tilts, relative to the molecular inertial axis, for Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers at face-packing orientations of (θ_1, θ_2) = (0°, 0°).

Fig. 3. Minimized E_{vdW} as a function of distance for Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers, calculated by the RRSM.

Fig. 4. In-plane packing structures of (a) Sn-C≡C-(CH$_2$)$_5$-C≡CH and (b) Sn-C≡C-(CH$_2$)$_6$-C≡CH at representative points along the E_{vdW} vs. distance curve. Minimum energy structures are located along the solid curve, nonminimum structures along the dashed line. Dark spheres represent Sn atoms, grey spheres C atoms, and white spheres H atoms.
A pronounced odd-even effect is seen for the various -(CH$_2$)$_n$- alkyl backbone lengths, in both the in-plane tilt values and the observation of a second E_{vdW} packing minimum at d = 5.0 Å. As shown in Fig. 4, these odd-even effects are related to the positioning of the uppermost C≡CH unit. Odd-number alkyl-backbone chains have greater natural inertial tilts than even-number chains (i.e., Sn-C≡C-(CH$_2$)$_5$-C≡CH inertial tilt = 24.3°, Sn-C≡C-(CH$_2$)$_6$-C≡CH inertial tilt = 19.6°) because the quasi-equatorial position of the uppermost acetylene group, opposite in direction to the lower C≡C group, requires a greater molecular tilt to align the upper acetylene with the lower Sn atom (the approximate inertial axis orientation) than an even-numbered chain. Therefore, odd-numbered chains display smaller tilts of the original inertial axis.

As separations increase from the d = 4.5 Å packing minimum, nonbonding energies decrease, because of reduced -CH$_2$- in-plane contacts. After a separation of 4.8 Å, enough free volume is introduced to the monolayer such that new close-packing conformations can be realized. For even-

numbered alkyl-backboned chains, tilting in the negative inertial axis direction reestablishes [$(n-1)/n$] close-contacts of the alkyl backbone, leading to the observed local minima. Similar [$(n-1)/n$] tilt structures have been recorded for alkanethiol monolayers on Au ($d = 4.97$ Å) (11, 19b, 21). Odd-number alkyl-backboned chains cannot undergo a negative axis tilt because of the equatorial and opposite position of the uppermost C≡CH group (Fig. 4a): negative inertial tilts put the upper acetylenes into repulsive contact. All Sn-C≡C-(CH$_2$)$_n$-C≡CH monolayers analyzed by the RRSM show significant out-of-plane tilts in the 4.8–5.0 Å region because at large separations, free volume cannot be filled through in-plane tilting alone. Close-contacts among densely packed in-plane rows are made by increasing the out-of-plane tilts.

For comparative insight, theoretical monolayers of Sn-(CH$_2$)$_n$-H ($n = 2$–10) were also analyzed by the RRSM. Figure 5 shows the minimized E_{vdW} energies for Sn-(CH$_2$)$_n$-H monolayers at distances between 4.0–5.0 Å, and Table 2 lists the orientation angles calculated for this distance range. The pure Sn-alkyl chains show nearly identical geometric and energetic results to the dialkyne-based monolayers, with isotropic hexagonal face-packing minima ((θ_1, θ_2) = (0°, 0°), (60°, 60°) etc.) and E_{vdW} packing minima at $d = 4.5$ Å. The Sn-(CH$_2$)$_n$-H chains do not show the strong odd-even effect observed for the dialkyne chains, because odd and even alkyl chains have similar inertial axes and geometries. All alkyl chains display the second packing minimum at $d = 5.0$ Å, because the quasi-equatorial position of hydrogen on an odd-number chain does not create significant repulsive overlaps for a negative inertial tilt orientation.

Given the similar nature of Sn-C≡C-(CH$_2$)$_n$-C≡CH and Sn-(CH$_2$)$_n$-H results, it is apparent that the alkyl backbone dominates the energy and geometry of Sn-C≡C-(CH$_2$)$_n$-C≡CH self-assembled monolayers. Although electronic π-π interactions are not directly calculable by the RRSM, at the E_{vdW} -CH$_2$- chain packing minimum the acetylene groups have a favourable 45° tilt orientation that corresponds to an ab initio calculated minimum geometry (22). The acetylene units, therefore, help stabilize the monolayer at the alkyl chain packing minimum, and play an important geometric role at higher chain separations.

Fig. 5. Minimized E_{vdW} as a function of distance for Sn-(CH$_2$)$_n$-H monolayers, calculated by the RRSM.
Analysis of phenyl-backboned monolayers by RRSM calculations

Rigid-rod energy scans were performed on phenyl-backboned, Sn-(C≡C)$_m$-p-C$_6$H$_4$-(C≡C)$_m$-H ($m = 0$–2) monolayers to determine theoretical close-packing conformations and energies over the $d = 4.0$–5.0 Å lateral movement range, and to examine the effect of alkyne length on phenyl monolayer structure. Figure 6 shows the minimized E_{vdW} packing energies as a function of distance for the phenyl-backboned monolayers, and Table 3 lists the calculated orientation angles from $d = 4.0$–5.0 Å. The RRSM analysis found consistent anisotropic packings for the phenyl-backboned chains, with (θ_1, θ_2) = (35°, –35°) throughout the distance range, regardless of alkynyl length.

Fig. 6. Minimized E_{vdW} as a function of distance for $Sn\text{-}(C\equiv C)_m$-$p\text{-}C_6H_4\text{-}(C\equiv C)_m\text{-}H$ monolayers, calculated by the RRSM.
As discussed previously (2, 10), the phenyl-based monolayer can only achieve close-packing (sixfold molecular contacts) in a herringbone arrangement, and all (θ_1, θ_2) E_{vdW} packing minima (Fig. 7) are equivalent through symmetry.

The steric and symmetric constraints required to pack phenyl-backboned monolayers into a restricted hexagonal space produces the unique herringbone structure that corresponds to minimum energy configurations observed by ab initio methods (23) and STM imaging of benzenethiol monolayers on Au (24). The phenyl chains do not have a local E_{vdW} lateral packing minima, however; instead, E_{vdW} minima are reached at 5.3–5.5 Å (not shown in Fig. 6), corresponding to the 5.1 Å van der Waals radius of Sn (15). Although the RRSM cannot identify the true π-π intermolecular assembly forces, it does correctly predict the geometric packing space, and shows generally favourable (negative) van der Waals energies at the ~4.5 Å natural packing density on SiO_2 surfaces (25).

Little change is seen in the $Sn\text{-}(C\equiv C)_m$-$p\text{-}C_6H_4\text{-}(C\equiv C)_m\text{-}H$ monolayer structure by varying m from 0 to 2. The most significant effect is an increase in molecular tilt at $d > 4.6$ Å, simply to reduce monolayer free volume. The steric bulk of the phenyl group dominates the assembly structure, strictly defining the conformations so that they are nearly independent of the intermolecular separation and alkynyl length.

Unnatural symmetry cells of alkyl-backboned monolayers

To more accurately determine the structures of alkyl-backboned monolayers at lateral separations away from the natural packing densities (*unnatural separations*), PGO-C calculations were performed on the RRSM-generated conformations, using the $Sn\text{-}C\equiv C\text{-}(CH_2)_6\text{-}C\equiv CH$ chain as a representative model. The PGO-C technique removes the rigid-

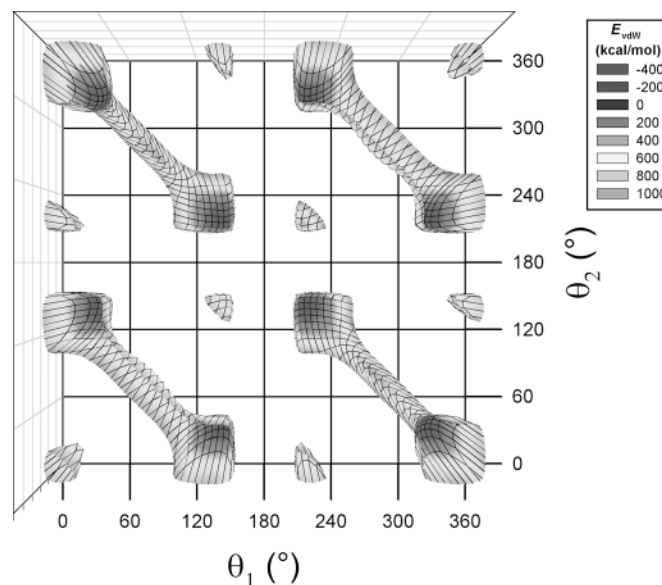
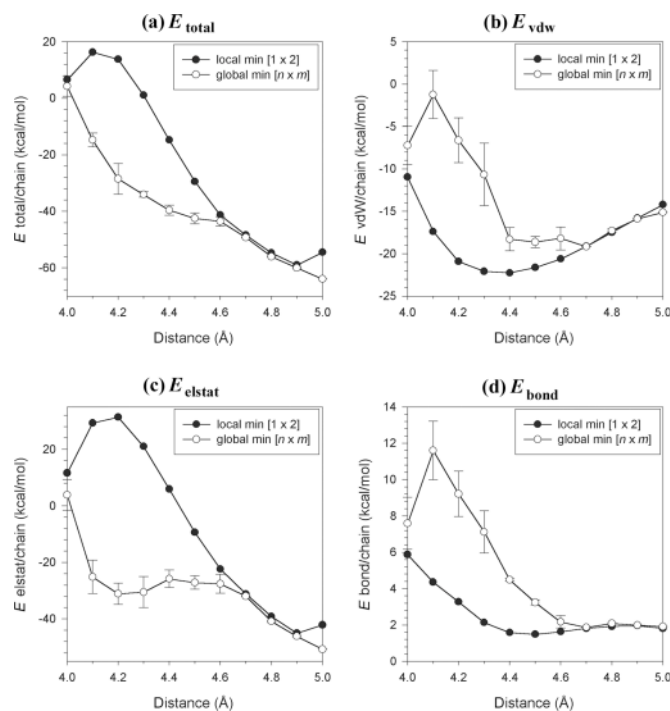
Fig. 7. RRSM plot of E_{vdW} as a function of (θ_1, θ_2) for $H\text{-}C\equiv C\text{-}p\text{-}C_6H_4\text{-}C\equiv C\text{-}Sn$ molecules at a hexagonal separation of 4.4 Å. All located energy minima are equivalent.


rod constraints, and optimizes for bond (E_{bond}), electrostatics (E_{elstat}), and E_{vdW} terms under periodic conditions to mimic an infinite surface structure. As well, by carefully choosing correct periodic boundary conditions (10), new, optimized units of symmetry can be found within the periodic box that effectively represent the infinite monolayer structure.

PGO-C calculations were carried out on $Sn\text{-}C\equiv C\text{-}(CH_2)_6\text{-}C\equiv CH$ structures at hexagonal intermolecular separations between 4.0 and 5.0 Å, and at six different initial face-packing orientations: $(\theta_1, \theta_2) = (0°, 0°)$, $(60°, 60°)$, $(120°, 120°)$, $(180°, 180°)$, $(240°, 240°)$, and $(300°, 300°)$. Two general types of structures were observed after the optimizations. By using a combination of minimization algorithms,[4] global minimum structures were obtained with [$n \times m$] symmetry descriptors (where the term [$n \times m$] refers to n in-plane by m out-of-plane units) that varied considerably

Fig. 8. PGO-C calculations of (*a*) E_{total} and the separate components, (*b*) E_{vdW}, (*c*) E_{elstat}, and (*d*) E_{bond} as a function of distance for Sn-C≡C-(CH$_2$)$_6$-C≡CH monolayers. The curve with open symbols corresponds to the global minimum structures, and the curve with filled symbols corresponds to the local minimum structures.

Fig. 9. Unnatural symmetry cells calculated by the PGO-C method for Sn-C≡C-(CH$_2$)$_6$-C≡CH monolayers, viewed in the *xy* and *xz* planes: (*a*) d = 4.2 Å, [6 × 6] symmetry; (*b*) d = 4.6 Å, [3 × 3] symmetry; (*c*) d = 4.7 Å, [1 × 2] symmetry; (*d*) d = 5.0 Å, [1 × 1] symmetry.


depending on the intermolecular separation d. Through use of lowered convergence conditions[6] and shorter iteration trials, local E_{vdW} minima were obtained with consistent [1 × 2] symmetry and geometries corresponding closely to the original RRSM results. In Fig. 8, the results of the PGO-C energy optimizations as a function of distance are shown, with separate curves representing the global minimum [$n \times m$] and local minimum [1 × 2] results. Error bars represent energy variations calculated for different initial (θ_1, θ_2) orientations. Total energies (Fig. 8*a*), and decompositions into van der Waals (Fig. 8*b*), electrostatic (Fig. 8*c*), and bonding (Fig. 8*d*) terms are presented, normalized for the number of chains per periodic box, where (16):

[1] $E_{total} = \sum E_{bond} + E_{vdW} + E_{elstat}$

and

[2] $E_{bond} = \sum E_{stretch} + E_{angle} + E_{torsion} + E_{inversion}$

Figure 9 diagrams the calculated geometries for selected symmetry units at unnatural separations, and Table 4 lists the PGO-C global minimum symmetry cells, calculated under 6 × 6 periodic boundaries.

In the distance range of 4.0–4.5 Å, a large energy difference exists between the local and global minimum structures because of repulsive interactions among the alkyl chains. Although the ordered [1 × 2] structures experience stabilizing (negative) E_{vdW} forces at these intermolecular separations, electrostatic repulsions from identically situated molecules result in high E_{total} values for the ordered structures. To re-

Table 4. PGO-C symmetries of packing for [$n \times m$] global minimum geometries of Sn-C≡C-(CH$_2$)$_6$-C≡CH monolayers at d = 4.0–5.0 Å, using initial [6 × 6] periodic boundary conditions.

5.0	[1 × 1]

duce the repulsive forces, the global minimum energy monolayers adopt lower symmetries of packing, from [6 × 6] to [3 × 3] to [1 × 3] unit cells, by orienting chains at slightly different angles of twist and tilt. The expense of higher van der Waals and bond energies is offset by the reduced E_{elstat}

energies for these structures. Figure 9a shows an example of a global minimum structure at 4.2 Å, with domain boundaries forming to reduce repulsions among ordered in-plane rows. The repulsive contacts increase the isotropy of the monolayer, and global minimum energies are observed to vary, depending on the initial face-packing angles, within this separation range. The global and local minimum curves converge at 4.0 Å because, at this low separation, the chain–chain separations fall into the range of intramolecular distances, producing inaccurate energy terms (Fig. 8).

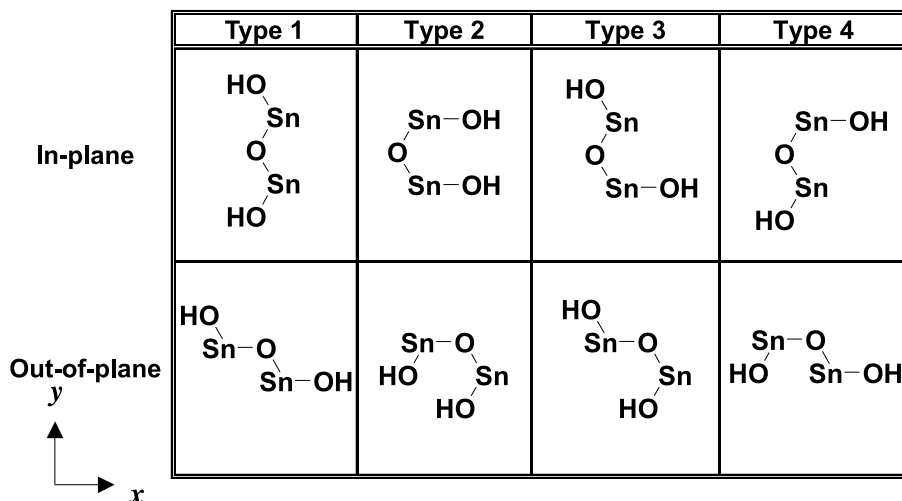
After the $-CH_2-$ van der Waals radii have been overcome, the two energy curves converge between 4.6–5.0 Å, and the global minimum structures demonstrate new, higher symmetries of packing, such as the herringbone structure at $d = 4.7$ Å (Fig. 9c) and the $[1 \times 1]$ structure at $d = 5.0$ Å (Fig. 9d). All energy terms show convergence, with identical results produced for each initial face-packing angle (Fig. 8). The global minimum models are energetically favoured because of more effective filling of surface free volume, through chain twists and tilts, than the rigid $[1 \times 2]$ structures with near identical conformations. The E_{total} values become more negative as the separation increases, mainly because of decreased Sn–Sn electrostatic interactions.

The PGO-C calculations show the range of possible structures available to the $Sn-C\equiv C-(CH_2)_6-C\equiv CH$ monolayer within the narrow distance range of 4.0–5.0 Å. The unnatural structures are highly isotropic in the range of alkyl chain overlap, but can become even more ordered than the natural symmetry structures with increasing intermolecular separation. These theoretical calculations suggest that decreasing the natural chain packing density, towards unnatural separations of 5.0 Å and beyond, will produce increasingly ordered thin films.

Unnatural symmetry cells of phenyl-backboned monolayers

PGO-C calculations were also performed on phenyl-backboned systems to determine the optimal symmetries of packing at unnatural separations beyond and below the natural chain densities. Calculations performed on $Sn-C\equiv C-p-C_6H_4-C\equiv C-H$ monolayers are used as representative of all phenyl-based chains. Figure 10 plots the calculated PGO-C energies (E_{total}) as a function of distance, and Fig. 11 shows the PGO-C geometry for the calculated symmetry cells. Optimizations from the initial RRSM herringbone orientations produced monolayers with $[1 \times 2]$ symmetry (Fig. 11a), nearly identical to the original scan structures. As shown in Fig. 10 the herringbone $[1 \times 2]$ units lie at or close to the global minima throughout the entire distance range. As in the RRSM results, energies are minimized at higher separations ($d = 5.0$ Å) to decrease electrostatic Sn–Sn repulsions. At lower, more repulsive separations ($d = 4.0$–4.2 Å), a lower symmetry, $[3 \times 2]$ packing cell was calculated to be the most favourable structure. As shown in Fig. 11c, the $[3 \times 2]$ unit cell is a modified herringbone structure, with four molecules having z-axis twists of ($\pm 45°$), and two at twists of ($\pm 15°$), to decrease repulsive interactions. Similar structures were previously observed for highly strained, natural phenyl surfaces on SiO_2 (10). Repetition of the PGO-C calculations, using the $[3 \times 2]$ produced models energetically equivalent to the $[1 \times 2]$ structures between $d = 4.3$–5.0 Å.

Fig. 10. PGO-C calculated energies as a function of distance for $Sn-C\equiv C-p-C_6H_4-C\equiv C-H$ monolayers.
Fig. 11. Unnatural symmetry cells calculated by the PGO-C method for $Sn-C\equiv C-p-C_6H_4-C\equiv C-H$ monolayers, viewed in the xy plane: (a) $d = 5.0$ Å, $[1 \times 2]$ symmetry; (b) $d = 5.0$ Å, $[1 \times 1]$ symmetry; (c) $d = 5.0$ Å, $[3 \times 2]$ symmetry.
To qualify the herringbone optimizations, $H-C\equiv C-p-C_6H_4-C\equiv C-Sn$ models with a face-packing orientation (θ_1, θ_2) = (0°, 0°) were also optimized from $d = 4.0$–5.0 Å. Only models from $d = 4.5$–5.0 Å yielded stable structures with a $[1 \times 1]$ symmetry (Fig. 11b), but at significantly higher energy than the $[3 \times 2]$ or $[1 \times 2]$ symmetry units. The periodic packing results confirm that the conformations of phenyl-backboned chains are uniquely determined by the steric and symmetry properties of the phenyl group, and these orientations remain approximately constant over the range of dis-

Fig. 12. Schematic representation of Sn-O-Sn dimers modelled on the tridymite surface. Each dimer type is repeated over the entire 6×6 surface for each minimization. View is normal to the model surface, with Sn—O—Si and Sn—C bonds omitted for clarity. The hydroxy positions match the tetrahedral oxygen projections of the underlying tridymite surface.


tances studied. However, decreasing the packing density away from the natural separation of 4.5 Å towards unnatural values of 5.0 Å is predicted, theoretically, to improve monolayer stability because of decreased electronic repulsions.

Surface bonding: Dimer structures of alkyl-backboned chains on a model surface

Repulsive alkyl chain forces prevent extensive cross-linking of the Sn headgroups, and therefore only small cross-linked units, such as dimers or trimers, are feasible for hydrolytic SAMs (6). As discussed previously (10), PGO-S calculations were performed on cross-linked, surface-bound $Sn-C{\equiv}C-(CH_2)_6-C{\equiv}CH$ dimers to accurately model a monolayer surface and to examine the effect of headgroup bonding on alkyl chain order. Eight different dimer surfaces, as shown in Fig. 12, were modelled with the PGO-S method to determine the minimum dimer conformation.

Because the alkyl monolayer energies and geometries were observed to be strongly dependent on the initial face-packing chain orientations in the distance range 4.0–4.5 Å (Fig. 8), the eight dimer surfaces were optimized at orientations $(\theta_1, \theta_2) = (0°, 0°)$, $(60°, 60°)$, $(120°, 120°)$, $(180°, 180°)$, $(240°, 240°)$, and $(300°, 300°)$. The calculated PGO-S energies, as a function of dimer type and face-packing orientation, are plotted in Fig. 13. There is no consistent ordering of the dimer surface energies over the six face-packing geometries considered. At each value of (θ_1, θ_2) the dimer surface energies fall within a broad 500–1000 kcal mol^{-1} range, with one or two outliers representing either exceptionally stable or strongly disfavoured Sn-O-Sn headgroup geometries. The relative positions of the dimer energies, and the surface energies themselves, vary as the face-packing angle is changed. Compressing the alkyl chain structure through headgroup cross-linking creates highly isotropic monolayer surfaces with variable energies, and symmetries ranging from [6 × 6] to [2 × 3] to [1 × 6]. The Sn-O-Sn cross-links cannot minimize to a preferred orientation, as their configurations are limited by the isotropic alkyl geometries. The

Fig. 13. PGO-S energies as a function of face-packing angle (θ_1, θ_2) and dimer type for cross-linked $H-C{\equiv}C-(CH_2)_6-C{\equiv}C-Sn$ dimers bound to a 6×6 tridymite surface.
most favoured structure, the out-of-plane type 2 dimer at $(0°, 0°)$ correlates with the minimum energy out-of-plane dimer calculated by PM3 semiempirical methods.

Fig. 14. PGO-S energies as a function of herringbone angle (θ_1, θ_2) and dimer type for cross-linked Sn-C≡C-*p*-C$_6$H$_4$-C≡C-H dimers bound to a 6 × 6 tridymite surface.

Surface bonding: Dimer structures of phenyl-backboned chains on a model surface

PGO-S calculations were also performed on surface-bound, cross-linked Sn-C≡C-*p*-C$_6$H$_4$-C≡C-H monolayers, using the eight dimer types shown in Fig. 12, and four possible herringbone orientations on the tridymite surface: (θ_1, θ_2) = (−35°, 35°), (35°, −35), (25°, 95°), and (95°, 25°). The calculated PGO-S energies as a function of dimer type and herringbone orientation are shown in Fig. 14. The surface energies show nearly consistent ordering for each different dimer type over the four packing angles studied. In particular, a global minimum dimer surface, out-of-plane dimer type 4, is observed at each herringbone orientation. Because the packing of phenyl chains is independent of distance, the most favoured Sn-O-Sn headgroup geometry can form at each herringbone orientation, with minimal surface disruption. The low energy dimer structures have either the [1 × 2] herringbone or the modified herringbone [3 × 2] symmetry previously seen for PGO-C results (Fig. 11). The most favourable bonding is out-of-plane herringbone, not in-plane face-packed, as confirmed by PM3 semiempirical calculations.

Monomer and trimer structures of phenyl-backboned chains on a model surface

Because the phenyl-based models form reproducible monolayer structures upon the tridymite surface, and are

computationally less demanding than the alkyl-backboned structures, PGO-S calculations on surface-bound Sn-C≡C-*p*-C$_6$H$_4$-C≡C-H monomers and two types of cyclic trimers (Fig. 15) were used to further elucidate the effect of headgroup structure on chain ordering. Calculated structures are presented in Fig. 16, and an energy comparison is detailed in Table 5. The monomer surface produces less-ordered surfaces (Fig. 16*a*) than the trimer or dimer monolayers. Interactions among nonbonded OH groups disrupt packing symmetry on a surface at full coverage. The trimer monolayers (Fig. 16*b* and 16*c*) produce highly ordered surfaces, with [3 × 2] and [1 × 2] symmetry units. The [3 × 2] trimer structure is slightly favoured energetically. These calculations show that, for a Sn-C≡C-*p*-C$_6$H$_4$-C≡C-H surface at full coverage, monomer, dimer, and trimer headgroup bonding is possible. However, Sn-O-Sn cross-linked dimers are most favourable, because they have less chain distortion than trimers, and have fewer repulsive interactions than surface-bound monomers.

Table 5. Total energies and symmetries of various Sn-C≡C-p-C$_6$H$_4$-C≡C-H monolayers on the tridymite surface, calculated with the PGO-S method.

Topochemical polymerization of Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayers

Monolayers containing diacetylene groups can be photopolymerized to form one-dimensional *poly*(diacetylene) upon exposure to UV radiation, if specific distances exist between neighbouring diacetylene units (12, 13), as shown in Fig. 17. Such polymerized structures increase the conductive and nonlinear optical potential of the thin film, and stabilize the monolayer through the extended bonding network. However, the extent of polymerization is critically dependent on the intermolecular separations, and hence, the structural order, within the self-assembled monolayer.

Topochemical polymerization has been observed experimentally for Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayers self-assembled on quartz substrates (9*a*) indicating that the Sn-alkyl SAMs are relatively well-ordered materials. To better understand the thin film structure and the polymerization mechanism, PGO-S optimizations were performed on the Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer, using a global-minimum out-of-plane type 4 dimer (Fig. 12) to represent the surface headgroups. The minimum energy, [3 × 2] structure calculated for this monolayer is shown in Fig. 18. The two

in-plane rows within this symmetry unit show different chain tilts, because the stress of packing two phenyl rings into the confined monolayer space compresses one row below the other. In the compressed row, Fig. 18*b*, the lower diacetylene groups are within the correct d_2 range (3.7–4.2 Å) for topochemical polymerization; no other diacetylene separation in the PGO-S unit cell meets the bonding requirements.

The PGO-S geometry of a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer, polymerized along the lower diacetylene row indicated in Fig. 18*b*, is shown in Fig. 19. Polymerization along this bottom row decreases the total energy by only 6%, from –235.59 kcal/mol·chain to –221.974 kcal/mol·chain, and does not significantly distort the monolayer. Instead, the nonpolymerized row (Row 2, Fig. 18*c*) tilts in the +*y* axis direction to fill the free volume in the monolayer created by the polymerization of Row 1. This free volume tilting now puts the upper diacetylenes into a d_2 range of 4.0–4.3 Å, sufficient for topochemical polymerization. No other diacetylenes groups in the monolayer are close enough to polymerize.

The calculated PGO-S structure of a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer polymerized along the bottom diacetylenes of Row 1 and the upper diacetylenes of Row 2,

Fig. 19. PGO-S calculated structure for a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer, polymerized along the lower diacetylenes of Row 1. (*a*) *xy* Plane view of the [3 × 2] cell (SiO$_2$ substrate and Sn—O—Sn bonds removed for clarity), (*b*) the polymerized in-plane Row 1, (*c*) the nonpolymerized in-plane Row 2, now tilted into the required topochemical distance range.

$E_{total} = -7991$ kcal/mol

d$_2$(top) = 5.0 - 5.2 Å
d$_3$(bottom) = 4.3 - 4.5 Å

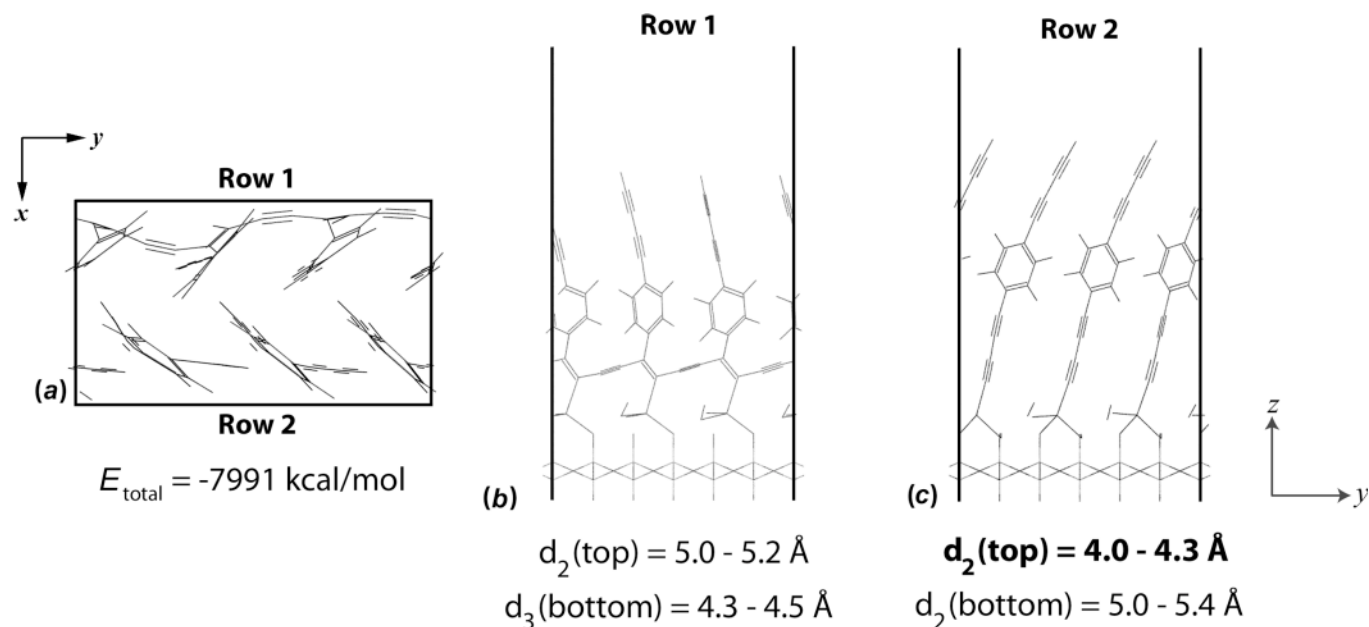
d$_2$(top) = 4.0 - 4.3 Å
d$_2$(bottom) = 5.0 - 5.4 Å


Fig. 20. PGO-S calculated structure for a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer, polymerized along the lower diacetylenes of Row 1 and the upper diacetylenes of Row 2. (*a*) *xy* Plane view of the [3 × 2] cell (SiO$_2$ substrate and Sn—O—Sn bonds removed for clarity), (*b*) the polymerized in-plane Row 1, (*c*) the polymerized in-plane Row 2. No more polymerization is possible in this model.

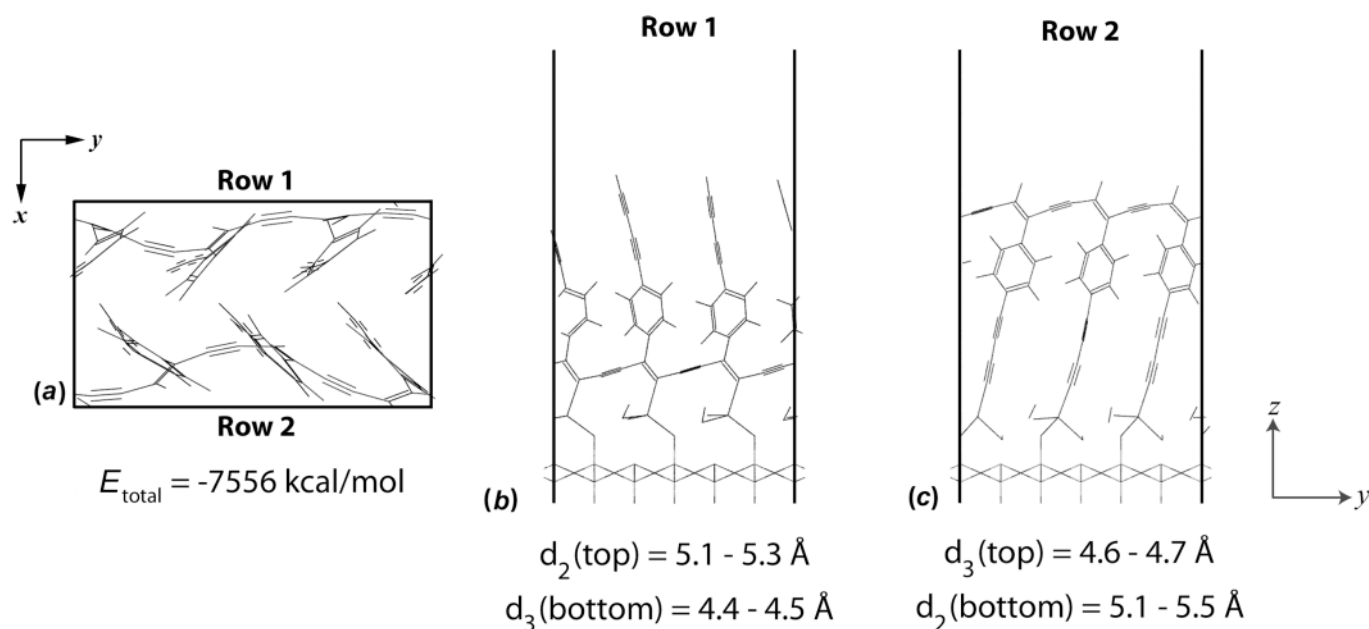
$E_{total} = -7556$ kcal/mol

d$_2$(top) = 5.1 - 5.3 Å
d$_3$(bottom) = 4.4 - 4.5 Å

d$_3$(top) = 4.6 - 4.7 Å
d$_2$(bottom) = 5.1 - 5.5 Å


is shown in Fig. 20. The polymerization is again energetically stable, decreasing the total energy by 5% from the half-polymerized structure of Fig. 19. At this point, the polymerization is complete. No more free volume exists in the monolayer, so the remaining acetylenes stay untilted, out of the polymerization range. Therefore, diacetylene polymerization occurs in this monolayer because compressive packing forces bend the lower acetylenes into the correct geometric range. A second polymerization occurs because

upper acetylenes tilt to eliminate free volume in the monolayer. The PGO-S calculations can be used to successfully interpret geometric thin film behaviour.

Conclusions

Geometric studies of phenyl- and alkyl-backboned monolayers, using the powerful RRSM, PGO-C, and PGO-S techniques, yield analytic insights into thin film growth and

stability. Mapping the potential energy surface, through a selected range of intermolecular distances, suggests that monolayers are more stable at unnatural packing densities. At the natural surface separation distances (20, 25) of 4.2–4.4 Å, both alkyl and phenyl monolayers experience highly repulsive interactions, producing more isotropic film structures. The symmetries of film packing increase and monolayer energies become more favourable at chain–chain separations greater than 4.6 Å. Modifying or eliminating the Sn-O-Sn headgroup cross-links that naturally compress interchain distances can therefore improve experimental film structures.

Analysis of headgroup bonding on a natural surface, using the PGO-S method, demonstrated that cross-linked Sn-O-Sn dimers yield the most stable monolayer energies. However, the extent of Sn cross-linking is critically dependent on the organic monolayer packing order. PGO-S calculations on a Sn-(C≡C)$_2$-p-C$_6$H$_4$-(C≡C)$_2$-H monolayer provide an elegant geometric interpretation of the experimental topochemical polymerizations. Proper molecular modelling techniques are therefore robust and predictive tools for the study and design of functional thin film systems.

Comparison of structures between platinum and palladium complexes of a tetrasilyldisilene[1]

Hisako Hashimoto, Yumiko Sekiguchi, Yohei Sekiguchi, Takeaki Iwamoto, Chizuko Kabuto, and Mistuo Kira

Abstract: The first η^2-disilene–palladium complexes were synthesized using two different reactions; the reactions of bis(phosphine)dichloropalladiums with a 1,2-dilithiotetrakis(trialkylsilyl)disilane, which was prepared by the reaction of a stable tetrakis(trialkylsilyl)disilene with lithium (Method A) and the direct reactions of the bis(phosphine)dichloropalladiums with the stable disilene (Method B). Comparison of X-ray structural parameters of the disilene–palladium complexes with those of the corresponding platinum complex has indicated that the palladium complex is a metallacycle but its π-complex character is stronger than that of the platinum complex.

Key words: disilene complex, palladium, platinum, X-ray structure, metallacycle, π-complex.

Résumé : On a réalisé la première synthèse de complexes η^2-disilène–palladium en faisant appel à deux réactions différentes: la méthode A implique la réaction de dérivés bis(phosphine)dichloropalladium avec un 1,2-dilithiutétrakis(trialkylsilyl)disilane préparé par réaction d'un tétrakis(trialkylsilyl)disilène stable avec du lithium alors que la méthode B implique la réaction directe de dérivés bis(phosphine)dichloropalladium avec le disilène stable. Une comparaison des paramètres structuraux obtenus par diffraction des rayons X pour les complexes disilène–palladium avec ceux du complexe correspondant du platine indique que le complexe du palladium est un métallacycle dont le caractère de complexe π est plus fort que celui du complexe du platine.

Mots clés : complexe disilène, palladium, platine, structure par diffraction des rayons X, métallacycle, complexe π.

[Traduit par la Rédaction]

Introduction

Olefin transition metal complexes have been studied as important reactive intermediates in various transition-metal-catalyzed reactions and their structures and bonding nature are well understood (1). In contrast, there have been very few reports on their silicon analogues, transition-metal complexes with η^2-silicon–silicon doubly bonded species as ligands, while a variety of stable free disilenes have been well investigated (2). Complexes **1** (3), **2** (4), and **3** (5) as shown in Chart 1 had been synthesized but only **2** had been investigated by X-ray crystallography before we started our study of transition-metal complexes with stable disilenes as a ligand (6).

The bonding of a disilene to a metal center is expected to be understood in terms of "ligand-to-metal σ-donation" and "metal-to-ligand π-back donation", similarly to that of an olefin (Dewar–Chatt–Duncanson model) (7). According to this model, the η^2-disilene transition-metal complexes can be described using two resonance structures of a π complex and

Chart 1.

1a, R' = Ph, R = *i*-Pr

2, M = W
3, M = Mo
a metallacycle as shown in Scheme 1. The relative contribution of the two structures could depend on the electronic properties of the metal and the disilene. Thus, the relative importance between the σ-donation and the π-back donation determines the π-complex character of the disilene transition-metal complexes; the π-complex character will increase with decreasing π-back donation.

Recently, we reported a platinum complex with a silyl-substituted η^2-disilene ligand (**4**) (6). The X-ray structural analysis has shown that **4** is better described as a metallacycle with a very weak π-complex character. Strong π-back donation from the electron-rich platinum to the disilene would account for the structural character of **4**. Since the π-back donation of palladium is calculated to be weaker than that of platinum by Sakaki et al. (8*a*), the palladium analogue of **4** is expected to have a π-complex charac-

ter stronger than **4**. We report here the first synthesis of the palladium η^2-disilene complexes **5a** and **5b** using two different methods and their molecular structures determined by X-ray crystallography. Comparison of the structural parameters among the corresponding platinum and palladium complexes (**4** and **5a**) revealed larger π-complex character for the palladium complex than that for the platinum complex, in conformity with the theoretical study (8*a*).

Results and discussion

Palladium η^2-disilene complexes **5a** and **5b** were synthesized using two different methods (Methods A and B). First, **5a** and **5b** were synthesized by applying a similar method used for the synthesis of **4** (Method A). Thus, complex **5a** was synthesized in 55% yield by the reaction of *cis*-(Me₃P)₂PdCl₂ (9) (**6a**; 0.20 g, 0.38 mmol) with 1,2-dilithio-tetrakis(*tert*-butyldimethylsilyl)disilane (10) (**7**; 0.14 g, 0.41 mmol) in THF at –50 °C for 3 h, as shown in eq. [1]; dilithiodisilane **7** was prepared as a white powder by the reduction of the corresponding stable disilene **8** with lithium metal (10). Likewise, complex **5b** was obtained as a yellow powder in 43% yield from (dmpe)PdCl₂ (8) (**6b**; 0.082g, 0.24 mmol) and **7** (0.13 g, 0.25 mmol). Complex **5a** and **5b** were synthesized also by the reactions of disilene **8** with bis(phosphine)palladium dichlorides **6a** and **6b**, as shown in eq. [2]. In the reactions shown in eq. [2], a 2 mol amount of disilene **8** was required for the complete consumption of palladium dichlorides **6a** and **6b**, suggesting that 1 mol of disilene is consumed in the reduction of **6a** and **6b** to the corresponding bis(phosphine)Pd(0) complexes, which react further with another mol of **8** to give **5a** and **5b**, respectively.

Recrystallization of **5a** and **5b** from diethyl ether and toluene, respectively, at –20 °C afforded yellow prisms suitable for a single-crystal X-ray diffraction study.[3,4] The molecular structures of **5a** and **5b** are shown in Figs. 1 and 2 with se-

lected bond lengths and angles. Both **5a** and **5b** have the crystallographic C-2 axis through the palladium and the center of the Si1—Si1* bond, and the η^2-coordination of the disilene moiety. Central palladium atoms in **5a** and **5b** adopt highly distorted square-planar geometries with the dihedral angles of 31.8° and 28.5°, respectively, between the P1-Pd-P1* and Pd-Si1-Si1* planes. Steric repulsion between the bulky trialkylsilyl substituents and the phosphine ligands would account for their distorted geometry.
Table 1 summarizes pertinent structural parameters of disilene–palladium complexes **5a** and **5b** and disilene–platinum complex **4**. The Si1-Si1* distances of **5a** (2.303(1) Å) and **5b** (2.318(6) Å) lie below the shortest limit of the reported Si—Si single bond (2.335–2.697 Å) (11). The Si-Pd distances in **5a** (2.4374(7) Å)) and **5b** (2.4184(4) Å) are a little longer than those of the reported bis(phosphine)(disilyl)palladium complexes (2.34–2.38 Å) (12). The bent angles (δ) of **5a** (25.5°) and **5b** (26.0°), which are defined as an angle between the Si2-Si1-Si3 plane and the Si1—Si1* bond, are far larger than that of free disilene **8** (0.1°) (13). The results indicate that **5a** and **5b** should be described still as a metallacycle with a very small π-complex character similar to platinum complex **4** (6). Small but significant differences were found in the structures around the disilene moiety between the platinum and palladium complexes (**4** and **5a**) with the same trimethylphosphine ligands. Thus, the elongation of the central Si-Si distance in **5a** ($\Delta l = 0.101$ Å) is slightly smaller than that in **4** ($\Delta l = 0.120$ Å). The bent angle (δ) for **5a** (25.5°) is a little smaller than that of **4** (28.4°). All these differences in **5a** and **4** are in good accord with those found theoretically between the model compounds (H₃P)₂Pd(Si₂H₄) and (H₃P)₂Pt(Si₂H₄) by Sakaki et. al. (8*a*) suggesting that the π-complex character for the disilene–

palladium complex **5a** is somewhat stronger than that for the corresponding platinum complex.

The ^{29}Si NMR resonance of the central silicon atoms appeared at –46.8 ppm for **5a** and –51.9 ppm for **5b** with a doublet of doublets signal pattern owing to two ^{31}P nuclei. These chemical shifts are considerably downfield-shifted compared to that of **4** (–79.7 ppm) (6), even though they are still upfield from that of the free disilene **8** (142.1 ppm) (13). The difference in the π-complex character between the palladium and platinum complexes may be responsible, in part, for the down-field shift in the former. Further works are in progress to reveal the dependence of the π-complex character in disilene – transition metal complexes on the central metals and ligands.

Experimental

General

^{1}H, ^{13}C, ^{29}Si, and ^{31}P NMR spectra were recorded on a Bruker AC-300P FT NMR spectrometer at 300, 75.4, 59.6, and 121 MHz, respectively, at 25 °C unless otherwise noted. Mass spectra and high resolution mass spectra were recorded on a JEOL JMS-600W (EI, 70 eV) and a HX-110 mass spectrometer (FAB, nitrobenzyl alcohol matrix). UV–vis spectra were obtained using a Hewlett-Packard HP8453 E spectrometer. Air-sensitive compounds were manipulated in a VAC MO-40-M glove box.

Bis(trimethylphosphine)dichloropalladium (**6a**) and [1,2-

bis(dimethylphosphino)ethane]dichloropalladium (**6b**) were prepared according to the procedures in the literature (9).

[η²-Tetrakis(*tert*-butyldimethylsilyl)disilene]bis(trimethylphosphine)palladium (5a)

Method A

To a mixture of *cis*-bis(trimethylphosphine)dichloropalladium (9) (**6a**, 0.102 g, 0.293 mmol) and 1,2-dilithio-1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)disilane (10) (**7**, 0.157 g, 0.296 mmol) in a Schlenk flask (50 mL) was introduced THF (5 mL) dried over a K mirror through a vacuum line. The mixture was stirred for 3 h at –50 °C and then the THF was distilled off at 0 °C. After the addition of toluene (40 mL) to the residue, the resulting precipitates were filtered off. Removal of toluene in vacuo gave the title compound (0.178 g, 0.163 mmol) in 55% yield.

Method B

Dry toluene (5 mL) was introduced to a mixture of **6a** (0.099 g, 0.30 mmol) and tetrakis(*tert*-butyldimethylsilyl)disilene (**8**) (13) (0.30 g, 0.60 mmol). The mixture was stirred for 3 h at –50 °C and then the toluene was distilled off. The ^{1}H NMR spectrum of the mixture showed the quantitative formation of disilene complex **5a** and 1,2-dichloro-1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)disilane (14).

5a:

Yellow crystals, mp 92 °C (decomp). UV–vis (hexane) λ_{max} (nm) (ε): 344 (5400), 421 (5000). ^{1}H NMR (C$_6$D$_6$) δ: 0.40 (s, 12 H), 0.49 (s, 12 H), 1.11 (d, $^2J_{P-H}$ = 5.4 Hz, 18 H), 1.22 (s, 36 H). ^{13}C NMR (C$_6$D$_6$, 70 °C) δ: 2.5, 2.7, 20.1, 21.5 (d, $^1J_{P-C}$ = 11 Hz), 29.7. ^{29}Si NMR (C$_6$D$_6$) δ: –46.8 (dd, $^2J_{P(trans)-Si}$ = 83.4 Hz, $^2J_{P(cis)-Si}$ = 22.1 Hz), 4.2. ^{31}P NMR (C$_6$D$_6$) δ: –31.33. MS (FAB) m/z (%): 773 (M$^+$), 698 (M$^+$ – PMe$_3$, 54), 622 (M$^+$ – 2PMe$_3$, 50), 535 (54), 460 (100). Anal. calcd. for C$_{30}$H$_{78}$P$_2$Si$_6$Pd (%): C 46.44, H 10.13; found (%): C 46.46, H 9.88.

[η²-Tetrakis(*tert*-butyldimethylsilyl)disilene][bis(dimethylphosphino)ethane]palladium (5b)

Method A

To a mixture of [bis(dimethylphosphino)ethane] dichloropalladium (9) (**6b**, 0.082 g, 0.24 mmol) and 1,2-dilithio-1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)disilane (10) (**7**, 0.132 g, 0.25 mmol) in a Schlenk flask (50 mL) was introduced dry THF (20 mL) through a vacuum line. The mixture was stirred for 3 h at –50 °C and then the THF was distilled off at 0 °C. After addition of toluene (40 mL) to the residue, the resulting precipitates were filtered off. Removal of toluene in vacuo gave the title compound (0.076 g, 0.0984 mmol) in 41% yield.

Method B

To a mixture of **6b** (0.16 g, 0.49 mmol) and **8** (13) (0.50 g, 1.00 mmol) was introduced dry THF (20 mL). The mixture was stirred for 3 h at –50 °C and then the toluene was distilled off. The ^{1}H NMR spectrum of the mixture showed the quantitative formation of disilene complex **5b** and 1,2-dichloro-1,1,2,2-tetrakis(*tert*-butyldimethylsilyl)di-

silane (14). Recrystallization from toluene gave pure **5b** (0.085 g, 0.11 mmol) in 22% yield.

5b:

Yellow crystals, mp 83 °C (decomp.). UV–vis (hexane) λ_{max} (nm) (ε): 305 (11 000, sh), 345 (7500, sh), 380 (5300). ^{1}H NMR (C$_6$D$_6$) δ: 0.39 (s, 12 H), 0.51 (s, 12 H), 0.91 (d, $^2J_{P-H}$ = 14 Hz, 4H), 1.11 (d, $^2J_{P-H}$ = 6 Hz, 12 H), 1.22 (s, 36 H). ^{13}C NMR (C$_6$D$_6$) δ: 3.4, 3.5, 16.4–16.6 (m), 19.7, 30.1. ^{29}Si NMR (C$_6$D$_6$) δ: –51.9 ($^2J_{P(trans)-Si}$ = 76 Hz, $^2J_{P(cis)-Si}$ = 15 Hz), +6.1. ^{31}P NMR (C$_6$D$_6$) δ: 7.41. Anal. calcd. C$_{30}$H$_{76}$P$_2$PdSi$_6$ (%): C 46.56, H 9.90; found (%): C 46.58, H 9.62.

X-ray data of **5a** and **5b** may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 202926 and 202927 contain the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc. cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc. cam.ac.uk).

Wide-rim functionalization of calix[4]arene: The di- and tetraisocyanocalix[4]arene assembling ligands and their silver(I) polymers and oligomers[1]

Pascal Mongrain and Pierre D. Harvey

Abstract: The 5,11- and 5,17-diisocyano-25,26,27,28-tetra-*n*-propoxycalix[4]arene bridging ligands (calix(NC)$_2$) have been prepared in four steps with 34 and 30% global yields, respectively. Their corresponding Ag(I) complexes have been prepared from the direct reaction of the ligand with AgBF$_4$ and are characterized from various spectroscopic and physical techniques. The MALDI-TOF spectra indicate the presence of polymers or oligomers of the type {Ag(calix(NC)$_2$)(BF$_4$)}$_n$. The compounds have been characterized further from TGA, DSC, and XRD and compared with the oligomeric species 5,11,17,23-tetraisocyano-25,26,27,28-tetra-*n*-propoxycalix[4]arene silver(I) (as a BF$_4^-$ salt).

Key words: silver, calix[4]arene, polymer, isocyanide, photosensitive, thermal gravimetric analysis.

Résumé : Les ligands pontants 5,11- et 5,17-diisocyano-25,26,27,28-tetra-*n*-propoxycalix[4]arène (calix(NC)$_2$) ont été synthétisés en 4 étapes chacune avec des rendements globaux respectifs de 34 et 30%. Les complexes correspondant d'Ag(I) ont aussi été préparés à partir de la réaction directe entre les ligands ci-haut et du AgBF$_4$. Les analyses MALDI-TOF indiquent la présence de polymères ou d'oligomères du type {Ag(calix(NC)$_2$)(BF$_4$)}$_n$. Ces composés ont ensuite été caractérisés à partir d'analyses d'ATG, de DSC et de DRX, qui ont par la suite été comparés à l'espèce oligomérique 5,11,17,23-tétraisocyano-25,26,27,28-tétra-*n*-propoxycalix[4]arèneargent(I) (contre-ion BF$_4^-$).

Mots clés : argent, calix[4]arène, polymère, isocyanure, photosensible, analyse thermogravimétrique.

Introduction

The wide-rim functionalization of the calix[4]arene molecule with transition metal fragments is an area that has not been exhaustively developed (1) in comparison with narrow-rim functionalization (2). This tetraphenolic molecule exhibits a "bowl shape" structure capable of acting as a host for cations and neutral molecules (2, 3), and numerous applications, such as ion transport, novel sensors, selective receptors, biomimetics, luminescence probes, nuclear waste treatment, and homogeneous catalysis, have been reported (3). In that context, this group recently developed the syntheses of the mono-, di-5,11-, di-5,17-, tri-, and tetraphosphinated tetra-*n*-propoxycalix[4]arene (phosphine group = Ph$_2$P-) (4) and applied these new ligands to the syntheses of pentamethylcyclopentadienyl rhodium(I) complexes (5).[3] In addition, the preparation and characterization of the mono- and tetraisocyanotetra-*n*-propoxycalix[4]arene ligands and the corresponding gold(I) chloride complexes have been the subject of a recent study (6). Such multiple wide-rim functionalizations provide an opportunity to build various molecular architectures. We now wish to report the syntheses and characterization of the 5,11-di- and 5,17-diisocyanocalix[4]arene ligands and their reactivity toward silver(I). These bidentate ligands compare well with the recently reviewed 1,8-diisocyano-*p*-menthane (dmb), which is known to form polymers with Ag(I) (7), but differ from the tetraisocyanocalix[4]arene analogue from a structure point of view (6).

Experimental section

Materials

The AgBF$_4$ salt was purchased from Aldrich and was used as received. The 5,11-dibromo- (**1**), 5,17-dibromo- (**7**), and 5,11,17,23-tetraisocyano-25,26,27,28-tetra-*n*-propoxycalix-[4]arene (**13**) starting materials were prepared according to procedures outlined in refs. 4 and 6. The solvents were purified according to general procedures (8).

5,11-Diphtalimido-25,26,27,28-tetrapropoxycalix[4]arene (2): (Cone)

A solution containing compound **1** (209 mg, 0.28 mmol), phthalimide (137 mg, 0.02 mmol), and Cu_2O (428 mg, 0.06 mmol) in collidine (10 mL) was refluxed for 4 days under inert atmosphere. The reaction mixture was cooled to room temperature and was poured in CH_2Cl_2 (100 mL). This solution was extracted twice with H_2SO_4 5% aqueous solution, NaOH 5%, and distilled water. The organic phase was dried over $MgSO_4$, filtered, and evaporated. The resulting solid was purified by column chromatography using CH_2Cl_2. Yield 55% (135.8 mg). Melting temperature (T_m) = 165 °C. IR (solid) (cm^{-1}) ν(C = O): 1715. ^{1}H NMR (CDCl$_3$) δ: 7.89 (m, 4H, Ph), 7.53 (m, 4H, Ph), 6.82 (s, 4H, Ph), 6.65–6.70 (m, 4H, Ph), 6.51 (t, 2H, J = 7.59 Hz, Ph), 4.45 (m, 4H, CH$_2$), 3.85–3.95 (m, 8H, OCH$_2$), 3.18–3.27 (m, 4H, CH$_2$), 1.95 (m, 8H, CH_2CH$_3$), 1.01 (t, 12H, J = 7.53 Hz, CH$_3$). ^{13}C NMR (CDCl$_3$) δ: 167.2, 157.1, 156.3, 135.8, 135.1, 133.9, 132.3, 128.8, 128.2, 127.1, 125.2, 124.4, 122.7, 31.2, 23.5, 11.0. EI-MS: 882 ([M]$^+$).

5,11-Diamino-25,26,27,28-tetrapropoxycalix[4]arene (3): (Cone)

A solution containing compound **2** (135 mg, 0.153 mmol) and hydrazine monohydrate (0.18 mL, 3.34 mmol) in ethanol (15 mL) was refluxed for 2 h. The solution was cooled to room temperature and evaporated. The resulting solid was dissolved in CH_2Cl_2 and extracted twice with NaOH 5% aqueous solution and distilled water. The organic phase was dried over $MgSO_4$, filtered, and evaporated. Yield 95% (90 mg). T_m = 209–210 °C. IR (solid) (cm^{-1}) ν(NH): 3525, 3395. ^{1}H NMR (CDCl$_3$) δ: 7.70–6.57 (m, 6H, Ph), 6.02 (s, 2H, Ph), 5.98 (s, 2H, Ph), 5.38 (dd, 4H, CH$_2$), 3.85 (t, 4H, OCH$_2$), 3.73 (t, 4H, OCH$_2$), 3.15 (br, 4H, NH$_2$), 3.05 (dd, 4H, CH$_2$), 1.92 (m, 8H, CH_2CH$_3$), 0.99 (m, 12H, CH$_3$). ^{13}C NMR (CDCl$_3$) δ: 157.1, 150.3, 139.7, 136.0, 134.9, 128.1, 124.5, 116.2, 30.9, 23.2, 10.5. EI-MS: 622 ([M]$^+$).

5,11-Di-N-formamyl-25,26,27,28-tetrahydroxycalix[4]arene (4): (Cone)

A solution containing compound **3** (97.6 mg, 0.157 mmol) in formic acid (4 mL) and toluene (20 mL) was refluxed for several hours. The excess of formic acid and water was eliminated, using a Dean–Stark apparatus, prior to evaporating the solution to dryness. The solid was purified by colomn chromatography using 1:4 acetone:CH_2Cl_2. Yield 92% (101.1 mg). IR (solid) (cm^{-1}) ν(C = O): 1686, ν(NH): 3400. ^{1}H NMR (CDCl$_3$) δ: 7.95–8.30 (m, 2H, C(O)H), 6.28–7.15 (complex, 10H, Ph), 4.40–4.45 (dd, 4H, CH$_2$), 3.70–4.00 (complex, 10H, OCH$_2$, NH), 3.05–3.20 (m, 4H, CH$_2$), 1.80–1.95 (m, 8H, CH_2CH$_3$), 0.90–1.10 (m, 12H, CH$_3$). ^{13}C NMR (CDCl$_3$) δ: 163.5, 160.1, 158.5, 158.0, 157.5, 155.0–153.5, 137.2–134.3, 132.1–130.5, 129.4–128.6, 121.8, 121.5–120.3, 119.4–119.0, 31.4, 23.8, 10.4. EI-MS: 678 ([M]$^+$).

5,11-Diisocyano-25,26,27,28-tetrapropoxycalix[4]arene (5): (Cone)

A solution containing compound **4** (52 mg, 0.077 mmol) and Et$_3$N (44.2 µL, 0.32 mmol) in dry CH_2Cl_2 (5 mL) was refluxed under inert atmosphere. A CH_2Cl_2 solution containing diphosgene (0.1 mL) was added over a period of 1 h.

The solution was refluxed for 1 day and cooled to room temperature. The resulting solution was extracted and evaporated. The solid was purified by column chromatography using CH_2Cl_2. Yield 70% (34.6 mg). IR (solid) (cm^{-1}) ν(N≡C): 2131. ^{1}H NMR (CDCl$_3$) δ: 6.72 (d, 2H, J = 2.14 Hz, Ph), 6.62 (d, 4H, J = 2.15 Hz, Ph), 6.57 (d, 4H, J = 2.15 Hz, Ph), 4.36–4.43 (m, 4H, CH$_2$), 3.75–3.90 (m, 8H, OCH$_2$), 3.05–3.20 (dd, 4H, CH$_2$), 1.80–1.91 (m, 8H, CH_2CH$_3$), 0.98 (t, 12H, J = 7.55 Hz). ^{13}C NMR (CDCl$_3$) δ: 162.1, 157.5, 156.5, 137.4, 135.5, 134.1, 130.9, 128.8, 128.0, 126.7, 125.8, 126.6, 120.9, 65.9, 31.2, 23.8, 10.2. EI-MS: 642 ([M]$^+$).

Poly[(5,11-diisocyano-25,26,27,28-tetrahydroxycalix[4]arene) silver(I)] tetrafluoroborate (6): (Cone)

A solution containing compound **5** (34 mg, 0.053 mmol) in dry acetonitrile was added to an acetonitrile solution containing AgBF$_4$ (5.8 mg, 0.03 mmol). The solution was stirred for 1 h at room temperature, and the solvent was evaporated. Yield 100% (44.3 mg). IR (solid) (cm^{-1}) ν(N≡C): 2203, ν(BF$_4$): 1015. ^{1}H NMR (CDCl$_3$) δ: 6.87 (s + s, 4H, Ph), 6.60–6.70 (m, 6H, Ph) 4.40–4.50 (d, 4H, CH$_2$), 3.75–4.00 (m, 8H, OCH$_2$), 3.20–3.33 (d, 4H, CH$_2$), 1.85–1.95 (m, 8H, CH_2CH$_3$), 1.11 (m, 12H, CH$_3$). MALDI-TOF-MS: see Table 1. Anal. calcd. for C$_{42}$H$_{46}$O$_4$N$_2$AgBF$_4$: C 60.23, H 5.54, N 3.34; found: C 59.19, H 5.83, N 3.04.

5,17-Diphthalimido-25,26,27,28-tetrapropoxycalix[4]arene (8): (Cone)

A solution containing compound **7** (1.000 g, 1.33 mmol), phthalimide (0.8 g, 5.3 mmol), and Cu_2O (1.9 g, 13.3 mmol) in collidine (36 mL) was refluxed for 4 days under inert atmosphere. The reaction mixture was cooled to room temperature and was poured in CH_2Cl_2 (300 mL). This solution was extracted twice with H_2SO_4 5% aqueous solution, NaOH 5%, and distilled water. The organic phase was dried over $MgSO_4$, filtered, and evaporated. The resulting solid was purified by column chromatography using CH_2Cl_2. Yield 65% (762.4 mg). T_m = 165 °C. IR (solid) (cm^{-1}) ν(C=O): 1717. ^{1}H NMR (CDCl$_3$) δ: 7.61 (m, 8H, Ph), 6.86 (s, 4H, Ph), 6.60 (m, 6H, Ph), 4.51 (d, 4H, J = 13.08 Hz, CH$_2$), 3.90 (dt, 8H, OCH$_2$), 3.21 (d, 4H, J = 13.10 Hz, CH$_2$), 1.97 (m, 8H, CH_2CH$_3$), 1.03 (q, 12H, CH$_3$). ^{13}C NMR (CDCl$_3$) δ: 167.2, 156.5, 136.1, 134.5, 133.9, 131.8, 138.5, 126.4, 125.4, 123.3, 122.5, 31.5, 23.6, 10.5. EI-MS: 882 ([M]$^+$).

5,17-Diamino-25,26,27,28-tetrapropoxycalix[4]arene (9): (Cone)

A solution containing compound **8** (164 mg, 0.155 mmol) and hydrazine monohydrate (0.2 mL, 3.72 mmol) in ethanol (25 mL) was refluxed for 2 h. The solution was cooled to room temperature and evaporated. The resulting solid was dissolved in CH_2Cl_2 (150 mL) and extracted twice with NaOH 5% aqueous solution and distilled water. The organic phase was dried over $MgSO_4$, filtered, and evaporated. Yield 95% (91.5 mg). 5,17-Di-*N*-formamyl-25,26,27,28-tetrahydroxy-calix[4]arene (10): (Cone)

A solution containing compound **9** (550 mg, 0.88 mmol) in formic acid (20 mL) and toluene (70 mL) was refluxed several hours. The excess of formic acid and water was eliminated using a Dean–Stark apparatus prior to evaporating the solution to dryness. The solid was purified by column chromatography using 30:70 acetone:CH_2Cl_2. Yield 70% (417.6 mg). IR (solid) (cm^{-1}) ν(C = O): 1685, ν(NH): 3410. ^1H NMR ($CDCl_3$) δ: 8.00 (s + s, H, C(O)H), 7.89 (s + s, H, C(O)H), 6.81–7.11 (complex, 6H, Ph), 6.382 (d, 2H, Ph), 5.91 (s, 1H, Ph), 5.78 (s, 1H, Ph), 4.45 (dd, 4H, CH_2), 3.98 (dt, 4H, OCH_2), 3.66 (m, 4H, OCH_2), 3.13 (dd, 4H, $J = 13.05$ Hz, CH_2), 2.2 (vbr, 2H, NH), 1.91 (m, 8H, CH_2CH_3), 1.10 (q, 6H, CH_3), 0.90 (m, 6H, CH_3). ^{13}C NMR ($CDCl_3$) δ: 162.8, 159.5, 157.8, 154.0, 153.2, 152.5, 136.5, 135.1, 134.2, 131.0, 130.5, 129.2, 122.5, 119.6, 118.5, 31.2, 23.5, 10.4. EI-MS: 678 ([M]$^+$).

5,17-Diisocyano-25,26,27,28-tetrapropoxycalix[4]arene (11): (Cone)

A solution containing compound **10** (300 mg, 0.443 mmol) and Et_3N (0.8 mL, 4.72 mmol) in dry CH_2Cl_2 (50 mL) was refluxed under inert atmosphere. A CH_2Cl_2 solution containing diphosgene (0.6 mL, 4.85 mmol) was added over a period of 1 h. The solution was refluxed for 1 day and cooled to room temperature. The resulting solution was extracted and evaporated. The solid was purified by column chromatography using CH_2Cl_2. Yield 30% (85.3 mg). IR (solid) (cm^{-1}) ν(N≡C): 2130. ^1H NMR ($CDCl_3$) δ: 6.88 (m, 6H, Ph), 6.43 (s, 4H, Ph), 4.42 (d, 4H, $J = 13.12$ Hz, CH_2), 3.41 (t, 4H, $J = 7.39$ Hz, OCH_2), 3.75 (t, 4H, $J = 7.42$ Hz, OCH_2), 3.13 (d, 4H, $J = 13.12$ Hz, CH_2), 1.91 (m, 8H, CH_2CH_3), 1.07 (t, 6H, $J = 7.42$ Hz,

CH_3), 0.93 (t, 6H, $J = 7.40$ Hz, CH_3). ^{13}C NMR ($CDCl_3$) δ: 136.1, 135.2, 129.1, 125.7, 30.9, 23.3, 10.2. EI-MS: 642 ([M]$^+$).

Poly[(5,17-diisocyano-25,26,27,28-tetrahydroxy-calix[4]arene) silver(I)] tetrafluoroborate (12)

A solution containing compound **11** (90 mg, 0.14 mmol) in dry acetonitrile was added to an acetonitrile solution containing $AgBF_4$ (13 mg, 0.07 mmol). The solution was stirred for 1 h at room temperature, and the solvent was evaporated. Yield 100% (117.1 mg). IR (solid) (cm^{-1}) ν(N≡C): 2210, ν(BF_4): 1025. ^1H NMR ($CDCl_3$) δ: 7.27(d, 4H, Ph), 7.06 (t, 2H, Ph), 6.29 (s, 4H, Ph), 4.45 (d, 4H, CH_2), 3.95 (t, 4H, OCH_2), 3.71 (t, 4H, OCH_2), 3.22 (d, 4H, CH_2), 1.90 (m, 8H, CH_2CH_3), 1.11 (t, 6H, CH_3), 0.87 (t, 6H, CH_3). MALDI-TOF-MS: see Table 1. Anal. calcd. for $C_{42}H_{46}O_4N_2AgBF_4$: C 60.23, H 5.54, N 3.34; found: C 59.31, H 5.76, N 3.34.

Poly(5,11,17,23-tetraisocyano-25,26,27,28-tetrahydroxy-calix[4]arene) silver(I) tetrafluoroborate (14)

A solution containing compound **13** (137.6 mg, 0.198 mmol) in dry acetonitrile was added to an acetonitrile solution containing $AgBF_4$ (38.6 mg, 0.198 mmol). The solution was stirred for 1 h at room temperature, and the solvent was evaporated. The beige solid was filtered and washed with dimethyl ether and dried in vaccuo. Yield 98% (172.5 mg). IR (solid) (cm^{-1}) ν(N≡C): 2177, 2122, ν(BF_4): 1030. ^1H NMR (CD_3CN) δ: 7.09 (s, 8H, Ph), 4.37 (d, 4H, $J = 13.3$ Hz, CH_2), 3.85 (t, 8H, $J = 7.5$ Hz, OCH_2), 3.2 (d, 4H, $J = 13.5$ Hz, CH_2), 1.89 (m, 8H, CH_2CH_3), 1.00 (t, 12H, $J = 7.5$ Hz, CH_3). MALDI-TOF-MS: see Table 2. Anal. calcd. for $C_{44}H_{44}O_4N_4AgBF_4$: C 59.54, H 5.00, N 6.31; found: C 58.91, H 5.23, N 6.23.

Apparatus

The NMR spectra were acquired on a 300 MHz Bruker instrument (^1H, 300.15 MHz; ^{13}C, 75.478 MHz). The chemical shifts (δ) are reported with respect to tetramethylsilane,

Table 2. Selected MALDI-TOF data for **14**.

Peaks[a]	Relative intensity ($\pm 1\%$)	Assignment[b]	Calculated values
2020	6	$Ag_3calix_2(BF_4) + 2CN$	2021.79
1970	4	$Ag_3calix_2(BF_4)$	1969.79
1881	11	$Ag_3calix_2(BF_4)_2$	1882.99

[b]calix = ligand **13**.

TMS (^{1}H, ^{13}C), and were determined on the basis of residual proton solvent resonances. The coupling constants are reported in ppm. The FT-IR data were obtained on PerkinElmer spectrometer Model 1600. The mass spectra (EI) were mesured on a ZAB-1F instrument (VG model), while the MALDI-TOF data were obtained at the Université de Bourgogne from a Bruker proflex III linear mode spectrometer with a nitrogen laser (337 nm) with a dithranol matrix. Elemental analysis were performed at the Université de Montréal (Regional Services). The TGA analyses were performed using a PerkinElmer TGA 7 apparatus operating between 50 and 700 °C scanning at the rate of 3 °C min^{-1} under N_2 atmosphere. The thermal behaviour was analyzed using a PerkinElmer 5A DSC7 apparatus, equipped with a thermal control analyser 5B TAC 7/DS. The temperature calibrations were done with water and metallic indium as standards. The accuracy is ± 0.1 °C and $\pm 0.1\%$. The sample weights ranged from 5 to 10 mg, and the scan rate was adjusted at 10° min^{-1}. The X-ray powder diffraction patterns were acquired on a Rigaku, U.S.A. Inc. apparatus equipped with a copper source operating at 40 kV and 30 mA, in continuous standard, scans $2\theta/\theta$-reflection of 1° min^{-1}. The sample support was a standard aluminium support.

Computer modeling

The calculations were performed using the commercially available program PC-model from Serena Software (version 7.0), which uses the MMX empirical model.

Results and discussion

The diisocyanide compounds

The complexes **6** and **12** have been synthesized in 5 steps from the corresponding 5,11- (**1**) and 5,17-dibromo-25,26,27,28-tetra-n-propoxycalix[4]arene (**7**) compounds with overall yields of 34% and 30%, respectively (Schemes 1 and 2). The presence of n-propyl groups in the narrow-rim secures the cone conformation of the macrocyle, as confirmed by ^{1}H NMR all along the syntheses. The incorporation of the nitrogen atoms onto the *para*-position of the benzene rings proceeds by a substitution of the bromide atoms by phthalimides in modest yields, to generate **2** and **8**. The reduction of the phthalimide groups with hydrazine, followed by a condensation with formic acid, produces the corresponding formamides **4** and **10** in good yields. The following dehydration step using diphosgene leads to the desired diisocyanide ligands. The ligands **5** and **11** (calix(NC)$_2$) have been fully characterized from ^{1}H NMR, ^{13}C NMR, and IR spectroscopy, as well as mass spectrometry (EI).

The treatment of **5** and **11** with AgBF$_4$ cleanly gives **6** and **12**, respectively. The complexes exhibit strong and single $\nu(N\equiv C)$ absorptions at 2203 and 2210 cm^{-1}, respectively, in comparison with 2131 (**5**) and 2130 cm^{-1} (**11**) for their corresponding free ligands, confirming the coordination of the -$N\equiv C$ groups. The 1:1 stoichiometry of Ag:calix(NC)$_2$ is indicated by the chemical analyses. The MALDI-TOF mass data reveal the presence of polymers or oligomers of the type $\{Ag(calix(NC)_2)(BF_4)\}_n$ in both cases (Table 1). A polymer formed from a *para*-cyano-functionalized calix[4]arene and Ag(I) has been reported before (see molecule 1) (9). The fact that no IR band is associated with free $\nu(N\equiv C)$ indicates that the materials are either long polymers or cyclic oligomers in the solid state. Attempts to increase the number of diisocyanide calix[4]arene ligands about the silver(I) were not successful, which contrasts with the $\{Ag(dmb)_2^{2+}\}_n$ polymers (7). In addition, attempts to obtain crystals suitable for X-ray analysis for these thermally and light sensitive compounds in solution also stubbornly failed, as slow decomposition occurs with time. In addition, the XRD data indicate that these polymeric and (or) oligomeric materials are amorphous in the solid state.
Molecule 1   R = CH$_2$CH$_2$OMe

During the course of this study the physical properties of **6** and **12** in their solid state have been investigated. Both compounds do not exhibit obvious thermal absorption (or emission), such as a glass transition, melting, or decomposition between –20 and 90 °C, according to DSC findings. This result contrasts that of the "rigid stick" $\{Ag(dmb)_2^+\}_n$ polymers, for which a glass transition phenomenon has been

Scheme 1.

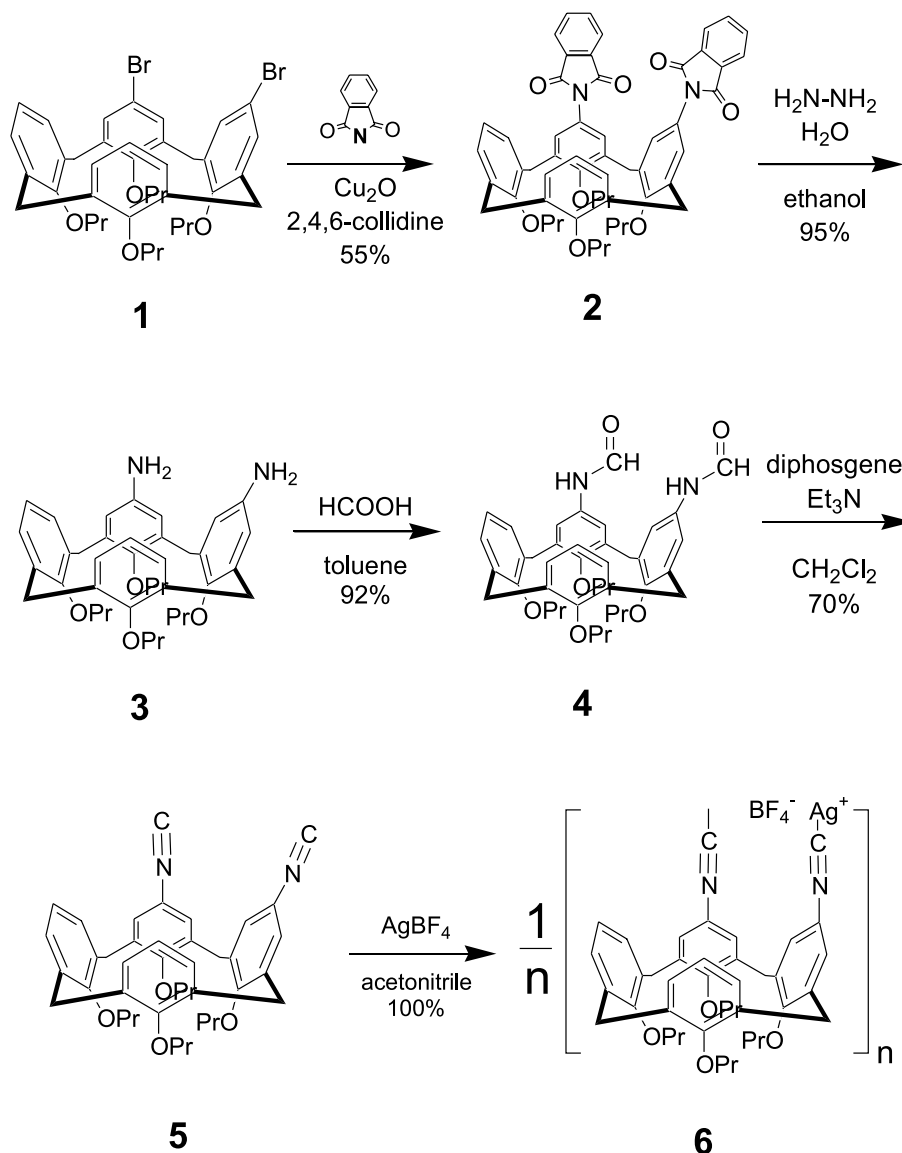
5 → (AgBF₄, acetonitrile, 100%) → **6**


attributed to the motion of the counterions in the solid (10). This result can be explained by the fact that the counterions cannot interact with the saturated and well-encapsulated Ag(I) ions in $\{Ag(dmb)_2^+\}_n$ but can with the unsaturated

Molecule 2

ones in **6** and **12**. This hypothesis is supported by the fact that counteranions generally interact with dicoordinated Ag(I) cations — strongly enough to induce significant deviations in CAgC angles (11). One example is the X-ray structure for the related $Ag(2,4,6-t-Bu_3C_6H_2NC)_2(PF_6)$ complex (molecule 2), which exhibits a bent structure where the CAgC, NCAg, and CNC angles are 156.1(6), 174.4(16), and 176.6(14)°, respectively (11a).

Both compounds **6** and **12** exhibit similar TGA traces (Fig. 1). Between 20 and 90 °C, no significant weight loss is noticed, consistent with the DSC data, but two to three barely noticeable plateaux are observed above 100 °C, up to 200 °C. The relative high sensitivity to heat is consistent with the unsaturated nature of the very reactive Ag(I) centre. At 350 °C, the remaining ~45–50% of materials indicates that there are still organic materials in the residues. Both complexes are found to be non-luminescent at room temperature, both in solution and in the solid state.

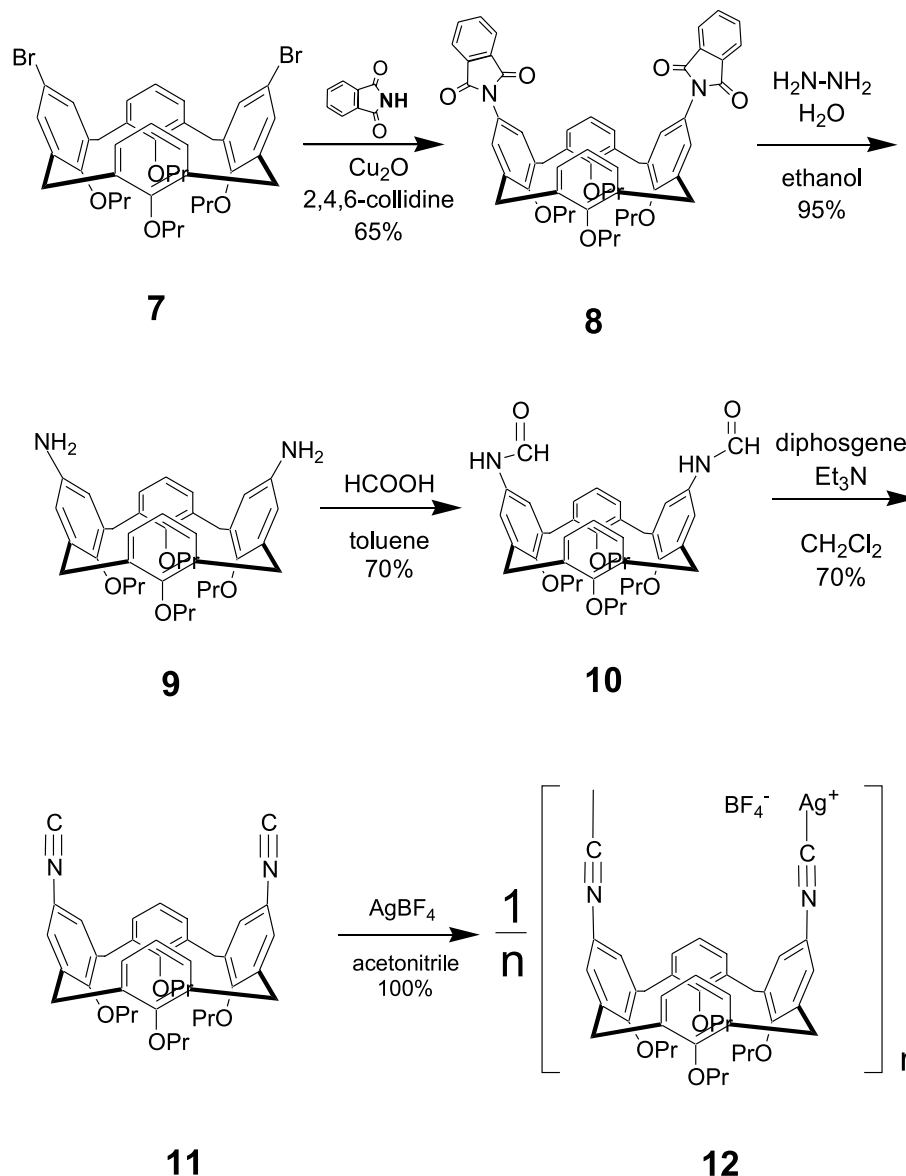
To understand why **6** and **12** form oligomers or polymers, the model dimer compounds $(6)_2$ and $(12)_2$ (i.e., the smallest
Scheme 2.


Fig. 1. TGA trace of 12. Scan rate = 3 °C min^{-1}. A small drift in the baseline is noted in the high temperature region.
possible cyclic oligomers) were examined using computer modelling (MMX). The testing of the method was performed on ligand **13**, for which X-ray data are available (6). This exercise allows one to compare non-bonding distances, which are sensitive parameters that best describe the cavity size, and gives an estimate as to what the deviations between a computed structure and reality might be. The comparison provided in Table 3 is found to be acceptable where the expected pinched cone structure is computed and where the selected non-bonded distances are only slightly overestimated. The greatest difference is found for the longest NC···CN separation; an unavoidable fact, taking into account that the orientation of the propyl chains (lever effect) and crystal packing influence this distance. Finally, the comparison of the bond lengths are also found to be acceptable.

The computed structures for the model dimers (**6**)$_2$ and (**12**)$_2$ are shown in Fig. 2, and selected calculated data are summarized in Table 2. Both models exhibit large

macrocycles, for which some deviation from the ideal 180° angles are depicted (Table 2). Dimer (**6**)$_2$ shows the largest deviation, where a ring stress is evident. Dimer (**12**)$_2$ shows a smaller macrocycle opening, for which the computed Ag···Ag distance is 3.38 Å, practically at the sum of the van der Waals radii (2 × 1.70 Å) (12). This anticipated shorter

Fig. 3. Comparison of the solid state FT-IR spectra of **13** (——) and **14** (······) in the ν(N≡C) region. Resolution: 1 cm^{-1}. No deconvolution is applied.
distance is due to the naturally occurring pinched cone structure of the calix[4]arene ligand. The greater ring stress in (**6**)$_2$ (compared with (**12**)$_2$) is also felt in the greater computed C—N, N—C, and C—Ag bond lengths as well. If the Ag···Ag interactions do occur, then the UV–vis spectra should exhibit a strong absorption band at 250–260 nm (ε > 10 000 L mol^{-1} cm^{-1}) associated with the well-known $d\sigma^*$–$p\sigma$ transition (13). However, this band is absent from the spectra, as **6** and **12** exhibit spectra that are identical to that of the free ligands. When computations are performed on non-cyclic oligomers (2, 3, and 4 units for examples), these angles become equal to 180°, indicating the absence of stress. These results strongly suggest that ligands **5** and **11** favour the polymer structure, and they corroborate the MALDI-TOF findings.

The tetraisocyanide complex 14

The 1:1 stoichiometric reaction between **13** and AgBF$_4$ provides compound **14** in a quasi-quantitative yield (Scheme 3). In comparison with compounds **6** and **12**, **14** does not darken with light and proves to be significantly more thermally stable in the solid state and in solution.

From experience with isocyanide complexes of Ag(I), dicoordinated Ag(I) compounds are found to be less stable than the tetracoordinated ones (10, 11*b*, 14, 15). Moreover,

Bond angles (°)		
CAgC	165.6	172.1
NCAg	170.5–175.2	176.8
CNC	171.0–175.3	177.9

Fig. 4. TGA trace of **14**. Scan rate = 3 °C min^{-1}. A small drift in the baseline is noted in the high temperature region.
14 is significantly more insoluble in common solvents than compounds **6** and **12**, which helps the purification process but, again, prevents one from getting crystals suitable for X-ray analysis. Nonetheless, a polymer and (or) oligomer structure is strongly suspected on the basis of the known structure of the related polymer 5,11,17,23-tetracyano-25,26,27,28-tetra-n-benzoxycalix[4]arene hexafluorophosphate (see molecule 3) (16). Because of its low solubility, the molecular weight for **14** cannot be measured using conventional techniques for polymers. However, the solid state IR spectrum (Fig. 3) indicates the presence of absorptions due to free end-of-chain isocyanide groups at 2122 cm^{-1} and complexed ones at 2177 cm^{-1}. The relative intensity of this band suggests that the ratio of the number of complexed -NC vs. free -NC is not very large and that **14** must be an oligomer. Because the absorptivity of the ν(NC) bands are not known, only an estimate of the number of units can be deduced. The relative area under these peaks is about 5:1 (complexed:free). Assuming that the structure found in molecule 3 is applicable, then **14** would be a trimer (C_{2v} point group). This formulation is not inconsistent with the MALDI-TOF data (Table 4). The rather small number of units may be driven by the low solubility. In addition, it is possible that other Ag(I) ion interactions with the benzene rings exist, somewhat similar to that reported by Puddephatt and collaborators (17) for unfunctionalized calix[4]arenes, but the chemical analysis indicates a 1:1 ratio

Molecule 3   Bn = CH$_2$Ph
(calix[4]arene:Ag(I)). This possibility is unlikely in this case.

The TGA trace for **14** also exhibits a cascade weight loss pattern, where three decomposition events are obvious between 300 and 700 °C (Fig. 4). The temperatures of these weight losses contrast greatly with **6** and **12**, for which most of the losses occur before 300 °C. The third event spreads from approximately 400 to 700 °C, a large temperature range that is normally associated with the presence of a polymer and (or) oligomer. Similarly to **6** and **12**, the residue must still contain organic materials at 700 °C, as the expected amount of Ag metal is only 22%.

The DSC trace recorded between –20 and 100 °C reproducibly exhibits a heat absorption associated with a second-order phase transition (i.e., glass transition, T_g = 56 °C, and $\Delta Cp = 0.08$ J °$^{-1}$ g^{-1}). Because of the rigidity of the suspected structure (molecule 3), ionic mobility may be responsible for this thermal behaviour. A similar behaviour was reported for the "rigid sticks" $[Ag(dmb)_2^+]_n$ polymers, where the counter anions were BF_4^-, PF_6^-, ClO_4^-, NO_3^-, and $TCNQ^-$ (10).

Conclusion

Ligands **5**, **11**, and **13** favour the formation of polymer structures, and much remains to be explored. Because of the relative rigidity, well-defined 1D materials are anticipated for some transition metals such as Cu(I). Ligand **13** is particularly interesting in that respect, if it can be rendered more soluble with appropriate groups in the narrow-rim. The greater thermal and light stability for **14** is also encouraging for the design of new materials with potential applications. Further research is in progress.

Chiral silicon-bridged 2-(*N,N*-dialkylamino)ethyl-substituted indenes as potential precursors for *ansa*-zirconocenes[1]

Timo Hagemeister, Peter Jutzi, Anja Stammler, and Hans-Georg Stammler

Abstract: Chiral amino-functionalized silicon-bridged indene derivatives **4a–4c** were synthesized from 3-(2-(*N,N*-dialkylamino)ethyl)indenes **2a–2c**. The C-Si coupling reactions are regioselective, leading exclusively to the formation of 1,3-disubstituted isomers in a *rac/meso* ratio of 1:1, as indicated by NMR spectroscopy. The solid-state structure of the dimethylsilyl-bridged bisindene (*R,R*)-**4a** is described. The formation of corresponding *ansa*-zirconocenes via amine elimination chemistry was monitored by ^{1}H NMR spectroscopy.

Key words: amino-functionalized indenes, silicon-bridged, *ansa*-metallocenes, chirality, regioselectivity, amine elimination chemistry.

Résumé : Utilisant les 3-(2(*N,N*-dialkylamino)éthyl)indènes **2a–2c** comme produits de départ, on a réalisé la synthèse des dérivés chiraux de l'indène à pont de silicium et portant une fonction amine **4a–4c**. Les réactions de couplage C-Si sont régiosélectives et elles conduisent exclusivement à la formation d'isomères 1,3-disubstitués qui, d'après la spectroscopie RMN, sont dans un rapport *rac/méso* égal à l'unité. On a déterminé la structure en phase solide du bisindène (*R,R*)-**4a** à pont diméthylsilyle. La formation des *ansa*-zirconocènes correspondants par le biais de la chimie d'élimination d'amine a été suivie par spectroscopie RMN du [1]H.

Mots clés : indène portant une fonction amine, pont de silicium, *ansa*-métallocènes, chiralité, régiosélectivité, chimie d'élimination d'amine.

Introduction

Donor-functionalized cyclopentadienes have recently attracted considerable attention as starting materials for the synthesis of corresponding complexes with elements from the *s*-, *p*-, *d*-, and *f*-blocks (1). In contrast, only a few examples of donor-functionalized indenes are known (2). Such compounds are promising substrates for the synthesis of chiral *ansa*-metallocenes.

Concerning *ansa*-metallocenes of group IV metals, potential applications include a wide variety of synthetic transformations, for instance olefin hydrogenation (3), epoxidation (4) and isomerization (5), allylation of aldehydes (6), ketone reduction (7), catalysis of Diels–Alder reactions (8), and dehydrogenative phenylsilane oligomerization (9).

In addition, transition metal complexes with pendant amino groups have been shown to provide special characteristics as precatalysts in olefin polymerization reactions. The option to heterogenize homogenous precatalysts due to interaction of the amino groups with Lewis or Broensted acidic surfaces is given (10). Furthermore, quaternization of the amino groups leads to a dramatically increased solubility in polar solvents and can enable the recycling of precatalysts by simple extraction procedures (11). Some recently described switchable catalyst systems exhibit a temperature-controlled allosteric effect, based on a reversible coordination of the cocatalyst MAO by the pendant donor function. As a consequence, either high- or low-molecular weight polymer products become accessible by employing an amino-substituted precatalyst (12).

Here we report on the regioselective preparation and on structural properties of chiral, silicon-bridged indene derivatives, which are substituted at the indene moiety by a dialkylaminoethyl group. New *ansa*-zirconocenes bearing such indenyl ligands are shown to be accessible via an amine elimination reaction.

Results and discussion

The 3-(2-(*N,N*-dialkylamino)ethyl)indenes (**2a–2c**), which were first described in 1967 but have been characterized only incompletely (13), served as starting compounds. Their synthesis was carried out according to a procedure introduced by Wang et al. and modified by Jutzi and Bangel for the preparation of the analogous cyclopentadienes (Scheme 1) (14).

T. Hagemeister, P. Jutzi,[2] A. Stammler, and H.-G. Stammler. Faculty of Chemistry, University of Bielefeld, 33615 Bielefeld, Germany.

Scheme 1.

rac/meso-**4a**, **4b**, **4c**
Reaction of the (2-chloroethyl)dialkylamines (**1a–1c**) with indenyl sodium in THF yielded the (dialkylaminoethyl)indenes **2a**, **2b**, and **2c** as colourless, distillable, and viscous liquids in analytical purity. The ^{1}H NMR data gave clear evidence that substitution exclusively occurred in position 3. This correlates with earlier observations (15) that the regioselectivity of coupling reactions is solvent-dependent. Reactions with electrophiles in nonpolar solvents predominantly take place at C(1), and in more polar media such as THF, mainly at C(3).

The compounds **2a–2c** were converted almost quantitatively into the intensively coloured potassium (dialkylaminoethyl)indenides **3a–3c** by reaction with KH in THF. Subsequent C—Si bond formation was achieved by metathesis of the salts with a slight excess of dimethyldichlorosilane (Scheme 1). After conventional work-up, the resulting chiral 1,3-bis(indenyl)dimethylsilanes **4a–4c** were obtained as pure, viscous orange-brown oils in 60–70% yields. The new compounds were characterized by ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy, mass spectrometry, as well as elemental analysis. They turned out to be remarkably air- and moisture stable; for instance stirring in water for 18 h did not lead to decomposition.

The ^{1}H NMR data of **4a–4c** indicated the regioselective introduction of the silicon-bridge under retention of the double bond position. The 1,3-substitution pattern was proved

by the observed AB spin-system leading to two doublets with equal intensities and ^3J (H$_A$, H$_B$) = 1.1 Hz. The presence of the double bond between C(2) and C(3) was most clearly demonstrated by ^{13}C NMR data. With $\delta_{C(2)}$ = 129.9–130.2 ppm and $\delta_{C(3)}$ = 145.2–146.1 ppm, the resonances for these carbon atoms remained almost unshifted relative to the parent compounds **2a–2c**.

The compounds **4a–4c** possess two asymmetric centres at C(1) and C(1′). Therefore, three stereoisomers are conceivable: the (*R*,*R*)- and the (*S*,*S*)-enantiomers forming a racemate and a meso compound (Scheme 2).

The NMR data were consistent with the presence of the three possible stereoisomers. The *rac/meso* ratio of 1:1 was most easily determined from ^{1}H NMR integrals of the cleanly separated signals for the silicon bridge protons (Fig. 1 for **4a**). In the *meso* compound, one methyl group (Me$_H$) was located between the annellated benzene rings, causing a proton resonance shifted to higher field. The other methyl group (Me$_D$) lies distant from the C$_6$-perimeters, which resulted in a downfield shifted signal of equal intensity. In the racemic compounds the bridge protons are equivalent. This led to an averaged signal with doubled intensity (Fig. 1).

In accordance with earlier investigations (16), two independent signal sets were found for all other proton and carbon resonances, which can be assigned to the *rac* and *meso*

Scheme 2.

isomers. As expected, the ^{29}Si NMR data of **4a**–**4c** also exhibited two resonances each.

In addition to NMR spectroscopy and elemental analysis, the compounds **4a**–**4c** were characterized by mass spectrometry. Electron impact MS data showed the appearance of each [CH$_2$NR$_2$]$^+$ fragment with intensities of 100%. These fragments are typical of moieties containing (β-*N,N*-dialkylaminoethyl) substituents (17).

So far, no solid-state structure of a dimethylsilyl-bridged bisindene has been cited in the literature. Thus, the dimethylamino-substituted derivative **4a** was characterized by single crystal X-ray diffraction studies; crystallographic

data are presented in Table 1, selected bond lengths and bond angles are listed in Table 2.

The analysis confirmed the assumptions based on NMR investigations; all bond lengths and angles were in the expected range. The solid-state structure of the (*R,R*)-enantiomer of **4a** is illustrated in Fig. 2.[3]

In a preliminary experiment the bridged bisindene *rac*/*meso*-**4b** was employed for the synthesis of corresponding group IV metal complexes. The reaction of **4b** with Zr(NMe$_2$)$_4$ was carried out in *n*-octane at 126 °C under a continuous argon stream. In regular intervals of 2 h, the reaction atmosphere was removed under reduced pressure and replaced with fresh argon. After a total reaction time of 8 h and complete removal of the volatiles in vacuo, a mixture of the chiral zirconocene bis(amide) *rac*-**6**, of its achiral diastereomer *meso*-**6**, and of the corresponding half-sandwich complexes **5** was obtained as a highly air- and moisture-sensitive red oil (Scheme 3). The formation of the new *ansa*-metallocenes was monitored by ^{1}H NMR spectroscopy.

From ^{1}H NMR integrals of the cleanly separated signals for the Zr(NMe$_2$)$_2$ groups, the overall NMR yield of *rac*-**6** and *meso*-**6** was determined as 40% with a *rac*/*meso* ratio of 4:1. This demonstrates the predominant formation of the desired racemic isomer, which in comparable situations is generally observed under the chosen reaction conditions (18).

In detail, after a reaction time of 4 h, the resonances of the free ligand *rac*/*meso*-**4b** almost disappeared due to the formation of the half-sandwich complex **5** in its two diastereomeric forms; unfortunately, their signals were par-

caused by the *rac* and *meso* isomer of **6**. Whereas the characteristic $Zr(NMe_2)_2$ groups exhibited only one singlet at $\delta =$ 2.39 ppm for *rac*-**6**, they showed two resonances at $\delta = 1.73$ and 3.00 ppm for *meso*-**6** because of the prochirality of these moieties; an identical signal pattern was observed for the silicon bridge protons of these complexes.

Based on the ^{1}H NMR data, an intra- or intermolecular coordination of the metal centers by the pendent dimethylamino groups can be excluded, although *rac*-**6** and *meso*-**6** are formally 16-VE-complexes. This result is supported by earlier studies, which have proved a partial double bond character for the M-amido bonds in comparable group IV metallocenes (19). As a consequence of this N → M π-donation, an additional coordination of the metal centers by the pendant donor functionalities should not be observed in the neutral complexes.

It is noteworthy that more drastic reaction conditions are required for the formation of the amino-functionalized *ansa*-zirconocenes than for the synthesis of the nonfunctionalized complexes (18). Thus, substantially higher reaction temperatures and the removal of the evolved amine are necessary to enrich the *ansa*-metallocenes *rac*-**6** and *meso*-**6** in the complex equilibrium mixture.

Summary

In this paper we have described the synthesis of novel chiral silicon-bridged indene derivatives which are selectively substituted in position 3 by a 2-(*N*,*N*-dialkylamino)ethyl group. The employed strategy yields the air-

tially overlapped and obscured. A prolonged reaction time accompanied by periodical exchange of the reaction atmosphere led to the appearance of new signal multiplicities

Fig. 2. Molecular structure of (*R*,*R*)-**4a** (ORTEP diagram; 50% probability ellipsoids). Hydrogen atoms have been omitted for clarity except for H(1) and H(14).
Scheme 3.
and moisture-stable functionalized bisindenes in analytical purity without further extensive purification steps. The first solid-state structure of a dimethylsilyl-bridged bisindene has been presented. The diethylamino-functionalized derivative was shown to be a useful precursor for the synthesis of new *ansa*-zirconocenes via an amine elimination reaction. The extension of this approach to the preparation and isolation of other *ansa*-metallocenes containing the novel ligands will be described in subsequent contributions.

Experimental

All reactions were performed under purified Ar atmosphere using standard Schlenk techniques. The commercially available solvents were purified by conventional means and distilled immediately prior to use. Indenyl sodium (**14**) and

$Zr(NMe_2)_4$ (**18**) were synthesized according to the literature. Yields refer to analytically pure samples. Isomer ratios were determined from suitable ^{1}H NMR integrals of cleanly separated signals. Elemental analyses were carried out at the Microanalytical Laboratory of the Universität Bielefeld. The NMR spectra were recorded on a Bruker Avance DRX 500 spectrometer at 300 K (^{1}H, 500.1 MHz; ^{13}C, 125.8 MHz; [29]Si, 99.4 MHz). Chemical shifts are referenced to the solvent as internal standard and are reported in ppm.

3-(2-(*N*,*N*-Dimethylamino)ethyl)indene (2a)

Typical procedure

(2-Chloroethyl)dimethylamine (**1a**) (42.50 g, 395.0 mmol) was generated via a solid-phase reaction of (2-chloroethyl)dimethylamine hydrochloride and powdered so-

dium hydroxide (1:2 molar ratio) followed by a vacuum distillation using a liquid N_2 cooled trap (14). At 0 °C, the solution of (2-chloroethyl)dimethylamine in THF (80 mL) was added dropwise to a suspension of indenyl sodium (55.3 g, 400.0 mmol) in THF (200 mL). Stirring overnight at room temperature (r.t.) and subsequent refluxing for 2 h gave a green reaction mixture. The volatile components were evaporated and the residue was hydrolyzed with cooled H_2O (400 mL). After extraction of the resulting maroon solution with petrol ether (bp 35/80) (4 × 125 mL), the combined organic phases were washed with H_2O (3 × 300 mL) and dried (Na_2SO_4). The solvent was removed in vacuo and the crude product was distilled to give **2a** as a colourless, slightly viscous liquid (25.16 g, 134.3 mmol, 34%), bp 77 °C (0.5 mbar). ^1H NMR ($CDCl_3$) δ: 2.37 (s, 6H, N-CH_3), 2.67 (t, 2H, $^3J_{H,H}$ = 7.7 Hz, N-CH$_2$-CH_2-), 2.79 (t, 2H, $^3J_{H,H}$ = 7.7 Hz, N-CH_2-CH$_2$-), 3.35 (d, 2H, $^3J_{H,H}$ = 1.5 Hz, allyl-H), 6.27 (t, 1H, $^3J_{H,H}$ = 1.5 Hz, vinyl-H), 7.24 (pseudo t, 1H, $^3J_{H,H}$ = 7.5 Hz, H5), 7.34 (pseudo t, 1H, $^3J_{H,H}$ = 7.5 Hz, H6), 7.42 (d, 1H, $^3J_{H,H}$ = 7.5 Hz, H4), 7.48 (d, 1H, $^3J_{H,H}$ = 7.5 Hz, H7). ^{13}C NMR ($CDCl_3$) δ: 26.0 (N-CH$_2$-CH$_2$-), 37.6 (C1), 45.3 (N-CH$_3$), 58.2 (N-CH$_2$-CH$_2$-), 118.6 (C4), 123.4 (C7), 124.3 (C6), 125.8 (C5), 128.1 (C2), 142.2 (C8), 144.1 (C9), 145.1 (C3). MS (EI, 70 eV) m/z (%): 187(1) [M$^+$], 129(4) [IndCH$_2^+$], 115(6) [Ind$^+$], 58(100) [Me$_2$NCH$_2^+$]. Anal. calcd. for $C_{13}H_{17}N$ (187.30): C 83.37, H 9.15, N 7.48; found: C 83.40, H 9.44, N 7.05.

3-(2-(*N,N*-Diethylamino)ethyl)indene (2b)

In the same manner as described above, **2b** was obtained by reaction of (2-chloroethyl)diethylamine (**1b**) (62.4 g, 460 mmol) with indenyl sodium (64.9 g, 470 mmol) in 59% yield, bp 87 °C (0.5 mbar). ^1H NMR ($CDCl_3$) δ: 1.09 (t, 6H, $^3J_{H,H}$ = 7.2 Hz, N-CH$_2$-CH_3), 2.64 (q, 4H, $^3J_{H,H}$ = 7.2 Hz, N-CH_2-CH$_3$), 2.74 (t, 2H, $^3J_{H,H}$ = 7.4 Hz, N-CH$_2$-CH_2-), 2.81 (t, 2H, $^3J_{H,H}$ = 7.4 Hz, N-CH_2-CH$_2$-), 3.33 (b, 2H, H1), 6.24 (b, 1H, H2), 7.20 (pseudo t, 1H, $^3J_{H,H}$ = 7.4 Hz, H5), 7.30 (pseudo t, 1H, $^3J_{H,H}$ = 7.4 Hz, H6), 7.39 (d, 1H, $^3J_{H,H}$ = 7.4 Hz, H4), 7.45 (d, 1H, $^3J_{H,H}$ = 7.4 Hz, H7). ^{13}C NMR ($CDCl_3$) δ: 11.6 (N-CH$_2$-CH$_3$), 25.0 (N-CH$_2$-CH$_2$-), 37.3 (C1), 45.3 (N-CH$_2$-CH$_3$), 51.2 (N-CH$_2$-CH$_2$-), 118.4 (C4), 123.3 (C7), 124.1 (C6), 125.6 (C5), 127.7 (C2), 142.4 (C8), 143.8 (C9), 145.0 (C3). MS (EI, 70 eV) m/z (%): 215(1) [M$^+$], 143(10) [IndCH$_2$CH$_2^+$], 115(6) [Ind$^+$], 86(100) [Et$_2$NCH$_2^+$]. Anal. calcd. for $C_{15}H_{21}N$ (215.34): C 83.67, H 9.83, N 6.50; found: C 83.54, H 9.90, N 6.44.

3-(2-(*N,N*-Diisopropylamino)ethyl)indene (2c)

Compound **2c** was prepared according to the procedures described for **2a** and **2b** from (2-chloroethyl)diisopropylamine (**1c**) (79.6 g, 486 mmol) and indenyl sodium (67.7 g, 490 mmol) in 62% yield, bp 110 °C (0.5 mbar). ^1H NMR ($CDCl_3$) δ: 1.09 (d, 12H, $^3J_{H,H}$ = 6.6 Hz, N-CH-(CH_3)$_2$), 2.71 (t, 2H, $^3J_{H,H}$ = 6.5 Hz, N-CH$_2$-CH_2-), 2.77 (t, 2H, $^3J_{H,H}$ = 6.5 Hz, N-CH_2-CH$_2$-), 3.12 (sept, 2H, $^3J_{H,H}$ = 6.6 Hz, N-CH-(CH$_3$)$_2$), 3.35 (b, 2H, H1), 6.26 (b, 1H, H2), 7.22 (pseudo t, 1H, $^3J_{H,H}$ = 7.5 Hz, H5), 7.33 (pseudo t, 1H, $^3J_{H,H}$ = 7.5 Hz, H6), 7.41 (d, 1H, $^3J_{H,H}$ = 7.5 Hz, H4), 7.48 (d, 1H, $^3J_{H,H}$ = 7.5 Hz, H7). ^{13}C NMR ($CDCl_3$) δ: 20.8 (N-CH-(CH$_3$)$_2$), 30.7 (N-CH$_2$-CH$_2$-), 37.8 (C1), 44.7 (N-CH$_2$-CH$_2$-), 48.9 (N-CH-(CH$_3$)$_2$), 118.9 (C4), 123.7 (C7), 124.4 (C6), 126.0 (C5),

128.0 (C2), 143.2 (C8), 144.3 (C9), 145.6 (C3). MS (EI, 70 eV) m/z (%): 243(1) [M$^+$], 228(2) [M$^+$ – CH$_3$], 115(14) [Ind$^+$], 114(100) [i-Pr$_2$NCH$_2^+$]. Anal. calcd. for $C_{17}H_{25}N$ (243.40): C 83.89, H 10.35, N 5.75; found: C 83.63, H 10.39, N 5.78.

Potassium [1-(2-(*N,N*-dialkylamino)ethyl)indenide] salts (3a–3c)

General procedure

The solutions of the 3-(2-dialkylaminoethyl)indenes **2a**–**2c** (50 mmol) in 20 mL THF were added slowly to a suspension of potassium hydride (2.01 g, 50.1 mmol) in THF (60 mL) at –40 °C. The reaction mixtures were allowed to warm up to r.t. and stirred for 18 h. The solvent was removed in vacuo and the residues washed with *n*-hexane (2 × 50 mL). After removal of the solvent, the potassium salts were obtained as green (**3a**) (49.1 mmol, 98%), yellow (**3b**) (40.6 mmol, 81%), or brown (**3c**) (46.1 mmol, 92%) solids.

(3a)

^1H NMR ([D]$_8$ THF) δ: 1.89 (s, 6H, N-CH_3), 2.35 (t, 2H, $^3J_{H,H}$ = 6.3 Hz, N-CH$_2$-CH_2-), 2.77 (t, 2H, $^3J_{H,H}$ = 6.3 Hz, N-CH_2-CH$_2$-), 5.56 (d, 1H, $^3J_{H,H}$ = 3.2 Hz, H2), 6.06 (d, 1H, $^3J_{H,H}$ = 3.2 Hz, H1), 6.27–6.31 (m, 2H, H4, H7), 7.05–7.12 (m, 2H, H5, H6). ^{13}C NMR ([D]$_8$ THF) δ: 26.9 (N-CH$_2$-CH$_2$-), 45.2 (N-CH$_3$), 62.9 (N-CH$_2$-CH$_2$-), 91.4 (C2), 104.9 (C1), 112.9 (C7), 113.6 (C4), 116.8 (C6), 117.5 (C5), 119.4 (C3), 126.0 (C8), 128.9 (C9).

rac/meso-[Bis(3,3′-(2-(*N,N*-dimethylamino)ethyl)indenyl)]dimethylsilane (4a)

Typical procedure

Potassium [1-(2-(*N,N*-dimethylamino)ethyl)indenide] (**3a**) (5.00 g, 22.2 mmol) was dissolved in THF (35mL) and cooled to –40 °C. After dropwise addition of dimethylchlorosilane (1.15 g, 8.91 mmol) in THF (25 mL), the ma-

roon mixture was allowed to warm to r.t. Stirring was continued for 18 h and subsequent removal of the solvent gave a residue that was extracted with *n*-hexane (70 mL). After filtration the solvent was again removed in vacuo yielding a *rac/meso* mixture of **4a** as an orange-red oil (2.57 g, 5.97 mmol, 67%). Crystals of the (*R,R*)-enantiomer suitable for X-ray structure analysis were obtained by storage at 4 °C for 6 weeks. ^{1}H NMR (C_6D_6) δ: –0.52, –0.32, –0.07 (3 × s, 6H, Si-CH_3), 2.16, 2.18 (2 × s, 12H, N-CH_3), 2.51–2.83 (m, 8H, N-CH_2-CH_2-), 3.47 (b, 2H, *H*1), 6.08, 6.29 (2 × b, 2H, *H*2), 7.17–7.49 (m, 8H, *H*5, *H*6, *H*4, *H*7). ^{13}C NMR (C_6D_6) δ: –7.0, –5.9, –4.5 (Si-CH_3), 26.6, 26.8 (N-CH_2-CH_2-), 43.8, 43.9 (*C*1), 45.5, 45.5 (N-CH_3), 59.2, 59.3 (N-CH_2-CH_2-), 119.6, 119.6 (*C*4), 123.4, 123.4, 124.3, 124.3, 125.3, 125.3 (*C*7, *C*6, *C*5), 130.2, 130.2 (*C*2), 140.6, 140.8 (*C*8), 145.1, 145.2 (*C*9), 145.9, 146.0 (*C*3). ^{29}Si NMR (C_6D_6) δ: 5.5, 6.0. MS (EI, 70 eV) *m/z* (%): 430(4) [M$^+$], 372(8) [M$^+$ – Me$_2$NCH$_2$], 58(100) [Me$_2$NCH$_2^+$]. Anal. calcd. for $C_{28}H_{38}N_2Si$ (430.72): C 78.08, H 8.89, N 6.50; found: C 78.21, H 9.17, N 6.33.

rac/meso-[Bis(3,3′-(2-(*N,N*-diethylamino)ethyl)indenyl)]dimethylsilane (4b)

According to the procedure described above, **4b** was prepared by reaction of potassium [1-(2-(*N,N*-diethylamino)ethyl)indenide] (**3b**) (5.63 g, 22.2 mmol) with Me$_2$SiCl$_2$ (1.15 g, 8.91 mmol). The oily orange-brown product was obtained as a mixture of both diastereomers (2.67 g, 5.48 mmol, 62%). ^{1}H NMR (C_6D_6) δ: –0.50, –0.32, –0.06 (3 × s, 6H, Si-CH_3), 0.99–1.03 (m, 12H, N-CH$_2$-CH_3), 2.49–2.54 (m, 8H, N-CH_2-CH$_3$), 2.71–2.84 (m, 8H, N-CH_2-CH_2-), 3.48, 3.50 (2 × d, 2H, $^3J_{H,H}$ = 1.1 Hz, *H*1), 6.09, 6.32 (2 × d, 2H, $^3J_{H,H}$ = 1.1 Hz, *H*2), 7.17–7.53 (m, 8H, *H*5, *H*6, *H*4, *H*7). ^{13}C NMR (C_6D_6) δ: –6.9, –5.9, –4.5 (Si-CH_3), 12.6, 12.6 (N-CH$_2$-CH_3), 26.3, 26.4 (N-CH$_2$-CH_2-), 43.8, 43.9 (*C*1), 47.3, 47.3 (N-CH_2-CH$_3$), 52.8, 53.0 (N-CH_2-CH_2-), 119.6, 119.6 (*C*4), 123.4, 123.5, 124.3, 124.4, 125.3, 125.3 (*C*7, *C*6, *C*5), 130.1, 130.2 (*C*2), 141.0, 141.2 (*C*8), 145.2, 145.3 (*C*9), 146.0, 146.0 (*C*3). ^{29}Si NMR (C_6D_6) δ: 5.3, 5.7. MS (EI, 70 eV) *m/z* (%): 486 (3) [M$^+$], 400 (10) [M$^+$ – Et$_2$NCH$_2$], 86 (100) [Et$_2$NCH$_2^+$]. Anal. calcd. for $C_{32}H_{46}N_2Si$ (486.83): C 78.95, H 9.52, N 5.75; found: C 78.44, H 9.76, N 5.75.

rac/meso-[Bis(3,3′-(2-(*N,N*-diisopropylamino)ethyl)indenyl)]dimethylsilane (4c)

The *rac/meso* mixture of **4c** was prepared in the same manner as described above from potassium [1-(2-(*N,N*-diisopropylamino)ethyl)indenide] (**3c**) (6.25 g, 22.2 mmol) and Me$_2$SiCl$_2$ (1.15 g, 8.91 mmol) as a highly viscous brown oil (2.90 g, 5.35 mmol, 60%). ^{1}H NMR (C_6D_6) δ: –0.47, –0.29, –0.03 (3 × s, 6H, Si-CH_3), 1.01–1.03 (m, 24H, N-CH-(CH_3)$_2$), 2.75–3.05 (m, 12H, N-CH_2-CH_2-, N-CH-(CH$_3$)$_2$), 3.48, 3.52 (2 × b, 2H, *H*1), 6.11, 6.35 (2 × b, 2H, *H*2), 7.17–7.59 (m, 8H, *H*5, *H*6, *H*4, *H*7). ^{13}C NMR (C_6D_6) δ: –6.9, –5.7, –4.2 (Si-CH_3), 21.1, 21.2 (N-CH-(CH_3)$_2$), 31.0, 31.0 (N-CH$_2$-CH_2-), 43.8, 43.8 (*C*1), 45.2, 45.3 (N-CH_2-CH_2-), 48.7, 48.8 (N-CH-(CH$_3$)$_2$), 119.7, 119.7 (*C*4), 123.5, 123.5, 124.3, 124.4, 125.4, 125.4 (*C*7, *C*6, *C*5), 129.9, 130.0 (*C*2), 141.4, 141.6 (*C*8), 145.4, 145.4 (*C*9), 145.9, 146.0 (*C*3). ^{29}Si NMR (C_6D_6) δ: 5.3, 5.7. MS (EI, 70 eV) *m/z* (%): 114 (100)

[*i*-Pr$_2$NCH$_2^+$]. Anal. calcd. for $C_{36}H_{54}N_2Si$ (542.92): C 79.64, H 9.80, N 5.16; found: C 79.26, H 9.80, N 5.14.

Formation of *rac/meso*-dimethylsilanediyl[bis(3,3′-(2-(*N,N*-diethylamino)ethyl)-indenyl)]zirconocenebis(dimethylamide) (*rac/meso*-6)

In a reaction flask fitted with a fractional distillation column (30 cm × 1.5 cm) Zr(NMe$_2$)$_4$ (0.30 g, 1.12 mmol) was dissolved in *n*-octane (20 mL). At r.t. *rac/meso*-**4b** (0.55 g, 1.12 mmol) was added via a syringe. After refluxing for 2 h under a continuous argon stream a ^{1}H NMR spectrum was recorded, which indicated the formation of the half-sandwich complexes **5**. Subsequently, the reaction was heated for a further 6 h under repetitive removal of HNMe$_2$ in vacuo. During this procedure a successive discolouration of the solution from yellow to red was observed. Removal of the volatiles in vacuo yielded a mixture of the half-sandwich complexes **5** (60%) as well as of the *ansa*-zirconocenes *rac*-**6** (32%) and *meso*-**6** (8%) as a highly air- and moisture-sensitive red oil. The key ^{1}H NMR data of **5**, *rac*-**6**, and *meso*-**6** are listed below.

(5)

^{1}H NMR (C_6D_6) δ: –0.04, 0.14, 0.32, 0.59 (4 × s, 4 × 3H, Si-CH_3), 2.77, 2.78 (2 × s, 2 × 18H, N-CH_3).

(rac-6)

^{1}H NMR (C_6D_6) δ: 0.63 (s, 6H, Si-CH_3), 2.39 (s, 12H, N-CH_3), 6.20 (s, 2H, *H*2).

(meso-6)

^{1}H NMR (C_6D_6) δ: 0.46 (s, 3H, Si-CH_3), 1.04 (s, 3H, Si-CH_3), 1.73 (s, 6H, N-CH_3), 3.00 (s, 6H, N-CH_3).

Dichloro(diphosphine)(2-pyridyl-ketone)ruthenium(II) complexes[1]

Salete L. Queiroz, Alzir A. Batista, Marcio P. de Araujo, Roberto C. Bianchini, Glaucius Oliva, Javier Ellena, and Brian R. James

Abstract: Described are the synthesis and characterization of Ru(II) complexes of the type $RuCl_2L_2$(N-O), where L_2 is either 1,4-bis(diphenylphosphino)butane (dppb) or $(PPh_3)_2$, and N-O represents chelated 2-benzoylpyridine (2-bzpy) or 2-acetylpyridine (2-acpy); the Ru presursors used were $[RuCl_2(dppb)]_2(\mu\text{-dppb})$ or $RuCl_2(PPh_3)_3$. The crystal structure of *cis*-$RuCl_2$(dppb)(2-bzpy) is presented, and three other $RuCl_2L_2$(N-O) complexes with cis-chlorines are isolated and characterized spectroscopically; of the trans-dichloro species, $RuCl_2(PPh_3)_2$(N-O) complexes are isolated, while the corresponding dppb species are characterized in situ. In all cases, thermodynamically stable cis-complexes are formed from initially formed trans-species.

Key words: ruthenium, phosphines, 2-benzoylpyridine, 2-acetylpyridine, X-ray structures.

Résumé : On décrit la synthèse et la caractérisation de complexes du Ru(II) du type $RuCl_2L_2$(N-O) dans lesquels L_2 = 1,4-bis(diphénylphosphino)butane (dppb) ou $(PPh_3)_2$ et N-O = 2-benzoylpyridine (2-bzpy) ou 2-acétylpyridine (2-acpy) chélatées; les complexes de Ru utilisés sont le $[RuCl_2(dppb)]_2(\mu\text{-dppb})$ ou $RuCl_2(PPh_3)_3$. On a déterminé la structure cristalline du *cis*-$RuCl_2$(dppb)(2-bzpy) et on a isolé trois autres complexes du $RuCl_2L_2$(N-O) portant des atomes de chlore en cis et on les a caractérisés de façon spectroscopique; des espèces trans-dichlorées, les complexes $RuCl_2(PPh_3)_2$(N-O) ont été isolés alors que les espèces correspondantes du dppb ont été caractérisées in situ. Dans tous les cas, les complexes cis thermodynamiquement stables se forment à partir des espèces trans obtenues initialement.

Mots clés : ruthénium, phosphines, 2-benzoylpyridine, 2-acétylpyridine, structures par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Some 25 years ago, one of our groups published a paper (1) that questioned a reported synthesis of $[RuCl_2(PPh_3)_2]_2$ from $RuCl_2(PPh_3)_3$ using catalytic amounts of the 2-pyridyl-ketones, C_5H_4N-COR (R = H, Me, Ph) (2). The reported

B.R. James.[3] Chemistry Department, University of British Columbia, Vancouver, British Columbia, Canada V6T 1Z1.

synthesis using 2-acetylpyridine (2) was repeated (1), and the product was identified as $RuCl_2(PPh_3)_2(C_5H_4N\text{-COMe})$ containing an η^2-*N,O*-bonded pyridylketone; the complex was identified by C, H, N, and Cl analysis, molecular weight, ^1H and ^{31}P NMR, and IR data in the ν(CO) and ν(Ru-Cl) regions: the $^{31}P\{^1H\}$ NMR AB pattern required the complex to have cis-phosphines, while trans-chlorines were "favoured slightly" based on the dominance of a single 325 cm^{-1} band in the 400–250 cm^{-1} IR region (1). An X-ray analysis of the supposed $[RuCl_2(PPh_3)_2]_2$ complex was reported "to be underway" (2); no X-ray structure was ever published, but the authors of ref. 2 did agree that their product was certainly not $[RuCl_2(PPh_3)_2]_2$.[4]

This present paper reports on the synthesis and structural characterization of the complex, *cis*-$RuCl_2$(dppb)(2-benzoyl-pyridine), where dppb = 1,4-bis(diphenylphosphino)butane; data on the corresponding trans-isomer, and on the analogous 2-acetylpyridine species, are presented also. The bis(triphenylphosphine) complexes containing these 2-pyridylketones are also described. It should be noted that 2-benzoylpyridine (2-bzpy) is also called 2-pyridylphenyl-ketone (3); we use the former-type nomenclature throughout this paper.

2-Pyridylketone complexes of transition metals have been known since the 1960s, particularly the 2-bzpy ligand systems (4). More recent interest in such ligands has generally focussed on bioinorganic model systems or their hemi-labile character for use in catalysis. Structural work describing bidentate, *N,O*-bonded 2-bzpy includes that on mono- and

bis-(2-bzpy) complexes of Zn(II) in relation to models for alcohol-dehydrogenases (3), and that on Cu(I) complexes (5), while the first structural work involving Ru species was that describing an η^2-*N,O*-bonded 2-pyridylketone moiety of an ONNS-bonded thiosemicarbazone of 2,6-diacetylpyridine bonded to Ru(II) (6). Very recent reports on Ru complexes have described the structures of [Ru(PMe$_3$)$_2$(CO)(COMe)(2-bzpy)]BPh$_4$ (7), [Ru(2,2′-bipyridine)$_2$(2-bzpy)][PF$_6$]$_2$ (8), and RuCl$_2$(DMSO)$_2$(2-acpy), where 2-acpy is 2-acetyl-pyridine (9). Complexes such as [Ru(NH$_3$)$_4$(N-O)][BF$_4$]$_2$, where N-O = 2-bzpy or 2-acpy, have been isolated and characterized spectroscopically (10). Structurally characterized complexes of other platinum metals containing 2-pyridylketones have been reported, for example, [Pd(η^1,η^2-C$_8$H$_{12}$OMe)(2-bzpy)]BF$_4$ (11), and several cationic chlororhodium(III) complexes containing 2-bzpy (4).

More generally, our earlier collaborative studies have developed methods for synthesizing *cis*- and *trans*-RuCl$_2$(dppb)L$_2$ and the corresponding bis(triphenylphosphine) complexes, where L = a N-donor or L$_2$ = a bidentate, *N,N*-donor, with a basic interest in their potential as hydrogenation catalysts (12, 13), and so extension to *N,O*-donor systems allows us also to obtain a broader data base for such complexes, as well as to comment more definitively on the nature of the RuCl$_2$(PPh$_3$)$_2$(2-acetylpyridine) species isolated in 1978 (1).

Experimental

General

Synthetic procedures were performed using standard Schlenk techniques under dry Ar because solutions of the precursor complexes [RuCl$_2$(dppb)]$_2$(μ-dppb) (14, 15) and RuCl$_2$(PPh$_3$)$_3$ (16) are air-sensitive. Common chemicals used were of reagent grade quality (Aldrich). Tetrabutylammonium perchlorate (TBAP) from Fluka was recrystallized from EtOH–H$_2$O, and dried under vacuum at 80 °C (caution!). Reagent grade solvents (Merck) were appropriately distilled, dried, and stored over Linde 4 Å molecular sieves.

IR spectra (in cm^{-1}) were recorded as CsI pellets on a Bomen–Michelson 102 instrument, and UV–vis spectra in CH$_2$Cl$_2$, given as λ_{max} or sh = shoulder in nm (ε, in M^{-1} cm^{-1}), on an HP 8452A spectrophotometer. NMR spectra were recorded on a Bruker 400 MHz spectrometer (400 MHz for ^{1}H, 100.6 MHz for ^{13}C, 162 MHz for ^{31}P) at room temperature (r.t., ~20 ºC) in CH$_2$Cl$_2$ or CD$_2$Cl$_2$. Residual solvent proton, solvent carbon, or external P(OMe)$_3$ (^{31}P, δ 141.00 relative to 85% aq. H$_3$PO$_4$) were used as references. Cyclic and differential pulse voltammetries were carried out at r.t. in freshly distilled CH$_2$Cl$_2$ containing 0.1 M TBAP, using a PAR model 273A potentiostat/galvanostat with an EG&G/PARC model 175 universal programmer as a sweep generator. A three-electrode system with resistance compensation was used throughout, the working and auxiliary electrodes being a stationary Pt foil and a Pt wire, respectively. The reference electrode was Ag/AgCl in a Luggin capillary in the CH$_2$Cl$_2$ medium, in which ferrocene is oxidized at 0.43 V (Fc$^+$/Fc); all potentials are reported with respect to the Ag/AgCl electrode. Elemental analyses were performed at the Institute of Chemistry of the University of São Paulo.

cis-RuCl$_2$(dppb)(2-bzpy) (*cis*-1)

cis-**1** was prepared by stirring [RuCl$_2$(dppb)]$_2$(μ-dppb) (97 mg, 0.06 mmol) and 2-bzpy (60 mg, 0.32 mmol) in C$_6$H$_6$ (8 mL) at r.t. for 2 h. The resulting blue solution was reduced in volume to ~1 mL, when Et$_2$O was added to precipitate a blue solid that was collected, washed with hexanes and Et$_2$O, and dried under vacuum. Yield: 70%. UV–vis: 300 (9685), 620 (3370), 720 sh (2010). Anal. calcd. for C$_{40}$H$_{37}$NOP$_2$Cl$_2$Ru: C 62.47, H 4.87, N 1.83; found: C 62.8, H 5.1, N, 1.5. Crystals suitable for X-ray analysis were grown by evaporation of a CH$_2$Cl$_2$–Et$_2$O–MeOH solution of the complex. *trans*-**1** was generated in situ in a NMR tube in C$_6$D$_6$ from a rapid reaction of [RuCl$_2$(dppb)]$_2$(μ-dppb) with excess 2-bzpy (see *Results and discussion*).

cis-RuCl$_2$(dppb)(2-acpy) (*cis*-2)

cis-**2** was made by refluxing [RuCl$_2$(dppb)]$_2$(μ-dppb) (97 mg, 0.06 mmol) and 2-acpy (0.1 mL, 0.89 mmol) in C$_6$H$_6$ (8 mL) for 48 h. The resulting purple precipitate was collected, washed with Et$_2$O, and dried under vacuum. Yield: 75%. UV–vis: 340 sh (2780), 557 (3175), 655 sh (1690). Anal. calcd. for C$_{35}$H$_{35}$NOP$_2$Cl$_2$Ru: C 58.41, H 4.91, N 1.95; found: C 57.9, H 4.9, N, 1.8. *trans*-**2** was generated in situ as described for *trans*-**1**, but using excess 2-acpy (see *Results and discussion*).

trans-RuCl$_2$(PPh$_3$)$_2$(2-acpy) (*trans*-3)

trans-**3** was prepared by dissolving RuCl$_2$(PPh$_3$)$_3$ (100 mg, 0.10 mmol) and 2-acpy (0.014 mL, 0.12 mmol) in CH$_2$Cl$_2$ (5 mL) at r.t. The solution immediately changed from brown to blue, when the volume was rapidly reduced to ~1 mL; hexanes was then added to precipitate a blue solid that was collected, washed with hexanes, and dried under vacuum. Yield: 68%. UV–vis: 376 (1705), 604 (1970). Anal. calcd. for C$_{43}$H$_{37}$NOP$_2$Cl$_2$Ru: C 63.16, H 4.56, N 1.71; found: C 62.4, H 5.0, N 1.3.

cis-RuCl$_2$(PPh$_3$)$_2$(2-acpy) (*cis*-3)

cis-**3** was prepared by stirring RuCl$_2$(PPh$_3$)$_3$ (50 mg, 0.05 mmol) and 2-acpy (0.014 mL, 0.12 mmol) in CH$_2$Cl$_2$ (5 mL) for 12 h at r.t. The volume of the resulting purple solution was reduced to ~1 mL and hexanes was added to precipitate a purple solid that was collected, washed with Et$_2$O, and dried under vacuum. Yield: 70%. UV–vis: 346 sh (4900), 554 (5200), 680 sh (2250). Anal. calcd. for C$_{43}$H$_{37}$NOP$_2$Cl$_2$Ru: C 63.16, H 4.56, N 1.71; found: C 62.8, H 4.7, N 1.8.

trans-RuCl$_2$(PPh$_3$)$_2$(2-bzpy) (*trans*-4)

trans-**4** is formed immediately on mixing RuCl$_2$(PPh$_3$)$_3$ (200 mg, 0.20 mmol) and 2-bzpy (57.2 mg, 0.31 mmol) in CH$_2$Cl$_2$ (5 mL) at r.t. The volume of the blue solution was reduced to ~1 mL, and Et$_2$O was added to give a blue solid that was collected, washed with Et$_2$O, and dried under vacuum. Yield: 62%. UV–vis: 280 sh (2520), 670 (5025). Anal. calcd. for C$_{48}$H$_{39}$NOP$_2$Cl$_2$Ru: C 65.53, H 4.47, N 1.59; found: C 65.15, H 4.6, N 1.6.

cis-RuCl$_2$(PPh$_3$)$_2$(2-bzpy) (*cis*-4)

cis-**4** was prepared as described for *trans*-**4**, but the reactant solution was left for 6 h at r.t. Yield: 65%. UV–vis: 292 (10 900), 604 (4045), 720 sh (2350). Anal. calcd. for C$_{48}$H$_{39}$NOP$_2$Cl$_2$Ru: C 65.53, H 4.47, N, 1.59; found: C 65.5, H 4.6, N 1.7.

The $^{31}P\{^1H\}$ NMR, IR, and electrochemical data for complexes **1–4** are summarized in Table 1; ^1H and ^{13}C NMR data spectra were measured, and the more significant findings are presented in the *Results and discussion* text.

X-ray crystallography of *cis*-RuCl$_2$(dppb)(2-bzpy) (*cis*-1)

A prismatic crystal was used in the single-crystal, X-ray diffraction experiment, measurements being made on an Enraf-Nonius CAD-4 diffractometer with graphite monochromated Mo Kα (λ = 0.71073 Å) radiation. Crystal and structure refinement data for *cis*-**1** are summarized in Table 2.[5] One standard reflection measured every 30 min was used to apply a decay correction, the maximum decay being 1%. The data collection and reduction were performed with the programs CAD-4 (17) and XCAD-4 (18), respectively.

The structure was solved by direct methods with SHELXS-86 (19), and the model refined by full-matrix least-squares on F^2 by means of SHELXL-97 (20). After inclusion of the complete complex in the refinement, the difference Fourier map showed two peaks that were interpreted as a MeOH solvent. All the H atoms were stereochemically positioned and refined with the riding model (20), with the C—H bond lengths in the aromatics rings, CH$_2$ and CH$_3$ groups, being set equal to 0.93, 0.97, and 0.96 Å, respectively. Once the complete isotropic model was obtained, an empirical absorption correction (21) was applied (minimum and maximum transmission factors were 0.9039 and 0.8469, respectively), after which all non-H atoms were refined anisotropically. The H atoms of the aromatic rings and CH$_2$ were set isotropic with a thermal parameter 20% greater than the equivalent isotropic displacement parameter of the C atom to which each one is bonded; this percentage was set to 50% for the H atoms of the Me group. The atomic scattering factors were taken from ref. 22.

Results and discussion

The RuCl$_2$(dppb)(2-bzpy) complex (**1**) is isolated from a simple, 2 h, r.t. reaction of excess 2-bzpy with [RuCl$_2$(dppb)]$_2$(μ-dppb), as outlined in eq. [1]. The structure of **1**, presented as an ORTEP in Fig. 1 (23), reveals the Ru(II) ion in a distorted octahedral environment, with cis-chlorines, one trans to a P atom of chelated dppb, and one trans to the O atom of chelated 2-bzpy, whose N atom is trans to the second P atom. The asymmetric unit consists of one molecule of *cis*-**1** and a MeOH solvent. Throughout the paper, the cis- and trans-nomenclature refers to the arrangement of chlorine ligands.

[1]
Relevant interatomic distances and angles are listed in Table 3. The Ru—Cl (avg 2.427 Å), Ru—N (2.126 Å), and Ru—P (avg 2.289 Å) bond lengths observed are within the normal, well-established range for those in Ru(II) complexes (12, 13, 24). The Ru—N bond is ~0.07 Å shorter than that in [Ru(PMe$_3$)$_2$(CO)(COMe)(2-bzpy)]$^+$ where the N atom is trans to CO (7), but is ~0.08 Å longer than that in [Ru(2,2′-bipyridine)$_2$(2-bzpy)]$^{2+}$ where the N atom is trans to a bipyridine-N (8); the expected trans influence (8, 25) is evident. The Ru—O bond length of 2.035(3) Å is the shortest found in the three Ru-(2-bzpy) complexes: trans to the COMe group in the monocation, the Ru—O length is 2.226(4) Å (7), while trans to a bipyridyl-N the value is 2.058 Å (8). Ru—N and Ru—O bond distances in *trans*-RuCl$_2$(DMSO)$_2$(2-acpy), where both N and O are trans to S-bonded DMSO, are 2.122(3) and 2.084(3) Å, respectively

[5] Supplementary data (full crystal data and details on data collection and refinement have been deposited along with tables of atomic coordinates, anisotropic thermal parameters, all bond lengths and angles, and torsion angles) may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 208536 contains the supplementary data for this paper. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, U.K.; fax +44 1223 336033; or deposit @ccdc.cam.ac.uk).

[a]At ~1 Å from the Ru atom.

(9). The Ru—O bond in *cis*-**1** is also shorter than that found for the acetylpyridine moiety of an ONNS-bonded thiosemicarbazone at Ru(II) (2.232 Å) (6) and for the coordinated acetone of $RuCl_2(CO)(PPh_3)_2(\text{acetone})$, 2.194 Å (26); the small value is readily rationalized in that in *cis*-**1**, the coordinated ketone moiety is trans to chloride, a π-donor, while in the other systems the ketone group is trans to PPh$_3$ (26) and an imine N atom (6), both π-acceptors. The bite angle of the benzoylpyridine ligand in *cis*-**1** (76.7(1)°) is close to those found, for example, in the other Ru-(2-bzpy) (7, 8) and Ru-(2-acpy) (9) complexes; the essential planarity of the five-membered chelate ring, with an approximate 45° twist of the benzoyl-phenyl from the planarity, is similar to those noted for the other two 2-bzpy complexes (7, 8). The structure of the "*cis*-$RuCl_2(dppb)$" component of *cis*-**1** is very similar to that in *cis*-$RuCl_2(dppb)(N\text{-}N)$ complexes, where N-N = 2,2′-bipyridine or 1,10-phenanthroline (12).

Table 1 lists some spectroscopic and electrochemical data for *cis*-**1** and the other 2-pyridylketone complexes studied in this work. The solution NMR data imply the solid state structure is maintained in solution: the $^{31}P\{^1H\}$ NMR AX pattern does not itself distinguish between *cis*-**1** and *trans*-**1** (see below), but two strong ν(Ru-Cl) bands in the IR spectrum are consistent with cis-geometry. We have recently established for Ru(II)-dppb species (with 18 data points) an

inverse dependence of the ^{31}P shifts on Ru—P bond length (12); the data for *cis*-**1** fit well with this correlation and imply that the δ values of 44.7 and 40.1 refer to P(1) and P(2), respectively. ^1H NMR data confirm the presence of one bzpy ligand per dppb, while the coordination shift of the H^N atom adjacent to the N atom (δ 8.68 → 9.03) and that of ν(C=O) (1668 → 1591 cm^{-1}) again show both *O*- and *N*-coordination of bzpy. The lower ν(C=O) value in the Ru(II) species vs. values for the Zn(II) complexes (~1620 cm^{-1}) (3) is consistent with the presence of significant Ru → carbonyl π-backbonding (27). A coordination shift of the ^{13}C resonance of the C=O group (δ 193.8 → 206.1) is also evident.

The blue colour of *cis*-**1** is manifested in an absorption maximum at 620 nm with a shoulder at 720 nm, while the CV reveals a reversible redox process ($i_{pa}/i_{pc} \cong 1$) with $E_{1/2} = 0.70$ V, the process being confirmed by differential pulse voltammetry. The Ru^{III}/Ru^{II} couple is ~10 mV more positive that for the structurally similar *cis*-$RuCl_2(dppb)(\text{bipy})$ (12), showing relative stabilization of the lower valence state by substitution of a 2-pyridyl by a benzoyl moiety.

Synthesis of the 2-acetylpyridine (2-acpy) analogue (*cis*-**2**) is as for *cis*-**1**, but requires the use of reflux conditions. The NMR and IR spectroscopic data and CV data (Table 1) are very similar to those of *cis*-**1**, and the structure is assumed to be the same (type **II** as in Fig. 1, see below and

Fig. 1. ORTEP view of *cis*-RuCl$_2$(dppb)(2-bzpy) (**1**), showing the atom labeling, with 30% probability ellipsoids.
also rxn. [1]). The Me resonance of the coordinated acetyl group is seen at δ 2.10 (upfield shifted from that of the free ligand at δ 2.71), while there is again a downfield shift (δ 8.68 → 8.85) for H^N. In contrast with *cis*-**1**, *cis*-**2** is purple and the solution spectrum shows an absorption maximum at 557 nm.

As described in the *Experimental* section, two complexes with the formulation RuCl$_2$(PPh$_3$)$_2$(2-acpy) (**3**) were isolated from the same reaction precursor RuCl$_2$(PPh$_3$)$_3$ but using different timescales. A blue solid is obtained after a few minutes, while a 12 h reaction time generates a purple solid, and the complexes have different spectroscopic properties. Three structural formulations are possible for the bis(triphenylphosphine) species: **I** (with trans chlorines), and **II** and **III** (with cis chlorines). The more stable, purple complex has ^{31}P NMR, IR, and CV data (Table 1) close to those found for *cis*-**1** and *cis*-**2**, and is thus assigned the cis-dichloro geometry **II** (cf. rxn. [1]). The ^{1}H NMR data (as for *cis*-**2**) show an upfield shift for the Me (δ 2.71 → 2.41) and a downfield shift for H^N (δ 8.68 → 9.51). The ^{31}P NMR data of a solution of the blue complex show about a 9 ppm difference between the δ$_A$ and δ$_X$ values vs. ~5 ppm for the cis-complexes, and the ν(Ru-Cl) region shows a single, sharp band at 325 cm^{-1}, findings that imply that the blue species is *trans*-**3**. Of note, the ^{1}H NMR shift for the Me is now slightly downfield (δ 2.71 → 2.79), while that for H^N is now slightly upfield (δ 8.68 → 8.60). These shifts are the reverse of those seen for the cis-complexes, and presumably reflect that the acetyl is now trans to the π-acceptor PPh$_3$ (structure **I**) vs. the π-donor chloride ligand (structure **II**). Further, the $E_{1/2}$ value of *trans*-**3** is 8–10 mV lower than those of the cis-species, again consistent with the trans formulation, as a

trans-dichloro species of this type invariably has a lower reduction potential than that of a corresponding *cis*-formulation (12, 28, 29). Of note, a solution of the blue *trans*-**3** isomerizes over time to the purple cis-species, a process that can be readily monitored by CV (30) (cf. Fig. 2, $t_{1/2}$ ~ 30 min at r.t.), ^{31}P or ^{1}H NMR, or by UV–vis spectroscopy. *trans*-**3** shows UV–vis absorption maxima at 376 and 604 nm, while *cis*-**3** has a maximum at 554 and a shoulder at ~680 nm.
cis- and *trans*-RuCl$_2$(PPh$_3$)$_2$(2-bzpy)$_2$ (**4**) are made similarly to the 2-acpy analogues (**3**), the initially formed kinetic product being the blue, trans-isomer, this then transforming to an isolable, purple cis-isomer (Table 1). Whether *cis*-**4** has geometry **II** or **III** is unclear; the ^{31}P NMR data are close to those of the other cis species (of structure **II**), but the ν(Ru-Cl) IR data are significantly different and may indicate structure **III**.

cis-RuCl$_2$(dppb)$_2$(2-bzpy) (*cis*-**1**) was isolated after a 2 h reaction time at r.t. (see above), but initially when the reactants are mixed, the trans-isomer is detected by in situ ^{31}P NMR (see Fig. 3 and Table 1). Corresponding behaviour is seen for the isolated *cis*- and in situ formed *trans*-

Fig. 2. Differential pulse voltammogram of *cis*- and *trans*-RuCl$_2$(PPh$_3$)$_2$(2-acpy) (**3**).

Fig. 3. ^{31}P{^{1}H} NMR in C$_6$H$_6$ of a mixture of *cis*- and *trans*-RuCl$_2$(dppb)(2-bzpy) (**1**): top, "immediately" after mixing [RuCl$_2$(dppb)]$_2$(μ-dppb) and 2-benzoylpyridine; bottom, after 25 min when just *cis*-**1** is seen.

^{31}P{^{1}H} NMR (δ_A 43.6, δ_X 38.8; J = 35 Hz) and ^{1}H NMR data (δ_{Me} 2.40; δ_H 9.54, H adjacent to N) in CDCl$_3$, and the purple colour (**1**), are all consistent with a *cis*-**3** formulation (see Table 1). The only contrary evidence is the reported single ν(Ru-Cl) value of 325 cm^{-1} (**1**) that pertains to *trans*-**3**. It is evident that the spontaneous trans/cis isomerization process was not recognized in the early work, and the data reported in this current paper, especially with the X-ray analysis for *cis*-**1**, characterize more completely the nature of these Ru(II) 2-pyridylketone complexes.

Acknowledgements

RuCl$_2$(dppb)$_2$(2-acpy) (**2**) species (Table 1). The trans → cis isomerization process is faster for all the systems in the presence of sunlight; details of possible isomerization mechanisms (31) for these chelated six-coordinate complexes remain to be elucidated.

Reevaluation of the 1978 data for the reported RuCl$_2$(PPh$_3$)$_2$(2-acpy) complex **3** in this current paper (see *Introduction*) can now be made. The previously reported r.t.

Synthesis and molecular structures of platinum(II) and platinum(IV) diimine complexes possessing fluoroalkyl ligands[1]

Russell P. Hughes, Antony J. Ward, Arnold L. Rheingold, and Lev N. Zakharov

Abstract: A range of Pt-diimine complexes possessing fluoroalkyl and hydrofluoroalkyl ligands were synthesized from the readily prepared [Pt(diimine)Me$_2$] complexes and the appropriate iodofluoroalkane. For complexes with diimine ligands containing substituents in the 2,6-positions of the aryl group, Pt(II) complexes were obtained due to in situ reductive elimination of MeI, while for complexes with diimine ligands of smaller steric demands (possessing substituents in the 3,5-positions or the 4-position), Pt(IV) complexes were obtained. Attempts to convert the Pt(IV) complexes to the desired Pt(II) species via reductive elimination of MeI, methane, or ethane resulted in either no reaction or degradation of the starting complex. Fluoroalkyl(methyl)platinum(II) complexes were then converted to the fluoroalkyliodoplatinum(II) complexes via addition of I$_2$ or by reaction with aq HI. Several complexes have been characterized crystallographically.

Key words: fluoroalkyl, organometallic synthesis, structure, platinum.

Résumé : Utilisant comme produit de départ des iodofluoroalcanes appropriés et des complexes [Pt(diimine)Me$_2$] qui peuvent facilement être préparés, on a préparé un éventail de complexes Pt-diimine portant des ligands fluoroalkyles et hydrofluoroalkyles. Pour les complexes avec des ligands diimines portant des substituants dans les positions 2,6 du groupe aryle, on a obtenu des complexes de Pt(II) en raison d'une élimination réductrice in situ de MeI alors qu'on a obtenu des complexes de Pt(IV) avec pour les complexes avec des ligands diimines dont les demandes stériques sont plus faibles (qui portent des substituants dans les positions 4 ou 3,5). Des essais en vue de transformer les complexes de Pt(IV) en espèces Pt(II) désirées par le biais d'une élimination réductrice de MeI, de méthane ou d'éthane n'ont pas donné de réaction ou une dégradation du complexe de départ. Les complexes fluoroalkyl(méthyl)platine(II) ont ensuite été transformés en complexes fluoroalkyliodoplatine(II) par le biais d'une addition de I$_2$ ou par une réaction avec du HI aqueux. Plusieurs complexes ont été cristallisés par diffraction des rayons X.

Mots clés : fluoroalkyle, organométallique, synthèse, structure, platine.

[Traduit par la Rédaction]

Introduction

Much recent work within our research group has focussed upon the synthesis of late transition metal–fluoroalkyl complexes, particularly those of metals from groups 9 (1–9) and 10 (10–12), utilizing oxidative addition of iodoperfluoroalkanes (11). While many such complexes have been synthesized previously using oxidative addition reactions (13–18), we have shown that such a route can often lead to fluoro-

alkylation at ligand sites rather than at the metal center in both early and late transition metals (19–22).

There have been many studies of oxidative addition of alkyl halides to square-planar Pt(II) precursors (23–27). In the majority of cases, the reaction of bromo- and iodoalkanes with dimethylplatinum(II) complexes occurs via a polar S$_N$2 mechanism to give a Pt(IV) complex with kinetically controlled trans stereochemistry (23), although subsequent isomerization has been shown in some cases to afford the cis product (28). On occasion, cationic five-coordinate intermediates have been detected spectroscopically (29). These five-coordinate species in the oxidative addition reaction have also been shown to serve as key intermediates for reductive elimination of methyl iodide or ethane from Pt(IV) (30–32).

The oxidative addition reactions of iodofluoroalkanes to transition metals is unlikely to proceed via polar S$_N$2 attack by the metal at carbon due to the unfavourable polarity of the C$^{\delta-}$—I$^{\delta+}$ bond (33, 34). In previous systems involving reactions of primary iodoperfluoroalkanes, we have postulated that the reactions proceeded via electron transfer to the iodofluoroalkane, followed by rapid loss of iodide from the

resultant radical anion, and very fast trapping of the fluoro-alkyl radical at the metal (21, 22).

While most studies of oxidative addition – reductive elimination to Pt(II) centers have involved complexes bearing monodentate or bidentate phosphorus ligands, complexes with chelating nitrogen ligands have also been examined (23). *cis*-Dialkyl- and -diarylplatinum(II) complexes with nitrogen donor ligands usually react with alkyl halides to afford the trans oxidative addition product (35–38). The corresponding cis-isomer can be formed either by a competitive cis oxidative addition pathway, or by trans oxidative addition with subsequent isomerization of the platinum(IV) product to a thermodynamically more stable cis-isomer (23). Dimethylplatinum(II) complexes possessing pyridine (35), 2,2′-bipyridine (39), 1,10-phenanthroline (39, 40), bis(*p*-tolylimino)acenaphthene (41), bis(phenylimino)camphane (41), various diimine ligands (42, 43), and tetramethylethyl-enediamine (tmeda) (44, 45) have been studied.

We have previously reported on the reactions of [Pt(tmeda)Me$_2$] with fluoroalkyl iodides to give Pt(IV) and Pt(II) fluoroalkyl complexes (11). Here we report on the corresponding reactions of dimethylplatinum(II) complexes bearing diimine ligands.

Results and discussion

Synthesis

In contrast to the very facile oxidative addition reactions of [Pt(tmeda)Me$_2$] with fluoroalkyl iodides (11), the corresponding reactions of the [Pt(diimine)Me$_2$] complexes **1** and **2** required heating at reflux in ethyl acetate to afford the fluoroalkyl Pt(IV)–diimine complexes **3–6** (Scheme 1). To reduce the possibility of light-induced radical chemistry of the fluoroalkyl iodides, the reactions were performed in the dark, although no attempts were made to evaluate whether light actually does cause problems in these cases. When [Pt(diimine)Me$_2$] complexes **7** and **8** were used, which possess a diimine ligand containing a 2,6-dimethylaryl fragment, the products formed were always the Pt(II) complexes **9–12** (Scheme 2). This can be ascribed to steric congestion around the Pt(IV) centre (initially formed by oxidative addition of the R$_f$I to the [Pt(diimine)Me$_2$] complex), resulting in in situ reductive elimination of MeI to form the square planar Pt(II) complex.

Owing to the solubility of **7** in hexane, the desired perfluoroalkyl complexes could also be obtained by heating at reflux in hexane for 8 h. The use of hexane, however, only resulted in better yields when the perfluoroalkyl group was C$_3$F$_7$. Hexane also afforded straightforward isolation of the Pt(II) complexes, which are insoluble in hexane. Unfortunately, the lack of hexane solubility for dimethyl complexes possessing other diimine ligands (**1**, **2**, and **8**) precluded its use as a general solvent for the synthesis of these complexes.

Before ethyl acetate was found to facilitate these oxidative addition reactions of [Pt(diimine)Me$_2$] complexes with iodo-fluoroalkanes, attempts were made to use benzene as a solvent. However, when benzene was used, the reaction was incomplete after heating at reflux for 24 h, and there was formation of elemental Pt. NMR of the crude reaction mixtures showed approximately 30%–40% conversion to the desired products after 24 h. However, isolation of the oxidative

addition products proved unsuccessful due to the very similar solubilities exhibited by the starting materials, free diimine ligand, and the oxidative addition products. The subsequent choice of ethyl acetate was based solely upon its slightly lower boiling point as compared to benzene, as previous experience within our research group has shown that certain oxidative addition reactions can be very temperature dependent (46). It may also have proven to be a fortuitous choice for a reaction that may proceed via a fluoroalkyl radical, since electrostatic repulsion of the oxygen atoms of the ethyl acetate has been shown to significantly inhibit hydrogen atom abstraction by fluoroalkyl radicals when compared with rates of abstraction from alkanes (47), thereby perhaps increasing the yield of organometallic product.

The Pt(IV) species obtained were invariably those in which the perfluoroalkyl moiety was mutually trans to the iodo ligand, giving rise to complexes with C_s symmetry, as shown for complexes **3**, **4**, and **6**. The ^{19}F NMR spectrum of **3** reveals two resonances for the *m*-CF$_3$ groups of the diimine ligand indicating that there is no free rotation about the *N*-aryl bonds on the NMR timescale. However, the ^{19}F NMR spectrum of **4** reveals only one resonance for the *m*-CF$_3$ groups of the diimine ligand indicating apparently free rotation of the aryl moiety, or an accidental equivalence of CF$_3$ resonances. In the case of **5**, the presence of a stereocenter at the α-C of the fluoroalkyl group results in a complex with C_1 symmetry. This is highlighted clearly in the ^{1}H NMR spectrum of this complex in which the Pt-bound methyl groups, the CH$_3$ groups of the diimine backbone, and the *m*-CF$_3$ substituents of the aryl rings display nonequivalence (two of which are coincident), indicating that rotation of the aryl rings is slow on the NMR timescale.

Attempts to convert the Pt(IV) complexes to Pt(II) species with procedures that we have used successfully for such reductions in cases when the ligands involved are tmeda, 1,2-bis(diphenylphosphino)ethane, or 1,2-bis(dimethylphosphi-no)ethane proved unsuccessful. The methods attempted to achieve this reduction included: (*i*) removal of iodide using AgBF$_4$ and heating at reflux in acetone to eliminate ethane, followed by addition of NaI to form the iodoplatinum(II) complex (32); (*ii*) heating a solution of the complex in the presence of NEt$_3$, to form the insoluble [Et$_3$NMe]I complex upon thermal elimination of MeI (11); and (*iii*) reaction of the complex with NaBH$_4$ (to convert the iodo ligand to a hydride) and then stirring at room temperature to allow the complex to thermally eliminate methane. In the first case, the starting complexes were obtained without any observable isomerization, while degradation of the Pt(IV) complex to elemental platinum occurred in the last two methods.

As discussed above, the only instances in which Pt(II) complexes were obtained were from reactions in which the diimine ligand possessed the 2,6-dimethylaryl substituent. The NMR spectra of these complexes are very diagnostic as the backbone protons (or methyl groups) of the diimine ligand are inequivalent due to the C_s symmetry of the square-planar complexes. In the ^{1}H NMR spectrum, the diimine backbone protons of complexes **9** and **10** exhibit Pt satellites: in the case of **9**, these $^3J_{\text{PtH}}$ coupling constants were 36 Hz (δ 9.01 ppm) and 84 Hz (δ 8.93 ppm), while for **10** the coupling constants were 37 Hz (δ 9.20 ppm) and 42 Hz (δ 9.06 ppm), respectively. A similar coupling was

previously seen in numerous unsymmetrical platinum diimine complexes (42, 48–54). Tilset (49) assigned the protons on the diimine backbone using a variety of NMR techniques, with the smaller coupling being ascribed to those protons transoid to the methyl ligand. Thus, some indication as to the relative trans-influence of the two different fluoroalkyl ligands in these complexes can be obtained: the partially fluorinated ligand ($CFHCF_3$) exerts a stronger trans influence than the perfluorinated ligand (C_3F_7). The complexes possessing methyl substitution of the diimine backbone (complexes **11** and **12**) do not exhibit any coupling to Pt.

The [Pt(diimine)(R_f)Me] complexes **9**–**12** are readily converted to the iodo complexes **13**–**16** via two methods, each of which results in selective cleavage of the Pt—CH_3 bond rather than the Pt—fluoroalkyl bond. The first involves the reaction of the complex with I_2 in CH_2Cl_2, possibly resulting in the formation of a transient diiodo–Pt(IV) complex, which undergoes thermal reductive elimination of MeI. The second pathway involves reaction of the methyl complex with 1 equiv. of aq HI in toluene (Scheme 2), resulting in the gen-

eration of methane followed by trapping of the resulting cationic Pt(II) fragment with iodide. Both methods afford the iodo complexes in 70%–80% yield after recrystallization from dichloromethane–hexane.

The NMR spectra of the iodo complexes are very similar to those of the methyl analogues. As was the case for the methyl complexes, the backbone protons of the diimine ligand in complexes **13** and **14** display platinum coupling: for **13**, $^3J_{PtH} = 102$ Hz (δ 9.00 ppm) and 40 Hz (δ 8.62 ppm), while for **14**, $^3J_{PtH} = 100$ Hz (δ 9.16 ppm) and 38 Hz (δ 8.68 ppm). Presumably, the large difference in the coupling constants for both complexes may be explained by the large cis-effect exerted by the iodo ligand. As was the case in the methyl complexes, no platinum satellites were observed for those complexes possessing methyl substitution on the backbone of the diimine ligand.

Crystal structures

X-ray diffraction quality crystals were obtained for several of the Pt(IV) complexes by slow recrystallization from CH_2Cl_2–hexane. Crystal structures were obtained for com-

plexes **3** (Fig. 1), **4** (Fig. 2), and **5** (Fig. 3). Details of the crystal data and structure determinations of all complexes are presented in Table 1. Selected bond lengths and angles for the coordination sphere of Pt are given in Table 2. For easy comparison, a common numbering scheme has been adopted: in the Pt(IV) complexes, the equatorial plane corresponds to the plane of N(1) and N(2) of the diimine ligand

and C(1) and C(2) of the two methyl groups, while C(3) (the α-carbon of the perfluoroalkyl moiety) is always trans to I.

The structures obtained for complexes **3** and **4** display disorder in the CF$_3$ groups of the diimine ligand, and, in the case of the structures for **4** and **5**, a small amount of disorder is also observed in the perfluoroalkyl moiety.

The crystal structures of complexes **3**, **4**, and **5** show the

Pt(IV) center to have approximate octahedral geometry. There is only a subtle deviation from the ideal angle of 180° for C(3)-Pt-I(1), with **5** showing the largest discrepancy with an angle of 175.8(3)°. The deviation is also observed for the C(3)-Pt-N(1) angle in **5**, which exhibits a value of 96.7(3)°, while complexes **3**, and **4** have angles close to 90°. In all structures, there is deviation from the expected angles in the plane of the Pt atom: the C(1)-Pt-C(2) angles are reduced substantially (especially in the case of **4** and **5**), presumably due to the bulk of the aryl groups on the diimine ligand. As a consequence, the C(1)-Pt-N(2) and the C(2)-Pt-N(1) bond angles are all in the region of 100°. The Pt—C(1) and Pt—

C(2) bond lengths for **3** and **5** are similar in all cases and are identical for each complex, except for complex **4**, in which there is a significant variation between the two bond lengths (2.072(11) Å and 2.031(12) Å, respectively). The source of this bond length variation is not clear. The Pt—C(3) bond lengths for **3** (2.129(8) Å) and **5** (2.076(8) Å) are significantly different, with an unexpectedly shorter bond to the partially hydrogenated α-CFH group. However, the Pt—I bond lengths for **3** (2.6769(4) Å) and **5** (2.7447(5) Å) do display the expected trend for the trans-influence of the alkyl group, with a greater degree of fluorination affording a weaker trans-influence (10, 55). Because the Pt—N(1) and

Pt—N(2) bond lengths for **3**, **4**, and **5** are similar in all cases and show no significant variation within each complex, there is clearly no cis-effect in the differently fluorinated alkyl groups.

No meaningful comparisons between the Pt(IV)–diimine complexes and the analogous Pt(IV)–tmeda complexes can be made, as the tmeda complexes isomerize from the initial trans-product to form the thermodynamically favored cis-product.[3]

Crystallization of **11** from CH_2Cl_2–hexane afforded red plates that were suitable for X-ray diffraction studies. The ORTEP diagram for complex **11** is shown in Fig. 4. Selected bond lengths and angles for the coordination sphere of Pt are given in Table 2. The numbering scheme adopted for complex **11** has N(1) trans to C(1) (the methyl group), while N(2) is trans to C(2) (the α-carbon of the perfluoroalkyl moiety).

The structure shows the complex is square planar, with no significant deviations of the ligands from the plane, but with significant bond angle deviations due to the steric bulk of the perfluoroalkyl ligand. The C(2)-Pt-N(2) bond angle of 176.1(5)° is close to the ideal angle, however, there is significant deviation observed for the C(1)-Pt-N(1) which has a bond angle of 171.0(6)°. Similarly, the C(2)-Pt-N(1) bond angle (101.8(6)°) shows a large distortion that is attributable to the steric requirements of the perfluoroalkyl moiety. Variations in the bond lengths to the Pt atom are also observed which is a consequence of the relative magnitude of the trans-influence for methyl and perfluoroalkyl ligands: the

---

[3] Our initial observations on this reaction were that the cis-product was formed. More careful studies have shown that the trans-isomer is the kinetic product. R.P. Hughes, M.A. Meyer, A.J. Ward, A. Williamson. Unpublished results.

Pt—C(1) bond length is 2.047(9) Å, while the Pt—C(2) bond length is slightly shorter at 2.032(9) Å. However, it is in the Pt—N bond lengths that the trans-effect is most clearly manifested: the Pt—N(1) bond length (trans to methyl) is 2.133(7) Å, while the Pt—N(2) bond length (trans to C_3F_7) is 2.077(8) Å.

Comparison of the structure obtained for **11** and that obtained previously for [Pt(tmeda)(C_3F_7)Me] (**11**) reveals that the presence of the diimine ligand results in significant steric crowding around the Pt center, and thus, there is some variation in bond lengths and bond angles between the two complexes. For example, the Pt—C(1) and Pt—C(2) bond lengths for the tmeda complex are 2.148(18) Å and 2.01(2) Å, respectively, compared to 2.047(9) Å and 2.032(9) Å for the same bonds in complex **11**. The Pt—N(1) and Pt—N(2) are 2.14(2) Å and 2.172(19) Å, respectively, for the tmeda complex, while they are 2.133(7) Å and 2.077(8) Å for **11**. Significant variation in bond angles is observed between the two complexes: C(1)-Pt-C(2) for **11** is 87.2(6)° and for the tmeda complex is 88.3(9)°; C(1)-Pt-N(2) for **11** is 93.9(6)° and for the tmeda complex is 92.3(8)°; C(2)-Pt-N(2) for **11** is 101.8(6)° and for the tmeda complex is 97.7(9)°. While these large variations are probably attributable solely to the large steric bulk of the diimine aryl groups, the data for the tmeda complex are of poor quality and preclude any more meaningful comparisons.

Experimental section

General considerations

Unless otherwise noted, all reactions were performed in oven-dried glassware, using standard Schlenk techniques, under an atmosphere of nitrogen (which had been deoxygenated over BASF catalyst), and dried using Aquasorb®. Solvents were deoxygenated and dried over activated alumina using an apparatus modified from that described in the literature (56). ^1H (300 MHz), ^{19}F (282 MHz), and ^{31}P (121.4 MHz) NMR spectra were recorded on a Varian Unity-300 spectrometer at 25 °C. Chemical shifts are reported as ppm downfield of TMS (^1H, referenced to solvent) or internal $CFCl_3$ (^{19}F). Coupling constants are reported in Hertz (Hz). Microanalyses were performed by Schwartzkopf Microanalytical Laboratory (Woodside, N.Y.).

Iodoperfluoroalkanes were purchased from PCR, (except for CF_3CFHI, which was purchased from ABCR) treated with $Na_2S_2O_3$ to remove residual I_2, and vacuum distilled before use. The complexes [Pt(3,5-$(CF_3)_2ArN=C(Me)C(Me)=N-3,5-(CF_3)_2Ar)Me_2$] (**1**) (57), [Pt(4-MeArN=CHCH=N-4-MeAr)Me_2] (**2**) (58), [Pt(2,6-$Me_2ArN=CHCH=N-2,6-Me_2Ar)Me_2$] (**7**) (59), and [Pt(2,6-$Me_2ArN=C(Me)C(Me)=N-2,6-Me_2Ar)Me_2$] (**8**) (59) were prepared as reported previously.

trans-*[1,2-Bis(3,5-bis(trifluoromethylphenylimino)-1,2-dimethylethane]dimethyl(heptafluoropropyl)iodoplatinum(IV)* (3)

To a solution of **1** (100 mg, 0.14 mmol) in degassed ethyl acetate (10 mL) was added heptafluoropropyl iodide (30 mL, 0.20 mmol) and the reaction mixture was heated at reflux for 2 h in the absence of light. The solvent was removed in vacuo. The residue was recrystallized from CH_2Cl_2–hexane to afford the product as an orange powder (86 mg, 71%). ^1H NMR (CDCl$_3$) δ (ppm): 8.44 (s, 2H, ArH), 7.96 (s, 2H, ArH), 7.37 (s, 2H, ArH), 2.49 (s, 6H, $^4J_{PtH}$ = 5 Hz, N=C(CH_3)), 1.37 (s, 6H, $^2J_{PtH}$ = 73 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –63.34 (s, 6F, m-ArCF_3), –63.47 (s, 6F, m-ArCF_3), –80.07 (t, 3F, $^4J_{FF}$ = 13 Hz, $^4J_{PtF}$ = 9 Hz, CF$_2$CF_3), –90.08 (m, 2F, $^2J_{PtF}$ = 298 Hz, PtCF_2), –122.03 (m, 2F, CF_2CF$_3$). Anal. calcd. for $C_{25}H_{18}F_{19}IN_2Pt$ (%): C 29.17, H 1.77; found (%): C 29.37, H 1.65.

trans-*[1,2-Bis(3,5-bis(trifluoromethylphenylimino)-1,2-dimethylethane]iododimethyl-(2H-tetrafluoroethyl)platinum(IV)* (4)

To a solution of **1** (100 mg, 0.14 mmol) in degassed ethyl acetate (10 mL) was added iodo-2H-tetrafluoroethane (23 μL, 0.20 mmol) and the reaction mixture was heated at reflux in the absence of light for 2 h. The solution was cooled and the solvent removed in vacuo. The residue was extracted with hot hexanes until no colour persisted in the washings. The volume of the combined extracts was reduced in vacuo to 5 mL and cooled to –30 °C. The product was obtained by filtration as a yellow powder (86 mg, 66%). ^1H NMR (CDCl$_3$) δ (ppm): 8.42 (s, 2H, ArH), 7.94 (s, 2H, ArH), 7.45 (s, 2H, ArH), 5.45 (tt, $^2J_{FH}$ = 55 Hz, $^3J_{FF}$ = 6 Hz, $^2J_{PtH}$ = 11 Hz CF$_2$$H$), 2.47 (s, 6H, $^4J_{PtH}$ = 5 Hz, N=C(CH_3)), 1.26 (s, 6H, $^2J_{PtH}$ = 72 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –63.30 (s, 12F, m-ArCF_3), –90.98 (dt, 2F, $^3J_{FF}$ = 3 Hz, $^3J_{FH}$ = 6 Hz, $^3J_{PtF}$ = 307 Hz, CF$_2$CF$_2$H), –131.69 (dt, 2F, $^3J_{FF}$ = 6 Hz, $^2J_{FH}$ = 55 Hz, $^2J_{PtF}$ = 27 Hz, CF$_2$CF$_2$H). Anal. calcd. for $C_{24}H_{19}F_{16}IN_2Pt$ (%): C 29.98, H 2.00; found (%): C 30.21, H 1.87.

trans-*[1,2-Bis(3,5-bis(trifluoromethylphenylimino)-1,2-dimethylethane]dimethyliodo(1H-tetrafluoroethyl)platinum(IV)* (5)

To a solution of **1** (100 mg, 0.14 mmol) in degassed ethyl acetate (10 mL) was added iodo-1H-tetrafluoroethane (23 μL, 0.20 mmol) and the reaction mixture was heated at reflux in the absence of light for 2 h. The solution was cooled and the solvent removed in vacuo. The residue was extracted with hot hexanes until no colour persisted in the washings. The volume of the combined extracts was reduced in vacuo to 5 mL and cooled to –30 °C. The product was obtained by filtration as a yellow powder (85 mg, 65%). ^1H NMR (CDCl$_3$) δ (ppm): 8.73 (bs, 1H, ArH), 8.39 (s, 1H, ArH), 7.94 (s, 2H, ArH), 7.41 (bs, 2H, ArH), 4.72 (dq, 1H, $^2J_{FH}$ = 47 Hz, $^3J_{FF}$ = 10 Hz, $^2J_{PtH}$ = 410 Hz, CFH), 2.48 (s, 3H, $^4J_{PtH}$ = 5 Hz, N=C(CH_3)), 2.45 (s, 3H, $^4J_{PtH}$ = 5 Hz, N=C(CH_3)), 1.27 (d, 3H, $^4J_{FH}$ = 1 Hz, $^2J_{PtH}$ = 70 Hz, PtCH_3), 1.12 (s, 3H, $^2J_{PtH}$ = 71 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –63.18 (s, 3F, m-ArCF_3), –63.27 (s, 3F, m-ArCF_3), –63.32 (s, 6F, m-ArCF_3), –72.95 (dd, 3F, $^3J_{FF}$ = 11 Hz, $^3J_{FH}$ = 11 Hz, $^3J_{PtF}$ = 61 Hz, CFHCF_3), –191.43 (dq, 1F, $^3J_{FF}$ = 11 Hz, $^3J_{FH}$ = 47 Hz, $^2J_{PtF}$ = 135 Hz, CFHCF$_3$). Anal. calcd. for $C_{24}H_{19}F_{16}IN_2Pt$ (%): C 29.98, H 2.00; found (%): C 29.87, H 1.99. X-ray diffraction quality crystals were grown from CH_2Cl_2–hexane.

trans-*[1,2-Bis(4-methylphenylimino)ethane]dimethyl(heptafluoropropyl)iodoplatinum(IV)* (6)

To a suspension of **2** (100 mg, 0.22 mmol) in hexane

(10 mL) was added C_3F_7I (47 µL, 0.33 mmol) and the reaction mixture was refluxed for 8 h. The solution was cooled and the solvent removed in vacuo. Recrystallization from hot hexane afforded the product as an orange microcrystalline solid (104 mg, 63%). ^{1}H NMR (CDCl$_3$) δ (ppm): 8.67 (t, 2H, $^3J_{PtH}$ = 26 Hz, N=CH), 7.45 (m, 4H, ArH), 7.31 (m, 4H, ArH), 2.44 (s, 6H, ArCH_3), 1.77 (t, 6H, $^2J_{PtH}$ = 74 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –80.01 (t, 3F, $^4J_{FF}$ = 12 Hz, $^4J_{PtF}$ = 18 Hz, CF_3), –91.93 (qt, 2F, $^2J_{PtF}$ = 362 Hz, $^4J_{FF}$ = 12 Hz, $^3J_{FF}$ = 3 Hz, PtCF_2), –121.79 (m, 2F, CF_2CF$_3$). Anal. calcd. for $C_{21}H_{22}F_7IN_2Pt$ (%): C 33.29, H 2.93; found (%): C 33.83, H 3.12.

[1,2-Bis(2,6-dimethylphenylimino)ethane](heptafluoro-propyl)methylplatinum(II) (9)

To a solution of **7** (100 mg, 0.20 mmol) in hexane (10 mL) was added C_3F_7I (44 µL, 0.31 mmol) and the reaction mixture was heated at reflux for 18 h. The solution was cooled. Filtration and washing with hexane afforded the product as a maroon microcrystalline solid (146 mg, 91%). ^{1}H NMR (CDCl$_3$) δ (ppm): 9.01 (t, 1H, $^3J_{Pt-H}$ = 36 Hz, N=CH), 8.93 (t, 1H, $^3J_{PtH}$ = 84 Hz, N=CH), 7.21 (s, 4H, m-ArH), 7.14 (m, 2H, p-ArH), 2.28 (s, 12H, CH_3), 1.21 (t, 3H, $^2J_{PtH}$ = 88 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –79.98 (t, 3F, $^4J_{PtF}$ = 36 Hz, $^4J_{FF}$ = 10 Hz, CF_3), –94.74 (q, 2F, $^2J_{PtF}$ = 420 Hz, $^4J_{FF}$ = 10 Hz, PtCF_2), –120.33 (s, 2F, $^3J_{PtF}$ = 116 Hz, CF_2CF$_3$). Anal. calcd. for $C_{22}H_{23}F_7N_2Pt$ (%): C 41.06, H 3.61; found (%): C 41.04, H 3.69.

[1,2-Bis(2,6-dimethylphenylimino)ethane](1H-tetrafluoro-ethyl)methylplatinum(II) (10)

To a solution of **7** (100 mg, 0.20 mmol) in ethyl acetate (10 mL) was added iodo-1H-tetrafluoroethane (70 mg, 0.31 mmol) and the reaction mixture was heated at reflux for 12 h in the absence of light. The solvent was removed in vacuo and the residue was washed with hexane until no colour persisted in the washings. The product was obtained as purple needles after recrystallization from chloroform–hexane (50 mg, 45%). ^{1}H NMR (CDCl$_3$) δ (ppm): 9.20 (s, 1H, $^3J_{PtH}$ = 37 Hz, N=CH), 9.06 (s, 1H, $^3J_{PtH}$ = 42 Hz, N=CH), 7.24–7.15 (m, 6H, ArH), 6.03 (dq, 1H, $^2J_{FH}$ = 50 Hz, $^3J_{FH}$ = 11 Hz, $^2J_{PtF}$ = 61 Hz, CFH), 2.36 (s, 3H, ArCH_3), 2.29 (s, 3H, ArCH_3), 2.27 (s, 3H, ArCH_3), 2.20 (s, 3H, ArCH_3), 1.36 (s, 3H, $^2J_{PtH}$ = 86 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –70.69 (dd, 3F, $^3J_{FH}$ = 14 Hz, $^3J_{FF}$ = 14 Hz, $^3J_{PtF}$ = 141 Hz, CF_3), –212.28 (dq, 1F, $^2J_{FH}$ = 50 Hz, $^3J_{FF}$ = 14 Hz, $^2J_{PtF}$ = 327 Hz, CFH). Anal. calcd. for $C_{21}H_{24}F_4N_2Pt•0.5CHCl_3$ (%): C 40.65, H 3.90; found (%): C 41.37, H 3.74.

[1,2-Bis(2,6-dimethylphenylimino)-1,2-dimethyl-ethane](heptafluoropropyl)methylplatinum(II) (11)

To a solution of **8** (100 mg, 0.19 mmol) in ethyl acetate (10 mL) was added C_3F_7I (42 µL, 0.29 mmol) and the reaction mixture was heated under reflux in the absence of light for 2 h. The solution was cooled and the solvent removed in vacuo. The residue was recrystallized from CH$_2$Cl$_2$–hexane. Filtration afforded the complex as a purple powder (66 mg, 51%). ^{1}H NMR (CDCl$_3$) δ (ppm): 7.19 (m, 4H, p-ArH), 7.12 (s, 2H, p-ArH), 2.21 (s, 12H, o-ArCH_3), 1.73 (s, 3H, N=C(CH_3)), 1.63 ((s, 3H, N=C(CH_3)), 0.70 (t, 3H, $^2J_{PtH}$ = 86 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –80.01 (tt, 3F,

$^4J_{FF}$ = 10 Hz, $^4J_{PtF}$ = 19 Hz, CF_3), –93.51 (tq, 2F, $^4J_{FF}$ = 10 Hz, $^2J_{PtF}$ = 410 Hz, PtCF_2), –119.74 (t, 2F, $^3J_{PtF}$ = 119 Hz, CF_2CF$_3$). Anal. calcd. for $C_{24}H_{27}F_7N_2Pt$ (%): C 42.92, H 4.06; found (%): C 43.1, H 4.12.

[1,2-Bis(2,6-dimethylphenylimino)-1,2-dimethyl-ethane]methyl(1H-tetrafluoroethyl)platinum(II) (12)

To a solution of **8** (100 mg, 0.19 mmol) in ethyl acetate (10 mL) was added C_3F_7I (42 µL, 0.29 mmol) and the reaction mixture was heated under reflux in the absence of light for 24 h. The solution was cooled and the solvent reduced to 5 mL in vacuo. Hexane was added. Filtration afforded the product as a purple microcrystalline powder (100 mg, 85%). ^{1}H NMR (CDCl$_3$) δ (ppm): 7.30–7.17 (m, 6H, ArH), 5.63 (dq, 1H, $^2J_{FH}$ = 49 Hz, $^3J_{FH}$ = 13 Hz, $^2J_{PtH}$ = 52 Hz, CFH), 2.28 (s, ArCH_3), 1.66 (s, 3H, N=C(CH_3)), 1.35 (s, 3H, N=C(CH_3)), 1.10 (s, 3H, $^2J_{PtH}$ = 86 Hz, PtCH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –70.73 (dd, 3F, $^3J_{FH}$ = 13 Hz, $^3J_{FF}$ = 14 Hz, CF_3), –211.64 (dq, 1F, $^2J_{FH}$ = 49 Hz, $^3J_{FF}$ = 14 Hz, CFH). Anal. calcd. for $C_{23}H_{28}F_4N_2Pt$ (%): C 45.76, H 4.69; found (%): C 45.77, H 4.53.

[1,2-Bis(2,6-dimethylphenylimino)ethane](heptafluoro-propyl)iodoplatinum(II) (13)

Method 1:

To a solution of **9** (100 mg, 0.16 mmol) in CH$_2$Cl$_2$ (10 mL) was added iodine (39 mg, 0.16 mmol) and the reaction mixture was stirred in the dark for 12 h. The solvent was reduced in volume to approximately 5 mL in vacuo. Hexane was added to precipitate the product as a brown powder. Recrystallization from CH$_2$Cl$_2$–hexane at –30 °C afforded the product as an umber microcrystalline solid (94 mg, 80%). ^{1}H NMR (CDCl$_3$) δ (ppm): 9.00 (t, 1H, $^3J_{PtH}$ = 102 Hz, N=CH), 8.62 (t, 1H, $^3J_{PtH}$ = 40 Hz, N=CH), 7.23–7.15 (m, 6H, ArH), 2.33 (s, 6H, CH_3), 2.30 (s, 6H, CH_3). ^{19}F NMR (CDCl$_3$) δ (ppm): –80.08 (t, 3F, $^4J_{FF}$ = 11 Hz, CF_3), –80.83 (tqd, 2F, $^2J_{PtF}$ = 288 Hz, $^4J_{FF}$ = 11 Hz, $^5J_{FH}$ = 4 Hz, PtCF_2), –114.69 (t, 2F, $^5J_{PtF}$ = 72 Hz, CF_2CF$_3$). Anal. calcd. for $C_{21}H_{20}F_7IN_2Pt$ (%): C 33.39, H 2.67; found (%): C 32.65, H 2.57.

Method 2:

To a solution of **9** (100 mg, 0.16 mmol) in toluene (10 mL) was added hydriodic acid (57% w/w, 20 µL, 0.16 mmol) and the reaction mixture was stirred at room temperature for 4 h. The solvent was removed in vacuo and the residue recrystallized from CH$_2$Cl$_2$–hexane to afford the product as an umber microcrystalline powder (83 mg, 78%).

[1,2-Bis(2,6-dimethylphenylimino)ethane](1H-tetrafluoro-ethyl)iodoplatinum(II) (14)

To a solution of **10** (100 mg, 0.19 mmol) in toluene (10 mL) was added HI (57% w/w, 33 µL, 0.29 mmol) and the reaction mixture was stirred at room temperature for 4 h. The solvent was removed in vacuo and the residue recrystallized from CH$_2$Cl$_2$–hexane to afford the product as a black powder (86 mg, 74%). ^{1}H NMR (CDCl$_3$) δ (ppm): 9.16 (s, 1H, $^3J_{PtH}$ = 100 Hz, N=CH), 8.68 (s, 1H, $^3J_{PtH}$ = 38 Hz, N=CH), 7.25–7.15 (m, 6H, ArH), 6.09 (dq, 1H, $^2J_{FH}$ = 50 Hz, $^3J_{FH}$ = 11 Hz, $^2J_{PtH}$ = 61 Hz, Hz, CFH), 2.39 (s, 3H, ArCH_3), 2.36 (s, 3H, ArCH_3), 2.29 (s, 3H, ArCH_3), 2.25 (s,

3H, ArCH$_3$). ^{19}F NMR (CDCl$_3$) δ (ppm): –68.61 (dd, 3F, $^3J_{FH}$ = 15 Hz, $^3J_{FF}$ = 11 Hz, $^2J_{PtF}$ = 91 Hz, CF$_3$), –211.67 (dq, 1F, $^2J_{FH}$ = 50 Hz, $^3J_{FF}$ = 11 Hz, $^2J_{PtF}$ = 359 Hz, CFH). Anal. calcd. for C$_{20}$H$_{21}$F$_4$IN$_2$Pt (%): C 34.94, H 3.09; found (%): C 35.32, H 3.36.

[1,2-Bis(2,6-dimethylphenylimino)-1,2-dimethylethane](heptafluoropropyl)iodoplatinum(II) (15)

To a solution of **11** (100 mg, 0.15 mmol) in toluene (5 mL) was added HI (57% w/w, 100 μL, excess) and the reaction mixture was stirred at room temperature for 8 h. The solvent was removed in vacuo. The residue was extracted with CH$_2$Cl$_2$ and the supernatant solution filtered. The solvent was reduced in vacuo to 5 mL and hexane was added. Filtration afforded the product as a brick-red powder (82 mg, 71%). ^{1}H NMR (CDCl$_3$) δ (ppm): 7.23–7.13 (m, 6H, ArH), 2.26 (s, 6H, ArCH$_3$), 2.23 (s, 6H, ArCH$_3$), 2.22 (s, 3H, N=C(CH$_3$)), 1.84 (s, 3H, N=C(CH$_3$)). ^{19}F NMR (CDCl$_3$) δ (ppm): –79.65 (qt, 3F, $^4J_{FF}$ = 11 Hz, $^3J_{FF}$ = 4 Hz, $^2J_{PtF}$ = 290 Hz, CF$_3$), –93.46 (t, 2F, $^4J_{FF}$ = 11 Hz, $^4J_{PtF}$ = 38 Hz, PtCF$_2$), –114.06 (t, 2F, $^3J_{FF}$ = 4 Hz, $^3J_{PtF}$ = 68 Hz, CF$_2$CF$_3$). Anal. calcd. for C$_{23}$H$_{24}$F$_7$IN$_2$Pt (%): C 35.26, H 3.09; found (%): C 35.15, H 3.32.

[1,2-Bis(2,6-dimethylphenylimino)-1,2-dimethylethane](1H-tetrafluoroethyl)iodoplatinum(II) 16

To a solution of **12** (100 mg, 0.17 mmol) in CHCl$_3$ (10 mL) was added HI (21 μL, 0.17 mmol) and the reaction mixture was stirred at room temperature overnight. The solvent was removed in vacuo. The residue was recrystallized from CH$_2$Cl$_2$–hexane to afford the product as a deep orange powder (88 mg, 74%). ^{1}H NMR (CDCl$_3$) δ (ppm): 7.23–7.08 (m, 6H, ArH), 5.60 (dq, $^2J_{FH}$ = 50 Hz, $^3J_{FH}$ = 11 Hz, $^2J_{PtH}$ = 51 Hz, CFH), 2.20 (s, 9H, 3 × ArCH$_3$), 1.56 (s, 3H, ArCH$_3$), 1.26 (s, 3H, C(CH$_3$)), 1.02 (s, 3H, $^4J_{PtH}$ = 86 Hz, C(CH$_3$)). ^{19}F NMR (CDCl$_3$) δ (ppm): –70.74 (dd, 3F, $^3J_{FF}$ = 11 Hz, $^3J_{FH}$ = 11 Hz, $^3J_{PtF}$ = 136 Hz, CF$_3$), –211.69 (dq, 1F, $^2J_{PH}$ = 50 Hz, $^3J_{FF}$ = 15 Hz, $^2J_{PtF}$ = 388 Hz, CFH). Anal. calcd. for C$_{22}$H$_{25}$F$_4$IN$_2$Pt (%): C 36.93, H 3.53; found (%): C 36.71, H 3.40.

Crystallographic structural determinations

Diffraction intensity data were collected with a Bruker Smart Apex CCD diffractometer. Crystal data collection and refinement parameters are provided in Table 1.[4] The structures were solved using direct methods, completed by subsequent difference Fourier syntheses and refined by full-matrix least-squares procedures on reflection intensities (F^2). SADABS absorption corrections were applied to all structures (60). All non-hydrogen atoms were refined with anisotropic displacement coefficients except the C and F atoms of disordered groups. The F atoms of CF$_3$ groups in **3**, **4**, and **5** and -CF$_2$-CHF$_2$, -CHF-CF$_3$ ligands in **4** and **5** are disordered. Hydrogen atoms were treated as idealized contribu-

tions. All software and sources of scattering factors are contained in the SHELXTL (5.10) program libraries (61).

The use of a chiral borate counteranion as a ¹H NMR shift reagent for cationic copper(I) complexes[1]

David B. Llewellyn and Bruce A. Arndtsen

Abstract: The chiral borate counteranion bis[(*R*)-1,1′-bi-2-naptholato]borate (**1**⁻) has been found to be a competent chiral ¹H NMR shift reagent for cationic copper(I) complexes. This has been demonstrated by the addition of the Cu(NCMe)₄⁺ salt of **1**⁻ to two classes of common chiral ligands in asymmetric catalysis: 2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphthyl (tol-BINAP) (**2**) and 2,2′-isopropylidenebis(4-phenyl-2-oxazoline) (**3**). In the case of ligand **2**, the addition of 1 equiv. of either (*R*,*R*)-**2** or (*S*,*S*)-**2** to Cu(NCMe)₄⁺**1**⁻ results in well-resolved ¹H NMR resonances for the two enantiomers. Examination of standard solutions of non-enantiopure **2** shows that the copper complex can be an effective NMR shift reagent of a wide range of enantiomeric compositions. Cu(NCMe)₄⁺**1**⁻ also generates distinct ¹H NMR resonances for the two separate enantiomers of 2,2′-isopropylidenebis(4-phenyl-2-oxazoline) (**3**). However, attempts to employ this copper salt as a chiral NMR shift reagent for *rac*-**3** led to the discovery of a new and unexpected equilibrium: [(*R*,*R*)-**3**]Cu⁺ + [(*S*,*S*)-**3**]Cu⁺ ⇔ [(*R*,*R*)-**3**][(*S*,*S*)-**3**]Cu⁺ + Cu⁺.

Key words: chiral counteranion, copper, chiral NMR shift reagent, ion pairing.

Résumé : On a trouvé que le contre-ion borate chiral, bis[(*R*)-1,1′-bi-2-naptalato]borate (**1**⁻) réactif de déplacement chiral utile en RMN du ¹H des complexes de cuivre(I) cationiques. On a établi cette propriété par l'addition du sel Cu(NCMe)₄⁺ du composé **1**⁻ à deux classes de ligands chiraux usuels dans la catalyse asymétrique, le 2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphtyle (tol-BINAP) (**2**) et la 2,2′-isopropylidènebis(4-phényl-2-oxazoline) (**3**). Dans le cas du ligand **2**, l'addition d'un équivalent de (*R*,*R*)-**2** ou de (*S*,*S*)-**2** au Cu(NCMe)₄⁺**1**⁻ conduit à un spectre RMN du ¹H dans lequel les résonances des deux énantiomères sont bien résolues. L'examen de solutions standard du composé **2** qui n'est pas énantiomériquement pur montre que le complexe de cuivre peut s'avérer être un réactif de déplacement efficace en RMN, sur une large gamme de compositions énantiomères. Le composé **1**⁻ génère aussi des résonances RMN du ¹H distinctes pour les deux énantiomères séparés de la 2,2′-isopropylidènebis(4-phényl-2-oxazoline) (**3**). Toutefois, les essais effectués en vue d'utiliser ce sel de cuivre comme réactif de déplacement en RMN pour le composé **3**-*rac* ont permis de mettre en évidence un nouvel équilibre inattendu : [(*R*,*R*)-**3**]Cu⁺ + [(*S*,*S*)-**3**]Cu⁺ ⇔ [(*R*,*R*)-**3**][(*S*,*S*)-**3**]Cu⁺ + Cu⁺.

Mots clés : contre-ion chiral, cuivre, réactif de déplacement RMN chiral, paire d'ions.

[Traduit par la Rédaction]

Introduction

Coupled to the growing demand for enantiopure compounds in the chemical and pharmaceutical industry (1) is also a demand for inexpensive, fast, and reliable techniques for the determination of enantiomeric composition. Enantiomeric excess is usually determined by chiral chromatogra-

phy (2) (i.e., HPLC and GC) or through the use of a chiral NMR shift reagent (3). NMR shift reagents are attractive because they can provide results rapidly, give an accurate measurement of optical purity, and require only an NMR spectrometer to perform the experiments. The most common NMR shift reagents are chiral lanthanide metal complexes (i.e., Eu(hfc)₃, hfc = heptafluorohydroxymethylene-*d*-camphorato) (3, 4). Other metals including palladium (5), cobalt (6), and iridium (7) have also been used in conjunction with chiral ligands and shown to be effective chiral NMR shift reagents.

We have recently reported that ion pairing of a chiral bis[(*R*)-binapthol]-based borate counteranion (**1**⁻) with a cationic copper center can induce enantioselectivity into metal catalysis (8). These results demonstrate a high level of communication between the metal catalyst and the counteranion in solution. This suggested that the chiral counteranion **1**⁻ might also be used as a chiral NMR shift reagent for cationic species. Indeed, Lacour and co-workers (9) have demonstrated that chiral phosphate counteranions

[(R,R)-**2**]Cu$^+$**1**$^-$ [(S,S)-**2**]Cu$^+$**1**$^-$

can be effective NMR shift reagents for a variety of cationic compounds. Particularly attractive about the use of the chiral borate **1**$^-$ is its facile synthesis in enantiopure form from readily available starting materials. It therefore does not require subsequent resolution, and does not racemize in solution (8). Furthermore, **1**$^-$ is easily generated as a borate acid, silver salt, or Cu(CH$_3$CN)$_4^+$ salt, allowing its potential association with a range of chiral cations or coordinating species (8).

We report below the results of our first studies directed towards the use of **1**$^-$ as a NMR shift reagent for chiral cationic transition metal complexes. This has been examined with the copper salt Cu(CH$_3$CN)$_4^+$**1**$^-$. This complex can undergo rapid ligand substitution, providing the potential to serve as a NMR shift reagent for chiral ligands upon coordination, as illustrated in eq. [1]. Representatives of two general classes of ligands have been probed: 2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphthyl (tol-BINAP) (**2**) and 2,2′-isopropylidenebis(4-phenyl-2-oxazoline) (**3**) both of which are important in the field of asymmetric catalysis (10).

Results and discussion

The ability of Cu(CH$_3$CN)$_4^+$**1**$^-$ to serve as a NMR shift reagent for chiral ligands was first probed with the chiral tol-BINAP derivative **2**. This general class of chiral ligand has found extensive utility in transition-metal-catalyzed enantioselective reactions (e.g., hydrogenations, hydrosilations, Heck couplings, Lewis acid catalysis) (11). The addition of racemic-**2** to 1 equiv. Cu(CH$_3$CN)$_4^+$**1**$^-$ in CD$_2$Cl$_2$ results in the immediate association of the chiral ligand to the copper center at ambient temperature. Examination of the ^{1}H NMR spectra reveals the presence of two separate tol-BINAP containing products formed in a 1:1 ratio. A portion of the ^{1}H NMR is shown in Fig. 1. The identity of these compounds can be determined by comparing this spectra to those obtained by the addition of enantiopure solutions of (S,S)-**2** (Fig. 1*b*) and (R,R)-**2** (Fig. 1*c*) to Cu(CH$_3$CN)$_4^+$**1**$^-$. These show that the compounds formed with *rac*-**2** correspond to the two separate enantiomers of **2** coordinated to the copper cation, wherein simple solution phase ion pairing with **1**$^-$ does indeed lead to a significant separation of the ^{1}H NMR resonances in the diastereomeric salts (eq. [2]). The largest degree of separation in the resonances for the enantiomers of **2** occurs for the aromatic hydrogens in the 5.6–6.2 ppm region (0.14 ppm) but reasonable separation is also observed for the tolyl–methyl resonances in the 2.4–2.6 ppm region (0.05 ppm).

Fig. 1. ^{1}H NMR spectra (400 MHz) in CD$_2$Cl$_2$ of: (*a*) *rac*-**2** with Cu(CH$_3$CN)$_4^+$**1**$^-$; (*b*) (S,S)-**2** with Cu(CH$_3$CN)$_4^+$**1**$^-$; and (*c*) (R,R)-**2** with Cu(CH$_3$CN)$_4^+$**1**$^-$ (δ 1.93 = CH$_3$CN).

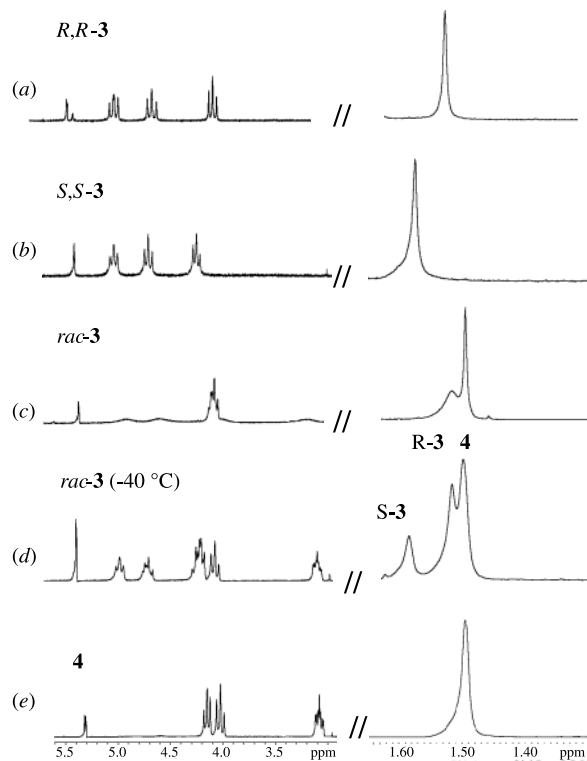
1
As anticipated, the degree of separation in the ^{1}H NMR resonances for the enantiomers of **2** is sensitive to the nature of the solvent used. For example, the peaks in the 1.7–1.9 ppm region are separated by 0.06 ppm in C$_6$D$_6$, which decreases to 0.016 ppm in CD$_2$Cl$_2$, and to 0 ppm in CD$_3$CN. The decrease in separation that is observed with an increase in solvent polarity is consistent with weaker ion pairing in the more polar solvents (12), which results in less contact between the ions, and therefore, less enantiomeric differentiation by **1**$^-$. It should be noted that while Cu(CH$_3$CN)$_4^+$**1**$^-$ in benzene solvent provides a large degree of peak separation for the two enantiomers, it gives an inaccurate determination of the enantiomeric excess of **2** (calculated ee = 18% for *rac*-**2**). Since the sample was not completely soluble in C$_6$D$_6$, this error is most likely a result of the different solubilities of the diastereotopic ion pairs.

The accuracy of **1⁻** as a chiral NMR shift reagent in CD₂Cl₂ was determined by preparing mixtures of tol-BINAP with known enantiomeric composition and examination by ¹H NMR in the presence of 1 equiv. Cu(CH₃CN)₄⁺**1⁻**. For example, a sample of **2** with a calculated enantiomeric excess of 33% showed an experimental enantiomeric excess of 32% by ¹H NMR. Furthermore, a linear relationship exists between the enantiomeric excess determined by ¹H NMR (400 MHz) and the calculated enantiomeric excess of the non-racemic samples of **2** (Fig. 2), which could be reproduced within 2% error. These results clearly demonstrate that ion-pairing interactions in solution between **1⁻** and the copper-bound BINAP derivative **2** can provide a facile and accurate method to determine %ee over a broad range of enantiomeric compositions.

In light of the accuracy of Cu(CH₃CN)₄⁺**1⁻** as a chiral NMR shift reagent with chelated phosphine ligand **2**, the generality of this system has been explored with the nitrogen-based chiral chelate 2,2′-isopropylidenebis(4-phenyl-2-oxazoline) (**3**). As shown in Fig. 3, the addition of the individual enantiomers of **3** to Cu(CH₃CN)₄⁺**1⁻** in CD₂Cl₂ also results in the immediate copper complexation of the ligand, and generation of complexes with significantly different ¹H NMR chemical shifts (spectra a and b). The most noticeable difference is observed for the methyl peaks in the backbone of the ligand. This signal in the (*R*,*R*)-**3** enantiomer occurs at 1.52 ppm (Fig. 3*a*) while the same signal for the (*S*,*S*)-**3** complex arises at 1.58 ppm (Fig. 3*b*). Thus, as with ligand **2**, ion pairing with **1⁻** can be used to distinguish the individual enantiomers of the copper-bound bis(oxazoline) ligand.

2   **3**
However, when *rac*-**3** was added to Cu(CH₃CN)₄⁺**1⁻**, broad resonances were observed in the ¹H NMR (Fig. 3*c*). This suggested a dynamic equilibrium was present in solution. Lowering the temperature to –40 °C significantly increases the sharpness of the ¹H NMR signals and reveals, rather than the anticipated two sets of resonances, three distinct products in solution (Fig. 3*d*). Two of the complexes correspond to the diastereotopic ion pairs of (*R*,*R*)-**3** with Cu(CH₃CN)₄⁺**1⁻** and (*S*,*S*)-**3** with Cu(CH₃CN)₄⁺**1⁻**, with ¹H NMR shifts identical to that of the optically pure compounds. The third product has been assigned as the heterochiral bis-ligated complex **4**. The identity of **4** has been confirmed by reacting 2 equiv. *rac*-**3** with Cu(CH₃CN)₄⁺**1⁻** in CD₂Cl₂ (Fig. 3*e*). Complex **4** can be isolated in 85% yield upon precipitation with diethyl ether and has been fully characterized by NMR, IR, and elemental analysis.

The formation of **4**, and the broadened ¹H NMR resonances at ambient temperature, suggests that the addition of

Fig. 2. Plot of enantiomeric excess, determined by the relative integration of the ¹H NMR resonances in the 5.6–6.2 ppm region, for samples of **2** with Cu(CH₃CN)₄⁺**1⁻** in CD₂Cl₂ vs. calculated enantiomeric excess for samples of **2**.
Fig. 3. ¹H NMR spectra (270 MHz) in CD₂Cl₂ of: (*a*) 1 equiv. (*R*,*R*)-**3** with Cu(CH₃CN)₄⁺**1⁻**; (*b*) 1 equiv. (*S*,*S*)-**3** with Cu(CH₃CN)₄⁺**1⁻**; (*c*) 1 equiv. *rac*-**3** with Cu(CH₃CN)₄⁺**1⁻**, 20 °C; (*d*) 1 equiv. *rac*-**3** with Cu(CH₃CN)₄⁺**1⁻**, –40 °C; and (*e*) 2 equiv. *rac*-**3** with Cu(CH₃CN)₄⁺**1⁻** (**4**).


rac-**3** to Cu(CH₃CN)₄⁺**1⁻** results in the equilibrium shown in eq. [3]. Based upon the relative ¹H NMR intensities, the K_{eq} has been calculated to be 0.43 at –40 °C. Thus, in contrast to enantiopure **3** or the more bulky BINAP derivatives (**2**), two differing enantiomers of **3** can be readily accommodated about the Cu⁺ center, even with the concomitant formation of 1 equiv. of Cu(NCMe)₄⁺. The stability of **4** is likely related to the tetrahedral geometry of the Cu(I) complex,

4
wherein the coordination of the two separate enantiomers of **3** forms a stable propeller-like arrangement of the phenyl groups. A similar bis-ligated complex with the same enantiomers of **3** would likely have strongly destabilizing phenyl–phenyl interactions. To our knowledge, this equilibrium has not been previously observed in solution with **3**, and its identification may help to explain nonlinear effects that are observed using non-enantiopure bis(oxazoline) ligands and copper(I) cations as asymmetric catalysts (13).

While the presence of **4** complicates the use of $Cu(CH_3CN)_4^+\mathbf{1}^-$ as a chiral NMR shift reagent for ligand **3**, it is notable that the diastereomeric salts formed by $\mathbf{1}^-$ and the copper salts of **3** are well resolved by ^{1}H NMR, in a fashion similar to that for the BINAP derivatives **2**. This demonstrates that strong solution-phase ion pairing occurs with both general classes of ligands, and suggests that ion pairing with counteranion $\mathbf{1}^-$ could prove to be a general method for the NMR resolution of well-defined chiral cationic copper(I) complexes.[3]

In conclusion, these studies have shown that ion pairing with the chiral borate counteranion $\mathbf{1}^-$ can be used as a simple and effective method to distinguish individual enantiomers of chiral cationic copper complexes in solution. In the case of BINAP derivatives, this provides an accurate ^{1}H NMR shift method to determine enantiomeric excess. The borate counteranion $\mathbf{1}^-$ is easy to prepare and incorporate into cationic complexes, allows for rapid ^{1}H NMR analysis, and lacks the line broadening often observed with paramagnetic chiral shift reagents, providing an attractive alternative to standard analytical techniques for the determination of enantiomeric excess. The fact that individual enantiomers of cationic copper complexes show distinct ^{1}H NMR resonances resulting from ion pairing with $\mathbf{1}^-$ also illustrates the important role of solution-phase ionic interactions with transition metal complexes. This provides a rationale for the strong counteranion influences often observed in asymmetric catalysis employing copper salts of ligands such as **3**, including our observation that the anion chirality can directly influence enantioselectivity in product formation (8). The ability to form $\mathbf{1}^-$ as either a proton or silver salt should prove useful in the further design of NMR shift reagents employing ion pairing with this anionic fragment.

Experimental section

General

All manipulations were performed under an inert atmosphere in a Vacuum Atmospheres 553-2 dry box.

$Cu(CH_3CN)_4^+\mathbf{1}^-$ was synthesized using a previously published procedure (8). Individual enantiomers of 2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphthyl (>98%) and 2,2′-isopropylidenebis(4-phenyl-2-oxazoline) (>98%) were purchased from Strem and Aldrich, respectively, and used as received. All other reagents were purchased from commercial suppliers and used as received. CH_3CN and CH_2Cl_2 were distilled from CaH_2 under nitrogen. Diethyl ether was distilled from Na–benzophenone under nitrogen. Deuterated solvents were dried as their protonated analogues but transferred under vacuum from the drying agent and stored under 4 Å sieves. ^{1}H, ^{11}B, and ^{13}C NMR were recorded on a JEOL-270 or Varian 400 spectrometer. Infrared spectra were recorded on a Bruker IFS-48 spectrometer.

Representative ^{1}H NMR analysis of 2 with $Cu(CH_3CN)_4^+\mathbf{1}^-$

A solution of *rac*-**2** (4.2 mg, 0.0062 mmol) in 1.0 mL CD_2Cl_2 was added to solid $Cu(CH_3CN)_4^+\mathbf{1}^-$ (5.0 mg, 0.0062 mmol) and mixed until a clear solution resulted. The ^{1}H NMR was taken immediately. ^{1}H NMR of (*R,R*)-**2** with $Cu(CH_3CN)_4^+\mathbf{1}^-$ (400 MHz, CD_2Cl_2) δ: 7.86 (d, 4H, *J* = 8.0 Hz), 7.77 (d, 4H, *J* = 8.0 Hz), 7.11–7.34 (m, 30H), 6.95 (m, 2H), 6.87 (m, 2H), 6.48 (d, 2H, *J* = 6.3 Hz), 6.28 (m, 4H), 5.84 (d, 4H, *J* = 7.4 Hz), 2.41 (s, 6H, P(C_6H_4C*H*_3)_2), 1.93 (s, 12H, C*H*_3CN), 1.81 (s, 6H, P(C_6H_4C*H*_3)_2). ^{1}H NMR of (*S,S*)-**2** with $Cu(CH_3CN)_4^+\mathbf{1}^-$ (400 MHz, CD_2Cl_2) δ: 7.89 (m, 8H), 7.44 (d, 2H, *J* = 8.4 Hz), 7.09–7.38 (m, 28H), 6.95 (m, 2H), 6.85 (m, 2H), 6.55 (m, 6H), 5.98 (d, 4H, *J* = 7.6 Hz), 2.46 (s, 6H, P(C_6H_4C*H*_3)_2), 1.93 (s, 12H, C*H*_3CN), 1.80 (s, 6H, P(C_6H_4C*H*_3)_2).

Representative ^{1}H NMR analysis of 3 with $Cu(CH_3CN)_4^+\mathbf{1}^-$

A solution of (*R,R*)-**3** (2.1 mg, 0.0062 mmol) in 1.0 mL CD_2Cl_2 was added to solid $Cu(CH_3CN)_4^+\mathbf{1}^-$ (5.0 mg, 0.0062 mmol) and mixed until a clear solution resulted. The ^{1}H NMR was taken immediately. ^{1}H NMR of (*R,R*)-**3** with $Cu(CH_3CN)_4^+\mathbf{1}^-$ (270 MHz, CD_2Cl_2) δ: 7.87 (d, 4H, *J* = 8.7 Hz), 7.86 (d, 4H, *J* = 8.1 Hz), 7.45 (d, 4H, *J* = 8.9 Hz), 7.15–7.27 (m, 14H), 7.08 (m, 4H), 6.94 (m, 4H), 4.92 (dd, 2H, *J* = 8.2, 10.4 Hz, OCH*H*CHPh), 4.62 (dd, 2H, *J* = 8.9, 10.2 Hz, OC*H*HCHPh), 4.11 (dd, 2H, *J* = 8.4, 8.9 Hz, OCHHC*H*Ph), 1.79 (s, 12H, C*H*_3CN), 1.52 (s, 6H, C(C*H*_3)_2). ^{1}H NMR of (*S,S*)-**3** with $Cu(CH_3CN)_4^+\mathbf{1}^-$ (270 MHz, CD_2Cl_2) δ: 7.87 (m, 8H), 7.46 (d, 4H, *J* = 8.7 Hz), 7.17–7.31 (m, 14H), 7.08 (m, 4H), 6.99 (m, 4H), 4.91 (dd, 2H, *J* = 8.2, 10.1 Hz, OCH*H*CHPh), 4.62 (dd, 2H,

---

[3] The ^{1}H NMR resolution of chiral tetrahedral copper(I) complexes of achiral nitrogen donor ligands has recently been reported with chiral phosphate counteranions (see ref. 9*e*).

J = 8.9, 10.1 Hz, OC*H*HCHPh), 4.16 (dd, 2H, J = 8.7, 8.9 Hz, OCHHC*H*Ph), 1.79 (s, 12H, C*H*$_3$CN), 1.58 (s, 6H, C(C*H*$_3$)$_2$).

Representative procedure for the determination of enantiomeric excess (Fig. 2)

(S,S)-**2** (33.3 mg, 0.049 mmol) and 66.6 mg (0.098 mmol) (R,R)-**2** was added to 3.0 mL CH$_2$Cl$_2$. The solution was mixed and the solvent evaporated under reduced pressure to give **2** as a white solid, ee = 33%. 4.2 mg (0.0062 mmol) of this solid in 1.0 mL CD$_2$Cl$_2$ was added to 5.0 mg (0.0062 mmol) Cu(CH$_3$CN)$_4$$^+$**1**$^-$ and the ^{1}H NMR was taken to give an experimental enantiomeric excess of 32%. Data for Fig. 3: ee (calcd./^{1}H NMR) 0%/0%, 15%/16%, 33%/32%, 50%/50%, 67%/64%, 85%/83%, 100%/100%.

Synthesis of 4

To a solution of Cu(CH$_3$CN)$_4$$^+$**1**$^-$ (20 mg, 0.025 mmol) in 5 mL CH$_3$CN was added 8.3 mg (0.025 mmol) (R,R)-**3** and 8.3 mg (0.025 mmol) (S,S)-**3**. The resulting solution was concentrated to 1 mL under reduced pressure, and the product precipitated by the slow addition of diethyl ether. The precipitate was dissolved in 1 mL CH$_2$Cl$_2$ and recrystallized by the addition of pentane to give **4**•0.5CH$_2$Cl$_2$ as a white solid (27.6 mg, 0.021 mmol, 85%). IR (KBr) (cm^{-1}): 3055, 2906, 1657, 1590, 1504, 1463, 1367, 1336, 1251, 1108, 987. ^{1}H NMR (270 MHz, CD$_2$Cl$_2$) δ: 7.89 (d, 8H, J = 8.15 Hz), 7.86 (d, 4H, J = 7.3 Hz), 7.46 (d, 4H, J = 8.7 Hz), 7.23–7.33 (m, 20H), 7.08 (m, 4H), 6.91 (m, 4H), 4.01–4.17 (m, 8H, OC*H*$_2$CHPh), 3.30 (m, 4H, OCH$_2$C*H*Ph), 1.50 (s, 12H, C(C*H*$_3$)$_2$). ^{13}C NMR (68 MHz, CD$_2$Cl$_2$) δ: 167.8, 156.6, 140.7, 133.4, 129.5, 128.9, 128.6, 128.1, 127.8, 127.4, 126.4, 125.0, 124.4, 122.4, 122.1, 73.4 (OCH$_2$*C*HPh), 69.7 (O*C*H$_2$CHPh), 39.1 (*C*(CH$_3$)$_2$), 24.3 (C(*C*H$_3$)$_2$). ^{11}B NMR (87 MHz, CD$_2$Cl$_2$) δ: 8.14. Anal. calcd. for C$_{82}$H$_{68}$N$_4$O$_4$BCu•0.5CH$_2$Cl$_2$: C 73.17, H 5.14, N 4.15; found: C 72.85, H 5.21, N 4.17.

The reversible hydration of the malaria pigment β-hematin[1]

D. Scott Bohle, Andrew D. Kosar, and Peter W. Stephens

Abstract: β-Hematin, the crystalline heme detoxification product of red blood cell digestion by the malaria parasite, can reversibly absorb up to 14% of its mass in water. Heating hydrated β-hematin to temperatures greater than 150 °C results in loss of the hydrated water, which is readily reabsorbed on standing in air at room temperature. The amount of water absorbed is source dependent with highly crystalline samples produced by the anhydrous-base-mediated dehydrohalogenation being twice as absorptive as more amorphous samples produced by the aqueous acid precipitation method. Infrared spectroscopy and thermal gravimetric analysis have been used to measure the amount of water lost and gained during these experiments. X-ray powder diffraction has been used to characterize the effect of hydration state on the lattice parameters. Taken together these experiments resolve literature discrepancies concerning the elemental composition of synthetic and extracted natural β-hematin.

Key words: malaria pigment, hemozoin, β-hematin, hydration, thermal gravimetric analysis, powder diffraction.

Résumé : La β-hématine, l'hème cristallin produit de désintoxication résultant de la digestion des cellules sanguines par le parasite de la malaria, peut de façon réversible absorber jusqu'à 14% de sa masse en eau. Le chauffage de la β-hématine hydratée à des températures supérieures à 150 °C provoque une perte de l'eau d'hydratation, qui est facilement réabsorbée par exposition à l'air à la température ambiante. La quantité d'eau absorbée dépend de la source. Dans le cas d'échantillons hautement cristallins, produits par la déhydrohalogénation en présence d'une base anhydre, l'absorption de l'eau est deux fois plus grande que dans le cas d'échantillons amorphes obtenus par la méthode de précipitation en milieux acide aqueux. La spectroscopie infrarouge et l'analyse gravimétrique thermique sont utilisées pour mesurer la quantité d'eau perdue ou gagnée au cours de ces expériences. On a utilisé la diffraction des poudres par rayon X pour caractériser l'effet de l'état d'hydratation sur les paramètres du réseau. Prises ensembles ces expériences font disparaître les différences que l'on retrouve dans la littérature sur la composition élémentaire de la β-hématine synthétique et naturelle.

Mots clés : pigment de la malaria, hémozoïne, β-hématine, hydratation, analyse gravimétrique thermique, diffraction de poudre.

[Traduit par la Rédaction]

Introduction

Hemoglobin digestion during the intraerythrocytic stages of malaria rapidly releases large quantities of heme (1). Heme is potentially toxic to both the parasite and the host, and must be efficiently detoxified by the parasite (1, 2). In biochemistry specific to the parasite, the heme is oxidized and crystallized as a material termed malaria pigment, or hemozoin, and this is released into the host vasculature during the next rupture–reinvasion event (3). It is now well established that malaria pigment and the synthetic phase β-hematin are crystallographically identical in that they have the same unit cells and same atomic structures (4). Furthermore, the two materials are morphologically similar and grow as relatively thin ribbons. Their structure corresponds to a hydrogen-bonded chain of iron(III)(protoporphyrin-IX) propionate linked dimers (**1**) (5). Prior systematic study of β-hematin's chemistry awaited a resolution of its structure (5) and purity (6). With these critical issues now resolved, its interfacial chemistry can be studied more precisely, in particular with regard to the nature of the pigment surface – quinoline antimalarial interactions (7, 8).

1
Although malaria pigment (9) and β-hematin, the insoluble anhydride of hematin (Fe(III)(protoporphyrin-IX)(OH)), were both described before the determination of heme's structure(10), their chemistry have only recently been investigated in any detail owing to the recognition of their association with antimalarial drugs (7, 8, 11, 12). Due to its insolubility, β-hematin was widely believed to be a polymer (6), and not too surprisingly the language of polymers has been extensively used to describe a hypothetical "chain growth termination step" by the quinoline antimalarials (13). However, the solution of its structure by Rietveld and simulated annealing experiments from powder diffraction data (5, 14) unambiguously demonstrates that the original coordination polymer structure was incorrect and that the structure is a simple lattice of hydrogen-bonded dimers. Under physiological conditions, β-hematin is profoundly insoluble, and it dissolves by reacting with strongly alkaline aqueous solutions, neat pyridine, and neat trifluoroacetic acid. Although the spectroscopy of malaria pigment and β-hematin are in complete accord with the crystallographically determined structure, and consistent with a high-spin five-coordinate iron(III) which is out of the plane of the porphyrin by ~0.4 Å, and has an η^1-propionate linkage (6, 15), all combustion analyses of these materials have been consistently low in carbon, hydrogen, and nitrogen (6, 16). One proposed solution to this problem was that for the aqueous acid precipitation syntheses (AAP), the product corresponds to an acetato complex (17). This somewhat bizarre suggestion is spectroscopically inconsistent with all of the above data and not too surprisingly it has been debated vigorously in the literature (17–21). If nothing else, the level of interest and discord in this fundamental problem of structure and composition reflects the difficulty in working with these materials and their importance.

The synthetic source of β-hematin is also an important factor in understanding many prior studies of its chemistry and biology. In general, IR spectroscopy is widely used to demonstrate the presence of β-hematin in its hematin precipitates. While this technique is very useful in determining the degree of short-range order in a sample, i.e., the presence of iron–propionate bonds, the materials from very different syntheses have similar spectra and these in turn are similar to the malaria pigment. Thus, IR spectroscopy alone is insufficient to distinguish these materials. This spectroscopic similarity masks a complicated set of phase distinctions among the preparations. For example, many preparations which utilize heat and acidic conditions to anneal a heterogeneous precipitate are prepared from hemin dissolved in base. These

materials have very low crystallinity as demonstrated by the presence of broadened Bragg diffraction peaks in the X-ray powder diffraction pattern, and are polydisperse with respect to both the size and morphology of the crystallites as determined by scanning electron micrographs (22). Samples prepared by this method are referred to as AAP (aqueous acid precipitation) in this paper, and are contrasted with the more crystalline materials prepared by slow crystallization by solvolyzed hemin in DMSO – noncoordinating bases, the ABM(anhydrous-base-mediated) method. While at first glance an aqueous method might seem to be more biomimetic than one that is anhydrous, the remarkably low solubility of Fe(protoporphyrin-IX) in all but strongly basic solutions requires that AAP methods start with the μ-oxo-dimer of Fe(protoporphyrin-IX) ((Por)Fe-O-Fe(Por)). We are aware of no evidence, spectroscopic or analytical, that this linkage is present at any stage and in any vacuole in the parasite. Thus, AAP syntheses of β-hematin, which use base solubilization – μ-oxo-dimer formation as a first step are no more or less biologically relevant than those of the ABM method.

In this manuscript, we present studies of β-hematin's reversible hydration, which has been characterized by elemental analysis, IR absorption spectroscopy, powder diffraction, and thermogravimetric analysis. Taken together these results demonstrate that malaria pigment reversibly and substoichiometrically adsorbs water. These results rationalize the observed variation in the elemental analyses for the condensed phases of β-hematin.

Experimental

Materials

Samples of β-hematin were prepared by either the ABM method (15), or by the AAP method (22), which is a modified version of a literature preparation (6). These two preparations give spectroscopically similar materials that have markedly different morphologies and habit (22). In particular, the AAP method, a thermal acidic annealing of a complex hematin containing precipitate from a uniform base solution of the μ-oxo-dimer, (PP-IX)Fe-O-Fe(PP-IX), is widely used. This precipitate consists of finely divided crystallites which vary from being near amorphous to microcrystalline. On the other hand, the ABM method, an anhydrous slow solvolytic-mediated crystallization from hematin in DMSO and 2,6-lutidine, gives larger, more uniform crystals, which have the same habit as those produced by the parasite. All samples were checked for homogeneity by elemental analysis and for identity by IR spectroscopy before use in these experiments.

Instrumental methods

Infrared spectra (IR) were measured as pressed potassium bromide pellets using a Midac M-100 FT IR spectrometer running Spectra-Calc software. Thermogravimetric analysis (TGA) experiments were conducted on a CAHN TG Systems model 2131 thermogravimetric analyzer and were processed using WINTGA software, version 1.2, run on a PC platform. Samples were placed in a quartz basket that was suspended in the instrument by a NiChrome wire. Helium and nitrogen gases were used as the furnace and purge gases

as necessary. The rehydration experiments were performed in a humidor which was fashioned from a plastic desiccator with a removable holed plate. The lower section was filled with water and the holed floor plate was replaced. The water level was maintained at a constant level throughout the rehydration experiments. The sample of β-hematin was placed in a quartz basket that was suspended in the instrument by a NiChrome wire. A stream of nitrogen gas was passed over the sample as it was heated and cooled with one of the following programs (with key observations in brackets):

• Program 1: The sample was heated to 200 °C over 50 min and held at 200 °C until weight loss ceased (approximately 2 h later).
• Program 2: The sample was heated to 180 °C over 2000 s and then held at 180 °C until all weight loss had ceased (approximately 3 h later).
• Program 3: The sample was heated to 200 °C over 2000 s and then held at this temperature for an additional 2000 s. It was then allowed to cool to 130 °C over 1500 s before being heated to 200 °C a second time. (No change in weight was observed during this cooling–reheating cycle. Weight loss had ceased at approximately 67 min, prior to the cooling portion of the cycle).
• Program 4: The sample was heated 150 °C over 45 min and held at 150 °C until weight loss ceased (approximately 2 h later).
• Program 5: The sample was heated to 180 °C over 30 min, held at 180 °C for 2 h and cooled to 35 °C. The sample was then reheated to 180 °C and allowed to cool back to room temperature. (Weight loss had ceased before the second heating cycle began).

Reversible adsorption and desorption experiments were performed on samples of β-hematin, which were placed in the humidor and allowed to stand undisturbed for 96 h. The sample was weighed and placed in an oven at 150 °C for 24 h, after which time the sample was weighed and the cycle was repeated five more times.

High resolution X-ray powder diffraction

Synchrotron radiation (λ = 1.14021 Å), at Beamline X3B1 of the National Synchrotron Light Source was used for high-resolution X-ray powder diffraction. Wavelength calibration was performed with Al_2O_3 standards. Samples were run as either a flat-plate or a spinning 1 mm capillary tube.

Dehydration of ABM β-hematin

A sample of ABM β-hematin (35.2 mg) was heated under a stream of nitrogen according to temperature program 4. The temperature was held at 150 °C until no further weight loss occurred Fig. S1a.[3] Weight loss ceases at approximately 8500 s, resulting in a 7.16% loss for a final weight of 32.9 mg. An additional sample (55.6 mg) was heated under a stream of nitrogen according to the same program until weight loss ceased (Fig. S1b).[3] The weight loss ended at approximately 10 500 s, resulting in an 11.25% weight loss, and a final weight of 49.2 mg. A final sample (TGA not shown; 323.6 mg) was heated according to temperature program 5. A loss of 14.3% was noted resulting in a final weight of 278.7 mg.

Results and discussion

Since the identity of malaria pigment has been a key question, the homogeneity and composition of the isolated hemozoin is very important. The two published separate elemental analyses of natural malaria pigment (Table 1) are unfortunately not in close agreement with one another. The results for malaria pigment isolated from *Plasmodium falciparum* are fortuitously much closer to that of the putative heme–acetate complex than for the predicted values for the anhydride (β-hematin). However, the results for samples isolated from *Plasmodium berghei* are closer to β-hematin, but are still low in all values except hydrogen and oxygen (16). Despite these deviations, it is a significant biochemical achievement that these groups were able to obtain values as close to the pure synthetic samples given the difficulty in isolating and purifying malaria pigment (23–25). But the results clearly show that some other factor is responsible for decreasing the %C and N values while increasing the %H and O values. Moreover, there are also significant and similar deviations in composition for completely synthetic preparations of β-hematin, which have similar deviations from theory (Table 1), regardless of the method of preparation. Of these results, the rigorously dried and sealed sample **P** has the only satisfactory elemental analysis, and most acid precipitation and anhydrous-base-mediated preparations have average values for %C and %N which are consistently lower than the theoretical value (6, 15).

The most likely rationale for these results is that malaria pigment and β-hematin are hygroscopic, with water being readily absorbed by the β-hematin crystallites. This would lower the carbon and nitrogen figures while raising the oxygen and hydrogen compositions upon combustion analysis. To test this hypothesis we used thermogravimetric analysis for dehydrated and rehydrated β-hematin. Water readily and reversibly adds to the crystallites, and is driven off by heating to ~150 °C. By carefully reducing external contaminants, it became apparent that the elemental analyses were always low in %C and %N and that this corresponds to a substoichiometric hydrate.

To determine the degree of sample hydration, several different TGA experiments were conducted with various β-hematin samples, as well as by X-ray diffraction, IR spectroscopy, and by rehydration TGA. For example, β-hematin (1.1711 g) prepared by AAP, was placed in the quartz TGA cell and heated to 200 °C in stepwise transitions from 30 to 200 °C over 50 min. The sample experienced a total weight loss of 2.6(±0.1)% through the course of the experiment (Fig. 1.) A separate, larger sample of the same batch of β-hematin (2.1547 g) was rapidly heated to 200 °C and held at this temperature for 55 min. Again, a weight loss of 2.8(±0.1)% was observed. IR analysis of the remaining black solids confirmed that the samples are spectroscopically identical for the heme modes, with the only significant

[a]β-Hematin synthesized by either: AAP (6) or ABM methods (15).

[b]Natural sources include *P. berg.* being the NYU-2 strain of *Plasmodium berghei* and *P. fal.* being the HB-3 clone of *Plasmodium falciparum*. Note that in addition to C, H, and N composition for *P. fal.* elemental analyses for Fe (7.5%), O (15.6%), and Cl (< 0.1%) and for *P. berg.* Fe (8.7%) and O (12.5%), were also measured. Calculated values for anhydrous β-hematin ($FeC_{34}H_{31}N_4O_4$) are Fe (9.07%) and O (10.40%).

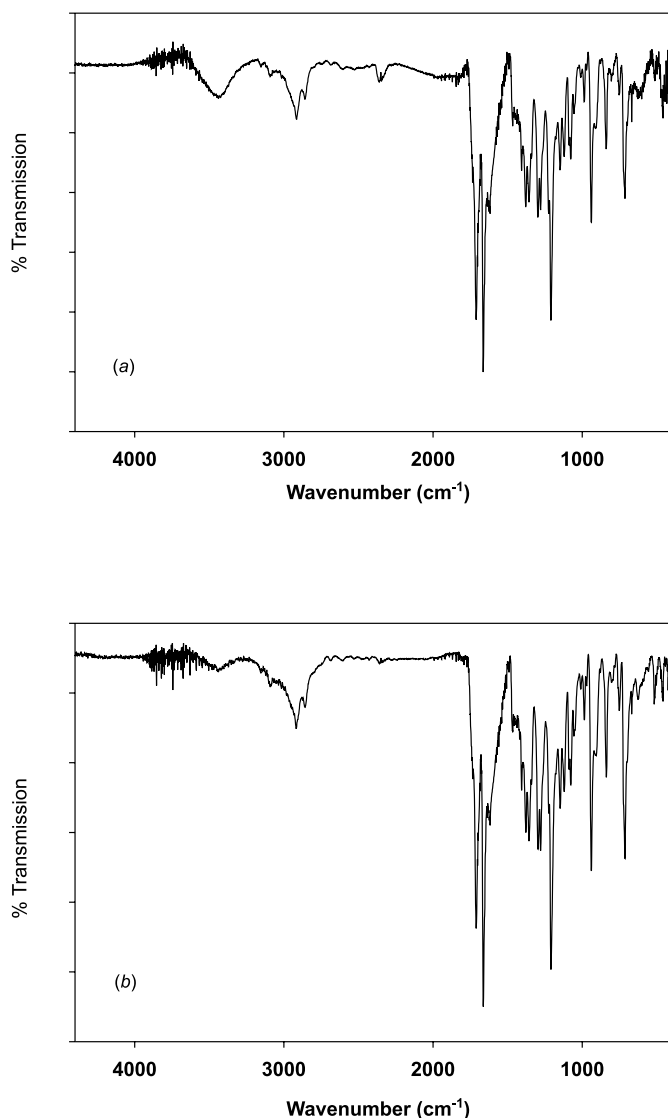
Fig. 1. Representative TGA of AAP β-hematin. Sample heated to 200 °C, according to program 1. Weight loss is approximately 2.6%.
spectral change being in the OH-stretching region. In this region (~3400 cm^{-1}), the broad OH stretch has nearly disappeared in the post-TGA heated sample; other bands in the spectrum remained unchanged (Fig. 2). These experiments demonstrate that most of the water is lost upon drying at temperatures ≥ 150 °C.

Similar results are found when samples of β-hematin prepared by ABM are treated in the same manner. For example,

β-hematin (253.2 mg) was placed in the quartz TGA cell and heated stepwise to 200 °C over 45 min. Upon reaching 200 °C, the sample was then held at a constant temperature of 200 °C for 400 min. The sample had a net weight loss of 2.6(±0.3)% over the whole experiment. A separate batch of β-hematin produced by this method (153.3 mg) was also assayed from 30 to 180 °C according to temperature program 2 (Fig. 3*a*). This batch showed a weight loss of 5.3(±0.2)%, for a final weight of 145.3 mg. IR analysis of the remaining black solids confirmed that they were still β-hematin with the only modification being in the ν(OH) region, as previously described. Significantly, freshly isolated batches of β-hematin prepared by the ABM methods did not exhibit a similar thermal dehydration unless exposed to normal atmospheric conditions during storage. These solids have a larger capacity to absorb water than the more amorphous and less crystalline materials produced by the AAP method.

In contrast, when a sample of AAP β-hematin (2154.7 mg) was subjected to the heating and cooling program in temperature program 3, it required 4000 s before becoming isogravimetric. Upon cooling to 130 °C and subsequent reheating to 200 °C, no weight gain or additional weight loss was noted (Fig. 3*b*). The final weight loss for this analysis was 2.86 (±0.02)%, resulting in a final weight of 2093.5 mg. Again, a smaller amount of water was lost more rapidly from the more amorphous AAP preparations. Related parallel experiments are shown in Fig. S1[3] for β-hematin prepared by ABM.

Fig. 2. Representative IR spectra for AAP β-hematin both pre- (A) and post- (B) TGA analysis. Sample analyzed as in Fig. 1.

Fig. 3. TGA analysis of AAP β-hematin according to temperature programs (A) 2 and (B) 3. Insert shows the temperature program.


The phenomenon of β-hematin dehydration was also studied by in situ IR spectroscopy with a rigorously dry KBr host matrix. In this case, a sample of hydrated ABM β-hematin in a pressed pellet had strong bands because of ν(OH) (Fig. S2).[3] This pellet was then placed in an oven at 150 °C for 15 min, removed, and reanalyzed. This cycle was performed three additional times with spectra being collected at 30 min, 24 h, and 72 h. Following the initial spectrum acquisition, only minor changes in the bands for Fe(PP-IX) were found, with the ν(OH) region at ca. 3400 cm^{-1} having the only significant change. Based on these observations, the majority of the water is driven off within the first 30 min of heating. Because the spectrum does not change and a subsequent hematin assay on the residue demonstrated that it had not decomposed, rearranged, or altered upon prolonged heating.

The reversibility of the dehydration of β-hematin was established with the use of a humidor. In Fig. 4, the data for the heating and room temperature humidifying is shown. The sample was initially heated to drive out any water that

may have been present. After 24 h at 120 °C, the sample was weighed and placed in the humidor at room temperature, where it was left undisturbed for 72 h before being reweighed. This cycle was performed two more times. The mass changes indicate that the water is reversibly absorbed by the sample of β-hematin. IR analysis after the final step confirmed that the β-hematin was spectroscopically identical to the starting material.

Synchrotron X-ray powder diffraction is able to detect subtle changes in the lattice of a compound upon dehydration. To determine the nature of any lattice changes during hydration, several aliquots of freshly prepared anhydrous

Fig. 4. Data for two batches of ABM β-hematin in the humidor and oven. The samples are cycled between 120 °C (dry) for 24 h and 23 °C (humid) for 72 h.
ABM β-hematin were hydrated in a humidor for 14 or 56 days, being exposed to constant humidity throughout. The samples were removed and sealed under nitrogen in rigorously dried capillaries and their X-ray diffraction patterns measured. Rehydration led to subtle changes in the positions and relative intensities of the Bragg reflections in the powder diffraction pattern (Fig. 5a). All three diffraction patterns have close indicies, and the increases in the relative intensities of the (100), (020), (2-21), and (131) peaks are not likely to be due to a single preferred orientation effect. In addition to changes in these relative intensities, there is a sharp improvement in the signal to noise ratio of the diffraction profile upon hydration. These results suggest that the sample is becoming more ordered as it is allowed to rehydrate. From the X-ray data, we found that as the sample was hydrated, the unit cell volume reduces from 1448.3 (22) to 1417.5 (15) $Å^3$ with the relative magnitudes of all three parameters (a, b, c) decreasing uniformly. Further hydration beyond 42 days results in only an additional 0.06% decrease in volume. The structural origin of this shift in the size of the lattice is difficult to definitely assign, with the refined structure from the dehydrated material being isostructural with the published structure (results not shown). Rehydration results in a smaller cell, but overall, water is not found in the lattice from the solution of the powder diffraction pattern. This suggests water mediates a type of ordering or annealing process, possibly between the layers of hemes. Regardless of its origin, β-hematin is able to absorb surprisingly large quantites of water. This situation is opposite to that known for vermiculite, where the hydration of charged ions between silicate layers results in the specific expansion of the lattice with one preferred direction (26).

These experiments rationalize the anomalous elemental analyses for β-hematin. However, they also point to a poten-

Fig. 5. Synchrotron X-ray powder diffraction (λ = 1. 14021 Å) data for ABM β-hematin rehydration experiments. Samples collected as spinning capillaries, with changes in the peaks are most noticeable for the (131) and (2-21). Samples were rehydrated for 0, 14, and 56 days prior to being stored for analysis as described in the *Experimental* section.
tially useful drug target. The observed reversible hydration naturally suggests that other materials might readily be absorbed by β-hematin, and, purely speculatively, a potential

consequence of this might be increased solubility and bioavailability of heme during the intraeyrthrocytic stages of the parasite. If such an adsorbate could be designed or discovered, it would be a candidate antimalarial. It is well known that the complex unique biochemistry within the malaria parasite's digestive vacuole presents many potential drug targets that can be exploited (27). Heme detoxification by the formation of β-hematin is one such drug target. Perhaps β-hematin deaggregation is another.

Conclusions

Water is adsorbed substoichiometrically by β-hematin with considerable variability depending upon its preparation and history. Among the factors which might be responsible for this are the inherent variations in morphology and phase homogeneity. In particular, the more crystalline ABM preparations absorb more water and release it more slowly upon heating. It is still unclear where the water adsorbs; possibilities include intercalation between the layers or adhesion to the surface of the crystallite. The water was found to be reversibly incorporated into the crystallites and can be removed with moderate heating. Two possibilities exist for the apparent increase in crystallinity following a rehydration–dehydration sequence. If the water is between the laminar planes, it is possible that the crystals fragment upon heating as the water is liberated, but if it is only weakly surface adsorbed, removal will be facile and will leave little trace following dehydration.

Synthesis, first structures, and catalytic activity of the monomeric rhodium(I)-siloxide phosphine complexes[1]

Bogdan Marciniec, Paulina Błażejewska-Chadyniak, and Maciej Kubicki

Abstract: Four new square-plane rhodium siloxide complexes of the general formula $[Rh(cod)(PR_3')(OSiR_3)]$ (where R = Me, i-Pr, O-t-Bu, R′ = Cy, Ph) were synthesized and the structures of three of them were resolved by the X-ray method. $[Rh(cod)(PCy_3)(OSiMe_3)]$ (**1**) appeared to be a very efficient catalyst for hydrosilylation of allyl glycidyl ether to yield, selectively, 3-glycidoxypropyltriethoxysilane, a commercially important silane coupling agent. Catalytic measurements and stoichiometric experiments of **1** with triethoxysilane suggest a mechanism where an unsaturated Rh-H species is responsible for the catalysis.

Key words: rhodium (phosphine) siloxides, hydrosilylation, catalysis.

Résumé : On a synthétisé quatre nouveaux complexes siloxyde de rhodium de géométrie plan carré et de formule générale $[Rd(cod)(PR_3')(OSiR_3)]$ (dans lesquels R = Me, i-Pr, O-t-Bu; R′ = Cy; Ph) et on a déterminé les structures de trois d'entre eux par diffraction des rayons X. Il semble que le $[Rh(cod)(PCy_3)(OSiMe_3)]$ (**1**) est un catalyseur très efficace pour l'hydrosilylation de l'oxyde d'allyle et de glycidyle conduisant à la formation sélective du 3-glycidoxypropyltriéthoxysilane, un silane commercialement important comme agent de couplage. Des mesures catalytiques et des expériences stoechiométriques du composé **1** avec le triéthoxysilane suggèrent un mécanisme dans lequel l'espèce Rh-H insaturée est responsable de la catalyse.

Mots clés : rhodium(phosphine)siloxydes, hydrosilylation, catalyse.

[Traduit par la Rédaction]

Introduction

Siloxides similar to alkoxides have been employed as ancillary ligands of transition metal (TM) complexes, markedly influencing the reactivity of a metal center by electronic and steric effects of the substituents at silicon. They can be regarded as very good molecular models of metal complexes supported on silica and silicate surfaces, which are known to catalyze a variety of organic and organometallic transformations particularly by early transition metal complexes (1). Unlike the early TM-siloxides the information on the late TM-siloxides is scarce. Only exceptional siloxy derivatives of Fe (2), Co (3), Ni (4), Ru (5), Rh (6–9), Pt (10), Os (11), and Ir (10c) have been synthesized and characterized spectroscopically, and the structures of all of them have been a subject of recent interest. The dimeric complexes included $[Rh(CO)_2(\mu\text{-}OSiR_3)]_2$, where R = Me (8), Ph (6b), and $[Rh(cod)(\mu\text{-}OSiPh_3)]_2$ (6b), $[Rh(diene)(\mu\text{-}OSiMe_3)]_2$, where diene = cod (7a, 7b), nbd (7c).

Catalytic activity of $[Rh(cod)(\mu\text{-}OSiMe_3)]_2$ has been illustrated in some reactions, i.e., in the hydrosilylation of alkenes (12) and allyl alkyl ethers (13, 14) and in the silylative coupling of vinylsilanes with alkenes (15).

The aim of this work was to prepare monomeric rhodium-siloxide complexes, to determine their structures by X-ray methods, and to assess their catalytic activity in the hydrosilylation process.

Experimental section

General methods and chemicals

All syntheses and operations were carried out using standard Schlenk techniques under a carefully deoxygenated and dried argon. ^1H, ^{13}C, ^{31}P, and ^{29}Si NMR spectra were recorded on Varian Mercury and Varian Gemini 300 VT spectrometers. The reagents were obtained from the following sources: C_6H_6 from OBR PR Plock (Poland), PPh_3 from Fluka, sodium trimethylsilanolate from Aldrich, THF and

C_5H_{12} from POCh Gliwice (Poland), $HOSi(O\text{-}t\text{-}Bu)_3$ and $i\text{-}Pr_3SiCl$ from ABCR Co. All solvents were distilled in an inert atmosphere prior to use. $[\{Rh(cod)(\mu\text{-}Cl)\}_2]$ (16, 17), $[\{Rh(cod)(\mu\text{-}OSiMe_3)\}_2]$ (**5**) (7*a*) were prepared according to the previously reported procedures.

Synthesis of the complex $[Rh(cod)(PCy_3)(OSiMe_3)]$ (1)

Portions of 0.1 g $[\{Rh(cod)(\mu\text{-}OSiMe_3)\}_2]$ (0.33 mmol) and 0.2 g (0.71 mmol) PCy_3 were placed in a Schlenk flask under Ar. Then 6 mL of dried and deoxygenated C_6H_6 was added. The reaction was carried out for 4 h at room temperature (r.t.). After this time, C_6H_6 was evaporated and 5 mL of dried and deoxygenated C_5H_{12} was added. The precipitate was decanted three times by C_5H_{12}. The complex was dried in vacuum for about 3 h. It was obtained with a yield of 75%. ^{1}H NMR (C_6D_6) δ: 0.46 (s, 9H, $-CH_3$), 1.20–2.02 (m, 33H, -Cy), 2.35 (m, 4H, $-CH_2$-), 3.26 (m, 4H, $-CH_2$-), 5.41 (m, 4H, =CH-). ^{13}C NMR (C_6D_6) δ: 6.0 ($-OSiMe_3$, $-CH_3$), 27.21, 28.28, 28.40, 29.07, 30.80, 31.80, 31.97, 32.50, 32.71, 34.07 (-Cy, $-CH_2$-), 62.83, 63.01 (cod, $-CH_2$-), 99.15, 99.26, 99.32, 99.42 (cod, =CH-). ^{31}P NMR (C_6D_6) δ: 25.28 (d, $J_{Rh\text{-}P}$ = 151 Hz). ^{29}Si NMR δ: –3.35. Anal. calcd. for $RhPSiOC_{29}H_{54}$: C 59.98, H 9.37; found: C 60.22, H 9.44.

Synthesis of the complex $[Rh(cod)(PPh_3)(OSiMe_3)]$ (2)

Complex **2** was prepared in a similar way to complex **1**, except for the fact that PPh_3 (0.09 g, 0.34 mmol) was used instead of PCy_3. The yellow complex was obtained with the yield of 70%. ^{1}H NMR (C_6D_6) δ: 0.30 (s, 9H, $-CH_3$), 1.68 (m, 4H, $-CH_2$-), 2.18 (m, 4H, $-CH_2$-), 2.88 (m, 2H, -CH=), 5.62 (m, 2H, -CH=), 7.07 (m, 9H, -Ph), 7.75 (m, 6H, -Ph). ^{13}C NMR (C_6D_6) δ: 5.06 ($-OSiMe_3$, $-CH_3$), 29.02, 33.67 (cod, $-CH_2$-), 64.60, 64.78 (cod, -CH=), 103.18 (bs, cod, =CH-), 130.10, 131.57, 132.38, 135.23 (-Ph). ^{31}P NMR (C_6D_6) δ: 25.21. ^{29}Si NMR (C_6D_6) δ: 21.55. Anal. calcd. $RhPSiOC_{29}H_{36}$ for: C 61.92, H 6.45; found: C 62.18, H 6.37.

Synthesis of the complex $[Rh(cod)(PCy_3)(OSi\text{-}i\text{-}Pr_3)]$ (3)

Preparation of $HOSi\text{-}i\text{-}Pr_3$

$i\text{-}Pr_3SiCl$ (10 mL) was added to a water–ether mixture (H_2O (300 mL), ether (150 mL)) that was stirred with a magnetic stirrer for 24 h at r.t. Then the aqueous phase was removed and the ether solution was dried by addition of $CaCl_2$. After 24 h it was filtered off by a cannula system and the solvent was evaporated to dryness. The product was obtained with a yield of 87%.

Preparation of $NaOSi\text{-}i\text{-}Pr_3$

Thirty mL portions of anhydrous and deoxygenated THF and 1.20 g (53 mmol) of metallic Na were placed into a 50 mL double-necked round-bottomed flask equipped with a reflux condenser and an attachment for gas supply. Then 7.8 g of $HOSiO\text{-}i\text{-}Pr_3$ (45 mmol) was added over 30 min with constant stirring by a magnetic stirrer. After this time, the mixture was heated at a boiling point for 6 h. After the reaction, the contents of the flask were filtered off hot by a cannula to a Schlenk flask. Having cooled the contents, the solvent was evaporated and the product was dried in vacuum for about 3 h. It was obtained with a 90% yield. ^{1}H NMR

(C_6D_6) δ: 1.02 (m, 3H, -CH=), 1.20 (d, 18H, $-CH_3$). Anal. calcd. for $NaOSiC_9H_{21}$: C 55.06, H 10.78; found: C 54.82, H 11.11.

Synthesis of the complex $[Rh(Cl)(cod)(PCy_3)]$

Portions of 0.22 g (0.8 mmol) of PCy_3 and 0.21 g (0.4 mmol) of $[\{Rh(cod)(\mu\text{-}Cl)\}_2]$ were placed in a Schlenk flask in an Ar atmosphere. Then 5 mL of dried and deoxygenated C_6H_6 was added and the mixture was stirred with a magnetic stirrer. After 2 h, C_6H_6 was evaporated and 5 mL of dried and deoxygenated C_5H_{12} was added. The precipitate was decanted three times by C_5H_{12}. The complex was dried in vacuum for about 3 h. It was obtained with a yield of 95%. ^{1}H NMR (C_6D_6) δ: 1.20–2.19 (m, 33H, -Cy), 2.32 (m, 4H, $-CH_2$-), 3.60 (m, 4H, $-CH_2$-), 5.72 (m, 4H, =CH-). ^{31}P NMR (C_6D_6) δ: 27.33 (d, $J_{Rh\text{-}P}$ = 350.7 Hz). Anal. calcd. for $RhPClC_{26}H_{45}$: C 59.26, H 8.61; found: C 59.82, H 8.84.

Synthesis of 3

Portions of 0.2 g (0.38 mmol) $[Rh(cod)(PCy_3)(Cl)]$ and 0.08 g (0.42 mmol) $NaOSi\text{-}i\text{-}Pr_3$ were placed in a Schlenk flask in an Ar atmosphere. Then 5 mL of dried and deoxygenated C_6H_6 was added. The reaction was conducted for 24 h at r.t. After this time, C_6H_6 was evaporated and 8 mL of dried and deoxygenated C_5H_{12} was added. The entire mixture was filtered off by a cannula system. The solvent was evaporated from the obtained filtrate leaving a yellow solid. The complex was isolated with a yield of 85%. ^{1}H NMR (C_6D_6) δ: 1.22 (m, 3H, -CH=), 1.48 (d, 18H, $-CH_3$), 1.57–2.28 (m, 33H, -Cy), 2.30 (m, 4H, $-CH_2$-), 3.47 (m, 4H, $-CH_2$-), 5.28 (m, 4h, =CH-). ^{13}C NMR (C_6D_6) δ: 16.99–20.32, 26.49–34.04 (m, $-OSi\text{-}i\text{-}Pr_3$ + -Cy), 61.75, 61.93 (cod, $-CH_2$-), 97.92, 98.03, 98.09, 98.19 (cod, =CH-). ^{31}P NMR (C_6D_6) δ: 27.40 (d, $J_{Rh\text{-}P}$ = 149 Hz). ^{29}Si NMR (C_6D_6) δ: –21.51. Anal. calcd. for $RhPSiOC_{35}H_{66}$: C 63.23, H 10.01; found: C 62.91, H 10.11.

Synthesis of the complex $[Rh(cod)(PCy_3)\{OSi(O\text{-}t\text{-}Bu)_3\}]$ (4)

Preparation of $NaOSi(O\text{-}t\text{-}Bu)_3$

Fifty mL portions of anhydrous and deoxygenated THF and 0.35 g (15 mmol) of metallic Na were placed into a 100 mL double-necked round-bottomed flask equipped with a reflux condenser and an attachment for gas supply. Then 4 g of $HOSi(O\text{-}t\text{-}Bu)_3$ (15 mmol) was added and the mixture was heated at a boiling point for 4 h. After the reaction, the contents of the flask were filtered off hot by a cannula to a Schlenk flask. Having cooled the contents, the solvent was evaporated and the white solid was washed with diethyl ether (3×5 mL). The product was obtained with a 90% yield. ^{1}H NMR (C_6D_6) δ: 1.57 (s, 27H, $-CH_3$).

Preparation of 4

Complex **4** was prepared in a similar way to complex **3**, except for the fact that $NaOSi(O\text{-}t\text{-}Bu)_3$ (0.12 g, 0.42 mmol) was used instead of $NaOSi\text{-}i\text{-}Pr_3$. The yellow complex was obtained with the yield of 90%. ^{1}H NMR (C_6D_6) δ: 1.56 (s, 27H, $-CH_3$), 1.81 (m, 33H,$-CH_2$-), 2.50 (m, 4H, $-CH_2$-), 3.25 (m, 4H, $-CH_2$-), 5.05 (m, 4H, =CH-). ^{13}C NMR (C_6D_6) δ: 26.91, 27.83, 27.96, 28.78, 30.87, 31.68, 32.62, 33.58, 33.80,

Anal. calcd. for RhPSiO$_4$C$_{38}$H$_{72}$: C 60.46, H 9.61; found: C 60.72, H 9.08.

Crystallization of the complexes

A portion of about 0.05 g of the complex and an amount of dry and deoxygenated C$_5$H$_{12}$ sufficient to obtain a clear solution were placed in a Schlenk flask. Crystallization was conducted for 10–14 days at –15 °C. A few crystals selected under a microscope were placed in glass capillary tubes of 0.3 mm in diameter and subjected to X-ray diffraction study.

X-ray crystallography

X-ray diffraction data was collected, from the crystals sealed in glass capillaries, on a KUMA KM4CCD diffractometer (18) using graphite-monochromated MoKα radiation (λ = 0.71073 Å). Data collections were performed in six separate runs (a total of 782 frames for **1** and **4**, and 588 frames for **3**) to cover an appropriate part of the reflection sphere. The ω-scan was used, two reference frames were measured after every 50 frames, and they did not show any systematical changes neither in the peak position nor in their intensities. The unit-cell parameters were determined by least-squares treatment of the setting angles of 9625 (**1**), 5103 (**3**), and 5665 (**4**) highest-intensity reflections, chosen

from the whole experiment. Lorentz and polarization effects were accounted for (19), and then data were corrected for absorption and merged with SORTAV (20). The structures were solved by direct methods with the SHELXS-97 program (21), and refined with full-matrix least-squares by SHELXL-97 (22). All non-hydrogen atoms, including those from the disordered solvent–pentane molecule in **3,** were refined anisotropically. The positions of hydrogen atoms were generated geometrically and they were refined as a "riding model". The U_{iso} parameters of hydrogen atoms were set at 1.2 times U_{eq} of the appropriate carrier atom.

A summary of crystal data, data collection and refinement is given in Table 1.

Results and discussion

Two types of reactions were used for the synthesis of the rhodium-siloxide complexes:

$$[Rh(cod)(\mu\text{-}OSiMe_3)]_2 + 2PR_3' \xrightarrow[\text{room temp.}]{C_6H_6,\ 2\ h}$$
$$2[Rh(cod)(PR_3')(OSiMe_3)]$$

where R′ = Cy, Ph and

$$[Rh(cod)(PCy_3)(CI)] + NaOSiR_3 \xrightarrow[\text{room temp.}]{C_6H_6,\ 24\ h}$$
$$[Rh(cod)(PCy_3)(OSiR_3)] + NaCI$$
Fig. 1. Anisotropic displacement representation of complex **1** showing the labelling scheme. Displacement ellipsoids are shown at the 33% probability level and hydrogen atoms are omitted for clarity.

Fig. 2. Anisotropic displacement representation of complex **3** showing the labelling scheme. Displacement ellipsoids are shown at the 33% probability level and hydrogen atoms are omitted for clarity.
where R = *i*-Pr, O-*t*-Bu. All the rhodium–siloxide products were characterized by ^1H, ^{13}C, ^{31}P, and ^{29}Si NMR spectroscopy.

The molecular structures of complexes [Rh(cod)(PCy$_3$)(OSiMe$_3$)] (**1**), [Rh(cod)(PCy$_3$)(OSi-*i*-Pr$_3$)] (**3**), and [Rh(cod)(PCy$_3$)(OSi(O-*t*-Bu)$_3$)] (**4**) with the atom-numbering scheme are depicted in Figs. 1, 2, and 3, respectively. Selected geometrical parameters are listed in Table 2.

In all three complexes the coordination of rhodium is square planar, providing that the middle points of the cyclooctadiene double bonds are regarded as the coordination sites X1 and X2. This is confirmed by the values of bond angles at rhodium (cf. Table 2) as well as by the least-squares calculation of the mean plane through five points: Rh, X1, X2, O, and P. Maximum deviation from this plane is 0.017(2) Å in **1**, 0.059(5) Å in **3**, and 0.005(2) Å in **4**. The cyclooctadiene double bonds are approximately perpendicular to the central coordination plane.

The bond lengths and angles are quite typical. All cyclohexyl rings are slightly distorted chairs, and the conformations of cyclooctadiene rings are close to a C_2 – twist-boat, the minimum energy conformation (23, 24). Despite these similarities there are some quite interesting differences in the overall conformation between alkyl-substituted siloxide complexes **1** and **3** and, on the other side, the alkoxy-substituted siloxide complex **4**. For example, the disposition of the substituents at the Si atom with respect to the O—Si bond can be described as +*sc*,–*sc*, *ap* (Rh-O-Si-C torsion angles approximately +60°, –60°, 180°) in **1** and **3**, while in **4** it is +*ac*,–*ac*, *sp* (Rh-O-Si-O values are close to +120°, –120°, 0°).

All the monomeric rhodium-siloxide complexes **1**–**4** were tested in the hydrosilylation of allyl glycidyl ether by triethoxysilane leading to glycidoxypropyltriethoxysilane, which is a commercially important silane coupling agent.
The reaction gives the hydrosilylation product (**A**) with very high yield accompanied by products of the dehydrogenative silylation (**B** + **C**) according to the following scheme:
The effect of the catalyst **1**–**4** concentrations as well as other conditions (temperature and time of the reaction) on the yield of the main product and by-products is compiled in Table 3. Dimeric [Rh(cod)(μ-OSiMe$_3$)]$_2$ (**5**), whose structure (7*b*) and catalytic activity in this reaction (13, 14) was reported previously, is used for comparison.

The order of the activity is as follows:
[Rh(cod)(μ-OSiMe$_3$)]$_2$ ≈ [Rh(cod)(PCy$_3$)(OSiMe$_3$)] ≥
　　　　5　　　　　　　　　　　　　**1**
[Rh(cod)(PPh$_3$)(OSiMe$_3$)] ≈ [Rh(cod)(PCy$_3$)(OSi-*i*-Pr$_3$)] >>
　　　　2　　　　　　　　　　　　　**3**
　[Rh(cod)(PCy$_3$)(OSi(O-*t*-Bu)$_3$)]　and can be explained by
　　　　4

increasing steric effects of the siloxy group influencing directly the rate of the hydrosilylation process as well as by a complex stereoelectronic effect of the trisubstituted phosphine (**1** ≥ **2**). The latter effect is a result of facile oxygenation and dissociation of PCy$_3$ vs. PPh$_3$ caused mainly by an

increase in electron-donor properties of the former phosphine.

Similarly to the hydrosilylation by dimeric rhodium siloxide **5** (25), monomeric phosphine rhodium siloxides (**1–4**) undergo an oxidative addition with triethoxysilane followed by elimination of disiloxane according to the mechanistic pathways proposed in Scheme 1.

Preliminary ^{1}H NMR study on the stoichiometric reactions of (**1**) with triethoxysilane performed in C$_6$D$_6$ in room temperature and in air, right away after mixing of the substrate, revealed the presence of several doublets at δ ~ –13.35 and

$J_{Rh\text{-}H}$ ~ 43 in the spectra to be formed in the mixture of the penta-coordinate complexes similarly to the spectra observed previously in the system – dimeric complex **5**

of dehydrogenative silylation observed (1% to 2%), is omitted from the scheme for clarity.

Conclusions

Four new monomeric, square-planar rhodium siloxide complexes of the general formula $[Rh(cod)(PR_3')(OSiR_3)]$ where R′ = Cy, Ph, R = Me, *i*-Pr, O-*t*-Bu were synthesized and three of them were structurally characterized.[3]

The complex (**1**) ($[Rh(cod)(PCy_3)(OSiMe_3)]$) appeared to be a very efficient catalyst for hydrosilylation of allyl glycidyl ether occurring in air. All catalytic data and stoichiometric reactivities of (**1**) with triethoxysilane are consistent with a mechanism involving a generation of tetra-coordinated Rh-H species (responsible for catalysis).

Hydrosilylation of alkenes and ketones catalyzed by nickel(II) indenyl complexes[1]

Frédéric-Georges Fontaine, René-Viet Nguyen, and Davit Zargarian

Abstract: Abstraction of Cl⁻ from the complexes (indenyl)Ni(PPh₃)Cl generates cationic species that are effective precatalysts for the hydrosilylation of some olefins and ketones. For instance, the mixture of (1-Me-indenyl)Ni(PPh₃)Cl and NaBPh₄ (or methylaluminoxane) reacts at room temperature with ca. 100 equiv. each of PhSiH₃ and styrene to produce [1-phenyl-1-ethyl](phenyl)silane, PhCH(CH₃)(SiPhH₂), in 50%–80% yield. The same system can also catalyze the hydrosilylation of 1-hexene and norbornene, but the products arising from these substrates consist of mixtures of regio- and stereoisomers. On the other hand, ketone hydrosilylation is regiospecific, giving the corresponding silyl ethers in high yields. A number of experimental observations have indicated that the initially generated Ni-based cation is not the catalytically active species. Indeed, the cationic initiators may be replaced by LiAlH₄ or AlMe₃, which generate the corresponding Ni-H or Ni-Me derivatives, respectively. Moreover, the observed regioselectivity for the addition of PhSiH₃ to styrene (i.e., predominant addition of the silyl fragment to the α-C) is opposite of what would be expected if the reaction mechanism involved carbocationic intermediates. A new mechanism is proposed in which the active species is a Ni-H species originating from the transfer of H⁻ from PhSiH₃ to the initially generated Ni cation.

Key words: hydrosilylation, nickel indenyl complexes, cationic complexes, hydride intermediates.

Résumé : L'abstraction des ions chlorures des complexes (indényle)Ni(PPh₃)Cl génère des espèces cationiques qui sont des précatalyseurs efficaces pour la réaction d'hydrosilylation de certaines oléfines et de certaines cétones. Par exemple, le mélange de (1-Me-indényle)Ni(PPh₃)Cl et de NaBPh₄ (ou de méthylaluminoxane) réagit à la température de la pièce avec environ 100 équivalents de PhSiH₃ et 100 équivalents de styrène pour donner le [1-phényl-1-éthyl](phényl)silane, PhCH(CH₃)(SiPhH₂) avec un rendement allant de 50 % à 80 %. Le même système peut également catalyser l'hydrosilylation du 1-hexène et du norbonène, mais on obtient dans ces conditions des mélanges de régio- et de stéréo-isomères. Par ailleurs, l'hydosilylation des cétones est régiospécifique, et conduit aux éthers silylés correspondants avec des rendements élevés. Plusieurs observations expérimentales ont révélé que le cation à base de nickel généré initialement n'est pas l'espèce active catalytiquement. Effectivement l'initiateur cationique peut-être remplacé par le LiAlH₄ ou par le AlMe₃ qui génèrent respectivement les dérivés Ni-H ou Ni-Me correspondants. De plus, la régiosélectivité observée lors de l'addition du PhSiH₃ sur le styrène (i.e. l'addition prédominante du fragment silylé sur le carbone en α) est à l'opposé de ce à quoi on pourrait s'attendre si le mécanisme réactionnel impliquait un carbocation intermédiaire. On propose un nouveau mécanisme dans lequel l'espèce réactive est le Ni-H provenant du transfert de H⁻ à partir du PhSiH₃ vers le cation nickel généré initialement.

Mots clés : hydrosilylation, complexes indényle-nickel, complexes cationiques, hydrures intermédiaires.

[Traduit par la Rédaction]

Introduction

Based on their pioneering studies on the mechanism of the olefin hydrosilylation reaction, Harrod and Chalk proposed, in 1965, a general mechanistic scheme involving hydrido(silyl) intermediates of the type L$_n$M(H)(SiR₃) (Scheme 1) (1). According to this scheme, insertion of the olefin into the M—H bond generates an alkyl intermediate that undergoes

[2]Corresponding author (e-mail: zargarian.davit@umontreal.ca).

reductive elimination to give the final product. The main elements of the Chalk–Harrod mechanism have served as useful guiding principles for the development of numerous hydrosilylation catalysts over the past four decades (2–4).

We became interested in the hydrosilylation reaction during our studies on the oligomerization of PhSiH₃ catalyzed by Ni(II) indenyl precursors (5). The presumed involvement of Ni-H or Ni-SiR₃ intermediates in these reactions suggested that the same Ni-indenyl systems might also promote the hydrosilylation of olefins or ketones if these unsaturated substrates were present in the reaction mixture. This assertion was borne out by a series of tests, which indicated that the presence of certain olefins effectively inhibited the Si—Si bond formation step in favour of the hydrosilylation reaction. These initial results prompted us to carry out a literature survey, which revealed that a number of related Ni complexes are known to promote the hydrosilylation of ole-

Scheme 1.

fins, as follows: the dimeric complex {CpNi(μ-CO)}$_2$ catalyzes the addition of HSiCl$_3$ to styrene to give PhCH-(SiCl$_3$)Me (6); CpNi(PPh$_3$)Ph reacts with butadiene and Me$_3$SiH to give a mixture of products arising from 1,4-hydrosilylation (MeCH=CHCH$_2$SiMe$_3$), coupling–hydrosilylation (2,6-octadienyltrimethylsilane), and dimerization–cyclization (1,5-cyclooctadiene) (7); CpNi(PR$_3$)R′ reportedly catalyzes the hydrosilylation of methyl acrylate and allyl formate with HSiCl$_3$ (8). Although little is known about the way these systems work, their mechanisms might involve intermediates similar to those operating in our systems.

Thus, we undertook to investigate the effectiveness of our Ni(II) indenyl complexes in the hydrosilylation reaction and examine the mechanism of these reactions. The present report describes the hydrosilylation of alkenes and ketones catalyzed by the precursors IndNi(PR$_3$)X (Ind = indenyl ligand and its substituted derivatives; R = Ph, Me; X= Cl, alkyl, or positive charge).

Results and discussion

Our initial experiments focused on the reaction of PhSiH$_3$ and styrene with a catalytic system based on the combination of IndNi(PR$_3$)Cl and methylaluminoxane (MAO); the selection of this Ni–MAO system was based on the knowledge that it promotes the dehydrogenative polymerization of PhSiH$_3$ (5a). A typical experiment was carried out as follows: to the toluene mixture of (1-Me-Ind)Ni(PPh$_3$)Cl (**1**), styrene, and PhSiH$_3$ (1:100:100 ratio) was added a toluene solution of MAO (10 equiv. with respect to Ni); the wine-red mixture darkened immediately, but no gas evolution was observed, implying that the Si—Si bond formation reaction (and its concomitant formation of H$_2$ gas) had been circumvented by the presence of styrene.

The reaction mixture was stirred for 8 h and worked-up; analysis of the nonvolatile products by GC–MS confirmed that styrene had been hydrosilylated.[3] Distillation gave a colourless oil, which was shown to consist, almost exclusively, of the α-isomer ((1-phenyl)ethylphenylsilane). This assignment was based on the following features of the ^{1}H NMR spectrum of the final product (Fig. 1): the multiplet due to the benzylic methyne proton at 2.55 ppm (PhC*H*(Me)SiH$_2$Ph), the signals due to the diastereotopic SiH$_2$ protons and their ^{29}Si satellites at 4.35 ppm, and the doublet at ca. 1.4 ppm assigned to the methyl protons ($^3J_{H-H}$ = 7 Hz); the benzylic protons of the minor isomer

(PhC*H*$_2$CH$_2$SiPhH$_2$) were barely perceptible at ca. 2.7 ppm. These assignments are consistent with the reported data for these products (9).

Subsequent experiments showed that the hydrosilylation of styrene promoted by IndNi(PPh$_3$)Cl–MAO is fairly sluggish, requiring several hours of reaction time for ca. 70% yield (see runs 1–4 of Table 1). Curiously, using more catalyst or a higher temperature did not accelerate the catalysis (compare runs 5 to 2, and 6 to 4); on the other hand, combining these two variations did increase the rate, but did not affect the yield (compare run 7 to runs 6 and 5). It should be noted here that the higher temperature reactions tend to give higher proportions of the β-isomer (ca. 5%–10%); the significance of this observation for the probable mechanism of the catalytic reaction will be discussed later. The reaction rate also improved upon using the 1-i-Pr-Ind analogue of **1** as precatalyst (compare run 8 to run 2), whereas using the PMe$_3$ analogue of **1** did not offer any advantage (compare run 9 to run 5).

Although the precise role of MAO in the present system is not known yet, our previous studies (10) have shown that a small excess of MAO (ca. 5 equiv.) serves primarily to methylate the Ni—Cl bond, while a large excess (>10 equiv.) leads to both methylation and ionization in varying proportions. For example, ^{31}P{^{1}H} NMR analysis of a 1:25 mixture of **1** and MAO showed the formation of an approximately 50:50 mixture of the Ni-Me analogue of **1** ((1-Me-Ind)Ni(PPh$_3$)Me) and the cationic complex [(1-Me-Ind)Ni(PPh$_3$)$_2$]$^+$. Previous studies have shown that the latter complex forms when the highly electrophilic cation [IndNi(PPh$_3$)]$^+$ is generated in the absence of suitable ligands or nucleophilic substrates (11). We conclude, therefore, that the MAO:Ni ratios used in our studies (ca. 10:1) convert the Ni-Cl precursor to a mixture of the analogous Ni-Me derivative and [IndNi(PPh$_3$)]$^+$. To determine which, if any, of these in situ generated derivatives is crucial for the hydrosilylation reaction, we tested the catalytic effectiveness of each species separately, as follows.

Tests with the complex (1-Me-Ind)Ni(PPh$_3$)Me, either preformed (12) or prepared in situ from **1** and AlMe$_3$, showed that it was less than half as effective as the combination of **1**–MAO (compare runs 10 and 11 to run 4). The weak activity of the Ni-Me derivative is perhaps not surprising since this compound is inert toward styrene insertion and reacts only very sluggishly with PhSiH$_3$ (5b). On the other hand, the Ni-(i-Pr) derivative, which reacts faster with PhSiH$_3$ than the Ni-Me analogue (10b), showed a better level of activity (run 12). Interestingly, the catalytic activity of the Ni-Me complex improves somewhat when MAO is added to the reaction medium (compare runs 10 and 11 to run 13); this result implies that the main role of MAO in this system is not simply methylating the Ni—Cl bond. We concluded, therefore, that the reactivity of the Ni-Me complex alone could not account for the activity levels shown by the combination of **1** and MAO, and set out to assess the importance of ionization in the **1**–MAO-catalyzed reactions.

To examine the reactivity of the cationic species [IndNi(PPh$_3$)]$^+$ in the absence of the Ni-Me derivative, we

---

[3] Control experiments have shown that neither the Ni-Cl complexes nor the initiators used in this study (MAO, AlMe$_3$, NaBPh$_4$, LiAlH$_4$) can promote the hydrosilylation reaction when used alone.

Fig. 1. ^{1}H NMR (C_6D_6) of the product obtained from the Ni-catalyzed hydrosilylation of styrene with PhSiH$_3$. The peaks denoted by * represent the satellites due to the J_{29Si-H} coupling, while the peaks denoted by the # represent the internal standard (ca. 2.1 ppm), residual Et$_2$O (ca. 3.4 and 1.1 ppm), and SiMe$_4$.
generated this species in situ by the direct abstraction of Cl$^-$ from **1** by NaBPh$_4$;[4] this approach gave results comparable to those obtained with MAO (compare run 14 to run 4). To our surprise, even the cation [(1-Me-Ind)Ni(PPh$_3$)$_2$]$^+$, which is normally quite inert in ligand substitution and other catalytic reactions (10*b*), showed some reactivity in the absence of MAO (run 15). These observations suggested that the electronically and coordinatively unsaturated species [IndNi(PPh$_3$)]$^+$, which is generated in situ by the abstraction of Cl$^-$ by NaBPh$_4$ or MAO, can initiate the hydrosilylation reaction. Thus, during the second round of the optimization tests we focused our efforts on finding the best conditions for the catalytic hydrosilylation of styrene using NaBPh$_4$ as a cationic initiator, as described below.

The initial experiments showed that the ratio of **1**:NaBPh$_4$ used in the catalytic runs has a direct effect on the yield, excess of NaBPh$_4$ giving higher yields (Table 2, runs 1–4). Since only one equivalent of the initiator should be sufficient for generating the cationic species, the need for a large excess (run 4) is presumably due to the limited solubility of NaBPh$_4$. Even though a [Ni]:NaBPh$_4$ ratio of 1:50 gave the best yield, using such a large excess of the initiator is not practical, and so we adopted a 1:10 ratio as a reasonable compromise. As before, a higher reaction temperature does

not seem to improve the catalytic activity (run 5), but gave a higher proportion of the β-isomer. Using the 1-*i*-Pr-Ind derivative does not offer any advantages (runs 6 and 7), while using the PMe$_3$ analogue of **1** led to considerably lower activities (runs 8 and 9). The latter observation is interesting: that the more active precatalyst is the one bearing the less nucleophilic phosphine ligand might imply that the hydrosilylation reaction involves a PR$_3$ dissociation. Consistent with this possibility, the presence of added PPh$_3$ ([Ni]:PPh$_3$ = 1:2) hindered the catalysis significantly (run 10). This point will be elaborated further during the discussion of the mechanism of these reactions (vide infra).

The scope of the hydrosilylation reactions promoted by **1**–NaBPh$_4$ has been explored briefly, as follows. Norbornene and 1-hexene were hydrosilylated with PhSiH$_3$ to ca. 1:1 mixtures of regio- (for 1-hexene) and stereoisomers (endo- and exo-products from norbornene), while *trans*-β-Me-styrene gave the α-isomer in ca. 10:1 ratio (ca. 50% overall yield). On the other hand, cyclohexene, indene, and *trans*-stilbene gave no hydrosilylation products; for the latter two olefins, the reaction mixtures displayed broad signals in the NMR spectra implying poly(olefin) formation, but no further analyses were performed to confirm this possibility. Although PhSiH$_3$ has been used in almost all of our studies,

---

[4] The abstraction of Cl$^-$ from **1** by NaBPh$_4$ is clean but generally sluggish, especially in nonpolar solvents such as toluene, in which NaBPh$_4$ has a very limited solubility. Although AgBF$_4$ is much more efficient for Cl$^-$ abstraction, its higher cost and the possibility of secondary reactions (e.g., electron transfer with the Ni complex and redistribution with PhSiH$_3$) render it less practical than NaBPh$_4$ for our purposes.

$^\$$This run was carried out at 65 °C.

the reactivity of other silanes was also examined briefly. Thus, we found that tri-substituted silanes such as Et$_3$SiH and (EtO)$_3$SiH are inactive in the hydrosilylation of styrene, but Ph$_2$SiH$_2$ does add to styrene to give the products PhCH(CH$_3$)(Ph$_2$SiH) and PhCH$_2$CH$_2$(Ph$_2$SiH) in ca. 60:40 ratio (ca. 28%–48% overall yield). The inertness of tri-substituted silanes is presumably due to steric hindrance. Finally, acetophenone and 2-nonanone were hydrosilylated very efficiently to the corresponding PhH$_2$Si–ethers, giving nearly quantitative conversions by NMR.

Mechanistic considerations

The results described above show that the hydrosilylation reactions can be promoted by the in situ generated species (Ind)(PPh$_3$)Ni(Me) or [(Ind)(PPh$_3$)Ni]$^+$, the latter being more effective in most cases. This section considers the various ways in which these two species can initiate the catalysis. It should be emphasized at the outset that whereas [(Ind)(PPh$_3$)Ni]$^+$ can, in principle, react with either the olefin or the silane, the Ni-alkyl derivatives are known to be in-

ert towards the insertion of olefins and must, therefore, react first with PhSiH$_3$. For simplicity, we begin the mechanistic discussion with the latter systems.

The complexes (1-Me-Ind)(PR$_3$)Ni(Me) are known to convert PhSiH$_3$ (without a co-catalyst) to (PhSiH)$_n$ (R = Me, Ph; n = 3–16) (5*b*). Whereas the reactions involving the PPh$_3$ analogue were quite sluggish, those of the PMe$_3$ analogue proceeded at a conveniently rapid rate and were, therefore, subjected to detailed kinetic and D-labeling studies. On the basis of these studies, we have proposed that the oligomerization of PhSiH$_3$ is initiated by a concerted, σ-bond metathesis reaction as opposed to an oxidative addition – reductive elimination sequence. Analysis of the side products of this reaction pointed to the formation of methane and 1-(SiPhH$_2$)-3-Me-Ind, but not PhMeSiH$_2$, suggesting that the initial reaction leads to a Ni-silyl intermediate, as shown in Scheme 2. The putative Ni-SiPhH$_2$ intermediate would then react further with PhSiH$_3$ to initiate the oligomerization process, while its decomposition (by reductive elimination) could form 1-(SiPhH$_2$)-3-Me-Ind (Scheme 2) (5*b*).
Scheme 2.
Scheme 3.

To determine if the pathway depicted in Scheme 2 is also followed by the PPh$_3$ analogue, we did a similar analysis (by TOCSY ^{1}H NMR) of the products of the reaction of (1-Me-Ind)(PPh$_3$)Ni(Me) with PhSiH$_3$. This study revealed the presence of traces of PhMeSiH$_2$ and 3-Me-Ind, but not 1-(SiPhH$_2$)-3-Me-Ind. We infer from these observations that, unlike its PMe$_3$ analogue, the precursor (1-Me-Ind)(PPh$_3$)Ni(Me) reacts with PhSiH$_3$ to eliminate PhSiMeH$_2$ (instead of methane) and form the hydride derivative (eq. [1]; [Ni] = (1-Me-Ind)Ni(PPh$_3$)). The latter could then react with styrene to initiate the hydrosilylation catalysis, while its decomposition (by reductive elimination) would produce 3-Me-Ind (instead of 1-(SiPhH$_2$)-3-Me-Ind) (eq. [2]). The precise reasons for this difference in reactivity between the PMe$_3$ and PPh$_3$ derivatives are not known with certainty. Modeling studies suggest that the greater steric bulk of the PPh$_3$ derivative might favour the transfer to the Ni centre of the less-hindered side of PhH$_2$Si-H (i.e., the H, see Scheme 3), but electronic factors cannot be ruled out (the more electron-rich PMe$_3$ analogue might stabilize the Ni—Si bond).

[1]   PhSiH$_3$ + [Ni]-Me → PhMeSiH$_2$ + [Ni]-H

[2]   3-Me-Ind + (PPh$_3$)$_n$Ni(0) ← [Ni]-H
→ hydrosilylation

To test the likelihood that a Ni-H derivative is involved in the hydrosilylation catalysis promoted by the present system, we tested the effectiveness of LiAlH$_4$ as co-catalyst (or initiator, (instead of MAO or NaBPh$_4$) in the hydrosilylation of styrene. Thus, stirring a toluene solution of styrene–PhSiH$_3$–**1**–LiAlH$_4$ (100:100:1:2.5) at room temperature for 16 h resulted in the usual product (PhCH(CH$_3$)(PhSiH$_2$)) in 41% yield. This result establishes that the hydrosilylation reaction can be catalyzed by a Ni-H intermediate generated either from **1**–H$^-$ or by the reaction of the Ni-Me precursor and PhSiH$_3$.

Let us now turn to discussing the mechanism of the hydrosilylation reactions initiated by the in situ generated cationic species [IndNi(PPh$_3$)]$^+$. Given the highly electrophilic nature of this species and the fact that various Lewis acids can catalyze hydrosilylation of olefins (13), we considered the likelihood of our Ni cations acting as Lewis acids to promote the observed hydrosilylation reactions. A recent example of such Lewis-acid-catalyzed hydrosilylation has been reported by Gevorgyan and co-workers (14) who have shown that 5–10 mol% of B(C$_6$F$_5$)$_3$ can catalyze the hydrosilylation of a range of olefins with various aryl- or alkyl-silanes. These authors have drawn on the findings of Lambert et al. (15) and Piers and co-workers (16) to argue, quite convincingly, that these B(C$_6$F$_5$)$_3$-catalyzed reactions are initiated by the formation of [R$_3$Si]$^+$[HB(C$_6$F$_5$)$_3$]$^-$. The silylium cation R$_3$Si$^+$ is believed to add to the C=C to generate a carbocationic intermediate, which abstracts a hydride from the anion [HB(C$_6$F$_5$)$_3$]$^-$ to release the final product. The regiochemistry of the hydrosilylation products obtained by Gevorgyan and co-workers is consistent with a carbocationic mechanism; for instance, styrene is converted to the PhCH$_2$CH$_2$SiR$_3$, presumably via the intermediate [PhC$^+$HCH$_2$SiR$_3$].

By analogy to Gevorgyan's proposed abstraction of H$^-$ by B(C$_6$F$_5$)$_3$, we considered a scenario involving the abstraction of H$^-$ from PhSiH$_3$ by [IndNi(PPh$_3$)]$^+$ to give IndNi(PPh$_3$)H and a silylium species; the main question is whether the aptitude of the species [IndNi(PPh$_3$)]$^+$ for abstracting H$^-$ from PhSiH$_3$ can be assumed to be comparable to that of B(C$_6$F$_5$)$_3$. This question was investigated by the following NMR experiments that allowed some measure of the relative Lewis acidities of these electrophiles. First, monitoring mixtures of IndNi(PPh$_3$)Cl and B(C$_6$F$_5$)$_3$ (1:5) showed that the ionization of the Ni—Cl bond is very slow (<ca. 20%–30% ionization in 30–60 min). Next, adding B(C$_6$F$_5$)$_3$ to solutions of IndNi(PPh$_3$)Me (1:2) did not lead to ionization, forming instead what we believe is a species featuring a Ni•••Me•••B moiety.[5] Hence, it appears that [IndNi(PPh$_3$)]$^+$ and B(C$_6$F$_5$)$_3$ have similar Lewis acidities and should have similar aptitudes for abstracting H$^-$ from PhSiH$_3$. Unfortunately, it has not been possible to find direct evidence for the formation of

---

[5] NMR evidence supporting this assertion includes the observation of a broad signal in the upfield region of the ^{1}H NMR spectrum, slightly downfield of the original Ni-Me signal at ca. –0.7 ppm, and the absence of the characteristic AB signals for the formation of the species [IndNi(PPh$_3$)$_2$]$^+$. Significantly, none of the B- or Al-based Lewis acids tested in our study abstract the Ni-bound phosphine ligands, implying that the Ni centre is a strong Lewis acid.

Ni-H intermediates in the mixtures of $PhSiH_3$ and in situ generated $[IndNi(PPh_3)]^+$, because the putative Ni-H species reacts with $PhSiH_3$ at a faster rate than it is produced. However, we have obtained indirect evidence for the generation of such a Ni-H species, as described below.

Given that a number of late transition metal hydride bonds react with C—Cl bonds, especially those of chloroform, we reasoned that if the Ni-H species could be generated in a chlorinated solvent, chlorination might give the Ni-Cl derivatives, which could be easily detected. Thus, we monitored the NMR spectra of two $CDCl_3$ samples, one containing the independently prepared cationic complex [(1-Me-Ind)$Ni(PPh_3)_2$][BPh_4] alone, the other containing the same complex in addition to ca. 10 equiv. of $PhSiH_3$. The NMR spectra showed that the cationic complex is stable in $CDCl_3$ for at least 24 h in the absence of the silane (no new peaks in the $^{31}P\{^1H\}$ NMR spectrum), whereas the sample containing $PhSiH_3$ displayed many new $^{31}P\{^1H\}$ NMR signals, including that of the complex (1-Me-Ind)$Ni(PPh_3)Cl$ (31.1 ppm). We believe that the latter compound likely arises from the reaction of the Ni-H intermediate with $CDCl_3$. The $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture also showed signals at 16–20 ppm, which is close to the spectral region associated with the signals for phosphonium salts such as $Ph_3MeP^+I^-$ (ca. 22 ppm); these signals might be due to phosphonium species such as $[Ph_3P(SiR_3)][BPh_4]$. Finally, the ^1H NMR spectrum of this sample showed traces of 3-Me-Ind, which could originate from the reductive elimination of a Ni-H intermediate.

The above observations provide indirect support for the proposal that the in situ generated Ni cations react first with $PhSiH_3$ (as opposed to styrene)[6] to form Ni-H and silylium species. The next question that arises is which one of these intermediates would react with the olefin to initiate the hydrosilylation reaction. On this question, the regioselectivity of the Ni-catalyzed reactions can help rule out the possibility that these reactions proceed by the same reaction pathway proposed for the $B(C_6F_5)_3$ system above, i.e., the addition of R_3Si^+ to the olefin. Thus, Ni-catalyzed hydrosilylation of styrene gives α-silylation, which is the opposite of that observed with the $B(C_6F_5)_3$ system discussed above; moreover, the hydrosilylation of 1-hexene gives a 50:50 mixture of α- and β-silylation instead of the exclusive α-silylation expected from a carbocationic path. On the other hand, the regioselectivities observed in our system are consistent with a Chalk–Harrod type mechanism involving M-H intermediates. These considerations favour the insertion of the olefinic substrate into the Ni—H bond over reaction with the silylium species. The latter is presumably stabilized by $[BPh_4]^-$ and (or) the solvent (17), but our results do not shed any light on the fate of this species.

Therefore, we envisage the following sequence of steps for the hydrosilylation reactions promoted by the present system: (a) the Ni-H analogue of **1** is generated by the reaction of $PhSiH_3$ with the in situ formed $[IndNi(PPh_3)]^+$ or the Ni-Me analogue;[7] (b) insertion of the olefin (or ketone) into the Ni—H bond of the intermediate generates a new Ni-alkyl (or Ni-alkoxy) derivative, which reacts subsequently with another molecule of silane to form the C—Si (or O—Si) bond and regenerate the Ni-H intermediate.[8] The regiochemistry of the hydrosilylation reaction is determined at the insertion step; in the case of styrene, this gives the alkyl intermediates $Ni-CH_2CH_2Ph$ and (or) $Ni-CH(Me)Ph$. Although the latter intermediate should, in principle, be more susceptible to β-H elimination, we propose that it is in fact more stable because of the possibility of reverting to an η^3-benzyl derivative, as shown in Scheme 4. It is worth noting that Brookhart and co-workers (18) have proposed such η^3-benzyl intermediates for the addition of $HSiR_3$ (R = Et, i-Pr) to styrene catalyzed by the cationic complexes [(1,10-phenanthroline)$Pd(Me)L][BAr_4$].[9] The likelihood of such intermediates being involved in our system is supported by the following observations: (a) Monitoring a catalytic run by $^{31}P\{^1H\}$ NMR spectroscopy showed that the initial signal of the precatalyst **1** (ca. 31 ppm) is replaced by the signal for free PPh_3 (ca. –4 ppm) and a number of new signals at ca. 43–45 ppm. The latter region is associated with the $^{31}P\{^1H\}$ signals for complexes (1-Me-Ind)$Ni(PPh_3)R$, wherein R is a secondary alkyl such as i-Pr or cyclohexyl (45 ppm), and sec-Bu or neopentyl (42–43 pm) (5b). The presence of free PPh_3 is also consistent with the earlier observation that the PMe_3 precursors are less effective for promoting the hydrosilylation reaction; (b) Recall that using higher reaction temperatures or Ph_2SiH_2 resulted in somewhat higher proportions of the minor regioisomer, $PhCH_2CH_2SiPhRH$ (R = H, Ph). Higher temperatures should accelerate the β-H elimination from $Ni-CH(Me)Ph$, thus favouring the $Ni-CH_2CH_2Ph$ intermediate; on the other hand, the more bulky Ph_2SiH_2 might be expected to react more readily with the less bulky $Ni-CH_2CH_2Ph$ intermediate.

Conclusions

The present study has shown that combining the complexes $IndNi(PPh_3)Cl$ with suitable cationic initiators gives rise to an efficient catalytic system for the hydrosilylation of olefins and ketones. This system is particularly attractive for styrene because it gives, almost exclusively, one regioisomer; this regioselectivity is comparable to that reported for organolanthanide-catalyzed hydrosilylation reaction (9). On the other hand, Pd(II){bis(imine)} complexes give the opposite regioselectivity (18), while similar Ni precursors bearing Cp ligands give complicated mixtures of products (6, 7). Future studies will be aimed at expanding the scope of these hydrosilylation reactions.

---

[6] The direct reaction of Ni-based cations with styrene would be expected to result in the oligo- or polymerization of styrene.

[7] One of the reviewers of our manuscript proposed the following alternative mechanism: the redistribution reaction involving the intermediate $[IndNi(PR_3)]^+$ might take place to produce $[IndNi(PR_3)_2]^+$ and phosphine-free species such as "IndNiCl" or $[IndNi]^+$; the latter might react with the hydrosilane to generate a Ni-H species. This alternative scenario is consistent with our observations and merits consideration.

[8] The latter step likely proceeds by a concerted, σ-bond metathesis pathway as opposed to an oxidative addition – reductive elimination route involving Ni(IV) intermediates.

[9] This Pd-based system leads to various mixtures of products arising from hydrosilylation and dehydrogenative silylation. The proposed mechanism involves the insertion of styrene into the Pd—SiR_3 bond as opposed to the Pd—H bond.

Scheme 4.
A number of observations, including the fact that LiAlH$_4$ can be used instead of NaBPh$_4$ and MAO to activate the Ni-Cl precursor, have pointed to the involvement of the corresponding Ni-H derivative (X = H) as the active intermediate in these reactions. In the case of the reactions involving cationic initiators, we have proposed that this Ni-H intermediate is generated via the transfer of H$^-$ from the silane to the coordinatively unsaturated and highly electrophilic species [IndNi(PPh$_3$)]$^+$. This Si $\rightarrow$ Ni$^+$ hydride transfer process is very interesting because it provides a convenient route to the reactive Ni-H intermediate.[10] Studies are currently underway with the objective of elucidating the main parameters controlling this reactivity and investigating the feasibility of catalytic hydroboration reactions with the same system (i.e., transfer of hydride from R$_2$BH).

Experimental

General

Unless otherwise specified, all manipulations were performed under an inert atmosphere of N$_2$ or argon using standard Schlenk techniques and a dry box. Dry, oxygen-free solvents were employed throughout. The complexes (1-Me-Ind)Ni(PPh$_3$)Cl (**1**) (12), (1-Me-Ind)Ni(PMe$_3$)Cl (19), (1-*i*-Pr-Ind)Ni(PPh$_3$)Cl (20), (1-Me-Ind)Ni(PPh$_3$)Me (12), and [(1-Me-Ind)Ni(PPh$_3$)$_2$][BPh$_4$] (12) were prepared according to previously published procedures. PhSiH$_3$ was either purchased from Aldrich and used as received, or prepared from PhSiCl$_3$ according to a previously published procedure (21). Styrene was purchased from Aldrich and treated by (*a*) passing it through a plug of alumina, and (*b*) storing over 4 Å molecular sieves prior to use. All other reagents, including MAO, AlMe$_3$, LiAlH$_4$, and NaBPh$_4$, were purchased from

Aldrich and used as received. The NMR spectra were recorded using the following spectrometers: Bruker DMX600 (2D ^{1}H-^{29}Si), Bruker AMX400 (^{1}H at 400 MHz, ^{13}C{^{1}H} at 100.56 MHz, and ^{31}P{^{1}H} at 161.92 MHz), and Bruker AV300 (^{1}H at 300 MHz for TOCSY). GC–MS analyses were carried out on a Hewlett Packard 6890 series gas chromatograph equipped with a split mode capillary injector and a HP 5973 mass selective detector. The following operating parameters were used: the injector and detector temperatures were 250 °C; the carrier gas was hydrogen (2 mL/min); the column used was HP-5MS, 5% phenyl methyl siloxane; temperature program: 40 °C for 2 min, 10 °C/min up to 140 °C, 20 °C/min up to 280 °C.

Details of catalytic runs

Unless otherwise specified, all reactions were carried out under a nitrogen atmosphere. The catalytic runs were conducted as NMR-scale experiments or on a larger scale in Schlenk vessels. For the NMR-scale reactions, the following general procedure was followed. The Ni-Cl precursor complex (ca. 8 mg, 0.016 mmol) and the internal standard (hexamethyl benzene, ca. 15 mg, 0.09 mmol) were dissolved in C$_6$D$_6$ (0.8 mL); styrene and PhSiH$_3$ (100–200 µL, 50–100 equiv. of each) were then added to the resultant red solution. Prior to initiating the catalysis, a ^{1}H NMR spectrum was recorded to register the integral ratios for the signals of the internal standard and the reactants (Si-*H* of PhSiH$_3$ and vinylic protons of styrene). The NMR sample was then taken inside the dry box to add the initiator. For the room temperature experiments, the sample was kept in an ultrasonic bath throughout the reaction time to ensure agitation and homogeneity; for the high-temperature experiments, the sample was kept in a 65 °C water bath. If required, the progress of the catalysis was monitored periodically by ^{1}H NMR spectroscopy. The final yields were determined by comparing the intensities of the C*H*$_3$ signals of the product and the internal standard. The final values were checked against a calibration curve prepared by plotting the integral ratios obtained for various mixtures of the internal standard (C$_6$Me$_6$) and the main product (PhCH(PhSiH$_2$)CH$_3$) (slope = 1.069, R^2 = 0.9997).

The larger-scale catalytic runs were conducted as follows. Inside the dry box, the Ni precursor (ca. 10 mg) and the initiator were weighed into a Schlenk vessel containing a stirring bar; the capped vessel was then taken out of the dry box. The reactants and the solvent (benzene, unless otherwise specified) were then added under nitrogen in rapid succession (<1 min), and the mixture was stirred at room temperature or 65 °C. The work-up consisted of removing the volatiles on a rotoevaporator, extracting the residues with water–Et$_2$O, and evaporating the combined organic layers. The resulting yellow oil was distilled under vacuum to give the product(s) as a clear oil. When little product was obtained, the yield was determined based on the ^{1}H NMR spectrum of a carefully prepared mixture of the product and hexamethyl benzene as internal standard, according to the protocol described above.

---

[10]The same Ni-H intermediate might also be accessible from the reaction of PhSiH$_3$ with Ind(PPh$_3$)Ni(Me), but this reaction is generally sluggish.

Control experiments

To ascertain that the initiators used in our studies (MAO, NaBPh$_4$, LiAlH$_4$, and AlMe$_3$) do not promote the hydrosilylation reactions in the absence of Ni complexes, we prepared mixtures of styrene, PhSiH$_3$, and the initiator (in a molar ratio of 1:1:0.2) and analyzed them by ^{1}H NMR spectroscopy. No hydrosilylation product was detected in any of the experiments, and the ratio of styrene and PhSiH$_3$ remained unchanged. When AgOTf was tested with the substrates, gas evolution was observed and analysis of the sample showed that a small degree of silane redistribution had taken place (e.g., PhH$_2$Si–SiPhH$_2$ was detected by ^{1}H NMR).

Cadmium complexes of the tripodal [Te(N-*t*-Bu)$_3$]$^{2-}$ dianion and the HgCl$_2$ adduct of a tellurium diimide dimer[1]

Tristram Chivers and Gabriele Schatte

Abstract: The reactions of CdCl$_2$ or HgCl$_2$ with {Li$_2$[Te(N-*t*-Bu)$_3$]}$_2$ in *n*-hexane–THF give rise to two distinctly different types of product. In the former case the complexes [Li(THF)$_x$][(CdCl)$_3$\{Te(N-*t*-Bu)$_3$\}$_2$] (**7a** (*x* = 4), **7b** (*x* = 3)) are obtained. The tetrasolvated complex **7a** is a solvent-separated ion pair. The trisolvated complex **7b** is a contact ion pair in which the fourth coordination site at the Li$^+$ centre is occupied by one of the Cl ligands of the anion. The polycyclic anion in **7a** and **7b** is comprised of two tripodal [Te(N-*t*-Bu)$_3$]$^{2-}$ dianions that exhibit different coordination modes to the three CdCl$^+$ units. One ligand is *N*,*N*′-chelated to all three metal centres, and each nitrogen atom bridges two Cd atoms, whereas the other is bonded in a tris-*N*-monodentate fashion in **7b**. In **7a** there is an additional weak Cd–N interaction. The reaction of HgCl$_2$ with {Li$_2$[Te(N-*t*-Bu)$_3$]}$_2$ produces the adduct [*t*-BuNTe(μ-N-*t*-Bu)$_2$TeN-*t*-Bu]HgCl$_2$ (**8**), in which the dimeric tellurium diimide ligand in its *cis*(*exo*,*exo*) configuration is *N*,*N*′-chelated to mercury. Polymeric strands parallel to the *b* axis are formed by weak Te•••Cl interactions (3.5248(16) Å, 3.5876(15) Å) involving both Cl atoms, but only one Te atom of the ligand.

Key words: imido ligands, cadmium, mercury, tellurium.

Résumé : Les réactions du CdCl$_2$ ou du HgCl$_2$ avec le {Li$_2$[Te(N-*t*-Bu)$_3$]}$_2$, dans un mélange de *n*-hexane–THF, conduit à la formation de deux types forts différents de produits. Dans le premier cas, on obtient des complexes du type [Li(THF)$_x$][(CdCl)$_3$\{[Te(N-*t*-Bu)$_3$]\}$_2$] (**7a** (*x* = 4), **7b** (*x* = 3)). Le complexe tétrasolvaté du composé **7a** est une paire d'ions séparée par un solvant. Le complexe trisolvaté du composé **7b** est une paire d'ions de contacts dans lequel le quatrième site de coordination au centre Li$^+$ est occupé par un des ligands Cl de l'anion. L'anion polycyclique dans les composés **7a** et **7b** se trouve entre les deux anions tripodes [Te(N-*t*-Bu)$_3$]$^{2-}$ qui présentent des modes différents aux trois unités CdCl$^+$. Un ligand est *N*,*N*-chélaté aux trois centres métalliques et chaque atome d'azote sert de pont entre deux atomes de Cd alors que dans **7b** l'autre est lié d'une façon tris-*N*-monodentate. Dans le composé **7a**, on observe aussi une interaction additionnelle faible Cd–N. La réaction du HgCl$_2$ avec le {Li$_2$[Te(N-*t*-Bu)$_3$]}$_2$ conduit à la formation de l'adduit [*t*-BuNTe(μ-N-*t*-Bu)$_2$TeN-*t*-Bu]HgCl$_2$ (**8**) dans lequel le ligand diimide tellure dimère dans une configuration *cis*(*exo*,*exo*) est *N*,*N*′-chélaté au mercure. Les chaînes polymériques parallèles à l'axe *b* se forment par des interactions Te•••Cl faibles (3,5248(16) Å; 3,5876(15) Å) impliquant les deux atomes de chlore, mais un seul atome de Te de chaque ligand.

Mots clés : ligands imido, cadmium, mercure, tellure.

[Traduit par la Rédaction]

Introduction

The tripodal ligand [Te(N-*t*-Bu)$_3$]$^{2-}$ was first obtained as the dilithium derivative **1**, which has a dimeric, hexagonal prismatic structure (1). Investigations of metathetical reactions of this reagent with main group element halides have revealed both bidentate and tridentate bonding modes as exemplified by complexes with trivalent group 13 and group 15 elements, e.g., (**2**) (1), (**3**) (2), and (**4**) (3).

In some cases metathesis is accompanied by redox processes involving imide transfer. For example, the treatment of **1** with PhPCl$_2$ produces a spirocyclic phosphorus(V) complex (**5**) and elemental tellurium (1), while the stannatellurone (**6**) is obtained from the reaction of **1** with tin(II) salts (4). Fleischer and Stalke (5) have reported similar redox behaviour and imide transfer in the formation of Ge$_4$S(N-*t*-Bu)$_4$ from the reaction of the sulfur congener {Li$_2$[S(N-*t*-Bu)$_3$]}$_2$ with GeCl$_2$.

copy. The reagents $CdCl_2$ and $HgCl_2$ (Strem, 99%) were commercial samples used as received. All solvents were dried with appropriate drying agents and distilled onto molecular sieves before use. All reactions and the manipulation of moisture-sensitive products were carried out under an argon atmosphere using standard Schlenk techniques or a drybox.

Instrumentation

^{1}H, ^{7}Li, ^{13}C, ^{113}Cd, and ^{125}Te NMR spectra were recorded on a Bruker DRX400 NMR spectrometer at 25 °C in C_4D_8O using a 5 mm broadband probe (BBO) operating at 399.873, 155.405, 100.559, 88.714, and 126.349 MHz, respectively. Relaxation delays of 3 and 1.5 s were applied when measuring the ^{13}C and ^{125}Te NMR spectra, respectively. Line-broadening parameters used in the exponential multiplication of the free induction decays were 10 to 1 Hz. ^{1}H and ^{13}C NMR chemical shifts are reported relative to Me_4Si in $CDCl_3$. The samples for ^{7}Li NMR were externally referenced to 1.0 mol L^{-1} LiCl in D_2O (0 ppm). The samples for ^{125}Te and ^{113}Cd NMR were externally referenced to a saturated solution of K_2TeO_3 in D_2O (1723 ppm) and referred to Me_2Te (0 ppm), and to a saturated solution of $CdCl_2$ in D_2O (0 ppm), respectively. Elemental analyses were performed by Analytical Services, Chemistry Department, University of Calgary.

Preparation of $[Li(THF)_4][(CdCl)_3\{Te(N-t-Bu)_3\}_2]$ (7a)

The reagents **1** (0.500 g, 0.704 mmol) and $CdCl_2$ (0.387 g, 2.112 mmol) were added to a Schlenk vessel. n-Hexane (20 mL) and THF (10 mL) were then transferred to the vessel, and the yellow slurry was stirred for 3.5 days at 23 °C. The yellow solution was separated from the precipitate of LiCl by using a cannula. The solvents were removed under vacuum to give **7a** (0.829 g, 0.583 mmol, 83%). The product was recrystallized from n-hexane–THF. ^{1}H NMR (THF-d_8, 23 °C) δ: 3.62 (m, THF), 1.78 (m, THF), 1.50 (s, CMe_3). ^{13}C NMR (THF-d_8, 23 °C) δ: 68.27 (THF), 60.15 (CMe_3), 37.93 (CMe_3), 26.43 (THF). ^{125}Te NMR (THF-d_8, 23 °C) δ: 1564 (s). ^{7}Li NMR (THF-d_8, 23 °C) δ: –0.52 (s). ^{113}Cd NMR (THF-d_8, 23 °C) δ: 272.4 (s). Anal. calcd. for $C_{40}H_{86}Cd_3Cl_3LiN_6O_4Te_2$: C 33.80, H 6.10, N 5.90; found: C 31.57, H 6.02, N 4.89.[3]

To probe the ligand behaviour of $[Te(N-t-Bu)_3]^{2-}$ towards other divalent metals, we have now investigated the reactions of **1** with $CdCl_2$ and $HgCl_2$. An additional motivation for this study is the interest in complexes of group 12 metals with tellurium-containing ligands as potential single-source precursors of the corresponding binary tellurides, i.e., CdTe and HgTe, which are important semiconductors with applications in IR, solar cell, and optoelectronic devices (6).

We report here that these reactions give rise to distinctly different types of products. The reaction of **1** with $CdCl_2$ in THF produces the complexes $[Li(THF)_x][(CdCl)_3\{Te(N-t-Bu)_3\}_2]$ (**7a** (x = 4), **7b** (x = 3)). By contrast the reaction of **1** with $HgCl_2$ gives rise to an adduct of the tellurium(IV) diimide dimer t-BuNTe(μ-N-t-Bu)$_2$TeN-t-Bu with $HgCl_2$ (**8**).

Experimental

Reagents and general procedures

The reagents t-BuNTe(μ-N-t-Bu)$_2$TeN-t-Bu (**7**) and $\{[Li_2Te(N-t-Bu)_3]\}_2$ (**1**) were prepared by literature procedures and their purity was ascertained by ^{1}H NMR spectros-

---

[3]Loss of THF solvent resulted in inconsistent elemental analyses. This is a common problem with highly solvated s-block element complexes.

Preparation of [Li(THF)₃(μ-Cl)Cd(CdCl)₂{Te(N-*t*-Bu)₃}₂] (7b)

The reagents **1** (0.500 g, 0.704 mmol) and CdCl₂ (0.258 g, 1.408 mmol) were added to a Schlenk vessel. *n*-Hexane (20 mL) was transferred to the mixture at 23 °C to give a pale yellow slurry. Subsequent addition of THF (10 mL) produced a yellow solution. The reaction mixture was stirred for 24 h and then the precipitate was removed by filtration through a PTFE disk (pore size 0.45 μm). The solvents were removed under vacuum and the residue was extracted with *n*-hexane–THF to give an insoluble white solid (0.399 g). Removal of solvents from the filtrate yielded 0.325 g of a bright yellow solid that was shown by ¹H NMR to be a mixture of **7b** and unreacted **1** in the approximate ratio 2:1. X-ray quality crystals of **7b** were obtained by layering *n*-hexane onto a THF solution of this product (4 days at 23 °C).[3] ¹H NMR (THF-d_8, 23 °C) δ: 3.62 (m, THF), 1.77 (m, THF), 1.46 (s, C*Me*₃). ¹³C NMR (THF-d_8, 23 °C) δ: 68.29 (THF), 58.43 (*C*Me₃), 38.96 (C*Me*₃), 26.43 (THF). ⁷Li NMR (THF-d_8, 23 °C) δ: 0.04 (s). ¹²⁵Te NMR (THF-d_8) δ: 1546 (s).

Preparation of [*t*-BuNTe(μ-N-*t*-Bu)₂TeN-*t*-Bu]HgCl₂ (8)

n-Hexane (10 mL) and then THF (8 mL) were added to a solid mixture of **1** (0.500 g, 0.704 mmol) and HgCl₂ (0.574 g, 2.113 mmol) at 23 °C in a Schlenk vessel. After 18 h the solution was bright yellow and a yellow-orange precipitate had formed. The precipitate was separated by filtration through a PTFE disk (pore size 0.45 μm) and solvents were removed under vacuum to give an orange solid (0.964 g). A portion of this solid (0.495 g) was extracted with MeCN (50 mL and then 10 mL) and the volume of the solution was reduced to 20 mL to give an orange precipitate of **8** (0.157 g). After storage at –17°C for 14 days the MeCN solution produced a mixture of prism-like and plate-like orange crystals (0.070 g), which were identified by X-ray crystallography as **8**•2MeCN and **8**•MeCN, respectively. The combined masses of **8** and **8**•(MeCN)ₙ (*n* = 1, 2) correspond to an overall yield of ca. 72%. Data for **8**: ¹H NMR (CD₃CN, 23 °C) δ: 1.52 (s, NC*Me*₃). ¹H NMR (THF-d_8, 23 °C) δ: 1.37 (s, NC*Me*₃). ¹³C NMR (THF-d_8, 23 °C) δ: 58.38 (*C*Me₃), 38.23 (C*Me*₃). ¹²⁵Te NMR (THF-d_8, 23 °C) δ: 1558 (s). Anal. calcd. for C₁₆H₃₆Cl₂HgN₄Te₂: C 23.69, H 4.47, N 6.91; found: C 22.67, H 4.12, N 7.36.

X-ray analyses

Single crystals of **7a**, **7b**, and **8**•2MeCN were coated with Paratone oil, mounted on thin glass fibers, and frozen in the cold nitrogen stream of the goniometer. The X-ray data were collected on a Nonius Kappa CCD diffractometer (**7a**) and a Bruker AXS Platform/Smart 1000 CCD diffractometer (**7b** and **8**•2MeCN). Data reduction was performed using SAINT software (8). An empirical absorption correction was applied to the data (SADABS) (9). Relevant parameters for

the data collections and crystallographic data are summarized in Table 1.[4]

The structures were solved by direct methods (**7a**: SIR-97 (10*a*); **7b** and **8**•2MeCN:[5] SHELXS-97 (10*b*)) and refined by the full-matrix least-squares method based on F^2 using the SHELXL-97-2 (11). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions (C—H and N—H bond distances, 0.95 Å) and were not refined. The isotropic thermal parameters of the hydrogen atoms were fixed at 1.2 times that of the preceding carbon or nitrogen atom. Three of the four THF molecules in **7a** were disordered. The disorder was refined using the split-atom model. Details of the crystallographic data for **7a**, **7b**, and **8**•2MeCN are summarized in Table 1.

Results and discussion

Synthesis and X-ray structures of [Li(THF)ₓ][(Cd-Cl)₃{Te(N-*t*-Bu)₃}₂] (7a (*x* = 4), 7b (*x* = 3))

The outcome of the reaction of CdCl₂ with the dimeric reagent **1** in *n*-hexane–THF depends on the stoichiometry. Initial attempts to generate a complex with the empirical formula Cd[Te(N-*t*-Bu)₃] by using a 2:1 stoichiometry gave a mixture of **7b** and unreacted **1**. Complex **7b** was shown by X-ray crystallography to be the contact ion pair [Li(THF)₃(μ-Cl)Cd(CdCl)₂{Te(N-*t*-Bu)₃}₂] (vide infra). In an attempt to optimize the yield of a complex with this composition the reaction was conducted with a 3:1 stoichiometry. This resulted in the formation of the solvent-separated ion pair [Li(THF)₄][(CdCl)₃{Te(N-*t*-Bu)₃}₂] (**7a**) which was isolated in a much-improved yield (83%) (eq. [1]).

[1]   {Li₂[Te(N-*t*-Bu)₃]}₂ + 3CdCl₂ $\xrightarrow{\text{THF}}$

        [Li(THF)₄][(CdCl)₃{Te(N-*t*-Bu)₃}₂] + 3LiCl
The structures of **7a** and **7b** are shown in Figs. 1 and 2, respectively, and pertinent bond lengths and bond angles are compared in Table 2. In view of the similarity between the two structures, the ensuing discussion will focus on the atomic arrangements in the [(CdCl)₃{Te(N-*t*-Bu)₃}₂]⁻ anion of **7a**. In this monoanion two pyramidal [Te(N-*t*-Bu)₃]²⁻ dianions are coordinated, in different fashions, to three CdCl⁺ cations. One of these ligands is asymmetrically *N*,*N*′-chelated to all three cadmium atoms and each of these nitrogen atoms bridges two cadmium centres. The second [Te(N-*t*-Bu)₃]²⁻ anion is bonded in an *N*-monodentate manner to all three cadmium atoms. In **7a** there is an additional weak Cd-N interaction (Cd(2)-N(5) = 2.626(4) Å). The corresponding separation of 3.036(3) Å in **7b** is beyond the range for Cd—N covalent bonds. As a result, the nitrogen atoms in the former ligand are four-coordinate whereas those in the latter are three-coordinate. The structure of the anion in **7a** is related

Fig. 1. Thermal ellipsoid (30% probability) plot and atomic-numbering scheme for the anion in **7a**. Only the α-carbon atoms of *tert*-butyl groups are shown.

to the "deck-chair" structure[6] of the binuclear indium complex **4** (2). The two InCl^{2+} cations in **4** are replaced by CdCl$^+$ units and the third CdCl$^+$ unit occupies a vacant corner site. Charge balance is provided by the [Li(THF)$_4$]$^+$ cation.

As expected, the mean Te—N bond length is ca. 0.01 Å longer and the mean bond angle ∠ NTeN is ca. 5° smaller for the [Te(N-*t*-Bu)$_3$]$^{2-}$ ligand that is involved in trischelation. The structural parameters for the other pyramidal TeN$_3$ ligand are very similar to those in the dilithium derivative **1** in which the nitrogen atoms are also three-coordinate (1, 12). The three cadmium atoms are in a highly distorted four-coordinate environment with bond angles ranging from ca. 73° to ca. 136°. The mean Cd—N bond length involving the three-coordinate nitrogen atoms is ca. 2.20 Å. The Cd—N bond lengths involving the four-coordinate nitrogen atoms are distinctly unequal with mean values of ca. 2.29 and 2.48 Å (cf. *d*(Cd-N) = 2.279(13) Å in [CdCl(NPEt$_3$)]$_4$ (13) and 2.22–2.26 Å in tris(pyrazolyl)borato complexes of cadmium (14, 15)). The mean Cd—Cl bond distance of 2.458(1) Å is typical (the sum of covalent radii for Cd and

Fig. 2. Thermal ellipsoid (30% probability) plot and atomic-numbering scheme for **7b**. Only the α-carbon atoms of *tert*-butyl groups and the oxygen atoms of THF molecules are shown.
Cl is 2.47 Å). The coordination of a Cl ligand of the anion to Li⁺ in **7b** elongates the Cd(2)—Cl(2) bond by ca. 0.04 Å. The Li-Cl distance of 2.332(8) Å in **7b** falls within the normal range of Li—Cl bond lengths (16).

The ¹H NMR spectra of **7a** in C_4D_8O exhibit a singlet at 1.49 ppm for the *t*-Bu groups throughout the temperature range 183–298 K rather than the expected set of three resonances (assuming an approximate C_{2v} structure in solution). This observation indicates a highly fluxional structure for the anion in **7a** in solution. The ¹¹³Cd NMR chemical shift of 272.4 ppm observed for **7a** is within the range of 200–380 ppm reported for cadmium bonded to nitrogen ligands (17–19). The ¹²⁵Te NMR chemical shifts of 1564 and

Fig. 3. Thermal ellipsoid (30% probability) plot and atomic-numbering scheme for **8**•2MeCN (the two molecules of MeCN are not shown).
1546 ppm for **7a** and **7b**, respectively, are typical values for complexes of the trisimidotellurite ligand (2, 3).

Synthesis and X-ray structure of the adduct [*t*-BuNTe(μ-N-*t*-Bu)₂TeN-*t*-Bu]HgCl₂ (8)

In contrast to the reaction with CdCl₂, the reaction of **1** with HgCl₂ in *n*-hexane–THF in a 1:3 molar ratio results in cleavage of one of the N-*t*-Bu groups from tellurium to give **8**, a 1:1 adduct of HgCl₂ and the tellurium diimide dimer [*t*-BuNTe(μ-N-*t*-Bu)₂TeN-*t*-Bu] (**9**) (eq. [2]). It was found that the optimum yield of **8** was obtained when the solvents were added to a mixture of the *solid* reagents. Attempts to identify the other product of this imido transfer process were unsuccessful. Surprisingly **8** could not be obtained from the direct reaction of **9** with HgCl₂ under similar conditions.

[2] $\{Li_2[Te(N-t-Bu)_3]\}_2 + 3HgCl_2 \longrightarrow$

$\{[Te_2(N-t-Bu)_4]HgCl_2\} + 2\text{"}HgN-t-Bu\text{"} + 4LiCl$
The identity of **8**, after recrystallization from acetonitrile, was determined by X-ray crystallography. The recrystallization process gives two types of crystals which were identified as **8**•MeCN and **8**•2MeCN. Since the structural details for **8** are essentially identical in these two solvates, we will describe only the structure of **8**•2MeCN. As indicated in Fig. 3, the metal centre in the HgCl₂ adduct **8**•2MeCN is chelated by the ligand in its *cis*(*exo,exo*) configuration. This configuration is also found for the adduct **9**•LiCl (20) and in complexes with Ag⁺ (21). Coordination to Cu⁺, however, initiates a cis → trans isomerization of the ligand (21). The two molecules of MeCN do not interact with **8**. Selected bond distances and bond angles are summarized in Table 3. The geometry at the mercury center is distorted tetrahedral with ∠ NHgN = 119.84(16)° and ∠ ClHgCl = 103.06(5)° indicating strong coordination of the ligand to the mercury center. Consistently, the mean Hg-N distance of 2.260 Å is at the lower end of the range of values

[a]Symmetry transformations used to generate equivalent atoms: –x + 1/2, +y + 1/2, –z + 1/2.

reported for four-coordinate mercury complexes with an N₂Cl₂ coordination sphere (22–24). The most interesting feature of the structure of **8** is the existence of weak Te•••Cl contacts (3.5248(16) Å, 3.5876(15) Å, cf. 3.85 or 4.00 Å (25, 26) for the sum of the van der Waals radii for Te and Cl) that give rise to polymeric strands parallel to the *b* axis (Fig. 4). This polymeric motif may account for the poor solubility of **8** in common organic solvents. The Te•••Cl interactions involve only one of the tellurium atoms [Te(1)] and give rise to a minor asymmetry in the Te—N and Hg—N bond lengths. The mean Hg-Cl distance of 2.537 Å in **8** is ca. 0.2 Å longer than typical values of 2.31–2.34 Å for organic complexes of HgCl₂ (23), presumably as a result of the Te•••Cl interactions. The mean Te—N bond distance in the Te₂N₂ ring is 2.019(6) Å and the mean terminal Te—N bond length is 1.910(5) Å (cf. 2.081(10) and 1.876(10) Å,

Fig. 4. Unit cell of **8**•2MeCN showing the intermolecular Te•••Cl contacts.

○ Te ● Hg ○ Cl ○ N ● C
respectively, in **1**) (27). Although the bond angles in the four-membered Te_2N_2 rings in **8** are similar to the corresponding values for **9** ($|\angle \ NTeN| = 74.9°$ vs. 75.6(4)°, $|\angle TeNTe| = 104.6°$ vs. 101.0(6)°), chelation brings about a contraction of the bond angle $\angle N_{endo}TeN_{exo}$ from 113.1(5)° in **9** to 95.0° (range 93.55(19)°–96.44(19)°) in **8**. As found for other metal complexes of **9** (20, 21), the Te_2N_2 is much less puckered in **8** compared to the free ligand. The torsion angle N(2)-Te(1)-N(1)-Te(2) is 7.31(19)° (cf. 19.8(5)° in **9**). The geometry at the bridging nitrogen atoms is essentially planar ($\Sigma \angle$ [N(1)] = 357.3° and Σ [N(2)] = 356.7°).

Conclusions

Different types of behaviour were observed in the reaction of $[Te(N\text{-}t\text{-}Bu)_3]^{2-}$ with group 12 dihalides. In the case of cadmium dichloride, one of the halide ions was displaced by the dianion to give a monoanionic, trimetallic complex. By contrast, the corresponding reaction with mercury dichloride resulted in imide transfer and the formation of the $HgCl_2$ of the tellurium diimide dimer so formed.

Chemistry of zwitterionic penta-coordinate silicon compounds of the (ammoniomethyl)bis[glyco-lato(2–)-O^1,O^2]silicate type in aqueous and nonaqueous solution[1]

Reinhold Tacke, Rüdiger Bertermann, Andreas Biller, Christian Burschka, and Martin Penka

Abstract: The zwitterionic spirocyclic $\lambda^5 Si$-silicates bis[glycolato(2–)-O^1,O^2][(trimethylammonio)methyl]silicate ([OCH$_2$C(O)O]$_2$SiCH$_2$NMe$_3$, **3**) and bis[2-methyllactato(2–)-O^1,O^2][(trimethylammonio)methyl]silicate ([OCMe$_2$C(O)O]$_2$SiCH$_2$NMe$_3$, **4**) were synthesized by treatment of the zwitterionic $\lambda^5 Si$-silicate F$_4$SiCH$_2$NMe$_3$ with 2 mol. equiv. of Me$_3$SiOCR$_2$C(O)OSiMe$_3$ (R = H, Me) (formation of 4 mol. equiv. of Me$_3$SiF). Compounds **3** (isolated as **3**•2/3MeCN after drying in vacuo) and **4** were studied by solution ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy and by solid-state VACP/MAS ^{13}C, ^{15}N, and ^{29}Si NMR experiments, and the solvates **3**•MeCN and **4**•2MeCN were structurally characterized by single-crystal X-ray diffraction. These experimental investigations were complemented by computational studies of the zwitterions **3** and **4** and the anionic model species bis[2-methyllactato(2–)-O^1,O^2]hydridosilicate(1–) ([OCMe$_2$C(O)O]$_2$SiH$^-$, **8**). Compounds **3**•2/3MeCN and **4** and their already known derivatives [OCH$_2$C(O)O]$_2$SiCH$_2$NMe$_2$H (**1**) and [OCMe$_2$C(O)O]$_2$SiCH$_2$NMe$_2$H (**2**) were studied for their dynamic behavior (Λ/Δ-enantiomerization) in solution by VT ^{1}H NMR spectroscopy. In addition, compounds **1**, **2**, **3**•2/3MeCN, and **4** were studied in CD$_3$OD and D$_2$O with ^{1}H, ^{13}C, and ^{29}Si NMR experiments.

Key words: penta-coordinate silicon, zwitterionic $\lambda^5 Si$-silicates, Λ/Δ-enantiomerism, NMR spectroscopy, computational chemistry.

Résumé : On a synthétisé les $\lambda^5 Si$-silicates spirocycliques et zwitterioniques bis[glycolato(2–)-O^1,O^2][(triméthylammo-nio)méthyl]silicate ([OCH$_2$C(O)O]$_2$SiCH$_2$NMe$_3$, **3**) et bis[2-méthyllactato(2–)-O^1,O^2][(triméthylammonio)méthyl]silicate ([OCMe$_2$C(O)O]$_2$SiCH$_2$NMe$_3$, **4**) en faisant réagir le $\lambda^5 Si$-silicate zwitterionique F$_4$SiCH$_2$NMe$_3$ avec deux équivalents de Me$_3$SiOCR$_2$C(O)OSiMe$_3$ (R = H, Me), avec formation de quatre équivalents molaires de Me$_3$SiF. On a étudié les composés **3** (isolé sous la forme solvatée **3**•2/3MeCN après séchage sous vide) et **4** à l'état de solution en faisant appel à la spectroscopie RMN du ^{1}H, du ^{13}C et du ^{29}Si et à l'état solide par des expériences de RMN « VACP/MAS » du ^{13}C, ^{15}N et ^{29}Si; de plus, on a déterminé les structures de composés **3** et **4** à l'état solvaté en faisant appel à la diffrac-tion des rayons X sur un cristal unique. Ces études expérimentales ont été complétées par des études théoriques des zwitterions **3** et **4** de l'espèce anionique modèle bis[2-méthyllactato(2–)-O^1,O^2]hydridosilicate(1–) ([OCMe$_2$C(O)O]$_2$SiH$^-$, **8**). On a aussi étudié les composés **3**•2/3MeCN et **4**, ainsi que les dérivés déjà connus [OCH$_2$C(O)O]$_2$SiCH$_2$NMe$_2$H (**1**) et [OCMe$_2$C(O)O]$_2$SiCH$_2$NMe$_2$H (**2**), pour leur comportement dynamique (énantiomérisation Λ/Δ) en solution par spec-troscopie RMN du ^{1}H à température variable. De plus, les spectres RMN du ^{1}H, du ^{13}C et du ^{29}Si des composés **1**, **2**, **3**•2/3MeCN et **4** ont aussi été étudiés en solution dans le CD$_3$OD et le D$_2$O.

Mots clés : silicium pentacoordiné, $\lambda^5 Si$-silicate zwitterionique, énantiomérisation Λ/Δ, spectroscopie RMN, chimie théorique.

[Traduit par la Rédaction]

Introduction

Some years ago, we reported on the synthesis and struc-tural characterization of the zwitterionic $\lambda^5 Si$-silicates **1** and **2** (1). Surprisingly, compound **2** could be crystallized from water to give the corresponding hydrate **2**•H$_2$O in almost quantitative yield (1). The structurally related zwitterionic $\lambda^5 Si$-silicate **5** (2) and the zwitterionic $\lambda^5 Si,\lambda^5 Si'$-disilicates

1–4

5

6

7

8
6 (3) and (+)–7 (4) were also crystallized from aqueous solutions to afford the respective hydrates 5•H$_2$O, 6•8H$_2$O, and (+)–7•3H$_2$O. In view of the well-known sensitivity of the Si—OC bond against hydrolysis, the existence of 2 and 5–7 in aqueous solution is quite remarkable. To get more information about the nature of such solutions, we conducted a multinuclear NMR study with compounds 1 and 2 and their hitherto unknown N-methyl derivatives 3•2/3MeCN and 4. These quarternary ammonium compounds were included in these investigations to overcome potential problems with the acidic NH group of 1 and 2, especially in context with changes of the pH value which controls the degree of protonation of the nitrogen atom in aqueous solution.

In earlier studies, we already investigated the dynamic behavior of 2 in solution (1). As shown by VT ^{1}H NMR experiments (complemented by computational studies), the Λ- and Δ-enantiomers of 2 undergo an intramolecular enantiomerization (Λ/Δ-interconversion) in organic solvents, with an energy barrier of $\Delta G^{\ddagger} = 76 \pm 1$ kJ mol^{-1} ([D$_6$]DMSO), $\Delta G^{\ddagger} = 75 \pm 1$ kJ mol^{-1} (CD$_3$CN), or $\Delta G^{\ddagger} = 82 \pm 2$ kJ mol^{-1} (CDCl$_3$). To get information about the influence of the two bidentate ligands (glycolato(2–) vs. 2-methyllactato(2–)) and the ammoniomethyl group ((dimethylammonio)methyl vs. (trimethylammonio)methyl) on the energy barrier of the enantiomerization process, VT ^{1}H NMR studies were performed with compounds 1, 2, 3•2/3MeCN, and 4.

We report here on the syntheses of 3 (isolated as 3•2/3MeCN) and 4, the crystal structure analyses of 3•MeCN and 4•2MeCN, and solution ^{1}H, ^{13}C, and ^{29}Si NMR studies of 1, 2, 3•2/3MeCN, and 4 in water and in organic solvents, including VT ^{1}H NMR experiments which

were complemented by computational studies of the zwitterions 3 and 4 and the anionic model species 8. These investigations were carried out as part of our systematic studies on zwitterionic λ^{5}Si-silicates (5, 6; for reviews dealing with compounds of higher-coordinate silicon, see ref. 7). In addition, the NMR studies of 1, 2, 3•2/3MeCN, and 4 in aqueous solution were also of some interest in context with our research activities in silicon biochemistry (8). Preliminary results of the studies presented here have already been reported elsewhere (9).

Results and discussion

Syntheses

Compounds 3 and 4 were prepared by reaction of the zwitterionic λ^{5}Si-tetrafluorosilicate 9 (10) with 2 mol. equiv. of Me$_3$SiOCH$_2$C(O)OSiMe$_3$ (10) (11) and Me$_3$SiOCMe$_2$C-(O)OSiMe$_3$ (11) (12), respectively (formation of 4 mol. equiv. of Me$_3$SiF). The syntheses were carried out in acetonitrile at 20 °C, and compounds 3 and 4 were obtained, after crystallization from acetonitrile, as the crystalline solvates 3•MeCN and 4•2MeCN. Upon drying in vacuo (3, loss of ca. 1/3 mol. equiv. of acetonitrile; 4, complete loss of acetonitrile), the products 3•2/3MeCN and 4 were isolated as colorless solids (yields: 3•2/3MeCN, 83%; 4, 73%). The identities of 3•2/3MeCN and 4 were established by elemental analyses (C, H, N) and solution and solid-state NMR studies. In addition, crystal structure analyses of the solvates 3•MeCN and 4•2MeCN were performed (Scheme 1).

Scheme 1.
Crystal structure analyses

The crystal data and the experimental parameters used for the crystal structure analyses of **3**•MeCN and **4**•2MeCN are given in Table 1; selected interatomic distances and angles are listed in Table 2. The structures of the zwitterions are depicted in Figs. 1 and 2.

The zwitterions **3** and **4** are chiral (C_1 symmetry), and the crystals of racemic **3**•MeCN (space group $P2_1/c$) and **4**•2MeCN (space group $P2_1/n$) contain pairs of the respective Λ- and Δ-enantiomers. As can be seen from Figs. 1 and 2 and Table 2, the Si-coordination polyhedra of **3**•MeCN and **4**•2MeCN are distorted trigonal bipyramids (transition trigonal bipyramid → square pyramid: **3**•MeCN, 18.3%; **4**•2MeCN, 15.5%; pivot atom C1) (13).[3] The axial positions are occupied by the carboxylato oxygen atoms O1 and O3, whereas the alcoholato oxygen atoms O2 and O4 and the carbon atom C1 are found in the equatorial sites. The Si—O distances amount to 1.6572(10)–1.821(3) Å, with the axial Si—O bonds (1.7829(9)–1.821(3) Å) being significantly longer than the equatorial ones (1.6572(10)–1.669(4) Å). The Si—C1 distances amount to 1.909(5) Å and 1.9150(12) Å. The Si-coordination polyhedra of **3**•MeCN and **4**•2MeCN are very similar to those reported for **1**, **2**•H₂O, and **2**•2MeCN (Si—O(ax), 1.7930(12)–1.822(2) Å; Si—O(eq), 1.656(2)–1.6751(13) Å; Si—C1, 1.8915(11)–1.896(2) Å) (1).

NMR studies

The zwitterionic $\lambda^5 Si$-silicates **3**•2/3MeCN and **4** were studied by ^{13}C, ^{15}N, and ^{29}Si VACP/MAS NMR experiments in the solid state and by ^{1}H, ^{13}C, and ^{29}Si NMR experiments in solution (solvent [D₆]DMSO). All these investigations were performed at 22 °C. The solid-state NMR data of **3** and **4** are compatible with the crystal structures of **3** in **3**•MeCN and **4** in **4**•2MeCN.[4] The isotropic ^{29}Si chemical shifts in the solid-state NMR spectra clearly characterize these ^{29}Si resonances as arising from penta-coordinate silicon atoms (**3**, δ = –91.9; **4**, δ = –101.3). As these ^{29}Si chemical shifts are very similar to those observed for **3**•2/3MeCN and **4** in solution (**3**•2/3MeCN, δ = –92.1; **4**, δ = –102.1), it is concluded that

penta-coordination is present in solution as well. The ^{29}Si NMR data obtained for **3**•2/3MeCN and **4** are quite similar to those reported for the related compounds **1** and **2** (1). The solution NMR data of **3**•2/3MeCN and **4** are compatible with the presence of one particular zwitterionic species (such as the trigonal-bipyramidal zwitterions observed in the crystals of **3**•MeCN and **4**•2MeCN), or with a rapid low-energy interconversion of different isomers (1). As the trigonal-bipyramidal Si-coordination polyhedron, with the two carboxylato oxygen atoms in the axial positions, is the energetically most favorable one, it is likely to assume that this particular structure is also dominant in solution.

The chiral nature of the $\lambda^5 Si$-silicate frameworks of **3** and **4** should be reflected by diastereotopism of the SiCH₂N protons (**3** and **4**, AB spin system), the CH₂ protons of the glycolato(2–) ligands (**3**, AB spin system), and the two CH₃ groups of the 2-methyllactato(2–) ligands (**4**, two resonance signals). Provided that the Λ- and Δ-enantiomers of **3** and **4** are configurationally stable on the NMR timescale, this diastereotopism should be detectable. In the case of the zwitterion **3**, diastereotopism of the SiCH₂N protons was only observed at temperatures below –23 °C (measured in [D₇]DMF, see below), and diastereotopism of the CH₂ protons of the glycolato(2–) ligands could not be detected even at –55 °C (in [D₇]DMF). For compound **4** (in [D₇]DMF), however, diastereotopism of both the SiCH₂N protons and the two CH₃ groups of the 2-methyllactato(2–) ligands was observed at 22 °C, indicating a higher configurational stability of its Λ- and Δ-enantiomers as compared to **3**.

To get more information about the configurational stability of **3** and **4** and their derivatives **1** and **2**, all these zwitterions were studied by VT ^{1}H NMR experiments at 300.1 MHz in the temperature ranges 22–100 °C (**1**), 22–120 °C (**2**), –55 to 22 °C (**3**), and 22–110 °C (**4**) using [D₆]DMSO (**1**, **2**) and [D₇]DMF (**3**, **4**) as the solvents. An AB spin system for the diastereotopic SiCH₂N protons of **1**, **2**, and **4** was observed at 22 °C, indicating that the Λ- and Δ-enantiomers of these compounds are configurationally stable on the NMR timescale at this temperature. Upon heating, coalescence could be observed at 80 °C (**1**), 112 °C (**2**), and 97 °C (**4**)

---

[3] The degree of distortion was calculated by using the dihedral angle method described in refs. 13a and 13b. All nine dihedral angles and the values for the reference geometry of the ideal square pyramid given in ref. 13a were considered for this calculation.

[4] Under MAS conditions (spinning rate, 5.0 kHz), the solvate **3**•2/3MeCN loses the acetonitrile completely. In the solid-state ^{13}C VACP/MAS NMR spectra of **3** and **4**, only one resonance signal was observed for the three NCH₃ groups. This could be explained by an unhindered rotation of the N(CH₃)₃ moiety around the N-CH₂ axis.

(Fig. 3). However, in the case of **3** a singlet for the SiCH$_2$N protons was detected at 22 °C, indicating a dynamic behavior of the enantiomers (Λ/Δ-enantiomerization) in solution. Upon cooling, coalescence was detected at –23 °C and on further cooling an AB spin system for the SiCH$_2$N protons was observed, indicating that Λ-**3** and Δ-**3** are configurationally stable on the NMR timescale under these conditions (Fig. 3). Furthermore, the ^{1}H NMR spectra of **2** and **4** each showed two resonance signals for the two diastereotopic CH$_3$ groups of the 2-methyllactato(2–) ligands at 22 °C. Upon heating, coalescence was observed at 85 °C (**2**, in [D$_6$]DMSO) and 60 °C (**4**, in [D$_7$]DMF). The temperature dependence of the ^{1}H NMR spectra of the zwitterions **1**–**4** is characterized by complete reversibility (Fig. 3). The calculated energy barriers for the Λ/Δ-interconversion amount to $\Delta G^{\ddagger} = 73.0 \pm 0.5$ kJ mol^{-1} (**1**), $\Delta G^{\ddagger} = 78.1 \pm 0.5$ kJ mol^{-1} (**2**; CH$_3$ groups), $\Delta G^{\ddagger} = 78.8 \pm 0.5$ kJ mol^{-1} (**2**; SiCH$_2$N protons), $\Delta G^{\ddagger} = 51.6 \pm 0.5$ kJ mol^{-1} (**3**), $\Delta G^{\ddagger} = 74.6 \pm 0.5$ kJ mol^{-1} (**4**; CH$_3$ groups), and $\Delta G^{\ddagger} = 76.1 \pm 1.0$ kJ mol^{-1} (**4**; SiCH$_2$N protons).

In addition, compounds **1**, **2**, **3**•2/3MeCN, and **4** were studied by ^{1}H, ^{13}C, and ^{29}Si NMR experiments in CD$_3$OD and D$_2$O at 22 °C. Except for small differences in the chemi-
Fig. 1. Structure of the zwitterion **3** (Δ-enantiomer) in the crystal of **3•MeCN** (probability level of displacement ellipsoids 50%).

Fig. 2. Structure of the zwitterion **4** (Δ-enantiomer) in the crystal of **4•2MeCN** (probability level of displacement ellipsoids 50%).
cal shifts due to the change of the solvent, the spectra of **2** and **4** recorded in CD_3OD (data not given) were analogous to those obtained in $[D_6]DMSO$, indicating that the zwitterionic $\lambda^5 Si$-silicates **2** and **4** are stable in the protic solvent CD_3OD. Compound **1** is almost insoluble in CD_3OD and **3•2/3MeCN** shows a very poor solubility, but exhibits hints for penta-coordinate silicon in the ^{29}Si NMR spectra (1D^{29}Si NMR, 2D^{29}Si,^{1}H HMBC: δ = –91.8). Thus, the zwitterion **3** seems to be stable in CD_3OD as well.

Saturated aqueous solutions of **1** (1.64 mmol in 1 mL of D_2O) and **3•2/3MeCN** (2.24 mmol in 1 mL of D_2O), however, show several resonance signals in the ^{29}Si NMR spectra (**1**, δ = –70.8, –69.3 (br), –61.5, –61.4, and –52.6; **3•2/3MeCN**, δ = –73.2, –73.1, –72.7, –63.6, –63.5, –63.4, and –54.5). The chemical shifts of these signals are not compatible with the existence of the zwitterions **1** and **3** in aqueous solution, but rather suggest the presence of tetra-coordinate silicon species. As no free glycolic acid could be observed, it is likely to assume that these species still contain both glycolato ligands (bidentate glycolato(2–) and (or) monodentate glycolato(1–) ligands); however, their structure could not be deduced unequivocally from the ^{1}H, ^{13}C, and ^{29}Si NMR spectra. In the ^{29}Si NMR spectra of saturated aqueous solutions of **2** (181 μmol in 1 mL of D_2O) (δ = –99.4, –61.4, and –52.4) and **4** (2.51 mmol in 1 mL of D_2O) (δ = –101.1, –63.6, –63.4, and –54.5) three and four resonance signals, respectively, were observed. Obviously, the zwitterions **2** and **4** and tetra-coordinate species as well exist in aqueous solution. Concentration-dependent NMR experi-

ments with solutions of **4** in D_2O indicate that the amount of the penta-coordinate zwitterionic species increases as the concentration gets higher. However, even saturated solutions of **1** and **3•2/3MeCN** in D_2O gave no hints for the presence of penta-coordinate silicon. Analogously to **1** and **3**, no free α-hydroxycarboxylic acid was observed upon dissolution of **2** and **4** in D_2O. As compounds **2** and **4** could be recovered almost quantitatively from their aqueous solution by slow evaporation of the water, a thermodynamic equilibrium among all species present in solution can be assumed. Attempts to recover **1** and **3** from their aqueous solution failed.

To get more information about the nature of the aqueous solutions, ^{1}H and 2D ^{29}Si,^{1}H HMBC NMR studies with **1** (491 μmol in 1 mL of D_2O), **2** (181 μmol in 1 mL of D_2O), **3•2/3MeCN** (491 μmol in 1 mL of D_2O), and **4** (491 μmol in 1 mL of D_2O) at various pH values were performed. Starting from the respective saturated solution (see above) (**1**, pH 3.6; **2**, pH 3.9; **3•2/3MeCN**, pH 3.6; **4**, pH 3.9; the pH values of the respective solutions in H_2O differ by about 0.1 unit), the pH value was increased stepwise by addition of solid potassium hydroxide (increase of ca. 1.0 pH unit per step). The spectra of **1** and **3•2/3MeCN** showed only signals arising from tetra-coordinate species over the whole range measured, and penta-coordination was not detected (**1** (pH = 3.6): δ = –70.7, –61.5, –52.4; **1** (pH = 13.0): δ = –67.8, –60.6, –51.8; **3•2/3MeCN** (pH = 3.6): δ = –72.8, –63.4, –54.2; **3•2/3MeCN** (pH = 13.1): δ = –76.9, –68.4, –60.1).[5] For compounds **2** and **4**, decreasing amounts of the respective $\lambda^5 Si$-silicate were observed, whereas tetra-coordination increased at the same time (**2** (pH = 3.9): δ = –99.5, –61.4, –52.3; **2** (pH = 13.2): δ = –67.9, –60.4, –51.4; **4** (pH = 3.9):

---

[5] The ^{29}Si chemical shifts measured for the saturated solutions of **1**, **2**, **3•2/3MeCN**, and **4** were determined by 1D NMR experiments providing a high spectral resolution. However, the ^{29}Si chemical shifts measured for the pH-dependent NMR experiments were extracted from 2D ^{29}Si,^{1}H HMBC NMR experiments delivering a lower spectral resolution in the indirect (^{29}Si) dimension. Due to this principal matter, we were not able to resolve as many different shifts of ^{29}Si as in the 1D NMR experiments.

Fig. 3. Temperature dependence of the ^{1}H NMR signals for the diastereotopic SiCH$_2$N protons of the zwitterions **3** and **4** (solutions in [D$_7$]DMF, 300.1 MHz). Zwitterion **3** (above): Spectra obtained upon cooling from 22 to –50 °C and subsequent heating to 22 °C. Zwitterion **4** (below): Spectra obtained upon heating from 22 to 110 °C and subsequent cooling to 22 °C.
$\delta = -101.1, -72.9, -63.5, -54.3;$ **4** (pH = 13.0): $\delta = -76.5,$ $-68.1, -60.0$). The λ^5Si-silicate **2** could no longer be detected between pH 7 and pH 13, whereas **4** disappeared at pH 6. After a solution with pH 13 was obtained, the respective starting pH was adjusted by addition of concentrated hydrochloric acid. In all cases, reversibility of the spectra of **2** and **4** upon acidification was observed.

In conclusion, penta-coordination only did not exist for

the bis[glycolato(2–)-O^1,O^2]hydridosilicate(1–) anion were already investigated by quantum chemical methods in an earlier study (1). In this paper, computational studies of the anionic model species bis[2-methyllactato(2–)-O^1,O^2]hydrido-silicate(1–) (**8**) and the zwitterions **3** and **4** were performed. The computational methods used in these studies are described in the *Experimental* section.

As shown in Fig. 4, seven different structures (**8a**–**8g**) were studied for the model species **8**. For energetic reasons, square pyramids with the hydrogen atom in a basal position were not considered. The trigonal-bipyramidal species **8a**–**8c**, **8f**, and **8g** and the square-pyramidal species **8d** are chiral and therefore exist as pairs of Λ- and Δ-enantiomers, whereas the square-pyramidal species **8e** is achiral. Calculations of the vibrational frequencies for **8a**–**8g** demonstrated that only the trigonal bipyramids **8a**–**8c** represent local minima (the isomer **8a** being the energetically most favorable one), whereas the species **8d**–**8g** are transition states (for selected geometric parameters for **8a**–**8g**, see Table 3). This result is in agreement with the experimentally established crystal structures of **3**•MeCN and **4**•2MeCN, indicating that the trigonal-bipyramidal geometry, with the carboxylato oxygen atoms in the axial sites, is the energetically most favorable one. Based on this particular structure, geometry optimizations at the SCF/TZP level were carried out for the zwitterionic λ^5Si-silicates **3** and **4** (Fig. 5). As can be seen from Table 2, the calculated interatomic distances and angles for the SiO$_4$C frameworks of **3** and **4** are very similar and are also in reasonable agreement with the experimentally established values for **3**•MeCN and **4**•2MeCN.[6]

These results suggest that the energetically preferred trigonal-bipyramidal Si-coordination polyhedra of **3** and **4**, with the carboxylato oxygen atoms in the axial sites, also play the major role in solution, all compounds being expected to exist as pairs of Λ- and Δ-enantiomers. The results

Fig. 5. Calculated structures (local minima, Δ-enantiomers) of **3** (above) and **4** (below) as obtained by SCF/TZP geometry optimizations.

obtained for the model species **8** further suggest that the antipodes of **3** and **4** can undergo an isomerization, leading to an inversion of absolute configuration of their chiral trigonal-bipyramidal λ^5Si-silicate skeletons (Λ/Δ-enantiomerization). According to the ab initio studies, the enantiomers Λ-**8a** and Δ-**8a** can be converted into each other via the transition state **8f** (Fig. 6), which is connected with other low-energy transition states and the intermediate **8b** in the whole enantiomerization pathway (in this context, see ref. 1). The conversions Λ-**8a** ⇌ **8d** ⇌ Δ-**8c** and Λ-**8b** ⇌ **8e** ⇌ Δ-**8b** can be described in terms of a Berry-type mechanism, with the hydrogen atom as the pivot ligand. In contrast, the conversions Δ-**8c** ⇌ **8f** ⇌ Λ-**8b** (Λ-**8c** ⇌ **8f′** ⇌ Δ-**8b**) and Λ-**8a** ⇌ **8g** ⇌ Δ-**8b** (Δ-**8a** ⇌ **8g′** ⇌ Λ-**8b**) (**8f**/**8f′** and

---

[6] A perfect agreement between the calculated and experimentally established structures of the zwitterions cannot be expected since the latter are influenced by intermolecular interactions in the crystal.

Fig. 6. Calculated intramolecular enantiomerization of **8a** via the transition state **8f** (Δ-**8a** ⇌ **8f** ⇌ Λ-**8a**).
8g/8g′ are antipodes) differ significantly from a Berry-type mechanism, the transition states being characterized by a distorted trigonal-bipyramidal Si-coordination polyhedron, with the hydrogen atom in an axial position. As the structures of these transition states are rather twisted (one of the two bidentate ligands occupies two equatorial positions), the term "twist mechanism" has been suggested for these particular intramolecular isomerization processes (1). The calculated relative energy of the transition state **8f** (71.6 kJ mol^{-1}) is in good agreement with the analogous transition state calculated for the related bis[glycolato(2–)-O^1,O^2]hydridosilicate(1–) anion (70.8 kJ mol^{-1} (1)), indicating that the nature of the two bidentate ligands (glycolato(2–) vs. 2-methyllactato(2–)) does not significantly affect the relative energy of the "twist" transition state. Except for the lower energy barrier for **3** (51.6 ± 0.5 kJ mol^{-1}), this result is also in good agreement with the experimentally established energy barriers for the enantiomerization processes of **1**–**4** (see *NMR studies*).

In conclusion, comparison of the calculated structures of **3** (glycolato(2–) ligands) and **4** (2-methyllactato(2–) ligands) does not reveal significant differences. The same holds true for the experimentally established structures of these two compounds. The structures and relative energies calculated for the anionic model species **8** and for the related bis[glycolato(2–)-O^1,O^2]hydridosilicate(1–) anion (1) are also very similar. In contrast to these distinct similarities, the zwitterions **3** and **4** (and their derivatives **1** and **2** as well) differ significantly in their chemical behavior in aqueous solution (see *NMR studies*). It is an open question as to how the bidentate ligands (glycolato(2–) vs. 2-methyllactato(2–)) control this chemical behavior.

Conclusions

The chemistry of the zwitterions **1**–**4** in nonaqueous solutions (solvent: [D$_6$]DMSO, CD$_3$OD) is characterized by dis-

tinct similarities. All zwitterions were found to be stable in both the aprotic solvent [D$_6$]DMSO and the protic solvent CD$_3$OD, and no tetra-coordinate silicon species could be detected in these solutions. Furthermore, similar energy barriers for the Λ/Δ-interconversion of the chiral zwitterions were observed; i.e., the nature of both the bidentate ligand (glycolato(2–) vs. 2-methyllactato(2–)) and the ammoniomethyl group ((dimethylammonio)methyl vs. (trimethylammonio)methyl) does not significantly control the behavior of **1**–**4** in nonaqueous solution. In contrast, in aqueous solution the zwitterions **1** and **3** (glycolato(2–) ligands) differ significantly from **2** and **4** (2-methyllactato(2–) ligands). In the case of **1** and **3** only tetra-coordinate silicon species could be detected, whereas the zwitterions **2** and **4** were found to exist in aqueous solution, along with tetra-coordinate silicon species. Obviously, the zwitterions **1**–**4** are not stable against ring-opening processes in aqueous solution, and in the case of **2** and **4** these processes are reversible and both compounds can be recovered almost quantitatively by slow evaporation of the water. Future mechanistic studies have to show how the different bidentate ligands control the hydrolytic stability of **1**–**4**.

Experimental

General

All syntheses were carried out under dry nitrogen. The solvents used were dried and purified according to standard procedures and stored under nitrogen. Melting points were determined with a Büchi Melting Point B-540 apparatus using samples in sealed capillaries. The ^{1}H, ^{13}C, and ^{29}Si solution NMR spectra were recorded at 22 °C on a Bruker DRX-300 NMR spectrometer (^{1}H, 300.1 MHz; ^{13}C, 75.5 MHz; ^{29}Si, 59.6 MHz). Chemical shifts (ppm) were determined relative to internal [D$_5$]DMSO (^{1}H, δ = 2.49), [D$_6$]DMSO (^{13}C, δ = 39.5), CHD$_2$OD (^{1}H, δ = 3.30), CD$_3$OD (^{13}C, δ = 49.0), HDO (^{1}H, δ = 4.70), or external TMS (^{29}Si, δ = 0).

Assignment of the NMR data was supported by ^{1}H,^{1}H COSY, ^{13}C DEPT 135, ^{13}C,^{1}H HMQC, ^{13}C,^{1}H HMBC, ^{15}N,^{1}H HMBC, and ^{29}Si,^{1}H HMBC experiments. Solid-state ^{13}C, ^{15}N, and ^{29}Si VACP/MAS NMR spectra were recorded at 22 °C on a Bruker DSX-400 NMR spectrometer with bottom layer rotors of ZrO$_2$ (diameter 7 mm) containing ca. 300 mg of sample (^{13}C, 100.6 MHz; ^{15}N, 40.6 MHz; ^{29}Si, 79.5 MHz; external standard, TMS (^{13}C, ^{29}Si; δ = 0) or glycine (^{15}N; δ = –342.0); spinning rate, 5.0–6.5 kHz; contact time, 1 ms (^{13}C), 3 ms (^{15}N), or 5 ms (^{29}Si); 90° ^{1}H transmitter pulse length, 3.6 μs; repetition time, 4 s).

[(Dimethylammonio)methyl]bis[glycolato(2–)-O^1,O^2]silicate (1)

This compound was synthesized according to ref. 1.

[(Dimethylammonio)methyl]bis[2-methyllactato(2–)-O^1,O^2]silicate (2)

This compound was synthesized according to ref. 1.

Bis[glycolato(2–)-O^1,O^2][(trimethylammonio)methyl]silicate–2/3acetonitrile (3•2/3MeCN)

Compound **10** (1.02 g, 4.63 mmol) was added dropwise at 20 °C within 2 min to a stirred solution of **9** (411 mg, 2.32 mmol) in acetonitrile (10 mL) (spontaneous evolution of Me$_3$SiF), and the reaction mixture was then stirred at 20 °C for 24 h (formation of a precipitate ca. 30 min after combining the reactants). The precipitate was filtered off and recrystallized from acetonitrile (cooling of a saturated solution from 20 to –26 °C). The product was isolated by filtration and then dried in vacuo (0.01 torr (1 torr = 133.322 Pa), 20 °C, 8 h) to give **3•2/3MeCN**[7] in 83% yield as a colorless solid (532 mg, 1.92 mmol); mp 185 °C (dec.). ^{1}H NMR ([D$_6$]DMSO) δ: 2.06 (s, 2 H, C*H$_3$*CN), 2.94 (s, 2 H, SiC*H$_2$*N), 3.06 (s, 9 H, NC*H$_3$*), 3.96 (s, 4 H, OC*H$_2$*). ^{13}C NMR ([D$_6$]DMSO) δ: 1.2 (*C*H$_3$CN), 55.3 (t, $^1J(^{13}$C,^{14}N) = 4.0 Hz, NC*H$_3$*), 59.5 (t, $^1J(^{13}$C,^{14}N) = 1.8 Hz, SiC*H$_2$*N), 62.6 (OC*H$_2$*), 118.1 (CH$_3$*C*N), 173.8 (*C*=O). ^{13}C VACP/MAS NMR (1535 transients) δ: 54.7 (3 C) (N*C*H$_3$), 58.4 (Si*C*H$_2$N), 62.6 (O*C*H$_2$), 64.0 (O*C*H$_2$C), 176.3 (*C*=O), 177.5 (*C*=O). ^{15}N VACP/MAS NMR (38 504 transients) δ: –328.6 (*N*CH$_3$). ^{29}Si NMR ([D$_6$]DMSO) δ: –92.1. ^{29}Si VACP/MAS NMR (97 transients) δ: –91.9. Anal. calcd. for C$_{9.33}$H$_{17}$N$_{1.67}$O$_6$Si: C 40.52, H 6.19, N 8.43; found: C 40.2, H 5.8, N 8.5.

Bis[2-methyllactato(2–)-O^1,O^2][(trimethylammonio)methyl]silicate (4)

The synthesis was carried out analogously to that of **3•2/3MeCN** by combining **11** (1.15 g, 4.63 mmol) with a solution of **9** (411 mg, 2.32 mmol) in acetonitrile (60 mL) (spontaneous evolution of Me$_3$SiF; formation of a precipitate ca. 30 min after combining the reactants). Compound **4** was isolated in 73% yield as a colorless solid (516 mg, 1.69 mmol); mp 255 °C (dec.). ^{1}H NMR ([D$_6$]DMSO) δ: 1.21 (s, 6 H, CC*H$_3$*), 1.26 (s, 6 H, CC*H$_3$*), 2.85 and 3.05 (AB

system, $^2J_{AB}$ = 15.5 Hz, 2 H, SiC*H$_2$*N; partial overlapping with the NC*H$_3$* signal), 3.08 (s, 9 H, NC*H$_3$*). ^{13}C NMR ([D$_6$]DMSO) δ: 26.4 (C*C*H$_3$), 27.7 (C*C*H$_3$), 55.0 (t, $^1J(^{13}$C,^{14}N) = 4.0 Hz, N*C*H$_3$), 59.9 (t, $^1J(^{13}$C,^{14}N) = 2.4 Hz, Si*C*H$_2$N), 73.6 (O*C*C$_3$), 178.2 (*C*=O). ^{13}C VACP/MAS NMR (92 transients) δ: 26.7 (C*C*H$_3$), 27.7 (C*C*H$_3$), 28.0 (C*C*H$_3$), 28.5 (C*C*H$_3$), 55.3 (3 C) (N*C*H$_3$), 60.6 (Si*C*H$_2$N), 74.6 (*C*CH$_3$), 75.4 (*C*CH$_3$), 179.5 (*C*=O), 180.6 (*C*=O). ^{15}N VACP/MAS NMR (13 102 transients) δ: –328.4 (*N*CH$_3$). ^{29}Si NMR ([D$_6$]DMSO) δ: –102.1. ^{29}Si VACP/MAS NMR (1107 transients) δ: –101.3. Anal. calcd. for C$_{12}$H$_{23}$NO$_6$Si: C 47.19, H 7.59, N 4.59; found: C 47.3, H 7.7, N 4.6.

Tetrafluoro[(trimethylammonio)methyl]silicate (9)

This compound was synthesized according to ref. 10.

(Trimethylsilyloxy)acetic acid trimethylsilyl ester (10)

This compound was synthesized according to ref. 11.

2-Methyl-2-(trimethylsilyloxy)propionic acid trimethylsilyl ester (11)

This compound was synthesized according to ref. 12.

Crystal structure analyses

Suitable single crystals of **3•MeCN** and **4•2MeCN** were obtained directly from the respective reaction mixture. The crystals were mounted in inert oil (perfluoroalkyl ether, ABCR) on a glass fiber and then transferred to the cold nitrogen gas stream of the diffractometer (Stoe IPDS diffractometer, graphite-monochromated Mo Kα radiation (λ = 0.71073 Å)). The structures were solved by direct methods (14). The non-hydrogen atoms were refined anisotropically (15). A riding model was employed in the refinement of the hydrogen atoms.[8]

VT ^{1}H NMR studies

The VT ^{1}H NMR studies of **1**, **2**, **3•2/3MeCN**, and **4** were carried out analogously to the standard ^{1}H NMR measurements using a Bruker DRX-300 NMR spectrometer. [D$_6$]DMSO and [D$_7$]DMF served as the solvents. Chemical shifts were determined relative to internal [D$_5$]DMSO (^{1}H, δ = 2.49) or [D$_6$]DMF (^{1}H, δ = 2.91). The thermocouple used with the probe was calibrated for low (high) temperatures according to ref. 16 using a 4% solution of CH$_3$OH in CD$_3$OD (80% solution of ethane-1,2-diol in [D$_6$]DMSO). Spectra were recorded in the temperature ranges 22–100 °C (**1**), 22–120 °C (**2**), –55 to 22 °C (**3•2/3MeCN**), and 22–110 °C (**4**). The time required for temperature equilibration was 15 min. From the ^{1}H NMR spectra obtained, the coalescence temperature T_C and the exchange rate k_C at the coalescence point were extracted, and the value for the activation free enthalpy $\Delta G^{\ddagger}$ for the exchange process was calculated by using the Eyring equation ($\Delta G^{\ddagger}$ = 19.14 T_C[10.32 + log(T_C/k_C)] (J mol^{-1})]) (17).

---

[7] The acetonitrile content (ca. 2/3 mol. equiv.) was determined by ^{1}H NMR spectroscopy. Further treatment of **3•2/3MeCN** in vacuo does not lead to a further loss of acetonitrile, whereas in the solid-state NMR experiments[4] total loss of the acetonitrile was observed.

[8] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 204727 (**3•MeCN**) and 204728 (**4•2MeCN**) contain the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Computational methods

Geometry optimizations at the SCF/TZP (18) level for the zwitterions **3** and **4** and at the SCF/TZP+ level for the anionic model species **8** were performed using the TURBOMOLE program system (19).[9] Stationary geometries and transition states were characterized as local minima (zero imaginary frequencies) and saddle points (one imaginary frequency), respectively, by calculation of the vibrational frequencies. The energies for **3**, **4**, and **8** include the single point MP2 energy and the zero point vibrational energy.

Preparation and electronic properties of rhenium(V) complexes with bis(diphenylphosphino)ethane[1]

François Baril-Robert and André L. Beauchamp

Abstract: Complexes of bis(diphenylphosphino)ethane (dppe) of the types ReOX$_3$(dppe) and ReO(OR)X$_2$(dppe) (with X= Cl or Br, and R = Me, Et, Pr, Ph, cyclohexyl (Cy), or -CH$_2$CH$_2$OH) were prepared to evaluate the influence of ligand changes on the low-energy d–d transitions in these Re(V) low-spin d^2 systems. Arylimido compounds Re(NR)Cl$_3$(dppe) (with R = Ph and p-ClC$_6$H$_4$) were also obtained. X-ray diffraction studies on ReO(OPr)Cl$_2$(dppe), ReO(OPh)Br$_2$(dppe), and ReO(OCy)Cl$_2$(dppe) confirmed the presence of the trans O=Re-OR unit and showed that the structural characteristics of the Re-O-R segment are not affected by the presence of a bulky cyclohexyl substituent or an aromatic phenyl group. The structure of the arylimido complex Re(p-ClC$_6$H$_4$N)Cl$_3$(dppe) was also determined. The electronic absorption spectra of the ReOX$_3$(dppe) compounds include two low-energy components at ~11 500 and ~16 000 cm^{-1}, assigned to the two spin-allowed d–d transitions expected for these low-symmetry systems. Substitution of the oxo ligand by an arylimido group has little effect on the lower-energy component, but moves the two components closer together. Replacing the halogen trans to the Re=O bond by an alkoxo group shifts the whole system to higher energies. These variations were found to correlate well with the energies of the frontier orbitals determined from DFT calculations. While attempting to prepare ReOCl$_3$(dppe) from ReOCl$_3$(PPh$_3$)$_2$, the Re(III) compound fac-ReCl$_3$(PPh$_3$){Ph$_2$PC$_2$H$_4$PPh$_2$(O)} was obtained, in which one end of dppe had become a phosphine oxide. Upon standing in DMSO, this compound gave the octahedral compound ReCl$_4${Ph$_2$PC$_2$H$_4$PPh$_2$(O)}, in which the formation of a chelate ring involving a phosphine and a phosphine oxide was ascertained by X-ray diffraction.

Key words: rhenium, crystal structure, DFT calculations, d–d electron transitions.

Résumé : Des complexes du bis(diphénylphosphino)éthane (dppe) de types ReOX$_3$(dppe) et ReO(OR)X$_2$(dppe) (où X = Cl ou Br, et R = Me, Et, Pr, cyclohexyl (Cy) ou -CH$_2$CH$_2$OH), ont été préparés afin d'évaluer l'influence de changements de ligands sur les transitions d–d de basse énergie dans ces systèmes d^2 de Re(V) à spin faible. Des composés arylimido Re(NR)Cl$_3$(dppe) (où R = Ph et p-ClC$_6$H$_4$) ont aussi été obtenus. Les études par diffraction des rayons X sur ReO(OPr)Cl$_2$(dppe), ReO(OPh)Br$_2$(dppe) et ReO(OCy)Cl$_2$(dppe) ont confirmé la présence du motif trans O=Re-OR et montré que les particularités structurales de l'ensemble Re-O-R ne sont pas affectées par la présence du substituant volumineux cyclohexyle ou du groupe aromatique phényle. La structure du complexe arylimido Re(p-ClC$_6$H$_4$N)Cl$_3$(dppe) a également été déterminée. Les spectres d'absorption électroniques des composés ReOX$_3$(dppe) comportent deux composantes de basse énergie à ~11 500 et ~16 000 cm^{-1}, attribuées respectivement aux deux transitions d–d permises de spin, attendues pour ces systèmes de basse symétrie. La substitution du ligand oxo par un groupe arylimido a peu d'influence sur la composante de plus basse énergie, mais elle rapproche les deux composantes l'une de l'autre. Le remplacement de l'halogène trans au lien Re=O par un group alkoxo déplace l'ensemble du système vers des énergies supérieures. Ces variations sont en bonne corrélation avec les énergies des orbitales frontières déterminées par calculs DFT. En tentant de préparer ReOCl$_3$(dppe) à partir de ReOCl$_3$(PPh$_3$)$_2$, le composé de Re(III) fac-ReCl$_3$(PPh$_3$){Ph$_2$-PC$_2$H$_4$PPh$_2$(O)} a été obtenu, dans lequel l'une des extrémités du dppe est devenue un oxyde de phosphine. En laissant reposer dans le DMSO, ce composé a conduit au complexe octaédrique ReCl$_4${Ph$_2$PC$_2$H$_4$PPh$_2$(O)}, où la formation de chélate impliquant une phosphine et un oxyde de phosphine a été confirmée par diffraction des rayons X.

Mots clés : rhénium, structure cristalline, calculs DFT, transitions électroniques d–d.

Introduction

Over the past decades, many research groups have been examining various rhenium(V) compounds containing the Re=O^{3+}, Re=NR^{3+}, and Re≡N^{2+} cores for eventual applica-

tions in radiopharmacy as labeling or therapeutic agents (1–4). Our contributions to this field include compounds with amino acids (5, 6), nitrogen heterocycles (7–12), and various bidentate ligands containing a soft phosphine group and a hard oxygen donor (13–18). Multiple-bonded Re(V) com-

pounds are of interest in many other fields of chemistry and biochemistry. For instance, their role in oxygen transfer and other catalytic processes is under active investigation at the moment (19–23). The optical properties associated with the multiple bonds have produced a large number of publications and are still extensively studied (24–28).

In the perspective of developing devices for storage of information at the molecular level, these simple diamagnetic d^2 centers would be potentially useful systems if a low-energy paramagnetic high-spin state can be readily accessed. The oxygen or nitrogen p_x and p_y orbitals of the multiple-bonded ligand form strong π bonds with the d_{xz} and d_{yz} orbitals, which become antibonding and higher in energy than the other interaxial d orbital (d_{xy} or $d_{x^2-y^2}$, depending on point group symmetry). Occupancy of the latter orbital by the two d electrons results in a diamagnetic ground state. However, in a previous study (29), we showed that the HOMO–LUMO gap is relatively small in certain oxo compounds (**I**) containing O-P ligands. If the gap becomes comparable with the pairing energy, the molecule could possess a high-spin excited state accessible at low energy cost via a spin–crossover process. Such systems may be of interest as catalysts and materials with unusual optical or magnetic properties.

I
To cast some light on the factors leading to small HOMO–LUMO gaps, we first examined a series of simple compounds retaining an equatorial *cis*-P,P arrangement perpendicular to an (axial) Re=O or Re=NR bond. The common bis(diphenylphosphino)ethane (dppe) ligand was chosen to provide this arrangement. The strongly π-donor *trans*-O=Re=O$^+$ and Re≡N^{2+} cores were not considered at this point, since their energy gaps had been found to be substantially higher (29). ReOCl$_3$(dppe) was originally prepared by Chatt and Rowe (30), and X-ray work showed that it indeed corresponds to the structural type considered (31). The corresponding phenylimido compound Re(NPh)Cl$_3$(dppe) was obtained by Cotton et al. (32). In the present study, the chloro and bromo compounds ReOX$_3$(dppe) were prepared, together with *trans*-ReO(OR)X$_2$(dppe) derivatives with various R groups. A few arylimido compounds were also included. In addition to the preparation and characterization of these compounds, we are reporting preliminary electronic spectra showing how absorption is affected by ligand substitution. DFT calculations are used to rationalize these results.

Experimental section

Reactants and methods

KReO$_4$, dppe, and all other reactants were obtained from Aldrich and used without further purification.

ReOCl$_3$(PPh$_3$)$_2$ was prepared by a literature method (30). Deuterated solvents were purchased from Aldrich or CDN Isotopes.

IR spectra were recorded on Perkin-Elmer 1600 (4000–400 cm^{-1}, KBr pellets) or 1430 spectrophotometers (4000–200 cm^{-1}, CsI pellets). The NMR spectra were measured with Bruker AMX-300, ARX-400, or AV-300 spectrometers. For the ^{1}H spectra, the residual solvent signal (DMSO-d_6, 2.50 ppm) was used as internal reference and the chemical shifts are expressed in ppm vs. SiMe$_4$. H$_3$PO$_4$ was used as an external reference ($\delta = 0$) for the ^{31}P{^{1}H} spectra. Electronic spectra were recorded in quartz cells with a UV–vis–NIR Cary 5E spectrometer. The solution spectra were taken as DMSO solutions. Spectra of crystalline samples were obtained with a tungsten-halogen lamp, the CCD detector of a Renishaw 3000 Raman imaging microscope, and a 10% neutral density filter to avoid blinding the detector. FAB$^+$ mass spectra in NBA were measured at the Centre de Spectrométrie de Masse de l'Université de Montréal. Elemental analyses were run at the Laboratoire d'Analyse Élémentaire de l'Université de Montréal.

Preparation of ReOX$_3$(dppe) (X = Cl, Br)

Modifications were introduced in the procedure originally described by Chatt and Rowe (30) for ReOCl$_3$(dppe) to eliminate impurities of MX salts and reduced complexes.

The K$^+$ ion of KReO$_4$ was first replaced by H$^+$ on a cation-exchange resin (Dowex 50W-X8, 20–50 mesh). The column (2 cm diameter) was filled with 10 g of resin, which was activated with 15 mL of 6mol/L HCl to obtain the H$^+$ form and washed with boiling water (75 mL) to neutrality. KReO$_4$ (1.5 g, 5.2 mmol) dissolved in a minimum amount (ca. 18 mL) of boiling water was poured into the hot column and the elution was done with boiling water. The HReO$_4$ solution was collected as long as it remained acidic. Water was then removed with a rotating evaporator and a viscous light yellow-green liquid containing HReO$_4$ and Re$_2$O$_7$ was obtained. To this oily material was added concentrated HX (5 mL) and the mixture was refluxed for 2 min. A 25 mL fraction of a chloroform solution of dppe (3.90 g, 9.80 mmol in 150 mL) was first added and the mixture darkened immediately. The rest of the dppe solution was then added in small portions over a period of 4 h. The mixture was cooled to room temperature (RT) and the precipitate (green for Br, blue for Cl) was filtered, washed with acetone (to remove water), chloroform, and diethyl ether. The compound was recrystallized from acetonitrile.

ReOCl$_3$(dppe)

Yield: 82%. IR (CsI, cm^{-1}): 980 (s) ν(Re=O); 320 (w), 290 (w) ν(Re-Cl). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.01 (m, 8H, H$_o$), 7.48 (s br, 12H, H$_{m,p}$), 3.79 (m, 2H, ethylene), 3.24 (m, 2H, ethylene). ^{31}P NMR (DMSO-d_6) (ppm) δ: 5.7 (s). MS FAB$^+$ (*m/z*): 706 [M]$^+$; 671 [M – Cl]$^+$. Anal. calcd. for C$_{26}$H$_{24}$OP$_2$Cl$_3$Re (%): C 44.17, H 3.42; found: C 44.24, H 3.34.

ReOBr$_3$(dppe)

Yield: 76%. IR (KBr, cm^{-1}): 971 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.03 (m, 8H, H$_o$), 7.48 (s br, 12H, H$_{m,p}$), 3.90 (m, 2H, ethylene) 3.17 (m, 2H, ethylene). ^{31}P

NMR (DMSO-d_6) (ppm) δ: –1.0 (s). MS FAB$^+$ (*m/z*): 840 [M]$^+$, 760 [M – Br]$^+$, 680 [M – 2Br]$^+$.

Preparation of ReOX$_2$(OR)(dppe) (X = Cl, Br)

Method A (R = Me, Et, Pr)

For ReOCl$_2$(OEt)(dppe), a suspension of ReOCl$_3$(dppe) (0.31 g, 0.44 mmol) in 35 mL of ethanol was refluxed for 3 days, during which time the blue solid progressively turned violet. It was filtered hot, washed with ethanol and diethyl ether, and recrystallized in acetonitrile.

This method was used to introduce alkoxo groups corresponding to low-boiling alcohols (methanol, ethanol, *n*-propanol). Reaction time varied (2–6 days) from one system to another. The reaction was stopped ~24 h after the reaction mixture has become clear violet. When there was no color change after 3 days, adding fresh alcohol helped to accelerate the reaction.

ReOCl$_2$(OEt)(dppe)

Yield: 90%. IR (KBr, cm^{-1}): 950 (s) ν(Re=O), 913 (s) δ(O-CH$_2$). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.14 (m, 8H, H$_o$), 7.48 (s br, 12H, H$_{m,p}$), ~3.31 (m, 2H, ethylene, near water peak), 3.14 (m, 2H, ethylene), 2.28 (q, 2H, ^3J = 7.0 Hz, ethoxo CH$_2$), –0.07 (t, 3H, ^3J = 6.9 Hz, ethoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 16.5 (s). MS FAB$^+$ (*m/z*): 716 [M]$^+$, 681 [M – Cl]$^+$, 671 [M – OEt]$^+$, 637 [M – Cl – OEt]$^+$. Anal. calcd. for C$_{28}$H$_{29}$O$_2$P$_2$Cl$_2$Re (%): C 46.93, H 4.08; found: C 46.66, H 3.94.

ReOCl$_2$(OMe)(dppe)

Yield: 79%. IR (KBr, cm^{-1}): 944 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.11 (m, 8H, H$_o$), 7.49 (s br, 12H, H$_{m,p}$), ~3.23 (m, 2H, ethylene, near water peak), 3.15 (m, 2H, ethylene), 1.91 (s, 3H, methoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 16.6 (s).

ReOCl$_2$(OPr)(dppe)

Yield: 85%. IR (KBr, cm^{-1}): 938 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.16 (m, 8H, H$_o$), 7.48 (s br, 12H, H$_{m,p}$), 3.34 (m, 2H, ethylene), 3.15 (m, 2H, ethylene), 1.99 (t, 2H, ^3J = 6.5 Hz, propoxo α-CH$_2$), 0.34 (m, 2H, propoxo β-CH$_2$), 0.11 (t, 3H, ^3J = 7.3 Hz, propoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 15.8 (s).

ReOBr$_2$(OEt)(dppe)

Yield: 61%. IR (KBr, cm^{-1}): 951 (s) ν(Re=O), 913 (s) δ(O-CH$_2$). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.12 (m, 8H, H$_o$), 7.50 (m br, 12H, H$_{m,p}$), 3.39 (m, 2H, ethylene), 3.07 (m, 2H, ethylene), 2.35 (q, 2H, ^3J = 6.8 Hz, ethoxo CH$_2$), –0.03 (t, 3H, ^3J = 6.9 Hz, ethoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 18.2 (s).

ReOBr$_2$(OMe)(dppe)

Yield: 75%. IR (KBr, cm^{-1}): 936 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.12 (m, 4H, H$_o$), 8.01 (m, 4H, H$_o$), 7.51 (s br, 12H, H$_{m,p}$), ~3.35 (m, 2H, ethylene, near water peak), 3.08 (m, 2H, ethylene), 2.02 (s, 3H, methoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 18.8 (s).

ReOBr$_2$(OPr)(dppe)

Yield: 74%. IR (KBr, cm^{-1}): 937 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.13 (m, 8H, H$_o$), 7.49 (s br, 12H, H$_{m,p}$), 3.38 (m, 2H, ethylene, near water peak), 3.08 (m, 2H, ethylene), 2.06 (t, 2H, ^3J = 6.5 Hz, propoxo α-CH$_2$), 0.38 (m, 2H, propoxo β-CH$_2$), 0.11 (t, 3H, ^3J = 7.4 Hz, propoxo CH$_3$). ^{31}P NMR (DMSO-d_6) (ppm) δ: 17.4 (s). Anal. calcd. for C$_{29}$H$_{31}$O$_2$P$_2$Br$_2$Re (%): C 42.50, H 3.81; found: C 42.78, H 3.87.

Method B (R = cyclohexyl, -CH$_2$CH$_2$OH)

A suspension of ReOCl$_2$(OEt)(dppe) (0.20 g, 0.28 mmol) in 25 mL of an acetone–cyclohexanol (or –ethylene glycol) (4:1, v/v) mixture was refluxed for 3 days. The color of the solid did not change appreciably during the reaction. The violet precipitate was filtered, washed with ethanol and diethyl ether, and recrystallized in acetonitrile. For the soluble ethylene glycol complex, the final mixture was evaporated to dryness, diethyl ether was added, and the violet product was filtered.

ReOCl$_2$(OCy)(dppe)

Yield: 72%. IR (KBr, cm^{-1}): 926 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.27 (m, 4H, H$_o$), 8.16 (m, 4H, H$_o$), 7.47 (s br, 12H, H$_{m,p}$), ~3.45 (m, 2H, ethylene, in the tail of the water peak), ~3.18 (m, 2H, ethylene, near water peak); cyclohexyl signals assigned from a 2D spectrum: 2.33 (m, 1H, α-CyO), 1.03 (m, 3H, γ/δ-CyO), 0.56 (m, 2H, β-CyO), 0.38 (m, 3H, γ/δ-CyO), –0.11 (m, 2H, β-CyO). ^{31}P NMR (DMSO-d_6) (ppm) δ: 16.9 (s).

ReOCl$_2$(OCH$_2$CH$_2$OH)(dppe)

Yield: 85%. IR (KBr, cm^{-1}): 948 ν(Re=O), 907 (s) δ(O-CH$_2$). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.10 (m, 8H, H$_o$), 7.49 (s br, 12H, H$_{m,p}$), 3.43 (m, 2H, ethylene, near water peak), 3.11 (m, 2H, ethylene), 2.42 (t, 2H, ^3J = 6.2 Hz, β-CH$_2$CH$_2$OH), 2.17 (t, 2H, ^3J = 6.3 Hz, α-CH$_2$CH$_2$OH). ^{31}P NMR (DMSO-d_6) (ppm) δ: 19.1 (s). MS FAB$^+$ (*m/z*): 732 [M]$^+$, 697 [M – Cl]$^+$, 671 [M – OC$_2$H$_4$OH]$^+$, 661 [M – 2Cl]$^+$, 636 [M – Cl – C$_2$H$_4$OH]$^+$.

Method C (R = Ph)

A solution of phenol (5.5 g, 59 mmol) in 70 mL of benzene was heated to the boiling point and ReOBr$_2$(OPr)(dppe) (0.49 g, 0.60 mmol) was added. The violet mixture turned orange quickly. After 1 day, the solvent was evaporated, the raw product was added to 50 mL of diethyl ether, and refluxed for 30 min to dissolve the unreacted phenol. The dark-brown precipitate was filtered hot, washed with diethyl ether, and recrystallized in acetonitrile.

ReOBr$_2$(OPh)(dppe)

Yield: 83%. IR (KBr, cm^{-1}): 959 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.13 (m, 4H, H$_o$), 8.00 (dd, 4H, ^3J = 7.6 Hz, $^3J_{H-P}$ = 10.9 Hz, H$_o$), 7.53 (s br, 6H, H$_{m,p}$), 7.35 (t, 2H, ^3J = 7.0 Hz, H$_p$), 7.26 (t, 4H, ^3J = 7.5 Hz, H$_m$), 6.62 (m, 3H, phenoxo H$_{m,p}$), 5.67 (d, 2H, ^3J = 8.0 Hz, phenoxo H$_o$), 3.55 (m, 2H, ethylene), 3.23 (m, 2H, ethylene). ^{31}P NMR (DMSO-d_6) (ppm) δ: 17.3 (s). MS FAB$^+$ (*m/z*): 854 [M]$^+$, 773 [M – Br]$^+$, 761 [M – OPh]$^+$, 680 [M – Br – OPh]$^+$.

Anal. calcd. for $C_{32}H_{29}O_2P_2Br_2Re$ (%): C 45.03, H 3.42; found: C 45.09, H 3.39.

ReOCl₂(OPh)(dppe)

Yield: 90%. IR (KBr, cm^{-1}): 960 (s) ν(Re=O). ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.13 (m, 4H, H$_o$), 8.00 (dd, 4H, ^3J = 7.7 Hz; $^3J_{\text{H-P}}$ = 11.1 Hz, H$_o$), 7.51 (s br, 6H, H$_{m,p}$), 7.30 (m, 2H, H$_p$), 7.23 (m, 4H, H$_m$), 6.59 (m, 3H, phenoxo H$_{m,p}$), 5.63 (d, 2H, ^3J = 7.9 Hz, phenoxo H$_o$), 3.57 (m, 2H, ethylene), 3.32 (m, 2H, ethylene, near water peak).^{31}P NMR (DMSO-d_6) (ppm) δ: 16.3 (s).

Preparation of Re(NPh)Cl₃(dppe)

The compound was prepared following the literature method (32). ReOCl₃(dppe) (0.15 g, 0.21 mmol) was added to 30 mL of a refluxing aniline–benzene (1:5, v/v) mixture. The blue solution was refluxed for 36 h, during which time it turned green. The light-green precipitate was filtered, and washed with benzene and diethyl ether. It recrystallized in acetonitrile as light-green fibers.

Re(NPh)Cl₃(dppe)

Yield: 75%. ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.16 (m, 4H, H$_o$), 7.96 (m, 4H, H$_o$), 7.52 (t, 1H, ^3J = 8.2 Hz, phenylimido H$_p$), 7.41 (s br, 6H, H$_{m,p}$), 7.16 (s br, 6H, H$_{m,p}$), 6.79 (t, 2H, ^3J = 8.5 Hz; phenylimido H$_m$), 6.15 (d, 2H, ^3J = 8.7 Hz, phenylimido H$_o$), ~3.59 (m, 2H, ethylene), 3.33 (m, 2H, ethylene). ^{31}P NMR (DMSO-d_6) (ppm) δ: 11.3 (s).

Preparation of Re(NC₆H₄Cl)Cl₃(dppe)

This variation of the previous method was used to introduce a phenylimido group derived from a solid aniline. A solution of *p*-chloroaniline (5.56 g, 43.6 mmol) in 25 mL of benzene was heated to its boiling point and ReOCl₃(dppe) (0.15 g, 0.21 mmol) was added. The solution was refluxed for 1 day, during which time the blue solution turned dark green. The solvent was evaporated completely, the solid obtained was placed in 50 mL of diethyl ether, and the solution was refluxed for 30 min to dissolve unreacted *p*-chloroaniline. The green precipitate was filtered hot, washed with diethyl ether, and recrystallized in acetonitrile.

Re(NC₆H₄Cl)Cl₃(dppe)

Yield: 78%. ^{1}H NMR (DMSO-d_6) (ppm) δ: 8.16 (m, 4H, H$_o$), 7.96 (m, 4H, H$_o$), 7.42 (s br, 6H, H$_{m,p}$), 7.19 (s br, 6H, H$_{m,p}$), 6.88 (d, 2H, ^3J = 8.8 Hz, arylimido H$_m$), 6.13 (d, 2H, ^3J = 8.6 Hz, arylimido H$_o$), 3.56 (m, 2H, ethylene), 3.33 (m, 2H, ethylene, near water peak). ^{31}P NMR (DMSO-d_6) (ppm) δ: 11.1 (s).

Preparation of ReCl₃(PPh₃)(dppe=O)

ReOCl₃(PPh₃)₂ (0.112 g, 0.13 mmol) was added to a solution of dppe (0.311 g, 0.79 mmol) in 25 mL CH₂Cl₂ under a dynamic inert atmosphere. The resulting lime-green solution was stirred at room temperature for 1 h. The beige precipitate formed during the reaction was filtered, washed with chloroform and diethyl ether. Yield: 51%. It corresponded to the 1.5CH₂Cl₂ solvate. IR (KBr, cm^{-1}): 1058 (s), 1125 (s). ^{1}H NMR (DMSO-d_6): see text. MS FAB$^+$ (*m/z*): 968 [M]$^+$, 933 [M – Cl]$^+$, 706 [M – PPh₃]$^+$, 635 [M – 2Cl – PPh₃]$^+$.

Anal. calcd. for $C_{45.5}H_{42}Cl_6OP_3Re$ (%): C 49.83, H 3.86; found: C 49.68, H 3.98.

X-ray diffraction studies

Three data sets were collected with a Bruker Smart 2K CCD diffractometer controlled by the SMART software (33), using the graphite-monochromatized CuKα radiation. Sets of 30 oscillation frames of 0.3° over a range of 9° were recorded in four regions of the reciprocal space, from which the reduced cell was determined by least-squares refinement. For data collection, frames were recorded for different orientations of the crystal and detector so as to cover at least 95% of the reciprocal sphere. At the end, the first 101 frames were remeasured to check for crystal decomposition. The frames were analyzed with the SAINT software (34), which determined the intensity and the position of each spot. Accurate cell parameters were obtained by least-squares refinement over the positions of the whole data set.

For one compound, the X-ray work was done with an Enraf-Nonius CAD-4 diffractometer using graphite-monochromatized CuKα radiation under the control of the CAD-4 software (35). The reduced cell was initially determined from 20 to 25 spots located on a preliminary rotation photograph and centered in the detector aperture. Accurate cell parameters were then determined from the positions of 25 high-angle reflections centered with the SETANG and DETTH procedures. The intensities were recorded by ω/2θ scan. Possible crystal decomposition was monitored by measuring five standard reflections every hour.

Another data set was collected with the Bruker P-4 diffractometer of the Université du Québec à Montréal, using the graphite-monochromatized MoKα radiation. The procedures to determine the cell parameters and collect the intensity data (XSCANS software) (36) were similar to those described above for the CAD-4 system. Three standard reflections were measured every 97 reflections during data collection.

The data were interpreted with the SHELXTL software (37). The XPREP procedure (38) was used to apply to the raw intensities an absorption correction based on crystal morphology and to determine the Laue symmetry, systematic absences, and space group. The structure was solved by the direct methods or the heavy-atom method with SHELXS (39). The heavy atoms were initially found and the remaining atoms were then located from structure-factor calculations and ΔF maps with SHELXL (40). The structure was refined by least squares on F^2. The non-hydrogen atoms were generally refined anisotropically. The hydrogens were first placed at idealized positions with the standard (C,N,O)-H distances of SHELXL and allowed to ride on the supporting atom. Their isotropic temperature factors (U_{iso}) were fixed at values related to the equivalent temperature factor (U_{eq}) of the supporting atom by $U_{\text{iso}} = k \times U_{\text{eq}}$ (where k = 1.5 (methyl) or 1.2 (others)). The ORTEP diagrams (40% probability ellipsoids) were produced with the XP routine of SHELXTL.

The crystals of Re(NC₆H₄Cl)Cl₃(dppe) and the three ReOX₂(OR)(dppe) compounds were obtained by slow crystallization of concentrated acetonitrile solutions, whereas those of ReCl₄(dppe=O) appeared in a DMSO solution of ReCl₃(PPh₃)(dppe=O) kept at room temperature for

3 months. In all cases, the intensities of the standard reflections revealed no crystal decomposition during data collection. Space groups were defined unambiguously from the Laue symmetry and systematic absences, except for the triclinic compound $ReCl_4(dppe=O) \cdot Me_2SO$. Crystal data are collected in Table 1.

In most cases, disorder was observed in the alkoxo group, phosphine phenyl rings, or lattice solvent molecules. It was modeled by means of two individual orientations, whose occupancies were first refined with a constraint applied to normalize the sum of the occupancies to unity. For the final cycles, these occupancies were rounded off to the nearest 0.05 and then fixed. The non-hydrogen atoms were usually refined anisotropically, but the thermal parameters were restricted (ISOR) so as to obtain reasonable ellipsoids. In severe cases, the interatomic distances were simultaneously constrained with DFIX. Details are provided in the CIF files.[3]

For $ReOCl_2(OPr)(dppe)$, the propyl unit adopted two conformations in a 80:20 ratio (Fig. S-1, supplementary material).[3] The major conformer (C61-C63) was stretched, whereas the other (C81-C83) was bent. DFIX constraints based on the average data found for propoxo groups in the Cambridge Structural Database (41) (C-O (1.42 Å), C-C (1.45 Å), $O \cdots C_\beta$ (2.39 Å), $C_\alpha \cdots C_\gamma$ (2.41) Å) were applied.

Data were also collected on crystals of the related $ReOBr_2(OPr)(dppe)$ complex. It is not isostructural with the chloro compound, since it belongs to the triclinic space group $P\bar{1}$ and the unit cell ($a = 9.848(3)$ Å, $b = 17.602(6)$ Å, $c = 18.082(6)$ Å, $\alpha = 78.83(2)°$, $\beta = 89.98(3)°$, $\gamma = 89.03(2)°$) contains four molecules. The two independent molecules are almost identical and differ very little from the chloro analog. Even the packing patterns of the two compounds are very close. However, the R factor could not be reduced below 0.094 and large correlations between the two independent molecules led to high instability in the refinement. Subtle twinning is suspected to be present and the structure of the bromo compound is not described in detail here.

In the case of $ReOBr_2(OPh)(dppe)$, rotational disorder about a P—C bond of dppe led to two orientations (60:40 ratio) for one of its phenyl groups (Fig. S-2).[3] With $ReOCl_2$-(OCy)(dppe), the cyclohexyl group in a chair conformation was disordered over two orientations (60:40 ratio, Fig. S-2).[3] In these cases, only ISOR restrictions were applied.

For $Re(NC_6H_4Cl)Cl_3(dppe)$, the crystal shape was difficult to describe and the absorption correction was not totally satisfactory. Nevertheless, the structure solved and refined normally.

The data for the triclinic $ReCl_4(dppe=O) \cdot (CH_3)_2SO$ compound were interpreted in the centric $P\bar{1}$ space group, which turned out to be the correct choice. The $ReCl_4(dppe=O)$ molecule itself showed no disorder, but the lattice DMSO molecule was found to be disordered over two interlocked orientations (0.65:0.35, Fig. S-3).[3] DFIX constraints based on the average distances found for lattice DMSO in the Cambridge Structural Database (41) (S=O (1.50 Å), C-S (1.76 Å), $C \cdots O$ (2.61 Å), $C \cdots C$ (2.65 Å)) were applied.

Results and discussion

Preparation of $ReOX_3(dppe)$ and $ReOX_2(OR)(dppe)$

The procedure originally described to prepare $ReOCl_3(dppe)$ (30) required a tedious series of recrystallizations to remove the MX salt and various reduction products. By starting with a $HReO_4$–Re_2O_7 solution and using chloroform as solvent, we obtained good yields of pure chloro and bromo compounds. The IR spectra show the strong $\nu(Re=O)$ band at 970–980 cm^{-1} expected for a mono-oxo system (42). Clean isotopic patterns are found in FAB$^+$ spectra for the parent ion and the $[M - X]^+$ fragment. The presence of only one $^{31}P\{^1H\}$ NMR singlet confirms the formation of the fac isomer, since the P donors would be inequivalent in the mer isomer. Although a "frozen" puckered chelate ring contains four inequivalent aliphatic protons, a fast flip-flop motion across the equatorial plane generates a vertical mirror plane (including the axial Re=O bond and bisecting the P-Re-P angle) on the NMR timescale. In the "average" molecule, the pair of protons on the same side of the equatorial plane become equivalent. Accordingly, two complex multiplets are found between 3 and 4 ppm, one of which is often obscured by the residual water peak in DMSO. Because of the anisotropic effect of the Re—oxo bond, the protons on the oxo side are believed to be the more deshielded (43, 44). Similarly, two distinct sets of phenyl signals are expected. However, only two complex peaks (2:3 intensity ratio) are found. The weaker one at ~8.0 ppm is due to the eight ortho protons, whereas the other at ~7.5 ppm includes the meta and para protons of both types of rings. This assignment is based on a comparison with $ReOX_2(OPh)(dppe)$, where one set of phosphine aromatic signals is displaced by the anisotropic effect of the phenoxo ring.

The $ReOX_2(OR)(dppe)$ compounds were obtained by controlled alcoholysis of $ReOX_3(dppe)$. For R = Me, Et, and Pr, refluxing for several days in the neat alcohol gave good yields of pure products. For the higher-boiling alcohols cyclohexanol and ethylene glycol, decomposition took place upon refluxing in the pure liquid and the reaction was carried out in a 4:1 acetone–alcohol mixture. With phenol, a solid, the reaction was run in benzene.

In all cases, halide substitution occurs only at the position trans to the Re=O bond. This is supported by the presence of only one singlet in the $^{31}P\{^1H\}$ spectra, downfield from that of the corresponding trihalo complex. The strong $\nu(Re=O)$ vibration appears at ~940 cm^{-1}. The ethoxo and 2-hydroxyethoxo compounds also give a very strong band at ~910 cm^{-1} involving an O-CH$_2$ deformation mode (30). The FAB$^+$ spectra generate characteristic patterns for the parent ion and other fragments obtained by removing X or OR. The ^1H aromatic regions of the alkoxo compounds are similar to those of the trihalo systems, except that the ortho signals are displaced downfield slightly (8.1–8.2 ppm). For $ReOX_2(OPh)(dppe)$, one of the two overlapping ortho signals is displaced upfield (~8.00 ppm) by the anisotropy of

---

the phenoxo ligand and it can be safely assigned to ortho protons, since $^3J_{\text{H-P}}$ couplings of ~11 Hz are observed (45). Anisotropy also displaces the meta and para signals upfield: they become resolved at ~7.3 (para) and ~7.2 ppm (meta), whereas the meta and para multiplets for the rings on the oxo side remain unresolved at ~7.5 ppm.

The alkoxo protons are shielded considerably compared with those of the corresponding alcohol. This is consistent with the alkoxo group lying trans to the oxo ligand, since it was noticed (13) that these protons are deshielded when they occupy a position cis to the oxo. For the 2-hydroxyethoxo compound, the protons α to the coordinated oxygen are assumed to be more shielded than the β protons, whose chemical shift returns to a normal value (3.34 ppm) (46) for free ethylene glycol. The phenoxo ligand gives a doublet at ~5.65 ppm for the ortho protons and a multiplet including the meta and para protons at ~6.60 ppm. Therefore, with respect to uncoordinated phenol, whose signals occur at 6.77 (ortho and para) and 7.16 ppm (meta), coordination induces upfield shifts whose amplitude decreased with the distance from the O atom.

Preparation of Re(NR)Cl₃(dppe)

Cotton et al. (32) first prepared the phenylimido compound by reacting ReOCl₃(dppe) with aniline. A similar procedure was used to obtain the *p*-chlorophenylimido complex here. The original stereochemistry of the oxo complex is retained, as evidenced from X-ray crystallography (see below) and from NMR spectroscopy, namely the presence of only one singlet in the ^{31}P{^{1}H} spectrum.

Isolation of reduced species

Attempts were made to obtain ReOCl₃(dppe) by displacing the phosphines of ReOCl₃(PPh₃)₂. When the reaction was run in CH₂Cl₂ at room temperature for 1 h, a beige solid precipitated. The parent peak and fragmentation pattern in the FAB⁺ spectrum were consistent with the presence of one PPh₃, one dppe, a ReCl₃ unit, and one extra oxygen. The absence of the strong IR ν(Re=O) band and the presence of ^{1}H NMR signals extending far outside the standard 0–10 ppm range ruled out the possibility of a diamagnetic oxorhenium(V) species. Therefore, rhenium-to-phosphorus oxygen transfer had probably occurred, generating a Re(III) center and a phosphine oxide, as observed before (47, 48). This was supported by the strong IR bands appearing at 1058 and 1125 cm⁻¹, one of which could be assigned to a ν(P=O) vibration (49). In the structure **II** proposed, the oxygen is part
II

δ (ppm)
of the bidentate Ph₂PC₂H₄PPh₂(O) ligand (dppe=O). The phosphine oxide unit is believed to be derived from dppe instead of PPh₃, since the fragmentation products observed in the FAB⁺ spectra correspond to the loss of PPh₃, not Ph₃PO. Furthermore, upon aging, this compound gives a Re(IV) compound ReCl₄(dppe=O), whose crystal structure is described hereafter. Even though the complex is paramagnetic, its ^{1}H NMR spectrum could be fully analyzed.

We previously reported ^{1}H NMR data of arylphosphine complexes of Re(III) and Re(IV) (50, 51). In these complexes, the aromatic phosphine signals usually occur between 10 and 20 ppm for the ortho protons, and between 7 and 11 ppm for the meta and para protons. As shown in Fig. 1 and Table 2, this generalization is obeyed here. ^3J couplings typical of aromatic rings are observed and proton positions around the rings are readily identified from multiplicities and integrations. A 2D experiment allowed us to distribute the nine peaks between 12 and 7.5 ppm into three groups of three, corresponding to PPh₃ and to the two inequivalent phenyl rings at the PPh₂ end of the dppe=O ligand. Two extra sets of three coupled signals are also found at higher field for the aromatic protons of two phenyl rings in the phosphine oxide group. In the latter sets, the ortho protons appear at relatively high field (1.8 and –3.0 ppm) and they are somewhat broadened. Finally, broad multiplets with suitable intensities are observed for the aliphatic protons, two of which occur at extreme chemical shifts (40.5 and –8.5 ppm, respectively). These multiplets, which were already complex for diamagnetic systems, showed extra broadening because of the paramagnetism. They did not give clear cross-peaks in the 2D spectrum and could not be assigned to individual protons.

These available data and the crystallographic results on ReCl₄(dppe=O) suggest that the metal center is coordinated to six ligands: three Cl, one PPh₃, and one Ph₂PC₂H₄PPh₂(O). Of the three possible isomers for an octahedral ReX₃L(L′-L″) compound, only the fac isomer (**II**) is consistent with the presence of four inequivalent phenyl

rings in the dppe=O ligand, as revealed by ^{1}H NMR spectroscopy.

Crystal structures of the $ReOX_2(OR)(dppe)$ compounds

Since the Re-O-R angle in the known structures of this type spans a broad range (125°–180°, based on 33 structures in the Cambridge Structural Database) (41) and the oxygen-to-rhenium π interactions could be sensitive to this factor, structures with three different OR groups were studied: the *n*-propoxo unit was considered as a "normal" group, the cyclohexyl substituent was expected to be sterically demanding, whereas the phenoxo group was used to probe the influence of an extended π system.

The three $ReOX_2(OR)(dppe)$ molecules (Fig. 2) consist of octahedral molecules containing the *trans*-oxo-alkoxo unit observed for the bis(diphenylphosphino)propane complex (52). Selected distances and angles are listed in Table 3.

In the three compounds, the O=Re-O unit shows a significant, but relatively small, deviation from linearity (171°–173°), corresponding to small displacements of the two oxygen donors to the dppe side. Despite the fact that the three R groups have different sizes and (or) electronic properties, the OR groups are all roughly end-on coordinated (Re-O-C ~ 160°). Our Re=O and Re-OR distances in the two alkoxo compounds are in good agreement with the mean values of 1.70(3) and 1.89(5) Å, respectively, obtained from the literature (41). For the phenoxo complex, our distances of 1.686(6) and 1.900(6) Å are not very different from those reported for $ReOCl_3(PPh_3)(L)$ with L = 2-diethylaminomethyl-4-methyl-phenol (1.669(3) and 1.915(3) Å, respectively), where the Re-O-C angle (166.0(3)°) is similar to ours (16). In the two other structures published so far with simple phenolates, the distances tend to be greater (1.666(6) and 1.969(5) Å, 1.703(6) and 1.989(6) Å, respectively) (53, 54), which could be correlated with the pronounced bent in the Re-O-C region (146.5(5)° and 137.7(6)°, respectively).

In the three known structures of 1:1 Re(V)-dppe compounds (31, 55), the mean Re-P distance is 2.45(2) Å, the bite angle P-Re-P is 82.9(6)°, and the P-C-C-P torsion angle in the chelate ring is 58(4)°. Our results are in good agreement with these data and the phenyl rings also adopt very similar orientations. The Re-Cl (2.428–2.457 Å, σ = 0.001 Å) and Re-Br (2.570(1), 2.599(1) Å) distances are appreciably greater than the mean values from the literature for Re—X bonds cis to Re=O (Re—Cl = 2.38(3) Å, Re—Br = 2.51(3) Å; based on 130 and 14 structures, respectively) (41). Although these bonds could be weakened by the phosphine trans influence, this cannot be the controlling factor, since the corresponding distances are normal in the $ReOX_3(dppe)$ complexes (Re—Cl = 2.38 Å, Re—Br = 2.52 Å) (31). The lengthening of the Re—X bonds may be ascribed to the good π donor character of the end-on coordinated OR group, whose donation into d_{xz} and d_{yz} makes these orbitals less electrophilic and reduces their ability to accept π-electron density from the equatorial halides. This pattern is also observed for the trans bis-PPh_3 complexes: the cis Re—Cl bonds in $ReOCl_3(PPh_3)_2$ (56) are shorter (2.397(1) Å) than in the related oxo-alkoxo complexes (2.41 Å) (31, 57, 58).

The oxo ligand tends to repel the adjacent bonds, resulting in a displacement of the Re atom from the "equatorial" P_2X_2 plane on the oxo side, as evidenced from the mean of the O=Re-L_{cis} angles being ~93° compared with ~88° for the RO-Re-L_{cis} angles. The puckered conformation of the ring creates systematic differences in the coordination geometry of the two ends of dppe. The *trans*-X_A-Re-P_A units (involving the P_A atom bonded to the methylene group on the oxo side of the P_2X_2 plane) are more linear (alkoxo (~177°), halo (~174°) (31)) than the *trans*-P_B-Re-X_B unit (alkoxo (~172°), halo (~164°)). Also, our Re-X_A distances are systematically ~0.025 Å longer than Re-X_B, whereas the opposite trend is noted, to a lesser extent, for the Re-P distances. This pattern of bond lengths is not shared by the $ReOX_3(dppe)$ compounds, however (31).

The molecules are packed in the unit cell with normal van der Waals contacts (Figs. S-4 and S-5).[3]

Crystal structure of $Re(NC_6H_4Cl)Cl_3(dppe)$

The $Re(NC_6H_4Cl)Cl_3(dppe)$ molecule adopts the structure shown in Fig. 3. The octahedral coordination of Re includes a multiple-bonded 4-chlorophenylimido group with the trans site filled by a chloro ligand, leading to the fac configuration observed for the corresponding bis(diphenylphosphino)ferrocene complex (59). Selected interatomic distances and bond angles are given in Table 4.

The Re=NR distance (1.707(5) Å) and the small departure from linearity in the Re=N-C unit (171.5(5)°) correspond well with the available data on arylimido complexes (mean values: Re=N (1.716(15) Å), Re=N-C (172(5)°); based on 42 structures) (41). A detailed comparison with the related compounds $Re(NPh)Cl_3(PPh_3)_2$ (*trans*-P,P) (60), $Re(NPh)Cl_3\{bis(diphenylphosphino)ferrocene\}$ (*cis*-P,P) (59), and $Re(NPh)Cl_3(PMe_3)_2$ (*cis*-P,P) (61) is provided in the supplementary material (Table S-1).[3] For the dppe ligand, the P-Re-P "bite" angle and the ring conformation are close to those of the above oxo-alkoxo compounds, but the Re—P

Fig. 2. ORTEP drawings of ReOCl$_2$(OPr)(dppe) (A), ReOBr$_2$(OPh)(dppe) (B), and ReOCl$_2$(OCy)(dppe) (C). For simplicity, only the major conformations are shown and the hydrogens are omitted.

A

B

C
bond lengths are ~0.01 Å shorter here. The Re-Cl distances range from 2.417(2) to 2.438(2) Å, in agreement with the average value of 2.40(3) Å from the literature. As noted for oxo-alkoxo complexes, the metal is displaced from the P$_2$X$_2$ plane on the nitrogen side by ~0.20 Å. Steric interactions with the dppe phenyl rings probably explain that the departure from linearity in the trans RN=Re-Cl unit (168.0(2)°) is slightly greater than commonly found (mean for 16 structures ~174(4)°). The phenyl rings at the P$_A$ end of dppe are oriented in the same way (Re-P$_A$-C$_i$-C$_o$ = 28° and –71°) as in the oxo-alkoxo complexes, but those of the P$_B$ phosphine group adopt a different orientation corresponding to the opposite pattern of torsion angles (Re-P$_B$-C$_i$-C$_o$ = –67° and 15°, respectively). This is likely due to stacking interactions between the C41-C46 dppe group and the phenylimido ring, roughly parallel to the Re—P$_A$ bond. This orientation, also observed in the phosphinoferrocene complex, positions the rings nearly parallel to each other (dihedral angle = 24.3(4)°) with a relatively small mean inter-ring distance of 3.6 Å. The complexes are packed individually in the unit

cell (Fig. S-6, supplementary material),[3] where the aromatic rings participate in various stacking interactions.

The Re(NC$_6$H$_4$Cl)Cl$_3$(dppe) molecule is compared to the isoelectronic ReOCl$_3$(dppe) compound in Table 4. In the imido complex, the Re—Cl$_{cis}$ bonds are ~0.05 Å longer, whereas the Re—P bonds are ~0.04 Å shorter. This is consistent with the fact that the π donation of the imido group into the metal d_{xz} and d_{yz} orbitals is greater that for the oxo ligand. This should strengthen the bonds with the π-acceptor phosphine, but weaken the Re—X bonds, since the halogens are competing with the oxo or imido ligands for π donation into the same metal orbitals. Interestingly, the orientations of the dppe rings in ReOCl$_3$(dppe) do not follow the pattern found for Re(NC$_6$H$_4$Cl)Cl$_3$(dppe) and the ReO(OR)Cl$_2$(dppe) compounds. This conformational change has no appreciable effect on the coordination geometry.

ReCl$_4$(dppe=O)•(CH$_3$)$_2$SO

In the ReCl$_4$(dppe=O) complex shown in Fig. 4, the Re(IV) center possesses an octahedral coordination. The

[c]Values corresponding to the two disordered orientations, occupancies within round brackets.

bidentate ligand is actually Ph$_2$PC$_2$H$_4$PPh$_2$(O), which is a dppe ligand in which one end has been oxidized to phosphine oxide. A similar arrangement was observed for ReCl$_4$(dppm=O). Selected interatomic distances and bond angles are given in Table 5.

The angles in the octahedron are close to ideality. The largest deviation, found for the mutually trans Re—Cl bonds, reflects a small displacement for the chlorines towards the chelate ring. The Re-ligand distances compare well with the literature results. For mutually trans Re—Cl

bonds, the distances observed here are close to the mean value 2.336(14) Å determined from 21 Re(IV) structures (41). When the chloro ligand sits trans to a different donor atom, the mean value from the literature (23 structures) is similar (2.325(30) Å), but it covers a broader range, mainly because it is sensitive to the trans influence of the opposite ligand. In our structure, the Re—Cl bond trans to oxygen (2.319(2) Å) is appreciably shorter than the one trans to the phosphine group (2.335(2) Å), whose trans influence is large.

[a]Torsion angles for Re(NC$_6$H$_4$Cl)Cl$_3$(dppe) calculated for the (−x, −y, −z) molecule for consistency with Table 3.
[b]Reference 31.

In the unit cell (Fig. S-7),[3] the molecules form layers parallel to the *a* axis and oriented along the cell diagonal. Between these layers, the superposition of DMSO molecules fills channels extending along the cell *a* axis.

Comparisons are made in Table 5 with ReCl$_4$(dppm=O) (62), which differs from our compound by the size of the chelate ring. The O-Re-P angle in the six-membered ring with dppe=O (89.2(2)°) is much greater than that of the dppm=O five-membered ring (80.7°). This leaves less space for the opposite chlorines, which get closer together: the Cl-Re-Cl angle is 93.46(9)° here, compared to 97.7° for the dppm=O complex. Another difference is the Re-O=P angle, which is 140.5(3)° here, but 130.1° in ReCl$_4$(dppm=O). This angle is known to be very flexible: it is ~155° for monodentate O=PR$_3$ ligands, but it can adjust readily to ex-

ternal strain. The very small angle for the dppm=O complex reflects the high constraint for a five-membered chelate ring.

One of the Re-Cl distances (2.215 Å) reported for the dppm=O complex is extremely small. This bond, trans to the phosphine oxide group, seems to be ~0.1 Å shorter than the corresponding bond in our dppe=O complex. Partial substitution of the Re(IV) complex ReCl$_4$(dppm=O) in the crystal by Re(V) molecules *mer*-ReOCl$_3$(dppm=O) (63, 64) could explain this "apparent" shortening, since the oxo ligand would be trans to the phosphine oxide in the latter species. Such solid solutions of "quasi-isostructural" oxo-Re(V) and chloro-Re(IV) complexes have already been detected (65) and in the resulting average structure, the "Re—Cl(O)" bond

seems to be shortened with respect to a normal Re—Cl bond, but to be stretched when compared to an Re=O bond.

Electronic spectra and DFT calculations

The low-energy portions (8000–25 000 cm^{-1}) of the absorption spectra of representative compounds are shown in Fig. 5. Spectra taken with crystalline $ReOX_3(dppe)$ and $ReOX_2(OR)(dppe)$ compounds confirmed that the species in the solid is retained in DMSO. In all cases, this spectral region shows two major components. The data are listed in Table 6.

Strictly speaking, the molecules examined here have no symmetry, but if chelate ring puckering and other minor distortions are ignored, a mirror plane containing the Re=O(NR) bond bisects the P-Re-P angle, so that the metal environment has an approximate C_s symmetry. Under this low symmetry, the antibonding d_{xz}/d_{yz} orbitals, which are de-

Fig. 5. Typical electronic spectra of the $ReEX_2(Y)(dppe)$ complexes in DMSO.
Fig. 6. Ground and low-energy excited states for the Re(V) d^2 systems: singlet ground state (S), first triplet excited state (T*), first singlet excited state (S*), second singlet excited state (S**).
generate under D_{4h} symmetry, become inequivalent. For this point group symmetry, the interbond orbital in the xy plane is labeled $d_{x^2-y^2}$ (instead of d_{xy}), and for consistency with the recent study on isoelectronic oxo-molybdenum(IV) systems by Da Re and Hopkins (66), the d_{yz} will be assumed to lie at lower energy than d_{xz}. The two absorption features in Fig. 5 are assigned to the two spin-allowed singlet–singlet transitions $(d_{x^2-y^2})^2 \rightarrow (d_{x^2-y^2})^1(d_{yz})^1$ [S → S*] and $(d_{x^2-y^2})^2 \rightarrow (d_{x^2-y^2})^1(d_{xz})^1$ [S → S**], respectively (Fig. 6). Therefore, the position of these bands can be used to estimate the two HOMO–LUMO energy gaps. Singlet–triplet processes [S → T*] could in principle take place, but there is no evidence for these much weaker spin-forbidden transitions in the spectra recorded here.

Two well-differentiated components (12 000 and 16 400 cm^{-1}) are visible for $ReOCl_3(dppe)$. Replacing Cl by Br produces similar red shifts on both (11 300 and 15 500 cm^{-1}). Upon substitution of the oxo ligand by a phenylimido group in $Re(NPh)Cl_3(dppe)$, the two components are not equally displaced: the low-energy component undergoes a very small red shift of ~900 cm^{-1}, whereas the shift on the other is greater (~3000 cm^{-1}). This could be connected with the different symmetries of these two ligands. For the cylindrical oxo ligand, the p_x and p_y orbitals are equally available for π interacting with the metal d_{xz} and d_{yz} orbitals. In contrast, for the imido group, the phenyl ring renders these orbitals inequivalent, since only one is participating in the aromatic π system. Consequently, π interactions with the metal d_{xz} and d_{yz} orbitals being no longer equal, the transitions to these orbitals are anticipated to be differently affected.

Substitution of the trans halogen of ReOX$_3$(dppe) by an -OR group has a more drastic effect. In the ReOX$_2$(OR)(dppe) compounds, both components undergo relatively large blue shifts to ~16 600 and 20 000 cm^{-1}, respectively, and the separation (~3000 cm^{-1}) is a little smaller than in the tris-halogen complexes (~4000 cm^{-1}). Again, these unequal variations can be ascribed to the noncylindrical symmetry of the bent alkoxo group. One of the oxygen p orbitals (perpendicular to the Re-O-C plane) remains suitably oriented for optimal π interacting with one of the d orbitals, but partial hybridization will decrease the participation of the other p orbital (in the Re-O-C plane) in π interactions.

To understand the behavior of these oxo- and arylimidorhenium(V) systems and orient our research strategies, theoretical calculations were performed with the PCSPARTAN PRO software (67). A simplified model was used to reduce computation time. Structure optimization on molecules containing dppe itself were time consuming, because adjusting the orientation of the four phenyl rings required many refinement cycles and convergence was not always reached. Since the comparisons to be made always involve the same diphosphine, the calculations were run using bis(dimethylphosphino)ethane (dmpe), in which the substituents are "cylindrical" methyl groups. On the other hand, since PCSPARTAN does not include rhenium parameters for DFT calculations, technetium was used in the model. The geometry and orbital energies were obtained by DFT calculations based on the generalized gradient approximation uti-

Fig. 7. Variation of the DFT-calculated energy gap as a function of the transition energy obtained experimentally from the spectra for each of the two transitions.
lizing the functionals proposed by Becke and Perdew (67). The BP86 (self-consistent model) and DN* (double numerical polarization) options were used. The calculated energies are listed in Table 7 and they are plotted against the experimental results in Fig. 7.

For each of the two transitions, there is an approximate linear relationship between the energies determined from the spectra and those predicted from the calculations. This suggests that the calculations reflect in a satisfactory manner the factors affecting the energy levels in these systems. The re-

duction of the transition energy upon substitution of the oxo ligand by an arylimido moiety and the energy increase by replacing the trans halogen with an -OR group are reproduced well by the calculations. Even the small red shift resulting from the substitution of chlorine by bromine is consistent with the DFT predictions. However, this approach was unable to explain various fine features, for instance the fact that the difference between the two transition energies does not vary smoothly. The calculations did not reveal any substantial effect of the orientation of the noncylindrical arylimido or -OR groups on the transition energies and it is not clear whether orientation is actually unimportant or masked by model simplification or other weaknesses in our approach. The fact that the calculations were actually carried out on Tc complexes could introduce some distortions when the results are applied to Re compounds, the more so that spin-orbit coupling, which cannot be taken into account in PCSPARTAN, could play a role. Another weakness of our results is that significant geometrical distortions, namely nonlinearity in the RN(O)=Re-L unit and displacement of the Re atom above the equatorial plane, were not accurately reproduced in the converged model and this could introduce small distortion in the orbital energy pattern. Nevertheless, the method is believed to reproduce the general absorption features sufficiently well to be useful in the orientation of future studies.

Concluding remarks

On the basis of the two low-energy UV–vis absorptions observed for the series of ReEX$_2$Y(dppe) compounds (with E = O or NR, X = Cl or Br, Y = Cl, Br, OR), it was established that the energies of the spin-allowed transitions between the nonbonding interbond orbital ($d_{x^2 - y^2}$) and the π-antibonding d_{xz}/d_{yz} orbitals follow the order RN=Re-X < O=Re-X < O=Re-OR. Replacing chlorine by bromine reduces the energies slightly, whereas the lengthening of the alkyl chain in the -OR group (R = Me, Et, Pr, -C$_2$H$_4$OH) had no detectable effect. We expected the bulky cyclohexyl substituent would force the Re-O-R segment to be more linear, but these expectations did not materialize (see crystal structure) and the absorption spectrum of this compound does not differ from those of compounds with a smaller R group. The aromatic group in ReOX$_2$(OPh)(dppe) seems to reduce the first transition energy slightly, but this is difficult to evaluate, because the weak d–d transitions are masked here by a strong allowed transition involving the phenoxo group.

Although the DFT calculations cannot explain all the fine details present in the data, the general trends observed experimentally are reproduced sufficiently well to attribute some predictive capability to this approach. Transition energies calculated for a few promising systems are included in Table 7. The calculations suggest that incorporating strong electro-attracting features into either the phenylimido or the phenoxo group should shift the transitions to lower energies. On this basis, perfluorophenoxo complexes ReOX$_2$-(OC$_6$F$_5$)(dppe) or perfluorophenylimido compounds Re(NC$_6$F$_5$)X$_3$(dppe) could be interesting candidates. Replacing chlorine or bromine by iodine also seems to be a possible strategy to reduce further transition energy. Preparative work is underway to test these predictions.

Structural elucidations of T_8 and Q_8 silsesquioxane cages containing two types of pendant group using ^{29}Si NMR spectroscopy[1]

Alan Richard Bassindale, David John Parker, Peter Geoffrey Taylor, and Alison Claire Watt

Abstract: The products from the reaction of octahydrosilsesquioxane (T_8-H) with different molar ratios of phenol and undec-1-ene or methyl 3,3-dimethylpent-4-enoate (MDP) in the presence of chloroplatinic acid have been analysed by ^{29}Si NMR spectroscopy. The distribution of the two different pendant groups leads to tetrad patterns where the relative chemical peak intensities reflect the selectivity for particular patterns of substitution. As well as analysing the cause of these tetrad patterns we also discuss how the regioselectivity of hydrosilylation can be determined.

Key words: T_8, Q_8, silsesquioxane, ^{29}Si NMR, hydrosilylation, tetrad pattern, regioselectivity, statistical modelling.

Résumé : Faisant appel à la spectroscopie RMN du ^{29}Si, on a analysé les produits obtenus par réaction du octahydro-silsesquioxane (T_8-H) avec divers rapports molaires de phénol et d'undéc-1-ène ou de 3,3-diméthylpent-4-énonate de méthyle (DPM), en présence d'acide chloroplatinique. La distribution des deux groupes pendants différents conduit à des patrons de tétrades dans lesquels les intensités relatives de pics chimiques sont un reflet de la sélectivité pour des patrons particuliers de substitution. En plus d'analyser la cause de ces divers patrons de tétrades, on discute aussi de la façon de déterminer la régiosélectivité de l'hydrosilylation.

Mots clés : T_8, Q_8, silsequioxane, RMN du ^{29}Si, patron de tétrade, régiosélectivité, modélisation statistique.

[Traduit par la Rédaction]

Introduction

We have long been interested in the chemistry of silsesquioxane cages from analysing their various structures, the means of selectively forming them, and the mechanism of their formation and interconversion. Amongst the most well-known and first-reported cages were the octasilsesquioxanes (the so-called T_8 and Q_8 cages) first reported by Barry et al. (1) by the base-catalyzed hydrolysis of alkyl trichlorosilanes. Subsequent studies by Martynova et al. (2) and Feher and Budzichowski (3) reported reasonable yields of T_8s by the hydrolysis of allyl- or aryltrichlorosilanes in ethanol or acetone. The simplest T_8 of all, octahydrosilsesquioxane (T_8-H), was first reported by Muller et al. (4) and has subsequently been widely used as a preformed cage precursor to many other functionalized T_8s, especially by hydrosilylation routes (5).

While much work has focussed on centro-symmetrical T_8 and Q_8 silsesquioxanes, where all eight pendant arms are the same, less work has been reported on non-centosymmetrical analogues with two or more different types of arms. Mono-septa-substituted cages **1** have been reported variously by the groups of Dutchateau (6) and Feher (7) and di-hexa-substituted cages **2** by Rebrov et al. (8) and Roesky and co-workers (9). The main reason for the lack of published work is the difficulty encountered in finding highly regiospecific routes to these mixed arm compounds and in separating the often numerous isomers formed from the typically non-regioisomer-specific routes that have been used to form them (Scheme 1).

The characterization of centro-symmetric T_8 and Q_8 cage compounds by solution ^{1}H, ^{29}Si, and ^{13}C NMR spectroscopy is relatively straightforward due to the simplicity of spectra caused by the equivalence of each silicon and pendant group. However, for non-centrosymmetric cages prepared under conditions where little or no regiocontrol is employed, more complex spectral patterns occur and separating the data for each isomer is a more complex task. Though from compound to compound the specific NMR spectra may be quite different, the NMR patterns produced by a single type of atom, for example the ^{13}C NMR of a particular carbon in a pendant group, can be indicative of the number and type of

structural environments present and so hint at the purity of the sample.

The technique of quantitatively examining the tacticity of polymers with NMR spectroscopy (normally ^{13}C or ^{1}H NMR measurements) by analysing spectral patterns has long been established as a powerful analytical tool for the polymer chemist (10), and more recently 3D triple resonance NMR techniques have been used to unambiguously assign NMR spectral patterns to individual stereosequences (11). Kawakami and co-workers (12) recently reported a stereoselective cross-dehydrocoupling reaction leading to optically active poly(methylphenyl)siloxane and used ^{13}C NMR chemical shift measurements and the triad peak patterns of the ipso carbon of the phenyl group to demonstrate the rich syndiotacticity of their polymer product.

In this work we consider the tetrad patterns observed in the ^{29}Si NMR spectra of the mixed products of the reaction between octahydrosilsesquioxane (T$_8$-H) and different ratio pairs of phenol and selected alkenes in the presence of chloroplatinic acid.

Results and discussion

To observe and analyse the mixed pendant silsesquioxanes we chose pairs of pendant groups that would give distinctly different NMR environments at silicon, specifically (alkyl-R)SiO$_3$ (T-silicon) and (aryl-O)SiO$_3$ (Q-silicon). The 40 ppm difference in the chemical shifts between these silicon environments is large enough to ensure that local electronic differences around the silicon atoms in any particular isomer will not be enough to cause the T and Q regions to overlap. Secondly, the large electronegativity difference between these two arms will ensure that there will be a big disparity between their long-range effects on the ^{29}Si NMR chemical shifts.

The ^{29}Si NMR spectra of the reaction products from the reaction of T$_8$-H with different molar ratios of phenol and undec-1-ene (T$_8$-H – phenol and undec-1-ene, 1:1) are shown in Fig. 1. Only the regions where peaks are found (i.e., the T and Q silicon regions) are shown for clarity.

Within the T silicon region there is a good separation of the silicon environments leading to four main peaks each of which is incompletely resolved into a further tetrad pattern. In the Q silicon region a similar pattern is observed although less pronounced, as its chemical shift range is far narrower and the signal-to-noise ratio is lower than for the T silicon

signals. The relative broadness and simple tetrad pattern we observe in the Q region also suggests that each of the peaks actually comprises an unresolved envelope of peaks and we propose that the same splitting pattern is occurring but that it is not fully visible due to resolution constraints. These practical limitations also mean that making meaningful conclusions on the changing isomer distribution from reactant ratio to reactant ratio is not possible using the Q silicon spectral data.

The ^{29}Si NMR spectra of the reaction products from the reaction of T$_8$-H with different molar ratios of phenol and methyl 3,3-dimethylpent-4-enoate (MDP) (T$_8$-H – phenol and MDP, 1:1) are shown in Fig. 2. Only the regions where peaks are found (i.e., the T and Q silicon regions) are shown for clarity. While we have not studied the ratios of α and β addition from the reactions of each alkene (Fig. 3) based on the reports of various groups (5), we would expect that α addition is the mechanism that predominates in each case.

Initial inspection of the T silicon region of the spectrum in Fig. 2 compared to that in Fig. 1 reveals excellent correlation between the two reaction systems and shows that the pattern we observe is not specific to a single reaction. The comments regarding the peak intensity patterns in the undec-1-ene system are equally applicable to these spectra. Similarly the Q-silicon peak pattern is less well resolved than that of the T silicons.

To explain these tetrad patterns we need to focus on one silicon (attached to the group W in Fig. 4) and examine the possible substitution patterns in its neighbours and next-nearest neighbours

In Fig. 4, all silicons attached to an X group (Si$_X$) have the same spatial relationship with the silicon Si$_W$. Similarly all silicons attached to a Y group (Si$_Y$) also have the same spatial relationship with Si$_W$. The dependency of the chemical shift of Si$_W$ on the electronegativity of the pendant groups Si$_X$, Si$_Y$, and Si$_Z$ depends primarily on the through-bond distance between them. Assuming there are two types of pendant groups A and B, there are four possible combinations of nearest neighbours (Si$_X$) that can surround Si$_W$, i.e., (1) AAA, (2) AAB, (3) ABB, (4) BBB.

For combinations 2 and 3, there are three subarrangements that cannot be distinguished by our one-dimensional NMR experiments but each of which is as probable as the next, meaning that combinations 2 or 3 are statistically 3 times more likely than 1 or 4. This will lead to an initial splitting of the Si$_W$ chemical shift into four peaks with a 1:3:3:1 ratio. In addition to this, for each combination of nearest neighbour pendant groups there are a similar set of four possible combinations of groups for the next-nearest neighbours. As for the nearest neighbours, there are three NMR-indistinguishable variants to combinations AAB and ABB in the next-nearest neighbours leading to a further splitting of the previous Si$_W$ chemical shifts in the ratio 1:3:3:1. In silicon environment Si$_Z$ there are two possible variations.

Assuming that A is a more electron-withdrawing pendant group than B, this leads to the overall set of group combinations shown in Table 1 in order of decreasing chemical shift (top to bottom in each column). Each of these combinations gives rise to a unique silicon environment.

Fig. 4. Equivalent positions around a T_8 silsesquioxane cage in relation to the Si—W bond axis.
In practice, the group attached to Si_Z has such a small and often immeasurable affect on Si_W that it cannot be easily resolved by ^{29}Si NMR spectroscopy so that all pairs of combinations "x (xxx) (xxx) A" and "x (xxx) (xxx) B" (where each x is a constant "A" or "B" in both) listed in Table 1 are typically seen to appear as a single unresolved peak. If the sites on the T_8 cage are statistically occupied based on a 4:4 reaction mixture of A and B with no selectivity for one over the other, this leads to the pair of tetrad patterns shown in Fig. 5.

To show that the sequence of chemical shifts for the structures we have proposed is reasonable, we have examined the ^{29}Si NMR spectra of a number of fully characterized mixed cages made within our group. In the following phenoxy- and cyclohexyl-substituted T_7Q_1 and T_6Q_2 cages (Fig. 6), phenoxy is the more electron-withdrawing group and so is equivalent to the generic A group in our previous discussion.

The cyclohexyl B groups occupy the remaining positions not occupied by phenoxy groups. The chemical shifts and corresponding A–B combination sequences of each highlighted silicon are also given.

Moving from left to right, as a second A group is introduced into the cage and then sequentially positioned closer, so the chemical shift of the symmetrically equivalent silicons to which they are attached increases in agreement with theory. It is also worth noting that the biggest single effect on the ^{29}Si NMR chemical shift is when the A groups are switched from a *meta* to an *ortho* relationship confirming that the influence of the pendant groups is proportional to the distance they are apart.

We have also made a number of other *ortho*-T_6Q_2 cage compounds of the type shown in Fig. 7 where Si_1 and Si_2 represent different, equivalent silicon positions in the cage and each of which has a corresponding A–B pendant group

Table 1. A summary of all the possible configurations for mixed T–Q$_8$ cages containing different numbers of pendant groups A and (or) B in the order Si$_W$ (Si$_X$) (Si$_Y$) Si$_Z$. The ^{29}Si NMR chemical shifts for these classes of compound decrease progressively down each column of the table.

neighbour and next-nearest neighbour combination. Their ^{29}Si NMR chemical shift data are displayed in Table 2. In each example, the **Si$_1$** sites are closer to the electron-withdrawing A groups than the *Si$_2$* sites, and hence, have the more downfield chemical shift.

Whilst the characteristic tetrad pattern is clearly observed in Figs. 1 and 2, the intensity ratios do not match that expected for a statistical distribution, suggesting the presence of regioselectivity that favours particular substitution patterns. These octa-substituted T–Q$_8$ cages are prepared by adding the pendant arms in a sequential manner. It is likely that one arm, for example A, may react faster than the other, B, and that once attached it may lead to the next arm (again more likely to be A) going into a specific position. This will lead to particular patterns of arm substitution with A or B being the preferred neighbour and (or) next-nearest neighbour.

To model the outcome of regioselectivity on the ^{29}Si NMR chemical shift peak pattern, we have designed a mathematical model to allow for nonstatistical distribution in the neighbours and next-nearest neighbours and calculate the relative peak intensities in the spectra for any given A–B reactant ratio. By introducing a large selectivity for B groups as neighbours to an A group and A groups as neighbours to a B group (so the A-B arrangement is arbitrarily about 9 times more likely than the A-A arrangement), the tetrad pat-

tern for a 4:4 mixture of A and B as reagents (Fig. 8) favours those regiomers where this preference is exercised and in particular the combinations A (BBB) (AAA) B and B (AAA) (BBB) A which give rise to the equal highest peaks in the distribution. A number of combinations are particularly unfavoured and their small peaks are not visible on this relative intensity scale.

By making an adjustment to the selectivity factor in our spectrum modelling equation to slightly favour A and B groups residing adjacent to each other (so the A-B arrangement is about 1.5 times more likely than the A-A arrangement), we obtain a peak distribution for Si_W-B silicons similar to that for the T silicon region in Fig. 1 or 2 at the reagent ratio 4:4. This would be in agreement with one reagent reacting faster than the other avoiding the *ortho* ar-

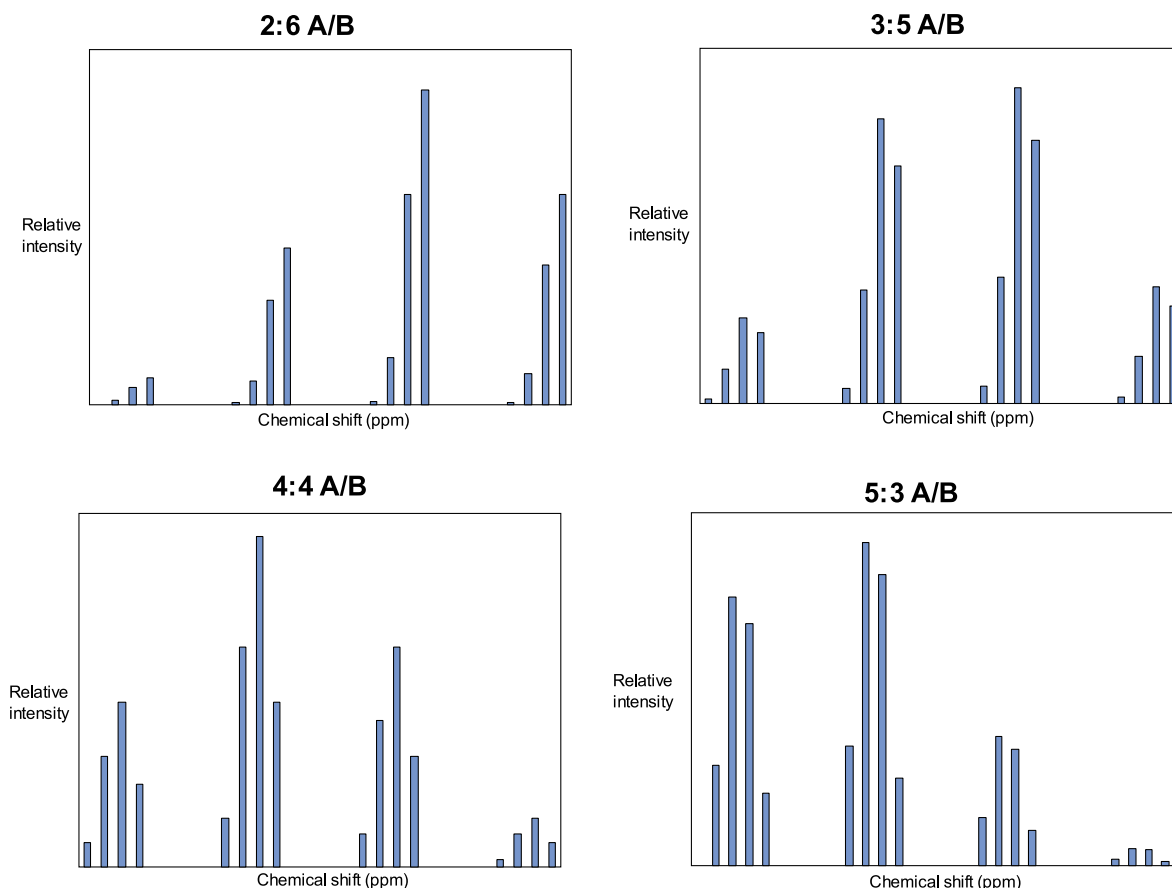
Fig. 8. The ^{29}Si NMR chemical shift tetrad pair pattern predicted for the reaction of 1 equiv. of T_8-H with a 1 equiv. of a 4:4 mixture of pendant groups A and B on the selectivity basis of an adjacent A-B arrangement being about 9 times more likely than an adjacent A-A arrangement.

4:4 A/B
rangement and these positions are then filled by the remaining reagent. Using the same selectivity factors, T-silicon peak intensity patterns for the other reagent mixtures can be obtained. In each case there is a strong resemblance between the predicted (Fig. 9) and obtained (Fig. 1 or 2) peak patterns.

Qualitatively, we have demonstrated a relationship among pendant group selectivity ratios and chemical shift peak intensity patterns in the ^{29}Si NMR spectra. We are currently undertaking quantitative studies on this reaction system with the aim of using these reproducible patterns to obtain selectivity information directly from spectral data.

Experimental

Reactions to prepare the mixed-cage T_8 compounds for NMR analysis were performed using the well-reported hydrosilylation route (5). Though thorough methods were used to eradicate moisture from our reactions such as by predrying our solvents, the presence of small traces of mois-

Fig. 9. The T-silicon ^{29}Si NMR chemical shift tetrad patterns predicted for the reaction of 1 equiv. of T_8-H with 1 equiv. of various ratios of pendant groups A and B on the selectivity basis of an adjacent A-B arrangement being about 1.5 times more likely than an adjacent A-A arrangement.


ture in the reaction pot cannot be ruled out. Careful control over the quantities and ratios of T_8-H, alkene, and phenol were used to minimize their residual appearance at the end of reactions.

In a typical reaction, T_8-H (0.400 g, 0.94 mmol), a phenol–alkene mixture (0.94 mmol), and 10 μL of a 0.02 mol/L solution of chloroplatinic acid in isopropyl alcohol were dissolved in dried toluene (5 cm³) in a small vial. The phenol–alkene mixture matched the particular molar ratio required in each reaction (i.e., 2:6, 3:5, 4:4, or 5:3).

The mixture was stirred and heated to 60 °C while being monitored by IR spectroscopy. The reaction was stopped upon the disappearance of the Si-H peak at 2156 cm⁻¹ and the solvent removed by rotary evaporation to yield the product mixture as a white solid (ca. 0.5 g). ^{29}Si NMR chemical shift measurements on a deuteriochloroform solution of this material was performed using a Jeol EX400 NMR spectrometer set to a pulse delay of 20 s. No further characterization or purification of the compound mixture was carried out.

Conclusions

We have demonstrated that ^{29}Si NMR spectroscopy can be used to analyse the mixed products of T–Q_8 cage preparations with two different types of pendant group. Without having to perform a difficult separation, the nature of the mixed-cage isomers can be judged from the relatively simple

and reproducible tetrad peak pattern. We have been able to observe different product mixtures by using different proportions of pendant groups and relate the changes in their molar ratio directly to the changes in the tetrad patterns.

In particular, we found that it was important to use pairs of pendant groups that gave rise to distinct silicon environments well-separated on the NMR chemical shift scale to ensure the peak pattern was well-resolved. In the case of the T silicons in our mixed, substituted Q–T_8 compounds, good separation and distinctive tetrad patterns were observed in both reaction systems studied. However, for the Q silicons, although elements of a tetrad pattern were observed, the chemical shift range was far narrower, meaning that much of the fine structure was unresolved in broadened peaks.

Since the analysis we are undertaking relates to the silicons in the cage, so long as the pairs of pendant groups chosen are suitably different in their effect on the silicon NMR environment then the nature of the pendant groups themselves is not important for the success of the analysis. By modelling the peak intensity ratios, we have demonstrated how selectivity may affect the ^{29}Si NMR spectrum and observed patterns within our acquired data that suggest some mild selectivity is being exercised in the reaction systems we have studied.

While we have demonstrated the application of this type of ^{29}Si NMR technique to silsesquioxane cage structures it is clear that the same methodology could have wider use in

other mixed compound systems such as in the analysis of mixed T–Q resins.

Synthesis, structure, and reactivity of hydridobis(silylene)ruthenium(IV)–xantsil complexes (xantsil = (9,9-dimethylxanthene-4,5-diyl)bis(dimethylsilyl)) — A stabilized form of key intermediates in the catalytic oligomerization–deoligomerization of hydrosilanes[1]

Masaaki Okazaki, Jim Josephus Gabrillo Minglana, Nobukazu Yamahira, Hiromi Tobita, and Hiroshi Ogino

Abstract: $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)(\eta^6\text{-}C_6H_5CH_3)$ (**1**) was found to be a catalyst for oligomerization–deoligomerization of $HSiMe_2SiMe_3$ to give $H(SiMe_2)_nMe$ (n = 1–8 at 90 °C for 2 days). Treatment of **1** with $HSiMe_2SiMe_2OR$ (R = Me, t-Bu) led to quantitative formation of $Ru\{\kappa^3(O,Si,Si)\text{-xantsil}\}(CO)(H)\{(SiMe_2\bullet\bullet\bullet O(R)\bullet\bullet\bullet SiMe_2)\}$ (R = Me (**2a**), t-Bu (**2b**)), which also worked as a catalyst for oligomerization–deoligomerization of $HSiMe_2SiMe_3$. Based on these experimental results, a mechanism involving silyl(silylene) intermediates was proposed for the oligomerization–deoligomerization of $HSiMe_2SiMe_3$. Complex **2a** reacted with MeOH in toluene-d_8 to give $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)(\eta^6\text{-toluene-}d_8)$ and $Me_2Si(OMe)_2$ with evolution of H_2. Under a CO atmosphere, **2a** was smoothly converted to its CO adduct $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)_2(H)\{(SiMe_2\bullet\bullet\bullet O(Me)\bullet\bullet\bullet SiMe_2)\}$ (**3**).

Key words: silylene complex, ruthenium, polysilane, dehydrogenative coupling, oligomerization.

Résumé : On a observé que le $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)(\eta^6\text{-}C_6H_5CH_3)$ (**1**) est un catalyseur pour l'oligomérisation–désoligomérisation du $HSiMe_2SiMe_3$ conduisant à la formation de $H(SiMe_2)_nMe$ (n = 1–8, à 90 °C pour deux jours). Le traitement du composé **1** avec du $HSiMe_2SiMe_2OR$ (R = Me, t-Bu) conduit à la formation quantitative du $Ru\{\kappa^3(O,Si,Si)\text{-xantsil}\}(CO)(H)\{(SiMe_2\bullet\bullet\bullet O(R)\bullet\bullet\bullet SiMe_2)\}$ (R = Me (**2a**), t-Bu (**2b**)) qui peut aussi être utilisé comme catalyseur pour l'oligomérisation–désoligomérisation du $HSiMe_2SiMe_3$. Sur la base de ces résultats expérimentaux, on propose un mécanisme impliquant des intermédiaires silyl(silylènes) pour l'oligomérisation–désoligomérisation du $HSiMe_2SiMe_3$. Le complexe **2a** réagit avec le MeOH dans le toluène-d_8 pour donner du $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)(\eta^6\text{-toluène-}d_8)$ et du $Me_2Si(OMe)_2$ avec évolution de H_2. Sous atmosphère de CO, le composé **2a** est facilement transformé en un adduit avec du CO, $Ru\{\kappa^2(Si,Si)\text{-xantsil}\}(CO)_2(H)\{(SiMe_2\bullet\bullet\bullet O(R)\bullet\bullet\bullet SiMe_2)\}$ (**3**).

Mots clés : complexe de silylène, ruthénium, polysilane, couplage déshydrogénant, oligomérisation.

Introduction

The chemistry of transition-metal silyl complexes is a continuously growing field and an area of active research over the past few decades (1). They have been found as key intermediates in the metal-mediated catalytic transformation reactions of organosilicon compounds (1, 2). However, studies on silyl complexes have mostly focused on the reactivity of the metal–silicon bonds which participate in the catalytic pathways (3) and only little attention has been paid to the possibility of silyl groups as ancillary ligands. Taking account of its strongly electron-releasing ability and exceptionally high trans influence (4), the silyl groups could work as an excellent ancillary ligand that generates an electron-rich and coordinatively unsaturated metal center (5, 6). Usual metal–silicon bonds are, however, highly reactive, and the

Scheme 1.

Scheme 2.

rich chemistry of transition-metal silyl complexes is derived from this reactivity (1). In most cases, the silyl ligands are lost from the metals as a result of reductive elimination, migratory insertion, nucleophilic substitution, and so on. To avoid this drawback of silyl ligands, we designed a new type of bis(silyl) bidentate ligand "xantsil" (7). Thermolysis of $Ru_3(CO)_{12}$ and 4,5-bis(dimethylsilyl)-9,9-dimethylxanthene (xantsil-H_2) at 120 °C afforded $Ru\{\kappa^2(Si,Si)$-xantsil$\}(CO)_4$ in which three carbonyl ligands can be further replaced with a η^6-toluene ligand on reflux in toluene to give $Ru\{\kappa^2(Si,Si)$-xantsil$\}(CO)(\eta^6$-$C_6H_5CH_3)$ (**1**) (Scheme 1). Complex **1** undergoes an extremely facile exchange of the toluene ligand for a free arene, indicating that **1** can formally become a source of either 12- or 14-electron, coordinatively unsaturated species (**I** or **II**), depending on the coordination mode of the xantsil ligand (Scheme 2). We report here the catalytic performance of **1** toward oligomerization–deoligomerization of $HSiMe_2SiMe_3$ to give $H(SiMe_2)_nMe$ ($n = 1$–8). We also describe the isolation and reactivity of the stabilized form of a silyl(silylene) complex, which can be considered as a key intermediate in the catalytic reaction. A part of this work has been communicated previously (7b).

Experimental section

General methods

Infrared spectra were obtained on a Horiba FT-730 spectrometer. NMR spectra were recorded on Bruker ARX-300 and AVANCE-300 instruments. Mass spectra were obtained on JEOL-HX110 and Hitachi M-2500S instruments operating in the EI mode. All reactions were performed under a dry nitrogen atmosphere using deoxygenated solvents dried with appropriate reagents. The organosilicon compounds p-Tol_2SiH_2 (**8**), $HSiMe_2SiMe_3$ (**9**), and $HSiMe_2SiMe_2OR$ (R = Me (**10**), t-Bu (**11**)) were synthesized according to published procedures. The complex **1** was synthesized by a procedure we previously reported (7a).

Reaction of 1 with p-Tol_2SiH_2

A Pyrex NMR tube (5 mm o.d.) was charged with **1** (5.0 mg, 0.00916 mmol) and was then attached to a vacuum line. p-Tol_2SiH_2 (19.5 mg, 0.00916 mmol) and chloroform-d (0.4 mL) were trap-to-trap transferred into it. The NMR tube
was flame-sealed and the reaction was monitored by ^1H NMR spectroscopy. The sample was heated at 60 °C for 3 h and a red solution was obtained. The ^1H NMR spectral data showed that **1** was completely consumed and free toluene and xantsil-H_2 were formed as the major products. Unidentified signals can also be observed but their signals are of low intensities.

Oligomerization–deoligomerization of $HSiMe_2SiMe_3$ in the presence of 1

(a) NMR scale monitoring of the reaction

A Pyrex NMR tube (5 mm o.d.) was charged with **1** (13.4 mg, 0.0246 mmol) and was then attached to a vacuum line. $HSiMe_2SiMe_3$ (65.0 mg, 0.492 mmol) and dichloromethane-d_2 (800 μL) were trap-to-trap transferred into it. The NMR tube was flame-sealed and the reaction was monitored by ^1H NMR spectroscopy. At room temperature, the solution turned yellow in color and several signals corresponding to oligomerization–deoligomerization products $H(SiMe_2)_nMe$ appeared. No further changes were observed after 40 h at room temperature.

(b) GC and GC–MS monitoring of the reaction with a catalytic amount of 1

$HSiMe_2SiMe_3$ (65.0 mg, 0.49 mmol), n-decane (10.0 μL as an internal standard), and **1** (270 μg, 0.1 mol%) were placed in a 5 mL flask and the solution was stirred at room temperature for 2 days. The reaction was monitored by gas chromatography. Formation of $H(SiMe_2)_nMe$ in the molar ratio of 81 ($n = 1$) : 56 ($n = 2$) : 11 ($n = 3$) : 3 ($n = 4$) : 1 ($n = 5$) was observed based on the peak areas of the gas chromatogram. The products were confirmed by GC–MS.

When the same reaction was performed at 90 °C for 2 days, formation of products with n of up to 8 were observed in the molar ratio of 346 ($n = 1$) : 96 ($n = 2$) : 83 ($n = 3$) : 64 ($n = 4$) : 35 ($n = 5$) : 13 ($n = 6$) : 4 ($n = 7$) : 1 ($n = 8$). These silicon-containing products were not isolated.

Synthesis of Ru{κ^3(*O,Si,Si*)-xantsil}(CO)(H){(SiMe$_2$•••O(Me)•••SiMe$_2$)} (2a)

HSiMe$_2$SiMe$_2$OMe (81.0 mg, 0.546 mmol) was added to a solution of **1** (150 mg, 0.275 mmol) in CH$_2$Cl$_2$ (2.0 mL). After 90 min of stirring at room temperature, volatiles were removed under reduced pressure to give a pale yellow solid. Washing the solid with hexane three times afforded a colorless solid that was characterized as Ru{κ^3(*O,Si,Si*)-xantsil}(CO)(H){(SiMe$_2$•••O(Me)•••SiMe$_2$)} (**2a**). Yield: 160 mg, 98%. MS (EI, 70 eV) m/z: 602 (M$^+$, 72), 512 (M$^+$ – HMe$_2$SiOMe, 79), 480 (100). Anal. calcd. for C$_{25}$H$_{40}$RuO$_3$Si$_4$: C 49.88, H 6.70; found: C 49.79, H 6.67.

Synthesis of Ru{κ^3(*O,Si,Si*)-xantsil}(CO)(H){(SiMe$_2$•••O(*t*-Bu)•••SiMe$_2$)} (2b)

HSiMe$_2$SiMe$_2$O-*t*-Bu (35.0 mg, 0.184 mmol) was added to a solution of **1** (50.0 mg, 0.0916 mmol) in CH$_2$Cl$_2$ (1.0 mL). After 90 min of stirring at room temperature, the reaction mixture was treated similarly as described for the synthesis of **2a** to afford **2b** as a colorless solid. Yield: 50.0 mg, 84%. MS (EI, 70 eV) m/z: 587 (M$^+$ – *t*-Bu, 26), 513 (M$^+$ – *t*-Bu-SiMe$_2$O, 41), 325 (100). Anal. calcd. for C$_{28}$H$_{46}$RuO$_3$Si$_4$: C 52.21, H 7.20; found: C 51.71, H 7.16.

Oligomerization–deoligomerization of HSiMe$_2$SiMe$_3$ in the presence of 2a

A Pyrex tube (7 mm o.d.) was charged with **2a** (10 mg, 0.017 mmol), HSiMe$_2$SiMe$_3$ (44 mg, 0.33 mmol), and decane (10 µL) and was connected to the vacuum line. The tube was flame-sealed under vacuum and placed in the oil bath at 90 °C. After heating for 2 days, the tube was unsealed in the glovebox. Formation of H(SiMe$_2$)$_n$Me with the molar ratio of 12 ($n = 1$) : 6 ($n = 2$) : 5 ($n = 3$) : 5 ($n = 4$) : 4 ($n = 5$) : 2 ($n = 6$) : 3 ($n = 7$) : 1 ($n = 8$) was observed based on the peak areas of the gas chromatogram. These organosilicon compounds were not isolated.

Reaction of 2a with MeOH in toluene-*d*$_8$

A Pyrex NMR tube (5 mm o.d.) was charged with **2a** (5.0 mg, 0.0083 mmol) and was then attached to a vacuum line. Toluene-*d*$_8$ (0.4 mL) and MeOH (6.7 mL, 0.17 mmol) were trap-to-trap transferred into it. The NMR tube was flame-sealed and the reaction was monitored by ^{1}H and ^{29}Si NMR spectroscopy. Within 1 h at room temperature, the signals of **2a** were cleanly replaced by those of Ru{κ^2(*Si,Si*)-xantsil}(CO)(η^6-toluene-*d*$_8$) (**1**-*d*$_8$) and Me$_2$Si(OMe)$_2$. NMR spectroscopic data of **1** were used to identify **1**-*d*$_8$ while an authentic sample matched the NMR and GC data for Me$_2$Si(OMe)$_2$. A singlet signal corresponding to H$_2$ was ob-served at δ 4.51. In this experiment, the products were not isolated.

Reaction of 2a with CO

A Schlenk tube was charged with **2a** (75 mg, 0.13 mmol) and toluene (12 mL). The solution was degassed by freeze–pump–thaw cycles and filled with CO introduced from a balloon. The procedure was repeated five times. After stirring the solution at room temperature for 16 h, volatiles were removed in vacuo. The yellow residue was washed with hexane to afford Ru{κ^2(*Si,Si*)-xantsil}(CO)$_2${(SiMe$_2$•••O(Me)•••SiMe$_2$)} (**3**) as a white solid. Yield: 67 mg, 85%. IR (KBr pellet, cm^{-1}): 1954 (ν (CO$_{asym}$)). MS (FAB) m/z: 630 (M$^+$, 17), 602 (M$^+$ – CO, 24), 512 (M$^+$ – CO – SiMe$_2$OMe, 64). ^{1}H NMR (300 MHz, C$_6$D$_6$) δ: –3.81 (s, 1H, RuH), 0.40 (s, 12H, SiMe), 1.05 (s, 12H, SiMe), 1.51 (s, 6H, CMe$_2$), 2.33 (s, 3H, OMe), 7.16 (t, ^3J = 7.4 Hz, 2H, Ar), 7.29 (dd, ^3J = 7.4 Hz, ^4J = 1.6 Hz, 2H, Ar), 7.56 (dd, ^3J = 7.4 Hz, ^4J = 1.6 Hz, 2H, Ar). ^{13}C NMR (75.5 MHz, C$_6$D$_6$) δ: 6.3, 9.8 (SiMe), 27.3 (C*Me*$_2$), 36.3 (*C*Me$_2$), 51.4 (OMe), 123.4, 124.9, 131.0, 133.2, 134.6, 160.1 (Ar), 202.2 (CO). ^{29}Si NMR (C$_6$D$_6$) δ: –8.7 (xantsil), 97.3 (silylene). Anal. calcd. for C$_{26}$H$_{40}$RuO$_4$Si$_4$: C 49.57, H 6.40; found: C 49.04, H 5.98.

X-ray crystal structure determination of 2b and 3

Intensity data for X-ray crystal structure analysis were collected at 150 K on a Rigaku RAXIS-RAPID Imaging Plate diffractometer with graphite-monochromated Mo Kα radiation. A total of 44 images, corresponding to 220.0° oscillation angles, were collected with two different goniometer settings. Exposure time was 0.30 min for **2b** and 2.00 min for **3** per degree. Readout was performed in the 0.100 mm pixel mode. Numerical absorption corrections were applied on each crystal shape. The structures were solved by Patterson methods (PATTY) and refined by the least-squares technique. All non-hydrogen atoms were located and refined anisotropically. An atomic coordinate of a hydrogen atom connected to Ru in **3** was determined by the difference Fourier synthesis and refined isotropically. Other hydrogen atoms were placed at their geometrically calculated positions. Data reduction and refinement were performed using teXsan software packages. Crystallographic data of **2b** and **3** are listed in Table 1.[6]

Results and discussion

Reaction of 1 with dihydrosilane

It has been reported that transition-metal complexes mediate the dehydrogenative coupling of polyhydrosilanes and (or) redistribution of substituents on silicon atoms (2). The activity of Ru{κ^2(*Si,Si*)-xantsil}(CO)(η^6-toluene) (**1**) toward this reaction was first investigated. When a solution of **1** and excess p-Tol$_2$SiH$_2$ in CDCl$_3$ was heated at 60 °C for 3 h, a red solution containing xantsil-H$_2$ and toluene as the major

[6] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). products was obtained (eq. [1]). The ^{1}H NMR spectrum showed the signals for xantsil-H$_2$, toluene, and other less-intense signals of the unidentified by-products, which did not provide any sign of dehydrogenative coupling or redistribution reaction of the dihydrosilane.

[1]

1 + p-Tol$_2$SiH$_2$ $\xrightarrow{\text{60 °C, 3 h}}$ xantsil-H$_2$ + C$_6$H$_5$CH$_3$ + etc.
Reaction of 1 with hydrodisilane

A CD$_2$Cl$_2$ solution of HSiMe$_2$SiMe$_3$ was treated with a catalytic amount of **1** (5.0 mol%) and the reaction was monitored by ^{1}H NMR spectroscopy. Oligomerization and deoligomerization occurred to give H(SiMe$_2$)$_n$Me (n = 1–5). Identification of the oligosilanes was carried out by comparison of spectroscopic data with authentic samples (9, 12).[7] The reaction was performed using 0.1 mol% of **1** and was monitored by GC and GC–MS spectroscopy. The oligomerization–deoligomerization reactions proceeded at

room temperature, and after 2 days, H(SiMe$_2$)$_n$Me (n = 1–5) was formed in the molar ratio of 81 (n = 1) : 56 (n = 2) : 11 (n = 3) : 3 (n = 4) : 1 (n = 5) (eq. [2]). A similar reaction performed at 90 °C provided H(SiMe$_2$)$_n$Me (n = 1–8) in the molar ratio of 346 (n = 1) : 96 (n = 2) : 83 (n = 3) : 64 (n = 4) : 35 (n = 5) : 13 (n = 6) : 4 (n = 7) : 1 (n = 8). The products were also confirmed by ^{1}H NMR spectral data.

Scheme 3.

[M] = Ru(xantsil)(CO)

HSiMe$_2$(SiMe$_2$)$_n$Me to a coordinatively unsaturated [Ru(xantsil)(CO)] species gives a hydrido(silyl)ruthenium(IV) intermediate **A**, which undergoes 1,2-silyl migration to form a hydrido(silyl)(silylene) intermediate **B**. Reductive elimination of Si-H gives H(SiMe$_2$)$_n$Me and a coordinatively unsat-

urated silylene complex **C**, which in turn undergoes oxidative addition of H(SiMe$_2$)$_m$Me to generate hydrido(silyl)(silylene) intermediate **D**. 1,2-Migration of the silyl ligand followed by Si-H reductive elimination regenerates the coordinatively unsaturated [Ru(xantsil)(CO)] species together with H(SiMe$_2$)$_{m+1}$Me. The 1,2-migration steps of the silyl groups are responsible not only for the cleavage of silicon–silicon bonds which leads to deoligomerization, but also for the formation of silicon–silicon bonds, which leads to oligomerization.

Transition-metal-mediated redistribution of hydropolysilanes have been reported for titanium (13), zirconium (13), and platinum (14). Complex **1** is the first ruthenium catalyst that is effective in the redistribution of hydropolysilanes.

Reaction of 1 with HSiMe$_2$SiMe$_2$OMe

The mechanism in Scheme 3 involves the silyl(silylene) complexes as key intermediates. This kind of complex having a metal–silicon double bond is highly reactive and difficult to isolate but can be internally stabilized by an alkoxy group (15). Thus, treatment of **1** with HSiMe$_2$SiMe$_2$OR (R = Me, *t*-Bu) in CH$_2$Cl$_2$ resulted in the clean formation of Ru{κ^3(*O,Si,Si*)-xantsil}(CO)(H){SiMe$_2$•••O(R)•••SiMe$_2$} (**2a** (R = Me), **2b** (R = *t*-Bu)), which were isolated in 98% and 84% yields, respectively (eq. [3]). Spectroscopic data of **2a** and **2b** are summarized in Table 2. Spectroscopic features of **2a**

Scheme 4.

R = Me (**2a**, 98%),
t-Bu (**2b**, 84%)

Si = SiMe$_2$
and **2b** are almost the same and, thus, all further discussions of spectroscopic data refer to **2a**. The ^{29}Si{^{1}H} NMR spectrum shows two singlet signals at δ 14.6 and 107.4, which are assigned to the xantsil silicon and silylene silicon atoms, respectively. The chemical shift of silylene moieties is characteristic of base-stabilized silylene complexes (1*c*). The ^{1}H NMR spectrum of **2a** shows a singlet at –1.75 ppm that can be assigned to Ru-H. Four singlet signals for the methyl groups on silicon atoms appear at –0.07 (6H), 0.67 (6H), 0.89 (6H), and 1.01 (6H), which are assigned to SiMe(1), SiMe(2), SiMe(3), and SiMe(4), respectively (see Table 2). The signals of the CMe$_2$ part on xantsil appear inequivalently at 1.21 (Me(5)) and 1.43 (Me(6)). These assignments are established by the combination of ^{29}Si-^{1}H COLOC and ^{1}H NOESY spectra. In the ^{1}H NOESY spectrum, a positive correlation peak is clearly observed between Ru-H and SiMe(4) resonances, indicating that the Ru-H hydrogen atom is located within the Si^A-Ru-Si^B angle.

The ^{1}H NOESY spectrum also shows a negative correlation peak between the signals of methyl groups on the silylene silicon atoms (Me(1) and Me(2)), implying the intramolecular exchange process of the methyl groups on the bis(silylene) ligand. The dynamic process probably involves the cleavage of a silicon–oxygen bond, followed by rotation of the resulting donor-free silylene moiety around the ruthenium–silicon double bond to exchange the methyl group environments (Scheme 4). This mechanism is essentially the same as those of the exchange of SiMe groups in Cp(CO)$_2$W{SiMe$_2$•••Do•••SiMe$_2$} (Do = OMe, NEt$_2$) (16) and Cp*(Me$_3$P)Ru{SiMe$_2$•••OR•••SiMe$_2$} (R = Me, *t*-Bu) (11). The strongly electron-releasing xantsil ligand is expected to make the ruthenium center electron rich. Enhanced back donation from the metal *d*π orbital toward the Si-O σ* orbital weakens the Si—O bond and accelerates its cleavage to generate the base-free silyl(silylene) complex **E**. This intermediate **E** is also stabilized by the electron-rich ruthenium center through back donation from the metal *d*π orbital toward the empty *p* orbital of the silylene silicon atom.

The ^{13}C{^{1}H} NMR spectrum displays the expected resonances for **2a** that are consistent with the ^{1}H NMR spectral

data. The IR spectrum shows a strong band at 1929 cm^{-1} attributable to the CO-stretching vibration mode. Elemental analysis and mass spectral data are in good agreement with the formula of **2a**.

X-ray structure analysis of 2b

The structure of **2b** was unequivocally determined by the X-ray diffraction study. The crystal contains two independent molecules **A** and **B**, but there is no essential difference between them. The selected bond lengths and angles for **2b** are listed in Table 3. All further discussions of structural details refer to molecule **A**. The ORTEP view of **A** is shown in Fig. 1. The Ru-H hydrogen atom could not be located crystallographically, but the ^{1}H NOESY spectrum clearly shows that it must be found inside the unusually widened Si(3A)-Ru(A)-Si(4A) angle (119.4(1)°). Thus, the molecule takes a distorted seven-coordinate pentagonal bipyramid geometry with the nearly planar arrangement of all four silicon atoms (mean deviation from the least square Si$_4$ plane: 0.0161 Å). The xanthene moiety is strongly bent (dihedral angle between the arene rings C(14A)-C(19A) and C(20A)-C(25A): 136.5°). The bond lengths of Ru-Si (bis(silylene)) (avg. 2.399 Å) are shorter than those of Ru-Si (xantsil) (avg.

Scheme 5.
Ru = Ru(xantsil)(CO), Si = SiMe$_2$

2.434 Å), but significantly longer than those of the previously reported bis(silylene) ruthenium complexes (2.31–2.33 Å) (17). This lengthening could be due to the trans influence of silyl groups (4) and (or) to the weaker back donation from the highly oxidized Ru(IV) center to silicon. The distance of Ru-O(2A) is 2.289(8) Å, which clearly indicates that the oxygen atom of the xanthene moiety is coordinated to the ruthenium center to satisfy the 18-electron rule. Thus, xantsil in **2b** is working as a terdentate ligand.

Catalytic oligomerization–deoligomerization of HSiMe$_2$SiMe$_3$ in the presence of 2a

To get further convincing evidence in support of the existence of silyl(silylene) complexes in the catalytic reaction of eq. [2], we carried out the thermal reaction of HSiMe$_2$SiMe$_3$ in the presence of a catalytic amount of **2a**. Indeed, HSiMe$_2$SiMe$_3$ was converted to H(SiMe$_2$)$_n$Me (n = 1–8) after 2 days at 90 °C with the molar ratios of 12 (n = 1) : 6 (n = 2) : 5 (n = 3) : 5 (n = 4) : 4 (n = 5) : 2 (n = 6) : 3 (n = 7) : 1 (n = 8). This result clearly showed that the bis(silylene) complex **2a** can be incorporated into the catalytic cycle in Scheme 3.

Reaction of 2a with MeOH

It has been reported that silylene complexes show high reactivity toward various nucleophiles such as alcohols (18). The reaction of **2a** with MeOH in toluene-d_8 was carried out and monitored by NMR spectroscopy. It proceeded cleanly to give Ru{κ^2(Si,Si)-xantsil}(CO)(η^6-toluene-d_8) (**1**-d_8) and Me$_2$Si(OMe)$_2$ with evolution of H$_2$ gas (eq. [4]). Spectroscopic data of **1** was used to identify **1**-d_8, while that of the authentic sample was used to identify Me$_2$Si(OMe)$_2$.

[4]

$$2a + 3 MeOH \xrightarrow[\text{Toluene-}d_8]{\text{r.t.}} 1\text{-}d_8 + 2 Me_2Si(OMe)_2 + 2 H_2$$
In a proposed mechanism for this reaction (Scheme 5), the highly polarized ruthenium–silylene bond is attacked by MeOH to give a hydrido(methoxysilyl)ruthenium intermediate **F**. Reductive elimination of dihydrogen gives bis(methoxysilyl) complex **G**. In path **a**, successive nucleophilic attacks of excess MeOH toward the silyl silicon atom, followed by reductive elimination of H$_2$, gives **1**-d_8 and two

Fig 1. An ORTEP drawing of **2b**.
molecules of Me$_2$Si(OMe)$_2$ via intermediate formation of **H**. An intramolecular nucleophilic attack of the methoxy group in **G** must also be considered, which leads to the formation of the silylene complex intermediate **I** (path **b**). Nucleophilic attack of MeOH on a silylene silicon atom in **I** gives **H**, which is finally converted to **1**-d_8 through an intermolecular nucleophilic attack by MeOH.

Reaction of 2a with CO

When the reaction of **2a** with 1 atm (1 atm = 101.325 kPa) of CO was monitored by means of ^{1}H NMR spectroscopy at room temperature, quantitative formation of **3** was observed (eq. [5]). An analytically pure sample was obtained in 85% yield by washing the residue with hexane.

[5]

Si = SiMe$_2$
The X-ray diffraction study of **3** was performed using a colorless crystal obtained by cooling a toluene–hexane solution at –30 °C. The structure of **3** is depicted in Fig. 2. The selected interatomic distances and bond angles for **3** are listed in Table 4. The distance of Ru-O(4) is 3.581(2) Å, indicating the cleavage of the Ru—O bond in **2a**. One CO molecule is coordinated to the resulting vacant site of the ru-

Fig 2. An ORTEP drawing of **3**.

Si(2)-Ru-H(1)	145(1)
Si(3)-Ru-H(1)	54(1)
Si(4)-Ru-H(1)	55(1)
C(1)-Ru-H(1)	88(1)
C(2)-Ru-H(1)	92(1)
Ru-Si(1)-O(3)	94.71(6)
Ru-Si(2)-O(3)	94.50(6)
Si(1)-O(3)-Si(2)	100.09(9)

thenium center. The hydrogen atom of the Ru—H bond was located inside the widened Si(3)-Ru-Si(4) angle (109.37(2)°) by the difference Fourier synthesis and refined isotropically. Thus, complex **3** also takes a distorted seven-coordinate pentagonal bipyramid geometry with the nearly planar arrangement of all four silicon atoms and one hydrogen atom. The bond lengths of Ru—Si (silylene) (avg. 2.41 Å) and Ru—Si (xantsil) (avg. 2.50 Å) are similar to the values of **2b**.

In the ^{1}H NMR spectrum, the CMe_2 portion and the Si-Me groups on xantsil, as well as the Si-Me groups on the bis(silylene) ligand each appear as one singlet signal at δ 1.51 (CMe_2, 6H)), 0.40 (SiMe, 12H), and 1.05 ppm (SiMe, 12H), although the assignment of Si-Me groups is not clear. If complex **3** maintains the crystal structure illustrated in Fig. 2 in solution without any dynamic behavior, six singlet signals should appear. However, this is not the case even at 210 K. A likely process is the rapid inversion of the puckered chelate ring of xantsil. This dynamic behavior of **3** is in sharp contrast with Ru{κ^2(*Si,Si*)-xantsil}$(CO)_4$. In this complex, each of the CMe_2 and $SiMe_2$ groups on xantsil shows two signals at 210 K. On warming, each of them coalesces and finally becomes a sharp singlet at room temperature (7*a*). Other spectroscopic features of **3** resemble those of **2**.

Conclusions

Over the past few decades, silyl(silylene) complexes have been proposed as intermediates in the stoichiometric and catalytic metal-mediated transformation reactions of organosilicon compounds (2, 3*b*). The results described here pro-

vide further evidence for the participation of silyl(silylene) complexes in the catalytic cycles of the metal-mediated oligomerization–deoligomerization of hydrodisilanes.

Reactivity of **2a** toward CO indicates that complex **2a** is labile and generates a *coordinatively unsaturated silylene complex* via dissociation of the xantsil oxygen atom under mild conditions. A number of metal-mediated stoichiometric and catalytic transformations of organosilicon compounds appear to involve coordinatively unsaturated silylene complexes (1, 2, 3, 19). Although synthesis and reactivity of silylene complexes have been reported, only scattered reports on coordinatively unsaturated ones are available (19). Complex **3** would be an ideal candidate for examining the reactivity of coordinatively unsaturated silylene complexes.

Solid-state NMR investigations of the polymer route to SiBCN ceramics[1]

Christel Gervais, Florence Babonneau, Lutz Ruwisch, Ralf Hauser, and Ralf Riedel

Abstract: Silicon based polymers obtained by ammonolysis of organochlorosilylboranes and their pyrolytic transformation into Si-B-C-N ceramics were studied by a detailed solid-state NMR investigation. Sol–gel polymerisation/pyrolysis routes were applied to form Si-B-C-N materials with exceptional high-temperature stability. The polymer to ceramic conversion was analyzed by ^{11}B, ^{13}C, ^{15}N, and ^{29}Si MAS NMR spectroscopy as well as by thermal analysis measurements coupled with mass spectroscopy (TGA–MS). The results showed that a significant change in the carbon-, silicon-, and boron-coordination environments occurs during pyrolysis. An evolution of cleavage of silcon–carbon–boron bridges and the formation of new BN_3 sites was observed. The NMR data obtained suggest the presence of a rather homogeneous dispersion of the boron atoms in the as synthesized silicon carbonitride phase, supporting the high thermal stability with respect to decomposition found in these compounds.

Key words: organosilicon polymers, polymer pyrolysis, SiBCN ceramics, solid-state NMR.

Résumé : On a fait une étude RMN détaillée à l'état solide des polymères à base de silicium obtenus par ammonolyse d'organochlorosilylboranes et de leur transformation pyrolytique en céramiques Si-B-C-N. On a utilisé des voies de polymérisation/pyrolyse sol–gel pour obtenir des matériaux Si-B-C-N ayant une stabilité exceptionnelle aux températures élevées. On a analysé la conversion du polymère en céramique par RMN à la rotation de l'angle magique (« MAS ») du ^{11}B, du ^{13}C, du ^{15}N et du ^{29}Si ainsi que par des mesures d'analyses thermiques couplées à la spectrométrie de masse (SM–ATG). Les résultats montrent qu'il se produit un changement significatif dans les environnements de coordination du carbone, du silicium et du bore au cours de la pyrolyse. On a observé une évolution du clivage des ponts silicium–carbone–bore et la formation de nouveaux sites BN_3. Les données de la RMN suggèrent la présence d'une dispersion relativement homogène des atomes de bore dans la phase carbonitrure de silicium telle que synthétisée et cette observation est en accord avec la grande stabilité thermique observée de ces composés vis-a-vis de la décomposition.

Mots clés : polymères organiques du silicium, pyrolyse de polymères, céramiques SiBCN, RMN à l'état solide.

Introduction

The polymeric approach to refractory non-oxide ceramics is a process of great interest offering possibilities of obtaining composite and shaped materials such as fibres, films, or bulk pieces from soluble or fusible starting polymers. Recently, it has ben demonstrated that Si-B-C-N ceramics derived from boron-modified polymers exhibit exceptional high-temperature stability (1–4).

The influence of the polymer architecture on the structure of the final ceramic has been clearly demonstrated for Si-C (5) and Si-C-N (6) systems. It is, therefore, essential to control as much as possible the polymerisation and ceramization steps and consequently to have effective characterization tools that can follow the changes in local environments during polymer-to-ceramic conversion. Solid-state NMR studies (^{11}B, ^{13}C, ^{15}N, and ^{29}Si) have been shown to be extremely useful in this field (7–13).

^{15}N is a spin $I = 1/2$ with a very low sensitivity in natural abundance (3.8×10^{-6} compared to ^{1}H) but this drawback may be overcome by ^{15}N enrichment and the use of cross-polarization (CP) techniques, taking advantage of the ^{1}H–^{15}N dipolar coupling. These techniques are consequently very sensitive to the proton environment of the nitrogen sites through the ^{1}H–^{15}N distances. Studies on B-N containing reference compounds have shown that it was possible to distinguish N sites depending on their degree of protonation by using the inversion recovery cross polarization (IRCP) sequence (14) and this technique was successfully extended to the study of polymers (11).

^{11}B, ^{13}C, and ^{29}Si are abundant enough to be studied without enrichment but ^{13}C spectra were always recorded with CP techniques to obtain a reasonable signal-to-noise (S/N) ratio. Measurement of high-resolution ^{11}B spectra ($I = 3/2$)

can be difficult because of the second-order quadrupolar interaction, which distorts the signals and can only be partially averaged by MAS (15).

In this paper, we present a detailed solid-state NMR characterization of the polymers obtained by ammonolysis of organochlorosilylboranes and their pyrolytic transformation into Si-B-C-N ceramics. By combination of the multinuclear NMR results, we succeeded in the characterization of intermediate species occuring during the ceramization process as well as of the amorphous solid-state structures formed.

Experimental

NMR experiments

The MAS NMR spectra were recorded on a Bruker MSL 300 spectrometer operating at 75.47 MHz for ^{13}C, 30.41 MHz for ^{15}N, and 59.63 MHz for ^{29}Si, and on a Bruker MSL 400 spectrometer at a frequency of 128.28 MHz using a Doty probe with no probe background for ^{11}B. Samples were spun at 4 kHz for the ^{29}Si experiments and at 5 kHz for the ^{13}C and ^{15}N experiments, using 7 mm ZrO$_2$ rotors, while samples were spun at 10 kHz for the ^{11}B experiments using 5 mm Si$_3$N$_4$ rotors. All rotors were filled up in a glovebox under a dried argon atmosphere. All the CP and IRCP were performed under the same Hartmann–Hahn match condition: both RF channel levels ($\omega_{1S/2\pi}$ and $\omega_{1I/2\pi}$) were set at about 42 kHz.

The ^{13}C CP-MAS NMR spectra were recorded with a spectral width of 20 and 50 kHz depending on the heat treatment temperature of the samples, using 2 K data points in the time domain. The number of transients per spectra varied from 200 to 1200. IRCP-MAS NMR spectra were recorded with inversion times (t_i) ranging from 5 to 300 µs and a contact time of 1 ms, which was chosen to maximize the polarization of the ^{13}C nuclei. The recycle delays between pulses was 6 s. The ^{13}C NMR chemical shifts were determined relative to TMS via solid adamantane (δ = 29.4 and 38.5 ppm).

The ^{15}N CP-MAS NMR spectra were recorded with a spectral width of 30 kHz, using 2 K data points and 2–4 ms contact time depending on the heat treatment temperature. The recycle delays between pulses was 10 s. Chemical shifts were referenced to solid NH$_4$NO$_3$ (10% enriched sample, $\delta_{iso}(^{15}NO_3)$ = –4.6 ppm compared to CH$_3$NO$_2$ (δ = 0 ppm)).

The ^{29}Si MAS NMR spectra were recorded with a spectral width of 30 kHz, a pulse angle around 25° (1.5 µs), and a recycle delay between pulses of 60 s, using 4 K data points. The ^{29}Si CP-MAS NMR spectra were recorded with recycle delays of 6 s and contact times ranging from 1 to 10 ms, while for the ^{29}Si IRCP-MAS NMR spectra, the inversion times varied from 5 µs to 1 ms, with an optimized contact time of 3 ms. Chemical shifts were determined relative to TMS (δ_{Si} = 0).

The ^{11}B MAS NMR spectra were recorded with a spectral width of 50 kHz, using 4 K data points. All ^{11}B NMR chemical shifts were determined relative to liquid BF$_3$OEt$_2$ (δ = 0 ppm) and the number of FIDs varied from 400 to 1500. A 1 µs single-pulse excitation was used ($t_{90°}(BF_3OEt_2)$ = 8 µs) with a 5 s repetition time.

Proton decoupling was always applied during data acquisition. A 50 Hz line broadening was applied to the FIDs be-

Table 1. Composition of the polycarbosilazanes and their pyrolysis products at 1000 °C.

Sample	Temperature	Chemical composition
1/1	Room temperature	$Si_{1.2}B_{1.0}C_{3.9}N_{2.2}H_{11.5}$
2/1	Room temperature	$Si_{2.0}B_{1.0}C_{6.3}N_{2.7}H_{19.2}$
3/1	Room temperature	$Si_{3.0}B_{1.0}C_{9.3}N_{2.9}H_{25.3}$

2/1	1000 °C	$Si_{2.0}B_{1.0}C_{3.4}N_{2.3}$
3/1	1000 °C	$Si_{3.0}B_{1.0}C_{4.3}N_{2.0}$

fore Fourier transform. The spectra were simulated with the DMFIT program (16), which has been developed specifically for solid-state NMR experiments, including the simulation of quadrupolar shapes (17).

TGA–MS measurements

The thermal gravimetric analysis of the ceramics was performed by heating up to 1200 °C in a helium atmosphere (0,1 MPa He, heating rate 2 °C/min) with a Netzsch STA 429 coupled with a mass spectrometer (Balzers 420). Al$_2$O$_3$ crucibles were used for measurements.

Sample preparation

The investigated polyborocarbosilazanes were synthesized by reaction of NH$_3$ with organochlorosilylboranes (eq. [1]).
These molecular precursors, obtained by hydroboration reactions of unsaturated organosilanes, exhibit well-defined Si/B ratios ranging from 3/1 to 1/1 (18). Three distinct polymers were investigated, exhibiting Si/B ratios of 1/1, 2/1, and 3/1. It is important to note that the Si/B ratios are fully retained after ammonolysis (Table 1). ^{15}N-enriched polymers were obtained using 10% ^{15}N enriched ammonia (purchased from Isotec). The proposed molecular structures of the polymers as presented in Fig. 1 are based on the synthesis procedure as well as on liquid-state NMR and FT-IR studies (19).

Results and discussion

Native polymers

^{11}B MAS NMR

The ^{11}B MAS NMR spectra obtained for the polymers with particular Si/B-ratios 1/1, 2/1, and 3/1 are quite different and exhibit broad signals around 25, 40, and 70 ppm, respectively (Fig. 2). It should be noticed that ^{11}B is a quadrupolar nucleus (I = 3/2) and that the isotropic value of the chemical shift for such a nucleus doesn't correspond to the barycentre of the resonance signal, which is dominated by the second-order quadrupolar broadening (17). According to the proposed structures for each system, the presence of BCN$_2$-, BC$_2$N-, and BC$_3$-coordination environments are expected for the 1/1, 2/1, and 3/1 polymers (Fig. 1). The chemical shift values reported in solution for such sites are

Fig. 1. Proposed structures for 1/1, 2/1, and 3/1 polymers.

Fig. 2. ^{11}B MAS NMR spectra of 1/1, 2/1, and 3/1 polymers (* indicates spinning sidebands).
summarized in Table 2. BCN_2 signals are expected around 33 ppm in noncyclic structures up to 37 ppm in a $(B-N)_3$ six-membered ring structure, while BC_2N signals range between 44 ppm when the nitrogen atom is bonded to carbons, up to 59 ppm when it is bonded to silicon atoms. BC_3 signals are observed at much a lower field, around 86 ppm in $B(CH_3)_3$ for instance.

The spectrum obtained for the 1/1 sample can be simulated with a main signal at δ_{iso} = 37 ppm (C_Q = 2.8 MHz, η = 0) and a smaller one at δ_{iso} = 26 ppm (C_Q = 2.8 MHz, η = 0). The first one can be attributed to the expected BCN_2 site. The assignment of the second signal is more difficult but the chemical shift value suggests the presence of BN_3 sites. The 2/1 sample can be simulated with a unique signal at δ_{iso} = 45 ppm assigned to a BC_2N site. Nonetheless, this spectrum is large (C_Q = 3 MHz), which is quite unusual. This finding suggests the presence of BCN_2 coordination. The spectrum recorded for the 3/1 sample is broad with superposition of a

spinning side band. Simulation of the spectrum gives a broad main signal around 78 ppm indicating a BC_3 environment and a smaller one at 42 ppm, which can be related to BC_2N sites. Moreover, the presence of fourfold-coordinated boron atoms with ^{11}B NMR signals also located at positive chemical shift values cannot be excluded.

The solid-state NMR results clearly show that the boron environment in the three synthesized polymers is more complex than expected. However, a predominance of BCN_2, BC_2N, and BC_3 sites in the 1/1, 2/1, and 3/1 polymers is analyzed. Other coordination sites at the boron atom such as BN_3 can also be found and are related to side reactions of residual B—H bonds in the polymers with NH_3 forming B—N instead of B—C bonds according to the following reaction (eq. [2]):
In particular, the type of reaction shown in eq. [2] explains the presence of the BN_3 sites measured in the 1/1 polymer.

^{15}N CP-MAS NMR

The spectra obtained for the preceramic polymers are also quite different with signals around –280, –305, and –340 ppm

*h-BN values recorded for the solid state.

for the 1/1 and 2/1 samples, and one unique signal at –333 ppm for the 3/1 polymer (Fig. 3). The different expected environments in these systems are NHSi$_2$, NHBSi, and NHB$_2$ (Fig. 1) and the corresponding chemical shift values reported in solution for such N-coordination sites are summarized in Table 3. NHSi$_2$ signals are observed around –340 ppm in [Si-N]$_3$ six-membered ring structures and around –330 ppm in [Si-N]$_4$ eight-membered ring structures. NHBSi sites show chemical shift values around –285 ppm in noncyclic structures, while NHB$_2$ sites appear between –266 and –275 ppm in (B-N)$_3$ six-membered ring structures and at a higher field in noncyclic compounds.

Simulation of the NMR spectrum of the 1/1 sample results in three signals at –281, –307, and –340 ppm that can be assigned to the NHB$_2$, NHBSi, and NHSi$_2$ sites, respectively. It should be noticed that the signal at –340 ppm is rather broad and may be constituted of two components: NHSi$_2$ sites in [Si-N]$_3$ and [Si-N]$_4$ cyclic structures (Table 3). The spectrum of the 2/1 sample can also be simulated with the same three signals at –282, –303, and –335 ppm, corresponding to the NHB$_2$, NHBSi, and NHSi$_2$ sites, respectively. The spectrum recorded for the 3/1 sample with its unique signal at –333 ppm is assigned to a NHSi$_2$-type coordination, which is in good agreement with the proposed molecular structure.

^{29}Si MAS NMR

It should be noticed that all the spectra have been first recorded in CP-MAS mode to improve the S/N ratio and to facilitate the simulation. Then the extracted parameters have been used to simulate the MAS spectra, to get quantitative information.

In contrast to the ^{11}B and ^{15}N NMR data, the spectra obtained for the three polymers are quite similar with a main signal at –4 ppm and a small and narrow one around –21 ppm attributed to contamination by silicone grease (Fig. 4). Considering the chemical shift values reported for SiN_xC_{4-x} coordination sites summarized in Table 4, the main signal can be easily attributed to an SiN_2C_2 environment, which nicely coincides with the expected structures of the individual polymers (Fig. 1).

^{13}C CP-MAS NMR

The synthesized polymers contain methyl groups bonded to silicon and carbon atoms. The latter type of methyl groups are formed by hydroboration of the vinyl groups that

leads to either -CH$_2$-CH$_2$- or -CH-CH$_3$ units according to eq. [3]:

[3] CH$_3$–Si–CH=CH$_2$ + HB⟨ → CH$_3$–Si–CH$_2$–CH$_2$–B⟨ / CH$_3$–Si–CH–B⟨ CH$_3$
The spectra recorded for the 1/1, 2/1, and 3/1 samples show three main signals at around 18, 10, and 2 ppm (Fig. 5). To identify these signals, IRCP measurements with variable inversion times were performed. In this type of experiment, the dynamics of polarization inversion depend on the proton environment (20–22). For the signal at 18 ppm, the IRCP curves show a behaviour typically found for CH groups, while the inversion dynamics of the other two peaks is slower. Since no quaternary carbon atoms can be expected to be present in these structures, these two signals at 2 and 10 ppm can be assigned to CH$_3$ environments exhibiting a weak ^{13}C–^{1}H dipolar coupling due to their mobility (23). In good agreement with the ^{13}C NMR chemical shift values observed for the polymer precursors in solution (Table 5), the peak at 2 ppm corresponds to a methyl group attached to Si,

Fig. 5. Experimental and simulated ^{13}C CP-MAS spectra recorded for 1/1, 2/1, and 3/1 polymers.
Table 5. ^{13}C NMR chemical shifts observed in solution for the 1/1, 2/1, and 3/1 polymer precursors.

Compounds	Groups	$\delta\ ^{13}C$ (ppm)
$\left(CH_3-\underset{\underset{Cl}{\mid}}{\overset{\overset{Cl}{\mid}}{Si}}-C_2H_4\right)_x BCl_{(3-x)}$ $x = 1\text{-}3$	Si-CH$_3$	4–7
	B(Si)-CH-CH$_3$	10–12
	B(Si)-CH-CH$_3$	20–34
	CH$_2$-CH$_2$	14–19

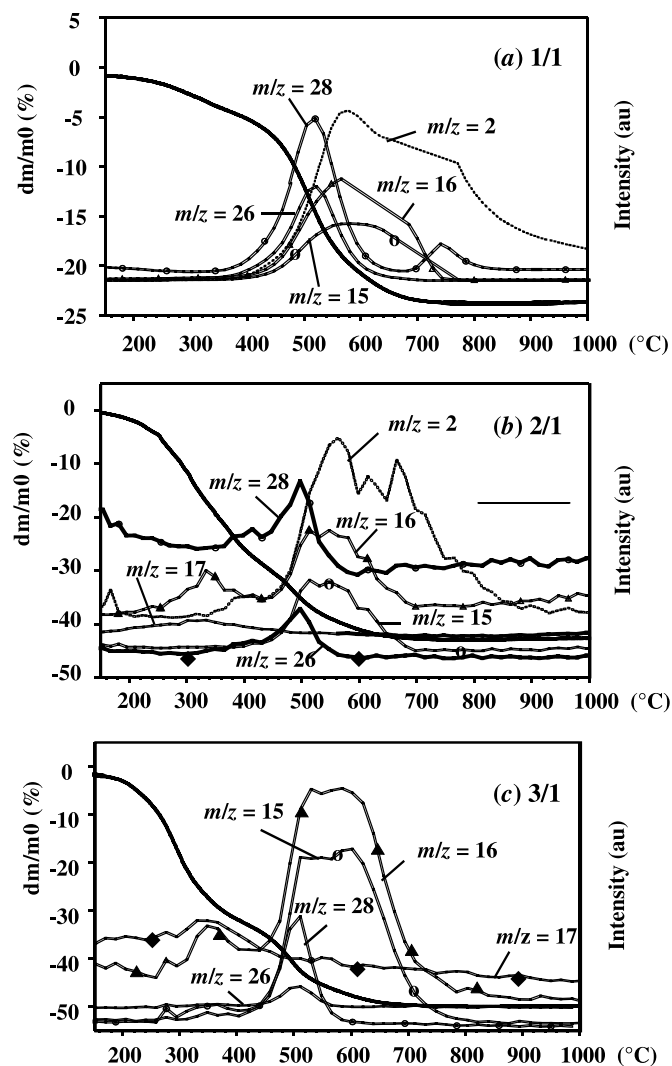
while the peak at 10 ppm is attributed to methyl bonded to a CH group.

In the 3/1 sample, the solid-state ^{13}C NMR spectrum shows an intensive signal at 30 ppm, which is assigned to a CH$_2$ group as it is derived from its IRCP behavior. This result indicates the presence of both structural units, namely >CH-CH$_3$ and -CH$_2$-CH$_2$- bridges interconnecting Si and B in the 3/1 native polymer.

Heat treatment and pyrolysis

TGA–MS

Figure 6 demonstrates the results of the thermal decomposition behaviour of the preceramic polymers. The polymer with the Si/B ratio = 1/1 shows a sharp mass loss of 25 wt% at around 500 °C due to the evolution of H$_2$ ($m/z = 2$), CH$_4$ ($m/z = 16$, 15, 14), CH$_3$-CH$_3$ ($m/z = 28$, 26), and a small quantity of NH$_3$. In contrast, the polymers with 2/1 and 3/1 as the Si/B ratio are characterized by a mass loss of 30 wt% below 350 °C due to the loss of NH$_3$ produced by polycondensation reactions. In a second step, the materials

Fig. 6. Thermogravimetric analysis and mass spectrometry of: (*a*) 1/1; (*b*) 2/1; and (*c*) 3/1 polymers. The m/z values are discussed in the text.


lose another 10 wt% between 500 and 600 °C related to the evolution of H$_2$, CH$_4$, NH$_3$ ($m/z = 17$, 16, 15), and C$_2$H$_4$. No further weight loss is detected above 700 °C and the overall ceramic yield amounts 75, 60, and 50 wt% are for the 1/1, 2/1, and 3/1 systems, respectively. The results of the elemental analysis performed on the samples pyrolyzed at 1000 °C are summarized in Table 1. It is worth noting that the Si/B ratio of the preceramic polymer is maintained after pyrolysis. In agreement with the TGA–MS study, the compositionnal changes for the three systems are as follows:

$$Si_{1.2}B_{1.0}C_{3.9}N_{2.2}H_{11.5} \longrightarrow Si_{1.2}B_{1.0}C_{1.7}N_{2.0}$$
$$+ 0.2NH_3 + (1.6 - 2x)CH_4 + xC_2H_4 + yH_2$$

$$Si_{2.0}B_{1.0}C_{6.3}N_{2.7}H_{19.2} \longrightarrow Si_{2.0}B_{1.0}C_{3.4}N_{2.3}$$
$$+ 0.4NH_3 + (2.9 - 2x)CH_4 + xC_2H_4 + yH_2$$

^{11}B MAS NMR

The ^{11}B MAS NMR spectrum of each sample progressively shifts to upper field values with increasing temperature (Fig. 7). All samples heat treated at 1000 °C exhibit a main signal with δ_{iso} around 30 ppm independent of the Si/B ratio. This finding indicates that a mixture of BN_3- and BCN_2-coordination sites have been formed. Considering BC_xN_{3-x} ($0 \leq x \leq 3$) as the only possible environments suggests that x tends to 0 with increasing temperature. The different spectra obtained were tentatively simulated with pure second-order quadrupolar shapes and the corresponding distribution of the BC_xN_{3-x} ($0 \leq x \leq 3$) sites vs. temperature are presented in Table 6. The experimental and simulated spectra obtained for the 2/1 system are shown in Fig. 8.

^{15}N MAS and CP-MAS NMR

Figure 9 shows the different ^{15}N MAS NMR spectra ob-

tained for the 2/1 polymer after heat treatment at 400, 600, and 1000 °C in an argon atmosphere.

The ^{15}N CP-MAS spectrum of the sample heat treated at 400 °C exhibits signals located at the same position as found for the native polymer. However, more than three peaks are necessary to simulate the ^{15}N IRCP-MAS NMR spectra recorded over a range of inversion times. Some signals exhibit an IRCP behaviour closer to the one expected for nonprotonated nitrogen atoms. Considering that $NCSi_2$, $NCBSi$, and NCB_2 chemical shift values (Table 7) are reported in the same range as $NHSi_2$, $NHBSi$, and NHB_2, respectively (Table 3), the spectrum of the 2/1 polymer pyrolyzed at 400 °C indicates the presence of a mixture of $NXSi_2$, $NXBSi$, and NXB_2 with X = H or C as the nitrogen coordination sphere. The formation of N—C bonds will be discussed later in the ^{13}C NMR study.

The ^{15}N IRCP-MAS NMR spectrum of the material an-

Fig. 8. Experimental and simulated ^{11}B MAS NMR spectra recorded for the 2/1 polymer and its pyrolysis products at 400, 600, and 1000 °C.

Fig. 9. Experimental and simulated ^{15}N CP-MAS NMR spectra recorded for the 2/1 polymer and its pyrolysis products at 400, 600 °C, and the ^{15}N MAS NMR spectrum of the sample heat treated at 1000 °C.
nealed at 600 °C can be simulated by three signals showing an IRCP behaviour characteristic of hydrogen-free environments and one signal corresponding to a Si-NH-Si site considering its chemical shift value (–337 ppm) and its inversion dynamics (Fig. 10). The hydrogen-free sites are assigned to NCX_2 environments (X = Si, B) based on their chemical shift values. This result strongly suggests that the removal of hydrogen from the nitrogen atoms is almost complete for the three systems at 600 °C.

Annealing of the 2/1 polymer at 1000 °C results in a broad and complex NMR signal ranging from –240 to –320 ppm that can be assigned to a distribution of NB_3-, NCB_2-, $NCBSi$-, and $NCSi_2$-coordination sites based on the corresponding expected chemical shift values (Table 7). A similar behaviour is observed for the 1/1 and 3/1 systems: the protonated signals disappear progressively with increasing temperature, while the amount of $NCXY$ (X,Y = B, Si) sites increases and an additionnal signal is present around –282 ppm due to the formation of NB_3 sites. The enhanced formation of new B—N bonds together with the decreasing amount of Si—N bonds with increasing annealing temperature as found in the ^{15}N MAS NMR study is in good agreement with the ^{11}B NMR results.

^{29}Si MAS NMR

The ^{29}Si MAS NMR spectra of the three heat-treated polymer systems reveal similar chemical shift values for a

given temperature. Figure 11 represents the NMR results on the basis of the 2/1 sample. Accordingly, the number of resonance signals increases after 400 °C treatment and is still pronounced after annealing at 1000 °C. Assignment is difficult due to the broadness of the peaks that can be explained by the presence of a great variety in the coordination of Si by carbon and nitrogen (SiN_xC_{4-x} where $0 \leq x \leq 4$ (Table 4). [29]Si CP-MAS spectra were therefore recorded up to 600 °C to enhance the S/N ratio and extract the number of signals and their corresponding parameters. But this sequence cannot be used for high-temperature samples (due to a lack of protons) and all sites may not be detected; [29]Si MAS spectra were consequently recorded for all samples.

Annealing at 400 °C

The signal around –4 ppm observed in the native polymers is still present, while a broad peak is found at –21 ppm, which can be assigned to a SiN_3C environment (see Table 4). Moreover, two further signals appear at positive chemical shift values: their assignment is not straightforward but the chemical shift at 5 ppm probably indicates the formation of $SiNC_3$ environments, while the peak at 15 ppm has to be at-

Table 7. ^{15}N NMR chemical shift values reported in the liquid state in for NCX$_2$ (X = Si, B), NB$_3$, and NSi$_3$ environments.

Sites NC	Compounds	δ ^{15}N (ppm)	Reference
NCSi$_2$	[(CH$_3$)$_2$SiNCH$_3$]$_3$	–332	28
	(CH$_3$)$_3$Si-NCH$_3$-Si(CH$_3$)$_3$	–370	
	(CH$_3$)$_3$Si-NC$_2$H$_5$-Si(CH$_3$)$_3$	–340	
NCBSi	(CH$_3$)$_2$B-NCH$_3$-Si(CH$_3$)$_3$	–287	28
	[structure: ring with N, B, H, B, N, N, B; R = CH$_3$]	–268	
	R = CH$_3$		
NCB$_2$	R = n-Bu	–248	31
NB$_3$	Hexagonal boron nitride*	–282	37
NSi$_3$	Si$_3$N$_4$*	–309	33

*Hexagonal boron nitride and silicon nitride values are for the solid state.

Fig. 10. Experimental and simulated ^{15}N IRCP-MAS spectra of the 2/1 sample pyrolyzed at 600 °C for two inversion time values: (*a*) t_i = 5 μs; and (*b*) t_i = 500 μs.
tributed to >Si=N-B< units as reported in a polyborosilazane-containing [Si-N]$_3$ structural units (24).

Annealing at 600 °C

The signal at 15 ppm has disappeared but those around 5, –4, and –21 ppm assigned to SiNC$_3$, SiN$_2$C$_2$, and SiN$_3$C sites, respectively, are still present. A new resonance peak at –33 ppm is tentatively assigned to another SiN$_3$C environ-

Fig. 11. ^{29}Si MAS NMR spectra recorded for the 2/1 polymer and its pyrolysis products obtained at 400, 600, and 1000 °C.
ment since the range for such signals is relatively big (Table 4).

Annealing at 1000 °C

The overall spectrum does not differ from the ones reported for pyrolyzed polysilazanes and polyborosilazanes and is typical for a distribution of SiN$_x$C$_{4-x}$ (0 ≤ x ≤ 4) sites (23) strongly supporting the presence of an amorphous phase of silicon carbonitride. Peaks around 5, –4, –19, –33 and –49 ppm assigned to SiNC$_3$, SiN$_2$C$_2$, SiC$_4$, SiN$_3$C, and SiN$_4$, respectively, are most probably present. The presence of silicon atoms coordinated by nitrogen or carbon exclusively shows the onset of a phase separation resulting in the formation of Si$_3$N$_4$- and SiC-rich domains.

^{13}C CP-MAS NMR

The ^{13}C CP-MAS spectrum of the 1/1 sample heat-treated at 400 °C (Fig. 12*a*) is similar to the one recorded for the native polymer. This finding is in good agreement with the TGA–MS results indicating a transformation of the network for temperatures beyond 500 °C (Fig. 6*a*). The samples with the Si/B ratios 2/1 and 3/1 annealed at 400 °C show an increase in the number of NMR signals (Fig. 12*b*) compared

Fig. 12. ^{13}C CP-MAS NMR spectra of the (*a*) 1/1, and (*b*) 2/1 polymers and their pyrolysis products at 400 and 600 °C.
with the starting polymers suggesting significant structural changes. The peaks at 2 and 10 ppm are still present but the relative intensity of the first one has decreased, methyl groups bonded to carbon being less stable than those bonded to silicon. Moreover, there are two additional peaks at 13 and 35 ppm. The first one can be assigned to a CH group based on its IRCP behavior, while the latter one at lower field is due to the presence of a X_3C-N environment (X = C, H) as already reported for borylborazine and polyborazine (25). The NMR results strongly suggest the formation of C—N bonds during the heat treatment and coincide with the ^{15}N NMR study showing >NCX_2 (X = Si, B) sites in the 2/1 polymer heat treated at 400 °C.

After tempering of the samples at 600 °C, the peak around 2 ppm assigned to CH_3 groups bonded to silicon is still present, while resonances attributed to methyl groups bonded to a CH function have strongly decreased due to the loss of methane as demonstrated by our TGA–MS study. The low-field shifted peak around 35 ppm observed at 400 °C in the 2/1 sample is still present and a new signal is observed in the same range for the 1/1 system annealed at 600 °C. The peak corresponds to the formation of C—N bonds since NCX_2 (X = Si, B) sites have also been found by ^{15}N CP-MAS NMR measurements of the same sample.

The spectra also show a broad peak around 150 ppm that can be assigned to aromatic carbon atoms suggesting the formation of graphite-like or amorphous carbon stemming from the decomposition of the organic side groups (26).

Conclusions

Native polymers
The ^{11}B, ^{13}C, ^{15}N, and ^{29}Si data support the different molecular structures proposed for the as synthesized polymers. ^{11}B MAS NMR spectra represent main signals assigned to BCN_2, BC_2N, and BC_3 sites in the samples with 1/1, 2/1, and 3/1 as the Si/B ratio, respectively. ^{15}N CP-MAS and ^{29}Si

MAS spectra confirm the presence of cyclic silazane ring structures [SiR(CH_3)-NH]$_x$ (x = 3, 4) for the three compounds. Moreover, B-NH-Si and B-NH-B bonds were also identified by ^{15}N NMR in the polymers with 1/1 and 2/1 Si/B ratios. These types of bonds are not found in the polymer with Si/B = 3/1. Boron atoms are linked to three silazane rings through >CH-CH_3 and -CH_2-CH_2- spacing groups as confirmed by ^{13}C NMR in the 3/1 polymer. In contrast, no ethylene–CH_2-CH_2-groups are clearly evidenced in the 1/1 and 2/1 polymers, indicating that boron and silicon atoms are only bonded through >CH-CH_3 groups.

Ceramization
The boron environment depends on the Si/B-ratio and is quite different in the individual native preceramic polymer. In contrast, the boron coordination resembles a mixture of BN_2C and BN_3 sites for the samples heat treated at 1000 °C independent of the Si/B-ratio. At the same time, the number of aliphatic carbons that make the interconnection between the silicon and the boron atoms decreases. This evolution suggests the cleavage of B—C bonds with evolution of methane and ethane, while some nitrogen atoms bonded to silicon sites migrate to boron groups as confirmed by the appearance of NB_3 sites. Moreover, the deprotonation of the nitrogen sites leads to the formation of C-NX (X = Si or B) structural units and a distribution of SiN_xC_{4-x} ($1 \leq x \leq 4$) sites is observed. This findings suggest that boron atoms are homogeneously dispersed in the silicon carbonitride phase supporting the high thermal stability observed in these compounds.

The activity of Pt/SiO$_2$ catalysts obtained by the sol-gel method in the hydrosilylation of 1-alkynes[1]

Rafael Jiménez, J. Merced Martínez-Rosales, and Jorge Cervantes

Abstract: Heterogeneous platinum catalysts (Pt/SiO$_2$) obtained by the sol-gel process at pH 3 and 9 have been used in the hydrosilylation reaction of 1-alkynes using various silanes. Once the catalysts were activated they were used in the hydrosilylation of 1-alkynes after a short induction period. The product distribution was quite similar in either case but important differences in catalytic activity and turnover reactions were observed. The catalyst obtained in the basic medium after each reaction lost its catalytic activity, so further activation was needed. To understand this behavior, the catalysts were characterized by ^{29}Si CPMAS NMR, FT IR, and BET surface area measurements. The ^{29}Si CPMAS NMR studies showed the presence of terminal and bridged hydroxyl groups in the Pt/SiO$_2$ catalyst at pH = 9. Similar results were observed by FT IR analysis because of the catalysts' synthetic conditions.

Key words: hydrosilylation, sol-gel, Pt/SiO$_2$, supported-metal catalysts, phenylacetylene, diphenylacetylene, ^{29}Si NMR CP-MAS.

Résumé : On a utilisé des catalyseurs homogènes de platine (Pt/SiO$_2$) obtenus par le procédé sol-gel à des pH de 3 et de 9 pour effectuer l'hydrosilylation d'alc-1-ynes à l'aide de divers silanes. Une fois les catalyseurs activés, ils étaient utilisés pour effectuer l'hydrosilylation des alc-1-ynes après une courte période d'induction. La distribution des produits est très semblable dans les deux cas, mais on a observé des différences importantes dans l'activité catalytique et dans les réactions de changement. Le catalyseur obtenu en milieu basique perd son activité après chaque réaction et on doit donc procéder à chaque fois à une nouvelle activation. Dans le but de comprendre ce comportement, on a procédé à une caractérisation des catalyseurs par RMN « CPMAS » du ^{29}Si, par spectroscopie IR à transformée de Fourier et par des mesures « BET » de l'aire de la surface. Les études de RMN CPMAS du ^{29}Si ont montré que la présence de groupes hydroxyles pontés et terminaux est minimale dans le catalyseur de Pt/SiO$_2$ obtenu à un pH de 9. Des résultats semblables ont été obtenus par l'analyse du spectre IR à transformée de Fourier en raison des conditions de synthèse du catalyseur.

Mots clés : hydrosilylation, sol-gel, Pt/SiO$_2$, catalyseurs métalliques déposés, phénylacétylène, diphénylacétylène, RMN CP-MAS du ^{29}Si.

Introduction

The aim in the preparation of catalytic materials to be used in industry is to obtain a product with high activity, selectivity, and stability (1). Heterogeneous catalysts are often prepared by wet chemistry methods such as precipitation, coprecipitation, hydrothermal synthesis, or by sol-gel process. The main advantage of this low-temperature process is to generate solids with large specific surface area and high porosity in the meso- and macropore ranges (2).

The sol-gel method represents a useful route in the synthesis of supported metal catalysts. The usefulness of this method is based on the fact that one can start with both the metal and support precursors in solution and design a cata-

lyst with well-defined physical properties. Advantages of the method include: superior homogeneity and purity, better micro structural control of the support, higher BET surface areas, better-defined pore size distributions, improved thermal stability of the metal support particles, and the facility to incorporate additional elements (3–5).

One of the important trends in the development of the hydrosilylation reaction has been the synthesis of heterogeneous catalysts for this reaction (6–9). On the other hand, immobilized complexes or anchored-metal complexes, in which the metal atom is bonded to a polymer support that plays the role of a macroligand, have been used. The supports consist of suitable modified ion-exchange resins (10), silica gel (11), and organic polymers such as divinylbenzene–

styrene co-polymer, polymethyl methacrylate (12), or polysiloxanes (13). The hydrosilylation reaction of unsaturated compounds such as olefins, acetylenes, imines, allylamines, and oxymes promoted by transition-metal catalysts is widely investigated for reduction of unsaturated groups or addition of Si—H bonds.

Catalytic hydrosilylation of olefins with soluble platinum complexes was first described by Speier et al. (14), Saam and Séller (15), and Ryan and Séller (16) and the commercial catalyst (hexachloroplatinic acid) bears Speier's name.

Interest in hexachloroplatinic acid and other metal-supported catalysts has been one of the focal areas of organosilicon chemists since the 1970s. It is assumed that supported-metal catalysts have the advantages of both homogeneous and heterogeneous systems. Among the advantages of using supported catalysts are: the ease of catalyst recovery and chemical modification of the active sites, and handling.

The addition of Si—H bonds to unsaturated compounds can be carried out by free radical chain reactions, or more conveniently by the use of catalysts such as platinum or other transition metals (17–19). Polizzi et al. (6) reported that homogeneous and heterogeneous catalysts derived from mesitylene-solvated platinum atoms were very reactive in the selective hydrosilylation of dienes and acetylenes.

Olefin hydrosilylation reactions are known to occur with the aid of a homogeneous and supported catalyst (20, 21). These reactions are conventionally known to be accomplished by other side reactions, such as olefin isomerization. The development of catalysts with higher activity and selectivity toward hydrosilylation is undoubtedly needed. In many cases, more expensive catalysts have been employed for this purpose (22–26).

However, little is known about the hydrosilylation of the carbon–carbon triple bond with supported-metal catalysts obtained by the sol-gel process under the usual reaction conditions. The sol-gel process provides a useful route of preparing supported-metal systems. For example, Ru-MgO has been used in the benzene hydrogenation reaction (27) and in the hydrogenolysis of cyclopentene (28). Caporusso et al. (7) reported a detailed investigation of the hydrosilylation of aromatic nitriles promoted by unsupported- and supported-rhodium metal nanoparticles. They were prepared from arene-solvated rhodium atoms and are excellent catalysts for the selective hydrosilylation of aromatic nitriles. Schubert et al. (29) reported the activity of $Rh(CO)Cl(PR_3)_2$ heterogenized by the sol-gel method in the hydrosilylation of 1-hexene with triphenylsilane.

We have reported on the use of Ru/MgO and Pt/MgO obtained by the sol-gel method in the hydrosilylation reaction (30). Terminal acetylene hydrosilylation is one of our areas of interest (see Scheme 1) (31).

In a recent preliminary study, we have also used the Pt/SiO$_2$-pH3 (**I**) and Pt/SiO$_2$-pH9 (**II**) in the hydrosilylation of phenylacetylene, diphenylacetylene, and 1-heptyne with several hydrosilanes R_3SiH (where R = Ph$_3$, Ph$_2$Me, and PhMe$_2$) (32). In the present report, the influence of the route of synthesis of the catalysts **I** and **II** in acidic or basic medium on the catalytic activity and selectivity was studied. Particular focus is given to the surface properties to understand the catalytic systems' behavior.

Scheme 1.
Experimental

Materials

The chemicals used were all reagent grade and available from suppliers such as Gelest, Inc. and Aldrich. All the glassware used was treated with KOH (1 mol/L) in EtOH solution, washed carefully with deionized water and acetone, and dried in an oven at 110 °C for several hours. Any contact with other organic materials such as silicon grease was avoided. Liquid hydrosilanes were purified by distillation in a nitrogen atmosphere. NMR measurements were performed in CDCl$_3$ solutions using a Varian Gemini 200 MHz spectrometer and a Varian Unity-Plus 300 MHz spectrometer. The catalysts used in this work were obtained at the Gasses Physicochemical Laboratory of the Molecular Simulation Program (Mexican Petroleum Institute, México, D.F.) The catalysts **I** and **II** were activated for 4 h at 500 °C and then left 1 h at room temperature in a hydrogen atmosphere.

Surface area and pore texture of catalysts

BET surface areas were determined using a Pulsechemisorb 2700 Micromeritics instrument and the automated gas volumetric method employing nitrogen as the adsorbate at 77 K. Samples were degassed under vacuum at 200 °C for 2 to 3 h prior to analysis.

NMR studies of the supported-metal catalytic system

The ^{29}Si CPMAS NMR measurements were performed using a Varian Unity-Plus 300 MHz spectrometer operating at 59.58 MHz. The rotor spin rate (Si$_3$N$_4$) was 4 kHz, with a delay time of 6 s. Transients (1600) were accumulated and the contact time used was 1500. The samples were dehydrated at 350 °C for 30 min in an oven prior to recording the NMR spectra. The internal reference was talc.

FT IR studies

FT IR spectra of the Pt/SiO$_2$ catalyst were recorded before and after activation in the range 4000–400 cm^{-1} using a PerkinElmer FT IR 1600 spectrometer.

Hydrosilylation procedure

All experiments were performed in a nitrogen atmosphere in a 50 mL two-necked flask equipped with a thermometer and a reflux condenser. The flask was charged with activated catalysts (25 mg Pt/SiO$_2$-pH3 or Pt/SiO$_2$-pH9, 0.5% Pt). The reactants, Ph$_2$MeSiH (4.01 mmol) and phenylacetylene (4.5 mmol), were subsequently added. Once the addition was completed, the mixture was stirred and heated by means of an oil bath at 80–90 °C for 2 h. The stirring was interrupted every 10 min to take aliquots of the solution and the product distribution was analyzed using ^{1}H NMR measurements.

Analysis of the reaction mixture

The isomeric ratio of the hydrosilylation products was derived from the areas of olefinic protons. Decrease of the $\equiv$C—H bond was comparable with the increase of the vinylic proton signals. The specific activity was calculated as mol of phenylacetylene transformed per g-atom of metal per h. Products were conveniently purified by distillation or crystallization. For Ph_3SiH with $PhC\equiv CH$, the product mixture was washed with a CH_2Cl_2/methanol (2:1) solution and crystallized at –5 °C to separate the β-trans and α-isomer from the solution. Turnover reaction for these catalytic systems was also studied. The product mixture was separated from the catalyst by decantation and then equal amounts of fresh silane and phenylacetylene were added to the catalyst to start the next hydrosilylation reaction. The decrease in integrals of the $\equiv$C—H bond were comparable to the increase of the vinylic proton signals, and then the specific activity was again measured as mol of phenylacetylene transformed per g-atom of metal per h.

Results and discussion

The Pt/SiO_2-pH3 (**I**) and Pt/SiO_2-pH9 (**II**) catalysts obtained by the sol-gel method were applied to well-known hydrosilylation reactions such as the hydrosilylation of phenylacetylene, diphenylacetylene, and 1-heptyne with various silanes (R_3SiH where R = Ph, Ph_2Me, and $PhMe_2$) and the catalysts were characterized by solid-state NMR, FT IR spectroscopy, and the BET method. Hydrosilylation of phenylacetylene was performed using both catalysts. In the other two reactions, only the Pt/SiO_2-pH-3 catalyst was used because of the loss of catalytic activity of the Pt/SiO_2-pH-9 catalyst after each reaction. Illustrative results are presented in Table 1. Structural assignment of the products were based on ^{1}H NMR measurements.

The ^{1}H NMR spectrum indicated two doublets, at 5.5 and 5.8 ppm, which are signals typical of the AX spin system. The coupling constant was J = 3 Hz, and the signals were assigned to the *geminal* hydrogen atoms of the ethylene group. The bands in the region of the relatively weaker field are assigned to the AB spin system with a coupling constant of J = 19 Hz. It indicates the trans position of vicinal protons of the HC=CH fragment.

The hydrosilylation reactions of acetylenes with several hydrosilanes using both **I** and **II** catalysts, were studied by FT IR. The catalytic activity was manifested by IR spectral analysis of the reaction products. Fingerprint analysis confirmed the concurrence of the hydrosilylation product. The intensity of the band at 960 cm^{-1}, characteristic for the Si-C=C bond in the hydrosilylation product increased progressively with time. At the same time, the IR absorption band of 2210 cm^{-1}, characteristic of the Si—H bond, decayed with time. Within the reaction temperature range (80–90 °C), no detectable olefin isomerization products were observed. The rate of increase in the intensity of the product band at 960 cm^{-1} was consistent with the rate of decay of the hydrosilanes band at 2210 cm^{-1}. Therefore, the reaction profiles were measured by following the disappearance of the band at 2210 cm^{-1} characteristic of the Si—H bond, and the extent of the hydrosilylation reaction was calculated based on the amount of the R_3Si-H consumed as the limiting

Table 1. Product distribution in the hydrosilylation of acetylenes by R_3SiH promoted by **I** and **II**.

Note: The reactions were performed at 80–90 °C for 2 h with conversions of over 95% of the initial reactants.

reactant. A typical representation of the hydrosilylation reaction progress with time is shown in Fig. 1.

The hydrosilylation reaction was conducted under a variety of reaction conditions. The effect of temperature, reactant concentration, and catalyst amounts on the rate of the hydrosilylation reaction were investigated, together with the catalysts' reuse.

The catalyst can be removed from the reaction mixture by filtration in N_2 or by removal of the filtrate and then washing with either one of the reactants. If the activated catalyst was removed from the hydrosilylation mixture by filtration and washed with the same reactant, the recovered catalyst showed little decrease in catalytic activity during four runs, ranging from 98% conversion in the first run to 92% conversion in the fourth run. It seems that some of the products are remaining on the surface, creating less active catalytic sites, although it is very important to say that the selectivity is maintained after the four runs, as can be seen in Table 2.

These results were true for **I**. Once the hydrosilylation reaction was performed using the two catalytic systems, it was observed that the catalyst obtained at pH 9 (**II**) loses catalytic activity and it has to be activated before a new reaction. It was decided to investigate the morphological characteristics of each system to obtain a better understanding of such behavior.

Solid-state NMR studies

The development of high-power decoupling, cross-polarization (CP), and magic-angle-spinning (MAS) techniques permits NMR studies. We applied both MAS and CP-MAS NMR to the molecular characterization of the surface of supported-metal catalysts obtained by the sol-gel method. Figures 2–4 contain the MAS and CP-MAS ^{29}Si NMR data for the surface-attached molecules. ^{29}Si NMR data do agree with information from the literature for silica-supported catalytic systems (33–36). It is important to observe that two catalysts (seen in figures as Pt/SiO_2 IMP and FQ) were prepared at the same conditions and the solid-state NMR information obtained is reported. The MAS ^{29}Si NMR spectrum of **I** (Fig. 2) shows a broad signal at –107 ppm as-

Table 2. Specific activity and isomeric ratio as a function of reaction time of Pt/SiO2-pH 3 (**I**) in the hydrosilylation of phenylacetylene with Ph_2MeSiH.

Cycles	Specific activity	Reaction time (h)	Product (%)		
			trans	gem	cis
1	3126	2	96	4	—
2	3126	2	96	4	—
3	3114	2	96	4	—
4	2997	2	96	4	—

Note: The reactions were performed at 80–90 °C for 2 h with conversions of over 95% of the initial reactants. The specific activity was calculated as mol of phenylacetylene transformed per g-atom of metal per h.

signed to $Si(OSi)_4$ with a small shoulder around –95 ppm attributable to the $(HO)Si(OSi)_3$ environment. From the MAS ^{29}Si NMR spectrum of **II** (Fig. 3), similar information was obtained but a bigger shoulder at –95 ppm is observed.

In the present case, the CP-MAS pulse sequence was more informative. Signals at –96 and –86 ppm were assigned to $(HO)Si(OSi)_3$ and $(OH)_2Si(0Si)_2$. More intense signals were observed in catalyst **II** obtained at pH 9 (Fig. 4). These results show that few hydroxyl groups remain on the silica surface of the supported-metal catalyst **I**. On the other hand, the surface of **II** has more hydroxyl groups. This is important evidence that tends to explain the different catalysts' behavior based on the synthetic conditions and particularly the loss of activity of **II**.

Porosimetry results

Nitrogen adsorption and desorption isotherms obtained at liquid nitrogen temperature for **I** and **II** are given in Figs. 5 and 6. The Pt/SiO$_2$-pH3 isotherm is type I and is typical of microporous materials. The totality of accessible pores are filled with adsorbate and the isotherm reaches a plateau that remains fairly invariant as $p/P_o \rightarrow 1$ (where p is the pressure of the adsorbate at equilibrium and P_o is the saturated pres-

Fig. 2. ^{29}Si MAS NMR spectra of Pt/SiO$_2$ at pH 3.
Fig. 3. ^{29}Si MAS NMR spectra of Pt/SiO$_2$ at pH 9.
sure at equilibrium). Its desorption isotherm does not exhibit any hysteresis.

In contrast, the Pt/SiO$_2$-pH9 isotherm is type III, typical of mesoporous solids. Monolayer and multilayer coverage are basically completed at $p/P_o \rightarrow 1$ (Fig. 6). Nitrogen uptake in this range of pressure increases in the order **I** < **II**, a trend consistent with the BET surface as shown in Table 3. After multilayer coverage is complete, capillarity condensation occurs in the mesopores. The small inclination of the isotherm step in Fig. 6 indicates that these mesopores are distributed over a range of sizes.

Pt/SiO$_2$-pH 9 (**II**)	160	0.03	31.6

FT IR studies of I and II catalysts

FT IR spectra were obtained for Pt/SiO$_2$ catalysts prior to the hydrosilylation reactions. Figure 7 illustrates the IR spectra that show peaks around 3500 cm^{-1} that correspond to Si—OH and OH bonds. The peaks are more intense in **II**. This information agrees with the results of solid-state NMR

Fig. 6. Nitrogen adsorption–desorption isotherms, at liquid nitrogen temperature, of catalyst **II**.
Fig. 7. FT IR spectra of catalysts **I** and **II**.
presented previously. When the catalysts were heated at the activation temperature (500 °C), it was possible to observe clearly that the intensity of the OH vibration peak decreases after 4 h.

From the information obtained by CP-MAS NMR, porosimetry, and FT IR, several aspects can be considered to address the difference in catalytic activity: The presence of

more OH groups in Pt/SiO$_2$ as a result of the preparation at pH 9 tend to affect its properties such as the surface area and pore characteristics. In Table 3, it is shown that there is a very important difference in surface area (529 m^2/g for **I** and 160 m^2/g for **II**). Pore size is bigger in **II**, and blocked pores can also be considered in the catalyst deactivation. At it has been pointed out, after each reaction, **II** is required to be activated.

Final remarks

The investigation of the use of Pt supported on silica obtained by the sol-gel method at different pHs provided significant results suggesting the actual possibility of preparing physically heterogeneous catalysts for hydrosilylation reactions. Additional work is needed to clarify the role of the pathway in connection to the possible activating affect of the acidic species on the surface of the support. Finally, the possibility of controlling stereochemistry and morphology by the heterogeneous phase is a matter of active study.

Reduction of hafnium(IV) complexes in the presence of molecular nitrogen: Attempts to form dinitrogen complexes of the heaviest group 4 element[1]

Michael D. Fryzuk, James R. Corkin, and Brian O. Patrick

Abstract: The reaction of $[P_2N_2]Li_2(dioxane)_2$ with $HfCl_4(THF)_2$ (where $[P_2N_2] = PhP(CH_2SiMe_2NSiMe_2CH_2)_2PPh$) results in the formation of the hafnium dichloride complex $[P_2N_2]HfCl_2$ (**1**). The behaviour of **1** as a potential precursor in the generation of a dinitrogen coordination complex is described. Reduction of **1** with potassium-graphite (C_8K), under dinitrogen, under a variety of conditions led to a number of products, one of which is the dinuclear derivative with bridging P-phenyl groups that has the general formula $\{[P_2N_2]Hf\}_2$ (**2**). Reduction of the hafnium diiodide $[P_2N_2]HfI_2$ (**3**) — prepared via the reaction of **1** with excess Me_3SiI — with C_8K results in the formation of $([P_2N_2]Hf)_2(\mu-\eta^2:\eta^2-N_2)$ (**4**) as the major product of the reaction, while $\{[P_2N_2]Hf\}_2$ (**2**) and $[P_2N_2]Hf(C_7H_8)$ (**5**) appear to be minor products. Reaction of **1** with 2 equiv of $MeMgCl$ gives $[P_2N_2]HfMe_2$ (**6**), which, upon exposure to an atmosphere of H_2, gives the hafnium tetrahydride $\{[P_2N_2]Hf\}_2(m-H)_4$ (**7**).

Key words: hafnium, dinitrogen, reduction, coordination chemistry, hydride, mixed donor ligands.

Résumé : La réaction du $[P_2N_2]Li_2(dioxane)_2$ avec le $HfCl_4(THF)_2$ {dans lequel $[P_2N_2] = PhP(CH_2SiMe_2NSiMe_2CH_2)_2PPh$} conduit à la formation du complexe de dichlorure d'hafnium, $[P_2N_2]HfCl_2$ (**1**). On décrit le comportement du complexe **1** comme précurseur potentiel pour générer un complexe de coordination du diazote. La déduction de **1** à l'aide de potassium sur graphite (C_8K), sous atmosphère de diazote, dans diverses conditions expérimentales conduit à la formation d'un certain nombre de produits, dont l'un est un dérivé dinucléaire de formule générale $\{[P_2N_2]Hf\}_2$ (**2**) portant des groupes P-phényles agissant comme ponts. La réduction par le C_8K du complexe de diiodure d'hafnium, $[P_2N_2]HfI_2$ (**3**), préparé par le biais d'une réaction de **1** avec un excès de Me_3SiI, conduit à la formation du complexe $\{([P_2N_2]Hf)_2(\mu-\eta^2:\eta^2-N_2)$ (**4**) comme produit majeur de la réaction alors qu'il semble y avoir formation $\{[P_2N_2]Hf\}_2$ (**2**) et de $[P_2N_2]Hf(C_7H_8)$ (**5**) comme sous-produits. La réaction de **1** avec deux équivalents de $MeMgCl$ conduit à la formation de $[P_2N_2]HfMe_2$ (**6**) qui, mis dans une atmosphère de H_2, fournit le tétrahydrure d'hafnium, $\{[P_2N_2]Hf\}_2(\mu-H)_4$ (**7**).

Mots clés : hafnium, diazote, réduction, chimie de coordination, hydrure, ligands donneurs fixés.

Introduction

The preparation of dinitrogen complexes of the early transition metals generally involves reduction of some suitable metal halide precursor in the presence of molecular nitrogen (1). While effective in many cases, certain early transition elements are not easily reduced, and as such, well-defined dinitrogen complexes are either unknown or extremely rare. Examples of this are the group 3 elements, Sc, Y, and La, for

which molecular dinitrogen complexes are not known and the group 4 element, Hf, for which only one dinitrogen complex has been reported (2). Reduction of $Cp^*_2HfI_2$ with Na–K in dimethoxyethane at –40 °C does result in the formation of $[Cp^*_2Hf(N_2)]_2(\mu-N_2)$ in rather low yields. In this case, the choice of the reducing agent and solvent and the use of the diiodide were critical to the success of this procedure. As has been reported earlier, reductive strategies to generate dinitrogen complexes can lead to other products (3), and so, the fact that reaction optimization required considerable variation in experimental conditions is not surprising.

In this paper we describe our efforts to extend the family of hafnium dinitrogen complexes by the attempted preparation of $([P_2N_2]Hf)_2(\mu-\eta^2-N_2)$ (**4**), in analogy to that reported previously for the zirconium complex $([P_2N_2]Zr)_2(\mu-\eta^2-N_2)$. The zirconium complex has been shown to add H_2 and primary silanes with concomitant formation of N—H and N—Si bonds, respectively (4). We reasoned that access to the hafnium dinitrogen complex congener might allow for similar reactivity and even perhaps different reactivity patterns. However, as will be shown in this work, changing the metal

from Zr to Hf results in a different set of reactions when reduction in the presence of dinitrogen is attempted.

Results and discussion

Preparation and structure of [P$_2$N$_2$]HfCl$_2$ (1)

Our initial strategy to prepare ([P$_2$N$_2$]Hf)$_2$(μ-η^2-N$_2$) (**4**) was to follow exactly the preparation of the zirconium analog ([P$_2$N$_2$]Zr)$_2$(μ-η^2-N$_2$), by reduction of the Hf(IV) dichloride complex, [P$_2$N$_2$]HfCl$_2$ (**1**), with an alkali metal reagent. We have already shown that reduction of [P$_2$N$_2$]MCl$_x$ (M = Zr, x = 2; M = Nb, x = 1) by potassium-graphite (C$_8$K) can generate good yields of the corresponding dinitrogen complexes ([P$_2$N$_2$]M)$_2$(μ-N$_2$) (M = Zr (**4**), M = Nb (**3**)). The starting dichloride **1** was prepared by the reaction of the THF adduct of hafnium(IV) tetrachloride with 1 equiv of [P$_2$N$_2$]Li$_2$(1,4-dioxane)$_2$. The optimal conditions for this reaction were found to require heating of a suspension of starting materials in toluene overnight at approximately 120 °C (Scheme 1).

Complex **1** was characterized by solution ^{1}H and ^{31}P{^{1}H} NMR spectroscopy, elemental analysis, and solid-state, X-ray structure analysis. Crystals of **1** suitable for X-ray diffraction were grown from a saturated DME solution; the ORTEP diagram is shown in Fig. 1.

The solid-state molecular structure of **1** is best described as distorted octahedral. N(1), N(2), Cl(1), and Cl(2) can be described as forming a square plane, with the sum of the four angles equal to 360.1°. P(1) and P(2) can then be described as adopting quasi-capping positions, with a P(1)-Hf(1)-P(2) angle of 153.76(3)°, which is drawn back from the optimum 180° because of the constraints of the macrocyclic ligand framework. The small cavity size of the [P$_2$N$_2$] ligand forces the hafnium atom to sit atop the ligand, which places the two chlorides *cis* to each other.

The [P$_2$N$_2$] framework is distorted and adopts a C_2 twist in the solid state, a feature that has been observed in many [P$_2$N$_2$] complexes (5–10). The solid-state structure of **1** is both isomorphous and isostructural with that of its zirco-

nium analogue, [P$_2$N$_2$]ZrCl$_2$, and Table 1 shows a comparison of selected bond lengths and angles for the two compounds. As with the zirconium analogue, the Hf—N, Hf—P, and Hf—Cl bond lengths are not unusual and compare well with other group 4 amido and phosphine complexes (5, 11–13).

Like the zirconium derivative, the solid-state molecular structure of **1** does not match the solution structure. The ^{1}H NMR spectrum of **1** is virtually identical to that of the zirconium analogue, with slight displacements of each characteristic signal. The solution structure is more compatible with a C_{2v} symmetry. Only two signals due to the silyl methyl protons are observed, reflecting the "top and bottom" asymmetry of **1**. If the C_2 symmetry of the solid state is held in solution, one would expect to observe four silyl methyl signals. It seems, therefore, that the [P$_2$N$_2$] framework is quite flexible in solution and undergoes a "rocking" motion centered at the trigonal silyl amide groups. The ^{31}P{^{1}H} NMR spectrum of **1** shows a singlet at –5.8 ppm, which is shifted 8.5 ppm downfield from that observed for the zirconium analogue.

Reduction of [P$_2$N$_2$]HfCl$_2$ (1)

While ease of reduction is difficult to compare, tables of reduction potentials indicate that Hf is more difficult to reduce than zirconium (14–15). The first attempt to reduce **1** followed a procedure identical to the one that formed the zirconium dinitrogen complex; it involved reduction of the starting chloride complex with 2 equiv of potassium graphite (4), but the results were unexpected. Instead of the desired dinitrogen complex, the major product was the hafnium dimer, {[P$_2$N$_2$]Hf}$_2$ (**2**), with coordination of the activated phenyl rings on one phosphorus to the other metal atom (Scheme 2).

The NMR spectra of **2** are consistent with this dimeric formulation. The ^{1}H NMR spectrum shows a set of phosphorus–phenyl resonances in a 2:2:1 ratio at 4.22, 4.15, and 3.39 ppm, respectively. Coupling information is transmitted through the coordinated arene ring between metal centers,

Fig. 1. An ORTEP diagram of [P$_2$N$_2$]HfCl$_2$ (**1**), showing the solid-state molecular structure (ellipsoids at 50% probability). The silyl methyl groups have been omitted for clarity; only the *ipso* carbons of the phosphorus phenyl groups are shown.

M(1)—Cl(2)	2.461(1)	2.448(2)			

leading to an AA′BB′ pattern in the ^{31}P{^{1}H} NMR spectrum. This compound also has a zirconium analogue, {[P$_2$N$_2$]Zr}$_2$, which is the major product when [P$_2$N$_2$]ZrCl$_2$ is reduced with C$_8$K in the absence of N$_2$, for example, under Ar or in a degassed vessel (3). {[P$_2$N$_2$]Zr}$_2$ was first noticed as an impurity in the reaction that produces {[P$_2$N$_2$]Zr}(μ-η^2:η^2-N$_2$). For the zirconium system, under N$_2$, the dimer was a fairly minor impurity. When the metal center is changed to hafnium, the dimer appears to be the major product of this reaction, at least under these conditions.

Preparation and reduction of [P$_2$N$_2$]HfI$_2$ (3)

The only known hafnium dinitrogen complex, {Cp$^*_2$Hf(N$_2$)}$_2$(μ-N$_2$), was prepared from the precursor, Cp$^*_2$HfI$_2$, after attempts to use a dichloride complex as a starting material were unsuccessful (2). Reaction of a toluene solution of [P$_2$N$_2$]HfCl$_2$ (**1**) with a slight excess of trimethylsilyliodide resulted in formation of [P$_2$N$_2$]HfI$_2$ (**3**) (Scheme 3).

Assuming an analogous structure for the diiodide as was found for the dichloride, one would expect little change in the NMR spectra upon replacement of chloride with iodide, and to a degree this is observed. The ^{31}P{^{1}H} NMR signal is still a singlet at –5.4 ppm, shifted only 0.4 ppm downfield of

the dichloride **2**. In the ^{1}H NMR spectrum of the diiodide complex, the two silyl methyl signals are now separated by 0.3 ppm, while for the dichloride complex the separation is less than 0.05 ppm.

Reaction of [P$_2$N$_2$]HfI$_2$ (**3**) with 2 equiv of C$_8$K under 1 atm (1 atm = 101.325 kPa) of dinitrogen produced a mixture of products and a solution with an intense blue color, a color characteristic of the {[P$_2$N$_2$]Zr}(μ-η^2:η^2-N$_2$) analogue. These products, their tentative assignments, and their percentages as determined by ^{31}P{^{1}H} NMR spectroscopy are summarized in Table 2.

The ^{31}P{^{1}H} NMR chemical shift of the speculated dinitrogen complex, combined with the intense blue color of the solution, was an excellent indication of dinitrogen complex formation, but it remained uncertain that the signal at –8.2 ppm could be assigned to {[P$_2$N$_2$]Hf}(μ-η^2:η^2-N$_2$).

In an attempt to increase the yield of the dinitrogen complex **4**, the reaction was repeated in a sealed reactor, under 4 atm of dinitrogen, for a period of 8 days (Table 3). With these changes in reaction conditions, the signal at –8.2 ppm became the major signal. The large increase in integration size of this signal, when the only change to the reaction was to increase the N$_2$ pressure, is further evidence that the signal can be assigned to the dinitrogen complex. However, a

higher percentage of starting material remains when compared with the same reaction using 1 atm of N$_2$, and the other impurities are still present, although in smaller amounts.

Further characterization of {[P$_2$N$_2$]Hf}$_2$(μ-η^2:η^2-N$_2$) (4)

Further evidence for the formation of complex **4** comes from mass spectrometry data. Shown in Fig. 2 is a portion of the EI mass spectrum. Figure 3 shows the theoretical mass

Fig. 2. Selected EI mass spectrometry data for $([P_2N_2]Hf)_2N_2$ (**4**).
Fig. 3. Theoretical isotope distribution pattern for EI mass spectrometry analysis of $([P_2N_2]Hf)_2N_2$ (**4**), as determined by Isotope Pattern Calculator™ v. 1.6.6.
spectrometry signature one would expect from complex **4**. The theoretical signature is a near exact match for the experimental one shown in Fig. 2. In Fig. 2, signatures for $\{[P_2N_2]Hf\}_2N$ (where a single nitrogen atom has been stripped from the parent compound) and for $\{[P_2N_2]Hf\}_2$ (**2**) can also be seen and are labeled.

Not shown here, but also observed in the EI mass spectrum, are the signatures for $[P_2N_2]Hf(C_7H_8)$ (**5**) and for

Scheme 4. Synthesis of $[P_2N_2]HfMe_2$ (**6**).
[P_2N_2]HfI and [P_2N_2]Hf. Interestingly, no signature is observed for $[P_2N_2]HfI_2$ (**3**), likely because of the weakness of the Hf—I bond.

To confirm the presence of a dinitrogen compound in the products from the reaction of $[P_2N_2]HfI_2$ (**3**) with 2 equiv of C_8K, the mixture of products was degraded with HCl and the resultant products analyzed to detect hydrazine, according to literature procedure (16). Hydrazine was detected, confirming the presence of a dinitrogen compound; however, it was not possible to determine the percent of hydrazine formed per mole of $\{[P_2N_2]Hf\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (**4**), owing to the inability to isolate **4** in pure form.

Preparation and structure of $[P_2N_2]HfMe_2$ (6)

We were also interested in the organometallic chemistry of hafnium with the $[P_2N_2]$ ligand. $\{[P_2N_2]Zr\}_2(\mu\text{-}H)_4$ was prepared[3] from $[P_2N_2]ZrCl_2$, using C_8K as a reducing agent, under 4 atm of H_2. Interestingly, it does not appear to be possible to form a zirconium hydride from $[P_2N_2]ZrMe_2$. $[P_2N_2]ZrMe_2$ is extremely thermally and light sensitive, making it difficult to prepare in sufficient quantities to use in subsequent reactions. It is a well-established precedent that certain organometallic hafnium(IV) compounds are more thermally stable than their zirconium analogues (12, 17–19). As well, the use of hafnium analogues can facilitate investigation of intermediates in cases where this proves difficult for zirconium compounds (2, 20, 21). The synthesis of $[P_2N_2]HfMe_2$ (**6**) was accomplished by the metathesis reaction of $[P_2N_2]HfCl_2$ (**1**) with 2 equiv of the Grignard reagent, MeMgCl (Scheme 4).

Compound **6** was characterized by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy, elemental analysis, and X-ray crystal structure analysis. In a manner similar to most other known

mononuclear group 4 metal $[P_2N_2]$ complexes, the dimethyl compound adopts C_{2v} symmetry in solution at ambient temperature, as evidenced by NMR spectroscopy. As expected, the methyl protons are coupled to two equivalent phosphorus nuclei and appear as a triplet at 0.65 ppm. Unlike the case of the zirconium analogue, their signal is not masked by the $[P_2N_2]$ ligand methylene protons. Interestingly, while it was not possible to grow crystals of the zirconium analogue of this compound, crystals of the hafnium analogue were grown easily from slow evaporation of a DME solution. An ORTEP diagram of complex **6** is shown in Fig. 4. The substitution of methyl groups for chloride moieties upon going from **1** to **6** has resulted in a substantial structural change. The geometry around the metal center is now best described as trigonal prismatic, with the two trigonal planes described by N(1), P(1), and C(25) and N(2), P(2), and C(26). The methyl carbons are not located in a square plane with the amido nitrogens but are rotated out of this plane. As well, the phosphine and amide "bite angles", P(1)-Hf-P(2) and N(1)-Hf-N(2), have both changed considerably. The phosphine bite angle has decreased from 153.76(3)° to 135.79(3)°, while the amide bite angle has increased from 96.6(1)° to 113.2(1)°. Table 4 shows selected bond distances and angles for complex **6**. The Hf—C, Hf—N, and Hf—P bond distances are, once again, not unusual and compare well with other group 4 methyl complexes (11).

Preparation of $\{[P_2N_2]Hf\}(\mu\text{-}H)_4$ (7)

While hydrogenolysis of $[P_2N_2]ZrMe_2$ did not result in a zirconium hydride complex, a hafnium hydride was synthesized through hydrogenolysis. Reaction of $P_2N_2HfMe_2$ with H_2 gas in benzene gave $\{[P_2N_2]Hf\}_2(\mu\text{-}H)_4$ **7** (Scheme 5). Complex **7** is sparingly soluble in benzene and precipitates

Hf(1)—C(26)	2.277(1)		

out of solution as yellow microcrystals, making separation from the parent compound a simple matter.

The change in the chemical shift of the phosphorus nuclei, when switching from $\{[P_2N_2]Zr\}_2(\mu\text{-}H)_4$ to its hafnium analogue,[3] is more drastic than in other $[P_2N_2]$ compounds. The signal is observed at 4.4 ppm, downfield from the zirconium analogue signal at –5.9 ppm. As well, the hydride quintet (2, 22–24) is observed at 9.3 ppm, downfield from 5.0 ppm in the zirconium analogue. The other characteristic signals in the ^{1}H NMR spectrum have not changed appreciably.

Conclusions

The hafnium chemistry presented in this paper, while similar to the previously reported zirconium chemistry, does have some notable differences. Although the X-ray crystal structure of $[P_2N_2]HfCl_2$ (**1**) is isostructural and isomorphous with that of its zirconium analogue, the reactivity of **1**, especially under reducing conditions, is quite different. It was not possible to synthesize the hafnium dinitrogen compound $\{[P_2N_2]Hf\}(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$, in any appreciable amount, from $[P_2N_2]HfCl_2$ (**1**); instead, a hafnium dimer, $\{[P_2N_2]Hf\}_2$ (**2**), was the major product. However, changing the hafnium starting material from the chloride complex, **1**,

to the iodide complex did result in the formation of the hafnium dinitrogen complex, $\{[P_2N_2]Hf\}(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$ (**4**), after reduction with C_8K, as shown by NMR spectroscopy, EI mass spectrometry, and hydrazine analysis. Unfortunately, it has not been possible to isolate compound **4** in the solid state. Synthesis of $[P_2N_2]HfMe_2$ (**6**) proceeded in a manner identical to that of its zirconium analogue. The dimethyl derivative, **6**, reacts with H_2 to generate the dinuclear hafnium hydride, $\{[P_2N_2]Hf\}(\mu\text{-}H)_4$ (**7**), via hydrogenolysis; this reaction fails for the zirconium analogue, $[P_2N_2]ZrMe_2$.

Experimental

Materials and apparatus

All manipulations were performed under prepurified nitrogen in a Vacuum Atmospheres HE-553-2 workstation equipped with an MO-40-2H purification system or using Schlenk-type glassware. The term "reactor" refers to a cylindrical, thick-walled Pyrex vessel equipped with a 5 mm (or 10 mm, for larger bombs) Kontes teflon needle valve and a ground glass joint for attachment to a vacuum line. These "reactors" allow pressures as high as 4 atm to be maintained inside the tube. $HfCl_4$ (<0.05% Zr) was purchased from Strem and used as received. THF was predried by refluxing over CaH_2 for at least 24 h and dried by refluxing over sodium benzophenone ketyl, followed by distillation under argon. Toluene and hexanes were purchased in anhydrous form from Aldrich, sparged with N_2, and deoxygenated by filtration through columns containing silica and Q-5 catalyst under a positive pressure of N_2 (25). Benzene, diethyl ether, and dimethoxyethane were also refluxed over sodium benzophenone ketyl and distilled under argon. Deuterated THF (C_4D_8O) and deuterated benzene (C_6D_6) were refluxed under vacuum with sodium–potassium amalgam (Na–K),

Scheme 5. Synthesis of $\{[P_2N_2]Hf\}_2(\mu\text{-H})_4$ (**7**).
vacuum transferred to a clean vessel, and "freeze–pump–thawed" three times prior to use.

The following compounds were prepared by published procedures: $HfCl_4(THF)_2$ (**26**), $[syn\text{-}P_2N_2]Li_2(dioxane)$ (**27**), C_8K (**28**), and $Mg(C_4H_6)(THF)_2$. Me_3SiI, MeMgCl, BzMgCl, and H_2 were used as received. Diatomaceous earth (Celite) was dried overnight at 170 °C before being taken inside the glovebox for use.

Analytical methods

^1H and $^{31}P\{^1H\}$ NMR spectroscopy were performed on a Bruker AMX-500 instrument (500.135 and 202.458 MHz) or a Bruker AC-200 machine (200.132 and 81.015 MHz). ^1H NMR spectra were referenced to internal C_6D_5H (7.15 ppm), and $^{31}P\{^1H\}$ NMR spectra were referenced to external $P(OMe_3)_3$ (141.0 ppm, with respect to 85% H_3PO_4 at 0.00 ppm).

The theoretical EI signature was created using Isotope™ v. 1.6.6, a program designed specifically to model mass spectrometry signatures.

C, H, and N microanalyses were performed by Mr. P. Borda of this department, the Department of Chemistry, University of British Colombia (UBC). The X-ray crystal struc-

tures were determined at UBC Crystallographic Services in this department by Dr. B. Patrick. The crystals were loaded in a small glass vial and covered with paratone oil in the glovebox to prevent decomposition. Details of the structure determinations are given in the Appendices.[4]

Hydrazine analysis (16)

The products from the reaction of $[P_2N_2]HfI_2$ (**3**) with 2 equiv of C_8K were weighed into a 200 mL Schlenk tube (0.280 g) and dissolved in 50 mL of Et_2O. Ten millilitres of 2.0 mol L^{-1} HCl in Et_2O was added to this solution. The solution immediately lost its blue color, and a white precipitate formed. The clear solution and white precipitate were stirred for 1 h, and the solvents were removed in vacuo. The flask was exposed to the air, extracted into 100 mL of H_2O, and filtered into a 500 mL volumetric flask, which was filled with 1.0 mol L^{-1} HCl. A 2.0 mL aliquot of this solution was added to 20 mL of a color developer (p-dimethylaminobenzaldehyde, 4.0 g; ethanol, 200 mL; 1.0 mol L^{-1} HCl, 20 mL) and diluted to 25.0 mL with 1.0 mol L^{-1} HCl. Absorbance readings of the sample were taken within 10 min. The spectrometer was set to 100% transmittance, using a blank solution consisting of

---

1.0 mol L^{-1} HCl. Absorbance readings of 0.33, 0.34, and 0.33 AU were obtained at 458 nm.

Synthesis of [P$_2$N$_2$]HfCl$_2$ (1)

Li$_2$(dioxane)[P$_2$N$_2$] (6.83 g, 10.8 mmol) and HfCl$_4$(THF)$_2$ (5.00 g, 10.8 mmol) were each weighed into a thick-walled reactor. Addition of 150 mL toluene to this intimate mixture resulted in a cloudy white solution. The reactor was sealed, and the mixture was heated for 18 h at 120 °C. The solvents were then removed in vacuo; the off-white residue was extracted into toluene (2 × 50 mL) and filtered through Celite. The filtrate was evaporated to dryness and the residue washed with hexanes (2 × 10 mL), yielding **1** (7.25 g, 86%) as a white powder. The product was crystallized by the slow evaporation of a DME solution.

^{1}H NMR (C$_6$D$_6$, 25 °C, 500.135 MHz) δ: 7.87 (m, 4H, *o*-H phenyl), 7.05 (m, 6H, *m/p*-H phenyl), 1.41 (ABX m, 4H, CH$_2$ ring), 1.32 (ABX m, 4H, CH$_2$ ring), 0.38 (s, 12H, SiMe$_2$ ring), 0.34 (s, 12H, SiMe$_2$ ring). ^{31}P{^{1}H} (C$_6$D$_6$, 25 °C, 202.458 MHz) δ: −5.8 (s). Anal. calcd. for C$_{24}$H$_{42}$Cl$_2$HfN$_2$P$_2$Si$_4$: C 36.85, H 5.41, N 3.58; found: C 37.04, H 5.48, N 3.56.

Synthesis of {[P$_2$N$_2$]Hf}$_2$ (2)

[P$_2$N$_2$]HfCl$_2$ (**1**) (0.73 g, 0.93 mmol) and C$_8$K (0.25 g, 1.86 mmol) were each weighed into a 200 mL thick-walled reactor, to which 50 mL of toluene was added, all in the glovebox. The reactor was removed from the glovebox and cooled to −198 °C in a liquid nitrogen bath while under a flow of N$_2$. After allowing 30 min for equilibration, the reactor was sealed and allowed to warm to room temperature. The reaction mixture was stirred for 8 days and filtered through Celite. Toluene was removed in vacuo, and the residues were dissolved in hexanes and filtered. The hexanes solution was left in a −40 °C freezer overnight, where **2** crashed out of solution as a yellow-brown powder. Yield: 0.22 g, 32.2%. Note: further studies showed that it does not matter what type of atmosphere (N$_2$, Ar, or near vacuum) is inside the reactor.

^{1}H NMR (C$_6$D$_6$, 25 °C, 200.132 MHz) δ: 7.40 (m, 4H, *o*-H phenyl), 7.10 (m, 6H, *m/p*-H phenyl), 4.22 (m, 4H, *m/p*-H activated phenyl), 4.15 (m, 4H, *m/p*-H activated phenyl), 3.39 (m, 2H, *o*-H activated phenyl), 1.49 (ABX m, 8H, CH$_2$ ring), 1.15 (ABX m, 8H, CH$_2$ ring), 0.52 (s, 12H, SiMe$_2$ ring), 0.50 (s, 12H, SiMe$_2$ ring), 0.31 (s, 12H, SiMe$_2$ ring), 0.04 (s, 12H, SiMe$_2$ ring). ^{31}P{^{1}H} (C$_6$D$_6$, 25 °C, 81.015 MHz) δ: −6.3 (m). Anal. calcd. for C$_{48}$H$_{84}$Hf$_2$N$_4$P$_4$Si$_8$: C 40.52, H 5.95, N 3.95; found: C 40.39, H 5.97, N 3.75.

Synthesis of [P$_2$N$_2$]HfI$_2$ (3)

Me$_3$SiI (10.0 mL, 70 mmol, ~10 equiv) was added to a stirred solution of [P$_2$N$_2$]HfCl$_2$ (**1**) (5.21 g, 6.66 mmol) in 80 mL of toluene at −78 °C. The reactor was sealed and the solution stirred for 18 h, during which time the solution acquired a very pale yellow-green color. Toluene was removed in vacuo and the residues washed with hexanes (2 × 10 mL), yielding **3** (2.8 g, 88%) as a very pale green powder.

^{1}H NMR (C$_6$D$_6$, 25 °C, 200.132 MHz) δ: 7.92 (m, 4H, *o*-H phenyl), 7.05 (m, 6H, *m/p*-H phenyl), 1.58 (ABX m, 4H, CH$_2$ ring), 1.27 (ABX m, 4H, CH$_2$ ring), 0.48 (s, 12H,

SiMe$_2$ ring), 0.39 (s, 12H, SiMe$_2$ ring). ^{31}P{^{1}H} (C$_6$D$_6$, 25 °C, 81.015 MHz) δ: −5.4 (s). Anal. calcd. for C$_{24}$H$_{42}$I$_2$HfN$_2$P$_2$Si$_4$: C 29.87, H 4.39, N 2.90; found: C 30.02, H 4.43, N 2.89.

Attempted synthesis of {[P$_2$N$_2$]Hf}$_2$(μ-η^2:η^2-N$_2$) (4)

C$_8$K (0.33 g, 3.32 mmol) and [P$_2$N$_2$]HfI$_2$ (**3**) (1.21 g, 1.26 mmol) were each weighed into a 200 mL thick-walled reactor, to which 50 mL of toluene was added, all in the glovebox. The reactor was removed from the glovebox and cooled to −198 °C in a liquid nitrogen bath while under a flow of N$_2$. After allowing 30 min for equilibration, the reactor was sealed and allowed to warm to room temperature. Following 16 h of stirring, a blue-purple color was observed. The reactor was then allowed to stir vigorously for another 7 days. The solution was then filtered through Celite and evaporated to dryness. Washing with a minimal amount of hexanes (2 × 10 mL) yielded 0.85 g of a dark solid. ^{31}P{^{1}H} NMR indicates the composition of this solid to be approximately 52% **4**, 19% **3**, 16% **2**, and 13% **5**. EI-MS: 1450 ([M]$^+$).

Synthesis of [P$_2$N$_2$]HfMe$_2$ (6)

To a solution of [P$_2$N$_2$]HfCl$_2$ (**1**) (3.02 g, 3.86 mmol) in THF was added 3.0 mol L^{-1} MeMgCl in THF (2.57 mL, 7.77 mmol) at 0 °C. The solution was warmed to room temperature and stirred for 1 h, after which the solvents were evaporated in vacuo. The off-white residue was extracted into toluene (2 × 20 mL) and filtered through celite. The filtrate was evaporated to dryness, and the residue was washed with hexanes (2 × 10 mL), yielding **6** (2.24 g, 77%) as a white powder. The product was crystallized by the slow evaporation of a DME solution.

^{1}H NMR (C$_6$D$_6$, 25 °C, 500.135 MHz) δ: 7.62 (m, 4H, *o*-H phenyl), 7.07 (m, 6H, *m/p*-H phenyl), 1.03 (m, 8H, CH$_2$ ring), 0.72 (t, 6H, Zr-CH$_3$), 0.22 (s, 12H, SiMe$_2$ ring), 0.20 (s, 12H, SiMe$_2$ ring). ^{31}P{^{1}H} (C$_6$D$_6$, 25 °C, 202.458 MHz) δ: −9.6 (s). Anal. calcd. for C$_{26}$H$_{48}$HfN$_2$P$_2$Si$_4$: C 42.12, H 6.53, N 3.78; found: C 42.14, H 6.52, N 3.74.

Synthesis of {[P$_2$N$_2$]Hf}$_2$(μ-H$_4$) (7)

Fifty millilitres of C$_6$H$_6$ was added to 1.02 g (1.3 mmol) of [P$_2$N$_2$]HfMe$_2$ (**6**) in a reactor, which was sealed. The reactor was "freeze–pump–thawed" three times to remove all gases. H$_2$ was introduced to the reactor, which was cooled to −198 °C. After the solvent had thawed, but prior to warming to room temperature, the reactor was shaken to promote dissolution of H$_2$ in the solution. The reactor was left overnight, during which time a microcrystalline yellow solid precipitated. This solid was collected on a frit, yielding **7** (0.345 g, 37.2%).

^{1}H NMR (C$_6$D$_6$, 25 °C, 500.135 MHz) δ: 9.07 (quintet, $^2J_{HP}$ = 4.43 Hz, 4H, Hf-H), 7.19 (m, 8H, *o*-H phenyl), 7.12 (m, 12H, *m/p*-H phenyl), 0.83 (m, 16H, CH$_2$ ring), 0.04 (s, 24H, SiMe$_2$ ring), −0.03 (s, 24H, SiMe$_2$ ring). ^{31}P{^{1}H} (C$_6$D$_6$, 25 °C, 202.458 MHz) δ: 4.4 (s). Anal. calcd. for C$_{48}$H$_{88}$HfN$_2$P$_2$Si$_4$: C 40.41, H 6.22, N 3.93; found: C 40.56, H 6.21, N 3.76.

Lewis acidity of group 14 elements toward intramolecular sulfur in ortho-aryl-thioanisoles[1]

Teresita Munguia, Ioana S. Pavel, Ramesh N. Kapoor, Francisco Cervantes-Lee, László Párkányi, and Keith H. Pannell

Abstract: The series of compounds $(o\text{-}CH_3SC_6H_4)CH_2EPh_3$ (E = Si (**1**), Ge (**2**), Sn (**3**), and Pb (**4**)) have been synthesized and characterized by NMR spectroscopy and by single crystal X-ray diffraction. Compounds **1** and **2** are isostructural with a triclinic crystal system and P-1 space group; however, morphotropic steps occur between Ge and Sn, and Sn and Pb. While the E-S distances in **1** and **2** are 3.985 and 3.974 Å, respectively, ~100% of the sum of the respective van der Waals (vdW) radii, there is a notable distortion from tetrahedral geometry about E. Compound **3** is also triclinic with P-1 symmetry, but has two molecules in the unit cell that demonstrate a distorted tetrahedral geometry and intramolecular Sn-S distances of 3.699 and 3.829 Å, 88% and 91% of the sum of the vdW radii. Compound **4** has a Pb-S distance of 3.953 Å (91% of Σ vdW radii). The structure of the Grignard coupling product $[o\text{-}(SCH_3)C_6H_4CH_2]_2$ is also reported.

Key words: intramolecular self-assembly, silicon, germanium, tin, lead, sulfur.

Résumé : On a réalisé la synthèse d'une série de composés de formule $(o\text{-}CH_3SC_6H_4)CH_2EPh_3$ dans lesquels E = Si (**1**), Ge (**2**), Sn (**3**) et Pb (**4**) et on les a caractérisés par spectroscopie RMN et par diffraction des rayons X par un cristal unique. Les composés **1** et **2** sont isostructuraux avec un système cristallin triclinique et un groupe d'espace P-1; toutefois, on notre des différences morphotropes entre le Ge et le Sn ainsi qu'entre le Sn et le Pb. Alors que les distances E-S dans les composés **1** et **2** sont respectivement de 3,985 et 3,974 Å, environ 100 % de la somme des rayons respectifs de van der Waals, on note une distorsion notable par rapport à la géométrie tétraédrique autour de E. Le composé **3** est aussi triclinique avec une symétrie P-1, mais la maille cristalline comporte deux molécules ce qui démontre la présence d'une géométrie tétraédrique déformée alors que les distances intramoléculaires Sn-S de 3,699 et 3,829 Å correspondent respectivement à 88 % et 91 % de la somme des rayons de van der Waals. Dans le composé **4**, la distance Pb-S est de 3,593 Å (91 % de la somme des rayons de van der Waals). On a aussi déterminé la structure du produit de couplage de Grignard $[o\text{-}(SCH_3)C_6H_4CH_2]_2$.

Mots clés : auto-assemblage intramoléculaire, silicium, germanium, étain, plomb, soufre.

Introduction

The system $(o\text{-}CH_3SC_6H_4)CH_2EPh_3$ (E = Si (**1**), Ge (**2**), Sn (**3**), and Pb (**4**)) offers the capacity to examine intramolecular sulfur–metal interactions via a five-membered ring involving the *ortho-* thiomethyl group S atom (Fig. 1), such that the varying Lewis acidities of the elements toward sulfur may be evaluated. Furthermore, this possible hyper-

John: It has been one of my pleasures to get together with you periodically to talk, drink, and generally enjoy your company as well as your chemistry. Cheers, Keith.

valency could impact the potential morphotropic steps as originally described by Kitaigorodskii (1), and observed for simpler group 14 systems where only tetrahedral structures were possible. For example, the system Ph_4E (E = Si (2), Ge (3), Sn (4), Pb (5)) has been analyzed with respect to such structural variations, and more recent studies by Párkányi et al. (6) illustrated a morphotropic step occurring in the heteronuclear intra(inter)-group 14 bonding organometallic compounds $(R_3EE'R'R_2)$. In these systems the packing coefficient, defined as:

$$\eta = \frac{ZV_m}{V}$$

where Z is the number of molecules in the unit cell, V_m is the volume of the molecule, and V is the unit cell volume, must be significantly decreased to change the packing motif and create a morphotropic step (6). Thus, **1–4** present an appealing series with which to study whether the size changes of the group 14 element would be sufficient to change the packing coefficient. Furthermore, would the potential intramolecular metal–sulfur interaction be adequate to distort the tetrahedral geometry about the metal center and further aid, or impede, the potential for a morphotropic step.

Fig. 1. Triphenyl group 14 derivatives of *o*-aryl thioanisol.
E = Si, Ge, Sn, Pb

Compounds in which systematic evaluations of the intramolecular interactions among group 14 organometallic compounds have been previously reported but were limited to investigations between tin and sulfur, as demonstrated by Wardell and co-workers (7), Tzschach and co-workers (8), and Dräger and co-workers (9) (Fig. 2).

Experimental section

General techniques

All syntheses were performed under a nitrogen atmosphere using standard Schlenk line techniques. Reagent grade tetrahydrofuran (THF) and hexanes were dried and distilled under nitrogen from a sodium benzophenone ketyl solution; benzene was dried and distilled from Na ribbon. Thionyl chloride was purchased from Fisher Scientific and purified by distillation; pyridine was purchased from E M Science and dried and distilled over KOH; Ph_3SiCl and Ph_3GeCl were purchased from Gelest; Ph_3SnCl, Ph_3PbCl, thiosalicylic acid, and dimethyl sulfate were purchased from Aldrich and were used as received. NMR spectra of all compounds were recorded on a Bruker 300 MHz spectrometer in $CDCl_3$. Elemental analyses were performed by Galbraith Laboratories.

Syntheses of *o*-(methylthio)benzoic acid (10), *o*-(methylthio)benzyl alcohol (10, 11), and *o*-(methylthio)benzyl chloride (12) followed literature procedures. *o*-(Methylthio)benzoic acid, mp 165 °C (lit. (10) value 167–169 °C). ^{1}H NMR ($CDCl_3$) δ: 2.5 (3H, s, S-CH$_3$), 7.2–7.5 (4H, m, Ph), 8.1 (1H, d, COOH). ^{13}C NMR ($CDCl_3$) δ: 15.6 (SCH$_3$), 123.5, 124.4, 125.5, 132.5, 133.3 (C$_{ipso}$), 144.4 (C$_{ipso}$), 171.5 (COOH). *o*-(Methylthio)benzyl alcohol, bp 156 °C/17 mmHg (1 mmHg = 133.322 Pa) (lit. (10) value 88 °C/0.001 mmHg (1 mmHg = 133.322 Pa)). ^{1}H NMR ($CDCl_3$) δ: 2.4 (3H, s, s-CH$_3$), 3.3 (1H, s, OH), 4.7 (2H, s, C*H$_2$*-OH), 7.2–7.4 (4H, m, Ph). ^{13}C NMR ($CDCl_3$) δ: 16.3 (S-CH$_3$), 63.2 (CH$_2$-OH), 125.7, 126.5, 128.0, 128.5, 136.8 (C$_{ipso}$),139.3 (C$_{ipso}$). *o*-(Methylthio)benzyl chloride, bp 123 °C/9 mmHg (1 mmHg = 133.322 Pa) (lit. (12) value 75 to 76 °C/1 × 10^{-2} mmHg (1 mmHg = 133.322 Pa)). ^{1}H NMR ($CDCl_3$) δ: 2.5 (3H, s, S-CH$_3$), 4.8 (2H, s, CH$_2$-Cl), 7.2–7.4 (4H, m, Ph). ^{13}C NMR ($CDCl_3$) δ: 16.7 (S-CH$_3$), 45.1 (CH$_2$-Cl), 126.0, 127.3, 129.9, 130.6, 136.0 (C$_{ipso}$), 139.1 (C$_{ipso}$).

The syntheses of the group 14 derivatives of *o*-(methylthio)benzyl chloride were accomplished as illustrated below for the silicon derivative in similar yields.

Synthesis of *o*-(methylthio)benzyl triphenylsilane (1)

To a suspension of Li metal (0.55 g, 79 mmol) in THF (20 mL) was added dropwise a solution of Ph_3SiCl (1.7 g, 5.8 mmol) in THF (15 mL) at 0 °C. The reaction mixture was allowed to warm to room temperature and stirred for 16 h resulting in a dark brown-black color. The solution was transferred via cannula to a dropping funnel and then added dropwise at –78 °C to a solution of *o*-(methylthio)benzyl chloride (*o*-(SCH$_3$C$_6$H$_4$)CH$_2$Cl, 1.0 g, 5.8 mmol) in THF (20 mL). This mixture was allowed to warm to room temperature and stirred for 16 h. The solvent was removed under reduced pressure, and the product was extracted with a solution of 80 mL of hexanes and 5 mL dichloromethane and subsequently filtered to remove LiCl. The crude material was recrystallized from a hot hexanes:dichloromethane solution (10:1).

o-(SCH$_3$C$_6$H$_4$)CH$_2$SiPh$_3$ (**1**) yield: 0.79 g (35%); mp 110–112 °C. ^{1}H NMR ($CDCl_3$) δ: 2.1 (3H, s, S-CH$_3$), 3.2 (2H, s, CH$_2$-Si), 7.5–6.9 (19H, m, Ph). ^{13}C NMR ($CDCl_3$) δ: 16.6 (S-CH$_3$), 21.2 (CH$_2$-Si), 125.1, 125.4, 127.3, 127.6, 129.0, 129.4, 134.4 (C$_{ipso}$), 135.9, 137.1 (C$_{ipso}$), 137.8 (C$_{ipso}$). ^{29}Si NMR ($CDCl_3$) δ: –11.9 Anal. calcd. for C$_{26}$H$_{24}$SSi: C 78.74, H 6.10; found: C 77.86, H 6.08.

Alternative synthesis of *o*-(methylthio)benzyl triphenyllead (4)

o-(Methylthio)benzyl chloride (1.0 g, 5.9 mmol) was added dropwise to a mixture of Ph_3PbCl (2.8 g, 5.9 mmol) and Mg turnings (0.15 g, 6.2 mmol) in THF (10 mL) at 0 °C. The reaction mixture was kept at 0 °C and allowed to stir until all the Mg had been consumed (16 h). The solution was transferred via cannula to another flask where the solvent was removed under reduced pressure and the product was extracted with 80 mL hexanes and 5 mL of dichloromethane and the solution filtered. The crude material was

recrystallized from a hexane:dichloromethane solution (10:1) and cooled to –20 °C to yield **4**, 1.2 g (70%). This method was also used for the synthesis of **3** in a similar yield.

X-ray structural analysis

Crystals suitable for X-ray diffraction were obtained for compounds **1–4**, and **5** from hexane–dichloromethane solutions. Five colorless crystals **1**, **2**, **3**, **4**, and **5** were mounted on glass fibers in a random orientation. Intensity data were collected at room temperature for **1**, **2**, **5** and –85°C for **3** using a Siemens/Bruker four-circle diffractometer with graphite-monochromated Mo Kα radiation. Unit cell parameters and standard deviations were obtained by least-squares fit of 25 reflections randomly distributed in reciprocal space in the 2θ range of 15°–30°. The ω-scan technique was used for intensity measurements in all cases. A range of 1.2° in ω and variable speed of 4.00–20.00 °/min was used for com-

pounds **1**, **2**, **3**, and **5**. Background counts were taken with a stationary crystal and total background time to scan time ratio of 0.5. Three standard reflections were monitored in all cases every 97 reflections and showed no significant decay. The data were corrected for Lorentz and polarization effects and a semiempirical absorption correction was also applied to the data set of **2** giving a min/max transmission ratio of 0.090:0.153. No absorption correction was applied to the data sets of **1**, **3**, and **5**.

Intensity data for compound **4** were collected at room temperature on a Bruker SMART system with an APEX CCD detector. All structures were solved by direct methods and refined using the PC version of the SHELEXTL PLUS crystallographic software by Siemens.[3] Full-matrix least-squares refinement of F^2 against all reflections was carried out with anisotropic thermal parameters for non-hydrogen atoms. Hydrogen atoms for **1**, **2**, **3**, and **5** were placed at calculated positions (C-H = 0.96 Å; U_H = 0.08) during refinements, whereas those in compound **4** were located on a difference map. The weighing scheme has the form $w^{-1} = \sigma^2(F_o^2) + (aP)^2 + bP$, where P is $[2F_c^2 + \max(F_o^2, 0)]/3$ and the final R factors have the form $R_1 = \Sigma |F_o - F_c| / \Sigma F_o$ and $R_{w2} = \{\Sigma [w(F_o^2 - F_c^2)^2 / \Sigma [w(F_o^2)^2]\}^{1/2}$; these and some other relevant crystallographic parameters are summarized in Table 1 and selected bond lengths and angles are presented in Tables 2 and 3.

Compounds **1**–**3** (Figs. 3–5, respectively) crystallize in the triclinic form with space group P-1. The latter compound has two independent molecules in the asymmetric unit (**3a** and **3b**). Compound **4**, in contrast, crystallized in the monoclinic crystal structure with a space group of $P2(1)/c$ (Fig. 6).

Results and discussion

Synthesis and characterization

We have used two salt-elimination reactions to attach the *o*-(methylthio)benzyl chloride ligand to the group 14 atom (eqs. [1] and [2]).
Both routes are successful; however, when using the Grignard route we observed the significant production of the coupling product ([CH$_2$(*o*-C$_6$H$_4$SMe)]$_2$ (**5**)). This is formed during the initial attempts to make the Grignard reagent prior to subsequent addition of the group 14 halide. Modification of the procedure to form the Grignard in situ in the

Fig. 3. Molecular diagram of **1**.
Fig. 4. Molecular diagram of **2**.
presence of the halide reduced the extent of this problem and resulted in the desired product in good yields (75%).

The reaction pathway involving the use of organometallic lithium salt was equally successful. However, we think the greater flexibility of the chemistry in eq. [1] makes this a more general and useful route to such compounds, where the organometallic lithium salts are less readily available. The spectroscopic and elemental analytical data for the compounds **1**–**4** are in total accord with their proposed structures, as is the data for **5**.

Periodic trends in the structural data for compounds 1–4

The E-S intramolecular distance in compounds **1**–**4** is an essential structural feature for analysis of the progressive change E = Si, Ge, Sn, and Pb. Not only is it an indirect

method of testing the Lewis acidity toward S of the central metal atom, but it also lends a conformational degree of freedom that may effect any potential morphotropic transition. Table 4 is a summary of covalent radii (13), van der Waals (vdW) radii (13, 14), their sums, and their comparison to experimental E-S distances. Both **1** and **2** exhibit E-S distances that are ~100% of the sum of the vdW radii indicating that there are no significant intramolecular interactions between the metal center and sulfur. The Sn-S interactions in compound **3** are 3.699 Å (**3a**) and 3.829 Å (**3b**), an average distance of ~90% of the sum of the vdW radii, similar to that in the lead compound **4**, Pb-S = 3.953 Å, 91% of the vdW radii.

Both the ipso phenyl C—E bond lengths in compounds **1**–**4** vary as expected because of the greater atomic radius of the group 14 elements in the order Si < Ge < Sn < Pb and are similar to those reported in the series Ph_4E (2–5). Bonds between E and benzyl groups are not well represented in the literature, with the exception of that in $Ph_3PbCH_2C_6H_5$ (15). The present examples also exhibit the expected increase in bond lengths from C—Si to C—Pb, C1—E (E = Si, Ge, Sn, Pb) = 1.896, 1.976, 2.174, and 2.244 Å, respectively.

Consequences of E–S interaction on tetrahedral geometry

In a perfect tetrahedral geometry, each angle is 109.5° and the sum of three threefold symmetry angles will equal 328.5°. Group 14 organometallic compounds do not necessarily exhibit perfect tetrahedral geometry and the amount of distortion varies from system to system. In the Ph_4E system, all the molecules are spherical, crystallizing in the tetragonal space group $P\,42_1c$ (2–5). Despite the spherical nature and symmetry of these molecules, the C-E-C dihedral angles have a range of 108.1–111.2 (2–5). The wide range of angles creates difficulty when comparing systems; as a result, all angles of compounds **1**–**4** are compared with perfect tetrahedral geometry. The "base" of the tetrahedral in this series is comprised of the bond angles that would be *pushed* up as the sulfur atom approaches the metal center trans to the "axial" phenyl group. The numbering schemes for compounds **1** and **2** are identical; however, the numbering is slightly different in the phenyl region for **3** and **4**. For compounds **1** and **2**, angle C1-E-C9 is smaller than 109.5°, ranging from 104.57°

Fig. 5. Molecular diagram of **3**.
Fig. 6. Molecular diagram of **4**.
for **1** to 104.84° for **2** with corresponding increases in C1-E-C15. As we would expect for compounds with no E–S interactions, the third angle (C9-E-C15) would also be close to 109.5°. The compounds **3a** and **4** (with E–S interactions of 88% and 91% of the sum of the vdW radii, respectively) have analogous angles that are smaller than 109.5° (108.0° and 107.0°, respectively). However, the other two angles in

the base do not adjust to preserve the sum of 328.5°, as in compounds **1** and **2**. When all three angles in the base plane are added together, **3a** and **4** have the largest differences from 328.5°, 333.4°, and 333.71° in that order, indicating that the C-E-C plane is being pushed up slightly by the E–S interactions. Table 5 summarizes the bond angles and their sums for compounds **1**–**4**.

Further indications of the distortion about the central metal atom are the axial angles. The sum of these angles under normal geometry would also be 328.5°. Once the base plane is pushed up by increasing E–S interactions, the sum of these three angles mentioned above should be *less than* 328.5°. Indeed after analysis, the two compounds with the smallest sums are **3a** (323.3°) and **4** (323.06°), precisely the compounds with the shortest E-S distances in terms of % Σ vdW radii.

Another trend that illustrates how the E–S interaction distorts the molecule is that as the E-S distance decreases, the C(2)-C(1)-E bond angle decreases as well. This makes sense because angle C(1)-C(2)-C(3) will not change much because of the rigid angle system dictated by the aromatic ring. As a result, the only angle within the "arm" substructure that gives flexibility is the C(2)-C(1)-E angle, which contains the methylene moiety. Shortening of the E-S distance would be facilitated by a contraction of the C(2)-C(1)-E angle. Indeed this angle does contract when comparing **1** and **2** with compounds **3** and **4**, with the minimum occurring at compound **3**.

Isostructural considerations

We have investigated the possible isostrucutural relationships of **1**–**4**. From their respective structural data **1** and **2** seem to be isostructural. However, due to the high degree of freedom of assigning a triclinic unit cell and putting the molecule in that cell with respect to the eight centers of symmetry, the observation is not truly a proof. We computed a least-squares fit of these two molecules including all non-

Fig. 7. Superposed structures of **3a** and **3b**.

Table 6. Molecular volumes and packing coefficients for **1**–**4**.

Molecule	Volume (Å^3)	Packing coefficient
Si	371.1	0.68
Ge	374.6	0.68
Sn 1	386.1	0.69
Sn 2	385.9	0.69
Pb	388.3	0.71

Fig. 9. Molecular diagram of **5**.

hydrogen atoms and the mean distance is 0.100 Å; RMS = 0.0823, a rather good fit. To prove absolutely we refined the Si structure with the coordinates of the Ge compound and in this manner proved that **1** and **2** are isostructural (*R* = 0.0476). The Sn and Pb derivatives do not belong (in the sense of isostructurality) to a homologous series.

A superpositioning of the two forms of the tin compound (**3a** and **3b**) is illustrated in Fig. 7 and their two distinct conformations are presented in Fig. 8. The two independent molecules are not superimposible, except to a high degree the Sn–S interaction grouping, despite their differing Sn-S distances. The two forms have fully staggered (**3b**) and partially eclipsed forms (**3a**), which is similar to other organometallic group 14 compounds (16). Thus, despite being relatively weak, the intramolecular Sn-S interactions have a significant effect upon the conformational character of the two molecules.

We have computed molecular volumes and packing coefficients for **1**–**4** (Table 6). These data illustrate a significant jump in the molecular volume between Ge and Sn, where the morphotropic step occurs. Overall, the packing coefficients are very similar, and the slight increase in the value for lead could be the driving force for the change in its crystal form.

Magnesium-induced dimerization of *o*-(SCH₃)C₆H₄CH₂Cl

The capacity of Grignard reagents to produce dimers of their parent organic halides is well established, thus the formation of **5** from such attempted reactions is not surprising. In 1980 an attempt by Zheltov et al. (17) to study the conjugation of aromatic disulfides by UV, mentions the preparation of compound **5**, however, studies were limited, hence we have performed a single crystal structural analysis.
Compound **5** (Fig. 9) crystallized in the monoclinic crystal group with a space group of *P*2(1)/*n*. In total its structure is unremarkable, however, the various bond lengths and angles about the S atom serve as a baseline to note any variations in **1**–**4** by virtue of the intramolecular E–S interactions (Table 5).

Synthesis and characterization of tantalum(V) metallaheterocycle (Me$_2$N)$_3$TaN(SiMe$_3$)SiMe$_2$CH$_2$ and chloro-mixed-amide (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$][1]

Hu Cai, Xianghua Yu, Tianniu Chen, Xue-Tai Chen, Xiao-Zeng You, and Ziling Xue

Abstract: A new mixed-amido complex (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (**1**) was prepared from the reaction of (Me$_2$N)$_3$TaCl$_2$ with 1 equiv. of LiN(SiMe$_3$)$_2$. The reactions of **1** with 1 equiv. of LiN(SiMe$_3$)$_2$ or (Me$_2$N)$_3$TaCl$_2$ with 2 equiv. of LiN(SiMe$_3$)$_2$ gave (Me$_2$N)$_3$TaN(SiMe$_3$)SiMe$_2$CH$_2$ (**2**) with a four-membered metallaheterocyclic ring through γ-hydrogen abstraction. In the solid state, **1** adopts a distorted trigonal bipyramidal geometry with the -N(SiMe$_3$)$_2$ and -Cl ligands in the equatorial and axial positions, respectively. The X-ray structure of **2** reveals that it is in a distorted trigonal bipyramidal geometry with a planar metallaheterocyclic ring.

Key words: tantalum, γ-hydrogen abstraction, C-H activation, amido complexes, metallacycle.

Résumé : On a préparé un nouveau complexe amido mixte, (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (**1**) par réaction du LiN(SiMe$_3$)$_2$ ou du (Me$_2$N)$_3$TaCl$_2$ avec 2 équivalents de LiN(SiMe$_3$)$_2$ conduit, par l'abstraction d'un hydrogène en γ, à la formation du (Me$_2$N)$_3$TaN(SiMe$_3$)SiMe$_2$CH$_2$ (**2**) comportant un cycle métallahétérocyclique à quatre chaînons. À l'état solide, le composé **1** adopte une géométrie bipyramidale trigonale déformée dans laquelle les ligands -N(SiMe$_3$)$_2$ et -Cl occupent respectivement des positions équatoriale et axiale. La structure du composé **2** déterminé par diffraction des rayons X révèle qu'il existe dans une géométrie bipyramidale trigonale déformée comportant un cycle métallahétérocyclique plan.

Mots clés : tantale, abstraction d'hydrogène en γ, activation du C-H, complexes amido, métallacycle.

[Traduit par la Rédaction]

Introduction

Early transition-metal amido complexes have been studied for their unique chemistry (1) and their potential applications in molecular approaches to metal nitrides and metal oxides as microelectronic materials (2, 3). Cyclopentadienyl-free, homoleptic dialkylamido d^0-complexes M(NR$_2$)$_n$ play an important role in the studies of the amido chemistry. Disilylamido ligand -N(SiMe$_3$)$_2$, as a bulkier and weaker p–d π back-bond donor than dialkylamido ligands (1a), has also shown unique chemistry and attracted much interest (4). Complexes containing -N(SiMe$_3$)$_2$ or NH(SiMe$_3$)$_2$ ligands have been used as precursors to yield metal nitrides (3a–3c) or metal silicates (metal oxide – SiO$_2$ ternary materials) (3d).

Molecular approaches to Ta-based materials from d^0-Ta amide precursors, in particular, have been studied in part because of unique properties of the Ta-based materials. For example, Ta$_2$O$_5$ appears to be the most promising replacement for SiO$_2$ as the new gate oxide material in microelectronic transistors because of its low porosity and high thickness uniformity (2d). Chemical vapor deposition of Ta$_2$O$_5$ thin films from Ta amide precursors is of intense current interest (2d–2f).

In the preparation of metal nitride and metal oxide thin films from -NMe$_2$ (2b, 2d), -N(SiMe$_3$)$_2$ (3b), -NH(SiMe$_3$) (3a), and NH(SiMe$_3$)$_2$ (3c) complexes, C incorporations into the films as metal carbides were often observed. Hydrogen abstraction reactions among amide ligands to yield M—C bonds are of current interest to understand the mechanism of M—C bond formation and are important to the design of precursors and molecular approaches to metal nitride and metal oxide materials (2a, 4c–4d, 5). β-H abstraction between -N(CHRR′)$_2$ ligands has been shown to give M—C bonds (5). The mechanism of M—C bond formation from ligands such as -N(SiMe$_3$)$_2$ with no β-hydrogen atoms is of current interest.

We recently reported several new d^0-amido silyl complexes and unusual reactions of homoleptic d^0-dimethyl-amido complexes (M(NMe$_2$)$_n$) with silanes to give amido hydrido complexes (5j, 6). In particular, Ta amide complexes and their reactivities are of interest to us in part because Ta-

Chart 1.

Me₂N, Me₂N—Ta—CH₂ with NMe₂ and the four-membered ring N—SiMe₂, Me₃Si

2
based microelectronic materials are known to have unique properties (2*d*–2*f*). We recently found that the reactions of $(Me_2N)_3TaCl_2$ with 2 equiv. of $LiN(SiMe_3)_2$ or $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**) with 1 equiv. of $LiN(SiMe_3)_2$ gave cleanly $(Me_2N)_3TaN(SiMe_3)SiMe_2CH_2$ (**2**) with a four-membered metallaheterocyclic ring containing a Ta—C bond (Chart 1). γ-H abstraction reaction with a Ta or a d^0 group 5 complex to give such a heterocycle has, to our knowledge, not been reported. The reaction of $(Me_2N)_3TaCl_2$ with 1 equiv. of $LiN(SiMe_3)_2$ replaced one Cl^- ligand to give $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**). These studies are reported here.

Results and discussion

Preparation and characterization of 1 and 2

Reaction of $Ta(NMe_2)_3Cl_2$ with $LiN(SiMe_3)_2$ in pentane gave $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**) in almost quantitative yield (Scheme 1). This complex is stable at room temperature. Its ¹H and ¹³C{¹H} NMR spectra at 23 °C showed single peaks for both the -N(SiMe₃)₂ and the three -NMe₂ ligands. These observations indicate fast rotations of these ligands and a fast exchange between the axial and two equatorial -NMe₂ ligands in distorted trigonal bipyramidal **1**, as revealed in its X-ray structure discussed below. The chemical shifts of 3.34 ppm for N*Me*₂, and 0.39 ppm for Si*Me*₃ in the ¹H NMR spectrum, and 49.63 ppm for N*Me*₂ and 4.23 ppm for Si*Me*₃ in the ¹³C{¹H} NMR spectrum, respectively, are typical for these amido groups.

The colourless four-membered metallaheterocyclic **2** in the current study could be prepared either by the reaction of $Ta(NMe_2)_3Cl_2$ with 2 equiv. of $LiN(SiMe_3)_2$ or by the reaction of **1** with 1 equiv. of $LiN(SiMe_3)_2$ in nonpolar solvents. Both gave almost quantitative yield of **2**. In the latter preparation, the reaction was ca. 75% complete in 1.5 h at room temperature in benzene-d_6. The formation of $HN(SiMe_3)_2$ in both reactions were observed in ¹H and ¹³C{¹H} NMR and GC–MS. The ¹H and ¹³C{¹H} NMR spectra of **2** were consistent with the cyclic structure in Chart 1. Overlapping ¹H NMR resonances of C*H*₂SiMe₂ and Si*Me*₃ were observed at 0.19 ppm in benzene-d_6 at 23 °C, and this was confirmed by ¹H NMR integration to 11H, and by 2D HMQC NMR studies. In the latter, crosspeaks between ¹H resonances at 0.19 ppm and ¹³C NMR resonances at both C*H*₂SiMe₂ (39.64 ppm) and Si*Me*₃ (4.45 ppm) were observed. In the DEPT-135 ¹³C NMR spectrum of **2**, the -CH₂- resonance at 39.64 ppm appeared as a negative peak, while those of -N*Me*₂, -Si*Me*₃, and -Si*Me*₂ were positive. In the ¹H NMR spectrum of **2** in toluene-d_8 at 23 °C, there was no overlap of the resonances of Si*Me*₃ and C*H*₂SiMe₂, and they were ob-

2
served at 0.16 and 0.14 ppm, respectively. The three chemically inequivalent -NMe₂ ligands in the distorted trigonal bipyramidal **2**, as its X-ray structure to be discussed below suggested, were observed as one single peak in both ¹H and ¹³C{¹H} NMR spectra at 23 °C, indicating a fast exchange among these ligands.

The reaction of $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**) with 1 equiv. of $LiNMe_2$ was found to give **2** as well. In 2 min, **2** was observed in the ¹H NMR spectrum along with HNMe₂ and several unidentified peaks in both -NMe₂ and -N(SiMe₃)₂ regions. Unreacted **1** and LiNMe₂ were observed as well. In 10 min, the formation of **2** was essentially complete (in ca. 27% yield). HNMe₂ was observed along with other unidentified products. ¹³C NMR of the solution confirmed the formation of **2**. These observations indicated that the reaction was not clean. In comparison, the reaction of **1** with $LiN(SiMe_3)_2$ gave almost quantitative yield of **2**. It is not clear, however, what the mechanism of the reaction between $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**) and LiNMe₂ is.

γ-Hydrogen abstraction reactions involving -N[Si(CH₃)₃]₂ ligands to give metallaheterocycles with M—C bonds have been reported (7–22). Complexes in Fig. 1 represent those with four-membered metallaheterocycles similar to that in **2**. Their formation involves similar γ-hydrogen abstraction from a -N[Si(CH₃)₃]₂ ligand in the C-H activation reactions.

Complex **2** was found to be inert to HNMe₂. A solution of **2** in benzene-d_6 was bubbled with HNMe₂ in N₂ for 4 h. Both ¹H and ¹³C NMR spectra of the solution afterwards showed only the peaks of **2** and HNMe₂.

Mechanistic considerations

The reaction of $(Me_2N)_3Ta(Cl)[N(SiMe_3)_2]$ (**1**) with $LiN(SiMe_3)_2$ in toluene-d_8 at 23 °C was monitored by ¹H NMR. Approximately 40% of **1** was converted to **2** in 4 min. When the mixture was cooled to –25 °C after 4 min at 23 °C, two broad peaks at 3.06 and 0.63 ppm were observed. At 23 °C, these two peaks were observed at 3.09 and 0.52 ppm, respectively; the former overlapped with the

-NMe₂ resonance of **2**. At 23 °C, these two broad peaks gradually disappeared, as the nearly quantitative conversion of **1** to **2** was complete. The emergence and disappearance of these two peaks are consistent with (Me₂N)₃Ta[N(SiMe₃)₂]₂ (**15**) as an intermediate in the formation of **2**. The presence of two bulky -N(SiMe₃)₂ ligands in **15** perhaps makes it unstable, driving the elimination of HN(SiMe₃)₂ from **15** and the formation of cyclic **2** (Scheme 2).

X-ray structures of 1 and 2

Crystal data and a summary of intensity data collection parameters for **1** and **2** are given in Table 1. Selected bond distances and angles in **1** and **2** are listed in Tables 2 and 3,

respectively.[3] ORTEP views of **1** and **2** are shown in Figs. 2 and 3, respectively.

The solid-state structure of **1** adopts a distorted trigonal bipyramidal (TBP) geometry with axial -Cl and -NMe₂ ligands and the bulky -N(SiMe₃)₂ ligand in the equatorial position. Such an arrangement, as predicted by the valence shell electron pair repulsion (VSEPR) theory (23), minimizes the ligand repulsion. Similar TBP geometries were observed in (Me₂N)₃Ta(p-tolyl)Br (24) and (Me₂N)₃Ta(X)SiR₃ (X = Cl, Br, R₃ = Si(SiMe₃)₃, **16a**, **16b**; X = Cl, R₃ = t-BuPh₂, **16c**) (6c), where the small halide and bulky silyl ligands adopt axial and equatorial positions, respectively. The trans N(3)-Ta-Cl(1) angle of 170.90(13)° is close to those in (Me₂N)₃Ta(p-tolyl)Br (173.1(2)°) (24), **16a**, **16b** (178.1(2)°

and 174.6(2)°), and **16c** (174.5(4)°) (6*c*). The Ta—N bond in Ta-N(SiMe$_3$)$_2$ (2.020(3) Å) is slightly longer than those in axial or equatorial Ta-NMe$_2$ (1.956(4)–1.987(4) Å) in **1** and those in [(Me$_3$Si)N]$_2$TaCl$_3$ (1.928(7) and 1.933(7) Å) (4*a*).

The Ta—Cl bond length of 2.4871(13) Å in **1** is comparable to those in **16c** (2.454(4) Å) (6*c*), and the terminal Ta—Cl bond distances in (Me$_2$N)(Me$_2$NH)TaCl$_3$ (2.391(2)–2.450(2) Å) (25), [(Me$_2$N)(Me$_2$NH)TaCl$_2$]$_2$O (2.417(2) and 2.505(2) Å) (25), [(Me$_2$N)$_3$TaCl$_2$]$_2$ (2.463(1) Å) (25), and [(Me$_3$Si)N]$_2$TaCl$_3$ (2.351(2)–2.366(2) Å) (4*a*).

A few transition metal complexes (**5**, **7–9**, and **12–14**, Fig. 1) with the metallaheterocycles similar to that in **2** have been structurally characterized. The structure of **2** adopts a distorted trigonal bipyramidal geometry with one amido ligand N(1) and the ring N(4) atom in the axial positions. The N(1)-Ta(1)-N(4) angle of 161.7(4)° deviated from the ideal 180°. The Ta atom is 0.0229 Å away from the equatorial plane defined by the N(2), N(3), and C(12) atoms, and the two axial atoms N(1) and N(4) are about at an equal distance (2.0578 and 2.0159 Å) from the plane. Both N(1) and N(4) atoms in the axial positions are tilted toward the C(12) atom in the equatorial plane with N(1)-Ta(1)-C(12) and N(4)-Ta(1)-C(12) angles of 87.0(3)° and 74.6(3)°, respectively. The angles of the axial N(1) atom with equatorial N(2) and N(3) atoms are N(1)-Ta(1)-N(2) = 92.9(3)° and N(1)-Ta(1)-N(3) = 91.9(3)°, respectively. In comparison, larger angles of the axial N(4) atom in the ring with N(2) and N(3) atoms (95.7(3)° and 97.4(3)°, respectively) were observed.

The four atoms in the ring are nearly coplanar with a 0.0549 Å deviation of the Ta(1) atom from the plane defined by the other three ring atoms (C(12), N(4), and Si(2)). The sum of angles inside the ring is 359.9°, consistent with the planar structure. In fact it is interesting to note that the Si(1) atom in the SiMe$_3$ group and the N(1) atom in the axial position are nearly coplanar with the four ring atoms Ta(1),

Table 3. Selected bond lengths (Å) and angles (°) in **2**.

Bond lengths (Å)	
Ta(1)—N(3)	1.975(7)
Ta(1)—N(2)	1.984(8)
Ta(1)—N(1)	2.039(8)
Ta(1)—N(4)	2.109(7)
Ta(1)—C(12)	2.228(9)
Si(1)—N(4)	1.715(9)
Si(2)—N(4)	1.726(9)
Si(2)—C(12)	1.844(10)
Si(2)—C(10)	1.870(11)
Si(2)—C(11)	1.886(12)
Bond angles (°)	
N(3)-Ta(1)-N(2)	120.8(4)
N(3)-Ta(1)-N(1)	91.9(3)
N(2)-Ta(1)-N(1)	92.9(3)
N(3)-Ta(1)-N(4)	97.4(3)
N(2)-Ta(1)-N(4)	95.7(3)
N(1)-Ta(1)-N(4)	161.7(4)
N(3)-Ta(1)-C(12)	119.7(4)
N(2)-Ta(1)-C(12)	119.5(4)
N(1)-Ta(1)-C(12)	87.0(3)
N(4)-Ta(1)-C(12)	74.6(3)
Si(1)-N(4)-Si(2)	131.8(5)
Si(1)-N(4)-Ta(1)	129.1(4)
Si(2)-N(4)-Ta(1)	99.0(4)
N(4)-Si(2)-C(12)	94.9(4)
N(4)-Si(2)-C(10)	113.8(6)
C(12)-Si(2)-C(10)	112.8(5)
N(4)-Si(2)-C(11)	112.8(5)
C(12)-Si(2)-C(11)	114.0(5)
C(10)-Si(2)-C(11)	108.3(7)
Si(2)-C(12)-Ta(1)	91.4(4)

Fig. 2. ORTEP view of **1** showing 30% probability thermal ellipsoids.
Fig. 3. ORTEP view of **2** showing 30% probability thermal ellipsoids.

C(12), N(4), and Si(2). In a plane defined by these six atoms, the mean deviation and the range of deviations are 0.0111 Å and 0.0024–0.0140 Å, respectively. An ORTEP view of this plane and a schematic view of the structure of **2** are given in Fig. 4 and Scheme 2, respectively. The lone pair p electrons in N(1) and N(4) may form conjugated, planar p–d π bonds with Ta, Si(1), and Si(2). The C(12) in the ring perhaps stays in the plane of N(1), N(4), Ta, Si(1), and Si(2) to minimize steric repulsion.

The Ta(1)-ring N(4) length of 2.109(7) Å is longer than those of Ta-NMe$_2$ in **2** (avg. 1.999(8) Å). The Ta-C(12) length of 2.228(9) Å is close to that in Nb(IV) **5** (2.277(6) Å) (Fig. 1) (8).[4] The Ta—N(4) bond (2.109(7) Å) is longer than the Ta—NMe$_2$ bonds in **2** and **1** (1.956(4)–2.039(8) Å), and the Ta—N(SiMe$_3$)$_2$ bond in **1** (2.020(3) Å).

In summary, the reactions of (Me$_2$N)$_3$TaCl$_2$ with 1 and 2 equiv of LiN(SiMe$_3$)$_2$ gave (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (**1**) and (Me$_2$N)$_3$TaN(SiMe$_3$)SiMe$_2$CH$_2$ (**2**), respectively. The reaction of **1** with 1 equiv. of LiN(SiMe$_3$)$_2$ was also found to give **2**. d^0-Pentaamido complex (Me$_2$N)$_3$Ta[N(SiMe$_3$)$_2$]$_2$ (**15**) was observed as an intermediate in the formation of **2**. Steric crowdedness in **15** makes it unstable. **15** undergoes clean γ-hydrogen abstraction in its decomposition to give almost quantitative yield of the cyclic complex **2** with a Ta—C bond. Such γ-hydrogen abstraction and M—C bond formation may give metal carbides in molecular approaches to solid-state materials using complexes containing -N(SiMe$_3$)$_2$ ligands.

---

[4] Nb and Ta complexes are often isomorphous, as a result of lanthanide contraction (26).

Fig. 4. ORTEP of **2** showing 30% probability thermal ellipsoids. The -Me groups have been omitted for clarity.
Experimental

All manipulations were performed under a dry nitrogen atmosphere with the use of either a drybox or standard Schlenk techniques. Solvents were purified by distillation from potassium – benzophenone ketyl. Benzene-d_6 and toluene-d_8 (Cambridge Isotope Laboratories) were dried over activated molecular sieves and stored under N_2. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded at 23 °C on a Bruker AC-250 or AMX-400 Fourier transform (FT) spectrometer and referenced to the solvent (residual protons in the ^{1}H NMR spectra). LiN(SiMe$_3$)$_2$ (Aldrich) was used as received. (Me$_2$N)$_3$TaCl$_2$ was prepared from Ta(NMe$_2$)$_5$ and 2 equiv. of Me$_3$SiCl by the literature procedure (25). A Hewlett-Packard 6890 gas chromatograph (GC) with a 5793 mass selective (MS) detector (MSD) was used to obtain GC–MS data. Elemental analysis was performed by Complete Analysis Laboratories Inc., Parsippany, New Jersey, U.S.A.

Preparation of (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (1)

(Me$_2$N)$_3$TaCl$_2$ (0.343 g, 0.893 mmol) was mixed with LiN(SiMe$_3$)$_2$ (0.150 g, 0.896 mmol), and, to this mixture, pentane (50 mL) was added at –50 °C with stirring. The mixture was allowed to gradually warm to room temperature and stirred overnight. After filtration to remove LiCl, the volatiles were removed under reduced pressure to give a yellow solid which, by ^{1}H and ^{13}C NMR, was essentially pure **1** (0.45 g, 0.88 mmol, 99% yield). Crystals of **1** were grown from a solution in Et$_2$O at –30 °C. Melting point: 110.5–112.0 °C (decomposed). Major IR peaks (KBr pellet, cm^{-1}): 2956.8, 2898.9, 2861.3, 2819.8, 2775.9, 1249.9, 952.6, 846.1, 795.2, 711.3, 673.8. ^{1}H NMR (benzene-d_6, 250.1 MHz) δ: 3.34 (s, 18H, NMe_2), 0.39 (s, 18H, SiMe_3). ^{13}C NMR (benzene-d_6, 62.9 MHz) δ: 49.63 (NMe_2), 4.23 (SiMe_3). Anal. calcd. for C$_{12}$H$_{36}$N$_4$ClSi$_2$Ta: C 28.32, H 7.13, N 11.01; found: C 28.15, H 7.06, N 11.21.

Preparation of (Me$_2$N)$_3$$\overline{\text{TaN(SiMe}_3\text{)SiMe}_2\text{CH}_2}$ (2) from Ta(NMe$_2$)$_3$Cl$_2$

To a mixture of Ta(NMe$_2$)$_3$Cl$_2$ (3.84 g, 10.0 mmol) and LiN(SiMe$_3$)$_2$ (3.35 g, 20.0 mmol) was added hexanes (120 mL) at –40 °C with stirring. The mixture was allowed to gradually warm to room temperature and stirred overnight. The colour of the solution changed slowly from yellow to colourless. After filtration, the volatiles were removed in vacuo to give **2** as a colourless oily liquid in almost quantitative yield. Colourless crystals of **2** (3.111 g, 6.58 mmol, 65.8% yield) were obtained after the oily liquid was cooled to 0 °C for 1 day. Melting point: 123.5–125.0 °C. Major IR peaks (KBr pellet, cm^{-1}): 2955.2, 2893.8, 2857.7, 2824.9, 2778.8, 1245.6, 998.5, 947.4, 865.5, 835.9, 800.72, 765.5. ^{1}H NMR (benzene-d_6, 400.18 MHz, 23 °C) δ: 3.08 (s, 18H, NMe_2), 0.48 (s, 6H, SiMe_2), 0.19 (s, 11H, CH_2SiMe$_2$, SiMe_3). The CH_2SiMe$_2$ resonance was further confirmed by DEPT-135 NMR studies. ^{1}H NMR (toluene-d_8, 400.18 MHz, 23 °C) δ: 3.09 (s, 18H, NMe_2), 0.43 (s, 6H, SiMe_2), 0.15 (s, 9H, SiMe_3), 0.14 (2H, CH_2SiMe$_2$). ^{13}C NMR (benzene-d_6, 100.63 MHz, 23 °C) δ: 44.41 (NMe_2), 39.64 (CH_2), 5.07 (CH$_2$SiMe_2), 4.45 (SiMe_3). ^{13}C NMR (toluene-d_8, 100.63 MHz, 23 °C) δ: 44.42 (NMe_2), 39.63 (CH_2), 5.05 (CH$_2$SiMe_2), 4.43 (SiMe_3). Anal. calcd. for C$_{12}$H$_{35}$N$_4$Si$_2$Ta: C 30.50, H 7.47, N 11.86; found: C 30.32, H 7.39, N 12.03.

GC–MS analyses of the volatiles that were collected from the reaction mixture revealed that it contained HN(SiMe$_3$)$_2$.

Preparation of 2 from (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (1)

To **1** (25.4 mg, 0.0500 mmol) dissolved in benzene-d_6 was added LiN(SiMe$_3$)$_2$ (8.4 mg, 0.050 mmol) at 23 °C. The colour of the solution gradually changed from yellow to colourless. The reaction was monitored by ^{1}H and ^{13}C NMR spectroscopy. In 1.5 h, the ratio of **1** to **2** in the solution was found to be ca. 1:3. In 18 h, ^{1}H and ^{13}C NMR spectra of the solution showed it was virtually a pure mixture of **2** and HN(SiMe$_3$)$_2$.

Reaction of (Me$_2$N)$_3$Ta(Cl)[N(SiMe$_3$)$_2$] (1) with LiNMe$_2$

To a mixture of Ta(NMe$_2$)$_3$(Cl)[N(SiMe$_3$)$_2$] (**1**, 30.2 mg, 0.059 mmol), LiNMe$_2$ (3.0 mg, 0.059 mmol), and 4,4′-dimethylbiphenyl (an internal standard) was added toluene-d_8 (0.40 mL) in a Young NMR tube at room temperature. ^{1}H NMR spectrum of the solution was monitored.

Determination of X-ray crystal structures of 1 and 2

The crystal structures **1** and **2** were determined on a Bruker AXS Smart 1000 X-ray diffractometer equipped with a CCD area detector and a graphite-monochromated Mo source (Kα radiation, 0.71073 Å) and fitted with an upgraded Nicolet LT-2 low-temperature device. Suitable crystals were coated with paratone oil (Exxon) and mounted on a hairloop under a stream of nitrogen at 173(2) K. The structures of **1** and **2** were solved by direct methods. Non-hydrogen atoms were anistropically refined. All hydrogen atoms in the two structures were treated as idealized contributions. Empirical absorption correction was performed with the SADABS program (27a). In addition the global refinements for the unit cells and data reductions of the two structures were performed using the Saint program (Version

6.02). All calculations were performed using SHELXTL (Version 5.1) proprietary software package (27*b*).

Organometallic reactions in aqueous media — Bismuth-mediated crossed aldol type reactions[1]

Yoon Joo Lee and Tak Hang Chan

Abstract: Bismuth metal, upon activation by zinc fluoride, can effect the crossed aldol reaction between α-bromocarbonyl compounds and aldehydes in aqueous media. The reaction was found to be regiospecific and syn-diastereoselective.

Key words: bismuth, zinc fluoride, aldol reaction, regioselectivity, aqueous media.

Résumé : En milieu acide, le bismuth métallique activé par le fluorure de zinc rend possible la réaction aldolique croisée entre des composés α-bromocarbonylés et des aldéhydes. On a observé que la réaction est régiospécifique et syn-diastéréosélective.

Mots clés : bismuth, fluorure de zinc, réaction aldolique, régiosélectivité, milieu aqueux.

Introduction

The aldol reaction has played an important role in organic synthesis for the formation of carbon–carbon bonds, providing β-hydroxycarbonyl compounds. However, under the classical aldol reaction conditions involving basic aqueous media, side products, such as regioisomers, dimers, polymers, self-condensation products, and α,β-unsaturated carbonyl compounds, are invariably formed as well. The formation of these side products is often attributed to the fact that the aldol reaction is an equilibrium process (1). To circumvent this problem, useful modifications of the classical aldol reaction, particularly using Lewis-acid-promoted reactions of enol silyl or tin ethers with carbonyl compounds, have been developed (2). In general, these methods employ organic solvents as reaction media. Recently, there has been considerable interest in conducting organic reactions in aqueous media (3) because of the need to reduce volatile organic solvents as a burden to the environment. In 1990 and subsequently, we reported on the possibility of conducting metal-mediated crossed aldol type reactions in aqueous media, using zinc, tin, and indium (4). The yields of the crossed aldol products were modest. In 1997, Shen et al. (5) reported using bismuth to mediate the crossed aldol type reactions in aqueous media. In the presence of bismuth(III) chloride and metallic aluminum, α-bromocarbonyl compounds **1** were found to react with various aldehydes **2** in water under a nitrogen atmosphere at 60 °C to afford the corresponding β-hydroxycarbonyl compounds **3** in good yields together with the dehalogenated products **4** (Scheme 1).

Very recently, J. Zhang and Y. Zhang (6) demonstrated that a bimetallic system of bismuth(III) chloride and samar-ium could mediate similar crossed aldol type reactions of α-bromoacetophenone with a variety of aldehydes in a mixture of THF and H_2O. Because of our continuing interest in this area, we have examined the bismuth-mediated reaction with the following objectives in mind: (1) use bismuth metal directly in place of the reduction of bismuth chloride for the crossed aldol reaction; (2) extend the reaction to aliphatic acyclic ketones since most reported examples of α-halocarbonyl compounds **1** have been limited to arylketones; and (3) examine the regioselection of the reaction.

Results

Study of different fluoride salts as promoters

In general, mechanically atomized metals are less reactive than metals chemically prepared by the reduction of metal salts with alkali metals or other reducing agents (7). The low reactivity of the bismuth metal powder may result from the insufficient removal of metal oxide layers from the metal surface and the low surface area of the metal particles. Thus, it is obvious that activation of the bismuth metal is needed for the reaction to proceed. Previous reports from our research group have shown that fluoride salts are quite effective in activating metals, such as aluminum (8) and antimony (9), to mediate organometallic reactions in aqueous media. More recently, we found that ammonium hydrogen fluoride (NH_4HF_2) could efficiently activate commercially available bismuth metal to reduce α-halocarbonyl compounds **1** to the corresponding dehalogenated products **4** in excellent yields (10). The reaction is presumed to proceed through the intermediacy of a bismuth enolate **5** (X = Br or F, Scheme 2). We were able to demonstrate that starting with 2-bromoisobutyrophenone (**1a**, R^1 = Ph, $R^2 = R^3$ = Me) and benzaldehyde in the presence of bismuth and NH_4HF_2, the crossed aldol product **3a** ($R^1 = R^4$ = Ph, $R^2 = R^3$ = Me) was obtained. The reaction was carried out in water as the reaction medium. However, reduction was a serious side reaction giving product **4a** in 44% yield, substantially lowering the yield of the aldol product **3a** to 56%.

hyde as a model reaction (Scheme 2), and the results are shown in Table 1.

As can be seen from Table 1, the main group metal fluorides (KF, CaF$_2$, and AlF$_3$) could not activate bismuth to mediate the reaction in D$_2$O (entries 1–3). Most of the transition metal fluorides tested were found to be inefficient in activating bismuth leading to unsatisfactory yields of the aldol product (entries 7–14). However, the reactions with TiF$_4$, VF$_4$, CrF$_3$, and CuF$_2$, which are not commonly used reagents in organic synthesis, afforded the corresponding aldol adducts in moderate yields. In the case of zinc fluoride, the aldol addition product was obtained predominantly along with a minimal amount of the reduction product (entry 15). Fluoride anion seemed to have a special activating effect as ZnCl$_2$ was ineffective (entry 16). Several different solvents were also screened using the same model reaction at room temperature with ZnF$_2$. The results are summarized in Table 2. Hardly any desired product was observed when ethanol or THF was employed as the solvent (entries 4 and

In this reaction, the use of ammonium hydrogen fluoride was found to be necessary since neither the crossed aldol type reaction nor the reduction proceeded with bismuth alone. In an attempt to search for a more effective promoter for bismuth metal activation, a wide range of fluoride salts was screened using the reaction of compound **1a** with benzalde-

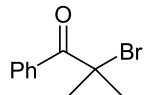
6). In a mixture of water and THF (1:1), the reduction product was formed to a significant extent as well (entry 5). Aqueous media, water, or deuterium oxide, proved to be the most suitable solvents for this bismuth-mediated crossed aldol type reaction (entries 2 and 3).

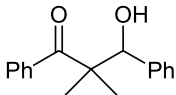
Scope of the bismuth-mediated aqueous crossed aldol type reaction

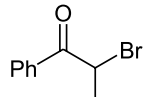
The bismuth-mediated aqueous crossed aldol type reactions of compound **1a** with a variety of aldehydes were surveyed (Table 3). In general, both aromatic and aliphatic aldehydes reacted smoothly with compound **1a** to provide the corresponding aldol products **3** in moderate to high yields. The exception appeared to be *p*-methoxybenzaldehyde (entry 3). The presence of the methoxy group seemed to have interfered with the activation process since unreacted **1a** could be recovered. On the other hand, for α-branched aldehydes or ketones (entries 8 and 9), compound **1a** was transformed efficiently to the presumed enolate and was protonated faster than the aldol condensation.

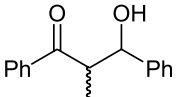
The generality of the reaction was also explored with various α-bromocarbonyl compounds using benzaldehyde under similar reaction conditions. The results are summarized in Table 4. Aromatic α-bromoketones generally reacted better to provide the corresponding β-hydroxyketones in higher yields (entries 1–3) in comparison with aliphatic α-bromoketones (entries 4 and 5). The reactions of α-bromocarboxylic acids with benzaldehyde resulted in the formation of the corresponding reduction products as the major product (entries 6 and 7).

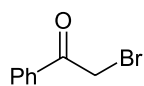
Discussions

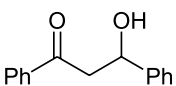
The ability of zinc fluoride to promote the crossed aldol reaction can be attributed to two factors. First, the fluoride anion may activate the metal for chemical reactions in aqueous media. Many metals, though considered to be reactive based on their ionization potentials, may be inert in aqueous


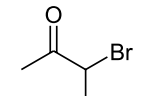


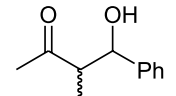


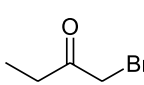


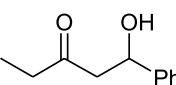


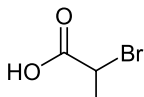


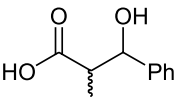


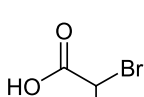


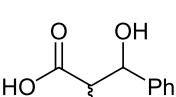












media because of the easy formation of insoluble metal oxide on the metal surface. Aluminum metal is a good example. It has a first ionization potential (5.984 eV) which is much lower than that of magnesium (7.646 eV) and is expected to be a reactive metal. On the other hand, aluminum is resistant to water because it readily forms a layer of insoluble Al$_2$O$_3$ and this prevents the metal from further reaction. It has been reported that trace amounts of fluoride anion in water dramatically increased the corrosion of aluminum metal (11). This effect is attributed to the reaction of fluoride ion with Al$_2$O$_3$ to form various water soluble fluoroaluminates (12). Bismuth metal may be activated by fluoride salts in a similar manner in that fluorobismuthates can be prepared from Bi$_2$O$_3$ and fluorides (13). The second factor is that the zinc ion must also play a role. Recently, Chan and co-workers (14) and others (15) have found that zinc fluoride acts as an effective Lewis acid in aqueous media by the coordination of the zinc cation with the carbonyl function. In the crossed aldol reaction, the bismuth enolate **5** may react with the Zn^{2+}- coordinated aldehyde in either the cyclic chair transition state (**6**) (16) or the extended *antiperiplanar* transition state (**7**) (17).

6   **7**
By comparing the products derived from 3-bromobutan-2-one (Table 4, entry 4) and 1-bromobutan-2-one (Table 4, entry 5), it is possible to conclude that the reaction is regiospecific. The two regioisomeric bismuth enolates (**8** and **9**) must have been generated separately. Reactions of the enolates with benzaldehyde led to different isomeric aldol

products. Furthermore, protonation of the enolates to give butan-2-one must not be reversible, otherwise both enolates would have been regenerated in the reaction mixture, which would have led to a mixture of regioisomers in both reactions (Scheme 3).

In the three examples where diastereomeric aldol products were formed, the syn-isomer was formed preferentially over the anti-isomer (Table 4, entries 2, 4, and 6). Using the condensation of 3-bromobutan-2-one as the example (entry 4), the syn/anti ratio was found to be 73:27. The preferred formation of the syn-isomer is usually explained by one of the following two (or more) possibilities: (1) in the formation of the bismuth enolate, *E*-**9** was formed preferentially, which then reacted with benzaldehyde via the extended antiperiplanar transition state **7** to give the syn- product; or (2) the *Z*-**9** bismuth enolate was formed preferentially, and it reacted with benzaldehyde via the cyclic chair transition state **6**. While there is insufficient experimental evidence to prefer one explanation over the other in the present reaction, similar stereochemical preference was observed in the bismuth-mediated coupling of crotyl bromide with aldehydes, and the acyclic transition state explanation similar to **7** was invoked (18).

Conclusion

The bismuth-mediated aqueous crossed aldol type reaction was investigated. The study showed that bismuth activated by several fluoride salts could mediate the aldol addition reaction of α-bromocarbonyl compounds with aldehydes in aqueous media. Zinc fluoride was found to be the promoter of choice. The scope of this bismuth-mediated aqueous crossed aldol type reaction was examined and the reaction was found to be regiospecific and diastereoselective.

Experimental

General information

Chemicals were purchased from Aldrich or the Alfa Aesar Chemical Company. All the aldehydes were purified by distillation or column chromatography prior to use. Thin layer chromatography was performed on plastic plates precoated with silica gel (60 F_{254}), which were developed using a mixture of hexane and ethyl acetate as an eluent. Analytes were visualized by UV light or by dipping the plate into a developing agent (a solution of ammonium molybdate and ceric sulfate in dilute sulfuric acid) and heating with a heat gun. Column chromatography was performed on 230–400 mesh silica gel.

Melting points were determined using a Gallenkamp apparatus and were uncorrected. Infrared spectra were recorded on an Avatar 360 FT-IR spectrometer and reported in cm^{-1}. ^{1}H NMR spectra and ^{13}C NMR spectra were recorded on a Varian Mercury 300 or 400 MHz spectrometer or a Varian Unity 500 MHz spectrometer at ambient temperature. Chemical shifts (δ) were reported in parts per million (ppm) and referenced to $CDCl_3$ at δ 7.25 ppm for ^{1}H and δ 77.00 ppm for [13]C. The multiplicity of each signal was indicated by s (singlet), d (doublet), t (triplet), q (quartet), quint (quintet), sept (septet), and m (multiplet). Coupling constants (J) were reported in Hz. The syn and anti configurations of **3h**, **3j**, and **3m** were assigned on the basis that the coupling constants of the methyl-bearing methine proton and the hydroxyl-bearing methine proton have greater values for anti- than for syn-isomers (19). Mass spectra were recorded on a Kratos MS25RFA mass spectrometer or on a HP 5980A GC–MS.

General procedure for bismuth-mediated aqueous crossed aldol type reaction

To a mixture of 2-bromoisobutyrophenone (1 mmol), an aldehyde (1.1 mmol), bismuth powder (1.2 mmol), and ZnF_2 (1.2 mmol) was added D_2O (1 mL). The reaction mixture was vigorously stirred at room temperature for the indicated time in Table 3 (12–24 h). Additional distilled water (10 mL) was added in the reaction mixture, and the product was extracted with diethyl ether (3 × 30 mL). The combined organic layer was dried over anhyd Na_2SO_4 and filtered. After the evaporation of solvent under reduced pressure, the crude product was purified by flash column chromatography on silica gel using 5% ethyl acetate in hexane as an eluent to give the corresponding pure aldol addition product.

A combined density functional theory and molecular mechanics (QM/MM) study of single site ethylene polymerization catalyzed by [Cp{NC(*t*-Bu)$_2$}TiR⁺] in the presence of the counterion (CH$_3$B(C$_6$F$_5$)$_3$⁻)[1]

Kumar Vanka, Zhitao Xu, and Tom Ziegler

Abstract: Calculations have been carried out to investigate the insertion of the ethylene monomer into the Ti–alkyl bond for the systems CpNC(*t*-Bu)$_2$RTi-μ-Me-B(C$_6$F$_5$)$_3$ (R = Me and Pr), using density functional theory. A validated QM/MM model was used to represent the counterion. The tertiary butyl groups in the ligands were modeled with QM/MM, with hydrogens being used as the capping atoms. Solvent effects were incorporated with single point solvent calculations done with cyclohexane (ε = 2.023) as the solvent. With R = Me (the initiation step), approach of the ethylene cis and trans to the -μ-Me bridge was considered. Insertion was found to be endothermic, with ΔH_{tot} being 12.7 kcal/mol (cis) and 15.5 kcal/mol (trans). The propagation step was then studied for the contact ion pair CpNC(*t*-Bu)$_2$PrTi-μ-Me-B(C$_6$F$_5$)$_3$ (**4**). Different conformations of the propyl chain in **4** were considered by altering θ, the dihedral angle formed between the C$_\beta$-C$_\alpha$-Ti and the C$_\alpha$-Ti-μC planes. The resting states were found to be at θ = –69° (**4a**), 177° (**4b**), and 53° (**4c**). A maxima was found near θ = 0° (**4d**). The cis and trans approaches of the ethylene monomer were considered for each of the four cases. The cis approach towards **4a** and trans approach towards **4d** led to insertion, with displacement of the counterion from the metal centre. The insertion barriers were found to be 17.8 kcal/mol, for the cis approach towards **4b** and 16.4 kcal/mol for the trans approach towards **4d**. The cis approaches towards conformers **4a** and **4c** showed common characteristics, with uptake barriers being higher than the subsequent insertion barriers in the two cases. Uptake barriers were 13.6 kcal/mol {**TS(4a–7a)**} and 10.7 kcal/mol {**TS(4c–8a)**}. The corresponding insertion barriers were 11.8 kcal/mol {**TS(7a–13a)**} and 8.4 kcal/mol {**TS(8a–13a)**}. The trans approaches towards conformers **4a** and **4c** led to insertion barriers of about 15.1 kcal/mol (lower than for the **4b** and **4d** cases). The cis approach towards **4d** and trans approach towards **4b** were found to lead to hydrogen transfer from the propyl chain to monomer, terminating the chain. Termination barriers were high — greater than 19.0 kcal/mol. This suggested that ethylene insertion would be favoured over termination during the propagation step.

Key words: homogeneous catalysis, counterion, initiation, propagation, termination.

Résumé : Faisant appel à la théorie de la densité fonctionnelle, on a effectué des calculs pour étudier l'insertion du monomère éthylène dans la liaison Ti–alkyle des systèmes CpNC(*t*-Bu)$_2$RTi-μ-Me-B(C$_6$F$_5$)$_3$ (R = Me et Pr). On a utilisé un modèle QM/MM pour représenter le contre-ion. On a modélisé les groupes *tert*-butyles des ligands avec le modèle QM/MM et les hydrogènes sont utilisés comme atomes de couverture. On a incorporé des effets de solvant à l'aide de calculs de solvant ponctuel en utilisant le cyclohexane (ε = 2,023) comme solvant. Avec R = Me, on a considéré les approches cis- et trans- (étape d'initiation) de l'éthylène. On a trouvé que l'insertion est endothermique, les ΔH_{tot} étant respectivement de 12,7 et 15,5 kcal/mol respectivement pour les approches cis- et trans-. On a alors étudié l'étape de propagation pour la paire d'ions de contact CpNC(*t*-Bu)$_2$PrTi-μ-Me-B(C$_6$F$_5$)$_3$ (**4**). On a considéré les diverses conformations de la chaîne propyle du composé **4** en faisant varier θ, l'angle dièdre formé entre les plans C$_\beta$-C$_\alpha$-Ti et C$_\alpha$-Ti-μC. On a trouvé des minima près de θ = –69° (**4a**), 177° (**4b**) et 53° (**4c**). On a trouvé un maximum près de θ = 0° (**4d**). On a considéré les approches cis- et trans- du monomère d'éthylène pour chacun de ces quatre cas. Les approches cis- vis-à-vis de **4a** et trans- vis-à-vis de **4d** conduisent à des insertions avec un déplacement du contre-ion du centre métallique. On a trouvé que les barrières à l'insertion sont de 17,8 et de 16,4 kcal/mol respectivement pour les approches cis- vis-à-vis de **4b** et trans- vis-à-vis de **4d**. Les approches cis- approches vis-à-vis de **4a** et de **4c** présentent des caractéristiques communes, avec des barrières à l'incorporation qui sont plus élevées dans les deux cas que les barrières d'insertion subséquentes. Les barrières à l'incorporation sont de 13,6 kcal/mol {**TS(4a–7a)**} et de 10,7 kcal/mol {**TS(4c–8a)**}. Les barrières correspondantes à l'insertion sont de 11,8 kcal/mol {**TS(7a–13a)**} et de

K. Vanka, Z. Xu, and T. Ziegler.[2] Department of Chemistry, University of Calgary, Calgary, AB T2N 1N4, Canada.

8,4 kcal/mol {**TS(8a–13a)**}. Les approches trans- vis-a-vis des conformères **4a** et de **4c** conduisent à des barrières à l'insertion d'environ 15,1 kcal/mol (plus faibles que celles pour les composés **4b** et **4d**). On a trouvé que l'approche cis- vis-a-vis de **4d** et que l'approche trans- vis-a-vis de **4b** conduisent à un transfert d'hydrogène à partir de la chaîne du monomère et que la chaîne est ainsi coupée. Les barrières à la réaction de terminaison sont élevées, plus que 19,0 kcal/mol. Ceci suggère que, durant l'étape de propagation, l'insertion de l'éthylène est favorisée par rapport à la réaction de terminaison.

Mots clés : catalyse homogène, contre-ion, initiation, propagation, terminaison.

Introduction

The field of single-site homogeneous catalysts has seen remarkabable growth and development over the past 20 years (1). Their ability to achieve higher stereoselectivity and narrower molecular weight distribution has made them emerge as viable alternatives to traditional Ziegler–Natta type heterogeneous catalysts, and revolutionized industrial polyalkene synthesis (2). The fact that they are structurally well-defined mononuclear active species has allowed the systematic modification of these structures allowing for enhanced control over polymer properties. The state-of-the-art homogeneous catalysts transform simple alkenes into polymers with rate accelerations and stereo- and regiospecificities that rival those of enzymatic catalysts.

Among the more highly active homogenous catalysts are metallocenes and related organometallic compounds containing a group IV transition metal. The general structure of these complexes contain a group 4 transition metal centre (M) coordinated to two ligands (L) and two alkyl groups (R): L_2MR_2. These complexes by themselves are not very effective as polymerization catalysts, but require activation by a co-catalyst or a counterion. The co-catalysts are generally Lewis acids, such as tris(pentafluorophenyl)borane or methylalumoxane (MAO), whose function is to abstract one of the alkyl groups as R^- to produce the activated metal catalyst, which is generally accepted (3) to be an electrophilic species: L_2MR^+. The process by which the co-catalyst can activate the complex is illustrated in Fig. 1. First, the alkyl group (R) is extracted by the acidic co-catalyst compound denoted as "A" in the figure. This leads to a charge-separated contact ion pair (L_2TiR-μR-A). The formation of this ion-pair species is exothermic, with the enthalpy of ion-pair formation denoted as ΔH_{ipf} in Fig. 1. To form the cationic complex (L_2MR^+), the contact ion pair must then dissociate, with an enthalpy of ion-pair separation denoted as ΔH_{ips}, to form the two separated charged species: the positively charged cationic catalyst (L_2MR^+), and the negatively charged counterion (AR^-).

The cationic catalyst thus formed can then partake in the catalytic processes for insertion. The accepted mechanism for the uptake and insertion of the olefin monomer into the metal–carbon bond in the cationic catalyst is shown in Fig. 2 with ethylene as the olefin monomer.

The well-defined molecular structure of metallocene catalysts and their analogues has also enabled thorough mechanistic investigations by theoretical methods, and several theoretical studies (4) have been conducted, using the bare cation (L_2MR^+) as the model for the single-site catalyst. These studies have helped improve the understanding of the mechanistic aspects of the monomer insertion process. How-

ever, recent findings indicate (3g–3j, 5) that the anionic counterion plays an important role in the polymerization process. Calculations showed (5) that the value of ΔH_{ips} was very high, implying that the total dissociation of the contact ion pair leading to formation of the bare cation would not take place. The counterion would therefore remain in the vicinity of the cation during the insertion process. Hence, the influence of the counterion has to be taken into account and the mechanism for the insertion has to be modified accordingly, as shown in Fig. 3.

In the modified mechanism of Fig. 3, the ethylene first approaches the contact ion pair [L_2TiR-μR-A] and binds to it, forming a weak olefin complex. The enthalpy of this complexation is denoted as ΔH_c. From this complexed state, the ethylene monomer then approaches the alkyl chain and attempts to insert into the metal–alkyl bond, leading to a four-centred transition state. The internal barrier of the reaction path, from the olefin complex to the transition state, is defined as ΔH_{ib}. The total barrier of the reaction is denoted as ΔH_{tot} and is the sum of ΔH_c and ΔH_{ib}.

Figure 3, however, shows only one of the ways in which the ethylene monomer can approach the contact ion pair (L_2TiR-μR-A). Depending on the position of the ethylene monomer relative to the μ-alkyl bridge of the ion pair, there are two ways in which the ethylene can approach, as shown in Fig. 4. It can approach cis to the μ-alkyl bridge, an approach we will henceforth call the "cis" approach. Nifant'ev et al. (6) have studied ethylene insertion via this approach for the $Cp_2ZrEt^+A^-$ ($A^- = CH_3B(C_6F_5)_3^-$, $B(C_6F_5)_4^-$) systems. Alternately, the ethylene monomer can also approach from the direction opposite (trans) to the μ-alkyl bridge, as shown in Fig. 4. This path will be referred to as the "trans" mode of approach. In each of the two cases, the approach of the ethylene leads to the formation of the olefin complex. The tetrahedral arrangement of the contact ion pair is converted to a trigonal bipyramidal structure when the olefin complex is formed. In the trans case of approach, the ethylene monomer occupies one of the axial positions of the trigonal bipyramid, while in the cis case, the ethylene monomer lies in the equatorial plane of the trigonal bipyramid.

Unfortunately, due to the size of the counterions, theoretical studies of the mechanism outlined in Fig. 2, where the counterion is incorporated, are difficult and involve considerable computational effort. Hence, few examples of such studies are found in the literature (7). Lanza et al. (7a) have investigated olefin insertion into the Ti—CH_3 bond of the $H_2Si(C_5H_4)(t$-BuN)$TiCH_3$-$CH_3B(C_6F_5)_3$ ion pair; Fusco et al. (7b) and Bernardi et al. (7c) studied the same process for $Cp_2(Ti/Zr)CH_3$-Cl_2 Al[O(Al(CH_3)$_3$AlHCH_3)]$_2$ and $Cl_2TiCH_3(μ$-$Cl)_2AlH_2$, respectively. Chan et al. (7d) have investigated the

formation of ethylene separated ion-pair complexes for ion pairs formed between different catalysts and the counterion $B(C_6F_5)_3CH_3^-$, as well as ethylene insertion (5a) into the $Zr—CH_3$ bond in the Cp_2ZrCH_3-μ-CH_3-$B(C_6F_5)_3$ system.

In an earlier theoretical study (8), we investigated the insertion of the ethylene monomer into the methyl chain of different catalyst systems of the type $L_1L_2TiCH_3^+$, in the presence of the counterion. The counterion used for the purpose of the investigation was $B(C_6F_5)_3CH_3^-$. For the sake of computational expediency, a QM/MM model was used for the counterion. This allowed us to study a large number of different systems. In the QM/MM model, the perfluoro phenyl (C_6F_5) groups in $B(C_6F_5)_3CH_3^-$ were replaced with MM atoms, and Cl atoms are used to cap the QM system. Thus, $B(C_6F_5)_3CH_3^-$ was replaced with $BCl_3CH_3^-$ in the QM system. This model has been validated (9a), and will be used to model the counterion in the ion pair systems studied here.

Other ion pair systems using the same model for the counterion are currently under investigation (9b).[3]

In this present study, we investigate the approach of ethylene and its insertion into the Ti–methyl (initiation step) and Ti–propyl (propagation step) bonds for the [CpNC(t-Bu)$_2$TiR$^+$][B(C$_6$F$_5$)$_3$CH$_3^-$] (R = CH$_3$ and C$_3$H$_7$) ion-pair systems. The different approaches of the ethylene monomer cis and trans to the μ-methyl group of the ion pair will be considered for each case. Before the investigation of the propagation step, i.e., ethylene insertion into the propyl chain, different chain conformers of the free ion pair will first be considered to determine the most favourable conformation, prior to insertion. The purpose of the investigation will be to isolate the important factors that contribute to the barrier of insertion, and to compare and contrast the initiation and propagation steps for the same ion-pair system, i.e., [CpNC(t-Bu)$_2$TiMe$^+$][B(C$_6$F$_5$)$_3$CH$_3^-$]. The effect of the sol-

vent on the insertion process will also be considered, with single-point solvation calculations to determine the energy of solvation for the ion pair, the olefin complexes, and the transition states. Cyclohexane ($\varepsilon = 2.023$) will be used as the solvent.

Computational details

The density functional theory calculations were carried out using the Amsterdam density functional (ADF) program, version 2000.01, developed by Baerends and co-workers (10) and vectorized by Ravenek (11). The numerical integration scheme applied was developed by te Velde and co-workers (12) and the geometry optimization procedure was based on the method of Verslius and Ziegler (13). Geometry optimizations were carried out using the local exchange-correlation potential of Vosko et al. (14) without any sym-

metry constraints. The electronic configurations of the atoms were described by a triple-ζ basis set on titanium ($n = 3$) for ns, np, nd, and $(n + 1)s$, augmented with a single $(n + 1)p$ polarization function. Double-ζ STO basis were used for carbon ($2s,2p$), hydrogen ($1s$), and nitrogen ($2s,2p$), augmented with a single $3d$-polarization function, except for hydrogen where a $2p$-polarization function was used. Shells of lower energy were treated by the frozen core approximation. A set of auxiliary s,p,d,f, and g STO functions centred on all nuclei was used to fit the molecular density and represent Coulomb and exchange potentials accurately in each SCF cycle (15). The gas-phase energy difference was calculated by augmenting the local density approximation energy with Perdew and Wang's nonlocal correlation and exchange corrections (PWB91) (16). The solvation energies were obtained from a single-point full QM calculation using the conductor-like screening model (COSMO) (17) and opti-

Fig. 5. The energy profile for the cis approach of the ethylene monomer towards the contact ion pair $[Cp\{NC(t\text{-}Bu)_2\}TiMe^+][CH_3B(C_6F_5)_3^-]$.
mized geometries from QM/MM calculations. A dielectric constant of 2.023 was used to represent cyclohexane as the solvent. The radii used for the atoms in Å were as follows: C 2.0, H 1.16, B 1.15, N 1.5, F 1.2, Ti 2.3, and Cl 2.1. Only the electronic contribution was calculated to evaluate the enthalpy of the reactions considered in this work. The enthalpies (ΔH) reported in the following sections are potential energy differences without zero-point corrections or vibrational finite temperature corrections. Such corrections are still too expensive to calculate for the size of molecules considered here. We expect these corrections to be of the order of ±2–3 kcal/mol. The insertion barriers were obtained by doing linear transit calculations for the same reaction coordinates, the C-C distance between one C of the ethylene and the C of the CH_3 or C_3H_7, which represent the growing chains. The MM atoms were described using the SYBYL/TRIPOS 5.2 force field constants (18*a*). The code for QM/MM in ADF has been implemented by Woo et al. (18*b*).

Results and discussion

First insertion process with the naked cation

The insertion of the ethylene monomer was first considered for the system $CpNC(t\text{-}Bu)_2TiMe^+$ in the absence of the counterion. QM/MM atoms were used to model the tertiary butyl groups, with hydrogens used as capping atoms — hence, the QM portion of the cation was $CpNCH_2TiMe^+$. The values of the ethylene complexation energy ΔH_c and the inter-

nal insertion barrier ΔH_{ib} were found to be –20.0 kcal/mol and 3.1 kcal/mol, respectively (after incorporation of solvent effects). The transition state for the ethylene insertion in these systems occured when the ethylene carbon was at a distance of about 2.4 Å from the methyl carbon. The total barrier for insertion, found by summing up the two values, was calculated to be equal to –16.9 kcal/mol, indicating that the process is highly exothermic in nature. Therefore, using just the naked cation as a model for the catalyst, one would be led to conclude that the cationic $CpNC(t\text{-}Bu)_2TiMe^+$ system is an excellent polymerization catalyst. We shall now see how this is modified by the inclusion of the counterion in the mechanistic studies.

First insertion study with inclusion of the counterion

We shall, in the following, include the anionic counterion $B(C_6F_5)_3CH_3^-$ to provide a more realistic description of the insertion process. A validated QM/MM model (9*a*) of the counterion was used for computational expediency, as discussed in the *Introduction*.

The cis approach of the monomer

The approach of the ethylene monomer towards the metal centre of the ion pair ($[CpNC(t\text{-}Bu)_2TiMe^+][CH_3B(C_6F_5)_3^-]$ (**2a**)) was studied using $\Delta R = R(Ti\text{-}\mu\text{-}C) - R(Ti\text{-}X)$ as the reaction coordinate. When the ethylene approaches from the cis direction, it can first form the π complex termed **2b** in Fig. 5, with the two carbons of the ethylene lying perpendicular to the plane formed by the metal centre, the methyl

Fig. 6. The energy profile for the trans approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiMe$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$].
chain, and the μ carbon of the counterion. This complex is 7.7 kcal/mol (including solvation effects) less stable than the ion pair and ethylene totally separated. The reason for the endothermic nature of this complexation is the displacement of the counterion from the metal centre, to accommodate the ethylene molecule — the Ti-μ-C distance is increased from 2.19 Å (in the ion pair, **2a**) to 2.39 Å in the complex **2b** (Fig. 5). There is some compensation, however, by the bonding between the metal centre and the incoming ethylene, which reduces the cost of displacement of the counterion to some extent.

The ethylene molecule, however, cannot insert into the Ti—C bond without being in the insertion plane. Hence, it has to rotate to bring itself into the insertion plane. There is a barrier to this rotation of about 2.8 kcal/mol, after which it forms the "in plane" olefin complex, which lies 10.3 kcal/mol (after incorporation of solvation effects) above the separated reactant species. In this weak olefin complex (**2c**), the Ti-ethylene midpoint distance has increased to 2.70 Å, with the counterion coming closer to the metal centre (Ti-μ-C distance 2.38 Å), and the ethylene is still fairly far (2.76 Å) from the carbon of the methyl chain (see Fig. 5).

After formation of the complex (**2c**), the ethylene then approaches the methyl chain, to enable insertion into the Ti—C bond. The system is slightly destabilized as a result, leading eventually to the transition state for insertion (**TS(2c–4a)**), lying 12.7 kcal/mol above the reactants. In this transition state, the ethylene carbon – methyl carbon distance is 2.3 Å,

and the Ti-μ-C distance is slightly elongated to 2.50 Å (see Fig. 5).

Hence, the total barrier to insertion for the cis approach is 12.7 kcal/mol. This is significantly different from the findings in the naked cation case, where the insertion transition state is lower in energy than the reactants. The transition states are also found to be somewhat different for the two cases. The ethylene carbon – methyl carbon distance is 2.61 Å in the cationic case, while it is 2.3 Å in **TS(2c–4a)**. Both transition states exhibit an α-agostic interaction between the metal centre and a hydrogen of the methyl group, but the Ti-H distances are slightly different: 2.06 Å in the cationic case compared to 2.17 Å in **2c**. The reason for the longer and presumably weaker α-agostic bond in the case with the counterion attached is the reduced acidity of the metal centre.

After formation of the transition state, the ethylene inserts and proceeds to form the product with the propyl chain, which lies at –24.0 kcal/mol below the separated species. In the ion pair, the counterion is found to be reassociated to the metal centre. Thus, for the subsequent insertion, ethylene will again have to displace B(C$_6$F$_5$)$_3$ CH$_3^-$ to some degree.

The trans approach of the monomer

The trans approach of ethylene towards the ion pair was also studied. Figure 6 displays the profile for the trans insertion. A weak olefin complex (**3c**) was first formed, with R(Ti-X) being 2.77 Å. The counterion was only slightly dis-

Fig. 7. Energy profiles for the back side and front side approaches of the ethylene monomer towards the cation Cp{NC(*t*-Bu)}TiPr⁺.

Fig. 8. The relative stabilities of the different chain conformations formed by rotation of the propyl chain in the contact ion pair [Cp{NC(*t*-Bu)₂}TiPr⁺][CH₃B(C₆F₅)₃⁻].
placed from the metal centre with R(Ti-μ-C) = 2.32 Å compared to 2.19 Å in the ion pair **IP**. The complex lay 13.2 kcal/mol above the totally separated, reactant **2a + Et** species. The ethylene molecule was found to be in the insertion plane and hence, unlike in the case of the cis approach, did not have to be rotated into the plane before insertion could proceed.

After formation of **3c**, the ethylene approached the carbon of the methyl chain, to enable the insertion to occur. This led to an increase in energy, until the transition state, shown as **TS** (**3c–4a**) in Fig. 6 was reached, lying 15.5 kcal/mol above the separated reactant species. At the transition state, an α-agostic interaction had been formed between the titanium metal centre and one of the hydrogens of the methyl chain, similar to the transition state observed in the naked cation and the cis approach. In this four-centred transiton state, the ethylene carbon has approached closer to the carbon of the methyl chain and lies at a distance of 2.20 Å. The counterion is displaced a little more from the metal centre in this case, in comparison to **3c**, with R(Ti-μ-C) being about 2.54 Å. This is still not a large displacement and it compares well with the R(Ti-μ-C) distance of 2.50 Å from the transition state **TS** (**2c–4a**) of the cis approach. Therefore, it can be concluded that for both the cis and trans insertion, the counterion is not detached to a great extent from the metal centre.

A comparison of the total insertion barriers for the cis and trans cases reveals that the total barrier of insertion for the cis case (12.7 kcal/mol) is lower in comparison to the trans
insertion (15.5 kcal/mol) by 2.7 kcal/mol. (Solvation effects have been incorporated in all calculations). Hence, it can be concluded that ethylene prefers to approach cis to the μ-methyl bridge of the ion pair, during the insertion process for the first insertion of the monomer into the metal–alkyl bond.

Fig. 9. The energy profile for the cis approach of the ethylene monomer towards the contact ion pair $[Cp\{NC(t\text{-}Bu)_2\}TiPr^+][CH_3B(C_6F_5)_3^-]$, with the propyl chain in the insertion plane, for the case **4b**.
The final product formed in each case was the ion pair with the elongated alkyl chain ($[CpNC(t\text{-}Bu)_2Ti\text{-}Pr^+][CH_3B(C_6F_5)_3^-]$) denoted as **4a** in the Figs. 5 and 6. It was found to be 24.0 kcal/mol more stable than the totally separated reactant **2a + Et** species.

Solvent effects had been taken into account in the calculations, as mentioned earlier. The corresponding gas-phase values are mentioned in parentheses in the Figs. 5 and 6. Since the displacement of the counterion was only slight during monomer insertion in both the cis and trans approaches, the charge separation between the negative counterion and the positive metal centre was also insignificant. Hence, the solvent effects were found to be minimal in either case.

Second insertion study with the naked cation

The product from the first insertion of ethylene into the Ti-Me chain, in the naked cation case, was the species $CpNC(t\text{-}Bu)_2TiPr^+$. The most stable conformation of this species had a β-agostic interaction between one of the hydrogens on the β-carbon of the propyl chain, and the titanium metal centre. It will be denoted as **I**, as shown in Fig. 7. The second insertion of ethylene, into the Ti-propyl chain, was investigated starting from this conformation. Unlike the first insertion in the naked cation ($CpNC(t\text{-}Bu)_2TiMe^+$) where there is only one approach possible for the ethylene monomer, the second insertion could proceed via two distinct pathways, as displayed in Fig. 7: it could approach trans (**4b**)

to the β-agostic bond, the "back side attack", leading to the formation of the species **IIIa**, or it could approach cis (**4b**) to the β-agostic bond, the "front side attack", which would lead to the formation of the species **IIa**. Both these approaches were investigated and the results are summarized in the following sections.

Back side attack of the ethylene monomer

As shown in Fig. 7, the attack of the ethylene trans to the β-agostic bond gives rise to the π-complex (**IIIa**) that is 11.9 kcal/mol more stable than the totally separated reactant species. This reaction is, therefore, less exothermic than the first insertion, where the complexation enthalpy was –22.3 kcal/mol. The reason for the decrease in exothermicity of the reaction is the increased steric congestion around the metal centre due to the increase in the chain length. After formation of this π-complex, the ethylene continues to approach the α-carbon of the chain, eventually leading to the insertion transition state (**IIIb**) lying 6.9 kcal/mol below the reactant species (**I + Et**). In this insertion transition state, the β-agostic bond of the titanium metal centre with the hydrogen is retained, with R(Ti-H) = 1.91 Å. The ethylene has moved closer to the α-carbon, with $R(C_{Et}\text{-}C_\alpha)$ being about 0.63 Å less in the transition state than in the π-complex, while the Ti-α-carbon distance has increased by 0.06 Å. Overall, in comparison to the first insertion, the back side insertion is about 10.0 kcal/mol less exothermic.

Fig. 10. The energy profile for the trans approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain in the insertion plane, for the case **4d**.
Front side attack of the ethylene monomer

The front side attack of the ethylene monomer, also shown in Fig. 7, gives rise to the front side π-complex (**IIa**), which is 12.7 kcal/mol more exothermic than the separated reactant species. In this π-complex, the two carbons of ethylene lie in the same plane as the metal centre and the hydrogen forming the β-agostic bond. This π-complex is 0.8 kcal/mol more stable than the corresponding backside π-complex (**IIIa**) (see Fig. 7). Starting from this π-complex, if insertion is to occur, then the ethylene has to approach the α-carbon. This can happen through rotation of the propyl chain along the Ti—α-C$_\alpha$ bond, leading to the loss of the β-agostic interaction and the rotation of the β-carbon, thereby facilitating the approach of the ethylene towards the carbon. The barrier to this process was found to lie 11.7 kcal/mol below the reactant species. Therefore, the overall barrier to insertion along this pathway is less by 4.8 kcal/mol in comparison to the back side approach.

However, this is not the only route that the ethylene can take during the front side approach. Starting from **IIa**, the ethylene can also abstract a hydrogen from the β-carbon of the propyl chain, a reaction that would lead to termination. As shown in Fig. 7, the transition state for this process (**IIc**) has the hydrogen nearly equidistant between the ethylene and the β-carbon, but slightly closer to the β-carbon of the chain, at a distance of about 1.40 Å. The hydrogen has re-

tained its agostic interaction with the metal centre at the transition state. **IIc** was found to lie 5.4 kcal/mol below the reactant species. This is 6.3 kcal/mol higher than **IIb** and 1.5 kcal/mol higher than **IIIb**. This suggests that, after the ethylene has approached the CpNC(*t*-Bu)$_2$TiPr$^+$ species, it would prefer to insert rather than undergo termination.

Overall, as for the first insertion, the results obtained suggest facile exothermic reactions during the insertion and termination processes for the naked cationic model. In the next section, we shall study how this picture is modified with the inclusion of the counterion.

Second insertion study with inclusion of the counterion

With the counterion included, the resting state of the catalyst after the first insertion is the ion pair [CpNC(*t*-Bu)$_2$TiPr$^+$][B(C$_6$F$_5$)$_3$CH$_3^-$], i.e., the product formed at the completion of the first insertion. The second insertion or propagation step involves the approach and insertion of the ethylene monomer cis and trans to the Ti-μ-C bond in this ion pair.

Resting state of the ion pair

In the ion pair, formed after the first insertion, the alkyl group attached to the metal centre has extended from a methyl to a propyl chain. This propyl chain can orient itself into several conformations, thus giving rise to a number of

Fig. 11. The energy profile for the cis approach of the ethylene monomer towards the contact ion pair [Cp{NC(t-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3$$^-$], with the propyl chain lying out of the insertion plane, for the case **4a**.
possible energy minima states for the ion pair. It is necessary to study these different conformations to determine the most stable resting state. This was done by a linear transit wherein the dihedral angle (θ) formed between the C$_\beta$-C$_\alpha$-Ti and the C$_\alpha$-Ti-μC planes was altered (see Fig. 8 below) from $-180°$ to $180°$ to rotate the chain so as to determine the most stable resting states. The accompanying energy profile in Fig. 9 shows that the most stable resting states of the ion pair correspond to the staggered conformations of the chain, with θ at $-69°$, $53°$, and $177°$, respectively. In contrast, the eclipsed conformation, with θ near $0°$ was found to be an energy maxima. The rotation of the chain from $\theta = 53°$ to $\theta = 0°$ (eclipsed conformation) leads to an increase in energy of 7.61 kcal/mol. This represents the barrier to rotation of the propyl chain. Figure 8 also shows the relative energies of the different possible conformations.

For the insertion studies, four different conformations of the propyl chain were considered, with to $\theta = -69°$ (**4a**), 177° (**4b**), 53° (**4c**), and 0° (**4d**). They correspond to the three minimum energy conformations of the ion pair **4a** ($\theta = -69°$), **4b** ($\theta = 177°$), **4c** ($\theta = 53°$), as well as the maxima for θ near 0° (**4d**). Beginning with the ion pair in these four conformations, the approach of the ethylene monomer cis and trans to the μ-methyl bridge was studied. The results of the investigations are discussed in the following sections. The relative energies of the olefin complexes and insertion barriers were calculated with respect to the totally separated species ethylene monomer and **4a**, the most stable conformation of the ion pair in its resting stage.

The approach of the olefin monomer cis and trans to the ion pair can lead to one of two possible outcomes: (*a*) insertion of the monomer leading to the extension of the alkyl chain; or (*b*) termination of the polymerization reaction by chain transfer from the alkyl chain to the monomer. In the next section, we will look at the first of the two possibilities — insertion — for the orientation of the chain in the insertion plane, i.e., for $\theta = 177°$ and $0°$. Both *cis* and *trans* approaches will be considered for the in-plane chain orientations. Following that, in Section *(iii)* and *(iv)*, we will investigate the insertion process for the out-of-plane chain orientations, i.e., for $\theta = -69°$ and $+53°$. Subsequent to that, we will investigate the other possibility — termination — for the cis and trans approaches.

Insertion for the in-plane chain conformations

The cis approach of the ethylene monomer towards conformation **4b** ($\theta = 177°$), and the trans approach of the monomer towards **4d** ($\theta = 0°$), were found to lead to insertion. The other two possibilities for the two in-plane chain conformations, i.e., trans approach towards **4b** and cis approach towards **4d**, led to termination, and will be discussed later.

Figure 9 shows the cis approach of ethylene towards **4b** and Fig. 10 shows the profile for the trans approach towards **4d**. The two approaches were found to share some common features, which are discussed in the following paragraphs:

(*a*) The approach of ethylene was found to lead to the formation of an in-plane π-complex in each case, denoted

Fig. 12. The energy profile for the cis approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain lying out of the insertion plane, for the case **4c**.
as **5a** and **6a**, respectively (see Figs. 9 and 10). In both these π complexes, the ethylene had approached quite close to the metal centre, with the ethylene–metal distance being about 2.4 Å. It achieved this by displacing the counterion from the metal to some extent, with R(Ti-μ-C) ≥ 3.0 Å (see Figs. 9 and 10). The cost of displacing the counterion caused the species **5a** and **6a** to be higher than the separated reactant species by about 11 kcal/mol. Moreover, this displacement of the counterion led to an uptake barrier, for both cases, before the π-complex could be formed. The uptake barriers were quite high — 15.5 kcal/mol for **TS(4b–5a)** and 16.7 kcal/mol for **TS(4d–6a)**.

(*b*) A stabilizing β-agostic interaction was found to be present in either of the π- complexes (**5a** and **6a**). They, therefore, resembled the π-complex (**IIIb**), formed during the back side insertion for the naked cationic case discussed earlier. R(Ti-H) was about 1.9 Å in each case.

(*c*) After the π-complex formation, the ethylene approached the α-carbon of the alkyl chain, leading to the barrier for insertion, corresponding to the transition states **TS(5a–13a)** and **TS(6a–13a)** in Figs. 9 and 10, respectively. The β-agostic interaction was retained in both cases, much like in the back side insertion of the naked cation, with R(Ti-H) = 1.9 Å. R(C$_{Et}$-C$_\alpha$) was about 2.0 Å in each case. The barrier to insertion was found to be high for both the cases, about 17.6 kcal/mol (see Figs. 9 and

10). The displacement of the counterion from the metal centre is the reason for the high barriers.

(*d*) Solvent effects were found to be substantial in both cases, due to the increased charge separation caused by the displacement of the counterion. Thus, the insertion barrier was reduced from 20.5 to 17.6 kcal/mol in **4b**, and from 19.4 to 17.7 kcal/mol for the **4d** chain conformation.

After the insertion of the monomer, the product, **13a** was formed in each case, lying 25.2 kcal/mol below the separated species **4a +Et**.

Insertion for the out-of-plane chain conformations (cis attack)

The ethylene monomer can approach the out-of-plane conformations **4a** (θ = –69°) and **4c** (θ = 53°) cis and trans to the μ-methyl bridge. This gives rise to four possible insertion profiles, shown in the Figs. 11–14. All four of these pathways were investigated.

Figures 11 and 12 show the profiles for the cis attacks for the out-of-plane conformers (**4a** and **4c**). The cis approach profiles displayed common features, which are discussed in the following paragraphs:

(*a*) As for the in-plane case, there was displacement of the counterion prior to formation of the π complexes **7a** and **8a**, respectively. Therefore, an uptake barrier had to be overcome before the respective π complexes could be

Fig. 13. The energy profile for the trans approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain lying out of the insertion plane, for the case **4a**.
formed. The considerable displacement of the counterion (>4.0 Å) in each case also meant that that solvent effects were significant. After the solvent effects had been incorporated, the uptake barriers were found to be 13.6 kcal/mol for the **4a** case and 11.5 kcal/mol for **4c** (see Figs. 11 and 12). These barriers are lower than the corresponding uptake barriers in the case of the in-plane conformers, discussed earlier. This can be attributed to steric factors — the out-of-plane orientation of the chain leads to less steric congestion around the coordination sphere of the metal.

(*b*) After formation of the π complexes **7a** and **8a**, the ethylene approached the α-carbon in each case, thereby giving rise to the insertion transition states **TS(7a–13a)** and **TS(8a–13a)**, respectively. The counterion remained highly displaced from the metal centre (R(Ti-μ-C) > 4.75 Å) (see Figs. 11 and 12) at this stage of the insertion. Both transition states exhibited an α-agostic interaction between one of the hydrogens of the chain and the metal centre, with R(Ti-H) being about 1.9 Å. After the solvation effects had been incorporated, the barriers obtained were found to be comparatively low, 11.8 kcal/mol for the **4a** case and 8.4 kcal/mol for **4c**. This was lower than the uptake barrier in each of the two cases. Therefore, the rate-determining step for the two cases was the displacement of the counterion and uptake of the ethylene monomer by the metal centre, rather than the subsequent insertion. This is an interest-

ing feature that had not been noticed before for the in-plane cases discussed earlier. It is also interesting to note that for the **4a** case, the gas-phase insertion barrier is higher than the gas-phase uptake barrier, but after taking solvent effects into account the uptake barrier becomes rate determining (see Fig. 11). This is because the counterion is displaced to a greater extent at the insertion transition state than during the uptake, and hence, the solvent effects are more significant during insertion. Thus, inclusion of solvent effects reduces the insertion barrier to a greater extent, and makes the uptake the rate-determining step.

(*c*) The contribution to the uptake barrier chiefly comes from the displacement of the counterion. Hence, with the uptake barrier becoming rate determining, the displacement of the counterion becomes the most important factor in the process for these two cases. This shows once again the importance of incorporating the counterion in the insertion studies.

The final pentyl-chain product (**13a**) was formed after insertion of the ethylene, and found to be –25.2 kcal/mol more stable than the separated reactants **4a + Et**.

Insertion for the out-of-plane chain conformations (trans attack)

Figures 13 and 14 show the profiles for the approach and insertion of the ethylene monomer into the propyl chain for the out-of-plane conformations (**4a** and **4c**). In these two

Fig. 14. The energy profile for the trans approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain lying out of the insertion plane, for the case **4c**.
cases, the approach takes place trans to the μ-methyl bond. The profiles show some similarities, and the salient features are discussed in the following paragraphs:

(*a*) A weak olefin adduct was formed by the approach of the ethylene towards the titanium centre for the two cases. In the adducts, termed **9a** and **10a**, respectively, in the Figs. 13 and 14, R(Ti-X) was more than 2.6 Å. This is in contrast to the π complexes formed for the in-plane chain orientations and for the in-plane cis attacks, discussed earlier, where the ethylene was found to approach closer to the metal centre. Moreover, the weak adduct formation is not preceded by any uptake barrier, due to the fact that the counterion is displaced only very slightly, just by about 0.1 Å (see Figs. 13 and 14). Consequently, the energy cost of adduct formation was not high. No β-agostic interaction was found in the adducts, as the chain continues to be out of the plane.

(*b*) After adduct formation, the ethylene approached the metal centre to insert into the metal–alkyl bond. This produced the transition states **TS(9a–13a) and TS(10–13a)**, respectively, shown in Figs. 13 and 14. Like in the adducts, the counterion was not much displaced, 2.54 Å in the **4c** case and 2.73 Å in **4a**. An α-agostic bond was observed at the insertion transition states, in contrast to the β-agostic bond observed at the transition states for the in-plane conformations.

(*c*) Solvation effects were found to be negligible in the two cases, due to the fact that the displacement of the

counterion was modest. After incorporating the minor solvent effects, the insertion barriers were found to be 15.1 kcal/mol in both the cases — lower than for the out-of-plane "back side" insertion cases, but higher than for the corresponding in-plane cis approaches.

For the approach and insertion of the ethylene, the results obtained and discussed in the previous sections showed that the cis approaches yielded the lowest barriers. The reason for this is the greater destabilization in the trans olefin complexes, in comparison to the cis (6). In the trans olefin complexes, three strong electron donors (L$_1$, L$_2$, and the alkyl group) (see Fig. 4) occupy the equatorial plane of the trigonal bipyramid. As a result, each experiences destabilizing trans-like influences from the other two ligands. In the cis olefin complexes, these destabilizing influences are less, since the equatorial plane has only two strong electron donors (L$_1$ and L$_2$) and a weak donor (ethylene). The cis olefin complexes are therefore relatively more stable, and as a result, the overall barriers are lower.

Comparison between the first and second insertions

In the *First insertion study with inclusion of the counterion*, we discussed the initiation step, or first insertion of ethylene into the Ti–methyl bond, from the cis and trans approaches following which we have presented the results for the propagation step, or the second insertion of ethylene. The steps have a few common features. The cis approach yields the lower barrier for the first insertion, and the same

Fig. 15. The energy profile for the cis approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain lying in the insertion plane, for the case **4d**.
is true for the second, where the cis approach towards the out-of-plane complex **4c** yields the lowest barrier. Also common to the first and second insertions is the presence of α-agostic interactions at the transition states in the preferred cis cases. The barriers are comparable, decreasing from 12.7 kcal/mol for the first insertion, to 11.5 kcal/mol in the second. Experimental observations corroborate this result — Liu et al. (19) observed a reduction of about 4.8 kcal/mol in the insertion barrier for the second insertion, in comparison to the first, for the [*rac*-(C$_2$H$_4$)1-indenyl)$_2$)ZrMe][MeB(C$_6$F$_5$)$_3$] system, with 1-hexene as the monomer.

However, there are a few differences between the first and second insertions, which are discussed in the following paragraphs:

(*a*) For the cis approaches in the out-of-plane complexes **4a** and **4c**, which yield the lowest barriers, it is the uptake of the ethylene that becomes the rate-determining step during the insertion, in contrast to the first insertion, where the uptake barrier was always lower than the subsequent insertion barrier.

(*b*) The counterion was displaced only slightly during the first insertion (~0.3–0.4 Å). However, during the second insertion, the counterion is displaced to a much greater extent during most insertions (>2.5 Å in the out-of-plane cis approaches). Hence, solvent effects become more significant for the second insertion.

The previous four sections focused on the mechanism for insertion of the ethylene monomer in the propyl chain of the

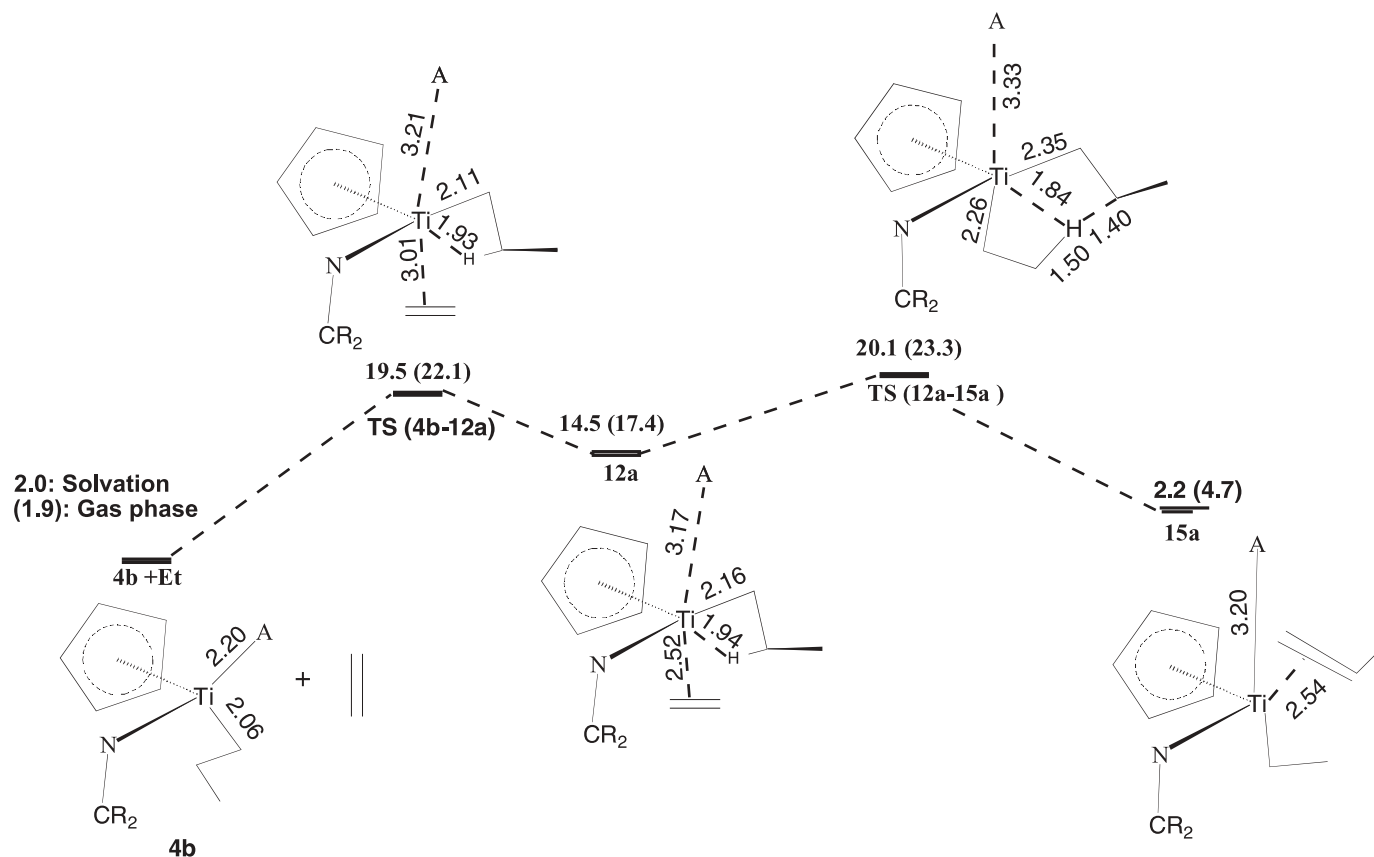
ion pair. In the next section, we will consider and discuss the possibility of termination by chain transfer, for the cis and trans approaches of ethylene towards the ion pair ([CpNC(*t*-Bu)$_2$TiPr$^+$][B(C$_6$F$_5$)$_3$CH$_3^-$]).

Termination studies

It may be recalled that the cis approach of the monomer towards the chain conformer **4b** and the trans approach towards **4d**, discussed previously, gave rise to π complexes that resembled the back side π complex (**IIIb**). This eventually led to ethylene insertion analogous to the back side insertion observed for the naked cationic case.

The other two possible cases for the in-plane chain conformers, i.e., cis approach towards **4d** and trans approach towards **4b**, were also investigated, and are shown in Figs. 15 and 16. Discussed in the following paragraphs are the salient features of the ethylene approach in the two cases:

(*a*) The approach of ethylene in either case led to the formation of π complexes **11a** and **12a** (see Figs. 15 and 16), similar to the front side π complex **IIb**, observed for the naked cation. A β-agostic interaction was observed in both π complexes (R(Ti-H) ~ 1.9 Å), and the counterion was displaced (>3.1 Å) from the metal centre to accomodate the ethylene. The cost of π complexation was high in both cases, 14.0 kcal/mol to form **11a** and 14.5 kcal/mol to form the complex **12a**. Solvent effects were found to be substantial due to the displacement (and the consequent charge separation) of the counter-

Fig. 16. The energy profile for the trans approach of the ethylene monomer towards the contact ion pair [Cp{NC(*t*-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3^-$], with the propyl chain lying in the insertion plane, for the case **4b**.


ion. Moreover, this displacement also resulted in a high uptake barrier (~19 kcal/mol) in each case preceding the formation of the π complexes.

(*b*) In the case of the naked cation, after formation of the front side π complex (**IIb**) the propyl chain rotated out of the plane to facilitate the approach of the ethylene towards the α-carbon of the alkyl chain, so that the insertion could take place. For the naked cationic case, this rotation was found to be quite facile, and the subsequent insertion took place without a high barrier. However, in the two cases, **11a** and **12a**, studied here, with the counterion attached, the steric crowding around the metal inhibited the out-of-plane rotation of the chain, which was therefore found to have a prohibitively high barrier (>22 kcal/mol). Instead, in both the cases, the system preferred to transfer the hydrogen which was taking part in the β-agostic interaction with the metal, to the ethylene monomer, thereby terminating the chain. This gave rise to the transition states **TS(11a–14a)** and **TS(12a–15a)** in the two cases, respectively (see Figs. 15 and 16), where the hydrogen being transferred was found to be almost equidistant from both the competing alkyl and ethylene carbons. This transfer was found to take place at a high energy cost, greater than 20.0 kcal/mol, in both cases, higher than any of the six insertion barriers obtained (and discussed in the earlier sections). Hence, for the [CpNC(*t*-Bu)$_2$TiPr$^+$][B-(C$_6$F$_5$)$_3$CH$_3^-$] system, insertion was found to be favoured over termination.

(*c*) For the naked cation case, the termination was 1.5 kcal/mol less favourable than the back side insertion, and 6.3 kcal/mol less favourable than the front side insertion (see Fig. 7). With the inclusion of the counterion, the odds appear to increase in favour of insertion, with termination becoming ~2.5 kcal/mol less favourable than the back side insertions and ~10.0 kcal/mol less favourable than the most favoured out-of-plane insertion case (discussed earlier). The need to displace the counterion during the formation of the in-plane π complex and its steric presence at the vicinity of the cation during the hydrogen transfer are the reasons for this.

(*d*) After transfer of the hydrogen, the product formed is a propylene moiety complexed to the metal centre, with the ethyl chain, formed from the hydrogen transfer, attached to the metal. The stability of the products (denoted as **14a** and **15a** in the Figs. 15 and 16, respectively) was found to be about 2.5 kcal/mol higher than the stability of the reactants, in each case. Solvent effects were found to be significant.

Overall picture of the second insertion

For the second insertion of ethylene into the ion pair **4**, we have investigated cis and trans approaches towards four chain conformations: **4a–4d**. This gave rise to eight possibilities, as summarized in Fig. 17 below. Six of the cases lead to insertion, and two to termination. The solvent-corrected and gas-phase uptake and insertion barriers are provided for

Fig. 17. Overall picture of the second insertion step — the barriers obtained from the cis and trans approaches of the ethylene monomer towards the contact ion pair [Cp{NC(t-Bu)$_2$}TiPr$^+$][CH$_3$B(C$_6$F$_5$)$_3$$^-$], with the propyl chain in different conformations.

each of the eight cases — with the gas-phase values indicated in parenthesis.

The approaches (cis and trans) for the out-of-plane conformations (**4a** and **4c**) both lead to insertion, and have lower barriers than for the in-plane cases (**4b** and **4d**). This suggests that the alkyl chain in the ion pair would prefer to sit out of the insertion plane during monomer approach. The most likely mode of insertion would be through the cis attack for the **4c** case. It is also clear from the values obtained that the ion-pair system **4** would strongly prefer insertion to termination, since the two approaches leading to termination have barriers much higher than the insertion barriers for **4a** and **4c**, with the difference in the barriers being about 10 kcal/mol between the termination barriers and the most favourable insertion case — cis approach (**4c**). The other noteworthy observation is that for the case **4a**, the insertion barrier is higher than the uptake in the gas phase, but after incorporation of solvent effects, the uptake barrier becomes higher — hence, the incorporation of solvent effects changes the rate-determining step in this case.[4]

Conclusions

A density functional study was conducted on the approach and insertion of the ethylene monomer into the Ti—C$_\alpha$ bond

(C$_\alpha$ representing the first carbon of the alkyl chain), for the naked cation (CpNC(t-Bu)$_2$TiR$^+$ (R = methyl, propyl)), and the ion pair CpNC(t-Bu)$_2$RTi-μ-Me-B(C$_6$F$_5$)$_3$ (R = methyl, propyl). QM/MM atoms were used to model the tertiary butyl groups, with hydrogens used as capping atoms. The counterion (B(C$_6$F$_5$)$_3$CH$_3$$^-$) was represented by a previously validated QM/MM model (9a). The chief conclusions from the study are summarized in the following paragraphs:

(a) The counterion plays a very significant role in the insertion process for both the first (R = methyl) and second (R = propyl) insertions of the ethylene monomer. The incorporation of the counterion makes the insertion processes highly endothermic, in contrast to the corresponding naked cationic cases, where the insertion is found to be exothermic. Moreover, for the second insertion, the presence of the counterion influences the alkyl chain conformation of the ion pair, making the out-of-plane chain conformations more favourable for insertion than the in-plane ones. The approach of the ethylene cis to the μ-methyl bond in the ion pair for the out-of-plane conformer **4c**, ends up being the most favourable for insertion. For this approach, the barrier to uptake of the monomer is found to be the rate-determining step corroborating experimental findings proving the significance of the counterion, since the main contribution to

---

the uptake barrier comes from the displacement of the counterion.

(*b*) The counterion also has an influence on the termination process. Inclusion of the counterion increases the difference between insertion and termination barriers for the second insertion (difference ~ 10 kcal/mol), in contrast to the naked cationic case (difference = 6.3 kcal/mol), thereby making insertion more favourable.

(*c*) The barrier to second insertion for the most favorable approach (11.5 kcal/mol) is found to be 1.2 kcal/mol lower than the barrier for the first insertion (12.7 kcal/mol). This reduction in the height of the barrier, upon going from first to second insertion, corroborates experimental findings (19).

(*d*) Solvent effects become important with the increasein the chain length. The displacement of the counterion increases during most approaches of the ethylene monomer during the second insertion, thereby increasing the charge separation between cation and anion. Therefore, incorporation of the solvent effects reduces the barriers to uptake and insertion to a significant extent. In fact, for the cis approach of ethylene towards **4a**, inclusion of solvent effects reverses the rate-determining step, making the uptake barrier higher than the insertion.

TRIBUTE

Professor John F. Harrod

This special issue of the *Canadian Journal of Chemistry* has been named in honour of John Frank Harrod, an accomplished scientist who has been a gracious colleague and mentor to many chemists in Canada and elsewhere. John Harrod is known primarily as an organosilicon chemist who has studied various aspects of this subject over most of his 42 year career in independent research. His contributions to the understanding of mechanisms in organosilicon chemistry, to the application of catalysis in organosilicon chemistry, and to the synthesis of compounds containing transition metal – Si bonds have formed the foundations of several of the most important areas of contemporary organosilicon chemistry.

John Harrod has also made significant contributions to the use of organosilicon compounds for the preparation of ceramics, use of the titanocene-catalyzed hydrosilation reactions for chiral synthesis, synthesis of organometallically substituted polysiloxanes, and spectroscopic analysis of organosilicon compounds. These studies have led to 88 papers in this field, a number of which are landmarks. Some other areas of chemistry in which Harrod's research has had an impact include: the synthesis and reactions of copper phenoxide complexes, reactions on clean metal surfaces, organonickel-catalyzed polymerization of butadiene, and mechanistic studies of oxidative addition to Ir complexes.

By dedicating this issue to John Harrod, we are both recognizing and celebrating his many contributions to the growth of inorganic/organometallic chemistry in Canada, his training of younger researchers in organometallic, silicon, and polymer chemistry, and his role in fostering respect and recognition for Canada's contributions to the advancement of inorganic chemistry. The following paragraphs provide a glimpse into John Harrod's life and career.

John Harrod was born and raised in Coventry, U.K. He attended the University of Birmingham, where he completed both a B.Sc. (1955) and a Ph.D. (1958) in Chemistry. His Ph.D. project, supervised by Sir Harry Melville, was an investigation of the polymerization of styrene by catalysts derived from the reactions of Grignard reagents with titanium tetrachloride. Upon completion of his Ph.D. degree, John Harrod took up a post-doctoral position (1958–1960) with Jack Halpern at the University of British Columbia. During this period, he assisted in Halpern's pioneering studies of the homogeneous catalytic activation of hydrogen, and made the first observation of an unequivocally homogeneous, coordination-catalyzed hydrogenation of an olefinic substrate.

In 1960, John Harrod moved to the General Electric Research Laboratory in Schenectady, NY, and stayed there until 1966; it is during this period that he discovered organosilicon chemistry (in a personal sense). Shortly after his arrival in Schenectady, Harrod became aware of the discoveries of John Speier and his co-workers at Dow Corning on the application of Noble Metal compounds, and in particular chloroplatinic acid, as remarkably effective catalysts for the addition of Si—H bonds to olefins. Having just participated in the discovery of a homogeneous, ruthenium-catalyzed hydrogenation of some olefinic compounds in Jack Halpern's laboratory, Harrod was in a privileged position to recognize the likely connection between Speier's chemistry and the many other homogeneous transition-metal-catalyzed reactions that

were being identified and developed in the late 1950s and early1960s.

In collaboration with his co-worker, Alan Chalk (also trained in Halpern's laboratory), Harrod carried out fundamental studies on metal-catalyzed hydrosilation chemistry. This work resulted in the proposal of a mechanistic scheme that explained, at least superficially, all of the organic and organosilicon chemistry that had been elaborated by the Dow Corning group. The so-called "Chalk–Harrod" mechanism, which is one of the earliest "text book" examples of a catalytic cycle based on coordination principles, has provided the foundation for the mechanistic understanding of a large body of hydrosilation chemistry. The original Chalk–Harrod report (J. Am. Chem. Soc. **87**, 16 (1965)) has since been cited several hundred times by many workers who have used its findings as a road map in their own investigations of hydrosilation reactions. It is of interest to note that only in 2002 were the final details confirming the essential correctness of the Chalk–Harrod mechanism, with respect to the platinum-catalyzed hydrosilation of olefins, reported (A. Roy and R.B. Taylor. J. Am. Chem. Soc. **124**, 9510 (2002)).

Harrod and Chalk also demonstrated the first case of an oxidative addition reaction of a hydrosilane to a transition metal centre, one of the earliest examples of an oxidative addition – reductive elimination process (J. Am. Chem. Soc. **87**, 1133 (1965)). This approach for the synthesis of transition metal silyl and silyl-hydride complexes via the addition of Si-H compounds to metal fragments stimulated decades of investigations on such reactions with essentially all of the transition elements.

After his stay at GE, John Harrod took up a position at McGill, where he stayed until his formal retirement in 1998. During his McGill years, Harrod rose through the ranks, chaired the Department of Chemistry, presided over the staff association, and received many honours and awards. For example, he was named a Killam Research Fellow of the Canada Council (1995–1997) and the 1997 Alcan Lecturer of the Chemical Institute of Canada. Harrod has also contributed to the Canadian scientific community by serving several terms on the grants and scholarship committees of the Fonds pour la formation des chercheurs et l'aide à la recherche (Québec) (FCAR) and on the Natural Sciences and Engineering Research Council of Canada (NSERC) Chemistry Grants Selection Committee (Inorganic and Organic). He has also served on the Editorial Board of *Organometallics* and the Comité de Parrainage of the French language science education journal *Didaskalia*. His continuing interest in industrial chemistry was reflected in his work as a retained consultant of Dow Canada in Sarnia (1966–1971) and of Dow chemical in Midland (1967–1980). His international stature as a researcher earned Harrod many invitations to lecture all over the world, the most memorable being his 2 years as a Professeur Invité, and France/Québec Fellow, at the Ecole Nationale Supérieure de Chimie de Paris. It was during a sabbatical leave in Paris (in 1983) when Harrod accidentally tapped a second fountainhead of new organosilicon chemistry, as described below.

The near absence of examples of silyl complexes of group 4 elements had intrigued Harrod for a number of years. In Paris he set up a collaboration with Dr. Edmond Samuel, a pioneer in group 4 metallocene chemistry, with the goal of

exploring the reactions of hydrosilanes with organometallocenes. These studies resulted in the discovery of the catalytic dehydrocoupling of hydrosilanes to polysilanes (C. Aitken, J.F. Harrod, and E. Samuel. J. Organometal. Chem. **279**, C11 (1985); C. Aitken, J.F. Harrod, and U.S. Gill. Can. J. Chem. **65**, 1804 (1987)). The recognition of the significance of this discovery was in large part due to Harrod's formal training as a polymer chemist and it occurred at a time of burgeoning interest in polysilanes. The catalytic dehydrocoupling reaction remains one of a small number of methods for synthesizing oligo- and polysilanes.

John Harrod's pioneering work in the dehydrocoupling of hydrosilanes inspired a number of talented investigators (notably Don Tilley, then at U.C. SanDiego, Don Berry at U. Pennsylvania, and Joyce Corey at U. Missouri in St. Louis) to pursue the preparation and reactivity studies of many new silyl complexes of group 4 metals. In addition, Harrod extended the principle of catalytic dehydrocoupling to the synthesis of new compounds containing Si-P and Si-N, by cross-reacting hydrosilanes with hydrides of N and P. In his hands, and those of others, such as Joyce Corey, Ian Manners, and Don Tilley, catalytic dehydrocoupling has been established as a new, general route for the synthesis of element–element bonds.

Very recently, Harrod returned to the field of hydrosilation chemistry after a long absence to make a number of significant contributions. As usual, his choice of chemistry involved intuition and luck, combined with the recognition that something interesting was afoot. Of particular note is the discovery of the titanocene-catalyzed hydrosilation of pyridines (L. Hao, J.F. Harrod, A.-M. Lebuis, Y. Mu, R. Shu, E. Samuel, and H.-G. Woo. Ang. Chem. Int Ed. Engl. **37**, 3126 (1998); R. Shu and J.F. Harrod. Can J. Chem. **79**, 1075 (2001)), which provided the first examples of the hydrosilation of a highly aromatic unsaturated substrate. These reactions also provide a new synthetic approach to a valuable family of *N*-heterocyles.

A recent exploration of the titanocene-catalyzed reactions of hydrosilanes with aromatic amides (K. Selvakumar and J.F. Harrod. Angew. Chem. Int. Ed. **40**, 2129 (2001)) resulted in the discovery of a new, high-yield route to the 1,2-diaryl-1,2-diaminoethanes, rather than the expected simple addition of the Si-H across the C=O bond. This new C—C bond forming reaction via inexpensive, widely available starting materials holds promise for the synthesis of a new family of polymers that would be extremely difficult to synthesize by other methods.

The above highlights have been chosen to illustrate the thread of originality that characterizes John Harrod's contributions to organosilicon chemistry. He had the luck to stumble upon exciting new chemistry, but he also recognized the major significance of these lucky accidents, in a number of different contexts, and initiated important new directions in the field.

In his nonprofessional life, John Harrod has pursued a variety of cultural and social activities. His love of the mountains, nurtured in the hills of the Celtic Fringe in the U.K., and then by the inspiring grandeur of the Western Cordillera of North America, endures to the present day. His lifelong concern for human suffering led Harrod to take a year's leave of absence in 1963–1964 to work as a volunteer, under the auspices of the International Voluntary Service (IVS), on reconstruction and development projects in northern Greece and in Algeria. The following summer he led an IVS team in the Tennessee Smokey Mountains to reconstruct a community water supply system that had been destroyed in the course of civil disturbances directed against the activities of some voter registration workers. He has also been a supporter of Amnesty International for many years.

John Harrod is now the G.H. Tomlinson Professor of Chemistry (Emeritus) at McGill.

Davit Zargarian

This special issue is dedicated to

Professor John Harrod

to honour his outstanding contributions to both homo-geneous catalysis and materials chemistry.

Associate Editors: Chris Orvig, Davit Zargarian, and I. Butler

Ce numéro spécial est dédié au

Professeur John Harrod

en reconnaissance de ses contributions exceptionnelles tant à la catalyse homogène qu'à la chimie des matériaux.

Directeurs scientifiques associés : Chris Orvig, Davit Zargarian, and I. Butler
The caricature was presented to John Harrod by his colleague
Mark Andrews on the occasion of his 60th birthday in 1994.
John counts this gift among his most treasured possessions.

Mark Andrews, un collègue de John Harrod, a remis cette
caricature à John à l'occasion de son 60e anniversaire, en 1994.
John affirme qu'il s'agit là d'une de ses plus précieuses possessions.

HOMMAGE

Professeur John F. Harrod

Ce numéro spécial de la *Revue canadienne de chimie* est dédié à John Frank Harrod, chercheur chevronné ainsi que collègue et mentor de nombreux chimistes du Canada et d'ailleurs. Harrod est surtout connu pour ses travaux en chimie des organosiliciés, ayant consacré la majorité de ses 42 ans de carrière à l'étude autonome de divers aspects de ces composés. Ses contributions à la compréhension des mécanismes qui sous-tendent la chimie des organosiliciés, à l'utilisation de la catalyse dans ce domaine et à la synthèse de composés caractérisés par des liaisons « Si-métaux de transition » ont établi les fondements de plusieurs des plus importants champs d'étude de la chimie contemporaine des organosiliciés.

John Harrod a également apporté des contributions importantes à l'utilisation des organosiliciés dans la préparation de céramique, à la synthèse chirale à l'aide de réactions d'hydrosilation catalysées par le titanocène, à l'élaboration de polysiloxanes par réaction de substitution organométallique et à l'analyse spectroscopique des composés organosiliciés. Ces études ont mené à la rédaction de 88 articles dans ce domaine, dont plusieurs ont fait époque. Parmi les autres secteurs de recherche ayant bénéficié de ses travaux figurent la synthèse des complexes de phénoxides de cuivre et leurs réactions, les réactions sur les surfaces métalliques propres, la polymérisation du butadiène par catalyse organonickelée et les études des mécanismes associés à l'ajout par oxydation des complexes de l'iridium.

Ce numéro spécial souligne et applaudit les nombreuses contributions que John Harrod a apportées au progrès de la chimie des composés inorganiques et organométalliques au Canada, à la formation de jeunes chercheurs dans le domaine de la chimie des organométaux, du silicium et des polymères ainsi qu'à son rôle dans la promotion du respect et de la reconnaissance de l'apport canadien à l'avancement de la chimie inorganique au Canada. Les paragraphes qui suivent offrent un aperçu de la vie de John Harrod et de sa carrière.

John Harrod naît et grandit à Coventry (Royaume-Uni). Il étudie à l'Université de Birmingham, où il obtient un B. Sc. (1955) et un Ph. D. (1958) en chimie. Son projet de doctorat, sous la direction de Sir Harry Melville, porte sur la polymérisation du styrène par catalyseurs dérivés de réactions des réactifs de Grignard à l'aide du tétrachlorure de titane. Après avoir obtenu son diplôme supérieur, Harrod accepte une affectation postdoctorale (1958–1960) auprès de Jack Halpern à l'Université de la Colombie-Britannique. Il prend part aux travaux pionniers de Halpern sur l'activation catalytique homogène de l'hydrogène et fait la première constatation d'une véritable hydrogénation par catalyse de coordination d'un substrat oléfinique.

En 1960, Harrod se joint au General Electric Research Laboratory (GERL) à Schenectady (New York), où il y travaille jusqu'en 1966. C'est au cours de cette période qu'il se familiarise avec les rouages de la chimie des organosiliciés. En effet, peu de temps après son arrivée à Schenectady, Harrod a vent des découvertes de John Speier et de ses collaborateurs à la société Dow Corning concernant l'application des composés de métaux nobles et, plus particulièrement, de l'acide chloroplatinique comme catalyseurs

hautement efficaces dans l'ajout de liaisons « Si—H » aux oléfines. Ayant récemment collaboré à la découverte d'une hydrogénation homogène par catalyse du ruthénium de quelques composés oléfiniques dans le laboratoire de Jack Halpern, Harrod se trouve ipso facto en position idéale pour reconnaître le lien probable entre la chimie de Speier et bon nombre de réactions homogènes par catalyse de métaux de transition mises au grand jour et élaborées vers la fin des années 1950 et le début des années 1960.

De concert avec son collègue Alan Chalk (également du laboratoire de Halpern), Harrod réalise des études fondamentales sur la chimie de l'hydrosilation par catalyse de métaux. Ces travaux mènent au développement d'un processus élémentaire qui explique, du moins superficiellement, l'ensemble de la chimie des composés organiques et organosiliciés élaborés par le groupe de la société Dow Corning. Le mécanisme dit « de Chalk–Harrod », l'un des premiers exemples typiques du cycle de la catalyse axé sur les principes de coordination, sert de pierre angulaire à la compréhension des mécanismes d'une grande partie de la chimie de l'hydrosilation. Par ailleurs, le rapport original de Chalk et Harrod (J. Am. Chem. Soc. **87**, 16 (1965)) est cité quelques centaines de fois par une pléiade de chercheurs qui utilisent ces résultats comme flambeau pour éclairer leurs propres recherches dans le domaine des réactions d'hydrosilation. Il est intéressant de noter que ce n'est qu'en 2002 qu'il devient possible de confirmer la justesse inhérente du mécanisme de Chalk-Harrod, quant à l'hydrosilation des oléfines par catalyse du platine (A. Roy et R.B. Taylor. J. Am. Chem. Soc. **124**, 9510 (2002)).

Harrod et Chalk présentent également le premier cas d'une réaction d'addition par oxydation d'un hydrosilane à un centre de métaux de transition, l'un des premiers exemples de processus d'addition par oxydation – d'élimination par réduction (J. Am. Chem. Soc. **87**, 1133 (1965)). De fait, cette approche utilisée dans la synthèse de complexes de métaux de transition de silyle et d'hydrure silylène par l'addition de composés Si-H à des fragments métalliques alimentera des décennies de recherche sur de telles réactions avec, pour ainsi dire, tous les éléments de transition.

Après son passage au GERL, John Harrod se joint à l'Université McGill, où il demeurera jusqu'à sa retraite officielle en 1998. Là, il gravit les échelons pour devenir directeur du Département de chimie, siège à titre de président de l'association du personnel universitaire et reçoit plusieurs prix et témoignages de reconnaissance. De plus, il est boursier de recherche du Conseil des arts du Canada (de 1995 à 1997) et conférencier Alcan 1997 de l'Institut de chimie du Canada. Harrod contribue également à la communauté scientifique canadienne en réalisant bon nombre de mandats au sein de comités de bourses d'études et de subventions du Fonds pour la formation des chercheurs et l'aide à la recherche (Québec) (FCAR) et du Comité de sélection des subventions en chimie (inorganique et organique) du Conseil de recherches en sciences naturelles et en génie (CRSNG). Il siège également au Comité de rédaction de la revue *Organometallics* et au Comité de parrainage de la revue française *Didaskalia*, spécialisée dans les recherches sur la communication et l'apprentissage des sciences et des techniques. Son intérêt assidu envers la chimie industrielle se reflète dans ses travaux de consultant au compte des sociétés Dow Canada, à

Sarnia (de 1966 à 1971), et Dow Chemical of Canada Ltd., à Midland (de 1967 à 1980). Sa renommée internationale en tant que chercheur lui vaut de nombreuses invitations comme conférencier, la plus mémorable étant son affectation de 2 ans à titre de professeur invité et boursier France/Québec à l'École Nationale Supérieure de Chimie de Paris. Lors de son congé sabbatique à Paris (en 1983), Harrod insuffle par hasard une nouvelle vie à la chimie des organosiliciés dans les circonstances qui suivent.

L'absence presque complète d'exemples de complexes de silyle des éléments du groupe 4 excite la curiosité de Harrod depuis plusieurs années. À Paris, il collabore avec Edmond Samuel, un pionnier de la chimie des métallocènes du groupe 4, et examine les réactions des hydrosilanes avec les organométallocènes. Ces études résultent en la production de polysilanes par couplage déshydrogénant catalytique des hydrosilanes (C. Aitken, J.F. Harrod et E. Samuel. J. Organometal. Chem. **279**, C11 (1985); C. Aitken, J.F. Harrod et U. S. Gill. Can. J. Chem. **65**, 1804 (1987)). La reconnaissance de l'importance de cette découverte est attribuable en grande partie aux antécédents et aux connaissances fondamentales de Harrod dans le domaine de la chimie des polymères et survient à un moment où l'intérêt à l'égard des polysilanes s'avive. Le couplage déshydrogénant catalytique demeure l'une des quelques méthodes utilisées dans la synthèse d'oligosilanes et de polysilanes.

Ses travaux avant-gardistes sur le couplage déshydrogénant des hydrosilanes incitent une légion de chercheurs, dont Don Tilley, qui travaille à l'époque à l'Université de la Californie (San Diego), Don Berry de l'Université de la Pennsylvanie et Joyce Corey de l'Université du Missouri (Saint Louis), à préparer d'autres complexes de silyle du groupe 4 et à étudier leur réactivité. De plus, Harrod applique le principe de couplage déshydrogénant à la synthèse de nouveaux composés caractérisés par des liaisons « Si-P » et « Si-N » à l'aide de réactions croisées entre les hydrosilanes et les hydrures d'azote et de phosphore. Grâce à ses efforts et à ceux de ses collègues, notamment Joyce Corey, Ian Manners et Don Tilley, le couplage déshydrogénant catalytique devient une voie nouvelle et générale de synthèse de liaisons « élément–élément ».

Harrod a récemment renoué avec la chimie de l'hydrosilation après une longue absence, ce qui lui a permis d'apporter de nombreuses contributions d'importance. Comme d'habitude, ce cheminement, intuitif et fortuit, a été mû par un fort pressentiment d'une réalisation imminente. Par ailleurs, il est intéressant de noter sa découverte de

l'hydrosilation des pyridines par catalyse du titanocène (L. Hao, J.F. Harrod, A.-M. Lebuis, Y. Mu, R. Shu, E. Samuel, et H.-G. Woo. Angew. Chem. Int. Ed. Engl. **37**, 3126 (1998); R. Shu et J.F. Harrod. Can. J. Chem. **79**, 1075 (2001)) qui démontre pour la première fois l'hydrosilation d'un substrat non saturé et hautement aromatique. Ces réactions offrent également une nouvelle approche synthétique pour une importante famille d'hétérocyles azotés. Une récente étude sur les réactions entre les hydrosilanes et les amides aromatiques catalysés à l'aide du titanocène (K. Selvakumar et J.F. Harrod. Angew. Chem. Int. Ed. **40**, 2129 (2001)) a permis de démontrer une voie nouvelle et très productive de synthèse des 1,2-diaryl-1,2-diaminoéthanes, plutôt que le simple ajout d'une liaison « Si-H » à une liaison C=O. Cette nouvelle réaction permettant de créer une nouvelle liaison « C—C » à l'aide de matériaux économiques et répandus est très prometteuse pour la synthèse d'une nouvelle famille de polymères autrement difficiles à fabriquer.

Lesglanures ci-dessus ont été choisies pour illustrer l'originalité profonde qui caractérise les contributions de John Harrod à la chimie des composés organosiliciés. Même s'il est tombé par chance sur un domaine novateur et prometteur de la chimie, il a su reconnaître l'importante signification de ces « découvertes accidentelles » et impulser de nouvelles recherches.

Sur le plan personnel, John Harrod s'adonne à une variété d'activités socioculturelles. Sa passion des montagnes, éveillée dans les collines des marges celtiques (Royaume-Uni), est plus que jamais exaltée par l'impressionnante grandeur des Cordillères pacifiques de l'Amérique du Nord. Sa grande sensibilité aux problèmes humanitaires et à la souffrance humaine l'a poussé à prendre un congé sabbatique (de 1963 à 1964) pour travailler à titre de bénévole, sous les auspices du Service civil international (SCI), à des projets de reconstruction et de développement dans le Nord de la Grèce et en Algérie. L'été suivant, il a dirigé une équipe du SCI chargée de reconstruire le système d'aqueduc d'une communauté des Smokey Mountains, au Tennessee, détruit à la suite de troubles sociaux causés par des irrégularités dans l'inscription électorale. Il appuie également Amnistie Internationale depuis de nombreuses années.

John Harrod est aujourd'hui titulaire de la chaire Tomlinson G.H. en chimie (professeur émérite) à l'Université McGill.

Vanadium and niobium diamidophosphine complexes and their reactivity

Michael P. Shaver, Robert K. Thomson, Brian O. Patrick, and Michael D. Fryzuk

Abstract: The tridentate ligand precursors $R'P(CH_2SiMe_2NR'')_2$ ($^{R'R''}$[NPN]: R' = Cy, Ph; R'' = Ph, Mes, Me) were prepared from metathesis reactions of a lithiated amine, chloro(chloromethyl)dimethylsilane, the appropriate 1° phosphine, and *n*-butyl lithium and were isolated as solvent adducts. Metathesis between ^{CyPh}[NPN]Li$_2$(OEt$_2$), **2**, and VCl$_3$(THF)$_3$ afforded (^{CyPh}[NPN]VCl)$_2$, **7**, whose solid-state structure was established by X-ray crystallography. Reduction attempts of the ($^{R'R''}$[NPN]VCl)$_2$ species with KC$_8$ incorporated molecular nitrogen but were complicated by imide formation and ligand decomposition. Metathesis of **2** with NbCl$_2$Me$_3$ afforded the highly unstable complex ^{CyPh}[NPN]NbMe$_3$, **15**. Attempts to hydrogenate this species were unsuccessful.

Key words: vanadium, niobium, metathesis, coordination chemistry, reduction, hydrogenation.

Résumé : Les précurseurs de ligand $R'P(CH_2SiMe_2NR'')_2$ ($^{R'R''}$[NPN] : R' = Cy, Ph; R'' = Ph, Mes, Me) ont été préparé des réactions de métathèse du amine lithié correspondant, chloro(chlorométhyl)diméthylsilane, le phosphine correspondant et *n*-butyl lithium. Les ligands ont été isolés comme adducts de solvant de selde dilithium. Les réactions de métathèse du ^{CyPh}[NPN]Li$_2$(OEt$_2$), **2**, avec VCl$_3$(THF)$_3$ ont donné (^{CyPh}[NPN]VCl)$_2$, **7**, dont de la structure d'état solide a été établie par crystallographie de rayons-X. Les tentatives de réduction de l'espèce ($^{R'R''}$[NPN]VCl)$_2$ avec KC$_8$ a incorporé l'azote moléculaire mais a été compliquée par la formation d'imide et la décomposition de ligand. Les réactions de métathèse de **2** avec NbCl$_2$Me$_3$ ont donné le complexe extrêmement instable ^{CyPh}[NPN]NbMe$_3$, **15**. Les tentatives de hydrogéner était infructueux.

Mots clés : vanadium, niobium, la métathèse, la chimie de coordination, la réduction, l'hydrogénation.

Introduction

Recent work from our laboratory has focused on the chemistry of tantalum dinitrogen complexes stabilized by the [NPN] ligand, where [NPN] = PhP(CH$_2$SiMe$_2$NPh)$_2$ (1–4). One of the most intriguing species is ([NPN]Ta)$_2$(μ-H)$_2$(μ-η^1-η^2-N$_2$), **A**, with a side-on, end-on bound dinitrogen unit. This complex has displayed remarkable reactivity with simple organometallic hydride reagents. The coordination chemistry of [NPN] with Ta — the heaviest member of group 5 — piqued our interest in the lighter elements of this group, namely V and Nb. In this manuscript we explore some of our successes and failures in trying to extend dinitrogen chemistry to low valent vanadium and niobium [NPN] complexes.

A
Experimental

General information

Unless otherwise stated, all manipulations were performed under an atmosphere of dry, oxygen-free dinitrogen by means of standard Schlenk or glovebox techniques (Vacuum Atmospheres HE-553-2 glovebox equipped with an MO-40-2H purification system and a –40 °C freezer). Thick-walled Pyrex reaction vessels with 5 or 10 mm Teflon needle valves and ground glass joints were used to maintain an inert atmosphere at pressures between 10^{-6} and 4 atm (1 atm = 101.325 kPa). Hexanes and toluene were purchased anhydrous from Aldrich and further dried by passage through a tower of alumina and degassed by passage through a tower of Q-5 catalyst under a positive pressure of nitrogen (5). Anhydrous diethyl ether, tetrahydrofuran (THF), benzene, and hexamethyldisiloxane (HMDS) were stored over sieves and distilled from sodium benzophenone ketyl under argon. Nitrogen was dried and deoxygenated by passage through a column containing activated molecular sieves and MnO. Deuterated benzene was dried by refluxing with molten potassium metal in a sealed vessel under partial pressure, then trap-to-trap distilled, and degassed by freeze-pump-thaw three times. Unless otherwise stated, ^{1}H, ^{31}P{^{1}H}, and ^{7}Li

NMR spectra were recorded on a Bruker AMX-500 instrument operating at 500.1 MHz for ^{1}H spectra. ^{1}H NMR spectra were referenced to internal C_6D_5H (7.15 ppm), $^{31}P\{^1H\}$ NMR spectra to external $P(OMe)_3$ (141.0 ppm with respect to 85% H_3PO_4 at 0.0 ppm), and $^7Li\{^1H\}$ NMR spectra to a 0.3 mol L^{-1} LiCl solution in MeOH (0.00 ppm). Elemental analyses were performed in the departmental facility; mass spectra were recorded on a Kratos MS 50. Clusters assigned to specific ions show appropriate isotopic distribution patterns, as calculated for the atoms present. $NbCl_5$ was purchased from Strem Chemicals and used without further purification. Anhydrous $ZnCl_2$ was purchased from Aldrich and dried by refluxing in excess $SOCl_2$ under N_2. $MeNH_3^+Cl^-$ was purchased from Fisher Chemicals and recrystallized out of hot ethanol and dried in vacuo prior to use. The reagents $PhNH_2$, $ClSiMe_2CH_2Cl$, $CyPH_2$, $MesNH_2$ ($MesNH_2$ = $2,4,6\text{-}Me_3C_6H_2NH_2$), and $PhPCl_2$ were purchased from Aldrich and purified by standard procedures (6). Solutions of MeLi (1.4 mol L^{-1} in diethylether) and ^{n}BuLi (1.6 mol L^{-1} in hexanes) were obtained from Acros Organics and used as received. The compounds $PhPH_2$ (7), ^{PhPh}[NPN]Li$_2$(THF)$_2$ (2), ^{CyPh}[NPN]Li$_2$(OEt$_2$) (8), VCl_3(THF)$_3$ (9), KC_8 (10), and $NbCl_2Me_3$ (11) were prepared by literature methods.

Crystallographic data[2] for compounds **4** and **7** appear in Tables 1 and 2, respectively. All measurements were made on a Rigaku–ADSC CCD area detector with graphite monochromated Mo Kα radiation. The data were processed (12) and corrected for Lorentz and polarization effects. The structure was solved by direct methods (13) and expanded by using Fourier (14) techniques. All nonhydrogen atoms were refined with anisotropic thermal parameters. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International tables for X-ray crystallography (15, 16).

^{CyMes}[NPN]Li$_2$(THF) (4)

A 300 mL ethereal solution containing 12.1 mL (11.640 g, 86.1 mmol) of $MesNH_2$ was cooled to –78 °C in a dry ice – isopropanol slush bath. A solution of 1.6 mol L^{-1} ^{n}BuLi in hexanes was added dropwise via syringe. After 30 min at –78 °C, the solution was warmed to room temperature (r.t.) and stirred for 60 min. Upon recooling the solution to –78 °C, 11.4 mL (12.320 g, 86.1 mmol) of $ClSiMe_2CH_2Cl$ was added and stirred for 30 min. After warming to r.t. and stirring for an additional 30 min, the solution was cooled to 0 °C and 5.8 mL (43.1 mmol) of $CyPH_2$ and 107.6 mL (172.2 mmol) of ^{n}BuLi was added consecutively via syringe. This solution was stirred for 30 min and allowed to warm to r.t. The resulting white suspension was concentrated in vacuo, and the white residue was dissolved in toluene (32 g) and filtered through Celite. Removal of toluene in vacuo yielded a foamy white solid, which was dissolved in hexanes (150 mL). Addition of 5.25 mL (0.0647 mol) of THF caused ^{CyMes}[NPN]Li$_2$(THF) (**4**) to precipitate as a white microcrystalline solid, which was col-

^{CyPh}[NPN]VCl)$_2$ (7)

An ethereal solution (100 mL) of ^{CyPh}[NPN]Li$_2$(OEt$_2$) (3.00 g, 4.23 mmol) maintained at –78 °C was added via cannula to a 3:1 mixture of Et$_2$O and THF containing VCl$_3$(THF)$_3$ (1.58 g, 4.23 mmol). After the addition, the solution was warmed to r.t. and stirred for 90 min. Upon removal of volatiles, the resultant brick-red powder was dissolved in toluene (100 mL); the solution was filtered through Celite to remove LiCl, and the toluene was removed in vacuo. The brick-red powder was washed with pentane and dried under vacuum (75.8%, 1.69 g). Crystals of **7** suitable for X-ray diffraction were grown from a concentrated solution of layered benzene–HMDS. The compounds (^{PhPh}[NPN]VCl)$_2$, **8**, (^{CyMes}[NPN]VCl)$_2$, **9**, (^{PhMes}[NPN]VCl)$_2$, **10**, (^{CyMe}[NPN]VCl)$_2$, **11**, and (^{PhMe}[NPN]VCl)$_2$, **12**, were prepared analogously. **7**: EI-MS m/z (%): 526 ([M$^+$] ^{CyPh}[NPN]VCl, 100). Reduction of 7 with 2.2 KC$_8$ under 4 atm N$_2$

A thick-walled reaction vessel was charged with a magnetic stir bar, 0.218 g (0.413 mmol) of **7**, and 0.056 g (0.909 mmol) of KC$_8$. Et$_2$O (50 mL) was vacuum transferred into the flask, frozen at –196 °C, and charged with 4 atm of N$_2$. The brick-red solution turned deep purple upon warming to r.t. The reaction was stirred for 24 h. Filtration through Celite and removal of solvent gave a waxy purple, pentane-soluble solid. EI-MS m/z (%): 505 ([M$^+$: ^{CyPh}[NPN]V≡N, 100), 491 (^{CyPh}[NPN]V, 22).

Reduction of 7 with 3.3 KC$_8$ under 4 atm N$_2$

Diethylether (50 mL) was vacuum transferred into a thick-walled reaction vessel charged with a magnetic stir bar, 0.218 g (0.413 mmol) of **7**, and 0.084 g (1.364 mmol) of KC$_8$ and frozen at –196 °C. The vessel was charged with 4 atm of N$_2$ and warmed to r.t. The brick-red solution changed to olive green and was stirred for an additional 24 h. Filtration through Celite and removal of solvent gave a dark green, pentane-soluble powder. EI-MS m/z (%): 1049 ([M$^+$]: K(^{CyPh}[NPN]V≡N)$_2$, 12), 505 ([M$^+$] – K(^{CyPh}[NPN]V≡N), 100), 491 (^{CyPh}[NPN]V, 20).

Reduction of 9 with 2.2 KC$_8$ under 1 atm N$_2$

Diethylether (50 mL) was transferred via syringe into a thick-walled reaction vessel charged with a magnetic stir bar, 0.252 g (0.413 mmol) of **9**, and 0.056 g (0.909 mmol) of KC$_8$ under an atmosphere of N$_2$. The vessel was sealed and the contents stirred for 24 h. Filtration through Celite and removal of solvent gave a brown, hexanes-soluble powder. Washing the powder with pentane produced an impure brown solid (^{CyMes}[NPN]V=NMes, **13**) and a brown solution, which, upon cooling to –37 °C, afforded brown needle crystals of MesN(SiMe$_2$CH$_2$)$_2$PCy, **14**. Reductions of **8** and **10**–**12** were conducted in the same manner. **13**: EI-MS m/z (%): 708 ([M$^+$] ^{CyMes}[NPN]V=NMes, 50), 575 ([M$^+$] – NMes, 100). **14**: ^1H NMR (C_6D_6, 25 °C, 200 MHz) δ: 2.28, 2.32 (s, 6H total, o-Ph-CH_3), 2.40 (s, 3H, p-Ph-CH_3), 6.90, 7.25 (s, 2H total, m-Ph-H), 0.05, 0.58 (s, 12H total, Si-CH_3), 0.85, 1.39, 1.97 (m, 15H total, CH_2 and C$_6H_{11}$). $^{31}P\{^1H\}$ NMR (C_6D_6, 25 °C) δ: –25.8 (s). Anal. calcd. for $C_{21}H_{38}NPSi_2$ (%): C 64.40, H 9.78, N 3.58; found: C 64.45, H 9.70, N 3.51. **Reduction of 8**: EI-MS m/z (%): 576 ([M$^+$] ^{PhPh}[NPN]V=NPh, 20), 485 ([M$^+$] – NPh, 100). **Reduction of 10**: EI-MS m/z (%): 702 ([M$^+$] ^{PhMes}[NPN]V=NMes, 35), 569 ([M$^+$] – NMes, 100). **Reduction of 11**: EI-MS m/z (%): 396 ([M$^+$] ^{CyMe}[NPN]V=NMe, 8), 367 ([M$^+$] – NMe, 100). **Reduction of 12**: EI-MS m/z (%): 390 ([M$^+$] ^{PhMe}[NPN]V=NMe, 12), 361 ([M$^+$] – NMe, 100).

CyPh[NPN]NbMe$_3$ (15)

In the dark, a solution of 5.601 g (0.0106 mol) of **2** in 150 mL of Et$_2$O maintained at –78 °C was added via cannula to a solution of 2.200 g (0.0106 mol) of NbCl$_2$Me$_3$ in 150 mL of Et$_2$O. The solution was stirred at –78 °C for 1 h, then warmed to –10 °C, producing an orange solution. Excess Et$_2$O was removed in vacuo, and the resulting solid was dissolved in toluene and filtered through Celite. Toluene was

removed in vacuo and the solid washed with pentane to afford **15** in 72% yield (4.42 g). The solid was highly light and thermally sensitive and was stored in a darkened vessel at –37 °C. Preparation of ^{PhPh}[NPN]NbMe$_3$, **16**, and ^{CyMes}[NPN]NbMe$_3$, **17**, was accomplished in the same manner. Reactions of **3**, **5**, and **6** did not afford the corresponding $^{R'R''}$[NPN]NbMe$_3$ species, as decomposition pathways prevented isolation of pure product. **15**: ^{1}H NMR (C$_6$D$_6$, 25 °C, 500 MHz) δ: 0.00, 0.34 (s, 12H, Si-(CH_3)), 0.75–1.42 (ov, m, 15H total, CH_2 and C$_6H_{11}$), 1.68 (s, 9H, Nb-(CH_3)$_3$), 6.96–7.12 (ov, m, 10H, N-Ph-H). ^{31}P{^{1}H} NMR (C$_6$D$_6$, 25 °C) δ: 10.8 (s). **16**: ^{1}H NMR (C$_6$D$_6$, 25 °C, 500 MHz) δ: –0.08, 0.35 (s, 12H total, Si-(CH_3)), 1.20 (m, 4H total, CH_2), 1.63 (s, 9H, Nb-(CH_3)$_3$), 6.80–7.38, 7.60–7.85 (s, 12H total, N-Ph, P-Ph). ^{31}P{^{1}H} NMR (C$_6$D$_6$, 25 °C) δ: 6.2 (s). **17**: ^{1}H NMR (C$_6$D$_6$, 25 °C, 500 MHz) δ: 2.29 (s, 9H, Nb-(CH_3)$_3$), 2.10, 2.16 (s, 12H total, o-Ph-(CH_3)), 2.39 (s, 6H, p-Ph-CH_3), 0.21, 0.29 (s, 12H total, Si-(CH_3)), 0.91–2.08 (m, 15H total, CH_2 and C$_6H_{11}$), 6.82, 7.02 (s, 4H total, m-Ph-H). ^{31}P{^{1}H} NMR (C$_6$D$_6$, 25 °C) δ: 11.2 (s).

Attempted hydrogenations of 15–17

Hydrogenations of the three $^{R'R''}$[NPN]NbMe$_3$ complexes were attempted using the same methodology as that shown for **15** below. A 75 mL ethereal solution of 0.500 g (0.864 mmol) of **15** was prepared in a thick-walled reaction vessel and immediately cooled to –78 °C. N$_2$ was removed by successive freeze-pump-thaw cycles. The solution was then frozen at –196 °C, flushed with H$_2$, sealed, warmed to r.t., and stirred for 24 h. Solvent was removed in vacuo, yielding a dark brown solid. Extensive decomposition of **15** complicated analysis. In situ NMR studies (1 atm) confirmed that no hydride resonances were observable during the hydrogenation attempts.

Results and discussion

One of the key advantages of the diamidophosphine ligands, referred to as [NPN], is their inherent ability to tune steric and electronic properties by varying the substituents on the amido and phosphine donors. In this report, $^{R'R''}$[NPN] refers to the ligand R'P(CH$_2$SiMe$_2$NR'')$_2$. The ligand precursors are isolated as solvent adducts of the dilithium diamidophosphines both for ease of purification and to facilitate reaction with metal chlorides. The synthesis of ^{PhPh}[NPN]Li$_2$(THF)$_2$, **1** (2), and ^{CyPh}[NPN]Li$_2$(OEt$_2$), **2** (8), were reported previously. This report details the preparation of four new [NPN] precursors: ^{PhMes}[NPN]Li$_2$(diox)$_2$, **3**, ^{CyMes}[NPN]Li$_2$(THF), **4**, ^{PhMe}[NPN]Li$_2$(diox)$_2$, **5**, and ^{CyMe}[NPN]Li$_2$(diox), **6**. A general synthesis of these derivatives is shown in Scheme 1.

Synthesis of **4** and **5** proceeds by metathesis of MesNHLi with ClCH$_2$SiMe$_2$Cl at –78 °C to form a silylamine that reacts in situ with the desired primary phosphine, RPH$_2$, and 4 equiv (with respect to MesNHLi) of ^{n}BuLi. When phenylphosphine is used in this methodology, the ligand precursor precipitates as a pale yellow solid, **3**, after addition of 2.5 equiv of dioxane to a hexanes solution of the product. Similarly, when cyclohexylphosphine is used in this methodology, white crystals (**4**) were isolated after addition of 1.5 equiv of tetrahydrofuran to a hexanes solution of the

product. ^{PhMe}[NPN]Li$_2$(diox)$_2$, **5**, and ^{CyMe}[NPN]Li$_2$(diox), **6**, were prepared by an analogous procedure, except the requisite amine hydrochloride salt MeNH$_3^+$Cl$^-$ is used to prepare MeNHLi prior to metathesis. The ligand precursors were characterized by ^{31}P{^{1}H}, ^{1}H, and ^{7}Li{^{1}H} NMR spectroscopy. Colorless platelet crystals of **4** were recrystallized from a saturated hexanes–toluene solution and analyzed by X-ray crystallography.

The molecular structure of **4** is shown as an ORTEP3 (17) drawing in Fig. 1. Relevant bond lengths and angles are listed in Table 3 and crystallographic data is located in Table 1. The X-ray data unambiguously show that **4** has a single coordinated THF molecule. The bond lengths from the amido nitrogen donors N1 and N2 to Li2 are approximately 0.2 Å shorter than the corresponding bond lengths from N1 and N2 to Li1, to which the THF molecule is coordinated. The P1—Li1 bond length is 2.589(4) Å, an average length for phosphorus—lithium bonds. Some disorder was evident. The crystalline lattice contained two different conformations of the ligand within the same unit cell. This manifested as overlapping opposite chair conformations of the cyclohexyl ring, as well as overlapping silyl methyl fragments.

Several interesting trends have been observed in the solution characterization of the six dilithio [NPN] precursors used in this report. The three ligand precursors with cyclohexyldonors (**2**, **4**, and **6**) are each monosolvent adducts, compared with **1**, **3**, and **5**, which have two coordinating solvent molecules. In each case, the solvent adduct isolated is the least soluble product. These same cyclohexylphosphine derivatives (**2**, **4**, and **6**) show no ^{31}P–^{7}Li coupling in solution (r.t.) that could suggest their solution behaviour is different than that found for **4** in the solid state (Fig. 1). One possibility is that the phosphine donor does not bind to the lithium ions in solution. However, a low temperature ^{31}P spectrum (–25 °C) of **2** shows a doublet due to ^{7}Li coupling ($^1J_{PLi}$ = 17.4 Hz). It is likely that the lithium ions are undergoing intermolecular exchange in solution, fast enough at room temperature to lose coupling information. However, at lower temperatures, this process is slow, and coupling between ^{7}Li and ^{31}P is observed. In solution, the structure of the dilithio derivative is therefore likely the same as in the solid state with phosphine bound to lithium.

^{PhPh}[NPN] and ^{CyPh}[NPN] ligand sets have already been applied to other group five metal-based systems. The complex ^{PhPh}[NPN]TaMe$_3$ reacts with H$_2$ to form (^{PhPh}[NPN]Ta)$_2$(μ-H)$_4$ (1, 2). Under an atmosphere of dinitrogen, this complex loses 1 equiv of H$_2$ and binds dinitrogen to form (^{PhPh}[NPN]Ta)$_2$(μ-H)$_2$(μ-η^1:η^2-N$_2$). This complex has an intriguing side-on, end-on coordination mode that promotes reactivity with E-H species (E = B, Si, Al) (3, 4). Dinitrogen activation has also been observed by a related niobium system supported by a [P$_2$N$_2$] ligand set. Upon thermolysis, the complex ([P$_2$N$_2$]Nb)$_2$(μ-N$_2$) (where [P$_2$N$_2$] = PhP(CH$_2$Si-Me$_2$NSiMe$_2$CH$_2$)$_2$PPh) decomposes into a bridging nitride species where one N atom from the activated N$_2$ inserts into the macrocycle backbone, forming the complex [P$_2$N$_3$]Nb(μ-N)Nb[PN$_3$] (where [PN$_3$] = PhPMe(CHSiMe$_2$NSiMe$_2$CH$_2$P-(Ph)CH$_2$SiMe$_2$NSiMe$_2$N)) (18). As well, the complexes ^{RPh}[NPN]NbCl(DME), (^{PhPh}[NPN]NbCl)$_2$(μ-N$_2$), and ^{RPh}[NPN]NbCl$_2$ (R = Cy, Ph; DME = dimethoxyethane) have been synthesized. The complex ^{CyPh}[NPN]NbCl$_2$

Bond distances (Å)	
P(1)—Li(1)	2.589(4)
N(1)—Li(1)	2.106(4)
N(1)—Li(2)	1.943(4)
N(2)—Li(1)	2.133(4)
N(2)—Li(2)	1.964(4)
O(1)—Li(1)	1.923(4)
Bond angles (°)	
C(7)-N(1)-Li(1)	103.74(15)
C(7)-N(1)-Li(2)	123.97(17)
C(22)-N(2)-Li(2)	94.27(16)
C(22)-N(2)-Li(1)	119.11(17)
Li(2)-N(2)-Li(1)	73.74(15)
Li(2)-N(1)-Li(1)	74.77(15)
O(1)-Li(1)-P(1)	121.74(16)
decomposes in solution to form an imide, ^{CyPh}[NPN]NbCl(=NPh), a cyclized [NP] ligand, CyP(CH$_2$-SiMe$_2$)$_2$NPh, and a niobium(III) product by an intermolecular N—Si bond scission (8). The goal of this work is to examine how ligand modifications would affect other group 5 precursors.

Application of these ligand sets to vanadium(III) could afford species of the form [NPN]VCl from which a number of reactivities can be explored. Behavior of these systems might mimic that seen for niobium and generate a dinitrogen complex directly, analogous to (^{PhPh}[NPN]NbCl)(μ-N$_2$) chemistry. Alternatively, if the [NPN]VCl system were reduced under a dinitrogen atmosphere it would give a complex isoelectronic with Mo(N^{t}BuAr)$_3$, which coordinates and splits molecular nitrogen to form the nitride (N^{t}BuAr)$_3$Mo≡N (19, 20). The cleavage of molecular nitrogen was also observed when a bisamidoamine vanadium chloride complex was reduced (21).

Treatment of a cooled solution of VCl$_3$(THF)$_3$ in THF with an Et$_2$O solution of ^{CyPh}[NPN]Li$_2$(OEt$_2$) gave a brick-red paramagnetic solid, ^{CyPh}[NPN]VCl, **7**. Mass spectrome-

try and elemental analysis confirmed the empirical formula. Recrystallization of **7** from a layered benzene–HMDS solution at –35 °C gave red block crystals of (^{CyPh}[NPN]VCl)$_2$. X-ray analysis of the crystals, isolated in 78% yield, showed that the compound exists as a chloride-bridged dimer. The molecular structure of **7** is shown as an ORTEP drawing in Fig. 2. Relevant bond lengths and angles and crystallographic data are listed in Tables 2 and 4, respectively. The V(1)—Cl(1) and V(1*)—Cl(1) bond lengths of 2.3632(4) and 2.4913(4) Å, respectively, are average for a loosely bound chloride dimer (22); the compound appears as the monomer in mass spectrometry studies. The vanadium amide bond lengths of 1.935(1) and 1.934(1) Å agree with other amido vanadium chloride systems (23). While the V(1)—P(1) bond length of 2.4323(5) Å is not unusual for vanadium phosphine systems (23), it is short for related vanadium chloride dimers (~2.6–2.7 Å) (24–27). The overall complex is distorted trigonal bipyramidal with chlorine and phosphine ligands occupying the apical positions.

Similar reactions of ligand precursors **1**, **3**, **4**, **5**, and **6** with VCl$_3$(THF)$_3$ produced the vanadium chlorides $^{R'R''}$[NPN]VCl (R" = Ph, Cy; R" = Ph, Mes, Me; **8–12**). Characterization by mass spectrometry and elemental analysis confirmed the empirical formula in each case. A general synthesis is shown in eq. [1].

Fig. 2. ORTEP 3 plot for **7** (50% probability; silyl methyl and R′ and R″ groups, save the attached carbons, have been omitted for clarity).

Reductions of **7**–**12** with potassium graphite (KC_8) were conducted under four conditions: 1 atm N_2 and 2.2 equiv of KC_8, 4 atm N_2 and 2.2 equiv of KC_8, 1 atm N_2 and 3.3 equiv of KC_8, 4 atm N_2 and 3.3 equiv of KC_8. Reduction of **7** at 4 atm of N_2 with 2.2 equiv of KC_8 at –78 °C gave a strongly purple colored solution upon warming to r.t. Removal of KCl followed by recrystallization from a saturated pentane solution gave a deep purple paste, highly soluble in common organic solvents. Mass spectral analysis of the product indicated the formation of a $^{CyPh}[NPN]V≡N$ species with a peak at m/z 505 ($C_{24}H_{37}N_3Si_2PV$), but repeated attempts to grow diffractable crystals failed. A paramagnetic impurity prevented purification and full characterization of the product. The observation of a mononuclear species by mass spectrometry does not, of course, prove its formulation. The species could have been generated in the experiment from a dinuclear bisnitride complex; however, it is unlikely to be generated from a compound with an intact N_2 moiety (18).

Reduction of **7** at 4 atm of N_2 with 3.3 equiv of KC_8 at –78 °C gave a deep olive green solution upon warming to r.t. From the solution, a dark green solid was isolated and characterized by mass spectrometry. A small peak at m/z 1050 ($C_{48}H_{74}KN_6P_2Si_4V_2$), corresponding to $K(^{CyPh}[NPN]V≡N)_2$, as well as a substantial $^{CyPh}[NPN]V≡N$ peak (m/z 505, 100%), suggested dinitrogen incorporation during the reduction process. Unfortunately, the reduced products could not be purified. Attempts to improve the synthesis of the vanadium nitride by changing solvent, reaction time, N_2 pressure,

reducing agent, or temperature were unsuccessful. Similarly, reductions of other vanadium chlorides (**8**–**12**) were unproductive. In several cases, there was no evidence of nitride formation.

The reduction of $(^{CyMes}[NPN]VCl)_2$, **9**, illustrated the problems associated with reduction of the vanadium chlorides. Upon workup of the reaction of **9** with 2.2 equiv of KC_8, a peak was observed in the mass spectrum at m/z 709, which corresponds to $^{CyMes}[NPN]V=NMes$, as supported by theoretical isotope pattern calculations. The vanadium imide moiety $^{CyMes}[NPN]V=NMes$ is the likely product of ring-closing of the [NPN] ligand on itself. Scissioning of one of the Si—N bonds and one of the N—V bonds in the ([NPN]VCl)$_2$ species during reduction would result in the vanadium imide species **13** and the elimination of a six-membered heteroatomic ring **14**, as illustrated in eq. [2]. Crystals of **14** formed out of a toluene–hexanes solution, and the structure was verified by ^1H NMR. Peaks corresponding to imide formation were observed in the mass spectra of each of the reductions conducted, no matter which substrate was reduced. As mentioned, decomposition of [NPN] metal complexes to form imides has complicated a previous study as well: the imide $^{CyPh}[NPN]NbCl(=NPh)$ was generated from the decomposition of $^{CyPh}[NPN]NbCl_2$ (**8**).

[2]
The [NPN] ligand may provide access to attractive Nb(V) complexes since the Ta(V) complex $^{PhPh}[NPN]TaMe_3$ reacts with H_2 to form $(^{PhPh}[NPN]Ta)_2(\mu-H)_4$, a precursor to the dinitrogen complex $(^{PhPh}[NPN]Ta)_2(\mu-H)_2(\mu-\eta^1:\eta^2-N_2)$ (2). We examined the formation of $^{R'R''}[NPN]NbMe_3$ and its reactivity with dihydrogen.

Production of $^{CyPh}[NPN]NbMe_3$ (**15**) was accomplished via addition of a –78 °C solution of ligand to a cooled solu-

tion of NbCl$_2$Me$_3$, freshly sublimed before use. After solvent removal at –10 °C, the resultant brown solid was extracted with pentane to generate an orange solid that was characterized by ^{1}H and ^{31}P{^{1}H} NMR and mass spectrometry. The product was extremely photo- and thermo-sensitive and was stored in an opaque vessel at –37 °C. Thermal instability precluded the use of elemental analysis and ^{13}C{^{1}H} NMR for characterization. A general reaction pathway is shown in eq. [3].

[3]

$$^{R'R''}[NPN]Li_2(S) + NbCl_2Me_3 \xrightarrow[-78\,°C]{Et_2O}$$

1-2, 4

15-17
Reactions of NbCl$_2$Me$_3$ with ligand precursors **1**, **3**, **4**, **5**, and **6** were not as successful. The products from these reactions were more thermally unstable and frequently decomposed prior to spectroscopic analysis. Only ^{PhPh}[NPN]NbMe$_3$ (**16**) and ^{CyMes}[NPN]NbMe$_3$ (**17**) were stable enough to characterize spectroscopically.

Hydrogenation of complexes **15**–**17** was attempted at 4 atm pressure. Following the addition of H$_2$, the reaction mixtures turned black and a precipitate formed. Analysis of the reaction mixture by NMR showed extensive decomposition. No hydride resonances were observed at the expected chemical shift for a niobium hydride. Attempts to vary reaction conditions to isolate the putative polyhydride species, by changing the concentration of reagents, temperature, exposure to light, pressure of H$_2$, solvent, or time of reaction, were unsuccessful. It is suspected that the trimethyl starting materials are too unstable to withstand the hydrogenation process.

Conclusions

While a number of reports have shown the applicability of Ta(V), Nb(III), and V(III) systems to dinitrogen activation, in this work we have shown that small changes to the electronics and sterics of these systems can prevent such reaction pathways. Six variants of the [NPN] diamidophosphine ligand were used to prepare ($^{R'R''}$[NPN]VCl)$_2$ complexes, to investigate their ability to coordinate and cleave dinitrogen upon reduction. Unfortunately, reduction of these complexes under a variety of conditions was complicated by ligand degradation to form a V(IV) imide. While some nitride-containing material was formed, it was not isolable. Similarly, the complexes $^{R'R''}$[NPN]NbMe$_3$ were prepared, with the goal that these highly unstable materials could be hydrogenated in an analogous manner to the formation of ([NPN]Ta)$_2$(μ-H)$_2$(μ-η^1:η^2-N$_2$); however, their thermal and photochemical decomposition occurred prior to hydrogenation. What becomes evident from this work is just how changes in ligand design or metal centres can lead to quite different and unpredictable reaction behaviour.

2-Acetoxy-2-methoxy-5,5-dimethyl-Δ³-1,3,4-oxadiazoline and acetoxy(methoxy)carbene

Wojciech Czardybon, Arkadiusz Klys, John Warkentin, and Nick Henry Werstiuk

Abstract: 2-Acetoxy-2-methoxy-5,5-dimethyl-Δ³-1,3,4-oxadiazoline undergoes two competitive 1,3-dipolar cyclorever-sions at 110 °C. It loses N_2, presumably to afford a short-lived carbonyl ylide that fragments to acetone and ace-toxy(methoxy)carbene. It also forms 2-diazopropane and the appropriate mixed anhydride. It is the only currently known source of acetoxy(methoxy)carbene.

Key words: acetoxy(methoxy)carbene, 2-diazopropane, 1,3-dipolar cycloreversion.

Résumé : À 110 °C, la 2-acétoxy-2-méthoxy-5,5-diméthyl-Δ³-1,3,4-oxadiazoline subit deux réactions de cycloréversion 1,3-dipolaire compétitives. Elle perd du N_2, probablement pour fournir un ylure de carbonyle de temps de vie très court qui se fragmente en acétone et en acétoxy(méthoxy)carbène. Elle forme aussi du diazopropane et l'anhydride mixte ap-proprié. C'est aussi la seule source actuellement connue d'acétoxy(méthoxy)carbène.

Mots clés : acétoxy(méthoxy)carbène, 2-diazopropane, cycloréversion 1,3-dipolaire.

[Traduit par la Rédaction]

Introduction

Although many alkylacetoxycarbenes have been studied (1–5) and found to rearrange by 1,2-acyl migration in com-petition with other intramolecular processes, such as 1,2 mi-gration of H, acyloxy(alkoxy)carbenes appear to be unknown. They are interesting intermediates, without the possibility of a 1,2-H migration. They have the potential for rearrangement by migration of the acyl group to the carbenic site, as well as the potential for fragmentation to alkoxy-carbonyl and acyl radicals. The 1,2-acyl migration of known acetoxy(alkyl)carbenes and the most likely reactions of acyloxy(alkoxy)carbenes are illustrated in Scheme 1.

We prepared and purified 2-acetoxy-2-methoxy-5,5-dimethyl-Δ³-1,3,4-oxadiazoline (**1**) (6), which is a potential precursor of acetoxy(methoxy)carbene (**3**). 2,2-Dialkoxy-5,5-dimethyl-Δ³-1,3,4-oxadiazolines undergo 1,3-dipolar cycloreversion by loss of N_2 at 110 °C to afford carbonyl ylides that fragment primarily to dialkoxycarbenes and ace-tone (7). There is a minor competitive 1,3-dipolar cyclo-reversion, in some cases, to 2-diazopropane (**4**) and dialkyl carbonate (8). Scheme 2 shows such cycloreversions for the case of **1**, which was expected to produce carbene **3**, via car-bonyl ylide **2**, and perhaps 2-diazopropane (**4**) and the mixed anhydride **5**. Moreover the carbene might undergo a con-certed rearrangement to methyl pyruvate (**6**) or a fragmenta-tion to the methoxycarbonyl–acetyl radical pair that could couple to afford **6** also, Scheme 3.

We now describe the thermolysis of **1**, which does indeed lead to the formation of both carbene **3** and 2-diazopropane

(**4**). At 110 °C in benzene, both the carbene and the diazopropane can be intercepted with chemical trapping agents.

Results and discussion

Thermolysis of **1** in benzene was studied in the absence of potential traps, in the presence of phenol (a carbene trap as well as a trap for diazo compounds and a hydrogen donor to radicals), in the presence of benzylidene malononitrile, and in the presence of TEMPO. TEMPO is a trap for radicals, and benzylidene malononitrile also can trap radicals, car-benes, and diazo compounds.

Thermolysis of **1** in benzene-d_6 containing internal stan-dard *tert*-butylbenzene gave a complex mixture of products. Yields of **4** or of acetone azine from **1** are unreliable for esti-mation of the yield of the former, because diazopropane would react with the mixed anhydride co-product (**5**). The yield of acetone (presumably from the carbenic pathway) was found to be about 55% by integration of the acetone sig-nal against those from the phenyl and *tert*-butyl groups of the internal standard. The two comparisons were in excellent agreement. Thus, the yield of acetoxymethoxycarbene was about 55% and that of 2-diazopropane about 45%. Methyl pyruvate was a major product (ca. 10%, isolated), but biacetyl and dimethyl oxalate, which might also be expected if the pyruvate had arisen by a radical coupling path, could not be detected by GC, with authentic samples in hand. It was also possible to detect (by GC) a trace of acetophenone, in keeping with the expectation that acetyl radicals would at-

Scheme 1.

Scheme 2.

Scheme 3.
tack the benzene solvent. Thermolysis of **1** in the presence of TEMPO led to the isolation of enough of the known (**9**) TEMPO adduct of the acetyl radical (1-acetoxy-2,2,6,6-tetramethylpiperidine) for an NMR spectrum. However, the known adduct (**10**) of TEMPO with the methoxycarbonyl radical could not be found.

The results listed thus far are accounted for in terms of Scheme 3, which shows not only parallel 1,3-dipolar cyclo-reversions but also a radical decomposition of **1**. That minor radical decomposition is assumed to be concerted, leading to **7** and **8**. TEMPO would have trapped both **7** and **8** but the product expected from **7** was not identified. The failure to find any evidence for the methoxycarbonyl radical indicates that acetyl and methoxycarbonyl radicals are probably not formed by fragmentation of carbene **3**.

Thermolysis of **1** in benzene containing phenol gave **9** (31%) and **10** (5%) but not **11**. Compound **9** probably arises from a transesterification reaction with **1**, while **10** and **11** are expected products from reactions of **4** and **3**, respectively, with phenol, Scheme 4. Protonation of **3** and ion-pair collapse would generate **11**, which has never been reported. Such compounds may be unstable at 110 °C.

Benzylidene malononitrile (**12**) was very successful in trapping intermediates from the thermolysis of **1**. Dinitrile **12** had been useful in helping to sort out the chemistry of dibenzyloxycarbene and benzyloxy(methoxy)carbene (**11**) because it reacts fast with nucleophilic carbenes, making it possible to trap some of them before they can fragment to radical pairs, Scheme 5. Thermolysis of **1** in the presence of **12** did not furnish a carbene adduct. Instead, the methoxy-

Scheme 4.
Scheme 5.
Scheme 6.
carbonyl radical, *apparently* resulting from carbene fragmentation to a radical pair, *appeared* to be trapped as **13** (30%), Scheme 6. Adduct **20**, expected on the basis of precedent (11) was not found, but **16** (17%) and **17** (12%) were also isolated.

The finding that **13** was formed from thermolysis of **1** in the presence of **12** but that **20** could not be found led us to

search the literature for analogues of **20**. Such compounds hydrolyze spontaneously when exposed to the atmosphere (12), Scheme 6. Thus, the most likely explanation for the formation of **13** is trapping of a carbene intermediate with **12** to form diastereomers **18** and subsequent ring-opening fragmentation to diradical **19**, followed by fragmentation and coupling to **20**, according to Scheme 6. Subsequent

deacylation of **20** (12), once the sample is exposed to the atmosphere, leads to **13**.

The concentration of **12** was increased from 0.455 to 2.127 mol·L^{-1} to improve the chances of trapping carbene **3**. There was little change, suggesting that the lower concentration was sufficient to trap essentially all of **3**. Compounds **16** and **17** can be attributed to reaction of **4** in the expected sense with **12** to afford **14**, which then loses N$_2$, Scheme 6. The higher concentration of **12** did lead to two very minor products (not identified) that were detected by GC–MS. Those compounds, which gave essentially the same mass spectrum as **16** and **17**, might be derived from cycloaddition of **4** in the alternative sense to form **15**, Scheme 6. Alkylidene malononitriles are known to react with diazo compounds by cycloaddition, and the resulting 3*H*-pyrazoles, not surprisingly (13), lose N$_2$ at 110 °C to afford diradicals that rearrange. Both regiochemistries of addition of diazomethane to a β-phenyl-α,β-unsaturated sulfone have been reported (14). Although **16** and **17**, as well as the minor products with the same MS, can be accounted for on the basis of **14** alone, formation and decomposition of some of compound **15** cannot be excluded.

The concerted rearrangement of the carbene and its fragmentation to a radical pair were modeled computationally with Gaussian 98 at the Becke3PW91/6-31+G(d, p) level (15). Concerted carbene rearrangement from one of the pos-

21   **22**
sible sickle conformations (**21**) has the lowest barrier (14.6 kcal·mol^{-1}), whereas the lowest barrier to fragmentation (28.8 kcal·mol^{-1}) is that from a second sickle conformation (**22**). Details of the computational work, which includes the examination of a number of other conceivable pathways, will be published separately.[2]

In summary, oxadiazoline **1** undergoes two competing cycloreversions at 110 °C in benzene, leading to both carbene **3** and diazopropane **4**. A minor, third thermolysis mechanism, currently regarded as tentative, is a radical process that generates the acetyl radical and **7**. Carbene **3** does not fragment to radicals but rearranges to methyl pyruvate by a 1,2-acyl migration, like other acetoxycarbenes (1–5).

Although thermolysis of **1** is far from ideal, in that it generates **3** in only about 50% yield and the co-products complicate the thermolysis, it is the only reaction available today to generate acetoxy(methoxy)carbene.

Experimental

General

A Bruker AC-200 spectrometer was used to obtain ^{1}H and ^{13}C NMR spectra, with CDCl$_3$ as solvent and with the signal from residual CHCl$_3$ in CDCl$_3$ set at δ = 7.25. GC–MS mass spectra were recorded with a Hewlett-Packard 5890 gas chromatograph equipped with an HP-5971A mass selective detector and a DB-1 capillary column (12 m × 0.2 mm). Other mass spectra were obtained with a VG Analytical ZAB-E double focusing mass spectrometer.

Synthesis of 1

A solution of the carbomethoxy hydrazone of acetone (30 g, 0.23 mol) was added slowly to an ice-cooled heterogeneous mixture of Pb(OAc)$_4$ (115.3 g, 0.26 mol), acetic acid (1 mL), and CH$_2$Cl$_2$ (114 mL). The yellow mixture was stirred under N$_2$, warmed to 25 °C after addition was complete, and stirred for an additional 3 h. The mixture was then filtered through Celite and washed with 5% Na$_2$CO$_3$ solution. The water fraction was back-extracted twice with 20 mL of CH$_2$Cl$_2$, and the combined organic fraction was dried over Na$_2$SO$_4$ before the solvent was evaporated. The yellow oil that remained weighed 39 g (90%) and consisted of **1** (ca. 72%) and an acyclic isomer (Me$_2$C-(OAc)N=NCO$_2$Me) (ca. 28%).

Purification of 1

A yellow mixture of **1** and its acyclic isomer (5 g) was chromatographed as rapidly as possible on neutral alumina (35 g) with hexane – ethyl acetate (9:1). The solvents were evaporated from the combined colourless fractions, and the residue was distilled under vacuum (2–5 mmHg (1 mmHg = 133.322 Pa)) to afford 2.2 g of pure **1** (61%). IR (neat) (cm^{-1}): 1771. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.52 (s, 3H), 1.63 (s, 3H), 2.11 (s, 3H), 3.59 (s, 3H). ^{13}C NMR (50.3 MHz, CDCl$_3$) δ: 21.44, 22.59, 24.49, 52.49, 122.15, 133.80, 161.67.

Thermolysis of 1 in benzene-*d*$_6$

A solution of **1** (0.157 mmol) and *tert*-butylbenzene (0.127 mmol) in C$_6$D$_6$ (0.7 mL) in an NMR tube fitted with a ground glass joint was degassed by means of three freeze–pump–thaw cycles before the tube was sealed and heated for 72 h at 110 °C. The ^{1}H NMR spectrum was acquired with the tube still sealed and with a pulse delay of 6 s to ensure complete relaxation of the acetone signal. Integrations of the acetone signal against those of the *tert*-butyl and aryl signals of *tert*-butyl benzene were in good agreement and gave the yield of acetone as 55%. Analysis by GC, with the column compartment cooled alternately to 7, 15, 21, and 32 °C, showed that methyl pyruvate (ca. 10%) and acetophenone (trace), both confirmed with authentic samples, were present. Biacetyl, dimethyl oxalate, acetaldehyde, and methyl formate were not detectable, as determined by injection of authentic samples under the same conditions, but there were peaks from unidentified volatile components.

Thermolysis of 1 in the presence of phenol

Thermolysis of **1** (1.596 mmol) in C$_6$H$_6$ (7 mL) containing phenol (3.191 mmol) gave a product mixture that was analyzed by GC. Major and minor products were phenylacetate (**9**) (ca. 30%) and isopropyl phenyl ether (**10**) (ca. 5%). The identities of those products were confirmed by GC of authentic samples prepared by standard methods. Acetaldehyde and methyl formate were not detectable.

Thermolysis of 1 in the presence of 12

A solution of **1** (1.596 mmol) and **12** (3.188 mmol) in dry benzene (7 mL) was degassed by means of three freeze–pump–thaw cycles before it was sealed into a glass tube and heated for 72 h at 110 °C. The product mixture was analyzed by GC and separated by centrifugal chromatography on a 2 mm silica gel plate (Chromatotron apparatus, hexane: ethyl acetate = 4:1).

1-(Methoxycarbonyl-1-phenylmethyl)propanedinitrile (13)

Yield: 16%. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 3.80 (s, 3H), 4.20 (d, J = 8.65 Hz, 1H), 4.39 (d, J = 8.65 Hz, 1H), 7.33–7.34 (m, 2H), 7.43–7.46 (m, 3H). ^{13}C NMR (50.3 MHz, CDCl$_3$) δ: 27.09, 51.87, 53.76, 110.96, 111.60, 128.30, 129.87, 130.12, 131.68, 169.25. Aqueous nonelectrolyte solutions — Part XX: Formula of structure I methane hydrate, congruent dissociation melting point, and formula of the metastable hydrate

David N. Glew

Abstract: Sixteen new measurements of high precision for structure I methane hydrate with water between 31.93 and 47.39 °C are shown to be metastable and exhibit higher methane pressures than found by earlier workers. Comparison of earlier measurements between 26.7 and 47.2 °C permit positive identification of the structure II and the structure I hydrates. Forty-nine equilibrium constants $K_p(h_1 \rightarrow l_1 g)$ for dissociation of structure I methane hydrate into water and methane, 32 between –0.29 and 26.7 °C for the stable hydrate and 17 between 31.93 and 47.39 °C for the metastable hydrate, are best represented by a three-parameter thermodynamic equation, which indicates a standard error (SE) of 0.63% on a single $K_p(h_1 \rightarrow l_1 g)$ determination. The congruent dissociation melting point $C(h_1 l_1 g x_m)$ of metastable structure I methane hydrate is at 47.41 °C with SE 0.02 °C and at pressure 505 MPa. The congruent equilibrium constant $K_p(h_1 \rightarrow l_1 g)$ is 102.3 MPa with SE 0.2 MPa. $\Delta H^{\circ t}(h_1 \rightarrow l_1 g)$ is 62 281 J mol^{-1} with SE 184 J mol^{-1}, and the congruent formula is CH$_4 \cdot 5.750$H$_2$O with SE 0.059H$_2$O. At the congruent point, $\Delta V(h_1 \rightarrow l_1 g)$ is zero within experimental precision, and its estimate is 1.3 with SE 1.6 cm^3 mol^{-1}. The stability range of structure I methane hydrate with water extends from quadruple point $Q(s_1 h_1 l_1 g)$ at –0.29 °C up to quadruple point $Q(h_1 h_2 l_1 g)$ at 26.7 °C, and its metastability range with water extends from 26.7 °C up to the congruent dissociation melting point $C(h_1 l_1 g x_m)$ at 47.41 °C.

Key words: methane hydrate, clathrate structure I, metastability range, dissociation equilibrium constant, formula, congruent melting point, metastability of structure I hydrate.

Résumé : Seize nouvelles mesures de haute précision ont été faites sur la structure I de l'hydrate de méthane avec de l'eau, entre 31,93 et 47,39 °C; elles montrent qu'elle est métastable et qu'elle comporte des pressions de méthane plus élevées que celles observées antérieurement par d'autres chercheurs. Une comparaison des mesures antérieures entre 26,7 et 47,2 °C permet d'identifier d'une façon positive les hydrates de structure II et de structure I. Quarante-neuf constantes d'équilibre $K_p(h_1 \rightarrow l_1 g)$ pour la dissociation de l'hydrate de méthane de structure I dans l'eau et le méthane, 32 entre –0,29 et 26,7 °C de l'hydrate stable et 17 entre 31,93 et 47,39 °C de l'hydrate métastable peuvent être représentées adéquatement par une équation thermodynamique à trois paramètres, avec une erreur standard (ES) de 0,63% pour une détermination unique de $K_p(h_1 \rightarrow l_1 g)$. Le point de fusion de dissociation congruente $C(h_1 l_1 g x_m)$ de l'hydrate de méthane de structure I métastable est de 47,41 °C avec une erreur standard de 0,02 °C et à une pression de 505 MPa. La constante d'équilibre congruente $K_p(h_1 \rightarrow l_1 g)$ est égale à 102,3 MPa avec une erreur standard de 0,2 MPa. Le $\Delta H^{0t}(h_1 \rightarrow l_1 g)$ est de 62 281 J mol^{-1} avec une erreur standard de 184 J mol^{-1} et la formule congruente est CH$_4 \cdot 5,750$H$_2$O avec une erreur standard de 0,059H$_2$O. Au point congruent, $\Delta V(h_1 \rightarrow l_1 g)$ est égal à zéro dans les limites expérimentales et il est évalué à 1,3 avec une erreur standard de 1,6 cm^3 mol^{-1}. La plage de stabilité de la structure I de l'hydrate de méthane avec de l'eau va du point quadruple $Q(s_1 h_1 l_1 g)$ à –0,29 °C jusqu'au point quadruple $Q(h_1 h_2 l_1 g)$ à 26,7 °C et sa plage de métastabilité s'étend de 26,7 °C jusqu'au point de fusion de la dissociation congruente, $C(h_1 l_1 g x_m)$ à 47,41 °C.

Mots clés : hydrate de méthane, clathrate de structure I, plage de métastabilité, constante d'équilibre de dissociation, formule, point de fusion congruent, métastabilité de l'hydrate de structure I.

[Traduit par la Rédaction]

Introduction

We are particularly fortunate to have three independent and accurate studies (1–3) of the equilibrium methane hydrate pressures with water in the temperature range 26.98 to 47.39 °C. The oldest data set MSK64 (1) provides 13 measurements between 26.98 and 46.87 °C and shows the 11 lowest methane hydrate pressures for the stable structure II hydrate phase h$_2$. Data set D&A96 (2) provides 13 measurements between 27.6 and 47.2 °C, which agree with data set MSK64 but also indicate the structure II methane hydrate phase h$_2$, with pressures about 0.69% larger than MSK64.

The most recent data set, NMO99 (3), of 16 measurements between 31.93 and 47.39 °C lists pressures for the structure I methane hydrate, phase h$_1$, and these pressures

are larger than those found in MSK64 (1) and by D&A96 (2). The continuity of the hydrate Raman spectral shifts by NMO99 (3) between 32 °C at 100 MPa and 47.4 °C at 493 MPa proves that their equilibrium hydrate phase is h_1 with structure I, which remains metastable over the temperature range of the data and for the period of the experimental study (3).

Recent work by Chou and co-workers (4, 5) shows the thermodynamic stability of structure I methane hydrate with water from the ice point up to about 33 °C and the metastability of the structure I hydrate at higher temperatures relative to the stable structure II methane hydrate with water.

Independent P–t analyses (6, 7) confirm that structure I methane hydrate, phase h_1, is the stable phase in equilibrium with water between the quadruple points $Q(s_1h_1l_1g)$ at –0.29 °C and 2.53 MPa and $Q(h_1h_2l_1g)$ at 26.7 °C and 55.5 MPa. At higher temperature structure II methane hydrate, phase h_2, is the stable phase (7) in equilibrium with water from the quadruple point $Q(h_1h_2l_1g)$ at 26.7 °C and 55.5 MPa up to the congruent dissociation melting point $C(h_2l_1gx_m)$ at 47.71 °C and 533 MPa.

Initially, for data set NMO99 (3), two equations are derived that accurately represent $P(h_1l_1g)$ from 31.93 to 45.14 °C and from 45.14 to 47.39 °C. These equations are used to estimate $P(h_1l_1g)$ at the temperatures of the earlier data sets MSK64 (1) and D&A96 (2). The estimate of $P(h_1l_1g)$ for the structure I hydrate is compared with the observed hydrate pressure $P(hl_1g)$, where the lower pressure characterizes the more stable hydrate.

Classical thermodynamics defines the stable methane hydrate phase as that which exerts the lowest equilibrium methane pressure with water at the same temperature.

This extends our study (6, 7) of methane hydrate to correctly define the individual measurements (1–3) and their pressure differences between the structure II and the structure I hydrates (8, 9), using the same numerical methods and thermodynamic equations as earlier.

With measurements for structure I methane hydrate extending from quadruple point $Q(s_1h_1l_1g)$ at –0.29 °C up to 47.39 °C, the best low-temperature measurements from ref. 6 are combined with data set NMO99 (3) to provide accurate estimates of $P(h_1l_1g)$, $K_p(h_1{\rightarrow}l_1g)$, $\Delta H^{\circ t}(h_1{\rightarrow}l_1g)$, and the approximate formula number r for structure I methane hydrate with water.

Equilibrium pressure $P(h_1l_1g)$ of structure I methane hydrate with water between 31.93 and 45.14 °C

In the temperature range from 31.93 to 45.14 °C the equilibrium total pressure $P(h_1l_1g)$ of methane hydrate h_1 with liquid water l_1 is best represented by the unbiased thermodynamic equation

[1a] $\ln P(h_1l_1g) = b_0 + b_1u_1 + b_2u_2 + b_3u_3$

This equation is mathematically equivalent to the numerically ill-conditioned unbiased thermodynamic equation

[1b] $\ln P(h_1l_1g) = A + B/T + C\ln T + DT$

Temperature variables u_1 to u_3 in eq. [1a] are described briefly in ref. 7 and fully in ref. 10.

The upper twelve rows of Table 1 present estimates of $P(h_1l_1g)$ between 31.93 and 45.14 °C, using the measurements of data set NMO99 (3). The arrangement of Table 1 is similar to that in ref. 7.

The least-squares estimates of the four parameters and their standard errors (SE) in eq. [1a] are $b_0 = 3.7265$ (0.0225), $b_1 = 46.131$ (1.67), $b_2 = -900.11$ (76.9), and $b_3 = 11\ 273$ (843). These parameters give an SE estimate of 0.0018 on $\ln P$ or of 0.18% on a single methane hydrate pressure determination with 8 degrees of freedom. The coefficient of determination R^2 is 0.99998. These are remarkably precise methane hydrate pressure measurements.

Equilibrium pressure $P(h_1l_1g)$ of structure I methane hydrate with water between 45.14 and 47.39 °C

In this work, following ref. 7, we use a similar numerical treatment to that used for the congruent dissociation melting point of structure II methane hydrate. In the temperature range from 45.14 to 47.39 °C the five methane hydrate pressures between 335 and 493 MPa from data set NMO99 (3) show that the hydrate temperature can be accurately represented by eq. [2] as an empirical cubic function of the equilibrium hydrate pressure,

[2] $t(°C) = e_0 + e_2(\Delta P)^2 + e_3(\Delta P)^3$

In eq. [2], $t(°C)$ is the equilibrium methane hydrate temperature (ITS-90), ΔP is the equilibrium pressure difference ($P(h_1l_1g)$ – 505 MPa), and 505 MPa is the estimated pressure at maximum hydrate temperature, t_{max}. The estimated maximum congruent dissociation temperature of structure I methane hydrate is $t_{max} = e_0 = 47.41$ °C with SE 0.020 °C. Parameter e_2 is –0.000102 with SE 4.4×10^{-6}, and parameter e_3 is -1.39×10^{-7} with SE 2.5×10^{-8}. The SE estimate on a single structure I methane hydrate temperature determination is 0.024 °C with one degree of freedom, in agreement with the ±0.02 °C accuracy of temperature measurement given by the authors (3). The coefficient of determination R^2 is 0.9998.

The estimate of parameter $e_0 = t_{max}$ is highly significant and could arise by random chance with a probability less than 0.05%. Parameter e_2 could arise by chance with about 1.5% probability and parameter e_3 could arise by chance at about 13% probability.

Although the five measurements indicate a metastable structure I methane hydrate congruent dissociation temperature $C(h_1l_1gx_m)$ at 47.41 °C and 505 MPa, this location must be considered tentative.

Equilibrium pressure of the methane hydrates with water between 26.7 and 47.71 °C

The three studies of methane hydrate measurements are outlined briefly to compare the reliability of the estimates given in Table 2. The studies of MSK64 (1) use a rocked stainless steel hydrate cell in a thermostat bath; the methane pressures are accurate to 0.1%, and temperatures are accu-

rate to 0.004 °C. The measurements of D&A96 (2) use a high-pressure DTA method, with pressures accurate to 1% and temperatures accurate to 0.1 °C. The measurements of NMO99 (3) use a 200 mm³ hydrate cell stirred by a vibrat-ing 2 mm glass ball, with pressures accurate to ±1 MPa and temperatures accurate to ±0.02 °C.

The pressure of metastable structure I methane hydrate is estimated at each experimental temperature for the measure-

ments of data sets MSK64 (1) and D&A96 (2). Columns one to three in Table 2 show the data set, the temperature $t(°C)$ (ITS-90), and the observed hydrate pressure $P(hl_1g)$ (MPa) for the 26 measurements from data sets MSK64 and D&A96 between quadruple point $Q(h_1h_2l_1g)$ at 26.7 °C and the congruent dissociation melting point $C(h_2l_1gx_m)$ at 47.71 °C. Earlier (6, 7) these measurements have been assumed to be characteristic of the structure II methane hydrate h_2 with water because they are observed above 26.7 °C, the transition temperature to structure II methane hydrate.

In the present study, the observed hydrate pressure $P(hl_1g)$, shown in column three, is under test and is compared with the pressure $P(h_1l_1g)$ (MPa) in column four, estimated at $t(°C)$ using eq. [1a] or [2].

The fifth column shows Diff = $(P(h_1l_1g) – P(hl_1g))$, MPa, the pressure difference of column four minus column three. When Diff is positive the structure II methane hydrate phase h_2 is the solid hydrate observed; when Diff is zero or negative the metastable structure I methane hydrate phase h_1 is observed experimentally.

The sixth column lists SE($P^\wedge$) (MPa), the standard error from eq. [1a] for the estimated pressure $P(h_1l_1g)$.

The seventh column shows Diff/SE($P^\wedge$), the pressure difference expressed as the number of standard errors from data set NMO99 (3).

Column eight shows the observed hydrate structure, S I for structure I phase h_1 and S II for structure II phase h_2 (8).

The pressures $P(h_1l_1g)$ listed in column four of Table 2 are generally larger than those of $P(hl_1g)$ in column three, and the estimate of Diff becomes systematically larger as the temperature increases to 46.87 °C. This confirms that the structure I methane hydrate phase h_1 is the thermodynamically metastable methane hydrate with water between $Q(h_1h_2l_1g)$ at 26.7 and 47.2 °C; contrariwise, this reconfirms our earlier assumption (6, 7) that structure II methane hydrate phase h_2 is the thermodynamically stable methane hydrate with water between 26.7 and 47.2 °C.

In columns five and seven of Table 2, of the 26 Diff estimates listed, 23 are positive, indicating that structure II methane hydrate is the thermodynamically stable phase. In column seven, 19 of the 26 data give estimates of Diff/SE($P^\wedge$) > 10, a convincing confirmation of the stable structure II methane hydrate between 26.7 and 47.2 °C.

The measurements at 26.98 °C and 56.92 MPa of data set MSK64 and at 30.4 °C and 84 MPa of data set D&A96 each exhibit a negative Diff, with estimates for Diff/SE($P^\wedge$) of –5.2 and –4.0, respectively. These measurements indicate equilibrium with a solid phase h_1 structure I methane hydrate, existing in metastable equilibrium just above the transition temperature 26.7 °C of $Q(h_1h_2l_1g)$.

One unexpected result in data set MSK64 is shown at 41.04 °C and 223.91 MPa, which gives Diff/SE($P^\wedge$) = –10.8 and confirms that the solid hydrate phase formed in this experiment is the metastable structure I methane hydrate phase h_1. This particular hydrate measurement is noted to give four positive residuals, two in Tables 7 and 8 of ref. 6 and two in Tables 1 and 2 of ref. 7. The level of metastability of 13.44 °C (40.14–26.7) is considered in refs. 6 and 7 to be too large and unlikely to occur experimentally in the middle of data set MSK64 (1). This assumption is shown here to be incorrect by the 16 experimental metastable measurements

of data set NMO99 (3) listed in Table 1, with levels of metastability up to 20.69 °C and with excess methane gas pressures of up to about 8%.

The complete data set NMO99 (3) shows that the metastable structure I methane hydrate phase h_1 can coexist with water and an excess pressure of methane gas for a time period of at least days. In the experiment of data set MSK64 (1) at 40.14 °C, the excess methane gas pressure 0.85 MPa is very small, 0.38%, and once the metastable solid structure I methane hydrate phase h_1 is formed, the same phase h_1 would remain until all the hydrate is decomposed.

We again note (7) the remarkable metastability of the completely filled structure I methane hydrate phase h_1, with all cavities occupied by a methane guest at temperatures and pressures greater than $Q(h_1h_2l_1g)$ at 26.7 °C and 55.5 MPa.

Equilibrium pressure $P(h_1l_1g)$ of structure I methane hydrate with water between –0.29 and 45.14 °C

Over this longer temperature range the best $P(h_1l_1g)$ data at the lower temperatures below 26.7 °C are combined with the new metastable measurements of NMO99 at the higher temperatures. Table 3 presents 45 estimates of $P(h_1l_1g)$ between –0.29 and 45.14 °C using the data sets $Q(s_1h_1l_1g)$, D&F40, MSK64, GRCK70, and V74 from ref. 6 together with 12 data sets from NMO99 (3). The arrangement of Table 3 is the same as Table 1 in ref. 7.

The least-squares estimates of the four parameters and their standard errors (in parentheses) in eq. [1a] are $b_0 = 3.7532$ (0.0081), $b_1 = 35.363$ (0.220), $b_2 = –11.59$ (6.32), and $b_3 = –2243.4$ (176.0). These parameters give an SE estimate of 0.0265 on $\ln P$ or of 2.68% on a single methane hydrate pressure determination with 41 degrees of freedom. The coefficient of determination R^2 is 0.9998.

The RMS (root mean squared) deviations of the residuals of $\ln P(h_1l_1g)$ from eq. [1a] for the individual data sets are the following: D&F40, 0.0136; MSK64, 0.0393; GRCK70, 0.0285; V74, 0.0209; and NMO99, 0.0248. These residuals are large and are found to be distributed non-randomly.

When combined with the new measurements of NMO99 (3) at higher temperatures we find that the 4-parameter equation is inadequate to properly represent the $P(h_1l_1g)$ measurements with the expected accuracy over their whole range.

Equilibrium constant for dissociation of structure I methane hydrate between –0.29 and 47.39 °C

The equilibrium constant for dissociation of 1 g molar mass of structure I methane hydrate of formula $CH_4 \cdot nH_2O$ phase h_1 into n mol of pure water l_1 plus 1 mol of gaseous methane is written $K_p(h_1 \rightarrow l_1g)$ and is defined by eq. [3],

[3] $\ln K_p(h_1 \rightarrow l_1g)$

$$= \ln f_2(h_1l_1g) + n\ln x_1^{11} + n(1/RT) \int_{0.1 \text{ MPa}}^{P(h_1l_1g)} (V_1^{11} - V_1^{h1}) \, dP$$

In eq. [3] V_1^{11} is the molar volume of water and V_1^{h1} the molar volume of structure I lattice water at pressure $P(h_1l_1g)$ and temperature T. Equilibrium values of $P(h_1l_1g)$ are given in column four of Tables 1 and 3. Equilibrium values of methane fugacity $f_2(h_1l_1g)$ are evaluated from $P(h_1l_1g)$ using the IUPAC fugacity equation (11) and are given in ref. 6 and in column eight of Table 1. Equilibrium volumes of compressed water are interpolated from tables by Haar et al.

(12). Equilibrium values of $x_1^{11} = (1 - x_2^{11})$ are from x_2^{11}, listed in column eight of Table 4 and evaluated using the equation of Rettich et al. (13). Estimates for V_1^{h1} (cm^3 mol^{-1}) at temperature t and at pressure $P(h_1l_1g)$ are as follows: 22.34 (SE 0.19) at –0.29 °C and 2.527 MPa; 22.41 (0.18) at 11.10 °C and 8.122 MPa; 22.42 (0.18) at 22.04 °C and 29.99 MPa; 22.49 (0.19) at 31.93 °C and 98 MPa; 21.77 (0.22) at 45.14 °C and 335 MPa; 21.32 (0.22) at 47.39 °C and 493 MPa.

Forty-nine equilibrium constants between –0.29 and 47.39 °C are converged as described in ref. 6 and are best (10) represented by the unbiased thermodynamic equation

[4] $\ln K_p(h_1 \rightarrow l_1 g) = d_0 + d_1 u_1 + d_2 u_2$

Temperature variables u_1 and u_2 and thermodynamic parameters d_0 to d_2 are defined at reference temperature $\Theta = 298.15$ K (25 °C). The data are sufficiently accurate and extensive so that the three-parameter eq. [4] can be converged and solved directly.

The parameters of the best converged eq. [4] are $d_0 = 2.9522$ (SE 0.0016), $d_1 = 23.451$ (0.018), and $d_2 = 14.24$ (0.89). The SE estimate on a single determination of $\ln K_p(h_1 \rightarrow l_1 g)$ of unit weight is 0.0063 or is 0.63% for $K_p(h_1 \rightarrow l_1 g)$ with 44 degrees of freedom. The number of degrees of freedom is counted from the 49 data, minus the three undetermined parameters, minus the two weighted data, leaving 44. The coefficient of determination R^2 is 0.99998.

Two data are assigned the low weights $w^{1/2} = 0.001$ to avoid bias of the final equation because their observed equilibrium constants deviate from the least-squares model by 19 and by 23 times their estimated standard errors.

The RMS deviations for weighted (unweighted) residuals of $\ln K_p(h_1 \rightarrow l_1 g)$ from eq. [4] are the following: D&F40, 0.0052; MSK64, 0.0091 (0.0136); GRCK70, 0.0090; V74, 0.0077 (0.0184); and NMO99, 0.0019.

Because the 33 best data from ref. 6 at low temperatures are taken together with the 16 new measurements of data set NMO99, the converged eq. [4] is expected to agree with eq. [8a] of ref. 6. The agreement with the earlier model is good and the limits of SE have been reduced from 0.0079 to 0.0063. The best equation for $\ln K_p(h_1 \rightarrow l_1 g)$ in this work is numerically slightly different from that given earlier in ref. 6 and is preferred because it covers a wider range of temperature.

Table 4 has the same arrangement as Table 2 in ref. 7 and extends the measurements of structure I methane hydrate to include both the stable region below and the metastable region above $Q(h_1h_2l_1g)$ at 26.7 °C.

Table 4 shows the 49 converged best estimates of the equilibrium constant, $K_p(h_1 \rightarrow l_1 g)$, for dissociation of structure I methane hydrate into liquid water and methane gas with $n = r$. Standard thermodynamic function changes refer to dissociation of one gram mole of CH$_4$·rH$_2$O h$_1$ at 0.10 MPa to form r mol of pure water l$_1$ at 0.10 MPa and 1 mol of methane gas at 1.0 MPa fugacity. Parameter r is used to indicate the best estimate of n, as described in ref. 7.

The estimates of $K_p(h_1 \rightarrow l_1 g)$ observed in column four of Table 4 are shown to increase steadily from 2.30 MPa at –0.29 °C to 102.3 MPa at 47.39 °C. The calculated

Table 4. Equilibrium constant for structure I methane hydrate with water from –0.29 to 47.39 °C.

$K_p(h_1{\rightarrow}l_1g)$ estimates in column five properly represent these changes with SE 0.63% on a single determination of unit weight.

Standard enthalpy change $\Delta H^{ot}(h_1{\rightarrow}l_1g)$ and formula number estimate r for structure I methane hydrate with water

In Table 5 columns one and two show the data set and the Celsius temperature (ITS-90). Columns three and four list the standard enthalpy change $\Delta H^{ot}(h_1{\rightarrow}l_1g)$ and its SE in J mol^{-1} for dissociation of structure I methane hydrate to liquid water and methane gas. Columns five and six give the converged best estimates of the approximate formula number r and its SE for standard dissociation of structure I methane hydrate $CH_4{\cdot}rH_2O$ into water and methane. The estimate and SE of the standard heat capacity change $\Delta C_p^{ot}(h_1{\rightarrow}l_1g)$ are, respectively, 118 and 7 J mol^{-1} K^{-1} at all temperatures; earlier estimates and SE are 112 and 23 J mol^{-1} K^{-1} given in ref. 6.

At quadruple point $Q(h_1h_2l_1g)$, 26.7 °C, the estimated formula for structure I methane hydrate h_1 is $CH_4{\cdot}5.753H_2O$ with SE 0.048H$_2$O; this agrees well with the earlier estimate $CH_4{\cdot}5.759H_2O$ with SE 0.077H$_2$O given in ref. 6. The new formula estimate for structure I methane hydrate at 26.7 °C is very near to the ideal $CH_4{\cdot}5.750H_2O$ and indicates that 99.94% of hydrate cavities are occupied by methane with 0.06% unoccupied with an SE 0.83%.

The number of methane guest molecules, defined as m per unit cell of 46H$_2$O, increases from 7.457 (SE 0.065) at –0.29 °C and 2.53 MPa, to 7.710 (0.062) at 11.10 °C and 8.12 MPa, to 7.798 (0.062) at 15.55 °C and 13.11 MPa, to 7.917 (0.064) at 22.04 °C and 29.99 MPa, and to 7.995 (0.066) at 26.7 °C and 55.5 MPa. These values of m between –0.29 and 26.7 °C show the increasing number of the 8 lattice sites that must be occupied by methane guests to stabilize the structure I methane hydrate against thermal collapse due to increasing temperature.

At temperatures and pressures above 26.7 °C at 55.5 MPa and up to 47.39 °C at 493 MPa all cavities of structure I methane hydrate are occupied within our limits of detection. It is reasonably assumed that m increases asymptotically towards 8 as the pressure increases to 493 MPa. Column five in Table 5 shows that the measurements of NMO99 (3) all have a structure I, phase h_1, methane hydrate with formula near to $CH_4{\cdot}5.750H_2O$ with SE between 0.049 and 0.059H$_2$O.

This agrees with the X-ray measurements of structure I methane hydrate by Hirai and co-workers (14, 15) who report a fully occupied, phase h_1, methane hydrate with lattice parameters 1.188, 1.184, and 1.172 nm at 260, 300, and 380 MPa, respectively, at room temperature. In this work the volume estimates for $K_p(h_1{\rightarrow}l_1g)$ yield the lattice parameters 1.189, 1.187, and 1.183 nm with SE 0.004 nm at 258 MPa and 42.59 °C, at 299 MPa and 44.05 °C, and at 376 MPa and 46.02 °C, respectively, in reasonable agreement with the X-ray measurements.

Table 5. Standard enthalpy change for dissociation and the formula of structure I methane hydrate with water.

$C(h_1l_1gx_m)$	47.41	62 281	184	5.750	0.059
$Q(h_1h_2l_1g)$	26.7	58 335	50	5.753	0.048

Note: The estimate and standard error for $\Delta Cp^{ot}(h_1{\rightarrow}l_1g)$ are 118 and 7 J mol^{-1} K^{-1}, respectively, at all temperatures.

Congruent dissociation melting point of metastable structure I methane hydrate with water

Although the five measurements of methane hydrate between 335 and 493 MPa in Table 1 are accurately represented by eq. [2], the paucity of measurements makes it difficult to be certain that a congruent maximum exists. For comparison with phase h_2 of structure II methane hydrate (7), we assume that phase h_1 of structure I methane hydrate shows a metastable congruent maximum dissociation temperature $C(h_1l_1gx_m)$ at 47.41 °C and at a pressure of 505 MPa.

At the congruent temperature t_{max}, $(dt/dP) = 0$, so that the volume change for the hydrate dissociation melting reaction is $\Delta V(h_1 \rightarrow l_1g) = (dt/dP) \; \Delta H(h_1 \rightarrow l_1g)/T = 0$, with $\Delta H(h_1 \rightarrow l_1g)/T > 0$. In the two-component methane–water system, the congruent dissociation melting point of structure I methane hydrate is an invariant three-phase point, denoted $C(h_1l_1gx_m)$, at which the volume and composition x_m of the equilibrium methane hydrate phase h_1 is equal to the volume and composition of its fused reaction products, liquid water and gaseous methane.

At the congruent point $C(h_1l_1gx_m)$, 47.41 °C and 505 MPa, the thermodynamic model gives a maximum equilibrium constant $K_p(h_1 \rightarrow l_1g)$ of 102.3 MPa with SE 0.2 MPa and a maximum CH_4:H_2O mole ratio for the methane hydrate formula $CH_4 \cdot (5.750 \pm 0.059)H_2O$, with an h_1 formula volume 122.4 ± 1.3 cm^3 mol^{-1} CH$_4$, and with cubic hydrate lattice (8) parameter 1.176 ± 0.004 nm. The equilibrium volume (11) of methane gas is 32.7 ± 0.3 cm^3 mol^{-1} CH$_4$, and the equilibrium water volume (12) of $5.750 H_2O$ l_1 is 91.0 ± 0.9 cm^3 mol^{-1} CH$_4$. At $C(h_1l_1gx_m)$ the estimated ΔV (products – reactants) = 1.3 ± 1.6 cm^3 mol^{-1} CH$_4$. Similarly, for the hydrate with formula $CH_4 \cdot (5.750 \pm 0.058)H_2O$ at 45.14 °C and 335 MPa, $\Delta V = 4.5 \pm 1.6$ cm^3 mol^{-1} CH$_4$, and with formula $CH_4 \cdot (5.750 \pm 0.059)H_2O$ at 47.39 °C and 493 MPa, $\Delta V = 1.5 \pm 1.6$ cm^3 mol^{-1} CH$_4$.

Between quadruple point $Q(h_1h_2l_1g)$, 55.5 MPa at 26.7 °C, and up to hydrate pressure 505 MPa at 47.41 °C, it is found that with increasing temperature and pressure, methane from the gas phase is forced into the equilibrium structure I methane hydrate lattice, increasing its methane content towards the ideal maximum formula $CH_4 \cdot 5.750$.

The estimates of the standard thermodynamic function changes for metastable structure I methane hydrate dissociation into water and methane reported here are entirely similar to those listed in ref. 7 for the stable structure II methane hydrate dissociation into water and methane.

Thermodynamics of binary mixtures containing a very strongly polar compound — Part 3: DISQUAC characterization of NMP + organic solvent mixtures[1]

J.A. González, U. Domanska, and J. Lachwa

Abstract: Binary mixtures of 1-methyl pyrrolidin-2-one (NMP) with alkanes, benzene, toluene, 1-alkanol, or 1-alkyne have been investigated in the framework of the DISQUAC model. The reported interaction parameters change regularly with the molecular structure of the mixture components. The model consistently describes a set of thermodynamic properties, including liquid–liquid equilibria, vapor–liquid equilibria, solid–liquid equilibria, and molar excess enthalpies. A brief comparison of the DISQUAC results and those obtained from the UNIFAC and ERAS models is presented. The experimental excess enthalpies are better represented by DISQUAC than by UNIFAC because this quantity strongly depends on molecular structure. For NMP + alkane mixtures, the liquid–liquid equilibria data are also better represented by DISQUAC, while UNIFAC more accurately describes the vapor–liquid equilibria measurements at temperatures close to the critical point. This result suggests that a mean field theory is not able to represent simultaneously, with the same set of interaction parameters, liquid–liquid and vapor–liquid equilibria at the mentioned temperatures. ERAS fails when treating mixtures with 1-alkanols. This has been attributed to the strong dipole–dipole interactions between NMP molecules, characteristic of the investigated systems. Mixture structure is briefly studied in terms of the concentration–concentration structure factor.

Key words: thermodynamics, NMP, organic solvent, self-association, dipole–dipole interactions.

Résumé : On a étudié des mélanges binaires de 1-méthylpyrrolidin-2-one (NMP) avec des alcanes, du benzène, du toluène, des alcan-1-ols et des alc-1-ynes dans le contexte du modèle « DISQUAC ». Les paramètres d'interaction rapportés changent régulièrement avec la structure moléculaire des composants du mélange. Le modèle décrit d'une façon consistante un ensemble de propriétés thermodynamiques, dont les équilibres liquide–liquide, les équilibres vapeur–liquide, les équilibres solide–liquide ainsi que les enthalpies molaires d'excès. On présente une brève comparaison des résultats « DISQUAC » et ceux obtenus avec les modèles « UNIFAC » et « ERAS ». Les enthalpies en excès expérimentales sont mieux représentées par le modèle « DISQUAC » que par le modèle « UNIFAC » parce que cette quantité dépend fortement de la structure moléculaire. Pour les mélanges de NMP avec des alcanes, les données d'équilibre liquide–liquide sont aussi mieux représentées par le modèle « DISQUAC » alors que le modèle « UNIFAC » décrit d'une façon plus précise les mesures d'équilibre vapeur–liquide, à des températures près du point critique. Ce résultat suggère qu'une théorie à champ moyen ne peut pas représenter simultanément, avec le même ensemble de paramètres d'interaction, les équilibres liquide–liquide et vapeur–liquide aux températures mentionnées. Le modèle « ERAS » ne peut pas être utiliser pour traiter des mélanges contenant des alcan-1-ols. Ceci est attribué aux fortes interactions dipôle–dipôle entre les molécules de NMP caractéristiques dans les systèmes étudiés. La structure du mélange a été brièvement étudiée en fonction du facteur de structure concentration–concentration.

Mots clés : thermodynamique, NMP, solvant organique, auto-association, interactions dipôle–dipôle.

Introduction

We are engaged in a systematic investigation of the thermodynamic properties of solutions that contain a compound with a very high dipolar moment in the gas phase (μ), such as sulfolane (μ = 4.81 D (1)), dimethyl sulfoxide (μ = 4.06 D (1)), propylene carbonate (μ = 4.94 D (1)) or 1-methyl pyrrolidin-2-one (NMP, μ = 4.09 D (1)).

The thermodynamic properties of solutions containing amides, amino acids, peptides, and their derivatives are of interest because they provide simple biochemical models. For example, aqueous *N*,*N*-dimethylformamide (DMF) is a model mixed solvent that represents the environment of the interior of proteins. NMP is an excellent dissociating solvent (2, 3), suitable for use in electrochemistry (4) or in organic syntheses requiring dipolar aprotic media (5). NMP and DMF are also used as highly selective extractants for the recovery of aromatic and saturated hydrocarbons from petroleum feedstocks (6, 7). On the other hand, NMP can replace with toxicological and environmental advantages solvents such as chlorinated hydrocarbons (6).

Mixtures of NMP + aromatic compound (8), + 1-alkyne (9), or + 1-alkanol (10–12) have been studied in the framework of the ERAS model (13), which combines the real association solution model (14) with Flory's equation of state (15) (physical term). In these applications, calculations were developed assuming that NMP is a self-associated molecule, which is not strictly justified. In fact, the properties of pure liquid tertiary amides are due to the dominance of the general dipole–dipole interactions over the more geometrical hydrogen bond (16, 17). However, there must be significant local order in view of the relatively high heat of vaporization of tertiary amides (17). The poor predictions for the excess enthalpy, H^E, for NMP + 1-alkanol systems (11, 12) obtained using ERAS may be because of the strong dipole–dipole interactions present in such solutions.

On the other hand, UNIFAC interaction parameters are available (18, 19) for NMP + alkane, + C_6H_6, + C_7H_8, or + 1 alkanol ($\neq$ methanol) mixtures. The model fails when describing H^E for solutions of NMP and C_6H_6, C_7H_8, or 1-alkanol. To some extent, this may be due to the fact that the interaction parameters were determined mainly from vapor–liquid equilibria (VLE) data (see below). Here, we apply DISQUAC (20), a purely physical model based on the rigid lattice theory developed by Guggenheim (21), to carry out a detailed study of mixtures containing NMP and one organic solvent (alkane, C_6H_6, C_7H_8, 1-alkanol, 1-alkyne) using our recent H^E measurements for these systems (9–12). In previous articles (22, 23), we have already shown that DISQUAC is a useful tool for the characterization of interactions in mixtures of sulfolane with alkanes, C_6H_6, C_7H_8, CCl_4, 1-alkanols, 1-alkynes, or nitriles.

Model

In the framework of DISQUAC, mixtures of NMP with an organic solvent are regarded as possessing the following four types of surface: (*i*) type n, N-CO in NMP; (*ii*) type a, aliphatic (CH_3, CH_2, in NMP, toluene, methylcyclohexane, 1-alkanols, or 1-alkynes); (*iii*) type c, c-CH_2 in cycloalkanes or NMP; and (*iv*) type s (s = b, C_6H_6 in benzene; s = p, C_6H_5

in toluene; s = h, OH in 1-alkanols; s = y, HC≡C in 1-alkynes).

Assessment of geometrical parameters

When DISQUAC is applied, the total molecular volumes (r_i), surfaces (q_i), and the molecular surface fractions (α_i) of the compounds present in the mixture are calculated additively on the basis of the group volumes R_G and surfaces Q_G recommended by Bondi (24). As volume and surface units, the volume R_{CH_4} and surface Q_{CH_4} of methane are used (25). For the amide group, N-CO, $r_{N\text{-}CO}$ = 0.93633 and $q_{N\text{-}CO}$ = 0.63103. The remaining geometrical parameters for the groups referred to in this work are given elsewhere (25–28).

Equations

The main features of DISQUAC are the following: (*i*) The partition function is factorized into two terms, in such a way that the excess functions are calculated as the sum of two contributions, a dispersive (DIS) term that represents the contributions from the dispersive forces and a quasichemical (QUAC) term that arises from the anisotropy of the force fields created by the molecules in solution. In the case of the molar Gibbs energy (G^E), the combinatorial term ($G^{E,COMB}$) is represented by the Flory–Huggins equation (25, 26). (*ii*) The interaction parameters are assumed to be dependent on molecular structure. The equations applied to calculate G^E and H^E are the same as those used in other applications (27). The reference value of the coordination number was used; that is, z = 4. This value is assumed to be the same for all the polar contacts. This represents one of the more important shortcomings of the model and is partially removed by the hypothesis of considering structure-dependent interaction parameters.

The temperature dependence of the interaction parameters g_{st}, h_{st}, and c_{pst} has been expressed in terms of the DIS and QUAC interchange coefficients (27), $C_{st,l}^{DIS}$ and $C_{st,l}^{QUAC}$, where s $\neq$ t = a, b, c, n, h, p, y; and l = 1 (Gibbs energy; $C_{st,1}^{DIS/QUAC}$ = $g_{st}^{DIS/QUAC}(T_0)/RT_0$); l = 2 (excess enthalpy; $C_{st,2}^{DIS/QUAC}$ = $h_{st}^{DIS/QUAC}(T_0)/RT_0$), l = 3 (heat capacity; $C_{st,3}^{DIS/QUAC}$ = $c_{pst}^{DIS/QUAC}(T_0)/R$). T_o = 298.15 K is the scaling temperature.

The calculation of liquid–liquid equilibria (LLE) coexistence curves was done by taking into account that the values of the mole fraction, x_1 (x_1', x_1'') relating to the two phases in equilibrium are such that the functions $G^{M'}$, $G^{M''}$ ($G^M = G^E + G^{ideal}$) have a common tangent (29).

The equation of the solid-equilibrium curve of a pure solid component 1, including two first-order transitions, is

$$[1] \quad -\ln x_i = \left(\frac{\Delta H_{fus1}}{R}\right)\left(\frac{1}{T} - \frac{1}{T_{fus1}}\right) + \left(\frac{\Delta C_{pfus1}}{R}\right)$$

$$\times \left[\ln\left(\frac{T}{T_{fus1}}\right) + \frac{T_{fus1}}{T} - 1\right] + \left(\frac{\Delta H'_{trs1}}{R}\right)$$

$$\times \left[\frac{1}{T} - \frac{1}{T'_{trs1}}\right] + \left(\frac{\Delta H''_{trs1}}{R}\right)\left(\frac{1}{T} - \frac{1}{T''_{trs1}}\right) + \ln \gamma_1$$

[b]Estimated values.

for temperatures below that of the phase transition (30). Conditions at which eq. [1] is valid have been specified elsewhere (22). In eq. [1], γ_1 is the activity coefficient of component 1 in the solvent mixture at temperature T. In this work, γ_1 is calculated using DISQUAC. ΔH_{fus1}, T_{fus1}, and ΔC_{pfus1} are, respectively, the molar enthalpy of fusion, the melting temperature, and the change of the molar heat capacity during the melting of component 1. ΔH_{trs1} and T_{trs1} stand for the molar enthalpy of transition and the transition temperature, respectively. The required physical constants are listed in Table A1 of the Appendix.

Estimation of the interaction parameters

The general procedure applied in the estimation of the interaction parameters has been explained in detail elsewhere (22) and will not be repeated here. Some remarks are given below.

NMP + alkane systems
These solutions are formed by three contacts, (a,c), (a,n), and (c,n). Because NMP is a five- membered ring, the (a,c) contacts must be fitted to experimental data for cyclopentane + n-alkane systems, which are described only by dispersive parameters (26, 31). The excess functions for binary mixtures with cyclopentane, or with another cycloalkane, show low values when a short-chain n-alkane is involved. For example, $H^E(x_1 = 0.5, 298.15$ K$) = 70$ J mol^{-1} for cyclopentane + n-heptane (32). Therefore, the corresponding interaction pa-

rameters also show low values. For the sake of simplicity, we used $C_{ac,l}^{DIS}$ ($l = 1, 2, 3) = 0$ in the present work. This approximation has been used previously for mixtures containing sulfolane (22, 23).

Once the (a,c) parameters are known, the (a,n) and (c,n) contacts can be simultaneously fitted (Table 1). This was done using the available database for NMP + n-alkane or + cycloalkane mixtures. Moreover, it was assumed that $C_{an,l}^{QUAC} = C_{cn,l}^{QUAC}$. This general rule is valid for many other solutions (see (22) and references given therein).

NMP + benzene or toluene systems
These mixtures are characterized by six contacts, (a,s), (a,c), (a,n), (c,s), (c,n), and (s,n), with s = b or p. The (a,s) parameters are known from a study of benzene or toluene + n-alkane mixtures (33). The interaction parameters for the (c,s) (s = b, p) contacts are assumed to be entirely dispersive. These parameters are not neglected in view of the rather high values of the corresponding excess functions. For example, at equimolar composition and 298.15 K, $H^E = 630$ J mol^{-1} for cyclopentane + benzene (34) and 365 J mol^{-1} for cyclopentane + toluene (34). Here, averaged values of the interchange coefficients are used, $C_{ct,1}^{DIS} = 0.23$ and $C_{ct,2}^{DIS} = 0.47$ (t = b, p). In the case of the cyclopentane + toluene system, the purely dispersive parameters of the (a,p) contacts must be considered. The values used are $C_{ap,1}^{DIS} = 0.39$, $C_{ap,2}^{DIS} = 0.59$, and $C_{ap,3}^{DIS} = –0.35$.

The determination of the parameters for the (s,n) contacts was done under the basic assumption that the mixtures with

benzene or toluene are characterized by the same QUAC coefficients but different DIS parameters. The same trend is observed in 1-alkanol (35) or 2-alkanol (36) or sulfolane (22) + benzene or + toluene mixtures. The final parameter values are listed in Table 1.

NMP + 1-alkanol systems

There are six contacts present in the mixtures: (a,c), (a,h), (a,n), (c,h), (c,n), and (n,h). The $C_{ah,l}^{DIS/QUAC}$ and $C_{ch,l}^{DIS/QUAC}$ (l = 1, 2, 3) coefficients have been previously determined from data for VLE, LLE, SLE (solid–liquid equilibria), H^E, and C_p^E for 1-alkanol + alkane systems (27, 37–39). Therefore, only the interaction parameters for the (h,n) contacts must be fitted (Table 1).

NMP + 1-alkyne systems

Here, there are also six contacts: (a,c), (a,n), (a,y), (c,n), (c,y), and (n,y). The $C_{ay,l}^{DIS/QUAC}$ and $C_{cy,l}^{DIS/QUAC}$ coefficients are known (28) from experimental data for 1-alkyne + n-alkane and + cycloalkane mixtures, respectively. So, only the $C_{ny,l}^{DIS/QUAC}$ coefficients must be determined (Table 1). Owing to the lack of G^E data, the first DIS and QUAC interchange coefficients were calculated using the available data for logarithms of activity coefficients at infinite dilution (40, 41).

Results

DISQUAC results

Results from the DISQUAC model are compared with experimental data for LLE, VLE, G^E, SLE, and H^E in Tables 2–5. Comparisons for selected mixtures are plotted in Figs. 1–4. For the sake of clarity, relative deviations for the pressure (P) and H^E, defined as

$$[2] \qquad \sigma_r(P) = \left\{ \frac{1}{N} \sum \left[\frac{P_{exptl} - P_{calcd}}{P_{exptl}} \right]^2 \right\}^{1/2}$$

$$[3] \qquad dev(H^E) = \left\{ \frac{1}{N} \sum \left[\frac{H_{exptl}^E - H_{calcd}^E}{H_{exptl}^E (x_1 = 0.5)} \right]^2 \right\}^{1/2}$$

are given in Tables 3 and 5, where N stands for the number of data points for each system.

We note that DISQUAC consistently represents the thermodynamic properties of the systems under study. The theoretical results for VLE and SLE suggest that the model can be applied over a wide range of temperatures (Tables 3, 4).

DISQUAC describes the LLE curves for the NMP + alkane systems (Fig. 1) reasonably well, considering that calculations were developed under the incorrect assumption that the excess functions are analytical close to the critical points, while the thermodynamic properties are, really, expressed in terms of scaling laws with universal critical exponents and universal scaling functions (65). For this reason, at temperatures near the UCST (upper critical solution temperature), the calculated LLE and H^E curves are more rounded that the experimental curves (Figs. 1, 2). This is in accordance with the results obtained for other mixtures, such as alkane + dimethyl carbonate (50), acetic anhydride (66),

methanol (38), phenol (67), sulfolane (22), or alkoxyethanol (68). Nevertheless, the coordinates of the critical points are represented in the correct range of temperature and composition (Table 2). It is remarkable that for NMP + n-alkane systems, the UCST does not increase regularly with the chain length of the n-alkane. So, for the solutions with n-C$_4$ or n-C$_5$, the UCST is higher than for the mixture with n-C$_6$ (Table 2). This has been ascribed to the alkane-rich phase approaching its gas–liquid critical point (42). DISQUAC cannot represent such behaviour, and larger differences between experimental and calculated UCST values are observed for the mentioned systems.

The rather poor theoretical results obtained for VLE for solutions with alkanes (Table 3) at temperatures close to the critical values merely underline that it is not possible to accurately and simultaneously represent VLE and LLE at those conditions using the same set of interaction parameters. Note that the model describes the composition dependence of H^E (Table 5) and the coordinates of the azeotropes quite accurately at high enough temperatures. For example, DISQUAC predicts, for the NMP(1) + n-dodecane(2) system

at 393.15 K, an azeotrope at $x_{1az} = 0.652$ and $P_{az} = 103.52$ kPa; the experimental values, at the same temperature, are $x_{1az} = 0.655$ and $P_{az} = 105.96$ kPa (51). However, the observed discrepancies for VLE are also due in part to the inadequacy of the Flory–Huggins combinatorial term (69), as well as to experimental errors (54). Note, for example, the extremely negative value of G^E for NMP + 1-propanol or + 1-hexanol mixtures (Table 3).

For systems with solvents other than alkanes, DISQUAC provides quite good results.

One of the most interesting features of the NMP + 1-alkanol systems is that the position of the maxima of the H^E curves is shifted to a higher mole fraction of the amide when the chain length of the 1-alkanol increases (11, 12). Similar behaviour is observed for mixtures of DMF (70), dimethylacetamide (71), or dimethylsulfoxide (70) with 1-alkanols. The opposite trend is encountered for mixtures formed by 1-alkanol with a nonpolar compound, such as benzene, or with a polar non-protonic solvent (e.g., cyclohexanone, 1,4-dioxane) (70). This complex behaviour is well described by DISQUAC (Fig. 3).

Comparison with other models

The experimental H^E data are better represented by DISQUAC than by UNIFAC (Fig. 4b) because the interaction parameters are considered to be dependent on the molecular structure. UNIFAC fails when representing H^E for the NMP + 1-alkanol mixtures. At equimolar composition and 298.15 K, the model predicts H^E (1-propanol) = 1555 J mol^{-1}, while the experimental value is 277 J mol^{-1} (11). This large discrepancy may be due the absence of H^E measurements and the determination of the interaction parameters using only VLE data. For this reason, UNIFAC improves VLE for the mixtures with alkanes (Fig. 4a). However, UNIFAC does not correctly represent LLE. For example, UNIFAC predicts ≈395 K for the UCST of the

Dashed curve: ERAS results (this work) for the mixture with methanol using $K_{AB} = 22$; $\Delta h^*_{AB} = -38.5$ kJ mol⁻¹; $\Delta v^*_{AB} = -14.2$ cm³ mol⁻¹; $X_{AB} = 12$ J cm⁻³ (for other ERAS parameters, see (10)).
associated, which is not justified (16, 17). In addition, self-association was also assumed for benzene, toluene, and 1-alkyne. For NMP + benzene, + toluene, or + 1-alkyne systems, the mean deviation of H^E from DISQUAC is ≈6.8%, while ERAS, under the specified assumptions, provides a mean deviation of ≈13%. However, the ERAS results are still meaningful because the model can also quite accurately represent the molar excess volume (V^E) of such solutions. This seems to indicate that ERAS could be applied to systems in which self-association and cross-association occur, owing to other interactions besides hydrogen bonding (8).

For NMP + 1-alkanol mixtures, calculations carried out in the present work show that there is no significant difference between results obtained when considering NMP to be a non-self-associated compound and those obtained when NMP is assumed to be self-associated.

In any case, the important point is that ERAS does not describe the thermodynamic properties of solutions of NMP with 1-alkanol. This may be due to the fact that ERAS cannot properly represent such large positive contributions from dipole–dipole interactions to the excess functions. Fig. 3 shows that for NMP + methanol mixtures, the calculated H^E curve is shifted towards higher mole fractions of the alcohol. This suggests that the model overestimates the chemical contribution to H^E or the role of the self-association of the alcohol in these mixtures. A similar trend was found for 1-alkanol + linear organic carbonate systems (72), although the representation of the mixture properties was acceptable, probably because the dipole–dipole interactions between the carbonate molecules are of less importance than those be-

NMP + decane system, whereas the experimental value is 337.73 K (47).

As already mentioned, ERAS has been applied to NMP + benzene, + toluene, + 1-alkyne, or + 1-alkanol mixtures. The calculations were carried out assuming that NMP is self-

$^dTS^E_{int} = H^E - G^E_{int}$; $G^E = G^E_{int} + G^{E,COMB}$.
^{e}Value at 353.2 K.

alkyne, + benzene, + toluene, or + methanol systems show very negative TS^E_{int} values. In the diagram where $G^E_{int}(x_1 = 0.5)$ is plotted against $H^E(x_1 = 0.5)$ (76), the mentioned solutions are placed on the left-hand side, indicating the importance of chemical interactions in such mixtures. For NMP + 1-alkanol ($\neq$ methanol) systems, TS^E_{int} becomes quite large and positive, indicating that association is not so important. It should be kept in mind that G^E and H^E of systems formed by NMP and one hydrocarbon or one aromatic compound are not described by the chemical theory of solutions (60). This suggests the transitional character (between associated and non-associated mixtures) of those solutions containing a very polar component (60).

Discussion

Concentration–concentration structure factor

Mixture structure can be studied using the concentration–concentration structure factor, $S_{CC}(0)$ (77), defined as

[4] $$S_{CC}(0) = \frac{RT}{(\partial^2 G^M/\partial x_1^2)_{P,T}} = \frac{x_1 x_2}{D}$$

with

[5] $$D = \frac{x_1 x_2}{RT}(\partial^2 G^M/\partial x_1^2)_{P,T} = 1 + \frac{x_1 x_2}{RT}\left(\frac{\partial^2 G^E}{\partial x_1^2}\right)_{P,T}$$

D is a function closely related to thermodynamic stability (65, 78). For ideal mixtures, $G^{E,id} = 0$, $D^{id} = 1$, and $S_{CC}(0) = x_1 x_2$. As stability conditions require, $S_{CC}(0) > 0$, and if the system is close to phase separation, $S_{CC}(0)$ must be large and positive (∞, when the mixture presents a miscibility gap). In contrast, if compound formation between components appears, $S_{CC}(0)$ must be very low (0, in the limit of complete

tween NMP molecules (note that the experimental UCST for the dimethyl carbonate + n-decane mixture is 286.62 K (73)).

Therefore, one can conclude that ERAS can be applied successfully to mixtures for which the thermodynamic properties arise from the self-association of one component (1-alkanol + alkane (74)) or from interactions between unlike molecules (1-alkanol + amine (75) or NMP +1-alkyne (9)).

Calculations of TS^E_{int} (= $H^E - G^E_{int}$, with $G^E = G^E_{int} + G^{E,COMB}$) support this conclusion (Table 6). NMP + 1-

reaction). So, if $S_{CC}(0) > x_1 x_2$ (i.e., $D < 1$), the dominant trend in the system is the separation of the components (homocoordination), and the mixture is less stable than the ideal mixture. If $0 < S_{CC}(0) < x_1 x_2 = S_{CC}(0)^{id}$ (i.e., $D > 1$), the fluctuations in the system have been removed, and the dominant trend in the solution is compound formation (heterocoordination). In this case, the system is more stable than the hypothetical ideal mixture.

Hereafter, we refer to values of the thermodynamic properties at 298.15 K and equimolar composition. For the NMP + n-C$_7$ system (T = 373.15 K), $S_{CC}(0) = 1.79$. This rather high value is characteristic of mixtures at temperatures close to the UCST and underlines the dominant role in such solutions of homocoordination (dipole–dipole interactions between NMP molecules; see also the high H^E values for this system (Table 2)). Similarly, $S_{CC}(0) = 1.72$ for NMP + cyclohexane.

For the NMP + methanol solution, $S_{CC}(0) = 0.17$. The $S_{CC}(0)$ curve is shifted to higher NMP concentration (Fig. 5), which means that several NMP molecules interact with one methanol molecule. From the study of NMP + 1-alkanol systems, in terms of the internal pressure (P_i) of the pure components and of their mixtures (79), it has been concluded that 1:1 (H-bond) and 1:2 (dipole–dipole interactions) aggregates are feasible only for the NMP + methanol system, whereas for the other 1-alkanols the associative and dispersion forces do not enable net heteroassociation. This conclusion was based on V^E and ΔG^{*E} (Gibbs energy of activation) data (79).

$S_{CC}(0)$ calculations using DISQUAC suggest that heterocoordination is still possible for NMP + 1-hexanol system (see Fig. 5), as $S_{CC}(0) = 0.21$.

For the NMP + 1-hexyne system, $S_{CC}(0) = 0.32$. However, $H^E = -880$ J mol^{-1} (9). This may be interpreted by assuming that, although there is a larger number of interactions between like molecules ($S_{CC}(0) > 0.25$), the interactions between unlike molecules are stronger.

Finally, the NMP + benzene system is characterized by $H^E = -500$ J mol^{-1} (61). In addition, SLE measurements suggest the existence of complex formation (1:2 type) (57). This evidence suggests interactions between unlike molecules. In contrast, $S_{CC}(0) = 0.25$. This may well be due to the low value of the G^E (Table 3), a possible consequence of enthalpic–entropic compensation.

The DISQUAC interaction parameters

(*a*) For mixtures containing n-alkanes, the first dispersive interaction parameter depends on the chain length of the n-alkane (Table 1). This is necessary to describe the LLE curves. Similar behaviour has been reported for mixtures of n-alkanes with sulfolane (22) or crown ethers (80).

(*b*) For mixtures containing 1-alkanol, the $C_{hn,l}^{QUAC}$ ($l = 1$, 3) coefficients are independent of the alkanol, while the enthalpic QUAC parameters differ only for the lower 1-alkanols (Table 1). Similar trends have been reported for other solutions, for example: 1-alkanol + n-alkane (27, 37), or + cyclohexane (39), or + aromatic compound (35), or + linear organic carbonate (72), or in alkoxyethanol + alkane mixtures (68). This reveals the different character (stronger self-association, higher dielectric constant) of first members of homologous series (methanol, ethanol, 2-methoxyetha-

Fig. 5. $S_{CC}(0)$ for NMP(1) + 1-alkanol(2) + mixtures at temperature T. Points, experimental values at 333.15 K (56). Solid curves, DISQUAC calculations at 333.15 K (methanol) or at 298.15 K (remaining 1-alkanols). Dashed curve, ideal mixture.
nol). The same conclusion was stated when treating 1-alkanol + organic solvent mixtures in the framework of Barker's theory (81, 82)

(*c*) The $C_{hn,l}^{DIS}$ coefficients remain constant for the longer 1-alkanols (Table 1), as reported previously for 1-alkanol + n-alkane (27, 37), + cyclohexane (39), + aromatic compound (35), or + linear organic carbonate (72) mixtures.

Conclusions

Mixtures of NMP with alkane, benzene, toluene, 1-alkanol, or 1-alkyne have been investigated in the framework of the DISQUAC model. The corresponding interaction parameters are reported. The model consistently describes a set of thermodynamic properties: LLE, VLE, SLE, G^E, and H^E. The dependence of the interaction parameters on molecular structure is similar to results reported previously for other mixtures.

Determination of the second stoichiometric dissociation constants of glycine in aqueous sodium or potassium chloride solutions at 298.15 K

Jaakko I. Partanen, Pekka M. Juusola, Pentti O. Minkkinen, and Virginie Verraes

Abstract: Equations were determined for the calculation of the second stoichiometric (molality scale) dissociation constant, K_{m2}, of glycine, in aqueous NaCl and KCl solutions at 298.15 K, from the thermodynamic dissociation constant, K_{a2}, of this acid and the ionic strength, I_m, of the solution. The ionic strength of the solutions considered in this study is determined mostly by the salt alone, and the equations for K_{m2} were based on the single-ion activity coefficient equations of the Hückel type. New data measured by potentiometric titrations in a glass electrode cell were used in the estimation of the parameters for the Hückel equations of glycine species. By means of the calculation method suggested in this study, K_{m2} can be obtained almost within experimental error up to an I_m of about 1.0 mol kg^{-1} for glycine in NaCl and KCl solutions. The K_{m2} values obtained by these methods were also compared with the values suggested in the literature for this quantity.

Key words: ionic strength dependence, stoichiometric dissociation constant, Debye–Hückel equation, potentiometry, glycine.

Résumé : Des équations sont développées pour le calcul de K_{m2}, la deuxième constante de dissociation stoechiométrique (en molalité) de la glycine en solution aqueuse de NaCl et KCl à 298,15 K. Ces équations sont déterminées à partir de la constante de dissociation, K_{a2}, de cet acide et de la force ionique, I_m, de la solution. La force ionique des solutions étudiées est imposée en presque totalité par le sel contenu en solution. Les formules pour K_{m2} sont alors déduites d'équations de type Hückel pour la détermination du coefficient d'activité d'un seul type d'ions. Les paramètres des équations d'Hückel pour les sels de glycine ont été approximés sur la base de mesures faites par titrations potentiométriques avec des électrodes de verre. Avec les meilleures méthodes de calculs présentées dans cette étude, K_{m2} peut être calculé avec une certitude presque équivalente aux erreurs expérimentales pour des solutions de glycine dans NaCl ou KCl ayant une force ionique I_m jusqu'à environ 1,0 mol kg^{-1}. Les valeurs de K_{m2} obtenues par ces méthodes sont aussi comparées aux valeurs trouvées dans la bibliographie.

Mots clés : influence de la force ionique, constante de dissociation stoechiométrique, équation de Debye–Hückel, potentiométrie, glycine.

Introduction

In this manuscript, we continue the studies (1–17) dealing with the thermodynamics of weak acid solutions. The purpose of these studies is to determine the stoichiometric dissociation constants (for example, the molality scale dissociation constants, K_m) for salt solutions of different weak acids, as reliably as possible from potentiometric titration data measured with glass electrodes. Additionally in these studies, calculation methods of the experimental K_m values for weak acids are also developed for literature data measured on galvanic cells without a liquid junction; see, e.g., ref. 1, and with a liquid junction, see ref. 16.

The other motivation of our studies in this field is to determine equations for the correlation of the experimental K_m values of different weak acids to the composition variables of salt solutions at 298.15 K. For this purpose, Hückel and Pitzer equations have been used in the previous studies for the single-ion activity coefficients. In the present study, Hückel equations were used for the analysis of potentiometric titration data of glycine in NaCl and KCl solutions. Pitzer equations, which are nowadays most often used for interpretation of thermodynamic data, were not considered in this study because Pitzer parameters are missing for the component salts of sodium and potassium glycinate in these solutions, and these parameters cannot be accurately determined solely from potentiometric titration data. Usually the binary Pitzer parameters for different salts have been deter-

mined, in the literature, from osmotic coefficients obtained from isopiestic data.

Glycine (NH_2CH_2COOH) is the simplest amino acid, and the dissociation of this acid in water solutions has been intensively studied. These works have been reviewed by the International Union of Pure and Applied Chemistry (IUPAC) (18). This review revealed, however, the absence of systematic studies on the influence of ionic strength, I_m, on K_{m1} and K_{m2} (i.e., on the first and second dissociation constants, respectively). For other weak acids, systematic studies are also rare, and the existing studies in this field are usually concentrated on acids used as pH buffer substances. The existing systematic glass electrode studies have been reviewed by Daniele et al. (19) and Sastre de Vicente (20). The stoichiometric dissociation constants of glycine in aqueous salt solutions have been determined in the following studies: Daniele et al. (21), in tetraethylammonium iodide solutions ($I_c = 0.01–1$ mol dm^{-3}, where I_c is the ionic strength on the concentration scale); Rey et al. (22), in KNO_3 solutions ($I_c = 0.025–0.5$ mol dm^{-3}); Herrero et al. (23), in KNO_3 solutions ($I_m = 0.30–1.6$ mol kg^{-1}, where I_m is the ionic strength on the molality scale); Fiol et al. (24), in NaCl solutions ($I_m = 0.05–1.021$ mol kg^{-1}); Fiol et al. (25), in artificial seawater ($I_m = 0.1–0.67$ mol kg^{-1}); Partanen (7), in NaCl solutions ($I_m = 0.1–3$ mol kg^{-1} for K_{m1} and $I_m = 0.1–0.3$ mol kg^{-1} for K_{m2}), by using King's data (26) obtained by Harned cells; and Alonso et al. (27), in $NaClO_4$, KCl, and KBr solutions ($I_m = 0.1–1$ mol kg^{-1}).

In the previous study (7), K_{m1} values for glycine were reliably obtained, up to NaCl molalities of 3 mol kg^{-1}, from the cell potential data measured by King (26) on cells containing a hydrogen and a silver – silver chloride electrode (i.e., on Harned cells), but K_{m2} values for this acid cannot be determined as accurately from these data because the data of K_{m2} extend in this case only up to a salt molality of 0.3 mol kg^{-1}. In the present study, therefore, potentiometric titrations were carried out to determine K_{m2} for glycine in more concentrated salt solutions. The titrations were carried out in NaCl and KCl solutions.

The determination of the second dissociation constant of glycine differed from our earlier studies in that the pH during titration was above 8 (basic environment). In earlier studies, the pH was always below 6 (acidic environment). The solutions titrated had to be protected, therefore, against atmospheric carbon dioxide. This was accomplished by bubbling argon through the solution before titration. An argon mattress was thus formed over the solution, and it protected the solution from absorption of CO_2. The present study shows for the first time that the experimental technique developed in this way allows the determination of K_m values with a glass electrode in basic solutions almost with the same accuracy as the one obtained by the best techniques with glass electrodes in acidic solutions (see, e.g., refs. 10 and 11). This technique seems, therefore, to be very promising for future thermodynamic studies of weak acids in basic solutions.

Experimental

Potentiometric titrations of glycine were carried out in aqueous NaCl and KCl solutions at 298.15 K. The two series

of salt solutions (the NaCl or KCl (pro analysi, Riedel-de Haën series) were prepared in RO-filtered water (Millipore), and the concentrations in these series were as follows: 0.080, 0.160, 0.240, 0.320, 0.400, 0.500, 0.700, and 1.350 mol L^{-1}. The experimental results from the NaCl series are shown in Table 1 and those from the KCl series in Table 2. A 0.0100 mol L^{-1} glycine (pro analysi, J.T. Baker) solution, a 0.100 mol L^{-1} NaOH (Fixanal, Riedel-de Haën) solution, and a 0.100 mol L^{-1} KOH (Titrisol, Merck) solution were also prepared.

The solutions to be titrated were prepared by mixing a volume of 100.0 cm^3 of a salt solution, 25.00 cm^3 of water, and 10.00 cm^3 of the glycine solution (for the details, see ref. 2). Since the glycine solutions were titrated in a basic milieu, the influence of carbon dioxide on the solutions had to be prevented by using argon gas, see above. This gas was bubbled through each solution for about 10 min. The gas stream was then stopped, and the titration vessel closed. In this way, an argon mattress was formed over the titrated solution, and it remained stable, as argon is heavier than air.

Titrations were then carried out by reading the cell potential difference (cpd) as a function of the added base volume. The increments of 0.050 cm^3 of the base solution were used. The cpd was measured by means of a BlueLine 12pH combination electrode and a CG841 pH meter, both manufactured by Schottgeräte. The resolution of the meter was 0.1 mV. The titrant was added by means of a Dosimat (Metrohm). Standard buffer solutions of pH = 4.005 and pH = 6.865 at 298.15 K, see Buck et al. (28), were used to control the stability of the measuring system between titrations. The pH meter usually reproduced readings within 0.2 mV in these buffer test solutions.

To further check the stability of the measuring system, a titration of formic acid was carried out before the glycine titration in each salt solution in similar conditions. An argon gas mattress was also adjusted over the formic acid solutions before titration. From the results of these formic acid titrations, the K_m values were determined by the method suggested in ref. 10. This method is principally the same as the one used here for glycine. The K_m values obtained from the titrations were always very close to those calculated from the equations recommended in ref. 10 for K_m of formic acid in NaCl or KCl solutions. The good agreement between the observed and recommended K_m values for this acid guarantees the quality of the new data for glycine.

Theory

In the Hückel method, the following equation is generally used for the calculation of the activity coefficient (γ) of a univalent ion i on the molality scale:

$$[1] \qquad \ln\gamma_i = -\frac{\alpha\sqrt{I_m}}{1 + B_i\sqrt{I_m}} + b_{i,MCl}\left(\frac{I_m}{m^\circ}\right)$$

where $m^\circ = 1$ mol kg^{-1}, I_m is the ionic strength on the molality scale, and α is the Debye–Hückel parameter at 298.15 K, equal to 1.17444 (mol $kg^{-1})^{-1/2}$; see Archer and Wang (29). B_i and $b_{i,MCl}$ are the parameters that are dependent on ion i, and $b_{i,MCl}$ is also dependent on the salt present in the system. Table 3 gives the parameter values determined previously for this equation and used here.

^{h}$q = b_A - b_{HA}$ for the glycine species determined from the titration data, and the standard deviation is also given.

[3] $\quad \ln\gamma_{HA} = b_{HA}\left(\dfrac{I_m}{m^\circ}\right)$

where b_{HA} is a constant. The second stoichiometric dissociation constant of glycine, K_{m2} in eq. [2], is defined by $K_{m2} = m_H m_A/(m_{HA}m^\circ)$. The following equation can be derived from eqs. [1], [2], and [3] for K_{m2} of glycine in aqueous NaCl or KCl solutions:

[4] $\quad \ln K_{m2,MCl} =$

$\ln K_{a2} + \alpha\sqrt{I_m}\left(\dfrac{1}{1+B_H\sqrt{I_m}} + \dfrac{1}{1+B_A\sqrt{I_m}}\right)$

$- [b_{H,MCl} + (b_{A,MCl} - b_{HA,MCl})]\left(\dfrac{I_m}{m^\circ}\right)$

where MCl refers to either NaCl or KCl. Here, the values of $B_H = 1.25$ (mol kg^{-1})$^{-1/2}$, $B_A = 2.2$ (mol kg^{-1})$^{-1/2}$, $b_{H,NaCl} = 0.238$, and $b_{H,KCl} = 0.178$ were used in this equation (see Table 3), and the thermodynamic dissociation constant, K_{a2}, and the parameters $b_{A,NaCl} - b_{HA,NaCl}$ (= q_{NaCl}) and $b_{A,KCl} - b_{HA,KCl}$ (= q_{KCl}) were determined from the new potentiometric titration data.

Results

Determination of the activity parameters for the dissociation reaction of water from Harned cell data

In basic solutions, the molality of hydrogen ions (needed for the glass electrode response) must be calculated from the molality of hydroxyl ions using the dissociation reaction of water. The necessary activity quantities for this reaction can be determined from the existing Harned cell data of Harned

and Hamer (32) and Harned and Mannweiler (33). In these studies the following cells were used:

[5] $\quad$ Pt(s) | H$_2$(g, f = 101.325 kPa) |

$\quad$ HCl(aq, m_{HCl} = 0.01 mol kg^{-1}),

$\quad$ MCl(aq, m_s) | AgCl(s) | Ag(s)

[6] $\quad$ Pt(s) | H$_2$(g, f = 101.325 kPa) |

$\quad$ MOH(aq, m_{MOH} = 0.01 mol kg^{-1}),

$\quad$ MCl(aq, m_s) | AgCl(s) | Ag(s)
where f is the fugacity. Harned and Hamer (32) measured KCl solutions (M = K$^+$), and Harned and Mannweiler (33) measured NaCl solutions (M = Na$^+$). The cell potential difference (cpd = E) of cell 6 is given by the following Nernst equation:

[7] $\quad E = E^\circ - \dfrac{RT}{F}\ln\left[\dfrac{\gamma_H\gamma_{Cl}m_H m_{Cl}}{(m^\circ)^2}\right]$

$= E^\circ - \dfrac{RT}{F}\ln(\gamma_H\gamma_{Cl}) - \dfrac{RT}{F}\ln\left(\dfrac{m_s}{m_{OH}}\right)$

$- \dfrac{RT}{F}\ln K_{a,w} + \dfrac{RT}{F}\ln\left(\dfrac{\gamma_H\gamma_{OH}}{a_w}\right)$

where w refers to water, Cl to chloride ions, and OH to hydroxyl ions, and the thermodynamic value of the ionic product of water, $K_{a,w}$, is defined by

[8] $\quad K_{a,w} = \dfrac{\gamma_H\gamma_{OH}m_H m_{OH}}{a_w(m^\circ)^2} = \dfrac{g_w m_H m_{OH}}{(m^\circ)^2}$

Harned and Hamer (32) determined a value of 1.008×10^{-14} for this quantity at 298.15 K. From the experimental data of cells 5 and 6, the g_w (= $\gamma_H\gamma_{OH}/a_w$) values shown in Table 4 were obtained. These values for KCl and NaCl solutions were correlated here to the ionic strengths by using the following equation, which contains only one new parameter, b_w:

[9] $\quad \ln\left(\dfrac{\gamma_H\gamma_{OH}}{a_w}\right) = \ln g_w = -\dfrac{2\alpha\sqrt{I_m}}{1+B_H\sqrt{I_m}} + b_w\left(\dfrac{I_m}{m^\circ}\right)$

The linear regression analysis used in the estimation of parameter b_w was based on equation

[10] $\quad \ln g_w + \dfrac{2\alpha\sqrt{I_m}}{1+B_H\sqrt{I_m}} = y_1$

$= y_0 + b_w x = y_0 + b_w\left(\dfrac{I_m}{m^\circ}\right)$

and the results for KCl solutions up to a salt molality of 2 mol kg^{-1} and for NaCl solutions up to a salt molality of 3 mol kg^{-1} were used. Parameter y_0 is associated with a possible small constant systematic error in these two old sets. The value of $(RT/F)y_0$ is 0.25 mV for the KCl set and 0.11 mV for the NaCl set, and these values were taken into

Table 4. Results of the comparison of the experimental values of g_w (= $\gamma_H\gamma_{OH}/a_w$) obtained by cells 5 and 6 with those predicted by eq. [9].

^{a}Determined from the data of Harned and Hamer (32).
^{b}Determined from the data of Harned and Mannweiler (33).
^{c}Calculated by the equation $e = (RT/F)$ [$\ln g_w$(observed) – $\ln g_w$(predicted)].

account in the calculation of the experimental g_w values in Table 4. From the slope of the resulting regression lines, a value of b_w = 0.482 was obtained for KCl solutions and a value of b_w = 0.412 for NaCl solutions. Equation [9] applies well to the experimental g_w values, as the errors for the points in Table 4 confirm. Error e in this table is defined by equation

$$[11] \quad e = \frac{RT}{F} \times [\ln g_w(\text{observed}) - \ln g_w(\text{predicted})]$$

and all absolute errors observed are smaller than 0.7 mV.

Determination of the experimental values for the stoichiometric dissociation constant from potentiometric glass electrode data

The theoretical equation for the molality of hydroxyl ions in a glycine titration was derived from the equation for the second stoichiometric dissociation constant, $K_{m2} = m_H m_A/(m_{HA}m°)$, from the mass balance equation, $m_t = m_{HA} + m_A$, and from the electroneutrality equation, $m_H + m_b = m_{OH} + m_A$. In the last equation, m_b is the molality of base, NaOH or KOH, in the solution titrated and $m_b = c_b V/w_1$, where c_b is the concentration, V is the volume of the base solution added in the titration, and w_1 is the mass of water in the solution titrated. In the mass balance equation, m_t is the total molality of glycine in the solution titrated, and $m_t = n_t/w_1$, where n_t is the total amount of this substance. For the molality of hydroxyl ions, the following equation can be derived from these equations and eq. [8]:

$$[12] \quad m_{OH}^2 + \left(m_t - m_b + \frac{K_{a,w}m°}{g_w K_{m2}}\right)m_{OH} - \frac{K_{a,w}m°}{g_w K_{m2}}m_b = 0$$

and this equation is second degree in the molality of OH$^-$ ions and can, therefore, be easily solved.

For the determination of K_{m2} of glycine from the titration data, the two glass electrode parameters, in addition to this dissociation constant, were simultaneously estimated from each titration data set. In general, the following equation is

valid for cell potential differences measured on a glass electrode cell:

$$[13] \quad E = E° + k\left(\frac{RT}{F}\right)\ln a_H$$

where a_H is the activity of protons, k is a glass electrode parameter, and $E°$ is another glass electrode parameter. The latter potential parameter includes the contributions of the reference electrode, liquid junction, standard-glass electrode, and asymmetry potentials; see, e.g., May et al. (34). It is assumed in all present titrations that this term remained constant during the titration. Equation [13] can also be presented in the form:

$$[14] \quad E = E° + \frac{kRT}{F}\ln\gamma_H + \frac{kRT}{F}\ln\left(\frac{m_H}{m°}\right)$$

$$= E_0 + \frac{kRT}{F}\ln\left(\frac{m_H}{m°}\right)$$

where $E_0 = E° + (kRT/F)\ln\gamma_H$ is also a glass electrode parameter that is constant during each titration at a constant ionic strength; see eq. [1]. Parameters E_0 and k must be estimated from the titration data.

K_{m2} and the glass electrode parameter E_0 were calculated for each glycine data set presented in Tables 1 and 2, containing N points, by the following equations:

$$[15] \quad \sum_{i=1}^{N}(E_i - E_{\text{predicted},i}) = 0$$

$$[16] \quad \ln\left(\frac{x_i}{m°}\right) = \frac{(E_i - E_0)F}{kRT}$$

$$[17] \quad o_i = \frac{K_{a,w}(m°)^2}{g_w x_i}$$

$$[18] \quad K_{m2,i} = \frac{x_i(m_{b,i} - o_i)}{\left(\frac{n_t}{w_{1,i}} - m_{b,i} + o_i\right)m°}$$

$$[19] \quad K_{m2} = \frac{\sum_{i=1}^{N} K_{m2,i}}{N}$$

$$[20] \quad y_i = \left(\frac{n_t}{w_{1,i}} - m_{b,i} + \frac{K_{a,w}m°}{g_w K_{m2}}\right)^2 + 4m_{b,i}\left(\frac{K_{a,w}m°}{g_w K_{m2}}\right)$$

$$[21] \quad m_{OH,i} = \left[\sqrt{y_i} - \left(\frac{n_t}{w_{1,i}} - m_{b,i} + \frac{K_{a,w}m°}{g_w K_{m2}}\right)\right]/2$$

$$[22] \quad m_{H,i} = \frac{K_{a,w}(m°)^2}{g_w m_{OH,i}}$$

$$[23] \quad E_{\text{pred},i} = E_0 + \left(\frac{kRT}{F}\right)\ln\left(\frac{m_{H,i}}{m°}\right)$$

[a]The second stoichiometric dissociation constant of glycine determined from the titration data in Table 2 by the method described in the text.
[b]The second stoichiometric dissociation constant of glycine calculated by eq. [4] with the value of $K_{a2} = 1.65 \times 10^{-10}$ and with the recommended activity parameters. Abbreviation "recd" means recommended.
[c]The assumed value of the glass electrode parameter k used in the calculation.
[d]The value of the glass electrode parameter E_0 used in the calculation of the cpd errors for Fig. 1. It was determined by requiring that the sum of errors in the data set be zero (i.e., by eqs. [20]–[22], [26], [27]).

where x_i and o_i are the experimental molalities of hydrogen and hydroxyl ions at point i, respectively. Additionally, the glass electrode parameter k was optimized by setting the following square sum, $S(E)$, at a minimum:

$$[24] \quad S(E) = \sum_{i=1}^{N}(E_i - E_{predicted,i})^2$$

This parameter had to be adjusted in the NaCl titrations (probably because of the selectivity problems of a glass electrode in aqueous NaCl solutions). In our earlier studies (see, e.g., refs. 8, 9, 11, and 12), parameter k also differed quite a lot from unity in aqueous NaCl solutions. In KCl solutions, k can be and was assumed to be exactly 1. The results from the calculations of the titration data in Tables 1 and 2 are shown in Table 5 (for NaCl) and 6 (for KCl).

Determination of activity parameters for glycine species from the experimental K_{m2} values obtained from titration data

A value of $B = 2.2$ (mol kg^{-1})$^{-1/2}$ was suggested in ref. 7 for eq. [1] for glycinate ions, and this value can also be used in the present study. The activity parameters $b_{A,NaCl} - b_{HA,NaCl}$ ($= q_{NaCl}$) and $b_{A,KCl} - b_{HA,KCl}$ ($= q_{KCl}$) and the thermodynamic value of the dissociation constant, K_{a2}, were determined from the new titration data. The experimental K_{m2} values, shown in Tables 5 and 6, were used in these determinations with the following equation derived from eq. [4]:

$$[25] \quad \ln K_{m2,MCl} - \alpha\sqrt{I_m}\left(\frac{1}{1+B_H\sqrt{I_m}} + \frac{1}{1+B_A\sqrt{I_m}}\right) =$$

$$y_2 = \ln K_{a2} - [b_{H,MCl} + q_{MCl}]\left(\frac{I_m}{m^\circ}\right)$$

This equation shows that y_2 is a linear function of (I_m/m°). The thermodynamic dissociation constant K_{a2} can be obtained from the intercept of the line with the y_2-axis, and the slope of the straight line is $-(b_{H,MCl} + q_{MCl})$. The results from the linear regression analysis are shown in Table 3. The resulting two estimates for K_{a2} of glycine agree very well with each other and with the value of 1.66×10^{-10} suggested in ref. 7 for this quantity. The latter value was determined by using the sparse literature data measured by King (26) with Harned cells. According to these results, a value of $K_{a2} = 1.65 \times 10^{-10}$ can now be recommended for the second dissociation constant of glycine. The value of 0.31 was determined in ref. 7 from King's data for the parameter q_{NaCl}. This value belongs to the 95% confidence interval of the value of this quantity suggested in Table 3 on the basis of new titration data. However, the new value of $q_{NaCl} = q_{KCl} = 0.39$ seems to be reliable, and this value is thus recommended for both NaCl and KCl solutions.

Discussion

The Hückel parameters recommended above for glycine species were tested with the titration data presented in Ta-

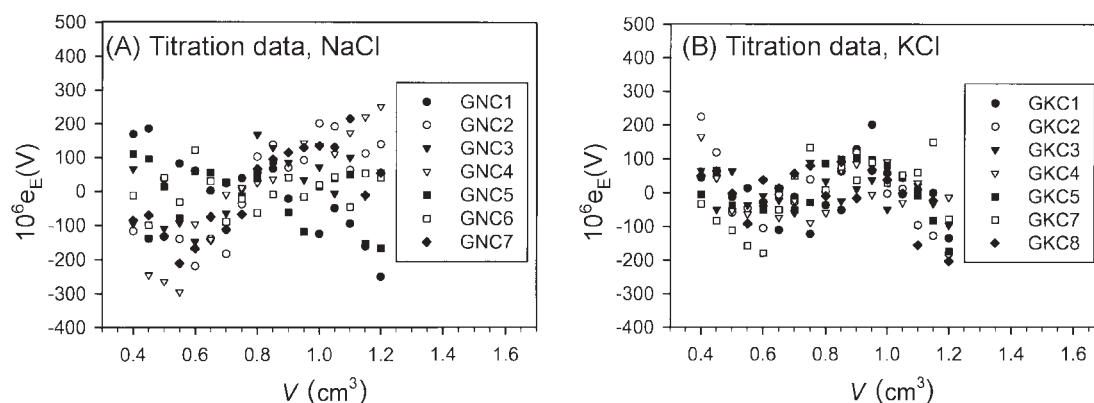
Fig. 1. The difference between the observed and predicted cpd values, e_E in eq. [28], as a function of the titrant volume in the titrations of glycine solutions with base (NaOH or KOH) solutions. Graph A shows the results of the titrations obtained for NaCl solutions (Series GNC), and graph B shows those obtained for KCl solutions (Series GKC). The predicted cpd was calculated by eqs. [4], [8], [9], [12], and [14] using the thermodynamic value of 1.65×10^{-10} for the second dissociation constant, the recommended activity parameters, and the glass electrode parameters k and E_0 shown in Tables 5 and 6. Symbols of the different sets are shown in the graphs.


Fig. 2. The difference, $e(\mathrm{p}K_{m2})$ in eq. [29], between the observed $\mathrm{p}K_{m2}$ values and those predicted by the recommended Hückel method as a function of the titrant volume in the titrations of glycine solutions with base (NaOH or KOH) solutions. Graph A shows the results of the titrations obtained for NaCl solutions (Series GNC), and graph B shows those obtained for KCl solutions (Series GKC). The observed K_{m2} was calculated from the titration points by eqs. [8], [9], [16], [17], and [18] with the glass electrode parameters shown in Tables 5 and 6. Symbols of the different sets are shown in the graphs.
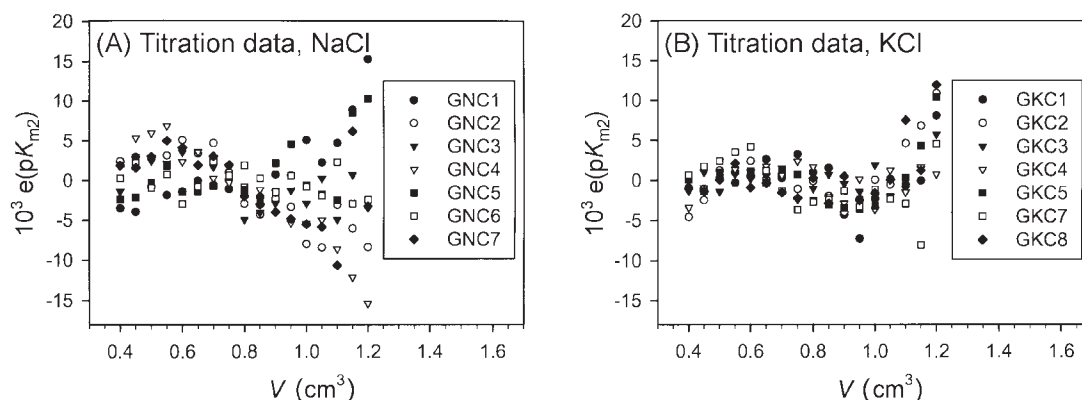

bles 1 and 2. The recommended K_{m2} values given in Tables 5 and 6 were used in these tests. Parameter E_0 for eq. [14] was calculated for each data set by using eqs. [20]–[22] and the following equations:

[26] $E_{0,i} = E_i - \left(\dfrac{kRT}{F} \right) \ln \left(\dfrac{m_{H,i}}{m^\circ} \right)$

[27] $E_0 = \dfrac{\displaystyle\sum_{i=1}^{N} E_{0,i}}{N}$

In these calculations, the values shown in Tables 5 and 6 were used for the other glass electrode parameter k. The resulting values for E_0 are included in these tables. The results of the tests are shown as error plots in graphs A (NaCl) and B (KCl) of Fig. 1, where the cpd error defined by

[28] $e_E = E(\text{observed}) - E(\text{predicted})$

is presented for each data set as a function of the added base volume. Most of the error plots in these graphs are random,

and most of the errors in these plots are comparable to the resolution of the pH meter (0.1 mV), and therefore, the titration data support well the suggested thermodynamic dissociation constant and the activity parameters used.

From every point of the titrations presented in Tables 1 and 2, an experimental value of K_{m2} can also be calculated from eqs. [16]–[18] by using the glass electrode parameter values shown in Tables 5 and 6. These values are compared with the recommended values in two graphs of Fig. 2. Graph A in this figure shows the NaCl results and graph B the KCl results. In these graphs, the $\mathrm{p}K_m$ ($= -\log(K_m)$) errors, defined by

[29] $e(\mathrm{p}K_{m2}) = \mathrm{p}K_{m2}(\text{observed}) - \mathrm{p}K_{m2}(\text{predicted})$

are presented as a function of the added base volume. All $\mathrm{p}K_{m2}$ errors in Fig. 2 are smaller than ± 0.015 and for most data sets they form a random pattern. The maximum error can also be compared with the conventional $\mathrm{p}K_m$ error of 0.06 suggested by Albert and Serjeant (35). These considerations also reveal how valuable the new activity coefficient models are.

Fig. 3. The difference, $e(pK_{m2})$ in eq. [29], between the pK_{m2} values determined by Fiol et al. (24) for glycine in NaCl solutions and by Alonso et al. (27) for glycine in KCl solutions and those predicted by the recommended Hückel method as a function of the ionic strength (I_m).

Table 7. The second stoichiometric dissociation constant (K_{m2}) of glycine at 298.15 K as a function of the ionic strength (I_m) in aqueous NaCl and KCl solutions.

I_m (mol kg^{-1})^a	$10^{10}\ K_{m2}$(NaCl)	$10^{10}\ K_{m2}$(KCl)
0	1.65	1.65
0.01	2.00	2.01
0.02	2.13	2.13
0.05	2.34	2.35
0.10	2.52	2.53
0.20	2.66	2.69
0.30	2.68	2.73
0.50	2.59	2.67
0.70	2.43	2.53
1.00	2.14	2.27

$^a I_m$ is the same as m_{NaCl} or m_{KCl}.

Fig. 4. The difference, $e(pK_{m2})$ in eq. [31], between the recommended pK_{m2} values (see Table 7) and those predicted by eq. [30] for glycine in NaCl and KCl solutions as a function of the ionic strength (I_m).

As mentioned above, Fiol et al. (24) have determined K_{m2} values of glycine in aqueous NaCl solutions, and Alonso et al. (27) have determined K_{m2} values of glycine in aqueous KCl solutions at 298.15 K by using potentiometric titration. These values were used to test the new models, and the results are shown as error plots in Fig. 3. The pK_{m2} errors, calculated from eq. [29], are given in this figure as a function of the ionic strength of the solution considered. The results in this figure show that the new models predict only satisfactorily these experimental data. It seems to us that the K_{m2} values obtained by the new models are more reliable.

Table 7 shows the recommended K_{m2} values for glycine in aqueous NaCl and KCl solutions at 298.15 K at rounded ionic strengths. These values apply to the case where NaCl or KCl effectively determines the ionic strength of solution. The K_{m2} values were calculated by using eq. [4] with the recommended value of $K_{a2} = 1.65 \times 10^{-10}$ and with the recommended parameter values shown in Table 3.

Recently, DeRobertis et al. (36) have proposed a general equation for the dissociation constant of carboxylic acids in aqueous sodium or potassium chloride solutions. If this equation is applied to the second dissociation constant of glycine, it has the following form:

$$[30] \quad \log K_{m2,MCl} = \log K_{a2} + \frac{2\sqrt{I_m / m°}}{2 + 3\sqrt{I_m / m°}}$$

$$- C_{MCl}\left(\frac{I_m}{m°}\right) - E_{MCl}\left(\frac{I_m}{m°}\right)^2$$

For NaCl solutions at 298.15 K, the values of parameters C and E are 0.092 and 0.00634, respectively, and for KCl solutions they are 0.1042 and 0.00522. The recommended K_{m2} values, presented in Table 7, were predicted by this equation, and the results are shown in Fig. 4 where pK_{m2} errors, defined now by the equation

$$[31] \quad e(pK_{m2}) = pK_{m2}(\text{recommended}) - pK_{m2}(\text{predicted})$$

are presented as a function of the ionic strength of the solution considered. Satisfactory agreement is obtained in this

figure up to a salt molality of 0.3 mol kg^{-1}. The error in pK_m is smaller in these cases than the conventional pK_m error of 0.06 suggested by Albert and Serjeant (35). However, it can be seen that, also in these cases, the pK_{m2} values obtained by eq. [30] are systematically smaller than the recommended values. Equation [30] does not, therefore, apply well to the K_{m2} values of glycine.

The syntheses and structures of lithium phosphinimide and phosphinimine complexes

Silke Courtenay, Pingrong Wei, and Douglas W. Stephan

Abstract: The preparation and structures of [Li(μ-NP*t*-Bu$_3$)]$_4$ **1**, [Li(μ-Cl)(HNP*t*-Bu$_3$)]$_4$ **2**, and [Li(μ-Cl)(HNPPh$_3$)]$_4$ **3** are described. The structure of **1** stands in contrast to that of the only other known Li-phosphinimide derivative, [Li(μ-NPPh$_3$)]$_6$. The impact of the steric bulk on the aggregation and the geometries of the Li$_4$N$_4$ and Li$_4$Cl$_4$ cores are considered and discussed.

Key words: lithium compounds, phosphinimine, phosphinimide, P-N ligands.

Résumé : On décrit la préparation et les structures des complexes [Li(μ-NP*t*-Bu$_3$)]$_4$, **1**, [Li(μ-Cl)(HNP*t*-Bu$_3$)]$_4$, **2** et [Li(μ-Cl)(HNPPh$_3$)]$_4$, **3**. La structure du composé **1** diffère de celles du seul autre dérivé Li-phosphimidide, [Li(μ-NPPh$_3$)]$_6$. On considère et on discute de l'impact de l'encombrement stérique sur l'agrégation et les géométries des entités centrales Li$_4$N$_4$ et Li$_4$Cl$_4$.

Mots clés : composés du lithium, phosphinimine, phosphinimide, ligands P-N.

[Traduit par la Rédaction]

Introduction

Main group derivatives of phosphinimine and phosphinimide ligands have been characterized and recently reviewed by Dehnicke and Weller (1). The chelating bis-phosphinimine H$_2$C(R$_2$PNSiMe$_3$)$_2$ has been used to prepare main group compounds as well (2–7). More recently, we, and subsequently Cavell and co-workers, have reported the first structure of a dilithio-methane derivative, [Li$_2$C(Ph$_2$PNSiMe$_3$)$_2$]$_4$ (7, 8). Cavell's group has also examined the chemistry of Al-bis(phosphinimine)methanide and methanediide complexes, HC(Ph$_2$PNSiMe$_3$)$_2$AlMe$_2$ and (Me$_2$Al)$_2$C(Ph$_2$PNSiMe$_3$)$_2$ (2, 3), as well as related Zn species (9), while the research groups of Cavell (4, 5) and Gamer and Roesky (6) have described the structural diversity of Li, Na, and K salts of [HC(Ph$_2$PNSiMe$_3$)$_2$]$^-$. We have recently described related Mg complexes (10). We have also been exploring main group derivatives of bulky, mono-phosphinimide ligands. The novel cationic linear species [(*t*-Bu$_3$PN)$_2$B]Cl and its chemistry has been recently reported (11). As well, we have recently described the chemistry of phosphinimide derivatives of Si, Ge, and Sn (12). Related alkali metal salts of phosphinimides, (KNPCy$_3$)$_4$, (KNPPh$_3$)$_4$ (13), (MNPCy$_3$)$_4$(OPCy$_3$) (M = K, Cs) (14), and [M(μ-NPPh$_3$)]$_6$ (M = K (15), Na (16), Rb (13)) have been structurally characterized. For related Li-phosphinimides, despite the fact that they have been known for 35 years (17) and are frequently used as reagents for the synthesis of main group (1,

11, 12, 18) and transition metal derivatives (19–24), only the structure of [Li(μ-NPPh$_3$)]$_6$ and [Li(μ-NPPh$_3$)(LiBr)]$_2$·(THF)$_4$ have been reported (25, 26). In this work, we describe the Li derivatives [Li(μ-NP*t*-Bu$_3$)]$_4$ and [(Li(μ-Cl)(HNPR$_3$)]$_4$ (R = *t*-Bu$_3$, Ph). The impact of the sterically demanding substituents in these compounds on the degree of aggregation and the structures of the Li$_4$X$_4$ (X = N, Cl) cores is discussed.

Experimental

General data

All preparations were done under an atmosphere of dry, O$_2$-free N$_2$, employing both Schlenk line techniques and a Vacuum Atmospheres inert atmosphere glove box. Solvents were purified by employing a Grubbs' type solvent purification system manufactured by Innovative Technology. All organic reagents were purified by conventional methods. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded on Bruker Avance-300 and 500 spectrometers. All spectra were recorded in C$_6$D$_6$ at 25 °C unless otherwise noted. Trace amounts of protonated solvents were used as references, and chemical shifts are reported relative to SiMe$_4$. ^{31}P{^{1}H} NMR spectra were recorded on a Bruker Avance-300 and are referenced to external 85% H$_3$PO$_4$. Combustion analyses were done in house, employing a PerkinElmer CHN Analyzer. *t*-Bu$_3$PNH was prepared as previously described (1, 27), using *t*-Bu$_3$P obtained from the Strem Chemical Co.

Synthesis of [Li(μ-NP*t*-Bu$_3$)]$_4$ 1

To a solution of *t*-Bu$_3$PNH (640 mg, 2.95 mmol) in 50 mL of hexanes was added MeLi (2.10 mL, 1.4 mol L^{-1} solution in ether, 2.95 mmol) at 25 °C. The resulting suspension was stirred for 1 h, concentrated, and allowed to settle for 10 min. The hexane layer was decanted, and the remaining white powder (yield > 95%) was washed twice with hexane and dried in vacuo. From the hexane washings, X-ray qual-

Synthesis of [Li(μ-Cl)(HNP*t*-Bu$_3$)]$_4$ 2 and [Li(μ-Cl)(HNPPh$_3$)]$_4$ 3

These compounds were prepared in a similar fashion, and thus one preparation is detailed. To a solution of *t*-Bu$_3$PNH (130 mg, 0.60 mmol) in 10 mL of THF was added LiCl (25.4 mg, 0.60 mmol) at 25 °C. The resulting suspension was stirred for 1 h, concentrated to a small volume, and allowed to stand. A white powder (yield > 90%) precipitated and was washed twice with hexanes and dried in vacuo. In examining related chemistry, X-ray quality crystals of **2** were fortuitously obtained as by-product from the reaction of **1** with CrCl$_3$ in wet THF. The two products were spectroscopically identical. **2**: ^{1}H NMR δ: 1.27 (d, |$^3J_{P-H}$| = 12 Hz, 27H, *t*-Bu). ^{13}C{^{1}H} NMR δ: 39.8 (d, |$^1J_{P-C}$| = 46 Hz, *t*-Bu), 30.5 (s, *t*-Bu). ^{31}P{^{1}H} NMR δ: 62.7. X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O$_2$-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1329 frames with 10 s exposure times (Table 1). The observed extinctions were consistent with the space groups in each case. The data sets were collected (4.5° < 2θ < 45–50.0°). A measure of decay was obtained by re-collecting the first 50 frames of each data set. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package operating on a Pentium computer.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (28). The heavy atom positions were determined using direct methods employing the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function ω $(|F_o| - |F_c|)^2$, where the weight ω is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases atoms were treated isotropically. C-H atom positions were calculated and allowed to ride on the carbon to which they are bonded, assuming a C—H bond length of 0.95 Å. H-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C-atom to which they are bonded. The H-atom contributions were calculated, but not refined. The locations of the largest peaks in the final difference Fourier map calculation, as well as the magnitude of the residual electron

densities in each case, were of no chemical significance. In the case of **2**, the relatively high *R* factor appears to reflect some degree of disorder in the *tert*-butyl group. The model presented represents the best solution we could obtain with the data. Additional details are provided in the supplementary data.[2]

Results and discussion

The Li salt of *t*-Bu$_3$PNH is readily prepared by reaction with an alkyl-lithium reagent (27). NMR data reflected clean conversion to a single species, **1**, although the degree of aggregation of this species in solution could not be determined spectroscopically. X-ray quality crystals of **1**·0.5C$_6$H$_{14}$ were obtained from hexane solution (Fig. 1). The structural solution revealed that **1** forms a tetramer of formulation [Li(μ-NP*t*-Bu$_3$)]$_4$, in which the phosphinimide N atoms bridge the Li centers. The Li—N distances vary from 2.025(4) to 2.066(4) Å. The Li and N atoms adopt a distorted cube (Fig. 2*a*). The Li(2), N(2), Li(1), and N(1) atoms are arranged with long (Li(2)—N(2) 2.065(4) Å, Li(1)—N(1) 2.066(4) Å) and short (Li(1)—N(2) 2.025(4) Å, Li(2)—N(1) 2.026(4) Å) distances. The remaining Li—N distances fall between 2.035 and 2.048 Å. Li-N-Li angles are similar, ranging from 72.82(16)°–73.57(15)°, while the N-Li-N angles fall between 103.91(17)° and 105.21(17)°. The P—N distances fall in the narrow range, from 1.5451(18) to 1.5505(18) Å. The P-N-Li angles fall into two ranges, from 140.88(16)° to 142.21(15)° and between 130.65(15)° and

137.07(15)°. The larger angles are distributed so as to minimize the steric congestion about the Li$_4$N$_4$ core.

Compound **1** is only the second species of general formula (LiNPR$_3$)$_n$ to be structurally characterized. It stands in contrast to the previous hexamers, [M(μ-NPPh$_3$)]$_6$ (M = Li (25), K (15), Na (16), Rb (13)), which were reported by Dehnicke's group. Presumably, the steric bulk in the present system precludes an expansion of the M–N core. In the case of the Li derivative [Li(μ-NPPh$_3$)]$_6$, a number of metric parameters are similar to those seen in **1**; however, the additional room about the core in [Li(μ-NPPh$_3$)]$_6$ (25) results in four of the Li—N distances being significantly shorter (1.983(8) Å) than those in **1**, while three Li-N-Li angles average 104.3(3)°, significantly greater than those seen in **1**. Such variations cannot be accommodated in **1**, as a result of the sterically bulky phosphinimide. This presumably ac-

counts for the lower degree of aggregation. The previously reported species $[M(\mu\text{-NPCy}_3)]_4$ (M = K, Cs) (14) also form tetranuclear structures. However, these compounds adopt distorted cubic geometries, with angles at M and N in these M_4N_4 cores that are closer to 90° than those in **1**. This, again, infers that the greater distortion of the Li_4N_4 core in **1** is a direct result of the steric demands of the $t\text{-Bu}_3PN$ groups.

The reaction of LiCl and the phosphinimine to give an LiCl adduct was performed. While spectroscopy inferred formation of a new material, **2**, X-ray quality crystals of the product **2** could not be obtained directly. Fortuitously, X-ray quality crystals of **2** were obtained as a by-product of the reaction of **1** and $CrCl_3$ in wet THF. X-ray analysis confirmed

the formulation of **2** as $[Li(\mu\text{-Cl})(HNP t\text{-Bu}_3)]_4$ (Fig. 3). Similarly, the species $[Li(\mu\text{-Cl})(HNPPh_3)]_4$ **3** (Fig. 4) was prepared by reaction of LiCl and $HNPPh_3$. In the case of **2**, the LiCl core of this molecule adopts a distorted cubic geometry (Fig. 2b). In **3**, crystallographic symmetry imposes twofold symmetry on the LiCl core (Fig. 2c).

Metric parameters are detailed in Table 2. In **2**, Li—Cl distances fall in the range from 2.35 to 2.466 Å with the exception of the Li(1)—Cl(4) distance, which is 2.55(2) Å, while in **3**, these distances are more uniform, ranging from 2.408(6) to 2.444(6) Å. While the Cl-Li-Cl and Li-Cl-Li angles in both compounds fall in the ranges from 94.9(6)° to 102.3(6)° and from 77.8(5)° to 83.4(7)°, respectively, it is generally observed that these ranges are broader for **2**, which

Fig. 3. ORTEP drawing of **2**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.
Fig. 4. ORTEP drawing of **3**; 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

is consistent with the steric issues arising from the bulkier phosphinimine. It is presumed that the dissymmetry of the core of **2** is an artifact of the phosphinimine ligand packing arrangement. This view is supported by the crystallographic symmetry seen in the less congested species **3**. Interestingly the Li—N distances in **2** range from 1.90(2) to 1.957(19) Å, while the Li—N distance in **3** is 1.852(5) Å. Both are shorter than those seen in **1**, presumably reflecting the terminal and

coordinate nature of the Li—N bonds in **2** and **3**. The P—N distances in **2** are similar to those seen in **1**, while the distances in **3** are significantly shorter, averaging 1.489(2) Å. This presumably reflects the lower basicity of the phenyl-substituted phosphinimine. The P-N-Li angles in **2** fall between 145.2(8)° and 149.6(9)°, while those in **3** were found to be 169.4(2)° and 159.5(2)°. The cause for these larger angles in **3** is unclear, although it may be that interactions between the phenyl rings among adjacent phosphinimines accounts for these distortions. The N-Li-Cl angles in both **2** and **3** vary widely, from 103.7(8)° to 128.9(9)°. While there is no pattern in the variations of these angles, it is noteworthy that in **2**, two of the three N-Li-Cl angles about Li(1) exceed 122°, consistent with the proximity of the long Li—Cl distance and the dissymmetry of the molecule.

These structural data for **1**–**3** infer that the proximity of four sterically demanding t-Bu$_3$PN or R$_3$PNH groups precludes higher degrees of aggregation and distortions in the Li$_4$X$_4$ (X = N, Cl) core geometry. The implications of these steric demands in the main group and transition metal chemistry of such bulky phosphinimides continues to be a focus of our interests.

The gas-phase reaction of the CF$_3$ radical with thiophene

Olga S. Herrera, Jorge D. Nieto, Silvia I. Lane, and Elena V. Oexler

Abstract: The reaction of CF$_3$ radicals, generated by photolysis of CF$_3$I or hexafluoroacetone with thiophene, was studied in the gas phase at 25 °C. At conversion of thiophene less than 20%, monosubstituted CF$_3$-thiophenes were found as the main reaction products, in addition to CF$_3$H, C$_2$F$_6$, and monosubstituted dihydro-CF$_3$-thiophene, the latter in very low proportion. An isomeric mixture of 2- and 3-CF$_3$-thiophene was obtained in a ratio of about 16, independent of the radical source used (CF$_3$I or hexafluoroacetone) to produce the CF$_3$ radicals. A plausible mechanism that accounts for the observed products is proposed, and the reactivity of thiophene toward the CF$_3$ radical at 25 °C was determined as $k_{add}/k_c^{1/2} = 106 \pm 4$ cm$^{3/2}$ mol$^{-1/2}$ s$^{-1/2}$.

Key words: thiophene, trifluoromethyl radical, reaction mechanism, reactivity.

Résumé : Opérant en phase gazeuse, à 25 °C, on a étudié la réaction du thiophène avec des radicaux CF$_3$ obtenus par photolyse du CF$_3$I ou de l'hexafluoroacétone. À des taux de conversion du thiophène inférieurs à 20%, les produits principaux obtenus en plus du CF$_3$H et du C$_2$F$_6$ sont les thiophènes monosubstitués par du CF$_3$ et les dihydrothiophènes monosubstitués par du CF$_3$ qui ne sont présent que dans de très faibles proportions. On obtient un mélange de 2- et de 3-trifluorométhylthiophènes présents dans un rapport d'environ 16 quelle que soit la source utilisée, CF$_3$I ou hexafluoroacétone, pour produire les radicaux. On propose un mécanisme plausible qui permet d'expliquer la formation des produits obtenus et on a déterminé que la réactivité du thiophène par rapport au radical CF$_3$, à 25 °C, est égale à $k_{add}/k_c^{1/2} = 106 \pm 4$ cm$^{3/2}$ mol$^{-1/2}$ s$^{-1/2}$.

Mots clés : thiophène, radical trifluorométhyle, mécanisme réactionnel, réactivité.

[Traduit par la Rédaction]

Introduction

The reactions of CF$_3$ radicals with unsaturated organic compounds such as olefins and aromatics in the gas phase have been the subject of a number of investigations (1). Kinetic parameters and mechanisms were, in most cases, rationalized via two major pathways, addition and abstraction.

To the best of our knowledge, however, very few studies have so far been undertaken of the reaction between CF$_3$ radicals and heteroaromatic compounds (2). In particular, with thiophene, the trifluoromethylation reaction was studied in the condensed phase using bis(trifluoroacetyl) peroxide (3), CF$_3$I, and Te(CF$_3$)$_2$ (4). In all cases the product yields were reported, monosubstituted CF$_3$-thiophenes being the main products obtained in good yields. Only with Te(CF$_3$)$_2$

was an addition product, monosubstituted dihydro-CF$_3$-thiophene, also reported.

In the gas phase, however, no studies have been undertaken of the reaction between CF$_3$ radicals and thiophene. To gain some insight into the distribution of the products, the reaction mechanism, and the reactivity of thiophene toward the CF$_3$ radical, we became interested in the study of this reaction, using the photolysis of CF$_3$I or HFA as CF$_3$ radical sources.

Results and discussion

Experiments were carried out at 25 °C; the CF$_3$ radicals were generated by the photolysis of CF$_3$I or HFA at $\lambda >$ 275 nm. Thiophene vapor has a weak absorption band starting at about 260 nm and becomes very strong below 240 nm (5). Therefore, under our experimental conditions, thiophene should not absorb. However, to ensure that there was no photolysis of thiophene, the spectral curve for the Corning glass filter employed was checked experimentally, and control photolysis experiments with neat thiophene were performed. Decomposition of thiophene was not observed.

The initial concentration of thiophene was varied between 2.42 and 15.1 × 10^{-7} mol cm^{-3}, while for the CF$_3$ radical sources, initial concentrations of 8.0 to 23.0 × 10^{-7} mol cm^{-3} and 5.09 to 10.8 × 10^{-7} mol cm^{-3} were used for CF$_3$I and HFA, respectively. Thus the molar ratio of thiophene:CF$_3$I or thiophene:HFA was always less than 2. Most of the experiments were performed at a conversion of thiophene lower

than 20%. Products analysis was performed after separation of the total content of the reaction cell by fractional condensation at –40 °C.

In the series of experiments carried out with CF_3I as the source of CF_3 radicals, the only products observed in the volatile fraction at –40 °C were CF_3H and C_2F_6, in addition to unreacted CF_3I.

In the heavier fraction analyzed by GC–MS, in addition to the unreacted thiophene, two isomers of monosubstituted CF_3-thiophene were separated and identified as 2- and 3-CF_3-thiophene. Monosubstituted dihydro-CF_3-thiophene was also found in very small proportion, as well as traces of 2-iodothiophene in the high-conversion runs. However, no other products, as from the addition of CF_3I to the double bond, were observed, in spite of an exhaustive search by GC–MS, even at high conversions. The colour of the heavier fraction, when it was condensed, showed clearly that iodine was also produced, but again no products from its addition reaction or the addition of I atoms to thiophene were observed. This was also confirmed experimentally by photolysis of I_2 in the presence of thiophene over periods much longer than those used in the actual experiments.

With HFA as the CF_3 radical source, the same products mentioned above — CF_3H, C_2F_6, monosubstituted CF_3-thiophenes, and monosubstituted dihydro-CF_3-thiophene — were found. We could not exclude that the CF_3CO radical is formed in the primary process when HFA is photolyzed, but several studies have shown that this radical is fairly unstable and rapidly decomposes by CO elimination (6, 7). In the present work, CO was detected by gas chromatography on a Molecular Sieves column, although its yield was not measured. However, even if CF_3CO radicals are formed, the data seem to indicate that they do not affect the reported measurements. Traces of a product, tentatively identified as disubstituted dihydro-CF_3-thiophene, were also observed in experiments at very high conversion but were practically absent in the series of experiments carried out with CF_3I.

The effect of variations of concentration of thiophene, CF_3I, or HFA and photolysis time on the yields of CF_3-thiophenes and the other products mentioned above are shown in Tables 1 and 2, respectively. Most of the runs were performed in triplicate to ensure that the separation procedure, previous to analysis, did not affect the precision of the results. Hence, the reported values of the yields are average values. Furthermore, a second series of runs carried out under the same experimental conditions but without fractional condensation at –40 °C was analyzed chromatographically on a Porapak T column, and the yields of CF_3H and C_2F_6 remained essentially unchanged within experimental error.

The total yield of (2+3)-CF_3-thiophenes shows a gradual increase with increasing concentration of thiophene employed. However, concentrations of thiophene higher than 5.0×10^{-7} mol cm^{-3} were not used because a light brown deposit, probably of a polymeric material, was observed on the wall of the reaction cell after several experiments with concentrations higher than 15.0×10^{-7} mol cm^{-3} had been carried out at high conversion. On the other hand, the separation of the reaction mixture into its components by GC on the SE 30 column was unsuccessful, largely because of the small difference in the retention times of 2- and 3-CF_3-thiophene with respect to thiophene.

Moreover, results in Table 2 also show that with HFA as the source of CF_3 radicals, the total yields of monosubstituted CF_3-thiophenes seem higher than with CF_3I (for the same thiophene concentration and photolysis time). This variation in measured yields would reflect a difference in efficiency of CF_3I or HFA as sources of CF_3 radicals.

One of the features worth noting in Tables 1 and 2 is the high ratio (~16) of 2-CF_3-thiophene : 3-CF_3-thiophene, regardless of the radical source. This evidence would support the well-known fact that the preferential position for electrophilic attack on thiophene is C_2 (8), also confirmed by computer charge density data of thiophene (9), which determined that the $C_2(C_5)$ positions are richer in electron density than $C_3(C_4)$.

It can also be observed in Tables 1 and 2 that in each run, the yield of CF_3H is practically equal to the total yield of (2+3)-CF_3-thiophene. While the yields of CF_3H increase with increasing concentrations of thiophene, the C_2F_6 yields decrease.

Figure 1 shows that a plot of $R_{CF_3H}/R_{C_2F_6}^{1/2}$ (R denotes rate of formation) against [thiophene], of the data points up to 20% conversion, is a straight line with a zero intercept and with a slope equal to 106 ± 4 cm$^{3/2}$ mol$^{-1/2}$ s$^{-1/2}$, irrespective of the source of CF_3 radicals (CF_3I or HFA) and also at different concentrations of these compounds.

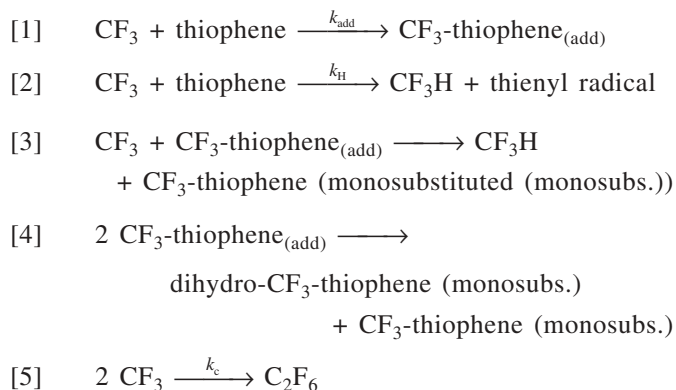
On account of these results, the following could be considered to be the main steps of the reaction mechanism for the reaction of the CF_3 radicals produced by the photolysis of CF_3I or HFA with thiophene:

[1] $CF_3 + \text{thiophene} \xrightarrow{k_{add}} CF_3\text{-thiophene}_{(add)}$

[2] $CF_3 + \text{thiophene} \xrightarrow{k_H} CF_3H + \text{thienyl radical}$

[3] $CF_3 + CF_3\text{-thiophene}_{(add)} \longrightarrow CF_3H$
        $+ CF_3\text{-thiophene (monosubstituted (monosubs.))}$

[4] $2\ CF_3\text{-thiophene}_{(add)} \longrightarrow$
        dihydro-CF_3-thiophene (monosubs.)
                    $+ CF_3\text{-thiophene (monosubs.)}$

[5] $2\ CF_3 \xrightarrow{k_c} C_2F_6$


Other reactions, such as the self-combination of CF_3-thiophene$_{(add)}$ or $CF_3 + CF_3$-thiophene$_{(add)}$ to give disubstituted dihydro-CF_3-thiophene, could also be included in this mechanism for the purpose of completeness. However, the products of these combination reactions were not found; only trace amounts of disubstituted dihydro-CF_3-thiophene were detected when HFA was used as the CF_3 radical source, as mentioned previously.

According to the reaction scheme, the formation of CF_3H could take place by the H-abstraction reaction, eq. [2], and by the pseudo-H-abstraction reaction, eq. [3], the latter equivalent to that proposed in the gas-phase reactions of CF_3 radicals with benzene (10) and substituted benzenes (11, 12) for the formation of CF_3H and CF_3-benzenes. In these, as well as in the present study, the concentrations of the substrates used were low, thus ensuring that the concentration of CF_3 radicals is large enough for the reaction described by eq. [3] to occur, at variance with what has been argued for

these reactions in the liquid phase, where pseudo-abstraction is unlikely to proceed (13).

In the absence of any extra production of CF_3H by reactions other than those described in eqs. [2] and [3], the rate of formation of CF_3H would be:

[6] $\quad R_{CF_3H} = k_H[CF_3][thiophene]$
$$+ k_3[CF_3][CF_3\text{-thiophene}_{(add)}]$$

Taking into account that monosubstituted dihydro-CF_3-thiophene was produced, to the extent of about 1% of the (2+3)-CF_3-thiophenes, the disproportionation reaction,

eq. [4], would be an unimportant channel for the formation of monosubstituted CF_3-thiophenes. Therefore, this reaction, eq. [4], which also consumes the adduct formed in the addition step in eq. [1], could be considered negligible, so that
[7] $\quad k_3[CF_3][CF_3\text{-thiophene}_{(add)}] \approx$
$$k_{add}[CF_3][thiophene]$$

and the rate of formation of CF_3H can be made approximately equal to

[8] $\quad R_{CF_3H} \approx (k_H + k_{add})\,[CF_3][thiophene]$

Fig. 1. Plot of $R_{CF_3H}/R_{C_2F_6}^{1/2}$ as a function of [thiophene] at 25 °C, of the data points up to 20% conversion. □ CF$_3$I, ~10 × 10^{-7} mol cm^{-3}; ■ CF$_3$I, ~23 × 10^{-7} mol cm^{-3}; ○ HFA, ~10 × 10^{-7} mol cm^{-3}.

Taking into account that

[9] $\qquad R_{C_2F_6}^{1/2} = k_c^{1/2}[CF_3]$

a simple expression can be found for the relative rate of formation of CF$_3$H

[10] $\qquad R_{CF_3H}/R_{C_2F_6}^{1/2} \approx \{(k_H + k_{add})/k_c^{1/2}\}[\text{thiophene}]$

A plot of $R_{CF_3H}/R_{C_2F_6}^{1/2}$ as a function of [thiophene], shown in Fig. 1, gives a straight line with zero intercept, which is indicative that eq. [10] holds, and thus, $(k_H + k_{add})/k_c^{1/2}$ may be related to the observed value 106 ± 4 cm$^{3/2}$ mol$^{-1/2}$ s$^{-1/2}$ obtained from the slope of Fig. 1 at 25 °C.

To evaluate the contribution made by the endothermic H-abstraction reaction, eq. [2],

$$CF_3 + \text{thiophene} \xrightarrow{k_H} CF_3H + \text{thienyl radical}$$
toward the formation of CF$_3$H, we calculated the activation energy and the pre-exponential factor for the H-abstraction reaction, eq. [2], applying the bond-strength–bond-length (BSBL) – transition-state-theory method, developed by Bérces and Dombi (14), based on the bond-energy–bond-order (BEBO) method. With this treatment, good results have been obtained for the estimation of the kinetic parameters for metathesis reactions involving unsaturated reaction centers. The BSBL reaction profile for the H-abstraction reaction was calculated along the reaction path, and the maximum value of the potential energy — that is, the potential activation energy and, consequently, the transition state — occurs in a late stage of the reaction, as expected for an endothermic process. The pre-exponential factor and the activation energy were estimated by considering that the activated complex is well represented by a linear five-mass-point model.

The following expression for k_H was obtained:

[11] $\qquad k_H = 5.5 \times 10^{11} \exp[-(5150) K/T]$ (cm^3 mol^{-1} s^{-1})

The rate constant for CF$_3$ recombination, k_c, has been measured near room temperature by various workers using different techniques, and the reported values (1) show more than an order of magnitude variation, ranging from about 1.3×10^{12} to 2.4×10^{13} cm^3 mol^{-1} s^{-1}. Thus, the rate constant at 25 °C for the H-abstraction reaction from thiophene relative to $k_c^{1/2}$ would be approximately a factor of 10^2–10^3 lower than $k_{add}/k_c^{1/2}$. Therefore, the disproportionation reaction, eq. [3], could be considered the main step for the production of CF$_3$H, and so the value of 106 ± 4 cm$^{3/2}$ mol$^{-1/2}$ s$^{-1/2}$ could be assigned to $k_{add}/k_c^{1/2}$.

As far as we know, insufficient data are available in the gas phase for the reactions of CF$_3$ radicals with aromatic and heteroaromatic compounds to allow any detailed comparisons. Moreover, the reported data are relative values of the rate constants. Absolute rate constants have only been reported for reactions of CF$_3$ radicals with alkenes in the gas phase (15) and in solution (16). However, we could compare the reactivity of thiophene toward CF$_3$ radicals with other nonsaturated compounds, alkenes such as ethene and butadiene, and aromatics such as benzene.

The values of $k_{add}/k_c^{1/2}$ for the addition reactions of CF$_3$ to the foregoing compounds are displayed in the first column of Table 3 for comparison purposes. The data obtained in this work indicate that the reactivity of thiophene towards CF$_3$ radical addition is intermediate between the olefins and benzene. A similar sequence in reactivity is observed in the reactions of these compounds with the electrophilic OH radical. This trend may reflect the effects of the resonance stabilization energies (resonance stabilization energies are ~138–151 kJ mol^{-1} for benzene, ~92 kJ mol^{-1} for thiophene, and ~15 kJ mol^{-1} for 1,3-butadiene (20)), indicating that resonance stabilization decreases the reactivity of the double bonds toward CF$_3$ radical addition, as has been pointed out previously by Atkinson et al. (21) for the OH addition to the same compounds.

We conclude that, for the reaction of CF$_3$ radicals and thiophene in the gas phase at 25 °C, the formation of the monosubstituted products, 2- and 3-CF$_3$-thiophene, can be explained through a similar mechanism to that proposed for other aromatic compounds (benzenes and halobenzenes) involving the addition of the CF$_3$ radical to thiophene followed preferentially by the subsequent disproportonation reaction. The addition rate constant is intermediate between that of the olefins and benzene.

Experimental section

The high-vacuum apparatus employed was similar to that described in ref. 12. Briefly, the photolysis experiments were carried out in a cylindrical quartz cell ($V = 109$ cm^3) connected through Teflon valves to a conventional grease-free vacuum line and storage traps, with the reactants kept at liquid N$_2$ temperature.

The light source was an Osram HBO 500 W high-pressure mercury lamp. A Corning Pyrex Glass Plate 7740 (2 mm thick) was used to remove wavelengths lower than 275 nm (22).

[d]This work.
[e]Extrapolated value calculated at 25 °C using the activation parameters reported in ref. 10.

In a typical experiment, the gaseous reactants were introduced into the evacuated reaction vessel, and pressures were measured. After a period of irradiation the reaction vessel contents were immediately collected in a trap cooled in liquid N_2 and separated by fractional distillation at –40 °C. In some experiments the volatile portion at this temperature was distilled into an evacuated gas chromatograph sample loop and passed through a 2 m column packed with Porapak T 80/100 mesh at 40 °C. Product samples were collected downstream for IR and MS identification. CF_3H and C_2F_6 were identified by comparison of their GC retention times and their IR and MS spectra with authentic samples. Known concentrations of the appropriate standards were used for calibration purposes.

The residue remaining at –40 °C was analysed by GC–MS using a capillary column (0.32 mm i.d. × 30 m, SE-30). To build up a sufficient amount of some of the products for identification, special preparative photolyses were carried out, generally at higher conversion. Mass spectrometry analysis (GC–MS) gave the theoretical parent mass for 2- and 3-CF_3-thiophene at m/z = 152 (23), for dihydro-CF_3-thiophene at m/z = 154, and for 2-iodothiophene at m/z = 210 (24).

Control experiments at room temperature in the dark showed that no product formation occurred thermally under standard reaction conditions, not even in periods 2–3 times longer than the usual irradiation times.

Infrared spectra were recorded using a Nicolet 55X FT infrared spectrometer and mass spectra were obtained with a Finnigan 3300 instrument and a PerkinElmer QM 910 GC–MS.

Thiophene, CF_3I, and HFA, as well as the reference compounds CF_3H, C_2F_6, and 2-iodothiophene, were obtained commercially and were trap-to-trap distilled in a vacuum line, several times, and thoroughly degassed prior to use. Their purity was checked by IR spectroscopy and GC–MS.

Oxazoline chemistry — Part IV: Synthesis and characterization of oxazoline complexes of the zinc halides[1]

Tosha M. Barclay, Ignacio del Río, Robert A. Gossage, and Sarah M. Jackson

Abstract: The synthesis and characterization of 11 zinc halide derivatives that contain monodentate oxazoline ligands is described. The treatment of ether solutions of $[ZnX_2]$ (X = Cl, Br, I) with 2-aryl- or 2-methyl-2-oxazolines results in the formation of mildly hygroscopic complexes of the general formulae $[ZnX_2(ox)_2]$ (ox = 2-methyl-2-oxazoline (**1**), 2,4,4-trimethyl-2-oxazoline (**2**), 2-phenyl-2-oxazoline (**3**), or 4,4-dimethyl-2-phenyl-2-oxazoline (**4**)), except in the case of ZnI_2, which does not form an isolable complex — likely for steric reasons — with oxazoline **4**. Treatment of $[ZnBr_2(4)_2]$ with **1** reveals (^{1}H NMR) that **1** only sluggishly displaces coordinated **4** at temperatures below 50 °C. The structural characterization, via single crystal X-ray diffraction, of six of the complexes, viz. $[ZnI_2(1)_2]$, $[ZnI_2(2)_2]$, $[ZnX_2(3)_2]$ (X = Cl, Br, or I), and $[ZnBr_2(4)_2]$, is also reported. All of these structurally characterized complexes are mononuclear zinc compounds with an overall distorted tetrahedral arrangement of the two halide and two oxazoline ligands around the zinc metal centre. The oxazoline series of complexes reported herein show little structural diversity, a facet which is in contrast to their substituted pyridine analogues.

Key words: oxazoline, zinc, X-ray crystal structure, coordination complex, NMR spectroscopy, Zn(II).

Résumé : On décrit la synthèse et la caractérisation d'onze dérivés d'halogénures de zinc contenant des ligands oxazolines monodentates. Le traitement de solutions éthérées de $[ZnX_2]$ (X = Cl, Br, I) avec des 2-aryl- ou 2-méthyl-2-oxazolines conduit à la formation de complexes faiblement hygroscopiques de formule générale $[ZnX_2(ox)_2]$ (ox = 2-méthyl-2-oxazoline [**1**], 2,4,4-triméthyl-2-oxazoline [**2**], 2-phényl-2-oxazoline [**3**] ou 4,4-diméthyl-2-phényl-2-oxazoline [**4**]); exceptionnellement, la réaction ZnI_2 avec l'oxazoline **4** ne conduit pas à la formation d'un complexe isolable, probablement en raison d'un encombrement stérique. La RMN du ^{1}H montre que le traitement du $[ZnBr_2(4)_2]$ avec **1**, à des températures inférieures à 50 °C, montre que le déplacement de **4** ne se fait que très difficilement. On rapporte aussi la caractérisation par diffraction des rayons X de six de ces complexes, soit $[ZnI_2(1)_2]$, $[ZnI_2(2)_2]$, $[ZnX_2(3)_2]$ (X = Cl, Br ou I) et $[ZnBr_2(4)_2]$. Tous les complexes dont la structure a été caractérisée sont des composés mononucléaires du zinc comportant un arrangement global tétraédrique déformé de deux halogènes et de deux ligands oxazoline autour du zinc central. La série de complexes avec des oxazolines qui est rapportée ici ne présente que de faibles variations structurales; cette caractéristique est en opposition avec ce qui a été observé avec leurs analogues comportant des pyridines substituées.

Mots clés : oxazoline, zinc, structure cristalline par diffraction des rayons X, complexe de coordination, spectroscopie RMN, Zn(II).

[Traduit par la Rédaction]

Introduction

The chemistry of zinc is one of the cornerstones of inorganic biochemistry (1). The element is characterized by the high stability of the +2 oxidation state and by the numerous examples of robust four-, five-, and six-coordinate zinc complexes (2, 3). The high Lewis acid character of the d^{10} Zn^{2+} ion leads to the formation of many stable compounds with *N*-donor ligands, including heterocycles such as pyridines (py), imidazoles, pyrazines, oxazoles, and others (3–8).

Zinc complexes are also part of a burgeoning network of bio-active and (or) pharmaceutical inorganic compounds (9),

and even simple solutions of Zn^{2+} ions or $[Zn(N\text{-donor})_x]^{2+}$ complexes have a number of noteworthy biological activities (10). For example, $[ZnCl_2(H_2N^iPr)_2]$ has recently been shown to prolong (i.e., stabilize) the potency of enzymes in aqueous media (11). The presence of zinc ions can also increase the potency of certain biologically active compounds, such as the enzyme inhibitory effect of bis(5-amidino-2-benzimidazolyl)methane (BABIM). This enhancement has been shown to be due to the binding of a [Zn(BABIM)] complex into the active site of a protease enzyme (12a). Recently, zinc complexes of neocuprine, a phenanthroline derivative, have been shown to be site-specific RNA cleavage agents (12b). Related simple Zn coordination complexes have also shown promise in the treatment of diabetes (12c, 12d).

In direct relation to this study is the hypothesis that oxazoline-containing drug candidates (12e) such as 4-carbomethoxy-2-phenyl-2-oxazoline (viz., **L-573,655**: Fig. 1) inhibit lipid A biosynthesis by coordination with an enzyme-bound Zn atom (i.e., a Zn–oxazoline complex is formed with **L-573,655**; refs. 12f–12i). As part of a larger study concerning the coordination and medicinal chemistry of zinc (13) and oxazoline (i.e., 4,5-dihydro-2-oxazole) ligands in general (14),[5] we have undertaken a study of simple monodentate oxazolines (**1–4**: Fig. 1) as ligands for binding to the zinc halides. In this report, we detail the synthesis and characterization (NMR and X-ray analyses, etc.) of a series of Zn halide complexes that incorporate monodentate 2-oxazoline (15) derivatives. A further reason for this investigation is the knowledge that zinc halides are commonly used as catalysts to form oxazolines via treatment of organic cyanides with amino-alcohols (14c). A possible by-product of this procedure is an oxazoline–Zn complex, and hence, we wanted to begin a general investigation of such species.

Results and discussion

Syntheses and spectroscopic characterization

The treatment of ether solutions (or suspensions) of the zinc halides (ZnX_2; X = Cl, Br, or I) with an excess of a 2-oxazoline (Fig. 1) leads to rapid formation of isolable white precipitates. A sole exception to this observation is the reaction of ZnI_2 with oxazoline **4**; this particular reaction invariably leads to the formation of oily inextractable mixtures, from which no pure compounds could be obtained. Metathesis reactions, involving exchange of Br or NO_3 anions with I^- sources, were likewise unsuccessful. The aforementioned isolated materials are moderately hygroscopic, a property that is more pronounced with the 2-methyl oxazoline complexes (i.e., **5–10**) when compared with the 2-phenyl derivatives **11–15**. All compounds decomposed on melting in air to form colourless oils. The initial isolated materials in all cases are white powders; crystalline samples, obtained as described in the Experimental section, are clear and colourless but darken over several weeks in air.

Fig. 1.
Examination of **5–15** by elemental analysis measurements are, in all cases, consistent with the formation of complexes of general formula $[Zn_nX_{2n}(\text{oxazoline})_{2n}]$ (i.e., 2:1 ligand:ZnX_2 species). Characterization of these complexes by ^{1}H NMR spectroscopy reveals the presence of a single oxazoline ligand environment. Further to this, the ^{1}H NMR resonances for the presumably coordinated oxazolines are shifted relative to that of the free ligands,[6] a situation that is mimicked by observation of a decrease in the $\nu(C{=}N)$ IR stretching frequencies of the oxazoline for the complexes, as expected. Specifically, all ^{1}H NMR chemical shifts of complexes incorporating **1** are notably deshielded relative to the free ligand form,[6] an observation consistent with donation of electron density from the ligand to the Lewis acidic Zn centre. Complexes of **2** show a similar trend; however, the methyl resonances on C-2 of the oxazoline are notably shielded relative to free **2**. This suggests that this methyl group is forced to be in close proximity to the metal centre, likely because of steric effects of the methyl substituents on C-4 (vide infra). In the case of ligands **3** and **4**, shifts are less pronounced relative to the free ligands, although the methylene protons of **3** show a small shift (positive in the case of the Br and I derivatives and negative for the Cl) upon coordination.

Zinc halides are often employed as catalysts for the synthesis of 2-oxazolines via treatment of an alkyl or aryl cyanide with an appropriate amino-alcohol at elevated temperatures (14c, 15, 16). With this in mind, it seems feasible that Zn–oxazoline complexes may also be produced as by-products in these reactions. We have taken a cursory look at the stability of some of these species by a simple metathesis reaction. Treatment of complex **15** in an NMR tube with 2 equiv of **1** and maintenance at room temperature (RT) for a period of 1 day does not result in any loss of signal intensity of **15**, nor presence of any form of an intermediate, and

Fig. 2. ORTEP representation of complex **7**.
no evidence for the formation of complex **5**. Heating this mixture for 12 h at about 50 °C results in only a small amount (<10%) of **5** being detected. These results indicate a robust nature of these materials, and it seems that only by treating with a large excess of water, as is typically done in the synthesis of ligands **1**–**4** employing Zn halides (14c, 15, 16), are the free oxazolines released. This is also suggested by the relatively hygroscopic nature of these complexes, a property that is a likely cause of our inability to obtain a reproducible elemental analysis in the case of complex **14**.

Solid-state (crystal) structures

   Zinc halides are well known to react with *N*-donor compounds to form mononuclear complexes with an overall distorted tetrahedral disposition of ligands around the Zn atom. For example, $ZnCl_2$ forms simple complexes of the general formulae [$ZnCl_2(N)_2$] with *N* = py, 4-(vinyl)py, 4-(NC)py, 4-(acetyl)py, 3,4,5-Cl_3py, 3-(F_3C)py, and 4-(Me)py (17). However, a number of interesting polymeric materials are formed (3, 6, 17a) with other pyridine derivatives. For example, both 3,5-Cl_2py and 3,5-Br_2py form polymeric complexes with $ZnCl_2$ (i.e., [$Zn(\mu$-$Cl)_2$(3,5-Xpy)_2$]_∞$) in which the Zn atom is in an octahedral coordination geometry. Linear (and tetrahedral at Zn) bridged species are formed with 4,4′-bipy and $ZnCl_2$ (i.e., [$ZnCl_2$(4,4′-bipy)]_∞), but Magnus-type salts (i.e., [Zn([MeO]_2py)_4$]$^{2+}$ [Zn_2Br_6]$^{2-}$) can be formed by treating $ZnBr_2$ with 2,6-(MeO)_2-py (17a).

   There is currently a dearth of structural information on *monodentate* oxazoline complexes (15), despite the fact that the coordination chemistry of bis-oxazolines and cyclo-

metallated (i.e., η^2-*N,C*) 2-aryl-2-oxazolines has been the subject of numerous studies (15). To our knowledge, there is no structural data of any Zn halide complex with a monodentate oxazoline; hence, we felt a structural investigation of this class of materials was in order. Thus, we have carried out single crystal X-ray structure analysis of six of the complexes (**7**, **10**–**13**, and **15**) synthesized herein. In addition, there are very few structurally characterized [ZnI_2(*N*-donor)$_n$] complexes (18–20), and thus the characterization of three (**7**, **10**, and **13**) such derivatives will help to expand the structural database on this class of ZnI_2 coordination compounds.

   The molecular structures of complexes **7**, **10**–**13**, and **15** can be found in Figs. 2–7, respectively, and the general crystal data can be found in Tables 1 and 2.

   All six complexes are mononuclear species in the solid state with an approximate tetrahedral array of the two halide and two oxazoline ligands around the metal centre. As expected, the binding of the oxazoline fragment is, in all cases, via coordination of the imine *N*-atom of the heterocyclic ring (15). Comparative examples of related structurally characterized Zn oxazolines are few (21–24) but include complexes such as [η^2-*N,N′*-(1,2-bis{4*S*-4-isopropyl-2-oxazolin-2-yl}benzene} zinc(II) chloride] (21). The bond lengths between Zn and the donor ligands for complexes **7**, **11**–**13**, and **15** are in the range typical (3–8, 15–25) for Zn—N and Zn—X bonds (Table 2). These data can be compared with, for example, the halide complexes (4c, 17a, 18b) [$ZnCl_2$(4-Me-py)$_2$] (Zn—N_{av} = 2.044 Å; Zn—Cl_{av} = 2.208 Å), [$ZnBr_2$(3-CF_3-py)$_2$] (Zn—N = 2.084 Å; Zn—Br = 2.375 Å),

Fig. 3. ORTEP representation of complex **10**.
Fig. 4. ORTEP representation depicting both molecules of complex **11** found in the unit cell.
and [ZnI$_2$(2-amino-2-thiazole)$_2$] (**17**: Zn—N$_{av}$ = 2.023 Å; Zn—I$_{av}$ 2.384 Å). Complex **10** is perhaps the most unusual of the set, as it displays Zn—I bonds that are at the upper range of known Zn—I bond lengths (cf. **17**). Similar long Zn—I bonds are found (18*a*) in the complex [ZnI$_2$(η^2-*N*,*N*′-{C$_5$H$_4$N}$_3$N)] (**18**). The reason for the long bonds found here may be because of steric effects imposed on the large I atoms relative to tightly bound oxazoline **2** (26). Note that this particular fragment contains two sterically bulky methyl substituents on carbons (labelled) C4 and C10 (Fig. 3) of the oxazoline ring. This structure sheds some light on the observed solution properties that involve the shielding of the

proton resonances (vide supra) of the methyl group (C1). The Zn1—C1 and C7 distances are 3.43 and 3.38 Å, respectively. The I-Zn-I angles (Table 2) of **10** and **13** are considerably narrower than that of **18** (117.48(3)°) but similar to that found in the complexes [ZnI$_2$(Bps^{Me2})] (113.48(5)°; Bps^{Me2} = [bis(3,5-dimethylpyrazolyl)dimethylsilane]), [ZnI$_2$(C$_6$H$_{12}$N$_4$)$_2$] (111.5(1)°), and [ZnI$_2$(3,5-[^{t}Buph]$_2$pzH)$_2$] (112.2(1)°), all of which have sterically demanding *N*-donor ligands (19, 20*a*, 20*b*). Complexes **11** and **12** both contain two unique molecules of the complex in the unit cell. The main differences between these molecules is the torsion angles between the phenyl group formally on C-2 and the

Fig. 5. ORTEP representation depicting both molecules of complex **12** found in the unit cell.

[a]Refers to the formal N=C of the oxazoline ligands containing N1.
[b]Two distinct molecules in the unit cell; values given for Zn1 complex only (see Supplementary data).
[c]Symmetry code = $-x - 1/2$, $-y + 1/2$, z.

Conclusions

The treatment of ether solutions of ZnX_2 with oxazolines **1–4** results in the formation of mildly hygroscopic mononuclear bis-oxazoline complexes, except in the case of X = I *and* oxazoline **4**. Six derivatives have been characterized by single crystal X-ray diffraction. These materials represent the first series of mononuclear oxazoline complexes of Zn^{2+} to be fully characterized. The medicinal properties of these materials are currently under investigation and will be reported in a separate disclosure.

Experimental

General

All reactions were carried out in air, using commercially available, reagent-grade solvents. Zinc halides and ligands **1–4** (Fig. 1) were purchased commercially and used as received, with the exception of $ZnCl_2$. This material was dried by heating thrice to the melt under vacuum (approximately (approx.) 2000 Pa), and then the solid was cooled to RT under an atmosphere of dry argon gas. THF was stored over

4 Å molecular sieves. ^{1}H NMR spectra ($CDCl_3$ solution) were recorded at RT using a Bruker AC-250 NMR spectrometer located at the Atlantic Regional Magnetic Resonance Centre (ARMRC) (Halifax, N.S., Canada), operating at 250 MHz, or were recorded using a Bruker Avance 300 NMR spectrometer located at the Acadia Centre for Microstructural Analysis (ACMA) (Wolfville, N.S., Canada), operating at 300 MHz. Chemical shifts are reported in ppm using TMS (and (or) residual solvent resonance) as internal standard ($\delta_{TMS} = 0.00$ ppm). Coupling constants are reported in Hertz. IR spectra were recorded as nujol muls (except where noted) on a PerkinElmer 683 or 283B IR spectrometer; reported values are in units of cm^{-1}. Melting points were recorded in air on a Mel-Temp II apparatus and are uncorrected. Elemental analyses measurements were performed at the Lakehead University Centre for Analytical Services (LUCAS) located in Thunder Bay, Ont., Canada.

Synthesis of [dichlorobis{η^1-*N*-(2-methyl-2-oxazoline)}zinc] (5)

Solid zinc chloride (4.2 g, 31 mmol) was dissolved in 150 mL of diethylether by stirring the mixture at RT for

15 min. This mixture was then filtered to remove any undissolved material. To the rapidly stirring (clear and colourless) solution was added (via syringe) 8.0 mL (94 mmol) of **1** in a single portion. A white precipitate began to form almost immediately. Stirring was continued for a further 12 h at RT, and the resulting solid was isolated by filtration. This material was then washed thrice with Et$_2$O (35 mL) and then allowed to dry in air. Yield 8.0 g (84%) of a white, slightly hygroscopic solid. Crystals of **5**, suitable for X-ray diffraction, grew after a CH$_2$Cl$_2$ solution of **5**, layered with Et$_2$O, was left standing for several days at RT. mp > 105 °C (decomposition temperature (decomp.)). IR: 1650 (st). ^{1}H NMR (250 MHz) δ: 4.50 (t, 2H, J = 9.8, CH_2O), 3.98 (t, 2H, J = 9.8, CH_2N), 2.27 (s, 3H, CH_3). Calcd. for C$_8$H$_{14}$N$_2$O$_2$Cl$_2$Zn·(H$_2$O) (%): C 29.72, H 4.55, N 8.67; found: C 29.72, H 4.97, N 8.63.

Synthesis of [dibromobis{η^1-*N*-(2-methyl-2-oxazoline)}zinc] (6)

In a reaction analogous to that used to produce **5**, zinc bromide (1.0 g, 4.4 mmol) in Et$_2$O was treated with **1** (2.1 equiv). Yield 1.6 g (92%, hygroscopic solid). mp > 72 °C (decomp.). IR: 1650 (st). ^{1}H NMR (250 MHz) δ: 4.50 (t, 2H, J = 9.8, CH_2O), 4.00 (t, 2H, J = 9.8, CH_2N), 2.29 (s, 3H, CH_3). Calcd. for C$_8$H$_{14}$N$_2$O$_2$ZnBr$_2$·0.5(H$_2$O): C 23.76, H 3.74, N 6.93; found: C 23.53, H 3.63, N 6.85.

Synthesis of [diiodobis{η^1-*N*-(2-methyl-2-oxazoline)}zinc] (7)

As for **5**, zinc iodide (3.0 g, 9.4 mmol), suspended in Et$_2$O–THF (60 mL : 10 mL), was treated with 2.4 mL (28 mmol) of **1**. Yield 4.0 g (87%, hygroscopic white solid). Crystals, suitable for X-ray diffraction, were grown from a solution of **3** (CH$_2$Cl$_2$ layered with Et$_2$O) that had been left standing at RT for several days. mp > 94 °C (decomp.). IR: 1650 (st). ^{1}H NMR (250 MHz) δ: 4.50 (t, 2H, J = 9.8, CH_2O), 4.02 (t, 2H, J = 9.8, CH_2N), 2.29 (s, 3H, CH_3). Calcd. for C$_8$H$_{14}$N$_2$O$_2$ZnI$_2$·0.25(H$_2$O): C 19.45, H 2.96, N 5.67; found: C 19.21, H 2.76, N 5.57.

Synthesis of [dichlorobis{η^1-*N*-(2,4,4-trimethyl-2-oxazoline)}zinc] (8)

As for **5**, zinc chloride (1.2 g, 8.8 mmol) in Et$_2$O was treated with **2** (2.2 mL, 17 mmol), and the solid was washed with Et$_2$O (2 × 35 mL) and petroleum ether (50 mL); the product can be further recrystallized from a 1:1 mixture of CH$_2$Cl$_2$–Et$_2$O. Yield 2.0 g (65%). mp > 124 °C (decomp.). IR: 1635 (st). ^{1}H NMR (250 MHz) δ: 4.17 (s, 2H, CH_2O), 2.27 (s, 3H, N=C-CH_3), 1.61 (s, 6H, CH_3). Calcd. for C$_{12}$H$_{22}$N$_2$O$_2$Cl$_2$Zn·0.5(CH$_2$Cl$_2$): C 37.06, H 5.72, N 6.92; found: C 37.29, H 5.86, N 6.92.

Synthesis of [dibromobis{η^1-*N*-(2,4,4-trimethyl-2-oxazoline)}zinc] (9)

As for **5**, using ZnBr$_2$ (1.4 g, 6.2 mmol; ether suspension) and **2** (1.7 mL, 13 mmol). Yield 2.7 g (96%). mp > 172 °C (decomp.). IR: 1625 (st). ^{1}H NMR (250 MHz) δ: 4.18 (s, 2H, CH_2O), 2.29 (s, 3H, N=C-CH_3), 1.68 (s, 6H, CH_3). Calcd. for C$_{12}$H$_{22}$N$_2$O$_2$Br$_2$Zn: C 31.92, H 4.91, N 6.20; found: C 32.16, H 4.59, N 6.21.

Synthesis of [diiodobis{η^1-*N*-(2,4,4-methyl-2-oxazoline)}zinc] (10)

As for **5**, ZnI$_2$ (3.3 g, 10 mmol; ether suspension) was treated with **2** (2.7 mL, 21 mmol). Yield 4.9 g (90%). Crystals, suitable for X-ray diffraction, grew from a sealed solution of **10** (CH$_2$Cl$_2$) layered with Et$_2$O, after standing at RT for several days. mp > 159 °C (decomp.). IR: 1630 (st). ^{1}H NMR (250 MHz) δ: 4.17 (s, 2H, CH_2O), 2.27 (s, 3H, N=C-CH_3), 1.61 (s, 6H, CH_3). Calcd. for C$_{16}$H$_{18}$N$_2$O$_2$ZnI$_2$ (%): C 26.42, H 4.06, N 5.14, found: C 26.27, H 3.86, N 5.02.

Synthesis of [dichlorobis{η^1-*N*-(2-phenyl-2-oxazoline)}zinc] (11)

As for **5**, ZnCl$_2$ (2.0 g, 15 mmol) in Et$_2$O (125 mL) was treated with **3** (3.9 mL, 30 mmol), and the resulting white solid was washed with Et$_2$O (2 × 15 mL) and then air-dried. Yield 4.77 g (74%). mp > 179 °C (decomp.). IR: 1618 (st). ^{1}H NMR δ: 7.78 (d, 2H, J = 7.5, ArH), 7.61 (t, 1H, ArH), 7.41 (t, 2H, J = 7.6, ArH), 4.33 (m, 4H, CH_2CH_2). Calcd. for C$_{16}$H$_{18}$N$_2$O$_2$Cl$_2$Zn: C 50.20, H 4.21, N 6.51; found: C 50.47, H 4.26, N 6.68.

Synthesis of [dibromobis{η^1-*N*-(2-phenyl-2-oxazoline)}zinc] (12)

As for **5**, ZnBr$_2$ (2.1 g, 9.3 mmol) in Et$_2$O (100 mL) was treated with **3** (2.5 mL, 19 mmol), and the solid was washed with Et$_2$O (2 × 15 mL) and then air-dried. Yield 4.71 g (48%). mp > 170 °C (decomp.). IR: 1620 (st). ^{1}H NMR δ: 7.76 (d, 2H, J = 8.0, ArH), 7.58 (t, 1H, ArH), 7.35 (t, 2H, J = 7.9, ArH), 4.47 (m, 4H, CH_2CH_2). Calcd. for C$_{16}$H$_{18}$N$_2$O$_2$ZnBr$_2$: C 41.61, H 3.49, N 5.39; found: C 41.66, H 3.49, N 5.30.

Synthesis of [diiodobis{η^1-*N*-(2-phenyl-2-oxazoline)}zinc] (13)

As for **5**, ZnI$_2$ (1.4 g, 4.4 mmol) was suspended in Et$_2$O (25 mL), and the mixture was then treated with **3** (1.1 mL, 8.4 mmol), and the light yellow solid was washed with Et$_2$O (2 × 10 mL) and then air-dried. Yield 2.55 g (99%). mp > 193 °C (decomp.). IR: 1620 (st). ^{1}H NMR δ: 7.76 (d, J = 7.9, 2H, ArH), 7.61 (t, 1H, ArH), 7.38 (t, 2H, J = 8.0, ArH), 4.43 (m, 4H, CH_2CH_2). Calcd. for C$_{16}$H$_{18}$N$_2$O$_2$ZnI$_2$ (%): C 35.24, H 2.96, N 4.57; found: C 34.90, H 2.97, N 4.43.

Synthesis of [dichlorobis{η^1-*N*-(4,4-dimethyl-2-phenyl-2-oxazoline)}zinc] (14)

A sample of ZnCl$_2$ (2.25 g, 16.5 mmol) was dissolved in 100 mL of Et$_2$O, and the solution was then filtered. Compound **4** (5.6 mL, 33 mmol) was added, and the mixture was then stirred at RT for 2 h. The resulting white solid was collected by filtration and washed with Et$_2$O (2 × 25 mL). Yield 4.2 g (58%). mp > 174 °C (decomp.). IR: 1620 (st). ^{1}H NMR δ: 7.86 (m, 2H, ArH), 7.28 (m, 3H, ArH), 3.95 (s, 2H, CH_2), 1.25 (s, 6H, CH_3). Calcd. for C$_{22}$H$_{26}$N$_2$O$_2$Cl$_2$Zn: C 54.29, H 5.38, N 5.76; found: a reproducible elemental analysis (±0.4%) could not be obtained for this material.

Synthesis of [dibromobis{η^1-*N*-(4,4-dimethyl-2-phenyl-2-oxazoline)}zinc] (15)

As for **5**, ZnBr$_2$ (2.0 g, 8.9 mmol) in Et$_2$O (100 mL) was treated with **4** (3.0 mL, 18 mmol), then stirred for 2 h, and

then evaporated at RT. Yield 2.0 g (65%). mp > 168 °C (decomp.). IR: 1618 (st). ^{1}H NMR δ: 7.86 (m, 2H, Ar*H*), 7.28 (m, 3H, Ar*H*), 3.95 (s, 2H, C*H*$_2$), 1.25 (s, 6H, C*H*$_3$). Calcd. for $C_{22}H_{26}N_2O_2ZnBr_2$: C 45.90, H 4.55, N 4.87; found: C 45.68, H 4.46, N 4.84.

Single crystal X-ray structure determinations

X-ray structure of 7

Suitable white crystals were obtained by slow diffusion of Et$_2$O into a CHCl$_3$ solution of the complex. Diffraction data were collected on a Nonius Kappa-CCD diffractometer equipped with a 95 mm CCD camera and a k-goniostat, using graphite-monochromated Cu Kα radiation. Data were reduced to $F_o{}^2$ values. A numerical absorption correction was applied using Gaussian integration (27), with max and min transmission factors of 0.024 and 0.009, respectively. The structure was solved by Patterson interpretation, using the program DIRDIF-96 (28). Isotropic and full matrix anisotropic least-squares refinements were carried out using SHELXL-97 (29). All non-H atoms were refined anisotropically, except N2, C5, and O2, which were isotropically refined. All the hydrogen atom positions were geometrically calculated and refined riding on their parent atoms. The molecular plots were made with the EUCLID program package (30). The WINGX program system (31) was used throughout the structure determinations.

X-ray structures of 10–13 and 15

Suitable crystals were grown from solutions of the complexes in dichloromethane that had been layered with Et$_2$O and allowed to stand at RT (or at –10 °C) for several days. Crystals were mounted on a glass fibre, covered in epoxy, and data was collected on a Smart 1000 CCD diffractometer using Mo Kα radiation (graphite monochromated). Isotropic and full matrix anisotropic least-squares refinements were carried out using SHELXL-97 (29). It should be noted that complex **15** has twofold imposed crystallographic symmetry.

Thermochemical behavior of dissolved carboxylic acid solutes: Solubilities of 3-methylbenzoic acid and 4-chlorobenzoic acid in organic solvents

Charlisa R. Daniels, Amanda K. Charlton, Rhiannon M. Wold, William E. Acree, Jr., and Michael H. Abraham

Abstract: The Abraham general solvation model is used to correlate the solubility behavior of 3-methylbenzoic acid and 4-chlorobenzoic acid in alcohol and ether solvents. The mathematical correlations take the form of

$$\log(C_S/C_W) = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H + v \cdot V_x$$

$$\log(C_S/C_G) = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H + l \cdot \log L^{(16)}$$

where C_S and C_W refer to the solute solubility in the organic solvent and water, respectively; C_G is a gas-phase concentration; R_2 is the solute excess molar refraction; V_x is the McGowan volume of the solute; $\Sigma \alpha_2^H$ and $\Sigma \beta_2^H$ are measures of the solute hydrogen-bond acidity and hydrogen-bond basicity; π_2^H denotes the solute dipolarity–polarizability descriptor; and $L^{(16)}$ is the solute gas-phase dimensionless Ostwald partition coefficient into hexadecane at 298 K. The remaining symbols in the above expressions are known solvent coefficients, which have been determined previously for a large number of gas–solvent and water–solvent systems. The Abraham general solvation model was found to describe the experimental solubility data and published literature partitioning data of 3-methylbenzoic acid and 4-chlorobenzoic acid to within overall standard deviations of 0.079 log units and 0.085 log units, respectively.

Key words: 3-methylbenzoic acid solubilities, 4-chlorobenzoic acid solubilities, alcohol solvents, partition coefficients, molecular solute descriptors, solubility predictions.

Résumé : On a utilisé le modèle de solvatation générale d'Abraham pour établir une corrélation du comportement de solubilité de l'acide 3-méthylbenzoïque et de l'acide 4-chlorobenzoïque dans des alcools et des éthers comme solvants. Les corrélations mathématiques sont de la forme:

$$\log(C_S/C_W) = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H + v \cdot V_x$$

$$\log(C_S/C_G) = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H + l \cdot \log L^{(16)}$$

dans laquelle C_S et C_W se réfèrent respectivement à la solubilité du soluté dans le solvant et l'eau, C_G est une concentration dans la phase gazeuse, R_2 est la réfraction molaire en excès du soluté, V_x est le volume de McGowan du soluté, $\Sigma \alpha_2^H$ et $\Sigma \beta_2^H$ sont des mesures de l'acidité et de la basicité de la liaison hydrogène du soluté, π_2^H est le descripteur de la dipolarité–polarisabilité du soluté et $L^{(16)}$ est le coefficient de partage sans dimension d'Oswald du soluté en phase gazeuse dans l'hexadécane, à 298 K. Les autres symboles de ces expressions sont des coefficients connus des solvants qui ont été déterminés antérieurement pour un grand nombre de systèmes gaz–solvant et eau–solvant. On a trouvé que le modèle de solvatation générale d'Abraham permet de décrire les données expérimentales de solubilité et les données publiées dans la littérature pour les coefficients de partage de l'acide 3-méthylbenzoïque et l'acide 4-chlorobenzoïque avec des déviations globales standard respectivement de 0,079 et 0,085 unités de logarithme.

Mots clés : solubilités, acide 3-méthylbenzoïque, acide 4-chlorobenzoïque, solvants alcooliques, coefficients de partage, descripteurs moléculaires du soluté, prévisions de solubilités.

Introduction

Researchers have recognized for years the importance of liquid–liquid equilibria. Chemical engineers design separation and purification processes based upon partition coefficient data. Solute partitioning between two immiscible phases is the basis of all chromatographic separations. Biologists correlate partition and bioaccumulation data to better understand the fate of organic pollutants in the environment. Civil engineers need partition and adsorption coefficient data

to design water treatment facilities to remove organic compounds from drinking water. Partition coefficients are required as input values in pharmacokinetic and toxicokinetic models that mathematically predict the adsorption, excretion, and metabolism of drug molecules in the body. The latter models involve tissue–air and tissue–blood partitioning; however, studies have shown that biological partitioning processes can sometimes be mimicked by select organic solvents like hexane, oleyl alcohol, and 1-octanol.

Historically, many of the very early studies focussed exclusively on developing correlational equations based upon octanol–water partition coefficients, which are readily available for most organic compounds (1). As additional experimental data became available, researchers expanded their studies to include more organic solvents, as well as aqueous micellar solvent media. In this regard, Abraham and co-workers (2–9) developed expressions for describing the partition of solutes between water and an organic solvent and between the gas phase and a given solvent. The Abraham general solvation model is based upon two particular linear, free-energy relationships for describing the partition of solutes between water and a given solvent (2–9)

$$[1] \qquad \log P = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H + v \cdot V_x$$

and between the gas phase and a given solvent

$$[2] \qquad \log L = c + r \cdot R_2 + s \cdot \pi_2^H + a \cdot \Sigma \alpha_2^H + b \cdot \Sigma \beta_2^H \\ + l \cdot \log L^{(16)}$$

The dependent variables in eqs. [1] and [2] are $\log P$ (the partition coefficient of solute(s) between water and a given solvent) and $\log L$ (Ostwald solubility coefficient). The independent variables are the solute descriptors, as follows: R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively; $\Sigma \alpha_2^H$ and $\Sigma \beta_2^H$ are measures of the solute hydrogen-bond acidity and hydrogen-bond basicity; π_2^H denotes the solute dipolarity–polarizability descriptor; and $L^{(16)}$ is the solute gas-phase dimensionless Ostwald partition coefficient into hexadecane at 298 K. The Ostwald partition coefficient, L, is the inverse of the Henry's law constant. It should be noted that the various c, r, s, a, b, v, and l coefficients depend on the solvent phase under consideration. The tendency of the phase to interact with solutes through polarizability-type interactions, mostly via electron pairs, is given by the r-coefficient. The s-coefficient is a measure of the solvent phase dipolarity and (or) polarity, while the a- and b-coefficients represent the solvent phase hydrogen-bond basicity and hydrogen-bond acidity, respectively. The l- and v-coefficients are a combination of the work needed to create a solvent cavity wherein the solute will reside and the general dispersion interaction energy between the solute and solvent phase. In the case of partition coefficients, where two solvent phases are involved, the c, r, s, a, b, v, and l coefficients represent differences in the solvent phase properties.

To date, mathematical expressions have been deduced for approximately 40 or so dry solvents. The derived mathematical expressions allow one to predict the partitioning and solubility behavior of organic and organometallic solutes, provided that one knows the numerical values of the various solute descriptors. Development of a single correlation equation requires experimental data for at least 40 or so different solutes. It is important that the data set contain solutes that span as wide a range of solute descriptors as possible in order to derive meaningful correlations. Partition coefficients of volatile solutes can be measured directly as the solute gas–liquid chromatographic retention volumes on the given organic solvent stationary phase, or they can be calculated from infinite dilution activity coefficients. This latter information is available in the published literature in the form of binary liquid–vapor equilibria data. Solubility measurements provide a very convenient means for including nonvolatile solutes in the regression analysis. Here, the partition coefficient is calculated as the ratio of the solute molar solubility in the organic solvent under consideration and water (or saturated vapor concentration in the case of the gas–liquid partition).

Presently, we are in the process of developing and (or) updating correlation equations for additional and (or) existing solvent systems (8–11) and in the process of developing new computational methodologies for calculating solute descriptors from available experimental data and (or) structural information (12–17). Solubility measurements have been used in the determination of molecular descriptors of the two equilibrium tautomeric forms (azo(phenolic) and quinone(hydrazone)) of Sudan I (18). Several of our preliminary unpublished correlation equations were derived from very limited experimental databases. As new experimental data becomes available, existing correlation equations have been periodically updated and existing values of the molecular solute descriptors have been refined by combining "practical" partitioning and saturation solubility data. Such analysis allows us to assess the internal consistency of large experimental databases and to identify possible outlier data points in need of remeasurement. For example, outlier data points would be identified by large differences between experimental and calculated values.

Of particular interest are the carboxylic acid solutes that possess large numerical values for their hydrogen-bonding acidity descriptors. The existing values that we have for the molecular descriptors of many of the carboxylic acid solutes were derived almost entirely from "practical" partitioning data. For some solutes, there was only very limited experimental partitioning data, and one or two incorrect data points could lead to the calculation of incorrect values for the molecular descriptors, as was the case in a recently completed solubility study involving acetylsalicylic acid.[2] We need to determine if the values that were previously calculated for several solute molecules that we plan to use in developing additional solvent and (or) process equations are compatible with existing correlation equations for dry organic solvents. Moreover, we want to examine whether or not our existing correlation equations for dry alcohol and dry ether solvents correlate with the solubility behavior of the less soluble carboxylic acid solutes. The databases used in deriving the correlations for many of the dry alcohol and dry ether solvents contained very few carboxylic acid solutes. Most of the experimental data for carboxylic acid and other very acidic solutes were in the form of saturation solubili-

---

ties, which were in the 1–3 mol L^{-1} range. There is no guarantee that the correlation equations will work for carboxylic acid solutes that have much smaller solubilities. For this reason, solubilities of 3-methylbenzoic acid and 4-chlorobenzoic acid were measured in numerous organic solvents of varying polarity and hydrogen-bonding characteristics. Both carboxylic acids are expected to exist almost exclusively in monomeric form in each of the solvents studied. Results of these measurements are interpreted using the Abraham general solvation equation.

Materials and methods

3-Methylbenzoic acid (Aldrich, 99%) and 4-chlorobenzoic acid (Acros, 99%) were purchased from commercial suppliers and were used as received. The purity of both carboxylic acids was 99.8% (±0.3%), as determined by nonaqueous titration with freshly standardized sodium methoxide solution to the thymol blue endpoint, according to the method of Fritz and Lisicki (19), with the exception that toluene was substituted for benzene. 1-Propanol (Aldrich, 99+%, anhydrous), methanol (Aldrich, 99.8%, anhydrous), ethanol (Aaper Alcohol and Chemical Company, absolute), 1-butanol (Aldrich, HPLC, 99.8+%), 1-pentanol (Aldrich, 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 1-octanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 2-butanol (Aldrich, 99+%, anhydrous), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 2-methyl-1-butanol (Aldrich, 99%), 3-methyl-1-butanol (Aldrich, 99%, anhydrous), 1-decanol (Alfa Aesar, 99+%), 2-methyl-2-propanol (Arco Chemical Company, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 2-pentanol (Acros, 99+%), 4-methyl-2-pentanol (Acros, 99+%), methyl acetate (Aldrich, 99.5%, anhydrous), ethyl acetate (Aldrich, HPLC, 99.9%), butyl acetate (Aldrich, HPLC, 99.7%), diethyl ether (Aldrich, 99+%, anhydrous), diisopropyl ether (Aldrich, 99%, anhydrous), dibutyl ether (Aldrich, 99.3%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), 1,4-dioxane (Aldrich, 99.8%, anhydrous), and propylene carbonate (Aldrich, 99.7%, anhydrous) were stored over molecular sieves and distilled shortly before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol % or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1 °C for at least 24 h (often longer) with periodic agitation. After equilibration, the samples stood unagitated for several hours in the constant temperature bath to allow any finely dispersed solid particles to settle. Attainment of equilibrium was verified both by repetitive measurements the following day (or sometimes after two days) and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a slightly higher temperature. Aliquots of saturated carboxylic acid solutions were transferred through a coarse filter into a tared volumetric flask, to determine the amount of sample, and diluted quantitatively with methanol for spectrophotometric analysis at 279 nm (3-methylbenzoic acid) and 272 nm (4-chlorobenzoic acid) on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance vs. concentration working curve.

Table 1. Experimental 3-methylbenzoic acid mole fraction solubilities, X_S, in select organic solvents at 25 °C.

Organic solvent	X_S
Methanol	0.1430
Ethanol	0.1617
1-Propanol	0.1618
1-Butanol	0.1595
1-Pentanol	0.1773
1-Hexanol	0.1828
1-Heptanol	0.1910
1-Octanol	0.1985
1-Decanol	0.1630
2-Propanol	0.1653
2-Butanol	0.1895
2-Methyl-1-propanol	0.1345
2-Methyl-2-propanol	0.2267
2-Methyl-1-butanol	0.1470
3-Methyl-1-butanol	0.1632
2-Pentanol	0.1965
2-Methyl-1-pentanol	0.1668
4-Methyl-2-pentanol	0.2133
Diethyl ether	0.1889
Tetrahydrofuran	0.3329
1,4-Dioxane	0.1860
Methyl acetate	0.1364
Ethyl acetate	0.1391
Butyl acetate	0.1263
Propylene carbonate	0.03892

Experimental molar concentrations were converted to solubility mass fractions via multiplying by the molar mass of carboxylic acid, the volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance vs. concentration working curve and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from solubility mass fractions using the molar masses of the solute and solvent. Experimental 3-methylbenzoic acid and 4-chlorobenzoic solubilities, X_S, for the different organic solvents studied, are listed in Tables 1 and 2, respectively. Numerical values represent the average of between four and eight independent determinations. Reproducibility ranged from ± 1.5% for solvents having the lower mole fraction solubilities to ±2.0% for solvents having the larger 3-methylbenzoic acid solubilities, where an extra dilution was necessary to keep the measured absorbances within the Beer–Lambert law region.

Computational methodology

Equation [1] actually predicts partition coefficients, and for select solvents, both "dry" and "wet" equation coefficients have been reported. For solvents that are partially miscible with water, such as 1-butanol and ethyl acetate, partition coefficients calculated as the ratio of the molar solute solubilities in the organic solvent and water are not the same as those obtained from direct partition between water (saturated with the organic solvent) and organic solvent (saturated with water). Care must be taken not to confuse the

two sets of partitions. In the case of solvents that are fully miscible with water, such as methanol, no confusion is possible. Only one set of equation coefficients have been reported, and the calculated $\log P$ value must refer to the hypothetical partition between the two pure solvents. And for solvents that are "almost" completely immiscible with water — such as alkanes, cyclohexane, dichloromethane, trichloromethane, tetrachloromethane, and most aromatic solvents — there should be no confusion because indirect partition (see eq. [3]) will be nearly identical to direct partition.

The predictive applicability of the Abraham general solvation model is relatively straightforward. We start with the set of equations that we have constructed for the partition of solutes between water and a given solvent. Table 3 gives the coefficients in eq. [1] for the water–solvent partitions we shall consider. The actual numerical values may differ slightly from values reported in earlier publications. Coefficients are periodically revised when additional experimental data becomes available. Note that many of these are "hypothetical partitions" between pure water and the pure dry solvent; these are shown as "dry" in Table 1. Although "hypothetical", these partitions are very useful; as we show later, they can be used to predict solubilities (and activity coefficients) in the pure dry solvent. The partition coefficient of a solid between water and a solvent phase is related to the molar solubility of the solid in water, C_W, and in the solvent, C_S.

[3] $\qquad P = C_S/C_W \qquad$ or $\qquad \log P = \log C_S - \log C_W$

Hence, if C_W is known, predicted $\log P$ values based upon eq. [1] will lead to predicted molar solubilities through eq. [3]. Three specific conditions must be met to use the Abraham solvation model to predict saturation solubilities. First, the same solid phase must be in equilibrium with the saturation solutions in the organic solvent and in water (i.e., there should be no solvate or hydrate formation). Second, the secondary medium activity coefficient of the solid in the saturated solutions must be unity (or near unity). This condition generally restricts the method to those solutes that are sparingly soluble in water and to nonaqueous solvents; however, we are finding that this restriction may not be as important as initially believed. Equations [1] and [2] have shown remarkable success in the correlation of the solubility of several very soluble crystalline solutes like benzil (16) and acetylsalicylic acid.[2] Finally, for solutes that are ionized in aqueous solution, C_W refers to the solubility of the neutral form. For many carboxylic acids the correction should be fairly small, provided that the solute is not highly insoluble and does not have a large acid dissociation constant. We use the solubility of 3-methylbenzoic acid in water, $\log C_W = -2.14$ (20, 21), and of 4-chlorobenzoic acid, $\log C = -3.56$ (20–24) (corrected for ionization), to convert the predicted partition coefficients to saturation solubilities, which can then be compared with the experimentally determined values. Ionization is not a concern in the organic solvents that have dielectric constants much smaller than water.

For partition of solutes between the gas phase and solvents, eq. [2] is used. (Equation coefficients are given in Table 3 for several organic solvents.) Predicted $\log L$ values can also be converted to saturation molar solubilities, provided that the solid saturated vapor pressure at 298.15 K, $VP°$, is available. $VP°$ can be transformed into the gas-phase concentration, C_G, and the gas–water and gas–solvent partitions, L_W and L_S, can be obtained through eqs. [4] and [5], respectively.

[4] $\qquad L_W = C_W/C_G \qquad$ or $\qquad \log L_W = \log C_W - \log C_G$

[5] $\qquad L_S = C_S/C_G \qquad$ or $\qquad \log L_S = \log C_S - \log C_G$

As before, the computational method will be valid if conditions discussed above are met. If one is unable to find an experimental vapor pressure for the given solute molecule, an estimated value can be used in the preliminary computations. The value can be adjusted then, if necessary, to reduce the $\log L$ deviations and to make the $\log P$ and $\log L$ predictions internally consistent.

Results and discussion

Solubility data for 3-methylbenzoic acid and 4-chlorobenzoic acid is available in the chemical literature for only one of the solvents listed in Tables 1 and 2. Thuaire (25) investigated the solubility behavior of 19 substituted benzoic acid derivatives in binary aqueous–ethanol solvent mixtures. Our experimental mole fraction solubility of $X_S = 0.1617$ for 3-methylbenzoic acid differs from the published value of Thuaire, $X_S = 0.1620$, by less than 1%. Agreement is not quite as good in the case of 4-chlorobenzoic acid. Our experimental value of $X = 0.01013$ is smaller than the published literature value of $X = 0.01229$ (25). Both literature values were determined by transferring a weighed aliquot

Note: The solvents denoted as "dry" are those for which partitions refer to transfer to the pure dry solvent. The other partitions are from water (more correctly, water saturated with solvent) to the solvent saturated with water (see text). For the HPLC processes, the specific mobile and stationary phases are described in detail in refs. 28–32. As an example, for HPLC-HAF-60 and HPLC-HAF- 75, the stationary phase was 5 µm Hypersil ODS and the mobile phases were aqueous–methanol mixtures having 60 and 75 volume % methanol, respectively.

into a tared container and allowing the solvent to evaporate at room temperature. The solubility was then determined from the mass of the residue that remained. This particular method, though often used, is subject to experimental errors, particularly in the case of solutes of low solubilities. Care must be taken to thoroughly remove all of the liquid solvent. Nonvolatile impurities in either the solvent and (or) solute add to the mass of the residue, which would result in a positive experimental error. For solutes having small solubilities, the residue from the dissolved solute is very small. Trace impurities in the solute and (or) solvent generally affect spectroscopic solubility determinations only if the impurity has an appreciable absorbance at the analysis wavelength.

From previous computations, numerical values exist for the molecular descriptors of 3-methylbenzoic acid ($R_2 = 0.730$, $\pi_2^H = 0.874$, $\Sigma\alpha_2^H = 0.600$, $\Sigma\beta_2^H = 0.401$, and $V_x = 1.0726$) and 4-chlorobenzoic acid ($R_2 = 0.840$, $\pi_2^H = 0.970$, $\Sigma\alpha_2^H = 0.630$, $\Sigma\beta_2^H = 0.280$, $V_x = 1.0541$, and $\log L^{(16)} = 4.976$). The computations were based upon a very limited number of "practical" partition coefficient data points. Our molecular descriptor database does not contain a numerical value of $\log L^{(16)}$, as 3-methylbenzoic acid has not been used previously to develop any $\log L$ correlation. For most noncarboxylic acid solutes, this descriptor can be estimated from chromatographic measurements of the gas–liquid partition coefficient of the solute on a hexadecane stationary phase. The experimental method is not applicable to carboxylic acid solutes, in that measured retention times are generally quite large at the 298.15 K column temperature. The value of $\log L^{(16)}$ can be obtained through calculation, by setting the values of R_2, π_2^H, $\Sigma\alpha_2^H$, $\Sigma\beta_2^H$, and V_x at their current numerical values and then using the Microsoft Solver program to calculate the numerical value of $\log L^{(16)}$ that best describes the experimental $\log L$ data. The computational procedure using Microsoft Solver is discussed in detail elsewhere (17).

Given the large number of additional solubilities in Tables 1 and 2, we decided to reanalyze all of the available experimental data to determine if a better of set of descriptor values could be obtained. Gathered in Tables 4 and 5 are the available "practical" partition coefficient (1, 26, 27), saturation solubility, and high-performance liquid chromatographic retention (28–32) data for systems for which $\log P$ and $\log L$

correlations exist. We eliminated from consideration a few practical partition coefficients for 3-methylbenzoic acid that involved alkane and other highly nonpolar organic solvents (33, 34). Carboxylic acids are known to exist largely in dimeric form in such solvents. While the published experimental values presumably had been corrected to remove dimerization effects, the calculated $\log P$ values for the monomeric solute depends to a large extent on the numerical value taken for the dimerization constant. We did not want to adversely affect the regression analysis by including experimental values that might be subject to large errors and (or) uncertainties.

Measured mole fraction solubilities, X_S, were converted to molar solubilities by dividing X_S by the ideal molar volume of the saturated solution (i.e., $C_S \approx X_S /[X_S V_{Solute} + (1 - X_S) V_{Solvent}]$). The molar volume of the hypothetical subcooled liquid 4-chlorobenzoic acid, $V = 117.08$ cm^3 mol^{-1}, was estimated as the molar volume of benzoic acid ($V_{Solute} = 104.38$ cm^3 mol^{-1}) + molar volume of chlorobenzene ($V_{Solute} = 102.1$ cm^3 mol^{-1}) – molar volume of benzene ($V_{Solute} = 89.40$ cm^3 mol^{-1}). A value of $V_{Solute} = 121.8$ cm^3 mol^{-1} was used for the molar volume of 3-methylbenzoic acid (35). Any errors resulting from the estimation of the hypothetical subcooled liquid molar volume of 4-chlorobenzoic acid, V_{Solute}, or from the ideal molar volume approximation should have only a very small effect on the calculated C_S values. 3-Methylbenzoic acid and 4-chlorobenzoic acid are not overly soluble in many of the solvents considered, and the $X_S V_{Solute}$ term contributes very little to the molar volume of the saturation solution.

Included in the 3-methylbenzoic acid regressional analysis is the experimental aqueous solubility measurement. The published amended correlation of Abraham and Le (20)

$$[6] \quad (\log C_W)/5 = 0.104 - 0.201R_2 + 0.154\pi_2^H$$
$$+ 0.434\Sigma\alpha_2^H + 0.848\Sigma\beta_2^H - 0.672\Sigma\alpha_2^H \cdot \Sigma\beta_2^H$$
$$- 0.797V_x$$

and its updated version (unpublished)

[d]Experimental data taken from ref. 31.

[e]Experimental data taken from ref. 29.

[f]Experimental data taken from ref. 30.

[g]Experimental data taken from ref. 32. This particular value was found after the regression analysis was performed, and it is not included in the statistical information.

$$[7] \quad (\log C_W)/5 = 0.079 - 0.191 R_2 + 0.064\pi_2^H$$
$$+ 0.231\Sigma\alpha_2^H + 0.651\Sigma\beta_2^H - 0.157\Sigma\alpha_2^H\cdot\Sigma\beta_2^H$$
$$- 0.666 V_x$$

are used for the aqueous solubilities. Both correlations provide reasonable solubility estimations, provided that the melting point temperature is not too large. The cross $\Sigma\alpha_2^H\cdot\Sigma\beta_2^H$ term was added to the model to account for hydrogen-bond interactions between the acidic and basic sites in the pure liquid or solid solute. Such interactions are not normally included in partition coefficient correlations, as the dissolved solute is surrounded by solvent molecules. In solubility determinations, the equilibrium phase may be the pure crystalline solute, in which case solute–solute interactions become significantly more important. Crystal lattice forces would have to be overcome in dissolving a crystalline material.

Combining the two sets of linear, free-energy relationships, we have a total of 42 equations for 3-methylbenzoic acid and a total of 49 equations for 4-chlorobenzoic acid, for which partition data and equation coefficients are available. The respective McGowan volumes of 3-methylbenzoic acid ($V_x = 1.0726$) and 4-chlorobenzoic acid ($V_x = 1.0541$) are calculated from the individual atomic sizes and the number of bonds in each molecule (36). The excess molar refractions are estimated as $R_2 = 0.730$ (3-methylbenzoic acid) and $R_2 = 0.840$ (4-chlorobenzoic acid). The sets of 42 and 49 equations were then solved, using Microsoft "Solver", to yield the numerical values of the remaining solute descriptors that best described the experimental $\log P$ and $\log L$ partitioning. The new refined calculated descriptor values are given in Table 6, along with the "old" values. The final set of molecular descriptors reproduce the experimental $\log P$ and $\log L$ values for 3-methylbenzoic acid and 4-chlorobenzoic acid to within an overall standard deviation of 0.079 log units and 0.085 log units, respectively, as shown in Tables 4–6. The calculated descriptors are consistent with those for benzoic acid ($R_2 = 0.730$, $\pi_2^H = 0.900$, $\Sigma\alpha_2^H =$

$\log P$ standard deviation	0.080	0.077	0.080	0.078
$\log L$ standard deviation		0.083	0.100	0.098

0.590, $\Sigma\beta_2^H = 0.400$, and $\log L^{(16)} = 4.395$). For a homologous series, the $\log L^{(16)}$ descriptor increases by about 0.45 units per CH_2. Equations [6] and [7] gave 3-methylbenzoic acid aqueous molar solubilities of $(\log C_W)/5 = -0.323$ and $(\log C_W)/5 = -0.357$, which are in good agreement with published experimental values. Careful examination of the numerical entries in Table 6 further reveals that there is virtually no difference between the refined and the old set of descriptors. The older numerical values mathematically describe the experimental partitioning data for 3-methylbenzoic acid and 4-chlorobenzoic acid to within an overall standard deviation of 0.084 log units and 0.089 log units, respectively. Computations clearly show that the numerical values of the solute descriptors determined previously for both 3-methylbenzoic acid and 4-chlorobenzoic

acid, based entirely on "practical" partitioning data, are compatible with the solvent equations that were developed for the dry alcohol and ether solvents.

Dibutyl ether was excluded from the solubility analysis because we felt that dimerization of the carboxylic acids was inevitable in this larger ether solvent. Carboxylic acids are known to dimerize in saturated hydrocarbon and aromatic hydrocarbon solvents. It was noted when the equation coefficients for dibutyl ether were calculated that the derived equations did not describe the solubility behavior of several carboxylic acids (benzoic acid, 2-hydroxybenzoic acid, 4-hydroxybenzoic acid, and 3-nitrobenzoic acid) (11). The calculated $\log P$ values were always less than the observed $\log P$ values by the solubility method, as would be expected if dimerization did occur in dibutyl ether. Solubility measurements determine the total carboxylic acid concentration in the organic solvent, and unlike in the case of "practical" partition measurements, there is no convenient experimental means to correct the measured value for dimerization effects. Correlation equations for diethyl ether, tetrahydrofuran, and 1,4-dioxane did describe the solubility behavior of benzoic acid, 2-hydroxybenzoic acid, and 4-hydroxybenzoic acid (10). The latter three ether solvents were included in the solubility analysis.

Readers will note that while the Abraham general solvation model has been employed to describe mathematically the solubility of 3-methylbenzoic acid and 4-chlorobenzoic acid in organic solvents, the computational methodology can be applied to other molecules of interest. The computational methodology requires experimental solubility data of the solute molecule in water and in about a dozen or so solvents for which equation coefficients are known. The solute descriptors, after they have been calculated, can be used to predict the solute solubility in any of the organic solvents for which equation coefficients are known. To date we have derived equation coefficients for 40 or so dry organic solvents and have calculated molecular descriptors for over 3000 common organic and pharmaceutical compounds. Molecular descriptors also enable the prediction of a wide range of biological properties through previously derived correlations (37–47), as well as the prediction of the distribution of solutes between water and micellar surfactants (27, 48–52), between air and micellar solvents (53), and between water and room temperature ionic liquids (54–56).
