Activity and stability of rat liver xanthine oxidase in the presence of pyridine

Kaveh Amini, Mohammad-Hossein Sorouraddin, and Mohammad-Reza Rashidi

Abstract: In the present study, rat liver xanthine oxidase activity and its thermostability in the presence of pyridine were investigated. The activity of the enzyme was determined by following the formation of uric acid spectrophotometrically. The thermal stability of the enzyme was studied in the presence of 0.0%–2.0% of pyridine in Sorenson's buffer. Thermal stability parameters (half-life, inactivation constant, and activation energies for enzyme inactivation), thermodynamic constants (ΔH^*, ΔS^*, and ΔG^*) and the kinetic parameters (K_m and V_{max}), were determined in pyridine-free and pyridine-containing buffer solution. A dramatic reduction was observed in xanthine oxidase activity in the presence of pyridine. However, the pyridine-treated enzyme showed a marked enhancement in thermal stability compared with the native enzyme. The ΔG values for the enzyme activity in the presence of pyridine were found to be about 1.5-fold larger than that calculated for the native enzyme, indicating that the enzyme becomes kinetically more stable in the presence of pyridine. The K_m value for xanthine oxidase in the presence of 0.5% pyridine increased by 4.8-fold compared with the enzyme in the pyridine-free buffer solution; however, there was 1.8-fold reduction in the V_{max} value in the hydro-organic solution compared with the enzyme activity in the buffer solution. As the stability of enzymes is one of the most difficult problems in protein chemistry, this thermostability property of xanthine oxidase could be of great value in developing novel strategies to improve and expand its application in various areas.

Key words: xanthine oxidase, pyridine, inactivation, thermostability, thermodynamic, kinetic constants.

Résumé : Dans ce travail, on a étudié l'activité et la thermostabilité de l'oxydase de la xanthine du foie de rat en présence de pyridine. On a déterminé l'activité de l'enzyme en suivant d'une façon spectrophotométrique la formation d'acide urique. On a étudié la stabilité thermique de l'enzyme en présence de 0,0 % à 2,0 % de pyridine dans un tampon de Sorenson. Les paramètres de stabilité thermique (demi-vie, constante d'inactivation et énergies d'activation de l'inactivation de l'enzyme), les constantes thermodynamiques (ΔH^*, ΔS^* et ΔG^*) et les paramètres cinétiques (K_m et V_{max}) ont été déterminés dans des solutions tamponnées sans pyridine ainsi que d'autres contenant de la pyridine. On a remarqué une diminution dramatique de l'activité de l'oxydase de la xanthine en présence de pyridine. Toutefois, l'enzyme traité par de la pyridine présence une augmentation marquée de sa stabilité thermique lorsqu'elle est comparée à l'enzyme non traité. On a trouvé que les valeurs du ΔG pour l'activité de l'enzyme en présence de pyridine est environ 1,5 fois plus élevée que celle calculée pour l'enzyme non traité; ceci indique que l'enzyme devient cinétiquement plus stable en présence de pyridine. Par comparaison avec l'enzyme dans une solution tamponnée sans pyridine, la valeur de K_m pour l'oxydase de la xanthine en présence de 0,5 % pyridine est 4,8 fois plus élevée; toutefois, on remarque la valeur de V_{max} pour l'activité de l'enzyme en solution hydro-organique est 1,8 fois plus faible que celle dans une solution tamponnée. Comme la stabilité des enzymes est un des problèmes les plus difficiles en chimie des protéines, cette propriété de thermostabilité de l'oxydase de la xanthine pourrait avoir une grande valeur dans le développement de nouvelles stratégies visant à améliorer et à étendre son application dans divers domaines.

Mots-clés : oxydase de la xanthine, pyridine, inactivation, thermostabilité, thermodynamique, constantes cinétiques.

Introduction

Although enzyme catalysis has been traditionally investigated in aqueous medium, the activity of enzymes in hydro-organic – nonaqueous media has undergone significant progress in recent years and enzymatic reactions in hydro-organic – nonaqueous systems have received a great deal of attention. The enzymatic reactions are usually reduced in the presence of organic solvents, but it is not always the case. Recent years have witnessed a growing interest in the application of hydro-organic – nonaqueous systems to increase enzyme activity.[1,2] These systems have also been used to enhance enzyme stability, particularly at higher temperatures.[3,4] As the stability of enzymes is one of the most

difficult problems in protein chemistry,[5] this application of hydro-organic – nonaqueous systems could be of great value.

Xanthine oxidase (EC 1.17.3.2) is a flavoprotein enzyme that plays an important role in the metabolism of endogenous purines, xenobiotics, and drugs. This enzyme serves as an important biological source of some reactive oxygen species that are involved in many pathological processes such as inflammation, atherosclerosis, cancer, and aging.[6,7] Xanthine oxidase has been used in biosensors for estimation of fish and meat freshness in the food industry,[8] evaluation of ischemic myocyte injury,[9] and measurement of theophylline.[10] In spite of these broad and important investigations on the activity of xanthine oxidase, there are only limited studies on the activity of this enzyme in nonaqueous media.[11–13] More recently, we investigated xanthine oxidase activity in various hydro-organic mixtures including pyridine.[14] According to this study, a dramatic reduction was observed in the xanthine oxidase activity in the presence of pyridine. Despite this significant inhibitory effect, the enzyme was quite stable in the presence of pyridine and >65% of the original activity remained after a 24 h incubation at 37 °C.[14] To evaluate this finding in more detail, the activity and thermal stability of rat liver xanthine oxidase in the presence of pyridine was investigated.

Experimental section

Chemicals

All experiments were performed with analytical reagent grade chemicals. Xanthine and uric acid were purchased from Sigma-Aldrich (Dorset, UK). All other chemicals were obtained from Merck (Darmstadt, Germany).

Apparatus and software

Spectrophotometric measurements were carried out using a Shimadzu 2550 UV–vis spectrophotometer that was controlled by a Shimadzu UV Probe personal software package including kinetics software. The instrument was connected to a Shimadzu cell temperature control unit. The cuvette used had a path length of 1.0 cm. The total volume used for the spectrophotometric measurements was constant at 1.0 mL. All data were saved in ASCII format.

Preparation of partially purified xanthine oxidase

Mature male Sprague–Dawley rats (150–250 g,; Tabriz University of Medical Sciences, Tabriz, Iran) were used in this study. They were fed with a standard laboratory diet and allowed food and water adlibitum. The temperature and humidity were kept at 18 ± 1 °C and 50%, respectively, and the lighting cycle was 7:00–19:00 h light and 19:00–7:00 h dark. Animals were handled with humane care in accordance with the National Institute of Health guidelines.

The animals were sacrificed between 9:00 and 10:00 by cervical dislocation. Livers were immediately excised, placed in an ice-cold isotonic potassium chloride solution (1.15% KCl *w*/*v*) containing 0.1 mmol/L EDTA. The livers were then homogenized on ice in a homogenizer fitted with a Teflon pestle. Partially purified enzyme was prepared from the liver homogenate by heat treatment and ammonium sulfate precipitation as described elsewhere.[15]

Enzyme activity assay

The activity of the enzyme solution was determined by following the formation of uric acid spectrophotometrically at 35 °C. After addition of 50 μL enzyme to a cuvette containing 0.95 mL of Sorenson's phosphate buffer (67 mmol/L, pH 7.0 containing 0.1 mmol/L EDTA) and 20 μmol/L of xanthine (prepared in the same phosphate buffer), the solution was immediately mixed and the formation of uric acid from xanthine oxidation was monitored at 295 nm up to 3 min. The initial rate was calculated from the linear part of the progress curve and one unit of xanthine oxidase was defined as the amount of the enzyme catalyzing the oxidation of 1.0 μmol/L xanthine to uric acid per minute at 35 °C.[16] The reaction was also carried out in the same manner in the presence of different concentrations of pyridine ranging from 0.5% to 2.0%. Experiments confirmed that the presence of either the substrate or pyridine did not affect the pH of the phosphate buffer significantly.

Thermal stability studies

The thermal stability of rat liver xanthine oxidase in the presence of pyridine was studied as follows: a volume of 1.33 mL of the enzyme solution (prepared in 67 mmol/L phosphate buffer, pH 7.0, containing 0.1 mmol/L EDTA) was mixed separately with 19 mL of Sorenson's buffer containing 0.0% (as a control), 0.5%, 1.0%, 1.5%, and 2.0% pyridine. The mixtures were then incubated in a water bath at 35, 45, 55 and 65 °C for 24 h and 750 μL of each solution was taken at different time intervals and the enzyme activity was measured as described above. The time-dependent loss in activity was used to calculate the half-life for each enzyme solution. According to the classical first-order kinetics of enzyme inactivation,[17] the first-order inactivation rate constants were determined as the slopes of the ln$V$ vs t plots, where V is the residual enzyme activity after incubation at a specific temperature for a specific period and t is the incubation time. Activation energies for the thermal inactivation were measured by plotting logarithms of the inactivation rate constants vs reciprocals of the absolute temperatures according to the Arrhenius equation.[18]

Kinetic data analysis

Thermal inactivation kinetics of rat liver xanthine oxidase was described using a first-order reaction model:

$$[1] \qquad -\mathrm{d}A/\mathrm{d}t = kA$$

where –dA/dt represents the loss of xanthine oxidase activity rate constant (min^{-1}), A is the xanthine oxidase activity after heating for time t, and k is the thermal inactivation rate constant of xanthine oxidase at the temperature studied.

The residual enzyme activity at treatment time t and at a constant temperature can be calculated by eq. [2] derived from eq. [1]:

$$[2] \qquad 1\mathrm{n}A/A_0 = kt$$

The inactivation rate constant (k) can be estimated by linear regression analysis of the natural logarithm of residual activity vs treatment time.

If the inactivation rate constants are obtained at different

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

temperatures, it would be possible to estimate the energy of activation for denaturation using the Arrhenius equation:

$$[3] \quad \ln k = \ln A - E_a/RT$$

where k is the rate constant at T, A is the Arrhenius constant, E_a the apparent activation energy, R and T are the universal gas constant (8.314 J/mol/K) and the absolute temperature, respectively.

The activation energy can be estimated by linear regression analysis of the natural logarithm of rate constant vs the reciprocal of the absolute temperature.

The thermodynamic parameters for thermostability were calculated by rearranging the Eyring's absolute rate equation derived from the transition-state theory[19] as described before:[20]

$$[4] \quad K_d = (k_B T/h)e^{(-\Delta H/RT)}e^{(\Delta S/R)}$$

where h = Planck's constant = 6.63×10^{-34} J s, k_B = Boltzmann's constant (R/N) = 1.38×10^{-23} J/K, and N = Avogadro's number = 6.02×10^{23} mol^{-1}.

$$[5] \quad \Delta H^* \text{ (enthalpy of activation)} = E_a - RT$$

$$[6] \quad \Delta H^* \text{ (free energy of activation)} = -RT \ln(k_d, h/k_B T)$$

where k_d is the first-order rate constant for thermal denaturation.

$$[7] \quad \Delta S^* \text{ (entropy of activation)} = (\Delta H^* - \Delta G^*)/T$$

Determination of Michaelis–Menten parameters

To obtain the Michaelis–Menten constant (K_m) and the maximum velocity of the reaction (V_{max}), the initial oxidation rate of different concentrations of xanthine in Sorenson's phosphate buffer (67 mmol/L, pH 7.0 containing 0.1 mmol/L EDTA) in the absence and presence of 0.5% and 2.0% pyridine at 55 °C following addition of the enzyme fraction was determined. The K_m and V_{max} values were obtained from the Lineweaver–Burk plots.

Results and discussion

Effect of pyridine on spectral changes of product formation

The activity of xanthine oxidase was assayed by measuring the production of uric acid at 295 nm in aqueous solution. No changes were observed in the spectrum of uric acid in the presence of pyridine. Therefore, it was possible to determine the activity of xanthine oxidase by following the formation of uric acid at 295 nm without any spectroscopic interference from pyridine.

Effect of pyridine on xanthine oxidase thermal stability

The thermal stability of both pyridine-free and pyridine-treated enzymes was studied by incubating the enzyme in Sorenson's phosphate buffer at different temperatures (35, 45, 55, and 65 °C) for 24 h and measuring the residual activities at desired time intervals. As expected, the activity of the enzyme either in the absence or presence of pyridine decreased with temperature and treatment time; however, pyridine-treated enzyme showed a marked enhancement in thermal stability compared with the native enzyme (Fig. 1).

As the concentration of pyridine increased from 0.5% to 2.0%, the thermal stability of the enzyme also increased. In the presence of 2.0% pyridine, there was >60% of the residual activity even 24 h after incubation of the enzyme at 35 °C, whereas the activity reached almost zero after 10 h in the absence of pyridine (Fig. 1). The half-life values for thermal inactivation of xanthine oxidase in the presence of 0.5%–2.0% pyridine at 35 °C were found to be 2.0- to 21.7-fold greater than that obtained in the absence of pyridine (Table 1). As temperature increased, the half-life was reduced for both pyridine-free and pyridine-treated enzymes. At all studied temperatures, the half-life values for xanthine oxidase in the presence of different concentrations of pyridine were much higher than those of the native enzyme, indicating that xanthine oxidase becomes more thermostable in the hydro-organic mixture.

The increase in the thermal stability of xanthine oxidase in the presence of pyridine was further supported by the inspection of the inactivation rate constants (k). The thermal inactivation of the enzyme appeared to follow first-order inactivation kinetics, giving correlation coefficient values in the range of 0.951 to 0.996. In Table 1, the inactivation rate constants together with the r values of the correlation have been summarized. The rate constants increased with higher heating temperatures. However, at all studied temperatures, the inactivation rate constants decreased in the presence of pyridine. A higher inactivation rate constant would imply a less stable enzyme. Therefore, an increase in the inactivation rate constant of xanthine oxidase in the presence of pyridine indicates that this organic solvent is capable of protecting the enzyme from thermal denaturation. This protective effect of pyridine was found to be concentration-dependent. It was also found that the protection of xanthine oxidase from thermal inactivation by pyridine decreased at higher temperatures. Therefore, the smallest k value (the highest protective effect) was obtained for the 2.0% pyridine-treated enzyme at 35 °C, which was ~22-fold smaller than that of the native enzyme.

The calculated inactivation rate constants were plotted against the pyridine concentration (Fig. 2). At any temperature examined, the k values decreased as the concentration of pyridine increased, which indicates that pyridine makes xanthine oxidase more heat stable than when no pyridine is present.

The dependence of the xanthine oxidase inactivation rate constants on temperature adequately fitted the Arrhenius equation. The E_a values for thermal inactivation of the enzyme were obtained from the Arrhenius plots of logarithms of the inactivation rate constants vs reciprocals of the absolute temperatures (Fig. 3).

The E_a value was determined to be 14.173 kJ/mol for the native enzyme. However, the E_a values increased with an increase in the pyridine concentration, giving the highest value of 64.663 kJ/mol in the presence of 2.0% pyridine (Table 1). The activation energy could be an index of the thermal stability of protein; lower activation energy for denaturation would imply a less stable enzyme.[21] Therefore, an increase in the E_a value in the presence of pyridine further suggests

that pyridine is able to protect xanthine oxidase against thermal inactivation.

The thermodynamic activation parameters ΔG^*, ΔH^*, and ΔS^* were evaluated from the temperature dependence of the inactivation rate constant using Eyring equations and are summarized in Table 2. The enthalpy of denaturation (ΔH^*) of xanthine oxidase increased markedly in the presence of pyridine. This thermodynamic parameter represents the amount of heat required to denature the enzyme. A large and positive enthalpic value obtained for the denaturation process in the presence of pyridine indicates that xanthine oxidase in a medium containing pyridine is more thermostable than the enzyme in the buffer solution, since higher ΔH^* values suggest that more energy is required for enzyme denaturation to take place. There was also an increase in the entropy of denaturation (ΔS^*) when pyridine was present in the solution. The entropic parameter is the amount of energy per degree involved in the transition from a native to a denatured state. The value of ΔS^* also increased significantly in the presence of pyridine. As a positive value for

ΔS^* is indicative of the disorder of the system upon denaturation, based on entropic considerations, it seems that the thermal stability of xanthine oxidase decreases in the presence of pyridine. The free energy of denaturation (ΔG^*), which includes the contributions from both enthalpic and entropic terms, is a more accurate and reliable indicator of enzyme stability. The ΔG^* values for the enzyme activity in the presence of pyridine were found to be ~1.5-fold higher than that calculated for the native enzyme. ΔG^* can be regarded as a parameter for the kinetic stability of protein; a smaller ΔG^* change is associated with a more spontaneous process. Therefore, it appears that the energy barrier for denaturation of xanthine oxidase in a pyridine-containing buffer is high, and the enzyme becomes kinetically more stable in the presence of pyridine. The observed stabilization effect was enhanced when the concentration of pyridine increased from 0.5% to 2.0% (Table 2).

The thermal denaturation of enzymes usually results in the breakage of noncovalent linkages with an increase in the disorder or ΔS^*. Pyridine is an aromatic heterocyclic organic compound and is miscible with a broad range of polar and nonpolar solvents such as water and hexane. An increase in the enthalpic term of the xanthine oxidase denaturation in the pyridine-containing solution may indicate that pyridine stabilizes the modified form of the enzyme by adding noncovalent bonds, probably through both polar and hydrophobic interactions. A more positive ΔS^* value obtained for the denaturation of xanthine oxidase in pyridine-containing media shows that the water ordering in the enzyme hydration shell decreases in the new environment following the interaction of pyridine with water molecules, and this interaction is accompanied by an increase in the disorder or ΔS^*. It is also possible that in a dehydrated state, the conformational rigidity of the enzyme and its resistance to deleterious processes increase.[22] As, there was also an increase in the ΔG^* value, it seems that formation of new noncovalent bonds between the enzyme molecule and pyridine-containing solution plays an important role in the thermal stabilization of xanthine oxidase. The increase in both the enthalpies and entropies of xanthine oxidase thermal denaturation is an example of enthalpy–entropy compensation.

To further elucidate the behavior of xanthine oxidase in a pyridine-containing buffer solution, the Michaelis–Menten constants (K_m and V_{max}) for xanthine oxidase-catalyzed oxidation of xanthine were also determined in the absence and presence of pyridine at 55 °C. For xanthine oxidase in a buffer solution, the apparent K_m and V_{max} values were found to be 8.0 μmol/L and 0.10 μmol/L/min, respectively. However, the apparent K_m for xanthine oxidase in the presence of 0.5% pyridine was increased by 4.8-fold compared with the enzyme in the pyridine-free buffer solution. Therefore, it appears that the affinity of xanthine oxidase towards xanthine decreases when pyridine is present in the reaction medium. The V_{max} value of the enzyme in the hydro-organic solution also decreased 1.8-fold compared with the enzyme activity in the buffer solution. No significant difference was found in the kinetic parameters when the concentration of pyridine increased from 0.5% to 2.0% (Table 3). Therefore, both the affinity and the turnover number of xanthine oxidase are altered in the presence of pyridine.

However, in spite of a reduction in the efficiency of the reaction (expressed by V_{max}/K_m) in a pyridine-containing solution, the thermal stability of the enzyme increases in the presence of pyridine. The reduction in the catalytic efficiency of xanthine oxidase in a pyridine-containing buffer

could be attributed to the destruction of the enzyme hydration shell by the interaction of the organic solvent with water molecules.[23] It has been recognized that the replacement of water molecules from the enzyme leads to the unfolding of the enzyme molecule making the inner important residues of the enzyme molecule more exposed to the organic solvent. A higher exposure to the organic solvent could result in a faster denaturation rate.[24] It is also possible that the observed changes in the reaction kinetics arise from a direct interaction of pyridine as an inhibitor of the enzyme or even from a reduction in the number of the enzyme ac-

For personal use only.

tive sites. Xanthine oxidase is a metalloenzyme composed of two identical subunits. Each subunit contains one atom of molybdenum, one molecule of enzyme-bound flavin adenine dinucleotide (FAD), and two iron–sulfur (2Fe–2S) centers, with the molybdenum center acting as the substrate-binding pocket.[25] There is some evidence indicating the sensitivity of the molybdenum center of xanthine oxidase for interacting with pyridine. According to Okamoto et al.,[26] the molybdenum center of xanthine oxidase is able to form a complex with 4-[5-pyridin-4-yl-1*H*-[1,2,4]triazol-3-yl]pyridine-2-carbonitrile (FYX-051, a potent inhibitor of xanthine oxidase). They showed that in the complex, a covalent linkage is formed between molybdenum and the pyridine ring of FYX-051. On the other hand, the presence of pyridine in an aqueous reaction medium provides a new environment in which the enzyme finds a new three-dimensional structure that is more resistant to deleterious processes.[22]

Conclusion

Xanthine oxidase activity was reduced in the presence of pyridine; however, in spite of this reduction, a remarkable increase was observed in the enzyme stability in the pyridine-containing reaction medium. As the stability of enzymes is one of the most difficult problems in protein chemistry,[15] this thermostability property of xanthine oxidase could be of great value in the development of novel strategies to improve and expand its application in various areas.

Abstract: The morphology of glassy carbon surfaces was investigated by the atomic force microscope (AFM) method. Multi-wall carbon nanotubes (MWCNTs) were purified and investigated with a scanning electron microscope (SEM) and a transmission electron microscope (TEM). An electrochemical technique based on the glassy carbon electrode (GCE) or MWCNT-modified GCEs was used for the detection of nitroaromatic compounds (NACs), namely 2,4,6-trinitrotoluene (TNT), 1,3,5-trinitrobenzene (TNB), 2,4-dinitrotoluene (2,4-DNT), and 1,3-dinitrobenzene (1,3-DNB). MWCNT-modified GCEs were more sensitive than GCEs to TNB, 2,4-DNT, and 1,3-DNB, with the detection limit down to ppb level, whereas the modified GCEs showed lower sensitivity to TNT. In varying degrees, the accumulation of nitro compounds can be promoted by MWCNT-modified GCEs in the detection process, a property which can be attributed to the large surface area and graphene-sheet structure of MWCNTs.

Key words: glassy carbon, carbon nanotubes, modified, electrochemical detection, nitro compounds, sensitivity.

Résumé : Faisant appel à la microscopie des forces atomiques (MFA), on a étudié la morphologie de la surface d'un carbone vitreux. On a purifié des nanotubes de carbone à surfaces multiples (NTCSM) et on en a étudié les propriétés par microscopie électronique à balayage (MEB) et par microscopie électronique de transmission (MET). On a utilisé une technique électrochimique basée sur une électrode de carbone vitreux (ECV) et des électrodes de carbone vitreux modifiées par des nanotubes de carbone à surfaces multiples pour la détection de composés nitroaromatiques (CNA), tels le 2,4,6-trinitrotoluène (TNT), le 1,3,5-trinitrobenzène (TNB), le 2,4-dinitrotoluène (2,4-DNT) et le 1,3-dinitrobenzène (1,3-DNB). Par comparaison avec les électrodes de carbone vitreux, on a observé une plus grande sensibilité des électrodes modifiées par des nanotubes de carbone à surfaces multiples pour le TNB, le 2,4-DNT et le 1,3-DNB alors que la limite de détection descend au niveau de la ppb; toutefois, pour le TNT, l'inverse est vrai. Dans le processus de détection, l'accumulation des composés nitrés peut être majorée à des degrés divers par les électrodes modifiées par des nanotubes de carbone à surfaces multiples et ceci peut être attribué à la grande superficie de sa surface et à la structure en feuille de graphène des nanotubes de carbone à surfaces multiples.

Mots-clés : carbone vitreux, nanotubes de carbone, modifié, détection électrochimique, composés nitro, sensibilité.

[Traduit par la Rédaction]

Introduction

Today, security and environmental protection are two important topics all over the world; for this reason, research in detecting ultra-trace amounts of explosive and toxic nitroaromatic compounds (NACs) has accelerated.[1–6] Many techniques are used in this research. Electrochemical detection has several advantages over other methods, in that the instrument is simple and suitable for constructing inexpensive and portable detectors. Moreover, electrochemical detection can utilize an excellent materials-based electrode or a chemically modified electrode (CME) for sensitive and selective analyses, and the electrode itself can act as a reactant to pump or withdraw electrons in the reaction (reduction–oxidation).[6–9] During detection, the target compounds such as NACs will selectively adsorb onto and enrich the chemically modified surface, making ultra-trace detection possible. Therefore, one way of improving the sensitivity of an electrochemical sensor is to use materials sensitive to the analytes; thus, the search for new materials sensitive to NACs becomes an important topic in security and environmental protection research.

Carbon materials with different morphology and structure are widely used as electrode materials. Among them, glassy carbon has a disordered structure, whereas the carbon nanotube (CNT) is built from sp^2 carbon units and has hexagonal honeycomb lattices. These structural distinctions result in their different properties, and the unique structural characteristic of CNT makes it of scientific interest. Recent studies have shown that CNTs can mediate electron transfer reactions when used as electrode materials, and CNTs have more useful properties than traditional carbon electrodes, including good conducting ability and high chemical stability.

More importantly, CNTs are excellent candidates for sensors because of their interfacial adsorption properties and enhanced electrocatalytic activity.[10–14]

We have previously demonstrated that SiO_2 based materials can improve the detection sensitivity of NACs, and that mesoporous MCM-41 and SiO_2 nanospheres show differing sensitivities to NACs owing to their different morphology and structure.[5] In an ongoing effort to find materials sensitive to NACs, we investigated the electrochemical sensitivity of carbon-based materials of glassy carbon and MWCNT to NACs. MWCNT-modified GCEs showed higher sensitivity to three NACs, namely, TNB, 2,4-DNT, and 1,3-DNB, and lower sensitivity to TNT, than unmodified GCEs. And the detection limits by MWCNT-modified GCEs to TNB, 2,4-DNT, and 1,3-DNB was down to the ppb level.

Experimental

Materials

TNT (1g/L in acetonitrile), TNB, 2,4-DNT, and 1,3-DNB were obtained from Tokyo Kasei Kogyo Co. Ltd; GCE and MWCNTs were obtained from Chenhua (Shanghai, China) and Shenzhen Nanotech Port Co., Ltd. (Shenzhen, China), respectively; and *N*,*N*-dimethylformamide (DMF) and sodium chloride (NaCl) were obtained from Beijing Chemical Reagent Ltd., China. All the water used in this experiment was Milli-Q water. The solid NACs (TNB, 2,4-DNT, and 1,3-DNB) were dissolved in acetonitrile to form 1 g/L solutions.

Before the experiment, MWCNTs were first purified by refluxing in nitric acid for 5 h, followed by centrifugation, resuspension, filtration, and drying under vacuum at 100 °C.

Morphological characterization

The morphology of the GCE surface was imaged on a Nano IIIa atomic force microscope (AFM) (Digital Instruments) operating in a tapping mode using hard silicon tips with spring constants of ~40 N/m. Purified MWCNTs were characterized using a scanning electron microscope (SEM) (Hitachi S-4300F) and a transmission electron microscope (TEM) (Philips TECNAI-20). For SEM and TEM observations, the samples of purified MWCNTs were redispersed in DMF by ultrasonic treatment and dropped onto a silicon substrate and a carbon–copper grid, respectively.

Electrochemical detection

Electrochemical detection was performed with an EG&G Princeton Applied Research (PAR) advanced electrochemical system (PARSTAT 2263) controlled by a microcomputer with EG&G PARC M250 software as reported previously.[10] All experiments were performed at room temperature (about 25 °C). An electrochemical cell with the three-electrode configuration was employed in the experiment, including a glassy carbon disk 3 mm in diameter as working electrode, a saturated calomel electrode (SCE) as the reference electrode, and a platinum wire as the counter electrode. Before modification, the GCEs were well polished with 0.3 μm alumina slurry, ultrasonicated in Milli-Q water, and finally dried in an oven at about 45 °C.

To modify the GCEs, the purified MWCNTs were first dispersed in DMF at a concentration of about 10 mg/mL, and 5 μL of this suspension was dispersed directly onto the surface of the clean and dried electrode. After DMF evaporation, a thin film of MWCNT formed on the surface of GCE. The supporting electrolyte used in the experiments was 0.5 mol/L NaCl aqueous solution, which was thoroughly deoxygenated by bubbling high-purity nitrogen gas before the experiment, and maintaning a constant flow of high-purity nitrogen over the solution during the measurements. The potential was scanned linearly at 100 mV/S in the electrochemical detection.

Results and discussion

Materials morphology

AFM images show that the surface morphology of GCE is composed of disordered nanoparticles (see Fig. 1).[15,16] The SEM and TEM images of the purified MWCNTs are shown in Fig. 2. From the SEM image, it can be seen that the sample of MWCNTs is composed of nanotubes with uniform shape. The average diameter of a tube is about 70 nm and its length is several μm. It is evident that these nanotubes possess multiple walls, as indicated in the TEM image.

Electrochemical detection by GCEs

Electrochemical studies on NACs have shown repeatedly that the reduction of the nitro group in nitro compounds usually occurs in two steps including the formation of amine and hydroxylamine. Each nitro group undergoes sequential 6 e^- reduction to an amine group.[17–22] The voltammograms of NACs (TNT, TNB, 2,4-DNT, and 1,3-DNB) on cleaned GCEs are shown in Fig. 3. On GCEs, the intensity of the redox peak weakens with the decrease of NAC concentration in the electrolyte solution. The detection limit is defined as the lowest concentration with identifiable response compared with the blank solution;[23] the detection limit for TNT by GCEs is about 120 ppb. The first two redox potentials of three nitro groups of TNT on GCEs are at –0.54 and –0.70 V, respectively, while the third redox potential cannot be identified in a solution concentration of 300 ppb. The three nitro groups of TNB are reduced at about –0.48, –0.63, and –0.74 V on GCEs, and the corresponding detection limit is down to 60 ppb. With 2,4-DNT, the redox potential of the two nitro groups are at –0.66 and –0.81 V, and its detection limit is about 120 ppb. As for 1,3-DNB, the two nitro groups are reduced at –0.65 and –0.78 V, and the detection limit of 1,3-DNB by GCEs is about 30 ppb. The influence of scan rate on NAC reduction on GCEs was investigated by voltammetry from 10 to 500 mV/S; in all cases, the peak current of these four NACs was found to be linear with the scan rate, illustrating that the reduction signal originates from NACs adsorbed onto the glassy-carbon-terminated surface. Further experiment showed that the peak intensity of NACs on GCEs is independent of increased accumulation times.[6b]

Electrochemical detection by MWCNT-modified GCEs

MWCNT-modified GCEs were also used to detect TNT, TNB, 2,4-DNT, and 1,3-DNB. As shown in Fig. 4a, the redox potential of the three nitro groups of TNT are at –0.50, –0.62, and –0.77 V, respectively. The intensity of the redox peak weakens with the decrease of TNT concentration in the

Fig. 1. Images of the GCE surface; (a) AFM height (z = 10 nm) and (b) AFM phase (z = 20 nm); scanning region is 1 μmol/L × 1 μmol/L.

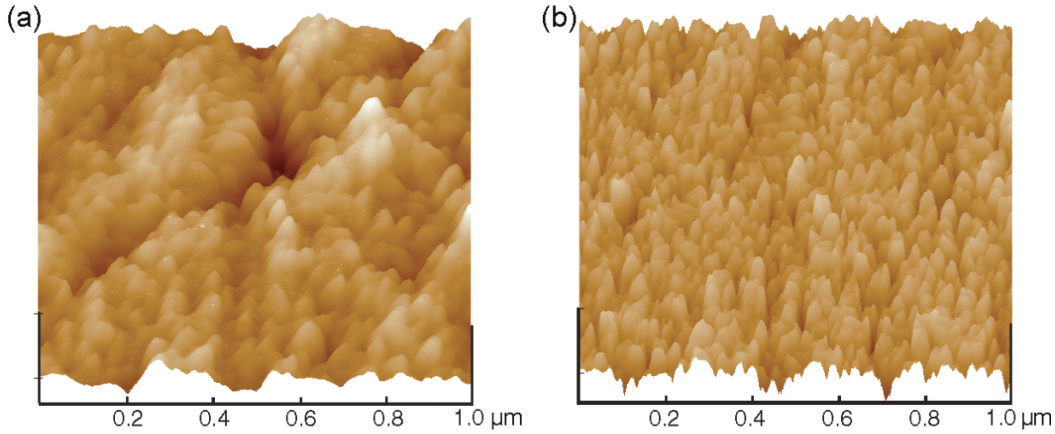

Fig. 2. SEM (a) and TEM (b) images of purified MWCNTs.

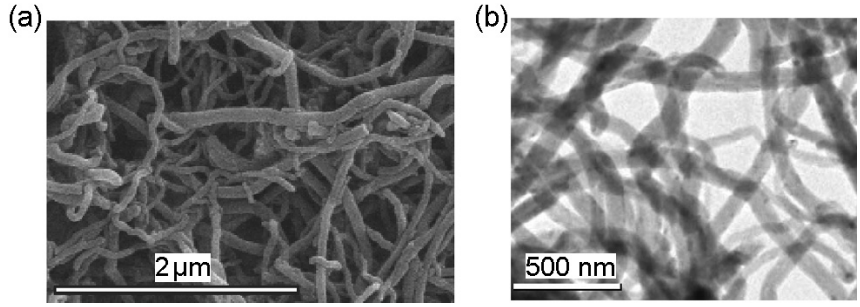

Fig. 3. Voltammograms of (a) TNT, (b) TNB, (c) 2,4-DNT, and (d) 1,3-DNB by unmodified GCEs in NaCl (0.5 mol/L) electrolyte.

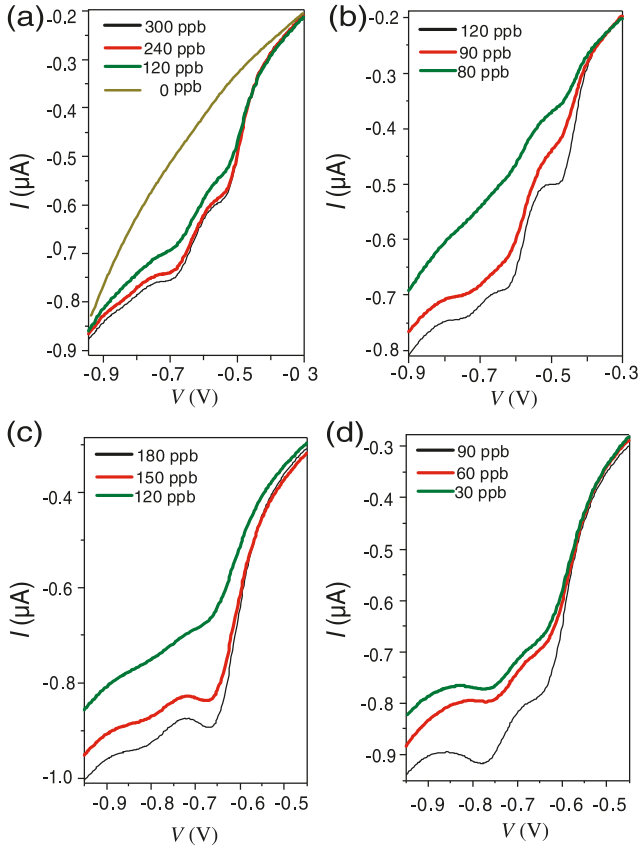

electrolyte solution, and the detection limit of TNT by MWCNT-modified GCEs is about 500 ppb without accumulation times.[6] Further experiments demonstrated that MWCNT-modified GCEs can greatly promote the accumulation of TNT as shown in Fig. 5a. With increasing accumulation times from 0 to 120 s, the intensity of the redox peak of TNT is distinctly enhanced, as has been reported in the literature.[6] The influence of scan rate on TNT reduction at MWCNT-modified GCEs was investigated by voltammetry from 10 to 500 mV/S. The relationship between peak current (I_p) and scan rate is linear (r^2 = 0.9952) with the equation of I_p = –0.30752(±0.00867)v – 8.81481(±2.28), which indicates that the reduction signal originates from TNT adsorbed onto the MWCNTs-terminated surface.

The voltammograms were then recorded in 0.5 mol/L NaCl solution containing different concentrations of TNB using MWCNT-modified GCEs, and the corresponding voltammograms are shown in Fig. 4b, indicating that MWCNT is very sensitive to TNB. TNB in a solution concentration of 36 ppb generates three well-defined redox signals at –0.49, –0.64, and –0.75 V, respectively. With decreasing TNB concentration, the peak intensity reduces. However, when TNB concentration was reduced to 6 ppb, the three redox peaks were still visible. This result indicates that MWCNTs is much more sensitive to TNB than is glassy carbon. Figure 5b shows the relationship between the accumulation times and the intensity of redox peak of TNB, showing that MWCNT-modified GCEs can also promote the accumulation of TNT, but that this promotion is weaker than with TNT. The relationship between the first peak current (I_p) of TNB and the scan rate is linear (I_p = –0.27833(±0.00401)v – 4.1853(±1.05387), r^2 = 0.9988).

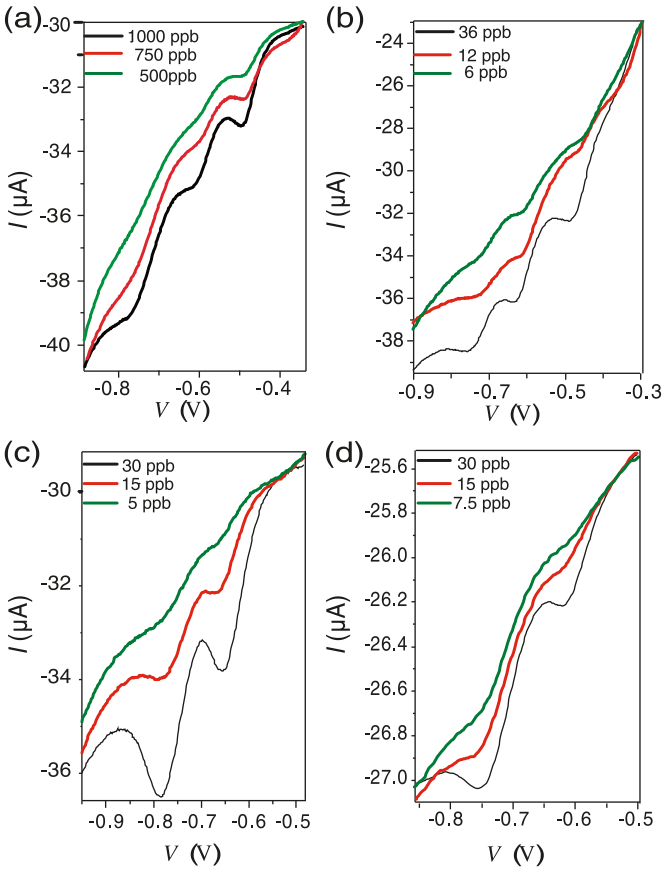
Fig. 4. Voltammograms of TNT (a), TNB (b), 2,4-DNT (c), and 1,3-DNB (d) by MWCNT-modified GCEs in NaCl (0.5 mol/L) electrolyte.

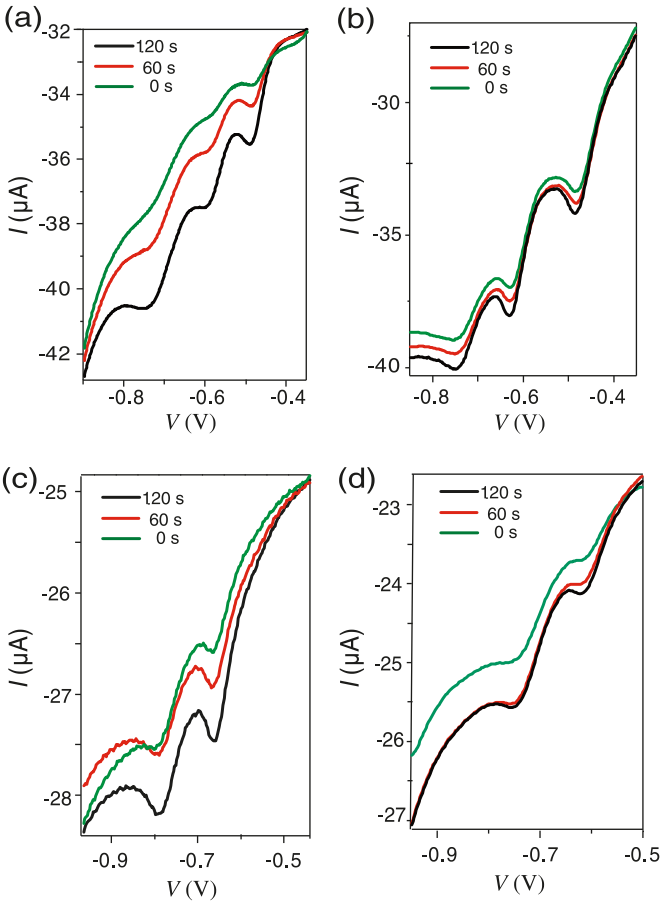


Experiments were also carried out to detect other NACs with MWCNT-modified electrodes in 0.5 mol/L NaCl solution. As shown in Fig. 4c, a 30 ppb 2,4-DNT solution generated two well-defined redox signals at –0.66 and –0.78 V, respectively, corresponding to the stepwise reduction of two nitro groups to the corresponding amine. There were still two weak peaks when 2,4-DNT concentration was reduced to 5 ppb. Experiment also showed that MWCNT-modified GCEs can greatly promote the accumulation of 2,4-DNT as shown in Fig. 5c. With increasing accumulation times from 0 to 120 s, the intensity of the redox peak of 2,4-DNT becomes clearly enhanced. The relationship between the first peak current and the scan rate is also linear.

Figure 4d shows the voltammograms of trace 1,3-DNB by MWCNT-modified GCEs. There are two strong redox signals at –0.62 and –0.75 V in 0.5 mol/L NaCl solution containing 30 ppb 1,3-DNB, corresponding to the stepwise reduction of two Ar–NO_2 groups to the corresponding Ar–NH_2 groups. And the detection limit of 1,3-DNB is down to 7.5 ppb. With increased accumulation times, the peak intensity of 1,3-DNB is also enhanced (see Fig. 5d). The peak current of 1,3-DNB is linear to the scan rate.

The redox potential and detection limit of four NACs on unmodified and MWCNT-modified GCEs are listed in Table 1. Without accumulation times, the detection limits for TNT, TNB, 2,4-DNT, and 1,3-DNB by MWCNT-modified GCEs are 500, 6, 5, and 7.5 ppb, respectively. By contrast,

Fig. 5. Voltammograms of NACs by MWCNT-modified GCEs in NaCl (0.5 mol/L) electrolyte at increasing accumulation times of 0, 60, and 120 s: (a) TNT at 1000 ppb concentration, (b) TNB at 71 ppb concentration, (c) 2,4-DNT at 30 ppb concentration, and (d) 1,3-DNB at 30 ppb concentration.



on unmodified GCEs, the detection limits for TNT, TNB, 2,4-DNT, and 1,3-DNB are 120, 80, 120, and 30 ppb, respectively. MWCNTs show higher sensitivity to TNB, 2,4-DNT, and 1,3-DNB than glassy carbon. Moreover, MWCNTs can greatly promote the accumulation of NACs onto electrodes in solution, which can further improve the detection sensitivity of NACs. This difference between glassy carbon and MWCNTs results from their distinct structure; the large surface area and graphene-sheet structure of MWCNTs contribute to this sensitivity.[6]

Conclusion

In the present study, the morphology of glassy carbon was studied by AFM. MWCNTs were purified and investigated by SEM and TEM. The electrochemical sensitivity of these two different carbon materials to NACs has been investigated by cathodic voltammetry. Compared with glassy carbon, MWCNT showed higher sensitivity to TNB, 2,4-DNT, and 1,3-DNB, and excellent accumulation of NACs, which may be attributed to the large surface area and graphene-sheet structure of MWCNTs. The results reported in this study indicate that the MWCNT-modified electrode is an excellent sensor candidate for high sensitivity and fast detection

Table 1. The redox potential and detection limit of four NACs on unmodified and MWCNT-modified GCEs.

	TNT	TNB	2,4-DNT	1,3-DNB
Unmodified GCEs				
Detection limit (ppb)	120	80	120	30
Redox potential (V)	–0.54, –0.70, –0.84	–0.48, –0.63, –0.74	–0.66, –0.81	–0.66, –0.78
MWCNT-modified GCEs				
Detection limit (ppb)	500	6	5	7.5
Redox potential (V)	–0.50, –0.62, –0.77	–0.49, –0.64, –0.75	–0.66, –0.78	–0.62, –0.75

of trace amounts of the nitro compounds TNB, 2,4-DNT, and 1,3-DNB. This will be important in both NAC sensor fabrication and carbon nanotube applications.

New active and recyclable catalytic systems based on $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ for alcohol oxidation with hydrogen peroxide in water

Yong Ding, Wei Zhao, Bao-chun Ma, and Wen-yuan Qiu

Abstract: A "sandwich" type tungstophosphate, $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, was used as the efficient and reusable catalyst for alcohol oxidation. The catalyst I of $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ and the catalyst II of $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2[Zn_4(H_2O)_2(PW_9O_{34})_2]$ were used to catalyze the oxidation of alcohols in water. High yields of the corresponding carbonyl compounds were obtained. The catalysts were recycled several times without loss in activity.

Key words: polyoxometalate, recyclable, catalyst, oxidation, alcohol.

Résumé : On a utilisé un tungstophosphate de type « sandwich », $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ comme catalyseur efficace et réutilisable pour l'oxydation d'alcools. On a utilisé les catalyseurs I, de formule $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$, et II, de formule $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2$ $[Zn_4(H_2O)_2(PW_9O_{34})_2]$, pour catalyser l'oxydation d'alcools dans l'eau. On a obtenu des rendements élevés des dérivés carbonylés correspondants. Les catalyseurs ont été recyclés plusieurs fois sans perte d'activité.

Mots-clés : polyoxométalate, recyclable, catalyseur, oxydation, alcool.

Introduction

Carbonyl compounds are important precursors of various chemicals.[1–3] The selective oxidation of alcohols to the corresponding carbonyl compounds is an active field of research. Hydrogen peroxide used as the oxidant in liquid-phase oxidation has attracted much attention from researchers from the viewpoint of green chemistry. It overcomes the disadvantage of the toxic traditional inorganic oxidants,[4] and it is much cheaper and safer than other organic peroxides or peracids.[5] Polyoxometalates as effective catalysts for oxidation reactions have attracted wide attention in the past. Most examples of alcohol oxidation with hydrogen peroxide employed polyoxometalates as catalysts and have been reported, e.g., $[(n\text{-}C_8H_{17})_3NCH_3]_3\{PO_4[WO(O_2)_2]_4\}$,[6] $[\pi\text{-}C_5H_5N(CH_2)_{15}CH_3]_3\{PO_4[MoO(O_2)_2]_4\}$,[7] tetrakis(diperoxotungsto)phosphates,[8] lacunary polyoxotungstate of $[\gamma\text{-}SiW_{10}O_{36}(PhPO)_2]^{4-}$,[9] sodium tungstate + quaternaryammoniumhydrogen sulfate,[10] $[PW_{11}O_{39}]^{7-}$,[11] $[NaP_5W_{30}O_{110}]^{14-}$,[12] and so on. However, in these catalytic systems, the use of chlorocarbon poisonous solvents or the difficult recovery and reuse of those catalysts has restricted their wide applications in industrial and laboratorial synthesis.

From the viewpoint of green chemistry, water as an excellent solvent used in the catalytic oxidation of alcohols has received much attention recently. Although a number of methods have been developed,[13–19] the search for effective, new, environmentally benign, and reusable procedures for alcohol oxidation still remains an important challenge.

To the best of our knowledge, the "sandwich" type tungstophosphate, $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, has not been reported on the catalytic activity for the oxidation of alcohols in water. We report here two new catalytic systems for alcohol oxidation using it as a recyclable and active catalyst with hydrogen peroxide in water. (*i*) The potassium of the tungstophosphate ($K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$) was used to oxidize several alcohols in water with hydrogen peroxide. The catalyst was reused for the next cycle from the organic product by separation of the aqueous phase. There was no discernable loss in activity and selectivity even after 10 cycles. (*ii*) High yields of ketones were obtained in the oxidation of secondary alcohols in water using $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2[Zn_4(H_2O)_2(PW_9O_{34})_2]$. The catalyst was separated from the reaction mixture by adding diethyl ether to the system after the reaction. Comparing previous reports, there are some advantages in using our system: (*i*) water (a green solvent) was used as the solvent in the oxidation, (*ii*) the active catalysts could be easily reused, and (*iii*) some solid alcohols like DL-menthol and benzhydrol were

also successfully oxidized with excellent yields in our catalytic system.

Experimental

Reagents

All chemicals were analytical grade, commercially available, and used without further purification unless otherwise stated.

Preparation of catalysts

The potassium of the sandwich type tungstophosphate, $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ (catalyst I), was synthesized by the procedure reported in ref. 20. The catalyst II of $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2[Zn_4(H_2O)_2(PW_9O_{34})_2]$ was obtained from $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ by the following procedure: 0.9 g of $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ was dissolved in 55 mL of water. To this solution, 0.9 g of dioctadecyl dimethyl ammonium chloride dissolved in 10 mL of *tert*-butyl alcohol was added slowly. The mixture was stirred vigorously for 4 h at 40 °C. A white solid was filtered off and then washed with an excess amount of water. The yield was 97%. Anal. calcd. for $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2[Zn_4(H_2O)_2(PW_9O_{34})_2]$: C 39.51, H 6.97, N 1.21, P 0.67, W 35.84, Zn 2.82; found: C 40.68, H 6.98, N 1.13, P 0.60, W 35.23, Zn 2.74.

Characterization techniques

Infrared spectra were recorded on a Nicolet FTIR-360 FTIR spectrometer. The catalysts were measured using 2%–4% (*w*/*w*) KBr pellets prepared by manual grinding. ^{31}P MAS NMR spectra were recorded at 9.4 T on a Bruker Avance-400 wide bore spectrometer. GC analyses were performed on Shimadzu GC-9AM with a flame ionization detector equipped with a FFAP capillary. Mass spectra were recorded on a Finnigan Trace DSQ (Thermo Electron Corporation) at an ionization voltage of 70 eV and equipped with a DB-5 capillary column. Chemical elemental analysis of the catalysts was done on an ICP-atomic emission spectrometer (IRIS ER/S), and C, H, and N contents were measured on a German Elementar Vario EL spectrometer.

Catalytic reaction

The oxidation was carried out in two procedures. Procedure A: catalyst I of $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ (9 μmol), water (3 mL), substrate (1 mmol), and H_2O_2 (5 mmol, 30% aq) were added to the reaction flask at 363 K. When the reaction was over, the organic products were separated from the aqueous phase by extraction. Then, readdition of alcohols (1 mmol) and H_2O_2 (30% aq) to the aqueous phase containing the catalyst were carried out for the next oxidation. Procedure B: catalyst II of $[(C_{18}H_{37})_2(CH_3)_2N]_8K_2[Zn_4(H_2O)_2(PW_9O_{34})_2]$ (18 μmol), substrate (4 mmol), and H_2O_2 (20 mmol, 30% aq) were added to the reaction flask. The reaction was carried out at 363 K. When the reaction was over, the catalyst precipitated with cooling and was collected completely from the solution by adding diethyl ether to the system. Assignments of products were made by comparison with authentic samples. Selected samples were also analyzed by GC–MS (Finnigan Trace DSQ), and some isolated products were characterized by NMR.

Results and discussion

Table 1 summarizes the catalytic oxidation of various alcohols with 30% H_2O_2 by catalyst I and II in procedures A and B, respectively. High yields of ketones were obtained in the oxidation of cyclohexanol and cyclopentanol in both procedures. For DL-menthol, a low yield of 8% was detected using procedure A after 10 h. However, a high yield of menthone (97%) was obtained using procedure B after 6 h. This difference should be attributed to whether the catalyst could be in good contact with the substrates during the oxidation. In procedure A, the poor water solubility of DL-menthol resulted in the substrate not being in good contact with the catalyst dissolving in water. But in procedure B, the cation of dioctadecyl dimethyl ammonium promoted the contact between the aqueous phase and the substrate. So, there were obvious differences between procedures A and B during the oxidation of these hydrophobic alcohols. This phenomenon was also presented in the oxidation of linear alcohols. For the oxidation of *sec*-butyl alcohol, 2-pentanol, and 2-octanol, the reaction time in procedure B was shorter than that in procedure A, but the activity of catalyst II in procedure B was much higher than that of catalyst I in procedure A. This was especially true for 2-octanol; the yield of 2-octanone in procedure A was only 39% in 10 h, but a high yield of 99% was obtained in procedure B after 6 h. Even so, procedure A based on catalyst I is actually an active catalytic system for most of the substrates listed in Table 1. Benzhydrol and 1-phenylethanol were oxidized to their corresponding ketones with high yields using procedure A, producing similar results with procedure B. For a more active substrate (1-phenylethanol), a two molar excess of H_2O_2 using catalyst I in water was sufficient (not listed here). Interestingly, catalyst I was also active for the primary alcohol of benzyl alcohol, and the products of benzaldehyde and benzoic acid were obtained, respectively, in high yields by controlling the amount of H_2O_2 in the system. Benzaldehyde is a very important chemical that has widespread applications in the fields of flavors, odorants, and pharmaceutical intermediates.[21] Therefore, we tried to get benzaldehyde from the oxidation of benzyl alcohol in our system. When the ratio of H_2O_2–substrate was 1:2, benzaldehyde as the sole product with a 94% yield was obtained using catalyst I in water. Increasing the amount of hydrogen peroxide to a molar excess five times greater than the substrate, the conversion of benzyl alcohol reached up to 100%, but benzoic acid as the main product was obtained with 93% selectivity. The results indicated that increasing the amount of hydrogen peroxide enhanced the activity of oxidation, but the excessive oxidant would also bring in deep oxidation.

$K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ is a "water-soluble" catalyst, and it effectively catalyzes the oxidation of alcohols in water. After reaction, the organic products were separated from the aqueous phase by extraction. The aqueous phase containing the catalyst could be kept to do the next oxidation. The catalytic results in the oxidation of cyclohexanol on catalyst I for different cycles are shown in Fig. 1. It can be seen that the activity of the reused catalyst did not

Note: Reaction conditions: Procedure A: 9 μmol catalyst I; 3 mL water; 1 mmol alcohol; 5 mmol (30 % aq) H_2O_2. Procedure B: 18 μmol catalyst II; 4 mmol alcohol; 20 mmol (30 % aq) H_2O_2; reaction temperature: 90 °C. The selectivity was based on ketone, aldehyde, or acid.
[a] 9 μmol catalyst I; 3 ml water; 2 mmol alcohol; 1 mmol (30 % aq) H_2O_2, the yield was based on H_2O_2; the selectivity was based on benzaldehyde.

change. Even after 10 consecutive cycles of the reaction, a 97% yield of the cyclohexanone with 99% selectivity was still kept in this catalytic system, indicating that this system is a robust and reusable oxidation system.

To evaluate the reusable property of catalyst II, the oxidation system in procedure B was investigated. The countercation of dioctadecyl dimethyl ammonium made the catalyst disperse in the mixture to form an emulsion with heating. After the reaction finished with the temperature dropping, the system changed to turbid. Then, some diethyl ether was added to the system to precipitate the catalyst completely. The catalyst was recovered by centrifugation and used for the next cycle. Table 2 shows the oxidation of 2-octanol using procedure B for different cycles. A yield of 98% was

kept after three cycles, indicating that this catalytic system based on catalyst II is also a recyclable oxidation system.

The fresh catalysts and the used ones were characterized with FTIR spectra. As shown in Fig. 2, the IR spectrum of

the fresh catalyst $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2{\cdot}20H_2O$ (Fig. 2*a*) exhibited characteristic peaks at 1034, 942, 886, and 756 cm^{-1} and were similar to the reference reports.[20] The single band at ~1034 cm^{-1}, near the P–O band position (1080 cm^{-1}) of $[PW_{12}O_{40}]^{3-}$, suggests that significant restoration of tetrahedral symmetry to the phosphate group has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

occurred on metal substitution. There were obvious differences between the IR spectra of the fresh catalyst I and the used one. Several peaks were moved to new positions at 1054, 955, 889, 831, and 762 cm^{-1}, indicating that the structure of the catalyst has changed. It was not surprising that it could be ascribed to the recovery method of the catalyst. There have been several papers[16,22] that reported that the alteration of polyoxotungstate catalyst in the presence of H_2O_2 followed by the recovery of the initial structure after evaporation of solvents has always taken place, and the change of the structures cannot be ruled out. Considering the activity of the used catalyst, the fresh catalyst of $K_{10}Zn_4(H_2O)_2(PW_9O_{34})_2 \cdot 20H_2O$ seems to act as a precatalyst, which then maintains the catalytic activity during the later cycles. The IR spectra of the fresh catalyst II and the used one are also shown in Fig. 2; the peaks at 2919 and 2850 cm^{-1} were attributed to the C–H bonds of the quaternary ammonium cation of catalyst II. The peaks at 1033, 933, and 881 cm^{-1} were similar to that of catalyst I. Those revealed that catalyst II was synthesized containing a sandwich type tungstophosphate joined with the quaternary ammonium cation. The IR spectrum of the used catalyst II (Fig. 2*d*) was similar to the fresh one (Fig. 2*c*) except that some intensities of the peaks changed. There were no obvious changes between the fresh catalyst II and the used one.

This phenomenon was consistent with the ^{31}P MAS NMR characterization of the catalysts. As shown in Fig. 3, the strong peak at –4.7 ppm in Fig. 3*a* could be attributed to the sandwich type tungstophosphate structure of $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, which was very different from the structure of the keggin polytungstophosphate of $[PW_{12}O_{40}]^{3-}$ at about –15.8 ppm.[23,24] There were obvious changes shown in Fig. 3*b* of the used catalyst I; new peaks at 1.0 and –11.9 ppm appeared, which might be attributed to other keggin structures of polytungstophosphate. The structure of the catalyst has changed during the recovery course by evaporation of H_2O_2 aqueous solution. The ^{31}P MAS NMR of the fresh catalyst II kept the original structure of $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ (shown in Fig. 3*c*) at –5.0 ppm. After oxidation, the main species was also the sandwich type structure. Other peaks at 4.3, –12.4, and –15.3 ppm should be different kinds of polytungstophosphate species, which were obtained during the reaction with hydrogen peroxide. The original structure of $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ that could be kept in the used catalyst II might be attributed to the solvent precipitation recovery method of the catalyst. In addition, the countercation of the catalyst was also an important factor in this behavior. The countercation of catalyst II could prevent the change of the catalyst during the reaction, and the different amount of water in the reaction conditions might also play an important role.

Conclusions

In summary, we have demonstrated two new active and recyclable catalytic systems based on a sandwich type tungstophosphate, $[Zn_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, for alcohol oxidation with hydrogen peroxide in water. Secondary alcohols were selectively oxidized to the corresponding ketones with high yields. Benzyl alcohol was converted to benzaldehyde at a high conversion rate and selectivity by controlling the amount of H_2O_2. The catalysts were recycled several times without an obvious loss in activity. These catalytic systems are environmentally friendly and practical systems for alcohol oxidation.

Gas-phase reaction chemistry of 1,1-dimethyl-1-silacyclobutane as a precursor gas in the hot-wire chemical vapor deposition process—Formation of tetramethylsilane and trimethylsilane

L. Tong and Y.J. Shi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12

Abstract: The secondary gas-phase reaction products of 1,1-dimethyl-1-silacyclobutane (DMSCB) and its isotopomer, 1,1-di(perdeuteratedmethyl)-1-silacyclobutane (DMSCB-d_6), in a hot-wire chemical vapour deposition reactor were investigated using vacuum UV laser single photon ionization with time-of-flight mass spectrometry. Dimethylsilylene, one of the primary decomposition products, undergoes π-type addition across the double and triple C–C bond and an insertion reaction into the Si–H bond. A short-chain reaction mechanism, initiated by methyl radicals produced in the primary decomposition, is found to exist for both the source DMSCB molecule and its stable secondary products. The formation of tetramethylsilane and trimethylsilane via the reaction of 1,1-dimethylsilene with a methyl radical and an H_2 molecule, respectively, has been demonstrated. These are two new reaction channels involving 1,1-dimethylsilene in secondary gas-phase reactions.

Key words: 1,1-dimethyl-1-silacyclobutane, gas-phase reaction chemistry, hot-wire chemical vapour deposition, vacuum UV laser single photon ionization mass spectrometry, silene, silylene.

Résumé : Faisant appel à la spectrométrie de masse en temps de vol avec ionisation par un photon unique d'un laser UV à vide, on a étudié la nature des produits secondaires de la réaction du 1,1-diméthyl-1-silacyclobutane (DMSCB) et de son isotopomère, le 1,1-di(perdeutérométhyl)-1-silacyclobutane (DMSCB-d_6) dans un réacteur à dépôt de vapeur chimique sur un filament chauffé. Le diméthylsilylène, un des produits de décomposition primaire, subit une addition de type-π sur les doubles et triples liaisons C–C et une réaction d'insertion dans la liaison Si–H. On a trouvé qu'il existe un mécanisme réactionnel à courte chaîne, initié par les radicaux méthyles produits dans la décomposition primaire, tant pour la molécule source DMSCB que pour ses produits secondaires stables. On a démontré qu'il y a formation de tétraméthylsilane et de triméthylsilane par le biais de la réaction du 1,1-diméthylsilène avec respectivement un radical méthyle et une molécule de H_2. Ce sont deux voies réactionnelles nouvelles impliquant le 1,1-diméthylsilène dans des réactions secondaires en phase gazeuse.

Mots-clés : 1,1-diméthyl-1-silacyclobutane, chimie d'une réaction en phase gazeuse, dépôt de vapeur chimique sur un filament chauffé, spectrométrie de masse avec ionisation par un photon unique d'un laser UV à vide, silène, silylène.

Introduction

1,1-Dimethyl-1-silacyclobutane (DMSCB) has been used as a single-source precursor to deposit SiC thin films by low-pressure chemical vapour deposition (LP-CVD)[1] and hot-wire CVD (HW-CVD)[2]. In this molecule, both Si–H bonds in the parent silacyclobutane are substituted by Si–methyl connections. The milestone experiment done by Flowers and Gusel'nikov[3,4] in 1967 demonstrated that pyrolysis of DMSCB produced a clean unimolecular decomposition to ethene and dimethylsilene that can either be trapped or allowed to dimerize to 1,1,3,3-tetramethyl-1,3-disilacyclobutane (TMDSCB). The pyrolysis[5–11] and photolysis[12–14] of DMSCB have since been widely studied. However, the secondary gas-phase reactions, especially those in the HW-CVD process, are not yet well understood. Zaharias et al.[2] showed that Si and CH_3 radicals were produced in the primary gas-phase decomposition of DMSCB in HW-CVD. Our group has recently demonstrated that aside from the decomposition route to produce ethene and 1,1-dimethylsilene found in the pyrolysis of DMSCB, two other decomposition channels exist to form methyl radicals via the Si–CH_3 bond cleavage and the propene–dimethylsilylene species.[15] (Equations [1]–[3]: primary decomposition pathways of DMSCB on a heated W filament).

We have shown that both ethene and propene are formed through a stepwise diradical mechanism via the cleavage of a ring C–C and ring Si–C bond, respectively. The formation of ethene is favoured over that of propene. When DMSCB was contained in a HW-CVD reactor with a partial pressure of 0.48 torr (1 torr = 133.3224 Pa), the dominant product detected came from TMDSCB, which resulted from the dimerization of the 1,1-dimethylsilene formed from direct hot-filament decomposition. The other two products detected were 1,1,3-trimethyl-1,3-disilacyclobutane (TriMDSCB) and 1,3-dimethyl-1,3-disilacyclobutane (DMDSCB), which indicates that the isomerization between dimethylsilylene and methylsilene occurs in the process. However, the secondary gas-phase reactions involving the methyl radicals were missing. In addition, other reactions involving the reactive silene and silylene species than the cycloaddition of silene were not studied. In this work, we have extended our previous work on the gas-phase reaction chemistry of DMSCB in a HW-CVD process to study the secondary gas-phase reaction products involving all reactive species and aim to provide a complete picture of the reaction chemistry. The products from secondary gas-phase reactions when using DMSCB as a source gas in a HW-CVD reactor were probed by nonresonant single-photon ionization (SPI) with a 10.5 eV vacuum UV (VUV) wavelength of 118 nm coupled with time-of-flight mass spectrometry. This technique ionizes all chemical species with an ionization potential <10.5 eV and minimizes the dissociative fragmentation if the appearance potential is >10.5 eV.[16–18] This proves to be advantageous in diagnosing the reaction products in a complex system, such as those characteristic of combustion,[19] pyrolysis,[20,21] and CVD[22,23] processes. An isotopomer of DMSCB, 1,1-di(perdeuteromethyl)-1-silacyclobutane (DMSCB-d_6), was also synthesized in this work, and similar experiments with it replacing DMSCB help to understand the details of the gas-phase reaction chemistry.

Experimental details

The experimental setup used to record the VUV laser SPI TOF mass spectra of the secondary gas-phase reaction products from a HW-CVD reactor has been previously described in detail.[23,24] Briefly, the reactor is a cylindrical chamber housing a resistively heated tungsten filament (10 cm in length and 0.5 mm in diameter), a sample inlet tubing, and an IR-grade window for filament temperature measurement using a two-colour pyrometer (CHINO Works America Inc., Torrance, California). The reactor is incorporated through a 0.15 mm diameter pinhole to the ionization chamber housing a linear TOF mass spectrometer (R. M. Jordan Co., Inc., Grass Valley, California). The total pressure in the reactor was kept at 12 torr using a mass flow controller (type 1179 A; MKS Instruments, Andover, Maryland) and was monitored by a capacitance manometer (MKS Baratron, type 626 A). This gives a partial pressure of 0.48 torr when using a 4% DMSCB (or DMSCB-d_6) in He mixture. At this pressure, collision-free conditions were not maintained; this allowed for the detection of secondary gas-phase reaction products from the reactor. The 118 nm VUV laser radiation (10.5 eV) used to ionize the chemical species sampled from the reactor was produced in a nonresonant third-harmonic generation process of the 355 nm UV output from a Nd:YAG laser (LAB-170-10; Spectra-Physics, Santa Clara, California) in a gas cell containing 210 torr of a phase-matched 10:1 Ar–Xe gas mixture. Signals from the microchannel plate (MCP) detector in the TOF-MS were preamplified, averaged over 512 laser pulses, and saved into a computer for analysis. In this work, mass spectra for filament temperatures ranging from 900 to 2000 °C were recorded. For each temperature, a mass spectrum was collected every 5 min for 1 h.

DMSCB (≥97%; Sigma-Aldrich, St. Louis, Missouri) was used without further purification, and its purity was verified in situ by our TOF-MS. DMSCB-d_6 was synthesized by reacting 1,1-dichloro-1-silacyclobutane with CD_3MgI (99% atom% D; Sigma-Aldrich) based on an established method.[8] Its structure and purity (>98%) were checked by NMR and GC–MS. The isotope purity of DMSCB-d_6 (99% atom% D) was confirmed by our TOF-MS. The DMSCB or DMSCB-d_6 in He mixtures were prepared by entraining the room-temperature vapour of either compound in He (99.999%; Praxair) after degassing the liquid sample using several cycles of freeze–pump–thaw.

Results and discussion

Figures 1a and 1b show the room-temperature mass spectra of DMSCB and DMCB-d_6, respectively. The parent ion peak at m/z = 100 (base peak) and two fragment ion peaks of $[(CH_3)_2Si{=}CH_2]^{+\bullet}$ at m/z = 72 (78.2% ± 1.7%) and of $[(CH_3)Si(CH_2)_3]^{+\bullet}$ at m/z = 85 (3.8% ± 0.3%) were found to dominate the mass spectrum of DMSCB. The percentage for each fragment ion represents the relative ratio to the base peak. The assignment of the two fragment peaks were confirmed by the mass spectrum of DMSCB-d_6 in Fig. 1b. The isotope peaks of the parent ion and the fragment peak at m/z = 72 ascribed to ^{29}Si, ^{30}Si, and ^{13}C were also observed. It was noted that the isotope peaks of the one at m/z = 85 were not resolved. This is due to the slow dissociation of the parent ion[25] through the Si–CH_3 bond cleavage. From the inset of Fig. 1a, other weak fragment peaks were observed at m/z = 43 ($[CH_3Si]^{+\bullet}$, 0.091% ± 0.009%), 44 ($[(CH_3)HSi]^{+\bullet}$, 0.094% ± 0.006%), 58 ($[(CH_3)_2Si]^{+\bullet}$, 0.042% ± 0.003%), and 59 ($[C_2H_7Si]^{+\bullet}$, 0.20% ± 0.03%). Their corresponding peaks for DMCB-d_6 (inset of Fig. 1b) were observed at m/z = 46, 48, 64, and 65, respectively. The impurity (125 amu) in the synthesized DMSCB-d_6 sample was found to be <1%, which is consistent with the results of the NMR analysis. Figure 2a shows the mass spectra of the 4% DMSCB–He mixture at 12 torr recorded after the filament was turned on for 15 min at different filament temperatures ranging from 900 to 1500 °C. For comparison, the room-temperature mass spectrum is also shown. The intensities of the parent mass peak at m/z = 100 and its two dominant photofragmentation peaks at m/z = 72 and 85 decrease with increasing filament temperatures. This indicates that the DMSCB molecules decompose on the filament and are consumed in the secondary gas-phase reactions in the HW-CVD reactor. The analysis of the intensity ratios of the peaks at m/z = 72 and 85, respectively, to that of the parent molecules at different filament-on times and different filament temperatures found that the ratio of $I(m/z = 72)$:$I(m/z = 100)$

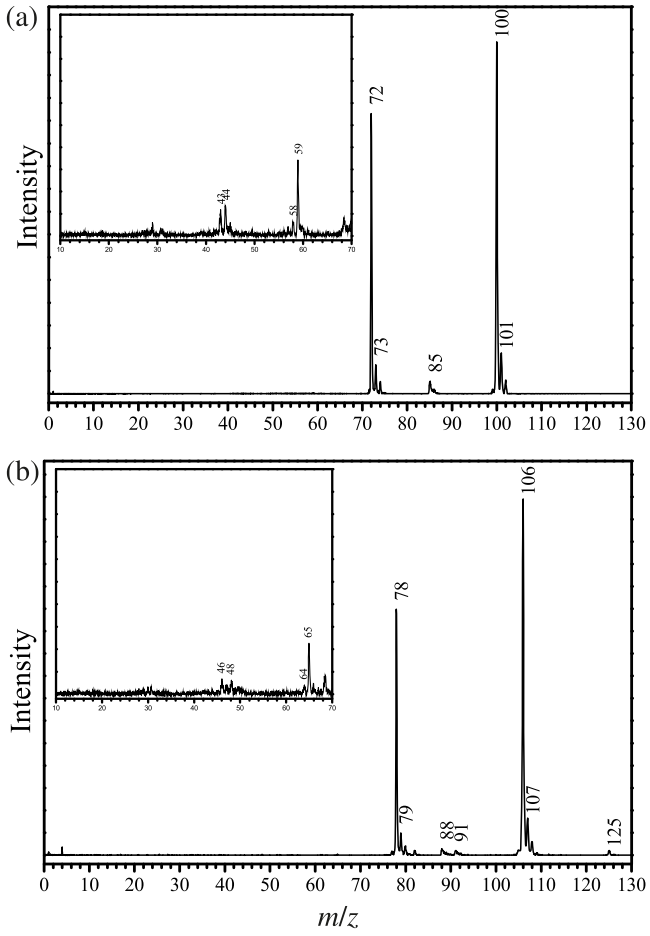
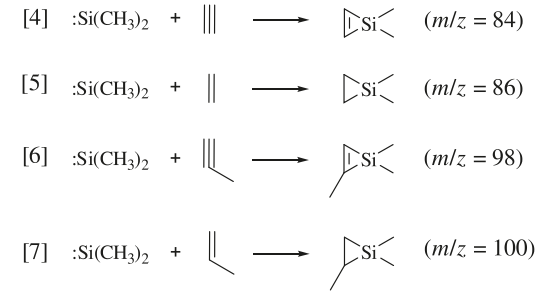
Fig. 1. Room-temperature mass spectra of (a) 1,1-dimethyl-1-silacyclobutane (DMSCB) and (b) 1,1-di(perdeuteromethyl)-1-silacyclobutane (DMSCB-d_6) recorded with 118 nm vacuum UV (VUV) laser ionization. The insets are expanded mass spectra in the mass region of 10–70 amu.



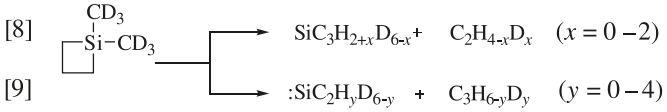
did not change with the filament-on time and filament temperatures, whereas the ratio of $I(m/z = 85)$:$I(m/z = 100)$ when the filament was on was above the room-temperature ratio of 0.038:1. This suggests that the peak intensity at $m/z = 72$ originates only from photofragmentation of the parent DMSCB ions, whereas sources other than the photofragmentation of the DMSCB ion are responsible for the peak intensity at $m/z = 85$. This will be discussed later. When the parent molecules decreased in intensity, new peaks at $m/z = 28$ (ethene), 42 (propene), 116 (DMDSCB), 130 (TriMDSCB), and 144 (TMDSCB) were observed, with the peak at $m/z = 144$ being the most dominant. The formation mechanisms for these dominant new mass peaks have been described in full detail in our previous study.[15] The enlarged mass spectra in three different mass regions are shown in Figs. 2b–2d. It is clear that other mass peaks at $m/z = 58$, 84, 86, 88, 98, 114, 128, 142, 156, 158, 170, 172, 174, 186, 188, 198, 202, 203, 217, 232, and 244 were also observed, although they were not as strong. This study focuses on understanding the formation of these new mass peaks, which originated from the stable products formed in the secondary gas-phase reactions in the HW-CVD reactor.

Reactions involving reactive intermediates silylenes

The decomposition of DMSCB on the hot W filament produced dimethylsilene and dimethylsilylene, as shown in eqs. [2] and [3]. Dimethylsilylene ($:Si(CH_3)_2$) is a very reactive species that once formed, can undergo a variety of reactions. They react with unsaturated alkenes and alkynes such as acetylene, ethene, propene, and propyne produced in the reactor, through π-type addition reactions.[26] Reactions shown in eqs. [4]–[7] produced 1,1-dimethylsilirene (84 amu), 1,1-dimethylsilirane (86 amu), 1,1,2-trimethylsilirene (98 amu), and 1,1,2-trimethylsilirane (100 amu). The first three peaks at m/z = 84, 86, and 98 are shown in Fig. 2b. The 1,1,2-trimethylsilirane (m/z =100) peak overlaps with the parent ion peak of DMSCB.



According to our previous study,[15] when using DMSCB-d_6, H–D scrambling for the peaks at m/z = 28 (ethene, C_2H_4) and m/z = 42 (propene, C_3H_6) was observed. Consequently, their complimentary peaks dimethylsilene (SiC_3H_8) and dimethylsilylene (SiC_2H_6) also show the H–D scrambling. The scrambling pattern is summarized in the following. (Equations [8] and [9]: the decomposition of DMSCB-d_6 on a heated W filament).



Therefore, the minimum mass shift for the peak at m/z = 84, representing the product from eq. [4], should be 2, and the maximum mass shift for the peak at m/z = 86 from eq. [5] should be 8. Figure 3 shows the mass spectra of the 4% DMSCB-d_6–He mixture recorded at a filament temperature of 1300 °C. It is clear from the expanded mass spectrum for the mass region of 70–170 amu (Fig. 3b) that a group of mass peaks between m/z = 86 and m/z = 98 was observed. As will be discussed later, the peaks from m/z = 95 to m/z = 98 originate from deuterated tetramethylsilane. Similarly, the minimum mass shift for the peak at m/z = 98 from eq. [6] should also be 2, which agrees well with the observation that the next group of peaks starts at m/z = 100. This suggests that π-addition reactions of dimethylsilylene occurred in our experiment. A second type of reaction involving dimethylsilylene is its insertion into the Si–H bond.[27] The DMSCB source molecule and the dominant secondary reaction product (TMDSCB) do not have Si–H bonds in their structures. However, the two other dominant products (DMDSCB (m/z = 116) and TriMDSCB (m/z = 130)) have Si–H bonds in their structures. The reactions of dimethylsilylene with DMDSCB and TriMDSCB (as demonstrated in

Fig. 2. (a) Mass spectra of a 4% 1,1-dimethyl-1-silacyclobutane (DMSCB) – He mixture at 12 torr (1 torr = 133.3224 Pa) at filament temperatures ranging from 900 to 1500 °C. The spectrum at 20 °C was recorded when the filament was off. The enlarged spectra of the mass regions of (b) 0–100 amu, (c) 100–200 amu, and (d) 200–300 amu.

eqs. [10]–[12]) produced species with masses of 174, 188, and 232 amu. Figures 2c and 2d clearly show that the three peaks were observed in our experiments.

[10] 
[11] 
[12] 
Our previous studies on tetramethylsilane,[24] hexamethylsilane,[28] and TMDSCB[29] demonstrated that a common and dominant photofragmentation pathway upon exposure to the 118 nm VUV radiation is the product of $[M-CH_3]^{+\bullet}$ radical ions. Similarly, the peaks at m/z = 116, 130, 174, 188, and 232 can lose one methyl group upon ionization by VUV radiation. This leads to the formation of various peaks with odd masses at m/z = 101, 115, 159, 173, and 217, all of which are shown in Figs. 2c and 2d. The peak at m/z = 101 overlaps with one of the isotope peaks of the parent molecule DMSCB. The contribution from ^{29}Si and ^{13}C at m/z = 101 amounts to 9.5% of the m/z = 100 peak intensity. However, the peak intensity ratio of m/z = 101 to m/z = 100 when the filament was on was found to be as high as 32.8%. The increase is likely due to the contribution from the photofragmentation of the peak at m/z = 116 (DMDSCB).

Formation of trimethylsilane (TriMS) and tetramethylsilane (TMS) — Reactions involving the reactive intermediate silene

In the experiments with DMSCB in the HW-CVD reactor, a new peak at m/z = 88 was observed starting from 1200 °C, as shown in Fig. 2b. This peak was assigned to TMS. TMS was also observed when using TMDSCB as a source gas,[29] where it was believed to be formed through the reaction between dimethylsilene and methyl radical followed by the addition of H_2 produced in the reactor.[30] In the room-temperature mass spectrum of TMS upon irradiation of the 118 nm VUV laser, the only characteristic photofragment peak was trimethylsilyl ion at m/z = 73 with an intensity four times that of the parent TMS ion.[24] In this work, the peak at m/z = 73 overlaps with one of the isotope peaks of the strong photofragment peak at m/z = 72 from the DMSCB parent ion. The contribution from the ^{29}Si and ^{13}C isotopes to the peak intensity at m/z = 73 amounts to 8.3% of the peak at m/z = 72 when the filament was off. However, the peak intensity ratio of m/z = 73 to m/z = 72 observed with DMSCB when the filament was on increased significantly with filament temperature when $T \geq 1200$ °C, as shown in Fig. 4. The photofragmentation of the formed TMS contributes partially to the peak intensity increase at m/z = 73.

The peak at m/z = 58 is a weak photofragment peak from the parent DMSCB ion; however, it was noted that the intensity of this peak increased with temperature and it sur-

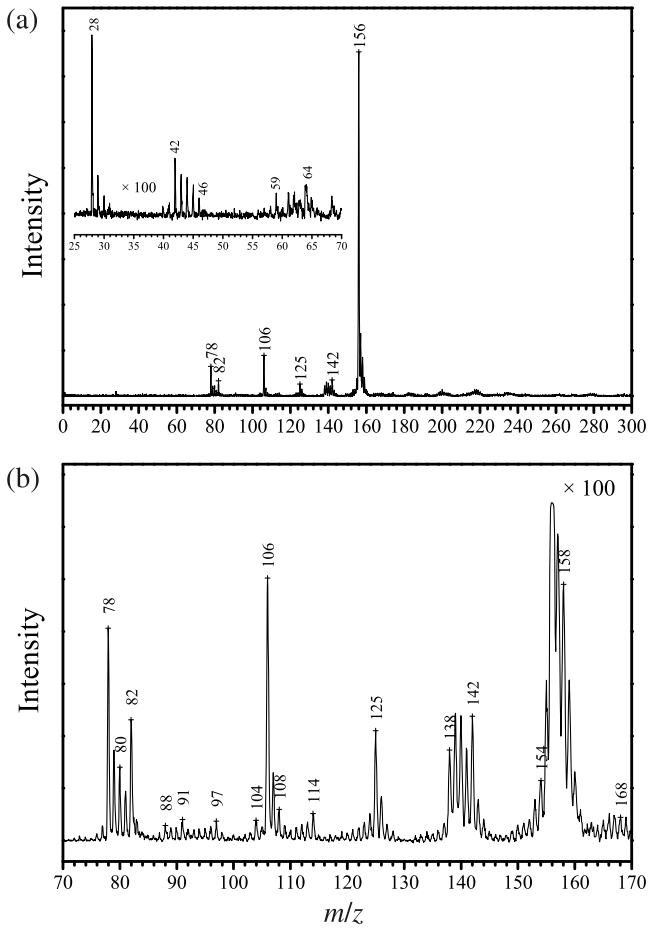
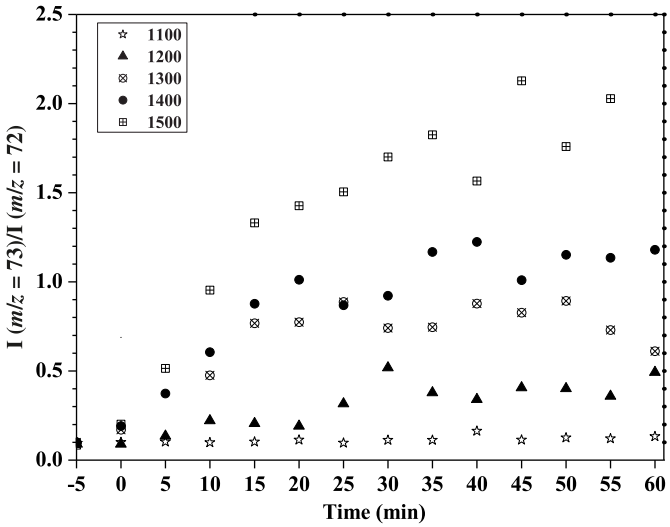
Fig. 3. (a) Mass spectra of a 4% 1,1-dimethyl-1-silacyclobutane (DMSCB)-d_6 – He mixture at 12 torr (1 torr = 133.3224 Pa) at a filament temperature of 1300 °C. Inset: enlarged mass spectra in the mass regions of 25–70 amu. (b) Enlarged mass spectra in the mass region of 70–170 amu.



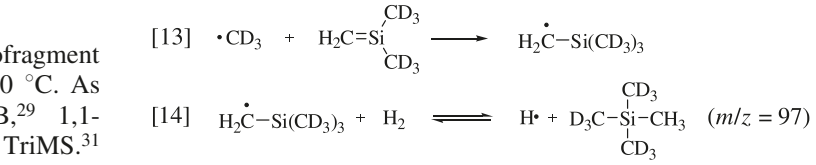
passed that of the peak at m/z = 59 (another photofragment peak from the DMSCB ion) at temperatures >1200 °C. As discussed in our previous study of TMDSCB,[29] 1,1-dimethylsilene can directly react with H_2 to form TriMS.[31] The room-temperature mass spectrum of TriMS when using 118 nm VUV laser ionization is dominated by two fragment peaks at m/z = 58 and 73 with an intensity ratio of 1:2.9. Therefore, the increase in the intensity of the peak at m/z = 58 is due to the formation of TriMS in the reactor and its photofragmentation upon VUV laser ionization. The photofragmentation of TriMS also contributes to the increase in the peak intensity at m/z = 73. Figure 5 shows the net intensity increase of the peak at m/z = 73 excluding the isotope contribution from the peak at m/z = 72 and the intensity contribution assumed from the photofragmentation of TriMS and TMS at 1400 and 1700 °C. It is clear that the intensity increase of the peak at m/z = 73 after the filament was turned on is mainly from the photofragmentation of TriMS and TMS. Similar behaviour was observed for other temperatures at 1300 and 1500–1600 °C. This strongly supports that both TriMS and TMS were produced in our HW-CVD reactor when using DMSCB as a source gas.

Moreover, if the aforementioned formation mechanisms

Fig. 4. The intensity ratio of the mass peak at m/z = 73 to that of the peak at m/z = 72 from a 4% 1,1-dimethyl-1-silacyclobutane (DMSCB) – He mixture at 12 torr (1 torr = 133.3224 Pa) vs filament-on time at different filament temperatures. The ratio at t = –5 min represents that at room temperature.



for the peaks at m/z = 58, 73, and 88 with DMSCB stand, a complex H–D scrambling for these peaks with DMSCB-d_6 is expected. As mentioned before, deuterated dimethylsilenes ($SiC_3H_{2+x}D_{6-x}$, x = 0–2) were produced from decomposition of DMSCB-d_6, with $SiC_3H_2D_6$ the most abundant of all[15]. H_2 will be the dominant species among H_2, HD, and D_2 formed via the elimination reaction from ethene, propene, and their isotopomers. Therefore, the deuterated TMS produced when using DMSCB-d_6 should have D atoms ranging from 7 to 10 and it is expected that TMS-d_9 (its formation shown in the following) should be the most abundant.



As shown in Fig. 3b, a group of peaks ranging from m/z = 95 to 98 were indeed observed, with the one at m/z = 97 being the most dominant of all. Upon irradiation by 118 nm VUV light, TMS-d_m (m = 7–10) fragments to produce deuterated trimethylsilyl ions (m/z = 77–82). These peaks are visible in Fig. 3b, of which the peak at m/z = 82 appeared to be the strongest. The peaks at m/z = 78–80 overlapped with the dominant photofragment ions (CH_2=$Si(CD_3)_2^{+\bullet}$) from the parent DMSCB-d_6 ion and their isotopes. TMS-d_9, the most abundant one, fragments to produce the peaks at m/z = 82 and 79 by losing one CH_3 and one CD_3 group, respectively. This explains the strong appearance of the peak at m/z = 82. The peak at m/z = 79 overlaps with one of the isotope peaks of the photofragment at m/z = 78 from the DMSCB-d_6 ion. However, after the filament was turned on, the peak intensity ratio of m/z = 79 to m/z = 78 increased with increasing filament temperature, as shown in Fig. 6. The ratio is much greater than the isotope contributions of 8.3%, and the photofragmentation from deuterated TMS ac-

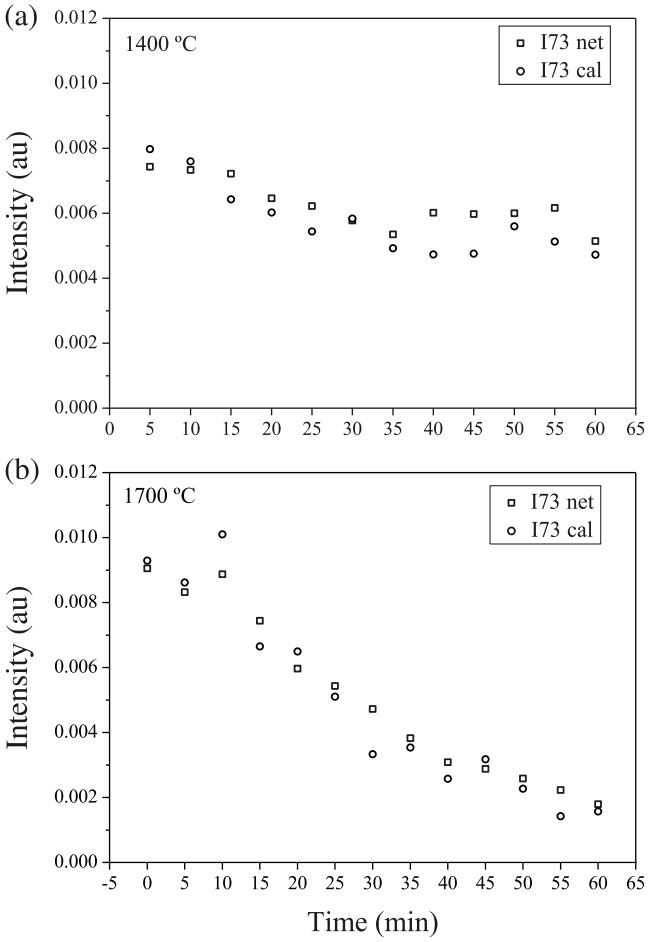
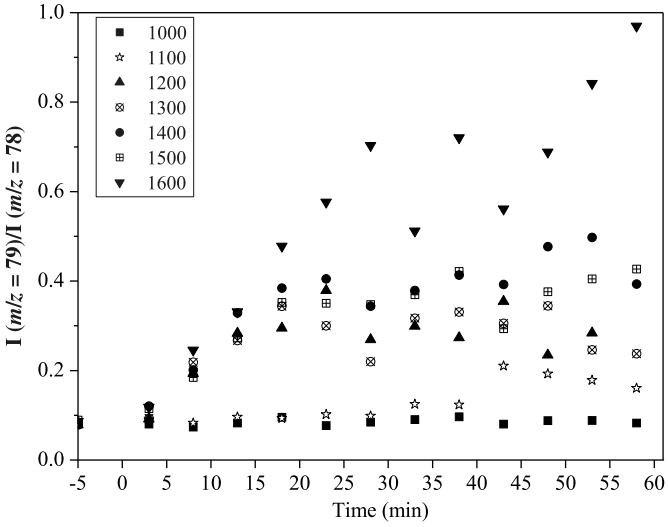
Fig. 5. The intensity of the peak at m/z = 73 from a 4% 1,1-dimethyl-1-silacyclobutane (DMSCB) – He mixture at 12 torr (1 torr = 133.3224 Pa) vs filament-on time at a filament temperature of (a) 1400 °C and (b) 1700 °C. I73net (□) represents the net increase in the peak intensity at m/z = 73 observed from the experiment excluding the isotope contribution from the peak at m/z = 72 and (○) represents the contribution to the peak intensity from the photofragmentation of TriMS and TMS combined.



counts for a majority of the increase in the peak intensity at m/z = 79.

One of the characteristic products from secondary reactions when using TMS in the same reactor was found to be ethyltrimethylsilane (TriMES, m/z = 102),[24] which was formed by a biradical combination reaction between methyl and trimethylsilylmethyl originated from H-abstraction reactions. When using DMSCB, this peak overlaps with one of the isotope peaks from the parent DMSCB (m/z = 100). However, the intensity ratio of the peak at m/z = 102 to the peak at m/z = 100 was found to increase with filament-on time and filament temperature. The ratio when the filament was on ranged from 5.6%–64.1%, which is much greater than the expected isotope contribution of 3.7%. Therefore, TriMES contributed to the increased intensity of the peak at m/z = 102 when the filament was turned on. When using DMSCB-d_6, based on the scrambling pattern described before, it is expected that TriMES-d_6 to -d_{12} will be produced, with TriMES-d_{12} being the most abundant of all. In Fig. 3b,

Fig. 6. The intensity ratio of the mass peak at m/z = 79 to the peak at m/z = 78 from a 4% 1,1-dimethyl-1-silacyclobutane (DMSCB-d_6 – He mixture at 12 torr (1 torr = 133.3224 Pa) vs filament-on time at different filament temperatures. The ratio at t = –5 min represents that at room temperature.



the peaks at m/z = 108–114 are shown. However, it should be noted that the H–D scrambling for the peak at m/z = 100 originating from eq. [7] could produce a mass shift between 2 and 10, contributing to the peaks up to m/z = 110. The peaks from m/z = 111 to 114 are believed to be from TriMES-d_9 to -d_{12}, and the peak at m/z = 114 is indeed the strongest.

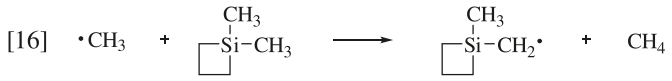
Following the same argument for the formation of deuterated TriMS with DMSCB-d_6, the reaction between the dominant dimethylsilene-d_6 and H_2 is shown in eq. [15].

Overall, TriMS-d_n (n = 4–8) with masses ranging from 77 to 81 amu could be produced. These peaks overlap with the photofragmentation peak of TMS-d_m (m = 7–10), which is not conclusive. However, upon VUV photoionization, TriMS-d_n (n = 4–8) could lose H (D) or (deuterated) methyl radicals. The latter will produce peaks ranging from m/z = 59 to 65, all of which was observed in our experiments, as shown in the inset in Fig. 3a. This provides more strong evidence that TriMS was formed in the reactor from the reaction between dimethylsilene and H_2 when using DMSCB.

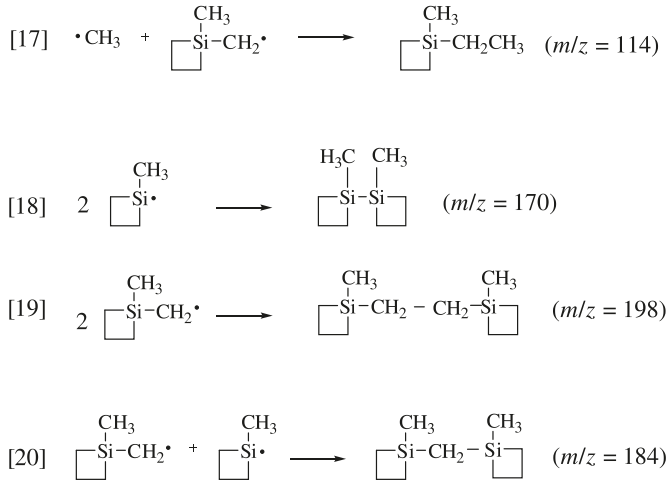
Hydrogen abstraction and biradical combination reactions

Our previous studies on TMS[24] and hexamethyldisilane[28] using the same process have shown that the H-abstraction reactions of either alkyl-substituted silanes or silyl-substituted alkanes by methyl radicals followed by biradical combination are the dominant pathways in the secondary gas-phase reactions. As shown in eq. [1], DMSCB also decomposes on the W filament to produce methyl and 1-methyl-1-

silacyclobutane-1-yl radicals. In the HW-CVD reactor, where the pressure of 4% DMSCB–He is 12 torr, the secondary gas-phase reactions of methyl radicals with the parent DMSCB molecule are likely to occur.



This can then be followed by the biradical combination reactions shown in the following:



The products of the above four reactions, namely 1-methyl-1-ethyl-1-silacyclobutane at m/z = 114, 1,1′-dimethyl-1,1′-bisilacyclobutane at m/z = 170, 1,2-bis(1-methyl-1-silacyclobutane-1-yl)ethane at m/z = 198, and 1,2-bis(1-methyl-1-silacyclobutane)methane at m/z = 184 were observed experimentally. This suggests that a H-abstraction reaction of DMSCB by methyl radicals occurred in the HW-CVD reactor. These four observed products contain the structure unit of 1-methyl-1-silacyclobutane-1-yl and could produce the fragment ion at m/z = 85 upon exposure to the VUV radiation. This explains the increase in the intensity ratio of m/z = 85 to that of the parent ion in the HW-CVD reactor when the filament was turned on. The 1-methyl-1-ethyl-1-silacyclobutane at m/z = 114 continues to react with methyl radicals through reactions similar to eqs. [16] and [17] to produce a series of peaks with a mass difference of 14, representing a CH_2 group, at m/z = 128, 142, 156, and 170. All these peaks were experimentally observed, as shown in Fig. 2c.

As shown in Fig. 2a, the peak intensities from the dominant product from the secondary gas-phase reactions, TMDSCB, surpasses that of the DMSCB source molecules at filament temperatures >1200 °C. Therefore, the primary decomposition reactions and secondary reactions involving TMDSCB play an important role at higher temperatures. The detailed reaction chemistry when using TMDSCB as a source gas in the same HW-CVD reactor has been reported previously.[29] It was found that TMDSCB decomposed on the W filament to produce methyl and 1,1,3-trimethyl-1,3-disilacyclobutane-1-yl radicals. In the HW-CVD reactor, the H-abstraction reactions and biradical combination reactions similar to those represented by eqs. [16]–[20] form species that are responsible for the peaks at m/z = 158, 286, 258, and 272, of which the peak intensity at m/z = 158 is the strongest. The observation of the peak at m/z = 158 (1,3,3-trimethyl-1-ethyl-1,3-disilcyclobutane) in our experiment with DMSCB (Fig. 2c) confirmed that TMDSCB was indeed formed from the secondary reactions in the reactor. It is interesting to note that although TMDSCB was produced relatively strongly at a low temperature at 1100 °C, its characteristic secondary gas-phase reaction products, e.g., 1,3,3-trimethyl-1-ethyl-1,3-disilcyclobutane at m/z = 158, were only observed at temperatures >1200 °C. This is consistent with the fact that the lowest decomposition temperature for TMDSCB in a HW-CVD reactor was 1200 °C.[29] As shown in Fig. 2c, the peak at m/z = 129 was also observed. The intensity ratio of this peak to that of the TMDSCB parent ion at m/z = 144 was found to be ~4% at temperatures <1200 °C. This is close to the same ratio when the filament was off.[29] This suggests that the peak at m/z = 129 is from photofragmentation of the parent TMDSCB ion at these low temperatures. When the filament temperature is >1200 °C, this intensity ratio increases with filament temperatures and filament-on time, ranging from 4% to 11.3%. Since 1,3,3-trimethyl-1-ethyl-1,3-disilcyclobutane and other products formed contain the structure unit of 1,1,3-trimethyl-1,3-disilacyclobutane-1-yl with m/z = 129, they could produce the fragment ion at m/z = 129 upon exposure to VUV radiation. This likely explains the increase of the intensity ratio of m/z = 129 to that of the parent TMDSCB at m/z = 144 when the filament temperature was >1200 °C.

Conclusions

When DMSCB is contained in a HW-CVD reactor with a relatively high pressure of 0.48 torr, secondary reactions in the gas phase between the source molecule and primary reactive species (e.g., CH_3, dimethylsilylene, and 1,1-dimethylsilene) formed from its decomposition on the heated W filament produced a variety of stable molecules that were detected by the TOF MS coupled with a "soft" ionization source. The π-type addition across the double and triple C–C bonds and the insertion reaction into the Si–H bond are important for dimethylsilyene in the HW-CVD reactor. The methyl radical produced on the hot W filament initiates a short-chain reaction, where it is quickly terminated by recombination between the radical chain carriers. This mechanism was found to dominate the gas-phase reaction chemistry when methyl is the main primary reactive species produced by hot-wire decomposition of source gases such as TMS and TMDSCB in our previous studies. When using DMSCB as a source gas, the H-abstraction and biradical combination reactions involving the source gas itself as well as the secondary products (i.e., TMDSCB, TriMDSCB, DMDSCB, and TMS) all occurred at the same time, making the gas-phase reaction chemistry quite complicated. Our previous study demonstrated that cycloaddition of the primary reactive intermediate, 1,1-dimethylsilene, produces the dominant secondary product, TMDSCB. The dominance of 1,1-dimethylsilene in the gas-phase chemistry when using DMSCB originates from the lower activation energy for its formation from the hot filament . In this work, two other reaction channels have been demonstrated to exist for 1,1-dimethylsilene, i.e., it reacts with CH_3 and H_2, respectively,

to form TMS and TriMS. The formation of TMS and TriMS via 1,1-dimethylsilene has been confirmed by examining the H–D scrambling pattern when using DMSCB-d_6 and the peak intensity distribution of the trimethylsilyl ions. This work, combined with our previous study on the primary decomposition and the dominant secondary reaction pathway, i.e., the cycloaddition of silenes, provides a relatively complete picture of the gas-phase reaction chemistry when using DMSCB in a HW-CVD reactor and will help in a future kinetic study of the key reaction steps.

Abstract: A series of five poly(3-hexylthiophene) (P3HT) polymers were prepared, and their spectroscopic properties were studied. These polymers were well defined, with polydispersity indices no larger than 1.20 and regioregularities that were above 90% for each member of the series. The P3HT polymers were characterized using UV–vis and fluorescence spectroscopy, and their specific refractive index increments were measured in tetrahydrofuran. The influence of the molecular weight of these polymers on their maximum absorbance and emission wavelengths, molar extinction coefficients, and refractive index increments was studied.

Key words: conjugated polymers, poly(3-hexylthiophene), regioregularity, polythiophenes.

Résumé : On a préparé une série de cinq polymères du poly(3-hexylthiophène) (P3HT) et on a étudié leurs propriétés spectroscopiques. Ces polymères sont bien définis, avec des indices de polydispersité qui ne dépassent pas 1,20 et des régiosélectivités supérieures à 90 % pour chaque membre de la série. Cette série de polymères du P3HT a été caractérisée par les spectroscopies UV–visible et de fluorescence et on a aussi mesuré leurs incréments d'indice de réfraction spécifique dans le tétrahydrofurane. On a étudié l'influence du poids moléculaire de ces polymères sur leur absorbance maximale et sur les longueurs d'ondes d'émission, sur les coefficients d'extinction molaire et sur les incréments d'indice de réfraction spécifique.

Mots-clés : polymères conjugués, poly(3-hexylthiophène), régiorégularité, polythiophènes.

Introduction

Polythiophenes have attracted interest because of their optical properties and their applications in photovoltaic devices.[1–3] The molecular weights of these polymers can affect their physical, structural, and spectroscopic properties.[4–6] Therefore, by studying the relationship between the molecular weight of a polymer and its physical properties, one can reveal basic information about the conformation of that polymer. Kline et al.[7] reported that the charge transport mobility of transistors composed of poly(3-hexylthiophene) (P3HT) was enhanced as the molecular weight of P3HT increased. This was also observed by Zen et al.,[8] who proposed that this behaviour resulted from the increased planarity of higher molecular weight polymers. Brinkmann and Rannou[9] used high-resolution transmission electron microscopy techniques to study the morphology of P3HT. They found that a 10-fold increase in the molecular weight of the polymer, from 7.3×10^3 to 6.96×10^4 g mol^{-1}, led to enhanced interconnectivity, with ordered polymers acting as bridges between different crystalline lamellae.

Interpretations of the relationship between the molecular weight of a polymer and its spectral properties can be affected by several parameters. The polydispersity index (PDI) of a polymer is an important factor, with interpretations being more accurate when a polymer with a narrow molecular weight distribution is studied.[10] Also, a polymer should have a high regioregularity, since a uniform chain microstructure can promote ordered chain packing and charge transport in solid films.[11] In particular, it has been demonstrated that polythiophenes that are coupled together by head-to-tail linkages have improved optical properties owing to their increased coplanarity.[5,12,13] The P3HT polymers analyzed in this study had a combination of regioregular structures and relatively low PDI values (ranging between 1.10 and 1.20) and also had regioregularities above 90% throughout the series. Although previous spectroscopic studies of regioregular P3HT included individual samples with PDI values as low as 1.1,[7] the PDI values within a given series ranged up to at least 1.4.[8,9,14,15]

In this study, we explored the relationship between the spectroscopic properties of P3HT and its molecular weight, using regioregular samples that had low polydispersity indices. The spectroscopic properties that we studied include the molar extinction coefficient, the wavelengths of the absorption and emission maxima, and specific refractive index

increments. A relationship was determined between the refractive index increment and the molecular weight of P3HT, which may potentially serve as a method of molecular weight determination of this polymer.

Results and discussion

Molecular weights, polydispersity indices, and regioregularities of the polymers

The five samples were denoted as T1, T2, T3, T4, and T5, and their properties are summarized in Table 1. The molecular weight differed between samples by at least 1000 g mol^{-1}. The regioregularities of these samples were all above 90%, with the major configuration being head-to-tail–head-to-tail. According to the size-exclusion chromatography (SEC) plots (Fig. 1), the five samples had a molecular weight range between 4 200 and 11 000 g mol^{-1}, and their PDI values were no higher than 1.20. The numbers of repeat units determined by SEC with the light scattering detector were also in close agreement with those determined by ^{1}H NMR integration.

Refractive index increments

Refractive index increments (dn/dc) of the samples were determined. From the change in the differential refractive index (DRI) detector voltage (ΔV), the difference in the refractive index between a pure solvent and the polymer solution (Δn) for each concentration c can be calculated as follows:

$$[1] \qquad \Delta n = \alpha \Delta V$$

where α is the DRI calibration constant. The slope of the Δn versus c plot represents dn/dc. The dn/dc values of the five polymer samples are summarized in Table 2.

UV–vis spectroscopy

The maximum absorbance wavelengths (λ_{max}) of the solution and thin-film samples of these polymers, as well as their molar extinction coefficients (ε), are summarized in Table 3. The spectra of the five samples in chloroform solution and as spin-coated thin films are shown in Fig. 2. In Table 3, it can be seen that the λ_{max} values are larger for the thin-film samples than for the solution samples of P3HT.

The absorbance spectra of the thin-film P3HT samples displayed vibrational fine structures, such as shoulder peaks on each side of the maximum absorbance peak. These features were enhanced by the coplanarization of the polymer and the corresponding π-electron delocalization. For example, the λ_{max} of sample T3 was observed at 541 nm and shoulder peaks were observed at 525 and 597 nm, corresponding to energy level transitions of 2.27, 2.39, and 2.08 eV, respectively. Enhanced red shifts and increased fine structures of thin-film samples of P3HT relative to those of solution samples were also observed by Trznadel et al.[4] and Zen et al.[8]

P3HT samples are shown in Table 4, while solution and thin-film fluorescence spectra are shown in Fig. 3. As shown in Table 4, the maximum emission wavelengths (λ_{em}) display red shifts as the molecular weight of the samples increases (as one progresses from T1 through to T5). This trend was observed for both the solution and the thin-film samples. Meanwhile, λ_{em} were longer for the polymers when they were analyzed as thin-film samples than when they were analyzed as solution samples. In a similar manner to the results of the UV–vis study, this may be due to enhanced π–π interactions within thin-film samples of the polymer compared with corresponding samples in solution. Owing to the self-quenching of the thin-film samples, the fluorescence spectra of the thin films were weaker in intensity than the corresponding solution spectra.

Effect of the molecular weight of P3HT on its spectroscopic properties

Refractive index increments

The dn/dc measurements increased from 0.24 to 0.28 mL g^{-1} with increasing molecular weight. These results are consistent with the accepted trend of dn/dc values increasing with increasing molecular weight for smaller polymers, and then leveling off once the molecular weight of the polymer becomes larger (such as above 10^4 g mol^{-1}).[16] By combining the results for the five different polymer samples in THF, we determined the following relationship:

$$[2] \qquad dn/dc = 0.316 - 298/M_n$$

The dn/dc value of 0.307 mL g^{-1} in THF reported by Pearson et al.[15] for a sample of P3HT having a molecular weight of 2.23×10^5 g mol^{-1} agrees closely with this equation, indicating a potential method for the determination of the molecular weight of P3HT based on its dn/dc values. Other polymers, such as poly(ethylene oxide), poly(methyl methacrylate), and polystyrene, have dn/dc values that range between 0.11 and 0.20 mL g^{-1}.[17–19] The higher dn/dc value of P3HT can be attributed to the presence of the sulfur atoms of the thiophene units, which contribute to the larger refractive index.[20]

The relationship between the refractive index and the molecular weight of P3HT can be explained in terms of the variation of the polarizability of the polymer as its molecular weight increases.[21] As a chain of P3HT bearing delocalized electrons is extended, the polymer becomes more polarizable. As a result, for a conjugated polymer such as P3HT there is a pronounced relationship between the molecular weight and refractive index values.

Spectral properties

The maximum absorbance and emission wavelengths increased as the molecular weight of the P3HT samples increased. This trend was observed for both the solution

Fig. 3. Fluorescence spectra of P3HT samples in chloroform solution (left) and as thin films (right).

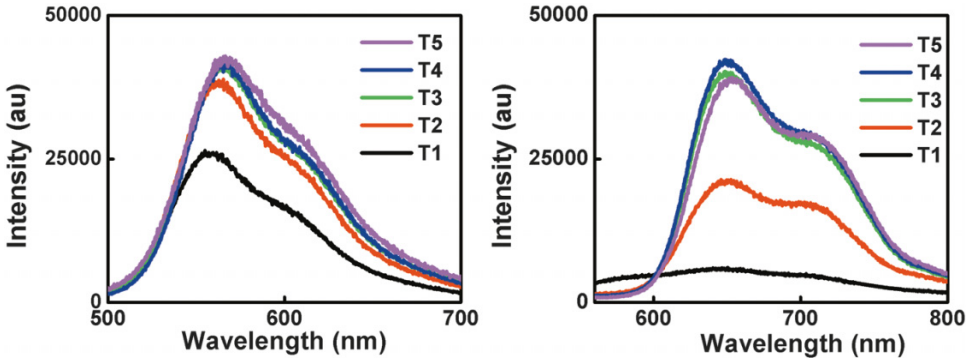

Fig. 4. Plots of the dependencies of λ_{max} (left) and λ_{em} (right) on the number of repeat units of P3HT, based on UV–vis and fluorescence data, respectively.

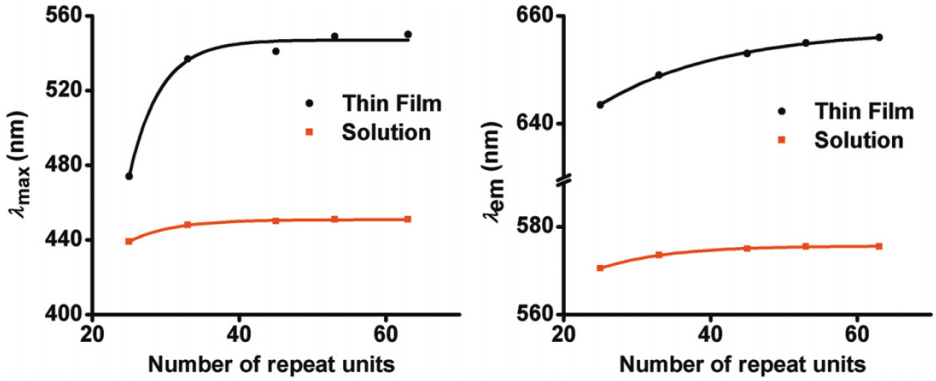

samples and the thin-film samples and was likely due to the decreases of the band gaps of the π–π* transitions as the lengths of the polymers increased and their conjugation was extended. The correlation between the absorbance and emission maxima of the P3HT samples and their number of repeat units is plotted in Fig. 4. The model used to fit this plot was that of Meier et al.,[22] and is described in the Supplementary data.

Extinction coefficient

In addition, a correlation exists between the molecular weight of the P3HT samples and their molar extinction coefficients (ε). For each P3HT sample, solutions were prepared in chloroform at varying concentrations. The values of ε were then plotted against the number of repeat units of the polymer samples, as shown in Fig. 5. The mathematical model[23] used to fit this plot is described in the Supplementary data. The ε values increased from 4700 to 8000 L mol^{-1} cm^{-1} as the molecular weight of the P3HT samples increased. As the conjugation length of a polymer is extended, its ε values also increase.[24,25] It is apparent from Fig. 5 that only slight increases of ε occurred once the molecular weight of the polymer exceeded 10^4 g mol^{-1}. This behaviour could explain the ε value of 8800 L mol^{-1} cm^{-1} reported previously for a P3HT polymer having a higher molecular weight of 4.8×10^4 g mol^{-1}.[26]

Izumi et al.[27] studied a series of well-defined beta-blocked oligothiophene derivatives and observed a continuous red shift of the absorbance maxima for polymers having up to 96 repeat units. They also observed dramatic increases of the molar extinction coefficient as the chain length increased, and large increases were observed even for samples with long chain lengths. In contrast, the molar extinction coefficients of P3HT observed by us increased only modestly as the length of the polymer exceeded 45 repeat units. Izumi et al. attributed their extended effective conjugation lengths to a lower degree of steric demand on their beta-blocked derivatives compared with that on derivatives bearing linear alkyl substituents, which may cause a greater extent of twisting of the backbone. This behaviour could also explain the saturation of the molar extinction coefficient increases that was observed in our samples beyond 45 repeat units (Fig. 5), as the bulk of the hexyl groups may have caused a greater degree of twisting of the polymer backbone, and thus a loss of conjugation, relative to the beta-blocked polythiophene derivatives studied by Izumi et al.[27]

Conclusions

From a series of five P3HT samples, a relationship between the molecular weight and the refractive index increment of this polymer was determined. Also, correlations between the molecular weight of P3HT and its spectral properties, such as its molar extinction coefficient and its maximum absorbance and emission wavelengths, were identified. The data presented in this study indicate that the refractive index increment (d*n*/d*c*), the maximum absorbance and emission wavelengths, and the extinction coefficients all increase with increasing molecular weight among our

samples of relatively low molecular weight (>2.0 × 10^4 g mol^{-1}) P3HT polymers. This study's focus on lower molecular weight polymers was beneficial, as it could be seen that the spectral changes were smaller at higher molecular weights. These results may serve as benchmarks for subsequent studies of polythiophene-based materials for applications such as photovoltaic devices, and also for the comparison of the physical properties of polythiophene derivatives. With a solid understanding of the relationship between the structural and spectral properties of P3HT in hand, it may be possible to tailor the polymer for specific applications.

Experimental section

Materials

Spectroscopic grade chloroform was purchased from Sigma-Aldrich. Methanol (ACS grade) was purchased from Fisher Scientific. Tetrahydrofuran (ACS grade) was purchased from Fisher Scientific and dried by passing it through two alumina columns in a Grubb's system for solvent purification. Ni(dppp)Cl_2 and a 1.0 mol L^{-1} THF solution of *tert*-butyl magnesium chloride were purchased from Sigma-Aldrich.

Synthesis of P3HT

Vinyl-terminated poly(3-hexylthiophene) was prepared by utilizing a modified Grignard metathesis reaction procedure, as described by McCullough and co-workers.[28] Following the synthesis, the crude polymer was dissolved in THF and purified by three repeated precipitations from methanol. Samples T1, T2, and T3 were prepared by fractionation, while higher molecular weight samples T4 (53 repeat units) and T5 (63 repeat units) were prepared from separate batches. During the fractionation of the lower molecular weight batches, a sample of $P3HT_{41}$ (2.310 g) was dissolved in THF. This solution was then added to methanol to precipitate the polymer. The precipitate was subsequently filtered, washed with a water/methanol (1/9, *v*/*v*) solvent mixture, and dried. The polymer was extracted with acetone in a Soxhlet apparatus until the extracting acetone became colourless. The acetone was then removed by rotary evaporation to yield 0.050 g of sample T1, which had 25 repeat units. The remaining fractions were then consecutively Soxhlet extracted with hexane and then dichloromethane. The hexane and dichloromethane fractions yielded samples T2 (33 repeat units) and T3 (45 repeat units), respectively. The purpose of the terminal vinyl group was to allow the subsequent use of the P3HT polymers as macroinitiators for the preparation of diblock copolymers by anionic polymerization, as described by Dai et al.[29] The preparation and study of diblock copolymers containing a P3HT block will be described in a later publication. Given the large number of double bonds present in these conjugated polymers, we do not believe that the presence of the additional vinyl group will significantly affect the physical or spectroscopic properties of the polymers. Further details of the synthesis of the polymer samples, as well as their characterization by ^{1}H NMR and SEC, are described in the Supplementary data.

Refractive index measurements

The refractive index increment (d*n*/d*c*) of P3HT was measured in dilute THF solution in the off-line mode, using a Wyatt Optilab rEX differential refractive index (DRI) detector. The experiments were conducted at a constant temperature (25 °C) and a flow rate of 0.33 mL min^{-1} using a syringe pump (RAZEL, model R99) connected directly to the DRI detector.

The P3HT samples were dried in a vacuum overnight before they were used. For each sample, 15.0 mg of P3HT was fully dissolved in 6.0 mL of THF and centrifuged at 2000*g*. A stock solution of P3HT was then prepared with an original concentration of 2.50 mg mL^{-1}. This solution was diluted to prepare the other four solutions, with concentrations of 2.00, 1.50, 1.00, and 0.50 mg mL^{-1}. THF was first eluted through the detector cell to establish a baseline. Each solution was then passed through the DRI detector, beginning with the samples at the lowest concentrations. The data were collected and processed using the ASTRA version 5.3.4.10 software package provided by Wyatt Technology Corp.

Size-exclusion chromatography

SEC analyses were conducted using a set of three styragel columns (MZ Analysentechnik) with packing materials having pore diameters of 500, 10^4, and 10^5 Å. The columns showed a linear separation in the range of 5.0 × 10^2 to 1.0 × 10^6 g mol^{-1} and were placed in a column compartment with a thermostat set to 25 °C. A Wyatt Dawn Heleos-II multi-angle light scattering detector (Wyatt Technology Corp.) and a Wyatt Optilab refractive index detector were used to measure light scattering and refractive index values, respectively. The laser sources of these detectors were operated at 690 nm.

Each polymer solution was filtered through a 0.45 μm Teflon syringe filter before injection. The SEC analyses were performed on THF solutions of P3HT at 25 °C, with sample concentrations of 5 mg mL^{-1} and eluent flow rates of 1 mL min^{-1}. The data processing was performed using the ASTRA 5.3.4.10 software package provided by Wyatt Technology Corp. The number of repeat units of the P3HT polymers (Table 1) was calculated by dividing the molecular

weight of the P3HT polymers (as determined by SEC using the light scattering detector) by the molecular weight of the repeat unit, which was 166 g mol^{-1}.

UV–vis and fluorescence spectroscopy

All P3HT solutions studied by UV–vis analysis were prepared using spectroscopic grade chloroform. The concentrations of the solutions ranged between 2.0×10^{-3} and 1.8×10^{-2} mg mL^{-1}. UV–vis measurements were performed using a Cary 300 Bio spectrophotometer (Varian) with a spectral range between 200 and 800 nm. Ten millimetre Varian quartz cells were used for all measurements, and spectroscopic grade chloroform was used as the blank.

To prepare the P3HT films, a chloroform solution of P3HT was spin-coated onto a pre-cleaned glass microscope slide at a speed of 1000 rpm for 50 s and subsequently annealed at room temperature under high vacuum for 12 h. The dried samples were then placed in a plate holder as described by Li et al.[30] for UV–vis analysis. We estimate that the thickness of these films is approximately 1 μm. This estimation was based on the Beer–Lambert Law, using a literature value of 1.1 g mL^{-1} as the density of P3HT.[31,32] These films were also used for analysis by fluorescence spectroscopy.

Fluorescence measurements were performed using a Photon Technology International Alphascan spectrometer with a 150 W Xenon compact light source, and 10 mm Hellma quartz cells were used. The P3HT solutions were prepared at a concentration of 2.0×10^{-3} mg mL^{-1} in chloroform, and the absorbances of the solutions at their maximum absorbance wavelengths were kept at 0.100. The excitation wavelength was 430 nm, and the excitation and emission slit widths were set at 5 and 3 nm, respectively.

^{1}H NMR spectroscopy

^{1}H NMR spectra were recorded on a Bruker Avance 400 MHz NMR spectrometer, with deuterated chloroform as the solvent. The relaxation delay was 3 s.

The regioregularities of the P3HT samples were calculated based on the relative integrals from the ^{1}H NMR spectra that corresponded to the head-to-tail–head-to-tail conformation.[33,34]

The number of repeat units could be determined by comparing the integrals of the end groups with those of the repeat units. This value could be used as a comparison to access the accuracy of the number of repeat units calculated based on SEC data.

Supplementary data

Supplementary data, including ^{1}H NMR spectra, formulae used to fit the plots in Figs. 4 and 5, d*n*/d*c* plots of the polymers, and further details of their preparation, are available on the journal Web site (canjchem.nrc.ca).

Computational study of proper and improper hydrogen bonding in methanol complexes

C. Dale Keefe and Zuzana Istvankova

Abstract: The bulk properties of alcohols, like those of aqueous solutions, are governed mostly by hydrogen bonding; however, in contrast with water molecules, the chemical structure of a simple alcohol such as methanol offers an opportunity to explore the effects of both proper and improper hydrogen bonding on a single hydrogen donor. The presence of the hydroxyl group generally gives rise to a strong proper hydrogen bond, while the methyl group of methanol is likely involved in the weaker improper hydrogen bond, among other weak non-covalent interactions. The effects of the two types of hydrogen bonds on the stability, geometric parameters, and properties of electron density of methanol complexes are examined while considering different geometrical arrangements of the methanol dimer and the binary complexes of methanol with water, acetonitrile, and chloromethane. Subsequently, potential conclusions about the nature of improper hydrogen bonding and the origin of the C–H bond contraction that results upon complex formation are discussed. Quantum theory of atoms in molecules and natural bond orbital methods were used in the analysis; all calculations were performed at the MP2(full)/6-311++G(d,p) level of theory.

Key words: infrared frequencies and intensities, red and blue shift, ab initio, atoms in molecules, methanol dimer, methanol complexes with water, acetonitrile, chloromethane, hydrogen bonding.

Résumé : Les propriétés globales des alcools, comme celles des solutions aqueuses, sont principalement déterminées par les liaisons hydrogènes ; toutefois, contrairement à ce qui est observé avec les molécules d'eau, la structure chimique d'un alcool simple, tel le méthanol, permet d'explorer les effets tant des liaisons hydrogènes propres et impropres d'un donneur d'hydrogène spécifique. La présence d'un groupe hydroxyle donne généralement lieu à une forte liaison hydrogène propre alors que le groupe méthyle du méthanol est vraisemblablement impliqué dans une liaison hydrogène impropre et plus faible parmi d'autres interactions faibles non covalentes. On a examiné les effets de ces deux types de liaisons hydrogènes sur la stabilité, les paramètres géométriques et sur les propriétés de la densité d'électron des complexes du méthanol tout en considérant divers arrangements géométriques du dimère du méthanol et de complexes binaires du méthanol avec l'eau, l'acétonitrile et le chlorométhane. On discute ensuite de conclusions potentielles concernant la nature de la liaison hydrogène impropre et de l'origine de la contraction de la liaison C–H qui résulte de la formation de complexes. Pour cette analyse, on a fait appel aux méthodes de la théorie quantique des atomes dans les molécules et de l'orbitale de liaison naturelle; tous les calculs ont été effectués au niveau MP2(complet)/6-311++G(d,p) de la théorie.

Mots-clés : fréquences et intensités infrarouges, déplacements vers le rouge et vers le bleu, ab initio, atomes dans les molécules, dimère du méthanol, complexes du méthanol avec l'eau, l'acétonitrile et le chlorométhane, liaison hydrogène.

Introduction

Among several different types of non-covalent interactions, the hydrogen bond (HB) plays an exceptionally important role in many fields of chemistry, biochemistry, and molecular biology.[1–4] The experimental and theoretical study of hydrogen bonding in methanol complexes has been an active topic of research for many years.[5–17] The idea of an unconventional improper HB has been brought forward by Hobza and Havlas.[18] Whereas the traditional HB is generally defined as an X–H···Y interaction, where X is an electronegative atom and Y is a region of excess electrons (lone electron pairs, π system), it has been found that a stabilizing intermolecular interaction also exists between carbon proton donors and regions rich in electron density.[19–21] Numerous experimental and theoretical studies have been performed on the C–H bond interactions involving both aromatic and nonaromatic molecules as electron density donors (HB acceptors),[21–28] as well as on other weak electron density acceptors (HB donors, such as Si–H and P–H bonds as well as N–H and F–H bonds).[29–32] A recent ab initio study from our laboratory investigated the interaction of X_3CH (X=H, F, Cl, or Br) with benzene and hexafluorobenzene.[33] Generally, the formation of a HB is associated with a vibrational spectral shift. A shift towards lower frequencies (red shift) is observed for proper HBs, together with an increase in vibrational intensity and, typically, bond elongation; on the other hand, a shift towards higher frequencies (blue shift) is usually observed for improper HBs, along with a decrease in

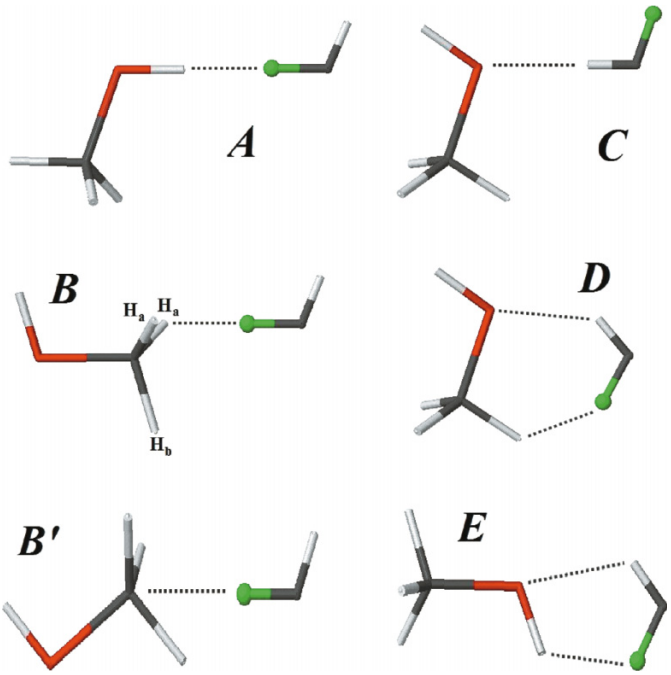
vibrational intensity and bond contraction.[34] The major source of the attraction in a proper HB is electrostatic interaction, explaining its strength and directionality.[19] Even though many similarities between proper and improper HBs have been reported in recent years,[18,31,32,35–37] the nature of unconventional hydrogen bonding and the origin of the bond contraction and concurrent blue shift of the stretching frequency are being actively studied by many groups, and several theories have emerged in recent years. Hobza and Havlas reported several similarities between the two HB types; however, they concluded that in contrast to the proper HB, the improper HB is formed by an indirect, two-step process where the charge transfer from the electron-rich region of the HB acceptor is directed mainly to the antibonding orbitals or the lone electron pairs in the remote parts of the HB donor.[19] A secondary effect is the structural reorganization of the proton donor, resulting in the strengthening and contraction of the X–H bond and the blue shift of the X–H stretching frequency.[19] Tsuzuki and Fujii[38] found that the nature of the CH···π interaction depends on the acidity of the interacting C–H bond. While the major source of attraction in CH···π bonding has been attributed to a dispersion interaction, similar to the interaction in a van der Waals cluster, the nature of some activated CH···π interactions of highly acidic C–H bonds may have some similarity with proper HBs. However, the electrostatic contribution in the activated CH···π interactions is substantially weaker than that in proper HBs, where the electrostatic contribution is the dominant attraction.[38]

On the other hand, Scheiner and Kar[35] concluded that there is no fundamental difference between the proper HB and the improper HB, and they attributed the changes in the X–H bond length to the net resultant of 2 sets of forces, the first (electrostatic interaction, polarization, charge transfer, and dispersion) tending towards elongation and the second (exchange forces associated with steric repulsion) tending towards contraction. Whereas in the proper HB the former set of forces dominates and results in the weakening of the X–H bond and the red shift of its stretching frequency, in the improper HB the short-range repulsive forces overcome the former set and the resulting stabilized complex exhibits the X–H bond strengthening and consequent blue shift of its stretching frequency. Likewise, other studies, for example those by Hermansson,[36] Alabugin et al.,[31] Qian and Krimm,[39] Li et al.,[32] and Joseph and Jemmis,[40] concluded that the red-shifted and blue-shifted HBs are governed by interactions of the same nature.

Although the same theory using perturbation model analysis, as suggested by Buckingham and colleagues,[37] could describe proper and improper HBs reasonably well, it still cannot unambiguously explain the origin of the C–H bond contraction and consequent blue shift of its stretching frequency. In many cases electrostatic models can give a good description of the nature of both red- and blue-shifting hydrogen bonding,[37] where the necessary condition for the meaningful use of these models is the negative sign of the proton donor dipole moment derivative with respect to the stretching coordinate,[36] which means that the dipole moment increases with the bond contraction; however, as Hobza and colleagues have indicated, the improper, blue-shifting HB has also been detected in complexes where the proton donor does not exhibit a negative gradient.[41]

Fig. 1. Schematic representation of the methanol complexes investigated. System **A**: a proper hydrogen bond (HB) in which the hydroxyl hydrogen of methanol is the HB donor. System **B**: an improper HB in which the methyl group of methanol is the HB donor. System **B′**: C···Y interaction in which the methyl group of methanol is the HB donor. System **C**: methanol is the HB acceptor. System **D**: two improper HB interactions, one involving the methyl hydrogen of methanol (HB donor) and the second involving the oxygen atom of methanol (HB acceptor) (could be thought of as a combination of **B** and **C**). System **E**: two HB interactions involving the hydroxyl group of methanol as HB donor and HB acceptor (could be thought of as a combination of **A** and **C**). The two equivalent hydrogens of the methyl group of methanol are labeled H_a, while the methyl hydrogen in the C–O–H plane is labeled H_b.



In this paper, we present the results of a computational study of methanol dimers and binary complexes of methanol with water, acetonitrile, and chloromethane. The optimized geometries, stabilization energies, harmonic frequencies, and vibrational intensities are reported. A net attraction is predicted for all of the optimized structures, and most of the complexes have no imaginary frequencies and are minima on the potential energy surface; small imaginary frequencies (less than $i40$ cm^{-1}) are observed for some systems and are noted where applicable. The purpose of this study is not only to analyze the changes that result upon complex formation in the bonds directly involved in the hydrogen bonding, but also to focus our attention on the changes in the remote parts of the molecules not directly involved in the intermolecular interactions to investigate whether the nature of proper and improper HBs is significantly different. The atoms in molecules (AIM) method provides useful insights into the description of chemical bonding[42–46] and it was used in the analysis of the electronic structure of the monomers and binary methanol systems. The topological features of the electron density can be described in terms of

Fig. 2. Topologies of the methanol complexes investigated; molecular graphs were constructed using AIM2000 software.[57] The larger circles represent the nuclei and the smaller red and yellow circles represent bond and ring critical points, respectively. The curves represent the bond paths linking the nuclei via bond critical points. [a]The structures are optimized to stable complexes, but calculated frequencies show one small imaginary frequency. [b]The structures are optimized to stable complexes, but calculated frequencies show two small imaginary frequencies. [c]The optimization of the methanol complex with chloromethane starting with the "**A**" structural arrangement of monomers always resulted in the optimized structure "**E**" when counterpoise (CP) correction was included. [d]The optimization of **D** and **E** arrangements of the CH_3OH/H_2O complex was not successful at the level of theory used. [e]For the CH_3OH/CH_3CN complex, only system **B′** (and not system **B**) was successfully optimized at the MP2 level with the CP correction included.

the critical points, the regions where the gradient vector of electron density is zero. The electron density, $\rho(r_c)$, and the Laplacian of the electron density, $\nabla^2\rho(r_c)$, evaluated at the intermolecular bond critical points and at the ring critical points as well as the integrated atomic properties were used in the description of proper and improper HBs. The natural bond orbitals (NBO) analysis, developed by Weinhold and co-workers, was performed to evaluate the orbital interactions within the pairs of interacting atoms.[47–49] NBO describes the chemical bonding in terms of hybridization or charge donation;[50,51] we have examined the occupancy and its changes upon HB formation at the lone pairs of the electronegative atom (O, N, and Cl) and at the antibonding orbitals of CO, CH, and OH, as well as the hybridization changes of the carbon atom and oxygen atom in the methanol molecule as an HB donor or HB acceptor.

The analysis of the above parameters is performed on the complexes with several different geometrical arrangements. Our goal is to complement earlier work on proper and improper HBs as well as to aid in describing the results of the experimental spectroscopic study of methanol complexes performed in our laboratory.[52]

Computational methods

The ab initio calculations were performed using Gaussian 03[53] on an AMD Opteron cluster. The geometries of all of the monomers and complexes were optimized at the second-order Møller–Plesset theory with the inner shells included (MP2(full)), with the 6-311++G(d,p) basis set; the energies, vibrational frequencies, and intensities were calculated at the same level of theory with the basis set superposition error approximated using the counterpoise correction method of Boys and Bernardi,[54] included in Gaussian 03. The stabilization energy of each dimer system was calculated as the difference between the calculated energy of the complex and the sum of the calculated energies of the isolated monomers, including the zero-point vibrational energy. Atomic charges were evaluated at the MP2(full)/6-311++G(d,p) level of theory using NBO (natural bond orbital),[55] a built-in subroutine of Gaussian 03, and using the AIM method.[44] Electron densities, bond critical point (BCP) properties, and atomic properties were analyzed using AIMAll software[56] and molecular graphs were constructed using AIM2000.[57]

Results and discussion

Five different arrangements (systems **A**, **B**, **C**, **D**, and **E**) of the binary complexes were considered. The structural arrangement of the monomers within each system is illustrated in Fig. 1. In systems **A** and **B**, methanol is a HB donor. In system **A**, a traditional HB exists between the hydroxyl hydrogen of methanol and the acceptor atom Y (Y= O, N, Cl), while in system **B** the unconventional HB interactions between the methyl group of methanol and Y are considered. Systems **B** and **B′** are very similar, though the AIM analysis shows 2 different electron density distributions (Fig. 2): in system **B** the BCP is found between a hydrogen atom and the acceptor Y, whereas in system **B′** the BCP is found between the carbon atom and the acceptor Y. Hence, system **B′** generally would not be considered as hydrogen bonded because the bond path does not connect the H atom to the Y acceptor atom through the BCP.[44] We first considered these systems as distinct; however, no significant difference with respect to the investigated parameters, other than the location of the BCP, was found between structures **B** and **B′**.

In system **C**, the oxygen atom in methanol acts as a HB acceptor (**C** and **C′** are used to distinguish between an improper HB and a proper HB, respectively). Systems **C** and **C′** were included in the study to examine the effects of the HB formation on the methanol molecule accepting the proton and to differentiate between changes due to HB donor and HB acceptor roles. The oxygen atom of methanol is the atom primarily involved in the HB interaction in these systems; however, the remote parts of the molecule, specifically the methyl group, show significant changes in the investigated parameters upon the non-covalent bond formation. System **D** has two improper HBs: one involves the methyl group of methanol and a Y atom, while the second involves the oxygen atom of methanol and a methyl group of the second unit of the complex. Finally, system **E** has the hydroxyl group involved in a proper HB and an improper HB (in the case of the methanol dimer the optimization of this arrangement resulted in a distinct interaction between two hydroxyl groups (we call it **E′**), and it will be treated separately). The optimizations of the **D** and **E** arrangements of the methanol–water complex were not successful at the level of theory used.

The stabilization energies and the corresponding distances between the monomers in the hydrogen-bonded complexes along with the values of the electron density and its Laplacian evaluated at the BCP found between the interacting atoms are summarized in Table 1, and the corresponding molecular graphs are illustrated in Fig. 2. It was found that with decreasing distance between the monomers within a hydrogen-bonded complex, the stabilization energy generally increases, and the values of the electron density, $\rho(r_c)$, and the Laplacian of electron density, $\nabla^2\rho(r_c)$, increase as well.[51,58,59]

Additionally, a good exponential relationship was observed between $\rho(r_c)$ or $\nabla^2\rho(r_c)$ and the intermolecular distance, as reported by others,[26,35,42,58,60–63] and an excellent linear relationship was found between $\rho(r_c)$ and $\nabla^2\rho(r_c)$, as

shown in Fig. 3. Reasonable logarithmic correlation was obtained between ΔE and the sum of the electron density evaluated at all critical points found between the monomers, or between ΔE and the sum of $\rho(r_c)$ evaluated at all BCPs between the monomers; the latter correlation was somewhat better, in agreement with the discussion by Rozas in the review of the nature of HBs.[21]

As expected,[41] the proper HB complexes (systems **A** and **C**′) are the most stable among all of the systems investigated, and the calculated stabilization energies (in the range

of –12 to –17 kJ mol^{-1}) are typical values for normal HBs.[21] The interaction energies for the improper HB complexes (systems **B** and **C**) are much smaller; however, stabilization energies in the range of –1 to –8 kJ mol^{-1} are still predicted upon complex formation. Furthermore, when two intermolecular improper HBs are present between the monomers, such as in systems **D**, the stabilization energies increase (approximately twice those of corresponding systems **B**), so cooperativity is predicted with two improper HBs within one system, where the directionality is known to make a smaller contribution to the strength of the interaction.[38,64] In contrast, changing the geometry of system **A** and introducing an additional CH···O interaction in addition to the proper OH···Y hydrogen bond (systems **E**) results in a slight lowering of the stabilization energy. The loss of directionality, which is known to be very important for proper HBs owing to a large contribution of the orientation-dependent electrostatic interaction, as well as an increased steric strain on the hydroxyl group contribute to the decrease in the stability of these complexes with respect to system **A**.

Vibrational frequencies and integrated intensities for the methanol monomer and the shifts in the vibrational frequencies for each of the complexes studied are summarized in Table 2. Corresponding changes in the bond lengths and changes in the electron density at BCPs are summarized in Table S2 of the Supplementary data. We shall emphasize the correlations between the frequency shifts of the stretching vibrations, the bond length changes, and the changes in the electron density evaluated at the intramolecular BCPs, which give a clear indication of either bond strengthening (bond length contraction, blue shift of the vibrational frequency, and decrease in the $\rho(r_c)$) or bond weakening (bond length elongation, red shift of the vibrational frequency, and increase in the $\rho(r_c)$) upon HB formation. To gain a better understanding of the nature of the interaction, all of the parts of the molecule directly or indirectly involved in the HB were examined; hence, we would like to draw attention to the remote parts of the methanol molecule in addition to the bonds directly involved in the HB.

The conceptual summary of the above relating to the frequency shifts of the methanol stretching vibrations is shown in Table 3. The significant red shift of the O–H stretching frequency (with the large increase in the vibrational intensity) and the blue shift of the C–O stretching frequency are observed only when methanol is donating a hydroxyl hydrogen in the proper HB (systems **A** and **E**), whereas the red shift of the C–O stretching frequency is expected for the improper HB involving the methyl hydrogen (systems **B** and **D**); however, the red shifts are smaller in magnitude, corresponding to weaker interactions. The considerable red shifts of the C–H stretching frequencies with the increase in the intensity of absorption are observed only for the proper HB complexes involving the hydroxyl hydrogen of methanol (systems **A**), in agreement with the study by Scheiner[65] investigating the spectroscopic patterns of CH···O hydrogen bonds in proteins. In all other cases, such as the improper HB involving hydrogen of a methyl group or the proper or improper HBs with methanol as an HB acceptor, blue shifts

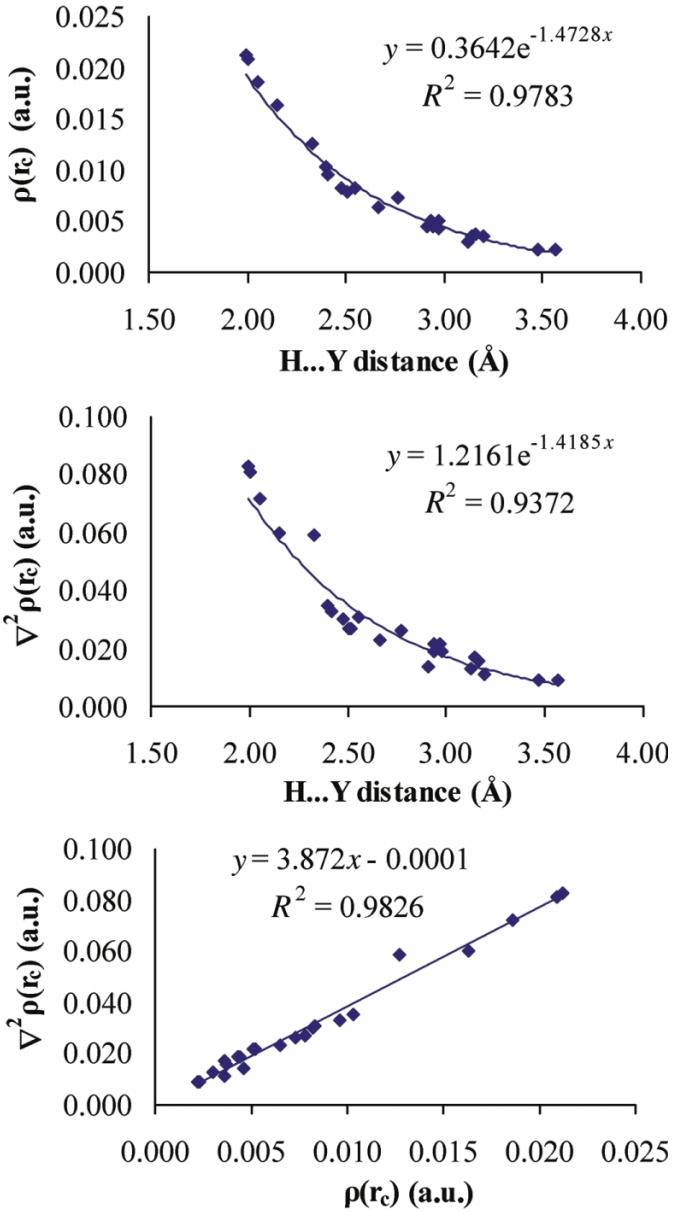
Fig. 3. The relationship observed between $\rho(r_c)$ or $\nabla^2\rho(r_c)$ and the intermolecular distance, as well as the relationship between $\rho(r_c)$ and $\nabla^2\rho(r_c)$, calculated at the MP2(full) level using quantum theory of atoms in molecules for the binary methanol complexes with methanol, water, acetonitrile, and chloromethane.



of the C–H stretching frequencies are predicted. The frequency shifts of the C–H stretching vibrations towards higher wavenumbers observed experimentally in the methanol solutions[52] might be an indication of hydrogen bonding involving the methyl group as HB donor, or they can also be understood as a result of methanol acting as an HB acceptor through the electronegative oxygen atom. The larger blue shifts in the C–H stretching frequencies result upon improper HB formation involving the methyl group of methanol as a proton donor or when methanol acts as an electron density donor in the proper HB, while the blue shifts of the C–H stretching frequencies are smaller when methanol acts as a proton acceptor in the improper HB (refer to Table 2). This might prove to be useful information when analyzing the experimental vibrational spectra of various methanol solutions; therefore, it is possible to conclude that the changes occurring at the remote parts of the molecule as a result of the intermolecular interactions should be considered an important factor in the description and characterization of the proper and improper hydrogen bonds.

AIM and NBO atomic charges are given in Table S3 of the Supplementary data. In the discussion below we refer to the AIM charges, since these were found to be more suitable[66] (carbon atom carries a positive charge when calculated with the AIM method and a negative charge when calculated using the NBO method); however, both methods give similar trends with respect to the charge distribution in methanol. The additional NBO data, including the changes in the atomic charges, in the natural bond orbital occupancy, and in the orbital energy, are listed in the Supplementary data (Tables S4, S5, and S6, respectively). The magnitude of the charge transfer from the HB acceptor to the HB donor and the most significant values of $E(2)$, the stabilization energy associated with delocalization for the intermolecular orbital interactions, are summarized in Table 4, while the changes in $E(2)$ corresponding to the intramolecular orbital interactions in the methanol molecule are shown in Table 5.

Joseph and Jemmis[40] have suggested that two complexes having the same density distribution, regardless of their nature, will give the same NBO data because the natural bond orbitals are generated from the final density of the complex; therefore, the NBO data alone cannot fully explain the origin of the C–H bond contraction in the improper HB. However, since the changes associated with the occupancy in σ*(C–H) are correlated with the inter- and intramolecular orbital interactions, the analysis of these could provide a considerable amount of information about the red- and blue-shifting nature of hydrogen bonds.[19,67] Intramolecular hyperconjugation plays a significant role in the electronic structure of methanol, contributing to the molecular stability of the methanol monomer, so it is reasonable to examine the changes in the intramolecular orbital interactions that occur upon the formation of a HB within the strongly or weakly bound complexes.

The charge transfer from HB acceptor towards HB donor is considerable (Table 4) for the proper HB methanol complexes (systems **A, C′**, and **E**). Although the percent s character of O in OH increases upon complex formation, the O–H bond is weakened and elongated owing to the dominant effect of the charge density being directed from the lone pair on the HB acceptor atom (Y) into the antibonding O–H orbital, σ*(O–H) (Table 4). The intramolecular orbital interaction LP(O) → σ*(C–H) in methanol increases in systems **A** (Table 5), in correlation with the C–H bond elongation and the red shift of the C–H stretching frequencies upon proper HB formation involving the hydroxyl hydrogen (refer to Table 2 and Table S2). In contrast with systems **A**, a decrease in the intramolecular orbital interaction LP(O) → σ*(C–H) is generally observed for systems **E**, possibly because of the presence of an O···HC interaction, and thus less charge is transferred to the antibonding CH orbital from LP(O) and could explain the C–H bond strengthening and contraction as the calculated $E(2)$ decreases.

The intermolecular charge transfer from HB acceptor towards HB donor is considerably smaller (Table 4) for the

Table 3. Summary of the changes in the vibrational frequencies of the OH, CH, and CO stretching vibrations of the methanol molecule involved in proper and improper hydrogen bonds (HBs) as either HB donor or HB acceptor.

	Proper HB	Improper HB
CH_3OH as HB donor		
OH	Large red shift	No change
CH	Red shift	Blue shift
CO	Blue shift	Red shift
CH_3OH as HB acceptor		
OH	No change	No change
CH	Blue shift	Small blue shift
CO	No change	No change

improper HB methanol complexes (systems **B, C**, and **D**). The electron density is directed away from H_a and slightly towards H_b, which could relate to the observation that the BCP is not found between H_b and Y (Y is the HB accepting atom) in systems **B** and **B′**, even though H_b carries the most positive charge (refer to Fig. 1). The insignificant charge transfer from the HB acceptor towards the HB donor might suggest that the changes in the atomic charges within the HB donor molecule are predominantly due to the intramolecular charge redistribution, and as suggested by Li,[67] the intramolecular hyperconjugation plays an important role along with the intermolecular hyperconjugation in the red- and blue-shifted HBs. A slightly weaker LP(Y) → σ*(C–O) intermolecular orbital interaction and a significant increase in the occupancy in σ*(C–O) are predicted, which correlates with the C–O bond weakening and elongation. A decrease in the LP(O) → σ*(C–H) intramolecular orbital interaction is observed for the improper HB complexes; therefore, a consequent decrease in occupancy in the σ*(C–H) orbital could explain the strengthening and contraction of the C–H bond. The occupancy in the σ(C–H) bonding molecular orbital decreases as well; however, it is of lower magnitude, so its effects would not prevail.

When methanol acts as a HB acceptor, the strengthening of the C–H bonds upon complex formation can be attributed to a decrease in the LP(O) → σ*(C–H) intramolecular orbital interaction and subsequent decrease in the NBO occupancy in σ*(C–H_a) and σ*(C–H_b), where the changes are larger for the proper HB, correlating with the larger frequency shifts. At the same time, the occupancy in one lone pair on the oxygen atom decreases, while for the second lone pair the occupancy increases by a small amount, and the increase in the NBO occupancy in σ*(C–O) corresponds to the C–O bond weakening, elongation, and subsequent red shift of its stretching frequency.

In systems **D**, the positive atomic charge on H_b, the hydrogen primarily involved in the HB interaction, increases considerably; this increase is comparable to the increase in the positive charge on the hydroxyl hydrogen involved in the proper HB (systems **A**). Even though the intermolecular orbital interaction LP(Y) → σ*(C–H) is more important in systems **D,** blue shifts of all of the C–H stretching frequencies are predicted; in contrast, the LP(Y) → σ*(C–H) interaction would have the opposite effect. The C–H bond contraction can be explained by the intramolecular charge transfer within the methanol molecule — specifically, by a decrease in the LP(O) → σ*(C–H) intramolecular orbital interaction — along with the considerable rehybridization of C in CH (percent s increase). However, there is also an important accepting role of the oxygen involved in the complex formation in systems **D**, and as described earlier, this additional interaction increases the complex stability; the charge transfer from the lone pair on the oxygen of methanol directed towards the HB donor would also cause C–H bond contraction.

Using the AIM analysis we also included evaluation of the 8 criteria for hydrogen bonding proposed by Popelier.[44] These criteria are as follows: (1) a BCP and two bond paths are found between the interacting atoms; (2) the meaningful range for the electron density, ρ(r), evaluated at the BCP is between 0.002 au and 0.04 au; (3) the range for $\nabla^2\rho(r)$ evaluated at the BCP is positive and between 0.02 and 0.15 au; (4) there is a penetration of the hydrogen atom and an acceptor atom (typically, the ρ value of the contour as an approximate boundary of the molecule in each monomer is taken to be 0.001 au); (5) the hydrogen atom loses electrons and (6) is destabilized; and (7) the dipolar polarization as well as (8) the atomic volume of the hydrogen atom decrease upon complex formation.

The results of the AIM analysis are given in Table 6. Since criteria 2 and 4–7 are satisfied for all of the complexes investigated, we will not discuss these in any more detail here, and only note that there seems to exist a correlation between the strength of the interaction and the magnitude of the change in the specific parameter, which might arise because not all of the proposed criteria are completely independent.[44]

Conventional hydrogen bonds (OH···Y interaction, Y=O, N, Cl (systems **A**, **C′** and **E**)) satisfy all 8 criteria, and as suggested by Popelier[44] and Koch and Popelier,[61] the verification of medium to strong hydrogen bonding is successful using the above analysis. Relatively large values of $\nabla^2\rho(r_c)$ correlate with the large decrease in the atomic volume of the hydroxyl hydrogen involved in the traditional OH···H hydrogen bond when the O–H–O angle is approximately 180° (systems **A** and **C′**), and these values decrease with a decreasing O–H–O angle (system **E**), as does the stabilization energy (Table 1). For the methanol dimer system **E′,** the intermolecular BCP is found between two oxygen atoms instead of between the hydrogen atom and oxygen atom; therefore, the basic topological character of traditional hydrogen bonding is not met. Considering that all of the other 7 criteria for hydrogen bonding are satisfied, this arrangement might be classified as a strained hydrogen-bonded complex. The calculated imaginary frequency might suggest that this arrangement is not the minimum at the potential energy surface; however, the size of the imaginary frequency is on the order of numerical accuracy and indicates a flat potential energy surface.[68]

The CH···O interaction within systems **E** and **D,** where the oxygen of methanol is the HB accepting atom, also satisfies all 8 criteria. In contrast, for the CH···Y interaction, where the methyl group of methanol is donating hydrogen (systems **B** and **D**), the calculated values of the Laplacian

Table 4. The magnitude of the charge transfer from the HB acceptor to the HB donor (positive values) calculated using the AIM method, and the most significant values of $E(2)$, the stabilization energy associated with delocalization for the intermolecular orbital interactions obtained from NBO analysis.

of electron density at the BCP are generally too low and outside of the suggested range; however, as pointed out by Popelier, the range of the values of electron density and its Laplacian at the intermolecular BCP serves more as a guide than as a rigid constraint.[44] For some cases though, the atomic volume of hydrogen increases upon complex formation; therefore, this criterion for hydrogen bonding would not be met in addition to the low value of $\nabla^2\rho(r_c)$.

The close similarity between systems **B** and **B′** (or systems **E** and **E′**) suggests that the presence of a BCP between the hydrogen and the Y atom is not as significant in the description of a HB as the value of the Laplacian at the particular critical point or the change in the atomic volume of an interacting atom, as has been proposed by Li and Yan.[69] Alternatively, electron density and its Laplacian evaluated at an intermolecular BCP might be used to quantify the strength of the HB interactions.[21] As Parthasarathi et al. discussed,[63] the smooth change in the nature of non-covalent interactions proceeds from the dispersive forces dominated by van der Waals interactions through classical to strong hydrogen bonding, which is mainly electrostatic in nature. This differs from the dramatic change in $\nabla^2\rho(r_c)$ from positive to negative values observed when going from a strong non-covalent hydrogen bond to a covalent bond.[63]

Conclusion

Several distinct geometrical arrangements of methanol dimers and binary systems of methanol with water, acetonitrile, and chloromethane were considered in this study, and the nature of proper and improper hydrogen bonds was investigated. The formation of a considerably stronger, proper HB interaction involving the hydroxyl hydrogen of methanol leads to weakening and elongation of the O–H bond, accompanied by a red shift of the O–H stretching frequency and an increase in the intensity of absorption. On the other hand, the improper HB involving the methyl group of methanol is a weak interaction and leads to strengthening and contraction of the C–H bond, accompanied by a blue shift of the C–H stretching frequencies and a decrease in the vibrational intensity.

The changes occurring at the remote parts of the HB donor molecule as a consequence of the intermolecular interaction should be considered an important factor in the description and characterization of proper and improper hydrogen bonds. The frequency shifts of the C–H stretching vibrations towards higher wavenumbers could be used as an indication of hydrogen bonding involving the methyl group as a HB donor, or these could also be understood as a result of methanol acting as a HB acceptor through the electronegative oxygen atom. The red shift of the C–H stretching frequency is predicted only upon proper HB formation involving the hydroxyl hydrogen of methanol. This might prove to be useful information when analyzing the experimental vibrational spectra of various methanol solutions.

Our study of binary methanol complexes suggests that along with a balance between opposing physical forces (electrostatic interaction, polarization, Pauli exclusion) that influence the lengthening or contraction of the bonds involved in the non-covalent interactions, the orbital overlap and electron charge transfer also play an important role and influence the resulting observable red or blue shift of the corresponding stretching frequencies. A close resemblance between the topological features of the electron density and its Laplacian for a proper HB and an improper HB suggests that the nature of these hydrogen bonds is similar, though there are some differences in the molecular orbital interactions and electronic charge transfer within the monomers or between the monomers of proper and improper HB complexes. The charge transfer from the HB acceptor to the HB

Note: In the cases where the BCP exists between the HB acceptor atom (Y) and an HB donor atom other than hydrogen (O or C), the atomic properties values are calculated for the hydrogen atom closest to the HB acceptor rather than for the oxygen or carbon atom linked to the Y atom via the BCP. ΔN, ΔM, and ΔV are the change in charge, dipolar polarization, and volume upon complex formation.

donor is significant in a strong proper HB, which is mostly electrostatic in nature. The electrostatic forces and the intermolecular charge transfer are less dominating for an improper HB; instead, the intramolecular hyperconjugation plays a more significant role in the electronic structure of the improper HB methanol complexes.

Although the fundamental nature of proper and improper hydrogen bonding seems to be comparable, the origin of the C–H bond contraction in an improper HB can be explained by a different effect than the origin of the O–H bond elongation in a proper HB. Specifically, the elongation of the O–H bond is predominantly due to a strong electrostatic interaction between the OH group of the HB donor and an electron-rich region, accompanied by a considerable intermolecular charge transfer from the HB acceptor toward the antibonding σ*(O–H) orbital, upon which the weakening of the O–H bond is observed. On the other hand, the contraction of the C–H bond arises from a decrease in the intramolecular LP(O) → σ*(C–H) orbital interaction, causing strengthening of the C–H bond and a consequent blue shift of its stretching frequency. The weakening of the intramolecular LP(O) → σ*(C–H) orbital interaction in an improper HB complex can be explained as a result of a secondary structural reorganization of the proton donor due to the interactions between a HB acceptor and the remote parts of the HB donor, supporting the theory of Hobza.[19,41] Further work is ongoing to gain a better understanding of the above interactions and to extend existing theories, so that it will be possible to predict the spectroscopic shifts in the stretching frequencies based solely on the nature of the HB donor and HB acceptor and to use the experimental spectroscopic data to predict a possible type of non-covalent bonding interaction between the molecules.

Supplementary material

Supplementary data for this article, including the archives for all geometry optimizations of the structures discussed in this paper, are available on the journal Web site (canjchem.nrc.ca). Figures S1 and S2 show the relationships between the stabilization energy, the HB distance, and the sum of ρ(r) or the sum of $\nabla^2\rho(r)$ evaluated at the intermolecular BCPs and at all intermolecular critical points; the calculated data are listed in Tables S1 and S2. Figures S3–S6 show the envelope maps of the Laplacian of electron density. Changes in the stabilization energy in the formation of proper and improper hydrogen bonds with a methyl substitution in the HB donor and HB acceptor are illustrated in Fig. S7. Atomic charges calculated using AIM and NBO methods are compared in Table S3. Tables S4–S6 show the additional NBO results. Molecular graphs illustrating additional H_2O, MeCN, and MeCl complexes are shown in Fig. S8; corresponding data are summarized in Table S7.

Abstract: A poly(*para*-phenylene ethynylene) with water-solubilizing groups and Gd(III) chelates conjugated to the polymer backbone was designed and synthesized. Pre- and post-polymerization functionalization approaches were explored and the pre-polymerization approach for the introduction of the Gd(III) chelate was found to be more successful. The UV–vis absorption and fluorescence emission properties of the protected polymers were characterized and were found to be consistent with the results expected for this class of polymers. Removal of the protecting groups followed by chelation of Gd(III) led to a water-dispersible polymer. Relaxivity measurements were performed on this polymer with the aim of evaluating its potential as a new MRI contrast agent, and an r_1 of 1.37 L mmol^{-1} s^{-1} at 310 K and 20 MHz was determined. These results, along with dynamic light scattering analyses, suggested that the polymers formed micrometre-sized assemblies in aqueous solution. Although the relaxivity was relatively modest, these results provide important insights into the assembly properties of this new class of polymers and into the design criteria for future agents.

Key words: poly(*para*-phenylene ethynylene), magnetic resonance imaging, contrast agent.

Résumé : On a développé et synthétisé un poly(*para*-phénylèneéthylène) portant des groupes solubles dans l'eau et des chélates de Gd(III) conjugués au squelette du polymère. On a exploré des approches de fonctionnalisations avant et après les polymérisations et on a trouvé que l'approche prépolymérisation est meilleure pour l'introduction du chélate de Gd(III). On a caractérisé les propriétés d'absorption UV–visible et d'émission de fluorescence des polymères protégés et on a trouvé qu'ils sont en accord avec les résultats attendus pour cette classe de polymères. L'enlèvement des groupes protecteurs, suivi par la chélation du Gd(III) conduit à l'obtention d'un polymère qui peut être dispersé dans l'eau. On a effectué des mesures de relaxation sur ce polymère dans le but d'évaluer son potentiel comme un nouvel agent de contraste en imagerie de résonance magnétique (IRM) et on a déterminé que sa valeur de r_1 est égale à 1,37 L mmol^{-1} s^{-1}, à 310 K et à 20 MHz. Ces résultats, avec les analyses de dispersion dynamique de la lumière, suggèrent qu'en solution aqueuse les polymères forment des assemblées de la taille du micron. Même si la relaxation est relativement faible, ces résultats fournissent connaissances importantes dans les propriétés d'assemblage de cette nouvelle classe de polymère et dans les critères de conceptualisation des futurs agents.

Mots-clés : poly(*para*-phénylèneéthylène), imagerie de résonance magnétique (IRM), agent de contraste.

[Traduit par la Rédaction]

Introduction

Over the past few decades, magnetic resonance imaging (MRI) has emerged as a powerful noninvasive diagnostic tool in medicine.[1–3] It provides excellent spatial resolution and soft tissue contrast for conveying anatomical structure. In cases where the inherent soft tissue contrast is insufficient to distinguish diseased tissues from normal tissues, contrast agents are routinely used.[2,3] These agents are typically stable chelates of the lanthanide ion Gd(III). While these small-molecule agents have enabled significant advancements in MRI, they possess several limitations.

First, the relaxivities of the commercially available agents are only a few percent of the theoretically predicted values.[4] The low sensitivity of these agents imparts a requirement for gram-scale doses to obtain the required contrast. This raises concerns regarding the toxicity of these agents, particularly in patients with kidney disease.[5] Furthermore, there is increasing interest in the development of contrast agents tar-

geted to specific diseases via binding to receptors in the target tissues. Considering a stoichiometric 1:1 binding of the agent to the target, the target must be present at a concentration of approximately 125 μmol L^{-1}.[3] Unfortunately, many targets are not present at this relatively high concentration in vivo.

To address these limitations, significant efforts have been aimed at enhancing the relaxivities of Gd(III)-based contrast agents. It has been predicted by Solomon–Bloembergen–Morgan theory that increases in the rotational correlation times of the current agents can result in significantly increased relaxivities.[6,7] As macromolecules have slower tumbling rates in solution, much research has involved the conjugation of Gd(III) chelates such as diethylenetriaminepentaacetic acid (DTPA) and 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) to macromolecules. Early efforts involving conventional linear macromolecules led to relatively disappointing results.[8–14] However, the conjugation of these chelates to macromolecules such as proteins[15,16] and dendrimers[17–25] provided much greater enhancements in relaxivity. These results highlight the importance of macromolecular structure and architecture, as flexible backbones allow the Gd(III) chelates to tumble in solution in a manner similar to the small molecules, while those structures possessing well-defined and rigidified conformations provide longer rotational correlation times and thus higher relaxivities.

With the importance of molecular rigidity in mind, our group was interested in investigating poly(*para*-phenylene ethynylene) (PPE) as a backbone for the conjugation of Gd(III) chelates. This polymer backbone, comprising alternating phenyl and alkyne moieties, exists in an elongated linear conformation, with backbone conjugation leading to high levels of fluorescence.[26–31] This fluorescence and its sensitivity to its environment have been exploited for the development and commercialization of sensors.[29–31] More recently, water-soluble analogues of these polymers have been developed and have been investigated as sensors for DNA,[32–34] proteins,[35] and bacteria.[36,37] However, to the best of our knowledge PPEs have never been investigated as MRI contrast agents. We proposed that the rigidified, elongated conformation of PPE would lead to significant enhancements in relaxivity of conjugated Gd(III) chelates. Furthermore, the fluorescence may enable the optical detection of these agents in cells and tissues, thus facilitating biological studies of the agents and potentially providing a dual modality imaging probe, perhaps even with sensor capabilities. Described here is the synthesis of a new PPE with conjugated Gd(III) chelates and the characterization of its optical properties and relaxivity.

Results and discussion

Polymer design

The structure of the target copolymer **1** is shown in Fig. 1. A modified DTPA[38] was selected as the Gd(III) chelate in this polymer, as the extra carboxylate incorporated in the aspartic acid linker allows 8 chelation sites of the ligand to be preserved for binding to the metal ion. Direct use of one of the carboxylates of DTPA for conjugation to the polymer backbone would lead to decreased complex stability, thus increasing the chances of transmetallation by Zn(II), a process that would potentially release toxic free Gd(III) in vivo.[39] In addition, although the conjugation of the modified DTPA chelate to the phenols of the polymer backbone would be expected to provide the highest relaxivity, this conjugation was not efficient in preliminary work. Therefore, an ethyl spacer was incorporated between the polymer backbone and the chelate to introduce a more nucleophilic amine group for the conjugation to the acid-functionalized DTPA.

Although the chelates were expected to impart some aqueous solubility to the PPEs, water-solubilizing oligo(ethylene glycol) moieties were also incorporated in the design. PPEs, like other conjugated polymers having a rigid and hydrophobic backbone, have inherently very poor water solubility that results in aggregation and subsequent fluorescence quenching.[40–42] Carboxylic acid terminated oligo(ethylene glycol) moieties were chosen because they have been previously demonstrated by Wosnick et al. to impart aqueous solubility to PPEs.[37] Indeed, preliminary work in our laboratory demonstrated that neutral tri(ethylene glycol) monomethyl ether derivatives were insufficient to impart aqueous solubility.

PPEs are typically prepared from diiodophenylene and dialkyne monomers via Sonogashira–Hagihara copolymerizations.[43,44] Based on this strategy, the proposed design incorporated the modified DTPA chelates into the diiodophenylene monomer **2** and the tetra(ethylene glycol) moieties into the dialkyne monomer **3** (Fig. 1). In addition, it was of interest to explore the postpolymerization functionalization of the PPE backbone as an alternative means of preparing the target polymers. This would potentially provide a versatile synthetic method that would allow easy incorporation of targeting ligands in future generations of the agent. Therefore, polymer **4** was also designed as a target, which would be prepared from monomers **3** and **5**.

Monomer syntheses

The synthesis of the dialkyne monomer **3** was performed following a protocol similar to that reported by Wosnick et al. for slightly different oligo(ethylene glycol) lengths (di(ethylene glycol) and penta(ethylene glycol)).[37] As shown in Scheme 1, 2,5-diiodo-1,4-hydroquinone (**6**)[30] was reacted with the tosylate **7**,[45] providing **8**. The alkyne moieties were then introduced by a Sonogashira reaction with trimethylsilylacetylene (TMSA) in the presence of catalytic copper(I) iodide and bis(triphenylphosphine)palladium(II) chloride. Finally, the trimethylsilyl protecting groups were removed by treatment of **9** with tetrabutylammonium fluoride (TBAF), providing **3**.

The synthesis of monomer **2** began with the reaction of the tosylate **10**[46] with 2,5-diiodo-1,4-hydroquinone to give the diazide **11** (Scheme 2). The azides were then reduced to amines under Staudinger conditions, providing **12**. Finally, the amines were conjugated to the previously reported DTPA derivative **13**[38] using dicyclohexylcarbodiimide (DCC) in the presence of 4-(dimethylamino)pyridine (DMAP) and 4-(dimethylamino)pyridinium *p*-toluenesulfonate (DPTS) to provide monomer **2**. For the preparation of monomer **5**, *tert*-butyl carbamate (Boc) protected 2-bromoethylamine (**14**)[47] was reacted with 2,5-diiodo-1,4-hydroquinone as shown in Scheme 3.

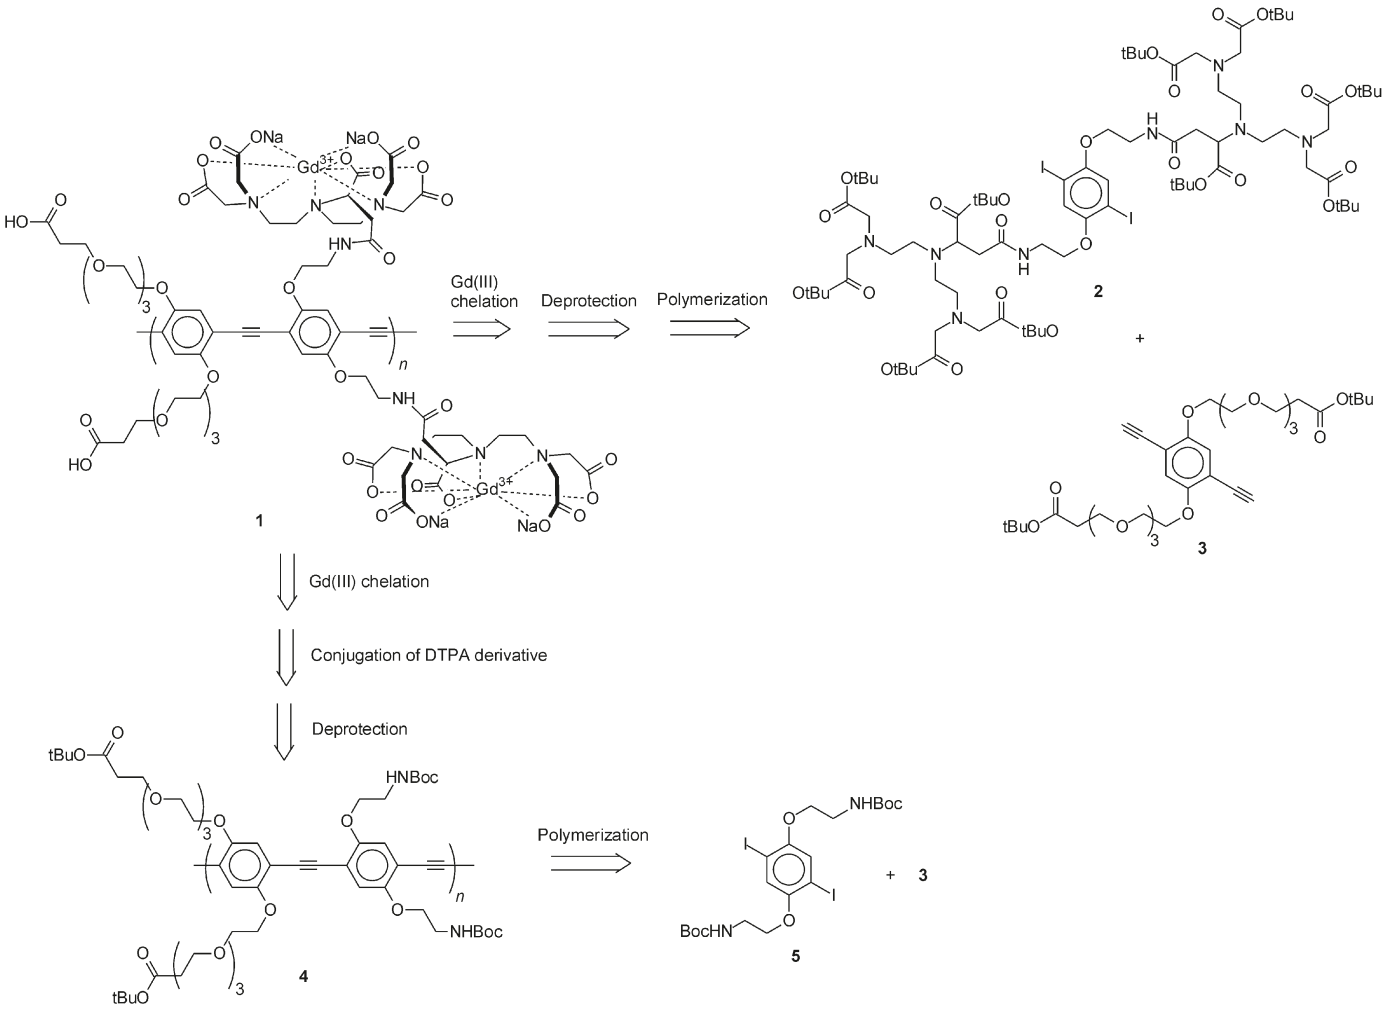
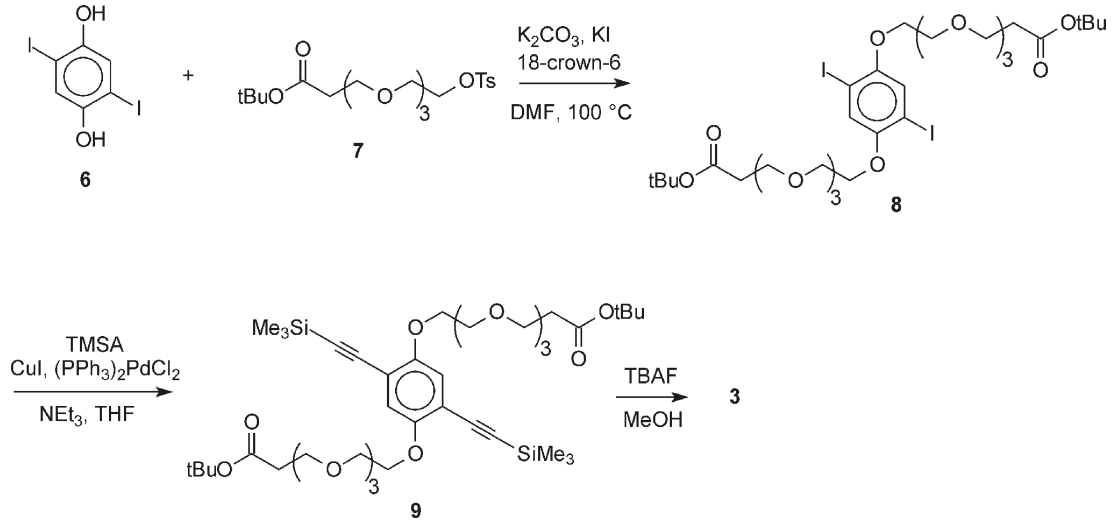


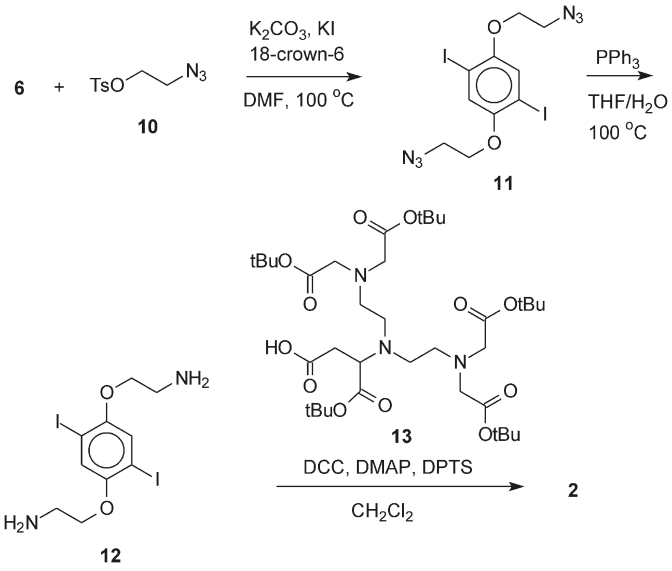
Scheme 1. Synthesis of monomer **3**.



Polymer syntheses and characterization

Monomers **2** and **3** were copolymerized under Sonogashira–Hagihara conditions[43,44] to provide the protected polymer **15**, which was purified by dialysis in *N*,*N*-dimethylformamide (DMF) (Scheme 4). Using size exclusion chromatography (SEC) (Fig. 2), **15** was found to have a weight-average molecular weight (M_w) of 31 300 g mol^{-1} and a polydispersity index (PDI) of 2.6 as determined by a conventional calibration relative to polystyrene standards. Following determination of the refractive index increment (d*n*/d*c*) for

Scheme 2. Synthesis of monomer **2**.



Scheme 3. Synthesis of monomer **5**.

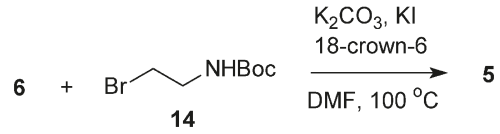


Fig. 2. Size exclusion chromatography traces for polymers **15** and **4**.

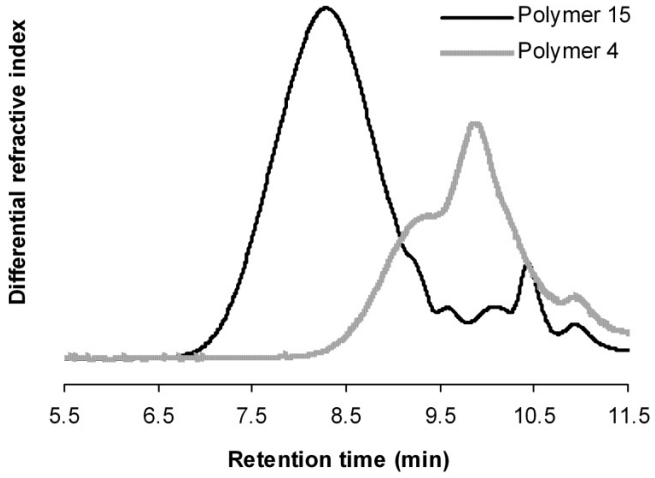

the polymer, its absolute molecular weight was also determined by multi-angle light scattering (MALS). This measurement provided an M_w of 40 500 g mol^{-1} and a PDI of 1.9. The values obtained by the conventional calibration and light scattering were therefore in relatively good agreement.

Monomers **3** and **5** were polymerized under the same conditions described above, leading to polymer **4**, which was also purified by dialysis in DMF. This polymer was found by SEC (Fig. 2) to have an M_w of 2640 g mol^{-1} and a PDI of 2.4. The lower M_w of this polymer in comparison with **15** can be attributed at least in part to the lower average monomer molecular weight but was also likely due to a lower degree of polymerization for unknown reasons.

As shown in Fig. 3, both polymers **15** and **4** exhibited red-shifted absorption maxima (λ_{max}) at 430 nm and 406 nm, respectively, relative to that of the dialkyne monomer **3** at 327 nm. This bathochromic shift can be attributed to the significantly increased conjugation of the polymers relative to the monomer and is typical of PPEs.[26,29] Concomitantly, the emission maxima also shifted to 465 nm and 460 nm for polymers **15** and **4**, respectively, relative to the monomer's emission λ_{max} of 372 nm (Fig. 4). These emission maxima are similar to those of other previously reported PPEs.[37,48]

Polymer deprotection and Gd(III) chelation

The *tert*-butyl ester groups on both the tetra(ethylene glycol) and DTPA derivatives of polymer **15** were easily removed by treatment of the polymer with 1:1 trifluoroacetic acid (TFA):CH_2Cl_2 to provide polymer **16** (Scheme 5). The resulting polymer was then dissolved in pure water and the pH was adjusted to 7.4 prior to the introduction of Gd(III) in the form of $GdCl_3 \cdot 6H_2O$, giving the target polymer **1**. Following purification by extensive dialysis, the Gd(III) content was measured by inductively coupled plasma mass spectrometry. Based on these measurements, Gd(III) was successfully introduced into each chelation site and no extra Gd(III) was detected.

Polymer **4** could also be fully deprotected by treatment with 1:1 TFA/CH_2Cl_2 to give **17** (Scheme 6). The next step towards the target was the introduction of the Gd(III) chelates by reaction of **17** with an *N*-hydroxysuccinimidyl ester derivative of **13** or the commercially available *p*-isothiocyanatobenzyl derivative of DTPA. Unfortunately, although **17** was soluble in organic solvents such as DMF and $CHCl_3$ when the amines were present as their TFA salts, all attempts to neutralize or basify the solution or to dissolve the polymer in aqueous buffer for the conjugation led to rapid polymer precipitation. The use of other polar solvents such as dimethylsulfoxide or methanol did not result in enhanced solubility, so this polymer could not be further functionalized.

Relaxivity measurements

The longitudinal relaxivity (r_1) of polymer **1** in 100 mmol L^{-1} pH 7.4 phosphate buffer was measured at 298 and 310 K between 0.01 and 35 MHz using a field cycling relaxometer. The results are shown in Fig. 5. When calculated on a per Gd(III) ion basis, the results corresponded to an r_1 of 1.37 ± 0.03 L mmol^{-1} s^{-1} at 310 K and 20 MHz. This result was unexpectedly low relative to the value of 4.1 L mmol^{-1} s^{-1} measured for Gd-DTPA under the same conditions.[15] In addition, although **1** appeared "soluble" upon first inspection, it was noted that after prolonged standing some material settled from solution, resulting in even lower relaxivities. This material could be redispersed by mixing, resulting in recovery of the relaxivity to the original value. This behaviour, along with a complete lack of polymer fluorescence, suggested that the polymer may have assembled into micrometre-sized particles in solution.

The suspension of polymer **1** was investigated by dynamic light scattering. As shown in Fig. 6, micrometre-sized particles were indeed detected. Optical microscopy was also

Scheme 4. Synthesis of polymer **15**.

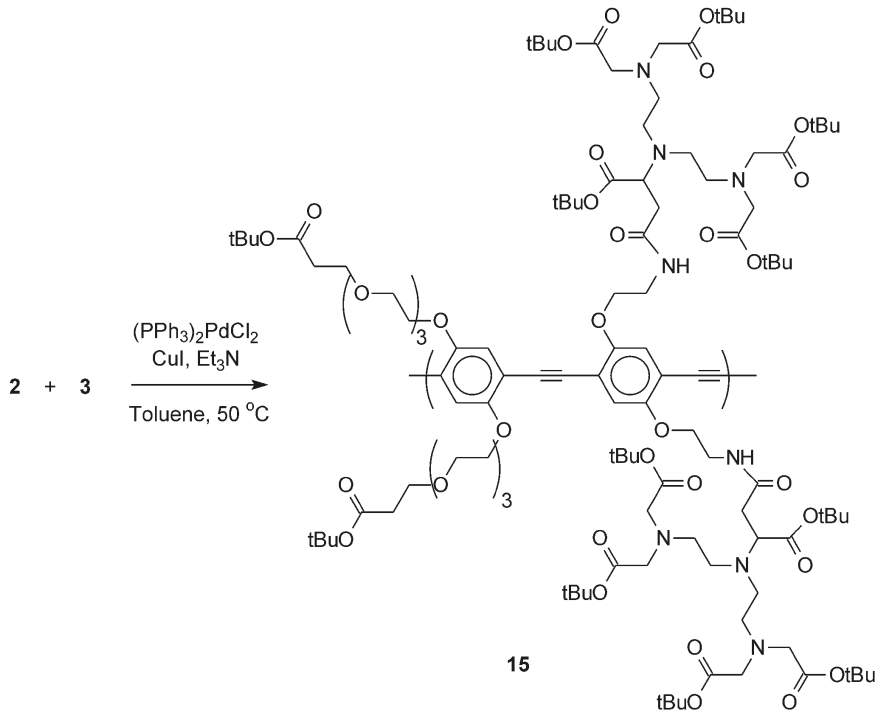

Fig. 3. UV–vis absorption spectra of polymers **15** and **4** and monomer **3** (in CH_3OH).

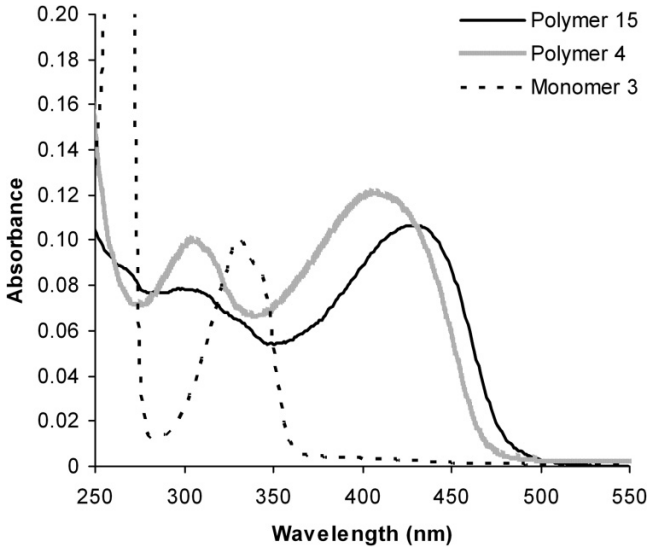

Fig. 4. Fluorescence emission spectra of polymers **15** and **4** and monomer **3** (in CH_3OH).

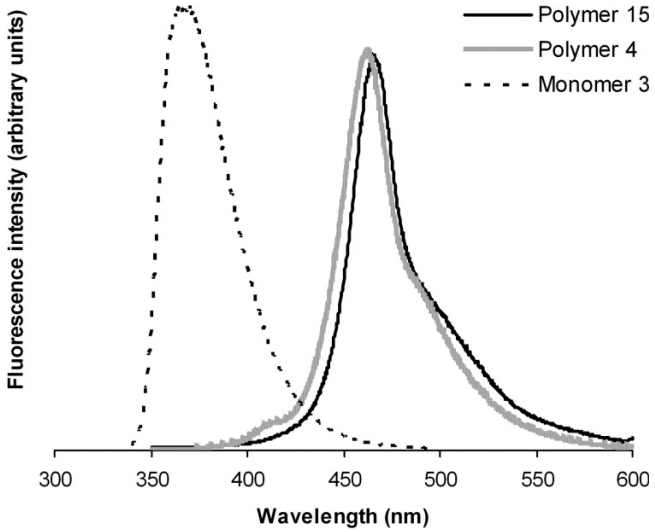

used to verify the size and revealed that the particles were solid and approximately spherical (Fig. 7). By extensive centrifugation it was possible to remove essentially all of the polymer from the suspension. Combined, these results suggest that the relaxivity exhibited by polymer **1** arose primarily through the interaction of water molecules with the Gd(III) ions at the surface of the particles, while the Gd(III) ions on the interior would have very poor access to water, a property that is known to substantially decrease the relaxivities of Gd(III) agents.[49–51] As the r_1 value was calculated based on the total concentration of Gd(III) ions in the sample, it is likely that the relaxivities of the complexes on or near the particle surface were much higher than 1.37 L mmol^{-1} s^{-1}, while those on the interior were much lower. For example, based on a mean particle size of 1.5 μm and assuming that water can freely penetrate the particle to a depth of 10 nm, the relaxivity on a per Gd(III) ion basis would be approximately 35 L mmol^{-1} s^{-1}, much higher than that for Gd-DTPA. However, this estimation is clearly very dependent on the value used for the depth of water penetration and the result ranges from 115 L mmol^{-1} s^{-1} for a penetration depth of 3 nm to 3.9 L mmol^{-1} s^{-1}, very close to the relaxivity of Gd-DTPA, if a penetration depth of 100 nm is assumed (see Supplementary data).

Overall, the significant aggregation of polymer **1** was surprising given the solubilizing carboxylic acid terminated

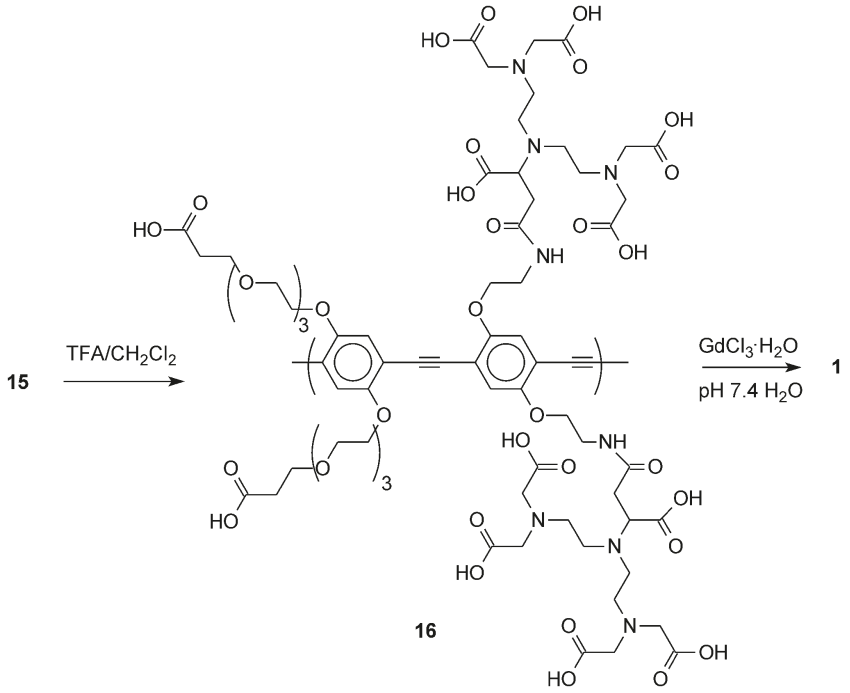
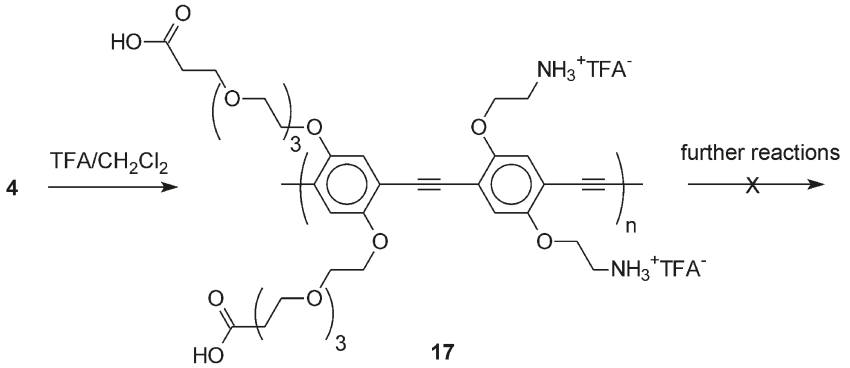
Scheme 5. Synthesis of the target polymer **1**.



Scheme 6. Deprotection of polymer **4**.



tetra(ethylene glycol) units, the inherently water-soluble Gd(III) complexes, and the previous reports of water-soluble PPEs bearing similar densities of charged moieties.[32,34,37] Considering the multiple competing effects that the incorporation of the polymeric complexes into the micrometre-sized aggregates would have on the relaxivity, it is not possible to confirm definitively that increased relaxivity would result from the rigidified polymer backbone. Thus, the unexpected assembly of polymer **1** introduces a new form of Gd(III) where each particle carries many Gd(III) ions along conjugated polymer backbones. However, to further investigate the effects of the PPE backbone on relaxivity and to exploit its fluorescence properties it will be necessary to design polymers that do not aggregate in water.

Conclusions

In summary, a PPE with conjugated water-solubilizing groups and DTPA derivatives was designed with the aim of obtaining Gd(III) complexes with high relaxivity due to the rigidity of the polymer backbone. Two synthetic routes to the target were explored, one involving the polymerization of a DTPA-functionalized monomer and the other involving a postpolymerization modification. While the postpolymerization modification was not successful owing to poor polymer solubility, the former route successfully led to a polymer having two Gd(III) complexes on alternating phenyl rings. Unexpectedly, this polymer assembled into microparticles in aqueous solution with a relaxivity of 1.37 L $mmol^{-1}$ s^{-1} on a per Gd(III) ion basis. This relaxivity is likely an average of Gd(III) complexes on the microparticle surface with high relaxivities and complexes on the particle interior with low relaxivities due to poor water accessibility.

Experimental

General procedures and materials

All chemicals were purchased from commercial suppliers and used without further purification unless otherwise noted. Anhydrous *N*,*N*-dimethylformamide (DMF), tetrahydrofuran

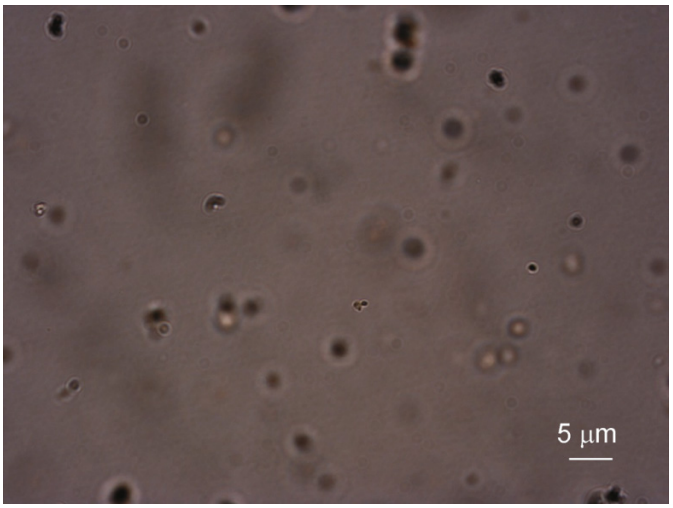
(THF), and toluene were obtained from a solvent purification system. CH_2Cl_2 and NEt_3 were distilled over CaH_2. Ultrapure water was obtained from a Barnstead EASYpure II system. Column chromatography was performed using silica gel (0.063–0.200 mm particle size, 70–230 mesh). ^{1}H NMR spectra were obtained at 400 MHz and ^{13}C NMR data were obtained at 100 MHz. Chemical shifts are reported in ppm and are calibrated against residual solvent signals of $CDCl_3$ (δ 7.26, 77.2) or D_2O (δ 4.75). High-resolution mass spectrometry (HRMS) was performed using a Micromass LCT (electrospray time-of-flight (ES+)) mass spectrometer or a Finnigan MAT 8200 mass spectrometer in time-of-flight ES+ mode. UV–vis absorption spectroscopy was performed on a Varian Cary 300 Bio UV–vis spectrophotometer. Emission spectra were obtaining using a Photon Technology International QM-4 SE spectrofluorometer. Size exclusion chromatography (SEC) was performed in THF using a Waters 515 HPLC pump, Wyatt Optilabrex RI and miniDAWN-TREOS detectors, and a ResiPore (300 mm × 7.5 mm) column from Polymer Laboratories. Column calibration was performed using polystyrene standards from Polymer Laboratories. Dynamic light scattering was performed on a Zetasizer Nano ZS instrument from Malvern Instruments. Optical microscopy was performed using an Olympus model IX71S8F-3 microscope equipped with a 20× (NA 0.50) objective. Dialyses were performed using Spectra/Por regenerated cellulose membranes with a molecular weight cutoff of 3500 Da. The inductively coupled plasma mass spectrometry (ICP-MS) analysis was performed at the Environmental Analytical Laboratories of the Saskatchewan Research Council. Relaxation rate measurements were performed on a Stelar Spinmaster FFC2000 1T C/DC relaxometer. The concentration of the polymer was 0.17 mg mL^{-1} in a 100 mmol L^{-1} pH 7.4 phosphate buffer solution.

Fig. 7. Optical microscopy image of assemblies formed by polymer **1**.



Synthesis of compound 8

To a flame-dried flask were added 2,5-diiodo-1,4-hydroquinone (0.64 g, 1.8 mmol, 1.0 equiv.), the tosylate **7** (1.9 g, 4.4 mmol, 2.5 equiv.), potassium iodide (0.15 g, 0.88 mmol, 0.50 equiv.), potassium carbonate (1.5 g, 11 mmol, 6.0 equiv.), and 18-crown-6 (0.92 g, 3.5 mmol, 2.0 equiv.). DMF (30 mL) was added and the resulting solution was heated to 100 °C for 48 h under an argon atmosphere. The solvent was removed in vacuo and the resulting residue was dissolved in a small amount of CH_2Cl_2, concentrated to dryness on a small amount of silica gel, and purified by column chromatography on silica gel (20:80 ethyl acetate – hexanes eluent) to yield compound **8** (0.71 g, 46%). IR (cm^{-1}, thin film from CH_2Cl_2): 3088, 2967, 2866, 1726. ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.44 (s, 18 H), 2.49 (t, J = 6.63 Hz, 4 H), 3.57–3.80 (m, 20 H), 3.83–3.91 (m, 4 H), 4.04–4.12 (m, 4 H), 7.23 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 170.8, 153.1, 123.4, 86.4, 80.4, 71.1, 70.7, 70.5, 70.4, 70.2, 69.6, 66.9, 36.24, 28.1. HRMS calcd. for $[M]^+$ ($C_{32}H_{52}I_2O_{12}$): 882.1548; found: 882.1546.

Synthesis of compound 9

Compound **8** (0.69 g, 0.78 mmol, 1.0 equiv.) was added to a flame-dried flask and put under argon atmosphere. Dry THF (6 mL) was added, followed by trimethylsilylacetylene (0.76 g, 7.8 mmol, 10 equiv.) and triethylamine (5.4 mL, 39 mmol, 50 equiv.). Copper(I) iodide (4.5 mg, 23 μmol, 0.029 equiv.) and bis(triphenylphosphine)palladium(II) chloride (11 mg, 16 μmol, 0.020 equiv.) were added to the solution under a flow of argon. The mixture was stirred at room temperature for 48 h, and then the solvent was removed in vacuo. The resulting residue was purified by column chromatography (10:90 ethyl acetate – hexanes to 40:60 ethyl acetate – hexanes eluent gradient) to afford compound **9** (0.54 g, 96%). IR (cm^{-1}, thin film from CH_2Cl_2): 3010, 2954, 2867, 2151, 1729, 1495. ^1H NMR (400 MHz, $CDCl_3$, δ): 0.17 (s, 18 H), 1.37 (s, 18 H), 2.42 (t, J = 6.64 Hz, 4 H), 3.46–3.75 (m, 20 H), 3.80 (t, J = 4.88 Hz, 4 H), 4.05 (t, J = 4.88 Hz, 4 H), 6.85 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 170.8, 153.8, 117.7, 114.1, 100.8, 100.3, 80.4, 71.1, 70.7, 70.5, 70.3, 69.6, 69.4, 66.8, 36.2, 28.0, –0.1. HRMS calcd. for $[M + Na]^+$ ($C_{42}H_{70}O_{12}NaSi_2$): 845.4304; found: 845.4329.

Synthesis of monomer 3

To a solution of compound **9** (0.51 g, 0.71 mmol, 1.0 equiv.) in methanol (4 mL) was added 1 mol L^{-1} tetrabutylammonium fluoride in THF (1.8 mL, 2.5 equiv.). The resulting solution was stirred for 12 h, and then the solvent was removed in vacuo and the resulting residue was purified by column chromatography (50:50 ethyl acetate – hexanes to 80:20 ethyl acetate – hexanes eluent gradient) to afford monomer **3** (0.36 g, 87%). UV–vis absorption (CH_3OH) λ_{max}: 327 nm. Emission λ_{max}: 372 nm. IR (cm^{-1}, thin film from CH_2Cl_2): 3242, 3010, 2972, 2866, 2092, 1727, 1495. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.42 (s, 18 H), 2.48 (t, J = 6.64 Hz, 4 H), 3.34 (s, 2 H), 3.51–3.77 (m, 20 H), 3.84 (t, J = 5.08 Hz, 4 H), 4.12 (t, J = 4.88 Hz, 4 H), 6.97 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 170.9, 154.0, 118.2, 113.5, 82.8, 80.4, 79.5, 71.0, 70.6, 70.5, 70.4, 69.6, 69.5, 66.8, 36.2, 28.1. HRMS calcd. for $[M]^+$ ($C_{36}H_{54}O_{12}$): 678.3615; found: 678.3605.

Synthesis of compound 11

To a flame-dried flask were added 2,5-diiodo-1,4-hydroquinone (3.3 g, 9.0 mmol, 1.0 equiv.), the tosylate **10** (5.1 g, 23 mmol, 2.5 equiv.), potassium iodide (0.60 g, 3.6 mmol, 0.40 equiv.), potassium carbonate (5.0 g, 36 mmol, 4.0 equiv.), and 18-crown-6 (2.4 g, 9.2 mmol, 1.0 equiv.). DMF (30 mL) was added and the resulting solution was heated at 100 °C for 48 h under an argon atmosphere. The solvent was removed in vacuo and the resulting residue was dissolved in a small amount of dichloromethane, concentrated to dryness on a small amount of silica gel, and purified by column chromatography (10:90 ethyl acetate – hexanes to 30:70 ethyl acetate – hexanes eluent gradient) to yield compound **11** (1.3 g, 32%). IR (cm^{-1}, KBr pellet): 3043, 2920, 2867, 2106, 1692. ^1H NMR (400 MHz, $CDCl_3$, δ): 3.65 (t, J = 5.08 Hz, 4 H), 4.11 (t, J = 5.08 Hz, 4 H), 7.23 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 153.1, 123.7, 85.9, 67.8, 49.2. HRMS calcd. for $[M]^+$ ($C_{10}H_{12}I_2N_6O_2$): 499.8955; found: 499.8964.

Synthesis of compound 12

The diazide **11** (0.25 g, 0.58 mmol, 1.0 equiv.) and triphenylphosphine (0.76 g, 2.9 mmol, 5.0 equiv.) were dissolved in THF (10 mL). Water (5 mL) was added and the resulting mixture was heated at 60 °C for 2 h. The solvent was then removed in vacuo and the residue was purified by column chromatography (90:10 dichloromethane–methanol to 100% methanol eluent gradient) to yield compound **12** (0.19 g, 88%). IR (cm^{-1}, KBr pellet): 3360, 3038, 2925, 2869, 1693, 1526. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.51 (br s, 4 H), 3.10 (t, J = 4.88 Hz, 4 H), 3.99 (t, J = 4.88 Hz, 4 H), 7.21 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 152.8, 123.5, 86.3, 69.8, 45.3. HRMS calcd. for $[M]^+$ ($C_{10}H_{14}I_2N_2O_2$): 447.9145; found: 447.9158.

Synthesis of monomer 2

To a flame-dried flask were added the diamine **12** (0.038 g, 0.10 mmol, 1.0 equiv.), DTPA derivative **13** (0.18 g, 0.25 mmol, 2.5 equiv.), DMAP (0.012 g, 0.10 mmol, 1.0 equiv.), and DPTS (0.029 g, 0.10 mmol, 1.0 equiv.). The flask was placed under nitrogen and dry CH_2Cl_2 (5 mL) was added. Once the reagents had dissolved, DCC (0.12 g, 0.60 mmol, 6.0 equiv.) was added and the reaction mixture was stirred for 3 h at room temperature. The reaction mixture was then filtered through cotton to remove the dicyclohexylurea by-product and the solvent was removed in vacuo. The resulting material was purified by column chromatography (20:80 ethyl acetate – cyclohexane eluent) to afford compound **2** (0.074 g, 40%). IR (cm^{-1}, thin film from CH_2Cl_2): 3310, 3060, 2974, 2925, 1729, 1663, 1535, 1455. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.36–1.56 (m, 90 H), 2.55 (br s, 2 H), 2.72 (br s, 2 H), 2.80 (br s, 16 H), 3.38–3.47 (m, 16 H), 3.61–3.81 (m, 4 H), 3.88 (br s, 2 H), 3.94–4.14 (m, 4 H), 7.23 (s, 2 H), 7.83 (br s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 178.4, 171.2, 170.4, 152.8, 123.2, 86.3, 81.5, 81.0, 68.9, 60.9, 55.8, 53.1, 50.1, 41.9, 29.6, 28.21, 28.17. HRMS calcd. for $[M + H]^+$ ($C_{82}H_{141}I_2N_8O_{24}$): 1875.8148; found: 1875.8074.

Synthesis of monomer 5

To a flame-dried flask was added 2,5-diiodo-1,4-hydroquinone (0.56 g, 1.5 mmol, 1.0 equiv.), bromide **14** (0.86 g, 3.8 mmol, 2.5 equiv.), potassium iodide (0.13 g, 0.76 mmol, 0.50 equiv.), potassium carbonate (1.3 g, 9.2 mmol, 6.0 equiv.), and 18-crown-6 (0.81 g, 3.1 mmol, 2.0 equiv.). DMF (30 mL) was added and the resulting solution was heated at 100 °C for 24 h under an argon atmosphere. The solvent was removed in vacuo and the resulting residue was dissolved in a small amount of dichloromethane, concentrated to dryness on a small amount of silica gel, and purified by column chromatography on silica gel (10:90 ethyl acetate – hexanes eluent) to yield compound **5** (0.39 g, 40%). IR (cm^{-1}, thin film from CH_2Cl_2): 3356, 3052, 2974, 1688, 1532. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.47 (s, 18 H), 3.56 (dt, J = 5.08, 5.07 Hz, 4 H), 4.01 (t, J = 5.07 Hz, 4 H), 5.08 (br s, 2 H), 7.19 (s, 2 H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 164.6, 152.77, 123.2, 86.5, 71.5, 69.9, 40.8, 28.42. HRMS calcd. for $[M]^+$ ($C_{20}H_{30}I_2N_2O_6$): 648.0193; found: 648.0176.

Synthesis of polymer 15

Monomer **2** (61 mg, 33 μmol, 1.0 equiv.) and monomer **3** (19 mg, 33 μmol, 1.0 equiv.) were added to a flame-dried two-neck round-bottom flask. The monomers were put under a nitrogen atmosphere and dry toluene (2 mL) was added, followed by dry NEt_3 (0.23 mL, 1.6 mmol). To this solution were added bis(triphenylphosphine)palladium(II) chloride (1.0 mg, 1.4 μmol, 0.040 equiv.) and copper(I) iodide (1.0 mg, 5.2 μmol, 0.16 equiv.). The reaction mixture was heated at 50 °C for 48 h. The solvent was removed in vacuo and the resulting residue was dissolved in DMF (2 mL). This solution was then dialyzed against DMF for 24 h to yield polymer **27** (71 mg, quantitative yield). UV–vis absorption (CH_3OH) λ_{max}: 430 nm. Emission λ_{max}: 465 nm. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.23 (s, 18 H), 1.42 (s, 90 H), 2.29–2.46 (m, 10 H), 2.69–2.94 (m, 16 H), 3.06–4.15 (m, 52 H), 7.00 (br s, 2 H), 7.42 (br s, 2 H). SEC: M_w (conventional calibration) = 31 300 g mol^{-1}, PDI = 2.6; M_w (MALS; d*n*/d*c* = 0.138) = 40 500 g mol^{-1}, PDI = 1.9.

Synthesis of polymer 4

Monomer **3** (0.37 g, 0.63 mmol, 1.0 equiv.) and monomer **5** (0.41 g, 0.63 mmol, 1.0 equiv.) were added to a flame-dried two-neck round-bottom flask. The monomers were put under a nitrogen atmosphere and dry toluene (5 mL) was added, followed by dry NEt_3 (4.4 mL, 32 mmol). To this solution were added bis(triphenylphosphine)palladium(II) chloride (8.0 mg, 13 μmol, 0.020 equiv.) and copper(I) iodide (4.0 mg, 19 μmol, 0.030 equiv.). The reaction mixture was heated at 50 °C for 48 h. The solvent was then removed in vacuo and the resulting residue was dissolved in DMF (2 mL). This solution was then dialyzed against DMF for 24 h to yield polymer **4** (0.29 g, 47%). UV–vis absorption (CH_3OH) λ_{max}: 406 nm. Emission λ_{max}: 460 nm. ^1H NMR (400 MHz, $CDCl_3$, δ): 1.43 (br s, 36 H), 2.48 (t, *J* = 6.63 Hz, 4 H), 3.52–4.29 (m, 36 H), 7.06–7.09 (m, 4H). SEC: M_n = 1100 g mol^{-1}, PDI = 2.42.

Deprotection of polymer 15 and complexation of Gd(III)

In a flame-dried flask under a nitrogen atmosphere, polymer **15** (70 mg, 32 μmol, 1.0 equiv.) was dissolved in CH_2Cl_2 (1 mL) and trifluoroacetic acid (TFA) (1 mL) was added. The resulting solution was stirred for 2 h at room temperature and then the solvent was removed in vacuo and the resulting residue was dissolved in ultrapure water (2 mL). The solution was dialyzed against ultrapure water for 24 h. The resulting solution was then lyophilized to yield the deprotected polymer **16** (0.034 g, 71%). ^1H NMR (400 MHz, D_2O, δ; note that aromatic peaks were not observed, likely because of solubility limitations and aggregation): 2.30–2.42 (m, 8 H), 2.63–4.02 (m, 70 H). Polymer **16** (10 mg, 7.0 μmol, 1.0 equiv.) was then redissolved in ultrapure water (5 mL) and combined with a solution of gadolinium chloride hexahydrate (1.0 mg, 28 μmol, 4.0 equiv.) in 2 mL of ultrapure water and the pH was adjusted to 7.4 using 0.1 mol L^{-1} NaOH. The resulting solution was stirred for 12 h at room temperature and then the solvent was reduced in vacuo to a volume of 2 mL. This solution was then dialyzed against ultrapure water for 24 h. The solvent was removed using a lyophilizer to yield polymer **1** (12 mg, quantitative yield.). ^1H NMR could not be obtained because of the paramagnetic Gd. ICP-MS: mass of polymer analyzed: 0.2 mg; mass of Gd(III) expected: 35 μg; mass of Gd(III) found: 34.8 μg.

Deprotection of polymer 4

In a flame-dried flask under a nitrogen atmosphere, polymer **4** (0.28 g, 0.29 mmol, 1.0 equiv.) was dissolved in dichloromethane (1 mL) and TFA (1 mL) was added. The resulting solution was stirred for 2 h at room temperature and then the solvent was removed in vacuo and the resulting residue was dissolved in DMF (2 mL). The solution was then dialyzed against DMF for 24 h to yield the deprotected polymer **17** (0.118 g, 62%). ^1H NMR (400 MHz, D_2O, δ) 2.44 (br s, 4 H), 3.10–4.33 (m, 36 H), 7.01 (br s, 4 H).

Abstract: Bioassay-guided purification of methanol extract of the soft coral *Cladiella krempfi* (Octocorallia: Alcynocea) yielded a novel eunicellin-type diterpenoid, (–)-6α-hydroxy polyanthellin A (**1**), active against the cyprids of the fouling barnacle, *Balanus amphitrite* (EC_{50} 9.02 μg/mL; LC_{50} 36 μg/mL; and therapeutic ratio = 4). The structure of compound **1** was determined from its spectral data, including IR, NMR (1D and 2D NMR), and mass spectra.

Key words: biofouling, antifouling, *Cladiella krempfi*, *Balanus amphitrite*, diterpenes.

Résumé : Une purification orientée par des bioessais du produit obtenu par extraction au méthanol du corail mou, *Cladiella krempfi* (Octacorallia : Alcynocea), a permis d'isoler un nouveau diterpénoïde de type eunicelline, la (–)-6α-hydroxypolyanthelline A (**1**), active contre les cyprides de la barnacle encrassante, *Balanus amphritrite* (CE_{50} 9,02 μg/mL; CL_{50} 36 μg/mL) et un rapport thérapeutique de 4). La structure du composé **1** a été déterminée à partir de données spectroscopiques, dont les spectres IR, RMN (1D et 2D) et de masse.

Mots-clés : encrassage biologique, antisalissure, *Cladiella krempfi*, *Balanus amphritrite*, diterpènes.

Introduction

The genus *Cladiella* belongs to the order Alcyonacea, class Anthozoa. These soft corals, which grow as thick carpetlike colonies, extending up to several square meters are widely distributed in the tropical and subtropical shallow-water habitats.[1] Several bioactive cembrane/eunicellane diterpenes, sesquiterpenes, sterols, and glycolipids have been reported from this genus by different groups.[2] These include Cladidiol and polyanthellin A, an acetylcholinesterase-inhibiting sesquiterpene and an antibacterial diterpene, respectively, from a *Cladiella* sp. found in the Andaman and Nicobar area; a new hemiketal steroid, cladiellin A, with antioxidant activity from China; cladiellaperoxide, a diterpenoid (toxic to brine shrimps) from *Cladiella sphaeroides*; and several pregnane glycosides from *Cladiella krempfi* (antitumour) collected from Miyazaki Prefecture, Japan.[2–6]

Despite their abundance in Indian waters, only limited studies on their chemical/biological properties are available in the literature.[7] Herein, we report the isolation and structure determination of a novel diterpenoid, (–)-6α-hydroxy polyanthellin A (**1**), active against the cyprids of the fouling barnacle, *Balanus amphitrite*, from *C. krempfi* from Lakshadweep Islands (India).

Experimental

General

NMR spectra were recorded in $CDCl_3$ solution on Bruker Avance 300 and 500 MHz NMR spectrometers, using a standard 5 mm probe while HR-MS analysis was performed on an Applied Biosystem instrument (QTOF type) and IR spectrum was recorded using Jasco FTIR 4100 IR spectrometer. For column chromatography, silica gel (60–120 mesh size) from s.d. Fine Chem Limited was used. All solvents were procured from s.d. Fine Chem Limited (AR Grade) and used as received.

Cladiella krempfi was collected from the shallow coastal waters of Kavaratti Island (Lakshadweep, lat. 10°34′0 N; long. 72°37′0 E). The thick carpetlike colonies were light brown in colour. The specimen (1 kg wet mass) was washed with fresh water and soaked in methanol before being transported to the laboratory. In the laboratory, the animals were cut into smaller pieces and repeatedly extracted with fresh MeOH. The combined MeOH supernatants were concentrated under reduced pressure using a rotavapor. The crude extract was then partitioned into petroleum ether, ethyl acetate, and aqueous fractions in the usual way. The active petroleum ether fraction (Fr 1, 2 g) was purified on Sephadex LH-20 (eluant: chloroform/methanol, 1:1) into four broad fractions (Fr 1–1 to Fr 1–4). Bioassay of the fractions indi-

cated Fr 1–3 (100 mg) to be active, which was further purified on silica gel columns (gradient acetone/hexane), yielding the active compound as a single spot on TLC (R_f = 0.52). The structure of the purified compound (10 mg) was determined based on its IR, MS, and NMR spectral data.

The antibacterial screening of different fractions was carried out against seven strains of fouling bacteria (*Bacillus cereus*, *Bacillus pumilus*, *Bacillus megaterium*, *Pseudoalteromonas haloplanktis*, *Pseudomonas chlororaphis*, *Pseudomonas putida*, and *Pseudomonas aeruginosa*) using the disc diffusion method, with 100 μg of compound per disc.[8] The settlement inhibition activity was performed against *B. amphitrite* (= *Amphibalanus amphitrite*) cyprids at 50 μg/mL.[9,10] The effective and lethal concentrations (EC_{50} and LC_{50}) of the pure compound were determined using serial dilution method from 100 to 6.25 μg/mL.[8,11,12] The data were analyzed by one-way ANOVA, followed by Tukey's multiple comparison test at 95% confidence level.[13] One-way ANOVA was performed with SPSS, Version 10. EC_{50} and LC_{50} values were calculated using Probit analysis.[14,15] The experiment was repeated twice with different batches of larvae.

Results and discussion

Structure determination

IR absorptions of compound **1** (yield = 10 mg, $[\alpha]_D^{27} = -20^\circ$ (0.17%, $CHCl_3$) at 3450, 1730, and 1050 cm^{-1} indicated the presence of hydroxyl and ester groups in the molecule. Among these, the ester group could be an acetate, as confirmed by the characteristic NMR peaks at δ 2.01 (3H, s, CO–CH_3), 22.6 (CO–CH_3), and 170.1 (CO–CH_3) and the facile loss of 60 mass units in the mass spectrum (Table 1). ^{13}C NMR confirmed the presence of 22 carbons, distributed as four quarternary, seven CH, five CH_2, and six methyl carbons as confirmed by DEPT 135 and DEPT 90 spectra. Noteworthy was the presence of six oxygenated carbons (90.8d, 82.9s, 80.3d, 77.2s, 75.5d, and 74.6s) but relatively lower polarity of the compound (i.e., eluted with hexane/acetone,

Fig. 1. Schematic representation of the major HMBC correlations of (–)-6α-hydroxy polyanthellin A.

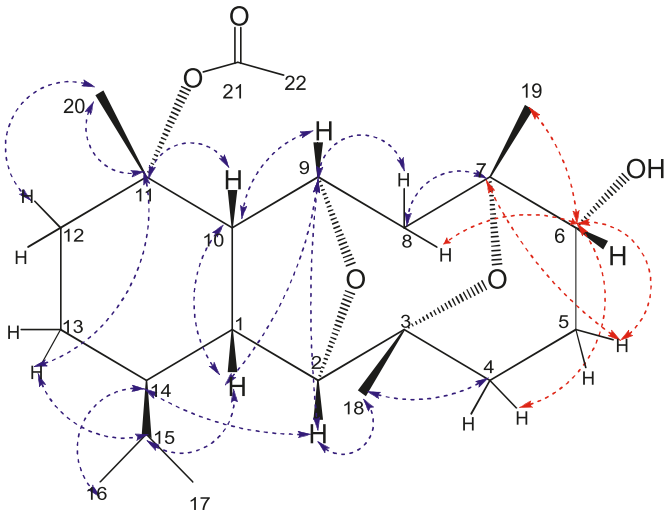

Fig. 2. Schematic representation of the strong and medium (dotted line) nOe correlations of (–)-6α-hydroxy polyanthellin A.

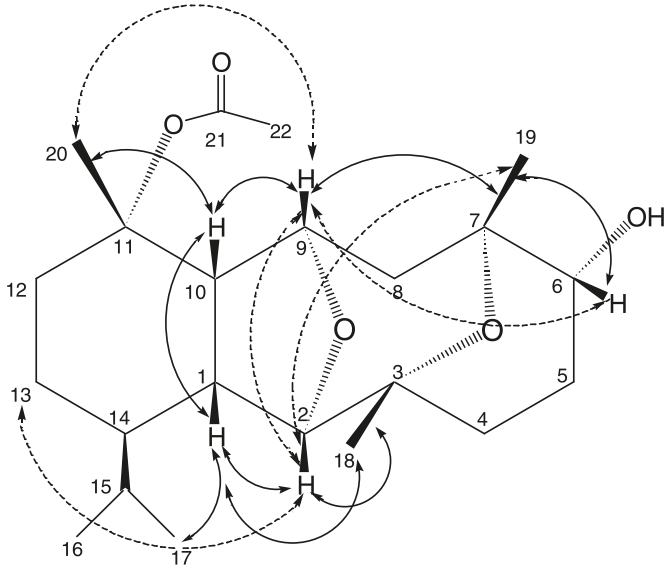

60:40, from SiO_2 column, R_f = 0.52 with hexane/acetone, 70:30, and its easy solubility in $CHCl_3$), indicating the possible presence of one or more cyclic ether/epoxides in the molecule. HR-MS revealed the accurate mass of its $[M + H]^+$ pseudomolecular ion to be 381.2630, corresponding to an elemental composition of $C_{22}H_{37}O_5$ (calcd.: 381.2635), thus indicating its diterpenoid nature. The above molecular formula indicated a degree of hydrogen deficiency of 5. One of these could be accounted for by the acetate group. NMR spectra ruled out the presence of any unsaturations, indicating that the molecule is tetracyclic.

Comparison of its NMR spectral data with those of different soft coral and gorgonian diterpenoids indicated its close structural similarity to polyanthellin A, a diterpenoid isolated from the gorgonian *Briareum polyanthes* (Table 2).[16] The major differences were the observed downfield shift of C-4 to C-6 signals from δ 36.2, 18.1, and 39.6 in polyanthellin A to δ 40.1 (CH_2), 29.2 (CH_2), and 80.3 (CH), respectively,

Fig. 3. (–)-6α-Hydroxy polyanthellin A.

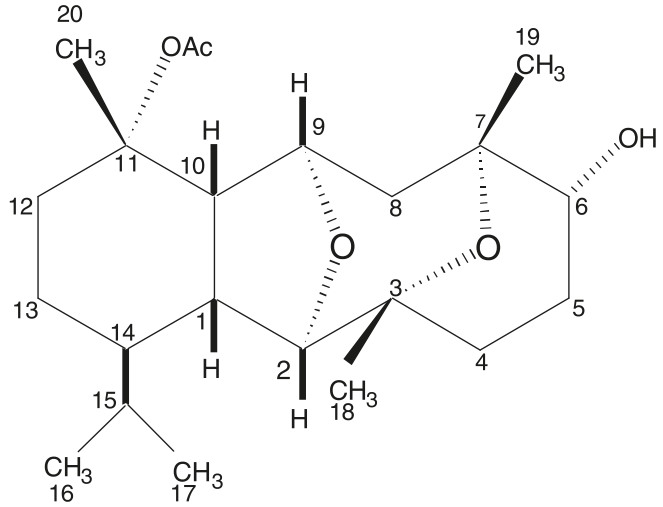

Fig. 4. Effect of (–)-6α-hydroxy polyanthellin A on the settlement and mortality of cyprids. (A) Batch 1 cyprids. (B) Batch 2 cyprids. % Settlement (▲); % mortality (●). Data plotted are means ± SD of six replicates.

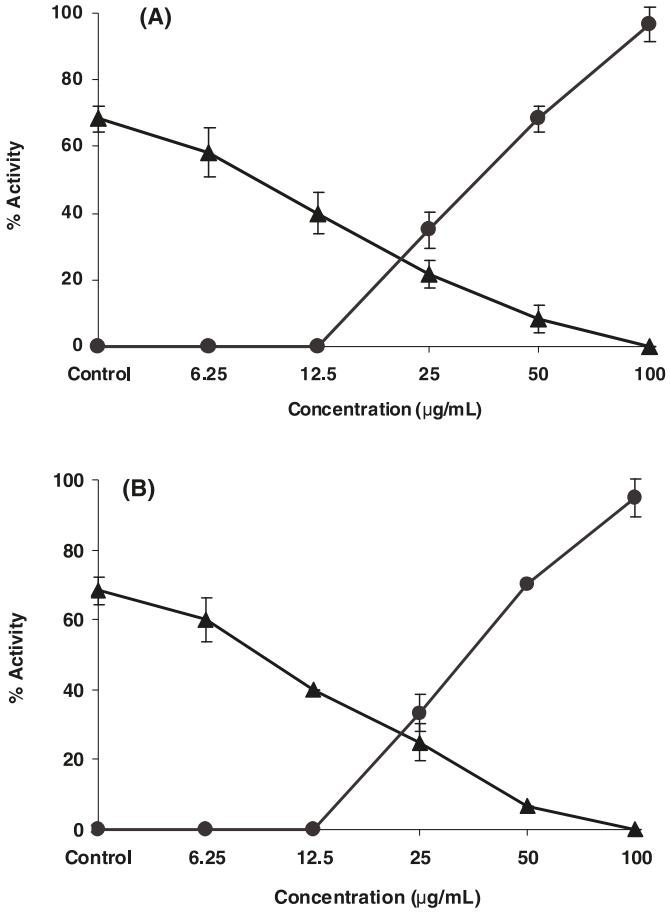

in compound **1**. Comparison of these values with those of related compounds briarellin M and O,[16] as well as examination of COSY, HSQC, and HMBC data indicated the presence of the additional hydroxyl group at C-6 (Table 2 and Fig. 1). The large downfield chemical shift of C-6 at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

δ 80.26 indicated the presence of a hydroxyl group at this position. This was confirmed by the expected downfield shifts of C-4 and C-5 by 4 and 11 ppm, respectively.

The similarities in ^{1}H and ^{13}C chemical shifts, except for C-4, C-5, and C-6 of the isolated compound and polyanthellin A, indicated their relative stereochemistry also to be identical. The relatively small coupling constant observed for the 6-H (J = 6.3 Hz) indicated this proton to be equatorial. The observed strong nOe cross peaks H1 (δ 2.20)/H10 (δ 2.84) and H2 (δ 3.54), H10/H9 (δ 4.05) and 20 Me (δ 1.47), H9/19 Me (δ 1.23) and 19 Me/H6 (δ 4.55), as well as the medium size cross peaks between H2/H9, H2/H19, and H6/H9 (Fig. 2) further confirmed the sterochemistry. The observed optical rotation of compound **1** ($[\alpha]_D^{27} = -20^\circ$ (0.17%, $CHCl_3$)) is also comparable to that of polyanthellin A ($[\alpha]_D^{20} = -9.9^\circ$ (*c* 1.0, $CHCl_3$)) and other related eunicellin diterpenoids, indicating the absolute stereochemistry to be the same. From the above results, the structure of compound **1** could be established as (–)-6α-hydroxy polyanthalin A (Fig. 3).

Antifouling activity

The crude extract, partially purified fractions/compounds, were inactive against the seven strains of fouling bacteria. Duplicate experiments with varying dosages between 6.25 and 100 μg/mL confirmed the anti-settlement properties of compound **1** against *B. amphitrite* cyprids in a dose-dependent manner (Fig. 4; batch 1: $p = 0.05$; $F_{5,30} = 184.818$, EC_{50} 8.82 μg/mL, LC_{50} 35.72 μg/mL; batch 2: $p = 0.05$; $F_{5,30} = 322.760$, EC_{50} 9.23 μg/mL, LC_{50} 36.22 μg/mL; one-way ANOVA). The therapeutic ratio was calculated to be 4 from the above results.

Marine invertebrates, especially soft corals and gorgonians are a rich source for novel and bioactive secondary metabolites.[17,18] Since the first isolation of eunicellin, a diterpene from *Eunicella stricta* in 1968, over 50 eunicellin and related cladiellins have been isolated so far.[19,20] Many of these metabolites possess promising cytotoxic properties.[17,19] while a few are known to play a functional role as antifeedants, as indicated by mollusc and fish lethality studies.[21]

To the best of our knowledge, no studies have been reported so far on the antifouling properties of cladiellin diterpenes. Our studies indicate (–)-6α-hydroxy polyanthalin A (**1**) to be active against cyprids of *B. amphitrite*. With an LC_{50} of ~36 μg/mL and favourable EC_{50} value of ~9 μg/mL, its therapeutic ratio works out to be 4, which agrees well with the recommended value (i.e., >1) for environmentally compatible antifouling coatings.[22] Further studies on structure–activity relationships of this compound using different synthetic analogs/derivatives may lead to an environmentally benign antifouling agent of commercial potential.

Abstract: Density functional theory (DFT) calculations were carried out to investigate the nonlinear optical (NLO) response for the donor-conjugated bridge-accepter (D–π–A) model of *p*-nitroaniline (PNA) – hexamolybdate derivatives and PNA–metal–carbonyl complexes. The bond length alternation (BLA) values decrease with lengthening of the π-conjugated bridge, especially for PNA–hexamolybdate derivatives, which dramatically enhances the NLO response. In addition, the introduction of Mo≡N in PNA–hexamolybdate derivatives is expected to provide a better electron transition channel, consequently generating lower BLA values and an outstanding NLO response compared with PNA–metal–carbonyl complexes. It is shown that the hexamolybdate acts as an electron donor when incorporating metal–carbonyl complexes into one molecule. All these behaviors reflect the superiority of hexamolybdate as a donor moiety in the D–π–A model for the design of potential NLO materials.

Key words: bond length alternation, PNA–hexamolybdate, metal–carbonyl complexes, NLO response, electron transition.

Résumé : On a effectué des calculs selon la théorie de la fonctionnelle de la densité (TFD) dans le but d'étudier la réponse optique non linéaire (ONL) du modèle D–π–A des dérivés hexamolybdate de *p*-nitroaniline (PNA) et des complexes PNA–métal–carbonyle. Les valeurs d'alternation de la longueur de liaison (ALL) diminuent avec un allongement du pont π-conjugué, particulièrement avec les dérivés hexamolybdatde de PNA qui augmentent d'une façon dramatique la réponse ONL. De plus, il est prévu que l'introduction de Mo≡N dans les dérivés hexamolybdatde de PNA conduira à une meilleure voie de transition pour les électrons et, en conséquence, qu'elle générera des valeurs plus basses pour l'ALL et une réponse ONL exceptionnelle par rapport à celle des complexes PNA–métal–carbonyle. On a démontré que l'hexamolybdate agit comme donneur d'électron lorsqu'il incorpore des complexes métal-carbonyle dans une molécule. Tous ces comportements reflètent la supériorité de l'hexamolybdate comme groupe donneur dans le modèle D–π–A de conception de matériaux potentiellement ONL.

Mots-clés : alternation de la longueur de liaison, hexamolybdate de *p*-nitroaniline, complexes métal–carbonyle, réponse optique non linéaire, transition électronique.

Introduction

The area of second-order nonlinear optical (NLO) properties continues to receive much attention in recent years. Organic compounds containing a donor and an acceptor connected by a conjugated bridge (D–π–A) have been confirmed to behave excellent NLO properties,[1–4] and the NLO response is related to the length of the organic bridge chain.[5–7] *p*-Nitroaniline (PNA) has been considered as a prototype of a conventional D–π–A model that exhibits a large NLO response, and a number of push–pull phenylene derivatives have been widely explored to investigate the charge transfer in the molecules.[8,9] Effective methods to enhance the second-order NLO response are applied by increasing the electronic asymmetry with more potent donating or accepting chromophores or increasing the length of the π-conjugated chain between the donor and the acceptor,[10–12] and the reduction of the bond length alternation (BLA) values for the π-conjugated bridge is another advisable approach.

As typical NLO materials, organic materials are of major interest because of their relatively low cost, high laser damage thresholds, low dielectric constants, and fast nonlinear optical response times. However, they have several disadvantages: low energy transitions in the UV–vis region result in a tradeoff between nonlinear efficiency and optical transparency with low thermal stability. Robust inorganic salts are available as large single crystals, and they possess a large transparency range and suffer very low optical losses, but the response times are slow. The organic–inorganic hybrid

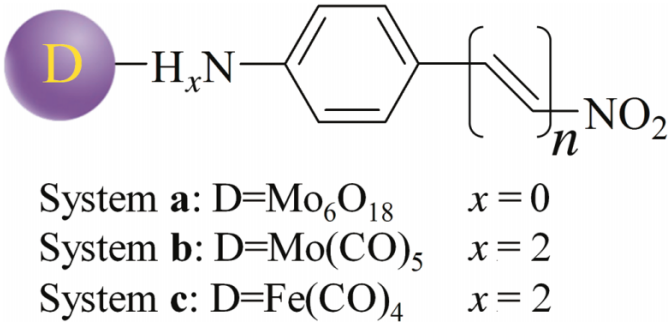
materials may combine the advantages of the two materials with little loss of optical transparency accompanying the large increase in β. The attachment of the chromophoric group to the main chain of the compound increases the stability of the orientation polarization.

The transition-metal complexes in organometallic and coordination chemistry offer large numbers of NLO structures closely related to their special metal *n*d configuration, oxidation states, etc.[13–17] The participation of the transition metals may induce low-energy metal-to-ligand charge transfer (MLCT), ligand-to-metal charge transfer (LMCT) or intraligand charge transfer (ILCT) excitation, consequently resulting in better NLO properties. Many metal complexes behave in an electronically amphoteric manner, i.e., as an ambivalent donor or acceptor, depending on the substituents on the conjugated side chain, and they can even replace the bridge moieties in the organic D–π–A structure and, consequently, with satisfactory NLO response. Among the transition-metal complexes, metalloporphyrins and metal Schiff base complexes with π-conjugated chains have been investigated to reveal dramatic NLO response.[18–20]

As large transition-metal oxides, polyoxometalates (POMs) are excellent electron acceptors and can form electron donor–acceptor compounds.[21,22] These compounds are favorable materials with high thermal stability and are expected to be better NLO materials than transition-metal complexes and pure organic compounds. Among many of the organic derivatives of POMs, organoimido derivatives have attracted more attention because of the fascinating synergistic effects resulting from the strong d–π interaction between the organic delocalized π electrons and the d electrons of the cluster.[23] The structure–property relationships with organoimido POM derivatives will be helpful in designing new promising NLO materials.[24–26] Although much research has been carried out on the NLO response for POMs, it is rare to compare POMs with organic or organometallic species for NLO properties, in particular the superiority of POMs. Previous work on the NLO properties for organoimido derivatives of hexamolybdate indicates that POMs act as an acceptor in the organoimido-substituted derivatives and they turn out to be donors with the increasing length of the organic conjugated chain.[27] Whether organometallic complexes act as donor or acceptor with the increasing length of a conjugated chain will be investigated, and a comparison of the donor ability of POMs with organometallic complexes will be performed.

Based on the typical D–π–A model PNA, three kinds of series are listed in Fig. 1: (*a*) PNA derivatives of a hexamolybdate compound (Mo_6NPhNO_2), (*b*) a PNA–molybdenum–pentacarbonyl complex (PNA–MoCO), and (*c*) a PNA–iron–tetracarbonyl complex (PNA–FeCO), as well as the derivatives with π-conjugated bridges for the three series. For series **a**, the hydrogen atom of the amido group in PNA has been replaced by hexamolybdate, consequently forming PNA derivatives of hexamolybdates. In general, metal–carbonyl fragments can be primarily regarded as electron-withdrawing groups with strong π acceptor abilities for CO ligands. However, the introduction of a strong acceptor (nitryl group) at the end of the conjugated side chain turns the metal–carbonyl into a donor moiety.

Fig. 1. The calculation models (n = 0–6).



Computational details

Systems as large as the polyoxometalate compounds of heavy metal atoms entail a large computational cost, and it is additionally complicated owing to the requirement for properly treating the electron correlation and relativistic effects. Therefore, ab initio and semiempirical methods are unreliable for these large systems. A sensible alternative is the DFT method, which has been confirmed to be effective for the treatment of heavy metal compounds.[28,29] Therefore, DFT calculations were carried out using the ADF2006.01 programs.[30,31] The zero-order regular approximation (ZORA) was adopted in all the calculations to account for the scalar relativistic effects.[32,33] The local density approximation (LDA) characterized by the Vosko–Willk–Nusair (VWN)[34] parametrization was adopted for the correlation functional. In addition, the generalized-gradient approximation (GGA) was employed in the geometry optimization by using Beck[35] and Perdew[36] nonlocal corrections for the exchange and for the correlation functionals, respectively. Triple-ξ plus polarization Slater basis sets were taken to describe the electron of main group elements (O, C, N, and H) and the valence electrons of all transition-metal atoms (Mo and Fe), applied with the frozen-core approximation. The approximation of a frozen core for O, N, and C atoms was used up to the 1s shell and to the 3d and 2p shells, respectively, for Mo and Fe atoms. As an effective method in the evaluation of electronic spectra for a wide range of compounds, time-dependent density functional theory (TDDFT) was carried out to calculate the excitation properties of the species mentioned in the title. Moreover, a finite field (FF) approach at MP2 level was executed to calculate the second-order polarizability. The natural bond orbital (NBO) analysis was carried out using the Gaussian03 program[37] to investigate the bond character between two atoms, and the B3LYP method was used at the LANL2DZ level for all the transition-metal atoms and the 6–31G(d) level for main group elements.

Results and discussion

In our present study, as a prototype for the series of D–π–A models, the second-order NLO response for PNA was calculated to be 7.9×10^{-30} esu, which is in good agreement with reported values.[38,39] When PNA replaces its amido hydrogen atoms with the terminal oxygen atoms of hexamolybdate, Mo_6NPhNO_2 (**a1**) was formed with a second-order NLO response four times higher than that of PNA. PNA–MoCO (**b1**) and PNA-FeCO (**c1**) were preferred for showing

For personal use only.

the effect on the second-order NLO response for transition-metal complexes. The series that could produce a larger enhancement in the NLO response was given more attention, and the conjugated repeating units $(C_2H_2)_n$ (n = 0–6) were introduced as π-conjugated bridges in series **a**, **b**, and **c** to observe the changes in the second-order NLO response.

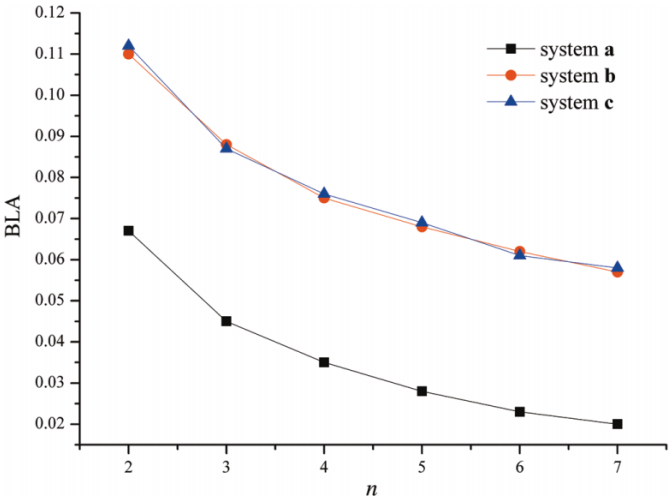
The BLA values

BLA values are defined as the average change of length between adjacent single and double bonds.[40] As an important organic NLO chromophore, the ground-state structure for a donor–acceptor substituted polyene molecule can be viewed as a combination of two resonance forms, differing in the extent of charge separation.[41,42] When the donor and acceptor substituents connected by the conjugated bridge are stronger, the contribution of the charge-separated resonance form to the ground state increases and the BLA values decrease. BLA values have been confirmed to be a significant factor in NLO properties. Figure 2 shows that BLA values tend to decrease with the growing conjugated chains in series **a** and **b**. However, the BLA values for PNA–Mo_6 derivatives (series **a**) are much lower than those for PNA–MoCO derivatives (series **b**) with the same conjugated bridge. For example, the BLA value for **a2** with one conjugated unit is 0.067, nearly half of that for **b2** with a value of 0.110. However, when the number of conjugated bridge units increases to six, the BLA value for **a7** decreases to 0.020 and becomes less than the half of the **b7** value (0.057). Another type of PNA–FeCO derivative (series **c**) was chosen to further confirm the influence of conjugated length on BLA values. Figure 2 demonstrates that the BLA values for series **c** are in accord with those in series **b**, and the two curves coincide well with each other. In other words, the decreasing rate of the BLA values for series **a** is faster than that for series **b** and **c** with increasing conjugation length, indicating a better NLO response for POM-substituted compounds than for organometallic complexes.

The bonding characters between metal and nitrogen atoms

It is very interesting to note that the BLA values for series **a** are much smaller than those in series **b** and **c**, which belong to organometallic complexes, and hence the bond characters between the metal and the adjacent nitrogen atom should be investigated. The bond characters in previous works verified strong triple Mo≡N bonds existing in organoimido-substituted POMs.[43] NBO analysis has successfully described the bonding characters when nitryl is introduced at the end of the phenyl in organoimido-substituted POMs. In our present study, the Mo–N bond with short length (1.822 Å) in compound **a1** is still composed of one σ bond ($0.4682sd^{1.85}$Mo + $0.8836sp^{0.85}$N) and two π bonds (0.5969dMo + 0.8023pN and 0.4544dMo + 0.8908pN), which confirms the significant covalent character of Mo≡N interaction, and the strong synergistic effect stabilizes the POM derivatives. However, the Wiberg bond indices for the M–N bond in compounds **b1** and **c1** are 0.200 and 0.243, respectively, much lower than the index of 1 expected for a single bond, indicating no chemical bond exists between the metal and nitrogen atom in organometallic complexes, whereas the strong donor–acceptor interaction may be

Fig. 2. The change trends in BLA values for each series with increasing n.



formed as treated by the second-perturbation energy $E(2)$ in eq. [1]:

$$[1] \qquad E(2) = E_{ij} = q_i F_{ij}^2 / \varepsilon_j \varepsilon_i$$

where F_{ij} is the off-diagonal element in the NBO Fock matrix, q_i is the donor occupancy, and ε_i and ε_j are diagonal elements (orbital energies). The values for $E(2)$ shown in Table 1 reveal that strong donor–acceptor interaction rather than covalent character exists from the lone electron pair of the nitrogen atom in the amido group to σ* of the M–C bond opposite to nitrogen, or to the lone pair of metal atoms. Therefore, the strong synergistic effect of Mo≡N in series **a** is expected to enhance the conjugation of the organic bridge and provide a better electron-transfer channel and, consequently, to improve the NLO response.

Static second-order polarizabilities

The total second-order polarizabilities β_0 for the studied series are defined using the following equation:

$$[2] \qquad \beta_0 = (\beta_x^2 + \beta_y^2 + \beta_z^2)^{1/2}$$

where β_x, β_y, and β_z are the components of the second-order polarizability tensor along the x, y, and z axes, respectively, and β_i is defined by eq. [3]:

$$[3] \qquad \beta_i = \beta_{iii} + \frac{1}{3}\sum_{j\neq 1}(\beta_{ijj} + \beta_{jij} + \beta_{jji})$$

From Table 2, the β_0 values for metal–carbonyl complexes **b1** and **c1** are 6.1 × 10^{-30} and 9.5 × 10^{-30} esu, respectively, and dramatically increases to 62.8 × 10^{-30} esu when the hexamolybdate moiety is substituted for the metal–carbonyl (nearly 8 times greater than that of PNA). Moreover, it is obvious from Fig. 3 that the β_0 values in the three series increase with the growing length of the conjugated bridges. However, the growth rate for β_0 in series **a** is dramatically faster, consequently resulting in larger second-order polarizabilities than in series **b** and **c** with the same conjugated bridge unit numbers.

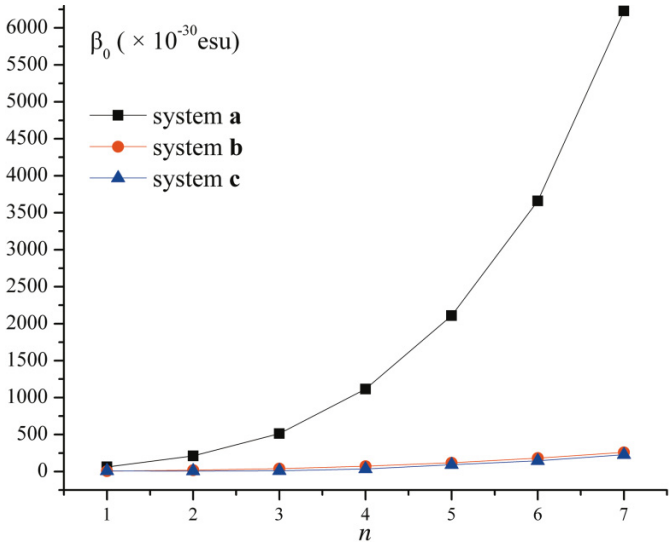
c7	227.5	8.54

Fig. 3. The change in trend of β_0 values for each series with different n.



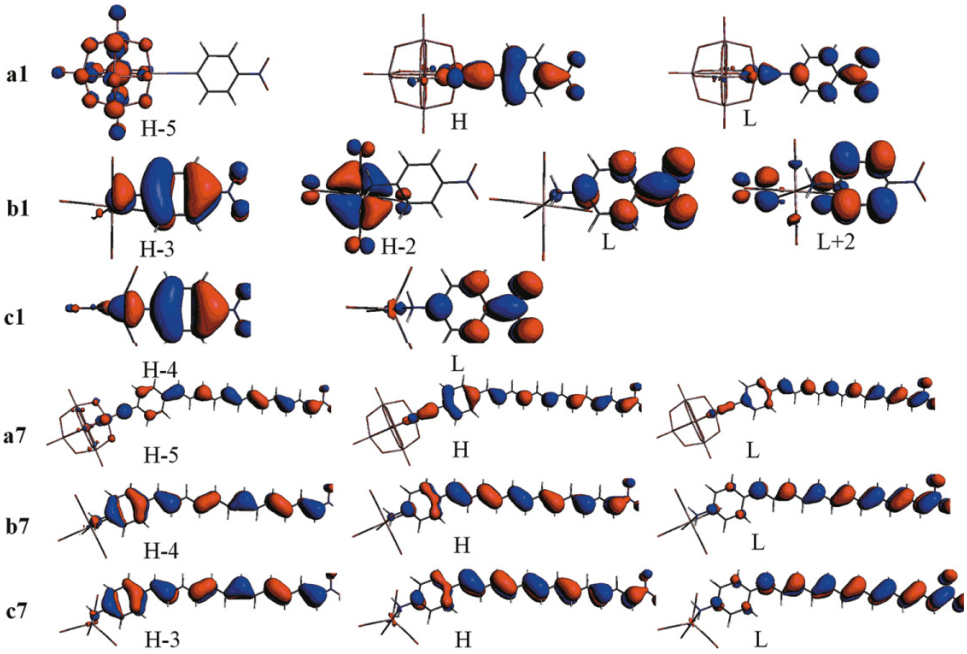
ble 2 are enhanced by increasing the length of the conjugated bridge, which lengthens the π conjugation of the molecule. Although the dipole moments for the first two compounds (n = 0 and 1) in series **a** are lower than the corresponding ones in series **b** and **c**, it starts to increase when n = 2. Therefore, the polarization for the ground-state molecule of the PNA–Mo_6 derivative (series **a**) tends to be higher than that of the organometallic complexes (series **b** and **c**), giving rise to larger NLO responses for series **a**, which is in agreement with the results calculated in Table 2.

The first main state with a large oscillator strength (f) value contributed to the electronic spectrum is shown in Table S1 (Supplementary data). As seen in Table S1, the transition energies E for the three series tended to decrease, and the f values increased as a result of the consecutive conjugated bridges, which is responsible for the increase in β_0 values (Fig. 3). For example, in series **a**, the value for E in compound **a1** is 2.74 eV and f increases to 0.739, resulting in a β_0 value of 62.8 $\times$ 10^{-30} esu, whereas E decreases to 1.58 eV and f increases to 1.950 in compound **a7** owing to the growing length of the conjugated bridge and generating a higher β_0 value of 6229.5 $\times$ 10^{-30} esu, nearly 30 times larger than compounds **b1** and **c1**. Similar trends were observed in series **b** and **c**. In comparison with the corresponding compounds with the same conjugated bridge in series **b** and **c**, the compounds in series **a** possess relatively smaller transition energies and greater oscillator strengths, which may induce a greater range of enhancement in β_0 values than in series **b** and **c**. The transition energies for compound **b7** and **c7** are 2.45 and 2.05 eV, respectively, indicating a blue-shift occurring in the organometallic complexes.

To further analyze the differences in the charge transfer between PNA–Mo_6 derivatives and PNA–MCO (M=Mo and Fe) complexes, the main contributions to the major transition were investigated and are found in Table S1 (Supplementary data). It was determined that the most important transitions for series **a** are generated by the promotion of the electron from HOMO to LUMO (HOMO and LUMO are represented by H and L, respectively, for simplicity), and the significant secondary transitions attribute the electron transition from H–5 to L. In comparison, the main transitions for series **b** and **c** are irregular, and the main donor moieties are located from H–4 to H with acceptor ones focusing on L and L+2. Therein, the first and seventh compounds in the three series have been chosen as representative, and the molecular orbitals contributing to the main transitions are shown in Fig. 4. It is obvious that the charge transfer in **a1** mainly originates from the π orbital of Mo≡N with a phenyl ring and partly from the p orbitals of oxygen atoms in the polyanion to the electron-withdrawing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

Fig. 4. The main charge transfer contributing to the major transition states for typical compounds.

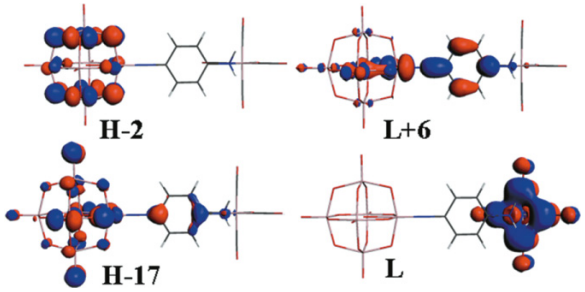


nitryl group. In contrast, **b1** and **c1** localize their donor moieties on the lone electron pair of the nitrogen atom in the amido group and the π orbital on the whole phenyl ring, and the acceptor ones concentrate on the nitryl group. In addition, Mo in **b1** also acts as a donor to offer d electrons to the π orbital of the phenyl ring and the electron transition can be assigned to MLCT. When the conjugated bridge linking donor and the acceptor moieties has been extended and the charge transfer has occurred in the conjugated bridge (ILCT) and tends to transfer to the part close to the nitryl acceptor. However, the electrons have been transferred throughout the conjugated chain according to the extended conjugated bridge and tend to transfer to the moiety with the nitryl acceptor. It is more interesting that the π orbital of Mo≡N in system **a** still contributes to the donor. Therefore, the electrons tend to transfer to the side with the acceptor moiety and the donor electrons not only concentrate on the left side, but begin to gradually extend over the conjugated bridge with the enhanced chain. In addition, it is proposed that the presence of Mo≡N in PNA–Mo_6 derivatives may take a role in transferring the electrons from the polyanion to the conjugated chain, consequently gaining more obvious electron transition to enhance the NLO response.

The electron transition for compound d

To shed further light on the superior donor properties of hexamolybdate over metal–carbonyl complexes in second-order NLO response in the D–π–A model, one new compound **d** combining a hexamolybdate framework and metal–carbonyl segment via a conjugated *p*-phenylenediamine bridge was investigated (Fig. 5). Compound **d** possesses a much large NLO response (362.2 × 10^{-30} esu), indicating the larger charge transfer from donor to acceptor. According to the TDDFT calculation, the main charge transfer with the largest oscillator strength originates from the polyanion framework to the conjugated bridge and the metal–carbonyl segment. Therefore, this revealed the superiority of hexamolybdate as a donor over the metal–carbonyl complexes and evoked its use for a promising NLO response.

Fig. 5. The main charge transfer contributing to the main transition states for compound **d**.



Conclusions

It is obvious that the NLO responses have been enhanced in each series with the growing length of the conjugated bridge and decreasing BLA values. However, the BLA values of PNA–Mo_6 derivatives are much lower than that of other organometallic complexes, resulting in a better NLO response. In addition, the link of hexamolybdate and PNA with Mo≡N is expected to supply a better electron-transfer channel and enhance the conjugation of the organic bridge and, consequently, generate outstanding NLO response over PNA–MCO complexes. In conclusion, POMs have exhibited a superiority in donor moiety as potential NLO materials.

Abstract: A novel catalytic system was prepared by impregnating ionic liquid immobilized 2,2,6,6-tetramethylpiperidyl-1-oxyl (TEMPO) and copper salt onto various silica supports. This catalytic system was capable of rapidly converting different benzylic and allylic alcohols into the corresponding aldehydes under O_2 atmosphere with high conversion. Recycling results showed that the catalyst could be easily recovered and reused.

Key words: supported ionic liquid, selective alcohol oxidation, 2,2,6,6-tetramethylpiperidyl-1-oxyl (TEMPO).

Résumé : On a préparé un nouveau système catalytique en imprégnant du 2,2,6,6-tétraméthylpiperidine-1-oxyle (TEMPO) immobilisé sur un liquide ionique et un sel de cuivre sur divers supports à base de silice. Ce système catalytique, dans une atmosphère d'oxygène (O_2), est capable d'oxyder divers alcools benzyliques et allyliques en aldéhydes correspondants avec des taux élevés de conversion. Des résultats de recyclage ont montré que le catalyseur peut facilement être récupéré et réutilisé.

Mots-clés : liquide ionique sur un support, oxydation sélective d'alcool, 2,2,6,6-tétraméthylpiperidine-1-oxyle (TEMPO).

[Traduit par la Rédaction]

Introduction

In general, heterogeneous catalysis is preferred in industrial processes to homogeneous catalysis. The attractive features of heterogeneous catalysis include a large interfacial reaction area, ease of separation of products and catalysts, high system stability, and the potential to use very simple processing techniques such as fixed-bed reactor technology.[1] However, in some heterogeneous catalysis reactions, the diffusion rate of the reactants to the solid catalyst is often so low as to lead to a decrease of the reactivity of the catalytic system. Moreover, in comparison with homogeneous catalysis, lower selectivity is often obtained.

Ionic liquids are defined as salts with melting points below 100 °C. Favorable properties such as low vapor pressure, tunable hydrophilic or lipophilic properties, high thermal stability, low toxicity, and ease of handling make ionic liquids attractive alternatives to traditional organic solvents.[2] Unfortunately, high viscosity of ionic liquids may lead to mass or heat transfer limitations in the reaction system, implying that highly energy-consuming stirring is needed for industrial applications. Consequently, a new strategy integrating the advantages of ionic liquids and heterogeneous catalysis would be highly desirable.

In this context, the concept of confining ionic liquids on solid supports to obtain heterogenized homogeneous catalyst systems, described as supported ionic liquid catalysts, has recently attracted increasing attention. In a supported ionic liquid system, a thin film of ionic liquid is supported on the surface of a solid material (such as silica gel, diatomic earth, molecular sieves, or montmorillonite) via covalent anchoring or adsorption. Compared with the homogeneous catalyst system, the supported ionic liquid system provides 3 major advantages: (*i*) a small amount of ionic liquid; (*ii*) good activity, which is attributed to a higher concentration of the active species at the ionic liquid film; and (*iii*) convenient product separation and easy recovery of catalyst.[3,4] During the last decade, supported ionic liquid catalysts have been applied in hydroformylation,[5,6] hydrogenation,[7,8] Heck reaction,[9,10] hydroamination,[11] aldol reaction,[12] and epoxidation.[13]

The selective oxidation of alcohols to the corresponding aldehydes or ketones is the foundation of many important industrial and fine-chemical processes. Many highly efficient systems have been developed for catalytic aerobic alcohol oxidation using transition metals such as palladium,[14] ruthenium,[15] copper,[16,17] iron,[18] and vanadium.[19] Of particu-

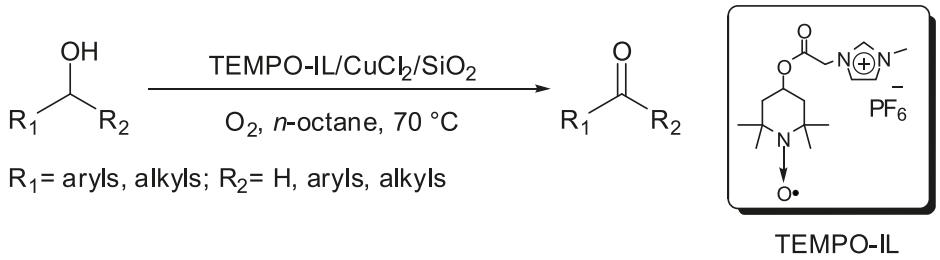
Scheme 1. Aerobic oxidation of alcohols catalyzed by TEMPO-IL/$CuCl_2$/SiO_2.



lar interest are the catalytic systems consisting of an inexpensive transition metal compound (e.g., copper) and 2,2,6,6-tetramethylpiperidyl-1-oxyl (TEMPO) for mild and selective aerobic alcohol oxidations. Recently, numerous immobilized TEMPO variants on both organic and inorganic supports have been developed.[20,21] For the aerobic alcohol oxidation promoted by these systems, the recycling of TEMPO could be achieved easily, but prolonged reaction times are usually needed for high conversion.[22]

Our recent work was focused on the oxidation of organic compounds with molecular oxygen as oxidant.[23,24] Earlier, we disclosed a catalytic system, TEMPO-IL/CuCl /MS3A (molecular sieve 3A), for the aerobic oxidation of a wide range of benzyl alcohols in the ionic liquid [bmim]PF_6, where MS3A serves as a heterogeneous Brønsted base to enhance the reaction rate remarkably.[25] In light of the newly developed supported ionic liquid catalyst systems, in this work we developed a novel catalytic aerobic oxidation system by impregnating the task-specific ionic liquid TEMPO-IL and copper salt onto various silica supports. The resulting system, TEMPO-IL/$CuCl_2$/SiO_2, catalyzed aerobic oxidation of most benzylic or allylic alcohols in *n*-octane to the corresponding aldehydes in less than 3 h with high conversion (Scheme 1). The catalyst system could easily be recycled and reused at least 3 times.

Results and discussion

The experimental results for *p*-nitrobenzyl alcohol oxidation using the supported task-specific ionic liquid catalyst system are listed in Table 1. Three kinds of copper salts — $Cu(OAc)_2$, $Cu(NO_3)_2$, and $CuCl_2$ — were used as co-catalyst in the TEMPO-IL/copper salt/SiO_2 catalyst system for the aerobic oxidation in *n*-octane (Table 1, entries 1–3). The catalyst system of TEMPO-IL/$CuCl_2$/SiO_2 was found to be most efficient, with more than 99% conversion in 1.5 h. The limitation of solvent for a supported ionic liquid catalyst system is that the solvent phase and the ionic liquid have to form a biphasic system without any ionic liquid leaching, otherwise the ionic liquid film would be washed out of the supporting material and the catalytic system would be deactivated.[4,26] The best catalytic activity was observed in *n*-octane (poor solvent for TEMPO-IL) (Table 1, entry 3); moderate catalytic activity was found in toluene, with 89% conversion in 12 h (Table 1, entry 4); and in the case of DMF and [bmim]PF_6 (good solvents for TEMPO-IL), poor catalytic activity was observed (Table 1, entries 5 and 6). In good solvents, TEMPO-IL and $CuCl_2$ are completely dissolved and the oxidation takes place mainly in solvent. In *n*-octane, on the other hand, the oxidation occurs mainly in the ionic liquid film, in which the relatively high concentration of catalyst may be beneficial to catalytic activity.

In previous studies, we found that when copper salt / TEMPO-IL catalyst systems were used for the aerobic oxidation of benzyl alcohols, CuCl exhibited better catalytic performance than $CuCl_2$.[23] Owing to the poor solubility of CuCl in water or methanol, it is hard to immobilize CuCl onto silica gel directly. However, we were surprised to find that the system of TEMPO-IL/$CuCl_2$/SiO_2 was even more effective for catalyzing the aerobic oxidation of benzyl alcohols than TEMPO-IL/CuCl. To verify the importance of immobilization in the catalysis, we carried out the oxidation of *p*-nitrobenzyl alcohol with TEMPO-IL/$CuCl_2$ as catalyst in the absence of the solid support. The results revealed that only a small amount of product could be achieved in the ionic liquid [bmim]PF_6 (Table 1, entry 7). In the case of *n*-octane as solvent (Table 1, entries 8 and 9), the substrate could be oxidized efficiently. However, the separation of the product from the reaction system and the recovery of the catalyst were tedious.

On the basis of the above results, we found that the immobilization of TEMPO-IL / copper salt resulted in higher activity as compared with their homogeneous counterparts. The question is, do other commonly used silicas have a similar effect on the aerobic oxidation of alcohol? We prepared the supported catalysts with three different silica supports: MCM-41, SBA-15, and silica gel (200–300 mesh). As shown in Table 2, the solid supports make hardly any difference in the oxidation of alcohol.

After determining the optimal reaction conditions for the supported task-specific ionic liquid catalysis, we examined the range of alcohols to which this catalytic aerobic oxidation could be applied. As shown in Table 3, benzylic alcohols were converted into their corresponding aldehydes in high conversions (Table 3, entries 1–5). The rates of these benzylic alcohol oxidations were not significantly affected by the electronic property of the substituents on the benzene ring. Similarly, allylic and heterocyclic primary alcohols could be smoothly oxidized to the corresponding aldehydes in high conversions using this catalyst system (Table 3, entries 6 and 7). The catalytic system shows high selectivity, only a trace amount of acid (less than 1%) was formed, and the double bond of allylic alcohol was unaffected. In spite of the good results with benzylic, allylic, and heterocyclic alcohols, the conversion obtained with aliphatic alcohol under the same conditions was quite low even after 12 h (Table 3, entry 8).

The recyclability of the catalyst system was then studied. At the end of each cycle the catalyst was separated by cen-

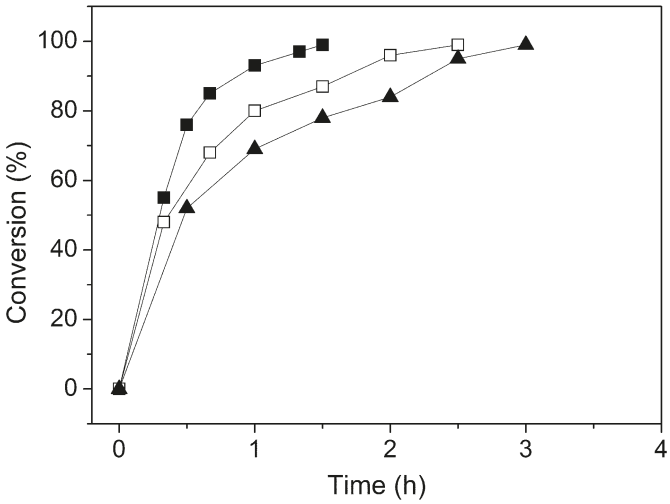
[b]Isolated yield.

trifugation and washed with *n*-octane. As shown in Fig. 1, the catalytic activity decreased gradually over 3 consecutive runs. However, the aerobic oxidation was still completed in 4 h at the 3rd cycle. In the supernatant, Cu was not detected by inductively coupled plasma analysis, whereas trace TEMPO-IL species were detected by HPLC analysis. The leaching of TEMPO-IL would be the main reason for the loss of activity, which may be due to the weak interaction between silica and TEMPO-IL.

Fig. 1. Recycling of the catalytic system for the oxidation of *p*-nitrobenzyl alcohol. Reaction conditions were as follows: *p*-nitrobenzyl alcohol (1 mmol), TEMPO-IL/$CuCl_2/SiO_2$ (0.1 g), and *n*-octane (10 mL) under O_2 at 70 °C; ■, run 1; □, run 2; ▲, run 3.



Conclusion

In summary, a highly efficient TEMPO-IL/$CuCl_2/SiO_2$ catalytic system based on the concept of supported ionic liquid catalysts has been developed and used for aerobic alcohol oxidation under an oxygen atmosphere. The amount of task-specific ionic liquid involved in the preparation of the catalyst was very low and the preparation procedure was simple. Moreover, the catalyst could be easily recovered by centrifugation and reused. From an economic point of view, our results indicate that supported task-specific ionic liquid

catalysis could be an interesting methodology. Further applications are currently under investigation in our laboratory.

Experimental

The ionic liquid [bmim]PF_6 was synthesized according to the literature.[27] Silica gel (200–300 mesh) was activated at 180 °C under vacuum overnight before use. All other chemicals were obtained from commercial sources with more than 99% purity and used without further purification. Gas chromatography (GC) analysis was performed on an Agilent GC-6820 equipped with a 30 m × 0.32 mm × 0.5 μm HP-Innowax capillary column and a flame ionization detector. The elemental analysis of copper was determined by inductively coupled plasma atomic emission spectroscopy (Thermo Scientific iCAP 6300). Products were all known compounds and were identified by comparing their physical and spectral data with those reported in the literature.

Catalyst preparation

TEMPO-IL was prepared according to the literature.[28] To a stirred solution of TEMPO-IL (1.0 g, 2.26 mmol) in 25 mL of methanol, $CuCl_2 \cdot 2H_2O$ (0.386 g, 2.26 mmol) was added. After that, silica gel (3.15 g) was added. The mixture was stirred for 5 h and then evaporated under reduced pressure for 3 h to give a powder of TEMPO-IL/$CuCl_2$/SiO_2. The obtained product was dried at 50 °C under vacuum overnight before use.

Typical experimental procedure for oxidation of alcohols

Alcohol (1 mmol) and TEMPO-IL/$CuCl_2$/SiO_2 (100 mg) were mixed with *n*-octane (10 mL) and stirred at 70 °C under O_2 (10 mL/min, 1 atm (1 atm = 101.325 kPa)) for the given time. After completion (monitored by TLC and GC), the mixture was centrifuged to separate the catalyst, which was washed several times with *n*-octane, dried, and recharged with fresh substrate and solvent for the next catalytic cycle. The combined solvent phase was concentrated under vacuum, and the crude product was purified by column chromatography (petroleum ether / ethyl acetate, 10/1) to provide the analytically pure aldehyde, which was characterized by ^{1}H NMR and IR analysis.

Abstract: Two new metabolites containing a 1-oxa-7-azaspiro[4.4]non-2-ene-4,6-dione core, pseurotin A_1 (**1**) and A_2 (**2**), as well as pseurotin A (**3**), were isolated from the holothurian-derived fungus *Aspergillus fumigatus* WFZ-25. These compounds were determined using extensive analysis of their spectroscopic data, including 1D and 2D NMR, HR-ESI-MS, and circular dichroism (CD) experiments.

Key words: pseurotin A, *Aspergillus fumigatus*, structure elucidation, cytotoxicity.

Résumé : On a isolé deux nouveaux métabolites à base de 1-oxa-7-azaspiro[4,4]non-2-ène-4,6-dione, les pseurotines A_1 (**1**) et A_2 (**2**), ainsi que la pseurotine A (**3**) à partir de l'*Aspergillus fumigatus* WFZ-25 dérivé de l'holothuriane. Les structures de ces composés ont été déterminées par une analyse extensive de leurs données spectroscopiques, dont des spectres de RMN 1D et 2D, de la spectrométrie de masse à haute résolution avec ionisation par électronébulisation (SM-HR-IEN) et des expériences de dichroïsme circulaire (DC).

Mots-clés : pseurotine A, *Aspergillus fumigatus*, élucidation de structure, cytotoxicité.

[Traduit par la Rédaction]

Introduction

In our ongoing efforts to discover antitumor metabolites from marine microorganisms, we found that ethyl acetate extracts of the marine-derived fungus *Aspergillus fumigatus* WFZ-25, isolated from the holothurian *Stichopus japonicus* collected from Lingshan Island, Qingdao, China, contained cytotoxic constituents. We have previously reported seven new prenylated indole diketopiperazine alkaloids and twelve known ones from this strain.[1] Further investigations of the active fractions led to the isolation of two new diastereomers of pseurotin A (**3**),[2] pseurotin A_1 (**1**) and A_2 (**2**) (Fig. 1).

Pseurotin A was previously isolated from the fungal strains *Pseudeurotium ovalis* Stolk and *A. fumigatus*,[3,4] and its absolute stereochemistry was determined by X-ray crystallographic analysis of its 12,13-dibromo derivatives.[3,5] Structurally, pseurotin A belongs to a family of natural products containing an unusual 1-oxa-7-azaspiro[4.4]non-2-ene-4,6-dione core and diverse biological activities. To the best of our knowledge, this family of natural products only possessed very few compounds, including pseurotins A-F1, F2 (8-*O*-demethylpseurotin A),[2,4,6,7] 14-norpseurotin A,[8] synerazol,[9] azaspirene,[10] FD-838,[11] and cephalimysins A–D.[12,13] In this paper, we report the isolation, structure elucidation, and cytotoxic activities of pseurotin A_1 (**1**) and A_2 (**2**).

Results and discussion

Compound **1** was isolated as a white amorphous powder. The molecular formula of $C_{22}H_{25}NO_8$ was established by HR-ESI-MS with a $[M + Na]^+$ peak at m/z = 454.1458 (calcd. for $C_{22}H_{25}NO_8Na^+$: 454.1478), indicating 11 degrees of unsaturation. The UV spectrum of **1** exhibiting absorption maxima at 251 (4.12) and 277 (3.97) nm was compatible with a phenyl ketone and one of the simple 3-(2*H*)-furanone systems.[14,15] The IR spectrum showed the presence of a lactame and an α,β-saturated ketone at 3204, 1726, 1706, and 1633 cm^{-1}.[2] In the ^1H NMR spectrum of **1**, four exchangeable protons appeared in the downfield region at δ 4.96 (d, J = 5.1 Hz, 11-OH), 5.75 (d, J = 5.5 Hz, 10-OH), 6.07 (d, J = 6.2 Hz, 9-OH), and 9.94 (s, 7-NH) owing to the presence of hydroxyl or amide protons. Five aromatic protons at δ 7.52 (2H, t, J = 7.7 Hz, H-20, 22), 7.63 (t, J = 7.3 Hz, H-21), and 8.10 (2H, d, J = 7.3 Hz, H-19, 23), as well as two olefinic methine protons at δ 5.39 (dd, J = 8.1, 11.0 Hz, H-

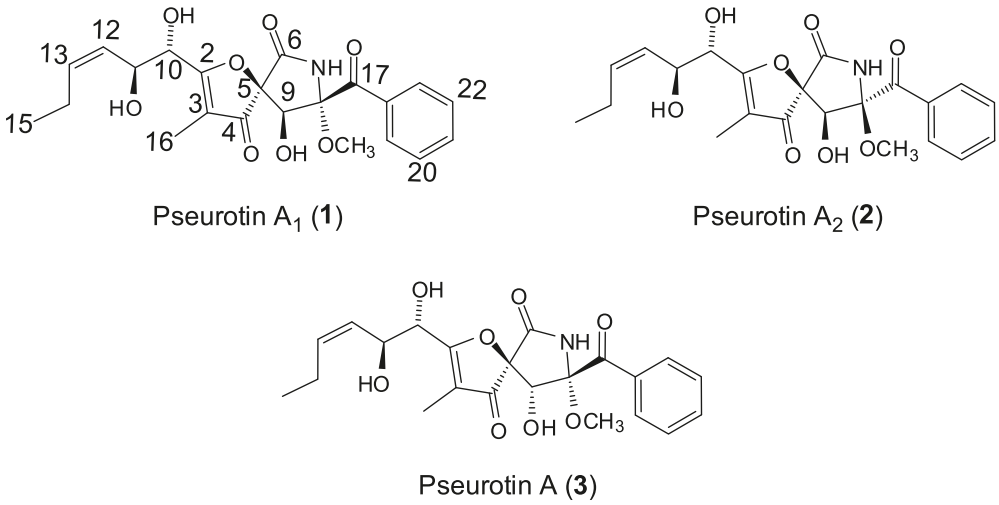
Fig. 1. Structures of compounds **1**–**3**.



12) and 5.42 (dd, J = 7.0, 11.0 Hz, H-13) in the downfield region, revealed the presence of one monosubstituted phenyl group and a cis double bond. Furthermore, three oxygenated methine protons at δ 4.36 (t, J = 5.2 Hz, H-10), 4.45 (ddd, J = 5.5, 7.7, 10.6 Hz, H-11), and 4.62 (d, J = 6.2 Hz, H-9), three methyl protons at δ 0.86 (3H, dd, J = 7.3, 7.7 Hz, H-15), 1.66 (3H, s, H-16), and 3.12 (3H, s, 8-OMe) as well as one methylene proton at δ 1.95 (m, H-14a) and 2.01 (m, H-14b) were observed. The ^{13}C NMR and DEPT spectra of **1** revealed the presence of 21 carbons, including three methyls, one mehylene, seven sp^2 methines, two sp^3 quaternary carbons, three sp^2 quaternary carbons (one oxygenated), and three carbonyls. The HMQC spectrum revealed all of the one bond H–C connectivities (Table 1). The above data together with the ^{1}H–^{1}H COSY and HMBC correlation experiments (Fig. 2) further established the planar structure of **1**, which possessed a 1-oxa-7-azaspiro[4.4]non-2-ene-4,6-dione skeleton and was a diastereomer of pseurotin A (**3**).[2] Further comparison of the 1D NMR spectral data of **1** with those of **3** showed the main differences were that the chemical shifts at δ 200.0 (s, C-4), 97.1 (s, C-8), and 4.62 (d, J = 6.2 Hz, H-9) of **1** were strongly deshielded compared with **3**, whereas δ 88.2 (s, C-5), 194.8 (s, C-17), and 6.07 (d, J = 6.2 Hz, 9-OH) were shielded (Table 1). These data indicated that the configuration of C-9 of the two compounds could be different. Further confirmation were provided by NOESY correlations between H-9 and 8-OMe (δ 3.12, s), 9-OH, and 10-OH (δ 5.75, d, J = 5.5 Hz) (Fig. 3). The circular dichroism (CD) spectra of **1** and **3** gave similar Cotton effects (Fig. 4), which also suggested that the stereochemistry of C-9 in **1** should be changed but not that of C-5 and C-8. The above results were finally identified by comparison with CD data of FD-838 and cephalimysin B in the literature.[13] The structural differences between compounds **1** and **2** resembled those between FD-838 and cephalimysin B, which was compatible with the changes of their CD data. So the structure of **1** was assigned as (5*S*,8*S*,9*S*,10*S*,11*S*,12*Z*)-8-benzoyl-2-(10,11-dihydroxy-12-hexenyl)-9-hydroxy-8-methoxy-3-methyl-1-oxa-7-azaspiro[4.4]non-2-ene-4,6-dione and named pseurotin A_1 (Fig. 1).

Compound **2** was isolated as a white amorphous powder. The HR-ESI-MS, showing a $[M + Na]^+$ peak at m/z = 454.1465 (calcd. for $C_{22}H_{25}NO_8Na^+$: 454.1478), established the molecular formula as $C_{22}H_{25}NO_8$, equal to those of **1** and **3**. Detailed analysis of the UV, IR, and 1D NMR data of **1**–**3** indicated that **2** was a diastereomer of **1** and **3**, and the structure of **2** was closer to that of compound **1**. The chemical shifts of C-8 (δ 94.8, s) and H-9 (δ 4.18, d, J = 9.9 Hz) in **2** were strongly shielded compared with **1**, whereas 9-OH (δ 6.35, d, J = 9.9 Hz) was deshielded. We speculated that the configuration of C-8 was different from that of **1** (Table 1). This could be further determined by the NOESY correlation experiment and the CD spectrum of **2**. A NOESY correlation between 9-OH and 10-OH (δ 5.87, d, J = 5.5 Hz) was observed, but no correlation between H-9 and 8-OMe (δ 3.20, s) was noted. These results supported the above supposition (Fig. 3). Compared with the CD spectrum of compound **1**, the spectrum of **2** displayed a different Cotton effect with maxima at 251.6 (–2.7) and 227 (+9.4) nm (Fig. 4). This showed that the configuration of C-8 in **1** should be changed and that the one of C-5 (δ 87.1, s) was the same as the one in **2**. Similar to compound **1**, the configuration of **2** was finally assigned by comparison with the CD data of cephalimysin C and its enantiomer. The similar Cotton effects showed that the configurations of C-5, C-8, and C-9 in compound **2** were the same as the ones in the enantiomer of cephalimysin C.[13] Therefore, the structure of **2** was assigned as (5*S*,8*R*,9*S*,10*S*,11*S*,12*Z*)-8-benzoyl-2-(10,11-dihydroxy-12-hexenyl)-9-hydroxy-8-methoxy-3-methyl-1-oxa-7-azaspiro[4.4]non-2-ene-4,6-dione and named pseurotin A_2 (Fig. 1).

Compounds **1**–**3** were evaluated for their cytotoxicities against the P388, HL-60, A549, and BEL-7402 cell lines. The results showed that compound **2** displayed a slight cytotoxicity against the A549 and HL-60 cell lines and that compound **3** was slightly cytotoxic against the HL-60 cell lines, and the IC_{50} values for them were 48.0, 70.8, and 67.0 μmol/L, respectively. VP16 (etoposide) was used as a positive control.[1]

The pseurotins and their analogs have an interesting spirofuranone–lactam core and diverse biological activities. Structurally, the changes in configuration of C-5, C-8, and C-9 in the core could produce some stereoisomers. Recently,

the absolute configurations of cephalimysins B–D and their synthetic stereoisomers were unambiguously established by studying CD Cotton effects.[13] Herein, we also successfully identified the absolute stereochemistry of **2** and **3** by comparison of their NMR data and CD spectra with those of pseurotin A (**3**). These results showed that the analysis of CD spectra was valuable for determining the absolute configuration of related compounds. However, the cytotoxicities of **1–3** against four tumor cell lines did not imply a structure–activity relationship.[13] Furthermore, the test of inhibitory activity of protein kinase for **1–3** is in progress.

spectrometer; in *m/z* (rel %). Semipreparative HPLC: ODS column (Shin-pak ODS (H), 20 mm × 250 mm, 5 μm, 4 mL/min) and monitored by a UV detector.

Fungal material

The fungus *A. fumigatus* WFZ-25 was isolated from the holothurian *S. japonicus* collected in August 2005 from Lingshan Island, Qingdao, China. It was preserved in the Key Laboratory of Marine Drugs, Chinese Ministry of Education, Institute of Marine Drugs and Food, Ocean University of China. Working stock cultures were prepared on potato dextrose agar slants and stored at –20 °C.

Fermentation, extraction, and isolation

The fungus was inoculated in 500 mL Erlenmeyer flasks containing 150 mL liquid medium (20.0 g maltose, 20.0 g mannitol, 10.0 g glucose, 10.0 g monosodium glutamate, 0.5 g KH_2PO_4, 0.3 g $MgSO_4$, 3.0 g yeast extract paste, and 1.0 g maize paste dissolved in 1.0 L seawater, pH 6.5), followed by shaking incubation at 165 rpm for 9 days at 28 °C. The fermented whole broth (60 L) was filtered through cheesecloth to separate the supernatant and the mycelia. The former was concentrated under reduced pressure to about a quarter of the original volume and then extracted three times with ethyl acetate to give an ethyl acetate solution, while the latter was extracted three times with acetone–H_2O (80:20). The acetone solution was concentrated under reduced pressure to afford an aqueous solution. The aqueous solution was extracted three times with ethyl acetate to give another ethyl acetate solution. Both ethyl acetate solutions were combined and concentrated under reduced pressure to give a crude extract (100 g).

The crude extract was separated into 10 fractions (Fr.1–Fr.10) on a silica gel column using a stepwise gradient elution of petroleum ether (PE) – $CHCl_3$ – MeOH. Fraction Fr.6 (6.5 g) was subjected to repeated silica gel CC using a stepwise gradient elution of PE–$CHCl_3$–MeOH, followed by chromatographing on Sephadex LH-20, eluting with $CHCl_3$–MeOH (1:1), to yield subfraction Fr.6-2-1 (780.0 mg). Subfraction Fr.6-2-1 was subjected to Sephadex LH-20 eluting with $CHCl_3$–MeOH (1:1) and then purified by semipreparative HPLC using MeOH–H_2O (60:40) at a wavelength of 201 nm to yield compounds **3** (47.2 mg), **1** (34.0 mg), and **2** (8.6 mg).

HR-ESI-MS: 454.1458 $[M + Na]^+$ (calcd. for $C_{22}H_{25}NO_8Na^+$: 454.1478).

Pseurotin A_2 (2)

White amorphous powder. $[\alpha]_D^{23}$ –30.6 (*c* 0.1, MeOH). UV (MeOH) λ_{max} (nm; log ε): 205 (4.28), 252 (4.17), 278 (4.01). CD (MeOH) λ_{max} (nm; $\Delta\varepsilon$): 206.6 (+14.6), 227.8 (+9.4), 251.6 (–2.7), 278.1 (–10.3), 315.8 (+0.8), 344.9 (–1.6). IR (KBr, cm^{-1}) ν_{max}: 3204, 1741, 1739, 1693, 1448, 1215,

1176, 877, 751. ^{1}H (600 MHz) and ^{13}C (150 MHz) NMR data, see Table 1. HR-ESI-MS: 454.1465 $[M + Na]^+$ (calcd. for $C_{22}H_{25}NO_8Na^+$: 454.1478).

Pseurotin A (3)

White amorphous powder. $[\alpha]_D^{23}$ –2.5 (*c* 0.1, MeOH). UV (MeOH) λ_{max} (nm; log ε): 206 (3.98), 252 (3.93), 280 (3.77). CD (MeOH) λ_{max} (nm; $\Delta\varepsilon$): 206.8 (+30.5), 228.1 (–8.1), 250.4 (+10.0), 277.7 (–25.2), 308.1 (+3.8), 312.5 (+7.1), 350.4 (–3.0). IR (KBr, cm^{-1}) ν_{max}: 3211, 1725, 1705, 1632, 1440, 1079, 1041, 1017, 807, 666. ^{1}H (600 MHz) and ^{13}C (150 MHz) NMR data, see Table 1. ESI-MS: 432.2 $[M + H]^+$, 454.2 $[M + Na]^+$, 470.2 $[M + K]^+$.

Biological assays

Active fractions were assayed using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) method with the P388 cell line. Cytotoxic activities were evaluated by the MTT method[16] using the P388 and HL-60 cell lines and the SRB (sulforhodamine B) method[17] using the A549 and BEL-7402 cell lines.

In the MTT assay, the cell suspensions (200 μL) at a density of 5×10^4 cells mL^{-1} were plated in 96 well microtiter plates and incubated for 24 h at 37 °C in a humidified incubator at 5% CO_2. The test compound solution (2 μL in DMSO) at different concentrations was added to each well and further incubated for 72 h under the same conditions. Then, 20 μL of the MTT solution was added to each well and incubated for 4 h. The old medium (150 μL) containing MTT was then gently replaced by DMSO and pipetted to dissolve any formazan crystals formed. Absorbance was then determined on a Spectra Max Plus plate reader at 540 nm.

In the SRB assay, 200 μL of the cell suspensions were placed in 96 well plates at a density of 2×10^5 cells mL^{-1}. Then, 2 μL of the test compound solution (in MeOH) at different concentrations was added to each well and the culture was further incubated for 24 h at 37 °C in a humidified incubator at 5% CO_2. Following drug exposure, the cells were fixed with 12% trichloroacetic acid and the cell layer was stained with 0.4% SRB. The absorbance of the SRB solution was measured at 515 nm. Dose–response curves were generated and the IC_{50} values were defined as the concentration of compound required to inhibit cell proliferation by 50%.

Abstract: The present study considers simple and cost-effective modifications to commercial pressurised solvent extraction cells to extract polychlorinated biphenyls (PCBs) from avian blood and serum. Blood and serum samples of mass 0.2 g were examined. Such masses are consistent with those which may be obtained from many avian species without sacrificing individuals or compromising breeding and (or) migratory success. Extraction vessels are modified by the use of Teflon inserts, which are readily fabricated at low cost. These inserts reduce internal cell volume and surface area. Thus, background contamination is reduced whilst extraction and rinse solvent is used more effectively to afford a small extract volume. Packing of the cell void with sodium sulfate and florisil achieves in situ sample dehydration and lipid removal. When combined with extraction concentration and large volume injection gas chromatography – ion-trap mass spectrometry (LVI-GC–ITMS), the extraction method is capable of polychlorinated biphenyl analysis without post-extraction clean-up. Validation was accomplished using commercial chicken whole blood and serum, and PCB congeners 28, 77, 105, 126, 153, 167, 170, 180, 183, and 194. Surrogate corrected recoveries in the range of 75% to120% for whole blood and 80% to115% for serum were obtained. Detection limits were in the range of 0.01 to 0.22 ng g^{-1} for whole blood and 0.03 to 0.45 ng g^{-1} for serum. The relative standard deviations for all congeners investigated were better than 15%.

Key words: polychlorinated biphenyls, pressurized solvent extraction, avian blood, large-volume injection gas chromatography, ion-trap mass spectrometry, tandem mass spectrometry.

Résumé : Dans ce travail, on considère diverses modifications simples et rentables aux cellules d'extraction commerciales avec solvants sous pression pour extraire les biphényles polychlororés (BPC) à partir de sang et de sérum aviaire. On a examiné des échantillons de sérum et de sang de masse égale à 0,2 g. De telles masses sont en accord avec celles qui peuvent être obtenues à partir de plusieurs espèces aviaires sans devoir sacrifier les individus ou compromettre les aptitudes à la reproduction et (ou) à la migration. Les tubes d'extraction ont été modifiés par l'utilisation d'insert en Teflon qui peuvent facilement être fabriqués à de faibles coûts. Ces inserts réduisent le volume et la superficie de la cellule. La contamination de fond est ainsi réduite alors que le solvant d'extraction et de rinçage est utilisé d'une façon plus efficace de façon à avoir un faible volume d'extraction. Le remplissage du vide de la cellule avec du sulfate de sodium et du florisil permet de réaliser in situ la déshydratation de l'échantillon et l'enlèvement des lipides. Lorsqu'elle est combinée avec une concentration de l'extraction et un appareil de spectrométrie de masse avec piège d'ion et une injection d'un grand volume (« LVI-GC–ITMS »), la méthode d'extraction permet d'effectuer une analyse de biphényle polychloré sans purification post-extraction. On a réalisé la validation de la méthode en utilisant des échantillons commerciaux de sang complet et du sérum de poulet avec les congénères 28, 77, 105, 126, 167, 170, 183 et 194 des BPC. On a obtenu des récupérations corrigées pour les substitutions qui varient de 75 % à 120 % pour le sang complet et de 80 % à 115 % pour le sérum. Les limites de détection varient de 0,01 à 0,22 ng g^{-1} pour le sang complet et de 0,03 à 0,45 ng g^{-1} pour le sérum. Les déviations standards relatives pour tous les congénères étudiés sont meilleures que 15 %.

Mots-clés : biphényles polychlorés, extraction par solvant sous pression, sang aviaire, chromatographie gazeuse à grand volume d'injection, spectrométrie de masse à trappe ionique, spectrométrie de masse en tandem.

Introduction

Polychlorinated biphenyls (PBCs) represent 209 congener compounds, which were historically produced as complex mixtures under a number of trade names, such as Aroclors. The commercialization of these mixtures, as well as their release and transport in the environment, environmental persistence, and negative environmental impacts, has been extensively documented.[1–4] Legislation and regulation, intended to ban PCB production, limit use of existing PCBs stocks, and require environmental remediation, began in the 1970s in developed nations, such as Canada[5] and has continued into the 21st century.[6,7] However, PCBs were employed in a number of dissipative applications such as plasticizers, paints, wood-floor finishes, and pesticide extenders.[8] Moreover, several locations associated with industrial applications, such as those in the US states of New York (General Electric Company), Illinois (Outboard Marine Corporation), Massachusetts (Federal Pacific Electric Company), and Pennsylvania (Westinghouse Elevator Company),[9–14] are acutely contaminated. Environmental transport from dissipative sources and acutely contaminated sites has made PCBs global contaminants.[15] As the result of legislation and remedial action, driven by public concern, PCBs levels in sediment, birds, and fish have decreased in areas such as the Great Lakes.[16–19] However, PCB concentrations in Great Lakes fish remain in the part per billion range (10^{-9}); concentrations that are sufficient to impact higher species within foodwebs and to restrict human consumption.[20,21] The lipophilicity of PCBs and their resistance to degradation contribute to this bioaccumulation.[2] The effects of PCBs include interferences with thyroid activities and developmental abnormalities, with piscivorous avian species being particularly effected.[22–26] Population declines, and more recently population stress, have been noted. Numerous studies have sacrificed individual birds to assess PCB burdens.[27–30] However, facile methods of low-cost analysis using samples that do not require the sacrifice of individual birds and animals remain important in the assessment of PCB distribution and transport. In a recent study, we reported the analysis of PCBs in avian blood using uniquely designed and engineered pressurized extraction cells.[31] The present work investigates a simplified, and low cost, modification to commercial extraction vessels for the analysis of small volumes of both whole blood and serum.

Experimental

Reagents and materials

Unless otherwise stated, consumables were obtained from ThermoFisher Scientific. Solvent and acid grades were as follows: acetone (pesticide grade), dichloromethane (Optima), absolute ethanol (certified A.C.S.), concentrated sulfuric acid (trace metal grade), and phosphoric acid (reagent grade). Double deionized water (17.8 MΩ) was prepared using an E-pure water purification system, Barnstead International. Teflon was obtained from Warehouse Plastics Inc. (Toronto, Ontario). Florisil was obtained from Diagnostix (Mississauga, Ontario). Whole blood and serum were obtained separately as pooled 500 cm^3 samples from Animal Technologies Inc. (Tyler, Texas). Protocols used to prevent clotting, temperatures and periods of storage, and protein denaturation methods are described elsewhere for whole blood.[31] Similar protocols were employed in the use and storage of serum. Heparin was added to the blood prior to shipping to prevent clotting.

PCB congener standards were obtained as five mixtures containing all 209 PCB congeners (M-1668A-0.01X) from Chromatographic Specialties Inc. (Brockville, Ontario). Elution order was confirmed for all congeners and the capacity to report the full congener series was retained. A three-point calibration in the range 0.1 to 10.0 ng cm^{-3} was employed with the requirement for the R^2 obtained by linear regression to exceed 0.99. Ten environmentally relevant congeners, including ortho-substituted congeners, were considered in the present study. Four $^{13}C_{12}$-labeled PCB congeners 32, 101, 153, and 194 (Cambridge Isotopes Laboratories Inc.) were used as surrogates. The congeners studied and surrogates for correction of extraction efficiency are shown in Table 1. The PAH internal standards (naphthalene-d_8, phenanthrene-d_{10}, anthracene-d_{10}, and benzo(*a*)anthracene-d_{12}) were prepared at a concentration of 20 ng cm^{-3} (Supelco). All standards were prepared in dichloromethane.

Pressurized solvent extraction (PSE)

An Applied Separations (Allentown, Pennsylvania) *fast* pressurized solvent extraction (PSE) unit, capable of six simultaneous extractions, was used. Cells were 33 cm^3 (internal volume) and constructed of stainless steel (Applied Separations). Teflon inserts (length: 3.0 cm, radius: 1.0 cm, centre bore hole: 0.10 cm) were designed and crafted by the Analytical Sciences Group for the extraction vessels (Fig. 1). Three inserts were placed in each extraction vessel to reduce the volume to approximately 5 cm^3 (Fig. 2). All extractions (whole blood or serum) were performed using the following procedure: Extraction vessels were loaded (Fig. 2) sequentially with Teflon inserts,[2] filter paper, florisil, sodium sulfate, sample (0.2 g whole blood or serum), glass wool, and Teflon insert. The PCB congener and internal standards were spiked directly onto the blood prior to being covered with glass wool. Extraction conditions were as follows: solvent (1:3, acetone–DCM), static cycles (3 static cycles of 5 min duration), flushing time (1 min), temperature (100 °C), and pressure (10 MPa). Sample extracts were evaporated at room temperature (25 °C) under a flow of nitrogen gas to a final volume of 2 cm^3. Deuterated PAH internal standards were added to the extracts prior to GC–MS analysis.

Lipid determination

Lipid determination was performed colorimetrically using a sulfo-phospho-vanillin reaction.[32] Extractions were performed using 0.8 g samples in the absence of florisil reagent and sodium sulfate. Five replicates of whole blood and serum extracts were evaluated. A detailed description of the methods used to assess lipid in blood and blood products has been described elsewhere.[31]

Gas chromatography – mass spectrometry (GC–MS)

GC–MS analysis was performed using a PolarisQ ion-trap mass spectrometer (ThermoFisher) fitted with a programmed temperature vaporizing injector (PTVI) capable of large-volume injection. An extract volume of 0.150 cm^3 was used

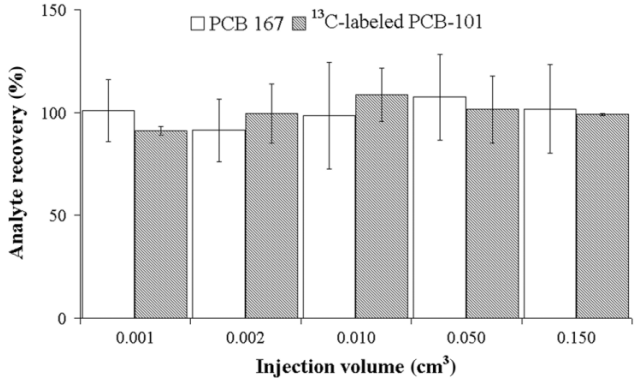
in split mode with an injection rate of 0.002 cm^3 s^{-1}. Separation was achieved in temperature-programmed mode using a Restek RTx-5MS fused-silica capillary column (60 m × 0.25 mm i.d., 0.25 μm phase thickness) and helium carrier gas. Full injection and separation parameters have been reported.[31] Mass spectral data were acquired in MS–MS mode using a damping/collision gas flow of 2.0 cm^3 min^{-1} and trap Q_v = 0.45. Mass ranges retained before and after collision, and well as collision voltages, are shown in Table 1. Data acquisition and analysis were performed using Xcaliber 1.4 software.

Fig. 3. Analyte percent recovery for 0.025 ng of PCB 167 and ^{13}C-labeled PCB 101 surrogate standard in 0.001, 0.002, 0.010, 0.050, and 0.150 cm^3 injection volumes. Recoveries are presented as the average of triplicate analysis; error bars denote the standard deviation of those triplicates.



Results and discussion

Lipid determination

As there is a tendency in the field to report PCBs as lipid-based concentrations, the lipid content of both the serum and whole blood used in this study was determined so that the data presented here may be easily compared against other studies. Using colorimetry, mean lipid content was measured in six replicates of each blood type (serum and whole blood) and one control sample (NIST 1589a). The control sample result was within 20% of the certified value (0.60%),[33] whilst the results for blood and serum were 0.66% ± 0.01% and 0.69% ± 0.04%, respectively. As expected, lipid results from whole blood and serum in the present study are statistically equivalent to those found in a different batch of chicken blood used in a previous study using novel PSE vessels.[31] Data are in good agreement with the findings of a recent study conducted using NIST 1589a.[34] Moreover, the

results compare well with other independent studies conducted using avian blood,[35,36] and the precision reported on the results is well within published values from more extensive studies.[37,38] However, from the literature, it is apparent that lipid determinations are highly dependent on the methodology used. Thus, the method used to determine lipid content of blood and serum in this study could be reliably compared against other internal studies of the same nature; however, given the variability in the results from lipid analyses as a function of the analytical procedure employed, it is likely more prudent to report PCB concentrations as whole blood or serum values, rather than lipid-based values, for interlaboratory comparisons.

Large-volume injection gas chromatography – ion-trap mass spectrometry (LVI-GC–ITMS)

Large-volume injection utilizes the separation of solvent and analyte at low temperatures using large split ratios. It is inevitable that a portion of the analyte will be lost during this process, and retention efficiencies will drop as analyte volatility approaches solvent volatility. Reproducible rather than complete transfer to the GC column is required. In the present work, equal analyte masses were injected using 0.001, 0.002, 0.010, 0.050, and 0.150 cm^3 injections. Mean injection efficiencies for PCB 167 and surrogate standard ^{13}C-labeled PCB 101, normalized to 0.001 cm^3, are presented in Fig. 3. It is evident that 0.150 cm^3 injections represent an efficient and precise method of sample introduction. Average injection efficiencies were >90% for all congeners studied, and relative standard deviation values ranged from 15% to 26%.

Blood and serum extraction

Extraction efficiency was determined by the analysis of control samples (m = 0.2 g; n = 5), which were prepared using chicken whole blood or serum. Samples were spiked directly with 10 PCB congeners in dichloromethane to afford a blood concentration of 10 or 1 ng g^{-1}, for whole blood and serum, respectively. Whole blood was spiked at a higher concentration, as elevated detection limits were expected due to the increased sophistication of the sample matrix. Extractions were performed using three static cycles, as other studies have demonstrated that PCB recovery is increased with additional extraction cycles.[34,39,40] Such work additionally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

demonstrates that little advantage accrues by the use of more than three cycles. Extracts were introduced directly to the GC–MS without additional clean up. The avoidance of post-extraction clean up increases throughput, reduces potential contamination and cross-contamination, and reduces analytical costs. However, the removal of sufficient matrix materials is also essential to facilitate large-volume injection, to avoid column and inlet contamination, and to prevent degradation of mass spectrometer performance. Tables 2 and 3 summarize relevant analyte data related to the proposed PCB extraction method for whole blood and serum samples, respectively. Recoveries were within 75% to 120% of expected values with corresponding RSD values of 15% or better. Surrogate and internal standard recoveries were all >90% when compared against calibration standard response. These data suggest that sufficient in-cell lipid removal has occurred to facilitate PCB analysis. The results conform well to those achieved using PSE to examine low-level PCBs in fatty foodstuffs[41] and to those reported from other solid phase extraction (SPE) studies as well as methods that use significantly greater sample volumes.[34,41–45] While SPE systems can detect PCBs in serum samples of comparable size, the method cannot be extended to whole blood; a challenge which does not extend to PSE systems.

Analytical performance is often assessed on the basis of a statistically based detection limit. Several methods may be employed to determine this limit.[46–49] As with our previous work,[31] the present study reports detection limits as both three times the signal-to-noise ratio of unspiked whole blood and serum samples and two times the standard deviation of replicate analyses multiplied by the Student's t value based on the appropriate number of samples used. The former calculation is used to place the data in the context of that reported by other workers.[41,43,44] The latter method was performed in accordance with ISO/IEC 17025, the standard that defines the competency of testing and calibration laboratories.[50] The increasing legal importance of environmental data in terms of legislation and litigation makes the use of the latter increasingly important. The detection limits based on a signal-to-noise ratio of 3:1 are between 0.01 and 0.22 ng cm^{-3} per congener for whole blood and between 0.03 and 0.45 ng cm^{-3} per congener for serum (see Tables 2 and 3). The detection limits based on replicate analysis, which are consistent with the ISO/IEC 17025 standard, are between 0.82 and 3.44 ng cm^{-3} per congener for whole blood and between 0.28 and 0.72 ng cm^{-3} per congener for serum (see Tables 2 and 3). Detection limits based on the signal-to-noise ratio, for both whole blood and serum, are in the same range as those reported for SPE serum extractions;[42,51] as SPE cannot be used for whole blood analysis, serum comparisons have been made. It is evident that replicate-based detection limits are generally higher for serum and whole blood than those obtained by signal-to-noise determinations. Inevitably, these detection limits will compare less favourably with those of other studies. Limits of detection calculated from replicate analyses in this study are at best comparable with some of the LODs reported elsewhere,[42,51] and in other instances, those limits are almost one order of magnitude higher. However, it must be noted that these differences represent a fundamentally different approach to the determination of detection limits, and that these less favourable data represent limits that could have a more widely accepted legal standing. In general, the proposed PSE method appears to produce broadly comparable results to more commonly used techniques. The replicate-based detection limits for whole blood were generally found to be higher in this study than in the study using novel pressurized solvent extraction vessels.[31] The detection limits for PCBs 77 and 126 were found to be approximately equivalent between studies; however, for the five other PCBs shared between studies, the detection limits in this study ranged from 4 (PCB 105) to 55 (PCB 194) times higher. However, the detection limits remain in the low part-per-billion range (10^{-9}) for 0.2 g samples. Similar detection limits using traditional methods often require sample masses 5 times greater than those used here to obtain comparable detection limits. Although the detection limits using the current system are somewhat higher than those using the more intricate extraction vessels, the limits obtained in the present work are consistent with the requirements of environmental analysis. Moreover, depending on the study and the level of sensitivity required, the use of Teflon inserts presents an attractive alternative as the cost associated with their fabrication is approximately 5% of the cost associated with manufacturing the more specialized extraction vessels; the approximate costs of coiled vessels and inserts being $500 and $25, respectively. Furthermore, coiled vessels require a level of engineering support that is not available to all laboratories.

Conclusions

The low blood volumes that can be taken from small avian species without sacrifice create specialized challenges for PCB extraction and quantification. A new extraction vessel was designed in 2010,[31] which offers detection limits at or under 1.5 ng g^{-1} per congener for the analysis of whole blood; however, the equipment is quite costly for the end-user. This study reports on the accuracy, precision, and detection limits for the extraction of 10 environmentally relevant PCB congeners from 0.2 g samples of avian whole blood and serum, using conventional PSE cells that have had their internal volume decreased by the use of Teflon inserts. These inserts can be fabricated for a mere fraction of the cost of the specialized vessels, yet they still allow the addition of lipid and moisture-removing packing materials in situ. Whilst the detection limits are somewhat higher in the present study, they still remain in the low ng g^{-1} range, making the technique competitive with more commonly used methods of PCB extraction. The detection limits for each of the congeners examined ranged from 0.01 to 0.22 ng g^{-1} in whole blood and from 0.03 to 0.45 ng g^{-1} in serum, with RSDs better than 15% in all instances. Given the findings of this study, the PSE method reported here should be considered suitable as a rapid and low-cost alternative for the analysis of environmentally relevant PCB congeners in both whole blood and serum samples.

Efficient process for the conversion of xylose to furfural with acidic ionic liquid

Furong Tao, Huanling Song, and Lingjun Chou

Abstract: An efficient and simple process for the dehydration of xylose into furfural was studied, which was catalyzed by 1-(4-sulfonic acid)butyl-3-methylimidazolium hydrogen sulfate (IL-1) under mild conditions. A xylose conversion of 95.3% with a furfural yield of 91.45% was achieved in a 25 min reaction time at 150 °C; the xylose conversion and furfural yield greatly depended on the operation conditions, such as reaction time and temperature. IL-1 could be recycled and exhibited constant activity for five successive trials. This system was an important improvement, relative to the reactions using mineral acids at high temperatures, for further development on a pilot scale.

Key words: xylose, dehydrate, furfural, ionic liquids.

Résumé : On a étudié une méthode simple et efficace de déshydratation du xylose en furfural qui est catalysée par le sulfate acide de l'acide 1-(4-sulfonique)butyl-3-méthylimidazolium (IL-1) dans des conditions douces. Avec un temps de réaction de 25 min à une température de 150 °C, on a obtenu un degré de conversion de 95,3 % du xylose en furfural et un rendement en furfural de 91,45 %; la conversion du xylose et le rendement en furfural dépendent fortement des conditions de la réaction, particulièrement du temps de réaction et de la température. Le IL-1 peut être recyclé et il présente encore une activité constante après cinq essais successifs. Dans l'optique d'un développement d'un système à l'échelle pilote, ce système correspond à une amélioration importante par rapport aux réactions faisant appel à des acides minéraux et à des températures plus élevées.

Mots-clés : xylose, déshydratation, furfural, liquides ioniques.

Introduction

Diminishing fossil fuel reserves and growing concerns about global warming indicate that sustainable sources of energy are needed in the near future.[1–5] The development of the chemistry of furanic compounds from carbohydrates for the preparation of nonpetroleum polymeric materials was recently updated.[6–13] Within this framework, furfural is one of the key compounds that is produced on an industrial scale, and improving the chemical technology for its production still remains of great interest.

At present, furfural is usually obtained through dehydration of pentoses, particularly xylose or hemicelluloses, at high temperature (200–250 °C) or in the presence of mineral acids as catalysts.[14] Under these conditions, the selectivity of furfural does not exceed 70%. Sako et al.[15] reported that in the case of continuous extraction with supercritical CO_2, the yield of furfural reached 80% in the hydrolysis of xylose. Moreau et al.[16] demonstrated that the selectivity of furfural was up to 90% over microporous solid acid catalysts at 170 °C from xylose. Recently, Zhang and Zhao[17] studied microwave-assisted conversion of lignocellulosic biomass into furans in ionic liquids; the yield of furfural was about 30%, and it was difficult to separate furfural from the reaction system.

In this work, we developed a simple and efficient catalytic process for the conversion of xylose into furfural, using water as a pertinent solvent, methylisobutylketone (MIBK) as a phase modifier,[18] and the acidic ionic liquid, 1-(4-sulfonic acid)butyl-3-methylimidazolium hydrogen sulfate (IL-1), was used as catalyst. With the given catalytic process and with xylose as the starting material, a furfural yield of 91.4% could be achieved at 150 °C for a reaction time of 25 min. The IL-1 could be recycled, and the catalyst exhibited constant activity over five cycles of evaluation.

Experimental

Materials

D-(+)-Xylose (98%), 1-methyl imidazole (CP, >99%), and 1,4-butanesultone (>99%) were purchased from Alfa Aesar and used without further purification. 4-Methyl-2-pentanone (AR, >90%), furfural (CP, >90%), and acetonitrile (HPLC) were purchased from Tianjin Chemical Reagent Company

(Tianjin, China). All other reagents and solvents were reagent grade and were used as received.

Preparation of IL-1

1-Methyl imidazole (16.4 g) and 1,4-butanesultone (27.28 g) were mixed in a flask (250 mL), stirred for 17 h at 42–45 °C, and a white solid was received. Then the white solid was ground, washed repeatedly with a small portion of ether, filtrated, and vacuumized for 4 h. Equimolar white solid was added to H_2SO_4 (98%), and the mixture was stirred at 80 °C for 6 h. The obtained viscous liquid was washed with ether three times and dried in vacuum to form the ionic liquid IL-1 (1-(4-sulfonic acid)butyl-3-methylimidazolium hydrogen sulfate). ^{1}H NMR (400 MHz, D_2O) δ: 1.53 (m, 2H), 1.80 (m, 2H), 2.72 (t, 2H), 3.67 (s, 3H), 4.02 (t, 2H), 7.24 (d, 2H), 8.47 (s, 1H). ESI-MS *m*/*z*: (+)218.6, (–)96.3.

General procedure for the conversion of xylose to furfural

Experiments were carried out in a stainless steel autoclave with a glass liner tube (100 mL); the reactor was loaded with 1.0 g of xylose, 0.5 g of catalyst, 1.5 mL of H_2O, and 8 mL of MIBK. The reaction mixture was heated by an electrical heating jacket to 150 °C for 25 min, and then the reactor was removed and quickly quenched in a cool water bath. After filtration, extraction, and separation, the organic and aqueous phases were collected to characterize the products. For the recycling of IL-1, furfural was extracted from the water phase five times with 8 mL of ethyl acetate. After extraction, the aqueous phase was heated at 60 °C for 24 h in a vacuum oven to remove water and residual ethyl acetate. The IL-1 was then used directly for the next run by adding xylose and solvents. All results were replicated at least three times.

Analyses

The xylose concentration in the products was analyzed by the dinitrosalicylic acid (DNS) method.[19] Analysis of furfural was performed by HPLC on an Waters Alliance 2695 series equipped with a Waters 2996 PDA detector and an intersil ODS-EP C18 reversed-phase column (250 mm × 4.6 mm, 5 μm). During this process, the column temperature remained constant at 30 °C, and the mobile phase applied was water–acetonitrile (15:85, *v*/*v*) at a flow rate of 0.5 mL/min with UV detection at 280 nm.

Results and discussion

Xylose conversion with various catalysts

To obtain efficient acidic catalysts for the hydrolysis of xylose, the catalytic activities of different catalysts were tested. As shown in Fig. 1, the present method was effective for various acidic catalysts, which included mineral acids (HCl, H_2SO_4), Lewis acids ($AlCl_3$, $SnCl_2$), heteropolyacid ($H_3PW_{12}O_{40}$), and acidic ionic liquids (IL-1, $C_4mimH_2PO_4$). It can be seen that $H_3PW_{12}O_{40}$ exhibited weaker catalytic activity than others under the same experimental conditions, whereas HCl and $C_4mimH_2PO_4$ had obvious activity. On the other hand, IL-1, $SnCl_2$, and H_2SO_4 showed very high catalytic activity for the conversion of xylose to furfural. Under the reaction conditions, IL-1 gave a 95.3% of xylose conversion and 91.4% of furfural yield at 150 °C for 25 min. Since the results were most favorable for IL-1, this catalyst was chosen to be studied in detail.

Also, compared with the results that other authors have achieved with ionic liquids for xylose conversion to furfural, our work showed that the efficiency and simplicity of xylose dehydration mainly depended on the reaction media and catalyst employed. It has been reported that there was an obvious relationship between activity and catalyst acidity in the reaction, and that high catalyst acidity leads to high reaction activity.[9] So we considered that the higher acidity of IL-1 over that of other catalysts, such as $AlCl_3$ and

	35	97.5	88.7	91.0

$H_3PW_{12}O_{40}$, should probably be responsible for its higher catalytic activity in this work.

Effect of catalyst dosage on xylose conversion and furfural yield

Figure 2 shows the effect of the catalyst dosage on xylose conversion and furfural yield. The amount of IL-1 used was 0.1, 0.3, 0.5, and 0.7 g. In the absence of catalyst, at a 150 °C reaction temperature, no xylose conversion was observed for a reaction time of 25 min (not shown in Fig. 2). In the presence of IL-1, the formation of furfural occurred. When the catalyst dosage increased from 0.3 to 0.5 g, the furfural yield increased from 88% to 92%. However, when the amount of IL-1 was increased from 0.5 to 0.7 g, there was little change in xylose conversion and furfural yield. As the xylose conversion and furfural yield had no further change with further IL-1 dosage over 0.5 g, this implied that there were sufficient catalytic sites available for the substrate xylose (1.0 g) in the system at this experimental condition.

Effect of reaction temperature and time

The effects of reaction temperature and time on xylose conversion are shown in Table 1. It can be seen that the reaction temperature and time had a large effect on both the xylose conversion and furfural yield. When the reaction temperature was 60 °C, with a 40 min reaction time, the xylose conversion was 45.5% and a furfural yield of 31% was obtained. The furfural yield increased from 31% to 83.5% when conditions changed from 60 to 120 °C in a 25 min reaction time. A furfural yield of 91.45% could be obtained for 25 min at a reaction temperature of 150 °C.

As listed in Table 1, by prolonging the reaction time, the reaction proceeded more thoroughly, and the color of the organic phase changed from almost colorless to a deep yellow. The selectivity of furfural was up to 96% when the reaction was performed at 150 °C for 25 min, which was a little higher than the results for 35 min at the same temperature. Indeed, it was reported that further degradation of furfural led to fragmentation reactions of furfural to compounds identified as pyruvaldehyde, formaldehyde, glyceraldehyde, or glycolaldehyde.[14] Other side reactions, such as condensation or resinification of furfural, were easier to perform than fragmentation reactions. We considered that maybe it was these side reactions that led to the decrease of furfural selectivity. Nevertheless, it should be mentioned in the case of xylose dehydration that the formation of heavy compounds is less probable compared with what occurs in fructose hydrolysis to 5-hydroxymethylfurfural (5-HMF), which can react through its hydroxymethyl function, thus yielding higher molecular weight compounds.

Effect of initial xylose concentration

From a practical point of view, if higher concentrations of xylose could be used as feedstock, the technique could be economical. In the acid catalytic dehydration of xylose, the initial xylose concentration has a large effect on furfural yield and selectivity. Different initial concentrations of xylose were studied, which were 0.3, 0.7, 1.0, 1.5, and 2.0 g. It can be seen from Fig. 3 that the rate of xylose conversion had little effect with different initial concentrations of xylose, but the furfural yield reduced gradually with increasing initial xylose concentration. As shown in Fig. 3, the highest furfural yield was 91.4% with 1.0 g of initial xylose loadings, but the yield was reduced to 78% when the amount of xylose was 2.0 g. The loss in furfural yield was thought to be due to the higher xylose concentration, which would increase the probability that reactive compounds such as xylose and furfural would collide with each other or cross polymerize.[20]

Influence of water content on the conversion of xylose

Since IL-1 is a hydrophilic ionic liquid, the influence of water content on xylose dehydration was studied, which is shown in Fig. 4. Previous works already indicated that water had a negative effect on the dehydration of fructose to 5-HMF;[8,21–22] this point was also suitable for the hydrolysis of xylose. As shown in Fig. 4, when the water content in the system was <1.5 g, it had little effect on the xylose conversion and furfural yield. However, as the amount of water increased from 1.5 to 3.5 g, the conversion of xylose and furfural yield decreased significantly, only 86% and 79%, respectively. Zhao et al.[23] also reported on adding water or organic solvents such as glycerol into ionic liquids and proposed that lowering the dielectric constant of the reaction media would result in the loss of catalytic activity.

Recycling of IL-1

In the principles of green engineering,[24] the recycling of a catalyst is essential, so this walso also examined in our work. Experiments were conducted at 150 °C for a reaction time of 25 min. As the catalyst IL-1 was only in an aqueous phase after the reaction, the product furfural was separated from the water phase after reaction by extracting five times with 8 mL ethyl acetate, which is similar to the procedure in the literature.[25] IL-1 and xylose were found to be insoluble in ethyl acetate and furfural was the sole product in the

For personal use only.

Fig. 3. Effect of xylose initial loading on the reaction (IL-1 = 0.5 g, H_2O = 1.5 mL, methylisobutylketone (MIBK) = 8 mL, T = 150 °C, t = 25 min, P = 1 atm; 1 atm = 101.325 kPa).

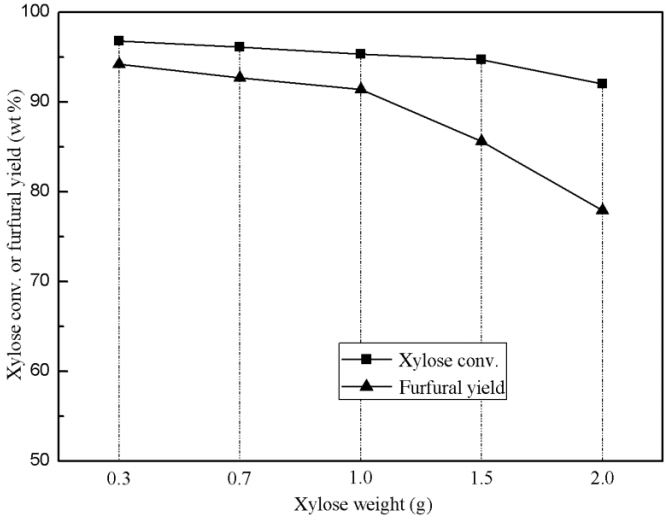

Fig. 4. Influence of water content on xylose conversion (xylose = 1.0 g, methylisobutylketone (MIBK) = 8 mL, T = 150 °C, t = 25 min, P = 1 atm; 1 atm = 101.325 kPa).

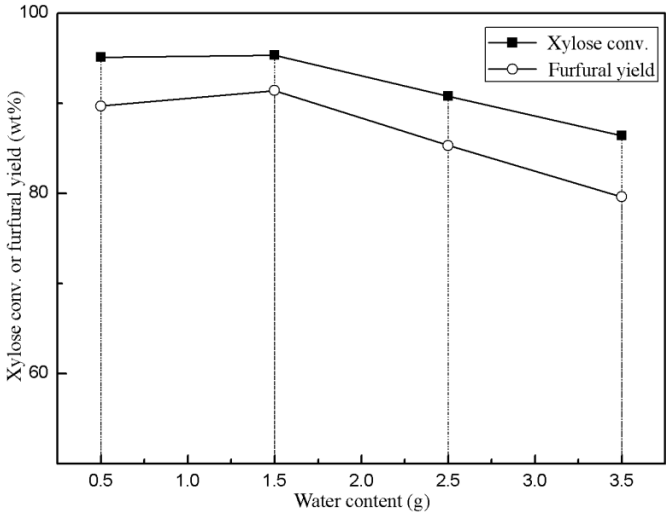
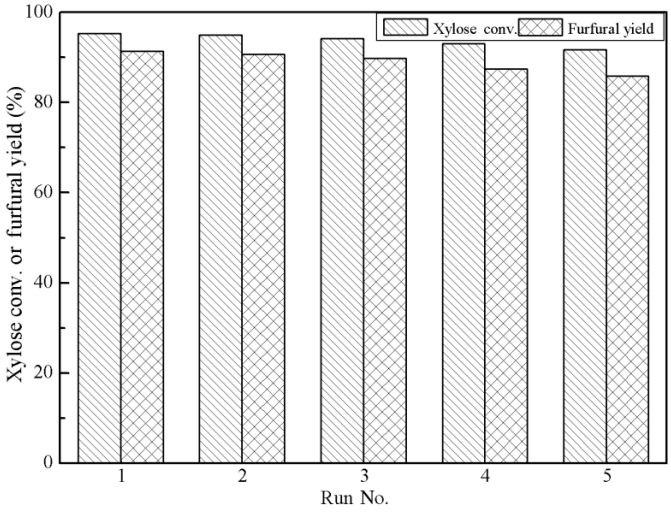


ethyl acetate phase, similar to that noted by Hu et al.[21] After extraction, the aqueous phase was heated at 60 °C for 24 h in a vacuum oven to remove the water and residual ethyl acetate. Such an operation is rather important as three water molecules are produced during the course of the reaction. It was then used directly for the next run by adding an equal amount of xylose and solvents. It can be seen in Fig. 5 that in the recycled reaction, IL-1 gave almost a comparable amount of furfural, which indicated that the catalyst IL-1 retained a very high activity for the conversion of xylose into furfural. The yield of furfural and xylose conversion were not obviously decreased over five runs with the recycled catalyst.

Conclusions

Preparation of furfural through the dehydration reaction of xylose is one of the most important approaches to utilize

Fig. 5. Recycling of IL-1 (xylose = 1.0 g, IL-1 = 0.5 g, H_2O = 1.5 g, methylisobutylketone (MIBK) = 8 mL, T = 150 °C, t = 25 min, P = 1 atm; 1 atm = 101.325 kPa).



biomass as a promising substitute for petroleum-based chemicals. It was demonstrated herein that this reaction could be smoothly carried out by using the acidic ionic liquid IL-1 as catalyst in a biphase separation system. The process we developed was shown to be efficient, and a xylose conversion of 95.3% with a 91.45% furfural yield was obtained when the reaction was carried out at 150 °C for a reaction time of 25 min. As the reaction time increased to 35 min at 150 °C, the selectivity of furfural decreased from 95.9% to 91%. Initial loadings of up to 2.0 g of xylose in the system led to an obvious decrease in furfural yield, which was about 14%, but the conversion of xylose seldom decreased (~2%). A water content <1.5 g had little effect on the xylose conversion and furfural yield, but a significant decrease was detected both in the xylose conversion and furfural yield when water content was >1.5 g. The catalyst IL-1 could be recycled almost without loss of activity for five times after the product furfural was separated with ethyl acetate. The results strongly suggested that the ionic liquid IL-1 could play an important role in exploring new, efficient, and easy-to-use processes for the preparation of furfural from xylose. Although the process developed efficiently for the conversion of xylose to furfural, further work is required to improve the furfural yield under milder conditions.

Synthesis of a new chiral auxiliary — Non-cross-linked polystyrene-supported oxazolidine-2-selone

Xiping He, Jia Li, Cuifen Lu, Zuxin Chen, and Guichun Yang

Abstract: A new chiral auxiliary, non-cross-linked polystyrene-supported oxazolidine-2-selone was synthesized using *N*-Boc-L-tyrosine ethyl ester as starting material. The structure of the target product was detected by IR, NMR, elemental analysis, and the spectrum result was consistent with the molecular structure.

Key words: non-cross-linked polystyrene, support, oxazoline-2-selone, chiral auxiliary.

Résumé : Faisant appel à l'ester éthylique de la *N*-Boc-L-tyrosine comme produit de départ, on a réalisé la synthèse d'un nouvel auxiliaire chiral, l'oxazolidine-2-sélone supportée par du polystyrène non réticulé. La structure du produit de synthèse a été confirmée par spectroscopies IR et RMN et par analyse élémentaire et les résultats spectraux sont en accord avec la structure moléculaire.

Mots-clés : polystyrène non réticulé, support, oxazoline-2-sélénone, auxiliaire chiral.

Introduction

Carbon–carbon bond-forming reactions involving asymmetric aldol reactions have emerged as powerful tools in organic synthesis. Chiral oxazolidine-2-selone was found to be an excellent auxiliary in asymmetric aldol reactions.[1–4] However, in most cases, the separation and purification of the chiral auxiliaries were troublesome. To recycle and reuse expensive chiral auxiliaries is a challenge in organic synthesis.

Insoluble polymer supports, such as Merrifield resin and Wang resin provided a simple procedure "filtration" for rapidly achieving the isolation of desired compounds or recovering expensive reagents or catalysts attached onto solid support for recycling.[5,6] But several shortcomings were shown because of nonlinear kinetic behavior, unequal distribution or access to the chemical reaction, and synthetic difficulties in transferring standard organic reactions to the solid phase. Soluble polymer supports have been studied as a way to overcome the problems of insoluble supports. Soluble polymer supports allow expeditious transfer of solution-based synthetic protocols, circumventing the extensive optimization process often required in heterogeneous reactions.[7,8] After the addition of an appropriate poor solvent, the polymer support can be precipitated and filtered, allowing its expeditious recovery.

Non-cross-linked polystyrene (NCPS) and functionalized NCPS show a more restrictive solubility profile because of their high stereoregular configuration of phenyl rings along the polymer main chain and the resulting tendency toward crystallization.[9,10] We theorized that this solubility versus recovery relationship of crystalline polymer — a well-known phenomenon in polymer chemistry — could lead to a better recovery yield of the polymer support when precipitated with a poor solvent.

Our group has undertaken a research program to develop novel chiral auxiliaries using NCPS as support.[11,12] In this article, we report the synthesis of a new NCPS-supported oxazolidine-2-selone chiral auxiliary from *N*-Boc-L-tyrosine ethyl ester (Scheme 1). Reagents and conditions: (a) K_2CO_3 (2.0 equiv), BnBr (1.2 equiv), DMF (dimethylformamide), 40 °C, 24 h; (b) $LiAlH_4$ (1.2 equiv), THF, 0 °C ~ RT (RT, room temperature), 18 h; (c) acetyl chloride (1.1 equiv), EtOAc–MeOH (1:2, *v*/*v*), 0 °C ~ RT, 24 h ; (d) DMF–DMA (dimethyl acetal) (1.1 equiv), TsOH (catalytic amount), N_2, toluene, reflux, 48 h; (e) 20% $Pd(OH)_2$ (catalytic amount), THF–MeOH (1:1, *v*/*v*), RT, 6 h; (f) K_2CO_3 (3.5 equiv), functionalized NCPS (**1**, 1.05 equiv), 40 °C, 24 h; and (g) Methyl lithium (1.2 equiv), hexamethyl disilylamine (1.15 equiv), Se (1.0 equiv), –78 °C ~ RT, 2 h.

Results and discussion

As shown in Scheme 1, NCPS-supported oxazolidine-2-selone was synthesized using *N*-Boc-L-tyrosine ethyl ester as the starting material. A benzylation reaction is used as the most common way to protect the hydroxy, therefore, *N*-Boc-L-tyrosine ethyl ester was first treated with BnBr to

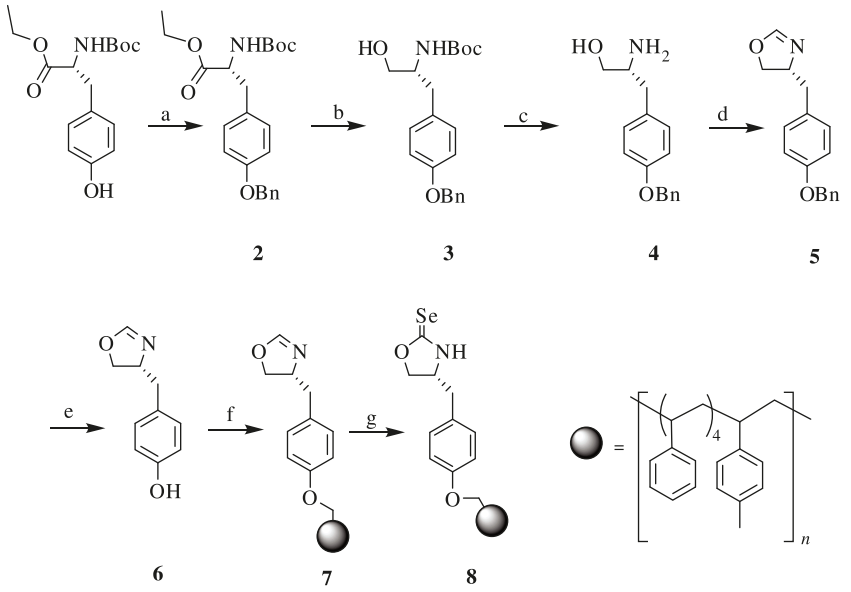
Scheme 1. Synthesis of non-cross-linked polystyrene (NCPS)-supported oxazolidine-2-selenone **8**.



afford the benzylated product **2** in 80% yield. Then compound **2** was reduced by $LiAlH_4$ to obtain the alcohol **3** in 84% yield. Removal of the Boc group from **3** using acetyl chloride under MeOH–EtOAc obtained the amino alcohol **4** in 87% yield. Treating **4** with DMF–DMA produced the oxazoline **5** through a ring-closing reaction.[7] Removal of the benzyl group of **5** was carried out by 20% $Pd(OH)_2$ under H_2 to provide the chiral oxazoline **6** in 84% yield. Then **6** was linked to **1** to afford NCPS-supported oxazoline **7**. Compound **1** (Fig. 1) was prepared according to ref. 9, by copolymerizing 4-vinylbenzyl chloride and styrene in a ratio of 1:4. Finally, **7** was treated with selenium in the presence of lithium amide to obtain NCPS-supported oxazolidine-2-selone **8** in 75% yield. The structure of the chiral auxiliary **8** was detected by IR, NMR, elemental analysis, and the spectrum result was consistent with the molecular structure. This chiral auxiliary is soluble in typical organic solvents, such as $CHCl_3$, CH_2Cl_2, EtOAc, THF, DMF, and benzene, and insoluble in MeOH, EtOH, and H_2O, and this solubility versus recovery relationship of the crystalline polymer could lead to better recovery yield of the chiral auxiliary.

Conclusions

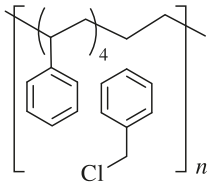
In conclusion, we have developed a new NCPS-supported oxazolidine-2-selone chiral auxiliary. This chiral auxiliary has potential value in asymmetric reactions such as high stereoselectivity and better recovery yield. Further application of this NCPS-supported oxazolidine-2-selone chiral auxiliary in aldol reactions is currently underway in our laboratory.

Experimental

General

All solvents were obtained from commercial sources and dried or purified by standard procedures before use. Melting points were measured on a WRS-1A digital melting point apparatus and uncorrected; optical rotations were measured

Fig. 1. Functionalized non-cross-linked polystyrene (NCPS).



using a sodium D line on a WZZ-2B automatic polarimeter; IR spectra were recorded on a IR-spectrum one (PerkinElmer) spectrometer. NMR spectra were recorded on a Varian Unity INOVA 600 spectrometer in $CDCl_3$ using TMS as the internal standard; elemental analyses were done on a VarioEL III (Elementar, Germany) analyzer.

Synthesis of *N*-Boc-*O*-benzyl-L-tyrosine ethyl ester (2)

To a solution of *N*-Boc-L-tyrosine ethyl ester (8.64 g, 27.95 mmol) in dry DMF (50 mL) were added benzyl bromide (3.98 mL, 33.54 mmol), anhyd K_2CO_3 (7.71 g, 55.90 mmol), and 18-crown-6 (catalytic amount). Then the resulting mixture was stirred at 40 °C for 24 h. After evaporation of the solvent, the residue was dissolved in ethyl acetate (100 mL) and washed with brine (3 × 10 mL). The organic phase was dried over $MgSO_4$, filtered, and concentrated to afford a pale yellow solid. Recrystallization from EtOAc and petroleum ether (PE; 1:5, *v*/*v*) gave **2** (8.9 g, 80%); mp 63.2–63.7 °C. $[\alpha_D^{25}]$ = +16.2 (*c* 0.05, THF). IR (NaCl, cm^{-1}): 3371, 1716, 1611, 1584, 1511. ^1H NMR ($CDCl_3$, 600 MHz) δ: 7.43–7.27 (m, 5H), 7.05 (d, J = 7.8 Hz, 2H), 6.90 (d, J = 8.4 Hz, 2H), 5.04 (s, 2H), 4.96 (t, J = 7.8 Hz, 1H), 4.51 (s, 1H), 4.15 (dd, J_1 = 7.2 Hz, J_2 = 13.8 Hz, 2H), 3.03 (dd, J_1 = 6.0 Hz, J_2 = 11.4 Hz, 2H), 1.43 (s, 9H), 1.23 (t, J = 6.9 Hz, 3H). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 172.1, 158.3, 155.6, 137.7, 131.0, 128.8, 128.6, 128.2, 127.7, 115.2, 80.5, 70.6, 61.3, 54.5, 37.4, 28.3, 14.3.

Synthesis of *N*-Boc-*O*-benzyl-L-tyrosinol (3)

To a solution of compound **2** (8.65 g, 21.65 mmol) in anhyd THF (50 mL), $LiAlH_4$ (0.96 g, 25.98 mmol) in THF (20 mL) was added dropwise at 0 °C. The mixture was allowed to stir at RT for 18 h before acidification to pH 6∼7 with 1 N HCl, and the insoluble solid was filtered. After evaporation of the solvent, the residue was dissolved in ethyl acetate (100 mL), washed with brine (3 × 10 mL). The organic phase was dried over $MgSO_4$, filtered, and concentrated to afford a white solid. Recrystallization from EtOAc and PE (1:3, *v*/*v*) gave **3** (6.2 g, 84%); mp 105.0–105.6 °C. $[\alpha_D^{25}]$ = –17.5 (*c* 0.02, THF). IR (NaCl, cm^{-1}): 3360, 2923, 1816, 1611, 1524, 694. ^1H NMR ($CDCl_3$, 600 MHz) δ: 7.43–7.26 (m, 5H), 7.12 (d, *J* = 8.4 Hz, 2H), 6.91 (d, *J* = 8.4 Hz, 2H), 6.05 (s, 2H), 5.03 (s, 2H), 3.81 (m, 1H), 3.63 (m, 1H), 3.58 (m, 1H), 2.77 (d, *J* = 7.2 Hz, 2H), 1.42 (s, 9H). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 158.6, 156.5, 137.3, 130.1, 129.4, 128.5, 127.8, 115.6, 80.3, 70.5, 64.7, 60.3, 54.1, 37.5, 29.3.

Synthesis of *O*-benzyl-L-tyrosinol (4)

To a solution of compound **3** (5.6 g, 15.68 mmol) in mixed solvents of EtOAc (30 mL) and MeOH (60 mL) was added acetyl chloride (3.91 mL, 31.36 mmol) at 0 °C. After 30 min, the reaction mixture was stirred at RT for 24 h. NaOH (1.5 N) was added to counteract produced acids, then most of the solvent was removed under reduced pressure. The residue was dissolved in CH_2Cl_2 (100 mL) and washed with brine (3 × 10 mL). The organic phase was dried over $MgSO_4$, filtered, and concentrated to afford a yellow solid. The crude product was further purified by column chromatography (MeOH–CH_2Cl_2, 1:20, *v*/*v*) to give **4** (3.5 g, 87%); mp 174.4–174.8 °C. $[\alpha_D^{25}]$ = –12.0 (*c* 0.04, CH_3OH). IR (NaCl, cm^{-1}): 3704, 3360, 3032, 1609, 1580, 748. ^1H NMR ($CDCl_3$, 600 MHz) δ: 7.45–7.35 (m, 5H), 7.19 (d, *J* = 8.4 Hz, 2H), 7.01 (d, *J* = 9.0 Hz, 2H), 5.13 (s, 2H), 3.74–3.55 (m, 2H), 3.47 (m, 1H), 2.89 (d, *J* = 6.6 Hz, 1H), 2.77 (t, *J* = 6.9 Hz, 1H), 1.85 (s, 3H). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 157.3, 137.5, 131.1, 130.6(2C), 129.7, 128.3, 127.8, 115.6, 70.1, 66.2, 54.7, 40.1.

Synthesis of (4*S*)-4-(4′-benzyloxy)benzyl-4,5-dihydrooxazoline (5)

DMF–DMA (1.16 mL, 8.79 mmol) and TsOH (0.06 g) under N_2 were added to a solution of **4** (2.06 g, 8.0 mmol) in toluene (85 mL). The solution was refluxed for 48 h in a flask equipped with a Soxhlet extraction device containing 20 g of 4 Å molecular sieves under N_2. The reaction mixture was washed with 10% $NaHCO_3$ (30 mL) and brine (30 mL) and dried over Na_2SO_4. The residue was purified by flash column chromatography (EtOAc–PE–Et_3N, 1:4:1, *v*/*v*) to give **5** (1.71 g, 80%) as a white solid; mp 117.9–118.3 °C. IR (NaCl, cm^{-1}): 3035, 1630, 1513, 1114. ^1H NMR ($CDCl_3$, 600 MHz) δ: 8.10 (s, 1H), 7.30–7.42 (5H, m), 7.09 (d, *J* = 9.0 Hz, 2H), 6.91 (d, *J* = 9.0 Hz, 2H), 5.01 (s, 2H), 4.18 (t, *J* = 3.0 Hz, 1H), 3.70 (d, *J* = 7.2 Hz, 1H), 3.58 (dd, J_1 = 3.6 Hz, J_2 = 10.2 Hz, 1H), 2.82 (m, 2H). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 161.8, 157.9, 137.2, 130.6, 130.4, 129.7, 128.8, 127.7, 115.3, 70.2, 63.8, 52.2, 36.2.

Synthesis of (4*S*)-4-(4′-*p*-hydroxy)benzyl-4,5-dihydrooxazoline (6)

Compound **5** (1.34 g, 5.0 mmol) was dissolved in THF (25 mL) and MeOH (25 mL), and 20% $Pd(OH)_2$ (0.27 g) was added, and the mixture was then stirred under H_2 at room temperature for 6 h. After filtration through Celite, washing with methanol and THF, and evaporation of the solvents, the residue was purified by flash column chromatography (EtOAc–PE–Et_3N, 1:2:1, *v*/*v*) to give **6** (0.74 g, 84%) as a white solid; mp 60.5–60.8 °C. $[\alpha_D^{20}]$ = –68.6 (*c* 0.04, MeOH). IR (NaCl, cm^{-1}): 3197, 1628, 1515, 1380, 1244. ^1H NMR ($CDCl_3$, 600 MHz) δ: 8.10 (s, 1H), 7.12 (d, *J* = 9.0 Hz, 2H), 6.89 (d, *J* = 9.0 Hz, 2H), 5.40 (s, 1H), 4.24 (t, *J* = 4.2 Hz, 1H), 3.84 (d, *J* = 8.4 Hz, 1H), 3.52 (dd, J_1 = 4.8 Hz, J_2 = 12.4 Hz, 1H), 2.64 (m, 2H). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 160.4, 157.9, 130.6, 130.4, 115.3, 76.2, 70.2, 39.8.

Synthesis of NCPS-supported (4*S*)-4-substituted 4,5-dihydrooxazoline (7)

To a solution of compound **6** (0.66 g, 3.71 mmol) in DMF (30 mL) were added the functionalized NCPS **1** (2.20 g), anhyd K_2CO_3 (1.80 g, 13.0 mmol), and 18-crown-6 (catalytic amount). The resulting mixture was stirred at 40 °C for 24 h. Then most of the solvent was removed under reduced pressure. The viscous solution was dropped into cold EtOH (100 mL), and the precipitated solid was filtered and dried to afford polymer **7** (2.43 g, 85%). IR (NaCl, cm^{-1}): 3302, 1629, 1237, 699. ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 158.0, 155.0, 145.5, 130.4, 130.1, 128.2, 127.8, 125.9, 115.1, 70.8, 70.2, 66.9, 52.0, 41.0, 40.5. Elementary analysis for polymer **7**: C, 86.31%; H, 7.21%; N, 1.89%.

Synthesis of NCPS-supported (4*S*)-4-benzyloxyl oxazolidine-2-selenone (8)

Methyllithium (2.26 mL, 3.17 mmol) and hexamethyl disilylamine (0.63 mL, 3.04 mmol) were added to dry THF (15 mL) under N_2 at 0 °C. The solution was stirred for 10 min and then cooled to –78 °C. Compound **7** (1.50 g, 2.64 mmol) in dry THF (30 mL) was added dropwise to the solution and the mixture was stirred for 30 min at –78 °C. Se (0.24 g, 2.68 mmol) was added in batches, stirred for an additional 2 h at RT, and then the pH was adjusted to 4–5 by aq saturated citric acid. After filtrating through Celite, the filtrate was concentrated under reduced pressure. The viscous solution was dropped into cold EtOH (50 mL), and the precipitated solid was filtered and dried to afford polymer **8** (1.30 g, 75%). IR (NaCl, cm^{-1}): 3340, 1510, 1261, 698. ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 188.2, 158.1, 137.6, 136.4, 136.3, 130.1, 127.7, 127.1, 126.5, 126.3, 115.7, 114.2, 75.5, 68.8, 56.9, 52.2, 39.2. ^{77}Se NMR ($CDCl_3$, 150 MHz) δ: –319.80 (relative to (*R*)-4-benzyloxazolidine-2-selenone at –328.70). Elementary analysis for polymer **8**: C, 77.71%; H, 6.58%; N, 1.69%.

Electronic structure of *S*-nitrosothiols from sulfur K-edge X-ray absorption spectroscopy

Vlad Martin-Diaconescu, Inna Perepichka, D. Scott Bohle, and Pierre Kennepohl

Abstract: Sulfur K-edge X-ray absorption spectroscopy (S K-edge XAS) was applied to investigate the electronic structure of primary and tertiary *S*-nitrosothiols. Our experimental data, supported by density functional calculations, indicate that changes at C_α affect the *S*-nitroso group through both inductive and direct orbital effects. Furthermore, our data are consistent with a weakening of the S–N bond in tertiary *S*-nitrosothiols as compared to their primary *S*-nitroso analogues. These results support existing computational models and suggest that the reactivity of *S*-nitrosothiols is not dominated by the electronics of the S–N bond.

Key words: *S*-nitrosothiols, X-ray absorption spectroscopy (XAS), *S*-nitroso-*N*-acetylpenicillamine (SNAP), nitrosoglutathione.

Résumé : On a fait appel à la spectroscopie d'absorption des rayons-X près du seuil K du soufre (SAX près du seuil K du soufre) pour étudier la structure électronique de *S*-nitrothiols primaires et tertiaires. Les données expérimentales et les calculs de la fonctionnelle de la densité indiquent que les changements au niveau du C_α affectent le groupe *S*-nitroso par des effets inductifs ainsi que par des effets directs d'orbitales. De plus, les données sont en accord avec un affaiblissement de la liaison S–N dans les *S*-nitrosothiols primaires par rapport à leurs analogues *S*-nitroso primaires. Ces résultats supportent les modèles existants dérivés de calculs théoriques et ils suggèrent que la réactivité des *S*-nitrosothiols n'est pas dominée par les effets électroniques de la liaison S–N.

Mots-clés : *S*-nitrosothiols, spectroscopie d'absorption des rayons X (SAX), *S*-nitroso-*N*-acétylpénicillamine (SNAP), nitrosoglutathion.

[Traduit par la Rédaction]

Introduction

S-Nitrosothiols are important nitric oxide (NO) derivatives with potential therapeutic applications.[1] Nitric oxide has been implicated in various physiological processes, including neurotransmission,[2] induction of smooth muscle relaxation,[3,4] inhibition of platelet aggregation,[5] and modulation of enzyme activity via S-nitrosation.[6] Nitric oxide release from *S*-nitrosothiols is facilitated by heat, light, and catalyzed by metal ions such as Cu^+.[7] However, the factors that control the reactivity of *S*-nitrosothiols have yet to be completely elucidated.

It is generally accepted that primary *S*-nitrosothiols are less stable than their tertiary counterparts. For example, the primary nitrosothiol *S*-nitroso-*N*-acetylcysteine (SNAC) has a very short lifetime,[8,9] whereas tertiary *S*-nitrosothiols such as *S*-nitroso-*N*-acetylpenicillamine (SNAP) and trityl thionitrite (Ph_3CSNO) are inert and isolable.[10] One exception is *S*-nitrosoglutathione (GSNO), which can be readily obtained even though it is a primary *S*-nitrosothiol.[11] The general stability of tertiary versus primary *S*-nitrosothiols has been attributed to steric constraints, which hinder the formation of disulfides, the primary product of *S*-nitrosothiol decomposition.[9] In the case of GSNO, its resistance to Cu^+-mediated decomposition has been attributed to chelation of the metal ions, which might explain the resistance of GSNO to Cu^+ decomposition as compared to SNAP.[12]

To address the reactivity of *S*-nitrosothiols, several theoretical models for S–NO bonding have been proposed. Density functional methods have been used to suggest that the S–N bond is most appropriately described as a single bond;[13] such single bond character seems to be supported by the long S–N bond observed in trityl thionitrite.[14] However, the identification of cis–trans isomers with a measurable rotational barrier about the S–N bond (by ^{15}N NMR) suggests the presence of significant S=N double bond character.[14,15] More recently, valence-bond calculations have supported this idea, implying that significant S=N character is required.[16]

We have used sulfur K-edge X-ray absorption spectroscopy[17,18] (XAS) as a means of probing details of the electronic structure of a series of *S*-nitrosothiols (see Fig. 1); an earlier study provided a preliminary assignment and analysis

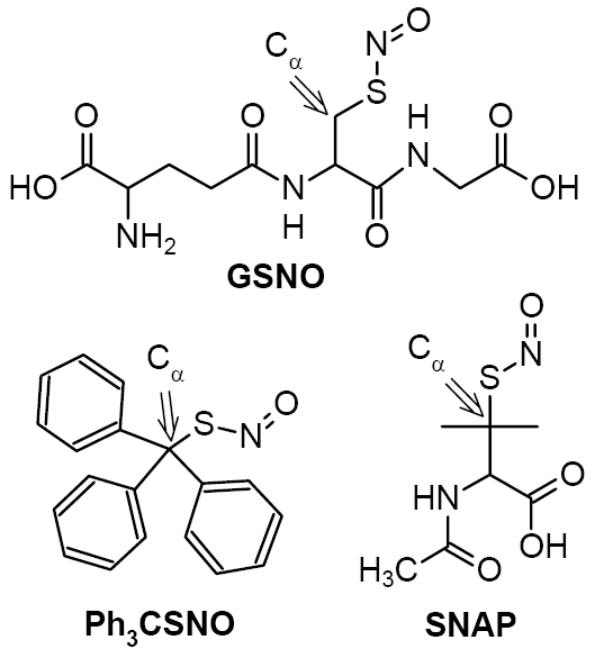
Fig. 1. *S*-Nitrosothiols model compounds investigated using sulfur K-edge XAS: *S*-nitrosoglutathione (GSNO), trityl thionitrite (Ph_3CSNO), and *S*-nitroso-*N*-acetylpenicillamine (SNAP).



of the electronic structure of GSNO and SNAP XAS.[19] However, we have undertaken a more detailed analysis to more directly evaluate the electronic effects of C_α substitution. We have therefore used a combination of S K-edge XAS and DFT methods to explore the bonding in GSNO, SNAP, and Ph_3CSNO and provide experimental insights into the nature of bonding in these nitrosylated thiols.

Results and discussion

Normalized and energy-calibrated sulfur K-edge XAS spectra of selected *S*-nitrosothiols are shown in Fig. 2. The spectrum of the primary *S*-nitrosothiol (GSNO, Fig. 2A) exhibits three intense low energy features at 2471.4 eV, 2473.4 eV, and 2475.0 eV; these have been previously attributed to the $SN_{\pi^*} \leftarrow S_{1s}$, $SN_{\sigma^*} \leftarrow S_{1s}$, and $SC_{\sigma^*} \leftarrow S_{1s}$, respectively.[19] SNAP, a tertiary alkyl *S*-nitrosothiol, exhibits a similar spectroscopic profile; however, the features are shifted to lower energy (see Fig. 2B): the $SN_{\pi^*} \leftarrow S_{1s}$ shifts only slightly to 2471.2 eV ($\Delta E \approx -0.2$ eV), but the $SN_{\sigma^*} \leftarrow S_{1s}$ (2472.8 eV) and $SC_{\sigma^*} \leftarrow S_{1s}$ (2474.5 eV) transitions are shifted by –0.6 eV and –0.5 eV, respectively. The overall shift to lower energy in tertiary alkyls has been previously attributed to increased electron donation from the alkyl substituents on the proximal carbon (C_α), which would decrease the effective nuclear charge (Z_{eff}) of the sulfur atom and thus increase the energy of the S_{1s} orbital.[19] However, the observed shift in the $SN_{\pi^*} \leftarrow S_{1s}$ transition is quite different from that observed for the $SN_{\sigma^*} \leftarrow S_{1s}$ and $SC_{\sigma^*} \leftarrow S_{1s}$ transitions, which suggests that other factors likely contribute.

The S K-edge XAS spectrum of Ph_3CSNO (Fig. 2C) exhibits even greater spectroscopic differences, with only two major features visible in the spectrum. The feature due to the $SN_{\pi^*} \leftarrow S_{1s}$ transition at 2471.1 eV is well-resolved

Fig. 2. Sulfur K-edge XAS spectra with features assigned according to acceptor orbitals of sulfur 1s bound transitions for (A) *S*-nitrosoglutathione (dashed), (B) *S*-nitroso-*N*-acetylpenicillamine (solid), (C) trityl thionitrite (dotted), and (D) second derivative of XAS spectra.

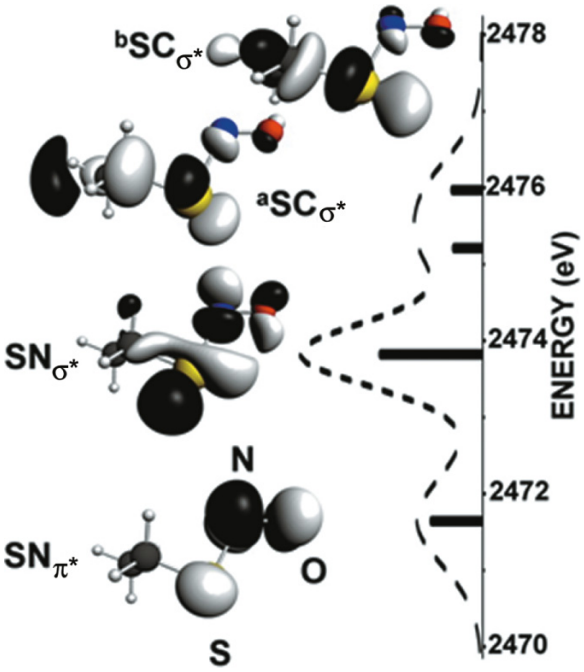
from a single broad feature at 2473.1 eV. The presence of this broad feature suggests strong overlap between the $SN_{\sigma^*} \leftarrow S_{1s}$ and $SC_{\sigma^*} \leftarrow S_{1s}$ transitions, yielding a single feature at 2473.1 eV. Given that the energy of this broad feature is in good agreement with the $SN_{\sigma^*} \leftarrow S_{1s}$ transition in GSNO and SNAP, it is most reasonable to anticipate that the $SC_{\sigma^*} \leftarrow S_{1s}$ transition has shifted to lower energy due to aryl substitution, with much smaller changes in the energetics of the $SN_{\sigma^*} \leftarrow S_{1s}$ transition. This interpretation is in good agreement with DFT calculations (vide infra). Unsurprisingly, changes in the substitution at C_α produces large energy shifts in the $SC_{\sigma^*} \leftarrow S_{1s}$, with more subtle effects occurring in the S–NO bonding manifold (as represented by the $SN_{\pi^*} \leftarrow S_{1s}$ and $SN_{\sigma^*} \leftarrow S_{1s}$ transitions).

To further explore possible contributions to the observed effect, time-dependent density functional theory (TD-DFT) calculations were carried out on a series of primary, secondary, and tertiary model systems. Qualitatively, our TD-DFT results match the spectroscopic assignments (see Fig. 3); our results are also consistent with previous calculations on these and related systems.[15,16,19] As observed experimentally, primary *S*-nitrosothiols exhibit three major features in their simulated S K-edge XAS spectra in the following energy order: $SN_{\pi^*} \leftarrow S_{1s} < SN_{\sigma^*} \leftarrow S_{1s} < SC_{\sigma^*} \leftarrow S_{1s}$. The observed splittings between the different features corresponds quite well with experiment (see Supplementary data S1 for details). The intensity of the lowest lying SN_{π^*} feature directly reflects the degree of π character in the S–N bond. The strong intensity of the SN_{π^*} feature clearly indicates the importance of π contributions, in agreement with recent theoretical work.[16] A more quantitative determination of π-contributions and its modulation with solvation and other effects is currently ongoing.

Our computational results also indicate a splitting of the $SC_{\sigma^*} \leftarrow S_{1s}$ contributions into two transitions, due to mixing with CH_{σ^*} at C_α (e.g., see Fig. 3). Not surprisingly, this mixing decreases as a function of substitution, with tertiary systems exhibiting only a single feature in this energy range (vide infra, see Fig. 4). In addition to this loss of mixing, the energy of $SC_{\sigma^*} \leftarrow S_{1s}$ decreases markedly with substitution, in agreement with our S K-edge XAS data. The shift in $SC_{\sigma^*} \leftarrow S_{1s}$ transition energy brings this feature closer to the $SN_{\sigma^*} \leftarrow S_{1s}$ peak, consistent with the behavior seen in Ph_3CSNO.

Calculated $SN_{\pi^*} \leftarrow S_{1s}$ and $SN_{\sigma^*} \leftarrow S_{1s}$ excitation energies also decrease with increasing substitution but the changes are more subtle. In each of these transitions, the largest effect occurs between the methyl and ethyl nitrosothiols (–0.3 eV and –0.4 eV), with only small changes occurring upon further substitution (–0.03 eV and –0.1 eV). As has been noted previously,[19] the $SN_{\pi^*} \leftarrow S_{1s}$ transition should not be directly affected by changes in SC bonding, since its π interaction is perpendicular to the σ framework. We further note that our DFT results also indicate that the SN_{π^*} orbital is not significantly affected by changes at C_α. Therefore, shifts in the energy of the $SN_{\pi^*} \leftarrow S_{1s}$ can be used as an indicator of the Z_{eff} of the sulfur atom. From this, we find that $Z_{eff}^{S(GSNO)} > Z_{eff}^{S(SNAP)} > Z_{eff}^{S(Ph_3CSNO)}$. However, this effect does not account for the larger shifts observed in the energies of the $SN_{\sigma^*} \leftarrow S_{1s}$ and $SC_{\sigma^*} \leftarrow S_{1s}$ transitions. These additional shifts to lower energy are observed both experimentally and computationally and appear as the result of a lowering of the energy of the SN_{σ^*} and SC_{σ^*} acceptor orbitals, respectively. This implies that changes at C_α decrease the magnitude of the σ interactions and result in weakening both the SC and SN σ bonds. This is in agreement with previously reported SC bond dissociation energies for alkylthiols, which decrease in energy with increased alkyl substitution at the C_α,[20] as well as calculated bond dissociation energies, which predict that S–N bonds in tertiary *S*-nitrosothiols should be slightly weaker than S–N bonds in the primary ones.[21]

Fig. 3. TD-DFT generated electron density contour plots (isovalue = 0.05 e Å^{-3}) of acceptor orbitals corresponding to the lowest empty valence molecular orbital of the primary *S*-nitrosothiol, ethyl-*S*-nitrosothiol.



As previously noted, primary *S*-nitrosothiols are generally less stable than tertiary *S*-nitrosothiols, with GSNO being a notable exception.[8–11] Such behavior has been attributed to steric effects,[9] given that electronic differences have generally been assumed to be relatively small. This assumption has previously been explored theoretically, but direct experimental validation was lacking until now. Our current work demonstrates that electronic differences do exist between primary and tertiary *S*-nitrosothiols, indicating relatively large differences in the S–C bond and somewhat more modest differences in the S–N bond. Our data strongly suggest that the S–N bond in tertiary nitrosothiols is weaker than S–N bond in primary nitrosothiols, as indicated by a decrease in the energy of the $SN_{\pi^*}/SN_{\sigma^*} \leftarrow S_{1s}$ transitions in Ph_3CSNO and SNAP vs. GSNO. This would imply that the reactivity of *S*-nitrosothiols should be greater in the tertiary cases, in apparent contradiction with observed thermal and Cu^+-catalyzed disulfide bond formation as a function of C_α substitution (see Fig. 4).

The relative differences in S–N bonding between these species are inconsistent with direct electronic control of either the thermal or Cu^+-catalyzed reactivity of *S*-nitroso-

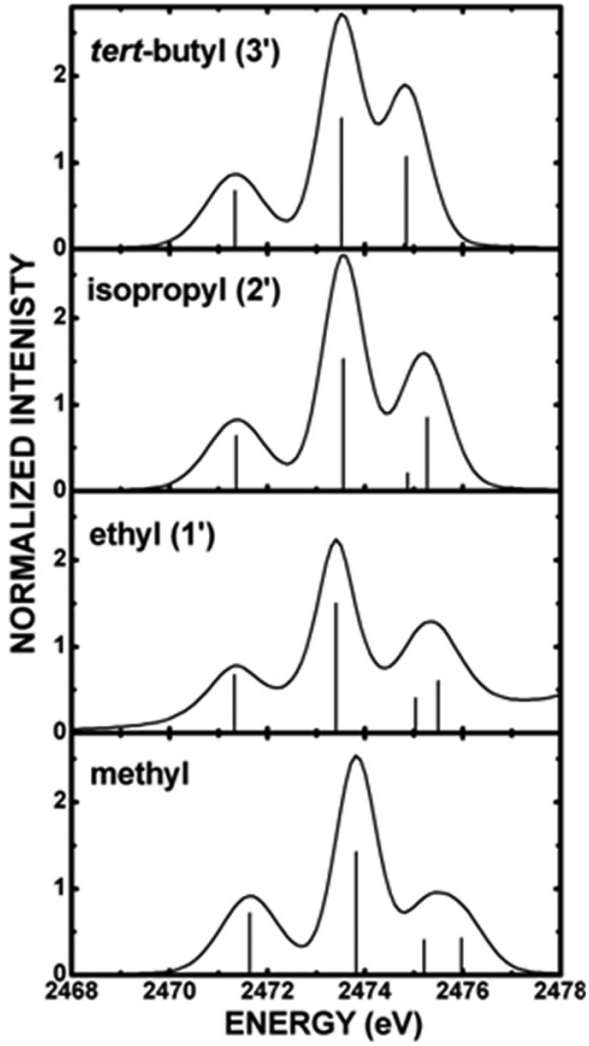
Fig. 4. TD-DFT simulated sulfur K-edge XAS spectra for the primary (1′) *S*-nitrosothiols with a methyl and ethyl molecular backbone; the secondary (2′) *S*-nitrosothiol with an isopropyl molecular backbone; and the tertiary (3′) *S*-nitrosothiol with a *tert*-butyl molecular backbone. Excitation energies were shifted by +77.3 eV from calculated values.



thiols, leaving either indirect (e.g., solvation) and (or) steric factors as primary considerations. We have begun to explore these alternative factors to provide an effective predictive model for the reactivity of *S*-nitrosothiols.

Experimental

Materials

The RSNO compounds used in this study, *S*-nitrosoglutathione,[11] *S*-nitroso-*N*-acetylpenicillamine,[10,14] and tritylthionitrite were prepared and purified by literature methods.[14]

XAS data collection

Sulfur K-edge XAS data were acquired at the new beamline 4–3 of the Stanford Synchrotron Radiation Lightsource (SSRL), using a low *Z* setup allowing low-temperature data acquistions.[22] Samples were mixed with 50% (*v*/*v*) boron nitride to minimize self-absorption, and mounted as a thin layer of finely ground powder on sulfur-free Kapton tape. Data were acquired using a Lytle detector at ambient temperature and pressure (~1 atm, 298 K) (1 atm = 101.325 kPa). Spectral energy calibration was carried out using hydrated sodium thiosulfate with the first pre-edge feature being calibrated at 2472.02 eV.[23] Spectra were normalized according to previously published procedures using BlueprintXAS.[24]

DFT calculations

DFT calculations were carried out using the Amsterdam Density Functional Package Software 2007.01.[25–27] Full geometry optimizations were carried out for the model compounds: methyl-*S*-nitrosothiol (CH_3SNO), ethyl-*S*-nitrosothiol (CH_3CH_2SNO), isopropyl-*S*-nitrosothiol ($(CH_3)_2CHSNO$), and *tert*-butyl-*S*-nitrosothiol ($(CH_3)_3CSNO$); followed by single-point calculations and TD-DFT using a TZ2P basis set, BP86 (Becke-Perdew 86) functional, and no molecular symmetry. XAS spectra for sulfur 1s excitations were calculated using no core for any of the atoms and the ModifyExcitation key (see Supplementary data, S2–S5). The resulting excitations were shifted by +77.3 eV to account for computational discrepancies in the calculated core excited-state energies.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

Luminescence studies of copper(I)-containing [2]pseudorotaxanes

Breeze N. Briggs, Fabien Durola, David R. McMillin, and Jean-Pierre Sauvage

Abstract: This report describes photoluminescence studies of copper-containing [2]pseudorotaxanes that mimic elements of functioning molecular machines. Excitation with visible light induces a formal oxidation of the metal center and simulates an actuation process. In all four [2]pseudorotaxanes studied, the ring ligand is the same, but the thread ligand is variable, namely 2,9-di(anisol-4-yl)-1,10-phenanthroline (dap), 6,6′-di(anisol-4-yl)-2,2′-bipyridine (o-dabipy), 5,5′-di(anisol-4-yl)-2,2′-bipyridine (m-dabipy), or 8,8′-di(anisol-4-yl)-3,3′-bi-isoquinoline (dabiiq). The absorbance bandshapes suggest that aryl substituents extending from the core ligands engage in stacking interactions and induce a partially flattened structure in the ground state. More severe flattening occurs in the excited state and precludes the observation of emission if inter-ligand steric forces do not limit the distortion. Thus, the [2]pseudorotaxanes containing dap or o-dabipy as the thread ligand exhibit uncorrected emission maxima at around 720 nm in room-temperature dichloromethane, while the less constrained analogues, containing dabiiq or m-dabipy, are not emissive in fluid solution and barely exhibit a signal in rigid media. In dichloromethane, the luminescence quantum yields of the dap- and o-dabipy-containing systems are 6×10^{-4} and 4×10^{-4}, and the excited-state lifetimes are 98 ns and 90 ns, respectively.

Key words: copper(I), luminescence, rotaxane, charge transfer.

Résumé : On a effectué des études de photoluminescence de [2]pseudorotaxanes contenant d cuivre et qui imitent les éléments de machines moléculaires opérationnelles. L'excitation à l'aide de lumière visible induit une oxydation formelle du centre métallique et simule un processus d'activation. Dans les quatre [2]pseudorotaxanes étudiés, le noyau du ligand est le même, mais le ligand commun est variable, soit la 2,9-di(anisol-4-yl)-1,10-phénanthroline (dap), la 6,6′-di(anisol-4-yl)-2,2′-bipyridine (o-dabipy), la 5,5′-di(anisol-4-yl)-2,2′-bipyridine (m-dabipy) et la 8,8′-di(anisol-4-yl)-3,3′-biisoquinoléine (dabiiq). Les formes des bandes d'absorption suggèrent que les substituants aryles qui s'orientent vers l'extérieur des ligands de coeur donnent lieu à des interactions d'empilement et qu'ils induisent une structure partiellement aplatie dans l'état fondamental. Un aplatissement plus important se produit dans l'état excité et il empêche l'observation de l'émission si les forces stériques inter-ligand ne limitent pas la distorsion. Ainsi, les [2]pseudorotaxanes qui contiennent du « dap » ou du « o-dibipy » comme ligand commun donnent lieu à des maxima d'émission non corrigée autour de 720 nm, à la température ambiante, dans le dichlorométhane, alors que les analogues avec moins de contraintes, contenant du « dabiiq » ou du « m-dapiry » ne donnent pas lieu à de l'émission en solution fluide et ils présentent à peine un signal en milieu solide. Dans la dichlorométhane, les rendements quantiques de luminescence des systèmes contenant du « dab » ou du « o-dabipy » sont de 6×10^{-4} et 4×10^{-4} et les temps de vie des états excités sont respectivement de 98 et 90 ns.

Mots-clés : cuivre(I), luminescence, rotaxane, transfert de charge.

[Traduit par la Rédaction]

Introduction

Copper(I) is a useful templating agent for the synthesis of molecules exhibiting interesting topologies.[1] An example is a two-component molecular assembly known as a [2]rotaxane, which threads together like an axle through a wheel. Elaborate versions can function as molecular machines, i.e., molecular device prototypes that execute mechanical motion in response to an external input.[2–4] For example, a copper-containing [2]rotaxane with 1,10-phenanthroline and 2,2′:6′,6″-terpyridine stations in the ring ligand is capable of displaying rotary motion, as recently demonstrated by Raehm et al.[5] Electrochemical actuation is possible because the copper(I) and copper(II) oxidation states characteristically prefer different coordination numbers. Thus, the thermodynamically favored copper(I) form is four-coordinate and

entails complexation to the phenanthroline embedded in the ring component. Upon oxidation of the copper center, the metal prefers to be five-coordinate, hence the ring ligand pirouettes about the thread and coordinates to the metal via the terpyridine moiety.[5] Regeneration of the phenanthroline-bound form occurs with reduction back to copper(I).

Photoluminescence studies are potentially relevant to the dynamics of the system because population of the emitting metal-to-ligand charge-transfer (MLCT) excited state entails formal oxidation of the metal center.[6–9] In general, two important structural changes occur in a $Cu(NN)_2^+$ system after absorption to the Franck–Condon state. (Herein, NN designates a diimine ligand such as 1,10-phenanthroline or 2,2′-bipyridine). First, the excited state undergoes a flattening distortion,[7–11] which is complete in less than a picosecond.[12,13] Subsequently, at least in donor media, expansion of the coordination number and solvent-induced exciplex quenching occurs on a nanosecond time scale.[12,13] There are, however, few reports about luminescence studies involving copper(I)-containing [2]rotaxanes and related systems.[14] Most of the work focuses on systems designed to produce charge separation. Armaroli et al.[15] have, for example, studied a copper(I)-containing [2]rotaxane that incorporated a bis(1,10-phenanthroline) ligand environment for the metal center as well as bulky C_{60} groups as termini at both ends of the thread ligand. They find that photoexcitation induces net electron transfer from the copper center to a C_{60} and virtually complete quenching of the CT emission from the copper center as well as the fluorescence from the C_{60} unit.[15] Using a related structure, which included a zinc porphyrin as well, Li et al. have detected MLCT luminescence from the bis(1,10-phenanthroline)copper center, but the lifetime is very short due to oxidative quenching by C_{60} acceptors.[16]

For convenience, the emission studies described below utilize [2]pseudorotaxanes, which lack the bulky "stopper" groups that prevent unthreading in a true [2]rotaxane. Figure 1 shows the structure of the m-30 ring ligand, which all systems have in common. The thread component is any one of four different ligands also depicted in Fig. 1, namely 2,9-di(anisol-4-yl)-1,10-phenanthroline (dap), 6,6′-di(anisol-4-yl)-2,2′-bipyridine (o-dabipy), 5,5′-di(anisol-4-yl)-2,2′-bipyridine (m-dabipy), or 8,8′-di(anisol-4-yl)-3,3′-bi-isoquinoline (dabiiq).

Experimental

Synthesis

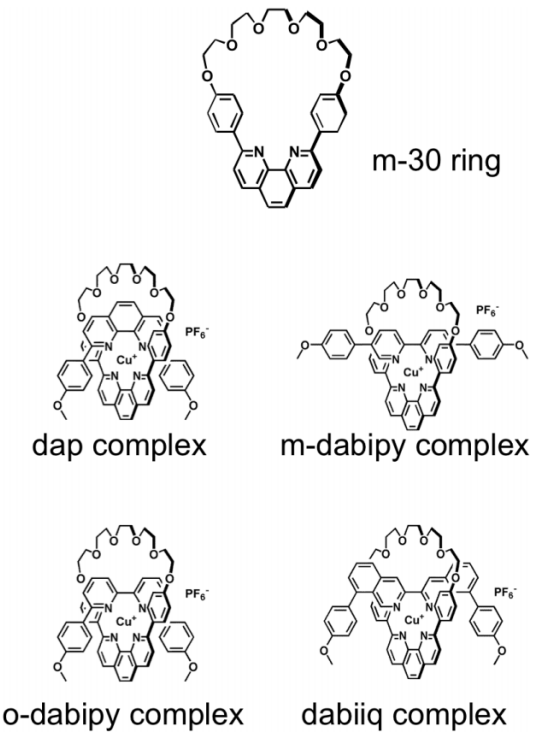
Previously published procedures yielded the coordinating macrocycle m-30[17] and the ligands dap,[18] o-dabipy,[19] and dabiiq.[20]

5,5′-Dianisyl-2,2′-bipyridine (m-dabipy)

The 5,5′-dibromo-2,2′-bipyridine precursor[21] (150 mg, 0.32 mmol), 4-methoxyphenyl boronic acid (106 mg, 0.704 mmol), and Na_2CO_3 (675 mg, 6.4 mmol) were placed in a two-necked round-bottom flask under argon. Then, toluene (30 mL), deionized water (10 mL), and ethanol (5 mL) were added. The solution was degassed and stirred under argon, then $Pd(PPh_3)_4$ (37 mg, 0.032 mmol) was added. The mixture was then degassed again and stirred at 90 °C for 16 h. Solvents were evaporated and a poorly soluble product was obtained. The crude product was thoroughly washed with water to remove sodium carbonate. The product was then washed five times with CH_2Cl_2 to remove starting material and soluble byproducts. The title product was thus obtained pure as a white solid (54 mg, 46% yield).

^{1}H NMR (DMSO-d_6, 300 MHz): δ (ppm) = 9.00 (d, 2H, J = 2.3 Hz), 8.45 (d, 2H, J = 8.3 Hz), 7.93 (dd, 2H, J = 8.3, 2.3 Hz), 7.79 (d, 4H, J = 8.8 Hz), 7.10 (d, 4H, J = 8.8 Hz), 3.84 (s, 6H).

Fig. 1. Copper-containing [2]pseudorotaxanes studied along with m-30 the ring ligand for each.



Threaded complexes: Cu(m-30)(NN)$^+$ PF_6^-

In a typical procedure, $Cu(CH_3CN)_4PF_6$ (1 equiv.) in degassed CH_3CN (0.5 mL per mg of complex) was added to a stirred degassed solution of macrocycle m-30 (1 equiv.) in CH_2Cl_2 (0.3 mL per mg of m-30). A deep orange color appeared instantly. A short while later, a solution in CH_2Cl_2 (0.3 mL per mg ligand) of 1 equiv. of the diimine ligand (NN, respectively, dap, o-dabipy, m-dabipy, or dabiiq) was added at room temperature, and the solution immediately turned dark red. After the solution was stirred for 2 h under argon at room temperature, the solvents were removed under vacuum. The dark red solid thus obtained was dissolved again in a minimum of degassed CH_3CN. As a precaution, the solution was filtered, after which evaporation of the filtrate yielded the copper complex quasi-quantitatively.

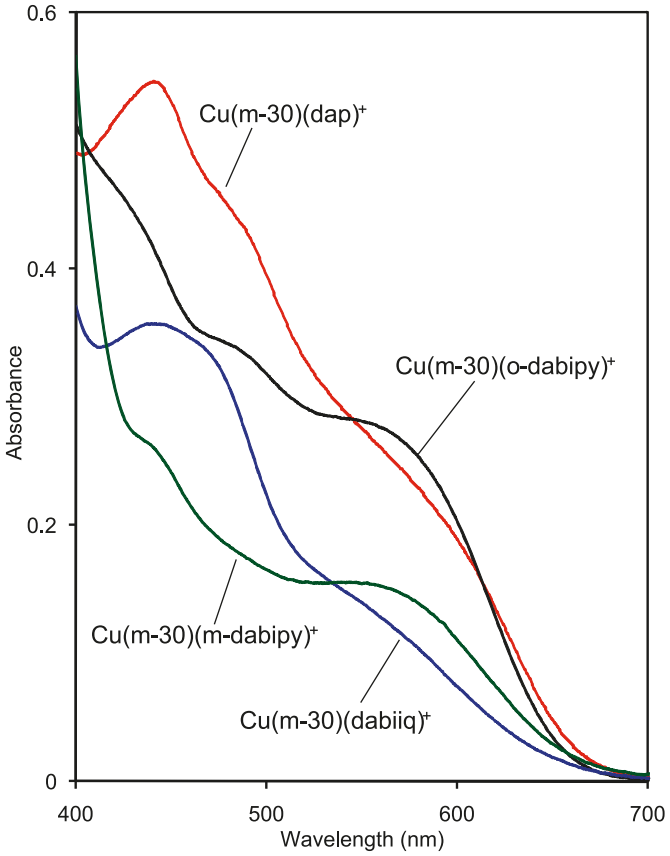
Methods

In the emission studies involving solid-state or frozen-glass samples, a 620 nm long-pass filter was in place to reject scattered light. The excitation beam also passed through a notch filter centered at 450 nm. For excitation and emission, the slit settings were 10 nm and 20 nm, respectively. The glassing solvent was a 4:1 mixture of ethanol:methanol, and the sample holder was a 3 mm i.d. quartz tube immersed in a finger dewar filled with liquid nitrogen. The same assembly without cryogen also allowed for measurements from solid-state samples. For frozen glass and solid-state emission measurements, the blank was either an empty capillary tube or one loaded with a non-emissive, solid-state copper(I) compound. The procedure for deoxygenation of dichloromethane entailed a sequence of freeze–pump–thaw cycles. For lifetime measurements, a combination of 620 and 700 nm long pass filters prevented scattered light from impinging on the detector. The setup also included a 450 nm notch filter in the laser beam. The laser dye was Coumarin 440 in ethanol at a concentration of 6.1×10^{-3} mol/L. The method of Parker and Rees yielded estimates of emission quantum yields.[22] Residual solvent protons (^{1}H NMR: CD_3CN: 1.96 ppm, DMSO-d_6: 2.50 ppm) served for referencing NMR signals.

Instrumentation

The spectrophotometer for the absorbance measurements was a Varian Cary 300 Bio unit. A Varian Cary Eclipse unit yielded photoluminescence data. A description of the apparatus used for the lifetime measurements is in the literature.[23] The NMR spectrometer was a Bruker AVANCE 300 (300 MHz). The mass spectrometer was a Bruker MicroTOF (ES-MS).

Fig. 2. Absorbance spectra of dap, o-dabipy, dabiiq, and m-dabipy complexes in dichloromethane at room temperature.



Results

The solvent employed for most of the solution work was dichloromethane (DCM) wherein the four copper complexes exhibit the visible absorption spectra depicted in Fig. 2. In each case, a strong, variably structured absorption occurs in the vicinity of 450 nm along side a broad shoulder that appears at ~580 nm. The shoulder is especially prominent in the spectra of the o-dabipy and m-dabipy complexes. Despite similar absorption throughout the series, only the dap and o-dabipy complexes exhibit a detectable emission signal in room-temperature solution. The emission is broadband in both cases and maximizes between 710 nm and 720 nm (Table 1); see Fig. 3 for data pertaining to the o-dabipy complex. In deoxygenated DCM at room temperature, the luminescence quantum yields are 6×10^{-4} and 4×10^{-4} for the dap and o-dabipy complexes, respectively. The corresponding emission lifetimes are 98 ns and 90 ns. In an alcohol glass at 77 K, the same two complexes exhibit an emission maximum at about 740 nm, and the lifetime of the emission signal extends considerably to 990 ns for the dap complex and 870 ns for the o-dabipy analogue. In the frozen glass, the dabiiq and m-dabipy complexes also emit, though very weakly, and exhibit lifetimes of 185 ns and 155 ns, re-

Fig. 3. Uncorrected emission spectra of the hexafluorophosphate salt of Cu(m-30)(o-dabipy)$^+$ measured in room-temperature dichloromethane (thin), the solid state (thick × 1/2), as well as a 77 K alcohol glass (-Δ- × 1/6), and from the corresponding salt of Cu(m-30)(m-dabipy)$^+$ in an alcohol glass at 77 K (-□-). Emission intensities are arbitrary.

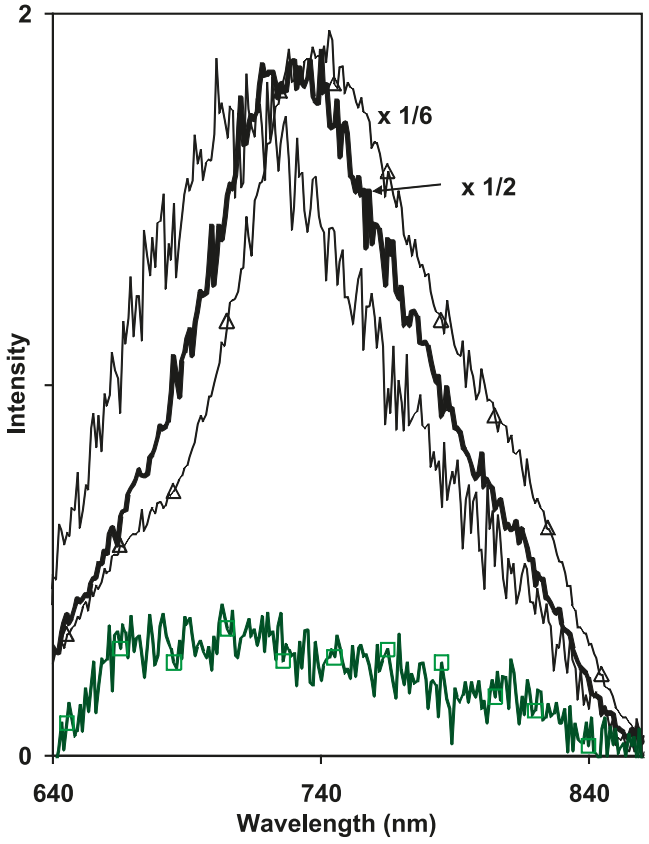

Fig. 4. Uncorrected emission spectra measured from solid samples of [Cu(m-30)(dap)]PF_6, [Cu(m-30)(o-dabipy)]PF_6, [Cu(m-30)(m-dabipy)]PF_6, and [Cu(m-30)(dabiiq)]PF_6 at room temperature.

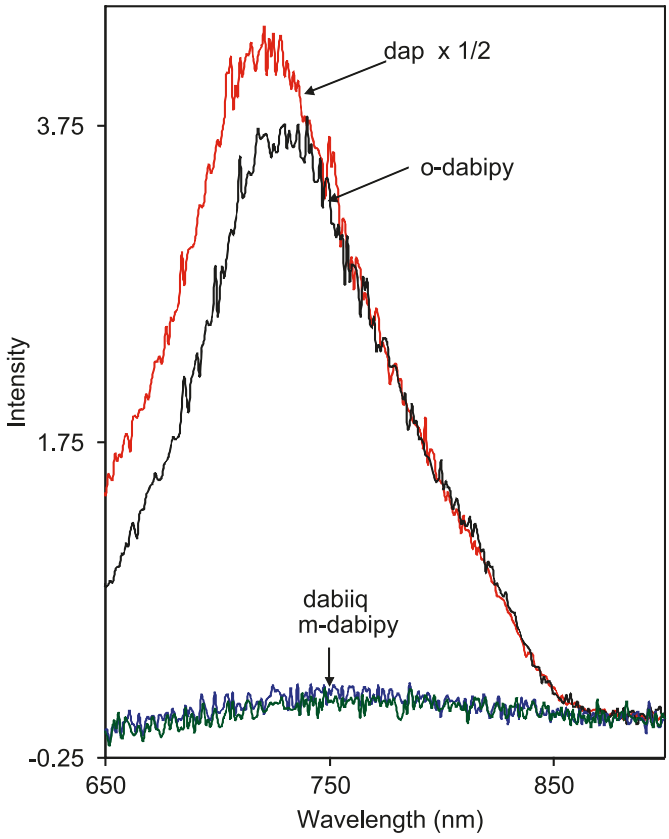

spectively. See Fig. 3 for the 77 K spectrum of the [2]pseudorotaxane with m-dabipy as the thread ligand. The emissions from the dap and o-dabipy complexes are both much more intense and durable enough to persist in the weakly basic solvent acetonitrile at room temperature, although the lifetimes contract to 50 ns and 30 ns, respectively.

The emission results are qualitatively similar in the solid state; see Fig. 4. In the case of the dap complex, the solid-state emission spectrum virtually coincides with that obtained in room-temperature, fluid solution, but the lifetime extends to 270 ns. On the other hand, the emission maximum for the o-dabipy complex shifts to slightly longer wavelength (730 nm), and that may account for the smaller increase in the emission lifetime (to 150 ns). Figure 4 shows that the dabiiq and m-dabipy complexes both exhibit weak emissions, centered at ~770 nm in the solid state. Unfortunately, neither signal is strong enough to permit a lifetime measurement.

Discussion

CT absorption and emission

Previous work has shown that the MLCT excitation that dominates the visible spectrum of a Cu(NN)$_2^+$ complex originates in the dπ orbitals of the metal that have nonzero overlap with empty π*(NN) acceptor orbitals of the ligand.[24,25] The presence of ligands with chemically distinct π systems in the thread and ring components may introduce

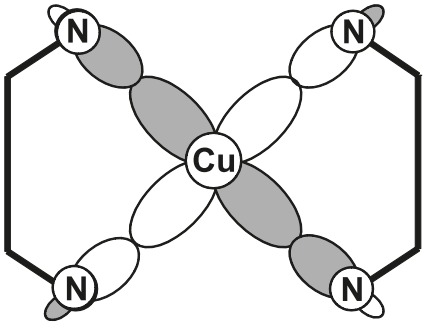
Fig. 5. Schematic view of bonding overlap formed by the half-occupied dσ orbital of a copper(II) center and the donor orbitals of two α,α-diimine ligands in the limit of a planar coordination geometry.



a broadening of the visible spectrum. Moreover, the shoulders that appear at λ ~575 nm in Fig. 2 are *characteristic* of $Cu(NN)_2^+$ systems in which at least one of the ligands has an aryl substituent positioned ortho to one or both of the imine nitrogens.[26,27] The shoulders result from two distinct *ground-state* distortions that destroy idealized D_{2d} symmetry and split the dπ orbital energies.[28–30] One is a "rocking" distortion that imparts a pyramidal coordination geometry, probably promoted by the formation of a stacking interaction involving an aryl substituent on one ligand and the aromatic core of the opposite ligand.[29] The second distortion entails a tetragonal flattening of the N_4 donor set about the copper center.[30] For the latter distortion, the driving force is presumably the mesomeric interaction(s) that results (result) when the aryl substituent(s) adopts (adopt) smaller dihedral angle(s) relative to the mean plane of the NN ligand.[30] Significant flattening is possible with a very modest driving force because the major opposing force derives from interligand steric interactions when the central ion is a d^{10} closed-shell metal center. The same interactions account for notable differences in the formation constants of $Cu(NN)^+$ and $Cu(NN)_2^+$ systems with aryl- as opposed to alkyl-substituted NN ligands.[31]

Further structural changes occur in the MLCT excited state due to the d-shell vacancy created, another consequence of which is the shift in the X-ray absorption edge of the copper center.[12] Nominally containing copper(II), the thermally equilibrated excited state becomes even more flattened, as a consequence of a second-order Jahn–Teller effect.[11] In more descriptive terms, additional flattening occurs because it leads to improved overlap amongst sigma-donor orbitals of the ligand and the half-occupied d orbital of copper in the CT excited state (Fig. 5). Indeed, the same kind of flattening is evident in the structures of oxidized $Cu(NN)_2^{2+}$ analogues.[32,33] When the flattening is severe, as in the case of $Cu(phen)_2^+$, the excited-state potential energy surface may impinge on the ground-state surface. The emission yield then becomes vanishingly small due to efficient non-radiative decay, even in frozen solution.[34,35] Indeed, for a $Cu(NN)_2^+$ system to exhibit emission in solution, sterically active groups must be present adjacent to the donor nitrogens to limit the extent of flattening.[7,9,36]

Within the [2]pseudorotaxane series studied herein, the m-30 ring ligand is a key structural element that clearly has a salutary effect on the emission lifetime of the o-dabipy complex (90 ns in DCM). Normally, $Cu(NN)_2^+$ complexes based on 2,2′-bipyridine ligands have relatively short-lived excited states, e.g., 34 ns for Cu(6,6′-diphenyl-4,4′-dimethyl-2,2-bipyridine)$_2^+$.[33] For comparison, the corresponding excited-state lifetime is 310 ns for Cu(2,9-diphenyl-4,7-dimethyl-1,10-phenanthroline)$_2^+$.[37] Ligand-dependent distortions may account for the difference in lifetimes of the two controls, especially torsional relaxation about the 2,2′ bond of the bipyridine ligand. In each case, bond length changes also occur in the excited state due to population of a π* orbital of the ligand. Bond length changes are apt to be greater in a bipyridine complex because the π* orbital delocalizes over fewer atoms than is the case with a phenanthroline moiety. One possibility is that the structural changes are less important in the o-dabipy-containing [2]pseudorotaxane because the CT excitation actually localizes on the m-30 ring ligand. In line with this possibility, the emission occurs at about the same energy whether the thread ligand is dap or o-dabipy. The m-30 ring ligand is no panacea, however, because the bis-thread complex $Cu(dap)_2^+$ exhibits a *longer* excited-state lifetime (260 ns[26]) than the dap-containing [2]pseudorotaxane. Vibrationally assisted radiationless decay may be less efficient for $Cu(dap)_2^+$ if the absence of a ring ligand permits better nesting of the ground- and excited-state potential energy surfaces.

Moreover, the m-30 ligand is not sufficiently structure-preserving to permit a photoluminescence signal if fluid solution from the [2]pseudorotaxane containing either m-dabipy or dabiiq as the thread ligand. In both cases, the anisole substituents of the thread ligand are evidently far enough removed from the opposite m-30 ligand that appreciable flattening occurs in the excited state and quenches the emission. Even in the solid state, where packing forces can come into play and help preserve structure,[11] the emissions from the m-dabipy and dabiiq complexes are very weak and maximize at relatively long wavelengths.

In summary, absorbance bandshapes reveal that all of the [2]pseudorotaxanes studied adopt low symmetry, partially flattened structures due to intra- and inter-ligand interactions involving bulky anisole substituents. Sterically active ligand substituents must be present to inhibit a flattening distortion in the excited state that quenches the photoluminescence. However, the steric interactions may produce inter-ligand "friction" that affects the mechanical response time. In fact, the [2]pseudorotaxanes that contain either the relatively open dabiiq or m-dabipy ligand (and exhibit faster mechanical motion[38]) are non-luminescent in room-temperature dichloromethane solution, whereas the dap and o-dabipy analogues exhibit emissions that maximize at ~720 nm and decay with time constants of 98 ns and 90 ns, respectively. The lifetime for the Cu(m-30)(o-dabipy)$^+$ system is more than twice what one would expect for a simple bis-bipyridine analogue. At 77 K in a frozen glass, the decay times for the emissions from Cu(m-30)(dap)$^+$ and Cu(m-30)(o-dabipy)$^+$ extend to almost a microsecond, whereas in room-temperature acetonitrile solution, the same complexes undergo solvent-induced exciplex quenching on a time scale of just under a microsecond, according to lifetime data.

Reverse Stern–Volmer behavior for luminescence quenching in carbon nanoparticles

Li Cao, Parambath Anilkumar, Xin Wang, Jia-Hui Liu, Sushant Sahu, Mohammed J. Meziani, Ethan Myers, and Ya-Ping Sun

Abstract: Photoluminescence properties of carbon nanoparticles from different treatments in various suspensions were evaluated, and the results were in general agreement with those available in the literature. An interesting observation was that the quenching of luminescence emissions in the aqueous suspended carbon nanoparticles by aliphatic amines deviated from the classical Stern–Volmer behavior in a somewhat unusual fashion, exhibiting reversed quenching (increasing luminescence intensities) at very low quencher concentrations. The implication of the observation to the mechanistic framework that may account for photoluminescence emissions in both functionalized and naked carbon nanoparticles is proposed and discussed.

Key words: carbon nanoparticles, luminescence, quenching, surface passivation, Stern–Volmer.

Résumé : On a évalué les propriétés de photoluminescence de nanoparticules de carbone obtenues par divers traitements dans des suspensions variées et les résultats obtenus sont généralement en accord avec eux qu'on retrouve dans la littérature. On a toutefois fait l'observation intéressante que la décroissance des émissions de luminescence des nanoparticules de carbone en suspension aqueuse, sous l'influence d'amines aliphatiques, dévie du comportement classique de Stern–Volmer d'une façon assez inhabituelle alors qu'elle présente une décroissance inversée (augmentation des intensités de luminescence) à des concentrations très faibles de désactivateur. On propose et on discute des implications de ces observations aux concepts mécanistiques qui pourraient expliquer les émissions de photoluminescence des nanoparticules nues ou fonctionnalisées.

Mots-clés : nanoparticules de carbone, luminescence, désactivation, passivation superficielle, Stern–Volmer.

[Traduit par la Rédaction]

Introduction

Quantum-sized semiconductor nanoparticles or quantum dots (QDs) have attracted much attention for their excellent optical properties and many related potential applications.[1–6] Among well-established QDs are those based on cadmium selenide nanoparticles and associated core–shell nanostructures.[7,8] However, since cadmium is a heavy metal known for its significant toxic effects and environmental hazards,[9–12] there has been extensive effort on the search for alternative QD-like photoluminescent materials. For example, nanosized silicon as an indirect bandgap semiconductor has been modified and (or) processed specifically for much improved fluorescence quantum efficiencies.[13–15]

Carbon is hardly considered as a member of the "semiconductor family", but it was found and demonstrated unambiguously by Sun and co-workers[16,17] that nanoscale carbon particles could be made brightly fluorescent with both one- and two-photon excitations. There have since been a large number of studies on fluorescent carbon nanoparticles from many different sources and processing or functionalization schemes and conditions.[18–24] While the bright fluorescence (with yields up to 50% and, performance-wise, competitive with that of the well-established semiconductor QDs)[18] has generally been associated with surface-functionalized carbon nanoparticles, there have been a number of reports on the detection of luminescence emissions in "naked" carbon nanoparticles.[21,25–30] For example, photoluminescence was found in acid-treated candle soot in aqueous suspension,[25,26] and subsequently many other suspended soot-like carbon materials (such as natural gas soot[27] or carbonized sugars[21]). Among other naked carbon nanoparticles found to be photoluminescent were those from electrochemical decomposition and (or) oxidation of carbon-based or carbon-rich nanomaterials suspended in water or other solvents.[28–30] These carbon nanoparticles were generally small (less than 10 nm), and their luminescence quantum yields were generally low (mostly less than 1%).

In the work reported here, we examined carbon nanoparticles from different treatments for evaluation and confirmation of their photoluminescence properties in suspensions

under various experimental conditions. An interesting observation was that the quenching of luminescence emissions in the aqueous suspended carbon nanoparticles by aliphatic amines deviated from the classical Stern–Volmer behavior in a somewhat unusual fashion, exhibiting reversed quenching (increasing luminescence intensities) at very low quencher concentrations. The implication of the results to the mechanistic framework that may account for photoluminescence emissions in both functionalized and naked carbon nanoparticles is proposed and discussed.

Results and discussion

The aqueous suspension of the as-purified carbon nanoparticles (produced in the arc discharge of pure graphite rods) was centrifuged at 3 500*g* to yield a colored supernatant. Upon dialysis against pure water, the apparently homogeneous particle suspension was still colored (denoted as fraction S, Fig. 1), with the observed absorption spectrum of a featureless curve (Fig. 1). The excitation at various visible wavelengths resulted in significant luminescence emissions (Fig. 1), in general agreement with what has been reported in the literature for suspended carbon nanoparticles from different sources and preparations.[21,25–30] The observed emission quantum yields (for example, 0.24% at 440 nm excitation) were at the lower end of the values already in the literature.

The carbon nanoparticles in the homogeneous suspension were, size-wise, broadly distributed according to atomic force microscopy imaging (Fig. 2). The results from transmission electron microscopy (TEM) analysis of the same sample were generally consistent with such an assessment, though the relatively low contrast between the smaller carbon nanoparticles and the carbon coating on the TEM grid hindered a more quantitative determination of size distributions.

The carbon nanoparticles could also be suspended in polar organic solvents, in which the luminescence emission properties were somewhat different. The luminescence spectra remained very broad, with some variations in the spectral peak and band width (Fig. 3), and the observed emission quantum yields were clearly solvent dependent, obviously more luminescent in the solvent dimethyl sulfoxide (DMSO) (Table 1).

The presence of solvent was apparently necessary for the observation of luminescence emissions from carbon nanoparticles. No luminescence could be detected for the same particles under solvent-free conditions (for example, deposited on solid substrate). This has generally been the case for other naked carbon nanoparticles from different sources and preparations. Thus, it seems logical to assume that the solvent molecules may passivate the particle surface, similar to but understandably less effective than the surface passivation agents in the much more fluorescent functionalized carbon nanoparticles (dubbed "carbon dots").[16–18,21] In this regard, the higher luminescence quantum yields of the carbon nanoparticles suspended in DMSO (Table 1) might simply be due to relatively more effective particle surface passivation by DMSO molecules (conceptually similar to weak surface noncovalent "functionalization" of the carbon nanoparticles). Therefore, the photoluminescence in all

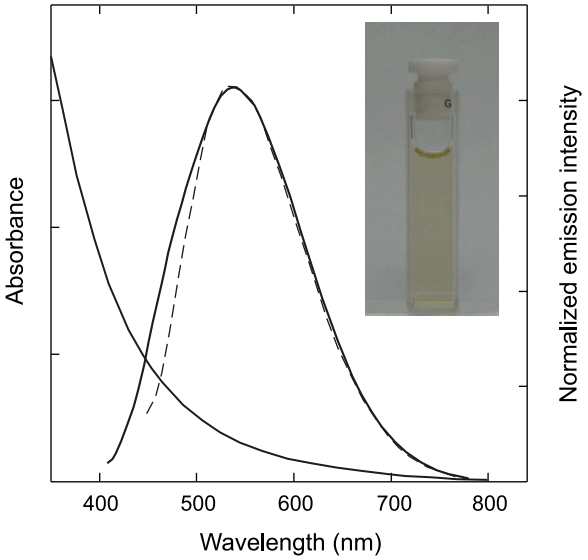

Fig. 2. A typical atomic force microscopy image of the carbon nanoparticles (fraction S).

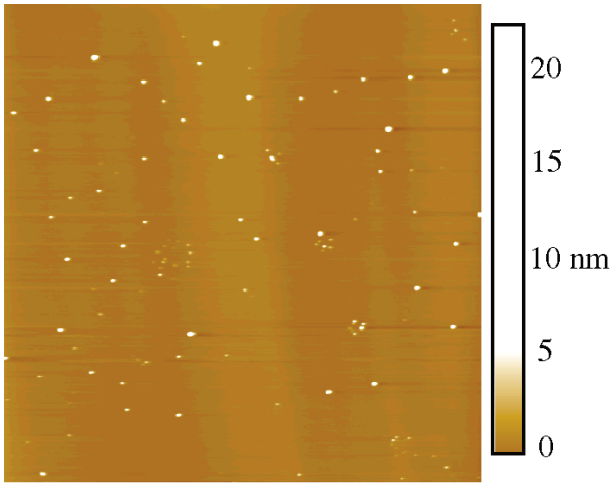

small carbon nanoparticles (naked or functionalized carbon dots) could have the same origin: the emissive energy trapping sites on the passivated surface of carbon nanoparticles.[16]

The effect of surface passivation on luminescence properties of the carbon nanoparticles was also reflected in the unusual quenching results with aliphatic amines as quenchers. Specifically for diethylamine (DEA) in aqueous suspension of the carbon nanoparticles, as a representative example, the observed luminescence intensities increased with an increasing amount of quencher molecules at low DEA concentrations, namely the reversed Stern–Volmer quenching behavior (Fig. 4). Beyond the low concentration region (~4 mmol/L for DEA in aqueous solution), the normal quenching took over, though the Stern–Volmer plot was curved downward at higher DEA concentrations (Fig. 4). The absorption and luminescence emission spectra of the carbon nanoparticles remained largely unchanged with DEA

concentration in both the reversed and normal Stern–Volmer quenching regions.

The reversed Stern–Volmer quenching behavior at low quencher concentrations might be explained by the same mechanistic framework as that for the functionalized carbon nanoparticles, namely that the DEA molecules in initially low population could be "adsorbed" onto the carbon nanoparticles to improve the surface passivation, phenomenologically similar to weak noncovalent functionalization, to result in higher luminescence intensities. The effect of improved passivation might be overtaken by the normal Stern–Volmer quenching at higher quencher concentrations. Interestingly, similarly different quenching behaviors in low and high DEA concentration regions were observed for the carbon nanoparticles in methanol (Fig. 5), but not in DMSO (Fig. 5). The latter was a solvent in which the carbon nanoparticles were found to be significantly more luminescent (Table 1). The absence of the reversed quenching behavior in DMSO was consistent with the argument that the

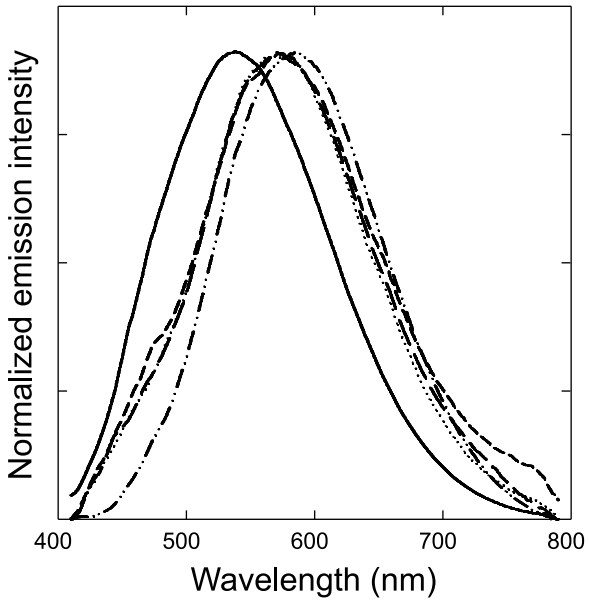
Fraction R_2	0.15 (0.11)
Fraction R_3	0.16 (0.13)
Fraction R_4	0.14 (0.11)

observed higher luminescence quantum yields in DMSO could be attributed to the more effective surface passivation by the solvent molecules, with which the similar passivation effect by the low-concentration DEA molecules was apparently not competitive.

Other water-soluble amines such as ethylamine and methoxy polyethylene glycol amine ($CH_3O(CH_2CH_2O)_{11}CH_2CH_2NH_2$, PEG_{550N}) exhibited similar reversed quenching behavior at

Fig. 7. Normalized luminescence spectra (400 nm excitation) of the carbon nanoparticles in water: fraction S (—), fraction R_1 (· · ·), fraction R_2 (– – –), fraction R_3 (– · · –), and fraction R_4 (— —).



lower quencher concentrations (Fig. 6). The subsequent turnover in Stern–Volmer plots could again be attributed to the competition between the initial enhancement in luminescence intensities due to the improving particle surface passivation and the normal luminescence quenching. The latter was likely due to photoinduced electron transfer processes.[31]

The dispersion of purified carbon nanoparticles in aqueous solution was dependent on the solution pH, being more stable under neutral than acidic conditions. Therefore, the centrifugation at 3 500*g* to obtain the supernatant for the experiments described above was performed with the as-purified (nitric acid-treated, thus acidic) sample, followed by dialysis of the supernatant to result in an even more stable aqueous suspension at neutral pH (fraction S, as compared below with the other fractions). The residue from the same centrifugation was also dialyzed against deionized water to neutral pH (as fraction R), and the fraction was subdivided into various fractions (fraction R_1, R_2, R_3, and R_4, Table 2) via sequential centrifugation at different *g* values, as described in more details in the Experimental section. The fractions thus obtained were characterized and evaluated for their luminescence properties, in reference to those of the sample (fraction S) described above.

The atomic force microscopy results for these fractions suggested no major differences from fraction S (Fig. 2), except for the observation of some larger particles in low population (insignificant statistically). The absorption and luminescence properties of these fractions were also found to be mostly similar among fractions R (Fig. 7), though the luminescence spectra were somewhat shifted from that of fraction S (Figs. 1 and 7), and the observed luminescence quantum yields were also lower (Table 2). Nevertheless, for such inhomogeneous samples of suspended carbon nanoparticles, the changes in spectroscopic results across all samples could hardly be considered as dramatic, or they are actually qualitatively similar.

The results from this study, in general agreement with those reported in the literature, confirmed that neat carbon nanoparticles in aqueous and other solvent suspensions were photoluminescent, though with much lower emission quantum yields than those found in functionalized carbon nanoparticles or carbon dots. The fractionation aimed at size selection in terms of different centrifugation fields was apparently not so effective, probably because the gravimetric properties of the suspended carbon nanoparticles were affected by not just the particle sizes, but also surface characteristics such as the presence and population of oxidized groups (carboxylic acids, especially). Nevertheless, the general insensitivity of the observed spectroscopic properties to the fractionation seemed to suggest that the photoluminescent emissions were qualitatively similar across all of the suspended carbon nanoparticles. Mechanistically, the luminescence in these nanoparticles likely has the same origin as that in the functionalized carbon nanoparticles, both due to passivated surface energy trapping sites. A major difference is that the suspended carbon nanoparticles are passivated by solvent molecules (so the naked particles are not so naked after all), whereas the nanoparticles in brightly emissive carbon dots are passivated by surface functionalization. The significance for the observation of reversed Stern–Volmer quenching behavior in this study is that it helps to illustrate the importance of surface passivation to the luminescence emissions in carbon nanoparticles.

Experimental section

Materials

Fine-extruded graphite rods (carbon content > 99.9%) were purchased from Graphitestore.com, Inc. Dialysis membrane tubing was supplied by Spectrum Laboratories. Water was deionized and purified by being passed through a Labconco WaterPros water purification system.

Measurements

A Baxter Megafuge (model 2630) and Beckman-Coulter ultracentrifuge (Optima L90K with a type 90 Ti fixed-angle rotor) were used for centrifugation at various *g* values. Atomic force microscopy analyses were conducted in the acoustic AC mode on a Molecular Imaging PicoPlus system equipped with a multipurpose scanner for a maximum imaging area of 10 μm × 10 μm and a NanoWorld Pointprobe NCH sensor (125 μm in length). Transmission electron microscopy (TEM) studies were performed on Hitachi 9500 TEM and Hitachi HD-2000 S-TEM systems. Optical absorption spectra were recorded on a Shimadzu UV-2501PC spectrophotometer. Luminescence emission spectra were measured on a Jobin-Yvon fluorescence spectrometer equipped with a 450 W xenon source, Gemini-180 excitation monochromator and Tirax-550 emission monochromator, and a single-photon counting detector (Hamamatsu R928P PMT at 950 V). Quinine sulfate and 9,10-bis(phenylethynyl)-anthracene were used as the fluorescence standard.

Carbon nanoparticles

The carbon soot containing nanoparticles was produced in the arc discharge of graphite rods.[32] The discharge chamber was in a floating helium atmosphere (1 atm; 1 atm = 101.325 kPa) while the rods were burned with a direct current of 70 A (28 V). The as-produced carbon soot was dispersed in dimethylformamide (DMF) with ultrasonication (Crest Ultrasonics, Model 950DA, 50–60 Hz) for 24 h. The dispersion was then evaporated to remove DMF for the recovery of carbon particles.

The particle sample (3 g) in aqueous nitric acid solution (2.6 mol/L, 240 mL) was refluxed for 12 h. The resulting acidic suspension at room temperature was centrifuged at 3 500*g* for 5 min to collect the supernatant. It was then neutralized with sodium carbonate, followed by dialysis (membrane molecular weight cutoff ~500) against fresh deionized water for 3 days. The resulting stable dispersion of carbon nanoparticles, denoted as fraction S, was used in most of the measurements, including those that required a transfer from aqueous to another solvent.

The residue from the centrifugation above, denoted as fraction R, was added to water for the same dialysis to result in an aqueous suspension at neutral pH. Upon settling after 12 h, the sediment was harvested as fraction R_1, and the supernatant was centrifuged at 55 000*g* for 1 h to obtain the residue as fraction R_2. The new supernatant was again centrifuged in a higher field of 393 000*g* for 1 h to yield the residue as fraction R_3 and the final supernatant as fraction R_4.

Concentrations of the carbon nanoparticles in suspensions were generally low, less than 10 mg/L. At such low concentrations, the particle concentration effect on spectroscopic results was negligible.

A photoswitchable bichromophoric oxazine with fast switching speeds and excellent fatigue resistance

Erhan Deniz, Stefania Impellizzeri, Salvatore Sortino, and Françisco M. Raymo

Abstract: In search of strategies to regulate the photochemical and photophysical properties of photochromic oxazines, we designed a multichromophoric compound incorporating 3*H*-indole, benzooxazine, and 2-(4-dimethylaminophenyl)ethynyl fragments. We synthesized this molecule in two steps in an overall yield of 51%, starting from commercial precursors. The ultraviolet irradiation of this photochrome opens a [1,3]oxazine ring in less than 6 ns to generate a zwitterionic isomer with a quantum yield of 0.10. In particular, the photoinduced ring opening generates a 4-nitrophenolate anion and a 3*H*-indolium cation. Additionally, this process brings the 2-(4-dimethylaminophenyl)ethynyl appendage into conjugation with the 3*H*-indolium cation. As a result, two distinct bands for the anionic and cationic fragments of the photogenerated zwitterion appear in the visible region of the absorption spectrum. The photogenerated isomer has a lifetime of 2 μs and switches back to the original form with first-order kinetics. Furthermore, this bichromophoric photochrome tolerates hundreds of switching cycles with no sign of degradation and can be operated within rigid polymer matrices. Thus, this particular structural design can lead to the development of a new family of bichromophoric photochromes and photoresponsive materials with microsecond switching times and excellent fatigue resistances.

Key words: heterocycles, molecular switches, oxazines, photochromism, photoisomerization.

Résumé : Dans le cadre d'une recherche sur des stratégies qui pourraient permettre de régulariser les propriétés photochimiques et photophysiques d'oxazines photochromiques, on a développé un composé multichromophorique comportant des fragments 3*H*-indole, benzooxazine et 2-(4-diméthylaminophényl)éthynyle. Cette molécule a été synthétisée en deux étapes, avec un rendement de 51 %, à partir de précurseurs commerciaux. L'irradiation ultraviolette de ce photochrome provoque l'ouverture d'un noyau [1,3]diazine en moins de 6 ns pour conduire à la formation d'un isomère zwitterionique avec un rendement quantique de 0,10. En particulier, l'ouverture de cycle photoinduite génère un anion 4-nitrophénolate et un cation 3*H*-indolium. De plus, ce processus conduit le groupe 2-(4-diméthylaminophényl)éthynyle à se placer en conjugaison avec le cation 3*H*-indolium. Il en résulte que la région visible du spectre d'absorption comporte deux bandes distinctes, l'une pour le fragment anionique et l'autre pour le fragment cationique du zwitterion photogénéré. Le temps de vie de l'isomère photogénéré est de 2 μs et il retourne à la forme originale avec une cinétique du premier ordre. De plus, ce photochrome bichromophorique tolère des centaines de cycles sans signe apparent de dégradation et il peut être utilisé dans des matrices de polymères rigides. Cette structure particulière pourrait donc conduire au développement d'une nouvelle famille de photochromes bichromophoriques et de matériaux photosensibles ayant des temps de commutation de l'ordre de la microseconde et une excellente capacité à résister à la fatigue.

Mots-clés : hétérocycles, commutateurs moléculaires, oxazines, photochromie, photoisomérisation.

[Traduit par la Rédaction]

Introduction

The term photochromism refers to the photoinduced and reversible change in color of a collection of molecules.[1–5] The process can be a consequence of photoinduced ring opening–closing steps, cis–trans isomerizations, intramolecular proton transfers, intermolecular electron transfers, cycloadditions, or the reorganization of ligands around a metal center. All these transformations alter the electronic structure of the photoresponsive compound and result in significant changes in the absorption spectrum. In addition, these structural alterations at the molecular level can translate into noticeable changes in refractive index. As a result, photochromic transformations can be exploited to modulate the absorption coefficient and refractive index of a substrate under the influence of optical stimulations. Indeed, a diver-

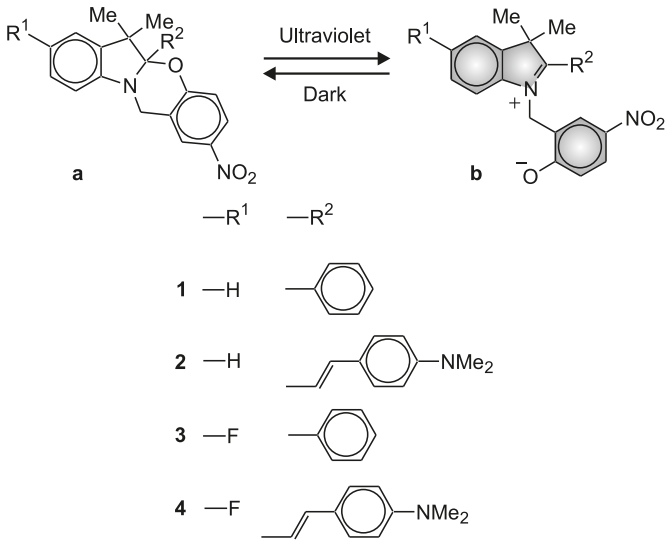
sity of photoresponsive materials and devices have already been designed around the absorptive and dispersive effects associated with photochromic compounds.[6–8] In fact, promising examples of all-optical logic gates,[9–13] optical limiters,[14–18] photoresponsive filters,[19] and photoswitchable probes[20–26] have all been implemented on the basis of the photochromism associated with certain organic compounds.

Nitrospiropyrans switch from a colorless to a colored state under ultraviolet irradiation and revert thermally to the original form.[27–31] Because of their photochemical behavior and their synthetic accessibility, they have become one of the most popular classes of photochromic compounds. However, their switching speeds are relatively slow and a full switching cycle can only be completed on a timescale of minutes. Furthermore, the involvement of the triplet state in the photoisomerization mechanism tends to encourage degradation and these compounds can only tolerate a few tens of switching cycles. In search of strategies to improve their switching speeds and fatigue resistances, we developed a new family of photochromic compounds based on the photoinduced opening and thermal closing of [1,3]oxazine rings.[32] Our molecules switch from a colorless to a colored state in less than 6 ns upon ultraviolet excitation and revert to the original form on a nanosecond timescale. In addition, they survive thousands of switching cycles unaffected, even in the presence of molecular oxygen, and can be operated in solution as well as within rigid polymer matrices. The integration of these compounds into photonic materials and devices, however, requires a basic understanding of the stereoelectronic factors regulating their spectroscopic signature and photochromism. In particular, we need to learn how their molecular skeleton should be modified to tune the color of the photogenerated state, the timescales of the isomerization processes, and the quantum efficiency of their coloration without compromising their excellent fatigue resistance.

Laser excitation of **1a** (Fig. 1) at 355 nm opens its [1,3]oxazine ring in less than 6 ns to generate the zwitterionic isomer **1b** with a quantum yield of 0.10 in acetonitrile at 20 °C.[32a,32b] The original state **1a** does not absorb in the visible region, while the 4-nitrophenolate chromophore of the photogenerated species **1b** absorbs at 440 nm. Therefore, the photoinduced transformation of **1a** into **1b** is accompanied by the appearance of a transient band in the visible region of the absorption spectrum. This band decays monoexponentially on a nanosecond timescale with the thermal reisomerization of **1b** back to **1a**.

The introduction of a 2-(4-dimethylaminophenyl)ethynyl group in place of the phenyl ring of **1a** generates a bichromophoric switch in the shape of **2a**.[32g] Specifically, the photoinduced opening of the [1,3]oxazine ring of this compound brings the 2-(4-dimethylaminophenyl)ethynyl appendage into conjugation with the 3*H*-indolium cation. The resulting chromophore absorbs at 540 nm and, hence, the formation of **2b** is accompanied by the appearance of a transient band centered at this wavelength together with one at 440 nm for the 4-nitrophenolate anion. Both bands decay monoexponentially on a microsecond timescale and with identical kinetics, as **2b** reisomerizes thermally to **2a**. Thus, structural modifications of the group (R^2 in Fig. 1) attached to the chiral center at the junction of the two heterocyclic fragments

Fig. 1. Photoinduced transformation of the [1,3]oxazines **1a**–**4a** into the zwitterions **1b**–**4b**.



of our oxazines can be exploited to regulate the absorption properties of their photogenerated states in the visible region and impose bichromophoric character on them. However, the transition from **1a** to **2a** has a depressive effect on the photoisomerization efficiency and the quantum yield decreases from 0.10 to 0.07.

The introduction of a fluorine substituent in the para position (R^1 in Fig. 1) relative to the nitrogen atom of the 3*H*-indole fragment of **1a** facilitates the photoinduced opening of the [1,3]oxazine ring. Specifically, the quantum yield increases from 0.10 to 0.29 with the transition from **1a** to **3a**.[32g] On the basis of these considerations, we envisaged the possibility of introducing a fluorine substituent also on the 3*H*-indole fragment of the bichromophoric switch **2a** to improve the quantum yield for its photoisomerization. In particular, we designed compound **4a** and here we report its synthesis, spectroscopic characterization, and photochemical properties in solution and within a rigid polymer matrix.

Results and discussion

Synthesis

We synthesized **4a** in two steps (Fig. 2), starting from commercial precursors, with an overall yield of 51%. Specifically, the condensation of 2,3,3′-trimethyl-5-fluoro-3*H*-indole with *N,N*-dimethyl-4-aminobenzaldehyde under acidic conditions gave the extended 3*H*-indole **5**, which was reacted with 2-chloromethyl-4-nitrophenol to afford the target oxazine **4a**. Similarly, the reaction of **5** with methyl iodide produced the iodide salt of the model 3*H*-indolium cation **6**.

Steady-state absorption spectroscopy

The spectrum of **4a** reveals a band centered at 306 nm (*a* and *d* in Fig. 3) for the overlapping absorptions of the 2-(4-dimethylaminophenyl)ethynyl and 4-nitrophenoxy chromophores. Upon addition of acid, the [1,3]oxazine ring of **4a** opens to generate the cationic species **4c** (Fig. 4). This transformation extends the conjugation of the 2-(4-dimethylaminophenyl)ethynyl appendage and shifts its absorption to

Fig. 2. Synthesis of the [1,3]oxazine **4a** and model compound **6**.

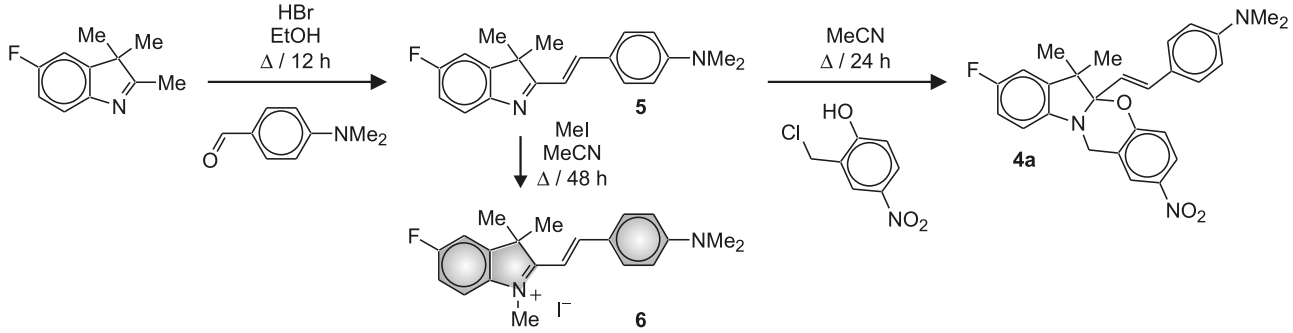

Fig. 3. Steady-state absorption spectra of solutions (0.1 mmol/L, MeCN, 20 °C) of **4a** before (*a* and *d*) and after the addition of either CF_3CO_2H (1 equiv., *b*) or Bu_4NOH (5 equiv., *e*), **6** (*c*), and 4-nitrophenol after the addition of Bu_4NOH (4 equiv., *f*).

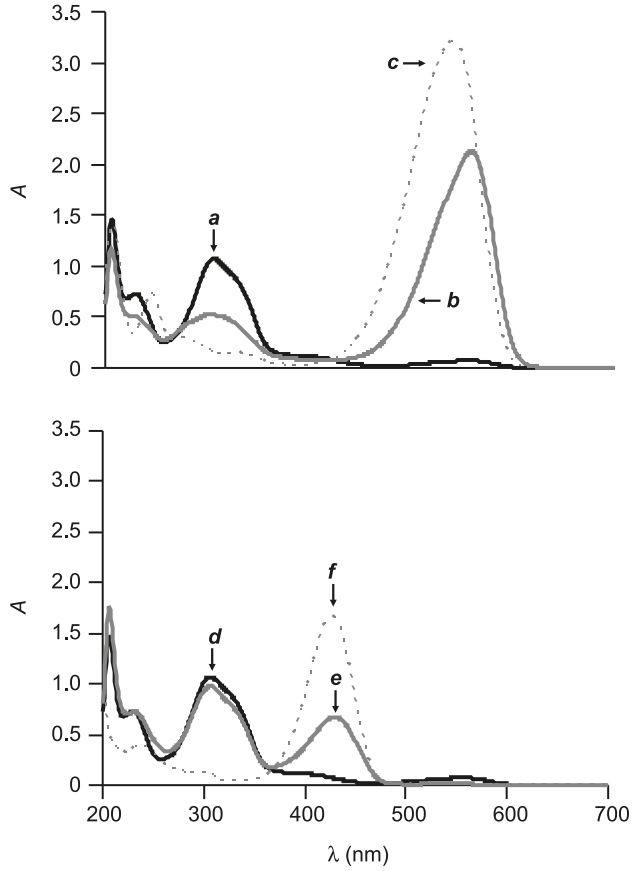

559 nm (*b* in Fig. 3). Indeed, this band resembles that of the model 3*H*-indolium cation **6** (*c* in Fig. 3).

The addition of base also opens the [1,3]oxazine ring of **4a** to generate the anionic species **4d**. This process causes the appearance of a band at 427 nm (*e* in Fig. 3), corresponding to the 4-nitrophenolate chromophore of **4d**. In fact, this absorption is reminiscent of that associated with the tetrabutylammonium salt of 4-nitrophenolate (*f* in Fig. 3).

Transient absorption spectroscopy

In acetonitrile at 20 °C, the laser excitation of **4a** at 355 nm is accompanied by the appearance within 6 ns of two transient bands at 420 and 540 nm (*a* in Fig. 5) in the absorption spectrum. They resemble those observed in the steady-state spectra of **4d** and **4c**, respectively (*e* and *b* in Fig. 3) and correspond to ground-state absorptions of the 4-nitrophenolate anion and 3*H*-indolium cation, respectively, of **4b**. Thus, the [1,3]oxazine ring of **4a** opens upon excitation to generate the bichromophoric isomer **4b**, in analogy to the behavior of **2a** and **2b**. However, the transition from **2a** to **4a** results in an increase in quantum yield from 0.07 to 0.10.[33] Indeed, plots (*b* and *c* in Fig. 5) of the absorbance change measured at 540 nm upon laser excitation against the pulse energy show a noticeable increase in slope on going from **2a** to **4a**, consistent with an enhancement in quantum efficiency. Thus, the presence of a fluorine substituent on the 3*H*-indolium fragment of **4a** facilitates the photochromic transformation. Presumably, this effect is a consequence of the reduced electron density on the nitrogen atom of the 3*H*-indole fragment of **4a**, relative to that of **2a**, with the suppression of competitive photoinduced electron transfer to the adjacent nitro group. Indeed, the cyclic voltammograms of the model compounds **7** and **8** (Fig. 6) demonstrate that the oxidation potential of the 3*H*-indole fragment shifts by 70 mV in the positive direction with the introduction of an electron-withdrawing fluorine substituent.[34]

The photogenerated isomer **4b** reverts spontaneously to **4a** on a microsecond timescale. As a result, the two bands of **4b** decay with identical first-order kinetics. Curve fitting of both temporal profiles (*d* and *e* in Fig. 5) reveals the lifetime of **4b** to be 2 μs in acetonitrile at 20 °C. This value is identical to that of **2b**, demonstrating that the fluorine substituent has no influence on the reisomerization kinetics. Thus, a full switching cycle can be completed in a few microseconds with both photochromic systems. In addition, they tolerate hundreds of switching cycles with no sign of degradation. Specifically, the steady-state absorption spectra recorded before and after 300 excitation cycles are virtually identical, indicating the lack of any significant degradation under these experimental conditions.

The bichromophoric photochrome **4a** can be incorporated within a rigid poly(methyl methacrylate) (PMMA) matrix on the basis of a spin-coating procedure. The laser excitation of the resulting film at 355 nm is also accompanied by the appearance within 6 ns of two transient bands (*a* in Fig. 7). Once again, these bands resemble those observed in the steady-state spectra of **4d** and **4c** in solution and correspond to ground-state absorptions of the 4-nitrophenolate anion and

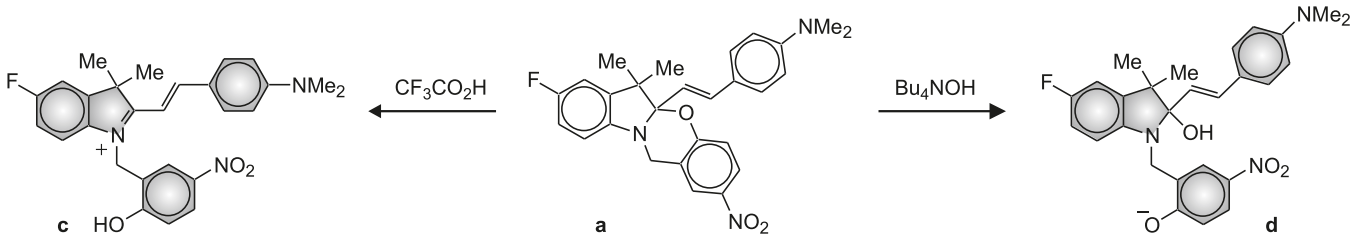
Fig. 4. Transformation of the [1,3]oxazine **4a** into the cation **4c** or anion **4d** under the influence of acid or base, respectively.



3*H*-indolium cation of **4b**. As observed in solution, the photogenerated isomer **4b** reverts spontaneously back to **4a** also within the PMMA matrix. Concomitantly, both absorption bands decay with the reisomerization process, though with biexponential kinetics in this instance. Curve fitting of the corresponding temporal profiles (*b* in Fig. 7) indicates lifetimes of 4 and 130 μs. The biexponential decay is consistent with that observed for **2b** in PMMA and suggests the coexistence of two main environments for the photochromic dopants within the polymer matrix.

Conclusions

Bichromophoric photochromes can be synthesized in two steps, starting from commercial precursors, by fusing 3*H*-indole and benzooxazine fragments and appending a 2-(4-dimethylaminophenyl)ethynyl group to the chiral center at the junction of the two heterocycles. The ultraviolet excitation of these compounds opens their [1,3]oxazine ring in less than 6 ns to produce a zwitterionic isomer, incorporating a 4-nitrophenolate anion and a 3*H*-indolium cation. These two chromophoric fragments absorb at 440 and 540 nm, respectively, and, therefore, the photoinduced transformation is accompanied by the appearance of two bands in the visible region of the absorption spectrum. The introduction of a fluorine substituent in the para position, relative to the nitrogen atom, of the 3*H*-indole heterocycle increases the photoisomerization quantum yield. Indeed, the electron-withdrawing character of the substituent reduces the electron density on the nitrogen atom of the 3*H*-indole heterocycle and facilitates the photoinduced ring-opening process. Instead, this particular substituent has essentially no influence on the lifetime of the photogenerated isomer, which reverts to the original form with first-order kinetics on a microsecond timescale. In fact, these bichromophoric photochromes can be switched back and forth between their two states in a few microseconds and tolerate hundreds of switching cycles with no sign of degradation. In addition, they can be operated within rigid PMMA matrices, though with slower reisomerization kinetics than in acetonitrile solution. Thus, our structural design for the realization of bichromophoric photochromes can lead to the development of novel photoresponsive materials with fast switching speeds and excellent fatigue resistances.

Experimental procedures

Materials and methods

Chemicals were purchased from commercial sources and used as received with the exception of MeCN, which was distilled over CaH_2. Compounds **7** and **8** were prepared according to literature procedures.[32a,32g] All reactions were monitored by thin-layer chromatography, using aluminum sheets coated with silica (60, F_{254}). Fast atom bombardment mass spectra (FABMS) were recorded with a VG Mass Lab Trio-2 spectrometer in a 3-nitrobenzyl alcohol matrix. Nuclear magnetic resonance (NMR) spectra were recorded with Bruker Avance 400 or 500 spectrometers. Steady-state absorption spectra were recorded with a Varian Cary 100 Bio spectrometer, using quartz cells with a path length of 0.5 cm. Time-resolved absorption spectra were recorded with a Luzchem Research mLFP–111 spectrometer, after excitation with a Continuum Surelite II–10 Nd–YAG laser (pulse width = 6 ns (FWHM), wavelength = 355 nm). The photochromic films were prepared by spin-coating a CH_2Cl_2 solution of **4a** (1.0 mg/mL) and PMMA (52 mg/mL) on a glass plate at 420 rpm for 9 s. The thickness (6 μm) of the resulting films was measured with a Tencor Instruments 10-00090 surface profilometer. Cyclic voltammograms were recorded with a CH Instruments 660 workstation in degassed MeCN solutions of Bu_4NPF_6 (0.1 mol/L) under an atmosphere of Ar, using a glassy-carbon working electrode, a platinum counter electrode, and a Ag/AgCl reference electrode.

Synthesis of 5

A solution of 2,3,3′-trimethyl-5-fluoro-3*H*-indole (1.09 g, 6.15 mmol), *N,N*-dimethyl-4-aminobenzaldehyde (0.92 g, 6.15 mmol), and HBr (0.5 mL, 33% in AcOH) in EtOH (10 mL) was heated under reflux for 12 h. After cooling to ambient temperature, the solvent was distilled off under reduced pressure. The residue was dissolved in CH_2Cl_2 (30 mL) and washed with a saturated aqueous solution of $NaHCO_3$ (2 × 20 mL). The organic phase was dried over Na_2SO_4 and the solvent was distilled off under reduced pressure to give **5** (1.6 g, 85%) as an orange solid. ^{1}H NMR ($CDCl_3$) δ : 1.44 (6H, s), 2.98 (6H, s), 6.69 (2H, d, J = 8 Hz), 6.85 (1H, d, J = 16 Hz), 7.00 (2H, t, J = 7 Hz), 7.49–7.51 (3H, m), 7.66 (1H, d, J = 16 Hz). ^{13}C NMR ($CDCl_3$) δ: 24.4, 40.6, 53.4, 109.3, 112.5, 115.0, 121.0, 124.3, 129.4, 139.0, 148.9, 150.7, 151.6, 160.3, 162.7, 184.3. FABMS *m/z*: 310 $[M + H]^+$.

Synthesis of 4a

A solution of **5** (278 mg, 0.9 mmol) and 2-chloromethyl-4-nitrophenol (169 mg, 0.9 mmol) in MeCN (20 mL) was heated under reflux for 24 h. After cooling to ambient temperature, the solvent was distilled off under reduced pressure and the residue was dissolved in CH_2Cl_2 (3 mL). The addition of Et_2O (20 mL) caused the precipitation of a purple solid. The solid was dissolved in CH_2Cl_2 (30 mL) and washed with H_2O (20 mL). The organic phase was dried over Na_2SO_4 and the solvent was distilled off under reduced

Chemoselective photochemical surface reaction — Ketene versus carbene reactivity from the photolysis of saturated monolayers of pyridyl diazoesters on single-crystal Pt

Jason L. Pitters, Dana K. Adkinson, Keith Griffiths, Peter R. Norton, and Mark S. Workentin

Abstract: Irradiation of saturated monolayers of 3- and 4-substituted pyridyl diazoacetates on single-crystal Pt surfaces leads to either the corresponding reactive carbene or stable ketene intermediate with the chemoselectivity determined by the position of the photoreactive substituent on the pyridyl ring, which ultimately directs the available interactions with neighboring substrates.

Key words: ketene, carbene, diazoester, saturated monolayer, photochemistry, Pt surfaces.

Résumé : L'irradiation de monocouches saturées de diazoacétates de pyridyles substitués dans les positions 3 et 4 sur des surfaces de monocristaux de platine conduit à la formation soit du carbène réactif correspondant ou de l'intermédiaire cétène stable dans lesquels la chimiosélectivité est déterminée par la position du substituant photoréactif sur le noyau pyridyle qui en fin de compte dirige les interactions disponibles avec les substrats avoisinants.

Mots-clés : cétène, carbène, diazoester, monocouche saturée, photochimie, surfaces de platine.

[Traduit par la Rédaction]

Introduction

The ability to precisely control the reactivity of organic molecules as saturated monolayers on metal surfaces is a significant challenge. Results of such studies remain of interest because of the continued need for efficient methods for the selective chemical modification of the surface for a host of applications.[1] Most studies with these goals concentrate on monolayers based on long alkyl chains with surface active groups bound to Au or Si, while studies of smaller, less flexible organic molecular architectures are relatively unexplored.[2,3] Monolayers of smaller and more rigid molecules should allow for more careful control and understanding of the orientation of the organic substrate and allow for selectivity in the interfacial reactivity as a function of the position of the reactive moiety on the rigid structure of the moiety forming the monolayer.

Here, we report a remarkable and unprecedented chemoselectivity in a monolayer surface photoreaction, namely the photoreaction of pyridyl diazoacetates (3- and 4-PDE) on single-crystal platinum surfaces. The chemoselectivity results from the relative position of the reactive group on the rigid molecular architecture of the base pyridyl rings. Diazoesters are known to react thermally and photochemically with loss of nitrogen to form the corresponding carbene intermediate.[4] Unlike diazoketones or diazoaldehydes, they do not generally undergo efficient Wolff-type rearrangements to generate a ketene because of the poor migratory aptitude of the –OR group; instead, they generally react through a carbene.[4] For example, aryl diazoester derivatives show only traces (<1%) of Wolff rearrangement.[4c] Pyridyl diazoesters are not well studied, and only in the case of 3-PDE was the formation of a ketene observed, but this was at 10 K in an Ar matrix.[5] In solution, we found 98% of the products from irradiation of 3- or 4-PDE are from trapping of the carbene intermediate.[6] However, in this report, we show that we can select the reactivity between the carbene and ketene by simply altering the position of the diazoester function on the pyridyl ring that is bound to the metal surface (Scheme 1). Such control sheds important insights into the reactivity in this type of monolayer environment and suggests that this experimental approach also provides a method for characterizing reactive intermediates.

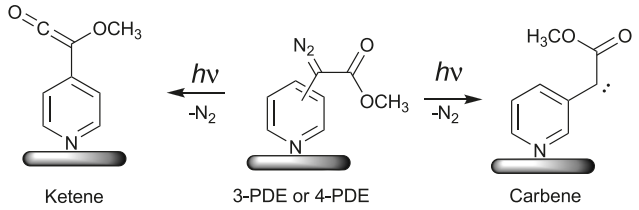
Scheme 1. Chemoselectivity in the surface photochemistry of 3- and 4-PDE on Pt.



Experimental

All ultra-high vacuum (UHV) experiments were performed in a stainless steel chamber pumped with a 330 L s^{-1} turbo molecular pump and a titanium sublimation pump. With these pumps, background pressures in the low 10^{-10} torr range (1 torr = 133.322 Pa) could be achieved. The chamber was interfaced to a Mattson Cygnus 100 Fourier transform infrared spectrometer for FTIR–RAIR (reflection absorption infrared) spectroscopy. The external optical system for the RAIRS consisted of a flat plane mirror that redirected the collimated IR light from the spectrometer to a parabolic mirror that focused the light on the sample surface in the chamber at a grazing angle. The reflected light from the sample then left the chamber to be re-collimated by another parabolic mirror and then focused on the detector with a final parabolic mirror. The UHV chamber was fitted with KCl windows, and a liquid-nitrogen-cooled narrow-band mercury cadmium telluride detector with a spectral range of 800–4000 cm^{-1} was used for the experiments. The optical system was purged with dried air and scrubbed of CO_2 with a Balston FTIR gas-purge generator system. A PIKE Technologies wire grid polarizer was also used to filter out the s-polarized light. Also interfaced to the UHV chamber was an Ar^+ ion gun, a quadrupole mass spectrometer for temperature-programmed desorption (TPD), and low energy electron diffraction (LEED) optics that could be substituted for an Auger system with a cylindrical mirror analyzer. Through a separately pumped gas manifold, Ar for sputtering, O_2 for cleaning, and CO could be introduced to the chamber with the use of leak valves. Two separate leak valves were also available for the introduction of samples to the surface for analysis. Dosing of samples was directed through steel tubes to the surface to ensure surface coverage without chamber contamination.

The Pt crystal, either Pt(110) or Pt(111), was attached to the sample mount (two nickel-coated copper posts) by spot-welding four 0.010 inch (1 inch = 2.54 cm) diameter Pt wire to the back of the crystal. A K-type thermocouple was spot-welded to the edge of the crystal for temperature monitoring. The crystal was initially annealed for 3 days at 1073 K with periodic Ar^+ sputtering to remove impurities from the bulk of the Pt. This was followed by a final annealing at 1273 K for 3 h. The crystals were also cleaned prior to each experiment. The cleaning procedure consisted of Ar^+ sputtering (3 KeV, 6 $\mu A\,cm^{-2}$ at an Ar pressure of 1×10^{-5} torr) at 298–1073 K, followed by annealing in 1×10^{-6} O_2 at 1273 K for up to 30 min. A final annealing at 1373 K for up to 20 min was also performed. The cleanliness of the crystal was checked with LEED and Auger electron spectroscopy (AES). The crystal was determined to be clean and ordered when impurities of carbon, sulfur, and oxygen were not observed with AES and a sharp LEED pattern was observed.[7]

The surface photochemical experiments were performed using a 200 W mercury–xenon arc lamp supplied by Oriel. The lamp was filtered with a series of mirrors and cut-off filters to transmit light from 300 to 400 nm. The light entered the UHV chamber through a quartz window and was focused on the sample through a series of external fused-silica optical lenses.

Methyl diazo(3-pyridyl)acetate (3-PDE)

A procedure adapted from Tomioka et al.[5] was used for the synthesis of 3-PDE. The compound 3-acetyl pyridine (30 g, 0.25 mol) was heated to reflux in morpholine (37.5 g, 0.43 mol) with sulfur (13 g, 0.41 mol) for 6 h in a modified Willgerodt reaction.[8] The mixture was poured onto ice and allowed to stand overnight. The resulting crystals were then filtered and recrystallized from a 50% benzene/petroleum ether mixture to give a pure thioacetomorpholide (63%). The thioacetomorpholide (8 g, 0.036 mol) was heated to reflux in 80 mL of a 50% ethanol/water mixture with excess KOH for 12 h. The water and ethanol were removed and the mixture was taken up in methanol (MeOH), which was acidified with dry HCl. This mixture was then heated to reflux for 24 h. The MeOH was removed and the salt was taken up in water and made basic with solid $NaHCO_3$. The resulting pyridyl ester was then extracted with ether and dried with magnesium sulfate and the ether was removed under vacuum to give a pale yellow liquid. This liquid was distilled at 100 °C at 0.1 mm Hg (1 mm Hg = 133.322 Pa) to give a colorless liquid of methyl (3-pyridyl)acetate (59%). The methyl (3-pyridyl)acetate (2 g, 0.013 mol) was stirred for 3 days at room temperature in 50 mL acetonitrile with tosyl azide (0.026 mol) and 4 g of KF/Al_2O_3 solid support.[9,10] The solid support was then filtered off and the acetonitrile was removed, leaving an orange solid. The solid was chromatographed on silica 60 (80 g silica per 1 g diazoester) with ethyl acetate. The removal of the ethyl acetate left an orange crystal that was shown to be pure methyl diazo(3-pyridyl)acetate (87%). Mp 58–60 °C. UV–vis (MeCN) λ_{max}, nm (ε, L mol^{-1} cm^{-1}): 272 (11800), 248 (12400), 207 (11770). Methyl diazo(4-pyridyl)acetate (4-PDE)

The synthesis of methyl diazo(4-pyridyl)acetate was accomplished using the method described above for the synthesis of methyl diazo(3-pyridyl)acetate, except that 4-acetyl pyridine was used as the starting material. Methyl diazo(4-pyridyl)acetate was isolated as a yellow powder. Mp 84–85 °C. UV–vis (MeCN) λ_{max}, nm (ε, L mol^{-1} cm^{-1}): 280 (14100), 250 (14300), 215 (13000). IR (CCl_4) ν (cm^{-1}): 3062, 3030, 2956, 2846, 2097 (C=N=N), 1719 (C=O),

Results and discussion

Saturated monolayers of analytically pure 3- and 4-PDE on Pt were formed through a sublimation process in a UHV chamber. In this method, the diazoester is introduced from the gas phase where it condenses onto a cooled and cleaned single-crystal Pt(110) or Pt(111) surface at 223 K using a technique we have previously described.[3,6] The multilayers resulting from the sublimation process are thermally desorbed by slowly warming the Pt crystal; the maximum rate of desorption for 3- and 4-PDE was found to be ~266–269 K using TPD and mass spectroscopic (MS) detection of the desorbed molecules. At temperatures above that of the maximum rate of desorption, only molecules chemisorbed on the metal are present. For subsequent experiments, dosing to form the monolayer was accomplished by holding the temperature of the cleaned Pt above the temperature for multilayer desorption, typically 293 K, but below that for any further reaction.

Reflection absorption infrared (RAIR) spectroscopy was used to characterize the resulting saturated monolayers formed using one of the two approaches presented above. The RAIR spectra of the saturated layer of 4-PDE and 3-PDE on Pt(110) are shown in Figs. 1 and 2, respectively. These are presented along with solution-phase transmission IR spectra for comparison. Key IR bands in the monolayer spectra include the C=N=N asymmetric and symmetric stretches at 2098 and 1337 cm^{-1} and 2093 and 1362 cm^{-1}, for 4-PDE and 3-PDE, respectively. The corresponding C=O stretches are at 1712 and 1710 cm^{-1}, respectively. Additional modes due to the C=C and C=N of the pyridyl ring in the range of 1570 and 1440 cm^{-1} are also evident. While there are slight intensity differences in the C=O and C=N=N bands between the solution and monolayer spectra due to the difference in the two experiments (transmission vs. RAIR) there is no significant shift in the position of the IR bands of either the diazo C=N=N or the ester C=O bands; the asymmetric and symmetric C=N=N and C=O bands in the solution-phase transmission spectra occur at 2091, 1361, and 1713 cm^{-1} and 2097, 1358, and 1719 cm^{-1} for 3- and 4-PDE, respectively. Because of this similarity, we conclude that these functional groups do not interact significantly with the metal surface in the monolayer. In the region between 1600 and 1400 cm^{-1}, there are differences on the order of 40–60 cm^{-1} when one compares the corresponding bands in the monolayer spectrum to those in the solution phase. The modes in this region are largely associated with the pyridyl ring. Together, the results indicate that the monolayer is bound through the pyridyl nitrogen, and that the rings have a mostly perpendicular orientation because of the strong $C{\equiv}N_2$ and C=O bands.[11] Similar spectra were recorded for 3- and 4-PDE on Pt(111) and these are provided in the Supplementary data.

Fig. 1. IR spectra of 4-PDE. (*a*) Solution transmission IR spectrum of 4-PDE in CCl_4 at 298 K, 4 cm^{-1}, scaled to fit. (*b*) RAIR spectrum of 4-PDE monolayer on Pt(110) at 298 K, 8 cm^{-1}. (*c*) RAIR spectrum of 4-PDE monolayer after photolysis, 8 cm^{-1}. Inset at top shows an expansion of the region between 2200 and 2000 cm^{-1} illustrating loss of C=N=N asymmetric stretch at 2098 cm^{-1} and growth of C=C=O stretch at 2124 cm^{-1}.

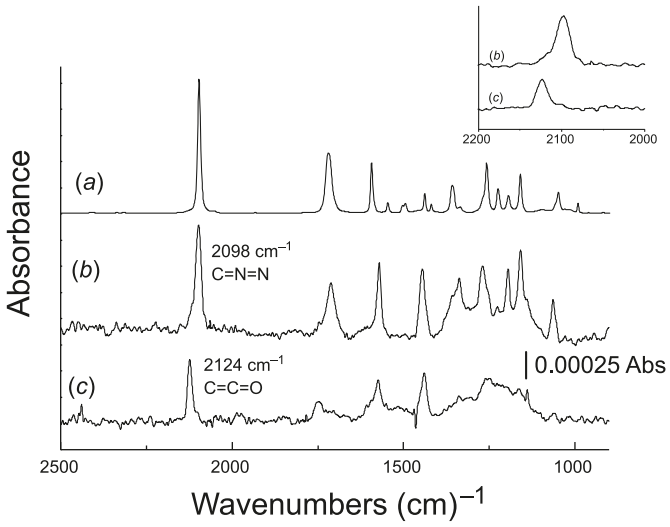

Fig. 2. IR spectra of 3-PDE. (*a*) Solution transmission IR spectrum of 3-PDE in CCl_4 at 298 K, 4 cm^{-1}, scaled to fit. (*b*) RAIR spectrum of 3-PDE monolayer on Pt(110) at 298 K, 4 cm^{-1}. (*c*) RAIR spectrum of 3-PDE monolayer after photolysis, 4 cm^{-1}.

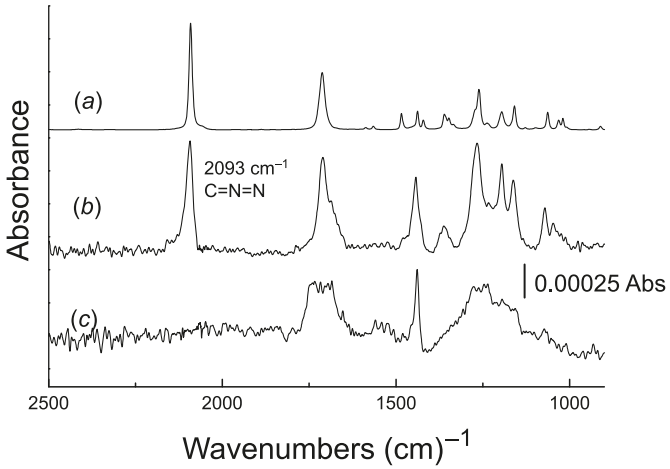

The monolayer was shown to be saturated by co-dosing carbon monoxide onto the monolayer formed as described above. Any available Pt sites would be indicated by the appearance of the Pt–CO stretch;[12] however, no Pt sites were observed. The thermal stability of the saturated monolayer was investigated by TPD experiments and by monitoring changes in the IR spectra as the temperature of the crystal was increased. The TPD spectra monitored several masses that corresponded to the major fragment ions for compounds (*m*/*z* = 106 and 78). The TPD spectra also monitored mass 28 to detect the release of nitrogen gas that evolves during the thermal decomposition of the diazoesters. For 3-PDE, the only detected signal was that of *m*/*z* = 28 and no other changes were detected for the fragments from the 3-PDE pa-

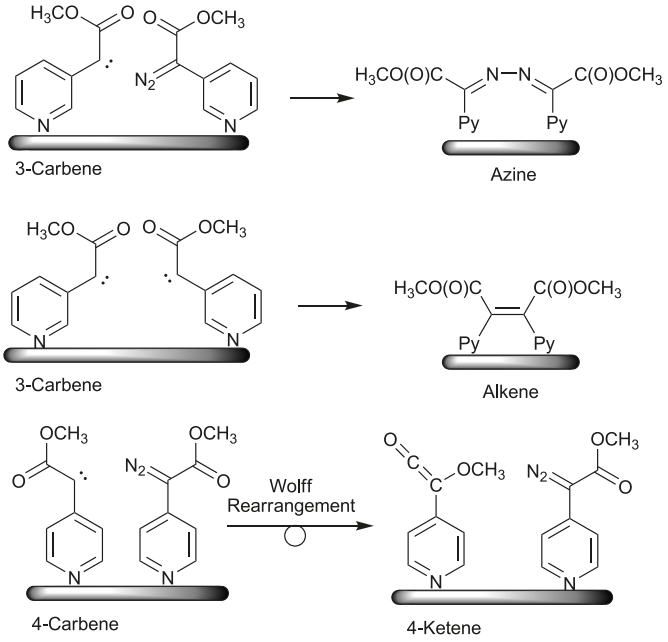
rent molecule. The detection of mass 28 indicated that there was a thermal decomposition of the diazo group during the heating of the monolayer. The onset of the detection occurred at 375 K and reached a maximum at 455 K. This decomposition temperature agrees well with that measured for similar diazoesters such as ethyl diazophenylacetate, where a half-life of 95 min at 373 K has been determined.[13] The fact that no fragments from the parent molecule were detected (m/z = 106 and 78) indicated that the diazo group decomposes on the surface before any desorption of the pyridyl groups occurs. Similar results were obtained for 4-PDE where the onset of the release of nitrogen was observed in the TPD at 390 K with a maximum at 465 K. The similarities between the thermal stability of the diazoesters as saturated monolayers and that measured for similar molecules when not bound to a surface suggest that the Pt surface does not alter the thermal stability of the diazo group, further indicating that this functionality is not interacting with the surface (vide supra). Saturated monolayers are stable indefinitely at temperatures below the temperature of onset of loss of nitrogen. Photoreactions described below were thus performed at 293 K, above the maximum rate of desorption of the multilayer and well below the thermal decomposition temperature.

RAIR spectra measured after irradiation of the saturated monolayers with light of wavelength 300–400 nm are shown in Figs. 1*c* and 2*c*, respectively. Particularly diagnostic during the photolysis in both is the loss of the asymmetric and symmetric C=N=N absorptions and the concomitant change in the C=O region. The loss of nitrogen occurs only during photolysis and this can be monitored by mass spectroscopy. In the case of 4-PDE, there is a concomitant growth of an absorption at 2124 cm^{-1} that can be assigned to the ketene C=C=O stretch.[5,14] The ketene formed remains stable indefinitely. The ketene is the result of the Wolff rearrangement and its observation is surprising because it has only been observed in an Ar matrix at 10 K. Under other conditions at higher temperatures, the ketenes are reactive. On the other hand, for 3-PDE, the ketene stretch does not form and the major change accompanying loss of the diazo stretches is a broadening and shifting of the C=O regions at 1730 cm^{-1} and 1100–1350 cm^{-1}.

The IR spectral changes observed on irradiation of 3-PDE are similar to those measured on irradiation of multilayers of these substrates. In multilayer (and in solid-state irradiations of 3- and 4-PDE),[6] it is easy to establish that the products observed are due to carbene reactions, either coupling to form the alkene or reaction with another 3- or 4-PDE to form an azine. In the multilayer and solid-state reactions, the azine and alkene products can be identified by MS (multilayer) and NMR and IR analytical spectroscopic techniques (solid state). Formation of the carbene and the resulting azine and alkene products on the saturated monolayer are less easy to characterize. The RAIR spectrum obtained (Fig. 2*c*) has less identifiable features. The only characteristic peak is a shifting and broadening of the absorption in the C=O region at 1730 cm^{-1}. A similar RAIR spectrum, with a broadened peak in the C=O region is obtained when the 3-PDE-saturated monolayer is heated above 373 K, the temperature where *thermal* loss of nitrogen occurs. For both the thermal and photochemical experiments, we obtained evi-

Scheme 2. Proposed surface reaction of surface-generated carbene.



dence for the formation of the azine and alkene products from carbene reaction by MS identification of their parent ions (and known major fragments) upon TPD of the photolyzed monolayers. The identification of the alkene and azine molecules was established by monitoring fragments unique to each of the alkene and azine, respectively. The fragmentation pattern for the alkene include major m/z at 298, 270, 267, and 239, while the azines had major m/z at 267 and 207. The parent ion for the azine at 326 amu could not be observed in the electron ionization mode. The fragmentation patterns of the alkenes and azines were determined from the solid-state photolysis experiments.[6] Because m/z 298 and 239 were unique for the alkene and 207 was unique for the azines, these masses were monitored during the TPD for identification of the molecules. Of course, other products from the carbene reacting through other pathways cannot be ruled out.

We attempted to trap the carbene intermediate on the surface by photolyzing the 3-PDE monolayer surface in the presence of an overlayer of known carbene traps, such as methanol, methyl amine (X–H insertion), and benzene (C=C insertion). In each case, the resulting RAIR spectrum looked identical to that shown in Fig. 2*c* (see Supplementary data) and suggests that even in the presence of the overlayer of reactant, the carbene reacts similar to when generated in the absence of the trap. The reasons for this may include that the intramonolayer reactions are faster than the reaction of the generated carbene with the trapping reagent or that the reaction with the trap is hindered because the experiment has to be done at temperatures where the reactant is in the solid state (frozen). Details are provided in the Supplementary data.

Taken together, the experimental evidence suggests that irradiation of the 3-PDE-saturated monolayer results in formation of the carbene that is efficiently scavenged by neighboring 3-PDE or analogous carbene to form alkene and azine structures on the surface (Scheme 2); these structures lead to a broadening of the C=O ester region.

The inescapable conclusion is that the difference in reactivity of 3- and 4-PDE as saturated monolayers of Pt is related to the position of the photoreactive substituent on the pyridyl ring. For 3-PDE, the initially formed carbene is presumably formed in an orientation more closely positioned with respect to its neighbors allowing bimolecular reactions to occur. By contrast, the 4-PDE carbene is held at an orientation where the inefficient Wolff rearrangement, with the migration of the $–OCH_3$ to form ketene, can compete because of the inability of intramonolayer carbene bimolecular reactivity. Besides the remarkable chemoselectivity observed in this study, the observation of the ketene for 4-PDE suggests that for pyridyl substrates, the surface can act to isolate molecules and allow for the characterization of reactive intermediates usually only seen in Ar matrixes. We are currently trying to exploit this possibility in addition to investigating the reactivity of the ketene and carbene monolayers.

Supplementary data

Supplementary data for this article (additional spectra for 3-PDE and 4-PDE on Pt(111), TPD data, tables of IR stretching frequencies with assignments, and details of carbene trapping experiments) are available on the journal Web site (canjchem.nrc.ca).

Aggregation of zinc tetraphenylporphyrin characterized by ensemble and single-molecule fluorescence spectroscopy

Jaclyn A. O'Brien, Yin Lu, Emma N. Hooley, Kenneth P. Ghiggino, Ronald P. Steer, and Matthew F. Paige

Abstract: The aggregation of metalloporphyrins is believed to play a crucial role in the excited-state annihilation process known as triplet–triplet annihilation, which in turn has significant potential applications in photon upconversion schemes. In this work, the propensity of the water-soluble metalloporphyrin zinc (II) *meso*-tetra(4-sulfonatophenyl)porphine to undergo aggregation when adsorbed to glass cover slips was investigated by single-molecule fluorescence microscopy. In proof-of-principle experiments, it was demonstrated (1) that individual molecules of the metalloporphyrin can be directly visualized in spite of their very weak fluorescence emission, and (2) that at low concentrations (10^{-8} mol/L), the molecule has a strong tendency to form multimolecular aggregates. A subset of the multimolecular aggregates shows a significant blue-shift in fluorescence emission, though at present the precise nature of the molecular aggregates remains unclear.

Key words: aggregation, spectroscopy, metalloporphyrin, single-molecule fluorescence, microscopy, photobleaching.

Résumé : On croit que l'agrégation des métalloporphyrines joue un rôle crucial dans le processus d'annihilation de l'état excité, connu comme annihilation triplet-triplet, qui a des applications potentielles dans les schémas de conversion ascendante du proton. Dans ce travail, faisant appel à la microscopie de fluorescence de molécules uniques, on a étudié la propensité d'une métalloporphyrine soluble dans l'eau, le sel de zinc (II) de la *méso*-tétra(4-sulfonatophényl)porphine, à subir une agrégation lorsqu'elle est adsorbée sur des lamelles de verre. Dans des expériences de principe de la preuve, il a été démontré (1) que des molécules individuelles de la métalloporphyrine peuvent être visualisées directement malgré leur très faible émission de fluorescence et (2) que, à très faible concentration (10^{-8} mol/L), la molécule possède une forte tendance à former des agrégats multimoléculaires. Un sous-ensemble d'agrégats multimoléculaires présente un déplacement important vers le bleu dans l'émission de fluorescence, même si pour le moment, la nature précise de l'agrégat moléculaire n'est pas claire.

Mots-clés : agrégation, spectroscopie, métalloporphyrine, fluorescence de molécule unique, fluorescence, microscopie, photoblanchiment.

Introduction

Intermolecular aggregation, both in solution and in solid media, plays an important role in a wide range of photochemical and photophysical phenomena. Of particular recent interest has been the influence of intermolecular aggregation on excited-state annihilation processes,[1–4] in part because of the potential application of these processes in non-coherent photon upconversion, the conversion of low-energy photons into high-energy photons. Photon upconversion has been proposed as an approach to enhance the energy conversion efficiency of dye-sensitized solar cells, and as such is an area of intense research interest and societal importance. At present, a number of groups are actively investigating the importance of intermolecular aggregation on the excited-state annihilation process known as triplet–triplet annihilation (TTA; schematically written as $2T_1 \rightarrow S_n\ (n \geq 1) + S_0$) because TTA holds significant practical promise for implementation in solar photon upconversion schemes, particularly in the photon-rich red and near-infrared regions of the solar spectrum.

Metalloporphyrins are arguably the most thoroughly investigated class of molecules for TTA upconversion schemes, in part because homomolecular TTA in porphyrins can populate higher excited states (S_n, $n = 1$) and potentially gather a larger fraction of the absorbed photon energy than systems in which $n \leq 1$ are the product states. Recently, Baluschev investigated TTA in a mixed Pt (or Pd) metalloporphyrin sensitizer and blue-emitter system in solution and

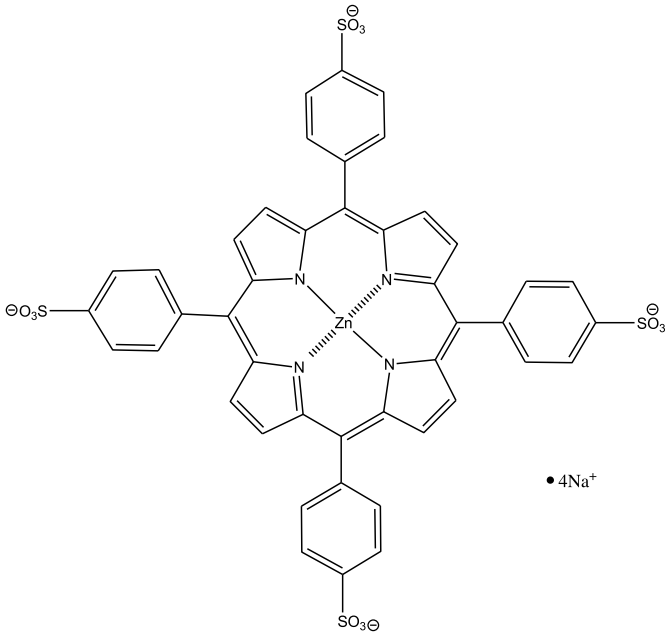
solid state, and proposed several schemes that give rise to photon upconversion.[1,2] The first involves homomolecular TTA between metalloporphyrins to yield an S_2 state, followed by intermolecular energy transfer (resonant) to the blue emitter compound, and the second requires heteromolecular energy transfer between the photoexcited sensitizer and blue emitter, leading to a triplet-state blue emitter, followed by homomolecular TTA in the blue emitter to yield a final blue emitter S_1 state. However, recent publications by Steer and co-workers[4–6] have called into question these mechanisms and suggested that aggregation of the porphyrin sensitizer (and (or) the acceptor, for the mixed sensitizer and emitter system) must be taking place for TTA to occur at the observed efficiencies. Experimental evidence for porphyrin aggregation under a variety of conditions has been reported previously by other researchers.[7–10] Furthermore, Steer and co-workers have reported aggregation of closed-shell zinc *meso*-tetraphenylporphine (ZnTPP) in thin poly(methyl methacrylate) (PMMA) films that exhibit TTA.[5] Evidence for aggregation included Soret absorption band widths that increased as a function of ZnTPP loading with no corresponding emission band broadening, and the ratio of emission to absorption band intensities (proportional to quantum yield at low dye loading levels) decreasing with the extent of dye loading, indicating self-quenching of the ZnTPP. Furthermore, fluorescence lifetime measurements of ZnTPP in PMMA give bi-exponential decays, with decreasing lifetime as a function of dye loading levels, which again is entirely consistent with intermolecular aggregation effects.

To gain further direct evidence for porphyrin aggregation in solid systems, we have applied a combination of ensemble and single-molecule fluorescence spectroscopy methods to samples of zinc (II) *meso*-tetra(4-sulfonatophenyl)porphine (ZnTPPS; structure shown in Fig. 1), a water-soluble variant of the model metalloporphyrin ZnTPP, immobilized on glass cover slips. Single-molecule fluorescence spectroscopy is an experimental approach in which the fluorescence emission of individual molecules is observed, typically through the use of ultrasensitive, laser-based fluorescence microscopy on highly diluted (10^{-8}–10^{-9} mol/L) samples.[11,12] Detecting the extremely low levels of fluorescence emission from an individual fluorophore is possible only through careful selection of fluorophores and detection systems; one seeks to minimize unwanted background fluorescence through the use of ultraclean samples while maximizing fluorescence signals through the use of high numerical aperture oil-immersion objective lenses, low noise, high-gain photodetectors, and fluorophores with sufficiently good spectroscopic properties.

Maximizing fluorescence signals is the primary challenge that one is faced with when applying single-molecule fluorescence approaches to detection of ZnTPP, its derivatives, and its aggregates. Typical fluorophores used in single-molecule measurements have high absorption cross-sections, high fluorescence quantum yields (and correspondingly long excited state lifetimes), an absence of triplet bottlenecks, and low photobleaching quantum yields. Although a wide range of fluorophores have been used (laser dyes and related fluorescent labels, autofluorescent proteins, and others[13]), metalloporphyrins, and ZnTPP in particular, would appear, at least upon initial inspection, to be challenging fluorophores for these measurements. ZnTPP has an S_1 fluorescence quantum yield of ~0.04[5,14] and a high intersystem crossing yield (ideal for a high triplet yield in TTA applications, but undesirable for single-molecule fluorescence, as these are "dark" states) and is known to undergo photodegradation in the presence of oxygen.[15] The molar extinction coefficient in the Q-band is typically modest (ε_{max} ~3000 cm^{-1} $(mol/L)^{-1}$ in water; see Fig. 2), though reasonably efficient Q-band excitation is possible through the use of a CW solid-state diode laser.

Fig. 1. Chemical structure of zinc (II) *meso*-tetra(4-sulfonatophenyl)phenylporphine.



Although the task of measuring individual ZnTPPS molecules and aggregates of the metalloporphyrin appears daunting in the face of this evidence, a series of recent publications by Kim[16–21] in which the single-molecule emission of covalently linked porphyrin arrays was reported suggest that these measurements might indeed be feasible. Of particular interest is a report by Kim in which the emission from linked zinc metalloporphyrin arrays (containing $n = 1$ up to $n = 96$ porphyrin monomer units) was observed.[16] In these systems, fluorescence time trajectories displayed steps corresponding to the photobleaching of individual zinc porphyrin units, up to $n = 8$ monomer units. After this limit had been reached, more complex photobleaching behavior was observed, which was explained by means of an excitonic coupling model. The observation of discrete steps in these array systems (albeit with a signal-to-noise ratio that was not ideal) provides reasonable hope that individual ZnTPPS molecules, as well as aggregates that contain a small number of molecules, can be detected and characterized through single-molecule fluorescence techniques.

On the basis of these results, we have carried out a combination of single-molecule and ensemble fluorescence measurements in an attempt to characterize the aggregation state of ZnTPPS at low concentrations (10^{-8} mol/L) on glass cover slips. Our selection of the water-soluble ZnTPPS over ZnTPP was made because of experimental limitations (many of the common organic solvents used to dissolve ZnTPP are

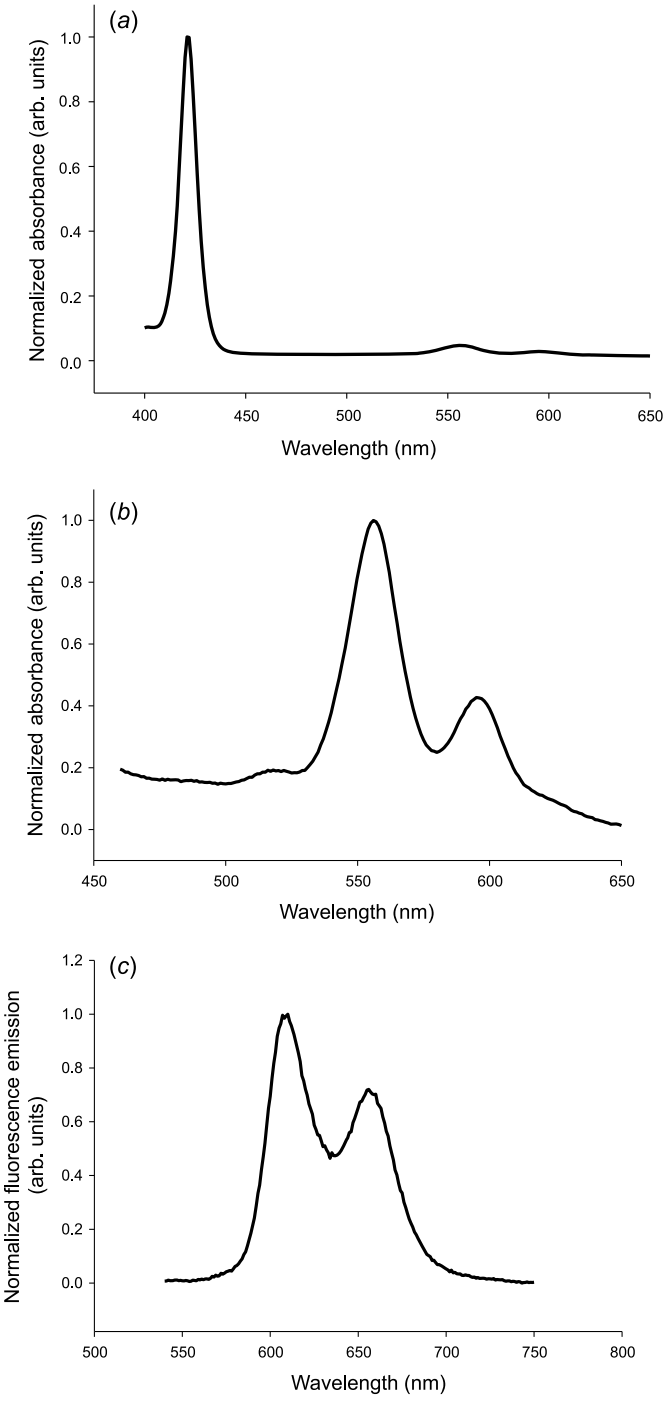
Fig. 2. (*a*) Expanded-scale absorption spectrum of ZnTPPS in water (1×10^{-5} mol/L) displaying both B- and Q-bands. (*b*) Absorption spectrum of ZnTPPS in water displaying the Q-band region of the spectrum. (*c*) Emission spectrum of ZnTPPS in water (5×10^{-4} mol/L). Fluorescence excitation was performed at 532 nm to provide a close spectral match to the excitation laser used in subsequent microscopy and spectromicroscopy measurements. Q-band emission has not been corrected for re-absorption events.



heavily contaminated with fluorescent impurities, making single-molecule measurements of such weakly fluorescent molecules extremely difficult), as well as because ZnTPPS has previously been reported to undergo a considerable amount of aggregation in aqueous solution (for a review of this and other relevant aggregation behavior see the review by Harvey[7]), thereby providing a simple method to ensure at least some degree of metalloporphyrin aggregation. Single-molecule epifluorescence microscopy has revealed the presence of both individual ZnTPPS molecules and multimolecular aggregates at the concentration regime investigated, providing direct supporting evidence of porphyrin aggregation at even these low concentrations. Further spectroscopic characterization of the aggregates (emission spectra) was carried out through spectromicroscopic characterization.

Materials and methods

Sample preparation

Samples were prepared by dissolving ZnTPPS (Frontier Scientific) in water (Millipore, resistivity 18 MΩ·cm) to a final concentration of ~10^{-8} mol/L. Glass cover slips (borosilicate float glass, VWR Scientific) were cleaned by repeated passes through the flame of a propane torch before sample deposition. Solutions were spin-cast onto the clean glass cover slips and imaged directly in the single-molecule microscope. Control samples of the cover slips alone and cover slips that had been treated with solvent alone showed no significant impurities when imaged in the fluorescence microscope.

Fluorescence microscopy

Single-molecule fluorescence imaging experiments were carried out on a wide-field epifluorescence microscope. A CW solid-state diode laser (532 nm, vertical polarization, Dragon Lasers) was focused onto the back focal plane of a 60×, 1.4NA oil-immersion microscope objective (PlanApo, Nikon) and fluorescence emission was passed through 2 long-pass filters (540LP, Omega Optical) before being focused onto an electron multiplying CCD camera (Cascade 512F, Photometrics).

For spectromicroscopy measurements, the microscope layout was altered. The excitation laser was focused via the oil-immersion objective into a small (estimated ~2 μm) spot; fluorescence emission was passed through the same long-pass filters as described above and then focused into an imaging spectrograph (MS125 Spectrograph, Newport (Oriel) Instruments). The spectrograph output was imaged onto an electron multiplying CCD camera (iXon, Andor Technology) and converted into a 2D spectrum of the region of interest. The wavelength of the instrument was calibrated with an Hg pen lamp. Since the quantum yield of the CCD camera does not change substantially over the spectral region of interest, there was no need to correct spectral data for the wavelength-dependent response of the photodetector. For spectromicroscopy measurements, a frame exposure time of 100 ms was used, and CCD pixels were binned to ensure maximum possible signal-to-noise ratio in the collected emission spectra.

Results and discussion

Absorption and emission spectra of ZnTPPS in ultrapure water were collected and are shown in Fig. 2. The absorption spectrum of ZnTPPS consisted of 2 well-defined bands

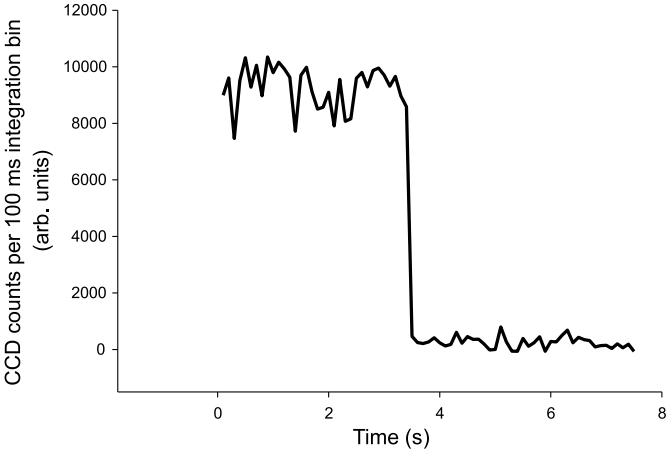
For personal use only.

(B-band and Q-band), the first centered at 421 nm and the second (2 peaks) at 557 nm and 596 nm, which is consistent with other metalloporphyrin absorption spectra found in the literature. Extinction coefficients of 3165 cm^{-1} $(mol/L)^{-1}$ and 1457 cm^{-1} $(mol/L)^{-1}$ were measured at 596 nm (the 0–0 transition from S_0 to S_1) and 532 nm (laser excitation wavelength used for fluorescence microscopy measurements), respectively. Again, the magnitude of the ε_{max} is quite modest, suggesting that the single-molecule fluorescence measurements will be challenging. For comparison purposes, consider the approximate difference in fluorescence signal that might be anticipated between ZnTPPS and an excellent laser dye such as R6G: R6G, a good dye for single-molecule measurements, has a molar absorptivity of ~63 000 cm^{-1} $(mol/L)^{-1}$ at 514 nm (limiting extinction coefficients for organic molecules with oscillator strengths $f = 1$ are approximately 10^5 cm^{-1} $(mol/L)^{-1}$), an excitation wavelength that is readily accessible with an argon-ion laser, and a fluorescence quantum yield in ethanol of 0.95.[14] Accounting for the differences in molar absorptivity and fluorescence quantum yield, one estimates that the approximate fluorescence intensity difference between R6G and ZnTPPS should be ~3 orders of magnitude. While R6G is readily detected in single-molecule fluorescence measurements, compensating for the anticipated 3 orders of magnitude loss in signal represents a considerable technical challenge. Details explaining how this challenge was met are described later in this manuscript. The fluorescence emission spectrum of ZnTPPS upon excitation at 532 nm consisted of 2 well-defined peaks at 610 nm and 656 nm, which is again consistent with reports found in the literature.

Heavily diluted samples of ZnTPPS (10^{-8}–10^{-9} mol/L) were deposited on clean glass cover slips and imaged in the single-molecule microscope. Extensive control testing was performed to ensure that any emission observed in these samples was from ZnTPPS alone, and not from any fluorescent contaminants that might be found in solvents or on cover slips or transferred from glassware or other sources. Control samples of the cleaned cover slips alone and cleaned cover slips that had been dosed with aliquots of fresh Millipore water (the solvent used for ZnTPPS) were tested rigorously for contamination. It is common in many single-molecule measurements to spin-cast a thin polymer layer onto the dye-covered cover slips to minimize exposure of fluorophores to oxygen and thereby decrease photobleaching. However, for these measurements, a polymer layer was not used because control experiments revealed extensive contamination of the polymer at the single-molecule level. It is worth noting that trace-level contamination of organic solvents and polymers places considerable limits on the range of samples and systems that can be investigated by single-molecule fluorescence. In many cases, the source of these contaminants is not clear (though for organic solvents, likely contributors are the products of photochemical-based radical reactions as well as trace levels of antioxidants added to minimize potential formation of peroxides), and this is an area of technical development that needs considerable attention to forward the field of research.

Samples prepared as described above yielded discrete, luminescent spots (~300 nm, as dictated by the diffraction limit of ~$\lambda_{exc}/2$) on a dark background when imaged in the single-molecule microscope. Time trajectories (Fig. 3), that is, plots showing fluorescence emission as a function of time, were collected for the luminescent spots and analyzed. In general, the luminescent spots demonstrated two different types of photobleaching behavior: one group photobleached in a single step and the other group photobleached in a more complex manner, either through multiple steps or through a gradual (approximately exponential) decrease in signal. There was typically a ~3:1 ratio of single-step photobleaching entities to more complex photobleaching entities observed per image. Single-step photobleaching in conjunction with low fluorophore concentration and diffraction-limited spots is a strong signature of individual molecules; therefore, we consider the spots that photobleached in a single step to be due to individual ZnTPPS molecules. Molecules that photobleached in a single step generally remained non-emissive for the remainder of the experiment and rarely exhibited repeated on–off "blinking", which has been reported in some other single-molecule systems.[11,13]

Fig. 3. Single-molecule fluorescence time trajectory for an individual molecule of ZnTPPS dispersed on clean glass cover slip substrates. The fluorescence intensity is plotted as CCD counts per 100 ms integration bin (arbitrary units) after subtraction of the mean background signal. The excitation intensity was 1.0 kW/cm^2, as determined by measuring laser power at the focal plane divided by the illumination area.



Before examining the fluorescent properties of individual ZnTPPS molecules in greater detail, it is worth considering more carefully some of the technical aspects of the microscopy experiments that made visualization of such a weakly fluorescent fluorophore possible. First, we have made use of the largest possible illumination intensity that could be used without immediately photobleaching the sample (typical fluorophores emit ~10^6 photons prior to photobleaching, with higher incident photon flux resulting in larger fluorescence signals but more rapid photobleaching). The illumination intensity was optimized such that the majority of molecules measured emitted for at least several CCD frame periods (100 ms integration period per frame) prior to photobleaching. Next, contamination issues aside, foregoing the use of a protective polymer layer reduces background scattering and hence results in improved signal-to-background ratios, though again, with commensurate increases in photobleaching rates. An additional key factor in these experiments, and

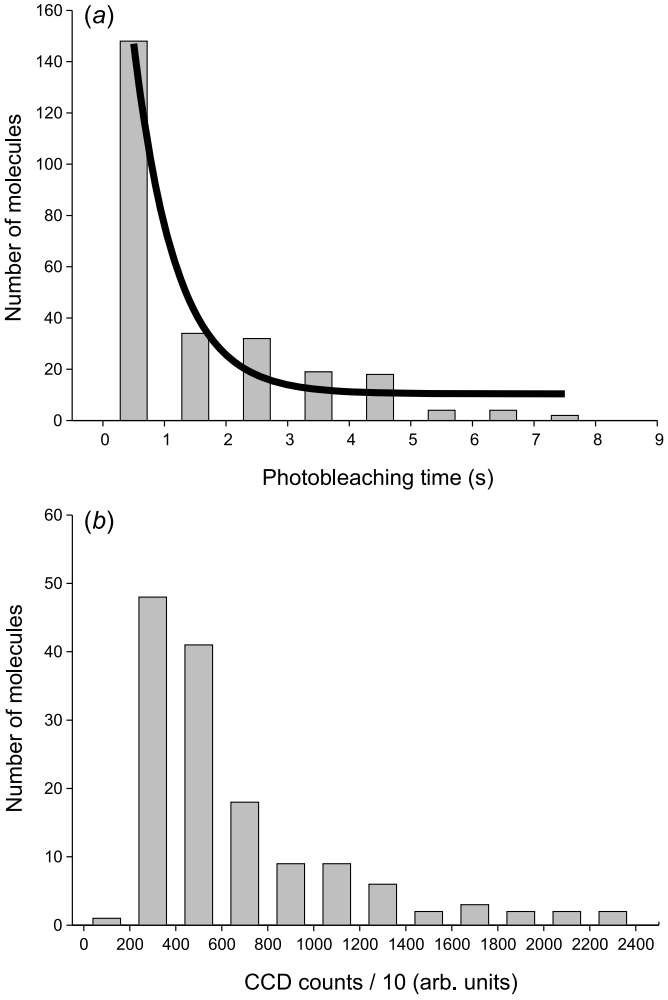
one that is often overlooked in single-molecule imaging, are recent improvements in the performance characteristics of fluorescence emission filters. Recent innovations in dielectric emission filter technology (see, for example, the 3RD Millennium line of filters from Omega Filters) have enabled the production of filters with much sharper cutoff frequencies, improved transmission properties, and greater attenuation than filters of previous generations. The primary role of the emission filter in single-molecule imaging is to remove scattered laser excitation light from the measurement, and steeper cutoff frequencies allow the selection of filters whose spectral cutoffs are extremely close (in some cases several nanometres) to the excitation wavelength. This in turn allows a greater fraction of the total fluorescence emission to be passed to the detector, resulting in substantially greater signals. Improved transmission properties of emission filters also give greater signal intensities in single-molecule imaging experiments, and these factors in combination contribute significantly to the successful visualization of such weak fluorophores.

By measuring large numbers of individual ZnTPPS molecules (entities that photobleached in a single step), histograms of useful spectroscopic parameters can be constructed. Figures 4*a* and 4*b* show histograms of single-molecule photobleaching times and single-molecule fluorescent intensities, respectively. The photobleaching time data are well represented by a single-exponential decay curve ($N = A_0\exp(-t/\tau_{on})$, where N is the number of molecules, A_0 is a fitting constant, and τ_{on} is a photobleaching time constant equal to 0.7 s), suggesting the existence of a single population of emitters adsorbed on the glass surface. For comparison purposes, previous measurements of R6G imaged under comparable illumination intensities but in the presence of a protective polymer coating gave a $\tau_{on} = 2.0$ s, indicating that ZnTPPS is less photostable than good organic dye molecules.[22] As stated previously, the participation of metalloporphyrin in oxygen-based photochemical reactions is well documented, consistent with its low photostability in single-molecule measurements.

In terms of fluorescence intensities (Fig. 4*b*), experimental results are again consistent with the existence of a single population of emitters on the glass substrates. Mean signal intensities were equal to ~4500 counts per 100 ms integration bin. It is notable that these intensities are comparable with those we have reported previously for a rhodamine-like calcium ion sensor (Calcium Green-1),[23] albeit with a significantly higher photobleaching rate and a significantly greater illumination intensity. While it is difficult to compare measurements quantitatively between different microscope setups and illumination conditions, we also note that our signal-to-noise ratios appear to be significantly better than those reported by Kim[16] in his initial investigations of metalloporphyrin-based arrays, though this is based only on inspection of a few published fluorescence time trajectories.

A similar analysis was undertaken for the second type of photobleaching behavior, in which more complex fluorescence trajectories were observed. Unlike for the single-molecule data, a wide variety of photobleaching behaviors were observed for this set of entities, 2 examples of which are shown in Figs. 5*a* and 5*b*. In the case of the trajectory shown in Fig. 5*a*, 3 clear-cut photobleaching events occur

Fig. 4. (*a*) Histogram of photobleaching times for individual ZnTPPS molecules collected from time trajectories. Excitation intensity was 1.0 kW/cm^2. Data have been fit with a single-exponential function ($N = A_0\exp(-t/\tau_{on})$), where τ_{on} is the photobleaching time constant. The photobleaching time constant was calculated to be $\tau_{on} = 0.7$ s. (*b*) Histogram of individual ZnTPPS molecule fluorescence intensities (measured in CCD counts / 10 (arbitrary units)).



sequentially, suggesting that the spot is due to an aggregate containing at least 3 independently radiating ZnTPPS molecules. Similar multiple-step photobleaching events have been reported in a number of single-molecule studies of multifluorophoric systems (see refs. 24 and 25, for example), including the low-monomer-number porphyrin arrays of Kim.[16] Finally, in still other systems, there have been demonstrations of more complex excitonic coupling between subunits, often resulting in collective photobleaching of the entire aggregate via the formation of exciton trap states.[24–26] However, this behavior is typically observed in highly organized antenna array-like systems rather than the nonspecific molecular aggregates that are likely formed here. The time trajectory shown Fig. 5*b* exhibits more complex behavior (in some instances, fluorescence intensity increases with time), though there are fluctuations in these trajectories that suggest the photobleaching of discrete molecular subunits. We note that substantially larger and brighter aggregates

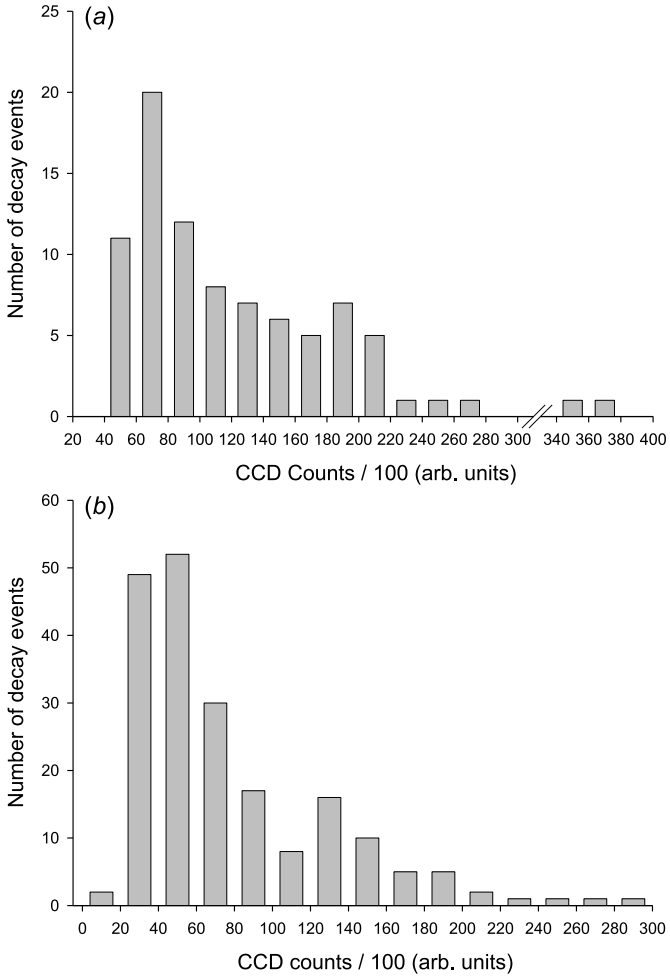
The excitation intensity was 1.0 kW/cm^2.



can be formed in this system through controlling the concentration of the dye solution.

A substantial fraction of the aggregates that were measured exhibited one or more quantized, step-like decay stages and were amenable to further analysis. The total fluorescence intensities of the aggregates as well as the intensities for individual photobleaching steps were determined and are shown as histograms in Figs. 6*a* and 6*b*. While the total intensity of an aggregate was greater than the intensity of an individual molecule, the intensity histogram for the individual photobleaching steps in the aggregate was comparable with the intensity histogram for the single-molecule measurements (Fig. 4*b*). There are several key points that can be extracted from these measurements. The first is that, given the correlation between the fluorescence intensity histograms, the individual photobleaching steps in the aggregates are likely caused by the photobleaching of individual molecules in the aggregate. In addition, given that independent photobleaching steps are detectable and there was no observable tendency for the aggregates to undergo collective photobleaching, it seems reasonable to assume that exciton coupling is of negligible importance in these aggregates, suggesting perhaps that they are not due to stacked arrays. Finally, since the aggregates themselves have a greater intensity than the individual constituent molecules, there appears to be minimal quenching upon aggregation, though of course this might simply be a selection bias of the experiment; if the emission is sufficiently quenched, then the aggregates will not be observable under these conditions.

To directly examine the effect of aggregation on the emission spectrum of the ZnTPPS aggregates, spectromicroscopic characterization was performed using a modified version of the fluorescence microscope setup. In these measurements, the excitation beam was focused into a small (~2 μm) spot and the fluorescence emission dispersed via a spectrograph onto an electron multiplying CCD detector. Although the spectromicroscopy setup was not sufficiently optimized for single-molecule fluorescence detection, the system was capable of measuring emission spectra from the more strongly fluorescent ZnTPPS aggregates when sufficiently high illumination intensities were used. A typical

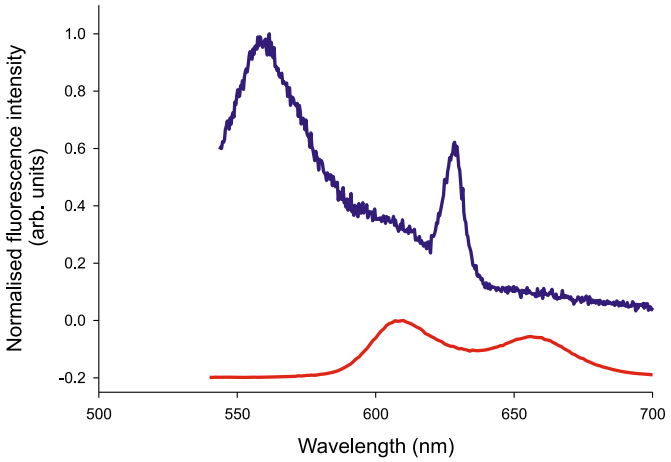
Fig. 7. Fluorescence emission spectrum of ZnTPPS aggregates taken from sample prepared at 1×10^{-8} mol/L concentration via spectromicroscopy (blue; excitation intensity = 17.0 kW/cm^2). For comparison purposes, the ensemble emission spectrum taken in water using a spectrofluorimeter is also shown (red). The sharp peak located at 629 nm in the blue spectrum is caused by Raman scattering from the glass cover slip.



emission spectrum from an aggregate is shown in Fig. 7; the bulk emission spectrum of ZnTPPS in water collected on a spectrofluorimeter is also shown (in red) for comparison purposes. The emission spectrum for the aggregates consisted of 2 strong bands, the first a broad band with a maximum at 562 nm and the second a sharp band with a maximum at 629 nm. Control experiments with a clean cover glass that had been dosed with water yielded a similar sharp peak at 629 nm, suggesting that this peak is caused by Raman scattering (observable because of the high excitation intensity, 17 kW/cm^2, used in these experiments) rather than fluorescence emission from the metalloporphyrin. The 562 nm band had a broad shoulder centered at ~600 nm, though the component peaks were strongly overlapped and resolving individual peak maxima was difficult. The peak separation is consistent with that measured for the two Q-bands in the absorption spectrum, and it is likely that these are the corresponding Q-band emission peaks. It is worth noting, however, that the emission spectrum collected from the spectromicroscopy measurements is significantly blue-shifted with respect to the ensemble counterpart measured in water (610 nm and 656 nm, respectively).

While spectral data for this system are currently limited and should be considered preliminary, we note that reports of J- and H-aggregate formation as well as nonspecific aggregates in metalloporphyrin systems are plentiful in the literature.[7–10,27] In comparison with the literature results, the precise nature of the aggregates formed in these experiments is currently unclear. For example, porphyrin dimers and trimers are known to exhibit significant blue-shifts of Soret absorption bands upon face-to-face π aggregation with an accompanying quenching in fluorescence.[7] While we are unable to carry out absorption measurements on the individual aggregates, the emission spectra show a significant blue-shift with respect to the ensemble measurements, and the samples are easily detected in the system, suggesting that quenching is minimal. However, as stated previously, these measurements may well be preferentially selecting for the most strongly fluorescent aggregates and few conclusions as to the precise nature of the aggregates can be made at this time. Further spectral analysis of the aggregates, in conjunction with ultrasensitive fluorescence lifetime imaging measurements, will provide greater insight into the precise nature of the aggregation state of the metalloporphyrin. It should also be noted that attempting to extrapolate these results to ZnTPP in polymer (the systems that were used to demonstrate TTA) must be done with considerable caution, because the sulfate functional groups that render ZnTPPS soluble in aqueous solution are likely to promote aggregation of the chromophore. Furthermore, direct adsorption of ZnTPPS to the hydrophilic glass surfaces may also give rise to aggregation. Therefore, these experiments should be considered only as proof-of-principle demonstrations of the single-molecule methodology for porphyrin analysis. Nonetheless, this approach has been successful in this regard and holds considerable promise for providing insight into porphyrin aggregation and the influence of aggregation on fluorescence upconversion processes.

Summary

Individual molecules and multimolecular aggregates of zinc (II) *meso*-tetra(4-sulfonatophenyl)phenylporphine deposited onto glass cover slips have been examined by single-molecule fluorescence microscopy and spectromicroscopy. Although the procedure is experimentally challenging, individual molecules of ZnTPPS can be visualized through careful optimization of single-molecule imaging parameters including sample preparation, illumination intensity, and selection of emission filters. Multimolecular aggregates of ZnTPPS photobleach in a complex manner, though in many cases their fluorescence time trajectories contain discrete photobleaching steps that correspond to the photobleaching of individual molecules. The more strongly fluorescent aggregates could be examined by spectromicroscopy, and the emission spectrum of these aggregates exhibited a significant blue-shift in comparison with the emission spectrum collected from standard fluorimeter-based ensemble measurements. These measurements show that metalloporphyrin aggregation occurs and is detectable even at 10^{-8} mol/L concentration, suggesting that the single-molecule fluorescence approach is a viable one for investigating the importance of metalloporphyrin aggregation in fluorescence upconversion schemes.

Photogeneration and reactivity of acyl nitroso compounds

Anthony S. Evans, Andrew D. Cohen, Zachary A. Gurard-Levin, Naod Kebede, Tevye C. Celius, Alexander P. Miceli, and John P. Toscano

Abstract: Acyl nitroso compounds have been generated by photolysis of several different classes of precursors including 9,10-dimethylanthracene adducts, nitrodiazo compounds, and 1,2,4-oxadiazole-4-oxides. Consideration of the nitronate-like resonance structure of nitrodiazo compounds led to an examination of the photochemistry of nitronates with α-leaving groups. Photolysis of such nitronates has been shown to generate an acyl nitroso species along with a carbene intermediate. Nanosecond time-resolved infrared (TRIR) spectroscopy has been used to detect photogenerated acyl nitroso compounds directly and to examine their reaction kinetics with amines and thiols. The mechanism of acyl nitroso aminolysis by primary amines involves general base catalysis, while the mechanism of aminolysis by secondary amines is strictly bimolecular. Thiols do not seem to be reactive with acyl nitroso compounds on the microsecond time scale, but thiolates are quite reactive. The reaction between benzoyl nitroside and an organic-soluble thiolate, tetrabutylammonium dodecanethiolate, proceeds via a proposed tetrahedral intermediate, which is observable by TRIR spectroscopy.

Key words: acyl nitroso, nitrodiazo, nitronate photochemistry, 1,2,4-oxadiazole-4-oxides, time-resolved IR spectroscopy.

Résumé : On a généré des composés acylnitroso par photolyse des plusieurs classes différentes de précurseurs, y compris des adduits du 9,10-diméthylanthracène, des composés nitrodiazo et des 4-oxydes de 1,2,4-oxadiazoles. Une considération de la structure des composés nitrodiazo qui est similaire à la structure de résonance des nitronates a conduit à un examen de la photochimie des nitronates possédant un groupe partant en position α. On a montré que la photolyse de tels nitronates conduit à la formation d'espèces acylnitroso aux côtés d'un intermédiaire carbène. On a fait appel à la spectroscopie infrarouge résolue en fonction du temps (IR-RT) pour détecter directement les composés acylnitroso photogénérés et pour déterminer la cinétique de leurs réactions avec des amines et des thiols. Le mécanisme de l'aminolyse d'un acylnitroso par les amines primaires implique une catalyse basique générale alors que le mécanisme de l'aminolyse d'un acylnitroso par les amines secondaires est strictement bimoléculaire. Les thiols ne semblent pas être réactifs vis-à-vis des composés acylnitroso à l'échelle de temps de la microseconde, mais les thiolates sont très réactifs. La réaction entre le nitroside de benzoyle et le thiolate organique soluble, décanethiolate de tétrabutylammonium, se fait par le biais d'une intermédiaire tétraédrique que l'on peut observer par spectroscopie IR-RT.

Mots-clés : acylnitroso, nitrodiazo, photochimie du nitronate, 4-oxydes de 1,2,4-oxadiazoles, spectroscopie infrarouge résolue en fonction du temps (IR-RT).

[Traduit par la Rédaction]

Introduction

Acyl nitroso (*C*-nitrosocarbonyl) compounds (**1**) are transient electrophiles that were originally proposed as intermediates in the pyrolysis of alkyl nitrites in the presence of aldehydes[1] as well as in the oxidation of hydroxamic acids.[2–4] Seminal work strongly suggesting the intermediacy of acyl nitroso compounds in the oxidation of hydroxamic acids was reported in a series of papers by Kirby[5] and Kirby and Sweeney.[6,7] Building on previous studies of the dienophilic character of nitrosyl cyanide, it was reasoned that the electron-withdrawing character of the carbonyl functionality ought to render acyl nitroso species reactive in [4 + 2] cycloadditions as well. Indeed, the mild periodate oxidation of aceto- and benzohydroxamic acid in the presence of a variety of conjugated dienes such as 9,10-dimethylanthracene (DMA) yields the Diels–Alder product **2** in high yield (Scheme 1). Further studies with these Diels–Alder adducts revealed that they can undergo a retro-Diels–Alder reaction at elevated temperatures and that the generated acyl nitroso intermediate could be trapped by a different diene.[7]

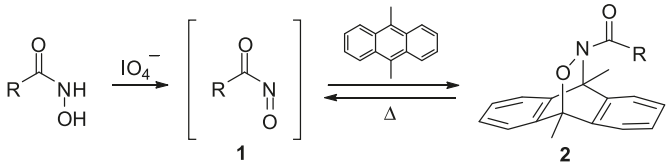
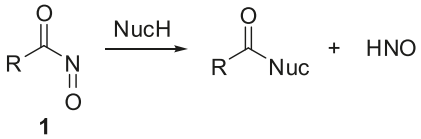
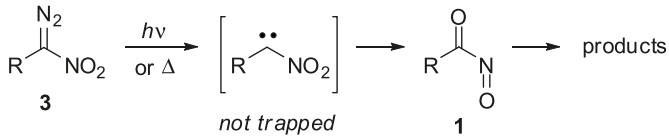
Scheme 1. The oxidative generation of acyl nitroso compounds (**1**) and subsequent reaction with DMA to form Diels–Alder adducts (**2**).



Scheme 2. The reaction of acyl nitroso compounds (**1**) with nucleophiles to generate HNO.



Scheme 3. The generation of acyl nitroso compounds (**1**) from nitrodiazo precursors (**3**).



Reactions of acyl nitroso species with nucleophiles had been suggested by initial observations but were more carefully examined by Corrie et al.[8] Periodate oxidation of benzohydroxamic acid in aqueous media yields predominantly benzoic acid, while tetraalkyl-ammonium periodate oxidation in dichloromethane yields *O*-benzoylbenzohydroxamic acid. Atkinson et al.[9] studied the reaction of acyl nitroso compounds with amines to give amides in reasonable yields. Clearly, **1** is able to acylate nucleophiles such as water, hydroxamic acids, and amines, presumably with concomitant generation of nitroxyl (HNO) (Scheme 2). The detection of nitrous oxide (N_2O), the product of HNO dimerization and subsequent dehydration, in the reaction of **1** with amines is consistent with HNO formation.[9]

Acyl nitroso species have also been proposed as intermediates in the decomposition of nitrodiazo compounds (**3**). Although nitrocarbene intermediates can be trapped following rhodium-catalyzed decomposition,[10–14] thermolysis or photolysis leads only to acyl nitroso-derived products (Scheme 3).[15,16] Calculations predict that singlet nitrocarbene has little to no barrier to rearrangement to nitrosoformaldehyde.[17]

Quadrelli et al. have developed 1,2,4-oxadiazole-4-oxide derivatives (**4**) as efficient photochemical[18] and thermal[19] precursors to acyl nitroso compounds (Scheme 4), and Quadrelli and Caramella[20] have made use of these precursors in a wide variety of synthetic applications. We have recently utilized 3,5-diphenyl-1,2,4-oxadiazole-4-oxide (**4**, R = Ph) in the first direct observation of an acyl nitroso species in solution by nanosecond time-resolved infrared (TRIR) spectroscopy.[21] In this study, the strongest diagnostic signal for benzoyl nitroside (**1**, R = Ph) appeared at 1735 cm^{-1}; it was produced faster than the time resolution of our spectrometer ($k_{obs} > 2.0 \times 10^7$ s^{-1}) and was stable for at least 1 ms in the absence of nucleophiles.

Scheme 4. The generation of acyl nitroso compounds (**1**) from 1,2,4-oxadiazole-4-oxide derivatives (**4**).

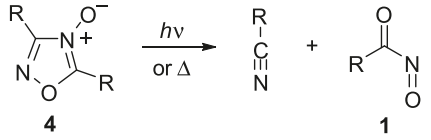


Fig. 1. TRIR difference spectra averaged over the time frames indicated following laser photolysis (266 nm, 5 ns, 3 mJ) of a 5 mmol L^{-1} solution of **2** (R = Ph) in dichloromethane.

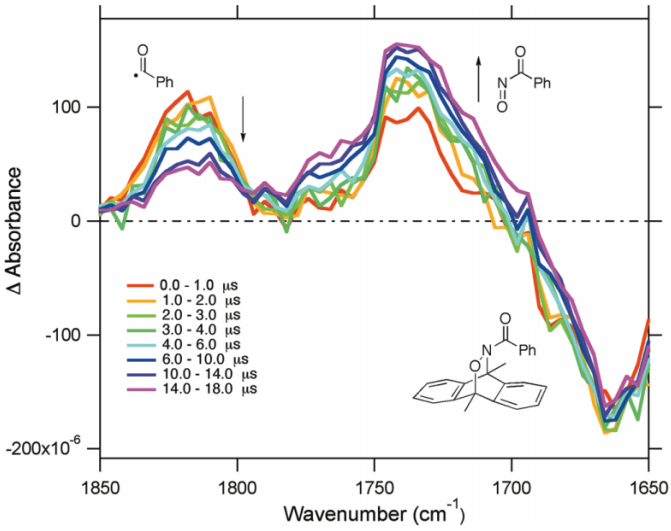

In this manuscript, we are pleased to extend our original TRIR studies of acyl nitroso compounds generated from **4** and also to report on the photochemistry of DMA adducts (**2**), nitrodiazo compounds (**3**), and related nitronate derivatives.

Results and discussion

Photogeneration of acyl nitroso compounds from DMA adducts

Following our initial TRIR studies of benzoyl nitroside generated from a 1,2,4-oxadiazole-4-oxide,[21] we have performed analogous studies on its DMA adduct (**2**, R = Ph). Laser photolysis (266 nm, 5 ns, 3 mJ) of a 5 mmol L^{-1} solution of **2** (R = Ph) in dichloromethane produces the TRIR difference spectrum shown in Fig. 1. Interestingly, in addition to the diagnostic acyl nitroso band at 1735 cm^{-1}, another prominent band is observed at 1820 cm^{-1}. The 1820 cm^{-1} band is formed faster than the time resolution of our spectrometer ($k_{obs} > 2.0 \times 10^7$ s^{-1}) and decays on the microsecond time scale with concomitant additional growth of the 1735 cm^{-1} acyl nitroso band.

IR absorbances above 1800 cm^{-1} are relatively rare for organic species and are typically observed only for highly strained carbonyls, carbonyls substituted with strongly electron-withdrawing groups, and acyl radicals. Acyl radicals have been extensively studied in hydrocarbon solvent by TRIR spectroscopy.[22,23] Benzoyl radical is reported to absorb at 1828 cm^{-1}, consistent with our 1820 cm^{-1} signal in dichloromethane. We envision two potential pathways consistent with the TRIR data of Fig. 1: (*i*) simple secondary photoly-

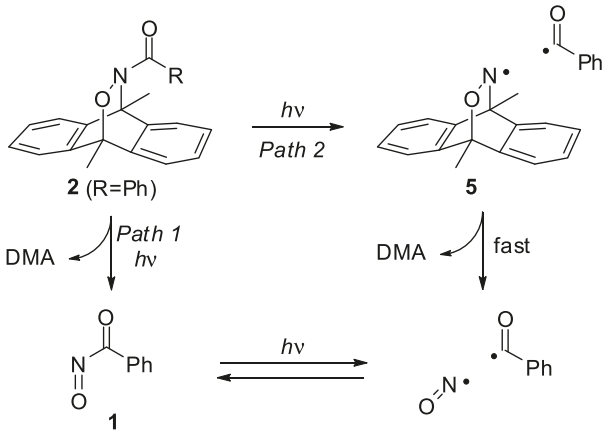
Scheme 5. Two potential photochemical pathways for the DMA adduct (**2**, R = Ph).



sis of benzoyl nitroside within the 266 nm laser pulse to form nitric oxide (NO) and benzoyl radical, which subsequently recombine (Scheme 5, path 1), or (*ii*) Norrish type I cleavage of precursor **2** to form benzoyl radical and NO/DMA adduct (**5**), which rapidly dissociates to NO and DMA, followed by NO–benzoyl radical recombination (Scheme 5, path 2). Similar photochemistry has very recently been proposed for other acyl nitroso Diels–Alder cycloadducts.[24]

Analogous TRIR experiments on the acetyl nitroside/DMA adduct (**2**, R = Me) reveal only the characteristic acyl nitroso band, in this case observed at 1780 cm^{-1} (consistent with B3LYP/6-31G* calculations), with no evidence for the acetyl radical (Supplementary data). Since acetyl nitroside is not expected to absorb at 266 nm, whereas benzoyl nitroside should, these experiments suggest that the secondary photolysis pathway (Scheme 5, path 1) is operative.

Photogeneration of acyl nitroso compounds from nitrodiazo compounds

We have also examined the photogeneration of acyl nitroso compounds from nitrodiazo precursors by TRIR spectroscopy. Ethyl nitrodiazoacetate (**3**, R = CO_2Et) and nitrodiazomethyl *tert*-butyl ketone (**3**, R = C(O)-*t*-Bu) both provide the characteristic acyl nitroso TRIR signal at 1788 and 1756 cm^{-1}, respectively, consistent with B3LYP/6-31G* calculations (Supplementary data). Each of these bands was produced faster than the time resolution of our spectrometer ($k_{obs} > 2.0 \times 10^7$ s^{-1}) and was stable for at least 1 ms in dichloromethane. In the spectral region between 2200 and 2000 cm^{-1}, we also observe diazo depletion bands with no TRIR evidence for the formation of ketene,[25,26] which could potentially be formed via Wolff rearrangement from either of these precursors (Supplementary data). Consistent with the lack of Wolff rearrangement, nearly quantitative yields of N_2O (formed via acyl nitroso-produced HNO) are observed following the photolysis of ethyl nitrodiazoacetate in 75:25 acetonitrile/water (Scheme 6).

Given the above results and previous observations that photogenerated nitrocarbenes are not trappable,[15,16] we have begun to explore an alternative photochemical pathway to acyl nitroso compounds from nitrodiazo precursors that arose from consideration of their nitronate-like resonance structure (**3-N**). Alkyl nitronates (**6**) have been shown to undergo a photoinduced rearrangment to hydroxamic acids (Scheme 7*a*).[27–31] An analogous reaction from a nitrodiazo compound leads to the *N*-oxirane intermediate **7**, which could undergo further rearrangement, via two potential pathways, to the acyl nitroso product (Scheme 7*b*).

Photogeneration of acyl nitroso compounds from nitronates with α-leaving groups

To test the reaction scheme shown in Scheme 7*b* we have examined the photochemistry of nitronates with α-leaving groups. Our initial studies have focused on phenylcyanonitromethane nitronate (**8**); results similar to those reported below have also been observed in preliminary experiments with the 4-chloro and 4-methoxy analogues.

Nitronate **8** is stable in sodium hydroxide or methanol solutions. As shown in Scheme 8, photolysis (Rayonet, 254 nm) of **8** in methanol cleanly provides two products, methyl benzoate (**10**) and methoxyphenylacetonitrile (**12**). HPLC and GC–MS analysis reveal a 29% ± 5% yield of **10** and a 63% ± 7% yield of **12** (values are means ± SD). The production of methyl benzoate was confirmed by comparison with an authentic sample; the GC–MS data for nitrile **12** match well with its reported mass spectrum.[32] N_2O quantification following photolysis of nitronate **8** in methanol indicates that HNO is formed in a 26% ± 5% yield, consistent with the yield of methyl benzoate.

To explain the formation of nitrile **12**, we propose that *N*-oxirane intermediate **9** partitions between the anticipated loss of cyanide ion and the loss of nitrite ion to form phenylcyano carbene (**11**), which is trapped by methanol to form nitrile **12**, as has been previously observed.[33,34] Although we have not yet conducted experiments that indicate whether carbene **11** is formed thermally or photochemically (analogous to epoxide photochemistry[34–36]) from *N*-oxirane **9**, this hypothesis is consistent with earlier studies of nitronate photochemistry where carbene intermediates were proposed.[30]

Further experimental evidence for the formation of carbene **11** is provided by additional trapping experiments. GC–MS analysis following photolysis of nitronate **8** in acetonitrile containing either cyclohexene or 2,3-dimethyl-2-butene reveals carbene–alkene adducts (both C–H and C=C insertion products).[36] Moreover, the addition of increasing concentrations of alkene to a methanol-containing acetonitrile solution of nitronate **8** results in a decrease of the carbene–methanol adduct **12** accompanied by a concomitant increase in carbene–alkene derived products. Finally, photolysis of nitronate **8** in THF results in products (**14** and **15**, Scheme 8) consistent with the rearrangement of carbene-derived ylide **13**. Analogous THF–ylide rearrangement products have been observed in the study of 2-naphthyl(carbomethoxy)carbene.[37]

Reactivity of acyl nitroso compounds with amines

We have examined the reactivity of three acyl nitroso compounds (**1**, R = Ph, Me, and 4-Cl-Ph) with a variety of amines in dichloromethane. Acyl nitroso compounds (**1**, R = Ph and 4-Cl-Ph) were generated from 1,2,4-oxadiazole-4-oxides (**4**), and acyl nitroso **1** (R = Me) was generated from

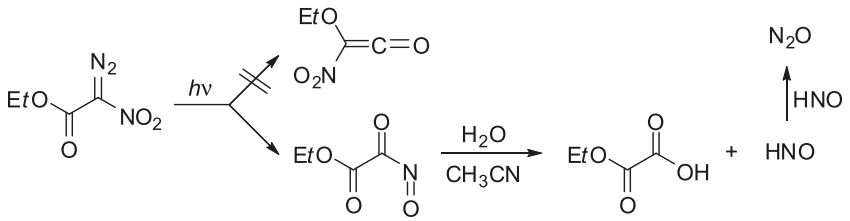
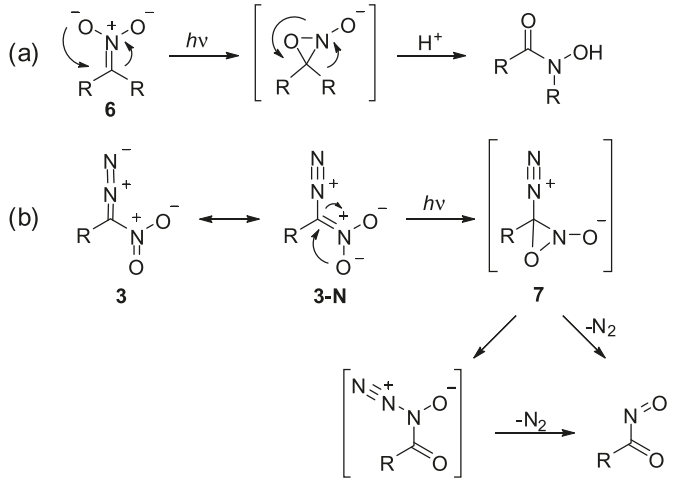


Scheme 7. (*a*) The photochemistry of alkyl nitronates. (*b*) The analogous photochemistry of nitrodiazo precursors to produce acyl nitroso compounds.



its DMA adduct (**2**). The decay kinetics of the characteristic acyl nitroso TRIR signals were monitored as a function of varying concentrations of added amine to derive reaction rate constants.

For the secondary amines, diethylamine (DEA) and piperidine (PIP), plots of observed decay rates (k_{obs}) versus amine concentration are linear and fit well to the pseudo-first-order rate equation $k_{obs} = k_o + k_{amine}$[amine] (Fig. 2 and Supplementary data). Derived second-order rate constants are shown in Table 1. (Note that the reaction of benzoyl nitroside (**1**, R = Ph) with DEA has been refined slightly from that originally reported ($k_{DEA} = 1.3 \times 10^5 \pm 0.5 \times 10^5$ L mol^{-1} s^{-1}).[21]) The twofold faster rate constant for the reaction of **1** (R = Ph) with PIP versus DEA is consistent with the decreased steric bulk of the ring-constrained PIP.

For the primary amines, *n*-butylamine (NBA) and benzylamine (BA), in contrast to the above secondary amines, plots of k_{obs} versus amine concentration are not linear, but rather fit to the rate equation $k_{obs} = k_o + k_{amine}$[amine]^2 (Fig. 3 and Supplementary data), indicating that the reaction of acyl nitroso species with primary amines is a third-order reaction, requiring two molecules of the primary amine. Relative rate constants derived for NBA and BA (Table 1) are again consistent with expected reactivity. No reactivity was observed with *tert*-butylamine (TBA), even at concentrations approaching 2 mol L^{-1}, owing to the steric bulk of this poorly nucleophilic amine.

The dependence of the reaction order of the aminolysis of acyl nitroso species on amine structure (i.e., primary vs. secondary) is consistent with previous reports of the aminolysis of esters by primary and secondary amines in organic solvent.[38–40] Our results indicate that the mechanism of acyl nitroso aminolysis by primary amines involves general base catalysis, while the mechanism of aminolysis by secondary amines is strictly bimolecular.

For a given amine, the rate of aminolysis is also dependent on the structure of the acyl nitroso compound. Consistent with expected electronic effects, **1** (R = 4-Cl-Ph) reacts 2 to 3 times more rapidly than **1** (R = Ph) with DEA and NBA, respectively. Also, aliphatic acyl nitroso (**1**, R = Me) reacts 2.5 to 10 times more rapidly than aromatic acyl nitroso (**1**, R = Ph) with NBA and PIP, respectively.

Reactivity of acyl nitroso compounds with thiols

We have also examined the kinetics and mechanism of the reaction of **1** (R = Ph) with thiols. Initial experiments surprisingly revealed no observed increase in the acyl nitroso decay rate upon the addition of up to 100 mmol L^{-1} *N*-acetylcysteine methyl ester (NAC). However, in the presence of 3.4 mmol L^{-1} NAC and 48 mmol L^{-1} DEA, the decay of **1** was observable and faster than that in the presence of 48 mmol L^{-1} DEA alone. We postulate that although the thiol itself is not reactive (on the microsecond time scale), the in situ generated diethylammonium thiolate is. We examined thiolate reactivity directly using organic-soluble tetrabutylammonium dodecanethiolate (TBA-D). The dependence of the acyl nitroso decay rate fit well to the pseudo-first-order rate equation $k_{obs} = k_o + k_{TBA\text{-}D}$[TBA-D] and a value of $k_{TBA\text{-}D} = 4.2\ (\pm 0.6) \times 10^7$ L mol^{-1} s^{-1} was determined (Supplementary data).

For all amines examined, acyl nitroso decay is accompanied by concomitant growth of the corresponding amide product ($\sim$1660 cm^{-1}). In the case of the reaction of TBA-D with **1** (R = Ph), however, the acyl nitroso (1735 cm^{-1}) decays over the microsecond time scale to a strongly absorbing intermediate that is observed at 1615 cm^{-1} (Fig. 4). This intermediate subsequently decays on the millisecond time scale to the product thiobenzoate (**17**), observed at 1706 cm^{-1}, consistent with the reported carbonyl stretching frequency of ethylthiobenzoate.[41] We have tentatively assigned this 1615 cm^{-1} band to tetrahedral intermediate **16** (Scheme 9), which is calculated (Supplementary data) to have a very intense N=O stretch at 1597 cm^{-1}, reasonably consistent with the observed TRIR band.

The rate of decay of the intermediate 1615 cm^{-1} band and the rate of growth of the 1706 cm^{-1} product band are both independent of the concentration of TBA-D, consistent with a unimolecular reaction of **16**. A similar tetrahedral intermediate has been proposed in the alkaline hydrolysis of thiobenzoates.[42]

Conclusions

Acyl nitroso compounds have been generated by photolysis of several different classes of precursors including DMA adducts (**2**), nitrodiazo compounds (**3**), and 1,2,4-oxadiazole-4-oxides (**4**). Consideration of the nitronate-like resonance structure of nitrodiazo compounds led to an examination of the photochemistry of nitronates with α-leaving groups (e.g., **8**). Photolysis of nitronate **8** has been shown to generate an acyl nitroso species along with a carbene intermediate.

Nanosecond TRIR spectroscopy has been used to detect photogenerated acyl nitroso compounds directly and to examine their reaction kinetics with amines and thiols. The mechanism of acyl nitroso aminolysis by primary amines involves general base catalysis, while the mechanism of aminolysis by secondary amines is strictly bimolecular. Thiols do not seem to be reactive with acyl nitroso compounds on the microsecond time scale, but thiolates are quite reactive. The reaction between benzoyl nitroside (**1**, R = Ph) and the organic-soluble thiolate TBA-D proceeds via a proposed tet-

Experimental section

General methods

Unless otherwise noted, materials were obtained from the Sigma-Aldrich Chemical Company, Fisher Scientific, or Cambridge Isotope Laboratories. All solvents were purified with a PureSolv MD 5 solvent purification system. All amines were redistilled prior to use and stored over potassium hydroxide.

^{1}H NMR spectra were recorded on a Bruker Avance 400 MHz FT NMR operating at 400 MHz; ^{13}C NMR spectra were recorded on a Bruker Avance 300 MHz FT NMR operating at 75 MHz. All ^{1}H resonances are reported in parts per million, and are referenced to solvent (^{1}H NMR (chloroform-*d*) δ: 7.26, (methanol-d_4) δ: 3.3). Melting points were recorded on a Mel-Temp apparatus and are uncorrected. High resolution mass spectra were obtained on a VG70SE double focusing magnetic sector mass spectrometer operating in fast atom bombardment ionization mode. Reported masses were referenced to a doubly potassiated PEGMME mass calibrant. Ultraviolet–visible (UV–vis) absorption spectra were obtained using a Hewlett Packard 8453 diode array spectrometer. Infrared (IR) absorption spectra were obtained using a Bruker IFS 55 Fourier transform infrared spectrometer. All density functional theory (DFT) calculations were performed using Spartan '04 (Wavefunction, Inc.) for Macintosh or

Spartan '08 (Wavefunction, Inc.) for Windows using the B3LYP/6-31G* method and basis set.

Time-resolved IR methods

TRIR experiments were conducted following the method of Iwata and Hamaguchi[43] as described previously.[25] Briefly, the broadband output of a $MoSi_2$ IR source (JASCO) is crossed with excitation pulses from a Continuum Minilite II Nd:YAG laser (266 nm or 355 nm) operating at 15 Hz. Changes in IR intensity are monitored using an AC-coupled mercury/cadmium/tellurium (MCT) photovoltaic IR detector (Kolmar Technologies, KMPV11-J1/AC), amplified, digitized with a Tektronix TDS520A oscilloscope, and collected on a Macintosh with IGOR for data processing. The experiment is conducted in dispersive mode with a JASCO TRIR 1000 spectrometer.

N_2O quantification via GC headspace analysis

GC headspace analysis was performed on a Varian CP-3800 instrument equipped with a Restek ShinCarbon ST 80/100 molecular sieve-packed column and an electron capture detector.

Photolysis of Angeli's salt (a classic HNO donor under physiologically relevant conditions[44]) has been shown to produce HNO/NO^-, which subsequently yields N_2O.[45] To quantify the amount of N_2O produced following photolysis of Angeli's salt, a 1 mmol L^{-1} solution in 0.01 mol L^{-1} NaOH was prepared and 1 mL of this solution was placed in series of 1 cm quartz cuvettes. The cuvettes were sealed with rubber septa and sparged with argon for 20 min. Samples were then photolyzed (Rayonet, 254 nm) until completion as indicated by the disappearance of the characteristic Angeli's salt UV absorbance at 254 nm. Samples were allowed to equilibrate at 37 °C for 1 h and then 100 μL of headspace was analyzed for N_2O. N_2O yields are taken as an average of five injections. The theoretical yield of Angeli's salt-derived N_2O was calculated for the NaOH solution using Henry's law and was found to be quantitative versus authentic samples. N_2O yields were determined analogously for ethyl nitrodiazoacetate (**3**, R = CO_2Et) in 75:25 acetonitrile/water and phenylcyano-nitromethane nitronate (**8**) in methanol and compared with that found for Angeli's salt (assumed to be 100%) in 75:25 acetonitrile/water and methanol, respectively.

GC–MS methods

GC–MS analysis was performed on a Shimadzu GC17A/QP5050A instrument equipped with electron ionization. Nitronate samples were prepared in methanol, THF, or acetonitrile, sparged with argon, photolyzed (Rayonet, 254 nm), concentrated under vacuum, reconstituted in 1 mL of methanol, and then analyzed by GC–MS. Carbene trapping by alkenes (cyclohexene and 2,3-dimethyl-2-butene) was analyzed analogously in acetonitrile solutions. Competitive carbene trapping by methanol versus alkene (cyclohexene or 2,3-dimethyl-2-butene) was also performed in acetonitrile with 10 mmol L^{-1} methanol and 0–50 mmol L^{-1} alkene. Yields are reported as an average of four individual experiments.

HPLC methods

HPLC data were collected on a Waters Delta 600 system equipped with a Model 6000A pump and a Model 2487 dual wavelength UV detector monitoring at 230 nm equipped with a Waters C-18 symmetry column. All HPLC eluents contained 0.1% trifluoroacetic acid. Nitronate samples were prepared in methanol, sparged with argon, and then photolyzed (Rayonet, 254 nm). HPLC analysis was then performed with a flow rate of 1 mL min^{-1} with 35:65 acetonitrile/water. Yields are reported as an average of four individual experiments.

General procedure for the synthesis of DMA cycloadducts (2)

The synthesis of DMA cycloadducts (**2**) was carried out in accordance with a literature procedure, using tetrabutylammonium periodate instead of tetraethyl-ammonium periodate.[7] Benzoyl nitroside/DMA cycloadduct (**2**, R = Ph): mp 126–128 °C (lit. value[7] mp 127–128 °C). Acetyl nitroside/DMA cycloadduct (**2**, R = Me): mp 133–136 °C (lit. value[7] mp 133–136 °C).

General procedure for the synthesis of nitrodiazocarbonyl compounds (3)

Ethylnitrodiazoacetate and nitrodiazomethyl *tert*-butyl ketone were synthesized by the method reported by Charette et al.[46] Ethylnitrodiazoacetate (**3**, R = CO_2Et): IR (film, cm^{-1}) ν_{max}: 2148, 1750, 1693. ^1H NMR ($CDCl_3$) δ: 4.42 (2H, q), 1.38 (3H, t). Nitrodiazomethyl *tert*-butyl ketone (**3**, R = C(O)-*t*-Bu): IR (film, cm^{-1}) ν_{max}: 2142, 2180, 1690, 1650. ^1H NMR ($CDCl_3$) δ: 1.35 (s, 9 H).

General procedure for the synthesis of 1,2,4-oxadiazole-4-oxides (4)

The synthesis of 1,2,4-oxadiazole-4-oxides was performed using a slight modification of a literature procedure.[47] The synthesis of 3,5-diphenyl-1,2,4-oxadiazole-4-oxide is shown below as a general procedure.

3,5-Diphenyl-1,2,4-oxadiazole-4-oxide (4, R = Ph)

Benzohydroximoyl chloride was prepared from benzaldehyde oxime in accordance with literature procedures and used directly for the next step.[48] Dehydrohalogenation was performed in ethanol using triethanolamine to yield benzonitrile oxide. The nitrile oxide dimerization was accomplished in situ with triethanolamine, yielding a mixture of three dimeric species. The desired dimer was initially purified by silica gel column chromatography (10%–30% ethyl acetate / hexanes). The column-purified product was further purified by recrystallization from methanol/water, yielding white needles; mp 132–133 °C (lit. value[49] mp 134 °C).

3,5-Bis(4-chlorophenyl)-1,2,4-oxadiazole-4-oxide (4, R = 4-Cl-Ph)

Prepared from 4-chlorobenzaldehyde oxime using the general procedure; mp 189–190 °C (lit. value[49] mp 189–190 °C).

General procedure for the synthesis of arylcyanonitromethane potassium nitronates

Arylcyanonitromethane potassium nitronate derivatives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

were prepared via modification of a literature procedure.[50] Synthesis of phenylcyanonitromethane potassium nitronate is shown below as a general procedure.

Phenylcyanonitromethane potassium nitronate (8)

Benzyl cyanide (2.93 g, 0.025 mol) was added to a solution of potassium *tert*-butoxide (9.25 g, 0.0825 mol) in 90 mL of THF at –50 °C in a dry ice / acetone bath. Isoamyl nitrate (7.3 g, 0.55 mol) was added dropwise, maintaining the temperature at –45 to –50 °C. The cooling bath was removed and the reaction mixture allowed to warm to room temperature. The precipitate that formed was filtered and washed with THF and then ether. The residue was recrystallized from ethanol/hexanes (2.25 g, 45%). IR (mineral oil, cm^{-1}) ν_{max}: 2201, 1495, 1455, 1417, 1366, 1339, 1310, 1284, 1264, 1190, 1167, 1034, 1005, 989, 762. ^1H NMR (methanol-d_4) δ: 7.15 (1H, t), 7.32 (2H, d), 7.90 (2H, d). ^{13}C NMR (D_2O) δ: 129.40, 128.52, 127.68, 125.87, 117.88, 102.10. HR-FAB-MS *m/z*: 238.9629 $[M + 2K]^+$. Calcd. for $C_8H_5K_2N_2O_2$: 238.9625.

4-Chloro-phenylcyanonitromethane potassium nitronate

Prepared from 4-chlorobenzyl cyanide using the general procedure. IR (mineral oil, cm^{-1}) ν_{max}: 2200, 1497, 1397, 1303, 1279, 1248, 1115, 1098, 996, 824. ^1H NMR (methanol-d_4) δ: 7.32 (2H, d), 7.90 (2H, d). ^{13}C NMR (D_2O) δ: 132.14, 128.31, 128.05, 126.89, 117.48, 101.49. HR-FAB-MS *m/z*: 272.9232 $[M + 2K, {}^{35}Cl]^+$, 274.9210 $[M + 2K, {}^{37}Cl]^+$. Calcd. for $C_8H_4ClK_2N_2O_2$: 272.9235.

4-Methoxy-phenylcyanonitromethane potassium nitronate

Prepared from 4-methoxybenzyl cyanide using the general procedure. IR (mineral oil, cm^{-1}) ν_{max}: 2205, 1600, 1514, 1412, 1351, 1310, 1290, 1241, 1189, 1151, 1028, 991, 828. ^1H NMR (methanol-d_4) δ: 3.79 (3H, s), 6.90 (2H, d), 7.80 (2H, d). ^{13}C NMR (D_2O) δ: 158.07, 127.60, 122.14, 117.60, 113.87, 101.80, 55.28. HR-FAB-MS *m/z*: 268.9726 $[M + 2K]^+$. Calcd. for $C_9H_7K_2N_2O_3$: 268.9731.

Synthesis of tetrabutylammonium dodecanethiolate (TBA-D)

The synthesis was carried out in accordance with the published procedure.[51,52]

Supplementary data

Supplementary data (additional TRIR data, kinetic analyses, and computational results) for this article are available on the journal Web site (canjchem.nrc.ca).

Supramolecular encapsulation of benzimidazole-derived drugs by cucurbit[7]uril

Apurba L. Koner, Indrajit Ghosh, Na'il Saleh, and Werner M. Nau

Abstract: UV–vis and NMR spectroscopic techniques were employed to demonstrate the ability of the synthetic macrocyclic host cucurbit[7]uril (CB7) to solubilize and stabilize widely used fungicides and anthelmintic drugs of the benzimidazole family in water, namely, albendazole (ABZ), carbendazim (CBZ), thiabendazole (TBZ), fuberidazole (FBZ), and the parent benzimidazole (BZ). CB7 binds the protonated forms of these guests very strongly (e.g., $K = 2.6 \times 10^7$ L/mol for ABZ) but their neutral forms significantly more weakly (e.g., $K = 6.5 \times 10^4$ L/mol for ABZ), which reflects a complexation-induced increase of their pK_a values by 2.6 units for ABZ, 2.5 units for CBZ, 4.0 units for TBZ, 3.8 units for FBZ, and 3.5 units for BZ. The absolute drug solubilities increased upon complexation from 0.003 to 0.300 mmol/L for ABZ, from 0.160 to 1.12 mmol/L for CBZ, from 0.110 to 1.11 mmol/L for TBZ, and from 0.25 to 0.75 mmol/L for FBZ (for BZ, the solubility enhancement was found to be insignificant). Complexation by CB7 further improves the photostability of the drugs and alters their photophysical properties.

Key words: supramolecular chemistry, cucurbit[*n*]urils, benzimidazole drugs, pK_a shifts, solubility enhancement, photostability, drug delivery.

Résumé : On a fait appel aux techniques spectroscopiques d'UV–vis et de RMN pour évaluer l'habilité de l'hôte macrocyclique de synthèse, cucurbit[7]urile (CB7) à solubilizer et à stabiliser dans l'eau des fongicides et des médicaments antihelmintiques largement utilisés, de la famille du benzimidazole, en particulier l'albenzole (ABZ), la carbendazime (CBZ), le thiabendazole (TBZ), le fubéridazole (FBZ) et le produit fondamental, le benzimidazole (BZ). Le CB7 se lie fortement à la forme protonée de ces hôtes (par exemple, $K = 2{,}6 \times 10^7$ L/mol pour l'ABZ), mais les formes neutres sont beaucoup plus faibles (par exemple, $K = 6{,}5 \times 10^4$ L/mol pour l'ABZ) ce qui est un reflet de l'augmentation induite par la complexation des valeurs de leurs pK_a qui est de 2,6 unités pour l'ABZ, de 2,5 unités pour le CBZ, de 4,0 unités pour le TBZ, de 3,8 unités pour le FBZ et de 3,5 unités pour le BZ. Les solubilités absolues des médicaments augmentent par complexation de 0,003 à 0,300 mmol/L pour l'ABZ, de 0,160 à 1,12 mmol/L pour le CBZ, de 0,110 à 1,11 mmol/L pour le TBZ et de 0,25 à 0,75 mmol/L pour la FBC ; pour le BC, on a trouvé que l'augmentation de solubilité est insignifiante. La complexation des médicaments avec le CB7 augmente de plus la photostabilité des médicaments et elle altère leurs propriétés photophysiques.

Mots-clés : chimie supramoléculaire, cucurbit[*n*]uriles, médicaments à base de benzimidazole, pK_a, administration des médicaments.

[Traduit par la Rédaction]

Introduction

When guest molecules are noncovalently encapsulated inside water-soluble macrocyclic container compounds such as cyclodextrins, calixarenes, or cucurbiturils, a modification of their chemical and physicochemical properties always occurs owing to the altered microenvironment as well as the confinement and isolation of the guest.[1–10] Frequently, the complexation of the guest has beneficial effects on its aqueous solubility, because the encapsulation reduces the tendency of the guest to undergo aggregation or unspecific adsorption.[11–15] Further, the complexation may enhance the thermal, as well as photochemical, stability of a guest by isolating it from the aqueous bulk and thereby preventing bimolecular reactions — in the simplest case, oxidation by molecular oxygen.[16,17] Such solubility and stability enhancements are particularly desirable for (hydrophobic) drug molecules. Accordingly, macrocyclic encapsulation of drugs has emerged as a viable complementary technique to other established formulation strategies, such as organic solvents as solubilizers[18] or the use of liposomes or micellar systems.[19–21] An important aspect for the use of macrocycles in drug delivery is the reversibility of the host–guest complexation process, which allows full or partial retention of the

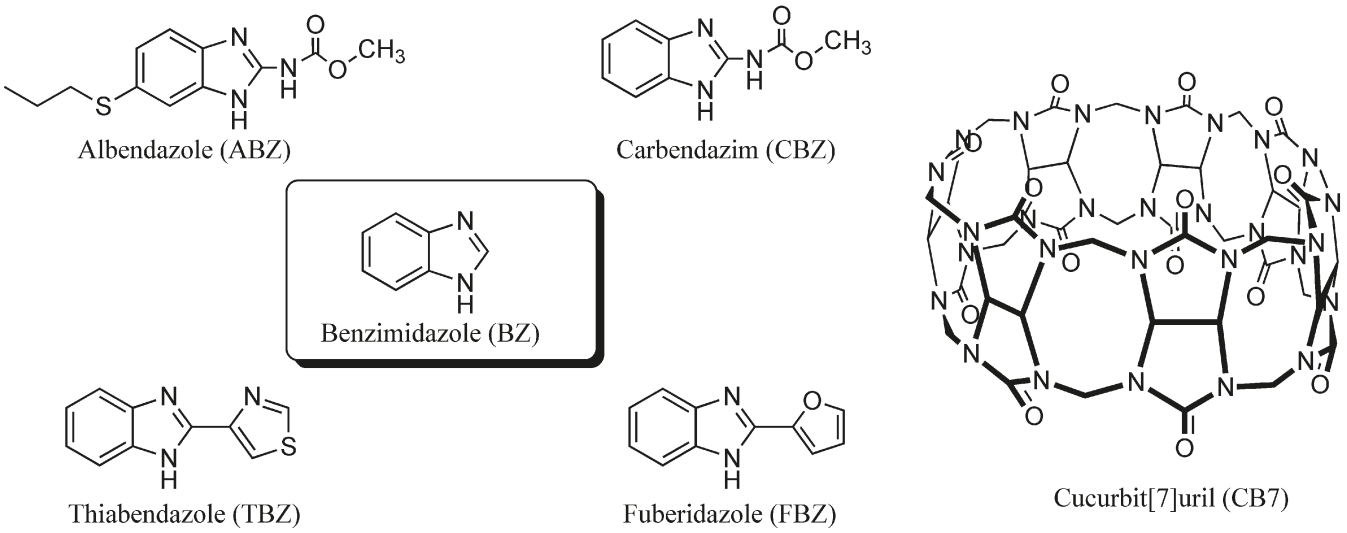
Scheme 1. Chemical structures of the examined benzimidazoles and cucurbit[7]uril.



biological or medicinal activity of the encapsulated drugs.[22–30]

Amongst the macrocyclic container compounds used in drug formulations, cyclodextrins have received the most attention owing to their availability from natural sources and their biocompatibility.[28–30] However, cyclodextrins frequently suffer from low binding constants, with typical values on the order of 10^3 L/mol,[1,31,32] which limits their application owing to the subtle concentration dependence of supramolecular complexation equilibria. Cucurbiturils, which have just recently been demonstrated to show a low, if not negligible, cellular and acute toxicity,[33] are another interesting class of macrocycles with potential for drug delivery and stabilization.[23–26] They stand out, in particular, with respect to their high binding constants with hydrophobic as well as cationic guest molecules.[3,9,34–41] Moreover, they have been shown to effectively shift the pK_a values of encapsulated guests,[5–7,12,41–47] which also differentiates them from cyclodextrins.[42] We have recently exploited these pK_a shifts for the development of fluorescent reporter pairs employed for assaying and sensing[7,42,48–51] and for supramolecular catalysis of hydrolytic reactions,[52] and have communicated the use for the activation and stabilization of prodrugs.[43]

In chemical and structural detail, cucurbit[*n*]urils (CB*n*) are cyclic oligomers composed of a varying number of, but more than four, glycoluril units bridged by methylene groups. They form a rigid barrel-like molecular container structure that can take up suitably sized guests through its two carbonyl-laced portals.[3,53] CB6 was first made in 1905[54] but was characterized only in 1981.[55] In the context of drug delivery, the subsequently prepared[56–58] larger homologue CB7 (see Scheme 1) has become especially important owing to its high water solubility[59] and intermediate cavity volume.[3,33] The latter allows the strong binding of mono-, di-, and trinuclear aromatic residues,[6,41,42,60,61] which are omnipresent in numerous drugs. More specifically, recent studies have revealed a high affinity of the benzimidazole residue with CB7,[6,23,43,62] which we have used as an incentive to study herein the binding of different benzimidazole-derived drugs, namely albendazole (ABZ), carbendazim (CBZ), thiabendazole (TBZ), and fuberidazole (FBC) (see Scheme 1), as well as the parent compound (benzimidazole, BZ) with CB7. We also studied the effects of CB7 on their photophysical properties, photochemical stabilities, and aqueous solubilities.

Results

Optical spectroscopy and determination of pK_a values of the uncomplexed guests

In water at pH 7.2, ABZ, CBZ, TBZ, FBZ, and BZ show far-UV absorptions (<320 nm) and fluorescence in the region of 290–360 nm (Table S1 in the Supplementary data). The absorption spectra undergo slight but characteristic shifts at lower pH values (Fig. S4 in the Supplementary data), which are attributable to a protonation of the benzimidazole residue. The pK_a values of the uncomplexed guests were accordingly determined by UV titrations (Table 1) and were found to be in good agreement with those previously reported for ABZ,[65] CBZ,[66] TBZ,[67] FBZ,[68] and BZ.[69]

Determination of binding constants

The addition of CB7 to the guests led to characteristic changes of their absorption spectra (see Fig. S2 in the Supplementary data), which were assigned, based on literature precedent for related compounds[6,43,70] and complementary NMR investigations (see the following), to the immersion of the benzimidazole residue inside the macrocyclic cavity. The effects of added CB7 on the fluorescence properties of the guests (fluorescence spectra, intensities, and lifetimes) were also determined, but were less systematic (see the Supplementary data). The host–guest binding constants were subsequently determined by means of UV titrations (see Fig. 1, Table 1). These titrations were performed either below the pK_a value of the uncomplexed guests or above the pK_a' values of the complexed guests (the latter were determined in a separate set of experiments, see the following) to ensure that the protonation state of the guest did not significantly change upon complexation. Note that CB7 acts as a cation receptor and accordingly displays consistently higher (at least two orders of magnitude larger) binding con-

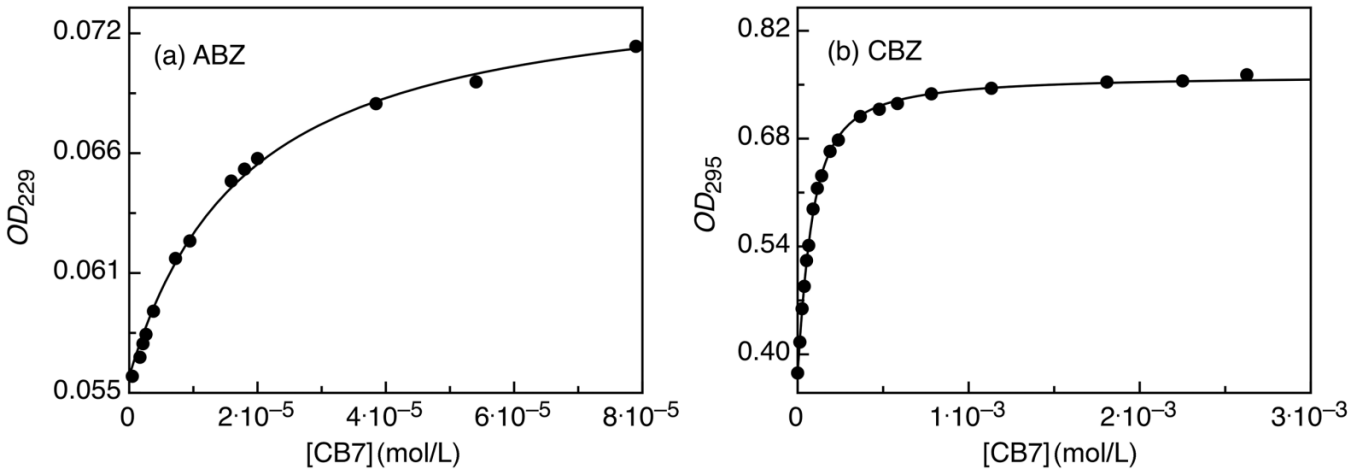
Table 1. pK_a values of benzimidazole derivatives in their uncomplexed (pK_a) and CB7-complexed states (pK_a') in water, and binding constants of their neutral (K_{BZ}) and protonated (K_{BZH^+}) forms with CB7.

Guest	pK_a	pK_a'[a]	ΔpK_a	K_{BZ} (10^3 L/mol)[b]	K_{BZH^+} (10^6 L/mol)[c]
ABZ	3.5	6.1	2.6	65	26
CBZ	4.5	7.0	2.5	24	7.6
TBZ	4.6	8.6	4.0	0.150±0.025	1.5
FBZ	4.8	8.6	3.8	0.05±0.01	0.32
BZ	5.5	9.0	3.5	1.5	4.7

[a]Obtained from fitting of the pH titrations in the presence of host according to a four-state model, cf. refs. 63 and 64; estimated error is ±0.3 units.
[b]Determined at pH 10.5 except for ABZ (pH 8.4); 10% error unless stated differently; error refers to the standard deviation of the nonlinear fitting according to a 1:1 complexation model.
[c]Estimated from the thermodynamic cycle in Scheme 2 and the relation $K_{BZH^+} = K_{BZ} \times K_a / K_a'$.

Fig. 1. Host–guest titrations of the unprotonated benzimidazole guests with CB7 for (*a*) ABZ at pH 8.4 and (*b*) CBZ at pH 10.5. The titration curves for the other guests as well as the actual variations in the UV–vis spectra with the addition of CB7 are shown in the Supplementary data (Figs. S1 and S2).

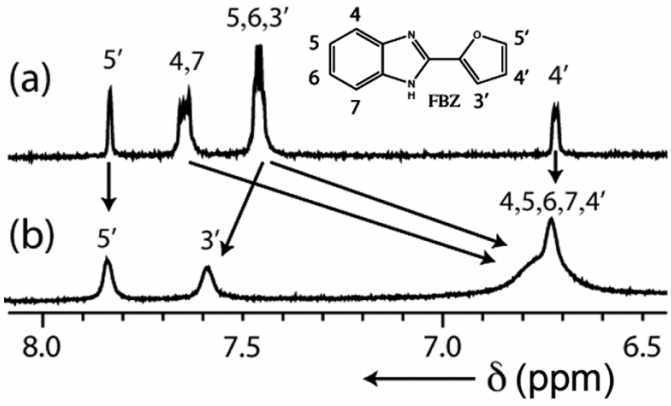


stants with the protonated guests (K_{BZH^+} vs K_{BZ} values in Table 1). For example, the binding constant of CB7 with the protonated form of ABZ is estimated to be 2.6×10^7 L/mol, with the neutral form only 6.5×10^4 L/mol. It should be noted that the host–guest titrations could be fitted in all cases according to a 1:1 binding model. This was also consistent with the isosbestic points observed in the UV titrations with CB7.

^{1}H NMR spectroscopy and determination of binding mode

NMR measurements were performed to gain structural insights into the host–drug complexes. As an example, the ^{1}H NMR spectrum of FBZ in D_2O at pH 2 (pD 2.4) in the absence and in the presence of 2.5 mmol/L CB7 is shown in Fig. 2 (see Table S2 in the Supplementary data for the complexation-induced chemical shifts of all guests). As can be seen, the imidazolium protons are upfield shifted in the presence of CB7 by up to 1 ppm, while the furanyl protons are hardly affected or even slightly downfield shifted (Fig. 2). In analogy to the NMR spectral shifts for other guest molecules complexed to cucurbit[7]uril,[43] these characteristic shifts are interpreted as a preferential encapsulation of the benzimidazole residue inside the CB7 macrocycle, while the furanyl ring is positioned near the rim

Fig. 2. ^{1}H NMR spectra of 0.25 mmol/L FBZ (*a*) without CB7 and (*b*) with 2.5 mmol/L CB7 in D_2O at pD 2.4.



region or slightly outside. The NMR spectral data for the remaining benzimidazole derivatives were consistent with this proposed binding mode; for ABZ, the hydrophobic propylthio moiety also shows upfield shifts (see the Supplementary data, Fig. S3), which suggests that this hydrophobic group also shuttles, at least occasionally, inside CB7, such that on average a partial or temporary inclusion applies.

As a negative control experiment, and to expose the bene-

For personal use only.

fitsof CB7 as the macrocycle of choice, we conducted the NMR measurements with CB6 as an alternative host, which, however, is too small to encapsulate the benzimidazole ring. This smaller macrocycle does indeed show (according to the complexation-induced shifts) no inclusion of the benzimidazole group,[71] but encapsulates other groups of the drugs, e.g., the carbamate methyl groups in ABZ and CBZ (upfield shift of 1 ppm, Table S2 in the Supplementary data). The ^{1}H NMR spectra of TBZ and FBZ in the absence and presence of CB6 were identical, suggesting the absence of sizable binding.

pK_a values of the complexed guests and complexation-induced pK_a shifts

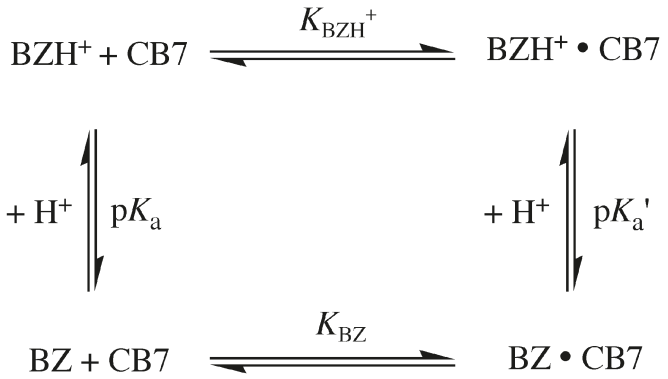
The protonated forms of the guests experience an additional stabilization due to ion–dipole interactions with the carbonyl portals of CB7. Accordingly, the propensity of the guests to become protonated is increased when they are complexed by CB7, an intuitive conjecture, which manifests itself experimentally in a pK_a shift upon addition of macrocycle, i.e., larger pK_a values in the complexed compared with the uncomplexed form. Others[5,45–47,72–74] and we[6,7,12,41–44,64] have previously observed such pK_a shifts accompanying host–guest complexation, and we have developed fitting algorithms for pH titrations in the presence of host based on a four-state model involving (*i*) the uncomplexed unprotonated guest, (*ii*) the uncomplexed protonated guest, (*iii*) the unprotonated host–guest complex, and (*iv*) the protonated host–guest complex, which are all connected through a thermodynamic cycle as illustrated in Scheme 2.[6,63,64,75]

The fitting allowed us to extract the pK_a' of the complexes (Fig. 3, Table 1) and to extrapolate the second binding constant when at least one of the binding constants and the pK_a value of the uncomplexed guest were known from independent measurements. In the case of the benzimidazole guests investigated herein, the binding constants of the unprotonated guests could be more accurately determined than those of the protonated guests; the latter were in several cases too high to allow precise determinations by UV titrations, and they were consequently estimated from the fitted pK_a values through the condition imposed by the thermodynamic cycle ($K_{BZH^+} = K_{BZ} \times K_a / K_a'$).[76] Note that the observed pK_a shifts range from 2.5 to 4.0 units, with the largest value observed for TBZ.

Solubility enhancement

The effect that the addition of CB7 has on the solubility of the guests was determined by UV spectrophotometry (see Fig. 4 and the Materials and methods) at the physiological pH (7.2). In the presence of 2 mmol/L CB7, the solubility of ABZ increased by a factor of 100, that of CBZ increased by a factor of 7, that of TBZ increased by a factor of 10 and that of FBZ increased by a factor of 3 (Fig. 4, Table S3 in the Supplementary data). In terms of absolute solubilities (these were determined from the optical density (OD) values), they increased upon complexation from 0.003 to 0.300 mmol/L for ABZ, from 0.160 to 1.12 mmol/L for CBZ, from 0.110 to 1.11 mmol/L for TBZ, and from 0.25 to 0.75 mmol/L for FBZ (for BZ, the solubility enhancement was found to be insignificant). Note that there appears to be a rough inverse correlation between the intrinsic water solubility of the drug (in the absence of CB7) and its binding constant with CB7 (in its unprotonated form, Table 1). This is expected, since both properties are governed by the hydrophobicity of the drug and guest.[63] The use of macrocycles for drug solubilization is consequently particularly promising for the least soluble drugs.

Scheme 2. Four-state complexation model of the neutral and protonated benzimidazoles with CB7.



Photostabilization

Encapsulation in CB7 also enhanced the photostability of FBZ and TBZ. Under intense UV irradiation at pH 2.4, FBZ decomposed 7 times more slowly and TBZ 3 times more slowly in their complexes with CB7 than in their free forms (Fig. 5). For ABZ, CBZ, and BZ, no significant photostabilizing effects caused by CB7 were observed.

Discussion

The benzimidazole-derived drugs investigated herein are being used extensively worldwide as fungicides and anthelmintic drugs.[23,77–85] TBZ is used against fungally caused diseases and for the preservation of citrus fruits and bananas. Even more, marketed as Mintezol, Tresaderm, or Arbotect, it is used to treat dogs and cats infected with hookworms and other helminthes.[77–80] ABZ, marketed as Albenza, Eskazole, or Zentel, is used against pork and dog tapeworm infestations.[23,82–85] Surprisingly, ABZ also exhibits antitumor activity and is toxic for a number of cancer cell lines including colorectal and ovarian cancers and leukaemia. CBZ and FBZ are used only as fungicides;[81–83] CBZ, in particular, is broadly used to protect cereals, fruits, rice, and tomatoes.[78–80] One common feature is their low aqueous solubility, which is particularly undesirable for their use as anthelmintic drugs.

As a potential additive to increase the solubility of benzimidazole-derived drugs, we have investigated herein CB7. CB7 was known from previous studies to bind strongly to the benzimidazole residues,[6,23,43,86] and we have combined this knowledge with our interest to investigate complexation-induced pK_a shifts of guest molecules.[5–7,12,41–47,64] Specifically, we have already communicated that the pK_a values of benzimidazole derivatives would dramatically increase upon complexation by CB7.[43] We presumed that this could interconvert an uncharged (at

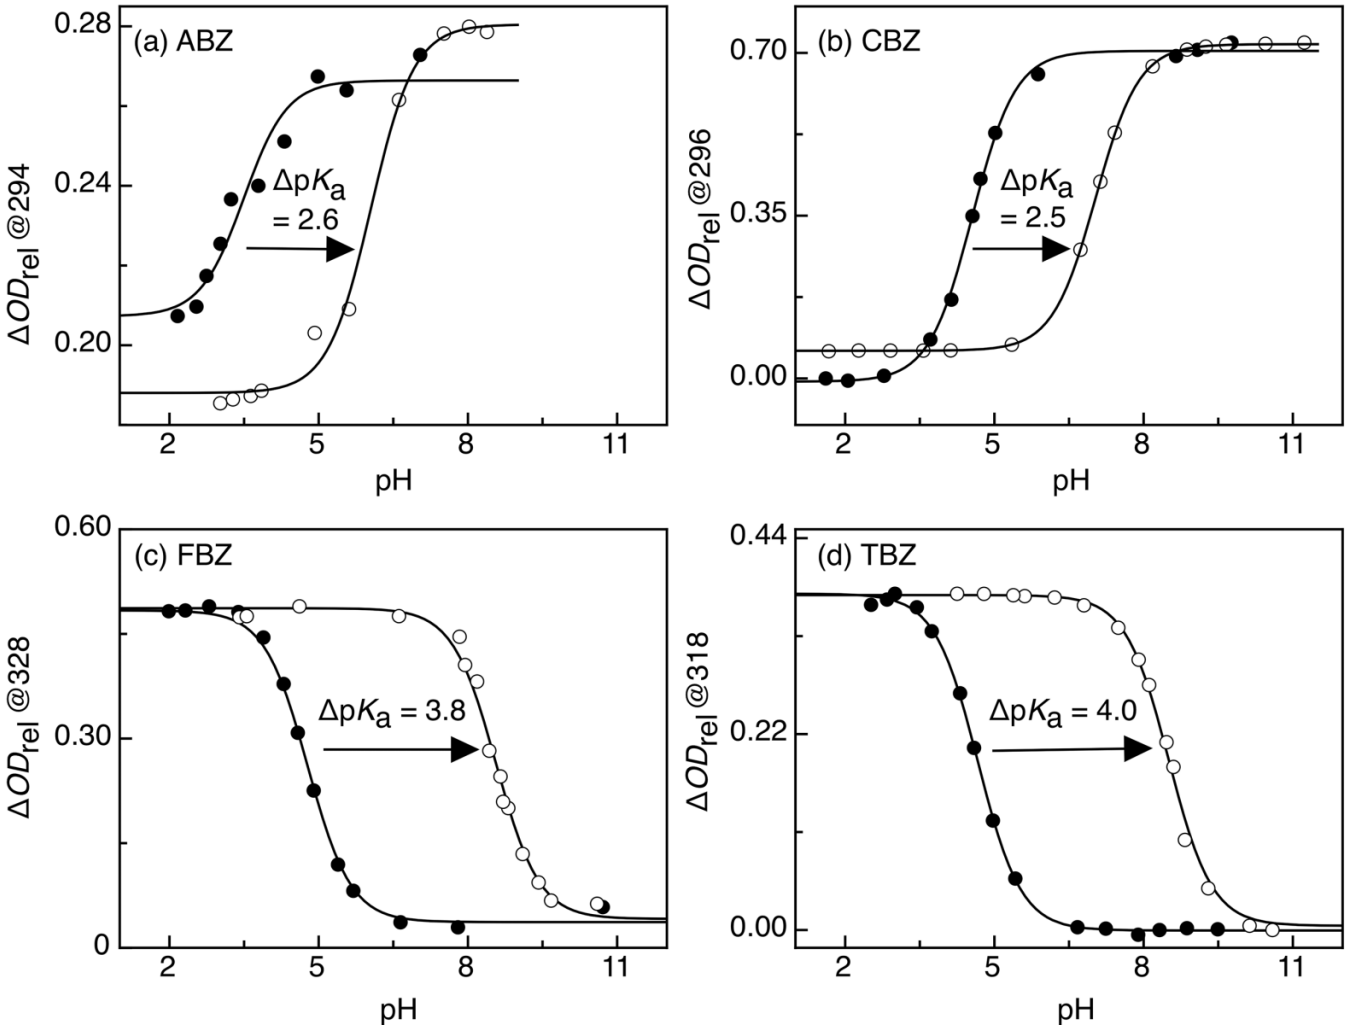
Fig. 3. pH titrations of the BZ drugs, monitored by UV in the absence (filled circles) and presence of CB7 (2.5 mmol/L, empty circles). The changes in the UV–vis spectra are shown in the Supplementary data (Figs. S4 and S5).



pH 7.2), intrinsically insoluble guest into an encapsulated charged guest with an intuitively expected higher solubility.

Supramolecular pK_a shifts, in particular those effected by macrocyclic complexation of guests, have recently attracted significant attention, for example, with the perspective of catalysis.[52,72] The largest presently known pK_a shifts reach values of 4.5 units, coming close to the values known for some enzymes.[44,73,64] pK_a shifts are caused either by a (relative) destabilization of charged species in hydrophobic environments or by a selective stabilization of a charged guest in macrocycles with cation or anion receptor properties. Cucurbiturils are cation receptors and as such stabilize cationic species, thereby facilitating the protonation of basic functionalities and increasing the pK_a values, for example, of ammonium ions. In detail, the carbonyl portals of CB7, the homologue used in the present study, stabilize cations by ion–dipole interactions. These electrostatic interactions add to the hydrophobic interactions that bind the guest even in its neutral form, which results in overall higher binding constants for the protonated forms. In fact, according to Scheme 2, the binding constants of the protonated forms can be readily predicted from a thermodynamic cycle.[63]

All investigated benzimidazoles indeed undergo large pK_a shifts upon complexation by CB7, ranging from 2.5 to 4.0 units. Even though the substituent-dependent variations of the absolute values of the pK_a shifts are not well understood at present, the large values reveal that, at a given pH value, the CB7 complexation increases the concentration ratio in favor of the protonated form of the benzimidazoles by 300 fold to 10 000 fold, owing to the logarithmic nature of the pK_a scale. Effectively, in the pH region in between the rise parts of the two titration curves (Fig. 3), i.e., also in the physiological pH region, the encapsulation of the drugs into CB7 converts a poorly soluble hydrophobic compound into a positively charged and presumably more soluble inclusion complex. This manifests itself in an apparently increased (from μmol/L to low mmol/L) solubility of the drugs, which reaches a factor of 100 in the most impressive case of the most hydrophobic (and least water soluble) drug, ABZ. Zhao et al.[23] have previously reported a larger solubility enhancement factor of 600–700 for ABZ, which could be related to the use of a higher CB7 concentration and (or) the use of deuterated water as an alternative solvent. Because the solubilization strongly depends on the degree of drug encapsulation, the solubility enhancement factor depends not

only on the binding constants but also on the concentration of CB7 used.

Any prospective applications of cucurbiturils in drug delivery must compete with those involving cyclodextrins as drug carriers. Both are expected to be useful additives to prevent aggregation by macrocyclic encapsulation. It turns out that CB7 enhances the solubility of the investigated drugs more efficiently, reflected in the use of lower additive concentrations as well as higher solubilities. For example, 2 mmol/L CB7 enhances the solubility of CBZ more (factor of 7) than even a five times higher concentration of β-cyclodextrin (factor of 1.6). For TBZ, the difference is similar (factor of 10 vs 1.9), while for FBZ the result is somewhat smaller, but still significant (factor of 3 vs 1.7). The lower efficiency of β-cyclodextrin encapsulation can be accounted for on one hand by its lower binding constants (<100 L/mol)[87] and on the other hand by its inability to induce protonation, and thereby increased solubility, of the drugs. In fact, cyclodextrins are known to affect pK_a shifts in the "wrong" direction[41] because they tend to preferentially complex the neutral forms of drugs.[63] The pK_a shifts effected by cucurbituril encapsulation therefore constitute a novel stand-alone feature of these drug carriers.

Conclusions

The macrocycle cucurbit[7]uril binds strongly to all investigated fungicides and anthelmintic drugs and increases their pK_a values, which results in host-induced protonation. The strong binding and protonation of the guests lead jointly to increased solubility, an effect that could be potentially exploited for drug delivery. Research along this line is assisted by the very low toxicity of cucurbiturils.[33]

Materials and methods

All guest molecules were purchased from Sigma-Aldrich and used as received. CB7 was synthesized according to our previously reported method.[56] Deionized and doubly distilled water was used. The pH of the solutions was adjusted (±0.2) using a pH meter (WTW 330i equipped with a combined Sen Tix Mic pH glass electrode) by adding the required amount of NaOH or HCl.

All UV–vis and fluorescence spectral measurements were performed using a Varian Cary 4000 UV–vis spectrophotometer and a Varian Cary Eclipse fluorometer (5 nm slit width for both excitation and emission monochromators). The fluorescence lifetimes of the drugs were measured by using time-correlated single photon counting (FLS920, Edinburgh Instruments Ltd., Livingston, UK). Excitation was made by using a PicoQuant pulsed LED (PLS-280, λ_{ex} = 280 nm, full width at half-maximum = 450 ps). ^{1}H NMR spectra were recorded with a JEOL ECX 400 MHz NMR spectrometer in D_2O (99.9% from Sigma-Aldrich). The photostabilization of the drugs was monitored through the change in the absorbance of the free and complexed drugs at pH 2.0 upon irradiation in a Luzchem LZC-4V photoreactor equipped with 14 Hitachi FL8BL-B UVA lamps (λ_{ex} = 350 nm).

In the solubility measurements, aqueous saturated solutions of the drugs were prepared by preadjusting the solution to pH 7.2. The solutions were then initially vortexed for about 10 min and then sonicated for 30 min. Then the solutions were filtered and absorption spectra were measured at pH 7.2. The same procedure was followed in the presence of 2.0 mmol/L CB7 at the same pH. The concentration of the drugs in water and inside the CB7 cavity was calculated from the obtained molar extinction coefficients measured independently in our laboratory.

(76) Another complication in the determination of the binding constants of the protonated guests was the low pH (approximately 2), which was required to ensure that the guests were quantitatively protonated. At such low pH, protonation of CB7 or competitive binding of hydronium ions might interfere. A UV absorption titration for ABZ at pH 2.4 indeed provided a slightly lower binding constant of the protonated form (5.9×10^6 L/mol) than the one projected from the thermodynamic cycle (2.6×10^7 L/mol, Table 1).

Strain-promoted 1,3-dipolar cycloadditions of diazo compounds with cyclooctynes

Joseph Moran, Craig S. McKay, and John Paul Pezacki

Abstract: Strain-promoted cycloadditions of diazo compounds with dibenzocyclooctyne proceed with second-order rate constants of >10 L mol^{-1} s^{-1} at 25 °C. These reactions display rate constants that are comparable or greater than those of the analogous reactions of nitrones or azides with cyclooctynes.

Key words: metal-free click chemistry, diazo compounds, 1,3-dipolar cycloaddition, dibenzocyclooctyne, rate constants.

Résumé : Les cycloadditions catalysées par une tension de composés diazo avec le dibenzocyclooctyne se produisent avec des constantes de vitesse du deuxième ordre supérieures à 10 L mol^{-1} s^{-1}, à 25 °C. Les constantes de vitesse de ces réactions sont comparables ou supérieures à celles de réactions analogues de nitrones ou d'azotures sur les cyclooctynes.

Mots-clés : chimie par cliquage sans métal, composés diazo, cycloaddition 1,3-dipolaire, dibenzocyclooctyne, constantes de vitesse.

[Traduit par la Rédaction]

Introduction

"Click chemistry" was first coined by Kolb et al. in 2001,[1] and has come to describe chemical reactions that are rapid, selective, thermodynamically favourable, and devoid of side products.[1] In less than a decade, this philosophy has been embraced in numerous areas of the chemical sciences, including small-molecule library synthesis,[2] the construction of supramolecular materials,[3] and biomolecule conjugation.[4] Although the vast majority of these examples have relied on the copper-catalyzed [3+2] azide–alkyne cycloaddition (CuAAC) to provide a reliable reaction, biological applications have demanded the development of "click" reactions that do not require the presence of toxic copper species. Biocompatible variants that are kinetically driven by strain-release of cyclooctynes activated by gem difluoro[5a–5c] or dibenzo[5d] groups have subsequently been shown to be as effective for azide–alkyne cycloadditions without the requirement of copper catalysis. Other bio-orthogonal reactions involving 1,3-dipoles, such as nitrile oxides[6] or photochemically generated nitrile imines,[7] have also been reported and have reaction kinetics that are comparable or superior to azide–alkyne cycloadditions and are also highly chemoselective in the context of biological systems.

Our laboratory has recently demonstrated that strain-promoted cycloadditions of nitrones with cyclooctynes are up to 25 times faster than comparable reactions of azides.[8] Nitrone cycloadditions have also been successfully applied to protein functionalization.[9] Increased reaction rates are valuable as a means for reducing the required concentration of labeling reagents in bioorthogonal reactions. Inspired by the pioneering work done by Huisgen et al.[10] on 1,3-dipolar cycloadditions of diazoalkanes with acyclic alkynes,[10–12] we set out to investigate whether a strain-promoted variant could serve as a rapid alternative to reactions of nitrones or azides with cyclooctynes (Fig. 1).[13] Herein, we report that diazoalkanes are rapid dipoles for 1,3-dipolar cycloadditions with cyclooctynes.

Fig. 1. Overview of strain-promoted 1,3-dipolar cycloadditions of azides, nitrones, and diazo compounds with cyclooctynes.

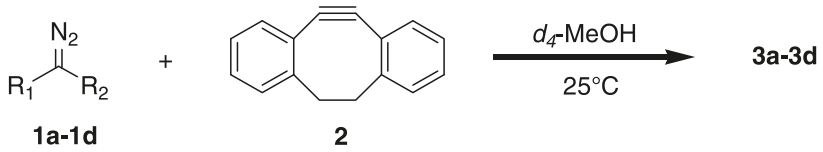
Table 1. Second-order rate constants, k_2 (L mol^{-1} s^{-1}), for the reactions of diazo compounds **1a**–**1d** with **2**.



1a-1d **2**

Entry	Diazo compound	Product	Time (min)	Yield %[a]	k_2 (L mol^{-1} s^{-1})[b]
1	**1a** 	**3a** 	98	>99	0.070 ± 0.003
2	**1b** 	**3b**[c] 	1062	97	0.0053 ± 0.0002
3	**1c** 	**3c**[c] 	<1 min	34	>10[d]
4	**1d** 	**3d**[c] 	<1 min	93	>10[d]

Note: Conditions: diazo compound (50 mmol/L); **2** (50 mmol/L), 25 ºC, d_4-MeOH.
[a] Isolated yield.
[b] Kinetic evaluation of diazo compounds: the appropriate substrate and **2** were predissolved in d_4-MeOH and mixed at an equimolar concentration of ~25 mmol/L.
[c] Representative tautomer isolated after column chromatography.
[d] Reactions were too fast to be measured by ^{1}H NMR even at 2.5 mmol/L of substrate.

Results and discussion

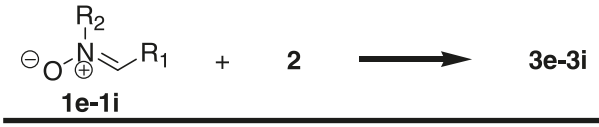
There are number of ways in which diazoalkanes can be conveniently synthesized.[14] Here, standard literature procedures were used to prepare diazoalkanes just prior to use.[15] The diazoalkane scope was evaluated with respect to its electronics and conformational rigidity (Table 1). The reaction of diphenyldiazomethane **1a** with dibenzocyclooctyne **2** in d_4-methanol yielded the substituted pyrazole **3a** in >95% yield within 96 min, corresponding to a second-order rate constant, k_2 = 0.07 L mol^{-1} s^{-1}. Substitution with stronger electron-withdrawing groups, such as ethyl 2-diazoacetate **1b**, reduced the reaction rate by 13-fold, k_2 = 0.0053 L mol^{-1} s^{-1} (Table 1, entry 2), reaching >95% conversion within 18 h.

Diazoalkanes bearing electron-donating groups or groups less capable of resonance stabilization displayed dramatic rate enhancements. Trimethylsilyl diazomethane (**1c**) reacted rapidly with **2** and reached maximum conversion within 1 min, and phenyl diazomethane reached >95% conversion within 1 min. We were unable to determine rate constants for diazoalkanes **1c** and **1d** by ^{1}H NMR, since reactions were complete upon acquisition of the first data point. The modest yield of **3c** most likely resulted from competitive reaction pathways, including carbene reaction pathways of **1c**. The cycloadducts arising from reactions of diazoalkanes **1b** and **1d** underwent rapid tautomerization to the aromatic pyrazoles **3b** and **3d**, respectively. The primary cycloadduct from the reaction of **1b** with **2** underwent loss of the trimethylsilyl group under the aqueous reaction conditions yielding **3c**.

In general, **2** reacts with resonance-stabilized diazoalkanes at rates comparable to acyclic nitrones bearing phenyl substituents at the α-position (Table 2, entries 1 and 2) or benzyl azide (k_2 = 0.062 L mol^{-1} s^{-1}).[8] However, more weakly stabilized diazoalkanes, **1c** and **1d**, displayed faster intrinsic kinetics for cycloaddition with **2** than either strained endocyclic nitrones (Table 2, entry 3)[8] or nitrones equipped with ester or amide[9] groups at the α-position (Table 2, entries 4 and 5).

Lastly, a screen of various deuterated solvents was used to evaluate the generality of the reaction as well as to determine if there was a solvent effect on the rate of cycloaddition. Fortunately, the reaction of **1a** with **2** proceeded to >95% yield in less than 4 h for all solvents employed (Table 3). In contrast to the solvent effect observed with nitrones, where protic solvents were slowest,[8] d_4-methanol

Table 2. Rate constants for the reactions of nitrones with **2**.



1e-1i

Entry	Nitrone		Product	k_2 (L mol^{-1} s^{-1})
1[a]	R_1= Ph	R_2= Bn	**3d**	0.09
2[a]	R_1= Ph	R_2= Me	**3e**	0.13
3[a]			**3f**	1.5
4[b]	R_1= CO_2Et	R_2= Me	**3g**	3.9
5[b]	R_1= C(O)NHBn	R_2= Me	**3h**	2.2

Note: Rate constants were determined by ^{1}H NMR in analogy with experiments involving diazoalkanes.

[a] See ref. 8.

[b] Unfunctionalized dibenzocyclooctynol was used in place of **2**; see ref. 9.

Table 3. Solvent screen for the reaction of **1a** with **2**.

1a

Entry	Solvent	Reaction time for 95% conversion to **3a** (min)
1	C_6D_6	245 + 15
2	*CD_3OD*	98 ± 5
3	*d_6*-DMSO	108 + 5
4	CD_3CN	139 + 5

Note: Conditions: **2** was added to **1a** (both pre-dissolved, 100 mmol/L, 1:1) in an NMR tube and monitored by ^{1}H NMR at 25 °C.

was found to be the optimal solvent, reaching 95% yield within 98 min.

Diazoalkanes can be protonated to form alkanediazonium ions in aqueous solution in biological systems that can alkylate nucleic acids as well as protein side chains, causing cellular stress and carcinogenesis.[16] Although the biomolecular rate constants for strain-promoted cycloaddition are slower than those of proton transfer ($k_{H^+} \approx 10^2$–10^6 L mol^{-1} s^{-1})[16] under neutral conditions, at physiological pH where hydronium ion concentration is low (10^{-7} mol/L), cycloaddition rates may be competitive or even dominate over diazonium ion chemistry. Interestingly, cyclooctynes might also serve as in vivo quenchers of diazoalkanes that might be formed through nitrosative stress.

Diazoalkanes can give rise to carbene intermediates either through photolytic or thermolytic processes.[17] Carbenes can then undergo O–H or C–H insertion reactions, cyclopropanation reactions, as well as intramolecular rearrangements such as 1,2-hydrogen shifts.[17] Pioneering work by Scaiano's group and others have established rate constants for many of these processes.[17–19] Although these rates can be high, any carbene intermediates formed in biological media would be expected to react preferentially with water to form the corresponding alcohol or undergo intramolecular rearrangements. However, the rate constants reported here suggest that even unstabilized diazoalkanes should react rapidly and spontaneously with cyclooctyne **2** before significant thermolysis or photolysis can occur under ambient conditions.

Conclusion

Strain-promoted cycloadditions of diazoalkanes with cyclooctynes represent an alternative rapid conjugation technique for material sciences and a valid method for constructing functionalized pyrazoles. Rate enhancements of >10 L mol^{-1} s^{-1} were observed for diazoalkanes containing electron-donating groups adjacent to the diazo moiety. These rates are comparable with those of analogous reactions involving endocyclic nitrones or nitrones bearing ester or amide moieties at the α-position. Optimization of the stability and reactivity of the diazoalkane group may lead to diazoalkanes as reactive and useful alternatives to nitrone and azide dipoles for use in strain-promoted cycloadditions with cyclooctynes.

A porphyrin-stabilized iridium oxide water oxidation catalyst

Benjamin D. Sherman, Smitha Pillai, Gerdenis Kodis, Jesse Bergkamp, Thomas E. Mallouk, Devens Gust, Thomas A. Moore, and Ana L. Moore

Abstract: Colloidal solutions of iridium oxide hydrate ($IrO_2 \cdot nH_2O$) were formed using porphyrin stabilizers bearing malonate-like functional groups at each of the four meso positions of the porphyrin ring. Cyclic voltammetry and monitoring of solution oxygen concentrations under constant applied potential demonstrated the electrochemical catalytic activity of the porphyrin–$IrO_2 \cdot nH_2O$ complexes for the oxidation of water to oxygen. Quenching of the porphyrin fluorescence in the complex implies strong interaction between the porphyrin and the $IrO_2 \cdot nH_2O$. These results mark a step toward developing a porphyrin-based photoanode for use in a photoelectrochemical water-splitting cell.

Key words: water oxidation, electrochemical catalysis, iridium oxide, porphyrin.

Résumé : Il se forme des solutions colloïdales d'hydrate d'oxyde d'iridium ($IrO_2 \cdot nH_2O$) lorsqu'on utilise comme stabilisants des porphyrines portant sur chacune des quatre positions méta du noyau porphyrine des groupes fonctionnels apparentés au malonate. La voltampérométrie cyclique et le monitorage des concentrations d'oxygène dans la solution, sous potentiel appliqué constant, démontrent l'activité catalytique électrochimique des complexes porphyrine–$IrO_2 \cdot nH_2O$ pour l'oxydation de l'eau en oxygène. Le piégeage de la fluorescence de la porphyrine dans le complexe implique une forte interaction entre la porphyrine et le $IrO_2 \cdot nH_2O$. Ces résultats marque une étape en avant dans le développement d'une photoanode à base de porphyrine pour l'utilisation d'une cellule photoélectrochimique pour la division de l'eau.

Mots-clés : oxydation de l'eau, catalyse électrochimique, oxyde d'iridium, porphyrine.

[Traduit par la Rédaction]

Introduction

Work carried out by Harriman et al. over 20 years ago demonstrated that hydrated iridium oxide ($IrO_2 \cdot nH_2O$) is an active, stable, and efficient catalyst for water oxidation.[1–3] Colloidal $IrO_2 \cdot nH_2O$ in solution with either $Ru(II)(bpy)_3$ (bpy = 2,2′-bipyridine) or porphyrin dye could carry out the photochemical generation of O_2 from water.[2,3] These studies, however, required the presence of a strong oxidant ($S_2O_8^{2-}$) to generate the photo-oxidized dye that would then oxidize the catalyst. Subsequent electrochemical studies by other groups investigated techniques for immobilizing $IrO_2 \cdot nH_2O$ on the surface of transparent glass electrodes.[4–6] Yagi et al. showed that adsorbed layers formed on the surface of indium-doped tin oxide and fluorine-doped tin oxide electrodes when the electrodes were allowed to soak in a solution containing citrate-stabilized colloidal $IrO_2 \cdot nH_2O$.[5,6] Electrochemical studies of prepared electrodes showed the onset of catalytic current near 1.0 V versus saturated calomel electrode (SCE) at pH 5.3 (no $IrO_2 \cdot nH_2O$ in solution). Murray et al. have studied $IrO_2 \cdot nH_2O$ particles formed at high pH, without the use of stabilizing groups, both on a surface and in solution.[7,8] Their work has shown the need for only 0.15 V of overpotential for the onset of water oxidation and 100% current efficiency for the generation of O_2 from water at an overpotential of 0.29 V.[7,8] Although the catalytic activity of $IrO_2 \cdot nH_2O$ has been well established, only recently has a system capable of driving the catalyst photoelectrochemically been demonstrated.[9]

We have reported the development of a water-splitting photoelectrochemical cell employing a $Ru(II)(bpy)_3$–$IrO_2 \cdot nH_2O$ based photoanode.[9] In that work, the dye–$IrO_2 \cdot nH_2O$ complex was formed using a heteroleptic $Ru(II)(bpy)_3$ complex containing phosphonate groups on one of the bipyridyl ligands and a malonate group on another. Previous work had demonstrated the preference of carboxylate groups over phosphonate groups for binding to the surface of $IrO_2 \cdot nH_2O$.[10] This chemistry allowed for the formation of small $IrO_2 \cdot nH_2O$ particles (1–5 nm) capped with $Ru(II)(bpy)_3$ dye molecules containing exposed phosphonate groups.[9,10] The dye–$IrO_2 \cdot nH_2O$ constructs could then be attached to metal oxide semiconductors, such as titanium dioxide (TiO_2), via the phosphonate group.

In this system, the photoanode consisted of the dye–$IrO_2 \cdot nH_2O$ complex adsorbed to a TiO_2 layer on top of a

fluorine-doped tin oxide electrode. When this photoanode was combined with a platinum cathode in a photoelectrochemical cell, the cell produced a photocurrent of 12.7 μA cm^{-2} upon illumination with 450 nm light at an intensity of 7.8 mW cm^{-2}, giving an internal quantum yield of 0.9%.[9] Three principal factors limited the performance of this system: slow electron transfer from the $IrO_2 \cdot nH_2O$ catalyst to the oxidized dye, bleaching of the dye likely resulting from nucleophilic attack on the oxidized dye, and the need for applied bias to achieve overall water splitting. Transient spectroscopic studies showed electron transfer from the $IrO_2 \cdot nH_2O$ to the photo-oxidized dye (2.8 ms) to be an order of magnitude slower than the back electron transfer from TiO_2 to the oxidized dye (0.37 ms).[9] An additional issue with Ru(II)$(bpy)_3$ complexes as photosensitizers is that they absorb strongly in the blue region of the spectrum but cannot efficiently utilize light in the red region of the spectrum.

The work outlined herein seeks to improve the stability, electron transfer rate, and spectral properties of the dye–$IrO_2 \cdot nH_2O$ complex by incorporating a porphyrin rather than the Ru(II)$(bpy)_3$ dye. We report the synthesis of a porphyrin–$IrO_2 \cdot nH_2O$ complex that shows an electrochemical catalytic response similar to that of other $IrO_2 \cdot nH_2O$ complexes.[5] Finally, fluorescence lifetime measurements indicate quenching of the porphyrin fluorescence in the porphyrin–$IrO_2 \cdot nH_2O$ complex.

Experimental

Materials

Sephadex with a 5 000 molecular weight cutoff, Na_2HPO_4, NaH_2PO_4, tetrabutylammonium hexafluorophosphate, and benzonitrile were obtained from Sigma-Aldrich. Benzonitrile was distilled prior to use. K_2IrCl_6 was used as received from Alfa Aesar. KNO_3 was obtained from Fluka. Tetrahydrofuran for synthesis was distilled from sodium/benzophenone. Dimethylformamide was dried over activated 4 Å molecular sieves. Dichloromethane used for chromatography was distilled from calcium hydride.

Porphyrin synthesis

General methods

5,10,15,20-Tetrakis(4-bromomethylphenyl)porphyrin was synthesized by a published method.[11] The malonate substitution and cleavage of the esters were performed by literature procedures used for related compounds.[12–14] Palladium insertion was achieved by adapting Durantini's procedure.[13]

Porphyrin 1

Sodium hydride (387 mg, 16 mmol) was suspended in 10 mL of dry THF under nitrogen atmosphere. Diethyl malonate (0.61 mL, 4 mmol) in 20 mL THF was added dropwise under ice cooling. After being stirred for 1 h at room temperature, a solution of 5,10,15,20-tetrakis(4-bromomethylphenyl)porphyrin (200 mg, 0.20 mmol) in 20 mL of dry THF was added dropwise to the mixture and stirred for 1 h. The reaction mixture was then poured into an ice-cold saturated NH_4Cl solution. The aqueous layer was extracted with CH_2Cl_2. The organic solution was washed thoroughly with water and dried over Na_2SO_4. The crude material was purified by column chromatography on silica gel (solvent CH_2Cl_2:EtOAc, 20:1). Yield: 120 mg (45%). UV–vis (CH_2Cl_2, nm) λ_{max}: 419, 516, 551, 591, 647. ^{1}H NMR (400 MHz, $CDCl_3$, RT) δ: –2.82 (s, 2H, NH), 1.34 (t, 24H, J = 7.2 Hz, ethyl CH_3), 3.56 (d, 8H, J = 7.7 Hz, CH_2), 3.96 (t, 4H, J = 7.7 Hz, CH), 4.3 (m, 16H, J = 7.2 Hz, ethyl CH_2), 7.58 (d, 8H, J = 8.0 Hz, phenyl CH_2), 8.10 (d, 8H, J = 8.0 Hz, phenyl CH_2), 8.77 (s, 8H pyrrolic H). MALDI-TOF–MS m/z calcd. for $C_{76}H_{78}N_4O_{16}$: 1302.54; found: 1302.67.

Porphyrin 1a

A 50 mg (0.038 mmol) portion of **1** and finely ground sodium hydroxide (292 mg, 7.5 mmol) were suspended in 40 mL of ethanol. The mixture was refluxed for 15 h and a precipitate was formed. The mixture was cooled to room temperature and filtered. The residue was washed with a little ice-cold ethanol and dried in high vacuum. Yield: 43 mg (89.5%). UV–vis (H_2O, nm) λ_{max}: 415, 519, 557, 582, 635. ^{1}H NMR (400 MHz, D_2O, RT) δ: 3.3 (d, 8H, J = 7.9 Hz, CH_2), 3.59 (t, 4H, J = 7.9 Hz, CH), 7.58 (d, 8H, J = 7.8 Hz, phenyl CH_2), 7.9 (d, 8H, J = 7.8 Hz, phenyl CH_2), 8.47 (s, 4H, pyrrolic H), 8.98 (s, 4H, pyrrolic H). MALDI-TOF–MS m/z calcd. for $C_{76}H_{78}N_4O_{16}$: 1079.02; found: 1079.41.

Porphyrin 2

To a solution of **1** (24 mg, 0.018 mmol) in 10 mL DMF was added palladium(II) chloride (32.6 mg, 0.18 mmol). The mixture was stirred for 1 h at 55 °C under nitrogen. The solvent was removed under reduced pressure and the compound was purified by column chromatography on silica gel (solvent CH_2Cl_2:EtOAc, 20:1). Yield: 21 mg (81%). UV–vis (CH_2Cl_2, nm) λ_{max}: 416, 523. ^{1}H NMR (400 MHz, $CDCl_3$, RT) δ: 1.35 (t, 24H, J = 7.2 Hz, ethyl CH_3), 3.56 (d, 8H, J = 7.7 Hz, CH_2), 3.96 (t, 4H, J = 7.7 Hz, CH), 4.3 (m, 16H, J = 7.2 Hz, ethyl CH_2), 7.58 (d, 8H, J = 8.0 Hz, phenyl CH_2), 8.06 (d, 8H, J = 8.0 Hz, phenyl CH_2), 8.75 (s, 8H, pyrrolic H). MALDI-TOF–MS m/z calcd. for $C_{76}H_{78}N_4O_{16}$: 1302.54; found: 1302.67.

Porphyrin 2a

Porphyrin **2** (20 mg, 0.014 mmol) and finely ground sodium hydroxide (107 mg, 2.7 mmol) were suspended in 20 mL of ethanol. The mixture was refluxed for 15 h and a precipitate was formed. The mixture was cooled to room temperature and filtered. The residue was washed with a little ice-cold ethanol and dried in high vacuum. Yield: 17 mg (88%). UV–vis (H_2O, nm) λ_{max}: 413, 522. ^{1}H NMR (400 MHz, D_2O, RT) δ: 3.28 (d, 8H, J = 7.9 Hz, CH_2), 3.59 (t, 4H, J = 7.9 Hz, CH), 7.58 (d, 8H, J = 7.8 Hz, phenyl CH_2), 7.96 (s, 8H, phenyl CH_2), 8.47 (s, 8H, pyrrolic H).

Preparation of the porphyrin–$IrO_2 \cdot nH_2O$ complex

The complex was formed in a solution containing 50 μmol L^{-1} of the porphyrin sodium salt, either **1a** or **2a**, and 1 mmol L^{-1} of K_2IrCl_6. The solution was adjusted to pH 8 with 0.25 mol L^{-1} NaOH and heated to 35 °C, and the reaction was allowed to proceed (~2–3 days) until the starting red-brown solution became pale yellow. The pH of the solution was monitored throughout the reaction period and NaOH was added as necessary to maintain mildly basic pH.

The resulting colloids were either used as such or purified by size exclusion chromatography using a Sephadex gel filtration medium. The malonate–$IrO_2{\cdot}nH_2O$ was prepared as previously described.[10]

Electrochemical measurements

All electrochemical measurements were done using a CH Instruments 760D potentiostat along with software provided by the manufacturer. A glassy carbon or platinum working electrode was used as indicated along with a Ag^+/Ag quasi reference or Ag/AgCl (in saturated KCl) reference and a Pt wire mesh counter electrode. Ferrocene was used to calibrate the potential of the Ag^+/Ag quasi reference with Cp_2Fe^+/Cp_2Fe taken as 0.45 V versus SCE. Cyclic voltammetric measurements of **1** and **2** were done in benzonitrile with 0.1 mol L^{-1} tetrabutylammonium hexafluorophosphate. Porphyrin–$IrO_2{\cdot}nH_2O$ measurements were done in 0.1 mol L^{-1} KNO_3 aqueous solution at the scan rates and potentials indicated. Some measurements were taken in 0.1 mol L^{-1} phosphate buffer with pH near 7 as indicated.

Clark electrode measurements

A Yellow Springs Instrument Co. 5300 Biological Oxygen Monitor was used to measure the percent O_2 in solution, with air-saturated solution set as 100% O_2. Solutions were purged of O_2 by bubbling Ar until the O_2 level reached 30%–50%. Argon was then flowed into the headspace of the cell to keep atmospheric O_2 from entering. After reading a stable percent O_2 level for 2–5 min, the amperometry experiment was initiated. A line was fitted to the stable percent O_2 reading for the 60 s before applying potential in the experiment and was subtracted from the trace to give $\Delta\%O_2$ (change in percent O_2 during the experiment) as shown in Fig. 1.

Time-resolved fluorescence measurements

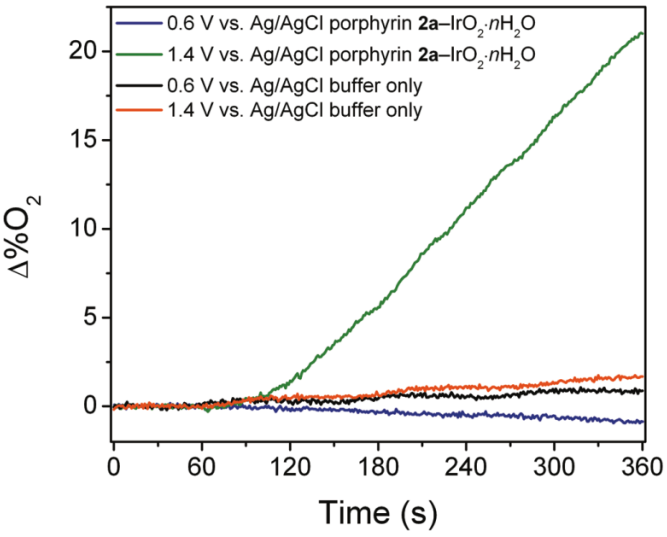
Fluorescence decay measurements were performed by the time-correlated single-photon-counting method. The excitation source for the system was a mode-locked Ti:Sapphire laser (Spectra Physics, Millennia-pumped Tsunami) with a 130 fs pulse duration operating at 80 MHz. The laser output was sent through a frequency doubler and pulse selector (Spectra Physics Model 3980) to obtain 370–450 nm pulses at 4 MHz. Fluorescence emission was detected at the magic angle using a double grating monochromator (Jobin Yvon Gemini-180) and a microchannel plate photomultiplier tube (Hamamatsu R3809U-50). The instrument response function was 35–55 ps. The spectrometer was controlled by software based on the LabView programming language and data acquisition was done using a single photon counting card (Becker-Hickl, SPC-830).

Data analysis was carried out using locally written software (ASUFIT) developed in a MATLAB environment (Mathworks Inc.). Random errors associated with the reported lifetimes obtained from fluorescence were typically ≤ 5%.

Results and discussion

This work centers on the use of tetrakis(methylphenylmalonate)porphyrins as stabilizers for the formation of $IrO_2{\cdot}nH_2O$ colloidal solutions. It builds on the previous finding that bidentate carboxylic acid groups act as effective stabilizers for the formation of small $IrO_2{\cdot}nH_2O$ colloidal particles.[10] The porphyrins used in this study contain methylphenylmalonate groups at each of the para positions of the four meso phenyl groups; it is expected that the colloidal particles formed with these stabilizers will be similar in structure to those reported by Hoertz et al.[10]

Green line: porphyrin **2a**–$IrO_2{\cdot}nH_2O$, glassy carbon working electrode poised at 1.4 V vs. Ag/AgCl. Blue line: porphyrin **2a**–$IrO_2{\cdot}nH_2O$, glassy carbon working electrode poised at 0.6 V vs. Ag/AgCl. Black line: buffer only, glassy carbon working electrode poised at 0.6 V vs. Ag/AgCl. Red line: buffer only, glassy carbon working electrode poised at 1.4 V vs. Ag/AgCl. All measurements taken in H_2O at pH 6.95 with 0.1 mol L^{-1} KNO_3 and 0.1 mol L^{-1} phosphate buffer. Potential applied starting at t = 60 s.



Colloidal $IrO_2{\cdot}nH_2O$ particles were successfully formed using porphyrin **1a** and its Pd analogue, **2a**, shown in Fig. 2 along with their protected ester forms (**1** and **2**). Synthesis of the $IrO_2{\cdot}nH_2O$ colloids entailed heating a solution containing K_2IrCl_6 and the porphyrin at 35 °C for ~2–3 days. The initial pH of the solution was adjusted to near pH 8 with NaOH and monitored and adjusted throughout the synthesis to maintain moderately basic conditions. The resulting colloidal solution was pale yellow. In some cases, the resulting preparation was purified over a size-exclusion column to remove salts and unused starting material. Solutions prepared in this way were stored under mildly basic conditions and remained stable on the benchtop for several months.

Cyclic voltammetry experiments were carried out to elucidate the electrochemical characteristics of the colloids. A typical voltammogram reveals the onset of strong anodic current near 1.1 V versus Ag/AgCl, indicative of water oxidation. Poising of the working electrode at sufficiently positive potentials causes the generation of bubbles at the electrode surface in solutions containing the porphyrin–$IrO_2{\cdot}nH_2O$. Figure 3 shows an overlay of several voltammograms performed in the presence of $IrO_2{\cdot}nH_2O$ catalysts. The various $IrO_2{\cdot}nH_2O$ complexes give comparable voltammograms, with strong anodic signals indicative of water ox-

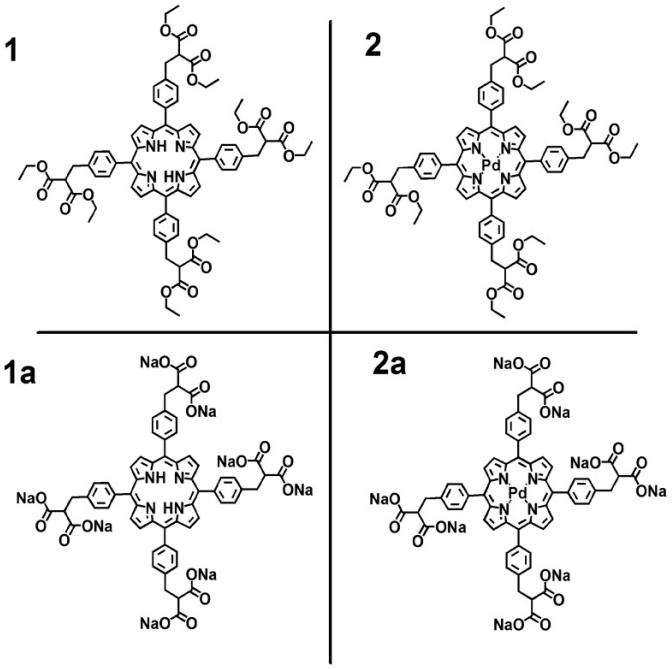

Fig. 3. Comparison of cyclic voltammograms taken in solutions containing porphyrin **1a**–$IrO_2{\cdot}nH_2O$ (red), porphyrin **2a**–$IrO_2{\cdot}nH_2O$ (orange), malonate–$IrO_2{\cdot}nH_2O$ (blue), or only supporting electrolyte (black). All scans were taken with a glassy carbon working electrode, at a scan rate of 100 mV s^{-1}, with voltages referenced to a Ag/AgCl electrode. The solutions contained $IrO_2{\cdot}nH_2O$ colloidal catalyst at different concentrations and the currents observed should not be taken as a quantitative comparison of catalytic activity.

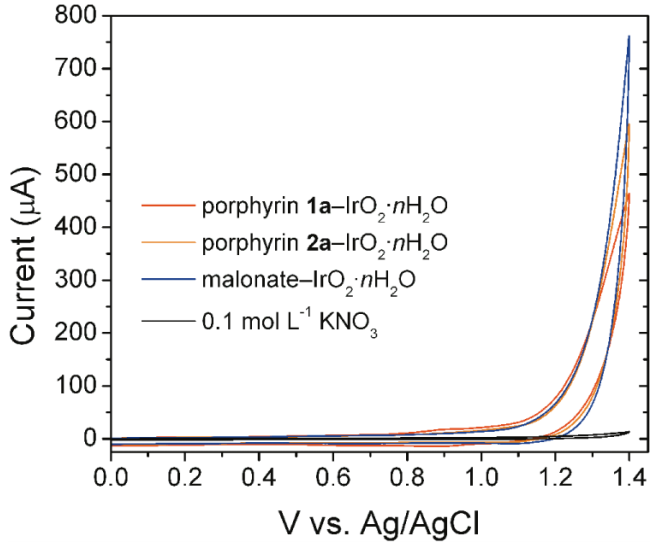
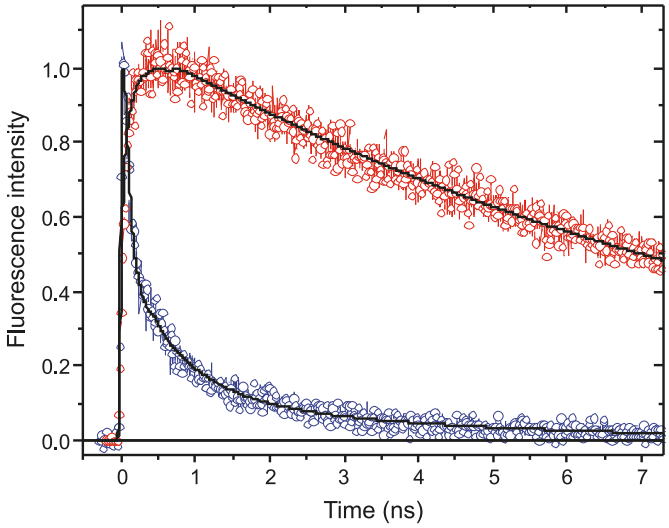


idation. Comparison with the scan in the absence of any $IrO_2{\cdot}nH_2O$ clearly shows the signal originates from the presence of the catalyst. It should be emphasized that Fig. 3 is not intended as a quantitative comparison between the various $IrO_2{\cdot}nH_2O$ complexes, as the concentration and likely the size of the colloid was different in each case, but rather as a means of demonstrating that the behavior of the

Fig. 4. Porphyrin fluorescence lifetime measurements. Red line: porphyrin **1a** in solution with malonate-stabilized $IrO_2{\cdot}nH_2O$, lifetime 8.79 ns. Blue line: porphyrin **1a**–$IrO_2{\cdot}nH_2O$ colloidal particles, major component lifetime 46.7 ps (see text).



porphyrin–$IrO_2{\cdot}nH_2O$ complexes is similar to that of the carboxylic acid (malonate or citrate) stabilized $IrO_2{\cdot}nH_2O$ complexes described in the literature.[5,6]

To demonstrate that the observed catalytic signal corresponds to the oxidation of water to O_2, a Clark electrode was employed to monitor the O_2 concentration in the solution during electrochemical measurements. After purging the cell of O_2 by bubbling with argon, the cell was sealed and the O_2 concentration was monitored while poising the glassy carbon working electrode at various potentials versus Ag/AgCl (Fig. 1). With porphyrin **2a**–$IrO_2{\cdot}nH_2O$ in solution, the O_2 concentration does not increase with time at 0.6 V versus Ag/AgCl but does increase at 1.4 V. When the same working electrode is used in a solution containing only supporting electrolyte and no catalyst, no increase in O_2 occurs at either 0.6 or 1.4 V versus Ag/AgCl. Thus, oxygen is produced only in the presence of the catalyst at a suitable potential.

As one means of assessing the interaction of the porphyrin dye with the $IrO_2{\cdot}nH_2O$, the porphyrin fluorescence lifetimes in the porphyrin–$IrO_2{\cdot}nH_2O$ complex and with the porphyrin dissolved in a solution containing malonate–$IrO_2{\cdot}nH_2O$ were determined. As shown in Fig. 4, the fluorescence lifetime of the free porphyrin **1a** in the presence of malonate–$IrO_2{\cdot}nH_2O$ was 8.79 ns. This lifetime is typical for a free base porphyrin of this general type. The fluorescence lifetime of the same porphyrin complexed with $IrO_2{\cdot}nH_2O$ was quenched, with the major component having a lifetime of 46.7 ps (70.4%), and minor components with lifetimes of 316.9 ps (18.6%), 1.81 ns (9.1%), and 7.09 ns (1.9%). These results suggest that different populations of porphyrin molecules in the material experience different interactions with the $IrO_2{\cdot}nH_2O$. The dominant short fluorescence lifetime component implies a significant interaction between the porphyrin and the $IrO_2{\cdot}nH_2O$ particle. Quenching by energy transfer, electron transfer, enhanced intersystem crossing, or some combination of these is possible; the exact mechanism has not been assigned. Fortunately, the porphyrin excited state is not quenched to the point that the

quantum yield of electron injection into a nanostructured Ti or Sn oxide would be expected to be limited.

In these photoanodes, the driving force for electron transfer from the $IrO_2 \cdot nH_2O$ catalyst to the sensitizer is provided by the electrochemical potential for the reduction of the porphyrin radical cation. Figure 5 shows cyclic voltammograms of free base porphyrin **1** and its Pd analog **2**. As seen in Table 1, the addition of Pd increases the potential by ~160 mV. Having these two sensitizers available will facilitate mechanistic studies designed to determine the yield-limiting steps in the photooxidation of water.

Conclusion

We report the use of a high-potential, porphyrin-based stabilizer in the formation of $IrO_2 \cdot nH_2O$ colloidal particles and have demonstrated catalytic electrochemical water oxidation by this complex. The porphyrin was designed to incorporate dicarboxylic acid groups at each of the four meso positions, as such groups are known to interact favorably with the $IrO_2 \cdot nH_2O$ surface.[10] This work is a step towards the synthesis of a high-potential porphyrin carrying the appropriate moieties, namely *para*-malonate and phosphonate groups on the porphyrin ring, to allow formation of the catalytic complex and then its subsequent adsorption to a transparent conductive electrode. This construct will be the photoanode of a porphyrin-based analogue of the $Ru(II)(bpy)_3$-based water-splitting photoelectrochemical cells that have previously been reported by us[9] as well as by others.[15]

Dye-sensitized solar cells made of titania nanoparticles structured into a mesoporous material

Carmela Aprile, Laura Teruel, Mercedes Alvaro, and Hermenegildo García

Abstract: Using cetyltrimethylammonium bromide as the structure-directing agent, titania nanoparticles (3–5 nm) were organized into a mesoporous material (8.6 nm average pore size and 99 m^2/g). The textural and spatial structuring of the mesoporous material were studied by isothermal gas adsorption, X-ray diffraction, and transmission electron microscopy. Dye-sensitized solar cells using mesoporous material exhibit a one order of magnitude increase in the overall efficiency with respect to analogous cells prepared using the same nanoparticles without periodic mesoporous material. This photovoltaic enhancement is due to increased adsorption of the dye (ruthenium polypyridyl N719) to the mesoporous material arising from the larger area of this mesoporous solid with respect to the same unstructured nanoparticles.

Key words: dye-sensitized solar cells, semiconductors, Pluronic as structure-directing agent, spatial ordering of titania nanoparticles, N719 dye.

Résumé : Utilisant le bromure de cétyltriméthylammonium comme agent dirigeant la structure, il a été possible d'organiser des nanoparticules (3–5 nm) de dioxyde de titane en un matériau mésoporeux (taille moyenne des pores de 8,6 nm et 99 m^2/g). On a étudié la structure texturale et spatiale du matériau mésoporeux par adsorption gazeuse isotherme, diffraction des rayons-X et microscopie électronique à transmission. L'efficacité globale de cellules solaires sensibilisées par un colorant et comportant de ce matériel mésoporeux donnent lieu à une augmentation d'un ordre de grandeur par rapport à des cellules analogues préparées utilisant les mêmes nanoparticules sans matériau mésoporeux périodique. Cette hausse photovoltaïque est due à une augmentation de l'adsorption du colorant (polypyridyl ruthénium N719) du matériau mésoporeux provenant de la plus grande surface du ce solide mésoporeux par rapport aux mêmes nanoparticules non structurées.

Mots-clés : cellules solaires sensibilisées par un colorant, Pluronic comme agent directeur de la structure, ordonnance spatiale de nanoparticules de dioxyde de titane, colorant N719.

[Traduit par la Rédaction]

Introduction

The dye-sensitized solar cell (DSSC) based on titanium dioxide is a topic of much current interest.[1,2] In this type of photovoltaic device, light in the visible region is absorbed by the dye, which upon excitation injects one electron into the semiconductor conduction band, leading to charge separation. The electron in the semiconductor conduction band goes through the external circuit to the metal cathode (typically a platinized electrode) and is transported by the electrolyte redox couple (typically I^-/I_3^-) to the positive hole of the dye. In this type of DSSC, the use of a layer of nanoparticulated titania (about 10 nm size) to construct the solar cell was a breakthrough in this area in the 1990s.[2] Because of the pivotal role played by titania, there is continued interest in producing new forms of this material that eventually can lead to improved photovoltaic activity.[2]

The preparation by Mobil researchers of mesoporous silicas, such as MCM-41 (Mobil Corporate Material Number 41), with remarkable spatial periodicity and strict uniformity of pore size in the nanometre scale was a significant contribution to material science.[3] Mesoporous silicas rank at the top of the list of large surface area solids, possessing high pore volumes and being able to adsorb large quantities of guests compared with amorphous or microporous silicas.[4] Since the initial reports describing the preparation of mesoporous silicas, there has been an interest in expanding these results to other metal oxides besides silica.[5] Preparation of periodic mesoporous oxides is a topic that has been extensively reviewed.[6–10] Given its photovoltaic and photocatalytic activity, titanium dioxide is one metal oxide that will benefit from being prepared with a large surface area and pore volume.[11–15] Thus, starting from compounds containing a single titanium atom, such as $Ti(OiPr)_4$, the synthesis of periodic mesoporous titania has been attempted using commercial amphiphilic polymer Pluronic 123 as the structure-directing agent to produce the spatial ordering in the nanometre length scale.[12–15]

One of the general problems encountered in mesoporous materials obtained from molecular precursors is the lack of structural stability upon removal of the structure-directing agent, leading to collapse of the material.[6,16] This instability is generally attributed to the thin walls constituted by a few metal–oxygen bonds. Moreover, in the particular case of titanium dioxide, most of the attempts to prepare periodic mesoporous materials from molecular compounds having a single Ti atom have led to the formation of nanoparticulated materials with a variable degree of ordering and porosity. One way in which this instability has been circumvented is by pyrolizing the organic template inside the mesopores instead of removing it.[17] The hard carbonaceous residue inside the channels produces remarkable stability, thereby preventing the collapse of the structure.[17] However, a disadvantage of this strategy for increasing the structural stability is that the pore volume is notably reduced and incorporation of dye molecules inside the mesopores is impeded by the remaining carbon.

Recently, we and others have reported the preparation of periodic mesoporous titania using small nanoparticles rather than molecular precursors as building blocks and have observed remarkable photocatalytic properties.[11,18] The advantage of using nanoparticles as building blocks to construct the material instead of condensing molecules of a single titanium atom is the robustness of the structure. It has been shown for related mesoporous metal oxides constituted by the corresponding nanoparticles that the mesoporosity can resist steaming for long periods.[19] Similar steaming treatment with much shorter time and milder conditions will produce the complete collapse of mesoporous solids synthesized from molecular precursors. In addition, the empty pore volume allows adsorption of a large dye loading that is crucial to reach high efficiencies of the photovoltaic cell.

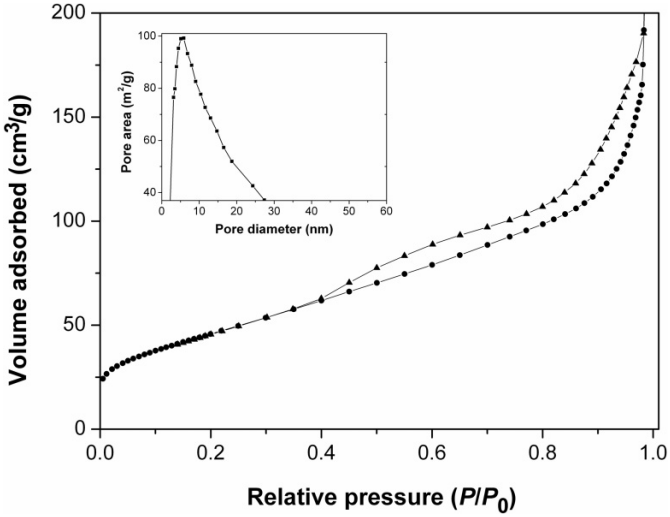
In this context, we report the spatial structuring of small titania nanoparticles (3–5 nm) (pre-TiO_2) in the micrometric length using cetyltrimethylammonium bromide (CTABr) as the structure-directing agent, forming a mesoporous material with some spatial structuring (mp-TiO_2), as determined by isothermal gas adsorption and transmission electron microscopy (TEM) images. The use of mp-TiO_2 leads to a one order of magnitude increase in the current density of DSSCs as compared with identical cells prepared with the unstructured precursor TiO_2 nanoparticles (pre-TiO_2). There are some precedents in the literature showing that spatial structuring of the photoactive titania layer or the use of structured mesoporous titania is beneficial for the efficiency of the resulting solar cells.[17,20–26] The main contribution of our work is to show that the origin of this remarkable enhancement is the larger amount of adsorbed sensitizing dye as compared with pre-TiO_2. This higher dye adsorption of mp-TiO_2 as compared with pre-TiO_2 arises from the increase in surface area upon nanoparticle structuring in the micrometric scale forming a mesoporous material.

Experimental methods

Synthesis of mp-TiO_2

In a typical procedure, CTABr was added to a solution of NH_4OH and deionized water, and the solution was stirred for 30 min in a closed polyethylene bottle to form a homogeneous solution. Nanoparticles of TiO_2 suspended in ethanol (20 mL) and the appropriate amount of tetraethyl orthosilicate (TEOS) dissolved in ethanol (5 mL) were mixed and added slowly to the CTABr solution at 50 °C for 2 h. TiO_2 nanoparticles (pre-TiO_2) were prepared by the hydrolysis of titanium isopropoxide in aqueous solution as previously reported.[18] The resulting sample consists of TiO_2 nanoparticles with a size distribution between 3 and 5 nm as determined by TEM, as has been previously reported.[18] The molar ratio of the materials was 1.00:0.12:8.0:114 $X : CTABr : NH_3$ (20%) : H_2O, where X corresponds to the sum of the Ti and Si atoms. The Ti:Si atomic ratio was 99:1. The mixture was stirred at 50 °C for 1 h. Then the resulting gel was heated at 100 °C in static conditions for 4 days. The solid obtained was washed thoroughly with water and ethanol and dried at 100 °C for 3 h. The structure-directing agent was removed by calcination using the following temperature program: room temperature, temperature increasing by 3 °C/min, 500 °C for 5 h. Initially the sample was purged with nitrogen (1 mL/min), and after the first 5 h the nitrogen flow was gradually replaced with air to complete surfactant combustion. An analogous preparation procedure in the complete absence of TEOS results in a material with significantly less spatial ordering and mesoporosity, as evidenced by isothermal gas adsorption and TEM.[18]

Fig. 1. Isothermal N_2 adsorption profile measured for mp-TiO_2. The inset shows the estimated pore-size distribution.



Photovoltaic measurements

DSSCs were prepared according to the literature.[27,28] Thus, pre-TiO_2 or mp-TiO_2 semiconductors (100 mg) were dispersed in an ethylcellulose (6%) – α-terpineol paste. The paste was spread onto freshly cleaned transparent conductive glass (FTO) and the layer was sintered at 450 °C. After cooling to 50 °C, the films were immersed in a 0.3 mmol/L solution of commercial polypyridyl ruthenium complex N719 dye (Solaronix) in a 1:1 CH_3CN–*tert*-butanol mixture for 2 days. The TiO_2 electrodes were assembled with platinized counter electrodes using a separator of adhesive polymer film (Surlyn M). To obtain the I–V curves of cells containing pre-TiO_2 and mp-TiO_2, a thin layer of these ma-

terials was prepared by spreading the semiconductor paste onto a transparent conductive FTO electrode, using the razor blade method. The resulting layer was sintered in an oven at 450 °C for 30 min. The photovoltaic cell was constructed by using the titania layer on FTO as anode and a platinized electrode as cathode and using a solution of 0.5 mol/L lithium iodide, 0.5 mol/L iodine, and 0.4 mol/L *tert*-butylpyridine in acetonitrile as electrolyte. The electrodes (0.6 cm × 0.6 cm) were connected to a potentiostat (Amel) and illuminated with a solar simulator (Oriel) with an AM 1.5G filter. The nominal power for the measurements was 1000 W/m^2.

Results and discussion

The preparation of mp-TiO_2 was undertaken using pre-TiO_2 nanoparticles (3–5 nm size) as building blocks and CTABr as the structure-directing agent in the presence of minimum amounts of TEOS as chemical binder. Under these synthesis conditions, the spatial structuring originated by the CTABr liquid crystal serves to template the mesopores of the solid, whose nanoparticles are bound by strong Si–O bonds from TEOS hydrolysis and co-condensation.[18] Isothermal nitrogen adsorption shows that mp-TiO_2 has mesoporosity with a broad pore size (distribution between 6 and 20 nm) having a maximum at 8.6 nm, and a BET surface area determined according to the Brunauer–Emmett–Teller algorithm[29] of 99 m^2/g was estimated (see inset of Fig. 1). This surface-area value compares favorably with the surface area of pre-TiO_2 (35 m^2/g) and that of conventional P25 TiO_2, which is typically around 45 m^2/g.

The solid was annealed from room temperature to 500 °C at a rate of 3 °C/min. The pre-TiO_2 used as building blocks was also submitted to the same treatment as mp-TiO_2 but in the absence of CTABr. Importantly, the anatase phase of pre-TiO_2 and mp-TiO_2 was established by Raman spectroscopy and X-ray diffraction (Fig. 2). The spectra and diffractograms of both pre-TiO_2 and mp-TiO_2 coincide with those expected for the anatase phase, which are different from those for the amorphous and rutile phases.[18] It is known that the photovoltaic activity of TiO_2 in the anatase phase is higher than that in the rutile phase.[18]

Transmission electron microscopy clearly demonstrates the presence of mesopores and the occurrence of some spatial ordering of mp-TiO_2. Figure 3 presents the TEM dark-field image showing that TiO_2 nanoparticles (small white spots) are well dispersed all over the material with some variation in size, whereas the bright field reveals the mesoporous structure of the material. Thus, the characterization based on isothermal gas adsorption, X-ray diffraction, and TEM images shows that the material consists of small TiO_2, the anatase nanoparticles, with some spatial structuring introduced by the surfactant as template.

Two sets of DSSCs were prepared by the same procedure using pre-TiO_2 or mp-TiO_2 as semiconductor, polypyridyl ruthenium complex N719 as dye, and a solution of 0.5 mol/L lithium iodide, 0.05 mol/L iodine, and 0.4 mol/L *tert*-butylpyridine in acetonitrile as electrolyte. For comparison, an analogous set of DSSCs was also prepared using standard P25 TiO_2 with an average particle size of 30 nm.

The performance of the DSSCs prepared with pre-TiO_2 and mp-TiO_2 was measured for a set of 3 independent cells. A summary of the data obtained is shown in Table 1. Figure 4 shows selected I–V plots from which the data of Table 1 have been obtained. As can be seen there, the voltage at open circuit (V_{OC}) was somewhat higher for mp-TiO_2, but the most remarkable difference is the higher current density

Table 1. Efficiency of DSSCs based on pre-TiO_2, mp-TiO_2, and P25.

	V_{oc} (V)	J_{sc} (mA/cm^2)	Fill factor	Efficiency (%)	Dye content (mol dye / mg $TiO_2 \times 10^8$)
Pre-TiO_2 (8 μm)	0.57	0.66	0.48	0.18	0.18
Mp-TiO_2 (8 μm)	0.66	4.87	0.52	1.67	3
P25 (18 μm)	0.66	5.53	0.52	1.89	2.4
Mp-TiO_2 (18 μm)	0.69	8.93	0.45	2.77	2.7

Fig. 4. I–V curves of pre-TiO_2 (8 μm) (*a*), mp-TiO_2 (8 μm) (*b*), P25 (18 μm) (*c*), and mp-TiO_2 (18 μm) (*d*).

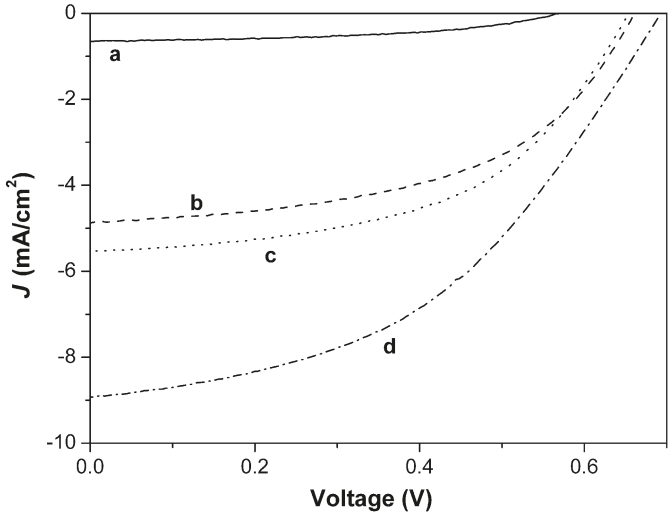

Fig. 5. Photocurrent spectra of solar cells based on pre-TiO_2 (*a*), mp-TiO_2 (*b*), and P25 (*c*).

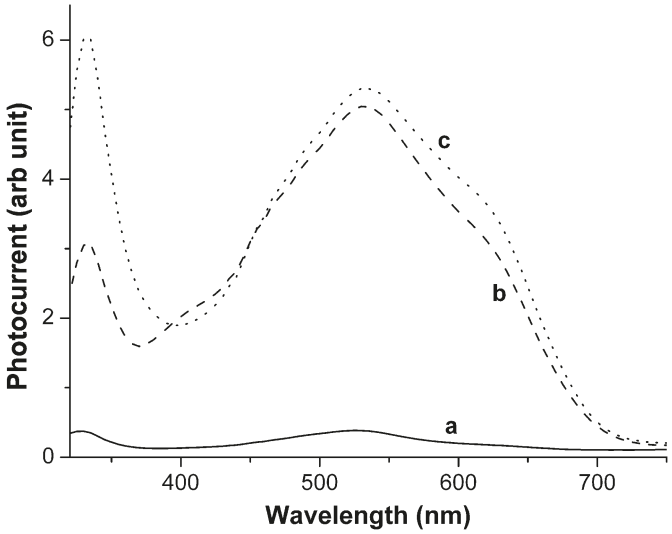

(J_{SC}) for mp-TiO_2 compared with pre-TiO_2. As a result of the higher J_{SC}, the efficiency of DSSCs prepared with mp-TiO_2 is significantly higher than that of DSSCs prepared with pre-TiO_2. As can also be seen in Table 1, the efficiency of the DSSC prepared with mp-TiO_2 is better than that obtained using the P25 TiO_2 standard when films of the same thickness are compared (Table 1). Concerning the efficiency data of Table 1, they are somewhat lower than the typical values previously reported in the literature for DSSCs, which are around 6%.[11,14] However, we notice that the absolute efficiency value strongly depends on the DSSC surface area and preparation conditions.[30] In our case, the DSSC cells were 0.6 cm × 0.6 cm, which is larger than the area of reported cells with higher efficiency.

Table 2. Mass of TiO_2 and dye content of the films in the photovoltaic cells depending on the material.

Material	Thickness (μm)	Mass content of the film (mg/cm^2)	Dye content (mol N719 / cm$^2 \times 10^9$)
Pre-TiO_2	8	0.53	1
Mp-TiO_2	8	0.78	24
P25	18	1.28	30
Mp-TiO_2	18	1.96	54

The data presented in Table 1 were obtained for cells immediately after addition of the electrolyte. No variation in the efficiency parameters was observed for measurements carried out 2 h after preparation. However, probably owing to solvent evaporation, no photovoltaic response was observed when the cells were measured days after preparation.

When comparing DSSCs of mp-TiO_2 and P25 of the same thickness, mp-TiO_2 is more active (Table 1). Comparison of DSSCs of the same thickness should minimize differences arising from light scattering. To confirm the higher efficiency of mp-TiO_2 DSSCs with respect to pre-TiO_2 DSSCs constituted by the same nanoparticles and correlate it with the spatial structuring of the material, we measured the photocurrent spectra of 3 solar cells based on pre-TiO_2, mp-TiO_2, and P25 (Fig. 5). As can be concluded from the plots presented in Fig. 5, and in agreement with the operation of DSSCs, the photocurrent spectra match the absorption spectrum of the dye (N719), indicating that this is the species harvesting light and injecting electrons to the semiconductor conduction band.

Based on this photocurrent spectrum, it becomes apparent that the loading of dye onto the semiconductor surface should be one of the most important parameters controlling the relative efficiency. For this reason, the mass of titania and the amount of N719 dye adsorbed in each cell were determined. Visually, the color intensity of the mp-TiO_2 layers was higher than that of pre-TiO_2 layers. Adsorbed N719 dye was quantified by colorimetry; the dye was desorbed by immersing the layer in diluted aqueous base and the optical density of a given volume of the resulting solution was measured at 530 nm. The dye content is given in Table 2. These data show that the amount of N719 adsorbed on mp-TiO_2 for the same thickness is 24 times higher than that adsorbed on pre-TiO_2. We also noticed that the mass of semiconductor for the same thickness is about 1.5 times higher for mp-TiO_2 than for pre-TiO_2. Both factors, but particularly the much higher dye content, favor the photovoltaic response

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

of mp-TiO_2 with respect to that of pre-TiO_2. A similar trend was found when comparing P25 and mp-TiO_2, i.e., higher dye adsorption (1.8 times) and higher mass (1.5 times) for mp-TiO_2 than for P25.

The ability of mp-TiO_2 to adsorb higher amounts of N719 is a reflection of its larger surface area (99 m^2/g) as result of the spatial structuring with respect to pre-TiO_2 (35 m^2/g). The high adsorption capacity of periodic mesoporous metal oxides compared with amorphous materials is well documented.[3] It has to be noted that the higher dye adsorption capacity of mp-TiO_2 is inherent to its mesoporous ordering and its total surface area. In other words, at the same thickness the amount of dye adsorbed by mp-TiO_2 has to be higher than that adsorbed by P25.

It is also noteworthy that structuring increases the mass density of mp-TiO_2 films compared with pre-TiO_2 and even P25 TiO_2 films. This higher density must be related to the morphology of the particles and the way in which these particles are packed. Apparently better loose-particle packing is achieved using small (pre-TiO_2) or medium-sized (P25) nanoparticles rather than mp-TiO_2.

In summary, by structuring titania nanoparticles in a mesoporous solid, the resulting material possesses higher pore volume and greater surface area than the nanoparticulated unstructured precursor. This high surface area plays a positive role, adsorbing significantly larger amounts of the photosensitizing dye. The result of this high adsorption capacity is an enhancement of the current density of DSSCs of about one order of magnitude. This result illustrates the advantages of high surface area titania for enhancing the efficiency of DSSCs.

Fluorescence studies of a series of monodisperse telechelic α,ω-dipyrenyl poly(*N*-isopropylacrylamide)s in ethanol and in water

Jamie Yip, Jean Duhamel, Xing Ping Qiu, and Françoise M. Winnik

Abstract: Steady-state and time-resolved fluorescence measurements were performed on solutions in ethanol and in water (23 °C) of a series of poly(*N*-isopropylacrylamide)s labeled with a pyrenyl group at each chain end (Py_2-PNIPAM) and ranging in molecular weight (M_n) from 5 900 to 44 500 g·mol^{-1}. Water and ethanol are of similar solvent quality towards the PNIPAM chain. The pyrene labels, in contrast, are soluble in ethanol but not in water. The efficiency of excimer formation for Py_2-PNIPAM samples in ethanol decreased with increasing chain length, a trend typical of pyrene end-labeled polymers in good solvents. The ratio I_E/I_M, where I_E is the Py excimer emission intensity and I_M is the Py monomer emission intensity, scaled as $M_n^{-1.4}$, where M_n is the number-average molecular weight of the sample. The kinetics of excimer formation were more complex for aqueous Py_2-PNIPAM solutions, as a consequence of pyrene–pyrene association prior to excitation. The excimer time-dependent profiles exhibited significantly faster rise times, compared with the situation in ethanol, and they could not be fitted with the traditional Birks scheme. The results are discussed in the context of the solution properties of telechelic amphiphilic PNIPAMs and are compared with data gathered previously in studies of dipyrenyl end-labeled poly(ethylene oxides), the only other polymers soluble in water and organic solvents subjected to similar studies in the past.

Key words: telechelic amphiphilic poly(*N*-isopropylacrylamide), pyrene excimer, time-resolved fluorescence spectroscopy, polymer cyclization dynamics.

Résumé : On a mesuré la fluorescence à l'état stationnaire et résolue en fonction du temps, de solutions dans l'éthanol ou dans l'eau, à 23 °C, d'une série de poly(*N*-isopropylacrylamides) marqués par un groupe pyrényle aux deux extrémités des chaînes (Py_2-PNIPAM) et dont les poids moléculaires (M_n) varient de 5 900 à 44 500 g·mol^{-1}. Les qualités de l'eau et de l'éthanol vis-à-vis des chaînes de PNIPAM sont semblables. Toutefois, le pyrène utilisé comme marqueur est soluble dans l'éthanol, mais pas dans l'eau. L'efficacité de la formation de l'excimère pour les échantillons de Py_2-PNIPAM dans l'éthanol diminue avec une augmentation de la longueur de la chaîne, une tendance typique dans les bons solvants pour les polymères marqués aux extrémités avec des pyrènes. Le rapport I_E/I_M dans lequel I_E est l'intensité de l'émission de l'excimère Py et I_M est l'intensité de l'émission du monomère Py, a une pente de $M_n^{-1.4}$, M_n étant la valeur moyenne du poids moléculaire de l'échantillon. En raison de l'association pyrène–pyrène avant l'excitation, la cinétique de la formation de l'excimère est plus complexe pour les solutions aqueuses de Py_2-PNIPAM. Par rapport à ce qui est observé dans l'éthanol, les profils de l'excimère en fonction du temps présentent des temps de croissance qui sont beaucoup plus rapides et ils n'ont pas pu être ajustés au schéma traditionnel de Birks. On discute des résultats dans le contexte des propriétés en solution des PNIPAM amphiphiles téléchéliques et on les compare aux données accumulées antérieurement dans les études de poly(oxydes d'éthylène) marqués aux extrémités par des groupes dipyrényles, les seuls autres polymères solubles dans l'eau et les solvants organiques à avoir été soumis à des études semblables dans le passé.

Mots-clés : poly(*N*-isopropylacrylamide) amphiphile et téléchélique, excimère pyrène, spectroscopie de fluorescence résolue en fonction du temps, dynamique de la cyclisation d'un polymère.

[Traduit par la Rédaction]

Introduction

Some 35 years ago, studies of the end-to-end cyclization of polymer chains were of considerable interest, since they shed light onto fundamental aspects of processes such as the synthesis of cyclic polymers, the cyclization of DNA, and the dynamics of chains in solution. An important breakthrough was achieved in the early 1980s when theoretical

predictions[1,2] and experimental observations[3,4] indicated that the end-to-end cyclization process can be probed by two pyrenyl moieties covalently attached to the ends of a monodisperse polymer and is described under these conditions by a single rate constant (k_{cy}). The experiment is straightforward: one pyrene chromophore is excited and its emission is monitored as it encounters a ground-state pyrene to form an excimer.[5] The extreme sensitivity of fluorescence allows one to conduct such experiments with solutions with concentrations usually low enough to ensure that no intermolecular interactions take place, so that the fluorescence signal being detected reports solely on processes that occur intramolecularly.[6–18] The rate constant of excimer formation is a measure of k_{cy}, which in turn provides information about the long-range polymer chain dynamics and as such is a measure of the flexibility of a given chain.

The most complete set of information about the rate constant k_{cy} has been obtained for a series of pyrene-labeled monodisperse polystyrenes, which were synthesized by anionic polymerization.[6] Other backbones that have been investigated include polytetrahydrofuran,[7] polydimethylsiloxane,[8–10] poly(ε-caprolactone),[11] polycarbonates,[12,13] and poly(ethylene oxide) (PEO).[14–18] The latter studies stand out, as PEO is the only polymer in the list that is soluble in organic solvents and also in water. Since the pyrene label is soluble in organic solvents, its presence at the ends of the chain does not significantly affect the properties of the polymer in organic solvents and, consequently, Py_2-PEO displays the typical kinetics expected for excimer formation via the diffusive encounters of two pyrenyl (Py) moieties in organic solvents.[14–18] Pyrene groups, however, are poorly soluble in water and their incorporation on PEO chain ends has profound effects on the properties of the polymer and on the kinetics of end-to-end cyclization. The photophysical properties of pyrene are also affected by its confinement in an aqueous environment.[16,18–22] For instance, a substantial fraction of the excimer is formed instantaneously through direct excitation of ground-state pyrene aggregates, which are stabilized by the water-soluble PEO backbone. Nonetheless, given that end-to-end cyclization is described by a single rate constant, it has been possible to derive kinetic models that follow relatively well the process of excimer formation in aqueous solutions of Py_2-PEO and also account for the presence of pyrene ground-state dimers.[16,18–23]

Our research interests have focused on poly(*N*-isopropylacrylamide) (PNIPAM), which, like PEO, is a nonionic polymer soluble in organic solvents and in water at room temperature. The two polymers share a number of properties and have often been compared with regard to their interactions with surfactants[24,25] and with proteins.[26] But in some important thermal and conformational properties, they differ markedly from each other. For instance, the lower critical solution temperatures (LCSTs) of aqueous PEO solutions show a strong molecular-weight dependence, while the LCST of PNIPAM is almost independent of the molecular weight, exhibiting very flat cloud point lines. Also, from molecular dynamics simulations, PEO chains are inferred to adopt a loose helical form (11/2 helix), and the size of each turn is such that it can accommodate one water molecule linked to the chain via hydrogen bonds. In contrast, PNIPAM chains in water are partially collapsed by the association of hydrophobic isopropyl groups. One may expect, therefore, differences in the end-to-end cyclization dynamics of PNIPAM and PEO in water and in organic solvents. The objective of the work reported here was to investigate the fluorescence properties of α,ω-dipyrenyl-PNIPAM in ethanol and in water to assess the cyclization dynamics of PNIPAM in the two solvents and to compare them with those of PEO in the same solvents, using data previously reported for Py_2-PEO.

Recent advances in controlled radical polymerization have led to the development of synthetic protocols for the preparation of monodisperse polymers bearing reactive groups at their ends,[27] creating entries into families of polymers soluble in water and (or) organic solvents carrying a fluorescent tag at one or both chain ends. Several examples can be found in the literature where PNIPAM prepared by living radical polymerization has been labeled with a pyrenyl group at one[28–31] or both chain ends.[32] Using a procedure similar to previously reported syntheses, we prepared Py_2-PNIPAMs ranging in number-average molecular weight (M_n) from 6 000 to 45 000 g·mol^{-1} and evaluated the steady-state and time-resolved fluorescence properties of the polymers in ethanol and in water. This study of the kinetics of excimer formation of monodisperse dipyrenyl end-labeled PNIPAM is the first new example, in addition to studies of Py_2-PEO, that provides the opportunity to compare the photophysics of identical pyrene-tethered chains in water and an organic solvent. Conversely, it allows one to gain further insight into the properties of amphiphilic telechelic PEOs and PNIPAMs, which have been compared and contrasted on the basis of scattering and rheology measurements that probe different length scales than the pyrene excimer.

Experimental

Materials

All chemicals were purchased from Sigma-Aldrich Chemicals Co. unless otherwise specified. *N*-Isopropylacrylamide (NIPAM, 99%) was obtained from Acros Organics and recrystallized from an acetone–hexanes (4:6, *v*/*v*) mixture. Acryloyl chloride (97%), sodium bicarbonate ($NaHCO_3$, 99.5%), anhydrous sodium sulfate (Na_2SO_4, 99.0%), and triethylamine (99.5%) were used as received. Dimethyl sulfoxide (DMSO, 99.9%) was used without purification. 1,4-Dioxane and tetrahydrofuran (THF) were purified by a solvent purification system with two packed columns of activated alumina provided by Innovative Technology Inc. 4-(1-Pyrenyl)butyl iodide was synthesized as described earlier.[28] All other solvents were of reagent grade and used as received. Water was deionized using a Millipore MilliQ system. Ethanol (Fisher Scientific, HPLC grade) was used as received.

Preparation of α,ω-dipyrenyl poly(*N*-isopropylacrylamide)

The polymer was prepared by a two-step end group transformation procedure, starting from a precursor telechelic polymer, α,ω-diisobutylsulfanylthiocarbonylsulfanyl poly(*N*-isopropylacrylamide) (iBS_2-PNIPAM),[27] prepared according to a previously reported procedure (Fig. 1).[32] In the first

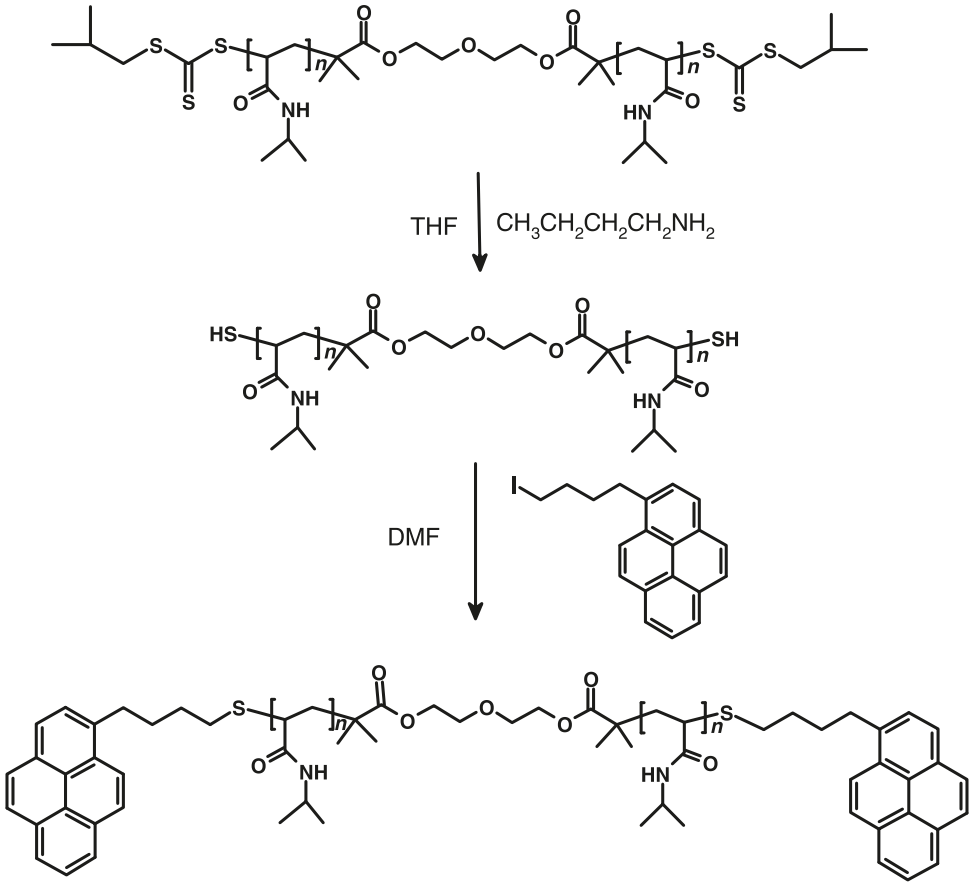
For personal use only.

Fig. 1. Synthetic scheme of telechelic α,ω-dipyrenyl poly(*N*-isopropylacrylamide).



step, the precursor polymer, iBS_2-PNIPAM, was aminolyzed by *n*-butylamine (10-fold molar excess with respect to the thiocarbonylthio moiety) in THF to generate α,ω-dimercapto PNIPAM (HS_2-PNIPAM). In the second step, HS_2-PNIPAM was reacted with 4-(1-pyrenyl)butyl iodide (1.5-fold molar excess with respect to the mercapto (SH) groups) in dimethylformamide (DMF) to yield the targeted polymer. This nucleophilic substitution reaction was catalyzed with potassium carbonate (K_2CO_3), and a small amount of the reducing agent triphenylphosphine was added to prevent the formation of disulfide linkages between polymer chain ends. The polymer in DMF was first recovered by precipitation in diethyl ether. It was purified by two consecutive precipitations from THF to diethyl ether.

Determination of pyrene end functionality

The pyrene end functionality was evaluated by UV–visible absorption spectroscopy. First, the isobutylsulfanylthiocarbonylsulfanyl (iBS) moiety content of the corresponding precursor polymer (iBS_2-PNIPAM) was determined for solutions of the polymer in chloroform, using the absorbance at 310 nm. A solution of diethylene glycol di(2-(1-isobutyl)-sulfanylthiocarbonylsulfanyl-2-methyl propionate) in chloroform was used as the standard (ε_{310} = 28 600 $L \cdot mol^{-1} \cdot cm^{-1}$). Second, the pyrene content of Py_2-PNIPAM was determined for solutions of the polymer in methanol, using the absorbance of the pyrenyl chromophore at 342 nm, where iBS moieties do not absorb. The molar extinction coefficient of the pyrenyl group in methanol was approximated by using that of 4-(1-pyrenyl)butanol (PyButOH) in methanol (ε_{342} = 43 450 $L \cdot mol^{-1} \cdot cm^{-1}$). The molar extinction coefficient of PyButOH was determined by preparing solutions with known concentrations of PyButOH in methanol and plotting their absorbance obtained with a 1 cm path length UV cell as a function of PyButOH concentration. A straight line was obtained whose slope yielded the molar extinction coefficient of PyButOH in methanol according to the Beer–Lambert law. A comparison of the iBS concentration (end functionality assumed to be 100%) and the measured pyrene concentration gave the pyrene functionality values listed in Table 1.

Sample preparation for fluorescence measurements

Since the pyrenyl pendants of the Py_2-PNIPAM samples form pyrene aggregates or dimers in aqueous solution, absorption measurements conducted in water must be carefully interpreted if they are to be used to determine polymer concentration. Indeed, it has been shown in one example that the molar absorption coefficient of a pyrenyl moiety is about 1.7 times larger when the pyrenyl unit exists as an isolated monomer than when it is part of a ground-state pyrene aggregate.[33] Taking this into consideration, the Py_2-PNIPAM concentrations in water were determined as follows. First, the polymer was dissolved in ethanol, where no pyrene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12

Table 1. Number-average molecular weights (M_n) and polydispersity indices (PDI) of the Py_2-PNIPAM samples.

Sample	M_n (kg·mol^{-1})	PDI	Py functionality (%)
Py_2-PNIPAM-6K	5.9	1.05	85.4
Py_2-PNIPAM-8K	7.6	1.08	82.6
Py_2-PNIPAM-14K	13.7	1.10	87.4
Py_2-PNIPAM-25K	25.4	1.07	75.5
Py_2-PNIPAM-45K	44.5	1.10	74.8

aggregates are generated. The concentration of pyrenyl pendants was determined from the molar absorption coefficient of 4-(1-pyrene)butanol in ethanol (ε_{342} = 42 600 L·mol^{-1}·cm^{-1}) determined in the laboratory. The Py_2-PNIPAM solution was diluted to the desired concentration of pyrenyl groups in ethanol. Then, the ethanol was evaporated off and the same volume of water was added to the dried film of Py_2-PNIPAM. This solution was placed in the fridge for 30 min. This counterintuitive procedure is often employed to enhance the dissolution in water of polymers, such as PNIPAM, that exhibit a lower critical solution temperature (LCST). For PNIPAM, the LCST is ~32 °C. The polymer loses its solubility in water above this temperature. Finally, the solution was stirred vigorously and allowed to warm to room temperature (23 ± 1 °C). Following this protocol, the pyrene concentration of the Py_2-PNIPAM solutions in water was the same as the one determined for the Py_2-PNIPAM solutions in ethanol. A pyrene concentration of 2.4×10^{-6} mol·L^{-1} was used for the fluorescence measurements done in ethanol. All Py_2-PNIPAM solutions in ethanol were degassed by bubbling a gentle flow of nitrogen through the solution for 30 min before steady-state or time-resolved fluorescence measurements were conducted. Aerated aqueous solutions of Py_2-PNIPAM were used for fluorescence measurements.

Size exclusion chromatography

The size exclusion chromatography system consisted of an Agilent 1100 isocratic pump, a set of TSK-gel α-M (particle size, 13 μm; exclusion limit, 1×10^7 Da for polystyrene in DMF) and TSK-gel α-3000 (particle size, 7 μm; exclusion limit, 1×10^5 Da for polystyrene in DMF) columns (Tosoh Biosep), a Dawn EOS multiangle laser light scattering detector (λ = 690 nm; Wyatt Technology Co.), and an Optilab DSP interferometric refractometer (λ = 690 nm; Wyatt Technology Co.) and the conditions were as follows: injection volume, 100 μL; flow rate, 0.5 mL·min^{-1}; eluent, DMF; and temperature, 40 °C. The refractive index increment (dn/dc) value of PNIPAM was determined to be 0.0738 mL·g^{-1} at 690 nm in DMF at 40 °C using an Optilab DSP interferometric refractometer (Wyatt Technology Co.).

Steady-state fluorescence

The fluorescence spectra of the Py_2-PNIPAM samples in ethanol and water were acquired on a Photon Technology International (PTI) LS-100 steady-state fluorometer. The fluorometer was equipped with an Ushio UXL-75Xe xenon arc lamp and a PTI 814 photomultiplier detection system. Py_2-PNIPAM solutions in ethanol and water were, respectively, degassed and nondegassed. The solutions were excited at 344 nm. The monomer fluorescence intensity (I_M) was obtained by taking the integral under the fluorescence spectrum from 372 to 378 nm. The fluorescence intensity of the excimer (I_E) was determined by first normalizing the fluorescence spectrum of 4-(1-pyrene)butanol at a concentration of 2.5×10^{-6} mol·L^{-1} in ethanol and 0.6×10^{-6} mol·L^{-1} in water to the peak at 375 nm of the fluorescence spectrum of the Py_2-PNIPAM solutions. At such low concentration, 4-(1-pyrene)butanol emits as the pyrene monomer. Second, the normalized spectrum of 4-(1-pyrene)butanol was subtracted from that of the Py_2-PNIPAM solution. Third, the fluorescence intensity of the subtracted spectrum was integrated from 500 to 530 nm to yield I_E.

Time-resolved fluorescence

The fluorescence decays of the pyrene monomer and excimer of the Py_2-PNIPAM solutions were acquired on an IBH time-resolved fluorometer equipped with a nano-LED light source. The Py_2-PNIPAM solutions were prepared with a pyrene concentration of 1.2×10^{-6} mol·L^{-1}. The solutions were excited at 344 nm and the fluorescence decays were monitored at 375 and 510 nm for the pyrene monomer and excimer, respectively, using a cutoff filter at 370 and 495 nm, respectively. A Ludox solution was used at the excitation wavelength to determine the instrument response function, which was convoluted with the desired theoretical function for the decay analysis.

Analysis of the fluorescence decays

All monomer and excimer fluorescence decays were first fitted with a sum of exponentials according to eq. [1].

$$[1] \qquad f(t) = \sum_{i=1}^{N} a_{X_i} \times \exp\left(-t/\tau_{X_i}\right)$$

where X = M (monomer) or E (excimer).

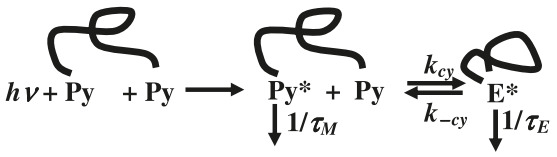
Themonomer and excimer fluorescence decays acquired for the Py_2-PNIPAM solutions in ethanol were also fitted with eqs. [2] and [3], which are based on the Birks scheme given in Scheme 1.[5] In Scheme 1, the parameters k_{cy}, k_{-cy}, τ_M, and τ_E represent the rate constant of excimer formation, the rate constant of excimer dissociation, the monomer lifetime, and the excimer lifetime, respectively.

$$[2] \qquad [Py^*] = \frac{[Py^*_{diff}]_0}{\sqrt{(X-Y)^2 + 4k_{cy}k_{-cy}}}\left((X-\tau_2^{-1}) \times \exp(-t/\tau_1) - (X-\tau_1^{-1}) \times \exp(-t/\tau_2)\right) + [Py^*_{free}]_0 \exp(-t/\tau_M)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

$$[3] \qquad [E^*] = \frac{k_{cy}[Py^*_{diff}]_0}{\sqrt{(X-Y)^2 + 4k_{cy}k_{-cy}}}\left(-\exp(-t/\tau_1) + \exp(-t/\tau_2)\right) + [Py^*_S]_0 \exp(-t/\tau_S)$$

Scheme 1. Birks' scheme for the formation of an excimer with a pyrene end-labeled monodisperse polymer.[5,18]



The parameters $X = k_{cy} + \tau_M^{-1}$ and $Y = k_{-cy} + \tau_E^{-1}$ are used in the expressions of the decay times τ_1 and τ_2, which are given in eqs. [4] and [5]. The initial concentrations of pyrenes that form an excimer by diffusion or do not form an excimer because they are attached to monolabeled chains are represented by $[Py^*_{diff}]_0$ and $[Py^*_{free}]_0$, respectively, in eqs. [2] and [3]. Occasionally, a short-lived pyrene species with a decay time of 2–4 ns and denoted as Py^*_S is encountered when excimer formation occurs in restricted geometries, such as when the pyrene pendants are confined to a polymer.[18] The origin of this spike is discussed further in the Results and discussion section. The monomer lifetime, τ_M, in ethanol was estimated to equal 220 ns by analyzing the monoexponential fluorescence decay of 4-(1-pyrene)butanol in ethanol.

$$[4] \qquad \tau_1^{-1} = \frac{X + Y + \sqrt{(X-Y)^2 + 4k_{cy}k_{-cy}}}{2}$$

$$[5] \qquad \tau_2^{-1} = \frac{X + Y - \sqrt{(X-Y)^2 + 4k_{cy}k_{-cy}}}{2}$$

The monomer and excimer fluorescence decays were fitted globally to ensure that the decay times τ_1 and τ_2 remained the same in the analysis of the monomer and excimer decays. The decay time τ_S was fixed to 2 ns in the analysis.

Results and discussion

Preparation and characterization of the polymers

The synthesis of α,ω-dipyrenyl poly(*N*-isopropylacrylamide)s (Py_2-PNIPAMs) is depicted in Fig. 1. First, PNIPAMs of narrow size distribution bearing a trithiocarbonate group at each chain end were prepared by reversible addition-fragmentation chain transfer polymerization of NIPAM using a difunctional trithiocarbonate compound, i.e., diethylene glycol di(2-(1-isobutyl)sulfanylthiocarbonylsulfanyl-2-methyl propionate), as the chain transfer agent.[27] The isobutyltrithiocarbonate groups were aminolyzed, yielding thiol end groups, which were subjected to nucleophilic substitution using 4-(1-pyrenyl)butyl iodide in the presence of sodium carbonate. Evidence for the successful end labeling was obtained by monitoring the UV absorption of the pyrenylbutyl pendants at 342 nm. The number-average molecular weight (M_n) and polydispersity index (PDI) of the polymers, shown in Table 1, were determined by size exclusion chromatography analysis in DMF, a good solvent for PNIPAM and its hydrophobically modified analogues.[32] The extent of pyrene incorporation onto the polymer chain ends (end functionality of the polymers, Table 1) was determined from the absorbance of the pyrenyl groups for solutions of the polymers in methanol.

Overview of the solution properties of the polymers in ethanol and in water

The two solvents selected for the study have similar viscosities at 25 °C (ethanol: η = 1.07 mPa·s; water: η = 0.89 mPa·s). The intrinsic viscosity of a commercial PNIPAM sample at 25 °C was determined to be 48.5 ± 0.5 and 46.6 ± 0.6 mL·g^{-1} in ethanol and water, respectively, indicating that the dimensions (radius of gyration or end-to-end distance) of the PNIPAM polymer coil should be similar in water and ethanol. All Py_2-PNIPAM samples were soluble in ethanol, but only the Py_2-PNIPAM samples with M_n values of 14 000 g·mol^{-1} or higher were soluble in water at 23 °C, which is the temperature of the fluorescence measurements reported here. Samples with lower molecular weight (5 900 and 7 600 g·mol^{-1}), which were reluctant to dissolve in water, were used only for the studies of Py_2-PNIPAM in ethanol. Fluorescence spectra, normalized at the 0-0 transition, of Py_2-PNIPAM samples in ethanol and in water are shown in Figs. 2A and 2B, respectively. The spectra present a strong contribution from the pyrene monomer emission, with bands at 376–396 nm, as well as a weak pyrene excimer emission, with its characteristic broad emission centered at 470 nm. The excimer emission intensity decreases with increasing chain length. The contribution of the excimer emission was weaker for polymers dissolved in ethanol, indicating that in water hydrophobic interactions between the pyrene end groups tend to overcome the natural tendency of the polymer to stretch owing to excluded volume effects, bringing the pyrene pendants into close contact under the form of pyrene aggregates where an excimer is generated efficiently.[16,18–21]

Solutions of Py_2-PNIPAM samples in ethanol

The experiments reported below aimed at characterizing intramolecular excimer formation. If an excimer is generated intramolecularly, its emission intensity, relative to the pyrene monomer intensity, should be independent of polymer concentration. We established that the ratio of pyrene excimer to monomer emission intensities, I_E/I_M, was constant (= 3.1×10^{-3}) for Py_2-PNIPAM-45K solutions in ethanol ranging in concentration from 23 to 530 mg·L^{-1}, equivalent to a pyrene concentration of 0.32 to 25 μmol·L^{-1}. The fluorescence spectra of all Py_2-PNIPAM samples in ethanol were acquired at a pyrene concentration of 2.5×10^{-6} mol·L^{-1}, a value for which excimer formation occurs exclusively be-

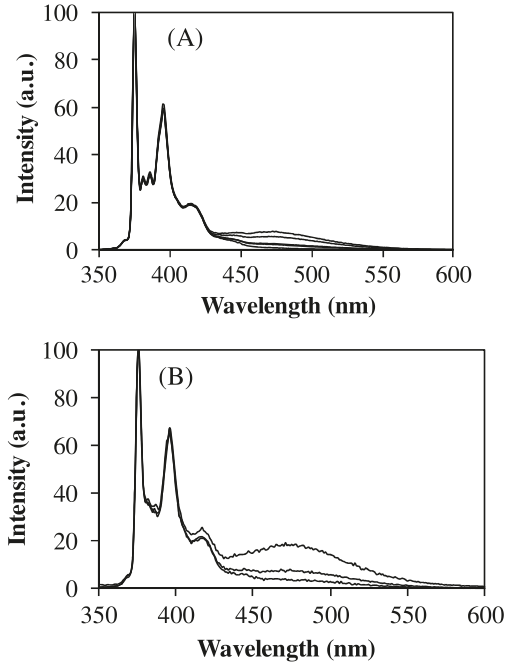
Fig. 2. Fluorescence spectra of pyrene end-labeled PNIPAM normalized at the 0-0 transition, λ_{ex} = 344 nm. (A) [Py] = 2.5 × 10^{-6} mol·L^{-1} in ethanol; top to bottom: Py_2-PNIPAM-6K, Py_2-PNIPAM-8K, Py_2-PNIPAM-14K, Py_2-PNIPAM-25K, Py_2-PNIPAM-45. (B) [Py] = 1.25 × 10^{-6} mol·L^{-1} in water; top to bottom: Py_2-PNIPAM-14K, Py_2-PNIPAM-25K, Py_2-PNIPAM-45K.



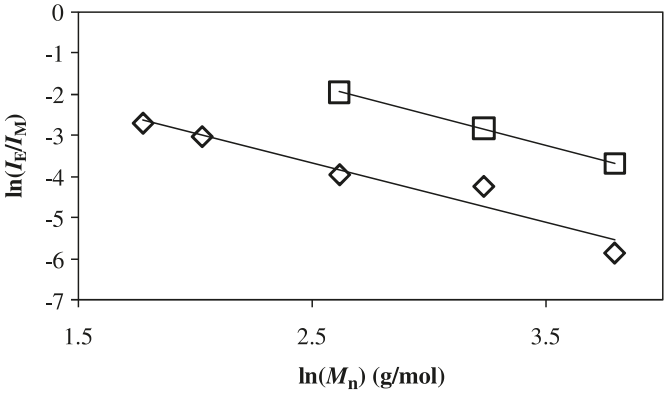
tween pyrenes linked to the same chain. The effect of chain length on the I_E/I_M ratio is seen in Fig. 3, where the I_E/I_M ratios are reported as a function of M_n. The slope of the log–log plot shown in Fig. 3 equals 1.4 ± 0.2 for solutions in ethanol (symbol: ◇).

The scaling relationship $I_E/I_M \propto M_n^{-1.4}$ found in ethanol for the Py_2-PNIPAM samples is in agreement with values expected from theoretical work conducted by Cuniberti and Perico,[34,35] who proposed eq. [6] to estimate the I_E/I_M ratio for pyrene-labeled polymers at temperatures <30 °C, where the rate constant for excimer dissociation can be neglected with respect to τ_E^{-1}.

$$[6] \qquad \frac{I_E}{I_M} = \kappa \frac{\phi_E^\circ}{\phi_M^\circ} \tau_M k_1 [Py]_{loc}$$

In eq. [6], κ is a constant that depends on the geometry and sensitivity of the spectrofluorometer used; k_1 is the bimolecular encounter rate constant, which for free pyrenes would equal 2 × RT/(3 × η) with R, T, and η being, respectively, the ideal gas constant, the absolute temperature in Kelvin, and the solvent viscosity; ϕ_M° and ϕ_E° are the fluorescence quantum yields of, respectively, the pyrene monomer and excimer; τ_M is the natural lifetime of the pyrene monomer; and $[Py]_{loc}$ represents the effective concentration of the unexcited chromophores in the neighborhood of the excited species. The end-to-end cyclization rate constant, k_{cy}, is taken as the product k_1 × $[Py]_{loc}$. Since the parameters ϕ_M°, ϕ_E°, κ, and τ_M are constants that do not depend on chain length, eq. [6] implies that the I_E/I_M ratio depends only on k_{cy}, which has been shown theoretically[35,36] and experimentally[6,8,12,14] to scale with the number-average degree of polymerization, N, as $N^{-\gamma}$, where γ has been found to take values between 0.9 and 1.9 depending on the polymer backbone and solvent. Based on the above, the I_E/I_M ratio found to scale as $M_n^{-1.4}$ (Fig. 4) for the Py_2-PNIPAM samples in ethanol conforms to what is theoretically[35,36] and experimentally[6,8,12,14] expected for the intramolecular excimer formation of a pyrene end-labeled monodisperse polymer in an organic solvent.

Fig. 3. Plot of $\ln(I_E/I_M)$ vs $\ln(M_n)$ for pyrene end-labeled PNIPAM in water (□, [Py] = 1.25 × 10^{-6} mol·L^{-1}) and ethanol (◇, [Py] = 2.5 × 10^{-6} mol·L^{-1}). Ethanol: slope = 1.4 ± 0.2; water: slope = 1.5 ± 0.1.



Next, fluorescence decays for the pyrene monomer and excimer emissions were acquired for the Py_2-PNIPAM samples in ethanol to gain information about the dynamics of excimer formation. All time-resolved fluorescence experiments were carried out with solutions where the pyrene concentration was 2.5 × 10^{-6} mol·L^{-1}. The decays recorded for the monomer and excimer emissions are shown in Figs. 4A and 4B, respectively. The pyrene monomer decay rate increases with decreasing polymer chain length, reflecting the increasingly more facile excimer formation. In fact, measurable excimer formation takes place only in ethanolic solutions of Py_2-PNIPAM samples of M_n = 14 000 g·mol^{-1} or less (see Fig. 2A), so that the excimer fluorescence decays of Py_2-PNIPAM-26K and Py_2-PNIPAM-45K in ethanol could not be acquired. The excimer fluorescence decays of the shorter chains exhibited a well-defined rise time (Fig. 4B), confirming that excimer formation occurs by diffusive encounters of the chain ends. As the polymer chain length increases, the excimer decays more slowly in the same manner as the pyrene monomer, which is a consequence of the coupling that exists between the concomitant disappearance of the pyrene monomer and formation of the pyrene excimer.[5] A spike was found early in the excimer decay of Py_2-PNIPAM-14K. The origin of this spike is debatable. Such a spike is usually observed for pyrene end-labeled polymers of high molecular weight or in viscous solvents when excimer formation by diffusion is not favored.[18,36] It can also be the result of some residual light scattering making its way through the detector and the monochromator despite the use of a 495 nm cutoff filter, or possibly it could originate from an impurity that emits weakly and is observed only when little excimer is formed.

The monomer and excimer fluorescence decays were first

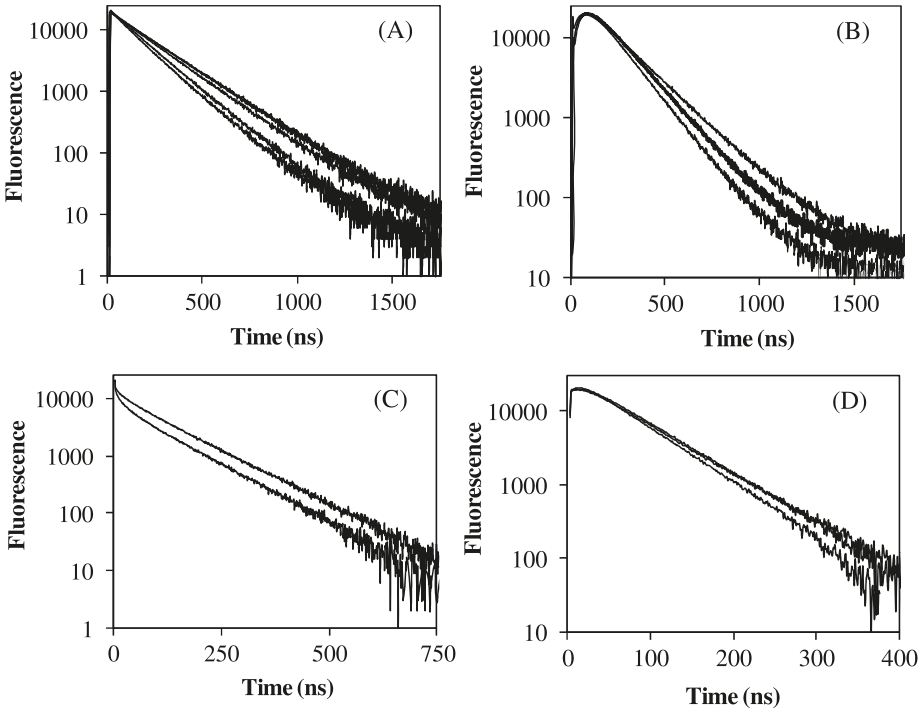
Fig. 4. Fluorescence decays of pyrene end-labeled PNIPAM, λ_{ex} = 344 nm. (A) Ethanol, [Py] = 2.5 × 10^{-6} mol·L^{-1}, λ_{em} = 375 nm; top to bottom: Py_2-PNIPAM-45K, Py_2-PNIPAM-25K, Py_2-PNIPAM-14K, Py_2-PNIPAM-8K, Py_2-PNIPAM-6K. (B) Ethanol, [Py] = 2.5 × 10^{-6} mol·L^{-1}, λ_{em} = 510 nm; top to bottom: Py_2-PNIPAM-14K, Py_2-PNIPAM-8K, Py_2-PNIPAM-6K. (C) Water, [Py] = 1.2 × 10^{-6} mol·L^{-1}, λ_{em} = 375 nm; top to bottom: Py_2-PNIPAM-45K, Py_2-PNIPAM-25K, Py_2-PNIPAM-14K. (D) Water, [Py] = 1.2 × 10^{-6} mol·L^{-1}, λ_{em} = 510 nm; top to bottom: Py_2-PNIPAM-45K, Py_2-PNIPAM-25K, Py_2-PNIPAM-14K.



fitted with a sum of exponentials (i.e., eq. [1]), yielding the pre-exponential factors and decay times listed in Tables 2 and 3. As the chain length of the Py_2-PNIPAM sample increases, the number-average lifetime ($<\tau>$) increases, eventually reaching a value close to 220 ns, which is the lifetime of 4-(1-pyrene)butanol in ethanol. The increase in $<\tau>$ reflects the decrease in efficiency for excimer formation as the pyrene end groups are separated by increasing chain length. For Py_2-PNIPAM-45K, the pyrenes are kept so far apart that they emit only as independent monomers and do not form excimers. The excimer decays have a short component whose origin could be light scattering, a trace of impurity, or ground-state dimers.[18,37] The ratio a_{E2}/a_{E3} is negative and equals –0.90 for Py_2-PNIPAM-6K and Py_2-PNIPAM-8K. This value is close to –1.0, which indicates that excimer formation is diffusion controlled, as expected from the prominent rise time observed in the excimer decays shown in Fig. 4B. As the chain length increases and excimer formation is less efficient, the a_{E2}/a_{E3} ratio becomes more positive and equals –0.72 for Py_2-PNIPAM-14K.

A global analysis of the monomer and excimer fluorescence decays of the Py_2-PNIPAM solutions in ethanol was performed according to Birks' scheme with eqs. [2] and [3]. The fits were excellent, with χ^2 values smaller than 1.30 and residuals and the autocorrelation function of the residuals being randomly distributed around zero. The parameters k_{cy}, k_{-cy}, τ_E, and f_{free} ($f_{free} = [Py^*_{free}]_0/([Py^*_{free}]_0 + [Py^*_{diff}]_0)$) retrieved from the analysis are listed in Table 4. The rate constant for excimer formation decreases with increasing chain length as $k_{cy} \propto M_n^{-\gamma}$ with $\gamma = 0.91 \pm 0.03$. The γ value is smaller than the values of 1.62 found for Py_2-polystyrene in cyclohexane at 34.5 °C,[6] 1.52 found for Py_2-polytetrahydrofuran,[8] and 1.9 and 1.7 found for Py_2-polycarbonate in acetonitrile and acetone, respectively,[12] but it is similar to the values of 1.1, 0.90, and 0.91 found for Py_2-poly(ethylene oxide) in diethyleneglycol diethyl ether at 50 °C, toluene at 45 °C, and tetrahydrofuran at 20 °C, respectively.[14] Although τ_E and k_{-cy} increase somewhat with increasing chain length (mostly for Py_2-PNIPAM-14K), this increase is believed to be an artifact because τ_E and k_{-cy} describe intrinsic properties of the pyrene excimer, which should not depend on polymer chain length as long as the chain is long enough, as should be the case with the Py_2-PNIPAM samples. This artifact is due to limitations in the Birks scheme analysis of fluorescence decays acquired with long pyrene end-labeled polymer constructs that do not generate much excimer. Indeed, as can be seen in Fig. 2, excimer formation is strongly reduced for the Py_2-PNIPAM samples having a M_n greater than 14 000 g·mol^{-1}. This increase of τ_E and k_{-cy} with increasing polymer chain length has been observed in at least one other instance.[37] If τ_E and k_{-cy} are averaged, one finds that the excimer lifetime equals 66 ± 7 ns, which is reasonable for a pyrene excimer in organic solvent.[5] The excimer dissociation rate constant is small and equals 6 ± 3 × 10^6 s^{-1}. These results are typical for excimer formation of a pyrene end-labeled monodisperse polymer in organic solvents.[5]

Solutions of Py_2-PNIPAM samples in water at 23 °C

In Fig. 5, the I_E/I_M ratio is plotted as a function of the molar pyrene concentration for solutions in water of Py_2-PNIPAM ($M_n \geq$ 14 000 g·mol^{-1}). The ratio I_E/I_M increases

linearly with increasing polymer concentration, an indication that intermolecular excimer formation is taking place in this concentration range ($1 < [Py] < 7 \times 10^{-6}$ mol·L^{-1}).[9] For solutions of identical Py concentration, the I_E/I_M ratio decreases with increasing chain length, as was the case for Py_2-PNIPAM in ethanol. The I_E/I_M ratio of the Py_2-PNIPAM solutions having a pyrene concentration of 1.25 μmol·L^{-1} was plotted as a function of M_n in Fig. 3 (symbol: □). For this pyrene concentration, the I_E/I_M ratio was found to scale as $M_n^{-\gamma}$, where $\gamma = 1.5 \pm 0.1$, an exponent similar to the one of 1.4 ± 0.2 found in ethanol and within the range of exponents obtained for other Py_2-polymers in organic solvents.[6,8,12,14] Since the viscosities of water and ethanol are rather close to each other, viscosity is not expected to significantly affect the value of k_1 in eq. [6]. Furthermore, the similarity of the intrinsic viscosity values of unmodified PNIPAM in water and in ethanol suggests that the dimensions of the polymer coil are the same in water and ethanol. Therefore, the enhancement of excimer formation observed in Figs. 2 and 3 for Py_2-PNIPAM in water is an indication that hydrophobic associations between pyrene pendants occur, inducing a decrease of the average size of the polymer coil and an increase in $[Py]_{loc}$ in eq. [6].

Fluorescence decays of Py_2-PNIPAM solutions in water were acquired only for the longer chains. The excimer decays were not biexponential (see Table 3), which rules out the possibility of using the typical Birks scheme to fit the fluorescence decays.[5] This departure from the traditional Birks scheme is attributed to the presence of ground-state pyrene aggregates, which form excimers instantaneously upon direct excitation, as previously observed in studies of aqueous solutions of Py_2-PEO.[18–22] The presence of ground-state pyrene aggregates is supported by the values taken by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

the ratio of the sum of the negative pre-exponential factors divided by the sum of the positive pre-exponential factors, a_{E-}/a_{E+}. For Py_2-PNIPAM-14K, the only polymer amenable to studies in both ethanol and water, the a_{E-}/a_{E+} ratio is more positive in water (–0.42) than in ethanol (–0.72). For aqueous solutions, the a_{E-}/a_{E+} ratio did not change much with M_n, having values of –0.40 and –0.43 for Py_2-PNIPAM-25K and Py_2-PNIPAM-45K, respectively. The presence of the ground-state pyrene aggregates complicates the quantitative analysis of the fluorescence decays. A detailed analysis of the decays is beyond the scope of this report.

Conclusions

Five pyrene end-labeled PNIPAM samples of narrow molecular weight distribution (ranging in size from $M_n \sim 6000$ to 45 000 g·mol^{-1}) (Fig. 1 and Table 1) were prepared and their solutions in ethanol and in water were studied by fluorescence spectroscopy. All polymers were soluble in ethanol, but only samples of $M_n \geq 14\,000$ g·mol^{-1} were water soluble. In the case of the polymers of M_n = 14 000, 25 000, and 45 000 g·mol^{-1}, the excimer emission was enhanced for polymers in water compared with solutions in ethanol, an effect attributed to the presence of pyrene aggregates via intra- and interchain association. This association process is triggered by the hydrophobicity of the pyrene end groups and bears similarity to the process of flower micelle formation in aqueous solutions of di-(*n*-octadecyl)-PNIPAM.[38] It is also akin to the micellization induced by Py in aqueous solutions of semitelechelic Py-PNIPAM reported previously.[39] Time-resolved fluorescence measurements, which revealed a diminished rise time in the excimer profiles of the Py_2-PNIPAM samples in water (Fig. 4), confirmed the presence of pyrene ground-state aggregates. The ratio I_E/I_M, taken as a measure of the rate of excimer formation, was found to scale as $M_n^{-\gamma}$, where $\gamma = 1.4 \pm 0.2$ and 1.5 ± 0.1 in ethanol and water, respectively. These exponents are within the range of exponents typically obtained with pyrene end-labeled monodisperse polymers.[6,8,12,14] All parameters retrieved from the analysis of the fluorescence decays of polymers in ethanol were reasonable, and the rate of excimer formation, k_{cy}, was found to scale as $M_n^{-0.9}$, an exponent that is smaller than the one obtained by analysis of steady-state data (I_E/I_M ratio). The discrepancy may be a consequence of the smaller set of data points available for k_{cy}. Since it was possible to determine k_{cy} accurately for only three polymers (Py_2-PNIPAM-6K, Py_2-PNIPAM-8K, and Py_2-PNIPAM-14K; see Table 4), whereas all five Py_2-PNIPAM samples yielded accurate I_E/I_M ratios (Fig. 3). The photophysical properties of Py_2-PNIPAM in ethanol are similar to those of Py_2-PEO of similar size in organic solvents, forming excimers according to Birks' scheme. As observed for solutions of Py_2-PEO in water, excimer formation kinetics are complex for aqueous solutions of Py_2-PNIPAM owing to the presence of aggregates of ground-state pyrenes, and they need to be subjected to a detailed data treatment to compare the properties of the two families of polymers in water. Work towards this goal is ongoing, as it is expected to unveil how differences in the hydration of the PEO and PNIPAM main chains[40] can impact the association of their amphiphilic derivatives in water monitored on the time and distance scales of pyrene excimer formation.

Insights into the effect of ketylimine, aldimine, and vinylene group attachment and regiosubstitution on the fluorescence deactivation of fluorene

Stéphane Dufresne, Thomas Skalski, and W.G. Skene

Abstract: The spectroscopic and electrochemical properties of a 9-substituted fluorene ketylimine (**3**) were investigated and compared with those of its vinylene analogue (**4**) to determine the origins of the quenched fluorescence of these compounds. The predominate mode of singlet excited state deactivation of the heteroatomic fluorene was found to be internal conversion involving bond rotation. Meanwhile, its carbon counterpart was found to undergo deactivation preferentially by intersystem crossing to form its triplet, which was confirmed by laser flash photolysis. Both **3** and **4** quenched the fluorescence of fluorene with diffusion-controlled rate constants, implying that the singlet excited states of **3** and **4** are also quenched by intramolecular photoinduced electron transfer (PET). This deactivation mode was found to be exergonically favorable (–90 kJ/mol for **3** and –81 kJ/mol for **4**) according to the Rehm–Weller equation. The position of the heteroatomic bond on the fluorene moiety was further found to influence the singlet excited state deactivation pathway. The 2-substituted regioisomer decayed predominately by intramolecular PET and its fluorescence can be restored by acid protonation. Conversely, the PET mechanism is a minor deactivation mode for the 9-substituted fluorene derivative and its fluorescence can be enhanced by suppressing bond rotational modes, possible at low temperature and potentially in thin films.

Key words: fluorenyl ketylimines, intramolecular photoinduced electron transfer, Stern–Volmer quenching, azomethines.

Résumé : Afin de déterminer les origines de la fluorescence dégénérée de ces composés, on a étudié les propriétés spectroscopiques et électrochimiques des cétylimines de fluorènes portant un substituant en position 9 (**3**) et on les a comparées à celles de son analogue vinylène (**4**). On a trouvé que le mode dominant de la désactivation de l'état singulet excité du fluorène hétéroatomique se produit par une conversion interne impliquant une rotation de liaison. On a trouvé par ailleurs que sa contrepartie carbonée subit une désactivation préférentielle par un croisement intersystème conduisant à la formation de son triplet, ce qui est confirmé par la photolyse laser éclair. Les composés **3** et **4** désactivent tous la fluorescence du fluorène avec des constantes de vitesse contrôlées par la diffusion impliquant que l'état singulet excité des composés **3** et **4** est aussi désactivé par un transfert d'électron photoinduit (TEP) intramoléculaire. On a trouvé que, suivant l'équation de Rehm–Weller, ce mode de désactivation est favorable d'un point de vue exorgonique (–90 kJ/mol pour **3** et –81 kJ/mol pour **4**). On a trouvé aussi que la position de la liaison hétéroatomique dans la portion fluorène influence aussi la voie de désactivation de l'état singulet excité. On a aussi observé que le régioisomère portant un substituant en position 2 se désactive d'une façon prédominante par un TEP intramoléculaire et que sa fluorescence peut être restaurée par protonation acide. Inversement, le mécanisme de TEP n'est qu'un mode mineur de désactivation pour les dérivés du fluorènes portant un substituant en position 9 pour lesquels la fluorescence peut être augmentée par une suppression des modes de rotation des liaisons possibles à basse température et possiblement dans des films minces.

Mots-clés : cétylimines de fluorényles, transfert d'électron photoindut (TEP) intramoléculaire, désactivation de Stern–Volmer, azométhines.

Introduction

Conjugated materials have received much attention as a result of their photophysical and electrochemical properties, which make them suitable for organic electronics such as field-effect transistors, light-emitting diodes, and photovoltaics, to name but a few.[1–4] In particular, fluorene-based materials have been extensively studied because of their

inherent high fluorescence, which makes them ideal for use in emitting devices.[5] Fluorene and its derivatives can additionally withstand the harsh oxidative and reductive environment of a device, further making them ideal materials for use in emitting devices.[6–8] Despite these advantages, the fluorescence quantum yield and color emitted by fluorene are highly sensitive to its environment and its substitution. This is evidenced by keto defects in the 9-position of fluorene, resulting in both decreased emission and undesired green emission.[6,9,10]

Although the fluorenone defect (**1**) (Chart 1) in polyfluorenes is undesired because it reduces device efficiency and results in color contamination, the ketone group is nonetheless interesting because it affords the means to introduce functionality into the conjugated fluorene polymer and to subsequently modulate the polymer's properties.[7,11–13] Simple condensation of amines with fluorene's ketone leads to ketylimines. The properties of the polyfluorenes such as solubility, electronic effects, color, and emission yields, to name but a few, can potentially be tailored by judicious choice of the amine used in preparing the ketylimine.

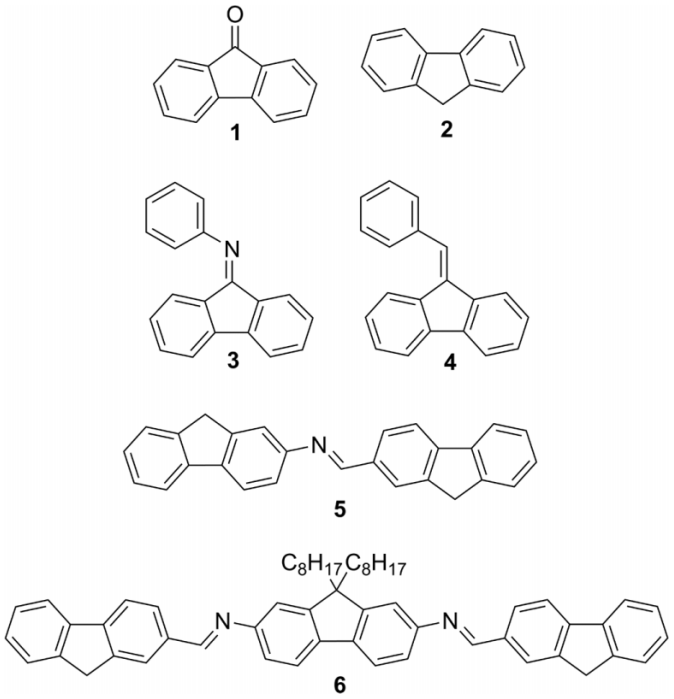
Despite the potential ease of preparing fluorene ketylimines such as **3** by simple condensation methods, few examples of these compounds are known.[14–16] Interestingly, no modern reports have described the successful synthesis of **3** or its derivatives, while only classic literature reports the preparation of some derivatives using harsh and extremely stringent reaction conditions.[17,18] The limited number of reports detailing the preparation of **3** and its derivatives, together with the absence of reported characterization, prompted us to prepare **3** to investigate the influence of the heteroatomic bond on the photophysical properties of fluorene. We were further incited to investigate the photophysical properties of both **3** and **4** by the lack of previous photophysical studies and by a desire to understand the origins of their unknown quenched fluorescence. The knowledge gained from investigating these model compounds is of importance not only for understanding the influence of the homo- and heteroatomic bonds on the photophysical properties, but also for designing and preparing future generations of fluorenyl compounds with tailored properties for specific applications. We additionally examined **3** because it is complementary to our previous aldimine studies of fluorene derivatives such as **5** and **6** and would provide vital structure–property information as well as information about the regiosubstitution effect on the photophysical properties.[19–24] The preparation and photophysical studies of **3** are therefore reported herein to understand the effect of the N=C group and its placement on the fluorenyl excited state properties.

Experimental procedures

General procedures

All reagents, including **1**, **2**, and **4**, were commercially available from Sigma-Aldrich and were used as received unless otherwise stated. Anhydrous and deaerated solvents were obtained with a Glass Contour solvent purification system. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker 400 MHz spectrometer with the appropriate deuterated solvents.

Chart 1.



Spectroscopic measurements

The absorption measurements were done on a Cary 500 spectrometer, while the fluorescence studies were performed on an Edinburgh Instruments FLS-920 fluorimeter after deaerating the samples thoroughly with nitrogen for 20 min. Fluorescence absolute quantum yields were measured at 10^{-5} mol/L by exciting the compounds of study at the corresponding maximum absorption in spectroscopic grade dichloromethane at room temperature in an integrating sphere.[25] The ΔE values were calculated from the intercept of normalized absorption and fluorescence spectra of the corresponding compounds. The spectroscopic band gaps (E_g) were calculated from the tangent from the absorption onset.

Electrochemical measurements

Cyclic voltammetric measurements were performed on a Bioanalytical Systems EC epsilon potentiostat. Compounds were dissolved in anhydrous and deaerated dichloromethane at 10^{-4} mol/L with NBu_4PF_6 at sufficient concentration to achieve highly conductive solutions. A platinum electrode was used as the auxiliary and the working electrode, while a saturated Ag/AgCl electrode was used as the reference electrode. Ferrocene was added at the end of the analyses to serve as an internal reference. The electrochemical band gaps (E_g) were calculated from the measured oxidation and reduction potentials according to $E_{pa} + E_{pc} + 0.4$.

Laser flash photolysis

Laser flash photolysis experiments were done on a Luzchem mini-LFP system exciting at 355 nm with the third harmonic of a Nd-YAG laser. The solutions were prepared with matched absorbances between 0.3 and 0.5 at the excitation wavelength and deaerated for 20 min with nitrogen.

Highest occupied molecular orbital (HOMO) and lowest

unoccupied molecular orbital (LUMO) energy levels were calculated semiempirically using density functional theory (DFT) calculation methods available in Spartan 06 (Wavefunction, Inc.) with the 6-31g* basis set. The bond angles, distances, torsions, and other parameters were experimentally derived from the X-ray data from the corresponding structures.

N-*(9H-Fluoren-9-ylidene)benzenamine (3)*

Aniline (153 mg, 1.64 mmol) was dissolved with DABCO (500 mg, 4.45 mmol) in anhydrous toluene at 0 °C. This was followed by the slow addition of 1.0 mol/L $TiCl_4$ solution in toluene (2.77 mL, 2.77 mmol). Compound **1** (100 mg, 0.55 mmol) was added and then refluxed for 3–4 h. The solvent was removed and the product was isolated as a yellow solid after purification by recrystallization in 50:50 dichloromethane/hexanes or by flash chromatography on alumina with neat hexanes with 1% triethylamine increased to hexanes/ethyl acetate (95:5) (57 mg, 41%); mp 92–94 °C. ^{1}H NMR (acetone-d_6) δ: 7.85 (d, 1H, J = 7.6 Hz), 7.77 (m, 2H), 7.52 (m, 1H), 7.43 (m, 4H), 7.21 (m, 1H), 6.98 (m, 2H), 6.55 (d, 1H, J = 8.0 Hz). ^{13}C NMR (acetone-d_6) δ: 164.0, 153.9, 145.6, 143.6, 139.4, 139.3, 133.9, 132.7, 131.2, 130.7, 130.3, 130.0, 129.5, 128.5, 127.1, 125.7, 124.8, 122.4, 121.8, 119.7.

Crystal structure determination

Diffraction data for **3** were collected on a Bruker FR591 diffractometer using graphite-monochromatized Cu Kα radiation (1.54178 Å). The structures were solved by direct methods (SHELXS97, University of Göttingen). All nonhydrogen atoms were refined based on Fobs2 (SHELXS97, University of Göttingen), while hydrogen atoms were refined on calculated positions with fixed isotropic U, using riding model techniques.

Synthesis

Given the limited experimental protocols for the preparation of **3** and the lack of its detailed characterization, we set out to prepare this compound. We first attempted to prepare **3** via our previously successful methods for aldimines by simple condensation of **2** with aniline in absolute ethanol and in neat aniline.[26–28] Although some desired product was detected by both TLC and crude NMR, purification by standard methods yielded insufficient material for characterization and photophysical studies. The low yield is most likely a result of reduced reactivity because of steric hindrance of the ketone, while the product formed was most likely extremely hydrolytically sensitive and subsequently decomposed with standard chromatographic preparative methods.[14,17,29,30] The latter is supported by the absence of isolated products after silica gel chromatography. Stringent reaction protocols using $TiCl_4$ and an excess of DABCO were used for activating the hindered ketone and preventing imine hydrolysis, respectively. Product isolation was possible by column chromatography over activated basic alumina. Alternatively, the desired product could also be obtained by recrystallization of the crude reaction mixture from a 50:50 dichloromethane/hexanes mixture. We also attempted to prepare an aliphatic derivative of **3** using butylamine to understand the photodeactivation modes of the N=C bond with a limited degree of conjugation on the fluorophores. However, the desired product could not be obtained despite the various reaction conditions employed. Its instability is most likely a result of its extreme sensitivity to hydrolysis and it spontaneously decomposes under ambient conditions. Nonetheless, the unprecedented and complete characterization by standard methods confirmed the formation of **3** in high purity and sufficient amounts for spectroscopic measurements, albeit in low yield.

X-ray crystallographic data

Unlike aldimines, ketylimines lack the characteristic imine peak, allowing for unequivocal product identification by ^{1}H NMR. The lack of characteristic proton resonance at 8.5 ppm makes product identification challenging. Undeniable evidence for correct product formation is, however, possible by X-ray diffraction. In addition to this, the relation of the phenyl unit to the fluorene moiety can be determined from the X-ray diffraction data, allowing for comparison of the structures with analogous aldimines such as **6**.

Compound **3** was crystallized by slow evaporation from a saturated solution of acetone to give small yellow plates. The resolved structure (Fig. 1, left panel) confirms that **3** was formed and crystallizes in an orthorhombic unit as per Table 1. Three different molecules of **3** were found within the crystal lattice for a total of 24 molecules per lattice. Despite the large number of different molecules per lattice, only small variances were found between them. As seen in the right panel of Fig. 1, depicting the crystal structure shown along the *b*-axis, the phenyl moiety is not coplanar with the fluorene moiety. In fact, the planes described by the two aromatic moieties are twisted by 70°, 80°, and 85° for each of the three distinct molecules isolated per lattice. The twisting between the two planes is required to minimize the steric hindrance between the ortho protons of the phenyl and fluorene units. This is evident from the calculated HOMO and LUMO energy levels seen in Fig. 2 using the X-ray crystallographic data for the optimized geometry. It should be noted that the observed twisting between the two planes is greater than that for its aldimine regioisomer (**6**), whose two terminal fluorenes are twisted by 26° and 65° relative to the central fluorene.[24] Although the mean plane angles differ for **3** and its regioisomer (**6**), the corresponding bond distances and angles for the two analogues are identical within experimental error. The large twisting angle between the aromatic units nonetheless implies not only that the 9-position of the fluorene is sterically hindered, but that **3** has a limited degree of conjugation extending only through the fluorene=N portion. The latter is supported spectroscopically (vide infra). The severe steric hindrance and the large twisting of the fluorenyl and phenyl mean plane angles observed from the crystallographic data for **3** prevent any higher ordered structure arising from intermolecular interactions. In fact, the three-dimensional crystal network of **3** is governed by only weak face-to-π interactions. This is in contrast to **6**, which has a high degree of 3D ordering owing to many intermolecular π-stacking and C–H–π interactions.

Spectroscopy

Given the limited reports examining the fluorescence of **3** and its analogous vinylene derivative (**4**),[31–33] we examined the photophysical properties of these two compounds. Such studies are required to understand the effect and the placement of the heteroconjugated bond on the fluorescence and the origin of the weak fluorescence of these compounds. This is possible by comparing the spectroscopic properties of **3**–**5**. As seen in Table 2, the three compounds exhibit approximately the same absorption maxima and differ only in their long wavelength absorption. The same trend of spectral shifts as a function of structures is also observed for their fluorescence spectra. It can be concluded from the absorption and fluorescence spectra of **3** and **4** that the heteroconjugated fluorene is more conjugated than its all-carbon counterpart. This is further supported by the shorter N=C bond distance (1.279 Å) compared with the corresponding C=C bond distance (1.340 Å) for **4**, derived from the X-ray crystallographic data. The shorter bond distance implies a greater sp^2 character to the bond and hence a higher degree of conjugation, which is further corroborated by the band gaps (E_g).

Both **3** and **4** possess substantially lower fluorescence quantum yields than **1** in dichloromethane, as seen in Table 2. More specifically, **4** does not fluoresce, while **3** only weakly fluoresces at room temperature. To better understand the origins of the differences between the two analogues and their quenched fluorescence relative to **1**, the fluorescence at 77 K was measured. All modes of rotational deactivation are suppressed at this temperature and an observed fluorescence increase would denote internal conversion deactivation by bond rotation. The fluorescence yield of **3** increased to 0.6 at 77 K, while no change was observed for **4** at this low temperature. Although an accurate ratio between the emission at 77 K and that at room temperature cannot be determined owing to the weak room temperature fluorescence, it can nonetheless be confirmed that the major mode of singlet excited state deactivation of **3** is by nonradiative means involving bond rotation, most likely the N–phenyl bond. Meanwhile, the singlet excited state deactivation of **4** occurs by other means. It can be concluded from the temperature fluorescence measurements that deactivation of excited fluorene is highly influenced by its substituents. This is evident from the temperature-dependent fluorescence of the regioisomers **3** and **4**, where two different deactivation modes occur despite the vinylene and imine bonds being isoelectronic. The different effect of the homoaryl and heteroconjugated bonds on the fluorene properties is further evidenced from the calculated HOMO and LUMO levels for **3** and **4**. As seen in Fig. 2, the HOMO is localized exclusively over the phenyl–N moiety and the LUMO is distributed across the fluorenyl moiety for **3**. This is in contrast to **4**, whose HOMO is distributed across the fluorenyl moiety while the

[a]Absolute fluorescence quantum yield measured using an integrating sphere.

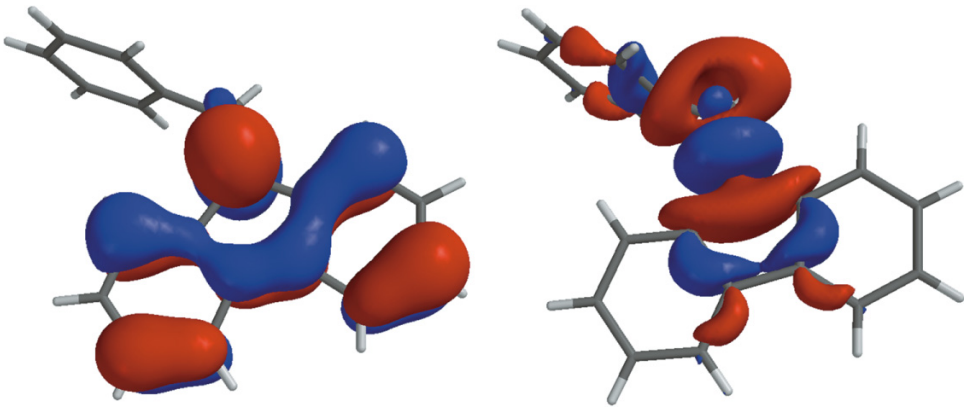
[b]Measured in CH_2Cl_2.

[c]Values in parentheses denote the most bathochromically shifted absorption maximum.

[d]Fluorescence quantum yield ratio measured at 77 K in a 4:1 methanol/ethanol matrix and at room temperature (RT) in methanol. The change in refractive index is minimal for the two temperatures, and therefore no temperature-dependent fluorescence correction is required.

[e]Ref. 21.

Fig. 3. HOMO (left) and LUMO (right) energy levels of **4** calculated using the DFT 6-31g* basis set using the X-ray crystallographic data for the optimized geometry.



LUMO covers the cyclopentyl, imino, and phenyl moieties (Fig. 3).

The nonexistent room temperature fluorescence and the absence of increased fluorescence at a reduced temperature of **4** would suggest the presence of deactivation modes other than internal conversion. A possible deactivation mode would be intersystem crossing to form the triplet state. Both **3** and **4** were therefore further investigated by laser flash photolysis to spectroscopically confirm the formation of a triplet state. As seen in Fig. 4, a strong transient signal is apparent at 450 nm for the excitation of **4** at 355 nm by laser flash photolysis. The quenching of this transient with 1,3-cyclohexadiene and the unimolecular decay confirm the triplet nature of the transient. The similar transient intensities observed for optically matched samples of xanthone and **4** suggest that the triplet quantum yield of **4** is similar to that of xanthone ($\Phi_{TT} = 1$).[34–37] Conversely, no transient signal was detected for **3**, implying the absence of triplet

Fig. 4. Transient absorption spectra of xanthone (black) and **4** (red) measured at 0.12 μs after the 355 nm laser pulse in deaerated dichloromethane. Inset: monoexponential decay of transient **4** monitored at 450 nm.

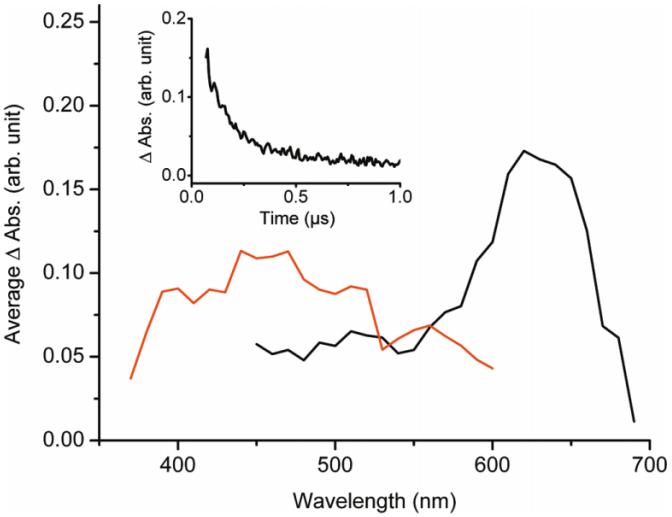

Fig. 5. Stern–Volmer fluorescence quenching of **2** with 0 (black), 20 (red), 40 (green), 60 (blue), and 80 (orange) mmol of **3** in dichloromethane. Inset: change in fluorescence of **2** with the addition of **3**, monitored at 318 nm.

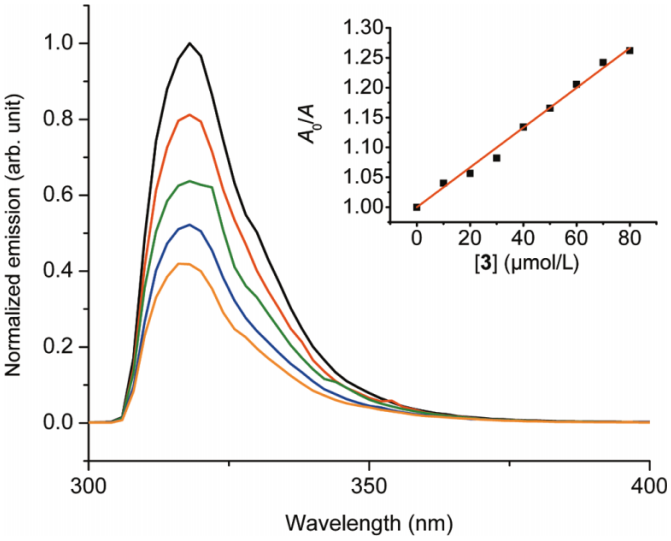

formation and hence no deactivation by intersystem crossing for the heteroatomic compound. The time-resolved and steady-state spectroscopic methods confirm that **3** preferentially deactivates by internal conversion, while the singlet excited state of **4** is predominately deactivated by intersystem crossing.

Although the temperature-dependent fluorescence confirms that the singlet excited state of **3** deactivates by internal conversion, the quantum yield of this process cannot be accurately measured. This is a result of the large error associated with comparing the intense fluorescence signal at 77 K with the extremely weak room temperature signal. Therefore, internal deactivation modes other than rotational internal conversion energy dissipation, such as photoinduced electron transfer (PET), cannot be dismissed. Stern–Volmer quenching studies of **3** and **4** were subsequently undertaken to determine whether other modes of singlet excited state deactivation occurred.[38] Owing to the quenched fluorescence of **3** and **4**, quantitative and accurate quenching studies were not possible using these two compounds as fluorophores. The quenching measurements were therefore done with fluorophore **2** because of its inherent high fluorescence yield. As seen in Fig. 5, **3** quenches the fluorescence of **2** with a bimolecular quenching rate constant (k_q) of 3.3×10^{11} L mol^{-1} s^{-1}, from the measured fluorescence lifetime of **2** (τ_o = 10 ns). Similarly, **4** also quenches **2** with $k_q = 4.0 \times 10^{11}$ L mol^{-1} s^{-1}. Higher quenching ratios of ϕ_o/ϕ would be beneficial to derive accurate k_q values. However, these were not possible because of spectroscopic screening effects of the quenchers at higher concentrations leading to deviations from linearity of the Stern–Volmer plots. The rate constants measured are slighter greater than the diffusion-controlled limit in dichloromethane ($k_q = 2 \times 10^{10}$ L mol^{-1} s^{-1}).[38] This is a result of overlapping absorbances between the fluorophore and the quencher at the excitation wavelength making it difficult to make accurate quenching measurements. Nonetheless, the calculated diffusion-controlled k_q confirm that the fluorene singlet excited state is efficiently deactivated by both **3** and **4**. The results are consistent with previous quenching studies of **1** with aliphatic imines that were deactivated by PET. The similarity of the quenching rate constants of **3** and **4** with their fluorophore-free quenching counterparts, concomitant with the favorable energetics (vide infra), implies that the singlet excited state deactivation occurs by intramolecular PET.[19–21]

The diffusion-controlled k_q quenching of **2** by both **3** and **4** implies deactivation by PET. The energetics of PET were empirically calculated according to the Rehm–Weller equation to corroborate the fluorescence quenching data: $\Delta G^\circ_{eT} = E_{pa}$ (fluorophore) – E_{pc} (quencher) – $\Delta E_{0,0}$ – λ.[39] The equation takes into account the fluorophore's oxidation potential (E_{pa}), the quencher's reduction potential by accepting the transferred electron from the fluorophore (E_{pc}), and the solvent reorganization energy (λ). The energy gap ($\Delta E_{0,0}$) between the ground and excited singlet states of **2** must also be taken into account, since PET involves electron transfer from the excited state. The required value is calculated from the intercept of the normalized plot of the absorption and fluorescence spectra of the fluorophores (see the Supplementary data). The E_{pa} and E_{pc} values (Table 3) were measured by cyclic voltammetry and correspond to the oxidation and reduction potentials of **2** and quenchers (**3** and **4**), respectively. The combined spectroscopic and electrochemical data (Tables 2 and 3) were used to calculate the energetics of PET. The exergonic values of –90 and –84 kJ/mol calculated for the quenching of **1** by **3** and **4**, respectively, support the Stern–Volmer quenching data and imply that deactivation of the singlet excited states of **3** and **4** also occurs by intramolecular PET. This deactivation mode is consistent with the 2-fluorenyl aldimine regioisomers that also deactivate by intramolecular PET.[19–21] Interestingly, the PET deactivation mode of 2-substituted regioisomers can be suppressed by protonating the azomethine, resulting in fluorescence yields near unity.[19–21] However, the fluorescence yield of **3** does not increase upon protonation (Table 2). This is most likely a result of the steric hindrance at the

3	1.50	–1.40	3.3
4	1.73	–1.85	4.0

fluorenyl 9-position and as such, the imine cannot be efficiently protonated. Nonetheless, the spectroscopic and electrochemical data support the conclusion that the singlet excited states of **3** and **4** deactivate by intramolecular PET. While this degenerate manifold is also efficiently deactivated by rotational internal conversion in the case of **3**, **4** is efficiently deactivated predominately by intersystem crossing to form its triplet. The net outcome of these different deactivation processes is suppressed fluorescence for both **3** and **4**.

Conclusion

The origin of the previously unknown fluorescence suppression for 9-substituted fluorenes has been determined. Deactivation of the fluorophore excited state occurs by combined efficient rotational internal conversion and intramolecular photoinduced electron transfer for the heteroatomic ketylimine **3**. Although the singlet excited state of its carbon analogue (**4**) also deactivates by PET, the major mode of deactivation is by intersystem crossing resulting in efficient triplet formation. While the triplet manifold was spectroscopically confirmed by laser flash photolysis, evidence for the intramolecular PET mechanism was supported by examining the fluorescence rate constants for quenching of fluorene by both the ketylimine and vinylene fluorene derivatives. The PET mechanism was further supported by calculating the energetics according to the Rehm–Weller equation. Not only was the PET mechanism found to be exergonically favorable with these two quenchers, but deactivation of the singlet excited state occurred with diffusion-controlled rate constants. Unlike its 2-substituted fluorenyl regioisomers, the fluorescence of **3** cannot be restored by suppressing the PET mechanism by protonation. Nonetheless, the fluorescence quenching of **3** occurs predominately by rotational internal conversion, while that of its 2-substituted regioisomer occurs predominately by PET. The fluorescence of **3** can therefore be dramatically increased by reducing bond rotation deactivation modes, which is possible at low temperature or potentially in the solid state (e.g., by spin coating as thin films). The fluorescence enhancement possible with 9-heteroatomic fluorenyl imines makes these compounds beneficial and better suited for emitting devices than both their vinylene and 2-substituted regioisomer analogues, which waste their desired singlet excited state energy by uncontrollable means. Although the N=C bond is understood to be isoelectronic to the C=C bond, it was found that deactivation of the singlet excited state occurs by different modes depending on the type of unsaturated bond. The location of the N=C moiety on the fluorene was also found to play an important role in determining the fluorescence quenching mechanism. The future generation of materials for a given emitting or sensing application can therefore be prepared with the knowledge gained from the discovered fluorescence quenching mechanism.

Abstract: In this work, we have evaluated the reactivity of methyl gallate, propyl gallate, and *n*-octyl gallate toward galvinoxyl radicals in homogeneous solution (ethanol) and sodium dodecyl sulfate micelles. In ethanol, the rate of galvinoxyl consumption was independent of the gallate's alkyl chain length. On the other hand, reaction rates in micelles were dependent on the length of the gallate alkyl chain. Measurements of the rate of the reaction at different pH show that, even at pH 7.0, the reaction mainly involves the monodeprotonated anionic form of the gallates. Plots of reaction rates as a function of the surfactant concentration allowed us to evaluate the distribution of the gallates (K_{GH}) and an apparent rate constant defined by the product between the intramicellar rate constant of the anion (k_{G^-}) and its partition constant (K_{G^-}). The values of the increment of the apparent rate constant per methylene group in the alkyl chain strongly suggest that intramicellar rate constant values are independent of the alkyl chain length. This points to a similar intramicellar localization of the phenolate moiety in the three gallates considered.

Key words: galvinoxyl radical, gallates, rate-constant values, sodium dodecyl sulfate (SDS) micelles.

Résumé : Dans ce travail, on a évalué la réactivité du gallate de méthyle, du gallate de propyle et du gallate d'octyle vis-à-vis les radicaux galvinoxyles, en solution homogène dans l'éthanol et dans des micelles de dodécylsulfate de sodium. Dans l'éthanol, la vitesse de disparition du galvinoxyle est indépendante de la longueur de la chaîne alkyle des gallates. Par ailleurs, les vitesses de réaction dans les micelles dépendent de la longueur de la chaîne alkyle des gallates. Des mesures de vitesse de réaction à divers pH montrent que même à un pH de 7,0, la réaction implique principalement la forme anionique monodéprotonée des gallates. Des courbes des vitesses de réaction en fonction de la concentration d'agent de surface a permis d'évaluer la distribution des gallates (K_{GH}) et une constante de vitesse apparente définie par le produit entre la constante de vitesse intramicellaire de l'anion (k_{G^-}) et sa constante de partition (K_{G^-}). Les valeurs des incréments de la constante de vitesse apparente par groupe méthylène de la chaîne alkyle suggèrent fortement que les valeurs la constante de vitesse intramicellaire sont indépendantes de la longueur de la chaîne alkyle. On a considéré ces points pour une localisation intramicellaire semblable de la portion phénolate dans les trois gallates considérés.

Mots-clés : radical galvinoxyle, gallates, valeurs des constantes de vitesse, micelles de dodécylsulfate de sodium (DSS).

Introduction

Oxidative stress imposed by reactive oxygen species may play a crucial role in the pathophysiology associated with neoplasia, atherosclerosis, and neurodegenerative diseases. The oxidative damage can be controlled by compounds that remove active free radicals. These compounds can be endogenous or exogenous and most of them have phenolic groups as active moieties. They show a wide range of activities in vitro and are thought to exert protective effects against major diseases such as cancer and cardiovascular diseases.[1–3] The efficiency of a compound to remove reactive radicals will depend on the reactivity of its phenolic groups and the relative localization of the radical and the free-radical scavenger.[4] The synthetic *n*-alkyl esters of gallic acid, in particular propyl and octyl gallates, are widely employed as antioxidants in food and pharmaceutical industries. Besides the antioxidant activity, other biological roles have been described for this group of molecules, such as anticancer, antibacterial, and antifungal roles.[5]

Several studies have shown a good correlation between the inhibition of lipid oxidation of a given compound and its reactivity toward stable radicals.[6,7] However, in dispersed (microheterogeneous) systems like emulsions, antioxidant activity is related to several parameters determined by the interface. In particular, depending on the emulsifier used, an

accumulation of antioxidants at the interface can be achieved. Although lipidic domains are the main sites of lipid peroxidation, association of antioxidants at the interface does not necessarily result in an improvement of their antioxidant activity. This efficiency can be determined by interactions between antioxidants and emulsifiers at the interface, which may be hydrophobic or due to hydrogen bonding.[6,7] The hydrophobicity of the substrate will strongly influence its distribution between the microphase and the external medium and can also determine the intraparticle substrate distribution, affecting its reactivity toward the hydrophobic radical.[6,8] In this work, we have evaluated the reactivity of methyl gallate (MG), propyl gallate (PG), and *n*-octyl gallate (OG) toward galvinoxyl radicals in homogeneous solution and sodium dodecyl sulfate (SDS) micelles. Galvinoxyl, a stable phenoxyl radical, has a strong absorption peak at 428 nm in ethanol. In the presence of phenolic compounds, it is reduced by electron and (or) hydrogen-atom transfer. This last process has been related to the O–H bond dissociation energy of the donor group.[6,9]

Results and discussion

Figure 1A presents the depletion of galvinoxyl radicals (3 μmol/L) in ethanol solution in the presence of 100 μmol/L methyl, propyl, or octyl gallate. This figure shows that the course of the reaction, and in particular the initial rate of the process, is barely modified by the length of the alkyl chain. This result suggests an identical reactivity of the phenol moiety in ethanol for methyl, propyl, or octyl gallate.[10]

On the other hand, different rates are observed for the different gallates in SDS solutions. Figure 1B represents, as an example, the depletion of galvinoxyl radicals (3 μmol/L) in SDS (0.1 mol/L) in the presence of 100 μmol/L MG, PG, or OG. In particular, the data obtained in these systems show that the rate of the process increases when the length of the gallate alkyl chain increases.

For a given gallate, at fixed gallate and galvinoxyl concentrations, the rate of the process depends on the surfactant concentration. Initial rates measured in these conditions are shown in Fig. 2. The data of this figure show that (*i*) over the whole surfactant concentration range, the initial rate of galvinoxyl consumption follows the order OG > PG > MG (observed differences are larger at low surfactant concentrations); and (*ii*) the rate of the process decreases when the surfactant concentration increases.

These results can be due to the following: (*i*) distribution of galvinoxyl between the external solvent and the micellar ensemble; (*ii*) distribution of the gallates between the external solvent and the micelles; and (or) (*iii*) dependence of the intramicellar rate constant on the length of the gallate alkyl chain.

To assess the localization and environment of galvinoxyl radicals, electron paramagnetic resonance (EPR) spectra were recorded in buffer and SDS solutions (0.025 and 0.1 mol/L). The spectra are shown in Fig. 3.

Galvinoxyl EPR spectra in buffer showed a broad singlet characteristic of solid microaggregates.[11] On the other hand, well-resolved spectra were observed in micellar solutions, with a hyperfine structure that is very little dependent on the surfactant concentration. This would indicate that, in the tested SDS range, all the radicals are incorporated to the micelles and that their surroundings are similar, independent of the surfactant concentration.[6]

Fig. 1. Depletion of galvinoxyl radicals (3 μmol/L) by 100 μmol/L methyl gallate (○), propyl gallate (△), and octyl gallate (□) in ethanol (A) and in 0.1 mol/L SDS in phosphate buffer, pH 7.0 (B).

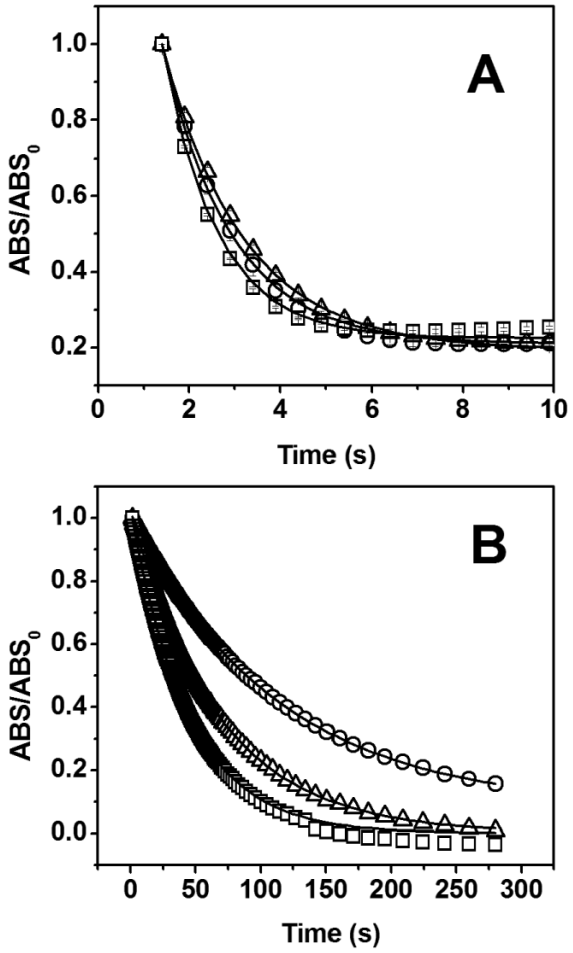

Fig. 2. Initial rate of galvinoxyl consumption elicited by the addition of 100 μmol/L methyl gallate (○), propyl gallate (△), and octyl gallate (□) as a function of SDS concentration.

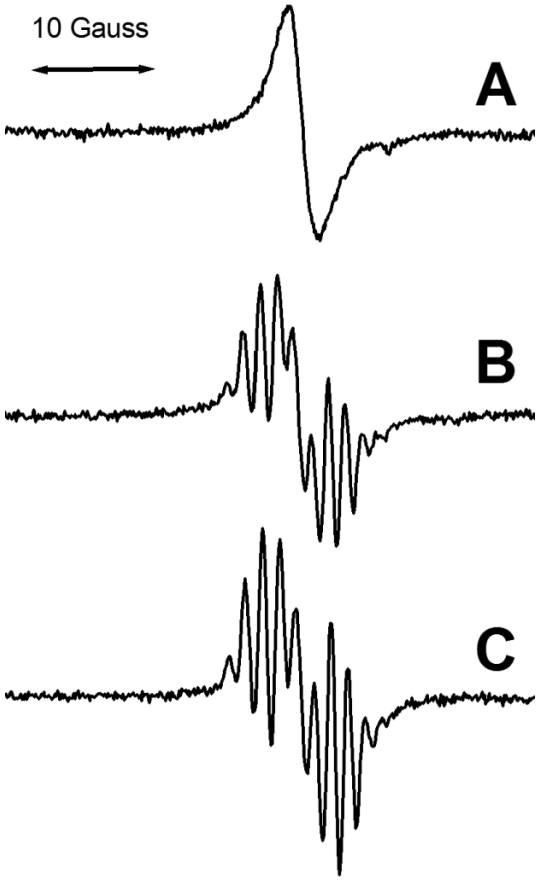
Fig. 3. Electron paramagnetic resonance spectra of 20 μmol/L gavinoxyl in phosphate buffer at pH 7 (A), 0.025 mol/L SDS (B), and 0.1 mol/L SDS (C).



Campos et al.[10] have developed a data treatment to evaluate the antioxidant partition constant and the intramicellar second-order rate constant for the reaction of gallates and 2,2-diphenyl-1-picrylhydrazyl (DPPH). The procedure assumes that the reaction takes place from the gallate in its phenolic form (non-ionized). Nevertheless, under our experimental conditions (phosphate buffer, pH 7 in bulk solution) gallates are partially deprotonated (pK_a = 8.03). The reactivity of gallates and their ionized forms toward galvinoxyl radicals can be different, as can their contribution to the overall reaction rate due to differences in their partition constants.

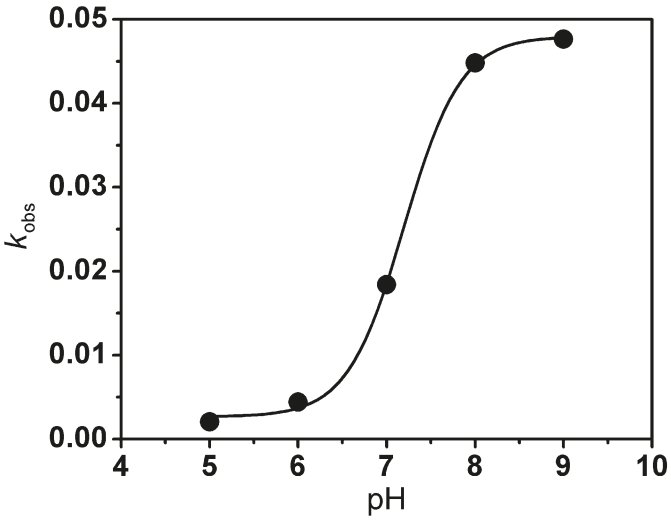
The galvinoxyl consumption rate in micelles was strongly dependent on the pH of the phosphate media. The data given in Fig. 4 show that, for MG, the reaction rate increases ~20 times when the pH changes from 5 to 9. These results clearly indicate a much faster reaction of the ionized gallate (G^-) than the protonated form (GH).

Measurements in SDS micelles at pH 7.0 showed a decrease in rate when SDS concentration increases (Fig. 5). The following mechanism can explain the reaction rate observed in the presence of micelles:

[1] $\mathrm{GH} = \mathrm{G}^- + \mathrm{H}^+$

[2] $\mathrm{GH} + \mathrm{SDS} = \mathrm{GH}_{\mathrm{mic}}$

Fig. 4. Observed first-order rate constant of galvinoxyl consumption by 100 μmol/L methyl gallate in 0.1 mol/L SDS at different pH values.



[3] $\mathrm{G}^- + \mathrm{SDS} = \mathrm{G}^-_{\mathrm{mic}}$

[4] $\mathrm{Galv}^{\bullet}_{\mathrm{mic}} + \mathrm{GH}_{\mathrm{mic}} \rightarrow \mathrm{Products}$

[5] $\mathrm{Galv}^{\bullet}_{\mathrm{mic}} + \mathrm{G}^-_{\mathrm{mic}} \rightarrow \mathrm{Products}$

where GH and G^- represent the non-ionized and ionized forms of gallates, respectively; Galv• is the galvinoxyl radical and the subscript mic indicates the micellar pseudophase.

The galvinoxyl depletion rate (v), due to eqs. [4] and [5], can be written as

[6] $$v/\mathrm{Galv}^{\bullet} = (k_{\mathrm{GH}}\mathrm{GH}_{\mathrm{mic}} + k_{\mathrm{G}^-}\mathrm{G}^-_{\mathrm{mic}})/f$$

where f is the fraction of volume of micelles, defined as $f = V^{\circ}[\mathrm{SDS}]/1000$, and V° is the surfactant molar volume.

The previous reaction can be expressed in terms of the concentration in aqueous phase if partition constants of the gallate (K_{GH}) and the ionized form (K_{G^-}) are incorporated in eq. [6].

[7] $$v/\mathrm{Galv}^{\bullet} = \frac{1000}{V^{\circ}}(k_{\mathrm{GH}}K_{\mathrm{GH}}\mathrm{GH} + k_{\mathrm{G}^-}K_{\mathrm{G}^-}\mathrm{G}^-)$$

From the data given in Fig. 4, it can be concluded that the contribution of the $k_{\mathrm{GH}}K_{\mathrm{GH}}$ factor is much smaller than that of the ionized gallate ($k_{\mathrm{G}^-}K_{\mathrm{G}^-}$). The overall rate can then be written as

[8] $$\mathrm{Galv}^{\bullet}[\mathrm{G}]/v = a + b[\mathrm{SDS}]$$

where [G] represents the analytical gallate concentration, $[\mathrm{G}] = \mathrm{GH} + \mathrm{G}^- + \mathrm{GH}_{\mathrm{mic}} + \mathrm{G}^-_{\mathrm{mic}}$, and

[9] $$a = \left(1 + \frac{K_a}{[\mathrm{H}^+]}\right) \Big/ \frac{1000}{V^{\circ}} K_{\mathrm{G}^-} \frac{K_a}{[\mathrm{H}^+]} k_{\mathrm{G}^-}$$

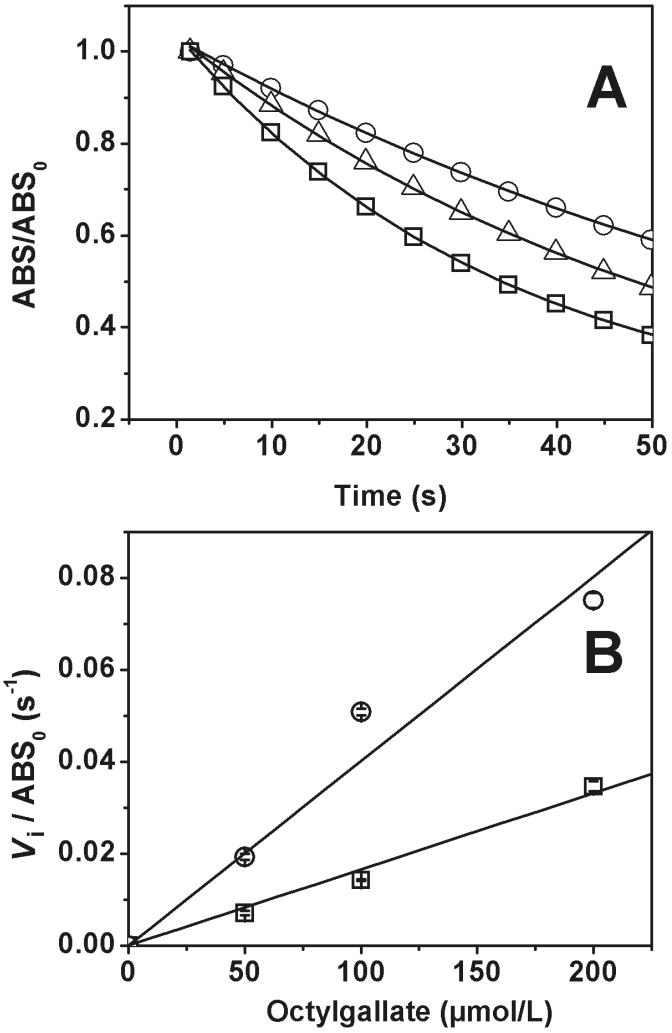
Fig. 5. (A) Depletion of galvinoxyl radicals by 100 μmol/L propyl gallate at different concentrations of SDS: 0.1 mol/L (○), 0.075 mol/L (△), and 0.025 mol/L (□). (B) Initial rate of galvinoxyl consumption elicited by the addition of octyl gallate in 0.1 mol/L (□) and 0.05 mol/L (○) SDS. Bar lines represent the standard deviation of three independent measurements.



$$[10] \qquad b = \left(K_{GH} + K_G \frac{K_a}{[H^+]}\right) \Big/ \frac{1000}{V^o} K_{G^-} \frac{K_a}{[H^+]} k_{G^-}$$

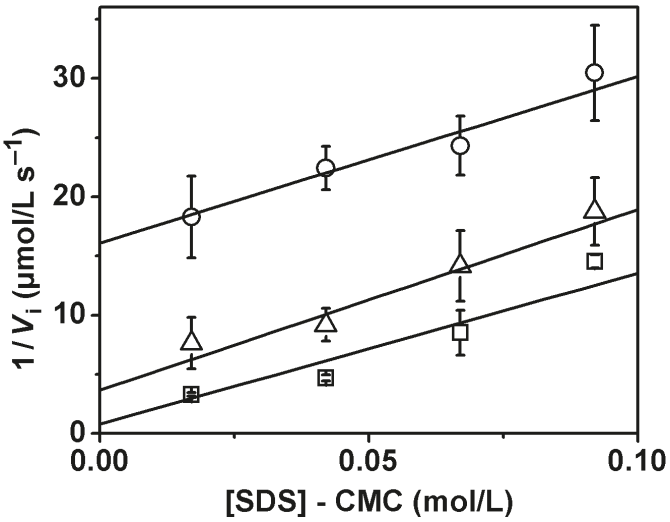
If the dissociation constant of the gallates (K_a) and the charge of the micelles are considered, it can be concluded that in our experimental conditions the concentration of the ionized gallate in the aqueous solution and in the micelle is much lower than the analytical gallate concentration. This consideration allows simplification of the values of a and b in this expression to

$$[11] \qquad a = V^o[H^+]/1000K_{G^-}K_a k_{G^-}$$

$$[12] \qquad b = K_{GH}V^o[H^+]/1000K_{G^-}K_a k_{G^-}$$

A plot of the left-hand side of eq. [8] against the free surfactant concentration (Fig. 6) allows the evaluation of K_{GH} (from the slope and intercept). It is interesting to note that

Fig. 6. Inverse initial rate of galvinoxyl consumption elicited by the addition of 100 μmol/L methyl gallate (○), propyl gallate (△), and octyl gallate (□) as a function of SDS concentration. Bar lines represent the standard deviation of three independent measurements. The critical micelle concentration was taken as 8 mmol/L.



in spite of the fact that the reactive species is the deprotonated gallate, the rate of the process is determined by the partition of GH. This apparent anomaly is due to the fact that the partition of GH regulates the amount of free G^- and that this determines the amount of the reactive species associated to the micelles.

If V° is taken as –250 mL/mol, the intercept of the plot allows determination of the product between the intramicellar rate constant of the ionized gallate and its partition constant ($K_{G^-}k_{G^-}$). These values are shown in Table 1, where the results obtained in homogeneous (ethanol) solution are also included.

The data treatment employed to obtain $k_{G^-}K_{G^-}$ values implies that K_{G^-} is independent of SDS concentration, in spite of the change in surface potential that could be elicited by the concomitant increase in free sodium concentration. To test the pertinence of this assumption, we measured the rate of galvinoxyl consumption by MG, employing a fixed SDS concentration (50 mmol/L) in the absence and presence of 30 mmol/L NaCl. No significant differences were observed (data not shown), indicating that under the present experimental conditions, we can assume that the factor $k_{G^-}K_{G^-}$ can be considered to be nearly independent of the free sodium concentration.

The data collected in Table 1 show that, as expected, the gallate association constant to SDS micelles increases with the length of the alkyl chain. A plot of $\ln(K_{GH})$ against the number of methylene groups in the gallate alkyl chain renders a contribution to the free energy of transfer ($\Delta\Delta G^o$) of nearly 1 kJ per methylene group. This value can be subject to a large error given the uncertainty in the OG distribution constant, but is similar to those reported in other systems comprising ionic micelles.[12,13] Furthermore, it is considerably larger than that obtained for the same gallates in Triton X-100 micelles.[9] This difference can be related to a more hydrophobic environment sensed by the gallates' alkyl chains in SDS than in Triton X-100 micelles.

For personal use only.

Table 1. Experimentally determined K_{GH} and $K_{G^-}k_{G^-}$ values in SDS micellar solutions.

	K_{GH} (L mol^{-1})[a]	$K_{G^-}k_{G^-}$ (L^2 mol^{-2} s^{-1})[b]	k_{EtOH} (L mol^{-1} s^{-1})
Methyl gallate	8.7	550	4900
Propyl gallate	41.7	2400	4600
Octyl gallate	157	11000	6500

[a]Values calculated in terms of molar surfactant concentrations.
[b]Values assuming V°= 250 mL/mol.

The factor $K_{G^-}k_{G^-}$ shows the same trend as the partition coefficient of the protonated gallate (K_{GH}) with the length of the gallate alkyl chain (Table 1). In agreement with this, a plot of $\log(K_{G^-}k_{G^-})$ versus the number of methylene groups renders a slope of 0.18, a value that is very close to that obtained for the change of K_{GH} with the number of methylene groups. If it is assumed that the length of the alkyl chain influences K_{G^-} and K_{GH} in similar ways, the similar slopes imply that k_{G^-} is nearly independent of the number of methylene groups. These results would suggest a similar intramicellar location of the reactive moiety.[7] Therefore, the differences observed (Fig. 1B) would be mainly a consequence of the different partition constants for the three deprotonated gallate alkyl esters.

A similar conclusion has been obtained regarding the reaction of gallates with DPPH in neutral Triton X-100 micelles.[10] The slower rates observed in SDS micelles compared with the rates observed in ethanol (Fig. 1) can be mostly ascribed to the small G^- fraction associated to the anionic micelles. This fraction can lead to an electron-transfer process at the micellar surface between the phenolate group of the gallate and the micelle-associated galvinoxyl radicals.

Conclusions

Different rates observed for the reaction of gallates with different alkyl chain lengths with galvinoxyl radicals in SDS micelle solutions are mainly due to partitioning of the anionic gallates. In fact, the results indicate similar intramicellar rate constants for the three compounds considered, indicating that the intramicellar localization of the reactive group is independent of the length of the alkyl chain.

Experimental

Materials

Thestable free-radical galvinoxyl (2,6-di-*tert*-butyl-α-(3,5-di-*tert*-butyl-4-*oxo*-2,5-cyclohexadiene-1-ylidene), anionic SDS (sodium dodecyl sulfate, 99%), and the gallates methyl gallate (98%), propyl gallate, and *n*-octyl gallate (98%) were obtained from Sigma-Aldrich. Stock solutions of the gallates and galvinoxyl were prepared daily in analytical grade ethanol (Merck). The reactions carried out in micelles contained 1% ethanol. Micellar solutions of SDS were prepared in 10 mmol/L sodium phosphate buffer, pH 7.0.

Instruments

UV–visible spectra were recorded using a UV–vis spectrophotometer (Hewlett Packard 8453; Palo Alto, California, USA). A stopped-flow apparatus from Applied Photophysics was used for kinetic measurements. The rate of the reaction was followed by registering the absorbance of galvinoxyl at 428 nm. EPR spectra were obtained on a Bruker EMX 1572 spectrometer that operates in the X-band (9.2–9.9 GHz), equipped with a thermal cavity at 25 °C.

Photochemistry of matrix-isolated 5-cyano-2*H*-pyran-2-one (δ-cyano-α-pyrone) and cyanocyclobuta-1,3-diene

Jessica L. Menke and Robert J. McMahon

Abstract: Matrix-isolation photochemistry (λ > 299 nm; Ar, 10 K) of 5-cyano-2*H*-pyran-2-one (**5**, δ-cyano-α-pyrone) shows complete conversion to a mixture of several ring-opened ketene isomers (**6**) and a ring-closed Dewar lactone (**7**), as detected by infrared spectroscopy. Subsequent irradiation (λ > 200 nm) causes decarboxylation of the Dewar lactone (**7**) to produce cyanocyclobuta-1,3-diene (**8**). Continued irradiation (λ > 200 nm) results in the photodecomposition of cyanocyclobuta-1,3-diene (**8**) to cyanoacetylene and acetylene. 4-Cyanopyridine (**10**) was explored as an alternative photochemical precursor to cyanocyclobuta-1,3-diene (**8**). It was found, however, that **10** does not exhibit observable photochemistry under our irradiation conditions.

Key words: astrochemistry, cyclobutadiene, matrix-isolation spectroscopy, physical-organic chemistry, reactive intermediates.

Résumé : La photochimie (λ > 299 nm; Ar, 10 K) de la 5-cyano-2*H*-pyran-2-one (**5**, δ-cyano-α-pyrone) isolée dans une matrice donne lieu à une conversion complète qui, d'après les détections faites par spectroscopie infrarouge, comporte un mélange de plusieurs isomères céténiques en chaîne ouverte, **6**, et un sous forme cyclique, la lactone de Dewar **7**. Une irradiation subséquente (λ > 220 nm) provoque une décarboxylation de la lactone de Dewar, **7**, et la formation du cyanocyclobuta-1,3-diène (**8**). Une continuation de l'irradiation (λ > 220 nm) conduit à une photodécomposition du cyanocyclobuta-1,3-diène (**8**) et à l'obtention du cyanoacétylène et de l'acétylène. On a aussi examiné la possibilité d'utiliser la 4-cyanopyridine (**10**) comme précurseur photochimique pour le cyanocyclobuta-1,3-diène (**8**). On a trouvé toutefois que le produit **10** ne donne lieu à aucune photochimie observable dans les conditions d'irradiation utilisées ici.

Mots-clés : astrochimie, cyclobutadiène, spectroscopie en isolement dans une matrice, chimie organique physique, intermédiaires réactifs.

[Traduit par la Rédaction]

Introduction

Interest in the photochemistry of 2*H*-pyran-2-one (**1**, α-pyrone) derives from its utility in generating cyclobuta-1,3-diene (**4**),[1–16] a reactive molecule of considerable theoretical interest in organic chemistry.[11,17,18] In the current study, we explored the photochemistry of 5-cyano-2*H*-pyran-2-one (**5**, δ-cyano-α-pyrone) in an effort to generate cyanocyclobuta-1,3-diene (**8**) (Scheme 1).

Our interest in producing cyanocyclobutadiene (**8**) stems from the general relevance of cyanoacetylene and other unsaturated organic nitriles to the chemistry of the interstellar medium[19–23] and the atmosphere of Titan, Saturn's largest moon.[24–27] Cyanocyclobutadienes are predicted intermediates in the thermal[28,29] and photochemical[30,31] trimerization of cyanoacetylene and acetylene to give cyanobenzenes, and recent computational work reveals that cyano substituents confer a thermodynamic stabilization to the cyclobutadiene ring.[32,33] We now describe the photochemical transformations involving cyanopyrone **5**, cyanoketene isomers **6**, Dewar lactone **7**, and cyanocyclobuta-1,3-diene (**8**). We also describe efforts to utilize 4-cyanopyridine (**10**) as an alternative photochemical precursor to cyanocyclobuta-1,3-diene (**8**).

Background

Irradiation of α-pyrone (**1**) initiates both a ring-opening reaction to produce ketene **2** and a ring-closing reaction to produce bicyclic lactone **3**, which we refer to as a Dewar lactone. Under photochemical reaction conditions, ketene **2** exists as multiple conformational and geometric isomers. Close examination of the ketene-stretching region of the IR spectrum gives insight into how many isomers are present and how they interconvert with further irradiation.[14,16] In the unsubstituted α-pyrone (**1**) system, a [1,5] sigmatropic hydrogen shift in ketene **2** is a degenerate process. In certain substituted systems, however, the [1,5]-hydrogen shift pro-

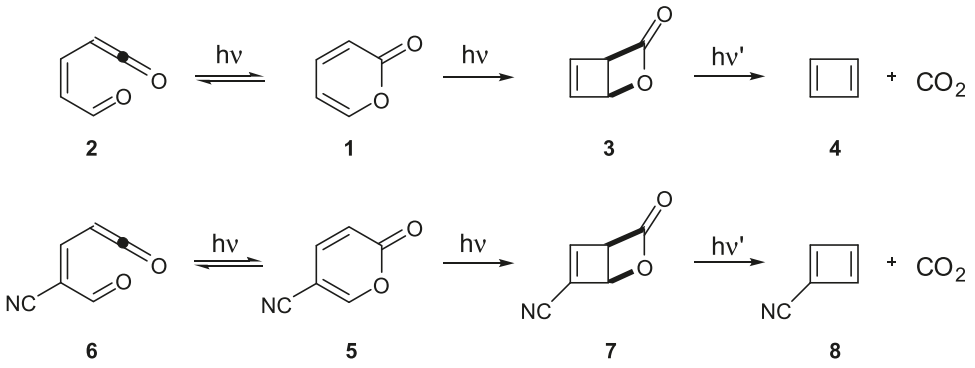
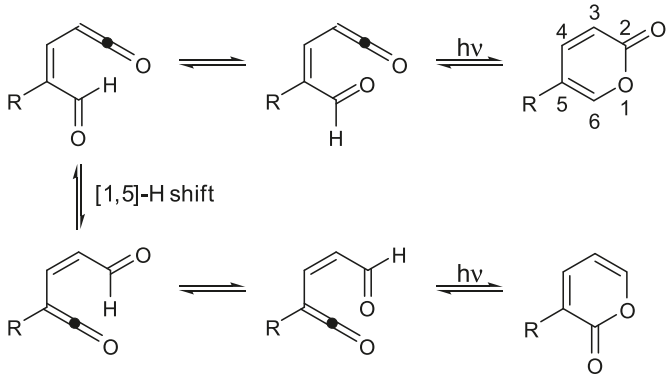
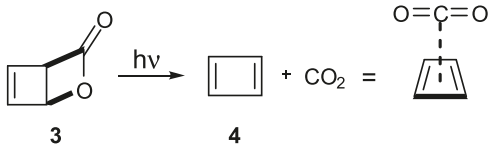
Scheme 1.



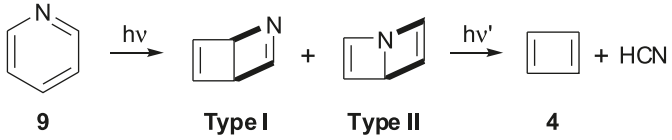
duces a different ketene isomer.[16] Ring-closing of this ketene can produce a different isomer of α-pyrone.



The Dewar lactone **3**, as well as several substituted derivatives, photodecompose to produce cyclobuta-1,3-diene (**4**) and CO_2.[2,3,5,6,9,10,12–16,34–40] When cyclobutadiene and CO_2 are cage-confined in a matrix, they form a complex in which CO_2 lies parallel to the plane of the cyclobutadiene ring.[13,41,42]



Pyridine (**9**) also serves as a photochemical precursor to cyclobutadiene.[3,43] A benefit of pyridine precursors is the lack of ring-opening products. However, two Dewar isomers are possible (type I and type II).[3,43–45] Kudoh et al. showed that pyridine (**9**) selectively forms the type I Dewar isomer under UV irradiation.[43] Careful selection of substituted pyridines may lead to the corresponding substituted cyclobutadienes.



Results and discussion

Photochemistry of 5-cyano-2*H*-pyran-2-one (5): IR spectroscopy

5-Cyano-2*H*-pyran-2-one (**5**) was sublimed at 70 °C and co-deposited with argon to afford a clean matrix-isolated sample. The IR spectrum obtained after deposition can be found as Supplementary data (Fig. S1). UV irradiation (λ > 299 nm, 2 h) provides complete conversion of **5** to a mixture of the Dewar lactone **7** and several ketenes **6** (Scheme 2) (Fig. 1). The production of a Dewar lactone has been seen previously for the parent system[2,5,7–10,12,14] and several substituted α-pyrones.[13,15,16] The identity of **7** is confirmed by comparison of the experimental and computed (B3LYP/6-31G*) IR spectra (Fig. 1). The shift of the carbonyl stretching vibration of **7** to higher frequency, relative to cyanopyrone **5**, is common for carbonyl groups in small ring systems and is a characteristic signature for the formation of Dewar lactones from α-pyrones. The complete disappearance of cyanopyrone **5** rules out the possibility of a photostationary state, as seen for 5-carbomethoxy-2*H*-pyran-2-one.[15] A raw spectrum showing the complete conversion of **5** to **6** and **7** can be found in the Supplementary data, Fig. S2.

The presence of the ring-opened ketene isomers **6** is revealed by the asymmetric –C=C=O stretching vibration centered at 2135 cm^{-1} (Fig. 2). Figure 2*a*, which is taken from the same experiment shown in Fig. 1, exhibits 4 absorptions, at 2146, 2140, 2134, and 2127 cm^{-1}, with an additional very weak band at 2118 cm^{-1}. For the unsubstituted system, several different ketene isomers (**2**) are also observed, and these isomers interconvert with further irradiation.[14] The absorption pattern for the cyanoketene isomers **6** (Fig. 2) is very similar to the spectrum obtained by Breda et al. after irradiation of α-pyrone at λ > 285 nm for 1 min. The peaks for the cyanoketene isomers **6** are shifted to higher frequency by approximately 10 cm^{-1}, relative to the unsubstituted system.[14]

An additional experiment was performed using a Xe lamp (lower intensity than the Hg lamp) to follow the isomerization of the ketene isomers. Figure 2*b* shows the evolution of the –C=C=O stretching region as a function of irradiation time (λ > 299 nm). The absorptions at 2140, 2134, and 2127 cm^{-1} appear to grow at a fairly consistent rate. The absorptions at 2146 and 2118 cm^{-1}, however, initially grow at a faster rate and then begin to disappear after 2 to 6 h of irradiation, indicating a secondary photochemical process.

Scheme 2.

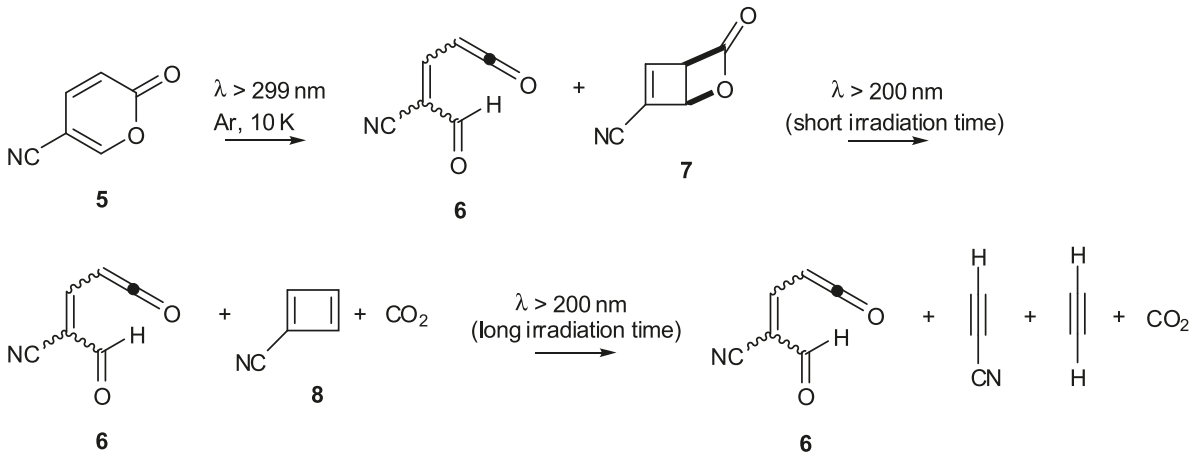

Fig. 1. Top: Unscaled computed (B3LYP/6-31G*) IR spectrum of Dewar lactone **7**. Middle: IR subtraction spectrum obtained after irradiation (λ > 299 nm; 2 h) of 5-cyano-2*H*-pyran-2-one (**5**) showing the appearance (positive peaks) of ketenes **6** and Dewar lactone **7** with the simultaneous disappearance (negative peaks) of **5** (Ar, 10 K). Bottom: Unscaled computed IR spectrum of **5**.

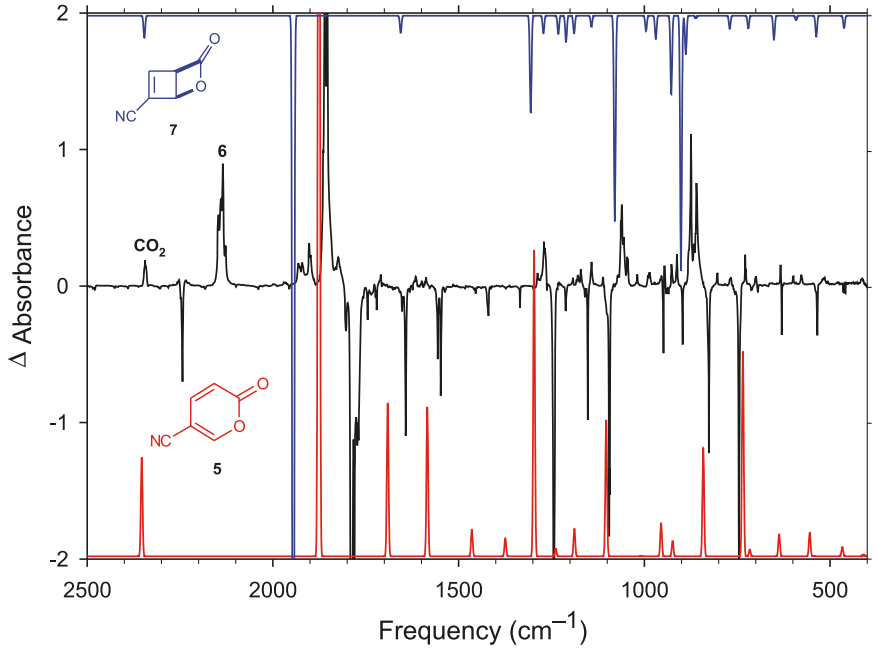

To better understand the structure, energetics, and spectroscopy of the possible cyanoketene isomers **6a**–**6g**, we performed a computational survey using DFT methods (B3LYP/6-31G*) (Fig. 3). The cyanoketene structures **6a**–**6g** lie within 8 kcal mol^{-1} of each other. Although not all of the transition states connecting the cyanoketene isomers were computed, the lowest (**6a** to **6b**) and highest (**6b** to **6f**) barriers reported for the unsubstituted isomers were computed. In terms of energetics, all structures appear to be viable intermediates under the photochemical reaction conditions. Despite the fact that the computed IR spectrum for each cyanoketene isomer **6a**–**6g** is available to us, we are unable to provide a detailed assignment for the isomers present in the experimental spectrum. Apart from the strong absorptions of the –C=C=O stretching vibrations, the remainder of the IR absorptions of **6a**–**6g** are relatively weak and are further obscured by the presence of the strongly absorbing Dewar lactone **7** in the matrix.

Photochemical conversion of Dewar lactone 7 to cyanocyclobuta-1,3-diene (8)

After the complete conversion of 5-cyano-2*H*-pyran-2-one (**5**) to ketenes (**6**) and Dewar lactone **7** (λ > 299 nm), the matrix was irradiated at shorter wavelengths (λ > 200 nm). After 30 min of irradiation, the major photoproducts were CO_2 (3702, 3596, 2345, 661 cm^{-1}),[46] acetylene (3284, 3268, 3257, 3247, 744, 736 cm^{-1}),[47] and cyanoacetylene (3315, 2269, 2076, 667 cm^{-1}),[48] as shown in Fig. 4*a*. In addition, several weak absorptions can be attributed to cyanocyclobuta-1,3-diene (**8**) (2184, 1211, 602, 518 cm^{-1}). These bands correspond rather well with the most intense absorptions in the computed IR spectrum of **8** (Fig. 4*a*, top). Apart from the nitrile stretch (2184 cm^{-1}), these bands are also similar to

Fig. 2. The asymmetric –C=C=O stretching region of the IR spectrum of ketenes (**6**). (*a*) Spectrum obtained after irradiation of 5-cyano-2*H*-pyran-2-one (**5**) with a Hg lamp (λ > 299 nm; Ar, 10 K) for 2 h. (*b*) Spectra obtained after irradiation of **5** with a Xe lamp (λ > 299 nm; Ar, 10 K) for 1, 10, 35, 60, 90 min; 2, 6, 8, 12, and 29 h. Absorptions at 2140, 2134, and 2127 cm^{-1} grow at a fairly consistent rate throughout the course of the irradiation.

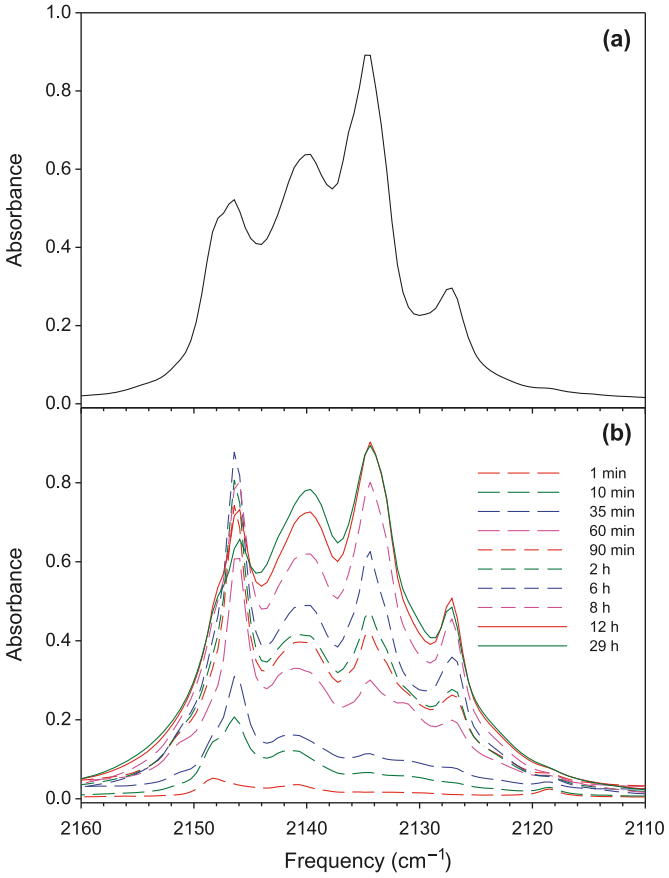

Fig. 3. Computed relative energies (kcal mol^{-1}, B3LYP/6-31G*, ZPVE included) of cyanoketene isomers (**6a**–**6g**), along with transition-state energies for the thermal conversion of **6a** to **6b** and **6b** to **6f**.

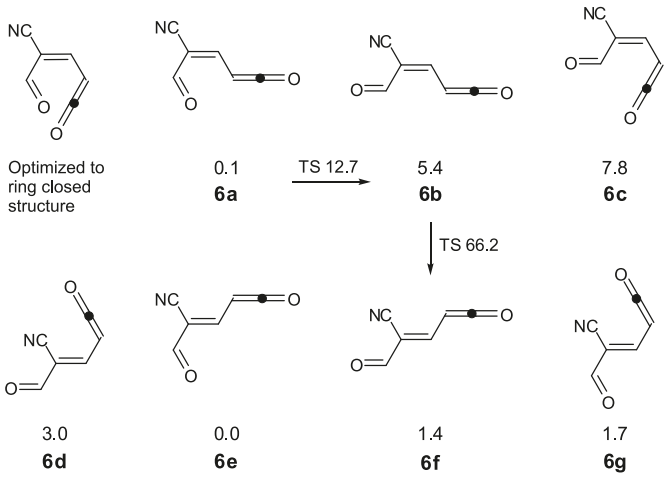

those of the unsubstituted cyclobutadiene (**4**) (1245, 655, 575 cm^{-1}).[2,6,8,12] Further support for the cyanocyclobuta-1,3-diene (**8**) assignment comes from consideration of the subsequent photochemistry. Continued irradiation (λ > 200 nm; 60 min) reveals an increase in the IR absorptions of both acetylene and cyanoacetylene with concomitant disappearance of the IR absorptions attributed to **8**.

When cyclobutadiene derivatives are photochemically produced from the corresponding Dewar lactones under matrix isolation conditions, the cyclobutadiene and CO_2 are formed in a single matrix cavity and thus exist as a complex.[9,14,41,49] To probe the possible involvement of a complex in the current system, we carried out a computational investigation of the complex between cyanocyclobuta-1,3-diene (**8**) and CO_2. A complex was indeed obtained as an energy minimum on the potential energy surface (B3LYP/6-31G*). The computed IR spectrum of the complex, however, did not display any significant differences when compared with the spectrum of **8** itself (see Supplementary data). There is a very slight decrease (0.7 kcal mol^{-1}) in the relative energy of the **8**–CO_2 complex as compared with the fully separated **8** and CO_2. Although it is likely that the complex is present in the matrix, this conclusion cannot be experimentally confirmed or denied on the basis of the data available to us.

During the short-wavelength irradiation (λ > 200 nm), additional minor changes are observed in the IR spectrum (Fig. 4). The simultaneous growth and loss of peaks in the –C=C=O stretching region (ca. 2135 cm^{-1}) indicate further photoequilibration of the ketene isomers **6**. New peaks at 2234 and 503 cm^{-1} remain unassigned at this time.

Photochemistry of 5-cyano-2*H*-pyran-2-one (5): UV–vis spectroscopy

The electronic absorption spectrum of 5-cyano-2*H*-pyran-2-one (**5**; Ar, 10 K) exhibits absorption maxima at 233 and 291 nm (Fig. 5). Photoexcitation into the longer wavelength absorption feature, using λ > 299 nm, bleaches the absorptions of **5**. The residual absorption maximum shifts to 250 nm, which presumably arises from the mixture of isomeric ketenes **6**, since the chromophore for the nonconjugated Dewar lactone **7** is expected to lie deeper in the UV. Irradiation at shorter wavelengths (λ > 200 nm) bleaches the absorption at 250 nm. The resulting spectrum reveals only the tailing absorptions of species absorbing in the deep UV. IR spectra, taken under analogous conditions, show the appearance of acetylene and cyanoacetylene, neither of which absorbs strongly at λ > 200 nm.[50] During the λ > 200 nm irradiation, we were unable to identify an absorption feature — first growing, then disappearing — that could be correlated with cyanocyclobuta-1,3-diene (**8**).

Cyanopyridines as photochemical precursors for cyanocyclobuta-1,3-dienes

In light of the earlier reports that pyridine serves as a photochemical precursor for the production of Dewar pyridine[3,43–45] and cyclobutadiene,[3,43,45] we identified 4-cyanopyridine (**10**) as a potential precursor for cyanocyclobuta-1,3-diene (**8**). Each of the cyanopyridine isomers is commercially available, but the 4-substituted isomer became

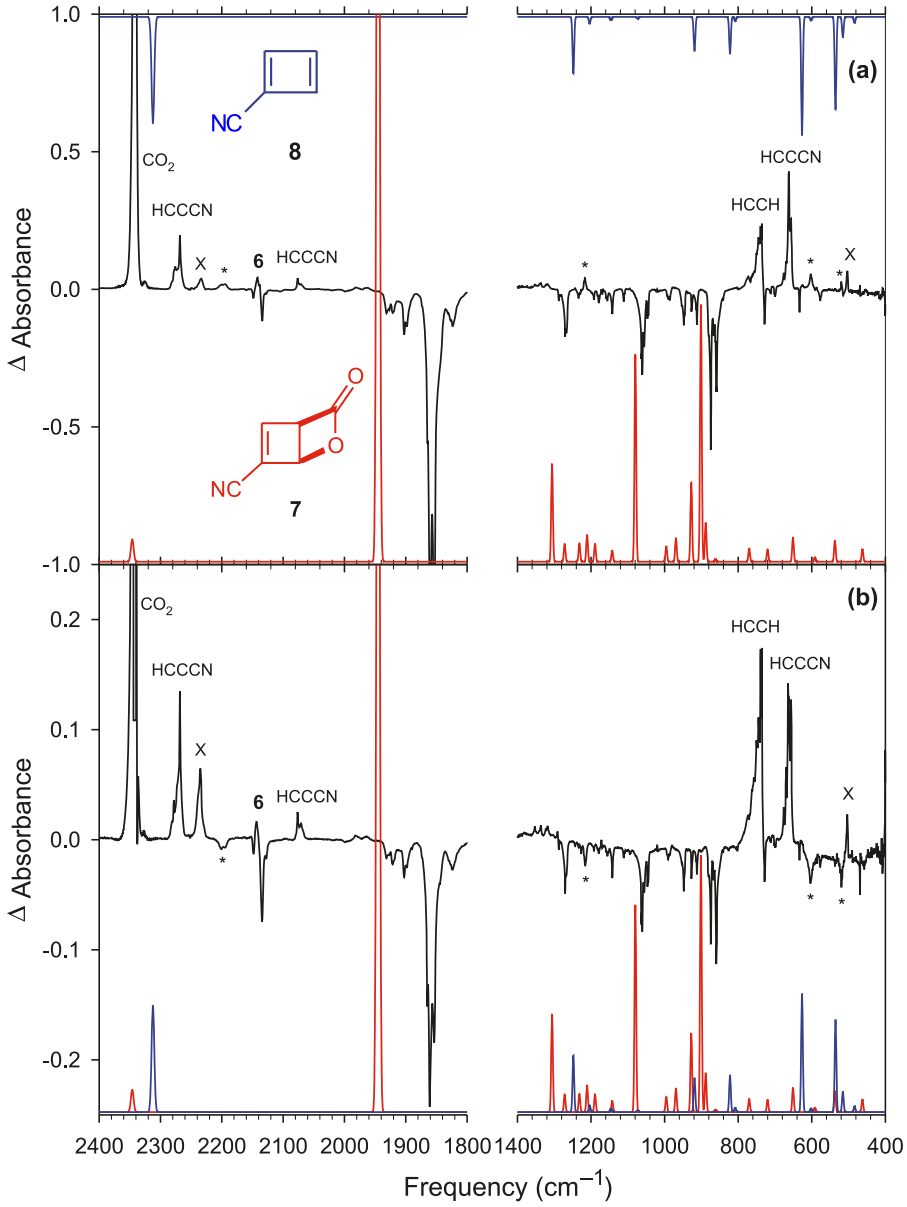
Fig. 4. (*a*) Top: Unscaled computed (B3LYP/6-31G*) IR spectrum of cyanocyclobuta-1,3-diene (**8**). Middle: IR subtraction spectrum obtained after irradiation (λ > 200 nm; 30 min) of a matrix containing ketenes **6** and Dewar lactone **7** showing the appearance of CO_2, acetylene (HCCH), cyanoacetylene (HCCCN), and cyanocyclobuta-1,3-diene (*, **8**) (Ar, 10 K). Isomerization of ketenes **6** and the presence of an unknown species (X) are also observed. Bottom: Unscaled computed spectrum of Dewar lactone **7**. (*b*) Middle: IR subtraction spectrum obtained after irradiation (λ > 200 nm; 60 min) showing the increase in acetylene (HCCH) and cyanoacetylene (HCCCN) and loss of cyanocyclobuta-1,3-diene (*, **8**) (Ar, 10 K). Bottom: Unscaled computed spectra of **8** (blue) and **7** (red). The 1800–1400 cm^{-1} spectral region is omitted for clarity. The full spectrum is available in the Supplementary data, Fig. S3.



the focus of our study because it would produce the fewest Dewar isomers (Fig. 6).

4-Cyanopyridine (**10**) was sublimed at 25 °C and co-deposited with argon to afford a clean matrix-isolated sample. The IR spectrum obtained after deposition can be found as Supplementary data (Fig. S4). The sample was irradiated at several wavelengths, including λ > 200 nm, for 10 h with no photochemical changes apparent by IR spectroscopy (Fig. S5). Thus, under our experimental conditions, 4-cyanopyridine is not a viable precursor for the production of cyanocyclobuta-1,3-diene (**8**). The cyano substituent apparently perturbs the excited state of the pyridine moiety such that photocyclization to the Dewar isomer does not occur. In this regard, it is worth commenting that the electronic absorption spectrum of 4-cyanopyridine (**10**) differs notably from that of pyridine (**9**),[51] and that 4-cyanopyridine is phosphorescent, while pyridine is not.[52]

Several dicyanopyridines are also commercially available and may be considered potential precursors to the dicyanocyclobuta-1,3-dienes. These systems were computationally surveyed (Fig. 7). 3,4-Dicyanopyridine (**13**) represents an attractive target because the Dewar isomer (2-aza-5,6-dicyanobicyclo[2.2.0]hexa-2,5-diene, **14**) is the lowest in energy of all the dicyano Dewar isomers, and because both type I

Fig. 5. UV–vis spectra obtained after 3 min deposition of 5-cyano-2*H*-pyran-2-one (**5**) at 50 °C (black) (Ar, 25 K), followed by irradiation at λ > 299 nm (Ar, 10 K) for 5 and 10 min, then irradiation at λ > 200 nm for 5 and 10 min. (Because UV–vis absorptions are much more intense than IR absorptions, the matrix used for UV–vis spectroscopy is much thinner than that used for IR spectroscopy, resulting in much shorter irradiation times.)

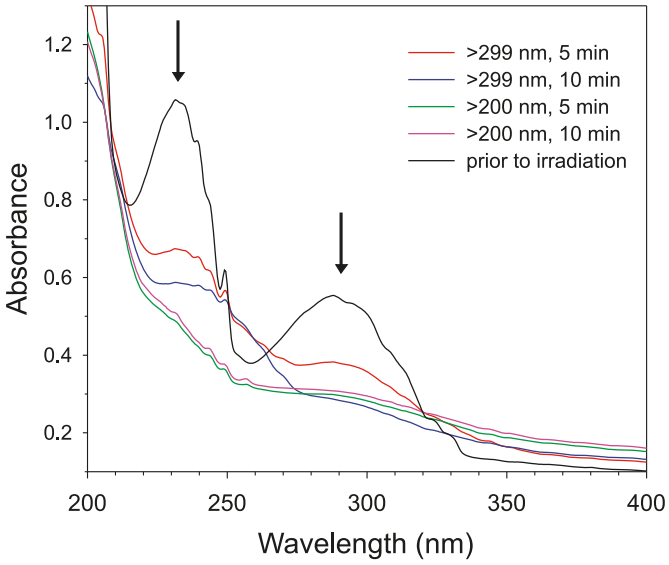

Fig. 6. Computed relative energies (kcal mol^{-1}, B3LYP/6-31G*, ZPVE included) for the cyanopyridine isomers and the corresponding Dewar isomers of type I and type II.

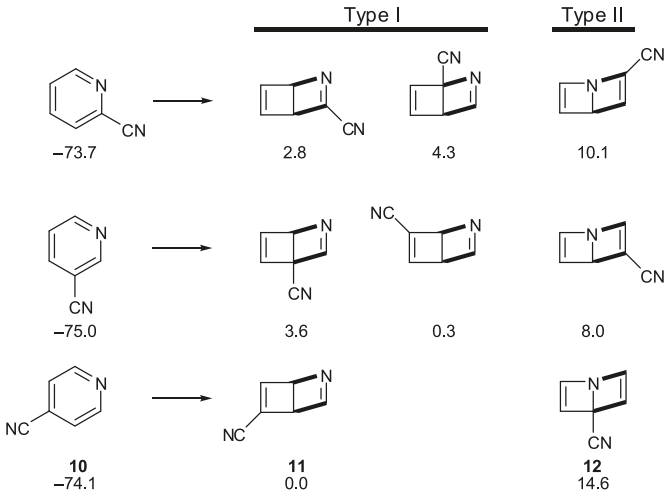
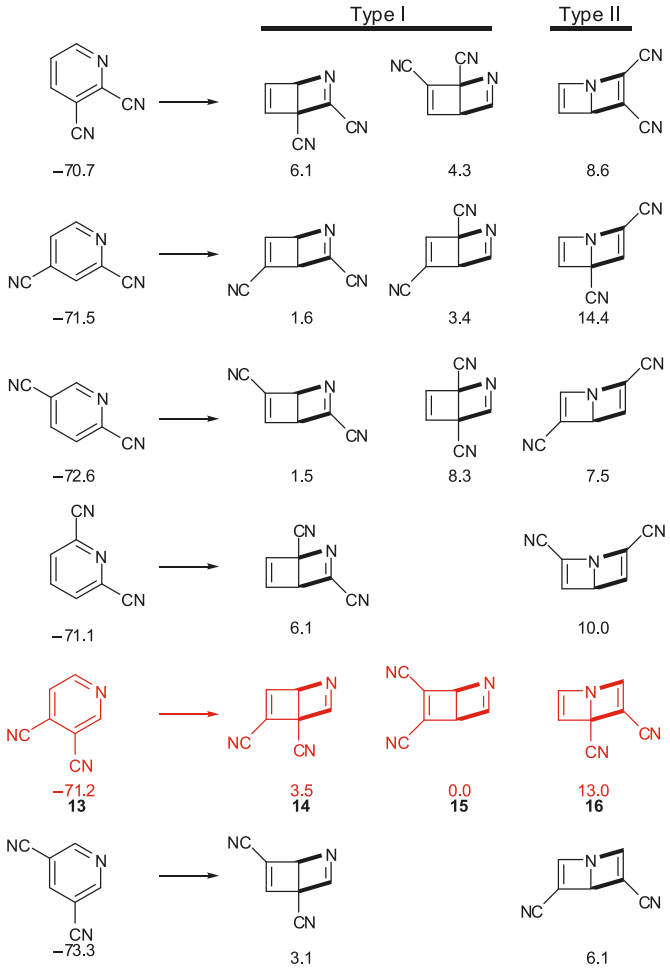


Dewar isomers (**14** and **15**) have the requisite connectivity to eliminate HCN to give a dicyanocyclobuta-1,3-diene. Future work will be directed toward the generation of dicyanocyclobuta-1,3-dienes from dicyanopyridines or other suitable precursors.

Summary

Matrix isolation photochemistry (λ > 299 nm) of 5-cyano-2*H*-pyran-2-one (**5**) shows complete conversion to a mixture containing several ring-opened ketene isomers (**6**) and a bicyclic Dewar lactone (**7**), as detected by infrared spectroscopy. Subsequent irradiation (λ > 200 nm) effects

Fig. 7. Computed relative energies (kcal mol^{-1}, B3LYP/6-31G*, ZPVE included) for the dicyanopyridine isomers and the corresponding Dewar isomers of type I and type II.



decarboxylation of the Dewar lactone (**7**) to afford cyanocyclobuta-1,3-diene (**8**). Continued irradiation causes photodecomposition of cyanocyclobuta-1,3-diene (**8**) to cyanoacetylene and acetylene. UV–vis spectra were also obtained, although they do not show features that can be assigned to **8**. Although pyridine (**9**) has been previously shown to serve as a photochemical precursor to cyclobuta-1,3-diene (**4**), 4-cyanopyridine (**10**) is not a viable precursor to cyanocyclobuta-1,3-diene (**8**) under our experimental conditions.

Methods

Computational methods

Density functional theory computations were performed using Gaussian03[53] and the Becke 3-parameter gradient-corrected exchange functional[54] with the correlation functional of Lee et al.[55] (B3LYP). The 6-31G* basis set[56] was employed for geometry optimizations, relative energies, and harmonic vibrational frequency computations. All energies have been corrected for zero-point vibrational energies (ZPVE). Vibrational frequencies were used to determine the nature of the stationary points as an energy minimum (no imaginary modes), transition state (one imaginary mode), or higher order saddle point (more than one imaginary mode).

For personal use only.

Estimated transition states for the thermal conversion of **6a** to **6b** and **6b** to **6f** were optimized under the constraint of a fixed dihedral angle of 90°.[14]

Experimental methods

Infrared spectra were obtained with a Thermo Nicolet Nexus 870-FT-IR instrument (MCT-B detector). UV–vis spectra were obtained on a Varian Cary 5000 UV–vis–NIR spectrophotometer. NMR spectra were obtained on a Varian MercuryPlus 300 spectrometer.

Matrix-isolation spectroscopy

The apparatus and experimental technique for low-temperature matrix-isolation spectroscopy have been described previously[57,58] and minor modifications are described here. The compressor for the closed-cycle refrigeration system was manufactured by ASC-Cryogenics (model 125). The window temperature was measured and controlled by a temperature controller from Lake Shore Cryotronics (model 331).

Sample deposition

Solid 5-cyano-2*H*-pyran-2-one (**5**) (0.010 g) was placed in a short glass tube and attached to the spectroscopic vacuum shroud. The deposition tube was evacuated, and the sample was kept under high vacuum for 1 h before the matrix-isolation apparatus was cooled to 25 K. The sample was heated with an oil bath to 70 °C for 45 min for an IR spectroscopy experiment (CsI inner window and KBr outer windows) and 3 min for a UV–vis experiment (sapphire inner window and quartz outer windows). The sample was deposited along with an inert gas (Ar or N_2) at a rate of approximately 1.5 Torr min^{-1} (1 Torr = 133.322 Pa). Two torr of Ar were deposited both before and after the sample deposition. The matrix window was then cooled to 10 K.

Solid 4-cyanopyridine (**10**) (Sigma-Aldrich, used without further purification) was deposited using a deposition tube with a stopcock, owing to the volatility of the sample. The sample (0.015 g) was held under high vacuum for 1 h (sample kept at 77 K) before subliming onto the matrix window at room temperature (2×10^{-7} Torr) along with Ar at a rate of approximately 1.5 Torr min^{-1}. Two torr of Ar were deposited both before and after the sample deposition.

Sample irradiation

Irradiations were performed using a Hg arc lamp (Photon Technology International 100 W Hg lamp and model LPS-220B power supply, voltage set to 26 V). A Xe arc lamp (ILC Technology LX300UV 300 W Xe lamp and EM500xl power supply) was used for one of the UV–vis experiments. Cutoff filters were used to provide proper wavelengths for irradiation.

Synthesis of 5-cyano-2*H*-pyran-2-one (5)

*Conversion of 2*H*-pyran-2-one-5-carboxylic acid (13) to 2*H*-pyran-2-one-5-carbonyl chloride (14)*

The procedure given by Csihony et al.[59] was followed, with a few modifications. 2*H*-Pyran-2-one-5-carboxylic acid (2.0 g, 14.3 mmol) and $SOCl_2$ (6 mL, 30.8 mmol) (both used as received from Sigma-Aldrich) were placed in a 3-neck, 50 mL round-bottom flask equipped with a reflux condenser, N_2 inlet, and magnetic stir bar. The reaction mixture was heated to 100 °C for 8 h. A hot 1:10 mixture of CH_2Cl_2–hexanes was added to the reaction mixture to dissolve the solid that formed during reflux. Additional hexane was added until a white precipitate formed. This mixture was then cooled to finish crystallization. 2*H*-Pyran-2-one-5-carbonyl chloride (**14**) was isolated as a light green solid by filtration (1.5 g, 67% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.39 (d, J = 10.5 Hz, 1H), 7.77 (d, J = 10.5 Hz, 1H), 8.58 (s, 1H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 162.9, 162.7, 158.2, 140.2, 116.6, 115.4.

*Conversion of 2*H*-pyran-2-one-5-carbonyl chloride (14) to 5-cyano-2*H*-pyran-2-one (5)*[60]

2*H*-Pyran-2-one-5-carbonyl chloride (**14**) (1.5 g, 9.5 mmol) and sulfamide (0.8 g, 8.3 mmol) were added to a 25 mL round-bottom flask equipped with an N_2 inlet. The solid mixture was heated to 120 °C for 1 h. The solids melted and bubbled as HCl was evolved, producing a dark red oil. When cooled, the reaction mixture solidified. The mixture was transferred to a separatory flask using 75 mL of 10% (*w*/*v*) $NaHCO_3$ solution. The product was extracted with 2 × 50 mL CH_2Cl_2. The organic layer was then washed with 2 × 25 mL sat. aq. NaCl. The organic layer was then dried using $MgSO_4$, and the product was isolated in vacuo to afford 5-cyano-2*H*-pyran-2-one (**5**) (0.23 g, 20% yield). Further purification was not undertaken because the NMR spectrum of the crude product was clean. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.0 (1:1:1 t, J = 1.3 Hz, 1H), 7.4 (dd, J = 2.9, 9.4 Hz, 1H), 6.4 (d, J = 9.4 Hz, 1H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 160.0, 157.3, 140.6, 117.3, 113.5, 95.3.

Determination of oxygen permeabilities in thin polymer films using quenching of upconverted fluorescence in porphyrins

Sunish K. Sugunan, Matthew F. Paige, and Ronald P. Steer

Abstract: Proof-of-principle is demonstrated for a method of measuring the oxygen diffusion properties of thin polymer films based on quenching of the delayed upconverted S_2 fluorescence of Zn(II) *meso*-tetraphenylporphine (ZnTPP). Empirical oxygen diffusion coefficients and permeability coefficients for poly(vinyl alcohol) (PVA) have been computed using Stern–Volmer kinetics in the steady-state regime and a nonlinear gas solubility model in the time domain. Simplified dual-mode theory has been used to calculate crude theoretical oxygen permeability coefficients to compare with the experimental values. It is confirmed that oxygen permeability in the PVA matrix is controlled largely by the characteristics of the polymer matrix, particularly its water content and distribution.

Key words: oxygen diffusion, triplet–triplet annihilation, upconverted fluorescence, Stern–Volmer kinetics, nonlinear gas solubility model, dual-mode theory.

Résumé : On présente une démonstration du principe de preuve pour une méthode de mesure des propriétés de diffusion de l'oxygène à partir de films minces de polymère ; elle est basée sur le piégeage de la fluorescence S_2 retardée et non convertie du sel de zinc(II) de la *méso*-tétraphénylporphyne (ZnTPP). On a calculé les coefficients empiriques de diffusion de l'oxygène et les coefficients de perméabilité de l'alcool polyvinylique en faisant appel à la cinétique de Stern–Volmer dans le régime d'état stationnaire et un modèle de solubilité gazeuse non linéaire dans le domaine du temps. On a fait appel à la théorie simplifiée du double mode pour calculer les coefficients bruts de perméabilité théorique de l'oxygène afin de les comparer aux valeurs expérimentales. Il est confirmé que la perméabilité de l'oxygène dans la matrice d'alcool polyvinylique est contrôlée principalement par les caractéristiques de la matrice de polymère, en particulier par son contenu en au et sa distribution.

Mots-clés : diffusion de l'oxygène, annihilation triplet–triplet, fluorescence non convertie, cinétique de Stern–Volmer, modèle de solubilité gazeuse non linéaire, théorie du double mode.

Introduction

The transport properties of gas molecules through polymer media has been an area of long-standing interest from both fundamental and applied perspectives.[1–3] In addition to the fundamental interest in the oxidative degradation of polymers,[2,3] research in this field is motivated by the many potential applications of polymers as protective barriers (for food, chemicals, etc.), as gas separation membranes, as an ingredient in pressure-sensitive paints, and, most recently, as host materials for organic or organometallic dyes in dye-sensitized solar cells.[2–9] Measuring the rate of molecular oxygen transport through polymer materials is therefore important and devising simple, accurate, and rapid methods to make such measurements continues to be an active area of research.

Over the years, many techniques have been developed to measure the diffusion rate of molecular oxygen in polymer thin films. In the time-lag method, a defined concentration of oxygen is applied to one side of a polymer membrane positioned at the center of an evacuated chamber and the buildup of a partial pressure of oxygen on the other side of the membrane is monitored as a function of time. This method suffers from technical difficulties such as the requirements for relatively large, free-standing, defect-free thick films, large chamber volumes, and long observation times for polymers having very low values of oxygen permeability.[8,10] The most widely used alternatives involve methods of optically sensing the oxygen concentration.[1–20] For most of these methods, an optically excited organic dye molecule or inorganic complex in its singlet or triplet state dissolved or embedded in a polymer thin film is quenched by molecular oxygen introduced into the film, thereby forming the ground state of the dye (plus singlet molecular oxygen in many cases). The rate of oxygen diffusion is monitored by observing either the luminescence quenching of the dye molecule or the rate of singlet oxygen production.

The rate of oxygen diffusion across the polymer matrix is then analyzed using either Fick's diffusion kinetics as a function of the time taken to reach a steady state of oxygen concentration in the film or Stern–Volmer and diffusion-controlled reaction kinetics once a steady state of oxygen concentration in the film is reached.[10] These methods are particularly attractive because of their high sensitivity, low consumption of oxygen, simple experimental setup, and shorter experimental time.[9] Typical dye molecules employed in optical oxygen sensing include porphyrins, transition-metal complexes, naphthalene, perylene, and triphenylene.[6,8–20] Even though other techniques such as mass spectrometry and fluorescence microscopy[5,9] can also monitor oxygen transport in polymers, the use of a simple steady-state or time-resolved spectrofluorimeter or phosphorimeter remains the simplest and the most popular method.

The method of finding the oxygen permeability of polymer films through steady-state Stern–Volmer kinetics was initiated by Jones[21] and was extended by Yekta et al.[10] and Douglas and co-workers.[14–17] In these cases, a sensor film composed of a phosphorescent dye molecule embedded in a polymer film was employed to provide the optical signal. Later, Rharbi et al.[7] used a method in which a polymer film was used as the separating membrane in the time-lag method described earlier, but the buildup of a partial pressure of oxygen in the receiving chamber was monitored by luminescence quenching of a separate sensor film containing a phosphorescent dye. Oxygen permeation through bilayer polymer films was investigated by Poulsen and Ogilby.[3] Here, the polymer film of interest was coated on a sensor layer composed of a porphyrin dissolved in a second polymer. The rate of oxygen permeation through the polymer film was measured by detecting the near infrared phosphorescence of singlet oxygen.

The oxygen permeability coefficients of different polymers have been summarized in a recent article by Hess et al.[8] The effects of water content on the permeability of poly(vinyl alcohol) (PVA), a test material used in our experiments, have recently been investigated by Lien et al.[22]

In this article, we aim to show proof-of-principle that oxygen permeability and diffusion kinetics in polymer films can be measured by observing the quenching of delayed (upconverted) fluorescence in a suitable dye. In this demonstration, we have chosen to examine oxygen transport through thin layers of PVA coated on a thicker layer of Zn(II) *meso*-tetraphenylporphine (ZnTPP) dissolved in poly(ethyl methacrylate) (PEMA). We have previously shown that upconverted S_2 (Soret band) fluorescence can be generated relatively efficiently both in solution and in the solid phase by triplet–triplet annihilation (TTA) in ZnTPP upon excitation in its Q band with a continuous wave (CW) laser at 532 nm.[23,24] When molecular oxygen quenches the triplet state of ZnTPP, the S_2 fluorescence of ZnTPP is also quenched. The mechanisms of TTA and the oxygen quenching of the triplets are outlined below.

$$[i] \quad S_0(\mathrm{ZnTPP}) + h\nu_{(532\,\mathrm{nm})} \rightarrow S_1(\mathrm{ZnTPP})$$

$$[ii] \quad S_1(\mathrm{ZnTPP}) \rightarrow T_1(\mathrm{ZnTPP})\ (\eta_{\mathrm{ISC}} \approx 1.0)$$

$$[iii] \quad 2T_1(\mathrm{ZnTPP}) \rightarrow S_2(\mathrm{ZnTPP}) + S_0(\mathrm{ZnTPP})$$

$$[iv] \quad S_2(\mathrm{ZnTPP}) \rightarrow S_0(\mathrm{ZnTPP}) + h\nu_{(\mathrm{upconverted})}$$

$$[v] \quad T_1(\mathrm{ZnTPP}) + O_2(^3\Sigma_g^-) \rightarrow {}^{1,3,5}(\mathrm{ZnTPP}\cdots O_2) \rightarrow S_0(\mathrm{ZnTPP}) + O_2(^1\Sigma_g^+) \text{ or } O_2(^1\Delta g) \text{ or } O_2(^3\Sigma_g^-)$$

Note that the TTA, step (*iii*), can occur by molecular diffusion in fluid media but relies on triplet exciton migration in porphyrin aggregates in thin films and other nonfluid media.

By measuring the rate of S_2 fluorescence intensity quenching of ZnTPP upon interaction of the annihilating triplets with different partial pressures of oxygen, one can, in principle, calculate the rate of oxygen diffusion in the PVA layer. Employing the quenching of TTA-generated upconverted fluorescence from ZnTPP for measuring the diffusion of oxygen in polymers offers two significant advantages over other optical techniques. (*i*) The S_2–S_0 fluorescence from ZnTPP occurs in the violet region of the spectrum; it is strongly allowed (oscillator strength, $f \sim 1$) and is therefore very easy to detect, even though the efficiency of the TTA process can be low.[23–25] (*ii*) The experimental setup required is very simple, involving only a steady-state spectrofluorimeter equipped with a vacuum sample chamber and a low-power CW visible laser as the excitation source.

Assumptions, theory, and data analysis

We have selected PEMA as the host polymer in the sensor layer to dissolve ZnTPP because PEMA has a very large oxygen permeability compared with PVA under the same conditions.[8,22] We chose PVA as the test polymer in this demonstration primarily because the fluorescent reporter in the sensor layer, ZnTPP, is relatively insoluble in it. Previous experience with trying to coat layers of organic solvent-soluble polymers on top of the sensor layer resulted in the dissolution and migration of the ZnTPP into the top test layer. We assume that the interface between the polymer sensor and test layers will not serve as a significant barrier to oxygen diffusion. On this basis, we then reasonably assume that the concentration of oxygen will be uniform in the sensor PEMA film on the time scale of the experiment and that diffusion of oxygen within the sensor layer will not interfere with measurements of the diffusion properties of oxygen in the PVA test film. We also assume that the oxygen diffusion process can be described by standard models and that the oxygen quenching of the triplet states that participate in the excited-state annihilation that produces the observed fluorescence is a pseudo-first-order kinetic process. We do nothing to control or measure the water content of the PVA film or to determine the degree of crystallinity of the polymer itself. We therefore do not anticipate being able to exactly reproduce any of the previous values of the oxygen diffusion and permeability coefficients that have been correlated with PVA's water content.[22]

The fundamental theories regarding the transport properties of gases in polymers have been summarized in an excellent monograph by Crank and Park.[26] The rate of luminescence decay at any time t from a sensor film when one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

side of a defect-free thin film of a polymer having thickness l is exposed to a partial pressure of oxygen is given by[27]

$$[1] \qquad I(t) = \int_0^1 I(X, t)\, \mathrm{d}X$$

where $I(X, t)$ is the luminescence intensity as a function of the position within the film, X, and the time of observation is t. X is the normalized depth of oxygen penetration in the film, which varies from 0 to 1 and is given by $X = x/l$, where x is the perpendicular depth within the film. Here, we assume a uniform distribution of ZnTPP in the PEMA film, a uniform layer of PVA on top of it, uniform laser illumination throughout the film, and a uniform rate of oxygen diffusion in the test film and through the interface between the films based on the assumption that the oxygen diffusion in the PVA layer is not affected by that in the PEMA layer. We use the nonlinear gas solubility model[27] to assess the oxygen concentration at any point in the film:

$$[2] \qquad \frac{I(X, t)}{I_0} = [\gamma a C^2 + (\gamma + a + b)C + 1]^{-1}$$

where C is the concentration of oxygen, γ, a, and b are fitting parameters, and I_0 is the unquenched luminescence intensity of the sensor film in the absence of oxygen.

Assuming that the polymer film is uniformly planar throughout the test area, the concentration of oxygen in the polymer film for all time scales is given by

$$[3] \qquad C = C_0 + (C_1 - C_0) \times \left\{ 1 - \frac{4}{\pi} \sum_{i=0}^{\infty} \left[\frac{(-1)^i}{(2i+1)} \right] \exp\left[\frac{-(2i+1)^2 \pi^2 D t}{4l^2} \right] \cos\left[\frac{(2i+1)\pi X}{2} \right] \right\}$$

where C_0 is the initial concentration of oxygen in the film, C_1 is the oxygen concentration at the film surface during the diffusion process, and D is the diffusion coefficient of oxygen in the film. Since our sample film is allowed to outgas under vacuum prior to the introduction of oxygen, we approximate that $C_0 = 0$. Because of the oscillatory behaviour of this equation and the large computational time required, we used an alternative form of it for shorter time scales assuming that $C_0 = 0$:

$$[4] \qquad C = C_1 \left[\sum_{i=0}^{\infty} (-1)^i \mathrm{erfc} \frac{(2i+1)l + lX}{\sqrt{4Dt}} + \sum_{i=0}^{\infty} (-1)^i \mathrm{erfc} \frac{(2i+1)l - lX}{\sqrt{4Dt}} \right]$$

where erfc is the complimentary error function.

Substituting eq. [4] into eq. [2] and subsequently eq. [2] into eq. [1] gives the rate of fractional luminescence intensity quenching ($I(t)/I_0$) as a function of time t.

Once the steady-state concentration of oxygen is reached in the film, the system should follow Stern–Volmer kinetics:

$$[5] \qquad \frac{I_0}{I_q} = 1 + k_q \tau_0 [O_2]$$

where I_q is the luminescence intensity under steady-state conditions where the oxygen concentration is $[O_2]$, k_q is the bimolecular quenching rate constant, and τ_0 is the lifetime (of the lowest triplet state of ZnTPP in our case) of the excited dye molecule.

Smoluchowski's diffusional encounter theory can be applied to relate the bimolecular quenching constant to the diffusion coefficient, k_{diff}, that specifies the limiting rate at which the oxygen molecule can form an encounter complex with the excited dye molecule:[8,10]

$$[6] \qquad k_q = \alpha k_{diff} = \alpha 4\pi\sigma N_A D$$

Here, the proportionality constant, α, is the luminescence quenching probability in an encounter complex of the dye with oxygen, σ is the diameter of the encounter complex (which should be the sum of the van der Waals' radii of the dye molecule and oxygen; a value of 10 Å is used), N_A is Avogadro's number, and D is the diffusion coefficient. Even though α may increase with multiple encounters between the dye molecule and oxygen trapped in the polymer, we take a value of 1/9 for α on the basis that both ZnTPP and molecular oxygen are in the triplet state prior to forming a diffusional encounter complex and the formation of the product singlet states is limited by a spin statistical factor of 1/9. Likewise, formation of the fluorescing S_2 excited state of ZnTPP is limited by a spin statistical factor of 1/9 when produced from the TTA encounter complex.[25]

Finally, Henry's law can be applied to relate the equilibrium oxygen concentration to the solubility coefficient of oxygen in the film (S) and the partial pressure of oxygen (P_{O_2}) in the low to moderate pressure range:[8,10]

$$[7] \qquad [O_2]_{eq} = S P_{O_2}$$

Combining eqs. [5], [6], and [7] gives the desired equation relating the steady-state luminescence intensity to the permeability (P) of oxygen, which is a product of the diffusion coefficient (D) and the solubility coefficient (S), i.e., $P = DS$:

$$[8] \qquad \frac{I_0}{I_q} = 1 + (P)(4\pi\alpha\sigma N_A \tau_0)(P_{O_2})$$

Both time-based and steady-state data were analyzed in Origin 7.5 (OriginLab). Simpson's rule for integration was used to numerically integrate the fitting function in eq. [2].

Experimental

Zn(II) *meso*-tetraphenylporphine (low chlorin; ZnTPP), poly(ethyl methacrylate) (PEMA; average molecular weight

(MW) ~ 515 000 by gel permeation chromatography (GPC)), and toluene (high-performance liquid chromatography (HPLC) grade, ≥99.9%) were obtained from Sigma-Aldrich and were used as received. Poly(vinyl alcohol) (PVA; 99.7 mol% hydrolyzed, MW ~ 78 000) was purchased from Polysciences and was used as received. Millipore water was used to prepare the PVA solution. The sensor films were prepared by spin casting (800 rpm) aliquots of solution containing 4.0 mmol·L^{-1} ZnTPP and 2.0% (*w*/*v*) PEMA in toluene onto thoroughly precleaned 1.2 mm thick glass slides (VWR). About 50 μL of the solution was used for a layer. For each test sample, 40 aliquots were spin cast sequentially. The thickness of the ultimate sensor layer was considerably less than the sum of the individual PEMA and ZnTPP layers deposited and the absorbance of the sensor film did not scale with the number of layers deposited, suggesting that dissolution and loss of ZnTPP occurred during the spin casting of each layer. Thin layers of the test film were made by spin casting (1000 rpm) about 100 μL per layer of the PVA solution in water onto the sensor film. The spectra and state of aggregation of the ZnTPP in such sensor films have been previously reported.[24]

The thickness of the PVA films was measured by using an LSE Stokes ellipsometer (7109-C-351A) using the thickness and psiC/DeltaC calculation mode. The oxygen diffusion measurements were performed on a Photon Technology International QuantaMaster spectrofluorometer custom fitted with a low-power, frequency-doubled 532 nm CW Nd:YAG laser (WSTech, TECGL-30) as the sample excitation source. A calibrated graded neutral density filter (Edmund Optics) was used to attenuate the power of the laser beam when necessary and a mechanical beam shutter (Copal shutter, Edmund Optics) was used to chop the laser beam at every 30 s to minimize photochemical damage to the sample from prolonged exposure to the laser radiation. A notch filter was placed between the sample and the emission monochromator to remove scattered excitation radiation. The laser "on" power density delivered to the sample at 532 nm was typically 0.38 W·cm^{-2}.

The sample slides were fitted as windows on the front side of an evacuated triangular brass cell with the sample thin film on the inner, evacuated side. The brass cell was evacuated by connecting it to a grease-free glass vacuum line. The sample was allowed to outgas under vacuum for at least 1 h prior to any experiment. The sample was excited at less than a critical angle of incidence of ~30° and the emission was collected in a front-face geometry. The sample was continuously irradiated with the laser prior to any experiment until stable fluorescence intensity at the S_2 peak maximum of ZnTPP (~435 nm) as a function of time was achieved. The porphyrin emission intensity decreased slightly during this preirradiation procedure and we assume that this was due to photo-oxidation of the dye by residual oxygen in the sensor films and possibly due to slight additional outgassing of water vapour from the PVA film upon gentle laser-induced warming of the sample in the excitation volume. The vacuum- and gas-handling system included a gas mixing chamber that was connected to N_2 and O_2 gas cylinders. Different proportions of dry N_2 and O_2 gases were mixed in this chamber by gentle heating and were then exposed to the outgassed sample at time $t = 0$. In all cases, the total pressure of N_2 and O_2 was constant and kept at slightly less than 1.0 atm (1 atm = 101.325 kPa). After completing a measurement, continuous pumping of gases from the sample chamber usually returned the upconverted fluorescence intensity to within a few percent of the intensity observed at $t = 0$.

Results and discussion

Figure 1 demonstrates proof-of-principle that variations in the intensity of delayed (upconverted) fluorescence caused by oxygen quenching of the triplet states of an appropriately chosen fluorescent dye can be used to measure the diffusion kinetics of oxygen in a polymer film. Figure 1*a* shows the time-of-exposure dependent S_2 fluorescence quenching of ZnTPP resulting from when a thin film of PVA spin cast from a 0.5% (*w*/*w*) solution is brought into contact with an oxygen partial pressure of 13.4 kPa in dry nitrogen at approximately room temperature. The dye luminescence is quenched and attains a constant value after about 500 s of exposure to oxygen. The best fit of eq. [1] to these data yielded a diffusion coefficient of $D = 4.5 \times 10^{-9}$ cm^2·s^{-1}. The time-of-exposure dependent quenching of a thin layer of PVA made from a solution having a concentration of 2% (*w*/*w*) PVA in water is shown in Fig. 1*b*. Here, the partial pressure of oxygen is 27 kPa and the luminescence profile reaches a steady state in slightly longer than 4500 s, but the relative steady-state (equilibrium) intensity is substantially higher than in the previous example. The best fit to these data resulted in a significantly smaller value of the diffusion coefficient, $D = 2.0 \times 10^{-10}$ cm^2·s^{-1}. Note that although the fits between the diffusion theory expression and the data are not perfect, two diffusional processes were not needed to obtain the observed agreement, thus substantiating the assumption that the oxygen concentration in the sensor layer is approximately constant on the time scale of the experiment. Note also that these two films were of similar thickness: 6.9×10^{-6} cm for the film cast from the 0.5% solution and 7.1×10^{-6} cm for the film cast from the 2% solution. Both the content and the distribution of the water in these two films, however, are expected to be rather different (vide infra).

A difference in the magnitude of the oxygen permeability values for samples prepared from 0.5% and 2.0% solutions was also found in the Stern–Volmer kinetic analysis of the samples under steady-state conditions. Here, the equilibrium intensity of the dye's upconverted S_2 fluorescence was measured for the same film exposed to different partial pressures of oxygen in dry nitrogen at a total pressure of a little less than 1 atm. The data are amenable to a straightforward Stern–Volmer analysis as shown in Fig. 2*a* for the sample prepared from 0.5% PVA in water. The slope of the curve is 1.3×10^{-3} Pa^{-1}, which, when substituted into eq. [8], gives a permeability coefficient of 2.2×10^{-16} cm^3(gas at STP)·cm·cm^{-2}·s^{-1}·Pa^{-1}. A Stern–Volmer kinetic plot for oxygen diffusion in a thin test layer of PVA made from a 2.0% solution in water, shown in Fig. 2*b*, resulted in a slope of 9.9×10^{-6} Pa^{-1} and a permeability coefficient of 1.7×10^{-18} cm^3(gas at STP)·cm·cm^{-2}·s^{-1}·Pa^{-1}, which is a factor of 130 lower than that found in the 0.5% sample. Note that the same value of the unquenched lifetime of triplet ZnTPP, τ_0 =

Fig. 1. Luminescence quenching profiles of (*a*) one thin layer of 0.5% (*w*/*w*) PVA exposed to a partial pressure of 100 torr (1 torr = 133.3224 Pa) of oxygen and (*b*) one thin layer of 2.0% (*w*/*w*) PVA exposed to a partial pressure of 200 torr of oxygen. The empty circles represent the data points and the solid curves represent the best fit for the data as determined by the reduced χ^2 values.

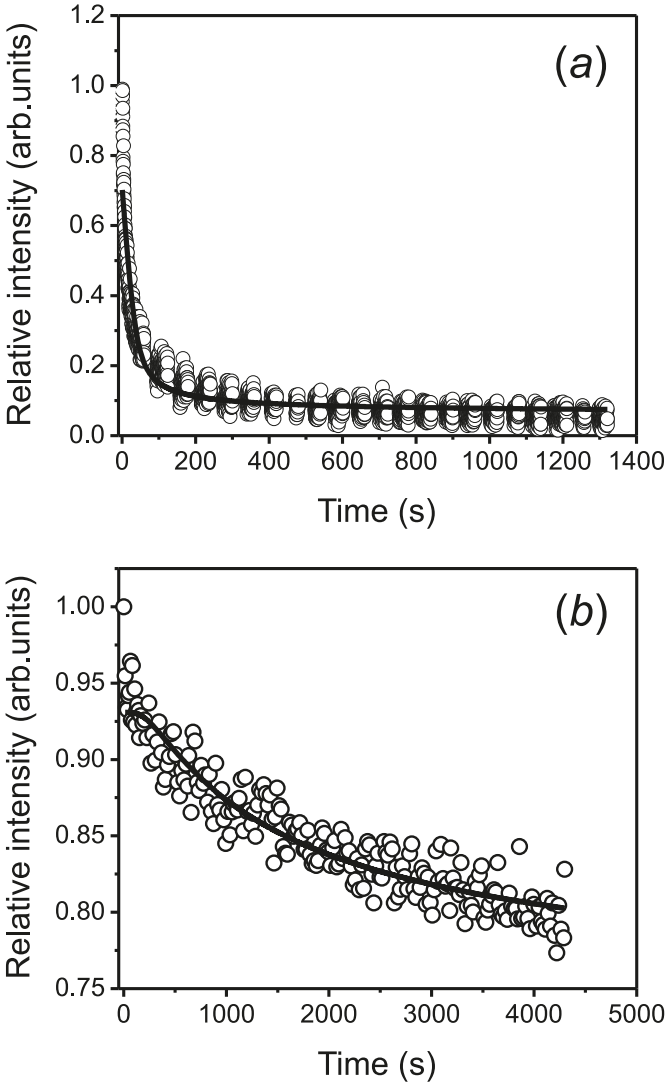

Fig. 2. Stern–Volmer kinetic analysis of (*a*) one layer of 0.5% (*w*/*w*) PVA and (*b*) one layer of 2.0% (*w*/*w*) PVA. The empty circles represent the data points and the solid curves represent the best least-squares fit to the data.

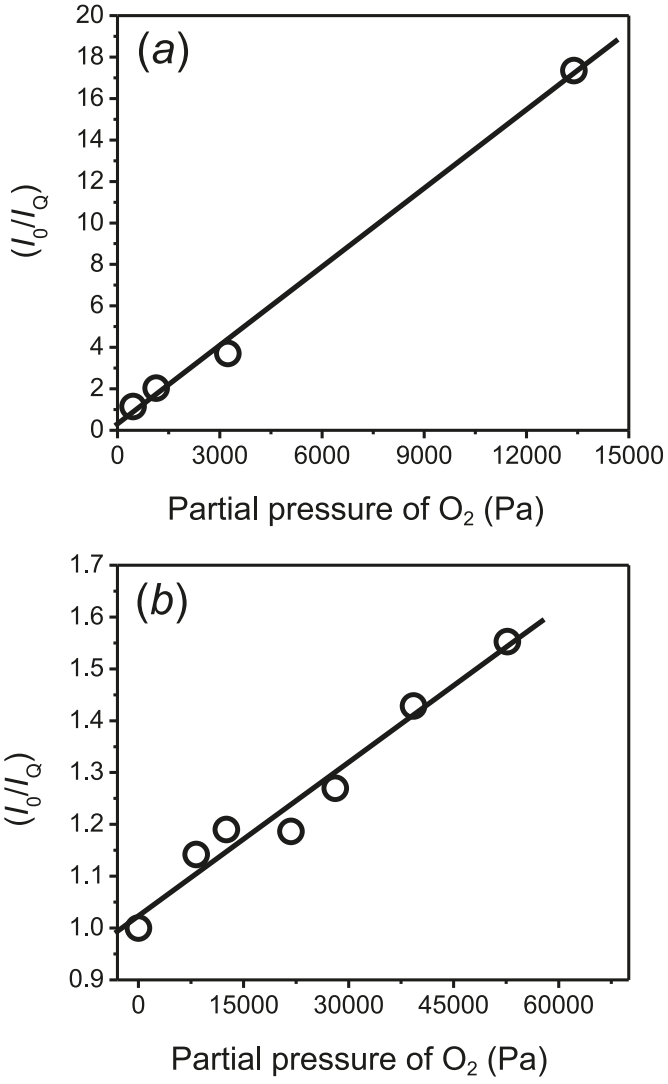

6.86×10^{-3} s, previously measured[28] for ZnTPP in PMMA, has been used in both of these calculations. The actual triplet lifetime was not measured in these proof-of-principle experiments, and any difference would constitute a source of systematic error in the determination of the values of *P* reported here.

We have also determined whether the thickness of the polymer membrane would affect the measured oxygen permeability of PVA. The temporal luminescence quenching profiles for two different thicknesses of PVA are shown in Fig. 3 and the corresponding diffusion coefficients calculated as above are shown in Table 1. Note that the value of the apparent oxygen diffusion coefficient decreases with increasing thickness of the PVA test film. Because both *D* and *P* should be independent of film thickness if the films themselves are of the same composition and morphology, this observation implies that at least one uncontrolled variable (in our case the water content and distribution and perhaps the degree of polymer crystallinity) is responsible for the differences.

These measured values of *D* and *P* can be compared only crudely with literature values because of the largely unknown water contents and distributions of both the samples under evaluation here and those for which data are reported in the literature. Values of *D* for absolutely dry PVA have been obtained[29,31] by molecular dynamics simulations for samples at 375 K ($D = 5.0 \times 10^{-7}$ cm^2·s^{-1}) and 500 K ($D = 1.6 \times 10^{-6}$ cm^2·s^{-1}). However, these values apply to conditions in which PVA will be in its glassy state with a large free volume, where a much faster rate of oxygen diffusion is expected compared with those measured here. The permeability values measured here may be compared with a reported[30] permeability value for oxygen diffusion in PVA (of unknown water content) of 9.16×10^{-16} cm^3(gas at STP)·cm·cm^{-2}·s^{-1}·Pa^{-1}, in order-of-magnitude agreement.

The glass transition temperature of PVA is near 358 K,

well above the near-room temperatures used in our experiments. When a polymer is in a semicrystalline state well below its glass transition temperature, nanocrystalline clusters dispersed in a continuous network of a low fraction of amorphous polymer are formed.[32–35] The crystalline part in the polymer matrix is generally impermeable to gas penetration, whereas gas diffusion is relatively facile in the amorphous phase. Moreover, PVA films prepared from aqueous media can contain variable amounts of water and this water can be distributed in a continuum of strongly to weakly bound environments.[22] Gas diffusion in the amorphous regions follows the free-volume model,[33] and whereas the diffusive motion of gas molecules is generally faster than the mobility of the polymer segments, the polymer does respond to provide space to accommodate the diffusing gas.[36] It is not unreasonable to assume that the free volume in the polymer thin film and hence the water content and distribution in our films will depend on the initial concentration of the polymer in solution and the exact conditions used to cast the film. All other factors remaining the same, the number density of the polymer molecules should be expected to increase with increasing concentration of the polymer in the spin-cast solution. The relation between the initial polymer concentration in aqueous solution and the resulting free volume and distribution of water in the thin film should explain why the measured diffusion coefficient and permeability are substantially reduced when the polymer concentration in the spin-cast solution is increased. We proceed with a largely empirical analysis based on this hypothesis.

Consider two different samples of the same polymer film that are formed from two different concentrations of the polymer in solution. The resulting films have different water contents and hence different oxygen solubilities, S_1 and S_2. Let the measured oxygen diffusion coefficients in the two films be D_1 and D_2, respectively, and let the measured permeability coefficients be P_1 and P_2, respectively. Since $P = DS$, the ratios of the values of P and D will give an estimate of the differences in oxygen solubilities in the two films. Using the data for D and P presented above, for the two starting PVA concentrations employed we find that $S_1 = 5.7S_2$, i.e., using this analysis, oxygen would be about 6 times more soluble in the PVA film made from the lower concentration solution. Since the two films are of approximately the same thickness, the pores of the film made from the lower concentration solution must be significantly larger and contain more bulk-like water than those in the film formed from the higher concentration solution. Since oxygen solubility increases with the bulk-like water content of PVA,[22] this interpretation is consistent with the above starting hypothesis.

The solubility of oxygen in the PVA thin film can be computed by correlating the equilibrium concentration of the oxygen dissolved in the polymer film (C) with the partial pressure, P_{O_2}, of the gas at the polymer surface using the dual-mode theory:[30,37]

$$[9] \qquad C = K_H P_{O_2} + C_\infty \frac{bP_{O_2}}{1 + bP_{O_2}}$$

Here, K_H is the Henry's law constant (Pa^{-1}), which characterizes the first term in eq. [9] as a Henry's isotherm; C_∞ is the steady-state concentration of oxygen in the polymer film; and b is the ratio of the rates of the adsorption and desorption processes, which, when included in the second term of eq. [9], yields a Langmuir-type isotherm. While using this model, it must be assumed that the absorption and desorption processes do not alter the PVA matrix, that the matrix is homogeneous, and that only one oxygen molecule occupies a given site in the polymer matrix at a time.

In addition, because oxygen is a small, rapidly diffusing molecule and the pressures of oxygen applied in the experiments are less than 1.0 atm, ideal gas behaviour for the dissolution of oxygen in the polymer can be assumed. If one can neglect the Langmuir-type isotherm part in eq. [9], as is the usual case,[30] then the solubility of oxygen in the PVA polymer matrix is governed by Henry's law for the gas pressures applied here. Therefore, the solubility coefficient can be computed by using the simple equation

Table 1. Experimental diffusion coefficients and calculated[29,30] (see text) permeability coefficients for oxygen in PVA membranes having different thicknesses.

Thickness of thin layers made from 0.5% solution of PVA, l (cm)	Experimental diffusion coefficient, D ($cm^2 \cdot s^{-1}$)	Calculated permeability coefficient, P (cm^3(gas at STP)$\cdot cm \cdot cm^{-2} \cdot s^{-1} \cdot Pa^{-1}$)
6.9×10^{-6}	4.6×10^{-9}	$2.0 \times 10^{-14} < \mu < 2.5 \times 10^{-14}$
5.5×10^{-5}	2.4×10^{-11}	$1.1 \times 10^{-16} < \mu < 1.3 \times 10^{-16}$
8.6×10^{-5}	7.8×10^{-11}	$3.4 \times 10^{-16} < \mu < 4.2 \times 10^{-16}$

Table 2. Experimental and calculated[29,30] (see text) diffusion coefficients and permeability coefficients of oxygen in thin films of PVA cast from two different concentrations of PVA in water.

Concentration of PVA (%, *w/w*) in aqueous solution	Experimental permeability coefficient, P (cm^3(gas at STP)$\cdot cm \cdot cm^{-2} \cdot s^{-1} \cdot Pa^{-1}$	Experimental diffusion coefficient, D ($cm^2 \cdot s^{-1}$)	Calculated solubility coefficient, S (cm^3(gas at STP)$\cdot cm^{-3} \cdot Pa^{-1}$	Calculated permeability coefficient, P (cm^3(gas at STP)$\cdot cm \cdot cm^{-2} \cdot s^{-1} \cdot Pa^{-1}$)
0.5	2.2×10^{-16}	4.5×10^{-9}	$4.4 \times 10^{-6} < \mu < 5.4 \times 10^{-6}$	$2.0 \times 10^{-14} < \mu < 2.5 \times 10^{-14}$
2.0	1.7×10^{-18}	2.0×10^{-10}	$4.4 \times 10^{-6} < \mu < 5.4 \times 10^{-6}$	$8.9 \times 10^{-16} < \mu < 1.1 \times 10^{-15}$

$$[10] \qquad S = K_H(T/T_0)P_0$$

where T = 298 K is the experimental temperature, P_0 = 1.0 atm, and T_0 = 273 K.

The Henry's constant, K_H, for dry PVA has been computed using Monte Carlo simulations by Cozmuta et al.[30] Owing to the complex dynamics of oxygen in the voids and channels of the polymer and owing to the possible structural modifications of the polymer matrix during the adsorption process, K_H was calculated as a 95% confidence interval rather than as an average value and was reported as ($0.4 < \mu < 0.5$) $cm^3 \cdot cm^{-3} \cdot atm^{-1}$. We have used the lower and upper limits of this range of K_H values to compute a theoretical solubility coefficient of oxygen in dry PVA, also expressed as a 95% confidence interval (Table 2). We then used this calculated solubility coefficient range together with the values of the experimentally observed diffusion coefficients to calculate a range of values of the permeability coefficient. These values are compared with the experimentally determined values of the permeability coefficients. The experimental permeability coefficients and experimental diffusion coefficients measured for PVA containing residual amounts of water are compared with the calculated solubility coefficient and the calculated permeability coefficients for dry PVA in Tables 1 and 2. The calculated permeability coefficients are two to three orders of magnitude larger than the experimentally observed ones (Table 2).

Although some of this discrepancy could be due to experimental uncertainties in the measured values of D and S, a more likely source is the presence of water in the polymer. It should be noted that severe discrepancies exist in the literature regarding the magnitudes of the oxygen permeation coefficients of a wide range of polymers.[8] For PVA, however, Lien et al.[22] have shown that the oxygen permeability is a strong function only of the water content of the films and increases rapidly by over a factor of 100 as the water content increases by a few weight percent.

Conclusions

We have demonstrated proof-of-principle that quenching of delayed fluorescence in a visible light absorbing system that exhibits photon upconversion can be used to measure the diffusion properties of oxygen in thin polymer films. Although we have used upconverted fluorescence from the S_2 state of ZnTPP as the reporting luminescence in this demonstration, other molecular systems exhibiting photon upconversion by TTA or by triplet–singlet annihilation could also be employed and might be useful in overcoming some of the limitations encountered in our study. Here, we have been limited by the choice of polymer matrices for the porphyrin-containing sensor; the capping test film must be chosen so that spin casting it onto the sensor film does not dissolve the porphyrin so that it becomes embedded in the test film. Although reliable diffusion and permeability coefficients cannot be claimed to have been measured with the system reported here, the data obtained were readily interpretable using standard gas transport and luminescence quenching methodology. Time-of-exposure luminescence decay data were amenable to analysis using standard diffusion models; luminescence quenching at equilibrium oxygen concentrations produced excellent linear Stern–Volmer plots. Order-of-magnitude agreement with literature data was obtained.

The discrepancies between the values of the diffusion and permeability coefficients for oxygen in PVA obtained by spin casting from aqueous solutions of different PVA concentrations have been rationalized by considering how the differences in film structure and water content affect the solubility of oxygen in the films. Water content and distribution in the PVA films were not controlled or measured. Future work, based on the useful report of Lien et al.[22] that identifies the role of water in the gas transport properties of PVA, should be expected to resolve the serious discrepancies that currently exist in the literature. Better results using the system described here might be obtained by using a sensor-containing polymer that has a glass transition temperature below room temperature. Such an arrangement would permit the test polymer layer to be deposited in intimate contact with the sensor layer and then, as needed for PVA, pre-equilibrated with water vapour at various partial pressures. Nevertheless, the existing information is extremely useful in assessing the viability of proposed photon upcon-

version schemes for improving the efficiencies of dye-sensitized solar cells,[23,24] in which oxygen quenching of triplet states must be avoided.

Dynamics of capsuleplex formed between octaacid and organic guest molecules — Photophysical techniques reveal the opening and closing of capsuleplex

Nithyanandhan Jayaraj, Steffen Jockusch, Lakshmi S. Kaanumalle, N.J. Turro, and V. Ramamurthy

Abstract: This manuscript is concerned with the opening and closing of a capsuleplex made up of organic guest molecules and two cavitand molecules known as octaacid (OA). The capsuleplex is loosely held together in water through weak interactions. We have investigated the opening–closing of the OA capsuleplex by monitoring the quenching of excited singlet and (or) triplet states of nine different guest molecules encapsulated within a capsule by molecular oxygen that is dissolved in water surrounding the capsule. The rate constants for oxygen quenching of the excited guest molecules were estimated by monitoring the intensity of fluorescence/phosphorescence or lifetimes of excited states of guest molecules in the presence of different concentrations of oxygen in water. Guest molecules were chosen such that one could probe the opening–closing process during a time range of 0.05 to 922 μs. We believe that the oxygen quenching constant reflects the accessibility of oxygen to the guest enclosed within the OA capsuleplex, and this in turn depends on the capsule opening–closing rate constant. Based on the quenching studies, we conclude that guests whose lifetimes are shorter than 5 μs are inaccessible to oxygen. Results presented in this report suggest that the extent and time scale for opening depends on the guest.

Key words: capsuleplex, octaacid, energy transfer, quenching by oxygen, capsule opening and closing.

Résumé : Dans ce travail on a étudié l'ouverture et la fermeture d'un capsuleplexe qui est formé de molécules organiques hôtes et de deux molécules de cavitands et qui est connu comme l'octa-acide (OA). Le capsuleplexe faiblement retenu ensemble dans l'eau par le biais de faibles interactions. On a étudié le cycle d'ouverture–fermeture du capsuleplexe OA en suivant la désactivation des états singulet excité et triplet des neuf molécules invitées différentes encapsulées par une capsule d'oxygène moléculaire qui est dissous dans l'eau entourant la capsule. On a évalué les constantes de vitesse de désactivation des molécules invitées excitées par l'oxygène en suivant l'intensité de fluorescence/phosphorescence ou les temps de vie des états excités des molécules invitées en présence de concentrations variables d'oxygène dans l'eau. Les molécules invitées ont été choisies d'une façon telle qu'on puisse étudier d'ouverture–fermeture durant un intervalle de temps allant de 0,05 à 922 μs. On croit que la constante de désactivation par l'oxygène est un reflet de l'accessibilité de l'oxygène à la molécule invitée incluse dans le capsuleplexe d'OA qui dépendrait à son tour sur la constante de vitesse d'ouverture–fermeture de la capsule. Sur la base des études de désactivation, on conclut que les invités dont les temps de vie sont inférieurs à 5 μs ne sont pas accessibles à l'oxygène. Les résultats rapportés ici suggèrent que le degré et l'échelle de temps pour l'ouverture dépendent de l'invité.

Mots-clés : capsuleplexe, octa-acide, transfert d'énergie, désactivation par l'oxygène, ouverture et fermeture de la capsule.

[Traduit par la Rédaction]

Introduction

This manuscript is concerned with the dynamics of a capsuleplex made up of an organic guest and two host molecules. The host octaacid (OA, **1**, Scheme 1), having a cuplike shape, belongs to a class of hosts known as cavitands.[1] The capsuleplex we are concerned with in this report is made up of two OA cavitand molecules and guest molecules that are loosely held by weak interactions in water. Examples of 1:2 and 2:2 (guest:host ratio) capsuleplexes of octaacid are known, and this article deals with both types of capsuleplexes.[2]

We have recently established that an organic guest molecule, confined within a capsule made up of two molecules of OA, undergoes motion corresponding to rotations along its

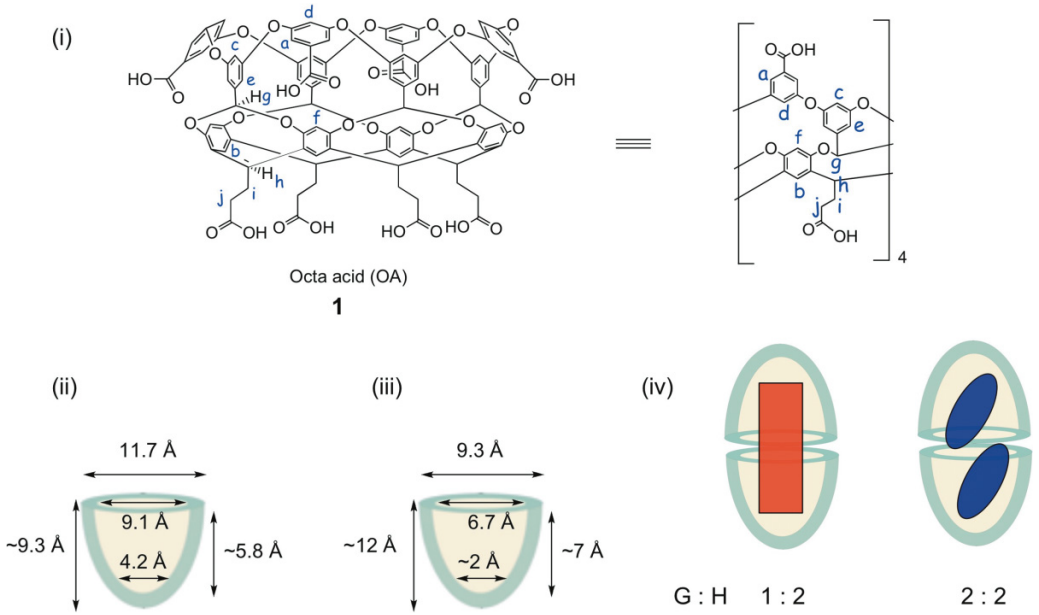
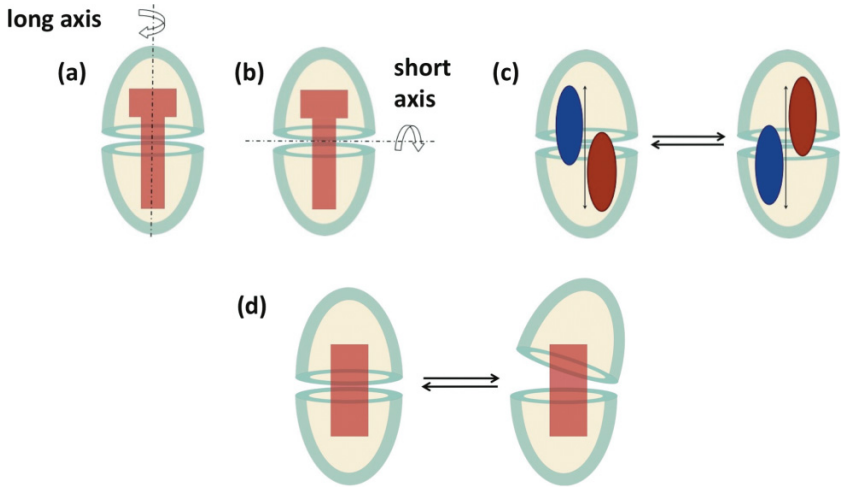
Scheme 1. (i) Structure and dimensions of the octaacid (OA) and its complexes; (a–h) represent the various protons in OA. The dimensions indicated for OA refer to atom-to-atom in (ii) and include van der Walls radius in (iii). Cartoon representations of the 1:2 and 2:2 octaacid complexes are shown in (iv).



Scheme 2. Three types of motions exerted by guests within octaacid (OA) capsuleplexes are illustrated in (a–c). The equilibrium between capsuleplex opening and closing is illustrated in (d).



short and long axes.[3] Examination of a number of guest molecules by ^{1}H NMR and EPR experiments suggested that the extent of rotation depends on the structure of the guest molecule. In addition, when two guest molecules form a capsuleplex with OA, they can undergo sliding motion. These three types of motion that we have established as occurring within the OA capsuleplex are illustrated in a cartoon fashion in Schemes 2a–2c. In this manuscript, we are concerned with yet another motion, namely partial opening and closing of the capsuleplex (Scheme 2d). We define opening to mean that the two cavitand molecules that make up the capsule come apart enough for a quencher such as oxygen to access the guest present inside. Since the capsuleplex is made up of two weakly interacting host molecules, a legitimate question comes to mind: "Does the capsuleplex remain closed all the time or does it open and close periodically? If the latter, what is the time scale in which such a process takes place?"

In this study, we have probed the opening–closing of a capsuleplex by monitoring the quenching of excited singlet and (or) triplet states of guest molecules (Scheme 3) present inside a capsule by molecular oxygen that is present outside the capsule. The rate of quenching was estimated by monitoring the intensity of fluorescence/phosphorescence or lifetimes of excited states of guest molecules in the presence of different concentrations of oxygen in water. Guest molecules were chosen such that one could probe the opening–closing process during a wide time range. Structures and molecular dimensions of guests employed whose excited-state lifetimes cover 0.05 to 922 μs are listed in Scheme 3. Based on the results presented in the following, we conclude that guests whose lifetimes are shorter than 5 μs are not accessible to

oxygen. However, guests with lifetimes longer than 15 μs are accessible to oxygen. Based on the measured quenching rate constants, we conclude that the extent and time scale for opening depends on the guest.

Results and discussion

Capsuleplexes composed of guests **2**–**10** and OA were prepared in water at pH ~9.0 (borate buffer).[4,5] Details are provided in the Experimental section of the Supplementary data. ^{1}H NMR spectral data confirmed the inclusion of guests within the OA capsule and provided information about the stoichiometry of the complex. NOESY experiments helped us infer the orientation of guest molecule(s) within the OA capsule. The ^{1}H NMR experimental details for one guest molecule, 4,4′-dimethoxythiobenzophenone (**8**), as a representative of guests **2**–**10**, are described in the following. A similar approach yielded information about the inclusion of other guest molecules and are listed in Scheme 3. The ^{1}H NMR spectra of free OA in water, **8** in $CDCl_3$, and **8**@OA_2 capsuleplex (represented as guest@host; stoichiometry indicated as a subscript) in water are provided in Fig. 1. In this case, the signals owing to OCH_3 in compound **8** appear at δ 3.9 ppm in $CDCl_3$, whereas within OA in D_2O, it is upfield shifted to δ –0.81 ppm. Such an upfield shift owing to diamagnetic shielding by the aromatic ring that forms the OA capsule has been established earlier.[6,7] Similar upfield shifts for various protons in compounds **2**–**7**, **9**, and **10** confirmed the inclusion of these probe molecules within the OA capsule (the spectra are provided as Supplementary data). As seen in Fig. 1, in addition to the shift in the ^{1}H signals of the guest, the signals owing to the OA molecule were also affected. Interpretation of these changes has been discussed in prior publications and will not be repeated here. ^{1}H NMR titration experiments established the stoichiometry of the **8**@OA_2 complex to be 1:2. Titration spectra in the case of OA with **8** are provided in Fig. 2. As can be seen in the spectra, upon addition of the guest up to 0.5 equiv, there are changes in the host region. Addition of more than 0.5 equiv of the guest did not result in any further changes in the spectra, suggesting that **8** forms a 1:2 complex with OA. Also, addition of more than 0.5 equiv of **8** to the OA solution resulted in turbidity, suggesting that **8** is insoluble in water in the absence of OA. The appearance of sharp signals owing to guest **8** and the absence of a shift in the guest peaks with varying ratios of host-to-guest suggested that in the NMR time scale, **8** remains within the OA capsule. Capsule formation was further confirmed by measuring the diffusion constant of the capsuleplex by ^{1}H NMR DOSY experiments. For example, free OA has a diffusion constant of 1.88×10^{-6} cm^2 s^{-1}, whereas the **8**@OA_2 complex has a diffusion constant of 1.38×10^{-6} cm^2 s^{-1}. Similar diffusion constants were observed for complexes of **2**–**7**, **9**, and **10** (see Supplementary data). Guest-to-host ratios for all capsuleplexes discussed in this study are included in Table 1.

The experiments we performed to gain information concerning the capsule opening–closing process rely on the quenching of excited states (S_1 or T_1) of guest molecules by molecular oxygen.[8] Guest molecules **2**–**8**, having very high rate constants of intersystem crossing (ISC) from S_1 to T_1, show phosphorescence at room temperature in solution (see Table 1 for the quenching of the excited state).[8,9] On the other hand, probes **9** and **10**, having low rate constants of ISC from S_1 to T_1, fluoresce at room temperature. In the first set of compounds (**2**–**8**), the T_1 state (phosphorescence), and in the latter two molecules (**9** and **10**), the S_1 state (fluorescence), are quenched by molecular oxygen via energy transfer in organic solvents with rate constants $>5 \times 10^8$ (mol/L)$^{-1}$ s^{-1} (Table 1).[10,11] Since pyrene (**9**) did not phosphoresce at room temperature, quenching in the case of the pyrene triplet was monitored by its T–T absorption. As indicated in Table 1, the pyrene triplet was quenched by oxygen in a cyclohexane solution with a rate constant of 1.6×10^9 (mol/L)$^{-1}$ s^{-1}.[10] Since the excited states of all the guest

molecules we chose were quenched with very high rate constants in solution,[12] we believed that oxygen should be able to quench the excited states of guest molecules **2**–**10** entrapped within the OA, provided that the excited guest molecules were accessible to oxygen during their lifetime. Alternatively, the quenching could occur through the wall of the capsuleplex. We believed that information on the rate constants of oxygen quenching of the excited states of various guests would be able to distinguish between the two mechanistic possibilities. If the quenching occurs through donor–acceptor contact, the accessibility of oxygen to the excited guest molecule would depend on the opening–closing of the capsuleplex. The cavitand that forms the capsule has two ports, one small and one large. Oxygen with a molecular width of ~3 Å (including the van der Waals' radius) will not be able to access the entrapped guest through the smaller port of the OA capsuleplex, which has a diameter of ~2 Å (including the van der Waals' radius, see Scheme 1). Therefore, we believe that oxygen and the entrapped guest could meet only through the larger port that is present at the middle of the capsuleplex. The larger port would become available only if the capsuleplex opens at least partially. We need to address several questions before drawing conclusions regarding the opening–closing process of the capsuleplex from the oxygen quenching data: (*i*) Is the probe molecule entrapped within a capsule accessible to oxygen? (*ii*) Is the quenching static or dynamic? (*iii*) What are the rates of quenching of the capsule-trapped guests? (*iv*) What is the rate-determining step in the quenching process?

In this section, we present experimental data for benzil (**3**) as a representative of guests **2**–**6**. Experimental data for guests **2** and **4**–**6** are provided in the Supplementary data. Room-temperature emission spectra of **3**@OA_2 in water (borate buffer) consisting of fluorescence, delayed fluorescence (480–520 nm), and phosphorescence (530–650 nm) are shown in Fig. 3a. As illustrated in the figure, the phosphorescence intensity is significantly reduced in the presence of oxygen compared with that in nitrogen-saturated buffer solution. The displayed spectra clearly show that emission intensities are dependent on the concentration of oxygen in water. The phosphorescence (530–650 nm) was significantly quenched by oxygen, whereas the fluorescence (direct and delayed fluorescence at 480–520 nm) shows only minor oxygen quenching. Consistent with the steady-state emission data, the excited triplet state decay profiles displayed in Fig. 3b also exhibit oxygen-concentration dependence.

Rate constants for quenching of the benzil triplet by oxygen were determined by monitoring the decay profiles of benzil triplet states at varying concentrations of oxygen. Triplet-state decay profiles were monitored by two independent methods, phosphorescence (Fig. 3b) and triplet–triplet absorption measurements. The rate constants for quenching were obtained from the slope of the plots of the pseudo-first-order decay rate constants of benzil triplet states vs the oxygen concentration (Fig. 4). Quenching rate constants obtained by the two methods (included in the figure) are identical within experimental error.[13,14] These data suggest that oxygen is able to quench the benzil triplet in spite of it being enclosed within the OA capsule. However, the rate constant for quenching of benzil in a capsuleplex is

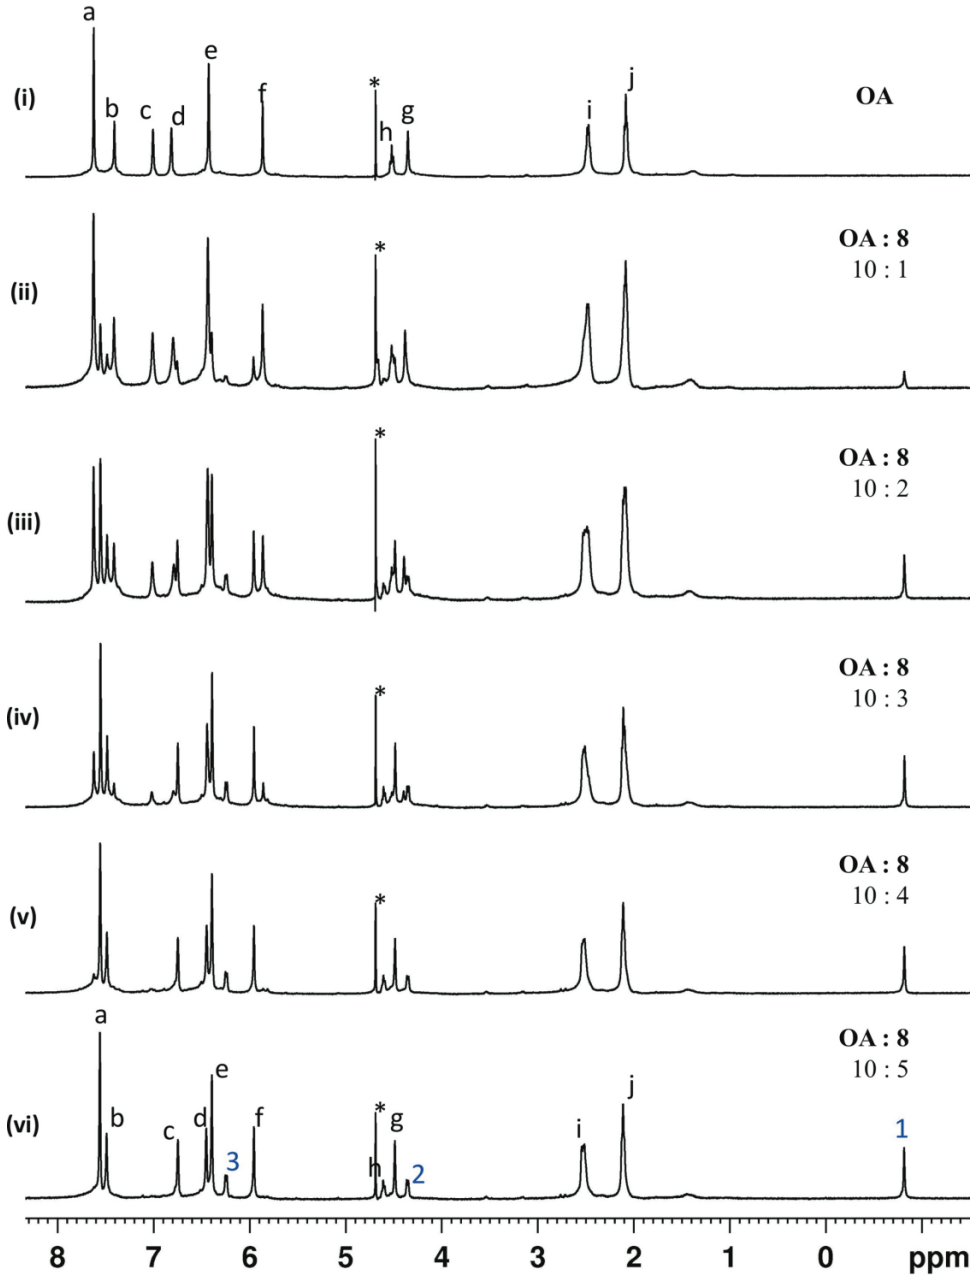
Fig. 2. ^{1}H NMR titration studies of the octaacid (OA) with **8** (500 MHz, D_2O). [OA] = 1 mmol/L in 10 mmol/L tetraborate D_2O buffer. Signals marked with * represent the residual proton resonances from the solvent.



significantly lower (1.2×10^7 $(mol/L)^{-1}$ s^{-1} vs 6.0×10^8 $(mol/L)^{-1}$ s^{-1}) than in an organic solvent (Table 1). Rate constants for oxygen quenching of the triplets of guest molecules **2**–**6** and **9** captured with the OA capsule are provided in Table 1. As noted, the numbers are more than an order of magnitude lower in the capsule than in an organic solvent.

To interpret the data, we need to ascertain whether the quenching is static or dynamic. The data provided in Fig. 3 suggest that the quenching is a dynamic process. Had it been a fully static process, no variation in lifetime would have occurred. Further support comes from the Stern–Volmer plots with points taken from both steady-state emission and lifetime data (Fig. 3c). The linear lines with almost identical slopes are consistent with a dynamic process. This conclusion is also consistent with the difference in rise time of singlet oxygen phosphorescence and decay time of benzil phosphorescence (Fig. 5c).

To probe the mechanism of the quenching process, phosphorescence emission from singlet oxygen was monitored upon quenching the **3**@OA_2 triplet by ground-state oxygen. As illustrated in Fig. 5a, quenching of benzil triplet resulted in phosphorescence from singlet oxygen, suggesting that quenching is the result of energy transfer. Furthermore, the difference in emission intensities (Fig. 5a) and lifetimes (Figs. 5b and 5c; 5 and 41 μs in H_2O and D_2O buffer, respectively)[15] of singlet oxygen observed between H_2O and D_2O solutions suggested that singlet oxygen, generated by the above energy-transfer process, spends most of its life-

time in water. Since our earlier studies have shown that the capsuleplex is nonpolar and has no water molecules inside the capsule,[16] we believe that singlet oxygen following energy transfer, if it occurs within the capsule, escapes to water. Alternatively, the energy transfer might be occurring when the capsule is partially open so that water molecules surround the donor and acceptor pair. We favor the latter model.

Triplets of xanthione (**7**) and 4,4′-dimethoxythiobenzophenone (**8**) included within OA capsule were not quenched by oxygen, although they were quenched at diffusion-limited rates in organic solvents.[17–19] Phosphorescence spectra and triplet decay profiles in the presence of oxygen and nitrogen, shown in Fig. 6 for xanthione, are distinctly different from those shown in Fig. 3 for benzil. In Fig. 6, the phosphorescence intensities and triplet decays are almost identical for nitrogen- and oxygen-saturated solutions. This behavior also extended to S_1 of pyrene (**9**) and phenanthrene (**10**). As illustrated in Fig. 7a, the fluorescence spectra of pyrene@OA_2 in nitrogen-saturated and oxygen-saturated buffer solutions are identical. The S_1 lifetime of pyrene was nearly identical under nitrogen- and oxygen-saturated conditions (Fig. 7b). This is distinctly different from that in cyclohexane solution where pyrene S_1 is quenched by oxygen at a diffusion-limited rate. Thus, while the S_1 states of pyrene and phenanthrene are quenched at diffusion-controlled rates in cyclohexane,[10,11] they are unquenched when they are included within the OA.

Examination of Table 1 reveals that there are two sets of molecules, one (triplet **2–6** and triplet **9**) includes the molecules that are quenched by oxygen when enclosed within the OA capsule, and the other (**7–10**) represents the molecules that are not quenched by oxygen when enclosed within the OA capsule. Since the second set of molecules involves both triplet (**7** and **8**) and excited singlet (**9** and **10**) states, we believe that the absence of quenching in the second set does not depend on the spin state. Closer examination of Table 1 suggests that the lifetime of the excited state is likely to play a role in the quenching process. Although in solution they are quenched at diffusion-controlled rate constants, guest molecules whose lifetimes are shorter than 5 μs are not quenched by oxygen when they are enclosed in the OA capsule. Also, it is important to note that the five guest molecules whose lifetimes span between 17 and 922 μs are quenched with rate constants varying between 5×10^5 (mol/L)$^{-1}$ s^{-1} and 8×10^7 (mol/L)$^{-1}$ s^{-1}. We need to address three important questions: (*i*) What exactly do the quenching rate constants imply? (*ii*) Why are some encapsulated guests quenched but not the others? (*iii*) Why do the quenching rate constants vary between the guests?

In Scheme 4, the sequence of steps involved in the energy-transfer process are summarized with rate constants listed above each step. The first step is the diffusion of the excited capsuleplex and oxygen to form a collision complex with a rate constant of k_d. The second step represents the access of oxygen to the excited guest present within the capsule. This step requires partial opening of the capsuleplex and the rate constant is represented as k_o. The third step is the true energy-transfer process between ground-state oxygen and the excited guest that are close to each other. This step is represented by the rate constant k'_{ET}. To differentiate between the energy transfer occurring across the wall of the capsuleplex and the one involving the collisional complex between ground-state oxygen and the excited guest (present within the host OA), the former process is represented by a rate constant of k_{ET}.

The sequence of steps involved in the quenching of guest@OA_2 by oxygen is shown in Scheme 4. We visualize

three possible mechanisms for the energy-transfer process: (*i*) Energy transfer occurs between the excited guest entrapped within the OA capsule and oxygen in water through the walls of the capsule. This type of energy transfer has been demonstrated to occur between benzil entrapped within a covalently linked capsule (carceplex) and oxygen.[20–24] The upper limit of the rate constant for this process was estimated to be 10^4 $(mol/L)^{-1}$ s^{-1}. Since the measured rate constants in the current study are orders of magnitudes higher, we believe that the energy transfer does not occur through the walls of the capsule. (*ii*) Energy transfer occurs between the donor guest and acceptor oxygen (both being present within the capsule). Under such conditions, static quenching is expected. Such a possibility has been ruled out by the results suggesting that the quenching is a dynamic rather than a static process (see Figs. 3 and 5 and related discussion). (*iii*) The third possibility, which we favor, is the one where quenching is controlled by the capsule opening–closing process. In this case, the quenching would be expected to be dynamic. In solution, the rate constant for energy transfer between benzil and oxygen was measured to be 6×10^8 $(mol/L)^{-1}$ s^{-1}, which is higher than the number measured in the presence of the OA.[13,14] Since the rate constants we have measured for benzil@OA_2 and five other guest@OA_2 capsuleplexes (Table 1) are lower than those in solution (in the absence of the OA), we believe that the measured rate constants do not represent the energy-transfer process, but they represent the accessibility of oxygen to the entrapped guest, which in turn depends on the capsule opening–closing process.

To fully understand the meaning of the quenching constant, we need to know exactly what the measured k_q represents. The steps involved in the quenching are the formation of the encounter complex between molecular oxygen and the excited guest – OA capsuleplex (k_d), the decomplexation of the encounter complex between oxygen and capsuleplex without energy transfer (k_{-d}), and the capsule opening that facilitates the interaction between oxygen and the excited encapsulated guest (k_o). Upon close interaction between ground-state oxygen and the excited guest, we assume that

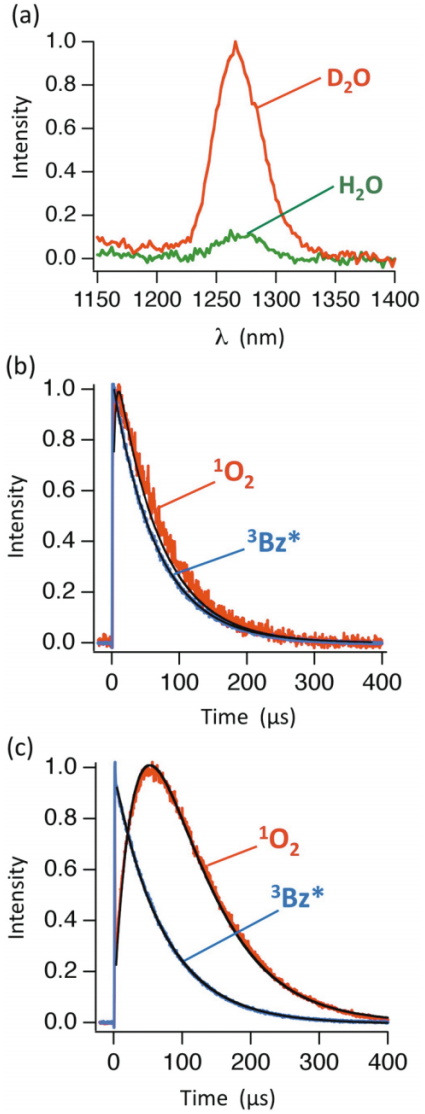
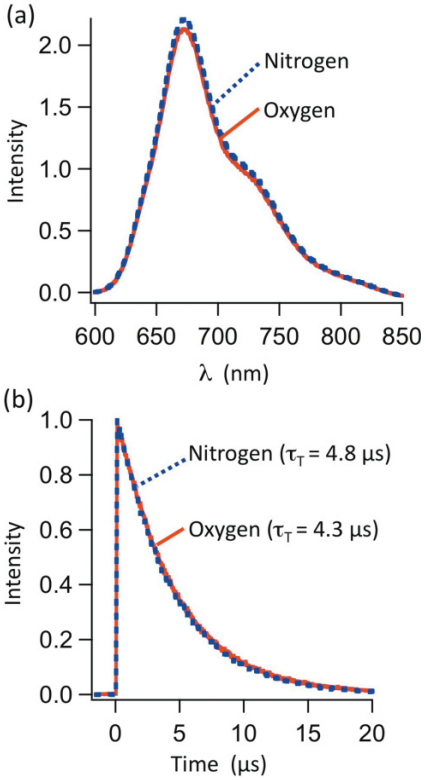
(b) (H_2O) and (c) (D_2O): Phosphorescence decay trace of **3** (blue trace observed at 560 nm) and $^1O_2$ (red trace observed at 1270 nm) after excitation with a laser pulse (308 nm, 15 ns pulse width). The **3**@OA_2 solutions in buffer were saturated with N_2/O_2 gas mixture (1:1). The black lines show the kinetic fits of benzil phosphorescence decay and growth + decay of $^1O_2$ phosphorescence. Bz in the figure represents benzil.



the energy transfer occurs instantaneously, and the slow step is the accessibility of oxygen to the trapped excited guest molecule. Under these conditions, the measured k_q would be given by eq. [1]. If we assume that $k_{-d} > k_o$, then k_q and k_o would be given by eqs. [2] and [3], respectively. Since no specific interactions are expected between oxygen and the capsuleplex, we believe that k_{-d} would be determined by the lifetime of the encounter complex (capsuleplex and oxygen) in water and k_d would be the diffusion rate constant in water, which is 7.4×10^9 $(mol/L)^{-1}$ s^{-1}.[25] Based on literature reports, we assume that the lifetime of the encounter complex between oxygen and the capsuleplex in water

Fig. 6. (a) Steady-state phosphorescence spectra of **7**@OA_2 in oxygen and nitrogen, excitation wavelength (400 nm). OA, octaacid. (b) Phosphorescence decay profile of **7**@OA_2 observed at 670 nm after excitation (355 nm, 5 ns pulse width) of **7**@OA_2 solutions in oxygen and nitrogen.



would be between 0.1 and 0.5 ns.[26,27] Thus, the value for k_{-d} would be between 2×10^9 and 1×10^{10} s^{-1}. Under such conditions, k_o would be between 0.3 and 1.3 $\times$ k_q. On the basis of these assumptions, we believe that the measured quenching constants listed in Table 1 indirectly reflect the rate constants for capsule opening and that the values vary over at least two orders of magnitude between the pyrene triplet and the 4,4′-dimethylbenzil triplet.

$$[1] \qquad k_q = \frac{k_d k_o}{k_{-d} + k_o}$$

$$[2] \qquad k_q = \frac{k_d k_o}{k_{-d}}$$

$$[3] \qquad k_o = \frac{k_{-d} k_q}{k_d}$$

Finally, we address the question of why the excited states of xanthione (T_1, 4.7 μs), 4,4′-dimethoxythiobenzophenone (T_1, 0.6 μs), pyrene (S_1, 0.3 μs), and phenanthrene (S_1, 0.05 μs) included within OA capsule are not quenched by oxygen (Table 1). To understand this process, one needs to recognize that guests with excited-state lifetimes longer than 17 μs are quenched by oxygen to varying percentages (see Table 1). For example, the phosphorescence of adamantanethione (**6**) with a lifetime of 17 μs is quenched to 48% by oxygen (based on relative phosphorescence intensities of

Scheme 4. Schematic representation of energy transfer between the encapsulated guest and oxygen. The rate constants indicated in the scheme are defined in the text.

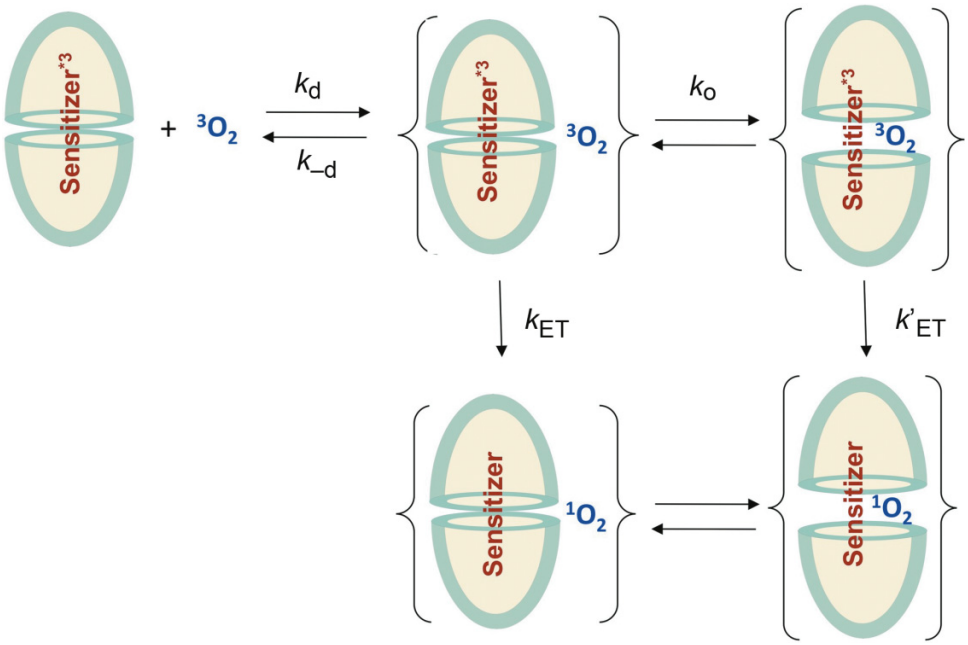

Fig. 7. (a) Steady-state fluorescence spectra of **9**@OA_2 in oxygen and nitrogen. OA, octaacid. (b) Fluorescence decay profile of **9**@OA_2 observed at 380 nm after excitation (330 nm) of **9**@OA_2 solutions in oxygen and nitrogen.

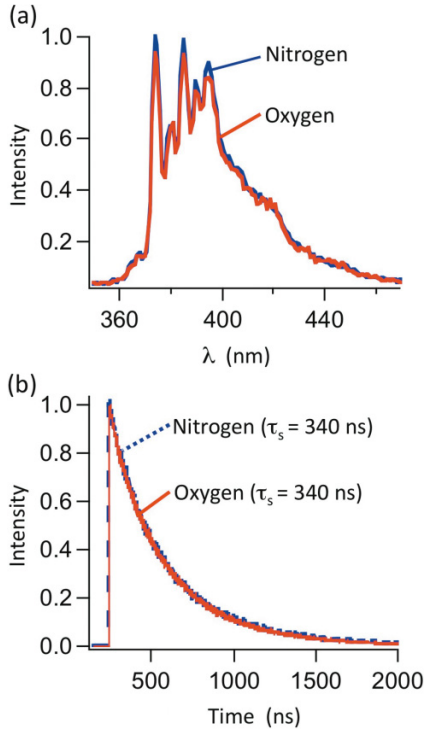
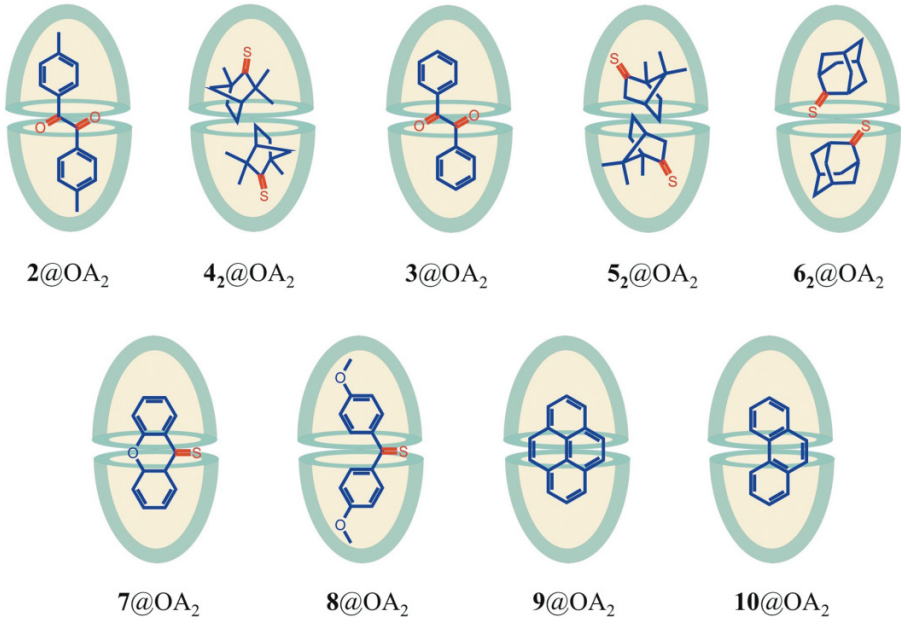


oxygen- and nitrogen-saturated solutions). On the other hand, 4,4′-dimethylbenzil with a lifetime of 596 μs is quenched to 85% of its initial phosphorescence intensity. Increased quenching cannot be solely due to the longer lifetime of the 4,4′-dimethylbenzil triplet. For example, the pyrene triplet with a much longer lifetime (922 μs) is quenched only to 38% as monitored by its T–T absorption. The most noteworthy feature is that molecules whose excited-state lifetimes are shorter than 5 μs remain unquenched by oxygen. We believe that 5 μs may be the cutoff point in terms of the accessibility of oxygen to the excited guest molecule. This suggests that the trapped guest excited state must live for longer than 5 μs for oxygen to access it. One could interpret this to mean that the capsule takes longer than 5 μs to open (at least in the case of xanthione).

As indicated by the quenching percentage (Table 1), the time it takes for the capsule to open may vary with the guest. The excited-state lifetime alone does not determine the quenching percentage. As seen in Table 1, there is no direct correlation between the lifetime and quenching percentage (compare the triplets of **2**, **6**, and **9**). The observed k_q range from 5×10^5 to 9×10^7 $(mol/L)^{-1}$ s^{-1}, depending on the guest molecule (Table 1). This variation in k_q values indicates that the structure of the guest plays an important role in the stability of the host–guest complex and the kinetics of the accessibility of oxygen to the entrapped guest. For example, for benzil, a k_q of 1.3×10^7 $(mol/L)^{-1}$ s^{-1} was observed, whereas for longer dimethylbenzil (11.8 vs 13.7 Å; see Scheme 3), a k_q approximately six times larger (8×10^7 $(mol/L)^{-1}$ s^{-1}) was observed (see Scheme 5 for cartoon representations of the capsuleplexes). This suggests that for the capsule to open just enough for oxygen to reach the excited guest, it takes about six times longer for benzil than for dimethylbenzil. Clearly, the length of the molecule that determines the compactness of the capsuleplex is important in the opening–closing process.

The most interesting observation was noticed with pyrene. In this case, a much smaller rate constant of 5×10^5 $(mol/L)^{-1}$ s^{-1} was observed. This small k_q could be explained by the different nature of the pyrene triplet state (π–π*) compared with the benzil derivatives with an n–π* nature. Triplet states of n–π* are localized at the C=O

Scheme 5. Structures of the guest@host complexes based on ^{1}H NMR data.



chromophore, which is located at the capsule entrance for benzil derivatives, and therefore, probably more accessible to oxygen. Pyrene triplet states (π–π^*) are delocalized over the entire molecule, which probably makes them less accessible to oxygen quenching at the capsule entrance. Thus, the measured quenching constant reflects the accessibility of oxygen to the excited guest for energy transfer to take place. Therefore, the extent of the required opening for each guest could vary, and this in turn may depend on the structure of the guest. We caution that the measured k_qs listed in Table 1 do not represent the same extent of opening in all cases. However, the lower than diffusion-limited value and higher than the energy-transfer rate constant (k_{ET}, Scheme 4) reported for a carcerand suggest that the measured k_qs provide information concerning the opening of the capsuleplex. From the quenching studies, we conclude that the capsuleplex is dynamic and it periodically opens and closes in the μs time scale.

The difference in rate constants between the three thiones **4**, **5**, and **6** is also interesting. In spite of having similar triplet-state lifetimes in solution, the triplet-state lifetimes and quenching constants in OA capsuleplexes differ by an order of magnitude between fenchthione and adamantanethione. Examination of the orientation of the thiones within the capsule accounts for the difference.[9] Orientations based on ^{1}H NMR data of the three thiones within the capsule are shown in Scheme 5. NMR experiments showed that the thiocarbonyl chromophore of fenchthione is deeply buried at the bottom of the OA cap, which shields the excited state from oxygen quenching and, consequently, a lower k_q is observed (1.6×10^6 (mol/L)$^{-1}$ s^{-1}). Clearly in this case, a small opening as in the case of benzil would not suffice for oxygen to reach the excited chromophore. On the other hand, in the case of adamantanethione, where the thione chromophore is in the middle of the capsule, it could be accessed (similar to benzil) with a slight opening of the capsule. The observed quenching constant for adamantanethione is comparable to that of benzil, although they have distinctly different lifetimes (17 vs 151 μs). From these studies, it is clear that capsuleplexes of organic guests and OA are dynamic, and one of the motions they exhibit is the opening and closing of the capsule (Scheme 2d). The time scale for this process depends on the structure and hydrophobicity of the guest. The extent to which the capsuleplex has to open for quenching to occur may vary with the orientation of the guest within the capsule.

Conclusion

In this study, we show that excited states of guests enclosed as capsuleplexes could be quenched by oxygen via an energy-transfer process. The rate constant measured for the quenching reflects the accessibility of oxygen to the guest enclosed within the OA capsuleplex, and this in turn depends on the capsule opening–closing. The rate constant of this process most likely depends on the structure of the guest.

Synthesis and spectroelectrochemical investigation of two tetraarylporphyrins

Robin A. Krüger, Andrea S. Terpstra, and Todd C. Sutherland

Abstract: A free-base tetraarylporphyrin was synthesized by the [2+2] macrocyclization of a dipyrromethane derivative with 3,4,5-tris(dodecyloxy)benzaldehyde in 61% yield. The free-base porphyrin was metallated with zinc acetate in 94% conversion. The free-base and metallated porphyrins show typical intense Soret bands at 426 and 425 nm, respectively, along with the expected number and intensity of Q-bands. Both porphyrins are also fluorescent and display small Stokes shifts between 13 and 18 nm. Cyclic voltammetry established that each porphyrin underwent two reversible one-electron oxidations at 492 and 725 mV (vs Fc/Fc^+ (ferrocene reference)) for the free-base porphyrin and at 329 and 589 mV (vs Fc/Fc^+) for the Zn-metalloporphyrin. Electron-transfer rates were also determined to fall between 1.2×10^{-3} and 2.4×10^{-3} cm s^{-1}. In addition, spectroelectrochemistry and density functional theory calculations of the oxidized products were carried out to confirm the macrocyclic ring oxidations.

Key words: porphyrinoids, electrochemistry, redox chemistry, photochemistry, density functional calculations.

Résumé : On a réalisé la synthèse d'une tétraaraylporphyrine sous la forme de base libre avec un rendement de 61 % par macrocyclisation [2+2] d'un dérivé de dipyrrométhane avec du 3,4,5-tris(docécyloxo)benzaldéhyde. On a effectué la métallation de la porphyrine à l'état de base libre, avec un rendement de 94 %, par traitement avec de l'acétate de zinc. La base libre et la porphyrine métallée présentent respectivement les bandes typiques intenses de Soret à 426 et à 425 nm ainsi que le nombre et l'intensité attendu des bandes Q. Les deux porphyrines sont aussi fluorescentes et elles présentent de faibles déplacements de Stokes, entre 13 et 18 nm. La voltampérométrie cyclique a permis d'établir que chaque porphyrine subit deux oxydations réversibles à un électron, à 492 et 725 mV (vs Fc/Fc^+) pour la base libre et à 329 et 589 mV (vs Fc/Fc^+) pour la Zn-métalloporphyrine. On a aussi déterminé que les vitesses de transfert d'électron se situent entre $1,2 \times 10^{-3}$ et $2,4 \times 10^{-3}$ cm s^{-1}. De plus, de la spectroélectrochimie et des calculs d'après la théorie de la fonctionnelle de la densité effectués sur les produits oxydés pour confirmer les oxydations des noyaux macrocycliques.

Mots-clés : porphyrinoïdes, électrochimie, chimie d'oxydoréduction, photochimie, calculs de la fonctionnelle de la densité.

[Traduit par la Rédaction]

Introduction

Porphyrinoids are commonly found compounds in both the animal and plant kingdoms, as they play important roles in the key steps of photosynthesis that ultimately convert sunlight into chemical energy.[1,2] Iron porphyrins play critical roles in oxygen transport,[3,4] peroxide reduction,[5–7] drug metabolism (cytochrome P450),[8,9] and the mitochondrial electron-transport chain.[10,11] Because of their prevalence in nature, exploration of their potential applications in organic materials is warranted. Photoinitiated charge-transfer reactions are key steps in solar energy conversion,[2,12,13] device applications,[14] and catalysis.[15,16] Progress in these applications necessitates a critical understanding of the thermodynamic factors that direct the charge-transfer reactions. Excited-state reactants are versatile intermediates because they are both better electron donors and better electron acceptors than their ground-state counterparts.[17–19] The reducing and oxidizing strength of these excited-state reagents is crucial to understanding the driving forces that are operating in the eventual applications. Generally, porphyrin ring systems can be easily oxidized to radical cations and sometimes dications.[20–24] Importantly, these cations are stable at room temperature and can be used as reactive intermediates that could be used in organic materials applications.

This contribution explores the electronic properties of two porphyrins and compares them with two well-characterized porphyrins, namely free-base tetraphenylporphyrin (TPP) and Zn-TPP. In addition, full electrochemical and density functional theory (DFT) studies were carried out to assess the charge-transport properties of the oxidized porphyrin ring systems. The goal of this work is to install electron-rich substituents to the meso positions of porphyrins to make stabilized cations for use as light-harvesting chromophores in solar cell applications. Important parameters for a candidate material are high molar absorptivity and excited-

state redox potential that are compatible with a typical *n*-type material, such as phenyl-C_{61}-butyric acid methyl ester (PCBM), and ground-state stability of the radical cation. Furthermore, these compounds were synthesized to explore whether supramolecular structures, such as liquid crystals, could form using meso-aryl substituted porphyrins. A common motif, the trisalkoxyphenyl group, has been employed in a variety of functional materials[25–29] to impart supramolecular long-range ordering that may enhance charge transport in solar applications.

Experimental

Zinc-porphyrin (4)

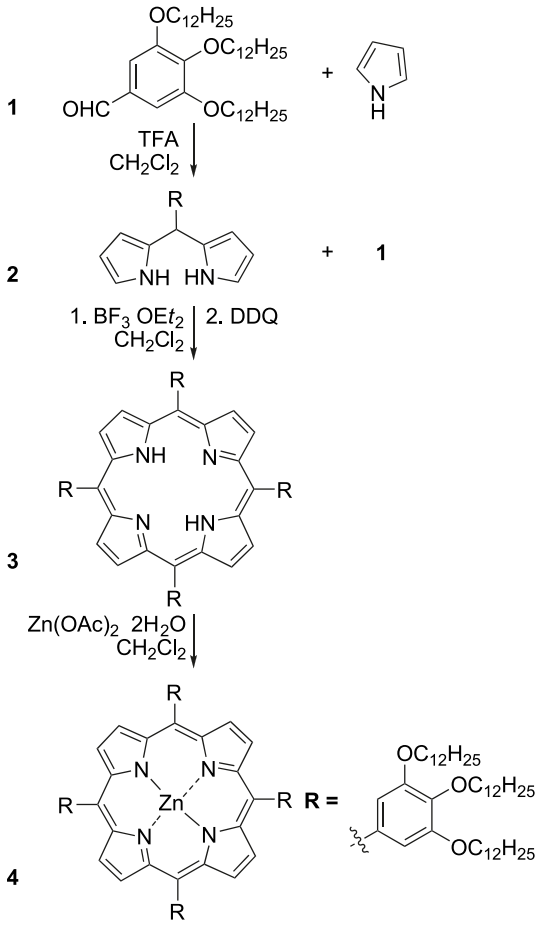
Free-base porphyrin (30 mg, 10.6 μmol), $NaHCO_3$ (100 mg, 450 μmol) and zinc acetate dihydrate (100 mg, 450 mmol) were stirred at ambient temperature in $CHCl_3$ for 4 h in the dark. The red solution was then poured on diluted aqueous $NaHCO_3$ solution (50 mL). After phase separation, the aqueous layer was extracted with CH_2Cl_2 (1 × 20 mL) and the combined organic layers were dried with $MgSO_4$ and evaporated. The crude red oil was purified by column chromatography using CH_2Cl_2 as the eluent on alumina (N, III) and collection of the first red fraction. The yield was 29 mg (10 μmol, 94%). ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 9.10 (s, 8 H, aryl-H), 7.45 (s, 8 H, pyr-H), 4.29 (t, J = 6.6 Hz, 8 H, OCH_2), 4.11 (t, J = 6.5 Hz, 16 H, OCH_2), 2.01–1.94 (m, 8 H, CH_2), 1.93–1.86 (m, 16 H, CH_2), 1.72–1.65 (m, 8 H, CH_2), 1.56–1.25 (m, 208 H, CH_2), 0.93 (t, J = 7.0 Hz, 12 H, CH_3), 0.87 (t, J = 7.0 Hz, 24 H, CH_3). UV–vis (CH_2Cl_2) λ_{abs} (nm) [ε (L mol^{-1} cm^{-1})] = 425 [130 000], 550 [6600], 589 [1300]. λ_{em} (nm) (relative intensity) (λ_{ex} = 425 nm) = 607 (0.96), 649 (1). HR–MS (MALDI-TOF) calcd. for $C_{188}H_{316}N_4O_{12}Zn$: 2886.353; found: 2886.365.

Results and discussion

The synthesis of metal-free porphyrin **3** and Zn-porphyrin **4** is shown in Scheme 1. The synthesis of **1** was carried out using literature methods.[30,31] Condensation of freshly distilled excess pyrrole and TFA with **1** resulted in the formation of the dipyrromethane **2** in 57% yield. Note that **2** was moderately stable at room temperature under N_2 atmosphere and was immediately used in the ring-closing condensation with **1** to produce the free-base porphyrin **3** in 61% yield.[32] Porphyrin **3** was easily metallated with Zn-acetate at room temperature in the dark to give Zn-porphyrin **4** in 94% yield. The electronic absorption and emission properties of porphyrins **3** and **4** are summarized in Table 1, and the spectra are included in the Supplementary data. Both **3** and **4** exhibit strong near-UV absorptions (Soret) attributed to the $S_0 \rightarrow S_2$ transition and sets of weaker visible transitions (Q-bands) attributed to the $S_0 \rightarrow S_1$ transitions, typical of porphyrins.[33] The absorption and emission properties of **3** and **4** are consistent with other reports, which have been extensively reviewed.[34]

The Soret peak, B(0,0), for **3** is positioned at 426 nm with a full width at half maximum (FWHM) of 20 nm, which is similar to the Soret band of **4** at 425 nm with a narrower FWHM of 14 nm (see Supplementary data). The Soret bands of **3** and **4** are slightly red-shifted compared with Soret bands of free-base tetraphenylporphyrin (H_2-TPP) and Zn-tetraphenylporphyrin (Zn-TPP) because of the electron-donating tris(alkoxy) meso-substituents.

Scheme 1. Synthesis of Zn-porphyrin.



The emission spectra of **3** and **4** are similar to the emission spectra of H_2-TPP and Zn-TPP, respectively. Note the excitation wavelength used in each compound was the peak of the Soret band. Free-base porphyrin **3** has two emission peaks at 661 nm and 722 nm with peak height ratios of 1 to 0.44. The Q(0,0) peak position of **3** is red-shifted by 11 nm compared with H_2-TPP, whereas the vibronic sideband of **3** is red-shifted by only 5 nm, accompanied by a ~50% decrease in peak intensity compared with H_2-TPP. The emission spectrum of Zn-porphyrin **4** also exhibits two red-shifted peaks compared with Zn-TPP at 607 nm and 649 nm. The emission peaks are typical for porphyrinoid compounds and are consistent with emission from singlet excited states. Triplet emissions typically show at 800 nm and greater wavelengths.

Charge-transfer dynamics were assessed by cyclic voltammetry (CV) for the oxidation reaction. Figure 1*a* shows the cyclic voltammagrams of **3** at various scan rates. Each voltammagram shows two quasi-reversible oxidation waves, which are assigned to two, one-electron oxidation steps, consistent with other reports of related porphyrins.[35–40] The half-wave potentials ($E^{ox}_{1/2}$) were calculated from the average of the anodic and cathodic peaks of each step, which results

Table 1. Absorption and luminescence peaks of **3** and **4** in CH_2Cl_2 at room temperature.

		Absorption peaks[a]			Luminescence peaks[b]			
	B(0,0)	$Q_y(1,0)$	$Q_y(0,0)$	$Q_x(1,0)$	$Q_x(0,0)$	Q(0,0)	Q(0,1)	Stokes shift (nm)
H_2-TPP[c]	419(413)	514(19.4)	547(8.2)	592(6.6)	646(4.6)	650(1)	717(0.84)	4
3	426(151)	518(7.1)	555(3.4)	592(2.2)	648(1.7)	661(1)	722(0.44)	13
Zn-TPP[c]	422(574)			548(29.9)	588(5.1)	595(1)	645(2.1)	7
4	425(130)			550(6.6)	589(1.3)	607(1)	649(1.1)	18

Note: H_2-TPP, free-base tetraphenylporphyrin; Zn-TPP, zinc-tetraphenylporphyrin.

[a]All absorption peaks are shown in nanometres followed by molar absorptivities in parentheses with units of 10^3 L mol^{-1} cm^{-1}.

[b]All luminescence peaks are shown in nanometres followed by ratio of intensities. Compounds were excited at B bands.

[c]These data were taken from PhotoChemCAD.

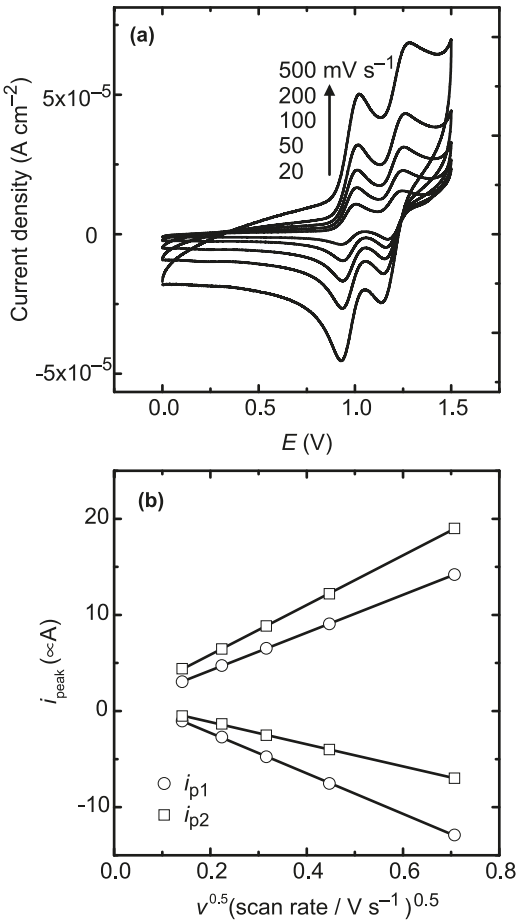
in $E^{ox}_{1/2}(1)$ of 492 mV and $E^{ox}_{1/2}(2)$ of 725 mV vs Fc/Fc^+ (ferrocene reference). The difference between the two oxidation half-wave potentials is 233 mV, which is similar to H_2-TPP.

The CV at slow scan rate (20 mV s^{-1}) provides a good indication of reversibility with peak separations of 78 mV between anodic and cathodic redox couples, where peak separations of 57 mV are considered ideal reversible Nernstian behaviour. The capacitive current, which is quantified as the difference between anodic and cathodic currents in a region that does not contain Faradic responses, is unexpectedly large. There are reports of alkyl-derivatized porphyrins that form liquid crystals[41–44] or films on electrodes[45–48] and this is possible with compound **3**; however, porphyrin **3** is very soluble in CH_2Cl_2, which should minimize film formation. In addition, the linear plot in Fig. 1*b* indicates the redox reaction is diffusion controlled. Peak current is related to scan rate according to eq. [1][49]

$$[1] \qquad i_p = (2.69 \times 10^5) n^{3/2} A D_O^{1/2} C_O^* \upsilon^{1/2}$$

where i_p is the peak current in amperes, n is the number of electrons involved in the redox reaction, A is the area of the electrode surface in cm^2, D_O is the diffusion constant of the oxidized species in cm^2 s^{-1}, C_O is the concentration of redox species in mol cm^{-3}, and υ is the scan rate in V s^{-1}. From eq. [1], plots in Fig. 1*b* can be used to determine the diffusion coefficient, assuming the diffusion coefficients of the oxidized and reduced porphyrins are equal ($D_O \approx D_R$). The diffusion coefficients for $\mathbf{3}^+$ and $\mathbf{3}^{2+}$ were found to be 3.3×10^{-7} cm^2 s^{-1} and 5.6×10^{-7} cm^2 s^{-1}, respectively. Using the Stokes–Einstein equation and assuming spherical compounds, these diffusion coefficients correspond to radii of 16 nm and 9 nm for $\mathbf{3}^+$ and $\mathbf{3}^{2+}$, respectively. Clearly, these hydration radii are much larger than the molecular dimensions and could indicate aggregates are forming in solution under CV conditions that are not present at the concentrations used for optical studies. The proposal of aggregate formation is also consistent with the large non-Faradic currents and broad peaks due to different sizes of aggregates. The estimate of the diffusion coefficient enables the use of Nicholson's approach[50] to calculating the electron-transfer rate constant from the difference in peak potentials at each scan rate. The standard rate constants (k_0) for the first and second one-electron oxidations, shown in eq. [2], are 2.4×10^{-3} cm s^{-1} and 1.4×10^{-3} cm s^{-1}, respectively, for **3**. The electron-transfer rate constants for **3** are typical for numerous porphyrin systems.[51]

Fig. 1. (*a*) Cyclic voltammagram of **3** (4.5×10^{-4} mol L^{-1}) in CH_2Cl_2 containing 0.1 mol L^{-1} tetrabutylammonium hexafluorophosphate ($TBAPF_6$) at various scan rates using a glassy carbon electrode, a Ag|AgCl|KCl3M reference electrode, and a Pt wire counter electrode at 25 °C. (*b*) Peak heights of the two oxidation and reduction peaks as a function of the square root of the scan rate for porphyrin **3**.



$$[2] \qquad \mathbf{3} \underset{k_0^1}{\overset{-e^-}{\rightarrow}} \mathbf{3}^+ \underset{k_0^2}{\overset{-e^-}{\rightarrow}} \mathbf{3}^{2+}$$

The CVs at increasing scan rates of Zn-porphyrin **4** are included in the Supplementary data because they are similar to those of the free-base porphyrin **3**, exhibiting two quasi-reversible, one-electron oxidation steps. The two redox waves are typical for several Zn-porphyrinoid compounds[52]

Table 2. Summary of electrochemical parameters.

Compound	$E^{ox}_{1/2}(1)$ (mV)	$E^{ox}_{1/2}(2)$ (mV)	ΔE (mV)	$D_O(1)$ (10^{-6} cm^2 s^{-1})	$D_O(2)$ (10^{-6} cm^2 s^{-1})	$k_0(1)$ (10^{-3} cm s^{-1})	$k_0(2)$ (10^{-3} cm s^{-1})	$r_H(1)$ (nm)	$r_H(2)$ (nm)
3	492	725	233	0.33	0.56	2.4	1.4	16	9
4	329	589	260	1.4	2.8	1.2	1.9	4	2

Note: All potentials are referenced to Fc/Fc$^+$. Diffusion coefficients of oxidized and reduced species were assumed to be the same. Rate constants were calculated using Nicholson's method. Hydration radii were calculated using solvent viscosity of CH_2Cl_2 at 0.413 mPa s.

and the peaks are also easier to oxidize than **3**. The two half-wave potentials of **4**, $E^{ox}_{1/2}(1)$ and $E^{ox}_{1/2}(2)$, were 329 mV and 589 mV vs Fc/Fc$^+$, respectively. The difference between the two oxidation half-wave potentials is 260 mV, which is similar to the difference in the case of Zn-TPP. The peak separation at the slowest scan rate (10 mV s^{-1}) is 88 mV and 81 mV for the first and second oxidation peaks, respectively, consistent with quasi-reversible redox reactions.

The capacitive currents in Zn-porphyrin **4** are much less than in the CVs for free-base porphyrin **3**, even though the concentration of **4** in the electrochemical cell was higher than that of **3**. In comparing the CVs of **3** and **4**, it is clear that the CV of **3** displays unique diffusion effects. Employing eq. [1], the diffusion coefficients were calculated to be 1.4×10^{-6} cm^2 s^{-1} and 2.8×10^{-6} cm^2 s^{-1} for $\mathbf{4}^+$ and $\mathbf{4}^{2+}$, respectively, resulting in hydration radii of 4 nm and 2 nm for $\mathbf{4}^+$ and $\mathbf{4}^{2+}$, respectively. Although the diffusion coefficients are much higher in the Zn-porphyrin case, the standard electron-transfer rates constants for the first and second oxidation reactions are 1.2×10^{-3} cm s^{-1} and 1.9×10^{-3} cm s^{-1}, respectively, which are similar to those of compound **3**. A summary of all electrochemical results is included in Table 2.

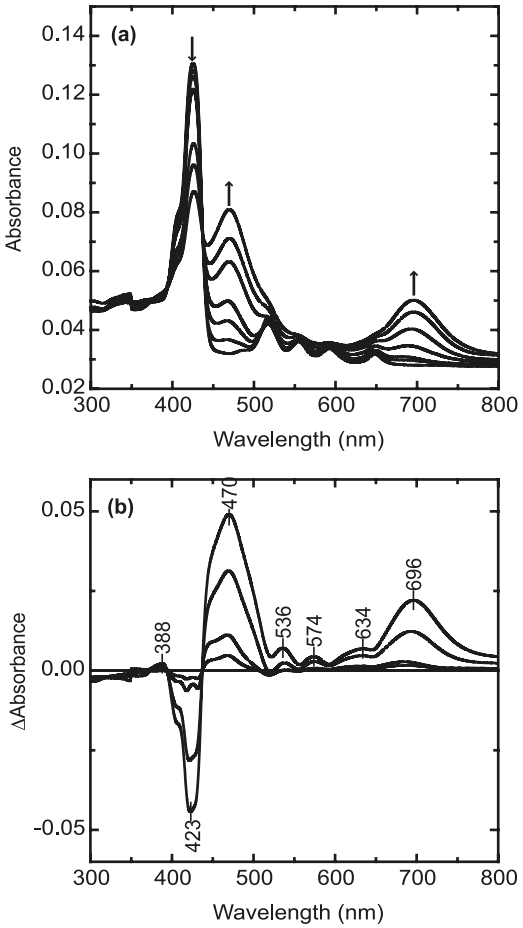
The electrochemical oxidation potentials in conjunction with the highest-energy fluorescent band, corresponding to the lowest-lying singlet state, allow for the estimation of the excited-state oxidation potential, first described by Rehm and Weller[53,54] in eq. [3].

$$[3] \qquad E^{*ox}_{1/2} = E^{ox}_{1/2} - E_{00} + \omega_r$$

where $E^{*ox}_{1/2}$ is the excited-state oxidation potential, $E^{ox}_{1/2}$ is the ground-state redox potential, E_{00} is the energy gap between the zeroth vibrational levels of the ground and excited states, and ω_r is the electrostatic work term. For this work, it is assumed that the electrostatic work term has been adequately accounted for within the measurement of the ground-state redox potentials. The excited-state oxidation potentials for **3** and **4** are –1.39 V and –1.71 V vs Fc/Fc$^+$, respectively. For comparison, H_2-TPP is estimated to have a singlet excited-state redox potential of –1.32 V vs Fc/Fc$^+$.[55] The second oxidation potential was not calculated because the fluorescence spectrum of the radical cation is unknown.

The absorption spectrum of **3** oxidized to $\mathbf{3}^+$ is shown in Fig. 2*a*. Figure 2*a* shows three main features consistent with the ring oxidation.[56–60] The first is the decrease in the Soret band intensity. Concomitantly, there are two new features increasing in intensity at 470 nm and 696 nm. The isosbestic points at 400 nm and 453 nm suggest the UV–vis spectra represent two species that are in equilibrium, which is consistent with the reversible nature of the CV results for **3**. Figure 2*b* shows the absorbance difference spectra of the data shown in Fig. 2*a*. The resulting plot shows more of the smaller transitions and clearly indicates isosbestic points as the data cross the $y = 0$ line. The growth of the largest peak at 470 nm is similar to other spectroelectrochemical results of other porphyrins and is tentatively assigned to the Soret band of the radical cation, $\mathbf{3}^+$.

Fig. 2. Spectroelectrochemistry of **3**. (*a*) UV–vis spectra of compound **3** at an applied potential of +1.0 V. Each spectrum is recorded at 2 min intervals and arrows indicate the direction of peak change. (*b*) The absorbance difference spectra of the data shown in Fig. 2*a*. Positive peaks indicate peak growth compared with neutral porphyrin.



The smaller features that are visible in the difference spectra (Fig. 2*b*) at 536, 574, and 634 nm are assigned to the Q-bands of the oxidized porphyrin. After exhaustive oxidation of **3** to $\mathbf{3}^+$, the potential was stepped to 1.2 V, where the conversion of $\mathbf{3}^+$ to $\mathbf{3}^{2+}$ is expected to occur. The absorption spectrum of $\mathbf{3}^{2+}$ is not shown; however, no significant changes were observed with the exception of a slight increase in the peak at 696 nm. The lack of visible changes is due to two factors. First, the electronic transitions of $\mathbf{3}^{2+}$

For personal use only.

could be weak, and second, the cell design uses a longer path length (1 mm) such that the resultant spectrum is a linear combination of all three species diffusing into the light path. In addition, the oxidized form may be more reactive and decompose. Although CV evidence supports a stable redox couple, the spectroelectrochemical cell design does not permit exclusion of O_2 from the cell.

Spectroelectrochemical experiments were carried out with **4** to investigate the electronic structure of the oxidized form of **4**, which is included in the Supplementary data. The oxidation of **4** to $\mathbf{4}^+$ shows a decrease in the Soret band with an applied potential of 0.8 V (first oxidation potential $\mathbf{4/4}^+$). Upon oxidation, a new Soret band is seen evolving at 442 nm, which is blue-shifted from the $\mathbf{3}^+$ radical cation species. New Q-bands of the radical cation ($\mathbf{4}^+$) appear at 523, 577, 643, and 680 nm. In addition, a new broad transition occurs at 897 nm. Spectroelectrochemical experiments were also carried out at applied potentials equal to the second oxidation. However, at the $E^{ox}_{1/2}(2)$, the spectral features were nearly the same as the spectrum of $\mathbf{4}^+$. After spectral subtraction of the oxidized spectrum ($\mathbf{4}^+$), a broad peak at ~900 nm was observed, but considering the long path length (1 mm), it is clear that the dication ($\mathbf{4}^{2+}$) spectrum consists of neutral **4**, radical cation $\mathbf{4}^+$, and the dication $\mathbf{4}^{2+}$, which precludes accurate spectral deconvolution.

Structures **3**, **4**, $\mathbf{3}^+$, $\mathbf{4}^+$, $\mathbf{3}^{2+}$, and $\mathbf{4}^{2+}$ were energy optimized using DFT methods with the B3LYP basis set and 6-31+G functional using the Gaussian03 software package.[61] The summaries of the frontier orbital energy levels are shown in Fig. 3. Based on the gas-phase calculations, the HOMO energy levels of the free-base porphyrin **3** and the Zn-metalloporphyrin **4** are very similar in energy. This HOMO energy level trend was not observed in the experimentally determined oxidation potential. Experimental results show the Zn-porphyrin is easier to oxidize, suggesting it has a higher-lying HOMO. This inconsistency could arise from solvent effects that are not accounted for in the calculations. The two highest occupied FMOs of **3** and **4** are nearly degenerate and both have nearly degenerate LUMOs, consistent with the four-orbit model.[33] The HOMO–LUMO energy gap is similar for **3** and **4**, which is consistent with the observed electronic absorption spectroscopy. Both radical cations, $\mathbf{3}^+$ and $\mathbf{4}^+$, show red-shifted adsorptions compared with their neutral parent compounds. The SOMO of $\mathbf{4}^+$ is nearly triply degenerate, whereas the SOMO of $\mathbf{3}^+$ does not follow the same pattern. The FMOs of $\mathbf{3}^+$ and $\mathbf{4}^+$ are shown in Fig. 4. The triply degenerate occupied orbitals of $\mathbf{4}^+$ are confined to the electron-rich trisalkoxy phenyl rings, in contrast to $\mathbf{3}^+$, where the SOMO orbital is delocalized over the macrocyclic ring and the four trisalkoxy phenyl rings. The dication species $\mathbf{3}^{2+}$ and $\mathbf{4}^{2+}$ show the lowest HOMO–LUMO energy difference of 0.8 eV, corresponding to 1550 nm, which was not observed in the absorption spectra. In addition, the HOMOs of both dications are triply degenerate and the LUMOs are non-degenerate.

FMOs for all compounds are included in the Supplementary data. Starting with the neutral porphyrins **3** and **4**, the doubly degenerate HOMOs and LUMOs show electron density confined to the porphyrin macrocyclic ring. In addition, the energy-minimized structures have the meso-substituted phenyl rings perpendicular to the macrocyclic ring, implying

Fig. 3. DFT-calculated (B3LYP/6-31+G) energy levels of the frontier orbitals of the neutral, radical cation, and dication of compounds **3** and **4**. The HOMO–LUMO energy differences are shown over the arrows.

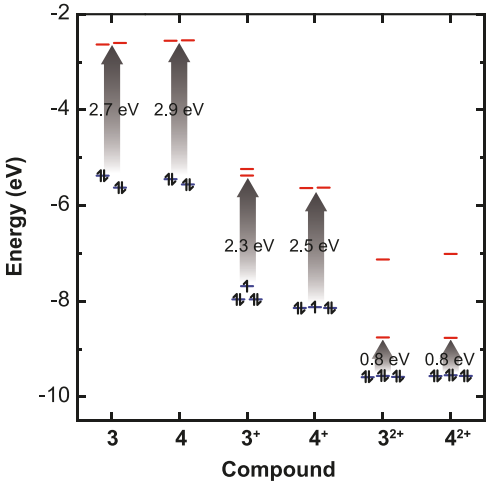

Fig. 4. FMOs of the radical cations $\mathbf{3}^+$ and $\mathbf{4}^+$ using DFT with the B3LYP basis set and 6-31G+ functional.

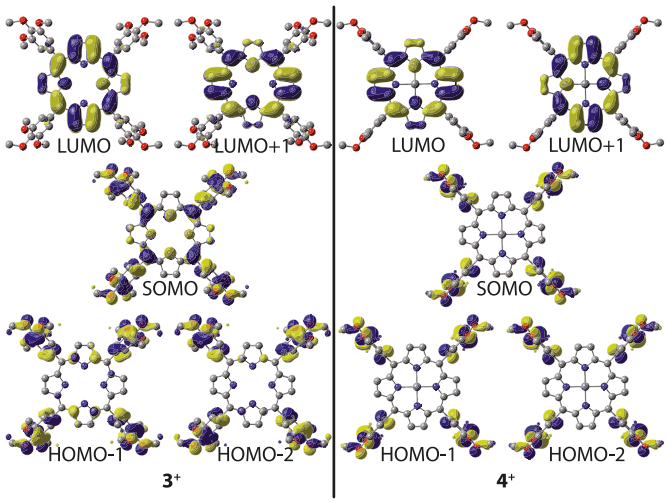

little electronic perturbations can occur from a meso-phenyl substitution pattern. The monocations $\mathbf{3}^+$ and $\mathbf{4}^+$ have different minimized structures. The free base $\mathbf{3}^+$ has a SOMO that is delocalized over the macrocyclic ring and the four phenyl meso-substituents and a twist in the meso-phenyl groups, such that contributions from the phenyl rings can participate in delocalization. In contrast, the Zn-porphyrin cation, $\mathbf{4}^+$, maintains the same geometry as neutral **4** and the SOMO is limited to the four meso-substituted phenyl rings. Both LUMO and LUMO+1 of both monocations ($\mathbf{3}^+$ and $\mathbf{4}^+$) are centered on the macrocyclic ring system. The removal of an additional electron to the dications results in HOMOs that reside on the four phenyl substituents. In addition, both dications $\mathbf{3}^{2+}$ and $\mathbf{4}^{2+}$ show a twist in the meso-phenyl substituents allowing for stabilization of the dicationic macrocycle. The LUMOs of the dications show coefficients on both the phenyl substituents and the macrocycle. The calculations indicate extensive electronic tuning is possible by modifying the β-pyrrole positions, and limited HOMO energy level tun-

ing is possible using phenyl-substituted meso positions. However, the mono- and dications can be strongly stabilized by electron-rich meso-derivatives.

Conclusions

The optical measurements of the tetraarylporphyrins display typical behaviour with intense Soret and Q-band absorptions and fluorescence spectra with small Stokes shifts. Electrochemical oxidations of both the free-base porphyrin **3** and Zn-metalloporphyrin **4** show two reversible one-electron redox waves by cyclic voltammetry methods. Further analysis of the cyclic voltammetry data revealed an unusually large diffusion coefficient for **3**, suggesting aggregate formation. Considering the size and number of alkoxy groups, aggregation is feasible, as others have used such motifs to build long-range order in liquid crystals. The electron-transfer rate constants were 1.2×10^{-3} cm s^{-1} and 2.4×10^{-3} cm s^{-1} for compounds **3** and **4**, respectively, which falls within the range of other porphyrins. Spectroelectrochemical experiments suggest that the electron removed to form the radical cations ($\mathbf{3}^{+}$ and $\mathbf{4}^{+}$) is part of the porphyrin macrocycle. In addition, the spectroelectrochemical results are supported by the DFT-calculated energy-optimized structures of **3** and **4** in their neutral and radical cation states. The reversibility and stability of the oxidized forms of both **3** and **4** support the use of these compounds in organic devices as light harvesters or supramolecular charge-transfer assemblies. Of particular utility could be the excited-state energy of the oxidized porphyrin ring systems to generate charge-separated components used in solar energy conversion. The electrochemically determined HOMO energy levels of **3** and **4** are –5.3 eV and –5.1 eV (assuming the HOMO energy level of Fc/Fc^{+} is –4.8 eV), respectively, which is comparable to the ubiquitous poly-3-hexylthiophene (P3HT) at –5.0 eV and LUMO energy of –3.3 eV. The Rehm and Weller equation gives an estimate of LUMO energy levels of **3** and **4** at –3.4 eV and –3.1 eV, respectively, which is similar to P3HT. The similar energy levels of **3** and **4** with P3HT indicate porphyrins with their superior molar absorptivities could be used as alternative light-harvesting compounds (*p*-type material) in organic photovoltaic cells. In addition, the LUMO level of PCBM, at –3.7 eV, is lower than the excited-state energy of either **3** or **4**, allowing for a thermodynamic driving force for charge separation. Unfortunately, the tetraaryl substituents did not impart supramolecular properties, which would lead to organized structures that could carry charge more efficiently over long distances. Nevertheless, the electron-rich, trisalkoxy meso-substituted porphyrins are remarkably air and electrochemically stable, which is a design necessity for devices.

Competing photodehydration and excited-state intramolecular proton transfer (ESIPT) in adamantyl derivatives of 2-phenylphenols

Nikola Basarić, Nikola Cindro, Yunyan Hou, Ivana Žabčić, Kata Mlinarić-Majerski, and Peter Wan

Abstract: 2-Phenylphenol derivatives strategically substituted with a hydroxyadamantyl substituent were synthesized and their photochemical reactivity was investigated. Derivatives **9** and **10** undergo competitive excited-state intramolecular proton transfer (ESIPT) from the phenol to the carbon atom of the adjacent phenyl ring and formal ESPT from the phenol to the hydroxyl group coupled with dehydration. These two processes (both via S_1) give rise to two classes of quinone methides (QMs) that revert to starting material or react with nucleophiles, respectively. ESIPT to carbon atoms was studied by performing photolyses in the presence of D_2O, whereupon deuterium incorporation to the adjacent phenyl ring was observed (Φ = 0.1–0.2). The competing formal ESPT and dehydration takes place with quantum yields that are an order of magnitude lower and was studied by isolation of photomethanolysis products. Derivative **8** did not undergo ESIPT to carbon atom. Owing to the presence of an intramolecular H bond, an efficient ESIPT from the phenol to the hydroxyl group coupled with dehydration gives a QM that efficiently undergoes electrocyclization (overall Φ = 0.33), to give chroman **16**. In addition, spiro[adamantane-2,9′-(4′-hydroxy)fluorene] (**12**) undergoes ESIPT, unlike the previously reported unreactive parent 2-hydroxyfluorene. The reactive singlet excited states of the prepared biphenyl and fluorene molecules were characterized by fluorescence spectroscopy, whereas laser flash photolysis (LFP) was performed to characterize the longer lived QM intermediates.

Key words: adamantanes, ESIPT, proton transfer, photochemistry, quinone methides, photosolvolysis.

Résumé : On a réalisé la synthèse de dérivés du 2-phényléthanol substitués d'une façon stratégique par un substituant hydroxyadamantyle et on a étudié leur réactivité photochimique. Les dérivés **9** et **10** subissent des transferts de proton intramoléculaire dans l'état excité (TPIEE) du phénol vers l'atome de carbone du noyau phényle adjacent et un TPIEE formel du phénol vers le groupe hydroxyle couplé avec une déshydratation. Ces deux processus, qui se font tous les deux par le biais d'une réaction S_1, conduisent à la formation de deux classes de quinométhanes (QM) qui respectivement se reconvertissent en produit de départ ou qui réagissent avec des nucléophiles. On a étudié les TPIEE vers les atomes de carbone en effectuant des photolyse en présence de D_2O qui ont permis d'observer l'incorporation de deutérium dans le noyau phényle adjacent (Φ = 0,1–0,2). La réaction formelle de TPIEE et de déshydratation qui est en compétition se produit avec des rendements quantiques qui sont un ordre de grandeur plus faibles et qui ont été étudiés en isolant les produits de photométhanolyse. Le dérivé **8** ne donne pas lieu à un TPIEE vers l'atome de carbone. En raison de la présence d'une liaison hydrogène intramoléculaire, un TPIEE du phénol vers le groupe hydroxyle, couplé avec une déshydration, conduit à un QM qui subit une électrocyclisation (rendement quantique global de 0,33) et donne le chromane **16**. De plus, contrairement à ce qui a été rapporté antérieurement pour le 2-hydroxyfluorène qui n'est pas réactif, le spiro[adamantane-2,9′-(4′-hydroxy)fluorène (**12**) subit un TPIEE. On a caractérisé les états excités singulets réactifs des molécules portant des biphényles ou un fluorène en faisant appel à la spectroscopie de fluorescence alors qu'on a fait appel à la photolyse laser éclair (PLE) pour caractériser les intermédiaires QM de durée de vie plus longue.

Mots-clés : adamantanes, transfert de proton intramoléculaire dans l'état excité (TPIEE), transfert de proton, photochimie, quinométhane, photosolvolyse.

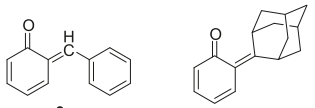
Introduction

Excited-state intramolecular proton transfer (ESIPT) is a fundamental chemical process that has been intensively investigated[1] since it was discovered by Weller.[2] It occurs when electronic excitation of a molecule enhances the acidity and (or) basicity of sites that are in close proximity, allowing a fast proton transfer (PT) to take place on the excited-state surface. The ESIPT gives rise to high-energy tautomers, which usually revert very rapidly to the starting molecules. However, the presence of the photo-tautomers can be detected by fluorescence or transient absorption spectroscopy. Additionally, in some cases, the photo-tautomers can be transformed to stable photochemical products.

As part of on-going research into excited-state acid–base reactions involving phenols,[3] many were found to give rise to quinone methides (QM). For example, on excitation of *o*-hydroxybenzyl alcohol (**1**), ESIPT from the phenol OH to the hydroxyl group, coupled with a dehydration, gives rise to QM **2** (eq. [1]).[4] Similarly, QM **2** can be photogenerated from hydroxybenzylacetate[5] or ammoniummethylphenol derivatives.[6] Since QM **2** is not a photo-tautomer of the starting molecule (as would be the case if generated via a pure ESIPT reaction), the addition of H_2O is required to convert it back to phenol **1**. Hence, QMs photogenerated by dehydration (or similar photochemical reaction) usually have long lifetimes that can be readily detected by laser flash photolysis, and sometimes by conventional UV–vis spectrometry. For example, QMs **3**[4] and **4**[7] (in 1:1 CH_3CN:H_2O) have lifetimes of 5–10 s, and 0.5 s, respectively.

[1] 
1 2



3 4

Since QMs are important intermediates in chemistry and biology, research on their photochemical formation and reactivity has intensified in the last few decades.[8] QMs are known to react with DNA and nucleobases.[9] They also have a pivotal role in the antibiotic action of antracyclines.[10] Rokita at al. have shown that electron-withdrawing groups make QMs more electrophilic and shorter lived, whereas electron-donating groups stabilize the structure.[11] Wan and co-workers have found that formal ESIPT reactions can give biphenyl[12] or terphenyl QM derivatives.[13] In these reactions, a basic site of the formal ESIPT is the oxygen of a benzyl alcohol moiety,[14,15] or a carbon atom of an adjacent phenyl,[16] naphthyl,[17] or the anthryl ring.[18] For example, irradiation of 2-phenylphenol (**5**) in the presence of D_2O gives deuterated QMs **6** and **7** (eq. [2]), which revert rapidly to the starting molecule **5**. However, the deuterium remains incorporated in **5** at the ortho (**5D2**) and the para positions (**5D4**) of the adjacent phenyl ring.

[2] 
5 6 7 5D2 5D4

Recently, Behin Aein and Wan[12c] reported the competition between ESIPT to carbon atoms of an adjacent phenyl ring and formal excited-state proton transfer to oxygen of a benzyl alcohol moiety (coupled with dehydration) using the compound 4-(2-hydroxy-2-ethyl)-2′-hydroxybiphenyl, with both processes giving rise to QMs. The study was performed by carying out photolyses in CH_3CN–D_2O and CH_3OH–D_2O.[12c] To further investigate to what extent can ESIPT to carbon atoms compete with the formal excited-state proton transfer to heteroatom substituents (e.g., benzyl alcohol moiety) that would normally lead to photosolvolysis, we report herein on the photochemical reactivity of a series of *o*-phenylphenols **8**–**10** wherein both processes are possible. In addition, these phenylphenols were strategically substituted with a hydroxyadamantyl moiety, since we have found that this increases quantum yields of QM formation in photodehydration reactions.[7] Furthemore, we report on the photochemical reactivity of ammonium salt **11** that was expected to be less prone to the ESIPT because of the presence of a good nucleofugal ammonium group, which would encourage photosolvolysis. In addition, we probed for ESIPT in the adamantyl fluorene derivative **12** and compared its photochemistry with the parent fluorene compound **13** that does not undergo ESIPT.[16] The mechanisms of photochemical reactions were investigated by preparative irradiations, fluorescence measurements, and laser flash photolysis.

Results and discussion

Materials

Methoxybiphenyl derivatives **14a**–**14c** were prepared by Suzuki reactions from dibromobenzenes and *o*-methoxyphenylboronic acid. The biphenyls were transformed to the Grignard reagents that were reacted with 2-adamantanone to furnish adamantyl biphenyls **8a**–**10a** (eq. [3]). The methoxy ethers **8a**–**10a** were then treated with Lewis acid BBr_3 to give phenols **9** and **10** (eq. [4]) and fluorene **12**. The ortho derivative **10** was obtained by a modification of the published procedure[19] by a cleavage of the ether by sodium ethylthiolate (Scheme 1). The ammonium derivative **11** was synthesized from alcohol **10** according to a modification of the published procedure.[20] Alcohol **10** was first transformed to azide **15** and then reduced by Raney Ni to the corresponding amine that was transformed to *N*-ethyl hydrochloride **11** by purging the diethyl ether solution with dry HCl (eq. [5]). In the later reaction, the alkylation of the amine moiety probably took place by a nucleophilic attack of the amine to the carbon atom of the protonated ethyl ether.

Preparative irradiations

According to previous reports on the photochemistry of benzhydrols,[4,5,7,15] and the corresponding similar biphenyl derivatives,[12,16] it is anticipated that electronic excitation of **8**–**10** in the presence of a protic solvent should give rise to a formal long range proton transfer from the phenol moiety to the alcohol that would couple with a dehydration. It should deliver QMs that can react with nucleophiles (e.g., CH_3OH) and give the substitution (or photosolvolysis) products. To probe for this photochemical process, **8**–**10** were photolyzed in CH_3OH–H_2O (4:1). The CH_3OH–H_2O mixture was chosen because it is known that proton transfer takes place more readily to the clusters of H_2O than CH_3OH.[21] Furthermore, photolyses of similar derivatives in neat CH_3OH sometimes led to the formation of by-products owing to competing pathways involving homolytic cleavage reactions.[7,15]

In aqueous solvent mixtures, the homolytic pathways can generally be reduced.

Photochemical reaction of **9** and **10** gave rise to methanolysis products **9b** and **10b** (eq. [6]), respectively, whereas **8** furnished chroman **16** (eq. [7]). The photolyses (254 nm, 16 lamps, 15 min) were clean, and the products from **8**, **9**, and **10** were isolated in 64%, 19%, and 19% yield, respectively. The unreacted starting materials could be completely recovered by chromatography. On irradiation of the ammonium derivative **11** under the same conditions, complete conversion was achieved. It delivered alcohol **10** (15%) and the methanolysis product **10b** (85%). Quantum yields of the photomethanolyses were determined by use of photomethanolysis of **1** as an actinometer (Φ = 0.23).[4] This actinometer was chosen because it undergoes the same type of reaction under the same conditions as investigated photolyses of **8**–**11**. In addition, it is very simple to analyze the composition of the irradiated solutions by HPLC. The results are compiled in Table 1.

[6] 
[7] 
To probe for the ESIPT to the carbon atom of the adjacent ring in **8**–**12**, irradiations were performed in CH_3CN–D_2O. The concentration of D_2O was 0.1% or 25%. After irradiations and washing with H_2O, the samples were analyzed by NMR and MS to determine the position and the extent of deuteration, respectively. Photolysis of **8** (5 min) gave solely **16** without incorporated deuterium (according to NMR). The MS analysis of the photolyzed sample, however, detected traces of **8** and **8D** (1% of D on photolysis in 0.1% D_2O, and 5% of D on photolysis in 25% D_2O, eq. [8]). Photolysis of **9** (15 min, 0.1% D_2O) gave rise to **9D2** and **9D5** (eq. [9]) in a ratio ~1:1 (according to NMR). The MS analysis showed presence of 30% of monodeuterated compound and 70% of dideuterated compound. Similarly, irradiation of **10** (15 min) gave rise to **10D** and **10D2** (eq. [10]), and the MS analysis showed presence of 22% **10D** and 77% of **10D2**. Interestingly, photolysis of fluorene **12** (1 h, 0.1% D_2O) also furnished the deuterated compound **12D** (eq. [11]), unlike **13** that under the same conditions was not deuterated.

[11] 
Quantum yields of deuterium exchange on photolysis of **9**–**12** were determined by the use of two actinometers, methanolysis of **1** (Φ = 0.23)[4] and deuterium exchange on photolysis of 2-phenylphenol (**5**, Φ = 0.041).[16] The extent of deuteration was determined by NMR and MS. Both actinometers gave quantum yields for deuteration that differed only within the experimental error of the method, so their mean value was reported (Table 1). It is interesting to note

that quantum yields of deuteration were higher in solutions with lower concentration of D_2O, suggesting that increase of H_2O (D_2O) content results in lower quantum yields of ESIPT to carbon. Furthermore, introduction of the hydroxyadamantyl moiety into the parent 2-hydroxybiphenyl structure **5** increased the quantum yield of deuterium exchange by up to 2–5 times. The measured quantum yields for **9** and **10** show that deuteration is a process that takes place by an order of magnitude more efficiently than photomethanolysis. On the contrary, deuterium exchange in **8** did not compete with the efficient formation of chroman **16**.

To additionally probe for the competition between the photomethanolysis and the deuterium exchange, **9** and **10** were irradiated in CH_3OD. The NMR spectrum after photolysis of **10** showed a presence of 10% of **10b** and indicated that **10** and (or) **10b** were 35% deuterated.[22] A similar result was also obtained on photolysis of **9**, indicating the competition of deuteration and formation of **9b**. These results obtained on photolysis in CH_3OD would seem to suggest a smaller difference between the quantum yield of the deuterium incorporation and the photomethanolysis in **9** and **10** than it is presented in Table 1. However, the results are not directly comparable, since experiments were not carried out under the same conditions.

Fluorescence

ESIPT and proton-transfer reactions of phenol derivatives are generally singlet excited-state processes.[1,4,12] Hence, we examined fluorescence of **8**–**10** and **12** to gain more insight into properties of the corresponding singlet excited states. Proton-donor ability of the solvent should influence both the ESIPT and the proton transfer reactions.[23] Therefore, the fluorescence spectra were recorded in CH_3CN and CH_3CN–H_2O (1:4). Quantum yields of fluorescence were determined by using fluorene in methanol as a reference (Φ_f = 0.68).[24] Singlet excited-state lifetimes were obtained by use of the single photon timing method. The results are compiled in Table 2 and in the Supplementary data.

Generally, in CH_3CN solutions, phenols **9** and **10** and fluorene **12** are strongly fluorescent with the maxima of the emission at ~330 nm (Fig. 1). On the contrary, phenol **8** is very weakly fluorescent and shows emission with the maximum at ~320 nm. In CH_3CN–H_2O (1:4) solutions of **8**–**10** and **12**, a dual fluorescence was observed, with the additional band at longer wavelengths (400–450 nm) clearly assignable to the formation of phenolates in the excited state. Accordingly, quantum yields of fluorescence in the aqueous solutions (CH_3CN–H_2O 1:4) are lower (except for **8** where it is double).

To get better insight into the effect of added protic solvent, fluorescence titrations of CH_3CN solutions with H_2O were performed. Addition of H_2O to the solutions of **9** and **10** initially induced fluorescence quenching, which on further additions (>10 mol/L) increased the fluorescence. For **8** and **12**, the initial addition of H_2O already increased the fluorescence (see Supplementary data). However, except for **8**, in CH_3CN–H_2O (1:4) solution, fluorescence is quenched compared with the neat CH_3CN. The unusual influence of added H_2O to fluorescence of **9**–**12** may be ascribed to high lipophylicity and unusual solvation of these derivatives, in accordance with previous report.[7] Addition of H_2O to the solution of **8** probably disrupts the intramolecular H bond between the phenol and the alcohol moiety in the ortho position. In turn, that probably results in a decrease of the efficiency of the ESIPT from the phenol to the alcohol, which is the major anticipated deactivation pathway of the singlet excited state of **8** in CH_3CN (causing low Φ_f and short τ). Similarly, an increase of Φ_f in aqueous media for **9** and **10** may be associated with a decrease of the Φ for the ESIPT pathway to the carbon at the ortho position, and hence, deuteration of the adjacent phenyl ring.

Singlet excited-state lifetimes for **8**–**10** and **12** in CH_3CN

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12

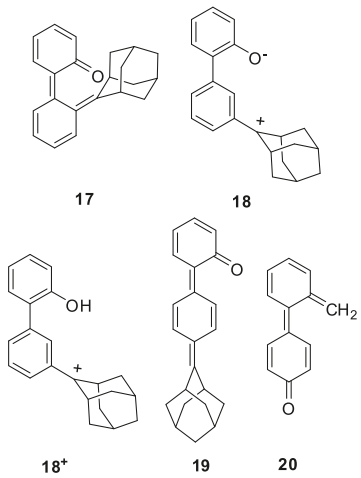
are in line with the quantum yields of fluorescence in that solvent (Table 2). For **8**–**10**, decays of the fluorescence could not be fitted to single exponential functions. In the case of **8**, the longer decay component probably corresponds to the lifetime of **16** that was formed during measurement. Two decay times for **9** and **10** may be ascribed to the presence of two excited states, ^1L_a and ^1L_b, or conformers with different excited-state lifetimes. Formation of aggregates was disregarded by recording a fluorescence decay of a diluted solution of **10** that was also fitted by a biexponential function. However, the unambiguous assignation of the decay component contributing with ~5% was not made. In aqueous solutions, **9** and **10** clearly showed presence of two decay components that were assigned to phenols, more contributing at shorter wavelengths, and phenolates, the rising components contributing mainly at longer wavelengths.

The formation of phenolates from **8**–**10** in CH_3CN–H_2O (1:4) and the observation of dual fluorescence are clearly due to enhanced acidity of the phenol moiety in the singlet excited state. It is well-known that phenols in the excited state become more acidic; for example, the pK_a value for the deprotonation of 2-phenylphenol (**5**) in the singlet state was reported (pK_a^* = 1.15).[25] However, for the ESIPT, a presence of the basic site is also required that is capable of accepting the proton from the phenol. Hence, we performed fluorescence titrations of **9**, **10**, and **12** with acid to estimate the basicity of the corresponding singlet excited states. The CH_3CN–H_2O (1:4) solutions were titrated with aqueous $HClO_4$ resulting in the fluorescence quenching of both the phenol and the phenolate emission. Furthermore, inspection of the normalized fluorescence spectra indicated that phenol fluorescence was more quenched than for the phenolate. That finding suggests that the protonation site in the excited state is indeed not phenolate, but rather a more basic site, a carbon atom or the alcohol moiety. Stern–Volmer analyses of the quenching (see Supplementary data) revealed the diffusion-limited quenching constants (k_q ~ 1.3–1.5 × 10^{10} (mol/L)$^{-1}$ s^{-1}). The basicity was determined by use of the global factor analysis fitting program Specfit.[26] For **9** and **10**, the following pK_a values for the dissociation of the conjugated acids were estimated: 2.0 ± 0.1 and 2.1 ± 0.1, respectively.

Laser flash photolysis (LFP)

LFP was performed for biphenyls **8**–**11** to characterize detectable QMs or other potentially relevant intermediates in their photochemistry. LFP of **8** in CH_3CN and CH_3CN–H_2O, however, only gave rise to negative transient absorptions at the wavelengths <550 nm owing to fluorescence and reversible bleaching of the chromophore. On the other hand, LFP of N_2-purged CH_3CN solutions of **9** and **10** produced a very strong positive transient absorption with a maximum at 390 nm and shoulder stretching over the whole visible region. The signal decayed with a rate constant k = 2.4 × 10^5 s^{-1} and k = 1.3 × 10^6 s^{-1} for **9** and **10**, respectively. Since the transient could be quenched by O_2, in analogy to similar transients seen with other hydroxybiphenyl derivatives,[16] it was assigned to the triplet states of **9** and **10**.



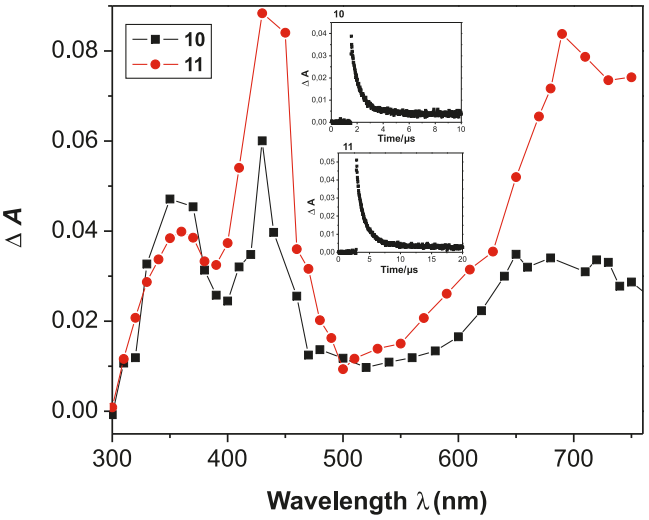
It is anticipated that photolysis of **9** in a protic solvent should give rise to zwitterionic QM **18**. Therefore, LFP was carried out in CH_3CN–H_2O and TFE (see Supplementary data). LFP in O_2-purged CH_3CN–H_2O gave rise to a fast-decaying transient (~30 ns) absorbing with a maximum at 400 nm and stretching to longer wavelengths (>500 nm) that partly overlapped with the signal of the triplet decaying with a similar rate constant. The fast-decaying transient might be ascribed to QM. However, it is more likely to be due to a radical cation. Transient spectra of radical cations with maxima at 350 nm and 550–650 nm decaying with similar lifetimes have been reported.[27] In TFE, which is a less nucleophilic solvent, radical cations, cations,[28] and zwitterionic QMs should be longer lived, and hence, more easily detectable. In an O_2-purged TFE solution of **9**, fast-decaying transient absorption (30–40 ns) was observed at 300–450 nm. Based on reported longer lifetimes of radical cations in TFE,[27] we tentatively assign it to the zwitterionic QM **18** or cation **18**$^+$. However, the transient overlapped with the signal of the triplet, which in addition to its short lifetime precluded further study.

In O_2-purged CH_3CN–H_2O (1:1) solutions of **10** and **11**, besides the signal of the quenched triplet (in O_2-purged solution, the triplet decays with the constant k = 3–5 × 10^7 s^{-1}), transients absorbing at 430 nm and longer wavelengths (550–800 nm) were observed (Fig. 2). These transients were not quenchable by O_2 or N_2O. Hence, they probably do not correspond to radicals, triplets, or solvated electrons. In addition, the intensity of the transient absorption depends linearly on the laser power, ruling out two-photon processes. However, the decay of the signal could not be fitted to a single exponential function. Two or three exponents were required, suggesting a presence of several species. The decay from **10** in O_2-purged solution (CH_3CN–H_2O 1:1) at 600 nm revealed a presence of the species with τ ~ 400 ns, 1 μs, and 30–60 μs, whereas transients from **11** were more persistent, with the main decay component at 600 nm corresponding to a lifetime of 6–8 μs. These transient absorptions in principle may be assigned as being due to radical cations and (or) QM **19**.

The positively charged molecule **11** is anticipated to be less prone to photoionization than noncharged alcohol **10**. On the contrary, the signal of the transient absorption was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

Fig. 2. Transient absorption spectra of **10** and **11** recorded in O_2-purged CH_3CN–H_2O (1:1) 0.5 μs after the laser pulse. Insets: decays at 600 nm.



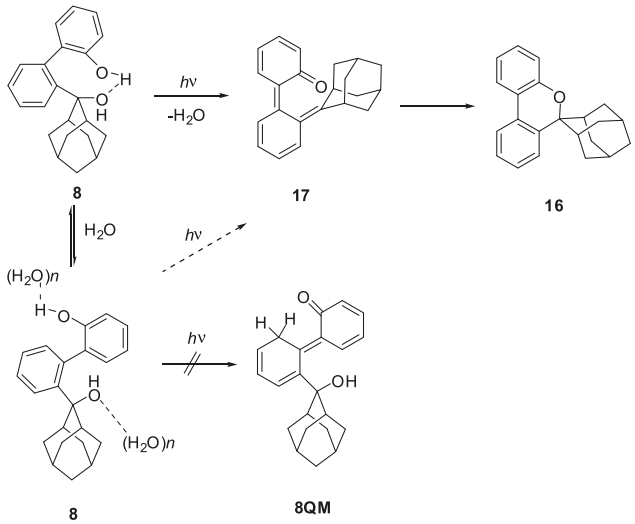
stronger for the ammonium derivative **11** than for alcohol **10**, suggesting that it is not due to the radical cation but rather the QM. The relatively high wavelength region of the transient absorption (550–800 nm), on the other hand, does not suggest that it would correspond to QM **19**. However, a similar transient absorption spectrum with a maximum at a similar wavelength region was reported for QM **20** (τ = 400 ns).[12b]

To be able to assign the transients (Fig. 2) to QM **19** or the radical cation, a quenching was performed with ethanolamine, an ubiquitous quencher of QMs. The transient from **10** decaying with $k = 1 \times 10^6$ s^{-1} was quenched with a rate constant $k_q = 7.7 \times 10^6$ $(mol/L)^{-1}$ s^{-1}. The value of the quenching constant is higher than the reported for the similar biphenyl QM derivative **20** ($k_q = 9 \times 10^4$ $(mol/L)^{-1}$ s^{-1}).[12b] However, it is smaller than those reported for the quenching of radical cations with primary amines (~2×10^9 $(mol/L)^{-1}$ s^{-1}).[27] To get further evidence for the assignation of the transients, LFP of the methoxy derivative **10a** was also performed. Namely, the photolysis of **10a** can give rise to radical cations but cannot give QMs. LFP of **10a** gave rise to transient absorption that in O_2-purged CH_3CN–H_2O showed maxima at 340 and 600 nm, decaying with a rate constant $k = 5 \times 10^4 - 8 \times 10^4$ s^{-1}. This transient was assigned to the radical cation of **10a**. Accordingly, we tentatively assign transients with similar decay times to those seen on the LFP of **10** and **11** to radical cations, whereas faster decaying transients (lifetime 1–6 μs) can be tentatively assigned to QM **19**. However, we were unable to record the representative transient spectrum corresponding only to QM **19** because of the overlapping with the signal of the radical cations.

Reaction mechanisms

From these product studies, fluorescence measurements, and LFP, a reaction mechanism can be proposed. In biphenyl **8**, because of the presence of an intramolecular H bond between the phenol OH and the alcohol at the ortho position, the major anticipated deactivation channel from the singlet excited state is ESIPT coupled with the dehydration. It takes place along the H-bond trajectory and gives rise to QM **17** that very rapidly and efficiently undergoes 6π electrocyclization giving chroman **16** (Scheme 2). The overall quantum yield for the formation of **16** in CH_3OH–H_2O (4:1) is 0.33. Since the electrocyclization reaction takes place very fast, QM **17** has a short lifetime (sub-nanoseconds), so we were unable to detect it by LFP. Because of efficient ESIPT and the formation of QM **17**, the quantum yield of fluorescence of **8** is low and the singlet-state lifetime is short. Addition of a protic solvent disrupts the intramolecular H bond, resulting in a decrease of the quantum yield of ESIPT from the phenol to the alcohol. In addition, in a highly protic medium, the singlet excited state of **8** deprotonates giving phenolates that may, or may not, undergo dehydration giving QM **17**. In any case, the ESIPT process from the phenol to the carbon atom of the adjacent phenyl ring giving **8QM** almost does not take place. That is, in the singlet excited state of **8**, protonation of the carbon atom of the adjacent phenyl ring cannot compete with the protonation of the hydroxyl group and dehydration.

Scheme 2.

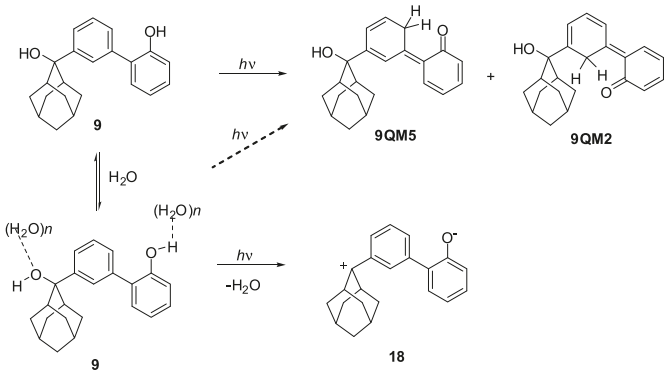


In biphenyl **9**, the hydroxyl group is further away from the phenol moiety. Hence, the intramolecular H bond does not exist, which is in line with the higher quantum yield of fluorescence and the longer singlet excited-state lifetime (compared with **8**). In the aprotic solvent, the phenolic OH probably forms a H–π interaction with the adjacent phenyl ring, as has been demonstrated for the parent system **5**.[12] The electronic excitation of the molecule results in the increased polarization of the resulting singlet state and the increased acidity of the phenolic OH ($pK_a^* = 1.15$).[25] These, coupled with the H–π interaction, probably form a trajectory for the ESIPT from the phenol to the C atom of the adjacent phenyl ring. The ESIPT gives rise to QMs **9QM5** and **9QM2** (Scheme 3), as indicated from the deuterium-exchange experiments. The QMs are formed in a 1:1 ratio, suggesting that there is no prevalence between the conformers of **9** in the ground state, or that free rotation between the phenyl rings in the singlet excited state is much faster than deactivation pathways.

Addition of a protic solvent probably partly disrupts the H–π interaction, leading to a decrease of the ESIPT to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

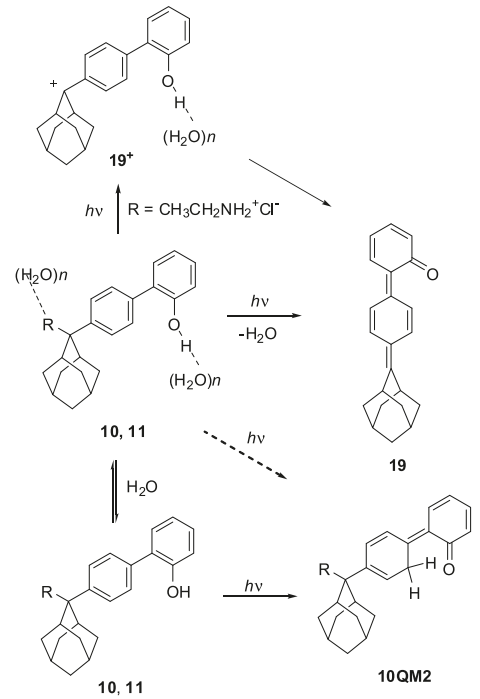
Scheme 3.



carbon atoms. Hence, in protic media **9QM5** and **9QM2** are formed with lower quantum yields, which is demonstrated by the lowering of the quantum yields for deuterium exchange on the increase of D_2O content. In highly protic media, phenol in the singlet excited state of **9** deprotonates giving phenolate, as evidenced from the fluorescence spectra. Furthermore, the fluorescence titration with acid indicated that the most basic site in the singlet excited state is not the phenolate. The finding is in accord with two mechanisms: (*i*) the ESIPT to the carbon atom and (*ii*) the formal ESPT from the phenol OH to the carbon atom or the hydroxyl group, via participation of H_2O molecules, which mediate this formal long-range proton transfer (Scheme 3). Consequently, in protic media, formal ESPT probably gives rise to both protonation of carbon giving **9QM5** and **9QM2** and dehydration delivering zwitterion QM **18**. Measured quantum yields for deuterium exchange and methanolysis demonstrate that ESIPT to carbon is by an order of magnitude more efficient than formal ESPT to the alcohol coupled with dehydration. QMs **9QM5** and **9QM2** are probably very short-lived. Their anticipated lifetimes are in the subnanosecond region. Hence, it was not possible to detect these on our nanosecond LFP. On the contrary, in TFE, we saw the transient absorption, which may be due to zwitterion QM **18** (lifetime ~30 ns).

Similar to **9**, in the singlet excited state of biphenyls **10** and **11** in aprotic solvent, the ESIPT from the phenol to the carbon atom of the adjacent phenyl ring represents an important deactivation pathway. It gives rise to **10QM2** (Scheme 4) and deuterium incorporation on irradiation in the presence of D_2O. Addition of a protic solvent opens new pathways. ESPT in the singlet excited state of **10** gives rise to phenolates, as seen by fluorescence. Phenolate may deliver **10QM2** or may dehydrate giving QM **19**. In protic media, formation of **10QM2** is minimally 5 times more efficient than formation of **19**. In **11**, on the contrary, ESIPT to carbon and formation of **10QM2** proceeds with similar efficiency to the formation of QM **19** because of the presence of a good nucleofugal ammonium group. Photochemistry of **10** and **11** gives rise to two classes of QMs. **10QM2** is probably too short-lived to be detected by nanosecond LFP. On the other hand, the transient absorption spectra of **19** overlap with the radical cationic intermediates observed for the LFP of **10** and **11**, which made its detection difficult. It is interesting to note that incorporation of the hydroxyadamantyl moiety increased quantum yields for the ESIPT to the carbon atom of the adjacent phenyl ring 3–5 times, as compared with the parent biphenyl **5**. This finding may be ascribed to an inductive effect of the adamantyl (alkyl) group that stabilizes the QM structure (e.g., *tert*-butyl $\sigma_m = -0.10$ and $\sigma_p = -0.10$).[24]

Scheme 4.



Wan and co-workers[12,16] reported that fluorene **13** does not undergo ESIPT because of the rigid planar structure wherein there is no interaction between the phenol OH and the π-electrons of the accepting ring. On the contrary, on irradiation of adamantylfluorene **12**, incorporation of the deuterium to the carbon atom indicated that ESIPT takes place, giving rise to **12QM** (eq. [12]), albeit with a low quantum yield of 2×10^{-3} to 3×10^{-3}. The reactivity of **12** can probably be ascribed to a slight change in the geometry upon introduction of the bulky adamantyl substituent. According to the B3LYP/6–31G calculation,[29] the most stable geometry of **13** is planar and the dihedral angle between the phenyl rings is 0°. On the contrary, in the most stable geometry of **12**, the biphenyl rings are not perfectly planar; the dihedral angle is 6.3°. In addition, owing to the angle between the phenyl rings, the phenolic OH comes slightly closer to the C atom with which it should form a new σ bond. The OH–C distance in **13** is 2.586 Å, whereas in **12** it is 2.523 Å. Furthermore, in the biphenyl systems **9** and **10**, it was shown that adamantyl increases the reactivity in the ESIPT reactions, presumably because of the inductive effect of the adamantyl (alkyl) group, which stabilizes the QM structure.

Conclusion

Adamantyl derivatives of 2-phenylphenol **8**–**11** were synthesized and their photochemical reactivity was investigated. Except for the ortho derivative **8**, excitation to the S_1 state leads to competitive ESIPT from the phenol to the carbon atom of the adjacent ring, and formal ESPT from the phenol to the alcohol, coupled with the dehydration. Both processes give rise to QMs that tautomerize to the starting molecules or react with nucleophiles (**18** and **19**). ESIPT to carbon takes place by an order of magnitude more efficiently than photodehydration. In the ortho derivative **8**, efficient ESIPT from the phenol to the alcohol, coupled with dehydration, gives QM **17** and, further, chroman **16**. ESIPT to the carbon atom of the adjacent phenyl ring in **8** cannot compete with the former efficient process. Introduction of the adamantyl moiety to the biphenyl increased reactivity of the molecule in the ESIPT reaction to the carbon atom. Furthermore, distortion of the planarity in the fluorene molecule by the introduction of the adamantyl opened a possibility for ESIPT reaction in the system, which is otherwise nonreactive. The results presented herein show the importance of the ESIPT to carbon atom in the photochemistry of a variety of biphenyl systems.

Experimental

General

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AV-300, 500, or 600 MHz instrument. The NMR spectra were taken in $CDCl_3$ or DMSO-d_6 at room temperature (RT) using TMS as a reference and chemical shifts are reported in ppm. Melting points were determined using an original Köfler mikroheiztisch aparatus (Reichter, Wien) and are uncorrected. UV–vis spectra were recorded on a Varian Cary 100 Bio spectrophotometer at RT. IR spectra were recorded on a FTIR ABB Bomem MB 102 spectrophotometer in KBr. MS were recorded on an Agilent 6410 triple quadrupole mass spectrometer using the electrospray ionization technique. The spectra were obtained in positive and negative modes in the presence of formic acid. HR-MS were obtained on an Applied Biosystems 4800 Plus MALDI TOF/TOF instrument (AB, Foster City, California). For the sample analysis, a Shimadzu HPLC equipped with a diode-array detector and a Phenomenex Luna 3u C18(2) column was used. The mobile phase was CH_3OH–H_2O (20%). For the chromatographic separations silicagel (Merck 0.05–0.2 mm) was used. Analytical thin layer chromatography was performed on Polygram SILG/UV_{254} (Machery–Nagel) plates. Irradiation experiments were performed in a Rayonet reactor equipped with 16 lamps with the output at 254 nm. During irradiations, the irradiated solutions were continuously purged with Ar and cooled by a tap-water finger condenser. Solvents for irradiation were of HPLC purity. Chemicals (dibromobenzenes, bromoanisoles, 2-adamantanone, and a solution of BBr_3) were purchased from the usual commercial sources and were used as received. Solvents for chromatographic separations were purified by distillation.

General procedure for Grignard reaction

The reaction was carried out in a two-neck round-bottom flask (100 mL) under a N_2 inert atmosphere equipped with a condenser and a dropping funnel. Magnesium (10 mmol), which was freshly activated prior to reaction, was placed in the flask and suspended in THF (10 mL). A THF solution (20 mL) of bromobiphenyl (10 mmol) was placed in the dropping funnel. A few drops of the solution were added to the suspension in the flask, and the reaction was initiated by adding a crystal of iodine and heating. The remaining solution in the funnel was added over 30 min at RT. After the addition was completed, the reaction mixture was refluxed until all the magnesium reacted (1–1.5 h). The solution of the Grignard reagent was cooled to RT and a THF solution (20 mL) of 2-adamantanone (10 mmol) was added dropwise over an 1 h period. After the addition was completed, the reaction mixture was refluxed for 4 h and stirred at RT overnight. The next day, a saturated solution of ammonium chloride (100 mL) was added to the reaction mixture, the layers were separated, and the aqueous layer was additionally acidified with 1 mol/L HCl until all solid dissolved. The acidified aqueous layer was extracted with diethyl ether (3×30 mL) and the organic extracts were combined and then dried over anhyd $MgSO_4$. After filtration and removal of the solvent, the crude product obtained was additionally purified by chromatography on silica gel using CH_2Cl_2 or CH_2Cl_2–EtOAc as an eluent.

2-(2-Hydroxyadamantan-2-yl)-2′-methoxybiphenyl (8a)

Grignard reagent was prepared from 2-bromo-2′-methoxybiphenyl (**14a**)[30] (1.80 g, 6.84 mmol) and magnesium (0.17 g, 6.84 mmol) and reacted with 2-adamantanone (1.03 g, 6.85 mmol) to afford 2.33 g of the crude product **8a** that was purified on a column of silica gel to give the product (1.74 g, 76%) in the form of colourless crystals; mp 114–115 °C. IR (KBr) ν_{max} (cm^{-1}): 3415 (OH), 2900 (CH), 2849 (CH). ^{1}H NMR ($CDCl_3$, 600 MHz) δ (ppm): 7.68 (d, 1H, J = 8.1 Hz, H-Ar), 7.38 (dt, 1H, J = 1.6 Hz, J = 8.1 Hz, H-Ar), 7.34 (dt, 1H, J = 1.7 Hz, J = 8.1 Hz, H-Ar), 7.27 (dt, 1H, J = 1.1 Hz, J = 7.4 Hz, H-Ar), 7.18 (dd, 1H, J = 1.6 Hz, J = 7.4 Hz, H-Ar), 7.00–7.04 (m, 2H, H-Ar), 6.93 (d, 1H, J = 8.3 Hz, H-Ar), 3.86 (br s, 1H, OH), 3.74 (s, 3H, OCH_3) 2.59 (br s, 1H, H-Ad), 2.34 (dt, 1H, J = 2.2 Hz, J = 12.4 Hz, H-Ad), 2.11 (dt, 1H, J = 2.2 Hz, J = 12.4 Hz, H-Ad), 1.80–1.90 (m, 2H, H-Ad), 1.60–1.72 (m, 5H, H-Ad), 1.54 (dt, 1H, J = 2.2 Hz, J = 12.4 Hz, H-Ad), 1.40 (dt, 1H, J = 2.2 Hz, J = 12.4 Hz, H-Ad), 1.32 (dq, 1H, J = 3.2 Hz, J = 12.4 Hz, H-Ad), 1.23 (dq, 1H, J = 3.2 Hz, J = 12.4 Hz, H-Ad). ^{13}C NMR ($CDCl_3$, 150 MHz) δ (ppm): 154.68 (s), 142.69 (s), 136.48 (s), 134.30 (s), 133.08 (d), 129.81 (d), 128.54 (d), 127.76 (d), 127.12 (d), 126.61 (d), 121.32 (d), 111.04 (d), 76.56 (s), 55.68 (q), 37.52 (t), 35.14 (d), 34.87 (t), 34.75 (d), 34.02 (t), 33.07 (t), 32.68 (t), 27.29 (d), 26.53 (d). 2-(2-Hydroxyadamantan-2-yl)-2′-hydroxybiphenyl (10)

The reaction was carried out under a N_2 atmosphere in a round-bottom flask (100 mL) equipped with a condenser and a dropping funnel, and the outlet of the N_2 from the condenser was purged through a solution of sodium ethoxyde in ethanol. Sodium hydride (0.46 g, 20 mmol) was placed in the flask and then suspended in 5 mL of dry DMF. The suspension was cooled using an ice bath, and a solution of ethyl mercaptane (1.4 mL, 20 mmol) in DMF (5 mL) was added dropwise. When the addition was completed, the reaction mixture was stirred for 10 min and the ice bath was removed. Methoxybiphenyl derivative **8a** (1.7 g, 5.08 mmol) was dissolved in DMF (10 mL) and added to the reaction mixture. After addition, the mixture was refluxed over 4 h, cooled, and poured into 100 mL of H_2O. The aqueous mixture was washed with hexane (2 × 50 mL) and acidified by a saturated solution of ammonium chloride. Extraction with ethyl acetate was carried out (3 × 100 mL), the extracts were dried over anhyd $MgSO_4$, the solid was removed by filtration, and then the solvent was removed on the rotary evaporator. The reaction furnished 1.61 g of the crude product, which was purified by crystallization from carbon tetrachloride to afford 1 g (62%) of the pure product **8** in the form of colourless crystals; mp 194–196 °C (lit.[33] mp 213–214 °C).

General procedure for the removal of the methyl ether groups from phenols with BBr_3

The reaction was carried out under a N_2 atmosphere in a three-neck round-bottom flask (250 mL) equipped with a septum and a syringe. Methoxybiphenyl derivative **8a**–**10a** (10 mmol) was placed in the flask, then dissolved in dry CH_2Cl_2 (100 mL), and the solution was cooled to 0 °C using an ice bath. To the cold solution, by use of a syringe, a solution of BBr_3 in CH_2Cl_2 (1 mol/L, 10 mL) was added dropwise over a 1 h period. After the addition was completed, the stirring was continued for 1 h at 0 °C and then at RT overnight. The next day, to the reaction mixture 100 mL of cold water was added, the layers were separated, and the aqueous layer extracted with CH_2Cl_2 (3 × 50 mL). The combined organic extracts were dried over anhyd $MgSO_4$, the solid was removed by filtration, and then the solvent was removed on a rotary evaporator. The obtained crude product was purified on a column filled with silica gel using CH_2Cl_2 or CH_2Cl_2–EtOAc (4:1) as the eluent.

Spiro[adamantane-2,9′-(4′-hydroxy)fluorene] (12)

From 2-(2-hydroxyadamantan-2-yl)-2′-methoxybiphenyl (**8a**, 0.94 g, 2.81 mmol) and a solution of BBr_3 (14.1 mL), the reaction gave 0.92 g (99%) of the crude fluorene product **12** that was additionally purified for the purpose of analysis on a column of silica gel using CH_2Cl_2 as the eluent. Colourless crystals, mp 158–160 °C. 4-(2-Azidoadamantan-2-yl)-2′-hydroxybiphenyl (15)

A two-neck flask (50 mL) was charged with sodium azide (127 mg, 1.96 mmol) and $CHCl_3$ (4 mL). The obtained suspension was cooled by a salt–ice bath and TFA (365 μL, 4.9 mmol) was slowly added using a syringe. After 10 min of stirring, a suspension of alcohol **10** (314 mg, 0.98 mmol) in $CHCl_3$ (3 mL) was added. The reaction mixture was stirred at –5 °C for 4 h and then at RT overnight. To the reaction mixture, aqueous ammonia (10 mL, 15%) was added and the layers were separated. The aqueous layer was extracted with $CHCl_3$ (2 × 25 mL) and with EtOAc (2 × 25 mL). The combined extracts were dried over anhyd MgSO4, the solution was filtered, and the solvent was removed on a rotary evaporator to afford pure azide (340 mg) quantitatively. Colourless crystals, mp 121–122 °C. IR (KBr) ν_{max} (cm^{-1}): 3516 (OH-phenol), 2942 (CH), 2901 (CH), 2856 (CH), 2103 (N_3). ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 7.57 (d, 2H, J = 7.5 Hz, H-Ar), 7.54 (d, 2H, J = 7.5 Hz, H-Ar), 7.22–7.30 (m, 2H, H-Ar), 6.96–7.03 (m, 2H, H-Ar), 5.30 (br s, 1H, OH), 2.67 (br s, 2H, H-Ad), 2.36 (br s, 1H, H-Ad), 2.31 (br s, 1H, H-Ad), 1.97 (br s, 1H, H-Ad), 1.73–1.86 (m, 9H, H-Ad). ^{13}C NMR ($CDCl_3$, 75 MHz) δ (ppm): 152.36 (s), 139.84 (s), 136.35 (s), 130.18 (d), 129.31 (d, 2C), 129.11 (d), 127.37 (s), 126.24 (d, 2C), 120.81 (d), 115.84 (d), 69.89 (s), 37.44 (t), 33.79 (t, 2C), 33.15 (t, 2C), 32.83 (d, 2C), 27.12 (d), 26.52 (d). HR-MS calcd. for $C_{22}H_{23}N_3O$–H: 344.1768; found: 344.1784.

4-[2-(N-ethylaminoadamantan-2-yl)]-2′-hydroxybiphenyl hydrochloride (11)

A two-neck flask (250 mL) equipped with a condenser was charged with an absolute ethanol solution (50 mL) of azide **15** (200 mg, 0.58 mmol). To the solution was added a suspension of freshly activated Raney Ni (~10 g). The suspension was heated at ~70 °C overnight. The next day, the reaction mixture was filtered to remove the Raney Ni, and the ethanol solution was evaporated to afford 200 mg of the crude amine. The amine was dissolved in dry ethyl ether (100 mL) and purged with HCl over a 30 min period whereupon colourless precipitate formed. The precipitate was filtered through a sinter funnel, washed with ether and CH_2Cl_2, and dried in vacuum to afford the pure product (60 mg, 27%). Colourless crystals, mp 242–245 °C. IR (KBr) ν_{max} (cm^{-1}): 3400–2800 (broad, NH, OH), 2920 (CH), 2860 (CH). ^{1}H NMR (DMSO-d_6, 300 MHz) δ (ppm): 9.69 (s, 1H, OH), 8.43 (br s, 2H, NH_2), 7.69 (d, 2H, J = 7.6 Hz, H-Ar), 7.65 (d, 2H, J = 7.6 Hz, H-Ar), 7.31 (dd, 1H, J = 7.3 Hz, J = 1.3 Hz, H-Ar), 7.18 (dt, 1H, J = 8.0 Hz, J = 1.5 Hz, H-Ar), 6.99 (d, 1H, J = 8.0 Hz, H-Ar), 6.89 (dd, 1H, J = 7.3 Hz, J = 8.0 Hz), 3.35 (q, 2H, J = 7.4 Hz, NCH_2), 2.90 (br s, 2H, H-Ad), 2.61 (br s, 1H, H-Ad), 2.47 (br s, 1H, H-Ad), 2.42 (br s, 1H, H-Ad), 1.94 (br s, 1H, H-Ad), 1.62–1.86 (m, 8H, H-Ad), 1.05 (t, 3H, J = 7.4 Hz, CH_3). ^{13}C NMR (DMSO-d_6, 75 MHz) δ (ppm): 154.51 (s), 138.80 (s), 133.77 (s), 130.23 (d), 129.13 (d, 2C), 128.82 (d), 127.73 (d, 2C), 126.43 (s), 119.45 (d), 116.24 (d), 67.11 (s), 37.33 (t), 36.52 (t), 33.55 (t, 2C), 30.64 (t, 2C), 30.60 (d, 2C), 26.45 (d), 25.58 (d), 11.55 (q). HR-MS calcd. for $C_{24}H_{30}ClNO$–HCl: 346.2176; found: 346.2183.

Photolysis experiments: general procedure

A CH_3OH or CH_3OH–H_2O (25%) solution (100 mL, c = 3.1 × 10^{-3} mol/L) of hydroxybiphenyl derivative **8**–**11** (100 mg, 0.31 mmol) was placed in a quartz vessel and irradiated in a Rayonet reactor using 16 lamps at 254 nm. Prior to (15 min) and during the irradiation, the solution was continuously purged with a stream of Ar and cooled by a cold-finger condenser. After irradiation, the solvent was removed on a rotary evaporator and the residue was chromatographed on a thin layer of silica gel using CH_2Cl_2 or CH_2Cl_2–EtOAc (30%) as the eluent.

Spiro[adamantane-2,6′-benzo[c]chromene] (16)

Yield: 60 mg (64%), mp 123–124 °C (lit.[33] mp 123–124 °C).

3-(2-Methoxyadamantan-2-yl)-2′-hydroxybiphenyl (9b)

Colourless crystals (20 mg (19%)), mp 179–181 °C. IR (KBr) ν_{max} (cm^{-1}): 3270 (OH-phenol), 2916, 2855 (CH). ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 7.54 (br s, 1H, H-Ar), 7.43–7.50 (m, 2H, H-Ar), 7.37 (dt, 1H, J = 1.8 Hz, J = 6.8 Hz, H-Ar), 7.20–7.28 (m, 2H, H-Ar), 6.99 (dt, 1H, J = 1.0 Hz, J = 6.3 Hz, H-Ar), 6.96 (d, 1H, J = 7.0 Hz, H-Ar), 5.20 (br s, 1H, OH), 2.83 (s, 3H, OCH_3), 2.63 (br s, 2H, H-Ad), 2.32 (br s, 1H, H-Ad), 2.28 (br s, 1H, H-Ad), 1.88 (br s, 1H, H-Ad), 1.60–1.80 (m, 9H, H-Ad). ^{13}C NMR ($CDCl_3$, 75 MHz) δ (ppm): 152.35 (s), 142.37 (s), 136.49 (s), 130.20 (d), 129.01 (d), 128.85 (d), 128.27 (s), 128.22 (d), 127.51 (d), 126.79 (d), 120.73 (d), 115.70 (d), 79.78 (s), 48.10 (q), 37.54 (t), 34.45 (t, 2C), 32.70 (d, t, 4C), 27.62 (d), 26.72 (d). HR-MS calcd. for $C_{23}H_{26}O_2$–H: 333.1860; found: 333.1875.

4-(2-Methoxyadamantan-2-yl)-2′-hydroxybiphenyl (10b)

Colourless crystals (20 mg (19%)), mp 157–158 °C. IR

(KBr) ν_{max} (cm^{-1}): 3234 (OH-phenol), 2933 (CH), 2901 (CH), 2856 (CH). ^1H NMR ($CDCl_3$, 300 MHz) δ (ppm): 7.55 (d, 2H, J = 8.4 Hz, H-Ar), 7.44 (d, 2H, J = 8.4 Hz, H-Ar), 7.18–7.26 (m, 2H, H-Ar), 6.92–6.98 (m, 2H, H-Ar), 5.33 (br s, 1H, OH), 2.82 (s, 3H, OCH_3), 2.63 (br s, 2H, H-Ad), 2.33 (br s, 1H, H-Ad), 2.29 (br s, 1H, H-Ad), 1.88 (br s, 1H, H-Ad), 1.60–1.85 (m, 9H, H-Ad). ^{13}C NMR ($CDCl_3$, 75 MHz) δ (ppm): 152.40 (s), 140.81 (s), 135.67 (s), 130.14 (d), 128.96 (d), 128.48 (d, 2C), 128.15 (d, 2C), 127.64 (s), 120.72 (d), 115.75 (d), 79.68 (s), 48.08 (q), 37.56 (t), 34.40 (t, 2C), 32.76 (d, 2C), 32.71 (t, 2C), 27.61 (d), 26.73 (d). HR-MS calcd. for $C_{23}H_{26}O_2$–H: 333.1860; found: 333.1875.

Quantum yields

Four quartz cuvettes, containing solutions of **8**–**11** (5 mg, 0.015 mmol or 0.013 mmol for **11**) in CH_3OH–H_2O (4:1, 25 mL, $c = 6 \times 10^{-4}$ mol/L), and a quartz cuvette with a solution of **1** (5 mg, 0.029 mmol) in CH_3OH–H_2O (1:1, 25 mL $c = 1 \times 10^{-3}$ mol/L) were purged with N_2 for 20 min, sealed, and irradiated at the same time in a Rayonet reactor equipped with 6 lamps with the output at 254 nm for 1, 2, 3, and 6 min. The composition of the irradiated solutions was analyzed by HPLC. Quantum yields for the methanolysis were calculated using the quantum yield for the methanolysis of **1** as the actinometer (Φ = 0.23).[4]

Alternatively, a quartz cuvette containing a solution of **8**–**11** (10 mg, 0.03 mmol) in CH_3CN–D_2O (100 mL, 0.1% or 25% D_2O) was purged with Ar for 30 min and irradiated in a Rayonet reactor equipped with 16 lamps for 3 min. After the irradiation, H_2O was added (100 mL) to the photolyzed solution and extractions with CH_2Cl_2 were carried out (3 × 50 mL). The extracts were dried over anhyd $MgSO_4$, the solution was filtered, and the solvent was removed on a rotary evaporator. The deuterium content was determined by NMR and MS. A solution of **1** in CH_3OH–H_2O (1:1, Φ = 0.23) was irradiated for 3 min and worked up in the same way under the same conditions. The conversion to the photomethanolysis product was obtained from the NMR spectrum. A solution of **5** (10 mg, 0.058 mmol) in 100 mL CH_3CN–D_2O (Φ = 0.041) also was irradiated under the same conditions.[16] After the workup, the content of deuterium was determined by NMR and MS. Using both actinometers, the quantum yields for deuterium incorporation in **8**–**11** were calculated and the mean value was reported.

Steady-state and time-resolved fluorescence measurements

The steady-state measurements were performed on a Photon Technology International (PTI) Quanta-Master QM-2 luminescence spectrometer. The samples were dissolved in CH_3CN or CH_3CN–H_2O (1:4), and the concentrations were adjusted to have optical densities at the excitation wavelength (270 nm) <0.1. Solutions were purged with nitrogen for 15 min prior to analysis. The measurements were performed at 20 °C. Fluorescence quantum yields were determined by comparison of the integral of emission bands with the one of fluorene in methanol (Φ = 0.68).[24] Typically, three absorption traces were recorded (and averaged) and three fluorescence emission traces were collected with excitation at three different wavelengths. Three quantum yields were calculated and the mean value was reported.

Fluorescence titrations were performed by adding aliquots (60 μL) of aqueous $HClO_4$ (pH 2.09) to 2 mL of the CH_3CN–H_2O (1:4) solution. The pH of aqueous $HClO_4$ was measured by a pH meter. The titration was performed at RT in air-saturated solutions.

Fluorescence-decay histograms were obtained on an Edinburgh instrument OB920, equipped with a hydrogen flash lamp, using a time-correlated single photon counting technique in 1023 channels. Histograms of the instrument response functions (using a LUDOX scatterer) and sample decays were recorded until they typically reached 3×10^3 counts in the peak channel (except for **8** where only 500 counts were collected). The half-width of the instrument response function was typically ~1.5 ns. The time increment per channel was 0.049 or 0.02 ns. Obtained histograms were fitted as sums of exponential using Gaussian-weighted nonlinear least-squares fitting based on Marquardt–Levenberg minimization implemented in the software package of the instrument. The fitting parameters (decay times and preexponential factors) were determined by minimizing the reduced χ^2. An additional graphical method was used to judge the quality of the fit that included plots of surface "carpets" of the weighted residuals vs channel number.

Laser flash photolysis (LFP)

All LFP studies were conducted at the University of Victoria LFP facility employing a YAG laser, with a pulse width of 10 ns and an excitation wavelength of 266 nm. Static cells (0.7 cm) were used, and solutions were purged with nitrogen or oxygen for 20 min prior to measurements. Optical densities at 266 nm were ~0.4–0.6.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

A computational study of the fluctional behaviour of group 14 substituted *ortho*-semiquinone radicals

K.U. Ingold and Gino A. DiLabio

Abstract: The dynamics of the 1,4-migration of some *O*-substituted 3,5-di-*tert*-butyl-*ortho*-semiquinone radicals have been calculated by density-functional theory (DFT). There is very good agreement in the rate constant and Arrhenius parameters between these calculations and experimental values for migration of H, D, and the Me_3Si group. For the Me_3Sn group, the calculations indicate an incredibly fast migration ($k^{293K} = 2.0 \times 10^{12}$ s^{-1}), a result that is consistent with experimental data ($k^{293K} > 10^9$ s^{-1}). Other *O*-substituents examined by DFT and compared with experimental data were H_3C and Me_2ClSn.

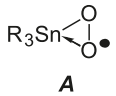
Key words: semiquinone radicals, group migration, group-coupled electron transfer, kinetics, density functional theory.

Résumé : Faisant appel à la théorie de la fonctionnelle de la densité (TFD), on a calculé la dynamique de la migration-1,4 de quelques radicaux 3,5-di-*tert*-butyl-*ortho*-semiquinones *O*-substituées. Il existe un très bon accord entre les constantes de vitesse et les paramètres d'Arrhenius calculées et les valeurs expérimentales pour la migration de H, D et du groupe Me_3Si. Pour le groupe Me_3Sn, les calculs prédisent une vitesse de migration incroyablement rapide ($k^{293K} = 2{,}0 \times 10^{12}$ s^{-1}), une valeur qui est en accord avec les données expérimentales ($k^{293K} > 10^9$ s^{-1}). Les autres *O*-substituants examinés par la TFD et comparés avec des données expérimentales sont le H_3C et Me_2ClSn.

Mots-clés : radicaux semiquinones, migration de groupe, transfert d'électron couplé à un groupe, cinétique, théorie de la fonctionnelle de la densité.

[Traduit par la Rédaction]

An anomaly in the electron paramagnetic resonance (EPR) spectra of tri-organo group 14 peroxyl radicals, $R_3XOO^{\bullet}$, recently drew our attention.[1] Briefly, the *g*-values for this family of radicals are rather similar (increasing from 2.015 for X = C, through 2.024 for X = Sn, to 2.034 for X = Pb), which implies that they all have rather similar structures. However, their ^{17}O hyperfine splittings (hfs) appeared inconsistent with similar structures. For X = C, Si, and Ge, the two oxygen atoms are magnetically inequivalent, with the outer ^{17}O hfs being larger than the inner ^{17}O hfs (outer/inner ^{17}O hfs ratios 1.33 (C), 1.74 (Si), 1.67 (Ge)), which implies an $R_3X–O–O^{\bullet}$ structure for these peroxyls. However, for X = Sn the two oxygen atoms had been reported[2] to be magnetically equivalent.[3] This led to the suggestion that trialkyltin peroxyl radicals have "a penta-coordinate, trigonal bipyramidal structure … in which the vacant Sn 5d orbitals are used to form a dative bond with the lone pair of electrons on the terminal oxygen" of the peroxy function, structure ***A***.[2] Since this appeared unlikely in view of the similarities in the *g*-values of the group 14 peroxyls, we hypothesized that $R_3SnOO^{\bullet}$ radicals had a similar structure, with the magnetically equivalent oxygen atoms arising from a fast (on the EPR time scale, i.e., > ~10^7 s^{-1}) 1,2-shift of the R_3Sn group, reaction 1. Density-functional theory (DFT) calculations supported this hypothesis, giving inequivalent oxygen atoms (outer/inner ^{17}O hfs ratio = 1.47 (Sn)), with $k_1 = 5 \times 10^8$ s^{-1} at the experimental temperature of ~200 K.[1]



A

[1]

Since the computed rate constant for reaction 1 could not be checked against experimental data, we searched for analogous reactions for which such data were available and settled on the 1,4-shift of some trisubstituted group 14 moieties between the two oxygen atoms in 3,6-di-*tert*-butyl-*ortho*-semiquinone radicals, reaction 2.[4]

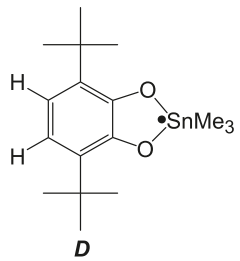
B ***C***

In these radicals, the two *tert*-butyl substituents serve three practical functions: (1) they simplify the EPR spectra to splittings only by the two aromatic hydrogen atoms (and **G**), (2) they ensure that the group, **G**, points towards the O• moiety (rather than away), and (3) they increase the persistence of the radicals, making the signals more intense and easier to measure than would be the case for the unsubstituted radicals. These two substituents probably cause some acceleration in the rates of reaction 2 relative to those of similar reactions in *ortho*-semiquinones that lack these bulky groups.

For **G** = Me_3Sn, reaction 2 has been reported to be so rapid that its rate constant could not be measured by EPR line-broadening effects even at 183 K, the lowest temperature employed[5] (a lower limit of 10^9 s^{-1} for this rate constant was later estimated at 293 K[6]). The possibility that the absence of line broadening effects with **G** = Me_3Sn was due to the formation of a symmetric bridged structure, ***D***, was considered improbable for two very good reasons[6]: (1) ***D*** would have considerable spin density on the tin and cause very significant hfs by the ^{117}Sn and ^{119}Sn isotopes, but these hfs were small (12.8 and 13.3 G, respectively)[6]; and (2) for **G** = Me_3Sn, the two ring protons give a 3.6 G triplet, indicating that they are magnetically equivalent. The 3.6 G hfs for this triplet was essentially identical to the hfs of the two ring protons in radicals with **G** = Me_2SnCl[5] and **G** = Me_3Si[6] at temperatures where these groups were migrating rapidly (on the EPR time scale) between the two oxygen atoms, namely 3.6 G[5] (3.7 G)[7] and ~3.9 G[6], respectively. For these last two **G**, the two aromatic hydrogen atoms become magnetically inequivalent at low temperatures, transforming into doublets of doublets: 5.2 and 2.6 G[5] (5.0 and 2.5 G)[7] for **G** = Me_2SnCl, and 8.4 and 0.62 G[6] for **G** = Me_3Si. For the tin-centered **G**, the earlier observations and conclusions have been confirmed by Davies and Hawari,[7] who greatly expanded the number of such tin-containing semiquinone radicals and who also examined the migration dynamics for **G** = Me_2PbCl.[8,9]



D

Values of k_2 and the Arrhenius parameters for reaction 2 have been estimated from EPR line-broadening effects and reported for **G** = Me_2SnCl[5,7] and Me_3Si[6] (see Table 1). The 1,4-shift for **G** = H_3C was too slow to measure.[6] It was concluded that the coordinative unsaturation of tin and silicon facilitates their coordination with a lone pair on the phenoxyl oxygen atom,[10,11] which lowers the barrier for group transfer.[6] It was suggested that Me_2SnCl migrates more slowly than Me_3Sn because the outer electrons of the chlorine interact with the tin d orbitals, reducing the coordinative unsaturation of the tin atom.[6] It is the dynamics of reaction 2 with **G** = Me_2SnCl and **G** = Me_3Si that we hoped to match by DFT computations to further support our hypothesis[1] that an $R_3SnOO^•$ radical has 2 magnetically equivalent oxygen atoms[2] because of a rapid 1,2-shift of the R_3Sn group.

Since line-broadening effects have also been employed to determine the values of k_2 and the Arrhenius parameters for **G** = H[12] and **G** = D[12] (see Table 1), our calculations were extended to cover these two *ortho*-semiquinones.[18–21] Before we describe our computational results, it is important to recognize that there are "oddities" in the reported Arrhenius parameters listed in Table 1 that probably arise from the quite limited temperature range available in EPR line-broadening kinetic measurements. That is, chemical thermodynamics[22] teaches us to "expect" an Arrhenius pre-exponential factor (A) for reaction 2 with **G** = H and **G** = D of ~$10^{13–14}$ s^{-1}. The same value, or possibly a slightly lower value (~$10^{12.5–13.5}$ s^{-1}), should be expected for **G** = Me_2SnCl and **G** = Me_3Si, implying that the experimental values for the former group[5–7] may have been slightly overestimated. The experimental pre-exponential factors for **G** = H and **G** = D are more than one log unit lower than "expected". This suggests that quantum mechanical tunneling may be significant for both H and D transfers at the temperatures investigated, an idea that is supported by the slightly higher value of $\log A_2$ for **G** = D than for **G** = H (see Table 1).

It is also important to keep in mind that theory is not yet capable of predicting Arrhenius parameters with high fidelity to experimental values. Although significant improvements in theoretical methods continue unabated, the exponential sensitivity of kinetic parameters to computed energies makes this a particularly challenging task for computational chemistry. For anything but the smallest systems, a better than order-of-magnitude accuracy from theory cannot (yet) be expected.

We begin with the intramolecular H and D transfer processes. (Analogous intramolecular transfers in diamagnetic systems have been studied by microwave and infrared spectroscopy.[23]) Our calculated values for $\log(A/s^{-1})$ for ***B*→*C*** with **G** = H and **G** = D are about 12.6 and are therefore in reasonable accordance with our "thermochemical expectations", being roughly one log unit larger than the reported values. Computed rate constants, with tunneling corrections obtained using an Eckart approach,[24] are in excellent agreement with experimental values. The computed kinetic isotope effect (k_H/k_D) of 10 with tunneling (4.3 without tunneling) is in very good agreement with the experimental value of 10.7.

In addition to quantum mechanical tunneling, the mechanism for the hydrogen and deuterium exchange must also involve intramolecular proton-coupled electron transfer (PCET).[25] Figure 1*a* shows a side view of ***B*** (**G** = H) showing relevant orbitals. The minimum energy structure of ***B*** has an intramolecular hydrogen bond between the OH group

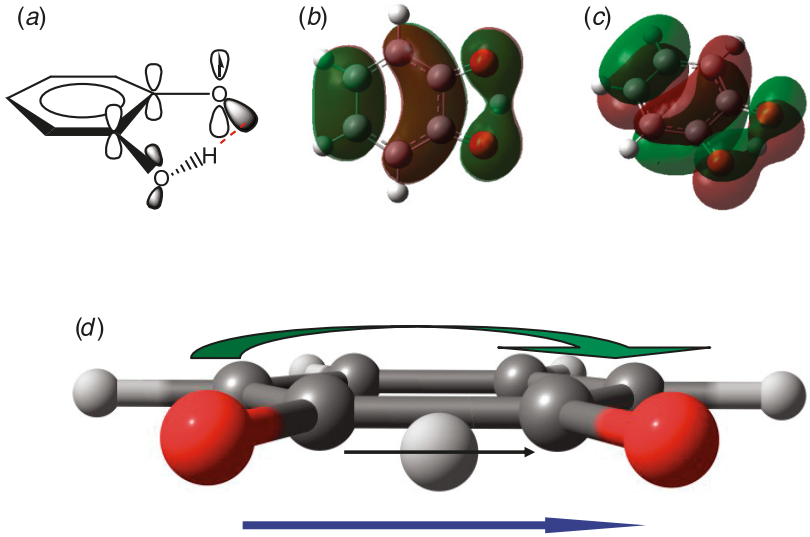
Fig. 1. (*a*) Simplified illustration of the orbitals of the minimum energy structure of ***B*** (di-*tert*-butyl groups omitted). The lone-pair orbitals are shaded gray and singly occupied orbitals are white. The intramolecular hydrogen bond is indicated by the red dashed line, which also indicates the path transited by the proton during the exchange reaction. (*b*) Top-down and (*c*) tilted views of the hydrogen exchange transition state (TS) of an unsubstituted semiquinone with its singly occupied molecular orbital (SOMO). The SOMO is π-type and delocalized across the O···H···O centres as well as through the ring. The colours of the orbital represent its relative phases. (*d*) Side view of a ball-and-stick model of the hydrogen exchange TS of semiquinone. The black arrow indicates the direction of transfer of a proton, the path for which lies in the plane of the ring. The blue arrow shows one possible route of the transferring electron, along a path that is parallel to the path of the proton but out of the plane of the ring. The green, curved arrow shows a second route for the electron, along a path through the ring orbitals and also out of the plane of the ring.



and the lone pair of electrons on the (formal) O• centre. This hydrogen bond lies in the plane of the ring. Hydrogen exchange cannot occur easily via a hydrogen atom transfer (i.e., a proton with its electron) because the lone pair on the "receiving" oxygen atom cannot accept an extra electron. Instead, exchange occurs through a transition state involving a proton transfer from the OH group to the O• across the hydrogen bond. Concurrent with proton transfer, an electron

Fig. 2. Transition state structures for reaction 2 with (*a*) **G** = CH_3, R(H_3C–O) = 2.09 Å, (*b*) **G** = Me_3Si, R(Me_3Si–O) = 1.98 Å, and (*c*) **G** = Me_2SnCl, R(Me_2ClSn–O) = 2.24 Å.

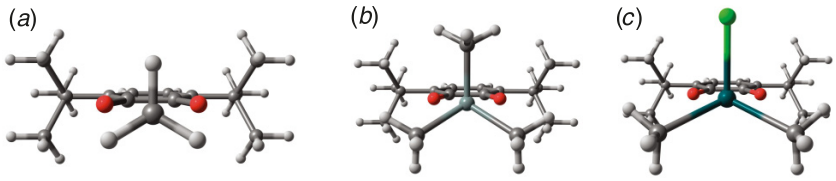

Fig. 3. (*a*) The minimum energy and (*b*) transition state (R(Me_3Sn–O) = 2.27 Å) structures for ***B*** with **G** = Me_3Sn.

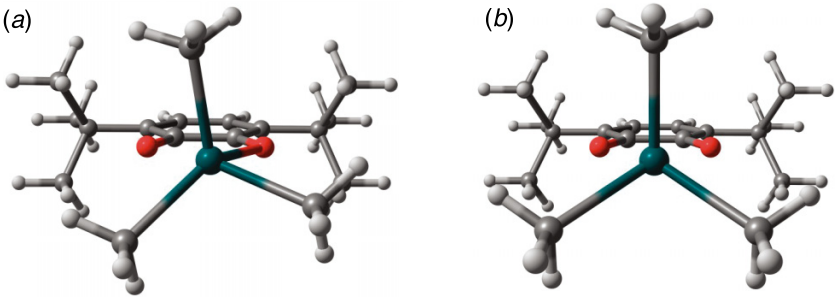

is transferred via the π-type bond involving the O···H···O atoms, which is perpendicular to the ring. This is clearly seen in the singly occupied molecular orbital (SOMO) of the hydrogen exchange transition state (TS) illustrated in Figs. 1*b* and 1*c*. The conjugative delocalization of the O orbitals into the ring provides a second "route" for the electron to take in the PCET process and this is also demonstrated by the SOMO shown in Figs. 1*b* and 1*c*. The path taken by the proton and possible paths used for transferring the accompanying electron are illustrated in Fig. 1*d*. Theory has previously implicated multiple paths for transferring the electron in PCET processes that involve the following bimolecular identity reactions: oxime + iminoxyl,[26] toluene + benzyl, and phenol + phenoxyl.[27]

In principle, processes similar to PCET as described for **G** = H and D in reaction 2 should also occur for other **G**, provided that the central atom in **G** is able to undergo facile valence shell expansion. If this is the case, we may generalize the PCET mechanism to "GCET", or group-coupled electron transfer. It is clear that for **G** = CH_3, GCET is not able to occur. This is simply because pentavalent carbon is energetically highly disfavoured (i.e., there is no energetically low-lying empty orbital on CH_3). The calculations indicate that the O–CH_3 bond would need to lengthen by 0.65 Å to reach the TS structure. Therefore, the barrier to group transfer is very high and results in a very low rate constant. A picture of the TS associated with reaction 2 for **G** = CH_3 is shown in Fig. 2*a*.

Additional calculations indicate that the barrier associated with hydrogen atom transfer from **G** = CH_3 to the (formal) O• is much more likely than group transfer. The activation barrier for this endothermic process is predicted by theory to be about 25.5 kcal/mol.

The calculated kinetic parameters with **G** = Me_3Si are in very gratifying agreement with experimental values. To reach the TS (see Fig. 2*b*), the O–$SiMe_3$ bond must lengthen by approximately 0.25 Å. This results in a much lower barrier height and larger rate constant for transfer with **G** = Me_3Si than for transfer with **G** = CH_3. A detailed examination of the reaction coordinate reveals that the TS can be reached by rotation of the $SiMe_3$ group about the Si–O bond. The resultant steric repulsion between the methyl groups on **G** and the neighbouring *tert*-butyl substituent is then sufficiently high that the Me_3Si–O bond is lengthened to the TS value.

For **G** = Me_2SnCl, the predictions made by theory are in somewhat poorer agreement with experimental data. However, the calculated log(A/s^{-1}) is in line with thermochemical expectations, vide supra. Calculations predict a rather small activation energy of 5.3 kcal/mol, which contributes to the large rate constant. The minimum energy structure of ***B*** with **G** = Me_2SnCl has the chlorine atom pointed toward the adjacent *tert*-butyl group. To reach the TS (Fig. 2*c*), the Me_2(Cl)Sn group must rotate by about 90° while the Me_2(Cl)Sn–O bond must lengthen by about 0.09 Å.

The case of **G** = Me_3Sn is particularly interesting. The calculations indicate that ***B*** (**G** = Me_3Sn) has an asymmetric energy minimum wherein there is no Me–Sn bond exactly perpendicular to the plane of the aromatic ring (Fig. 3*a*). This minimum energy structure produces all positive vibration frequencies, verifying that it is indeed a minimum on the potential energy surface. Similarly, the TS structure, shown in Fig. 3*b*, was verified as such with the calculations giving one imaginary frequency associated with group transfer (reaction 2). The magnitude of the imaginary frequency is only 37.8 cm^{-1}, indicating that reaching the TS requires very little energy. In fact, the Me_3Sn–O bond length in the minimum energy structure only needs to be lengthened by about 0.03 Å to reach its TS length. Vibrational analyses and potential energy surface scans show that the TS can be reached from the minimum energy structure by a slight rotation of the Me_3Sn group about the Sn–O bond, as is evident upon examination of Fig. 3. Inclusion of thermal corrections (293 K) to the electronic energies results in a predicted E_a of 0.70 kcal/mol. This calculated E_a value is too small to be reliable but it does imply that transfer of the **G** = Me_3Sn group is extremely facile, in accordance with the experimental observations.[28,29] Moreover, theory indicates that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

minimum energy structure should be represented by ***B*** and not by ***D***, which is also in accordance with the conclusions reached by Prokof'ev et al.[6] on the basis of EPR spectral evidence, vide supra.

The present calculations are in sufficiently good agreement with experimental data that it is fairly safe to conclude that we have been employing appropriate methodology to study these kinds of dynamic processes and they therefore provide additional support for our earlier conclusion[1] that the R_3Sn group in $R_3SnOO^{\bullet}$ radicals undergoes such a fast 1,2-shift that the two oxygen atoms are magnetically equivalent on the EPR time scale.

(10) In this connection, it has recently been demonstrated that oxygen-centered radical attack on alkyl and aryl borane substrates does not occur by a traditional S_H2 process.[11] Instead, it involves a nucleophilic attack of an oxygen lone pair on the empty boron p orbital. The unpaired electron on the oxygen is not directly involved, but the boron–ligand bond aligned with the SOMO cleaves and the ligand leaves promptly. The mechanism was described as a nucleophilic homolytic substitution at boron.

(18) It has been reported that "solvents capable of forming hydrogen bonds" retard the rate of reaction 2 for **G** = H.[4a] This is to be expected because phenols containing intramolecular H bonds are capable of forming bifurcated intra/intermolecular H bonds,[19] which reduces the rates of H-atom abstraction[20] just as intermolecular H bonding reduces the rates of abstraction from simple phenols.[21] Fortunately, the experiments in question[4a] were done in heptane, which is neither an H-bond donor nor acceptor, so the kinetic measurements should be directly comparable with the computed dynamics.

Abstract: The mechanisms of the reactions of diphenylgermylene ($GePh_2$) with CCl_4 in hydrocarbon solvents and in THF solution have been studied, employing 3,4-dimethyl-1,1-diphenylgermacyclopent-3-ene (**6a**) and 1,1-diphenylgermacyclobutane (**17**) as photochemical precursors to $GePh_2$. In hydrocarbon solvents, the reaction produces Ph_2GeCl_2 (**10**) and $Ph_2Ge(Cl)CCl_3$ (**12**) in a ratio of **10**:**12** $\approx$ 7, along with a variety of other radical-derived products and small amounts of $Ph_2GeH(D)Cl$ (**11**), which is formed partly by reaction of $GePh_2$ with adventitious HCl. The reaction is much cleaner in THF, where **12** is formed as the major product (**10**:**12** $\approx$ 0.8); a similar product distribution is obtained in hexanes containing 0.05 mol/L THF, while **12** is the exclusive product in hexanes containing 3 mmol/L NEt_3. Rate constants for the reactions of CCl_4 with $GePh_2$ and five ring-substituted derivatives were determined by laser flash photolysis, as well as Arrhenius parameters for reaction of the parent ($GePh_2$), in the two solvents. The reactions of $GePh_2$ with CCl_4 and $CHCl_3$ have also been studied in 3-methylpentane solution at 78–90 K. Different reaction mechanisms are clearly operative in hydrocarbon and complexing solvents, but both involve modest charge donation from germanium to the substrate in the transition state for the rate-determining step. For the reaction in hydrocarbon solvents, the data are consistent with inner-sphere electron transfer following or in concert with weak Lewis acid–base complexation. A similar mechanism is proposed for the reaction in THF solution, in competition with a second involving nucleophilic attack of the germylene–THF complex at a chlorine atom of the substrate. Rate constants were also determined for reaction of CCl_4 with the corresponding tetraaryldigermenes at low halocarbon concentrations in hexanes, along with Arrhenius parameters for the parent (Ge_2Ph_4). These reactions also proceed via initial Cl-atom abstraction, based on the identity of the products formed in the reaction of CCl_4 with tetramesityldigermene.

Key words: germylene, halocarbon, free radical, kinetics, abstraction, electron transfer.

Résumé : On a étudié les mécanismes des réactions du diphénylgermylène ($GePh_2$) avec le CCl_4, dans des solvants hydrocarbonés, en utilisant les 3,4-diméthyl-1,1-diphénylgermacyclopent-3-ène (**6a**) et 1,1-diphénylgermacyclobutane (**17**) comme précurseurs photochimiques du $GePh_2$. Dans les solvants hydrocarbonés, la réaction conduit à la formation de Ph_2GeCl_2 (**10**) et de $Ph_2Ge(Cl)CCl_3$ (**12**) dans un rapport **10**:**12** approximativement égal à 7, aux côtés d'une variété d'autres produits dérivés de radicaux et de faibles quantités de $Ph_2GeH(D)Cl$ (**11**) dont la formation résulte en partie d'une réaction adventice avec du HCl. La réaction dans le THF est beaucoup plus propre et elle la formation du produit **12** est majoritaire (**10**:**12** = 0,8); on obtient une distribution de produit semblable dans les hexanes contenant 0,05 mol/L de THF alors que le produit **12** est le produit exclusif dans les hexanes content 3 mmol/L de NEt_3. Les constantes de vitesse des réactions du CCl_4 avec le $GePh_2$ et les dérivés de cycles à cinq chaînons substitués ont été déterminées par photolyse éclair au laser et on a aussi déterminé les paramètres d'Arrhenius de la réaction du germylène parent, $GePh_2$, dans les deux solvants. On a aussi étudié les réactions du $GePh_2$ avec le CCl_4 et le $CHCl_3$, en solution dans le 3-méthylpentane et à des températures allant de 78 à 90 K. Il est clair que divers mécanismes de réaction interviennent dans l'hydrocarbure et les solvants complexants, mais les deux comportent une étape cinétiquement déterminante de l'état de un état de transition qui implique un modeste transfert de charge du germanium vers le substrat. Les paramètres d'Arrhenius pour la réaction du germylène libre dans les hexanes indiquent que l'état de transition est bien structuré mais faiblement lié; les données sont en accord avec un transfert d'électron dans la sphère interne à la suite de, ou de concert avec, une faible complexation acide–base de Lewis. On propose un mécanisme similaire pour la réaction en solution dans le THF; il serait en compétition avec un autre impliquant une attaque nucléophile du complexe germylène–THF au niveau de l'atome de chlore du substrat. On a aussi déterminé les constantes de vitesse pour la réaction du CCl_4 avec les tétraaryldigermènes correspondants à des faibles concentrations d'halocarbones dans les hexanes et on a aussi déterminé les paramètres d'Arrhenius pour le (Ge_2Ph_4) parent. Sur la base de l'identité des produits qui se forment dans la réaction du CCl_4 avec le tétramésityldigermène, ces réactions se produisent aussi par le biais d'un enlèvement initial d'un atome de chlore.

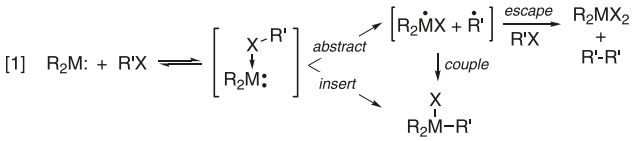
Introduction

There has been great interest over the past few decades in the chemistry of silylenes and germylenes, the silicon and germanium analogues of singlet carbenes, respectively. Much of this has been directed toward the synthesis and study of the structures and reactivities of isolable derivatives,[1–7] which owe their stabilities to electronic stabilization and (or) steric protection of the divalent group 14 atom by substituents. The dimerization process that these effects inhibit occurs at rates within a factor of about 10 of the diffusional limit in solution in the cases of simpler "tetrylenes" such as the dimethyl-, diphenyl-, and dimesityl-substituted derivatives.[8–12] These simpler derivatives and the parent dihydrides (SiH_2 and GeH_2) thus require fast time-resolved spectroscopic methods to be studied directly,[13] but they can be expected to provide a more precise definition of the range of chemical behavior inherent to silicon and germanium in their divalent states. They are also key intermediates in many thermal and photochemical reactions of organosilicon[14,15] and –germanium[16,17] compounds and are important ligands in a number of metal-catalyzed processes.[18]

Tetrylenes bearing hydrido or simple alkyl or aryl substituents are voracious electrophiles, reacting exceedingly rapidly with even weak nucleophiles such as alcohols and alkenes.[9,11,13,19–23] The large majority of the reactions these species undergo, particularly those with heteroatom (i.e., O–, N–, S–, etc.) containing substrates, are thought to begin with the formation of a Lewis acid–base complex between the tetrylene and the substrate.[4] Indeed, transient silylene-[9,19,22–25] and germylene-[20,21,25–27] donor complexes have been detected directly in a large number of instances, both in low-temperature matrix experiments and in solution at ambient temperatures by laser flash photolysis methods. Complexation with a nonreactive Lewis base such as THF reduces the reactivity of the tetrylene toward both dimerization and reactions with other substrates that require access to the vacant p orbital on the (ground-state singlet) tetrylene to proceed.[19,28–31] Complexation can also be expected to increase the nucleophilic character of the tetrylene, and hence promote reactions with electrophilic substrates that might be relatively unreactive toward the free species.[30,32–36]

The reactions of silylenes[3–5] and germylenes[4,16] with halocarbons are particularly fascinating, as they proceed in one of two directions depending on the halocarbon: C–X insertion and X-atom abstraction. Singlet carbenes behave similarly.[37,38] Halogen atom abstraction is the main process that occurs with benzyl halides and carbon tetrachloride, whereas C–X insertion predominates with allyl, vinyl, and (in the case of silylenes) aliphatic halides. Again, the reactions are generally thought to proceed via an initially formed tetrylene–halocarbon Lewis acid–base complex, which can then react by concerted insertion into the C–X bond or by homolytic C–X cleavage to form the corresponding singlet radical pair via an electron transfer process (eq. [1]).[3,39] The caged radical pair either couples to generate the formal R′–X insertion product or undergoes cage escape; the resulting halosilyl or halogermyl free radical then abstracts a halogen atom from a second molecule of the halocarbon to form the corresponding dihalosilane or –germane. Interestingly, the reaction of $GeMe_2$ with CCl_4 also proceeds in THF solution, with a rate constant only slightly smaller than that for reaction with the free germylene in hydrocarbon solvents.[30] While product studies were not carried out, it is relevant to note that the reaction of $GeMe_2$ with CCl_4 is known to afford the C–Cl insertion product essentially exclusively in the presence of catalytic amounts of triphenylphosphine.[40] This suggests that the presence of a "spectator" donor opens up yet another mechanistic pathway for reaction of the germylene with this halocarbon.



The reactions of halocarbons with disilenes[41,42] and digermenes,[43–45] the M=M doubly bonded dimers of silylenes and germylenes, respectively, also appear to proceed via initial halogen atom abstraction in most known cases. Kira et al.[42] carried out a detailed experimental study of the reactions of a series of three kinetically stable tetrasilyldisilenes (**1**) with CCl_4, $CHCl_3$, and various other chloro- and bromocarbons in hexane solution (eq. [2]), and found the product distributions and rate constants to vary systematically as a function of both the halocarbon and steric bulk in the disilene. Through a combination of kinetic, electron paramagnetic resonance (EPR), and electrochemical studies on these systems, they concluded that the reaction proceeds by simple chlorine atom abstraction to generate the corresponding halodisilanyl and R′ radicals (eq. [3]), which they proposed is promoted by a significant degree of 1,2-biradical character of the Si=Si bond. Mochida et al.[43] reported the major product of the reaction of (transient) tetramethyldigermene (Ge_2Me_4) with CCl_4 to be the corresponding 1,2-dichlorodigermane (**4**), whereas Baines and co-workers[45] isolated the formal Cl–R′ addition product (**5**) from the reaction of the sterically stabilized digermene Ge_2Mes_4 with $CHCl_3$ (eq. [3]). A similar difference in product distribution was also observed by Kira et al.[42] for the reactions of tetrasilyldisilenes **1a** and **1b** with these two halocarbons, CCl_4 being the more reactive of the two by roughly three orders of magnitude. The reactions of several simple disilenes and digermenes with CCl_4 have been studied computationally by Su,[46] the results of which indicate that Cl abstraction is indeed the lowest energy reaction pathway in these systems.

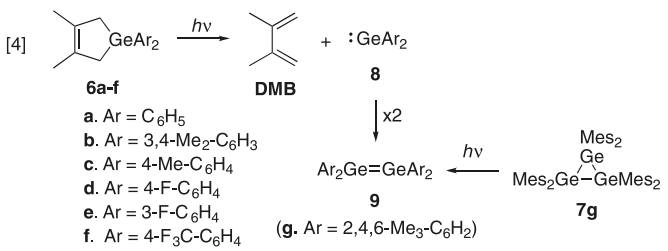
Kinetic studies of the reactions of CCl_4 with Ge_2Me_4,[11,43] Ge_2Et_4,[43] $(GeMePh)_2$,[47] and Ge_2Ph_4[20] in hydrocarbon solvents reveal a ca. 20-fold span in the rate constants, which decrease in the order $k_{Ge_2Et_4} \approx 2k_{Ge_2Me_4} \approx 6k_{GeMePh_2} \approx 20k_{Ge_2Ph_4}$. The trend may be indicative of a modest degree of charge transfer from the Ge=Ge bond to the halocarbon in the transition state for Cl abstraction, as Kira et al.[42] concluded from a kinetic study of the reactions of a series of substituted benzyl chlorides with disilene **1c**.

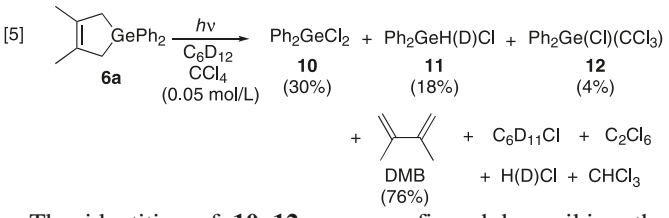
In the present paper, we report the results of product, kinetic, and low-temperature spectroscopic studies of the reactions of $GePh_2$ and its (digermene) dimer (Ge_2Ph_4) with CCl_4 in hexanes and THF solution, which was carried out with the goal of elucidating the detailed mechanisms of these reactions in both noncomplexing and (for $GePh_2$) complexing solvents. Arrhenius parameters have been determined, and the role of electronic factors in the transition states for the rate-determining steps of these reactions have been assessed through an examination of the effect of polar ring substituents on the absolute rate constants. As in earlier kinetic studies,[27,30,48] we employed the substituted 1,1-diaryl-3,4-dimethylgermacyclopent-3-enes **6a–6f** as photochemical precursors to the corresponding diarylgermylenes (**8a–8f**) and tetraaryldigermenes (**9a–9f**; eq. [4]), each pair of which can be studied in the same experiment. It is not practical to carry out product studies of the digermene reactions using these precursors because formation of the digermene requires dimerization of the significantly more reactive germylene, so tetramesityldigermene (**9g**) has been employed as a model compound. The latter was generated by low-temperature photolysis of hexamesitylcyclotrigermane (**7g**).[49,50]



Results

Product studies

Steady-state photolyses of deoxygenated solutions of **6a** (0.02 mol/L) in C_6D_{12} containing varying initial concentrations of CCl_4 (0.02–0.5 mol/L) and hexamethyldisilane (ca. 0.002 mol/L; internal standard) were monitored over the 0%–10% conversion range (in **6a**) by ^1H NMR spectroscopy and GC–MS, which allowed the identification of chlorogermanes **10–12** (eq. [5]), DMB, chlorocyclohexane-d_{11}, chloroform, and trace amounts of hexachloroethane (C_2Cl_6). The yields of DMB and **10–12** were determined relative to consumed **6a** from the slopes of concentration vs time plots, constructed for the five compounds from the NMR integrals. Significant amounts of unidentified products giving rise to resonances in the allylic (δ 3.4–3.7) and aliphatic (δ 1.5–2.2) regions of the NMR spectrum were also detected; their yields relative to the other products increased with increasing photolysis times, consistent with them being derived from (secondary) radical reactions involving (mainly) DMB, whose concentration vs time plots displayed significant downward curvature. Broad baseline absorptions in the aromatic region of the NMR spectra were also observed and became more pronounced with increased photolysis times, consistent with the formation of oligomeric material containing phenyl groups. The yields of these unidentified materials increased with increasing initial CCl_4 concentration, as did the severity of the curvature in the concentration vs time plots for DMB. This suggests that they arise to a large extent from secondary radical reactions resulting from photolysis of CCl_4,[51–53] which absorbs weakly at 254 nm (ε_{254nm} = 0.44 $(mol/L)^{-1}$ cm^{-1} compared with ε_{254nm} = 340 $(mol/L)^{-1}$ cm^{-1} for **6a**). Indeed, H(D)Cl was also detected qualitatively in the photolyzed mixtures in the head space above the solutions. Table 1 lists the yields of **10–12** and DMB (the latter calculated from the initial slopes of the curved plots) that were obtained in the experiments using initial CCl_4 concentrations in the 0.02–0.1 mol/L range (see Supplementary data).



The identities of **10–12** were confirmed by spiking the photolyzed mixtures with independently prepared authentic samples. Compound **12** was prepared by reaction of 2 equiv of PhMgBr with **13**[55] (eq. [6]), and was obtained as a viscous, moisture-sensitive liquid. Unintentional hydrolysis of the compound afforded germanol **14** (eq. [7]), whose structure was determined by single crystal X-ray crystallography (see Supplementary data). The crystallographic data are of fairly low quality, but nevertheless clearly establish the connectivity and identity of the compound.

Table 1. Product yields (%) from 254 nm photolysis of 3,4-dimethyl-1,1-diphenylgermacyclopent-3-ene (**6a**; 0.02 mol/L) with CCl_4 in deoxygenated C_6D_{12} or THF-d_8 solution under various conditions.

		Product yields (%)				
Solvent	$[CCl_4]$ (mol/L)	Ph_2GeCl_2 (**10**)	$Ph_2GeH(D)Cl$ (**11**)	$Ph_2Ge(Cl)CCl_3$ (**12**)	DMB	%D (**11**)
C_6D_{12}	0.02	20±4	22±3	3.3±0.7	96±6	67
C_6D_{12}	0.05	30±5	18±3	4.1±0.7	76±6	56
C_6D_{12}	0.10	33±4	27±4	3.9±0.5	78±8	44
THF-d_8	0.05	33±4	20±5	49±6	87±7	25

[7] $Ph_2Ge(Cl)CCl_3$ (**12**) $\xrightarrow[-HCl]{H_2O}$ $Ph_2Ge(OH)CCl_3$ (**14**)

Chlorodiphenylgermane (**11**) was readily recognizable in the NMR spectra of the photolysis mixtures owing to its characteristic Ge–H resonance at δ 6.76, which was present even after ca. 1% conversion of **6a**; its intensity relative to those of the (ortho) aromatic protons indicated the compound was ca. 50% deuterated. The concentration vs time plots for this product exhibited good linearity throughout the (ca. 10%) conversion range in most experiments, but exhibited mild upward curvature in those carried out at higher (>0.1 mol/L) CCl_4 concentrations. The yield of the compound relative to the other products also increased with increasing CCl_4 concentration >0.05 mol/L. One possible route for the formation of the compound is by reaction of $GePh_2$ with H(D)Cl,[56] produced by H(D) abstraction by chlorine atoms formed by competing photolysis of CCl_4. Indeed, photolysis of a solution of **6a** (0.04 mol/L) in C_6D_{12} saturated with HCl(g) resulted in the clean formation of **11** and DMB in high yields (eq. [8]). This mechanism is consistent with the significantly higher yields of the product that were obtained in runs carried out with the higher CCl_4 concentrations, where >0.5% of the incident light is absorbed by the halocarbon. HCl might also be formed by hydrolysis of **10** or **12** by water introduced inadvertently throughout the course of the photolysis; this seems a less likely possibility, but it cannot be ruled out.

[8]  (**6a**) $\xrightarrow[C_6D_{12}, HCl\ (sat)]{h\nu}$ Ph_2GeHCl (**11**) (83 ± 3%) + DMB (80 ± 2%)

Photolysis of **6a** (0.02 mol/L) in THF-d_8 containing CCl_4 (0.05 mol/L) afforded the same products as were obtained in C_6D_{12}, but the material balance was considerably higher and the formal C–Cl insertion product (**12**) was formed as the major product (eq. [9]) (see Supplementary data). The broad baseline absorptions in the aromatic region of the NMR spectrum were much less pronounced, the unidentified resonances in the δ 1.5–2.2 and δ 3.4–3.7 regions of the spectrum were absent, and the concentration vs time plot for DMB exhibited only slight nonlinearity over the 0%–10% conversion range in **6a**, indicating a significantly smaller contribution to the overall product distribution from radical-derived side reactions. The yield of **11** (relative to **11**-*d*) was also higher than in the C_6D_{12} photolyses, which we interpret as being due mainly to increased amounts of HCl being formed during the experiment. This could be due in part to hydrolysis of the other chlorogermane products by adventitious water in the solvent, the presence of which could be detected by NMR. The water peak broadened throughout the course of the experiment, an effect consistent with the formation of HCl in the product mixture,[57] and the concentration vs time plot for **11** exhibited upward curvature. These observations are all consistent with the main source of **11** (in this experiment) being via reaction of $GePh_2$ with HCl.

[9] (**6a**) $\xrightarrow[CCl_4\ (0.05\ mol/L)]{h\nu,\ THF\text{-}d_8}$ Ph_2GeCl_2 (**10**) (26%) + Ph_2GeHCl (**11**) (22%) + $Ph_2Ge(Cl)(CCl_3)$ (**12**) (35%) + DMB (80%)

A similar product distribution was obtained upon photolysis of a cyclohexane solution of **6a** (0.02 mol/L) containing CCl_4 (0.05 mol/L) and THF (0.06 mol/L), which afforded **10** and **12** in an approximate 1:1 ratio, according to GC–MS analysis of the mixture. Another experiment employing the same concentrations of **6a** and CCl_4 in cyclohexane containing triethylamine (NEt_3, 0.003 mol/L) afforded **12** as the major germanium-containing product, and only trace amounts of **10** and **11** could be detected by GC–MS.

The course of the reaction of CCl_4 with tetramesityldigermene (**9g**) was also studied, following the reported procedure for the synthesis of the digermene by low-temperature photolysis of hexamesitylcyclotrigermane (**7g**; 1.3 mmol/L) in deoxygenated toluene containing triethylsilane.[45,58] Addition of a cold solution of CCl_4 in toluene to a preprepared solution of **9g** at –40 °C ($[CCl_4] \approx 0.35$ mol/L) caused the characteristic yellow colour of the digermene to decolourize within a few seconds. The solvent was evaporated and the ^1H NMR spectrum of the residue showed evidence for the formation of several products (see Supplementary data), amongst which 1,2-dichlorotetramesityldigermane (**15**; eq. [10]) was identified by spiking the mixture with an independently prepared sample.[59] The yield of **15** was estimated to be ~20% from the contribution of the area of its aromatic proton resonance to the total area of the aromatic proton region of the spectrum (δ 6.50–8.85), excluding the contributions from residual **7g** and $Mes_2Ge(H)SiMe_3$.[60] Attempts to identify the other products by GC–MS allowed only C_2Cl_6 (in trace amounts) to be unambiguously identified in the mixture.

[10] $Mes_2Ge{=}GeMes_2$ (**9g**) $\xrightarrow[\text{-40 °C}]{CCl_4,\ \text{toluene}}$ $Mes_2Ge(Cl)-Ge(Cl)Mes_2$ (**15**, ca. 20%) + C_2Cl_6 + other products

Only trace amounts of **15** could be detected in the product mixture obtained in a similar experiment employing $CHCl_3$ as substrate. In this case, addition of a cold solution of $CHCl_3$ to a toluene solution containing **9g** at –40 °C ($[CHCl_3] \approx 0.8$ mol/L) resulted in no change in the yellow colour of the solution, even after standing at –40 °C for 30 min. Raising the temperature to ca. –20 °C caused the yellow colour to disappear within ~5 min. The ^{1}H NMR spectrum of the evaporated mixture was similar to that described previously by Baines and co-workers,[45] and verified the formation of compound **16** (eq. [11]) as the major product of the reaction of the digermene with $CHCl_3$.

[11] $Mes_2Ge{=}GeMes_2$ (**9g**) $\xrightarrow[\text{-20 °C}]{CHCl_3,\ \text{toluene}}$ $Mes_2Ge(Cl)-Ge(CHCl_2)Mes_2$ (**16**, ca. 25%) + other products

Laser flash photolysis studies

Laser flash photolysis experiments were carried out using flowed, deoxygenated solutions of **6a**-**6f** (ca. 0.003 mol/L) in anhydrous hexanes and the pulses from a KrF excimer laser (~25 ns, ~100 mJ, 248 nm) for excitation. The behaviour observed for the six compounds in the absence of added CCl_4 has been described previously.[10,27,30,48] Briefly, the photolysis pulse results in the prompt formation of the characteristic absorptions owing to the corresponding transient diarylgermylenes (**8a**–**8f**; λ_{max} = 300 nm and 480–500 nm), which decay with second-order kinetics with the concomitant growth of absorptions centered at ca. 440 nm owing to the corresponding digermenes (**9a**–**9f**). In each case, addition of CCl_4 causes the decay of the germylene absorptions (monitored at 500 nm) to accelerate and produces concomitant reductions in the maximum signal intensities and apparent lifetimes of the digermene absorptions, as we reported previously for **6a**.[20] The digermenes could be detected and their decay kinetics characterized in the presence of lower concentrations of CCl_4, over a range that varied depending on the reactivity of its germylene precursor toward the substrate. The germylenes remained detectable at much higher (0.1–1.0 mol/L) CCl_4 concentrations, where their decays proceeded completely to baseline and followed clean first-order kinetics. Rate constants for reaction of CCl_4 with each of the germylenes (**8a**–**8f**) and the corresponding digermenes (**9a**–**9f**) were obtained from the slopes of plots of the first-order decay rate coefficients (k_{decay}) vs [CCl_4] according to eq. [12], where k_0 is the hypothetical pseudo-first-order rate coefficient for decay of the monitored species in the absence of substrate and k_{CCl_4} is the second-order rate constant for reaction with the substrate, respectively. These plots exhibited good to excellent linearity in each case (see Supplementary data). For example, Fig. 1 shows selections of representative transient absorbance vs time profiles obtained for digermene **9c** and germylene **8c** in the presence of varying amounts of CCl_4, along with the corresponding plots of k_{decay} vs [CCl_4] as insets. The absolute rate constants obtained in the experiments with the six compounds are listed in Table 2; the values obtained for **8a** and **9a** are in excellent agreement with the previously reported values.[20]

$$[12] \qquad k_{decay} = k_0 + k_{CCl_4}[CCl_4]$$

Co-absorption of the excitation light by the substrate (ε_{248nm} = 1.23 mol/L^{-1} cm^{-1} for CCl_4, compared with ε_{248nm} = 290 mol/L^{-1} cm^{-1} for **6a**) was impossible to avoid in these experiments, and so a control experiment was carried out to assess the possible contributions to the germylene and digermene decay kinetics owing to the formation of HCl, trichloromethyl, and solvent-derived radicals[61,62] within the reaction volume owing to competing CCl_4 photolysis. We chose germacyclopentene **6d** for the experiment because the corresponding germylene and digermene exhibit reactivity toward CCl_4 that is roughly in the middle of the ranges exhibited by the six germylenes and corresponding digermenes that were studied in this work. Decay rate coefficients were determined for **8d** and **9d** at several CCl_4 concentrations between 0.03 and 0.5 mol/L as a function of excitation laser intensity, on which the concentrations of these CCl_4-derived species should depend. The decay rate coefficients for both species were found to be approximately constant over a two- to four-fold range in laser intensity at each CCl_4 concentration that was examined, indicating that co-absorption of the excitation light by the substrate has minimal effects on the measured rate constants for reaction of CCl_4 with **8a**–**8f** and **9a**–**9f** owing to the presence of HCl, CCl_3, and solvent-derived radicals produced in the laser pulse. The presence of CCl_4 did cause modest reductions in the intensities of the transient signals, but no more than would be expected because of simple screening of the excitation light by the substrate. It can thus be further concluded that CCl_4 does not quench the excited (singlet) states of **6a**–**6f** within the concentration ranges that were studied.

A transient absorption spectrum recorded with a solution of **6a** in hexanes containing 0.5 mol/L CCl_4, conditions under which the lifetime of $GePh_2$ is reduced to $\tau \approx$ 165 ns and digermene formation is completely suppressed, showed no difference in the relative intensities of the $GePh_2$ absorption maxima (500 and ca. 300 nm) compared to those in the absence of added substrate, and no new absorptions (transient or stable) that could be ascribed to intermediates or products of reaction of $GePh_2$ with the halocarbon.

We also attempted to measure a rate constant for the reaction of CCl_4 with tetramesityldigermene (**9g**) in hexanes, employing **7g** (1.3×10^{-5} mol/L) as precursor. Laser photolysis of **7g** produces the strong absorptions owing to **9g** (λ_{max} = 405 nm) both within the laser pulse and (in the absence of added substrates) over a 20–30 μs time period after the pulse owing to dimerization of $GeMes_2$ (**8g**), the photolysis co-product;[63] the latter was not monitored in these experiments. Addition of small amounts of CCl_4 to the solution caused the signal owing to **9g** to decay, exhibiting lifetimes that decreased from ca. 1.4 to 0.8 ms over the 1.3–5 mmol/L concentration range in added halocarbon. A plot of k_{decay} vs [CCl_4] afforded k_{CCl_4} = (2.0 ± 0.1) × 10^5 (mol/L)$^{-1}$ s^{-1} (see Supplementary data), which should be considered an upper limit of the true value; the lifetimes showed a modest dependence on laser intensity, suggesting

they may be affected by competing photolysis of the substrate, as discussed above.

Laser photolysis experiments with **6a**–**6f** in deoxygenated THF solution afforded the strong, long-lived transient absorptions owing to the corresponding germylene–THF complexes, as reported previously for **6a**, **6c**, **6d**, and **6f**.[30] The spectra and lifetimes measured for the THF complexes with **8b** and **8e** (see Supplementary data) were quite similar to those of the other four; the complexes exhibited absorption maxima in the 340–350 nm range and decayed over several tens of microseconds, coincident with the growth of weak absorptions (centered at 440 nm) owing to the corresponding digermenes.[30] Addition of 0.01–0.4 mol/L CCl_4 to the solutions caused the absorptions owing to the complexes to decay with clean pseudo-first-order kinetics and quenched the formation of the corresponding digermenes; again, plots of k_{decay} vs [CCl_4] according to eq. [10] were linear in each case (see Supplementary data), and afforded the absolute rate constants listed in Table 2. Figure 2*a* shows a series of representative transient decay profiles for the **8a**–THF complex at various substrate concentrations, whereas Fig. 2*b* shows the plot of k_{decay} vs [CCl_4]. Chloroform was also found to shorten the lifetime of the **8a**–THF complex, and a plot of k_{decay} vs [$CHCl_3$] was linear with slope k_{CHCl_3} = (2.4 ± 0.5) × 10^4 (mol/L)$^{-1}$ s^{-1} (see Supplementary data).

Rate constants were determined at four additional temperatures over the 10–60 °C range, for the reactions of CCl_4 with **8a** and **9a** in hexanes and with the **8a**–THF complex in THF (see Supplementary data). The resulting Arrhenius plots afford activation parameters of E_a = –0.7 ± 0.7 kcal/mol (1 cal = 4.184 J) and log(A/(mol/L)$^{-1}$ s^{-1}) = 6.5 ± 0.5 for the reaction of free **8a** in hexanes, E_a = +4.3 ± 0.8 kcal/mol and log(A/(mol/L)$^{-1}$ s^{-1}) = 9.6 ± 0.6 for that of **9a** in hexanes, and E_a = +5.9 ± 0.4 kcal/mol and log(A/(mol/L)$^{-1}$ s^{-1}) = 10.9 ± 0.3 for the reaction of the **8a**–THF complex in THF. Figure 3*a* shows the plots for **8a** (in hexanes) and **8a**–THF (in THF) and that for **9a** in hexanes is shown in Fig. 3*b*.

Low-temperature spectroscopic studies

A study of the reactions of $GePh_2$ (**8a**) with CCl_4 and $CHCl_3$ in 3-methylpentane (3-MP) solution at 78–95 K was also carried out. These experiments employed 1,1-diphenylgermacyclobutane (**17**) as the photochemical precursor to $GePh_2$, which is produced in ca. 20% chemical yield along with cyclopropane, 1,1-diphenylgermene (**18**; 60%), and ethylene from photolysis of this compound in hexanes at 25 °C (eq. [13]).[64] We anticipated that $GePh_2$ should be detectable from **17** under these conditions since its co-product (cyclopropane) is inert; we have previously shown that the photolysis of **6a** in low-temperature glasses does not afford

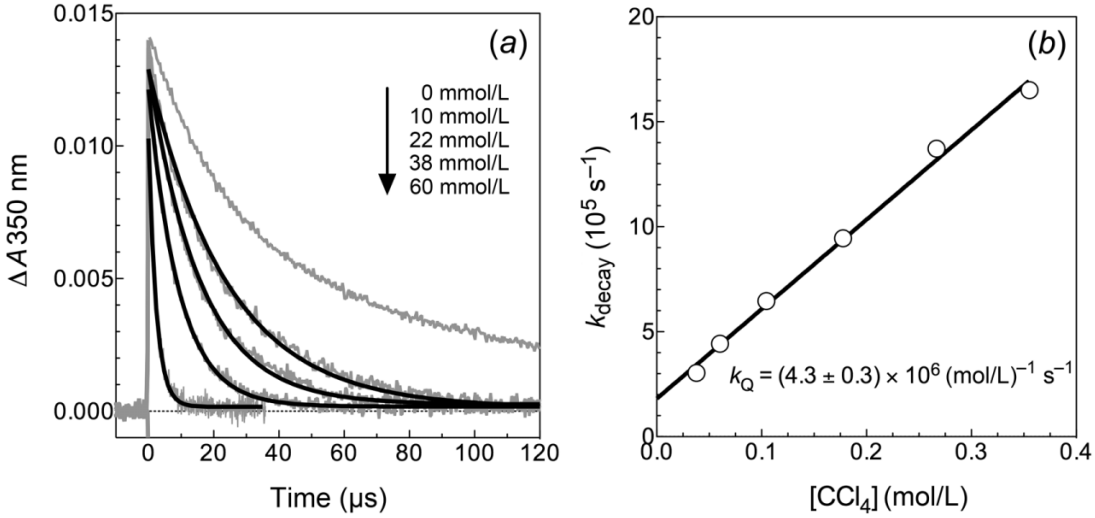

Fig. 3. Arrhenius plots for the reactions of CCl_4 with (*a*) $GePh_2$ (**8a**) in deoxygenated hexanes (○) and the **8a**–THF complex in THF (□), and (*b*) Ge_2Ph_4 (**9a**) in hexanes (○), determined by laser photolysis of **6a** over the range of 10–60 °C.

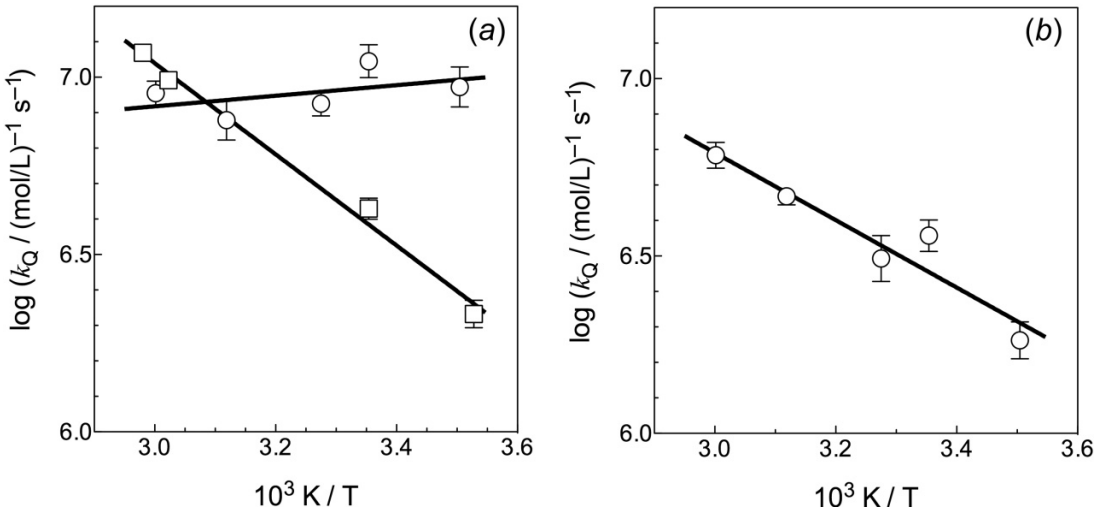

$GePh_2$ in detectable amounts owing (presumably) to rapid reaction with DMB in the solvent cage.[65]

[13] Ph_2Ge□ (**17**) $\xrightarrow{h\nu}$ $GePh_2$ + △ (**8a**, ~ 20%) + $Ph_2Ge{=}CH_2$ + $H_2C{=}CH_2$ (**18**, ~ 60%)

As expected, photolysis of a solution of **17** in 3-MP (glass transition temperature ≈ 77 K[66]) at 78 K afforded two distinct transient products that were detectable by low-temperature UV–vis spectroscopy, one exhibiting λ_{max} = 460 nm and a second exhibiting a shoulder absorption centred at 326 nm, on the edge of an intense band centred below 300 nm (see Fig. 4*a*). The absorption at 326 nm is assigned to germene **18**,[64,67] whereas the 460 nm absorption band is assigned to $GePh_2$. The latter spectrum agrees well with those obtained in low-temperature experiments using other precursors, such as the known disilylgermane **19**[26,68] and disilyldigermane **20**.[69] The solution was then warmed in 1 K increments and a spectrum was recorded at each temperature. At ca. 82 K the 460 nm absorption band began to decrease in intensity slightly and shift to longer wavelengths, ending up finally at λ_{max} = 474 nm; the spectrum recorded at 87 K is shown as the broken line in Fig. 4*a*. The spectrum also shows a slight red-shift of the band below 300 nm, which is also due (at least partly) to $GePh_2$. The red-shift of the spectrum upon warming the solution between 78 and 82 K is consistent with geometrical relaxation of the solute, formed in a nonequilibrium geometry during the photochemical reaction that produces it.[70,71] Warming the solution further caused an accelerated reduction in the intensity of the (474 nm) band and a slight blue-shift (to λ_{max} = 470 nm), until it had all but disappeared entirely by the time the temperature reached 91 K, and the remaining spectrum consisted mainly of that owing to **18**. The latter disappeared upon further warming of the solution, presumably because of dimerization.[67,72]

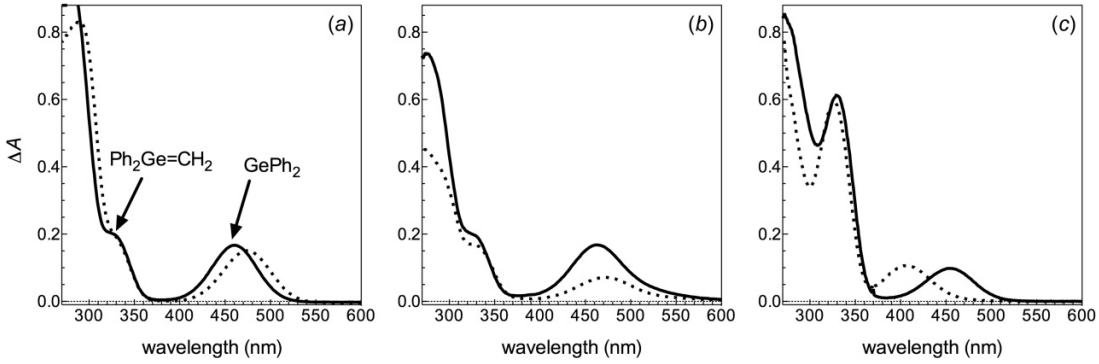
Fig. 4. (*a*) UV–vis spectra from photolysis of a deoxygenated 3-methylpentane solution containing **17** at 78 K (solid line); the same solution after warming to ca. 87 K is shown as the broken line. (*b*) As in (*a*) except the solution contained 0.15 mol/L CCl_4. (*c*) As in (*a*) except the solution contained 0.15 mol/L $CDCl_3$.



The procedure was repeated with a solution of **17** in 3-MP containing 0.15 mol/L CCl_4, the results of which are shown in Fig. 4*b*. In this case, warming the solution from 78 to 87 K resulted in a similar red-shift of the 460 nm band to what was observed in the absence of the halocarbon, but it was accompanied by a much more rapid decrease in intensity. This is consistent with reaction of $GePh_2$ with the halocarbon substrate; the spectrum showed no evidence for a detectable product of the reaction.

Finally, the procedure was repeated again with a solution of **17** in 3-MP containing 0.15 mol/L $CDCl_3$. This experiment afforded considerably different results than were observed in the others (see Fig. 4*c*); the 326 nm band at the end of the photolysis period was considerably more intense relative to the long wavelength band, and the latter was centered at slightly shorter wavelengths (λ_{max} = 453 nm). More importantly, warming the solution resulted in a blue-shift of the long wavelength band to 405 nm and a concomitant reduction in the intensity of the absorption below 300 nm; the intensity of the 326 nm band remained unaffected. Warming the solution past 88 K led to a gradual decrease in the intensity of the 405 nm absorption band until it eventually disappeared. This is again consistent with a halocarbon-induced reaction of $GePh_2$, but to yield a new transient product. Similar results were obtained (for the 450–460 nm band owing to $GePh_2$) using **20** as the $GePh_2$ precursor.

Taken together, the results of these experiments indicate that $GePh_2$ reacts with both CCl_4 and $CDCl_3$ at 82–90 K, but only with $CDCl_3$ does a transient product build up in high enough concentrations to be detected. We tentatively assign the species formed in the reaction with $CDCl_3$ under these conditions to the $GePh_2$–$CDCl_3$ Lewis acid–base complex.

Discussion

Reaction of CCl_4 with diarylgermylenes

The product studies are complicated somewhat by side reactions owing to the accompanying formation of H(D)Cl and the high reactivity of the diene co-product (DMB) toward radical reactions, but they nevertheless show conclusively that the reaction of $GePh_2$ with CCl_4 in hydrocarbon solvents proceeds mainly by initial Cl-atom abstraction, producing the corresponding germanium dichloride (**10**) as the major product along with minor amounts of the formal C–Cl insertion product, **12**. The behaviour is thus closely analogous to that exhibited by $GeMe_2$, which was studied by several groups using both thermal and photochemical methods and a variety of different precursors,[40,73–75] most of them considerably less prone to the radical side reactions that complicate the product mixtures in the present study. The formation of **11** is particularly difficult to account for completely, as it is clear that it is formed via a number of mechanisms. Roughly 50% of the compound is formed as the deuterated isotopomer, which must be derived ultimately from radical reactions involving the relatively strong C–D bonds associated with the solvent. Of the various radical species that we can anticipate being formed under the conditions of our experiments, only chlorine atoms possess sufficient potency to abstract deuterium from C_6D_{12}.[76] Some of the **11**-*d* that is formed could then arise from reaction of $GePh_2$ with DCl. The most obvious route to chlorine atoms is via photolysis of CCl_4,[61,77] yet the conditions of our steady-state experiments were such that only ca. 0.7% of the excitation light could be absorbed by the substrate at an initial concentration of 0.1 mol/L. The quantum yield for $GePh_2$ formation from **6a** is 0.55,[10] so it seems unlikely that all of the **11**-*d* is formed in this way unless the quantum yield for CCl_4 photolysis is significantly greater than the value of ~0.2 reported for the process in the gas phase.[52] It is similarly difficult to account completely for the formation of protiated **11**; its formation from the Ph_2GeCl radical via radical disproportionation processes and (perhaps) via H abstraction from an allylic hydrogen in the precursor, which is thermodynamically plausible based on predicted bond dissociation energies,[76,78] is a possibility at low conversions. We thus conclude that the cage-escape:recombination ratio of the (singlet)[73] [Ph_2GeCl + CCl_3] radical pair formed in the primary reaction of $GePh_2$ with CCl_4 in hydrocarbon solvents is on the order of about 10:1, assuming that roughly half of the **11** that is formed is derived from Ph_2GeCl radical reactions.

The present results also demonstrate that the presence of nonreactive Lewis bases such as THF or NEt_3, either as the solvent or in low concentration in hexanes, shifts the product

distribution in favor of the formal C–Cl insertion product, **12**. This too is consistent with early studies of $GeMe_2$; Egorov et al.[40] obtained high yields of the formal C–Cl insertion product from the reaction of $GeMe_2$ with CCl_4 in the presence of triphenylphosphine. It thus seems likely that the detailed mechanisms of the reactions of this halocarbon with $GePh_2$ and $GeMe_2$ are quite similar. Our reported rate constants for the reaction of $GeMe_2$ with CCl_4 in hexanes ($k = (9 \pm 1) \times 10^7$ $(mol/L)^{-1}$ s^{-1})[11,79] and THF ($k = (3.3 \pm 0.3) \times 10^7$ $(mol/L)^{-1}$ s^{-1})[30] are both 7–8 times larger than the corresponding values reported here for $GePh_2$, differences that are typical of those observed for the reactions of most (common) substrates with these two transient germylenes in solution.[11,20,21,30]

The various kinetic and spectroscopic data reported in the present work provide a potentially much more detailed picture of the mechanism of the reaction than has been possible in previous studies with $GeMe_2$. A Hammett plot of the rate constants for the reactions of the substituted derivatives in hexanes (Fig. 5*a*) shows a modest correlation, affording a reaction constant of $\rho = -0.4 \pm 0.1$. This indicates there is significant charge donation from germanium to the substrate in the rate-determining step for the reaction. The Arrhenius parameters for the reaction of the parent diarylgermylene (**8a**) in hexanes ($E_a = -0.7 \pm 0.7$ kcal/mol; $\log(A/(mol/L)^{-1}\ s^{-1}) = 6.5 \pm 0.5$; $\Delta S^{\ddagger} = -31 \pm 3$ cal K^{-1} mol^{-1} at 35 °C) indicate the reaction to be entirely entropically controlled, with no enthalpic barrier. Interestingly, these features are broadly similar to those exhibited by the reaction of (singlet) chlorophenylcarbene with CCl_4, which was studied in detail by Platz and co-workers[38] in the early 1990s.

The negative Hammett ρ value and the observed temperature dependence are consistent with a mechanism involving the initial reversible formation of a weakly bound germylene–halocarbon Lewis acid–base complex, which undergoes rate-controlling dissociative inner-sphere electron transfer (“iset”) from germanium to the halocarbon moiety to afford the [Ph_2GeCl + CCl_3] radical pair (eq. [14]). It should be noted that our data do not demand a discrete reactive complex as a steady-state intermediate in the reaction; it is merely suggested by our detection of the corresponding $GePh_2$–$CDCl_3$ complex in the low-temperature UV–vis experiments (vide infra). The data for CCl_4 are equally compatible with a single step concerted mechanism.[80] The reaction must involve a surface crossing with the (excited) open-shell singlet state of the germylene as it proceeds, as Platz and co-workers[38] indicated in their study of the reaction of PhCCl with CCl_4; this, presumably, is where the free energy barrier to the process is located.

[14] 
Ando et al.[26] reported the spectroscopic detection of the complexes of various germylenes (including $GePh_2$) with chlorohexane and chlorobenzene in hydrocarbon glasses at 77 K, prompting the later proposal by Neumann[16] for their involvement in the reactions of $GeMe_2$ with halocarbons; computational evidence for the intermediacy of analogous complexes in the reactions of some stable silylenes with CCl_4 has been reported by Su and co-workers.[81–83] If a reactive complex is involved as a discrete intermediate in the reaction of $GePh_2$ with CCl_4, we are unable to detect it even at 80–90 K, so the free energy barrier for its further transformation must be relatively small. The low-temperature experiments with $CDCl_3$ as substrate are consistent with the formation of a complex in this case, judging from the similarity of the spectrum to those of the complexes of $GePh_2$ with the chlorocarbons reported by Ando et al.[26] The rate constant for reaction of $GePh_2$ with $CHCl_3$ in hexanes at 25 °C is at least 50 times smaller than that with CCl_4,[20] consistent with a significantly higher barrier for the second step of the reaction with $CHCl_3$, whose C–Cl bond is ca. 5 kcal/mol stronger than that in CCl_4[76] and which is less easily reduced.[84] As a result, the $GePh_2$–$CHCl_3$ complex is detectable at low temperatures, whereas the putative $GePh_2$–CCl_4 complex (assuming it exists at all) is not. We were also unable to detect the product radical (Ph_2GeCl) in our laser photolysis experiments, which is an interesting point of difference between $GePh_2$ and its silicon homolog, $SiPh_2$. In the latter case, the primary reaction with CCl_4 produces a second intermediate that was assigned to the $SiPh_2Cl$ radical on the basis of its UV spectrum and the fact that its lifetime decreases with increasing CCl_4 concentration.[22] The reason for the difference is likely due to the fact that the primary Cl-abstraction step is roughly two orders of magnitude faster for the silylene than the germylene, but there is a much smaller difference in the rate constants for Cl abstraction by the Ph_2GeCl and Ph_2SiCl radicals.[85–87]

The reaction in THF, where the germylene exists essentially exclusively as the Lewis acid–base complex with the solvent, proceeds with a rate constant that is only ca. 3 times smaller than that of the free germylene in hexanes and produces a substantially higher yield of the formal C–Cl insertion product, **12**. While it is clear that some portion of the reaction continues to follow the free radical pathway, it appears to be a relatively minor component. We thus conclude that a different mechanism operates (either in whole or in part) in the presence of the nonreactive complexing agent compared with that in pure hexanes. The product distribution is quite similar in hexanes containing 0.05 mol/L THF and the reaction is similarly well-behaved, so it is clear that bulk solvent properties have nothing to do with the effect of the O donor on the product distribution. More dramatically, C–Cl insertion is essentially the exclusive reaction pathway (**10**:**12** $\approx$ 1:60) in hexanes containing 3 mmol/L NEt_3, which binds much more strongly to $GePh_2$ than does THF;[20,21] the presence of the amine would have the added benefit of soaking up any H(D)Cl that is formed, thus eliminating the formation of **11**. This all suggests that in the presence of O or N donors, the formation of the C–Cl insertion product proceeds via nucleophilic attack of the substrate by germanium in the germylene–donor complex. The Hammett plot of the rate constants for reaction of the substituted derivatives in THF solution (Fig. 5*b*) exhibits a significantly greater degree of scatter compared with that observed in hexanes, but is nevertheless broadly consistent with the germylene–O-donor complex playing the role of nucleophile in the reaction. The temperature dependence for the reaction of the parent (**8a**) leads to activation parameters of

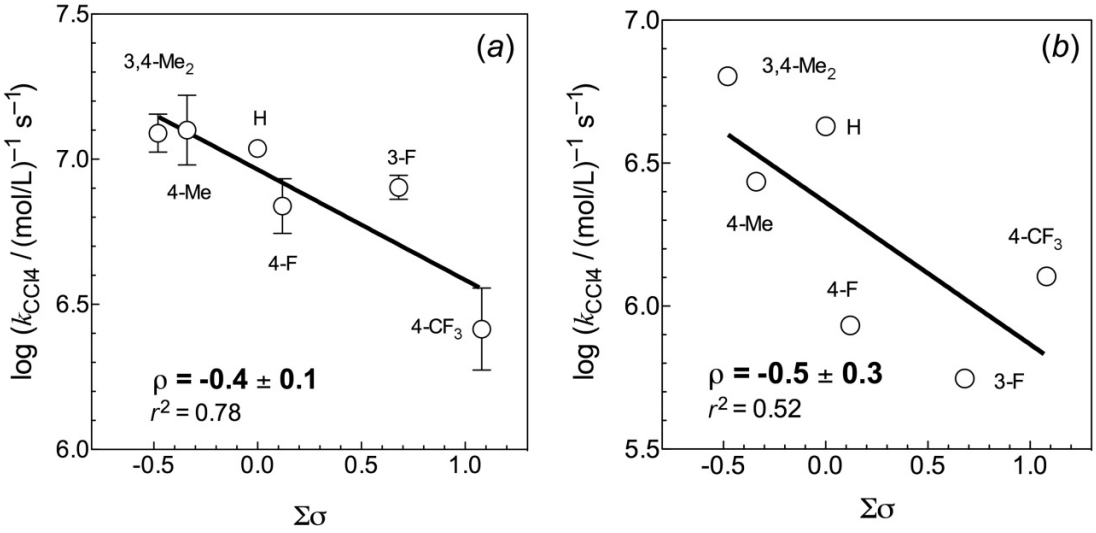
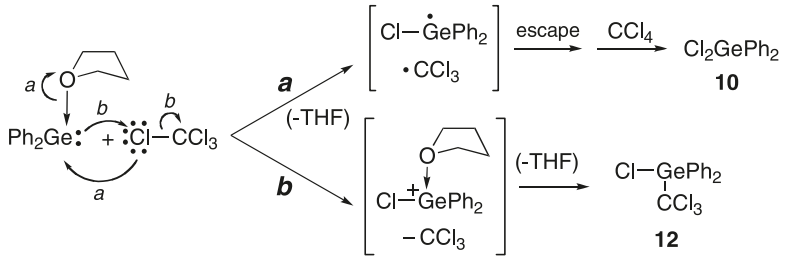
Fig. 5. Hammett plots of the rate constants for the reaction of CCl_4 with (*a*) free **8a**–**8f** in hexanes and (*b*) **8a**–**8f**–THF complexes in THF, at 25 °C.



E_a = +5.9 ± 0.4 kcal/mol and log(A/(mol/L)$^{-1}$s $^{-1}$) = 10.9 ± 0.3, the latter corresponding to an overall entropy of activation of $\Delta S^{\ddagger}$ = –11.6 ± 1.3 cal K^{-1} mol^{-1} at 35 °C.

The results suggest that the **8a**–THF complex reacts with CCl_4 via two competing mechanisms, as depicted in eq. [15]. We propose that the formation of **10** (along with perhaps a small fraction of the total amount of **12** that is produced) is due to Cl-atom abstraction as it is in hexanes, the only difference being that the coordinated THF moiety is liberated (presumably) at some stage during the formation of the resulting radical pair. We suggest that the formation of **12** arises mainly via nucleophilic attack of the germanium lone pair in the complex at a chlorine atom in the substrate, to yield a contact ion pair that rapidly annihilates to form the product. The process requires prior coordination with the Lewis base, both to impart nucleophilic character at germanium and stabilize the formation of the ion pair. This pathway would be expected to be enhanced relative to the other in the presence of a stronger Lewis base, as indeed we observe. The latter mechanism, as opposed to one involving nucleophilic attack at carbon in the substrate, is consistent with the roughly 200-fold lower reactivity of the $GePh_2$–THF complex with $CHCl_3$ ($k_{CHCl_3} \approx 2.4 \times 10^4$ (mol/L)$^{-1}$ s^{-1}) compared with CCl_4 under similar conditions. An electron-transfer mechanism might also be consistent with the observed results, provided the transfer of chlorine in the contact radical ion pair occurs largely as an atom transfer rather than ion transfer.

[15]



Reaction of CCl_4 with tetraaryldigermenes

The reaction of CCl_4 with tetramesityldigermene (**9g**) affords the corresponding 1,2-dichlorodigermane (**15**) as a major product, allowing the conclusion that Cl-atom abstraction to yield the 2-chlorodigermyl radical (**21**; eq. [16]) is a dominant mode of reaction of the Ge–Ge bond in this compound with CCl_4. The reaction produces a number of unidentified additional products, some of them presumably derived from side reactions resulting from the accompanying formation of the CCl_3 radical. This supports our inference that the primary reaction of the other tetraaryldigermenes (**9a**–**9f**) with CCl_4 is Cl-atom abstraction, as Mochida et al.[43] found to be the case for Ge_2Me_4. It is interesting to note that the reactions of **9g** with CCl_4 and $CHCl_3$[45] (which affords the 1,2-dichloride in only trace amounts; vide supra) exhibit similar differences in product distribution as Kira et al.[42] reported for the reactions of these two halocarbons with the less sterically hindered (**1a** and **1b**) of the three tetrasilyldisilene derivatives they studied. The more sterically hindered derivative (**1c**) afforded the corresponding 1,2-dichlorides in both cases; it did as well with CH_2Cl_2 as substrate, whereas **1a** afforded only the formal cage recombination product.

They interpreted these differences in terms of steric effects on the cage-escape–recombination ratio of the initially formed radical pairs, but the possibility that the formal recombination product (when it is observed) might be formed at least in part via an entirely different mechanism cannot be discounted. In any event, it is certainly clear that with all the disilenes they studied, the reaction with CCl_4 proceeds to a very large extent via initial Cl-atom abstraction. This is also true for Ge_2Me_4,[43] and probably as well for **9g** and the other less-hindered systems that we have characterized kinetically in the present work. It is also clear from the results of Kira et al.[42] that $CHCl_3$ *can* react the same way, and does so exclusively when the Si=Si bond is severely sterically hindered. It is also clear from their results that $CHCl_3$ is a characteristically much less reactive substrate than CCl_4 toward Si=Si bonds. This is true as well for the Ge=Ge bonds in Ge_2Me_4,[43] Ge_2Mes_4 (vide supra), and Ge_2Ph_4.[20] The difference in absolute rate constant is on the order of 1000 or more for both disilene **1c**[42] and Ge_2Me_4.[43] Kira et al.[42] reported activation parameters of $\Delta H^{\ddagger}$ = +7.0 ± 0.1 kcal/mol and $\Delta S^{\ddagger}$ = –43.9 ± 0.1 cal K^{-1} mol^{-1} for Cl abstraction from $CHCl_3$ by **1c**, but unfortunately did not study the temperature dependence of the corresponding reaction with CCl_4.

[16] $Mes_2Ge{=}GeMes_2$ (**9g**) $\xrightarrow{CCl_4}$ $[Mes_2Ge(Cl)-\dot{G}eMes_2 \cdot CCl_3]$ (**21**)

The Arrhenius plot of the absolute rate constants for reaction of **9a** with CCl_4 in hexanes (Fig. 3*b*) affords activation parameters of E_a = +4.3 ± 0.8 kcal/mol and $\log(A/(\text{mol/L})^{-1}\ s^{-1})$ = 9.6 ± 0.6, corresponding to an enthalpy and entropy of activation of $\Delta H^{\ddagger}$ = +3.7 ± 0.8 kcal/mol and $\Delta S^{\ddagger}$ = –16.7 ± 1.3 cal K^{-1} mol^{-1} at 35 °C, respectively, which we tentatively ascribe to those characterizing the Cl-abstraction process from this substrate by the Ge=Ge bond in Ge_2Ph_4. Su[46] reported a calculated value of $\Delta E^{\ddagger}$ = +0.6 kcal/mol at the B3LYP/6–311G(d,p) level of theory for the Cl-abstraction reaction of Ge_2Me_4 with CCl_4, which is the only direct comparison possible with the results of earlier studies on related systems.

The Hammett plot of the rate constants for the reactions of **9a** and the five substituted derivatives (Fig. 6) reveals an excellent correlation with substituent constants and affords a reaction constant of ρ = –0.31 ± 0.03. The value is indicative of significant charge donation from the Ge=Ge bond in **9** to the substrate in the transition state for the Cl-atom abstraction and is again broadly consistent with the results of Kira et al.[42] for disilene **1c**. They observed a good two-parameter correlation between the rates of reaction of disilene **1c** with a series of substituted benzyl chlorides and polar (Hammett σ_p) and spin delocalization (σ_{JJ}) substituent constants; the polar reaction constant was ρ = +0.9, which reflects the effects of substituent polarity from the opposite frame of reference to that probed in the present study.

Conclusions

The reaction of $GePh_2$ with CCl_4 in hydrocarbon solvents proceeds exclusively via Cl-atom abstraction, as is known also to be the case for $GeMe_2$ based on the results of early studies of the simpler germylene derivative using both thermal and photochemical methods for its generation. The present study affords considerably greater information in regards to the detailed mechanism of the process. The temperature dependence of the rate constant indicates the reaction is entropically controlled and possesses little or no enthalpic barrier, consistent with a two-step mechanism involving a reversibly formed intermediate whose collapse to the primary products is rate-controlling. It is well-established that $GePh_2$ (and other transient germylenes) form detectable Lewis acid–base complexes with other, less reactive halocarbons, and the present work extends the list of such substrates to include chloroform. We thus envisage the reaction with CCl_4 to begin with such an interaction, which allows the Cl-atom transfer to occur via a dissociative inner-sphere electron transfer process; if a discrete Lewis acid–base complex is involved, it is a steady-state intermediate that is undetectable even at very low temperatures. Reactivity is enhanced modestly by electron-donor substituents on the germylene, which supports the proposed mechanism. So too does the sizeable reduction in rate constants exhibited by the reactions of $GePh_2$ with $CHCl_3$ and other less easily reduced halocarbons.

A second mechanism comes into play in the presence of "spectator" donors such as THF (either as solvent or a catalyst) and NEt_3, which lead to increased yields of the formal C–Cl insertion product at the expense of radical-derived products, to an extent that depends on donor basicity. The reaction of $GePh_2$ with CCl_4 in THF solution exhibits activation parameters of E_a = +5.9 ± 0.4 kcal/mol and $\Delta S^{\ddagger}$ = –11.6 ± 1.3 cal K^{-1} mol^{-1} at 35 °C, the interpretation of which is complicated by the fact that competing reaction channels are operative and product studies have not been carried out over the full temperature range probed in the kinetic experiments. The rate constants for reaction of the substituted derivatives in this solvent correlate poorly with Hammett substituent constants, but show a trend toward higher reactivity with the more electron-rich derivatives in the series; this too may be a reflection of the competing reaction

Fig. 6. Hammett plot of the rate constants for the reactions of tetraaryldigermenes **9a**–**9f** with CCl_4 in hexanes at 25 °C.

For personal use only.

channels that may operate. Neverthless, a mechanism involving nucleophilic attack at the chlorine of the substrate by the germylene lone pair in the germylene–donor complex, to yield a contact ion pair that rapidly annihilates to form the observed product, is consistent with the data and explains the higher yield of formal C–Cl insertion product that is obtained.

The reaction of CCl_4 with the corresponding tetraaryldigermenes also proceeds via Cl-atom abstraction in hexanes solution, affording the corresponding 1,2-dichlorodigermane as the main product. Activation parameters of E_a = +4.3 ± 0.8 kcal/mol and $\Delta S^{\ddagger}$ = –16.7 ± 1.3 cal K^{-1} mol^{-1} have been determined for the reaction of Ge_2Ph_4, which are consistent with theoretical estimates for Ge_2Me_4 and the results of earlier studies of the corresponding reactions with sterically stabilized tetrasilyldisilenes. The process involves significant charge donation from the Ge=Ge bond to the substrate in the transition state for the rate-determining step, as revealed by an excellent correlation of the rate constants for reaction of the substituted tetraaryldigermenes with Hammett substituent constants.

Carbon tetrachloride represents an extreme in the reactions of transient germylenes, silylenes, and their corresponding dimers with halocarbon substrates, reacting exclusively by Cl-atom abstraction. This behaviour is shared by benzyl chloride, which possesses a C–Cl bond of similar strength to that in CCl_4. Interestingly, allyl chloride undergoes exclusive C–Cl insertion with $GeMe_2$ in spite of a similar C–Cl bond strength to those in CCl_4 and benzyl chloride.[16] This and other reactions of transient silylenes and germylenes are the subject of continued study in our laboratory.

Experimental

^1H and ^{13}C NMR spectra were recorded on Bruker AV200 or AV600 spectrometers in $CDCl_3$, CD_3CN, C_6D_6, C_6D_{12}, or THF-d_8 (Cambridge Isotope Laboratories). High-resolution mass spectra were recorded on a Micromass TofSpec 2E mass spectrometer using electron impact or chemical ionization (NH_3 reagent gas). MALDI mass spectra were recorded on a WatersMicromass MALDI MicroMX mass spectrometer operating in reflectron mode (matrix: α-cyano-4-hydroxycinnamic acid). GC–MS analysis of product mixtures was performed using a Varian Saturn 2200 GC–MS–MS system equipped with a VF-5ms capillary column (30 m × 0.25 mm; 0.25 μm; Varian, Inc.) using electron impact or chemical ionization (MeOH reagent gas); an asterisk by an *m/z* value indicates it is the most intense peak of a Ge isotopomeric cluster. X-ray crystallographic analysis was performed in the McMaster Analytical X-Ray (MAX) Diffraction Facility on a single crystal (grown from slow evaporation of hexanes), mounted and cooled to –100 °C on a SMART APEX II diffractometer with a 3 kW sealed tube Mo generator.

All synthetic preparations were carried out in flame-dried glassware under an atmosphere of dry nitrogen. The germacyclopentenes **6a**–**6f**,[10,27,30,48] hexamesitylcyclotrigermane (**7g**),[88] 1,2-dichloro-1,1,2,2-tetramesityldigermane (**15**),[59] 1,1-diphenyl-1-germacyclobutane (**17**),[67] and diphenylgermanium dichloride (**10**)[89] were prepared as previously described.

Trichloro(trichloromethyl)germane (Cl_3GeCCl_3) was prepared following the method of Nefedov and co-workers.[55] $GeCl_2$–dioxane (10.3 g, 44 mmol) was dissolved in CCl_4 (150 mL) and refluxed for 4 h under nitrogen. The reaction mixture was stirred under vacuum (~0.1 mm Hg; 1 mm Hg = 133.322 4 Pa) at ambient temperature until the solvent had been removed, yielding the crude product as a pale yellow solid. While still under vacuum, the flask was gently warmed with a water bath (ca. 40–50 °C) and the product, a white solid (8.68 g, 29 mmol, 66%), sublimed onto a cold-finger cooled to –(30–40)°C using dry ice – isopropanol. The melting point was measured in a sealed tube (mp 104–106 °C; lit.[55] mp 106–107 °C). MS (*m/z* (I)): 297.7* (3) $[M^+]$, 260.8* (80) $[M - Cl]^+$, 178.8* (28) $[M - CCl_3]^+$, 159.9* (18), 116.9 (100).

Chloro(trichloromethyl)diphenylgermane (**17**): A two-neck 250 mL round bottom flask, fitted with a dropping funnel and a condenser, was charged with Cl_3GeCCl_3 (0.80 g, 2.7 mmol) and anhyd ether (20 mL). The dropping funnel was charged with freshly prepared PhMgBr (10.8 mmol, 4 equiv) in ether (50 mL). The Grignard reagent was added dropwise over 40 min, causing the formation of white insoluble salts. After the addition was complete, the mixture was allowed to stir for 2 h at room temperature. The solvent was removed under vacuum and the residue was washed with pentane (5 × 20 mL). The combined washes were filtered and the solvent removed under vacuum to yield a yellow oil (0.66 g). The product was isolated from the crude reaction mixture by Kugelrohr distillation as a colourless oil (0.10 g, 0.3 mmol, 11%), distilling at 110–120 °C (P = 0.05 mm Hg). IR (cm^{-1}, intensity): 3075 (m), 3055 (m), 1960 (w), 1885 (w), 1816 (w), 1585 (w), 1485 (s), 1434 (s), 1092 (s), 998 (s). ^1H NMR (C_6D_{12}): 7.34–7.42 (m, 6H), 7.79–7.87 (m, 4H). ^1H NMR (CD_3CN): 7.55–7.59 (m, 4H, *ortho*), 7.61–7.67 (m, 2H, *para*), 7.87–7.91 (m, 4H, *meta*). ^{13}C NMR (CD_3CN): 92.05 (CCl_3), 130.19 (*ortho*), 130.69 (*ipso*), 133.09 (*para*), 135.38 (*meta*). Note: the ^{13}C shift of CCl_3 is consistent with literature data for this group on Ge.[40,90,91] GC–MS (Saturn, CI) *m/z*: 344.7* (20) $(M - Cl)^+$, 299.2* (44), 201.3 (100), 161.1 (30), 159.2 (50). GC–MS (Saturn, EI) *m/z*: 263.2* (100)$(M - CCl_3)^+$. MS (Micromass, CI) (*m/z*, intensity): 306.9* (7), 280.0* (4), 263.0* (18), 151.0* (8), 108.9* (9), 94.1 (24), 93.1 (28), 78.0 (100). HRMS calcd for $C_{12}H_{10}{}^{74}GeCl$ $(M - CCl_3)^+$: 262.9683; found: 262.9621.

Attempts to crystallize the compound were unsuccessful; however, slow evaporation of a hexane solution in contact with atmospheric moisture led to the formation of colourless crystals of trichloromethyldiphenylgermanol (**14**) (mp 65.6–67.7 °C). IR (cm^{-1}, intensity): 3375 (br, m), 1961 (w), 1882 (w), 1810 (w), 1481 (m), 1431 (s), 999 (s). ^1H NMR (CD_3CN): 7.50–7.54 (m, 4H, *ortho*), 7.56–7.60 (m, 2H, *para*), 7.82–7.87 (m, 4H, *meta*).

Chlorodiphenylgermane (**11**) was prepared following the method of Kunai and co-workers.[92] The product was isolated from the crude reaction mixture as a colourless oil by Kugelrohr distillation (T = 100 °C, P = 0.2 mm Hg). IR (cm^{-1}): 3071 (m), 3052 (m), 3008 (br, w), 2076 (br, s), 1484 (m), 1433 (s), 1334 (w), 1305 (w), 1095 (s), 1027 (w), 998 (w), 855 (br, w). ^1H NMR δ: 6.56 (s, H), 7.46–7.54 (m, 6H, *ortho/para*), 7.63–7.73 (m, 4H, *meta*). ^{13}C NMR δ:

128.9 (*meta*), 130.8 (*para*), 133.8 (*ortho*), 135.3 (*ipso*). MS *m/z* (I): 263.0* (15), 227.0* (13), 185.9* (100), 151.0* (48), 108.9* (49), 79.1* (60). HRMS $C_{12}H_{10}{}^{74}GeCl$ (M – H) calcd: 262.9683; found: 262.9675.

Steady-state photolysis experiments were carried out using a Rayonet photochemical reactor (Southern New England Ultraviolet Co.) equipped with a merry-go-round and 2 × RPR2537 (254 nm) lamps. For those monitored by NMR spectrosccopy, aliquots (ca. 0.7 mL) of solutions in C_6D_{12} or THF-d_8 containing Si_2Me_6 (ca. 2 mmol/L) as an internal integration standard were placed in quartz NMR tubes, sealed with a septum, and deoxygenated with a fine stream of dry argon for ca. 10 min prior to the experiment. Reaction products were identified by spiking the mixture with authentic samples as well as by GC–MS analysis at the end of the experiment.

For those monitored by GC–MS only, solutions of the compounds and CCl_4 were prepared in dry cyclohexane or THF (5 mL) containing dodecane (1 mmol/L) as the internal integration standard. If applicable, THF or NEt_3 (Sigma-Aldrich, refluxed over and distilled from KOH) was added as well. The solution was transferred to a quartz NMR tube, sealed with a rubber septum, and deoxygenated with a stream of dry argon for 5 min. Aliquots were removed at regular intervals and analyzed by GC–MS, repurging the sample with argon after each aliquot was taken.

Nanosecond laser flash photolysis experiments were carried out using the pulses from a Lambda-Physik Compex 120 excimer laser, filled with F_2–Kr–Ne (248 nm; ca. 25 ns; 100 ± 5 mJ) and a Luzchem Research mLFP-111 laser flash photolysis system, modified as described previously.[10] Solutions were prepared in a calibrated 100 mL reservoir fitted with a glass frit to allow bubbling of argon through the solution for at least 30 min prior to and then throughout the duration of each experiment. Concentrations were such that the absorbance at the excitation wavelength was between ca. 0.7 and 0.9. The solutions were pumped from the reservoir through Teflon tubing connected to a 7 mm × 7 mm Suprasil flow cell using a Masterflex 77390 peristaltic pump. The glassware, sample cell, and transfer lines were dried in a vacuum oven (65–85 °C) before use. In experiments carried out at 25 °C, solution temperatures were measured with a Teflon-coated copper–constantan thermocouple inserted into the thermostatted sample compartment in close proximity to the sample cell; those in which the solution temperature was varied were carried out using a flow cell that allowed insertion of the thermocouple directly into the sample solution. Reagents were added directly to the reservoir by microliter syringe as aliquots of standard solutions. Transient absorbance–time profiles at each concentration of scavenger are the signal-averaged result of 7–40 laser shots. Decay rate constants were calculated by nonlinear least-squares analysis of the transient absorbance–time profiles using the Prism 5.0 software package (GraphPad Software, Inc.) and the appropriate user-defined fitting equations, after importing the raw data from the Luzchem mLFP software and applying the necessary corrections to remove the minor contributions from the corresponding digermenes at low substrate concentrations.[20,27] Rate constants were calculated by linear least-squares analysis of decay rate – concentration data (generally 4–7 points) that spanned as large a range in transient decay rate as possible. Errors are quoted as twice the standard error obtained from the least-squares analyses. Rate constants determined at temperatures other than 25 °C were corrected for thermal solvent expansion.[93]

Low-temperature UV–vis spectrophotometry employed a 2 cm × 1 cm × 1 cm cuvette constructed from quartz tubing (Vitrocom, Inc.) and an Oxford Optistat liquid nitrogen cryostat equipped with an Oxford ITC601 temperature controller. Solutions of **6a** (ca. 0.001 mol/L; $A_{254\ nm} \sim 0.8$) in 3-methylpentane (Sigma-Aldrich spectrophotometric grade) were deoxygenated with argon, sealed in the cuvette with a rubber septum, and placed in the cryostat, which was then cooled to 78 K. The entire assembly was placed in a Rayonet photochemical reactor equipped with twelve RPR-2537 lamps to irradiate the sample, with UV–vis spectra being obtained before and during the photolysis procedure at selected time intervals. The cryostat was then warmed in 1 K increments and a spectrum recorded after ca. 5 min equilibration at the new temperature. The spectra shown in Fig. 4 are difference spectra, obtained by subtracting the UV spectrum obtained prior to photolysis from those obtained after irradiation and subsequent warming.

Supplementary data

Supplementary data (concentration vs time plots and representative NMR spectra from steady-state photolysis experiments and kinetic data determined in laser flash photolysis experiments) for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 788625 contains the X-ray data (for **14**) in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support and for a graduate scholarship to L.A.H. We also thank Teck-Cominco Metals Ltd. for a generous gift of germanium tetrachloride, Mr. S. Chitnis for the synthesis of **6b** and Drs. J. Britten and H. Jenkins for their assistance with X-ray crystallography. Finally, we thank Tito for his enthusiastic advice, guidance, and support over the past 30 (or so) years.

REVIEW / SYNTHÈSE

Photoinduced charge separation in microporous and mesoporous materials

Ranjit T. Koodali

Abstract: A review of photoinduced charge separation of organic molecules in microporous and mesoporous materials is presented. In particular, the photoionization of *N*-alkylphenothiazine (PC_n), *N*,*N*,*N*′,*N*′-tetramethylbenzidine (TMB), and porphyrin in microporous materials, such as zeolites, aluminophosphates (AlPOs), silicoaluminophosphates (SAPOs), and mesoporous materials, such as MCM-41, MCM-48, and SBA-15, is discussed.

Key words: photoinduced charge separation, photoionization, microporous, mesoporous materials.

Résumé : On présente une revue de la séparation de charge photoinduite des molécules organiques dans des matériaux microporeux et mésoporeux. On discute particulièrement des cas des *N*-alkylphénothiazines (PC_n), de la *N*,*N*,*N*′,*N*′-tétraméthylbenzidine (TMB) et de la porphyrine dans des matériaux microporeux tels les zéolites, les aluminophosphates (AlPO) et les silicoaluminophosphates (SAPO) ainsi que les matériaux mésoporeux tels le MCM-41, le MCM-48 et le SBA-15.

Mots-clés : séparation de charge photoinduite, photoionisation, matériaux microporeux et mésoporeux.

[Traduit par la Rédaction]

Introduction

Solar energy conversion and storage has gained renewed interest in the past few years.[1–11] The scientific community is engaged in the pursuit of exploring the possibility of using sunlight as the source to produce clean, renewable, and environment friendly based energy alternative to the widely used fossil fuels. Research in this area can be broadly classified into solar electricity (production of electricity through the use of inorganic and organic solar cells), solar fuels (photoelectrochemical cells), and solar thermal systems (typically through the use of solar concentrators). Nature provides scientists with inspiration and hope to find possibilities to solve this global challenge. In natural photosynthesis, solar energy is converted into chemical energy in the form of biomass. The overall efficiency is very low, i.e., <8% of the incident insolation is stored as chemical fuel. In spite of the relative low efficiency, this process is responsible for sustaining living organisms on earth. The natural photosynthetic process involves four essential steps. The first step is light absorption and propagation through an organized biomolecular membrane. This step is accomplished by nature through a light-harvesting complex that consists of several pigments (primarily chlorophylls, carotenes, and xanthophylls) and redox proteins that are arranged in a well-defined spatial geometry and work in tandem. The next step involves vectorial or unidirectional photoinduced electron transfer through a co-operative interaction between the various components of the membrane. This is followed by electron transport through a chain of reactions in which, ultimately, the electron is used to reduce NADP to NADPH. All of these three steps occur in the thylakoid membrane. The final step involves the fixation of carbon dioxide to generate energy in the form of carbohydrates and the simultaneous oxidation of water to oxygen.[12]

The intricate and highly organized structure found in nature has inspired chemists to explore the possibility of designing artificial photosynthetic systems. Intense research in this area is pursued with the purpose of harvesting sunlight and its conversion to electricity or fuels. From a chemist's perspective, the photoinduced electron transfer is a key step and, thus, the study of photoinduced electron-transfer reactions is important in the design of artificial photoredox systems.[13] Artificial photoredox systems may provide ways by which sunlight reaching the earth's surface can be exploited to generate useful energy or chemicals. Nature provides chemists with a toolbox for designing artificial photoredox systems, and it may soon be possible for us to mimic all, if not most, of the essential intricacies of the natural photosynthetic system with new and revolutionary discoveries being made in unraveling the photosynthesis mechanism at the atomic level. Indeed, artificial nanoscale assemblies consisting of organic–inorganic hybrid materials synthesized in the laboratory are capable of mimicking the photosynthesis reaction. One must, however, realize that success is limited to

the laboratory scale and, currently, the technology is not mature enough for large-scale deployment. The challenges are poor efficiency, long-term instability, and high cost.

The drawback of most photochemical processes is the thermodynamically favorable rapid back-electron transfer (BET) reaction that results in the loss of any converted energy in the form of heat. Thus, an objective is to design systems in which long-lived charge separation can be achieved; furthermore, it is desirable if this can be achieved at room temperature. An important requirement is to achieve net charge separation, since efficient photoionization followed by rapid BET is not a practical way of storing energy.

Photoinduced charge separation in organized molecular assemblies

The photoinduced charge separation can be represented by the following equations:

$$[1] \quad D \rightarrow D^*$$

$$[2] \quad D^* + A \rightarrow D^+ + A^-$$

$$[3] \quad D^+ + A^- \rightarrow D + A$$

where D and A represent donor and acceptor molecules. Light excitation in step [1] creates the excited species, D*. The second step is the photoionization step in which an electron transfer occurs. The excitation of the donor molecule makes it a better reducing agent and thus it can easily donate an electron to A. If the redox properties of D^+ and A^- are tailored appropriately then they may be used to drive reactions such as the photosplitting of water or the fixing of carbon dioxide to generate fuels. The reaction in step [3]) is the recombination or the BET reaction that occurs readily in homogeneous solutions and thereby wastes the energy created by excitation. An important goal is to minimize rxn. [3] so that the free energy converted from light may be stored and subsequently used for driving a chemical reaction.

As discussed, minimizing the BET reaction in photoredox systems is critical. Owing to the importance of this problem, many attempts have been made to design systems that can minimize BET.[14,15] In this respect, microheterogeneous systems provide appropriate spatial organization of both donor and acceptor molecules to retard BET and increase the lifetime of the photogenerated species.[16–19] The term microheterogeneous system encompasses several classes of systems ranging from surfactants, lipid vesicles, liposomes, micelles, and microemulsions to organic and inorganic materials. Extensive studies using molecular assemblies were carried out in the 1980s and 1990s, and several excellent papers and reviews were published and are not the focus of this review.[20–31] An important aspect of the microheterogeneous systems is the fact that they exhibit efficient light-induced electron transfer compared with homogeneous solvents. Also, efficiency losses owing to self-quenching reactions are minimized in microheterogeneous systems and thus a relatively high concentration of dye molecules may be used. Also, the observed photophysical behavior and the reaction kinetics in microheterogeneous systems are quite different when compared with homogeneous systems.

The photoinduced charge separation of organic molecules in lipids, micelles, vesicles, and polymers has been described in many reports.[26–31] The main drawback of these systems is that the lifetime of the photoproduced species is only a few milliseconds (ms), and, typically, these are stable only at relatively low temperatures, i.e., 77 K. In micelles and vesicles, the photoinduced charge separation efficiency is affected by many factors such as the nature of the head group of the surfactant, charge and alkyl length of the surfactant, location of the electron donors and acceptors relative to the surfactant–water interface, surface charge distribution of the surfactants, and the ionic strength of the interface. The net quantum efficiency of organic molecules in micelles and vesicles is typically higher than that in homogeneous solutions, but the photoinduced radicals are not typically stable at room temperature as stated previously.[30,31] The quantum efficiencies are usually higher in vesicles when compared with micelles. The yields showed a dependence upon the surface charge of the aggregate, increasing in the order anionic (micelles) < cationic (micelles) < anionic (vesicles) < neutral (vesicles) < cationic (vesicles).[29] Furthermore, in several instances, the quantum efficiencies in micelles and vesicles are limited by the solubility of the photoactive molecules. Polymer systems with chemical or physical incorporation of electron donors and acceptors show promise, but they still have significant degrees of molecular motion that decrease the stability of the photoproduced radicals.[32,33] The synthesis of acceptors and donors connected by covalent bonds or more complex combinations, such as donor–spacer–acceptor, have also generated new systems for efficient photoinduced charge separation.[34] But covalently linked architecture alone has not provided long-lived photoinduced charge separation at room temperature. A big drawback of the these systems is the fact that the photoinduced charge separation is short lived at room temperature, and, more importantly, photolysis of such systems was found to cause degradation of the systems and thus they were not very robust. It became clear that heterogeneous solid supports provide a novel way to arrange the photoactive molecules and they also have the potential of other functional requirements of an artificial photoredox system such as membranelike properties.[14,15]

Photoinduced charge separation in layered materials

Initial studies of the photoinduced charge separation of organic molecules in oxide materials were carried out on clay, alumina, and silica. The clays were a logical choice of support to be investigated as solid supports, since they were used extensively in the petroleum industry until the use of zeolites.[30,35] Clays may be broadly classified into expandable (in water) and nonexpandable materials or alternatively called as the 2:1 or 1:1 clay. The expandable clays, such as montmorillonite and hectorite, have interlayer space that can be varied depending on the nature of the material intercalated. The photoinduced charge separation of polycyclic aromatic hydrocarbons,which include anthracene, naphthalene, pyrene (Py), and tris(2,2′-bipyridine)ruthenium(II) ($Ru(bpy)_3^{2+}$), were the subject of numerous investigations in the laboratory of Thomas and co-workers.[36–44] The fluorescent probe $Ru(bpy)_3^{2+}$ was used to investigate the nature of the surfaces of both naturally occurring clays like hectorite and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

montmorillonite and synthetic clay such as laponite. The lifetime and quantum yield are dependent on the location of the adsorbed ions or molecules, for example, $Ru(bpy)_3^{2+}$ is adsorbed in the interlayer spacings in hectorite and montmorillonite, whereas it is adsorbed on the surface in laponite. The lifetime of the photogenerated species, namely $Ru(bpy)_3^{3+}$, is ~0.5 ms.[36] The photophysical properties of pyrene in alumina, silica, and laponite were studied by Thomas and co-workers[35–37] They reported that pyrene cation radicals are produced by irradiation with UV light and that the mechanism of photoionization on the solid can take place via a monophotonic or biphotonic process. The lifetime of the photoproduced pyrene cation radical was found to be ~10 ms. Aromatic amines such as benzidene (BD) and *N*,*N*,*N*′,*N*′-tetramethylbenzidine (TMB) have also been investigated.[45] UV irradiation ($\lambda < 400$ nm) leads to photoionization given by the following equation:

$$[4] \quad TMB \rightarrow TMB^{+} + e_{aq}^{-}$$

The hydrated electron reacts in the presence of oxygen to give the superoxide radical ($O_2^{-\bullet}$). The lifetime of the photoproduced TMB^+ is ~1 ms. Since studies with clays did not necessarily increase the lifetime of the photogenerated species, other layered materials such as zirconium phosphate were explored as hosts.

Inorganic layered phosphates such as α-zirconium phosphate (α-ZrP) have been used for constructing supramolecular assemblies.[46] The phosphate group carries an ionizable hydroxyl group that can be easily deprotonated, and hence cations can be incorporated by ion exchange. The photoinduced electron transfer of $Ru(bpy)_3^{2+}$, *N*-alkylphenothiazines (PC_n), and TMB have been examined in these layered materials.[47–49] The quantum efficiency of the PC_n cation radical increases from methyl to hexyl, and as the chain length increases further, the photo-oxidation yield decreases.[48] The stability of the photoproduced PC_n^+ cation was found to decrease from methyl to hexadecyl, and this was attributed to the increased inductive effect of PC_n^+ with an increase in the alkyl chain length. Also, it has been reported that with anincrease in chain length, the PC_ns tend to form clusters that may self-quench by a mechanism involving intermolecular transfer to a surface trap.[50] Thus, there is an optimum chain length in the quantum efficiency. In a separate study, Krishna and Kevan have reported the photooxidation of TMB in α-ZrP.[49] The half-life of TMB^+ was determined to be 10 h at room temperature, whereas the half-life of PC_n^+ was found to range from several days to several weeks depending on the chain length as discussed previously.

Photoinduced charge separation in silica gels

A dramatic increase in the lifetime (up to a few hours) of the photogenerated species was observed when the reactions were carried out in silica gels. The research group of Avnir has done pioneering study involving molecular excited states in sol–gel matrices.[51,52] Some interesting features of pyrene-doped SiO_2 gels are that the photoionization process is biphotonic, the lifetime of the solvated electron is fairly long, and phosphorescence is observed at room temperature. This has an important consequence in that the sol–gel matrix allows for photophysical studies to be usually conducted at room temperatures. Exceedingly long-lived photoinduced charge separation was reported in an artificial photosynthetic system that consisted of dimethylviologen (MV^{2+}) as the electron acceptor and Py as the electron donor immobilized in a porous sol–gel silica glass.[53–55] Photoinduced electron transfer from PC_ns, TMB, porphyrin, and $Ru(bpy)_3^{2+}$ in amorphous silica gels have also been reported.[22,23,56,57] The guest molecules were introduced into the host system either by their addition to the synthesis solution during the room-temperature synthesis process or were incorporated by a post-impregnation method after the silica gels were separately synthesized. The photoionization of PC_n and TMB were studied by ESR and diffuse reflectance spectroscopy. The quantum efficiency was found to depend on the pore size of the silica used. In a small-pore silica gel (average pore sizes of 1.7 and 2.5 nm), *N*-methylphenothiazine cation radical ($PC_1^{+\bullet}$) and TMB cation radical ($TMB^{+\bullet}$) have a larger quantum efficiency when compared with a large-pore-sized silica gel (6.0 and 14 nm).[22,56] The relatively low quantum efficiency in the larger pores was partly attributed to the formation of TMB_2^{2+}. Although the quantum efficiency was found to depend on the pore sizes, the stability of the photoproduced TMB^+ was found to be similar in all the silica materials examined in this study. The half-life of TMB^+ ions was found to be ~2 h. It was suggested that the mobility of the photoproduced cations controls the yield and photostability. Interestingly, no effect on the quantum efficiency and stability of the PC_n cation radicals were observed when the alkyl chain lengths were varied from 1 to 16 carbons. The results obtained for the photoionization of PC_n and TMB show the same dependency on pore size, suggesting that the photo-oxidation mechanisms for these two photochromic molecules are the same. These studies indicate that the silica gel framework acts as an electron acceptor and the surface silanol groups of silica gels are probably the principal sites responsible for the adsorption of PC_n and TMB. Surface hydroxyl groups may serve as electron acceptors in large-pore-sized silica with production of a hydrogen atom. However, in small-pore-sized materials no ESR signal owing to trapped hydrogen atoms were detected, although the yield of the photoproduced cations was found to be higher in them. Thus, the results do not clearly clarify the role of the silanol groups as electron acceptors. In a follow-up study, Xiang and Kevan[57] studied the effects of chloromethanes on the photoionization of *N*-methylphenothiazine in silica gels of 14 nm pore size at room temperature. The net quantum efficiency of $PC_1^{+\bullet}$ was compared with the samples that did not have the chloromethanes. It was found that addition of CCl_4 and $CHCl_3$ increased the photoionization yield of $PC_1^{+\bullet}$, and this was attributed to the higher electron affinities (2.12 and 1.75 eV).[58] In comparison, addition of CH_2Cl_2 and CH_3Cl did not enhance the quantum efficiency, presumably because of their lower electron affinities. MV^{2+} is an efficient electron acceptor and has been investigated extensively in photoredox systems. The quantum efficiency and stability of the photoproduced MV^+ radical was found to also depend on the pore size; however, the yield of MV^+ radical was higher in the large-pore silica (14 nm) compared with the small-pore silica (1.7 nm).[59] This trend was attributed to the fact that the counter chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

anion in the dimethylviologen dichloride was the electron donor. The separation distance between the MV^+ and the chloride trapping site is larger in the large-pore silica, and hence the BET is minimized in the 14 nm average pore size silica. Increasing the chain length of the viologen from one to seven did not significantly affect the quantum efficiency or stability when the pore size was kept the same. Interestingly, the method of incorporation was found to affect the quantum efficiency; the quantum efficiencies were found to be greater when the impregnation method was used compared with a direct incorporation of MV^{2+}.

The photo-oxidation of $Ru(bpy)_3^{2+}$ in silica gels was reported by Matsuura and Kevan.[23] The stabilization of $Ru(bpy)_3^{3+}$, particularly at room temperature, is usually a challenge, since the BET reaction is fairly rapid and usually exothermic. $Ru(bpy)_3^{3+}$ was stabilized in silica gel after photolysis in the presence of electron acceptors such as persulfonate ion or tetrachloro-1,4-benzoquinone (*p*-chloranil). The yield of $Ru(bpy)_3^{3+}$ was found to be similar for silica gels with average pore sizes of 2.5 and 14 nm at 77 K for the same loading of $Ru(bpy)_3^{2+}$ using $S_2O_8^{2-}$ as the electron acceptor. The yield of $Ru(bpy)_3^{3+}$ was calculated to be 50% and 1% in the presence of persulfonate and *p*-chloranil, respectively. The efficient quenching of the $Ru(bpy)_3^{2+*}$ by $S_2O_8^{2-}$ has been attributed to the strong affinity of $S_2O_8^{2-}$ and the strong attractive force between the positively charged $Ru(bpy)_3^{2+}$ and the negatively charged $S_2O_8^{2-}$ ions. The yield of $Ru(bpy)_3^{3+}$ is an order of magnitude lower at room temperature compared with the yield at 77 K, and this limits their applicability.

Metalloporphyrins are involved in several important electron transfer reactions in biological reactions and photosynthetic systems.[60–64] Metalloporphyrins can be easily photoionized. The photoionization can take place through the oxidation of the ligand or the central metal ion leading to the formation of metalloporphyrin π-cation radicals or an increase in the oxidation state of the metal ion.[65] In a study, the photoionization of several metalloporphyrins (H_2TPP, CuTPP, NiTPP, and ZnTPP) adsorbed in 4 nm silica gel irradiated with visible light was examined at room temperature and 77 K.[66] The photoionization efficiency was found to decrease in the order ZnTPP > H_2TPP > NiTPP >> CuTPP. The half-life of $Zn(II)TPP^{+\bullet}$ was determined to be 16 days at room temperature, a remarkable improvement compared with other systems investigated earlier. The main drawback of these studies is the fact that the average pore sizes of the silica materials were reported with no specific information regarding the pore-size distribution, and thus it is fairly difficult to correlate the effect of pore sizes on the quantum efficiencies, if any. In addition, silica gels have no long-range order and a have wide pore-size distribution compared with zeolites and may not serve as a useful biomimetic artificial photoredox system.

Photoinduced charge separation in microporous materials

Extensive research has been done on zeolites as hosts for photoinduced charge separation.[67–70] Over the last decade, considerable progress has been made in using zeolites to extend the lifetime of the photoproduced species from hours to several days, if not weeks. Zeolites are crystalline aluminosilicates with a three-dimensional structure made up of corner-sharing SiO_4 and AlO_4 tetrahedra with cations occupying extra framework positions to balance the charge of the negative framework. Zeolites have been popular choices as host materials because their periodic and regular framework not only replicates the spatial organization observed in nature, but the inherent electrostatic environment provides an opportunity to retard BET.[71–73] The negatively charged aluminosilicate framework provides a polar environment that can be further modified by varying the number and type of charge-compensating cations. The arrangement of channels and pores in these crystalline materials allows for the placement of molecules in well-defined and unique spatial arrangements. Thus, the architecture of zeolites allows for novel arrangements of molecules in space with considerable long-range order. The difference between molecules encapsulated in zeolites and species encapsulated in matrices such as micelles and vesicles is that the zeolite framework can act as an active host and influence the structure and reactivity of the encapsulated molecules. Kochi and co-workers studied the photoinduced charge transfer between neutral aromatic donors and cationic bipyridinium viologen acceptors in zeolite L, Y, mordenite, and mazzite cavities.[69,73–75] They found that the lifetime of the charge-separated state in the zeolite was in the order of milliseconds compared with that in homogeneous solution (picoseconds). Zeolites have also been employed as a medium for artificial supramolecular assembly of various donor–acceptor pairs in an effort to understand the factors that govern the charge-separation states. In particular, studies have been carried out to achieve long-lived charge separation across zeolite–solution interfaces.[13,16,17] Zeolites Y and L internally exchanged with electron acceptor MV^{2+} and externally with bulky electron donors $Ru(bpy)_3^{2+}$ or $Zn(II)Por^{4+}$ (Por = tetrakis(*N*-methyl-4-pyridyl)porphyrin); these were prepared and the photoinduced charge separation was studied.[76] The small quantum yield (0.0003%) suggests that the BET process is very fast and efficient. A dramatic improvement in the yield and efficiency of charge separation across the zeolite–solution interface was achieved by filling the empty cages of zeolite Y with an appropriate photosensitized donor $Ru(bpy)_3^{2+}$ and a charge-relaying compound *N*,*N*′-tetramethylene-2,2′-bipyridinium. The electron acceptor chosen was propylviologen sulfonate (PVS). On irradiation, the system approached a steady state as the radical yield reached ~60% of the total sensitizer concentration.[13] A further increase in the yield of charge separation across the zeolite–solution interface was obtained by simultaneously introducing an electron relay compound and electron donor in adjacent cages of a zeolite. This led to an approximately fourfold increase in the yield of charge separation.[17]

In a series of papers published from the Kevan group, the photoionization of PC_n, MV^{2+}, and TMB were examined in aluminosilicate zeolites.[77,78–80] Na forms of Zeolite A, X, and Y were ion-exchanged by Li^+, K^+, or Cs^+ and prepared first. Then, alkylmethylviologen (MV^{2+}_n) was ion-exchanged and the sample evacuated to 10^{-5} torr (1 torr = 133.3224 Pa) at 90 °C. Upon irradiation at 77 K, peaks corresponding to the methylviologen cation radical were observed. The yield was found to be in the order zeolites Y > zeolites X >> zeolite A. Experiments were also carried out using the dibromide

For personal use only.

salt of diheptylviologen, but the yield of the diheptylviologen cation radical was higher when compared with the yield of the dimethylviologen dichloride cation radical. This result suggests that the aluminosilicate framework of zeolites is the electron source because bromide is a weaker reducing anion than chloride, and one would have expected an opposite trend if the halide ions were the electron source. Furthermore, it is highly unlikely that the halide ions are ion-exchanged into the extra-framework positions because zeolites are known to selectively exchange cationic species only. In this study, the presence of Li^+, K^+, or Cs^+ instead of Na^+ did not have any observable effect on the yield of the MV^+ cation radical. This result was surprising, since it has been reported that the donor strength of the zeolites framework can be modulated by the extra-framework ions.[81–83] Alvaro et al.[84] reported that the yield of $MV^{+\bullet}$ was found to depend on the nature of the alkali metal ion-exchanged into zeolite Y. Yoon and co-workers[85] reported the formation of $MV^{+\bullet}$ in MV^{2+}–arene donor charge-transfer (CT) complexes in K^+-, Rb^+-, and Cs^+-containing zeolite X. However, in the absence of any arene, $MV^{+\bullet}$ was not detected. In subsequent studies, Ranjit and Kevan[78,79] reported that the quantum efficiency of $MV^{+\bullet}$ increased in the order Li–X < Na–X < K–X < Rb–X < Cs–X. The donor strength of the zeolite framework also increases in the same order, suggesting that the aluminosilicate framework is the electron donor. This was further confirmed by a linear correlation between the quantum efficiency and the Sanderson's partial charge of the framework oxygen. The half-lives for $MV^{+\bullet}$ were determined to be 63, 24, 20, 12, and 10 days for Cs–X, Rb–X, K–X, Na–X and Li–X zeolites, respectively, and consistent with the trend observed for the quantum efficiency. The quantum efficiency of $MV^{+\bullet}$ in Na–A zeolite was found to be two times lower than Na–X, and this was attributed to the fact that the pore opening in zeolite A is much smaller and that MV^{2+} is only adsorbed on the external surface. The photoionization of TMB was studied in chromium ion-exchanged zeolite X at room temperature.[80] The quantum efficiency of $TMB^{+\bullet}$ was found to be higher in Cr(V)–X zeolite compared with Cr(III)–X zeolite. The quantum efficiency of $TMB^{+\bullet}$ was determined to be highest in the sample containing the least amount of Cr, i.e., Si/Cr = 222. Increasing the Cr amount leads to the formation of greater amounts of non-paramagnetic $(TMB)_2^{2+}$ and evidence for this was supported by UV–vis diffuse reflectance spectroscopy (DRS) studies because ESR can only detect paramagnetic species such as $TMB^{+\bullet}$. Zeolites indeed have proven to be a versatile media for the study of photoinduced charge separation.

Other microporous materials such as ETS-10, clinoptilolite, and mordenite have also been examined for the photoinduced charge separation of methylphenothiazine (PC_1).[86–88] A series of metal-ion-exchanged microporous titanosilicates were prepared and *N*-methylphenothiazine (PC_1) was incorporated in them. UV irradiation at room temperature led to the formation of $PC_1^{+\bullet}$. The quantum efficiency of $PC_1^{+\bullet}$ was found to decrease in the order H–ETS-10 > Na,K–ETS-10 > Na–ETS-10 > Ni–ETS-10 > Li–ETS-10 > Cu–ETS-10 > Co–ETS-10. Also, the photoionization yield was found to decrease with an increase in chain length.[86] When clinoptilolite was used as the host, the quantum efficiency of $PC_1^{+\bullet}$ was found to decrease in the order H–clinoptilolite > Ni–clinoptilolite > K–clinoptilolite > Na–clinoptilolite > Co–clinoptilolite > Na,K–clinoptilolite > Cu–clinoptilolite.[87] Taken together, these results suggest that the photochemistry of PC_1 is sensitive to the pore opening and the nature of the metal ion. It has been suggested that the protons and the alkali metal ions act as electron acceptors in these two systems, which is consistent with previously reported systems; however, no studies confirming this postulate have been carried out.

H–, Na–, and Na,K–mordenites were examined as molecular hosts for the photoionization of *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD).[88] The quantum efficiency was found to decrease in the order Na–mordenite/TMPD > Na,K–mordenite/TMPD > Na–mordenite/TMB > Na,K–mordenite/TMB > H–mordenite/TMPD > H–mordenite/TMB. The higher quantum efficiency found for TMPD was due to the lower gas-phase ionization potential (4.9 eV) compared with 6.1 eV for TMB. However, the photostabilities of $TMPD^{+\bullet}$ and $TMB^{+\bullet}$ are only a few hours. Ion exchange of Na^+ by Ni^{2+} and Cu^{2+} further increases the quantum efficiency twofold.

Aluminophosphates (AlPO-*n*) belong to a class of microporous molecular sieves comparable to zeolites.[89] The structure of AlPO covers a wide range of structure types; some are analogous to zeolites such as chabazite (AlPO-34), but there are a number of AlPOs that are unique and have no zeolite analogue such as AlPO-5 and AlPO-11. In recent years, microporous AlPO and silicoaluminophosphate (SAPO) materials have been examined as hosts.[90,91] Furthermore, they seem more amenable to framework substitution of Al(III) and (or) P(V) by a variety of transition metal ions.[92–94] The AlPO-5 (SAPO-5) is composed of 4-ring, 6-ring, and 12-ring channels; AlPO-8 (SAPO-8) consists of 4-ring, 6-ring, and 14-ring channels, whereas AlPO-11 (SAPO-11) consists of 4-ring, 6-ring, and 10-ring channels. This leads to channels with pore openings of 7.3, 8.7, and 6.3 Å, respectively. The molecular dimensions of organic molecules PC_1 and Py are 6.5 Å × 10 Å and 6.9 Å × 10 Å, respectively.

One of the first reports of the photoionization of methylphenothiazine in a transition metal containing SAPO was reported by Kurshev et al.[95] They studied the photoionization of methylphenothiazine at room temperature in SAPO-5, SAPO-11 (channel-type microporous materials), SAPO-34, and VPI-5 (cage-type microporous materials structurally similar to AlPO-8). The quantum efficiency was found to decrease in the order Ni–VPI-5 > Ni–SAPO-5 >> Ni–SAPO-11 ~ Ni–SAPO-34. The yield and stability of the photoproduced cation radicals was found to negligible in H-SAPO-5 and H-AlPO-5. Thermogravimetric analysis (TGA) of the methylphenothiazine (PC_1) containing microporous materials showed that PC_1 completely penetrated inside the channels of Ni–VPI-5 and Ni–SAPO-5, only partly penetrated into Ni–SAPO-11 channels, and did not penetrate into the channels and cages of Ni–SAPO-34. This study clearly indicates that the pore diameter is a critical parameter affecting the quantum efficiency. In a subsequent study, the photoionization of PC_1 was examined in V- and Ti-containing AlPO-5 and AlPO-11 microporous materials.[91] The quantum efficiency of $PC_1^{+\bullet}$ was found to increase in the order AlPO-11< AlPO-5 < TAPO-11 < TAPO-5 <

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

VAPO-11 < VAPO-5. ESR studies clearly indicate the formation of V^{4+} on irradiation, suggesting that the V^{5+} ions act as electron-trapping sites. Efforts to detect Ti^{3+} were unsuccessful because the signal owing to Ti^{3+} overlaped with the signal formed owing to $PC_1^{+\bullet}$. The quantum efficiency was found to depend on the amount of V^{5+} and Ti^{4+} incorporated into the microporous material, and the optimum amount was found to vary depending on the nature of the host employed. In a closely related study, metal-containing silicoaluminophosphate M–SAPO-*n* (M = Cr, Fe, or Mn, and *n* = 5, 8, or 11) were examined as hosts for the photoionization of PC_1.[96] Cr–SAPO-8 exhibited the highest quantum efficiency among the transition-metal ions examined in this study. ESR studies indicated that the transition-metal ions acted as electron acceptors. These new microporous materials with "*built-in*" transition-metal ions as electron acceptors offer the potential for creating photoactive systems with long-lived charge separation. The photoionization efficiency was found to depend on the nature of the metal ion, the concentration of the metal ion, and also on the pore size of the microporous SAPO material used, with Cr–SAPO-8 exhibiting the highest quantum efficiency. The half-life of $PC_1^{+\bullet}$ in Cr–SAPO-5 (Si/Cr = 105) was estimated to be 100 days. The high quantum efficiency and excellent photostability in this material was attributed to the high electron affinity of Cr^{5+}. The photooxidation of TMB was examined in Cr-containing SAPO materials.[90] The quantum efficiency was found to decrease in the order CrH–SAPO-11 > CrH–SAPO-5 > CrH–SAPO-8. The pore size increased in the order SAPO-8 > SAPO-5 > SAPO-11. The decrease in the quantum efficiency in the larger pores was attributed to the greater mobility of $TMB^{+\bullet}$. The stability of the photoproduced $TMB^{+\bullet}$ was found to be significantly lower compared with $PC_1^{+\bullet}$. The half-life of $TMB^{+\bullet}$ in SAPO-5 was found to be <1 h. Nevertheless, these materials were able to stabilize the photoproduced cation radicals at room temperature. In another study, the photoionization of Py was examined in Cr–SAPO-5, Cr–SAPO-11, and Cr–SAPO-34 materials.[97] ESR studies indicated that Cr(V) acted as an electron acceptor. The quantum efficiency and stability of photoproduced $Py^{+\bullet}$ was found to depend on the pore size of the microporous material, the concentration, and the oxidation state of the chromium ions. The quantum efficiency was found to decrease in the order Cr–SAPO-5 > Cr–SAPO-11 > Cr–SAPO-34. The half-life ($t_{1/2}$) of $Py^{+\bullet}$ was estimated to be 45 days. The drawback of these host systems is that the pore size is too small for the incorporation of bulky molecules such as porphyrins and *N*-alkylphenothiazines (alkyl = hexyl, heptyl, octyl, decyl, etc.) and *N*-alkylpyrenes (alkyl = butyl, pentyl, hexyl, etc.).

Photoinduced charge separation in mesoporous materials

In heterogeneous reactions using microporous materials, diffusion of the reactant molecules and accessibility of the active sites to them are important factors. Bulky molecules with molecular dimensions >10 Å cannot be incorporated in the pores of microporous materials such as zeolites, AlPO, and SAPO.[98] Hence, it is important to study the feasibility of new materials with larger pore dimensions as hosts. Such materials can immobilize bulky photoactive molecules within their pores and stabilize them. *N*-Alkylphenothiazines PC_1, PC_3, PC_6, PC_{10}, and PC_{16} were incorporated into transition-metal-ion-containing mesoporous silicoaluminophosphates (Me–UHM-3, where Me = Cu, Cr, Ni, or Mn) and their photooxidation examined after UV excitation.[99] The pore diameter of these materials was determined to be 1.7 nm by using the Barrett–Joyner–Helena (BJH) equation and applying it to the desorption branch of the nitrogen isotherm. The effect of the ratio of Si/Al, the nature of the transition metal, and the concentration of the metal on the quantum efficiency was examined in this study. The highest quantum efficiency was obtained for mesoporous Cu–UHM-3 with PC_{10} as the electron donor. The TGA results indicate that PC_1, PC_3, PC_6, and PC_{10} mostly penetrate into the mesoporous host because their molecular dimensions are less than the pore diameter of the host employed. However, when the alkyl chain length increases to 16, the TGA results indicate that PC_{16} has very little penetration into the mesoporous material of Me–UHM-3. To examine the role of pore size in the photoionization of PC_n, mesoporous UHM-3 with three different pore sizes, 1.9, 2.9, and 3.8 nm, were prepared. The photoionization of PC_n (*n* = 1, 6, 10, or 18) was examined in these materials. The quantum efficiencies and stabilities of $PC_n^{+\bullet}$ generally increase with increases in pore size except for $PC_6^{+\bullet}$, which decreased with an increase in the pore size. This is attributed to the greater mobility, which leads to smaller quantum efficiencies and faster decay.

MCM-41 is mesoporous silica containing a regular array of uniform linear one-dimensional pores with a high surface area in the range of 700–1000 m^2/g and a pore-size distribution nearly as sharp as that of zeolites.[100,101] In addition, the pore diameter can be varied from 15 Å to as high as 100 Å. The tetrahedral Si(IV) ions in the MCM-41 framework can be replaced by other metal ions such as Al(III), Ti(IV), Mn(II), etc., further extending the range of materials that can be synthesized and examined as hosts.[102–104] Photoinduced electron transfer of bulky molecules such as 2,4,6-triphenylpyrylium cations,[105] tritylium cations[106], and porphyrins in MCM-41 mesoporous materials have been reported.[107,108] Porphyrin π-cation radicals ($H_2TPP^{+\bullet}$) were generated by visible light irradiation. The quantum efficiency was found to increase with an increase in pore size. Incorporation of Ti into the MCM-41 material was found to further increase the quantum efficiency of $H_2TPP^{+\bullet}$; however, substitution of Al into siliceous MCM-41 was detrimental to the quantum efficiency because protonation of H_2TPP to H_4TPP^{2+} was found to occur. The $H_2TPP^{+\bullet}$ radical decays only by 5% after 2 days at room temperature. Since the Ti-MCM-41 materials were promising hosts for enhanced quantum efficiency and stability, a further detailed study was carried out.[109] A series of TiMCM-41 materials with variable amounts of Ti in the MCM-41 framework was synthesized and used for the photoionization of PC_n. The quantum efficiency was found to increase in the order Si–MCM-41 < Al–MCM-41 < Ti–MCM-41. The photo-oxidation yields were found to decrease as the alkyl chain lengths increased from PC_1 to PC_{16}. An impregnated Ti-MCM-41 sample was also prepared for comparison, and the quantum efficiency was found to be lower compared with the sample Ti–MCM-41 in which Ti was incorporated into the framework (Si/Ti ratios of 200, 140, and 80). The stability of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

photoproduced $PC_n^{+\bullet}$ was found to increase from PC_1 to PC_{16} owing to the inductive effect. In a related study, transition-metal-ion-exchanged Me–AlMCM-41 was examined as a host for the photoionization of PC_n.[110] Among the transition-metal ions studied, Ni–AlMCM-41 exhibited the highest quantum efficiency compared with Fe– and Cu–AlMCM-41. The photoionization yield was found to decrease with an increase in the alkyl chain length as reported previously. To test the generality of the photoinduced charge separation, *N*-alkylpyrenes (Py_n) were photoionized in SiMCM-41 and transition-metal-ion-containing Me–MCM-41 (Me = Co^{2+}, Cu^{2+}, Ni^{2+}, V^{5+}, or Ti^{4+}).[111] The quantum efficiency was found to increase in the order Ti–MCM-41 > Ni–MCM-41 > V–MCM-41 > Si–MCM-41 > Co–MCM-41 > Cu–MCM-41. The quantum efficiency was found to decrease with an increase in the alkyl chain length. This was partly attributed to the formation of molecular aggregates because Py_ns with longer alkyl chain lengths are more prone to this phenomenon. Another reason for the decrease was due to the exclusion of Py_n with an increase in the alkyl chain length, a result confirmed by TGA experiments.

Mesoporous MCM-41 molecular sieves were found to be promising hosts for long-lived photoinduced charge separation between carotenoid radical cations and the MCM-41 framework.[112] Incorporation of metal ions such as Ni(II), Ti(IV), Cu(II), and Fe(III) into siliceous MCM-41 was found to enhance the efficiency of carotenoid oxidation.[113–115]

Among the M41S class of materials, extensive studies have been carried out using the hexagonal form, MCM-41. Less studied is the cubic form, MCM-48. One of the reasons for this is due to the fact that the synthesis of the cubic form is inherently challenging. Thus, the photoionization of PC_n and H_2TPP was examined in this material.[91,108] The photooxidation efficiency of $PC_n^{+\bullet}$ increased in the order Si–MCM-48 < Al–MCM-48 < V–MCM-48. The net quantum efficiency was found to increase monotonically with an increase in the V content in MCM-48. The quantum efficiency was found to decrease with increasing alkyl chain length, whereas the photostability was found to increase with an increase in the alkyl chain length, which is consistent with previous reports involving MCM-41.

SBA-15 belongs to the mesoporous family of materials and, unlike MCM-41, has relatively thicker pores (60 Å) and hence is thermally more stable.[116,117] It has a hexagonal structure with highly uniform tubular channels that can be varied from 50 to 300 Å. Hence, it is an interesting material for encapsulating guest molecules. V–SBA-15 was prepared by incipient wetness impregnation and used as a host for the photoionization of PC_n (n = 1, 6, 10, or 16).[118] The photoionization results indicate that $PC_n^{+\bullet}$s are more stable in V–SBA-15 compared with the siliceous form and that the quantum efficiency was found to increase with an increase in V loading. In contrast to previous studies, both the quantum efficiency and photostability were found to increase with an increase in the alkyl chain length. The half-life of $PC_n^{+\bullet}$ is, however, only a few days and lower compared with several microporous materials examined previously, indicating a high mobility in these large-pore-sized (53 Å) materials. In a follow-up study, the photoionization of PC_ns (n = 1, 6, 10, or 16) were examined in Ti–SBA-15 materials at room temperature.[119] The overall quantum efficiency and stability of $PC_n^{+\bullet}$ was found to increase with an increase in Ti content and with an increase in alkyl chain length for PC_n.

Conclusion and future outlook

This review clearly illustrates that heterogeneous solid supports are versatile materials for the encapsulation of photochromic molecules. Of the various microporous and mesoporous structures that have been synthesized and characterized, only a handful of framework types have been investigated in detail for applications related to photoinduced charge separation. There are a large number of structure types that have been unexplored and possibly untapped, and concerted research is required to bridge our gap using these materials. Although it is clear that periodic materials provide a novel way to arrange molecules in three-dimensional space and the potential to mimic the natural photosynthetic system, there are several challenges and issues that need to be addressed before they can be deployed in large-scale applications and become practical. These are outlined below:

1. The efficiency of the photoinduced charge separation process needs to be improved and BET further minimized to increase the lifetime of the photogenerated species.
2. Several of the artificial photoredox systems reported in the literature require the use of high-energy UV light or visible light. Chromophores should be designed such that they can absorb the broad spectrum of the solar radiation, including UV, visible, and the near-IR wavelengths, and transfer the energy efficiently to the active redox centers.
3. Currently, the host molecules are randomly or statistically encapsulated in the channels, cages, or pores of the host material. In principle, one should be able to achieve spatial control of the placement of these molecules a priori in predetermined and specific positions.

Abstract: The rates and the mechanism of intramolecular hydrogen-atom transfer across the rigid diketopiperazine spacer in two epimeric benzophenone–tyrosine dyads were studied by nanosecond laser flash photolysis in 12 non-protic and protic solvents. Effects of the stereochemistry on the ground-state structures and conformational equilibria and dynamics have been addressed by means of NMR-based population analysis and long-term molecular-dynamics simulations. The excited triplet state of the benzophenone is found to be quenched intramolecularly by the remote phenol moiety with rates that are highly dependent on the solvent and on the relative benzophenone–phenol orientation. In agreement with previous studies, the kinetic diversity, with rates ranging from $<10^5$ s^{-1} to 2×10^7 s^{-1}, can be attributed to retarding effects of the bulk viscosity and to effects of specific solvation, which can be both rate retarding and rate accelerating. As an extension of the previous knowledge, however, the phenomenology of the kinetic solvent effects, that is, the nature of the predominating solvent parameter and its absolute impact on the reactivity, is found to be highly correlated with structural effects.

Key words: kinetic solvent effect, stereoselectivity, biradicals, tyrosyl radical, molecular dynamics.

Résumé : Utilisant la photolyse laser éclair, au niveau de la nanoseconde, on a étudié les vitesses et le mécanisme de réaction du transfert d'atome d'hydrogène intramoléculaire à travers l'espaceur dicétopipérazine rigide dans deux dyades de benzophénone–tyrosine dans douze solvants protiques et aprotiques. Faisant appel à l'analyse de populations à l'aide de la RMN et de simulations de dynamique moléculaire à long terme, on a étudié les effets de la stéréochimie sur les structures de l'état fondamental et sur la dynamique et les équilibres conformationnels. On a trouvé que l'état triplet excité de la benzophénone est piégé d'une façon intramoléculaire par la portion phénolique éloignée avec des vitesses qui dépendent beaucoup du solvant et des orientations relatives de la benzophénone et du phénol. En accord avec les études antérieures, la diversité cinétique des vitesses qui varient de moins de 10^5 s^{-1} à 2×10^7 s^{-1} peut être attribuée aux effets de viscosité globale qui les diminuent et aux effets de solvatation spécifique qui peuvent soit les accélérer ou les retarder. Toutefois, comme extension aux connaissances acquises antérieurement, on a trouvé que la phénoménologie des effets cinétiques du solvant, c'est-à-dire la nature du paramètre prédominant du solvant et son impact absolu sur la réactivité, est intimement reliée aux effets structuraux.

Mots-clés : effet cinétique du solvant, stéréosélectivité, biradicaux, radical tyrosyle, dynamique moléculaire.

[Traduit par la Rédaction]

Introduction

Photoinduced hydrogen-abstraction reactions by triplet-excited carbonyl compounds have been a central topic of photochemical research for many years.[1] Starting off with the seminal study by Das and Scaiano in 1981,[2] the reactions of phenols with triplet-excited carbonyl compounds have stimulated recurrent interest.[3–26] Hydrogen-atom transfer (HAT) from the phenol to the excited carbonyl provides, quite invariantly with respect to the nature of the carbonyl compound, an efficient source of metastable radicals, namely the carbonyl-derived ketyl radical and the phenoxyl

radical. Ample use of these clean radical-affording pathways has allowed the selective formation and the characterization of biologically relevant phenoxyl radicals that are derived, for instance, from the phenolic amino acid tyrosine (Tyr)[7] and from the phenolic neurotransmitter adrenaline.[6] Selective generation of fluorinated tyrosyl radicals within biological matrices has allowed their use as a mechanistic probe and as an external trigger of proton-coupled electron transfer reactions in native proteins.[27]

This biochemical application was based on an intramolecular variation of the carbonyl–phenol theme within covalently bound dyads. Mechanistic studies of the intramolecular HAT pathways corroborated the view that such dyads share the reaction pathways with their bimolecular congeners and, thus, produce the corresponding biradicals with high selectivity and efficiency as long as the structural constraints of the dyad allow close contacts between the reacting moieties. The intramolecular HAT quenching of, for instance, the benzophenone triplet state (^{3}bp) by an H-atom donor, RH, implies that >C=O···HR distances below 3.1 Å are successful.[28] Studies of the intramolecular HAT of several benzophenone-based dyads have provided evidence that the chemical nature of the linker between the chromophores (that is, the flexibility and the directionality of the linker) is one major source of kinetic diversity. Remarkable variations in the reaction rates of isomeric benzophenone–phenol dyads (regiomers and stereomers) have been attributed to modulations of the distance distributions and relative orientations of the reacting moieties.[10,12,19]

In extension of previous work on the solvent effects of the intramolecular HAT by Scaiano, Miranda, Leigh, and others,[2,12,16,19,23] our recent systematic studies of the HAT reactions of peptide-linked benzophenone–tyrosine dyads (bp∪Tyr) have shown that this interpretation of structurally imposed kinetic effects is incomplete. Instead, specific solvent–solute interactions have been identified as the second important control of the intramolecular HAT dynamics.[29,30] Our results imply that the kinetic effects that are imposed by the solvent and those that are due to the dyad structure are correlated with each other and that they must not be treated separately. In non-protic solvents the intramolecular reactivity was generally found to be linearly correlated with the solvents' hydrogen-acceptor strength, which parallels the phenomenology of the solvent dependence of bimolecular HAT reactions of phenols.[31–36] In particular, the HAT reaction in two epimeric bp∪Tyr dyads exhibited significantly solvent-dependent stereoselectivity, which could be attributed to specific solvent–solute interactions.[29]

In the latter work the chromophores were connected by open-chain peptide structures (see Scheme 1; A denotes ^{3}bp as the hydrogen acceptor; HD denotes hydrogen donor PhOH), wherein the high intrinsic flexibility of the linker blurs the stereoselectivity. Therefore, limiting the flexibility of the peptide linker should allow deeper insights into the relations between the kinetic phenomenology and the molecular structure. The diketopiperazine (DKP) ring system provides such a peptide environment with reduced flexibility. First, the DKP ring imposes a distinct orientation between the reacting chromophores for epimeric dyads (see Scheme 1; from left to right, the structures denote the (L-L) and (L-D) epimers). In addition, the presence of the DKP ring exerts unique control over the conformations of the respective side chains of the attached amino acids. Previous studies of the conformations of substituted diketopiperazines revealed structural preferences that significantly differed from those of their open-chain analogues.[37,38] Such structural preferences are expected to be reflected in the nonbonding distances of the side chains and the inter-side-chain reactivity.

Preliminary work on the HAT between tyrosine and 4-benzoyl-phenylalanine (bpa) side chains of the epimeric diketopiperazines **1** and **2** (see Scheme 2*a*) actually showed significantly enhanced stereoselectivity.[39]

Herein, we present the results of extended laser-flash photolysis studies of **1** and **2** that address the medium dependence of the excited-state dynamics in more detail. These studies are supplemented by the results of molecular-dynamics simulations and NMR investigations of the ground-state structures and conformations that establish a quantitative picture of the conformer distributions of the dyads and define the molecular prerequisites of the individual quenching geometries. As will be shown, the presence of the rigid DKP linker imposes very different structural constraints on the intramolecular mobility of epimers **1** and **2**. These structural differences translate into individual phenomenology of the solvent effects for both of the dyads.

Experimental section

Synthesis and characterization

Chemicals and solvents (Sigma-Aldrich and BACHEM) for synthesis were of the highest available analytical grade and were used without further purification. Products were identified by means of NMR techniques and combustion analysis. Routine ^{1}H NMR and ^{13}C NMR spectra were recorded at 200/400 MHz and 50.3 MHz, respectively, in perdeuterated dimethyl sulfoxide (DMSO-d_6) and in deuterated trifluoroacetic acid (TFA-*d*), with the resonances being reported in parts per million downfield from tetramethylsilane. Assignments of ^{1}H and ^{13}C resonances were based on two-dimensional homo- and heteronuclear NMR techniques. An unambiguous assignment of the strongly overlapping β-proton resonances of the bpa and the Tyr residues in **1** and **2**, as required for the analysis of the ground-state rotamer distribution, was accomplished by two-dimensional nuclear Overhauser enhancement spectra (see Figs. S1 and S2 in the Supplementary data). The assignment of the $H^{\beta R}$ and $H^{\beta S}$ in the Tyr side chain of **1** and **2** as the high-field and the low-field doublet-of-doublet parts of the AB sub-spectrum, respectively, followed established conventions.[40] The same assignment was assumed to hold for the bpa side chain. The synthesis of the cyclic dipeptides (diketopiperazines, DKPs) **1** and **2** followed the method invented by Nitecki et al.[41] The fully protected open-chain precursors *N*-boc-(L/D)-bpa-(L)-Tyr-OMe were obtained by standard peptide-coupling methods as recently described in detail.[29] The cyclic peptides were obtained from the precursors after acidic deprotection of the N-terminus in formic acid followed by thermally

induced cyclization (full synthetic procedures and details of characterization are given in the Supplementary data).

Molecular modeling details

The conformational space of the DKPs **1** and **2** was sampled by means of Langevin dynamics (LD)[42–48] done in conjunction with the CHARMM27[49] all-atom empirical potential. Since there is no representation of the diphenylketone functionality in the original CHARMM force field, the parameters for the atoms of its aromatic rings were taken from the atoms of the phenylalanine residue. Similarly, the carbonyl oxygen and carbon atoms of the ketone functionality were calculated with parameters provided for these atoms in the peptide bond. To achieve consistency of charge distribution in the molecules, the atomic charges were recalculated using the partial equalization of orbital electronegativity method of Gasteiger and Marsili.[50] In the LD no explicit solvent molecules were used, but the usual LD frictional drag of the solvent was factored in using a collision frequency for all heavy atoms equal to approx. 20 ps^{-1}, which reflects the viscosity of acetonitrile, fitting molecular dynamics and experimental data.[44,51] The free LD simulations were done with the 2 fs time step and 100 ns propagation time, preceded by 12 ps of heating from 0 K to 300 K and 18 ps of equilibration. For the force field calculations we used version 7.1 of the HyperChem PC molecular modeling package,[52] which integrates the Langevin equation of motion using the method of Allen and Tildesley.[53]

The rate constants of the close-contact formation between the reacting moieties, here k_{OO}, have been evaluated from the simulations by means of number correlation functions, following the routines that have been described in detail previously.[54] If the reactive and non-reactive conformations are considered as being in equilibrium but the overall H-abstraction reaction is very fast compared with the relaxation of equilibrium between the conformations, then the observed rate constant k_H should be comparable to a theoretical rate constant, k_{OO}, computed from the simulation via eqs. [1–3].[54] The numerator, $\langle N_{OO}\rangle$, in eq. [1] is the fraction of the time that the distance between the carbonyl and hydroxyl oxygens was less than 4 Å during an 80 ns LD trajectory. The denominator, τ_{rxn}, in eq. [1] is the relaxation time for the equilibrium between the reactive and non-reactive conformations. It is related to a correlation function by the fluctuation-dissipation theorem.[55] The normalized number correlation function $C_N(t)$ was used for this calculation (see eq. [2]).

$$[1] \qquad k_{OO} = \frac{\langle N_{OO}\rangle}{\tau_{rxn}}$$

$$[2] \qquad \tau_{rxn} = \int_0^{+\infty} C_N(t)\,dt$$

which has the form

$$[3] \qquad C_N(t) = \frac{\langle \delta N_{OO}(t)\delta N_{OO}(0)\rangle}{\langle \delta N_{OO}{}^2\rangle}$$

Here $\delta N_{OO}(t) = N_{OO}(t) - \langle N_{OO}\rangle$ and $N_{OO}(t) = 1$ for $d_{OO} \leq 4.0$ Å and $N_{OO}(t) = 0$ for $d_{OO} \geq 4.0$ Å. Note that $\langle \delta N_{OO}{}^2\rangle = \langle N_{OO}\rangle - \langle N_{OO}\rangle^2$. The statistical error of the evaluation has been taken into account following the approach of Zwanzig and Ailawadi.[55,56]

Nanosecond flash photolysis

The setup for the nanosecond laser flash photolysis (LFP) experiments and the data acquisition system have been previously described in detail.[57,58] LFP experiments employed a pulsed N_2 laser (337 nm, 5 mJ, ≈8 ns) and a Nd:YAG laser (266 nm and 355 nm, 5 mJ, 7–9 ns) for excitation. Transient decays were recorded at individual wavelengths by the step-scan method with a step distance of 10 nm in the range of 320 to 700 nm as the mean of 10 pulses. Samples for LFP were deoxygenated with high-purity argon for 15 min prior to the measurements. Experiments were performed in rectangular quartz cells (1 cm × 1 cm). All experiments were performed with freshly prepared solutions at room temperature (295 ± 1 K). In the case of 266 nm photolysis, excitation of both chromophores (bp and Tyr) cannot be avoided. However, analysis of the molar absorption coefficients measured for bp and Tyr[59] shows that excitation of the tyrosine moiety was less than 10%. We used 266 nm excitation (which allowed us to use lower dyad concentrations) to avoid bimolecular hydrogen abstraction by the triplet state from the ground state of the dyad (self-quenching). Solvents for time-resolved spectroscopy were of the highest available analytical grade and were used without further purification.

Results

NMR study of ground-state conformations

A previous density functional theory (DFT) study of the DKPs **1** and **2** revealed the structural details of the respective quenching geometries and a qualitative interrelation between the inter-side-chain reactivity and structural preferences, which are reflected in the non-bonding distances of the side chains.[39] The cited work has shown that a variety of structures that differ in their relative side-chain orientations should be energetically accessible in solution. Therefore it was of interest to obtain quantitative information about the populations of the side-chain rotamers in the dyads' ground state. Herein we present the results of an NMR-based analysis of the absolute populations of the side-chain rotamers of the DKPs **1** and **2**. An important result is that the NMR-derived populations are distinctly different between the epimeric dyads **1** and **2**.

The populations of the rotamers $p(\boldsymbol{i})$ were extracted from the vicinal coupling constants of the diastereotopic β-protons and the α-protons of both of the amino-acid side chains, $^3J(H^{\alpha}–H^{\beta R})$ and $^3J(H^{\alpha}–H^{\beta S})$ (here bpa and Tyr; see Scheme 2*a* for the notation of the proton positions),[60] as recently used in the analysis of open-chain dyads.[29,30] The acronyms $\mathbf{E_N}$, $\mathbf{E_O}$, and **F** denote side-chain rotamers wherein the aromatic substituent R is extended to the adjacent nitrogen atom, extended to the adjacent carbonyl oxygen atom, and folded back across the DKP ring, respectively. This rotamer notation is based on the orientation of the side-chain substituent R (see Scheme 2*b*) rather than on the dihedral angles, to simplify the comparison between the epimeric compounds **1** and **2**. The computed rotamer populations for DMSO-d_6 and TFA-*d* are summarized in Table 1. The limited

Table 1. Summary of the side-chain rotamer populations $p(i)$ of the diketopiperazines **1** and **2** computed from experimental coupling constants (DMSO-d_6; 200 MHz).

	bpa residue			Tyr residue		
	$p(\mathbf{E_N})$	$p(\mathbf{E_O})$	$p(\mathbf{F})$	$p(\mathbf{E_N})$	$p(\mathbf{E_O})$	$p(\mathbf{F})$
1	0.22 (0.40)	0.10 (0.17)	0.68 (0.43)	0.18 (0.21)	0.07 (0.21)	0.75 (0.58)
2	0.42 (0.55)	0.20 (0.16)	0.38 (0.29)	0.26 (0.33)	0.20 (0.16)	0.54 (0.51)

Note: Estimated uncertainty $\Delta p(i) = \pm 0.02$ and ± 0.04 for $p(\mathbf{E_N})$ ($p(\mathbf{E_O})$) and $p(\mathbf{F})$, respectively. Data in parentheses denote the populations in TFA-*d*.

Fig. 1. DFT minimized structures of highly populated solution-phase conformations of **1** (**F–F**) and **2** (**F–E$_N$**). (Note that the **1** shown here is the stereoisomer used in the LFP experiments, but the **1** shown in Scheme 2 is the stereoisomer used in the NMR and LD simulations. These two species, both labeled **1**, are identical molecules, being the mirror image of each other, and a limited set of duplicate LFP experiments verified their identical chemical behavior.)

solubility of the DKPs under study interfered with a detailed investigation of the solvent dependence of the rotamer populations. It is noted that the population preferences of **1** and **2** are somewhat blurred in solutions of the very strong H-bond donor TFA.

The NMR-derived populations for DMSO solutions of **1** and **2** reveal side-chain conformational preferences that differ significantly from those of open-chain congeners. The aromatic side chains in linear peptides preferably populate the rotamer $\mathbf{E_N}$ in polar solvents such as DMSO, with $p(\mathbf{E_N}) \geq 0.7$.[61–64] In contrast, $\mathbf{E_N}$ appears to be much less favorable in the cyclic peptide **1**, where both aromatic residues preferably populate the back-folded **F** conformation instead. This behavior is quite common for the DKPs that carry aromatic amino acids and has been associated with dipole-induced dipole interactions between the DKP amides and the aromatic ring.[65,66] Based on the assumption that the conformer populations of the two side chains of **1** are statistically independent, a favored population of the **F–F** conformation can be expected with $p(\mathbf{F–F}) = 0.68 \times 0.75 = 0.51$. Thus, in full agreement with the outcomes of the previous DFT studies in an acetonitrile (ACN) continuum, a "double-sandwich" like structure of **1** also prevails in DMSO solution, which implies long inter-side-chain distances (see Fig. 1).

For **2**, wherein both aromatic residues share the same half-room above the DKP ring, the side-chain preferences are less expressed. When compared with dyad **1**, significantly smaller populations of the **F** conformation are obtained for **2**. In particular, the **F–F** conformation of **2** would contribute only with $p(\mathbf{F–F}) = 0.38 \times 0.54 = 0.20$, if statistically independent conformer populations can be reasonably assumed. In fact, the molecular-dynamics simulations show that this latter assumption is not valid for **2** and that even smaller populations prevail (vide infra). This finding of diminished populations of **F–F** is important for the interpretation of the excited-state dynamics of **2**, because photoinduced HAT within **2** is limited to the **F–F** conformation of the side chains wherein both aromatic moieties are back-folded across the DKP ring at the same time. It appears that repulsive interactions between the bulky aromatic groups favor the population of sterically less crowded conformations in the latter structure. In particular, a simultaneous population of the **F** rotamer by both side chains appears less probable.

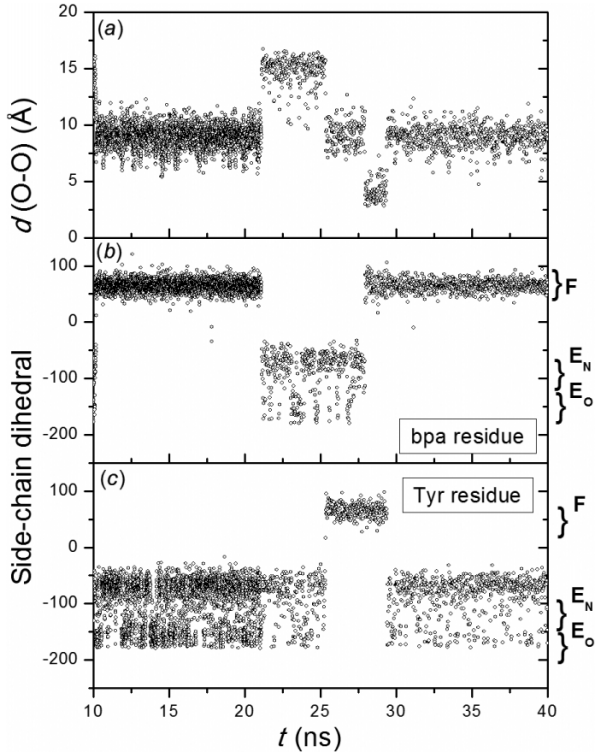
Fig. 2. Extracts of long-term molecular-dynamics simulations for **2** (Langevin dynamics; implicit-solvent model for ACN): (*a*) time variation of the inter-side-chain distance *d*(O–O) between the tyrosine (Tyr) hydroxylic oxygen atom and the 4-benzoyl-phenylalanine (bpa) carbonyl oxygen atom; (*b*) time variation of the bpa side-chain dihedral angle; (*c*) time variation of the Tyr side-chain dihedral angle.



Conformational dynamics

The interconversion between different molecular conformations has been studied by means of long-term molecular-dynamics simulations (100 ns duration; implicit-solvent model for ACN). Figure 2 summarizes the time variation of 3 molecular parameters (both side-chain dihedral angles and the characteristic inter-side-chain distance) within a 30 ns simulation window for dyad **2**. In Fig. 2*a* the sum of the resident times at each distance (*d*(O–O)) should be viewed in regard to the total period of the simulation (100 ns); i.e., when the sums of these resident times are divided by the total time of the simulation, they basically reflect the relative existence of the dyad at each O–O distance (probability distribution). (Respective plots for **1** are given in the Supplementary data.)

In agreement with the NMR results, mainly 3 rotamers ($\mathbf{E_N}$, $\mathbf{E_O}$, and **F**) of each side chain are populated during the simulation of both compounds. Of particular interest was the probability of the **F–F** conformation of **2**, which allows for close contacts of <4.0 Å (Fig. 2) between the reacting moieties and closely resembles the quenching geometry of this dyad. As stated above, the simulations strongly disfavor this conformation: the calculated probability of the population of the **F–F** conformation is only 1.4%. In conclusion, the **F–F** conformation, although shown to be a rare conformation during the simulations for **2**, irrespective of the chosen starting geometry, is sufficient to explain the reactivity toward intramolecular HAT in the range of 10^7 s^{-1} (see further discussion).

As shown by DFT studies, close contacts of <3.2 Å within dyad **1** require the population of conformations that do not refer to side-chain rotamers. The formation of such structures does not appear at all during the 100 ns simulation (see Fig. S3 in the Supplementary data).

Laser flash photolysis: spectral and kinetic analyses

The excited-state dynamics of the dyads **1** and **2** were studied by means of nanosecond laser photolysis in 12 different solvents and solvent mixtures. Transient products were identified, and the efficiency of their formation was quantified by means of transient-absorption spectroscopy and spectral resolutions.

In all cases the triplet state was identified as the predominate intermediate in the early spectra by its characteristic absorption maxima at 325 nm (not shown) and 520 nm in addition to a long-wavelength absorption above 600 nm. The triplet state spectra of both dyads were indistinguishable and showed little variation with the change in solvent.

For bp∪Tyr dyads that are related to **1–2**, intramolecular HAT was found to be the predominate quenching pathway. The quantum yields for the formation of the respective biradicals were reported to be unity.[61] Thus, any significant spectral evolution with a spectral shift from 525 to 540 nm and accompanied by a growth at 405 nm would be indicative of the formation of ketyl and tyrosyl radicals, respectively. We found that the two dyads showed distinctly different spectral evolution during and after the decay of the triplet state.

This effect of the structure is illustrated by the transient spectra observed for solutions of **1** and **2** in ACN (Fig. 3). While the spectrum obtained for **1** in pure ACN after 200 ns largely resembles the original triplet spectrum, with its distinctive 520 nm absorption, the spectrum obtained for **2** carries significant contributions from a tyrosyl radical and a ketyl radical after only 100 ns. Note in particular the spectral shift of dyad **2** from the initial maximum of 520 nm to 540 nm, indicating the transition from its triplet to its ketyl radical. As shown in Fig. 3*b*, a change in the solvent did not significantly affect the transient absorption spectra of dyad **2**, an observation that holds for all of the studied solvents. Accordingly, deconvolution of the transient absorption spectra for compound **2** in an ACN–H_2O (2:1 *v*/*v*) mixture gave the same results as previously reported for pure ACN.[39] The quenching is found to proceed intramolecularly with high efficiency. This finding is in accordance with the lack of a concentration dependence of the triplet decay rate constants (see below). However, the intermediate (biradical) decays on the same time scale as it is formed. This behavior interferes with biradical accumulation and is contrary to the general observation that biradicals decay on a much longer time scale than do their parent triplets.[12,16,19,61]

In contrast to the largely solvent-independent behavior of **2**, the evolution of the transient spectra of dyad **1** is strongly dependent on the nature of the solvent. In particular, the spectrum obtained after 200 ns in the ACN–H_2O (2:1 *v*/*v*) mixture differs dramatically from the one in pure ACN and is fully consistent with efficient formation of ketyl and tyrosyl radicals. To clarify the nature of this solvent effect, the

Fig. 3. Transient absorption spectra obtained during laser flash photolysis at 355 nm of deoxygenated solutions (9×10^{-4} mol L^{-1}) of (*a*) compound **1** with a time delay of 200 ns and (*b*) compound **2** with a time delay of 100 ns; measurements in ACN (filled symbols) and in ACN–H_2O (2:1 *v*/*v*) (open symbols).

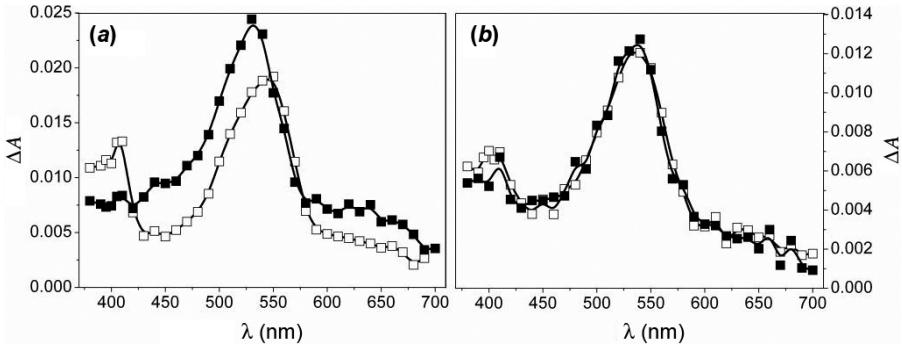


Fig. 4. (*a*) Resolutions of transient absorption spectra taken 1400 ns after 355 nm laser pulsing (5 mJ) of a solution of **1** in ACN. (*b*) Concentration profiles for the transients obtained from the deconvolution of transient absorption spectra of **1** in ACN. (*c*) Resolutions of transient absorption spectra taken 130 ns after 355 nm laser pulsing (5 mJ) of a solution of **1** in ACN–H_2O (1:1 *v*/*v*). (*d*) Concentration profiles for the transients obtained from the deconvolution of transient absorption spectra of **1** in ACN–H_2O (1:1 *v*/*v*). □, triplet state ^{3}bp; ○, ketyl radical bpH$^\bullet$; Δ, tyrosyl radical Tyr(O$^\bullet$); ◇, bp radical anion bp$^{\bullet-}$; *, experimental data. Solid curves are the resulting fits from the regression analysis.

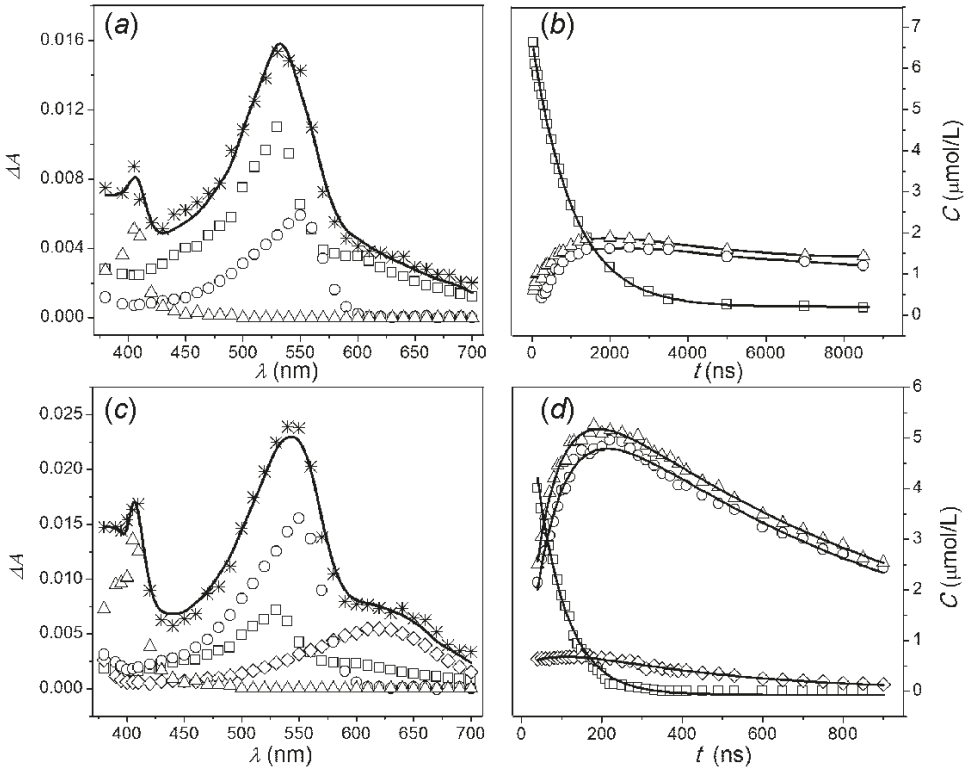

transient spectra obtained for compound **1** in ACN and ACN–H_2O (1:1 *v*/*v*) were deconvoluted into their spectral components, from which concentration–time profiles were constructed. Exemplary resolutions are given in Figs. 4*a* and 4*c* and the resulting profiles are displayed in Figs. 4*b* and 4*d*. These profiles reveal the distinct difference in the triplet quenching of dyad **1** in the two solvents. That is, the reaction is found to be intermolecular in ACN, whereas it is predominantly intramolecular in the ACN–H_2O (1:1 *v*/*v*) mixture. To simulate quantitatively the experimental data obtained in ACN for dyad **1**, only 3 components were needed: the triplet state ^{3}bp, ketyl radicals (bpH$^\bullet$), and tyrosyl radicals (Tyr(O$^\bullet$)) (see Fig. 4*a*). The concentrations of bpH$^\bullet$ and Tyr(O$^\bullet$) were found to be equal within the error estimation. The triplet decay obtained from the concentration profile is 1 μs, which is well in agreement with the triplet lifetime obtained from the kinetic traces at 630 nm. From the decomposition of the transient absorption spectra and the resulting concentration profile, the quantum yield for the formation of both radicals was calculated to be equal to 25% in ACN. Based on the long lifetimes of the radicals, which are decaying for tens of microseconds, we can conclude that they are formed mainly in self-quenching reactions (see Scheme 3).

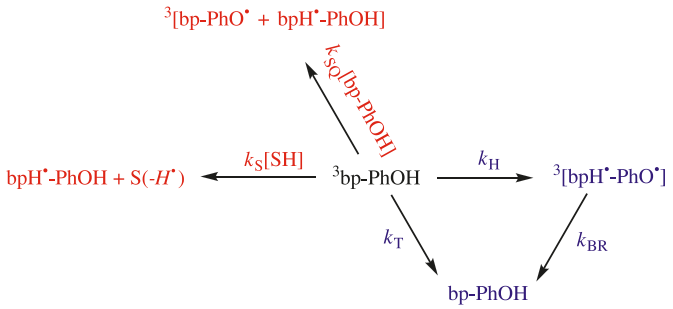
Scheme 3. Deactivation paths (red, bimolecular; blue, unimolecular) of the triplet-excited state of the dyads **1** and **2**.



A totally different situation was observed for dyad **1** in ACN–H_2O (1:1 *v*/*v*). First, the triplet lifetime was reduced by a factor of 10. Second, to reproduce the experimental data, 4 components had to be used, namely ^{3}bp, ketyl radicals (bpH$^\bullet$), bp radical anions (bp$^{\bullet-}$), and tyrosyl radicals (Tyr(O$^\bullet$)). The rates of formation of the radical species bpH$^\bullet$, bp$^{\bullet-}$, and Tyr(O$^\bullet$) were, within experimental error, identical to the triplet-decay rate of dyad **1**. The total amount of bpH$^\bullet$ and bp$^{\bullet-}$ together was equal to the Tyr(O$^\bullet$) concentration, within experimental error. Formation and decay of both the ketyl radical and the tyrosyl radical appear to follow the same decay law. This is in accordance with an intramolecular reaction mechanism. The initial triplet concentration, after extrapolation to the end of the pulse, was 7.1 μmol L^{-1}. The maximum concentration of the tyrosyl radical was determined to be 6.9 μmol L^{-1}. This value was obtained from fitting the Tyr(O$^\bullet$) concentration profile to a function that takes into account the growth and the decay of the species. From this value and the above triplet concentration (actinometer), the quantum yield of the tyrosyl radical is seen to be close to unity. The same procedure was applied to the bp radical anion, and its quantum yield of formation was estimated to be 0.18. The results proved that not only can dyad **1** (which has the benzophenone and phenol moieties on opposite sides of the DKP ring) undergo intramolecular HAT, but this reaction can occur with quantum yields close to unity. Analogous behavior has been observed in other solvents such as ACN–H_2O mixtures, 2,2,2-trifluoroethanol (TFE), and 1,1,1,2,2,2-hexafluoropropanol (HFIP), except that the bp radical anion was detected only in ACN–H_2O mixtures.

The steering effects of the solvents on the efficiency of the intramolecular triplet quenching of dyads **1** and **2** manifest themselves also in the triplet lifetimes, which exhibit a remarkably distinct influence of the solvents. Some exemplary kinetic profiles, recorded at 630 nm, that illustrate the distinct solvent dependencies of the triplet decays of **1** and **2** are given in Fig. 5. For dyad **2**, where the benzophenone and tyrosine moieties occupy the same side of the DKP ring, the kinetic profiles coincide with each other, irrespective of the solvent. This indicates little impact of the solvent on the triplet lifetimes. Contrasting behavior was seen in dyad **1**, where the triplet lifetimes were very sensitive to the solvents and varied between approx. 50 ns in HFIP and >1000 ns in ACN or EtOAc. In general, the triplet lifetimes of **1** are reduced dramatically on going from non-protic to protic solvents. Thus, in contrast to the previous study of a pair of open-chain epimeric dyads, the triplet lifetimes of the two cyclic structures studied here exhibit completely distinct solvent dependencies.

To study the solvent effects on the intramolecular HAT pathway, the corresponding rate constants, k_H, have been isolated from the observed gross triplet-decay rate constants, k_{obs}. The latter have been extracted from the decay profiles at 630 nm (mono-exponential fits), the decay profiles at 520 nm (bi-exponential fits), and, in some cases, the triplet component of the concentration profiles (as in Figs. 4*b* and 4*d*; mono-exponential fits). Agreement between these methods was within 5%. The absolute value of the triplet-decay rate constant, k_{obs}, is the sum of the rate constants of the individual decay processes (Scheme 3). The evaluation procedures take into account (*i*) the solvent dependence of the intrinsic triplet lifetime of the bp chromophore by referencing it to the behavior of unsubstituted bp in the respective solvent and (*ii*) the effects of self-quenching (see Supplementary data). Due to the low laser power, effects of triplet–triplet annihilation were negligible.

A detailed kinetics data evaluation and a description of the way that we dealt with competition between intra- and intermolecular quenching paths can be found in the Supplementary data.

While the triplet decay of dyad **2** exhibited no significant concentration dependence, LFP results for dyad **1** in non-protic solvents, such as ACN or dichloromethane, show that the values for k_{obs} were concentration dependent. This behavior is due to contributions to bimolecular quenching from self-quenching, which leads to the ketyl radical and the tyrosyl radical with the rate constant k_{SQ}. The latter species decayed by bimolecular processes within tens of microseconds and therefore gave a virtually constant offset in the transient spectra on the time scale of the experiment. The self-quenching process was efficient in non-protic solvents where the reactivity toward intramolecular HAT was small. Notably, the k_H calculated from experiments at different concentrations, 2×10^{-5} mol L^{-1} (λ_{exc} = 266 nm) or 9×10^{-4} mol L^{-1} (λ_{exc} = 337 nm), were in a good agreement (Table 2).

The rate constants for the intramolecular HAT, k_H, calculated for dyad **1** range from $<1 \times 10^5$ s^{-1} in EtOAc to 2×10^7 s^{-1} in HFIP (see Table 2). The rate constants for the intramolecular HAT for dyad **2** varied only from 2.2×10^7 s^{-1} in ACN to 8.2×10^6 s^{-1} in TFE. The uncertainty in the rate constant values derived in this manner increases significantly with H-abstraction contributions from the solvent.

The results presented in Table 2 show a striking contrast between the two diastereomers with regard to the dependence of their k_H on solvent. The results show that a change in the configuration of just one chiral center produced completely distinct changes in the reactivity of the intramolecular HAT with a change in the solvent. The reaction rates for dyad **1** were found to be strongly solvent dependent, while the solvent was found to be of minor importance for the reaction rates of dyad **2**.

This contrasting solvent behavior toward the intramolecular HAT observed in **1** and **2** is unusual for a pair of diastereomers. In this regard they are found to be a unique pair of diastereomers with a unique solvent dependence of the

stereoselectivity. Both epimers showed reactivity with respect to intramolecular HAT, but with a remarkable chiral discrimination in their rate constants, and this chiral discrimination strongly depends on the solvents. We and others previously reported stereoselection in HAT rates of diastereomeric ketone–phenol dyads in the range of 2–10 when expressed as the ratio of the rate constants of the intramolecular HAT between remote phenol and ketone moieties of these compounds.[16,19,29] The stereoselectivity ($S = k_H$ (**2**) / k_H (**1**)) found in this work varied from 131 to 0.74 (Table 2). In particular, the epimers revealed marked stereoselectivity in some of the non-protic solvents such as EtOAc and benzonitrile, much higher than has ever been reported previously. Quite unexpectedly, the stereoselectivity was significantly reduced in protic solvents. At extremes, compound **1**, which has the reactive moieties on opposite sides of the DKP ring, became more reactive than **2** in hexafluoro-2-propanol as a medium.

Discussion

In this study the excited-state dynamics of **1** and **2** have been taken as probes of structural effects on the efficiencies and rates of intramolecular hydrogen-atom transfer reactions. We find that the distinct steric constraints of the dyads, as outlined above, are reflected in distinct dynamics of the dyads' triplet states. The dyads particularly differ in their dependencies on the medium, as discussed below.

The intramolecular HAT in dyad **1** was found to be strongly solvent dependent, with the rate constants, k_H, ranging from $<1 \times 10^5$ s^{-1} to 2×10^7 s^{-1}. We recently observed a similar range of rate constants for the intramolecular HAT in one open-chain bp∪Tyr dyad,[30] whereas the HAT reactions in the open-chain congeners of **1** and **2** in a given solvent are generally faster by one to two orders of magnitude.[29] Such solvent-driven modulations of bimolecular HAT reaction rates of phenols have been generally attributed to effects of specific solvation of the phenol, which

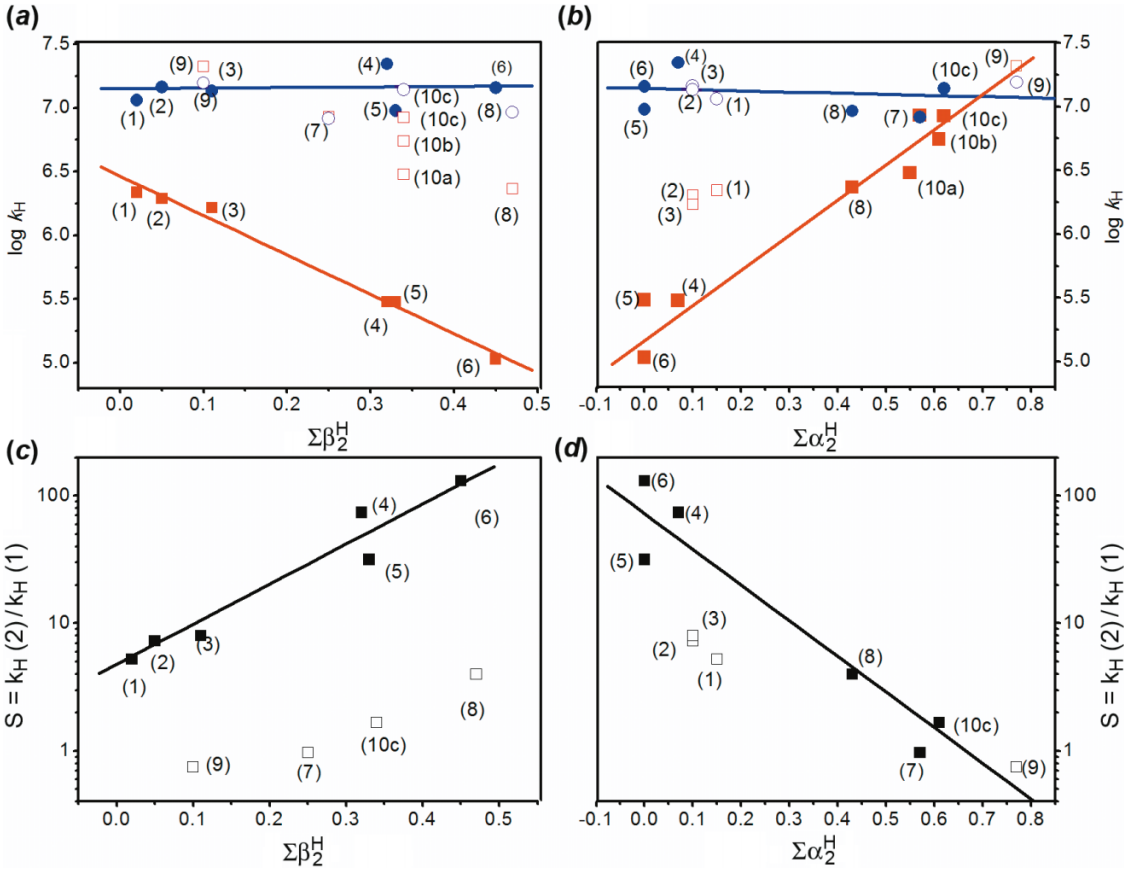
(*d*) Semilogarithmic plot of stereoselectivity of H-atom transfer in dyads **1** and **2** as a function of the solvents' H-bond donor ability; open symbols represent solvents with $\Sigma\beta_2^H \leq 0.11$. Solvent codes as in Table 2.



were coined as kinetic solvent effects. In particular, the previous work on the bimolecular HAT of phenols has shown that rate constants are correlated with the solvents' hydrogen-bond acceptor ability.[31–36,71,72] That is, the logarithmic rate constants depended linearly on a single solvent parameter, namely Abraham's H-bond acceptor ability,[71,73] irrespective of the molecularity of the reaction.[29] Notably, the solvent dependence cannot be fully explained by solute–solvent interactions of the tyrosine moiety. As shown here, the single-parameter dependence of the intramolecular HAT reaction that sufficed to explain the reactivity of the open-chain congeners of **1** and **2**[29] is not sufficient to explain the difference in reaction rate constants of the cyclic dyad **1**. Our results show that, in contrast to the phenomenology of the kinetic solvent effect, which necessarily connects specific solvation with reaction hindrance, specific solvation can also promote the HAT reactions of phenols.

In the following discussion the focus will first be on the data for dyad **1** displayed in Figs. 6*a* and 6*b* (red symbols).

A plot of the kinetic data for dyad **1** from Table 2 against the effective H-bond acceptor ability of the solvents (Fig. 6*a*) exhibits two different regions that reflect the character of the solvents. HAT rates in non-protic solvents with weak effective H-bond donor abilities, $\Sigma\alpha_2^H$ (red filled symbols in Fig. 6*a*), have a linear dependence on $\Sigma\beta_2^H$, with a slope $b = -3.1$ ($r^2 = 0.995$) and an intercept of 6.5. Thus, this dyad is another example where the slopes of the logarithmic intramolecular HAT rate constants versus $\Sigma\beta_2^H$ plots are characteristic for each dyad but not characteristic for each donor.[29,30]

The second region in Fig. 6*a* is that formed by the protic solvents with significant H-bond donor abilities. The protic solvents seem to allow much higher rate constants than their non-protic counterparts having similar H-bond acceptor abilities (nearly matching $\Sigma\beta_2^H$). For example, ethyl acetate and MeOH have almost the same H-bond acceptor ability, but k_H values for **1** differ by a factor of 10. Another example is the contrasting behavior of pure ACN and the ACN–H_2O (2:1 *v*/*v*) mixture, in which k_H values for **1** differ by a factor of 25. The large increase in the intramolecular HAT rate constant in protic solvents might be due to a switch in the mechanism.

The decrease of the HAT rates with the H-bond acceptor ability of the non-protic solvents suggests that negligible intramolecular reactivity is expected for dyad **1** in solvents with $\Sigma\beta_2^H > 0.3$. However, the data in Table 2 show that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

protic solvents with high $\Sigma\beta_2^H$ values show significant reactivity for dyad **1**. In Fig. 6*b*, data from Table 2 are plotted against $\Sigma\alpha_2^H$; with the exception of the chlorohydrocarbons, there is a linear correlation for dyad **1** with a positive slope of 2.3 ($r^2 = 0.977$) and an intercept of 5.2. That is, the reactivity increases with the strength of the solvent–solute interaction.

In summary, opposite effects were exerted by non-protic and protic solvents on intramolecular HAT in dyad **1**. The relevant solvent parameters favoring efficient intramolecular HAT for dyad **1** are the solvents' small $\Sigma\beta_2^H$ values and high $\Sigma\alpha_2^H$ values. This was realized by HFIP, for example. The opposite behavior was seen in the poor reactivity in EtOAc, which can be explained on the basis of its high $\Sigma\beta_2^H$ (0.45) and low $\Sigma\alpha_2^H$ (0.00).

In conclusion, the solvent dependence of the cyclic dyad **1** sharply diverges from the behavior of its open-chain congener[29] but largely coincides with the phenomenology observed recently for a more rigid open-chain dyad.[30] Obviously, the observed phenomenology of the kinetic solvent effects reflects structural parameters of the dyads. This is most evident from the behavior of the cyclic dyad **2**, which lacks any significant dependence on the H-bonding properties of the solvent.

The plot of the logarithmic rate constants versus $\Sigma\beta_2^H$ for dyad **2** exibits no significant variance with the solvents' H-bond accepting or H-bond donating properties (blue symbols in Figs. 6*a* and 6*b*). Actually, the slopes are close to zero in both cases, which means that the rate constants for HAT for dyad **2** are independent of these parameters. Accordingly, the stereoselectivity of the HAT in **1** and **2**, expressed as the ratio of the rate constants and shown in Figs. 6*c* and 6*d*, directly reflects the solvent dependence of the HAT of **1**. The sharp decrease of the HAT reaction rates for dyad **1** in non-protic solvents with hydrogen-bond acceptor tendencies and, on the other hand, the sharp increase of the reaction rates in protic solvents with hydrogen-bond donor tendencies are the dominant sources of the solvent dependence of the stereoselectivity (Figs. 6*c* and 6*d*). Our findings are in contrast with other results where the stereoselectivity of the HAT process was solely dependent on the $\Sigma\beta_2^H$, irrespective of the protic or non-protic character of the solvents.

In conclusion, we have studied the behavior of the two cyclic-bridged dyads **1** and **2** in 12 different solvents and mixtures. It was shown that the properties of a solvent, i.e., its ability to act as a hydrogen bond donor or acceptor, play an important role in determining the HAT rate constants in only one of the two epimers in this study.

The contrasting solvent dependencies of the HAT rate constants for dyad **1** in protic and non-protic solvents can be interpreted as being due to fundamentally different HAT mechanisms in the respective solvents. In favor of this interpretation are the significant enhancement of the reaction rates in protic solvents and the presence of the bp radical anion in an ACN–H_2O (1:1 *v*/*v*) mixture. In addition, it is important to note that the intercepts of the single-solvent parameter regressions in Figs. 6*a* and 6*b* (red lines) differ by almost 2 orders of magnitude. These values represent the isolated and solvent-independent HAT rate constants and, thus, they should not vary if there is only a single common mechanism of HAT in protic and non-protic solvents.[30]

Moreover, NMR, molecular-dynamics simulations, and DFT results[39] have shown that conformations with extremely long distances (12.8 Å) between the reactive moieties are the most favorable ones in solution (Fig. 1; Table 1). The HAT rates in non-protic solvents are limited by the accessibility of free (i.e., not H-bonded) tyrosine. In contrast, the kinetic data obtained in protic media show a correlation between HAT rates and the H-bond donor ability of the solvent. Thus, at least for intramolecular HAT reactions, the solvation of the abstracting species should be considered, a priori, as important as the solvation of the H-donating species. However, the action of the protic solvent in this case and its impact on the mechanism of the HAT step remain under discussion and are the subject of further work.

Several pieces of evidence favor electron transfer involving pathways that are driven by specific H-bonding interactions of the electron acceptor with the protic solvent. An electron-transfer pathway in protic solvents has been observed recently for a sterically restricted bp∪TyrOH dyad. In this structure, the directionality of the benzamide linker of the dyad effectively excludes close intramolecular contacts. Studies of the solvent effects on the nanosecond-transient dynamics and on the chemically induced dynamic nuclear polarization following LFP have shown that in protic solvents the H abstraction reaction is initiated by electron transfer (G. Hörner and colleagues, unpublished data). Similar conclusions have been drawn from studies of the bimolecular electron transfer between anisole and ^{3}bp, where dramatic activating effects of strongly H-bonding solvents on the one-electron oxidation of anisole by ^{3}bp show that this phenomenon is not limited to phenols and might be of general significance.[74]

In contrast to the above discussion, neither of the rate-determining effects of solvation seems to be important for the HAT in dyad **2**, as there was little variation in the k_H rate constant among solvents. The ratio of the highest k_H obtained in ACN and the smallest k_H obtained in TFE is just 2.4 for the triplet state of dyad **2**. The absence of a marked solvent dependence, which was observed for all other dyads, therefore deserves further consideration. In particular, it raises the question, what are the factors determining the rate constants if there is no impact of specific solvation?

The observation that the triplet state of dyad **2** was quenched slightly more slowly in solvents with higher viscosity, which led to smaller values of k_H (TFE and benzonitrile, see Table 2), points to the importance of the intramolecular dynamics. Similar observations were made for its open-chain analogue.[29] The observation of a greatly diminished triplet reactivity of **2** in highly viscous *tert*-butanol further corroborates viscosity as another source of kinetic diversity. That is, the dynamics of the molecular motions bringing dyad **2** to its reactive state appear to be rate determining in all solvents, which implies that the intrinsic HAT reaction rate of the dyad, irrespective of its state of solvation, markedly exceeds the rates of the intramolecular motions.

To check whether molecular dynamics are the rate-determining steps of the intramolecular HAT of dyad **2**, we have estimated the rate constant for the formation of close-contact conformations, k_{OO}, based on the LD trajectories de-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

scribed above. In the calculation of the relaxation time (τ_{rxn} from the integration in eq. [2]), we have neglected the negative values of $C_N(t)$, which occur for $t > 1.4$ ns, since they were becoming artificially large with increasing delay times. Neglecting these negative values of $C_N(t)$ means that our computed value of 0.4 ns for the relaxation time is an upper limit. The average fraction of conformations, $\langle N_{OO} \rangle$, with the O–O distance less than 4 Å was determined to be equal to 0.01. Using this value and the τ_{rxn} from eq. [2], the estimated value of k_{OO} was calculated to be $2.5 \pm 0.1 \times 10^7$ s^{-1} (from eq. [1]). The resulting good agreement between the rate constant of formation of close-contact conformations and the experimental value of the intramolecular HAT rate constant in ACN (see Table 2) indicates that intramolecular dynamics is the rate-determining step of the intramolecular HAT.

As discussed previously,[39] DFT calculations suggested the presence of a number of different conformers of **2** with nearly degenerate energies. In particular, calculations on dyad **2** in an ACN continuum highlighted the competition between a conformer with a short O–O distance (favorable for the quenching geometry) with other, more extended conformers of similar energy (but having unfavorable geometries for HAT). This situation has been put to the test in the current work using NMR studies and molecular-dynamics simulations. Taking into account the error in DFT calculations, we can state that the NMR data and the theoretical calculations are in quite good agreement. The NMR data and the simulations both show that conformers that allow for close contacts between the reacting centers have to overcome significant steric constraints.

While the energetic differences between all of the side-chain rotamers appear to be rather small according to the NMR data (<1.0 kcal mol^{-1}), other intrinsically non-reactive structures of dyad **2** with only one aromatic side chain folded over the DKP ring are certainly favored, as evident from NMR data and the simulations (Fig. 2). Thus, significant intramolecular rearrangements must precede the reaction and can even be rate determining as soon as the intrinsic HAT rate exceeds the rate of formation of the quenching geometry. This condition actually seems to hold for dyad **2**. As stressed before (see Fig. 2), the long-term dynamics simulations indicated that the formation of close-contact structures occurs for dyad **2**. In particular, the rate of this formation in an ACN continuum with $k_{OO} = 2.5 \pm 0.1 \times 10^7$ s^{-1} (computed from eqs. [1–3]) shows very good agreement with the observed rate constants of the HAT in this solvent (see Table 2).

Conclusions

In this work we addressed the solvent effects on unimolecular HAT reactions in two epimeric benzophenone–tyrosine dyads. In agreement with previous work,[29] effects of specific solvation as well as effects of the bulk viscosity have been identified as important controls of the intramolecular reactivity. Most interestingly, the limited intramolecular mobility imposed by the rigid peptide environment of the diketopiperazine spacer translates into a strongly contrasting phenomenology of the solvent effects between the two epimers. For the anti-configured epimer **1**, where both amino acid side chains occupy different half rooms of the diketopiperazine spacer, two solvent parameters influence the H abstraction rates, namely the effective H-bond acceptor ability, $\Sigma\beta_2^H$, and the effective H-bond donor ability, $\Sigma\alpha_2^H$, as defined by Abraham.[67] In sharp contrast, the syn-configured dyad **2** represents the first example for HAT reactions from a sterically unhindered phenol without any sizable dependence on specific solvation effects. The reciprocal dependence of the HAT rates of **2** on the bulk viscosity points to the intramolecular dynamics as the rate-determining step.

In conclusion, the presented experimental and theoretical work fully confirmed our hypothesis that the solvent-effect phenomenology of intramolecular HAT reactions of phenols is dependent on and correlated with the donor-acceptor geometry. Intramolecular HAT reactions from phenols yield kinetic solvent effects that are significantly correlated with structural features; that is, individual kinetic solvent effects are expected to prevail for every single system. This mechanistic feature will be put to the test in further work.

Zirconium oxide nanoparticles coated on sepiolite by sol–gel process — Their application as a solvent-free catalyst for condensation reactions

Sadok Letaief, Yun Liu, and Christian Detellier

Abstract: An inorganic nanocomposite made of zirconia nanoparticles coated on the external surfaces of the fibrous clay mineral sepiolite was prepared by using the sol–gel process under soft conditions using zirconium(IV) propoxide in 1-propanol as the precursor. The resulting materials were characterized by X-ray diffraction (XRD), thermal gravimetric analyses (TGA) and differential thermal analyses (DTA), microporosimetry, ^{29}Si magic-angle spinning (MAS) nuclear magnetic resonance (NMR), and high-resolution transmission electron microscopy (HR-TEM). The organic material from the precursor was fully removed after calcination at 450 °C, concurrently with the crystallization of the cubic phase of zirconium oxide. The coordinated water molecules of sepiolite were fully removed and its symmetrical layered structure was folded after calcination at 650 °C, as observed by XRD and ^{29}Si cross-polarization (CP)/MAS NMR. The arrangement of the nanoparticles of zirconium oxide on the sepiolite external surfaces maintains a fibrous morphology for the nanocomposite. This material was applied as a catalyst for the Knoevenagel condensation reaction of benzaldehyde and malononitrile under solvent-free conditions. Strongly improved yields of reaction, attributed to larger catalytically active surfaces, were obtained compared with either the sepiolite clay mineral or the zirconium oxide tested individually.

Key words: nanocomposites, zirconia, clay minerals, sepiolite, Knoevenagel reaction, condensation reaction, sol–gel process, nanohybrid materials, heterogeneous catalysis, solvent-free reaction.

Résumé : Faisant appel à un processus sol–gel dans des conditions douces et utilisant du propylate de zirconium(IV) dans le 1-propanol comme précurseur, on a préparé un nanocomposite inorganique fait de nanoparticules de zircone recouvrant les surfaces externes de sépiolite, un mineral d'argileux fibreux. Les matériaux résultant ont été caractérisés par diffraction des rayons-X (DRX), par analyse thermogravimétrique (ATG) et analyse thermique différentielle (ATD), par microporosimétrie, par RMN du ^{29}Si avec rotation à l'angle magique avec polarisation croisée (RMN ^{29}Si RAM/PC) et par microscopie électronique de transmission à haute résolution (ME–THR). Les résidus du produit organique précurseur ont été éliminés complètement, après calcination à 450 °C, et cette opération s'est produite simultanément avec la cristallisation de la phase cubique de l'oxyde de zirconium. Après calcination à 650 °C, tel qu'observé par DRX et RMN ^{29}Si RAM/PC, les molécules d'eau de coordination de la sépiolite étaient enlevées complètement et la structure en couche symétrique était repliée. L'arrangement des nanoparticules d'oxyde de zirconium sur les surfaces externes de la sépiolite permet au nanocomposite de maintenir sa morphologie fibreuse. On a appliqué ce matériel comme catalyseur pour une réaction de condensation de Knoevenagel du benzaldéhyde et du malonitrile, dans des conditions sans solvant. Par comparaison avec la sépiolite ou l'oxyde de zirconium utilisés individuellement, le nanocomposite conduit à des rendements beaucoup plus élevés pour la réaction et ce résultat est attribué à une plus grande quantité de surfaces catalytiquement actives.

Mots-clés : nanocomposites, zircone, mineraux argileux, sépiolite, réaction de Knoevenagel, réaction de condensation, processus sol–gel, matériaux nanohybrides, catalyse hétérogène, réaction sans solvant.

[Traduit par la Rédaction]

Introduction

Sepiolite, a nonswelling clay mineral, is a hydrated magnesio-silicate[1] with a theoretical half cell unit formula of $Si_{12}O_{30}Mg_8(OH)_4(OH_2)_4{\cdot}8H_2O$.[2] Unlike most other clay minerals (montmorillonite, vermiculite, kaolinite, etc.), it is characterized by a fibrous structure consisting of continuous talc-like two-dimensional octahedral layers of magnesium sandwiched between two tetrahedral layers of silicon. Different units are linked to each other through an inverted Si–O–Si bond happening every six silicon atoms.[3] This arrangement of discontinuous sheets creates an extended porous

structure of tunnels and channels of molecular dimensions at the interior and at the exterior, respectively, of the fibres. The cross section of each tunnel is approximately 10.6 Å × 3.7 Å in diameter and runs parallel to the fibre axis.[4] This particularity of the structure, shared only with palygorskite, a clay mineral of similar structure but with different tunnel dimension, gives sepiolite interesting physicochemical properties such as microporosity and absorption. Despite its fascinating chemical and structural properties, its applications in the industrial domain are still quite limited compared with montmorillonite or kaolinite for example.

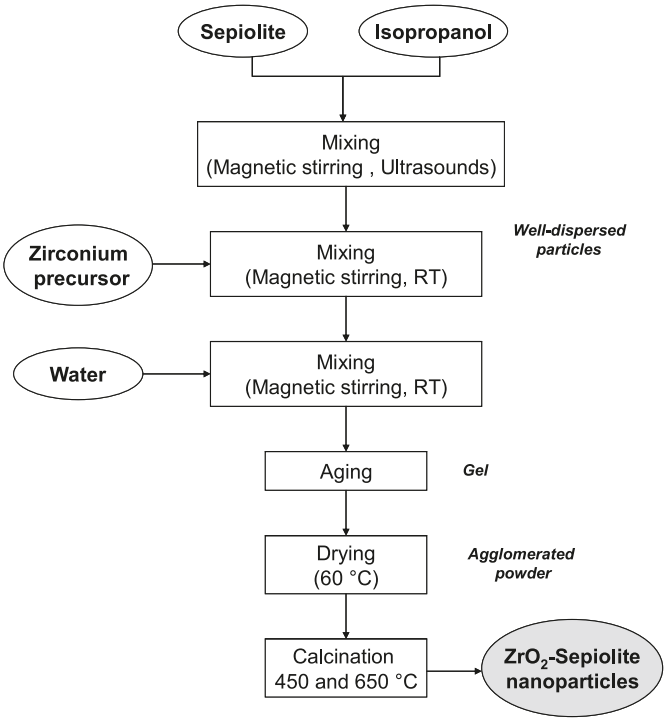
A small number of studies have reported on the preparation of metal nanoparticles supported on the external surfaces of sepiolite: by precipitation and reduction,[5,6] ion exchange,[7,8] impregnation,[9] grafting through vinylsilanes,[10,11] and sol–gel methods.[12,13] All these nanohybrid materials resulting from deposition of a variety of metallic species from, for example, titanium, osmium, iron, nickel, cupper, palladium, silver, platinum, gold, or cobalt have been used as heterogeneous catalysts or as support for potential use of their optical and magnetic properties.[5,7,12,14–21] To the best of our knowledge, the decoration of sepiolite fibres with zirconium oxide has not yet been reported.

Zirconium dioxide (ZrO_2) is one of the most studied ceramic materials owing to its chemical, mechanical, and optical properties. It is stable under three different structures: monoclinic, tetragonal, and cubic.[22] The monoclinic phase is stable from room temperature (RT) to 1175 °C. The tetragonal phase is stable from 1175 to 2370 °C and, finally, the cubic phase is stable from 2370 to 2680 °C. The stability of the phases may vary depending on the support surfaces.[22] Zirconium oxide was exploited for various applications such as catalysis,[23,24] electrochemistry,[25,26] and in membrane preparations.[27]

The Knoevenagel condensation is an important reaction in organic chemistry for the synthesis of intermediate compounds. It is one of the most useful and widely employed methods for carbon–carbon bond formation.[28] Generally, this reaction is performed in an organic solvent in the presence of a base such as an amine. In the search for more environmentally friendly reaction media, heterogeneous catalysts such as orthophosphates,[29] Ni impregnated on SiO_2 or TiO_2 supports,[30] K_2CO_3,[31] zeolites,[32] alkali-exchanged sepiolites,[33] silica gel,[34] ammonium acetate – basic alumina,[35] nanocrystalline ZnO,[36] ionic liquid[37,38], or mesoporous $Ce_xZr_{1-x}O_2$ solid solutions[39] have been reported for Knoevenagel condensations between aldehydes and malononitrile. Zirconia supported on MgO[40] or impregnated with sulfate ions[41] was used as catalyst for this reaction under solvent-free conditions.

In this study, the remarkable structural features of sepiolite were used to prepare an efficient catalyst for the Knoevenagel condensation of benzaldehyde derivatives with malononitrile under solvent-free conditions. The external surface of sepiolite was decorated by nanoparticles of zirconium oxide. These modifications, which take place at the nanometer scale under soft conditions, produce a functional nanocomposite material combining the textural properties of the pristine clay mineral and the catalytic activity of zirconium oxide. The material was characterized by a series of techniques. It was applied to the solvent-free reaction of condensation of benzaldehyde and malononitrile.

Scheme 1. A schematic illustration of the deposition of zirconium oxide nanoparticles on the external surfaces of sepiolite.



Experimental

Reagents

Sepiolite (SepSp-1) was obtained from the Source Clays Repository, Purdue University, West Lafayette, Indiana. Purified sepiolite was obtained by standard sedimentation techniques and the <2 μm fraction was used in the experiments. More details about the sepiolite purification procedures are described in the literature.[42]

Zirconium(IV) propoxide solution (70 wt% in 1-propanol) was purchased from Sigma-Aldrich and always kept in an anhydrous environment. Benzaldehyde, *para*-nitrobenzaldehyde, and *para*-hydroxylbenzaldehyde were purchased from Sigma-Aldrich and were used as received.

Preparation of ZrO_2–sepiolite nanoparticles (Scheme 1)

A procedure similar to previously reported ones for the preparation of silica–smectite,[43] titania–sepiolite,[12] or TiO_2/SiO_2 – clay porous materials[13] was used for the preparation of the nanocomposite sepiolite–zirconia nanoparticles using the sol–gel technique without addition of cationic surfactant, in contrast to the previously reported procedures.[12,13,43] Two grams of sieved sepiolite (<100 μm) were dispersed in 40 mL of 2-propanol. The suspension was stirred for 30 min, sonicated for another 6 min (3 × 2 min), and maintained again under magnetic stirring in a closed vial for 3 days to obtain a homogeneous dispersion. A selected amount of zirconium propoxide was slowly added to the suspension. Two sets of the experiment were carried out: (*i*) the amount of zirconium propoxide added was equal to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

amount of clay mineral and (*ii*) the amount of zirconium propoxide was twice the amount of clay mineral. The mixture was stirred again at room temperature for 20 min, and then the amount of water necessary for a complete hydrolysis of the propoxide was added dropwise under magnetic stirring. After the addition of water, the dispersion became very viscous because of the sol–gel transition. The resulting gel was then dried at 60 °C, grounded, and heated at two different temperatures (450 and 650 °C).

Catalytic activity

The catalytic properties of the zirconium oxide nanoparticles supported on the external surfaces of sepiolite were tested for the Knoevenagel condensation reaction between aromatic aldehyde derivatives (benzaldehyde, *para*-nitrobenzaldehyde, and *para*-hydroxylbenzaldehyde) and malononitrile. A mixture of 0.5 g of benzaldehyde (47 mmol), 0.34 g of malononitrile (51 mmol), and 40 mg of the sepiolite–zirconium oxide nanoparticle material was refluxed, vigorously stirred, and heated for 2 h at 100 °C. The resulting product was extracted by diethyl ether, purified using column chromatography on silica gel with diethyl ether – *n*-hexane, and analyzed by ^{1}H and ^{13}C NMR.

Characterization

X-ray diffraction (XRD) patterns were obtained with a Philips PW 3710 instrument equipped with a Ni filter and Cu Kα radiation (λ = 0.154 18 nm) operating at 45 kV and 40 mA. Differential thermal analyses (DTA) and thermal gravimetric analyses (TGA) were recorded on a SDT 2960 simultaneous DSC-TGA instrument under N_2 flow (100 mL/min) with a heating rate of 10 °C/min.

Transmission electron microscopy (TEM) and high-resolution (HR)-TEM images were obtained on a JEOL JEM-2100F electron microscope. Samples were suspended in ethanol for ~10 min under ultrasonic treatment before depositing them on carbon-film-coated copper grids. TEM photos of different areas of analysis at various magnifications were analysed.

Brunauer–Emmett–Teller (BET) surface area and micropore measurements of the samples were processed on a Micromeritics ASAP-2010 instrument. The samples were predegassed at room temperature under vacuum to eliminate adsorbed moisture and zeolitic water within the micropores. The degas process was terminated when the vacuum pressure decreased to 3 μmHg (1 mmHg = 133.3224 Pa). The molecular cross section of nitrogen used in the data analysis was 0.1620 nm^2. The typical range of thickness chosen for *t*-plot measurements was 3.5–5 Å.

^{29}Si cross-polarization / magic-angle spinning (CP/MAS) spectra were collected on a Bruker AVANCE 500 NMR spectrometer operating at 99.35 MHz. The ^{29}Si chemical shifts were referenced to TMS at 0 ppm using the high-frequency signal of tetrakis(trimethylsilyl) silane at 29.9 ppm as a secondary standard.

Results and discussion

TGA

Figure 1 gives a differential thermal gravimetry (DTG) comparison between pure sepiolite (Fig. 1a) and the hybrid material prepared by hydrolysis and condensation of zirconium propoxide at the external surface of sepiolite, dried at 60 °C (Fig. 1b). In the case of sepiolite, the first weight loss occurring at 77 °C corresponds to the zeolitic water elimination as well as surface water elimination. The second loss at 276 °C corresponds to the elimination of the first coordinated water molecule. The third loss at 524 °C corresponds to the elimination of the second coordinated water molecule. Finally, the fourth loss at 828 °C is due to the dehydroxylation of the internal Mg–OH bonds.[2,44] The DTG results of the hybrid materials show additional weight losses at 161 and 364 °C owing to the decomposition of the organic moieties. After production of the ZrO_2 nanoparticles, the loss of the second water molecule and the dehydroxylation of sepiolite take place in the same temperature range as in the case of the original sepiolite. This is an indication that the structure of sepiolite is not altered during the deposition of the zirconium oxide, as observed also on the XRD pattern (see Fig. 2d). It is clear from Fig. 1b that after heating the hybrid material at temperatures >400 °C, the organic material was fully removed, resulting in the formation of zirconium oxide. Two temperatures of calcinations were chosen, 450 and 650 °C. The DTG results are given in Figs. 1c and 1d, respectively. Two major weight losses, corresponding to the

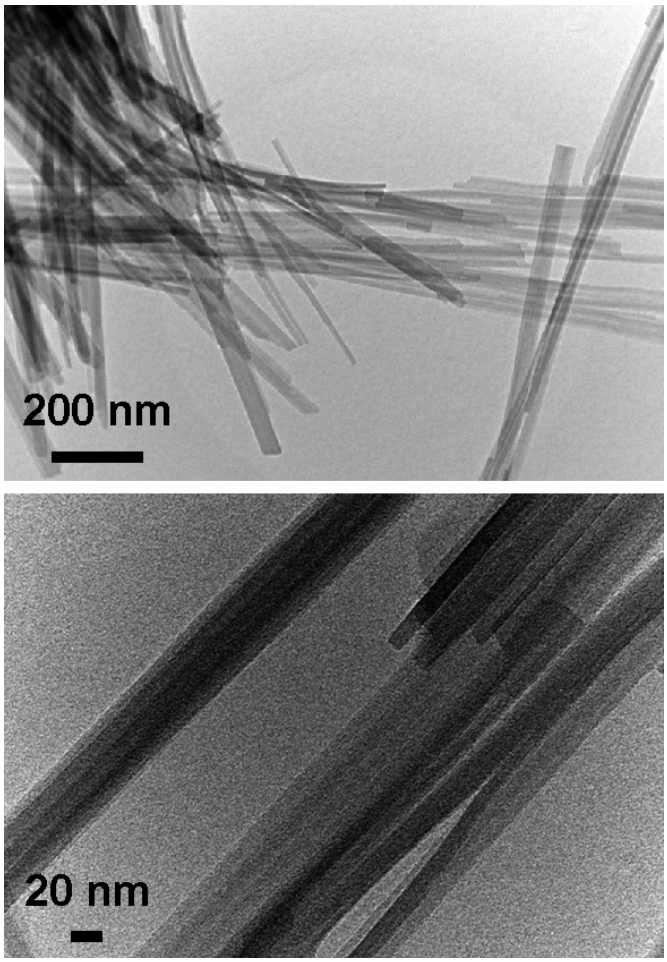
removal of water adsorbed at the external surface and to the dehydroxylation of sepiolite at high temperature, could be observed. TGA–DTG results indicate that the organic moieties on the nanohybrid materials can be removed by calcination above 450 °C. At these temperatures, ZrO_2 nanoparticles are formed. The coordinated water molecules are fully removed by calcination at 650 °C.

XRD

Figure 2 shows the XRD spectra of the starting sepiolite (Fig. 2a), the hybrid material prepared by hydrolysis and condensation of zirconium isopropoxide at the external surface of sepiolite and dried at 60 °C (Fig. 2c), and the hybrid material obtained after heating at 450 °C (Fig. 2d) and 650 °C (Fig. 2e). The diffractogram of the hybrid material recuperated after drying at 60 °C exhibits the typical reflections of sepiolite. It shows only wide bands around 2θ = 25°–35°, owing to the presence of amorphous solid, as expected. After calcination at 450 °C, new reflections appear

Fig. 3. Transmission electron microscopy (TEM) images of untreated sepiolite at two different scales.



in the XRD pattern at 2θ = 30.3°, 35.3°, 50.5°, and 60.2°. These reflections are characteristic of the zirconium oxide in tetragonal or cubic phase. They are more pronounced in the case of the nanohybrid material obtained after heating at 650 °C. Their positions are identical to the zirconium dioxide prepared by hydrolysis and condensation of zirconium propoxide without sepiolite (Fig. 2b). The values of the relative intensities of the reflections present in the X-ray diffractogram of the zirconium dioxide particles prepared in this work were compared with the relative intensities of reflections observed for zirconium dioxide in cubic and tetragonal phases.[45,46] The reflections observed at 30.3°, 35.3°, 50.50°, and 60.2° correspond to the (111), (200), (220), and (311) planes, respectively, of the cubic phase.

The disappearance of the 001 reflection of sepiolite (2θ = 7.8°) after heating the nanohybrid material at 650 °C indicates that the structure of sepiolite is folded.[47,48] As it will be discussed in the next section, even when sepiolite is folded, the arrangement of the nanoparticles of zirconium oxide maintains the fibre morphology.

HR-TEM

TEM analysis performed on the pristine sepiolite clay mineral (untreated sepiolite) show needle structures characterized by a variety of lengths between 100 and 600 nm

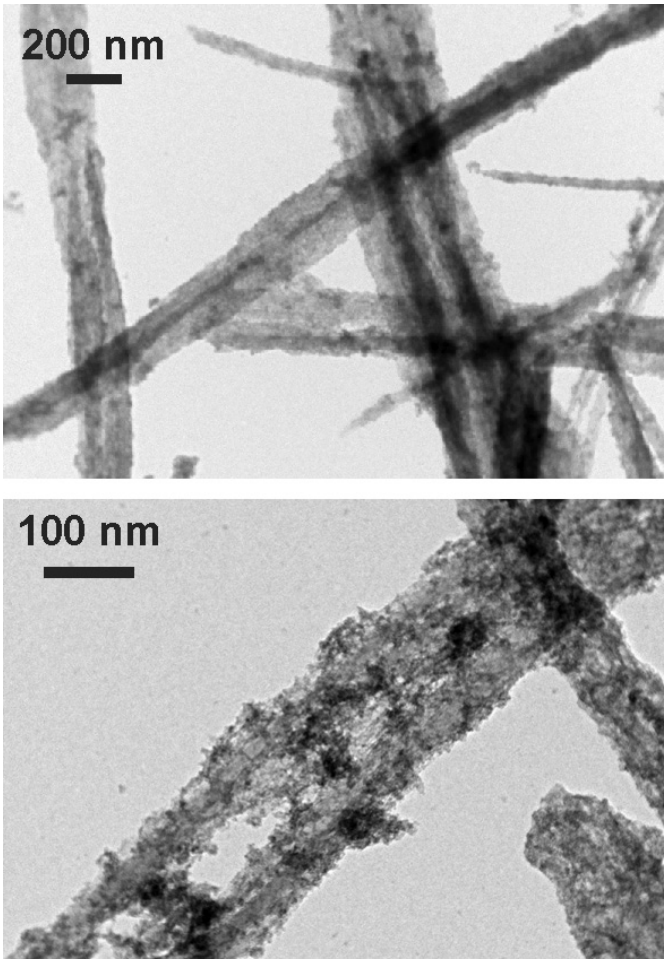
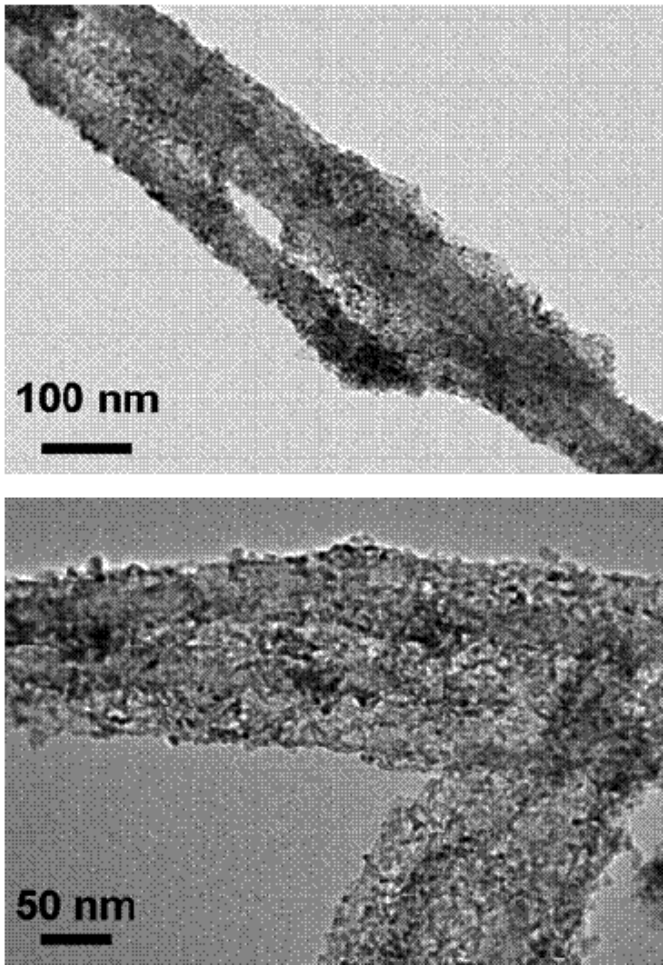
For personal use only.

Fig. 4. Transmission electron microscopy (TEM) images of the hybrid material prepared by hydrolysis and condensation of zirconium propoxide at the external surface of sepiolite and then dried at 60 °C.



(Fig. 3, top image). These needles are randomly distributed and formed by the superposition of a number of fibres. HR-TEM measurement on the untreated sepiolite shows smooth, thin fibres having a thickness close to 15 nm. These can be aggregated in needles of typically 50–100 nm in thickness (Fig. 3, bottom image). After deposition of the Zr propoxide on the sepiolite external surfaces, the TEM of the samples still show long needles randomly distributed (Fig. 4). The surfaces of the fibres have become rough compared with those of pure sepiolite. This is due to the sticking of zirconium propoxide on the external surfaces of sepiolite. In contrast with the case of sepiolite where it was possible to observe individual fibres, in the case of the nanohybrid material, an agglomeration of the fibres takes place during the deposition of zirconium oxide. This agglomeration results in needles with enlarged cross sections compared with those of sepiolite. Figures 5 and 6 show examples of ZrO_2 nanoparticles prepared at the external surfaces of sepiolite and calcined at 450 and 650 °C, respectively. ZrO_2 nanoparticles are easily distinguished because of the high contrast of zirconium. They are homogeneously distributed on the external surfaces of sepiolite. Even after calcination at 650 °C, the structure of the nanocomposite maintains a fibrous morphology. XRD results indicated that the structure of sepiolite is folded at this temperature.

Fig. 5. Transmission electron microscopy (TEM) image of the hybrid material after calcination at 450 °C.



^{29}Si NMR CP/MAS

^{29}Si NMR spectra of pure sepiolite and of the hybrid material prepared by hydrolysis and condensation of zirconium propoxide at the external surface of sepiolite showed the expected three Q^3 peaks within the sepiolite structure at approx. –92.0, approx. –95, and approx. –97 (Figs. 7a and 7b).[44,49] The Q^2 peak owing to the surface silanol groups was observed at –85 ppm.[4] This peak had diminished significantly in intensity after reaction with zirconium propoxide, an indication that the latter has reacted with the silanol groups. Heating the material at 450 and 650 °C results in the observation of more than three signals, indicating the loss of symmetry of the silicium atoms owing to a structural change of sepiolite.[4] At 450 °C, a fraction of the coordinated water molecules has been lost, the structure is partially folded, and the ^{29}Si NMR spectrum is the superposition of partially and fully dehydrated sepiolite. At 650 °C, sepiolite is fully dehydrated and completely folded,[4,47,48] resulting in the loss of the tunnel structure and in the loss of symmetry of the silicon atoms, with all six having become chemically distinct. At this temperature, the Mg(II) dehydroxylation has not yet been reached.

Porosimetry

Table 1 gives the surface area values calculated by the BET equation[50] from N_2 adsorption isotherms of pure sepiolite, pure zirconium oxide, and the resulting nanocomposites after calcinations at 450 and 650 °C. The sol–gel deposition of zirconium propoxide on sepiolite results in a decrease of the surface area from 298 m^2/g for pure sepiolite to 181 and 246 m^2/g for Sep–Zr 1/1 and Sep–Zr 1/2, respectively, where 1/1 and 1/2 represent the mass ratio of sepiolite to ZrO_2. The fibrous structure of sepiolite contains a series of channels and tunnels leading to a large surface area. The deposition of zirconium propoxide blocks some tunnels and also results in agglomeration of individual fibres of sepiolite. This textural change results in a decrease of the surface area after deposition of the zirconium propoxide. After calcination of the samples at 450 °C, the surface area of the nanocomposites is larger compared with the pristine sepiolite. At this temperature, pure sepiolite is partially folded and the nanocomposites are covered by zirconium oxide. After heating the nanocomposites at 650 °C, the surface areas of the resulting nanocomposites were decreased by more than 50% compared with those at RT because of the complete folding of the structure of the sepiolite and agglomeration of the fibres. Nanocomposites heated at 450 °C were used for catalytic tests because they have the highest surface area values.

Table 1. Values of the Brunauer–Emmett–Teller (BET) surface area for sepiolite (**Sep**), zirconium oxide (**ZrO_2**), and the nanohybrid materials made of ZrO_2 deposited on sepiolite with mass ratios of 1/1 (**Sep–Zr 1/1**) and 1/2 (**Sep–Zr 1/2**). The measurements were recorded on the samples unheated and preheated at 450 and 650 °C.

	RT (m^2/g)	450 °C (m^2/g)	650 °C (m^2/g)
Sep	298	114	99
Sep–Zr 1/1	181	156	82
Sep–Zr 1/2	246	140	103
ZrO_2	—	36	24

Catalytic activity

Catalytic activity studies were carried out under solvent-free conditions using untreated sepiolite, zirconium oxide, and zirconium oxide deposited on the external surfaces of

Table 2. Conversion and selectivity (%) of the Knoevenagel condensation reaction of benzaldehyde derivatives with malonitrile.

Derivative	Sep		Sep–Zr 1/1		Sep–Zr 1/2		ZrO_2	
	Yield	Sel.	Yield	Sel.	Yield	Sel.	Yield	Sel.
	37	*100*	94	*100*	83	*100*	44	*100*
	30	*100*	89	*100*	80	*100*	45	*100*
	49	*100*	83	*100*	88	*100*	38	*100*

Note: Sep, sepiolite. Values in italic typeface indicate selectivity.

sepiolite. The results of the Knoevenagel condensation of benzaldehyde derivatives are given in Table 2. The nature of the catalyst was found to influence the catalytic efficiency. When the reaction was carried out using untreated sepiolite as the support, the conversion was modest (<50%). These yields were improved but still limited when the reaction was carried out using zirconium oxide (Table 2). However, the nanohybrid catalysts calcined at 450 °C gave much higher conversion rates. For example, the yield obtained for the catalyst Sep–Zr 1/1 is 94% for the condensation of benzaldehyde and 88% for the catalyst Sep–Zr 1/2 in the case of the condensation of *para*-nitrobenzaldehyde.

A higher amount of ZrO_2 deposited on sepiolite does not significantly increase the yield of the reaction. On the contrary, it is lower in some cases. This result can be interpreted by the porosity of these materials. The BET surface area of Sep–Zr 1/2 (140 m^2/g) is lower than the area of sample Sep–Zr 1/1 (156 m^2/g), resulting in less accessibility of the substrate to the active catalytic sites.

Conclusion

The remarkable structural features of the clay mineral sepiolite were used to prepare an efficient catalyst for the Knoevenagel condensation of benzaldehyde derivatives under solvent-free conditions. An inorganic nanocomposite was prepared by the deposition of zirconium oxide nanoparticles on the external surfaces of sepiolite. The nanoparticles were prepared by a sol–gel technique, from solutions of zirconium(IV) propoxide in 1-propanol as precursor. After calcination at 650 °C, the organic material from the precursor was lost, the coordinated water of sepiolite was fully removed, and the layered structure of sepiolite was folded. However, the arrangement of the nanoparticles of zirconium oxide on the external surfaces maintains a fibrous morphology for the nanocomposite. These modifications, which take place at the nanometer scale under soft conditions, produce a functional nanocomposite material combining the textural properties of the pristine clay mineral and the catalytic activity of zirconium oxide.

The material was applied to the solvent-free reaction of the condensation of benzaldehyde and malononitrile. The condensation reaction, which necessitates mild basic conditions, is here governed by the porosity of the supporting sepiolite (increasing the density of supported nanoparticles) and the basicity and catalytic effect of the ZrO_2 nanoparticles. Strongly improved yields of reaction, attributed to larger catalytically active surfaces, were obtained in the case of the inorganic nanocomposite material, compared with either the sepiolite mineral or the zirconium oxide tested individually.

Photoautoionization structure in the halogen systems Br_2, I_2, BrCl, ICl, and IBr

Andrew J. Yencha and Devinder Kaur

Abstract: The photoabsorption ion-yield spectra of the titled molecules have been recorded in the threshold ionization region between the two spin-orbit components of the ground states of the molecular ions. All ion-yield spectra display rather simple autoionization structure superimposed on a smoothly rising continuum in the ionization energy region. The structure was analyzed in terms of autoionizing Rydberg states and their vibrational profiles simulated using Rydberg–Klein–Rees (RKR) derived potential energy curves and calculated Franck–Condon factors using Gaussian line-shape functions. All of the structure observed is attributed to spin-orbit autoionization. There seems to be a propensity for autoionization of sσ Rydberg states in all of the interhalogen molecules studied.

Key words: autoionization, Rydberg states, halogens, interhalogens, photoionization yields.

Résumé : On a enregistré les spectres de rendement ionique de photoabsorption des molécules mentionnées dans le titre en opérant dans la région de seuil entre les deux composantes spin-orbites des états fondamentaux des ions moléculaires. Tous les spectres de rendement ionique présentent une structure d'autoionisation relativement simple superposée sur un continuum croissant régulièrement dans la région d'énergie d'ionisation. On a analysé la structure en termes d'états de Rydberg autoionisants, on a simulé leurs profils vibrationnels en utilisant des courbes d'énergie potentielle dérivées du modèle de Rydberg–Klein–Rees (RKR) et on a calculé les facteurs de Franck–Condon en faisant appel à des fonctions gaussiennes de la forme des courbes. Toute la structure observée est attribuée à une autoionisation spin-orbite. Il semble qu'il existe une propensité à l'autoionisation des états sσ des états de Ryderg dans toutes les molécules interhalogènes qui ont été étudiées.

Mots-clés : autoionisation, états de Rydberg, halogènes, interhalogènes, rendements de photoionisation.

[Traduit par la Rédaction]

Introduction

The photochemical utility of diatomic halogen and interhalogen molecules in flash photolysis studies for the photodissociative production of excited- and ground-state halogen atoms has been known for a long time.[1–5] More recently, diatomic halogen and interhalogen molecules have received considerable attention owing to their interesting spectroscopic properties and because of the reactivity of their excited states, particularly with rare gas atoms related to excimer laser-light generation.[6] Theoretical studies have revealed how complicated the excited-state potentials are even in the simplest of these systems,[7–9] while experimental studies are beginning to unravel the potential-energy picture in the more complicated systems, as well as confirming theoretical predictions in simpler systems.[10] An important characteristic of these molecules is their ability to support numerous, stable, energetically low-lying valence ion-pair states because of the relatively low ionization potentials and high electron affinities of the atomic constituents. These states are known to possess potential minima at relatively long bond lengths, have large dissociation energies, exhibit small vibrational frequencies, and have a tendency to group in clusters. We are now beginning to understand that these ion-pair states can interact with Rydberg states lying in the vacuum-ultraviolet (VUV) spectral region affecting their absorption, fluorescence, and ionization spectroscopic properties. The situation is further complicated by the fact that the Rydberg states in these molecules are extensively predissociated by repulsive states associated with ground- and excited-state atoms. In addition, in all of the diatomic halogen and interhalogen molecules, except Cl_2, the thermodynamic dissociation limit for producing the lowest energy set of ion pairs occurs just below the onset of molecular ionization. Hence, Rydberg states lying in the energy region just above the ionization limit may interact with two types of continua, that is the ionization continuum and the ion-pair continuum. Thus, structures in the molecular photoionization yield spectra owing to autoionization in these molecules may possess a resemblance to the structure in the photodissociative excitation functions for ion-pair formation. Although the photoionization yield spectra have been obtained for 7 of the 10

diatomic halogen and interhalogen molecules,[11–19] only two, F_2[18] and Cl_2,[19] have been analyzed with respect to their autoionizing structure just above their lowest ionization limits. We have recorded both the photoionization yield spectra and the ion-pair photodissociative excitation function spectra in the vicinity of the ionization limits of the molecules Br_2, I_2, BrCl, ICl, and IBr and have analyzed these in terms of their formation mechanisms. We have found a strong correlation between these two types of spectra. We report here on the autoionizing structure in the photoionization yield spectra of these molecules. We have previously published our analyses of the ion-pair formation excitation function spectra for the same molecules.[20–22]

Experimental

The photoabsorption ion-yield spectra reported here were obtained using synchrotron radiation at the National Synchrotron Light Source (NSLS) facility of the Brookhaven National Laboratory, Upton, New York, on beam line U-11. The molecular beam apparatus used has been described in detail previously[23,24] and the method for recording photoexcitation spectra reported,[20–22,25–27] so only a brief experimental description will be given here.

A supersonic beam made up of a mixture of ~1%–2% of the halogen being studied in helium was produced using a 200 μm diameter glass nozzle, heated to ~100 °C with backing pressures in the range of 100–200 Torr (1 Torr = 133.3224 Pa), and a skimmer of 1 mm diameter located 5–10 mm downstream of the nozzle. The position of the nozzle relative to the skimmer was adjusted to give the maximum Ar^+ signal through the quadrupole mass spectrometer at an energy just above the ionization potential of Ar. The backing pressure of the sample plus helium, as measured on a Baratron capacitance manometer, was adjusted to give the maximum molecular ion signal at an energy just above the ionization limit of the molecule. Under typical conditions, the pressure in the nozzle chamber was of the order of 1×10^{-5} Torr, while the pressure in the interaction chamber was ~6×10^{-7} Torr. Based on an analysis of the hot-band structure in the ion-pair excitation functions for Br_2,[20] we estimated a vibrational temperature of our sample of ~250 K. This temperature was used throughout our analysis procedure for the simulated spectral results presented here (see the following). We have no information as to the rotational temperatures of our samples, but we assume them to be quite low (e.g., <20 K). The molecular beam intersected the focused (1 mm^2) tunable synchrotron radiation beam of 0.09 nm bandpass (FWHM) (equivalent to an energy resolution of ~48 cm^{-1} at 130 nm). Prior to entering the interaction chamber the synchrotron radiation was passed through a 2 mm thick LiF filter to eliminate second and higher order radiation. The resolution and calibration of the synchrotron light was accomplished by setting the monochromator wavelength scale to zero wavelength at the maximum intensity for zero-order radiation (totally reflective grating, i.e., acting as a mirror) and then by measuring the ionization threshold for argon in first order. In this way we found the wavelength scale to be accurate to within ±0.02 nm. The intensity of the synchrotron light intersecting the molecular beam was monitored using a sodium salicylate quantum converter plus photomultiplier. This signal allowed for correcting the quadrupole mass spectrometer signal for the decay with time of the synchrotron radiation as well as the wavelength-dependent transmission function of the monochromator. Ions formed in the interaction volume were extracted with a static field of ~50 V cm^{-1} and focused onto the entrance aperture of a quadrupole mass spectrometer where they were mass analyzed. Photoionization yield spectra were obtained by standard pulse counting procedures, a CAMAC interface, and a PDP 11/23 minicomputer.

The samples studied were obtained from the following sources: Br_2 (J. T. Baker Co., 99.8% purity), I_2 (Eastman Kodak Co., 99.9% purity), ICl (Eastman Kodak Co., 98% purity), and IBr (Aldrich Chemicals, 98% purity). BrCl was prepared from a stoichiometric mixture of Br_2 and Cl_2 (Matheson Gas Products, 99.9% purity). The mixture was refluxed about six or seven times by repeated heating and cooling (condensing) before being stored in a glass bulb. All samples were degassed at liquid nitrogen temperature prior to being used. Except for ICl and IBr, the samples were premixed (1%–2%) in helium and stored in separate 4 L stainless steel cylinders at a total pressure of ~7 atm (1 atm = 101.325 kPa). For ICl and IBr, 1%–2% mixtures in helium were prepared by passing helium gas over neat ICl or IBr, maintained at a constant temperature in a thermostated box, prior to entering the nozzle tube of the apparatus.

Analysis procedure

Analyses of the autoionizing structure found in the photoabsorption ion-yield spectra were accomplished by means of simulation calculations of the Franck–Condon factors for transitions from the ground states of the molecules to various accessible Rydberg states.[27] The energy levels (E_n) for the states in a particular Rydberg series can be calculated using the Rydberg formula:[28]

$$E_n = \mathrm{IP} - R/(n - \delta)^2$$

where IP is the ionization potential, R is the Rydberg constant = 109 737 cm^{-1}, n is the principal quantum number, and δ is the quantum defect. The δ (or screening constant) depends on the azimuthal (or orbital) quantum number l, and as l increases, δ rapidly approaches zero. As n increases, the energy increases and eventually approaches the convergence limit (or ionization potential).

Individual Rydberg systems were obtained employing Gaussian line-shape functions for each vibrational band, in which the identical width of all bands in a system was an adjustable parameter. The total simulated spectrum was derived from the sum of the individual Rydberg systems with appropriate (adjustable) weighting factors to give the best overall fit to the experimental spectrum. Contribution from hot bands were incorporated into the simulation calculations assuming a vibrational Boltzmann temperature of 250 K.[20–22,27] This procedure assumes that the coupling between the rovibrational levels of a Rydberg state with the ionization continuum is the same for all levels and, furthermore, that the coupling between different Rydberg states with the ionization continuum is also the same.

Results and discussion

The approach to analyzing and simulating the photoabsorption molecular ion-yield spectra in the threshold ionization region recognizes the so-called "heavy-atom effect" in the ionization properties of interhalogen molecules. That is, in mixed diatomic halogen molecules the lowest ionization potential is always associated with the heavier of two constituent atoms, whereas the second ionization potential is always associated with the lighter of the two constituent atoms. In his 1934 paper, Mulliken[29] presented formulations for the lowest energy electron configurations for the homonuclear and heteronuclear diatomic halogens. In the case of a diatomic homonuclear halogen (X_2), the initial approximation using molecular orbitals is

$$X_2 : \ldots (\sigma + \sigma, \sigma_g)^2(\pi + \pi, \pi_u)^4(\pi - \pi, \pi^*_g)^4, \quad {}^1\Sigma^+_g$$

where g and u indicate the even or odd symmetry property about the center-of-mass of the molecule. Since the atomic orbitals are identical in this case, the best approximation for the electron configuration is given using the atomic orbitals for the π electrons:

$$X_2 : \ldots (\sigma + \sigma, \sigma_g)^2(n\mathrm{p}\pi_u)^4(n\mathrm{p}\pi^*_g)^4, \quad {}^1\Sigma^+_g$$

where n is the principal quantum number of the outermost filled atomic orbital from which the molecular orbital was formed and ${}^1\Sigma^+_g$ is its term symbol using Hund's case (a) notation. The generalized valence electron configuration using pure atomic orbitals for the formation of the molecular orbitals for a mixed diatomic halogen molecule, XY, where X is the heavier atom, was given by Mulliken[29] as

$$XY : \ldots (\sigma_y + \sigma_x, \sigma)^2(n_y\mathrm{p}\pi)^4(n_x\mathrm{p}\pi^*)^4, \quad X\ {}^1\Sigma^+$$

where the g/u symmetry property no longer applies. It follows that the electron configurations of the three lowest energy ionized states of XY would be

$$X^+Y : \ldots (\sigma_y + \sigma_x, \sigma)^2(n_y\mathrm{p}\pi)^4(n_x\mathrm{p}\pi^*)^3, \quad X\ {}^2\Pi_{3/2,1/2}$$

$$XY^+ : \ldots (\sigma_y + \sigma_x, \sigma)^2(n_y\mathrm{p}\pi)^3(n_x\mathrm{p}\pi^*)^4, \quad A\ {}^2\Pi_{3/2,1/2}$$

$$(XY)^+ : \ldots (\sigma_y + \sigma_x, \sigma)^1(n_y\mathrm{p}\pi)^4(n_x\mathrm{p}\pi^*)^4, \quad B\ {}^1\Sigma^+$$

where the charge is localized on the atoms X^+ and Y^+, respectively, on the ground state (X) and first-excited state (A) of the molecular ions, and where the charge is symmetrically situated between the two atoms ($X^{\pm}Y$) in the second-excited state (B). In the homonuclear diatomic halogens, the term symbols of the ground and the first two excited states of the molecular ions are, respectively, X ${}^2\Pi_{3/2,1/2,g}$, A ${}^2\Pi_{3/2,1/2,u}$, and B ${}^1\Sigma^+_g$, using Hund's case (a) notation. In the discussion to follow the molecules with the same heavy atom are grouped together.

Formation of the molecular ions Br_2^+ and $BrCl^+$

The upper trace of Fig. 1 shows the experimental photoabsorption ion-yield spectrum of the parent molecular ion Br_2^+ in the threshold ionization region. It consists of a series of autoionization band structures superimposed on a steeply rising ionization function towards shorter wavelengths. We

Fig. 1. A comparison of the experimental photoabsorption ion-yield curve for Br_2^+ formation and calculated autoionization function for Br_2. The calculated spectrum was obtained from the sum of the three simulated autoionizing Rydberg state profiles shown in the figure. assigned and simulated this structure to be due to the Rydberg series [X 1/2]$_c n$pπ, for n = 9–11, where [X 1/2]$_c$ represents the core ion convergence limit Br_2^+ [X ${}^2\Pi_{1/2g}$] at 114.1 nm (87 645,[20,30] 87 647,[31] and 87 648[32] cm^{-1}). This series represents a continuation of a Rydberg state, [X 1/2]$_c$8pπ, found to be important in ion-pair formation in Br_2 at slightly longer wavelengths (118.73 nm, 84 225 cm^{-1}).[20] Also shown in Fig. 1 are the individual simulated Rydberg states with their calculated vibrational profiles and the summed calculated autoionization spectrum. The three Rydberg states were simulated using a quantum defect of 2.335 for the npπ Rydberg series derived from an analysis of the [X 1/2]$_c$8pπ Rydberg state using the (0,0) band position of 84 225 cm^{-1},[20] the convergence limit of the [X ${}^2\Pi_{1/2g}$] state of 87 645 cm^{-1},[20,30] an equilibrium internuclear distance of 2.188 Å, and vibrational constants of 353, 300, and 350 cm^{-1} for the 9pπ, 10pπ, and 11pπ states, respectively.[27] The calculated peak energy positions of the (0,0) bands for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12

the 9pπ, 10pπ, and 11pπ states were 85 174, 85 777, and 86 183 cm^{-1}, respectively, corresponding to the wavelengths 117.4, 116.6, and 116.0 nm, respectively. As can be seen in Fig. 1, there is a good correspondence between the observed and calculated autoionization structure in the ion-yield spectrum. No attempt was made to simulate the underlying ionization continuum in the calculated spectrum.

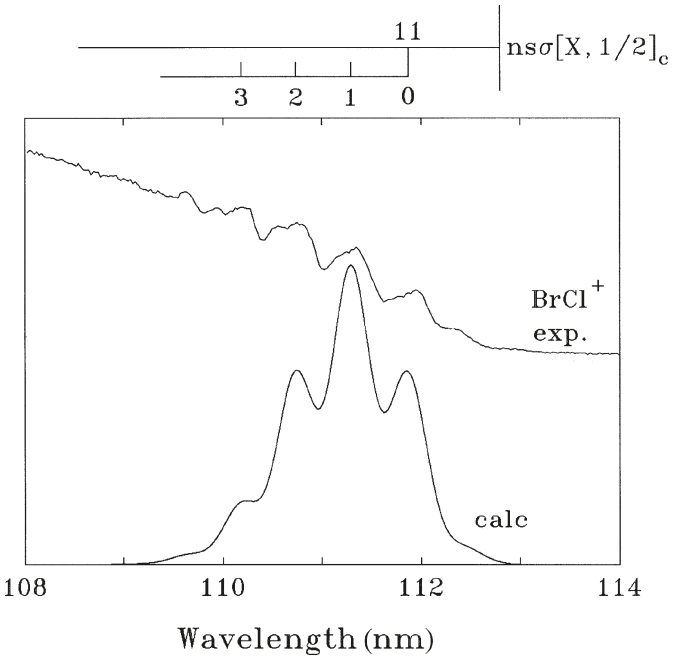
The experimental photoabsorption ion-yield spectrum of the parent molecular ion $BrCl^+$ in the threshold ionization region is shown as the upper trace in Fig. 2. The autoionization peak structure superimposed on a smoothly rising ionization function appears to be less extensive than for Br_2^+. In fact, the autoionization structure can be attributed mainly to a single Rydberg state, $[X\ 1/2]_c11s\sigma$, of BrCl, although a shoulder peak appears to shorter wavelengths on each of the major peaks. We have calculated the peak position of the (0,0) vibrational band of the 11sσ Rydberg state to be at 111.9 nm (89 332 cm^{-1}) using a quantum defect of 3.07[27] and the convergence limit for $BrCl^+$ [$X\ ^2\Pi_{1/2}$] formation of 11.29 eV[22] (109.8 nm, 91 060 cm^{-1}). This can be compared to the observed peak position of 111.8 nm. The vibrational profile for the 11sσ Rydberg state was calculated using an equilibrium internuclear distance of 2.045 Å[33] and a vibrational constant of 463 cm^{-1} and is shown as the lower trace in Fig. 2. No attempt was made to simulate an underlying ionization continuum or the shoulder peaks in the calculated spectrum. We note that the highest energy Rydberg state assigned in the ion-pair excitation functions of BrCl was the 10sσ state converging onto the X ($^2\Pi_{1/2}$) ion state of BrCl.[22] Hence, the autoionizing Rydberg state, $[X\ 1/2]_c11s\sigma$, of BrCl, represents a continuation of the Rydberg series $[X\ 1/2]_cns\sigma$ for n = 8–10, found to be important in ion-pair formation below the onset of ionization in BrCl at 112.5 nm (11.02 eV, 88 882 cm^{-1}).[22] We further note that the structure owing to ion-pair formation essentially ends upon the opening of the channels to the more dominant processes of photoionization and autoionization.

Formation of the molecular ions I_2^+, ICl^+, and IBr^+

The experimental photoabsorption ion-yield spectrum of the parent molecular ion I_2^+ in the threshold ionization region is shown as the top trace in Fig. 3. It is more complicated than the two previous ion-yield spectra for Br_2^+ and $BrCl^+$. The ion-yield spectrum for I_2^+ shows two very broad peak structures between 133 and 128 nm immediately following the onset of ionization at 133.2 nm (75 069[34–36] and 75 098[37] cm^{-1}) followed by more or less typical autoionizing structure superimposed on a steeply rising ionization function and terminating in the vicinity of the I_2^+ [$X\ ^2\Pi_{1/2g}$] ionization limit at 124.6 nm (80 266 cm^{-1}[34–36] and 80 228 cm^{-1}[37]). We interpret the two broad autoionizing features as owing to the overlapping of two Rydberg series: $[X\ 1/2]_cnp\pi$, for n = 9 and 10 and $[X\ 1/2]_cnf$, for n = 5 and 6, as identified in Fig. 3.

It is worthwhile discussing how we came to the conclusion that the 5f and 6f Rydberg states play a role in the autoionization structure in the ion-yield spectrum of I_2^+, in spite of the fact that the 4f Rydberg state was not identified as being present in the ion-pair excitation function.[21] Originally, the observed vibrational structure in the ion-pair excitation functions of I_2 was assigned[21] to three Rydberg states,

Fig. 2. A comparison of the experimental photoabsorption ion-yield curve for $BrCl^+$ formation and calculated autoionization function for BrCl. Each of the peaks is assigned to a simulated vibrational band v' (lower number) in the $[X\ 1/2]_c11s\sigma$ autoionizing Rydberg state as indicated in the figure.



$[X\ 3/2]_c9p\pi$, $[X\ 3/2]_c10p\pi$, and $[X\ 3/2]_c11p\pi$, whose origins were predicted at 72 463, 73 099, and 73638 cm^{-1} based on the high-resolution VUV absorption spectrum analysis of I_2.[38] Subsequently, a reanalysis of the absorption spectrum of I_2 using ionization energies determined from zero electron kinetic energy (ZEKE) – pulsed-field ionization (PFI) photoelectron spectra of I_2[39] indicate that the above Rydberg states should be reassigned to three $[X\ 1/2]_c4f$ Rydberg states whose origins are at 72 647, 73 138, and 73 658 cm^{-1}.[40] The approximate wavelength positions of the cluster of $[X\ 1/2]_cnf$ Rydberg states were calculated to be at 136.8, 132.1, and 129.7 nm for 4f, 5f, and 6f, respectively, using a quantum defect of 0.066.[41] The first wavelength position is very close to that derived from the mean energy of the three $[X\ 1/2]_c4f$ Rydberg states given directly above (73 148 cm^{-1}, 136.7 nm), and the second two wavelength values fall well within the two broad autoionizing features in the ion-yield spectrum, as shown in Fig. 3. Additional evidence for the involvement of f-state Rydbergs in autoionization comes from the high-resolution study of the photoionization of HI in the threshold ionization region.[42] The HI molecule is expected to behave very similarly in the threshold ionization region as the I_2 molecule. This is because in the threshold ionization region in both molecules the electronic structure is dominantly due to the nonbonding electrons localized on the iodine atom. The Rydberg series $[X\ 1/2]_cnf(\sigma,\pi)$ for n = 5–8 were clearly identified as the autoionization structure between the two lowest ionization potentials in HI.[42] The lack of perceptible vibrational structure in the two broad bands in the autoionization spectrum of I_2 suggests that a cluster of Rydberg states, e.g., $[X\ 1/2]_cnf(\sigma)$, $-nf(\pi)$, and $-nf(\delta)$, are present whose energy positions are very close and make for a continuum-like band

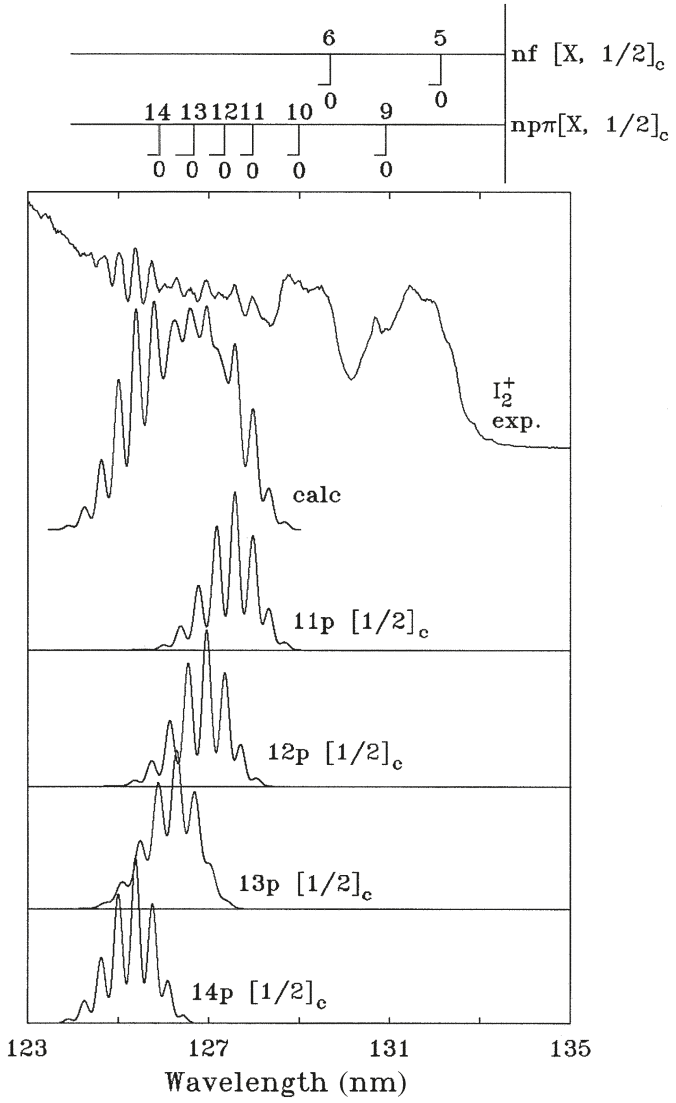
Fig. 3. A comparison of the experimental photoabsorption ion-yield curve for I_2^+ formation and calculated autoionization function for I_2. The calculated spectrum was obtained from the sum of the simulated ion-yield curves owing to transitions to the four autoionizing Rydberg states shown. The upper numbers in the assignment refer to the principal quantum numbers (n) and the lower numbers refer to the excited-state vibrational quantum numbers (v').



(see, for example, the photoionization spectrum of HI[42] and the VUV absorption spectrum of I_2.[38])

The extensive breadth of the two broad bands in Fig. 3 (between 133 and 128 nm) suggests that the widths of the observed features are primarily due to the separation of the origins of the unresolved component nf states. That is, the separation of the origins of the 4f states is ~1000 cm^{-1} (see above), so assuming that the quantum defect does not change with n, the equivalent separations of the 5f and 6f states should be ~600 and 350 cm^{-1}, respectively. This appears to be consistent with the observed spectrum.

An additional factor contributing to the broadness of the first two autoionization bands is the presence of the $[X\ 1/2]_c np\pi$ Rydberg states, for n = 9 and 10. The wavelength positions of the (0,0) bands for these two states have been calculated to be at 130.9 nm for 9pπ and 129.0 nm for 10pπ using the convergence limit for the I_2^+ $[X\ ^2\Pi_{1/2g}]$ state of 9.95 eV[34–37] and a quantum defect of 3.58[41] for the npπ series. However, a slight decrease of 0.01 eV in the convergence limit gave rise to a much better fit between the experimental and calculated values. The calculated wavelength positions of the (0,0) bands for the Rydberg series $[X\ 1/2]_c np\pi$, for n = 11, 12, 13, and 14 are 127.9, 127.2, 126.6, and 126.3 nm, respectively. All of the Rydberg states (11p, 12p, 13p and 14p) were simulated with respect to their vibrational profiles using an equilibrium internuclear distance of 2.578 Å and vibrational constants of 245, 250, 240, and 250 cm^{-1}, respectively, and are individually displayed in Fig. 3. In addition, the sum of these vibrational profiles is shown as the calculated spectrum. You will note that the calculated and experimental spectra agree quite nicely in peak positions and overall profiles. No attempt was made to simulate the two broad autoionization peaks nor the underlying ionization continuum in the calculated spectrum.

Owing to the similarity between the photoabsorption ion-yield spectra for ICl and IBr, these molecules will be treated together. As can be seen in the upper traces of Figs. 4 and 5, the experimental photoabsorption ion-yield spectra for the formation of the parent molecular ions ICl^+ and IBr^+, respectively, in the threshold ionization region are quite similar. The spectra consists of a fairly extensive number of autoionization peaks superimposed on a smoothly rising ionization function from the onset of ionization at 123.0 nm (10.076 eV)[43] in the case of ICl and at 126.6 nm (9.796 eV)[44] in the case of IBr. The appearance of these spectra are quite similar to the ion-yield spectrum for $BrCl^+$ (see Fig. 2). In fact, in all three interhalogen molecules, all of the autoionizing structure between the spin-orbit component states is assigned to sσ Rydberg states as given in Table 1.

We have calculated the peak positions of the (0,0) vibrational bands of the $[X\ 1/2]_c ns\sigma$ Rydberg series for n = 9–12 for ICl using a quantum defect of 4.01[27] and the convergence limit for ICl^+ $[X\ ^2\Pi_{1/2}]$ formation of 10.67 eV[22] (116.2 nm, 86 059 cm^{-1}) as shown at the top of Fig. 4. The vibrational profiles for these Rydberg states were simulated using an equilibrium internuclear distance of 2.225 Å[27] and vibrational constants of 415, 415, 440, and 447 cm^{-1} for n = 9, 10, 11, and 12, respectively, and are shown individually in the lower portion of Fig. 4. The calculated spectrum shown in Fig. 4 is the sum of these individual vibrational autoionization profiles. The calculated peak energy positions of the (0,0) bands for the 9sσ, 10sσ, 11sσ, and 12 sσ Rydberg states were 81 699, 83 056, 83 822, and 84 388 cm^{-1}, respectively, corresponding to the wavelengths 122.4, 120.4, 119.3, and 118.5 nm, respectively. As can be seen in Fig. 4, there is a good correspondence between the observed and calculated autoionization structure in the ion-yield spectrum. No attempt was made to simulate the underlying ionization continuum in the calculated spectrum.

Continuing our analysis procedure in IBr, we calculated the peak positions of the (0,0) vibrational bands of the $[X\ 1/2]_c ns\sigma$ Rydberg series for n = 9–14 for IBr using a quantum defect of 3.99[27] and the convergence limit for IBr^+ $[X\ ^2\Pi_{1/2}]$ formation of 10.39 eV[45,46] (119.3 nm, 83 801 cm^{-1}) as shown at the top of Fig. 5. The vibrational

profiles for these Rydberg states were simulated using an equilibrium internuclear distance of 2.383 Å[27] and vibrational constants of 280, 230, 276, 290, 290, and 290 cm^{-1} for n = 9, 10, 11, 12, 13, and 14, respectively, and are shown individually in the lower portion of Fig. 5. The calculated spectrum shown in Fig. 5 is the sum of these individual vibrational autoionization profiles. The calculated peak energy positions of the (0,0) bands for the 9sσ, 10sσ, 11sσ, 12sσ, 13sσ, and 14sσ Rydberg states were 79 491, 80 841, 81 566, 82 102, 82 440, and 82713 cm^{-1}, respectively, corresponding to the wavelengths 125.8, 123.7, 122.6, 121.8, 121.3, and 120.9 nm, respectively. As can be seen in Fig. 5, there is a good correspondence between the observed and calculated autoionization structure in the ion-yield spectrum. No attempt was made to simulate the underlying ionization continuum in the calculated spectrum.

Conclusions

Because all the autoionization structure in the photoabsorption ion-yield spectra presented here and listed in Table 1 for the treated halogen and interhalogen molecules

Fig. 5. A comparison of the experimental photoabsorption ion-yield curve for IBr^+ formation and calculated autoionization function for IBr. The calculated spectrum was obtained from the sum of the simulated ion-yield curves owing to transitions to the six autoionizing Rydberg states shown. The upper numbers in the assignment refer to the principal quantum numbers (n) and the lower numbers refer to the excited-state vibrational quantum numbers (v').

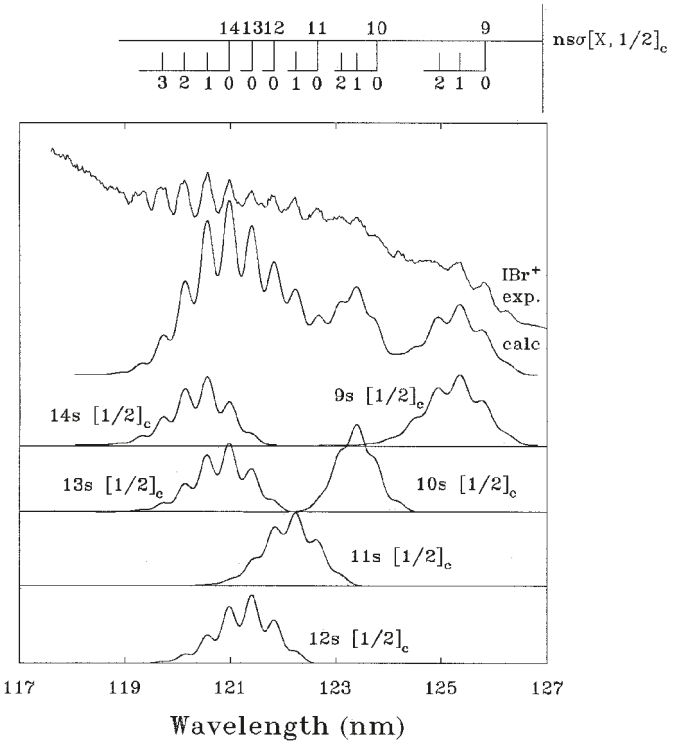

Table 1. Summary of the dominant autoionizing Rydberg state features assigned in the photoabsorption ion-yield spectra of some halogen and interhalogen molecules as identified in Figs. 1–5.

Molecule	Rydberg state assignment
Br_2	$[X\ 1/2g]_c np\pi_u$ for n = 9, 10, 11
I_2	$[X\ 1/2g]_c nf$ for n = 5, 6
	$[X\ 1/2g]_c np\pi_u$ for n = 9, 10, 11, 12, 13, 14
BrCl	$[X\ 1/2]_c ns\sigma$ for n = 11
ICl	$[X\ 1/2]_c ns\sigma$ for n = 9, 10, 11, 12
IBr	$[X\ 1/2]_c ns\sigma$ for n = 9, 10, 11, 12, 13, 14

reside between the ionization energies of the respective spin-orbit components of the ground-state ion, it is expected that spin-orbit autoionization[47] is the mechanism for the production of this structure. This type of autoionization is common for heavy-atom molecules.[47] The autoionization structures observed in the photoabsorption ion-yield spectra in the threshold ionization region of the halogen and interhalogen molecules studied here are all rather simple, in most cases only involving a single Rydberg series, the exception being the case of the iodine molecule. However, we point out that in this rather low-resolution study it is possible to not detect the presence of all contributing Rydberg systems. There appears to be a propensity for autoionizing sσ Rydberg states in the interhalogen molecules that represent a continuation of the same series found to be important

Photochromic benzo[*g*]quinoxalines

Muriel Rakotomalala, Michael Katz, Emilie Voisin, Tamara C. S. Pace, Cornelia Bohne, and Vance E. Williams

Abstract: The photochromism of two 2,3-diarylbenzo[*g*]quinoxaline derivatives was explored. Irradiating 2,3-diphenylbenzo[*g*]quinoxaline with 350 nm light led to the formation of its photodimer, which could be reverted to its monomers either thermally or photochemically.The resulting photodimer absorbs at a longer wavelength than analogous dianthracene derivatives. 2,3-Dipyridylbenzo[*g*]quinoxaline was also observed to undergo photodimerization. The ability of these readily prepared benzoquinoxaline derivatives to undergo [4 + 4]-photocycloaddition reactions makes them attractive alternatives to anthracene derivatives.

Key words: cycloaddition, photochromism, benzoquinoxaline.

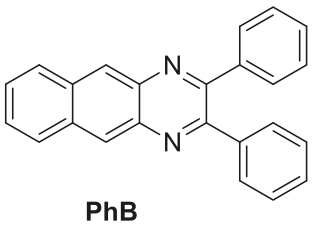
Résumé : On a étudié la photochromie de deux dérivés de 2,3-diarylbenzo[*g*]quinoxaline. L'irradiation de la 2,3-diphénylbenzo[*g*]quinoxaline avec de la lumière à 350 nm conduit à la formation de son photodimère qui peut revenir à sa forme monomère d'une façon soit thermique ou photochimique. Le photodimère qui en résulte absorbe à une longueur d'onde plus grande que celle des dérivés dianthracènes analogues. On a observé que la 2,3-dipyridylbenzo[*g*]quinoxaline subit aussi une photodimérisation. L'habilité de ces dérivés de la benzoquinoxaline facilement accessibles à subir des réactions de [4 + 4]-photocycloaddition en font des alternatives attrayantes aux dérivés de l'anthracène.

Mots-clés : cycloaddition, photochromie, benzoquinoxaline.

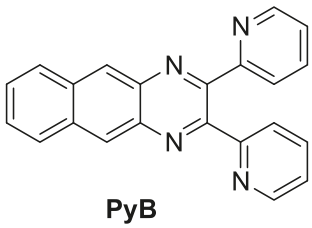
[Traduit par la Rédaction]

Introduction

Since the discovery of anthracene photochromism in the 19th century,[1] extensive studies have been carried out on the photodimerization of this and related molecules.[2,3] Although these reversible reactions have been exploited in a variety of contexts,[4–10] their practical utility is limited by the pronounced tendency of anthracene derivatives to photo-oxidize[3,11–13] and the short wavelengths (<300 nm) needed to photolyze the dimers back into their monomers.[3] Functional groups at the 2 and 3 positions of anthracene can shift the absorption of both the monomer and dimer to longer wavelengths, but such derivatives are often difficult to synthesize.[14–18] In contrast, 2,3-disubstituted benzo[*g*]quinoxalines can be prepared in a single step from commercially available starting materials[19] and, given their structural similarities to anthracene, are also expected to undergo [4 + 4]-photocycloaddition reactions. Although numerous benzo[*g*]-quinoxaline derivatives have been prepared,[20,21] their photochemistry has not been studied; indeed, the photochromism of nitrogen-containing analogues of anthracene remains largely unexplored.[22–29]



PhB



PyB

These considerations prompted us to investigate the photochemistry of two 2,3-diarylbenzo[*g*]quinoxaline derivatives, **PhB** and **PyB**. The presence of either phenyl or pyridyl groups at the 2 and 3 positions of these derivatives was anticipated to confer several advantages on these chromophores; not only are these groups expected to shift the absorbance to longer wavelengths, but they may also improve the solubility by inhibiting aggregation between the benzo[*g*]quinoxaline cores. The pyridyl derivative **PyB** was of further interest for its potential ability to complex to metals, which suggests a means to modulate the photoreactivity through chemical stimuli.

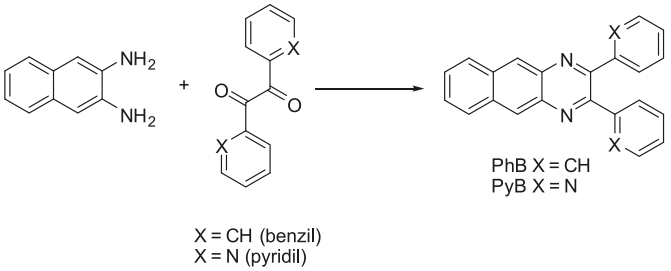
Scheme 1.



Results and discussion

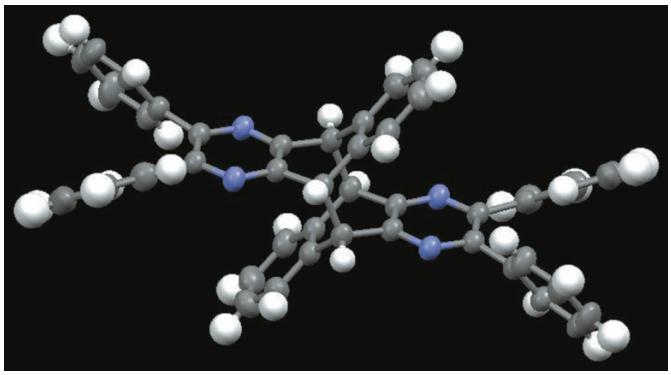
PhB and **PyB** were prepared from the condensation of 2,3-diaminonaphthalene with benzil[19] and pyridil,[30] respectively (Scheme 1). Pyridil was obtained in two steps via a benzoin condensation of picolinaldeyde followed by oxidation using a slightly modified literature procedure.[31]

The UV–vis absorption spectrum of **PhB** in acetonitrile reveals a strong absorbance centred at 270 nm and a less intense set of bands at longer wavelengths (λ_{max} = 380 nm). Irradiation of a degassed 4.4 mmol/L acetonitrile solution of **PhB** with lamps centered at 350 nm for 150 min led to the formation of a single photoproduct in a 20% yield. The yield of this reaction increased to 72% when a filter solution of KNO_3 was employed to block wavelengths below 340 nm,[32] which suggests that the product may be undergoing photoreversion to **PhB** upon exposure to shorter wavelengths. This conjecture was supported by the observation that the photoproduct has an absorption maximum at 328 nm, where there is considerable output from the lamps employed (vide infra). This photoproduct is thermally stable at room temperature and was readily separated from the starting material.

The MALDI-TOF spectrum of this photoproduct exhibits an intense peak at *m*/*z* 333 and a weaker peak at 665, which correspond to the M + 1 peaks of **PhB** and its photodimer, respectively. The low intensity of the dimer peak is in keeping with the behaviour of anthracene photodimers, which typically dissociate during mass spectrometry experiments.[2] The ^{1}H NMR spectrum of the product was consistent with that of the head-to-tail (ht) photodimer, ***ht*-di-PhB**. The most significant feature of this spectrum is a singlet at 5.06 ppm, which is within the range expected for protons attached to the sp^3-hybridized bridgehead carbons of dianthracene-like photodimers. The observation of only a single photoproduct from this reaction is likely due to the steric bulk of the phenyl groups, which may inhibit formation of the head-to-head (hh) stereoisomer, ***hh*-di-PhB**. It is also possible that this second isomer was formed in trace quantities that could not be detected, or that it exhibits appreciably lower thermal stability than the ht dimer and therefore decomposes.

The identification of the photoproduct as ***ht*-di-PhB** was confirmed by X-ray crystallography (Fig. 1) of single crystals obtained by slow evaporation of a 1:1 acetonitrile/chloroform solution. Under these conditions, the dimer crystallizes in the monoclinic space group *P*21*n*. The bond lengths between the sp^3-hybridized bridgehead carbons are 1.61(6) Å, which are longer than a typical carbon–carbon single bond, but similar to the lengths of the corresponding bonds in dianthracene (1.624 Å) and related systems.[2]

Fig. 1. Structure of the head-to-tail photodimer of 2,3-diphenylbenzo[*g*]quinoxaline (***ht*-di-PhB**) determined by X-ray crystallography.



The relatively long bridgehead bonds observed in the crystal structure suggested that, like anthracene derivatives, these dimers might thermally revert to monomers at elevated temperatures. The thermal stability of ***ht*-di-PhB** was studied by monitoring the UV–vis spectrum of a 1 mmol/L solution heated in DMSO at a variety of temperatures. No decomposition was observed for a sample heated at 120 °C for 5 h, indicating that the dimer is thermally stable at moderate temperatures. In contrast, heating this compound to 150 °C led to a continuous decrease in absorption bands and an accompanying increase in peaks associated with the monomer **PhB**. At this temperature, reversion of the dimer to **PhB** was complete after 2.5 h.

To examine whether ***ht*-di-PhB** also undergoes photoreversion, a 0.1 mmol/L acetonitrile solution of the dimer was irradiated with 328 nm light and the progress of the reaction was monitored by UV–vis spectroscopy (Fig. 2). During irradiation, the absorbance at 328 nm steadily decreased while a new peak at 380 nm grew in, indicating that the product dissociates to the corresponding monomer. The ^{1}H NMR spectrum confirmed that **PhB** was being formed during the course of these experiments. Dissociation reached completion after 240 min of irradiation. The spectral changes with time show that two isobestic points may be located at 321 and 342 nm. However, close inspection of these wavelength regions (Fig. 2, inset) reveals a very small systematic drift as time progresses, which suggests that only two major species are present in solution, but a minor species, probably present at very low concentrations, is also possibly formed. It is unclear at this time what the nature of this additional photoproduct is, although it may arise from the cyclization of the peripheral phenyl groups to form a triphenylene-like product.[33]

In an effort to better understand the mechanism of photodimerization, the excited state lifetimes of **PhB** were determined by single-photon counting for the singlet excited state and by laser flash photolysis for the triplet state. The singlet state lifetimes were found to be 1.9 ns ± 0.1 ns in acetonitrile and <0.5 ns in cyclohexane.[34] The triplet lifetimes are long (≥10 μs) in acetonitrile and cyclohexane. In comparison, the singlet excited state of anthracene has a lifetime of 5.3 ns in nonpolar solvents.[35] We observed no appreciable difference in the efficiency for photodimerization when this reaction was carried out in aerated solutions, which excludes reactivity from the triplet excited state. In addition, unlike

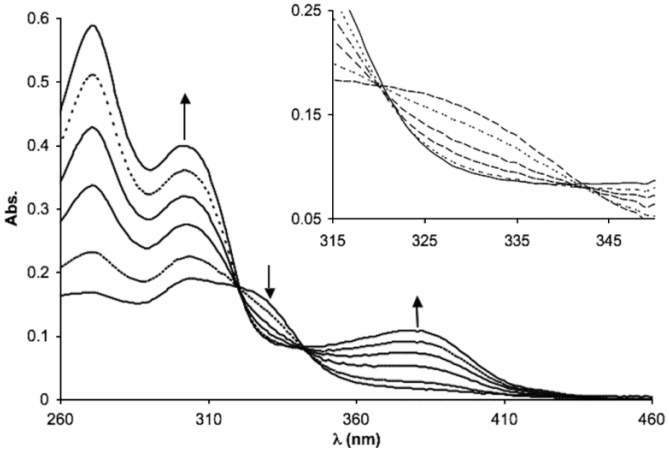
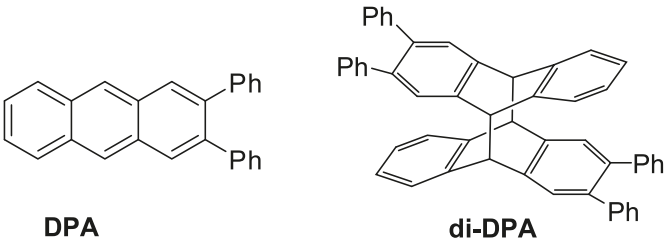
Fig. 2. UV–vis absorption spectra of the photodissociation of a 0.1 mmol/L solution of the head-to-tail photodimer of 2,3-diphenylbenzo[*g*]quinoxaline (***ht*-di-PhB**) in CH_3CN using a 328 nm light. Inset: expansion of the 315–355 nm region.



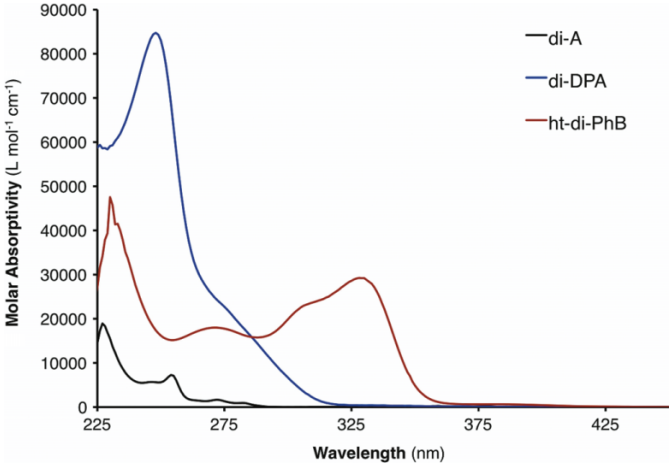
many anthracene derivatives, **PhB** does not appear to be prone to photoreactions with oxygen, as no additional products such as endoperoxides were observed when the reaction was performed in air. These results suggest that photodimerization occurs from the singlet excited state. The absence of endoperoxide formation makes it possible to perform the reaction in aerated solutions, which represents a distinct advantage of this system for practical applications.



The photochromic properties of **PhB** compare favourably to those of 2,3-diphenylanthracene, **DPA**.[35] **DPA** also undergoes [4 + 4]-cycloaddition to form a single photodimer, which also appeared to be the ht stereoisomer. The UV–vis absorption spectra of **DPA** and **PhB** are similar, although the absorption of the latter is redshifted by ~20 nm relative to that of the former. A dramatic difference is also observed between the absorption spectra of the corresponding photodimers (Fig. 3). Whereas ***ht*-di-PhB** exhibits a large peak at 328 nm, the photodimer of **DPA** (**di-DPA**) has no appreciable absorption above 320 nm, and the parent compound, dianthracene (**di-A**) does not absorb above 300 nm. As a consequence, switching between **PhB** and its dimer can be induced with longer wavelengths than is achievable with most anthracene derivatives. It is also worth noting that although both **PhB** and **DPA** can be prepared from benzil, **PhB** is prepared in a single step in a high yield, whereas **DPA** is prepared in three steps in considerably lower overall yields.[15,36]

The photochemistry of the dipyridyl derivative **PyB** is similar to that of **PhB**. A 1.33 mmol/L acetonitrile solution of **PyB** was irradiated with lamps centered at 350 nm for

Fig. 3. Absorption spectra of dianthracene (**di-A**), the photodimer of 2,3-diphenylanthracene (**di-DPA**), and the head-to-tail photodimer of 2,3-diphenylbenzo[*g*]quinoxaline (***ht*-di-PhB**) in acetonitrile.



150 min. The ^{1}H NMR spectrum of the residue obtained by evaporation of the reaction solvent showed a new set of peaks in the aromatic region accompanied by a singlet at 5.2 ppm associated with the formation of the bridgehead across the central ring of two benzo[*g*]quinoxaline moieties. The MALDI-TOF mass spectrum of this mixture showed a peak at *m*/*z* 669, corresponding to M(**di-PyB**) + 1, and a more intense peak for M(**PyB**) + 1. These results are therefore consistent with the identification of the photoproduct as **di-PyB**. The photoadduct formed could be separated from **PyB** by slow evaporation of CH_3CN, which led to selective precipitation of the photodimer. A priori, we expect the ht dimer, ***ht*-di-PyB**, to preferentially form as the major product. This prediction is borne out by the observation of an NOE between protons **a** and **b** (Fig. 4) in the NOESY spectrum of this photoproduct in $CDCl_3$. This NOE would not be expected for the hh dimer.

In addition to its photochromic properties, **PyB** is also capable of binding a variety of metal cations.[37–40] It would therefore be of interest whether the presence of species capable of binding to this compound would also alter its reactivity. However, initial attempts to modulate the tendency of this compound to undergo [4 + 4]-photocycloaddition reactions by the addition of transition metals such as zinc have been unsuccessful. Controlling the photoreactivity of this compound by protonation of the pyridyl groups also proved impractical, as **PyB** becomes insoluble at low pH. Further investigations into the reactivity of this compound in the presence of transition metals and other species are underway.

Conclusion

In conclusion, we have demonstrated that both **PhB** and **PyB** photochemically dimerize in solution. It was also shown that the dimer ***ht*-di-PhB** can be dissociated back to **PhB** using either heat or light. **PhB** offers several advantages over anthracene derivatives to which it is structurally related. This compound is straightforward to prepare, is not prone to photooxidation, and can be switched between its dimer and monomer forms using relatively long wavelengths

of light. As such, benzoquinoxalines represent a promising new class of photochromic compounds that overcome many of the shortcomings of anthracene derivatives, and we are currently investigating the photochemistry of other members of this family of molecules.

Experimental

Materials

All chemicals were used as provided from the supplier. Acetonitrile, 2,3-diaminonaphthalene, and benzil were purchased from Caledon Laboratories Ltd., Sigma-Aldrich Chemical Co., and Matheson Colleman & Bell, respectively. Potassium nitrate, acetic acid, and toluene were purchased from Anachemia.

Instruments

^{1}H NMR and ^{13}C NMR spectroscopic characterization were carried out using a Bruker AMX-400 400 MHz spectrometer; IR spectra were obtained using a Thermo Nicolet Nexus 670 FT-IR ESP spectrometer, performed in KBr. Low-resolution EI mass spectrometry (70 eV) was carried out using a Hewlett Packard 5985 mass spectrometer. MALDI-TOF mass spectra were carried out using a Perspective Voyager-DE STR from PE Applied Biosystems with a nitrogen laser (337 nm) and using 2,5-dihydroxybenzoic acid as the matrix. Microanalysis (C, H, and N) were performed at Simon Fraser University, Burnaby, British Columbia, by M. Yang and S. Wong. Melting points were determined using a Fisher melting point apparatus and are uncorrected. UV–vis absorption spectra were obtained on a Cary 300 biospectrophotometer.

Fluorescence spectra were measured with a PTI QM-2 spectrometer, and the singlet excited state lifetimes were measured with an OB920 single-photon counter from Edinburgh. The excitation wavelength was 380 nm and emission spectra were collected between 395 and 700 nm (slit bandwidth of 3 nm), while decays were collected at 460 nm in cyclohexane or 490 nm in acetonitrile (slit bandwidth of 16 nm). For a description of the laser flash photolysis system, see ref. 33. Samples were excited with a Nd:YAG laser at 266 nm, and the kinetics were monitored at 400–410 and 460 nm. For all photophysical experiments, samples were deoxygenated by bubbling nitrogen for 20 min.

X-ray crystallography

Crystal data for ht-di-DPBQ

$C_{48}H_{32}N_4$, MW = 664.79, monoclinic, space group = *P* 1 21/*n*1, a = 8.6132(9) Å, b = 18.4915(17) Å, c = 10.9618(16) Å, β = 96.550(6), V = 1734.5(4) Å^3, T = 293 K, Z = 2, ρ_{calcd} = 1.273 g/cm^{-3}, μ (Cu Kα) = 0.580, 3014 unique reflections, 2639 observed ($I_o > 2.5\sigma(I_o)$). The final RF = 0.0436 and RWF = 0.0645 (observed data).

Synthesis

Synthesis of 2,3-dibenzylbenzo[g]quinoxaline (PhB)

A solution of 2,3-diaminonaphtalene (1.0 mmol) and benzil (1.1 mmol) in acetic acid (10 mL) was refluxed overnight. Reaction progress was monitored by TLC (eluent: toluene). Once all 2,3-diaminonaphtalene was consumed, the hot reaction mixture was poured over crushed ice. The resulting off-brown suspension was then neutralized with satd. $NaHCO_3$. The aqueous solution was extracted with dichloromethane (3 × 80 mL). The organic washes were combined and dried over $MgSO_4$, filtered, and dried in vacuo yielding an off-yellow powder (88%). The product was purified by flash column chromatography (eluent: dichloromethane) to yield a yellow crystalline powder (75%). Uncorrected mp 184–185 °C (lit. value[19] mp 187–189 °C). UV–vis λ_{max} (nm) (ε ((mol/L)/cm): 271 (61 292), 302 (3683), 381 (12 341) 88. IR (KBr, cm^{-1}) ν: 3053, 2919, 2849, 1436, 1346, 1249. ^{1}H NMR (400 MHz, $CDCl_3$) δ_H: 8.75 (s, 2H), 8.13 (q, 2H), 7.57 (m, 6H), 7.37 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ_C: 154.1, 139.1, 137.9, 134.0, 129.8, 128.9, 128.5, 128.2, 127.5, 126.7. MS *m/e* (CI): 333.3 (M + 1). Anal. calcd for $C_{24}H_{16}H_2$ (%): C 86.72, H 4.85, N 8.43; found: C 86.56, H 5.00, N 8.21.

Synthesis of 1,2-di(pyridin-2-yl)ethane-1,2-dione (pyridil)

Picolinaldehyde (3.22 g, 30.0 mmol) and potassium cyanide (1.92 g, 30.0 mmol) were dissolved in ethanol (5 mL) and water (20 mL) and heated to reflux. After 4 h, TLC analysis (hexane / ethyl acetate, 1:1) showed that all picolinaldehyde was consumed; the hot reaction mixture was poured over crushed ice. The resulting brown suspension was filtered with a Buchner funnel and washed with cold ethanol to yield 2-hydroxy-1,2-di(pyridine-2-yl)ethanone (95%), which was used without further purification. ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ_H: 8.47 (d, J = 5.0 Hz, 2.0H), 7.93–7.88 (m, 2H), 7.84 (dt, J_1 = 8.2, J_2 = 1.8 Hz, 2H), 7.19 (ddd, J_1 = 7.3, J_2 = 5.0, J_3 = 1.2 Hz, 2H).

2-Hydroxy-1-(pyridine-2-yl)ethanone (1.611 g, 7.5 mmol) was dissolved in pyridine (25 mL). To this solution was added a solution of $CuSO_4$ (1.870 g, 7.5 mmol) in H_2O (10 mL). Once addition was complete, the reaction mixture was stirred at reflux for 1 h. The hot reaction was poured over crushed ice and filtered to yield 0.857 g of pure pyridil (54%) as a yellow crystalline solid; mp 155–157 °C (lit. value[31] mp 156–157 °C). MS *m/z* (CI): 213 (M + 1). ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ_H: 8.60 (d, J = 4.7 Hz, 2.0H), 8.23 (d, J = 7.8 Hz, 2H), 7.94 (dt, J = 7.7, 1.8 Hz, 2H), 7.50 (ddd, J_1 = 7.6, J_2 = 4.8, J_3 = 1.2 Hz, 2H).

Synthesis of PyB

This compound was synthesized according to literature procedure.[30] The product was recrystallized from hot ethanol yielding **PyB** (73%) as shiny yellow crystals; mp 183–185 °C (lit. value[30] mp 184–185 °C). MS *m/z* (CI) 335

(M + 1). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ_H: 8.80 (s, 2H), 8.36 (d, J = 4.8 Hz, 2H), 8.15 (m, 2H), 8.09 (d, J = 7.8 Hz, 2H), 7.87 (dt, J_1 = 1.7, J_2 = 7.7 Hz, 2H), 7.61 (m, 2H), 7.26 (m, 4H).

Photochemical experiments

All photodimerization experiments were carried out in glass tubes in a Rayonet photoreactor fitted with seven RPR3500A lamps.

For the experiments in which a filter solution was employed, 3.32 mg **PhB** was dissolved in 0.75 mL of CH_3CN. The solution was transferred to an NMR tube and immersed into a test tube filled with a 2.0 mol/L solution of KNO_3 in water. The sample was irradiated in a Rayonet for 150 min. The solvent was then removed in vacuo and redissolved in a minimum volume of $CDCl_3$. The ^{1}H NMR sprectrum showed a 4:1 ratio of dimer to monomer.

Synthesis of ht-di-PhB

PhB (3.3 mg) was dissolved in spectral grade benzene (1.5 mL) and deoxygenated. The sample was then irradiated in a Rayonet fitted with seven 350 nm lamps for 2 h. After irradiation, a white powder was precipitated on the side of the glass. The solution was decanted and the white product on the side of the glass vessel was collected. MALDI-TOF *m/z*: 665 (M + 1). UV–vis λ_{max} (nm) (ε (mol/L)/cm): 230 (47 543), 270 (17 967), 308 (23 337), 328 (29 242). IR (KBr, cm^{-1}) ν: 3057, 2959, 2919, 2849, 1389, 1144. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ_H: 7.23 (m, 16H), 7.14 (m, 8H), 7.03 (m, 4H), 5.05 (s, 4H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ_C: 156.3, 148.7, 140.4, 138.8, 129.4, 128.1, 128.0, 126.9, 52.7. (Note: due to the limited solubility of this compound, we were unable to observe the signals for quaternary carbons.) Anal. calcd for $C_{48}H_{32}N_4$ (%): C 86.72, H 4.85, N 8.43; found: C 86.61, H 4.98, N 8.15.

Thermal dissociation of ht-di-PhB

***ht*-di-PhB** (6.6 mg) was dissolved in 100 mL DMSO in a 100 mL volumetric flask. The solution (20 mL, 1.00×10^{-5} mol/L) was transferred into four 25 mL glass vials. The open vials were then heated in oil baths at 60, 80, 100, and 150 °C.

Photodissociation of ht-di-PhB

***ht*-di-PhB** (6.6 mg) was used to prepare a 10 mL solution of 1×10^{-4} mol/L in acetonitrile using several dilutions. The solution was transferred to a 1 cm quartz cuvette and irradiated at 328 nm in the fluorimeter. Dissociation progress was followed by UV–vis spectroscopy.

Synthesis of ht-di-PyB

***ht*-di-PyB** was prepared using the method described above for ***ht*-di-PhB** to afford a white solid that precipitated from the reaction solution. MALDI-TOF *m/z*: 669 (M + 1). ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ_H: 8.43 (d, J = 4.8 Hz, 2H), 7.69–7.63 (m, 2H), 7.45–7.37 (m, 2H), 7.25 (dd, J_1 = 5.4, J_2 = 3.3 Hz, 2H), 7.21–7.14 (m, 1H), 7.00 (dd, J_1 = 5.4, J_2 = 3.2 Hz, 2H), 5.16 (s, 2 H). ^{13}C NMR (125 MHz, $CDCl_3$, ppm) δ_C: 157.3, 156.9, 149.1, 147.9, 140.0, 136.2, 128.0, 127.3, 124.3, 122.6, 109.7, 52.7.

Supplementary data

Supplementary data (UV–vis absorption spectra of **PhB** with ***ht*-di-PhB** and spectra showing the progress of the thermal dissociation experiment) for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 653177 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowledgement

The authors gratefully acknowledge the Natural Sciences and Engineering Research Council of Canada (NSERC), the University of Victoria, Victoria, British Columbia, and Simon Fraser University, Burnaby, British Columbia, for funding; T.C.S.P. thanks NSERC for a Canada Graduate Scholarships – Doctoral (CGS-D) scholarship; and M.-K. Yang and F. Haftbaradaran are acknowledged for carrying out the microanalysis.

Fluorescence from the A $^2\Sigma^+$ state suggests a non-Franck–Condon $N_2O^{+\bullet}$ vibrational state population after keV collisional activation with helium

Yawei Lin and Paul M. Mayer

Abstract: A commercial analytical mass spectrometer coupled with a spectrograph and charge-coupled device (CCD) detector was used to obtain the collision-induced emission (CIE) spectra (190–1020 nm) from ion–molecule collisions between $N_2O^{+\bullet}$ and He at laboratory frame collision energies of 4–8 keV. The observed emissions were from the A $^2\Sigma^+ \rightarrow$ X $^2\Pi^+$ system of $N_2O^{+\bullet}$, excited fragments of the parent molecule, and the target gas. The relative emission intensities of the $N_2O^{+\bullet}$ ions and their fragments were independent of the ion translational energy within the 4–8 keV range, confirming the curve-crossing mechanism for translational-to-internal energy transfer in this system. Band emission intensities of 1_0^1 and 3_1^1 relative to the 1_0^0 band within the $N_2O^{+\bullet}$ (A $\rightarrow$ X) system have been measured and compared with reference data. The results indicated that the collisionally excited ion has a decidedly non-Franck–Condon vibrational state distribution.

Key words: Frank–Condon principle, curve-crossing mechanism, collisional activation, mass spectrometry, predissociation.

Résumé : On a utilisé un spectromètre de masse analytique commercial couplé à un spectrographe et à un dispositif détecteur de charge couplée pour obtenir des spectres d'émission induite par une collision (EIC) (190–1020 nm) à partir de collisions ion–molécule entre du $N_2O^{+\bullet}$ et du He à des énergies de collision de 4 à 8 keV disponible au laboratoire. Les émissions observées à partir du système A $^2\Sigma^+ \rightarrow$ X $^2\Pi^+$ du $N_2O^{+\bullet}$, les fragments excités de la molécule de base et du gaz cible. Les intensités relatives de l'émission des ions $N_2O^{+\cdot}$ et de leurs fragments sont indépendantes de l'énergie translationnelle dans la fourchette de 4 à 8 keV, ce qui confirme le mécanisme de croisement de coure pour le transfert d'énergie translationnelle à interne dans ce système. On a mesuré les intensités des bandes d'émission 1_0^1 et 3_1^1 par rapport à la bande 1_0^0 dans le système $N_2O^{+\bullet}$ (A $\rightarrow$ X) et on les a comparées avec des données de référence. Les résultats indiquent que l'ion excité par collision n'est définitivement pas une distribution d'état vibrationnel de Franck-Condon.

Mots-clés : principe de Franck–Condon, mécanisme de croisement de courbe, activation par collision, spectrométrie de masse, prédissociation.

Introduction

The triatomic ion $N_2O^{+\bullet}$ is isoelectronic with NCO, $CO_2^{+\bullet}$, and BO_2. It is the intermediate in an important ion–molecule reaction in the upper atmosphere (eq. [1]).[1]

$$[1] \quad O + (^4S_u) + N_2(X^1\Sigma_g^+) \rightarrow N_2O^{+\bullet}(A^2\Sigma^+) \rightarrow NO^+(X^1\Sigma^+) + N(^4S)$$

The dominant emission band systems of $N_2O^{+\bullet}$, extending from 335 to 405 nm, are the A $^2\Sigma^+ \rightarrow$ X $^2\Pi^+$ transitions from three dominant levels 1^0, 1^1, and 3^1 of the A state. Here the capital number represents the normal vibrational mode involved (1 being the symmetric stretch, 2 being the degenerate bend, and 3 the asymmetric stretch) and the superscript and subscript represent the vibrational quanta in the upper and lower states, respectively).[2] Higher excited states of $N_2O^{+\bullet}$, such as the B and C states, are predissociative and not observed in emission spectra.[3] Also, the state crossings between the potential surfaces of the predissociative states and that of the A $^2\Sigma^+$ state occurs near the bottom of the potential surface of the A state, restricting the number of vibrational levels in which the A state is formed.[4–6]

Emission cross sections and vibrational level ratios of $N_2O^{+\bullet}$ have been measured by a variety of techniques including photoionization, Penning ionization, electron impact, and charge exchange.[7–10] It is well-known that when an ion is formed by vertical excitation, the vibrational branching ratio is equal to the ratio of the corresponding Franck–Condon factors. Tokue et al.[11] determined the vibrational distributions of the 1^1 and 3^1 levels relative to the 1^0 level of the A state, using Penning ionization. The branching ratio for the 1^1 level strongly depended on the excitation energy, showing non-Franck–Condon behaviour, resulting from autoioni-

zation and shape resonant ionization, indicating that a vertical transition is not always available.

In this study, we have focused on keV (laboratory frame) ion–molecule collisional activation. In mass spectrometry, collisional activation is an essential method for fragmenting ions to gain further structure determination.[12–16] When a projectile ion with keV translational energy collides with a relatively stationary target gas moiety, a portion of the ion's translational energy is converted to internal energy, sufficient for the ion to undergo dissociation reactions. Of the potential mechanisms for this energy transfer, the most widely applicable one is the curve-crossing mechanism.[17–19] The qualitative and quantitative description of curve-crossing adiabatic energy transfer to produce electronic excitation has been described by Massey et al.[20] and Nikitin.[21] As shown in Fig. 1,[17] during the collision process, when the projectile ion approaches the target, the energy of the collision complex increases along the adiabatic curve of the ground state, until the ground-state potential surface crosses with that of an excited state through point C. The strength of the nonadiabatic coupling of the two curves can be represented as the Massey parameter, ξ, in the Massey equation $\xi = a\Delta E/h\upsilon$ (ΔE is the smallest energy gap between two adiabatic states, a is the width of the nonadiabatic interaction region, and υ is the classical nuclear velocity). The curve-crossing then brings about a radiationless transition between the ground and electronic excited states of the collision complex. During separation of the collision complex, the projectile ion may return to its original energy surface or remain in an excited electronic state. In the latter case, the electronic excitation can be removed by emission of a photon or converted to ro-vibrational excitation of the ground state by intramolecular vibrational relaxation (IVR). As the relative velocity of the interacting pair increases the time of interaction decreases, decreasing the Massey parameter, thereby increasing the probability that the system crosses into an excited state. Thus, this direct T→E (translational to electronic) energy transfer is operable at keV collision energies.

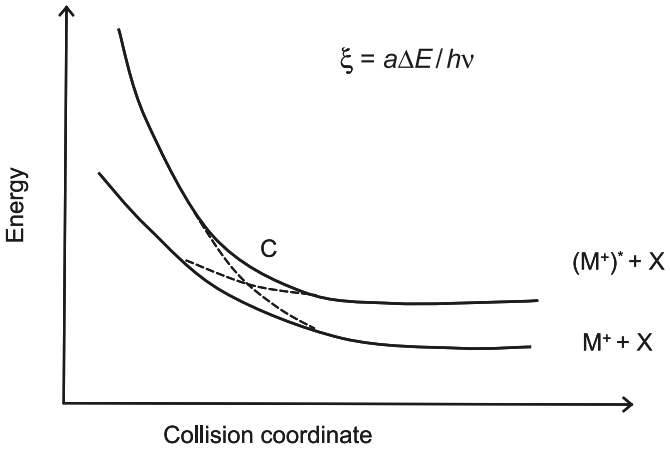
Recent work by our group showed that for keV $N_2^{+\bullet}$–He and $CO_2^{+\bullet}$–He collisions, the relative emission intensity between the fragments and the projectile ions are independent of ion translational energy in the 3–8 keV range, results consistent with the formation of a discrete distribution of excited states by the curve-crossing mechanism.[22–24] The purpose of this paper is to extend our collision-induced emission (CIE) study to the $N_2O^{+\bullet}$–He system, and by comparing our results with those obtained from other activation methods, to get a clearer picture of the mechanism of high-energy ion–molecule collisions.

Experimental procedures

All experiments were performed on a modified VG ZAB mass spectrometer[14] with an added third field-free region (3FFR) as previously described.[25,26]

$N_2O^{+\bullet}$ ions were generated from N_2O by 80–90 eV electron ionization in the ion source of the instrument. The ions were transmitted to the 3FFR where they collided with the target gas in the collision cell at a collision gas pressure that reduces the pre-cell ion flux by 10% (i.e., essentially single collision conditions).[14] With 80–90 eV electrons, ionization of $N_2O^{+\bullet}$ could result in $N_2O^{+\bullet}$ A $^2\Sigma^+$ being formed in the ion source.[27] However, the radiative lifetime of the A state is shorter than 400 ns.[28–30] When compared with the time required for the ions to reach the collision chamber, which ranges from 17 to 34 μs depending on the accelerating voltage, virtually all ions that are formed initially in the A $^2\Sigma^+$ would have returned to the ground state by the time they collide with the target gas.

Fig. 1. A simplified diagram illustrating curve-crossings during ion–target collisions. The behaviour of the excited states is drawn as a single entity.



A spectrograph (Acton SpectraPro 275, 27.5 focal length, 1200 g mm^{-1} holographic grating) and a thermoelectrically cooled charge-coupled device (CCD) detector (Andor DV401-UV, front-illuminated with UV coating) were installed above the collision cell for the detection of photon emissions resulting from ion–target collisions.[22] Emissions from the excited-state species were directly observed with the CCD detector cooled to a temperature of –35 °C. The time window of observation ranges from 30 to 60 ns for 8 to 4 keV $N_2O^{+\bullet}$. The entrance slit of the spectrograph was set to 3.0 mm, providing a spectral resolution of 8.5 nm (measured at full width at half-height for atomic lines). Optical emissions were recorded from 190 to 1020 nm using the Andor MCD 2.63.1.8 program and were recorded in 14 separate segments, each being 50–70 nm wide. Two accumulations of 30 min were collected at 8 keV ion translational energy for each segment at full vertical binning reading mode. For other ion translational energies, the total acquisition time for each of the separate segments ranged from 1 to 4 h. Each segment was background-subtracted, and background spectra were collected prior to signal acquisition with exactly the same conditions except without an ion beam. Spectral spikes resulting from cosmic rays were removed digitally by the program. Horizontal binning was performed manually in the ASCII file by combining data of every 20 pixel columns, and the overlapping portion of the spectrum at the two ends of each window was averaged.

A higher resolution spectrum (330–400 nm) was obtained by reducing the entrance slit width to 1.0 mm, resulting in a spectral resolution of 3.0 nm, and the data acquisition time of each segment was increased to 4 h.

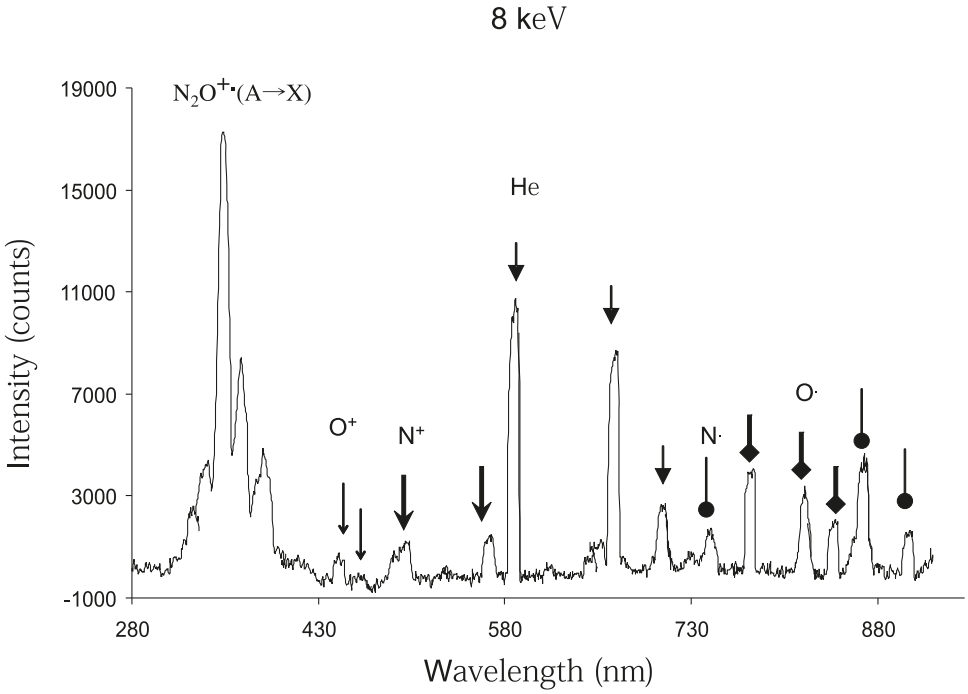
Fig. 2. Collision-induced emission spectra (190–1020 nm) of $N_2O^{+\bullet}$–He collisions at 8 keV. Collision gas pressure corresponded to 90% ion beam transmission. The arrows with different shapes represent photoemission from O^+, N^+, He, N, and O.



Results and discussion

Emission spectrum from $N_2O^{+\bullet}$–He collisions

The emission spectrum obtained from $N_2O^{+\bullet}$–He collisions at 8 keV ion translational energy is shown in Fig. 2 and is compared with those obtained at 6 and 4 keV in Fig. 3. A summary of the peak and transition assignments is presented in Table 1. Emission signals observed in the lower wavelength region (330–400 nm) correspond to the $N_2O^{+\bullet}$ ($A\ ^2\Sigma^+ \rightarrow X\ ^2\Pi^+$) system. Three dominant vibrational bands, 1^1, 3^1, and 1^0 were observed. Other peaks observed in the spectrum arise from the emissions of the target gas He and electronically excited fragments N^+, N, O^+, and O.

In our earlier study of the $CO_2^{+\bullet}$–He system,[24] two obvious band emissions resulting from electronic transitions of the $B\ ^2\Sigma_u^+$ and $A\ ^2\Pi_u$ states to the ground $X\ ^2\Pi_g$ state of $CO_2^{+\bullet}$ were observed. The vibrational progression in $CO_2^{+\bullet}$ $A\ ^2\Pi_u \rightarrow X\ ^2\Pi_g$ transition showed emission from high vibrational levels (7, 0, 0) in the $A\ ^2\Pi_u$ state. In the present $N_2O^{+\bullet}$He system, only the expected $A\ ^2\Sigma^+ \rightarrow X\ ^2\Pi^+$ transition was observed, and in addition, emissions arise only from low (indeed $v = 1$) vibrational levels of the A state. Also, the $CO_2^{+\bullet}$–He CIE spectra only showed two atomic emissions from the oxygen radicals O(^{5}P) and O(^{3}P), meanwhile in the $N_2O^{+\bullet}$–He CIE spectra, nine more atomic emissions from fragments N^+, N, O^+, and O were observed. The intensity ratio between the molecular emission and atomic emission from O(^{5}P) and O(^{3}P) were calculated: $I_{N_2O^+}/I_{O(^5P)}$ and $I_{CO_2^+}/I_{O(^5P)}$ are 19 and 31, respectively; $I_{N_2O^+}/I_{O(^3P)}$ and $I_{CO_2^+}/I_{O(^3P)}$ are 11 and 22, respectively, indicating the greater tendency to form excited fragments in the collisional activation of $N_2O^{+\bullet}$, in agreement with the dissociative nature of the $N_2O^{+\bullet}$ higher excited states.[3,33] According to ab initio calculations of the potential surfaces by Komiha,[33,34] shown in Fig. 4, two repulsive potential curves of $1^4\Pi$ and $1^4\Sigma^-$ state curve-cross with the A and X state surfaces, leading to different state-specified fragments. Also, there are avoided crossings between the $1^4\Sigma^-$ and $2^4\Sigma^-$ states. We have identified a number of higher energy fragments in our CIE spectra indicative of the dissociation of the higher electronic states of $N_2O^{+\bullet}$ (Table 1). This example shows that one benefit of the CIE experiment is that it not only offers rich information on the excited states of the projectile ion generated in a collision, but also on the excited states of CID products.

Relative intensities as a function of ion translational energy

The emission spectra over the wavelength range of 280–950 nm from 8 to 4 keV ion translational energy are presented in Fig. 3. The intensities of the emissions from the target gas cannot be directly compared with those from the projectile ions or the fragments, since the spatial distribution of collisions across the collision cell is unknown. The relative emission intensities of $N_2O^{+\bullet}$, N^+, O^+, and O at various collision energies are presented in Fig. 5. The intensities have been corrected for their differences in radiative lifetime, as only a portion of the emission from each excited-state species is detected. The correction was performed based on our previous conclusion that the majority of collision events take place under the window.[22] In Fig. 5, all the points falls on the $y = x$ line indicating that the relative emission intensities do not change with ion translational energy, supporting the curve-crossing mechanism for collisional excitation, which will produce the same distribution of excited states in the projectile ion, only the probability with which they are formed changes with translational energy according to the Massey equation.

Relative band strength for in the A $^2\Sigma^+$ state $N_2O^{+\bullet}$

Figure 6 shows a higher resolution CIE spectrum of the $N_2O^{+\bullet}$ A $^2\Sigma^+ \rightarrow$ X $^2\Pi^+$ system in the 330–400 nm region produced by 8 keV collisions. The three bands 1_0^0, 1_0^1, and 3_1^1 are located at 354 338, and 347 nm, respectively, together with related transitions 1_1^0 and 1_2^0 and the combination band $1_1^0\ 3_1^1$. Each $N_2O^{+\bullet}$ A $^2\Sigma^+ \rightarrow$ X $^2\Pi^+$ vibrational band consists of a pair of sub-bands with nearly equal intensity owiwng to the spin-orbit splitting of the X $^2\Pi^+$ state. The band-emission intensities have been lifetime-corrected for later calculation of the relative intensities.[30]

The relative emission cross section is known to be related to the vibrational branching ratios and emission intensities as described in equations below

$$[2] \quad \frac{\sigma_{em}(\upsilon_i', \upsilon_k'')}{\sigma_{em}(\upsilon_j', \upsilon_l'')} \doteq \frac{I_{em}(\upsilon_i', \upsilon_k'')/\varepsilon(\upsilon_i', \upsilon_k'')}{I_{em}(\upsilon_j', \upsilon_l'')/\varepsilon(\upsilon_j', \upsilon_l'')}$$

$$[3] \quad \frac{\sigma_{em}(\upsilon_i', \upsilon_k'')}{\sigma_{em}(\upsilon_j', \upsilon_l'')} \doteq \frac{\nu(\upsilon_i', \upsilon_k'')^3 q(\upsilon_i', \upsilon_k'')\sigma(\upsilon_i')f(\upsilon_i')}{\nu(\upsilon_j', \upsilon_l'')^3 q(\upsilon_j', \upsilon_l'')\sigma(\upsilon_j')f(\upsilon_j')}$$

where $I_{em}(\upsilon', \upsilon'')$, $q(\upsilon', \upsilon'')$, $\varepsilon(\upsilon', \upsilon'')$, and $\sigma_{em}(\upsilon', \upsilon'')$ are the emission intensity, the Franck–Condon factor, the transition frequency, and the cross section, respectively, for the υ'–υ'' band. The $f(\upsilon')$ and $\sigma(\upsilon')$ represent the fluorescence vs the predissociation branching ratio and excitation cross sections, respectively, for the υ' level of the A state. By transforming the equations and obtaining the $f(\upsilon')$ and $q(\upsilon', \upsilon'')$ values based on the photoelectron–photoion coincidence measurement,[27] the branching ratios can be determined from the relative intensities of the vibrational bands.[11,13] The band strength of the 1_0^1 and 3_1^1 bands relative to that of the 1_0^0 band are listed in Table 2, along with values from photoionization and Penning ionization. In photoionization, $I(1_0^1)/I(1_0^0)$ and $I(3_1^1)/I(1_0^0)$ maintain constant values of 0.27 and 0.05, respectively, when the photon energy is >45 eV. Since the energy range above 45 eV is free of autoionization and shape resonance, these values are regarded as the branching factors in the Franck–Condon limit. Penning ioni-

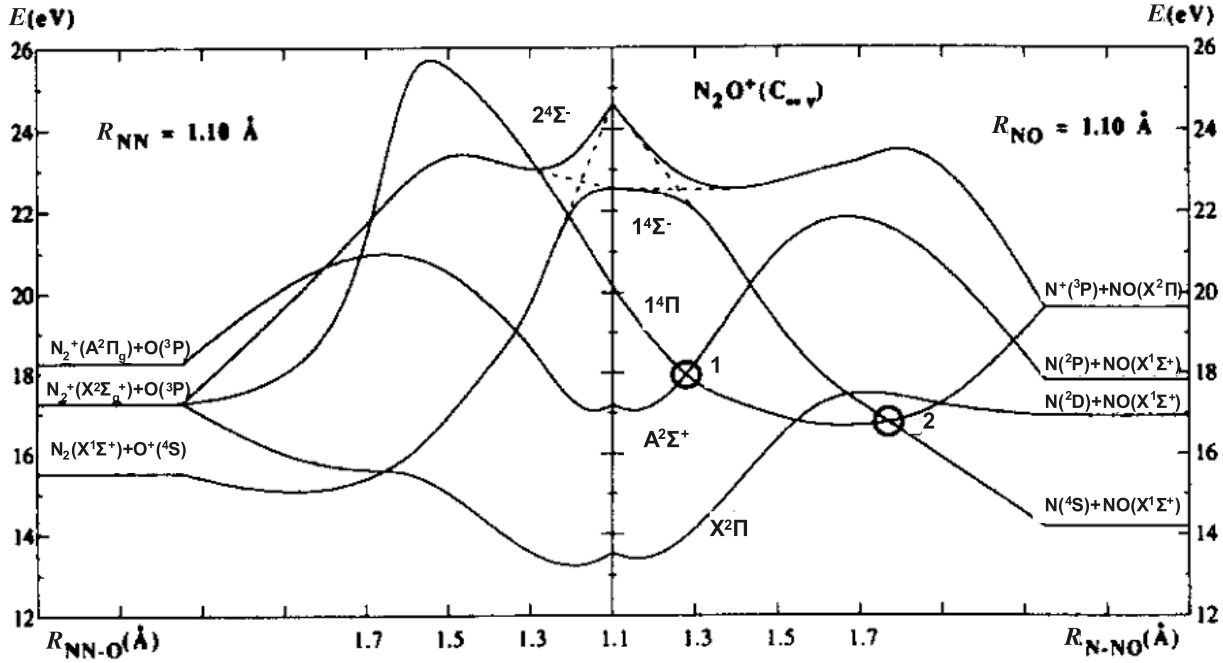

Fig. 5. The plot of the lifetime-corrected relative emission intensities of $N_2O^{+\bullet}$, N^+, N, and O at various ion translational energies vs those at 8 keV. All ion translational energies were obtained by varying the source accelerating voltages. Spectra are normalized to the ion flux at 8 keV. Collision gas pressure corresponded to 90% ion beam transmission.

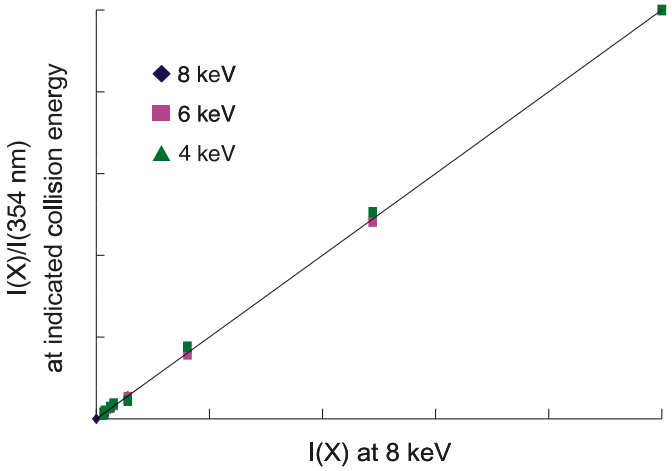

Fig. 6. Collision-induced emission spectrum (330–400 nm) of 8 keV $N_2O^{+\bullet}$–He collisions obtained with an entrance slit width of 1.0 mm (total data acquisition time per section was 8 h).

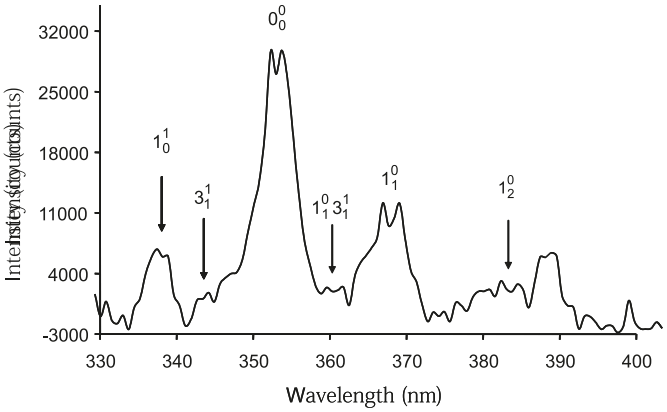

zation obtained by Ne(^{3}P: 16.6 eV) and He(2^3S: 19.9 eV) is similar to photoionization, showed non-Franck–Condon behaviour when the excitation energy was <45 eV. Since autoionization is from the Rydberg state of the neutral molecule and shape resonant ionization is due to the interaction of the photoelectron or metastable atom and the target neutral molecule,[35–31] neither of them have relevance to the $N_2O^{+\bullet}$–He system in this study. In the present CIE experiments, the$I(1_0^1)/I(1_0^0)$ and $I(3_1^1)/I(1_0^0)$ ratios in the $N_2O^{+\bullet}$ A state show obvious deviation from Franck–Condon behaviour, unlike our previous observations with $CO_2^{+\bullet}$–He.[23] This is a clear example of collisional excitation producing a decidedly non-Franck–Condon distribution of vibrational levels. This must be due to the fact that many predissociative states (such as the $1^4\Pi$ and $1^4\Sigma^-$ states, Fig. 4) cross with, and populate the vibrational levels of, the A state of $N_2O^{+\bullet}$.

Conclusion

Using a modified VG-ZAB mass spectrometer, the emission from electronic excited projectile $N_2O^{+\bullet}$ ions and their collision-induced dissociation products were observed, giving a relatively full picture of the activation process. Collision-induced emission spectroscopy produced from high keV $N_2O^{+\bullet}$–He collisions showed that the relative populations of electronically excited $N_2O^{+\bullet}$, N, O, O^+, and N^+ states remains constant as the collision energy is increased from 4 to 8 keV, a result consistent with the curve-crossing mechanism of collisional activation. The relative vibrational

branching ratios of $N_2O^{+\bullet}$ after collisional activation were compared with those obtained by different activation processes. Results indicate that owing to the complex curve-crossing between predissociation states and the A and X states of $N_2O^{+\bullet}$, the vibrational population in the A state appears more evenly distributed than that resulting from Franck–Condon photoexcitation. This was also different than that seen in the case of $CO_2^{+\bullet}$–He collisions and is the result of the many predissociative higher energy states populating the vibrational levels of $N_2O^{+\bullet}$ A $^2\Sigma^+$.

Abstract: Photophysical measurements of 6-methylcoumarin (**1**) encapsulated within cucurbit[8]uril (CB[8]) indicate a pronounced red shift in the fluorescence maximum with an increase in the emission quantum yield and fluorescence lifetime. In addition, at 77 K, there is observable phosphorescence upon encapsulation within CB[8]. The photophysical measurements add credibility to our previously proposed dynamic nature of the CB–coumarin complex in solution. The dynamic nature of the CB[8]–coumarin host–guest complex in water is critical to a CB acting as a supramolecular catalytic nanoreaction vessel to facilitate the photodimerization of coumarins leading to syn dimers.

Key words: cucurbiturils, supramolecular catalysis, host–guest photochemistry, coumarin photophysics, coumarin–CB[8] host–guest complex, lifetime of coumarin–CB[8].

Résumé : Des mesures photophysiques sur la 6-méthylcoumarine (**1**) encapsulée dans du cucurbit[8]urile (CB[8]) mettent en évidence un déplacement prononcé vers le rouge dans le maximum de fluorescence avec une augmentation dans le rendement quantique d'émission et le temps de vie de fluorescence. De plus, à 77 K, l'encapsulation dans du CB[8] provoque une phosphorescence qui peut être détectée. Les mesures photophysiques ajoutent de la crédibilité à la proposition que nous avons faite antérieurement relative à la nature dynamique du complexe CB–coumarine en solution. La nature dynamique du complexe hôte–invité CB[8]–coumarine dans l'eau est critique pour le CB qui agit comme récipient pour la nanoréacton catalytique supramoléculaire afin de faciliter la photodimérisation des coumarines conduisant aux dimères syn.

Mots-clés : cucurbituriles, catalyseur sapramoléculaire, photochimie hôte–invité, coumarine, photophysique, complexe hôte–invité coumarine–CB[8], temps de vie du complexe coumarine–CB[8].

[Traduit par la Rédaction]

Introduction

Coumarin has historically been the subject of intense photochemical and spectroscopic interest mainly as a consequence of its importance in biological systems and its use in various materials of commercial interest.[1–7] Based on this precedence, we chose to investigate the photophysics of coumarin upon complexation within cucurbit[8]uril (CB[8])[8–16] in aqueous solution to understand the environmental perturbations on the excited state of coumarins.[6,7]

In the last few years, we have been exploring the role of CB[8] in altering the photoreactivity of coumarin derivatives.[17–20] We chose 6-methylcoumarin (**1**) to understand the role of CBs in the alteration of the photochemistry of encapsulated coumarin guests. Photodimerization of **1** in water and in other isotropic media was postulated to occur from the triplet state.[21,22] Our investigations[17–19] revealed that CB[8] and **1** form a dynamic complex in water with a host–guest ratio of 1:1.6 and with a binding constant of 1.33×10^4 $(mol/L)^{-1}$ (K_1) and 2.00×10^6 $(mol/L)^{-1}$ (K_2).[23,24] Photodimerization proceeded very efficiently in the presence of CB[8]. There was no noticeable difference in the reaction efficiency under N_2-, air-, and O_2-saturated conditions. Additionally, we successfully employed a catalytic amount (10 mol%) of CB[8] leading to selective formation of syn dimers during photodimerization (Scheme 1). We proposed a catalytic cycle involving CB[8] where the high photodimerization rate within the cavity compared with the photodimerization in water outside the CB[8] cavity (background reaction) determines the efficiency of the catalytic cycle and the selectivity in the photodimerization process (syn–anti ratio). The extent of the background reaction compared with the reaction within the cavity was understood based on the photoproduct distribution. In the present case involving **1**, the anti dimer is formed only outside the cavity, whereas the syn isomers are formed within the cavity. Thus, the ratio of the syn–anti isomer not only reflects the selectivity within the confined environment of CB[8] but also the efficiency of the catalytic cycle. By employing CBs in catalytic amounts, we were able to overcome one of the limitations of employing CB[8] as a nanoreaction vessel for chemical transformations,

namely, limited solubility of CB[8] at higher concentrations in water (maximum solubility is ~0.2 mmol/L).[8–16] To rationalize the photochemical transformation under catalytic conditions, it is important to identify the reactive spin state in the catalytic cycle. Considering that the photodimerization of **1** in alcohol leads to the anti head-to-head (*anti*-HH; **3**) exclusively,[21] the photoproduct selectivity upon inclusion of **1** within CBs cannot be attributed to a change in polarity alone (as the polarity of the cucurbituril cavity was previously reported to be similar to that of *n*-octanol[25]). As all four dimers (**2**–**5**) could fit within CB[8],[18,19] characterizing the nature of the excited state (singlet and (or) triplet excited state, excited species lifetime inside the cavity) is critical to understanding the supramolecular aspects leading to catalysis.[17] In this report, we present the photophysical investigations for the comprehension of the role of CB[8] in altering the photochemistry of encapsulated **1**.

Results and discussion

To understand the photophysical aspects of **1** within CB[8], steady-state luminescence spectroscopy and fluorescence lifetime measurements at room temperature were performed in water in the presence and in the absence of CB[8]. In the absence of CB[8], a structureless emission centered around 411 nm with a lifetime shorter than 0.1 ns (Fig. 1) was observed (Table 1). The emission intensity increased upon increasing the mole equivalents of CB[8] from 5 to 190 mol% of CB[8]. The emission intensity remained constant when the mole equivalents of CB[8] were increased beyond 100 mol% to 190 mol%. In addition, there was a noticeable red shift in the emission maximum (Fig. 1). For example, the emission maxima shifted from 430 nm for 5 mol% to 443 nm for 100 mol%. Fluorescence lifetime measurements in the presence of CB[8] showed a bi- or triexponential decay with distinct lifetime components. The uncomplexed **1** in water decays in <0.1 ns and CB[8]–**1** host–guest (H–G) complexes decay at ~3.7 and ~0.7 ns. We tentatively assign the long-lived component (~3.7 ns) as the decay from a 1:1 H–G complex and the short-lived component (~0.7 ns) as the 1:2 H–G complex. As the fluorescence of the 1:2 H–G complex competes with photodimerization and nonradiative decay, a shorter lifetime when compared with a 1:1 H–G complex is expected for the 1:2 H–G complex. Because of instrumental limitations owing to the relatively long instrument response function compared with the fast decaying lifetime components, we fitted the fluorescence decays in the presence of CB[8] to only two components, which are listed in Table 1. In the biexponential fit, the long-lived component corresponds to a 1:1 H–G complex, whereas the short-lived component corresponds to both the free **1** and the 1:2 H–G complex. As we have a dynamic H–G complex, the relative contribution of the decay components depend on the mol% of CB[8]. Based on the biexponential fit (Table 1), we believe that the decay components of all three species, namely, uncomplexed **1**, the 1:1 H–G complex, and the 1:2 H–G complex, are present at a lower mol% of CB[8] (i.e., from 5 to 40 mol%). At a higher mol% of CB[8] (i.e., ≥100 mol%), the decay components from 1:1 H–G complex predominate with minor contributions from 1:2 H–G complex. Fluorescence quantum yield measurements (quinine sulfate in 0.5 mol/L H_2SO_4 as the standard) showed an increase in the quantum yield (Φ_{em}) from 0.008 in the absence of CB[8] to 0.04 in the presence

Note: CB[8], cucurbit[8]uril.

[a]Steady-state emission of **1** was recorded with λ_{ex} = 320 or 340 nm.

[b]Optical density (absorbance) of **1** is ~0.11 at λ_{ex} = 345 nm for determining the quantum yield. Quinine sulfate in 0.5 mol/L H_2SO_4 (Φ_{fl} = 0.55) was used as the standard. Reported Φ_{em} are an average of a minimum of three runs with an error <5%.

[c]λ_{ex} = 340 nm. Fluorescence decay was monitored at 411 nm (entry 1) and at 443 nm (entries 2–14). The percent intensity contributions are in brackets.

[d]Photodimerization quantum yields were measured using ferrioxalate actinometry. Irradiations were performed with a 450 W medium pressure Hg lamp using a 313 nm band pass filter. Reported values are an average of a minimum of 10 runs with an error <10%. The number of moles of the photodimer **2** formed was computed from the decrease in the absorbance of **1**, as there was a clear isosbestic point indicating a one-to-one conversion from **1** to **2**.

[e]Photodimerization rate (r_{dim}) was monitored by UV–vis spectroscopy. Reported r_{dim} are an average of a minimum of three runs with an error <10%. [**1**] = 0.05 mmol/L was irradiated with a 450 W medium pressure Hg lamp under an aerated condition.

of CB[8] in water (Table 1). The maximum Φ_{em} was observed for 100 mol% CB[8] (Fig. 1) with a Φ_{em} value of 0.04 and stayed constant upon increasing the CB[8] concentration beyond 100 mol%. (Note: Φ_{em} levels off beyond 100 mol% of CB[8] as shown in in Fig. 2A.) Additionally, in spite of forming a poor glass at 77 K, we were able to observe phosphorescence (Fig. 1C) in water with various mol% of CB[8], showing the formation of 6-methylcoumarin excited triplet (^{3}**1***).

The photodimerization of coumarins was originally postulated to depend on the multiplicity of the excited state, with the singlet excited state favoring the syn dimers and the triplet excited state favoring the anti dimer.[1–5] Recently,[21,22] the multiplicity dependent pathway was questioned for the photodimerization of **1** and a reactive triplet excited state (^{3}**1***) was postulated in isotropic media irrespective of the type of solvent. It was reasoned that the high intersystem crossing rate (isc), especially in polar solvents (water, trifluoroethanol, etc.), probably caused by appropriate shifting of spectroscopically not accessible energy levels led to the reactivity from the triplet excited state (^{3}**1***).[21,22] The excited triplet chromophore reacts with a ground state monomer to

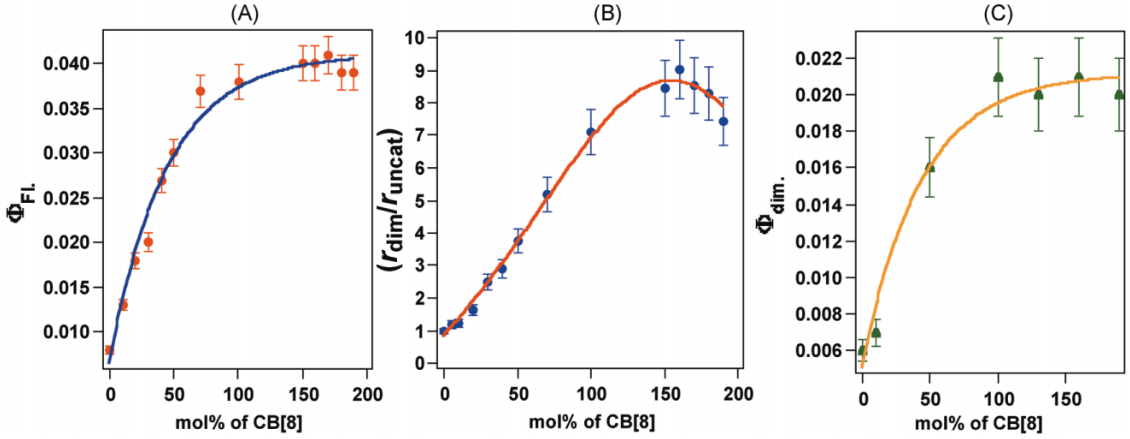
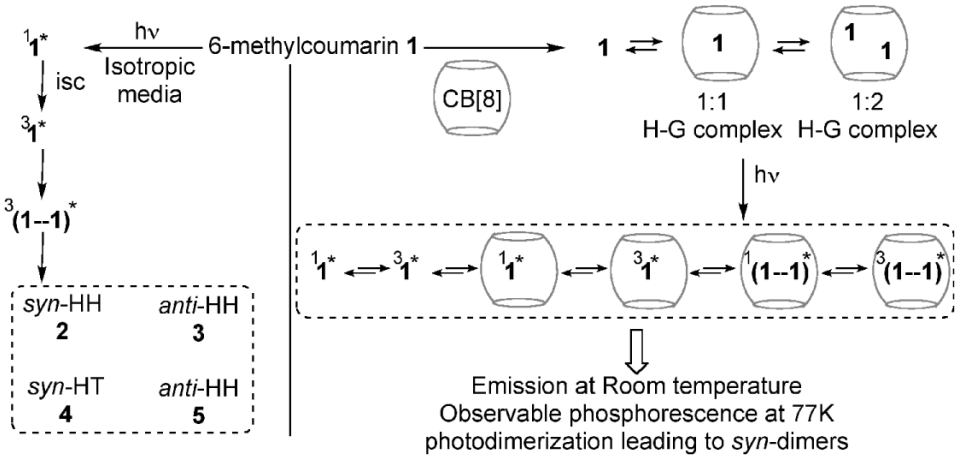
Fig. 2. (A) Change in fluorescence quantum yield, (B) photodimerization rate increase, and (C) photodimerization quantum yield (r_{uncat} = r_{dim} at 0 mol% of cucurbit[8]uril (CB[8])) upon varying the mol% of CB[8].



Scheme 2. Photodimerization of 6-methylcoumarin (**1**) within cucurbit[8]uril (CB[8]) in water.



form an excited complex, ^{3}(**1**–**1**)*. The stability of the complexes, namely, $^3(\mathbf{1}\text{–}\mathbf{1})_{\text{anti-HH}}$*, $^3(\mathbf{1}\text{–}\mathbf{1})_{\text{anti-HT}}$*, $^3(\mathbf{1}\text{–}\mathbf{1})_{\text{syn-HH}}$*, and $^3(\mathbf{1}\text{–}\mathbf{1})_{\text{syn-HT}}$*, and their corresponding reactive rates were theorized to determine the product distribution (Scheme 2).[21,22] Based on absorbance and emission measurements, the excited singlet and triplet states of **1** were assigned a ππ* configuration, with the singlet excited state at ~78 kcal/mol and the triplet excited state at ~61 kcal/mol.[21,22,26–30] The photophysics for **1** has been reported for various solvents. Low-temperature photophysical measurements (at 77 K) showed fluorescence emission maxima centered around 406 nm with a quantum yield (Φ_f) of 0.015 in ethanol.[26] The fluorescence lifetime of the emission centered around 405 nm was found to be ≤0.3 ns at 295 K in 1,4-dioxane.[27] Additionally, the phosphorescence spectra at 77 K[30] showed a (0,0) transition at 465 nm with a quantum yield (Φ_p) of 0.066 in ethanol[26] and a triplet quantum yield of 0.04 in benzene at 298 K.[27] Further, extensive photophysical investigations revealed that the greatest majority of the quanta are lost within the singlet manifold for **1**.[21,22,28] The very weak fluorescence from **1** at low concentrations in solvents of low and medium polarity and the low Φ_f in highly polar solvents were cited as the reasons for the exclusion of any significant contribution of a singlet state (or singlet state excited complex) during the photodimerization.

Upon complexation of **1** with CB[8], the room-temperature fluorescence intensity increases with a noticeable red shift. This cannot be attributed to polarity alone, as **1** is weakly fluorescent in a nonpolar solvent (the solvent polarity is less than that for methanol). We believe that the confinement of **1** within the hydrophobic CB[8] cavity is crucial and is likely responsible for the enhanced emission and longer lifetime. Similarly, the confinement of **1** within CB[8] is likely responsible for the observed phosphorescence at 77 K. The phosphorescence intensity cannot be quantified to a mol% of CB[8] under our experimental conditions, as water does not form a transparent glass at 77 K. Nevertheless, a clear increase in the phosphorescence intensity (Fig. 1C) was observed upon complexation with CB[8].

The quantum yield of photodimerization (Φ_{dim}) was calculated by ferrioxalate actinometry (Fig. 2C and Table 1). The Φ_{dim} was found to increase with an increase in the mole equivalents (mol%) of CB[8]. Upon increasing the mole equivalents of CB[8] beyond 100 mol%, there was no noticeable change in Φ_{dim}, indicating that the amount of photodimer formed per unit of time to the number of photons absorbed after 100 mol% of CB[8] occurs at the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

efficiency. (Note: Φ_{dim} levels off beyond 100 mol% of CB[8] as shown in Fig. 2C.) On the other hand, the rate of photodimerzation (r_{dim}) depends on the relative population of 1:2 H–G complex, 1:1 H–G complex, and uncomplexed **1**, which in turn are dependent on the amount of CB[8] present. We previously postulated a dynamic H–G complex of **1** with CB[8] (a mixture of 1:1 H–G complex, 1:2 H–G complex, and uncomplexed **1**) in solution to rationalize the catalytic nature of photodimerization. (Note: r_{dim} increases until 160 mol% of CB[8] and then decreases as displayed in Fig. 2B.) As the maximum r_{dim} was observed at 160 mol% of CB[8], this corresponds to a concentration at which the dynamic equilibrium favors the highest concentration of the 1:2 H–G complex, resulting in increased reaction efficiency. Increasing the mol% of CB[8] beyond this optimum concentration decreases the rate, as the dynamic equilibrium possibly shifts away from the 1:2 H–G complex, thereby lowering the reaction efficiency (Fig. 2B). Qualitatively, this aspect can be understood based on thermodynamic features leading to complexation. In the case of a 1:2 H–G complex, both host–guest interaction (H–G) and guest–guest (G–G) interaction play a dominant role. In the case of a 1:1 complex, the major interaction is the interaction between the host and the guest (H–G). So, to shift the equilibrium away from a 1:2 complex, the H–G interaction would have to override both the [(H–G) + (G–G)] interactions. Based on our data, it is clear that this happens at a CB[8] concentration >160 mol%. If the above aspect holds true, changing the coumarin concentration must shift the concentration of CB[8] that corresponds to the maximum photodimerization rate. We observed that the concentration of CB[8] corresponding to the maximum reaction rate changes with a change in the coumarin concentration (~160 and ~170 mol% of CB[8] for 0.05 and 0.04 mmol/L of **1**, respectively).[17,20]

The photophysical aspects can also be understood based on this dynamic behavior of the CB[8]–**1** H–G complex. Photoexcitation of the dynamic H–G complex and uncomplexed coumarin leads to their corresponding excited states (singlet and triplet excited states) in solution. The reactivity of the dynamic H–G complex depends on the lifetime of the excited species in solution. Thus, the cavity not only templates the coumarin leading to selective formation of syn photodimers but enhances the reactivity by altering the photophysics of the excited coumarin, which is reflected in the enhanced photodimerization rate.

One aspect that is yet to be ascertained is the nature of the reactive species involved in the photodimerization process. As the photodimerization of **1** in water and in other isotropic media was postulated to occur from the triplet state,[21,22] we carried out the reaction under N_2-, air-, or O_2-saturated conditions in the presence of CB[8].[20] There was no noticeable difference in the reaction efficiency in N_2-, air-, or O_2-saturated conditions. Recently,[31] triplet-energy transfer from CB-encapsulated methylene blue to molecular oxygen to yield singlet oxygen was observed to occur at a lower rate, when compared with the rate of singlet oxygen generation in the absence of CBs. This suggests that excited state quenching of CB-encapsulated guests is indeed feasible but at a lower rate. Thus, two distinct possibilities arise in our case for CB[8]–**1** H–G complex, namely, (*i*) the triplet state of encapsulated coumarins within CBs is shielded from external quencher(s),[25,32,33] namely, oxygen for a longer time compared with free coumarin **1** outside the cavity leading to photoreactivity from the triplet state; and (*ii*) the singlet spin state is involved in the photodimerization pathway within the CB[8]. As we have observed both fluorescence and phosphorescence, we cannot ascertain if the photodimerization occurs from the singlet or the triplet manifold and if the photodimerization likely involves a singlet ^{1}(**1**–**1**)* excited complex or a triplet ^{3}(**1**–**1**)* excited complex within CB[8]. Further studies are needed to understand this aspect.

Conclusion

Photophysical investigation of **1** within CB[8] adds credibility to our proposed dynamic behavior of the CB[8]–**1** H–G complex in water. We observe an increase in the emission quantum yield and an increase in fluorescence lifetime upon encapsulation within CB[8]. The maximum emission intensity is observed for the 1:1 complex, and the emission intensity decreases for the 1:2 complex. There is also observable phosphorescence at 77 K in the presence of CB[8].

Experimental

General methods

1 was purchased from Alfa Aesar and was used as received without further purification. CB[8] was synthesized using previously reported procedures.[34–38] Diethyl ether was used for the extraction process as received without further purification. Nanopure water (≥17.8 MΩ/cm, Barnstead Ultrapure) was used as the solvent for carrying out photoreactions and photophysical measurements. Stock solutions of CB[8] (0.1 mmol/L) and **1** (1 mmol/L) were prepared and diluted appropriately for the different experiments.

Photophysical methods[25,31–33]

Spectrophotometric solvents were used wherever necessary unless or otherwise mentioned. UV quality fluorimeter cells (with a range up to 190 nm) were purchased from Luzchem. Absorbance measurements were performed using a Shimadzu UV-2501PC UV–vis spectrophotometer. For actinometry studies, a 310 nm ± 5 nm band pass filter purchased from Aashi Spectra, Japan, was used.

Emission spectra were recorded on a Horiba Jobin Yvon Fluorolog 3 spectrometer (FL3-22) equipped with double-grating monochromators, a dual lamp housing containing a 450 W CW xenon lamp and a UV xenon flash lamp (FL-1040), Fluorohub/MCA/MCS electronics, and a R928 PMT detector. Emission and excitation spectra were corrected in all cases for source intensity (lamp and grating) and emission spectral response (detector and grating) by standard instrument correction provided in the instrument software. Fluorescence lifetime measurements were performed using a 340 nm nanoLED as the light source with a pulse repetition rate of 1 MHz. The instrument response function was collected using a scatter solution (Sigma-Aldrich, Ludox TM-40 colloidal silica). The goodness-of-fit was assessed by minimizing the reduced χ^2 function and further judged by the symmetrical distribution of the residuals. For Φ_{em}, optically dilute solutions (absorbance value $\sim$ 0.11) were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

used with quinine sulfate (recrystalized from water 3×)[39] in 0.5 mol/L H_2SO_4 (Φ_{fl} = 0.55) as the standard. Steady-state emission spectra were processed by FluorEssence software. Lifetime measurements were done using DAS6 v6.4 software.

Determining the quantum yield of emission[20]

Appropriate amounts of stock solutions[20] were mixed to get various ratios of the CB[8]–**1**. The emission was monitored by exciting at 345 nm with a slit width of 0.5 nm and monitoring from 360 to 660 nm with a slit width of 1.4 nm and an integration time of 0.1 s. Quinine sulfate in 0.5 mol/L H_2SO_4 (Φ_{fl} = 0.55) was used as the reference (Φ_{em}). Optically dilute solutions (absorbance value ~ 0.11 at excitation wavelength) were employed, and the emission was integrated using the FluorEssence software package. Using the following equation, the quantum yields for the solutions was calculated.[39]

$$\Phi_s = \Phi_r(I_s/I_r)(A_r/A_s)(\eta_s^2/\eta_r^2)$$

where Φ_s is the fluorescence quantum yield of the sample (i.e., **1**–CB[8] mixture), Φ_r is the fluorescence quantum yield for the reference solution (i.e., 0.5 mol/L H_2SO_4 quinine sulfate), I_s is the fluorescence intensity of the sample (**1**–CB[8] mixture), I_r is the fluorescence intensity of the reference solution (0.5 mol/L H_2SO_4 quinine sulfate), A_s is the absorbance value of the sample (**1**–CB[8] mixture), A_r is the absorbance value of the reference solution (0.5 mol/L H_2SO_4 quinine sulfate), η_s is the refractive index of the solvent (water) for the sample, and η_r is the refractive index of the solvent (water) for the reference (0.5 mol/L H_2SO_4 quinine sulfate).

Actinometry to determine photodimerization quantum yields[20]

The moles of product formed for the reaction of interest were done by irradiating the sample alongside the ferrioxalate actinometer solution (prepared by Hammond variation of the Hatchard and Parker procedure).[40] The moles of product formed were determined by the disappearance of the starting moles using UV–vis spectroscopy. As the reaction showed a clear isosbestic point indicating a one-to-one conversion of the reactant to photoproduct, the number of moles of product formed was computed from the decrease in absorbance (reacted starting material). The number of moles of product per unit time is related to the number of photons absorbed. The slope yields the quantum yield of the photoreaction (Φ_{dim}).[20]

Monitoring reaction rates by absorbance measurements[20]

Appropriate amounts of stock solutions were mixed to get various ratios of CB[8]–**1** with a total concentration of **1** being 5.00×10^{-5} mol/L and varying the CB[8] concentration between 0 and 2.50×10^{-6} mol/L.[20] The solution was irradiated (295 nm cutoff) under different reaction conditions (N_2, O_2, and air) with varying mole percents of CB[8] as listed in Table S4 in the Supplementary data, and the reaction progress was monitored at specified time intervals (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 25, 30, 35, 45, and 60 min). A clear isosbestic point under the conditions investigated indicated that the reaction was stoichiometric with a one-to-one conversion from **1** to the photodimer. This was also confirmed by NMR analysis,[20] which did not show any side products. Control studies were carried out simultaneously in the presence (various mol%) and in the absence of CB[8].[20]

Kinetics of photodimerization

The photodimerization with 0.05 mmol/L (or 0.04 mmol/L) of **1** (>295 nm irradiation) was followed by absorbance measurements at various mol% of CB[8], and the $r_{dim}$was computed. The percentage rate increase of uncatalyzed reaction (r_{uncat}) in the absence of CB[8] was taken as the reference for the computation of the the percent rate increase. The maximum rate increase (a 9× increase in reaction rate) was observed at ~160 mol% of CB[8] upon employing 0.05 mmol/L **1**. Similarly, the maximum rate increase (a 7.5× increase in reaction rate) was observed at ~70 mol% of CB[8] upon employing 0.04 mmol/L **1**.[20]

Fluorescence lifetime measurements[20]

The emission was monitored by exciting the samples using a 340 nm nanoLED light source and monitoring the emission at 411 nm (for **1** in water) and at 443 nm (for **1** with various mol% of CB[8]). The following parameter was maintained during acquisition: emission slit width = 5.0 nm. Fitting analysis was done by fitting to tri- or bi-exponential decay kinetics of the sample components taking the instrument response function (IRF) into consideration.

Phosphorescence measurements at 77 K[20]

The phosphorescence spectra were recorded at 77 K by exciting the samples at 345 nm using a pulsed Xenon lamp and monitoring the emission from 360 to 660 nm. The following parameters were maintained during acquisition: excitation slit width = 8 nm, emission slit width = 8 nm; flash per count = 10; and wavelength increments = 3 nm. For a sample window of 30 ms, time per flash of 100 ms with a delay time of 30 ms was employed. For a sample window of 10 ms, time per flash of 61 ms with a delay time of 10 ms was employed.

Photoirradiation of 1 in water at various mol% of CB[8]

Photoirradiation of **1** (0.05 mmol/L) with various mol% of CB[8] in water was carried out with a 450 W medium pressure mercury lamp. In a typical experiment, an appropriate amount of **1** stock solution[20] was pipetted to a 100 mL volumetric flask and made up to the mark with nanopure water. In a separate 100 mL volumetric flask an appropriate mol% of CB[8] stock solution was added and made to the mark with nanopure water. The two solutions were added to a 250 mL Erlenmeyer flask and mixed for 10 min. This solution was deaerated with N_2 or O_2 for 15 min and the Erlenmeyer flask was sealed. For aerated conditions, the flask was kept open without prior N_2 or O_2 bubbling. The aqueous solution was irradiated for 60 min (Pyrex cutoff) at room temperature. After photoirradiation, ammonium chloride (50 mg) was added to the solution followed by the addition of 50 mL of diethyl ether. The reaction mixture was stirred for 1 h at room temperature. The organic layer was separated and the aqueous layer was extracted with diethyl ether (2 × 25 mL). The combined ether extract was dried over anhydrous sodium sulfate and concentrated under reduced

pressure. The concentrated reaction mixture was analyzed by NMR spectroscopy without additional purification. Control studies were carried out under identical concentrations of **1** (0.05 mmol/L) without the addition of CB[8] to ascertain the role of CB[8] in the photodimerization processes.

Synthesis and characterization of a naphthalimide–dye end-labeled copolymer by reversible addition–fragmentation chain transfer (RAFT) polymerization

Binxin Li, Daniel Majonis, Peng Liu, and Mitchell A. Winnik

Abstract: We describe the synthesis of an end-functionalized copolymer of *N*-(2-hydroxypropyl)methacrylamide (HPMA) and *N*-hydroxysuccinimide methacrylate (NMS) by reversible addition–fragmentation chain transfer (RAFT) polymerization. To control the polymer composition, the faster reacting monomer (NMS) was added slowly to the reaction mixture beginning 30 min after initating the polymerization (ca. 16% HPMA conversion). One RAFT agent, based on azocyanopentanoic acid, introduced a –COOH group to the chain at one end. Use of a different RAFT agent containing a 4-amino-1,8-naphthalimide dye introduced a UV–vis absorbing and fluorescent group at this chain end. The polymers obtained had molecular weights of 30 000 and 20 000, respectively, and contained about 30 mol% NMS active ester groups.

Key words: RAFT, semi-batch polymerization, dye-labeled polymer, HPMA, *N*-hydroxysuccinimide methacrylate.

Résumé : On décrit la synthèse d'un copolymère fonctionnalisé aux extrémités du *N*-(2-hydroxypropyl)méthacrylamide (HPMA) et de méthacrylate de *N*-hydroxysuccinimide (NMS) par polymérisation impliquant une addition et une fragmentation radicalaire avec transfert de chaîne (AFRT). Dans le but de contrôler la composition du polymère, le monomère qui réagit le plus rapidement (NMS) est additionné lentement au mélange réactionnel 30 min après que la polymérisation a été initiée (conversion approximative de 16 % du HPMA). Un agent AFRT à base d'acide azocyanopentanoïque permet d'introduire un groupe –COOH à une extrémité de la chaîne. L'utilisation d'un agent AFRT différent, contenant un colorant 4-amino-1,8-naphtalimide, introduit un groupe fluorescent et absorbant dans l'UV–vis à l'extrémité de la chaîne. Les polymères obtenus possèdent respectivement des poids moléculaires de 30 000 et 20 000 et ils contiennent approximativement 30 mol% de groupes esters du NMS.

Mots-clés : polymérisation impliquant une addition et une fragmentation radicalaire avec transfert de chaîne (AFRT), polymérisation semi-discontinue, polymère marqué avec un colorant, *N*-(2-hydroxypropyl)méthacrylamide (HPMA), méthacrylate de *N*-hydroxysuccinimide (NMS).

[Traduit par la Rédaction]

Introduction

Poly-*N*-(2-hydroxypropyl)methacrylate (PHPMA) is a nontoxic, nonimmunogenic, and biocompatible polymer that offers great promise as the host carrier of polymer–drug conjugates. These conjugates (polymer therapeutics) offer some important advantages over conventional chemotherapeutic agents, such as increased solubility, longer circulation times, and lower nonspecific cytotoxicity.[1,2] Early examples of polymer–drug conjugates based on PHPMA involved polymers synthesized by traditional free radical polymerization.[3,4] This led to polymers with rather broad molecular weight distributions. More recently, there has been a strong interest in the synthesis of PHPMA and its copolymers by controlled radical polymerization as a means of obtaining material with a narrower molecular weight distribution. This is important in therapeutic applications because molecular weight can influence the phamacokinetics, toxicity, and inhibitory potency of the conjugate.[5,6]

Several groups have reported an indirect synthesis of PHPMA by atom transfer radical polymerization (ATRP). In this approach, one begins with the polymerization of *N*-methacryloxysuccinimide (NMS) followed by treatment of the PNMS obtained with excess 1-amino-2-propanol.[7] This approach takes advantage of the fact that the succinimide ester group of NMS can react with amines to form amides. For therapeutic applications, complete removal of the Cu ion catalyst can be problematic. This is one reason that a greater effort has been devoted to the development of the synthesis of PHPMA and its copolymers by reversible addition–

fragmentation chain transfer (RAFT) polymerization. McCormick and co-workers[8] prepared hydrophilic–cationic block copolymers of HPMA and *N*-[3-(dimethylamino)propyl]methacrylamide (DMAPMA) by RAFT polymerization in water. These polymers lack pendant functionality for attachment of drugs or dyes. To address this issue, they developed a synthesis of copolymers of HPMA with *N*-(3-aminopropyl)methacrylamide) (APMA). Here, APMA provided amine functional groups for bioconjugation. They described modification of these copolymers with folic acid[9] or with *N*-succinimidyl 3-(2-pyridyldithio)-propionate to attach 5′-thiolated RNAs through a thiol–disulfide exchange reaction.[10] Hong and Pan[11] reported the synthesis of P(HPMA-*b*-NIPAM) (NIPAM = *N*-isopropylacrylamide) block copolymers by RAFT polymerization. These polymers were obtained with molecular weights in the range of 7 800–26 300 g/mol with narrow polydispersites (PDI = 1.15–1.29). Zentel and co-workers[12] synthesized functional amphiphilic poly(*N*-(2-hydroxypropyl) methacrylamide)-*b*-lauryl methacrylate) by RAFT polymerization. They investigated the influence of nanoaggregates formed by this block polymer on cell viability and on the motility of adherent cells.

A more general strategy for the preparation of functional HPMA copolymers involves the synthesis of an activated polymer with pendant active ester groups along the backbone. A random copolymer of HPMA and NMS would be an effective scaffold for the attachment of amine derivatives of dyes or drugs. The challenge in this synthesis is that the reactivity ratios (r_{HPMA} = 0.12 and r_{NMS} = 3.46)[13] favor rapid consumption of the NMS comonomer. Kane and co-workers[13,14] addressed this problem by using a "semi-batch" approach to the synthesis,[15] by adding the more reactive monomer slowly as the RAFT polymerization proceeded. They monitored the kinetics of the reaction and the composition of the polymer as the reaction proceeded, obtaining polymer that contained ~20 mol% NMS groups throughout the reaction. These polymers could be functionalized with a peptide known to disrupt anthratoxin assembly. The reaction in DMSO involved substitution of the active ester with an amino group from the peptide.

We are interested in this approach to the synthesis of functional HPMA copolymers, but with a higher NMS content. Here, we report a modified synthesis that follows the Kane and co-workers[13] strategy, but introduces functional and dye-containing chain-transfer agents (CTAs). As is well-established for RAFT polymerization, these transfer agents allow one to introduce functional groups or dyes at the initiating end of the polymer chains.[16–18] We are particularly interested in dyes based on the naphthalimide ring structure. The 1,8-naphthalimide chromophore and its derivatives have been studied for many years.[19–22] Many of these derivatives are easily synthesized from the corresponding naphthalic anhydrides. They have relatively high fluorescent quantum yields, high photostability, and tunable spectroscopic properties. Many 1,8-naphthalimide derivatives have been incorporated covalently or non-covalently into various polymeric materials to study the properties and behavior of the polymers. Our group has examined a family of 1,8-naphthalimide derivatives as donor–acceptor pairs to monitor polymer morphology or the diffusion of polymers by Förster resonance energy transfer (FRET) measurements.[23] Polymers containing the 1,8-naphthalimide group have also been studied for other applications such as sensors, probes, OLEDs, and solar cells, as well as photochemotherapy.[24]

Here, we describe the synthesis of a copolymer of HPMA and NMS with a naphthalimide-labeled end through RAFT polymerization. This dye-containing polymeric precursor can be further modified and potentially used in bioconjugation, drug delivery, and gene delivery applications.

Experimental

General characterization

^{1}H NMR (400 MHz) spectra were recorded on a Varian Mercury 400 spectrometer. $CDCl_3$ and d_6-DMSO were purchased from Cambridge Isotope Laboratories, Inc. 3-(Trimethylsilyl)propionic acid-d_4 sodium salt (TSP) was purchased from Sigma-Aldrich. For gel permeation chromatography (GPC) measurements, the eluant was 1-methyl-2-pyrrolidinone (NMP) containing 0.2 wt% LiCl, and the column was calibrated with poly(methyl methacrylate) (PMMA) standards. The analysis was carried out at 80 °C at a flow rate of 0.6 mL/min using a Viscotek VE1121 GPC solvent pump, with a Viscotek VE 3580 refractive index detector and a Viscotek VE3210 UV–vis absorbance detector. UV–vis measurements were carried out with a PerkinElmer Lambda 6 spectrometer.

Materials

4-Bromo-1,8-naphthalimide anhydride (BNA) (95%, Sigma-Aldrich), isobutylamine (99%, Sigma-Aldrich), ethylenediamine (99%, Sigma-Aldrich), oxalyl chloride (98%, Sigma-Aldrich), 2,2′-azobis(2-methylpropionitrile) (AIBN) (98%, Sigma-Aldrich), 1,3,5-trioxane (≥99%, Sigma-Aldrich), *tert*-butyl alcohol (*t*-BuOH) (≥99.5%, Sigma-Aldrich), *N*,*N*-dimethylformamide (DMF) (99.8%, Sigma-Aldrich), 1-methyl-2-pyrrolidinone (NMP) (≥99%, Sigma-Aldrich), and other chemicals were used as received. *N*-(2-Hydroxypropyl)methacrylamide (HPMA) was prepared according the literature procedure reported by Ulbrich et al.[25] *N*-Methacryloxysuccinimide (NMS) was synthesized according to the literature procedure reported by Shunmugam and Tew.[26] 4-Cyanopentanoic acid dithiobenzoate (CIDB) was synthesized as described previously.[27]

Synthesis of 9-isobutyl-4-ethylenediamino-1,8-naphthalimide

9-Isobutyl-4-ethylenediamino-1,8-naphthalimide was synthesized in two steps. 4-Bromo-1,8-naphthalic anhydride (1.4 g, 5.1 mmol) and isobutylamine (2.0 mL, 21 mmol) were added to 1,4-dioxane (40 mL) at room temperature. The solution was stirred for 4.5 h at 100 °C. The solvent was removed by rotary evaporation. The yellow solid was purified by silica column chromatography using heptanes–acetone (12:1, v:v) as the eluent. Finally, the yellow solid product (9-isobutyl-4-bromo-1,8-naphthalimide) was dried under vacuum at 50 °C overnight. Yield: 1.14 g (72%); mp 130.0–131.5 °C. ^{1}H NMR ($CDCl_3$, ppm) δ: 0.98 (d, 6H), 2.24 (m, 1H), 4.04 (d, 2H), 7.85 (dd, 1H), 8.04 (d, 1H), 8.42 (d, 1H), 8.58 (d, 1H), 8.66 (d, 1H). Elemental anal. calcd: C 57.85, H 4.25, N 4.22; found: C 57.98, H 4.32, N 4.50.

69	31	54	24	16 000	18 000	18 000

Note: HPMA, *N*-(2-hydroxypropyl)methacrylamide; NMS, *N*-methacryloxysuccinimide; DP_{HPMA}, mean number of HPMA units per polymer; and DP_{NMS}, mean number of NMS units per polymer.

[a]Calculated with eqs. [1] and [2].

[b]From the determination of the moles of the dye end group using TPS as an internal standard, calculated as M_n = [mass of poly(HPMA-co-NMS)]/[moles of naphthalimide–dye].

[c]From the absorbance at 430 nm using a value of $\varepsilon = 1.3 \times 10^4$ $(mol/L)^{-1}$ cm^{-1}.

9-Isobutyl-4-bromo-1,8-naphthalimide (3.020 g, 9.123 mmol) was added to ethylenediamine (50 mL, 0.75 mol). The solution was stirred at 50 °C for 2.5 h. The reaction mixture was treated with toluene (200 mL), and then the volatile liquids were removed by rotary evaporation. The crude product was dissolved in 1 mol/L aq HCl (70 mL). The product was precipitated by adding 1 mol/L aq NaOH until the solution became weakly basic (pH ~8). The mixture was then filtered. The yellow solid product (9-isobutyl-4-ethylenediamino-1,8-naphthalimide) was dried under vacuum at 50 °C overnight. Yield: 2.66 g (94%); mp 162–164 °C. ^{1}H NMR ($CDCl_3$, ppm) δ: 0.98 (d, 6H), 1.24 (broad, 2H), 2.25 (m, 1H), 3.18 (t, 2H), 3.42 (m, 2H), 4.03 (d, 2H), 6.14 (broad, 1H), 6.72 (d, 1H), 7.62 (t, 1H), 8.16 (d, 1H), 8.45 (d, 1H), 8.58 (d, 1H). Elemental anal. calcd.: C 69.43, H 6.80, N 13.49; found: C 68.52, H 6.66, N 13.66.

Synthesis of bis(benzenethiocarbonyl) disulfide

Magnesium turnings (3.00 g, 0.125 mol) were placed into a round-bottom flask with a catalytic amount of iodine. Bromobenzene (18.84 g, 0.1200 mol) was mixed with dry THF (90 mL). Then a 10 mL mixture of bromobenzene and THF was added to the flask and heated slightly. The remaining mixture was added slowly, while the temperature of reaction remained below 40 °C. The reaction was then stirred at room temperature for 1 h, after which the flask was cooled to 0 °C. Carbon disulfide (9.15 g, 0.120 mol) was added to the Grignard mixture at 0 °C. When the reaction finished after 2 h, deionized water (350 mL) was added, and the salts were removed by filtration. Concentrated HCl (~10 mL) was added to the filtrate and the mixture was extracted with diethyl ether. After evaporating the solvent with a rotary evaporator, absolute ethanol (100 mL) was added into the dithiobenzoic acid along with DMSO (18.75 g, 0.24 mol) and a catalytic amount of iodine. The reaction proceeded at room temperature for 2 h, and then the mixture was filtered. The purple solid (bis(thiocarbonyl) disulfide) was dried under vacuum at room temperature overnight. Yield: 11.04 g (60%); mp 96–98 °C. ^{1}H NMR ($CDCl_3$, ppm) δ: 7.45 (t, 4H), 7.61 (t, 2H), 8.07 (t, 4H).

Synthesis of the naphthalimide–dye-labeled CTA (NapDB)

Oxalyl chloride (5.3 mL, 62 mmol) was added to a stirred suspension of 4,4′-azobis(4-cyanovaleric acid) (1.708 g, 6.775 mmol) in anhyd CH_2Cl_2 with a catalytic amount of *N*,*N*-dimethylformamide at room temperature. After 3 h, the reaction mixture turned clear and was evaporated with a rotary evaporator to leave a yellow solid of 4,4′-(diazene-1,2-diyl)bis(4-cyanopentanoyl chloride). Yield: 1.820 g (95.6%). ^{1}H NMR ($CDCl_3$, ppm) δ: 1.72 (d, 6H), 2.62 (m, 4H), 3.14 (m, 4H).

9-Isobutyl-4-ethylenediamino-1,8-naphthalimide (1.557 g, 4.788 mmol) was dissolved in 100 mL anhyd CH_2Cl_2. The solution was cooled to 0 °C. A solution of 4,4′-(diazene-1,2-diyl)bis(4-cyanopentanoyl chloride) (0.632 g, 2.19 mmol) and *N*,*N*-diisopropylethylamine (2.29 mL, 13.1 mmol) in 20 mL anhyd CH_2Cl_2 was added dropwise to the dye solution via an addition funnel under N_2 protection. The reaction was stirred for 12 h at room temperature and then concentrated with a rotary evaporator. The mixture was washed with saturated sodium bicarbonate solution, 1% aq HCl, and finally 2 mol/L aq NaCl. The organic layer was dried over magnesium sulfate, filtered, and concentrated. The naphthalimide–dye-labeled CTA precursor was precipitated in diethyl ether and lyophilized overnight. Yield: 1.36 g (79%). ^{1}H NMR ($CDCl_3$, ppm) δ: 0.98 (d, 12H, CH_3), 1.69 (d, 6H, CH_3), 2.22–2.52 (m, 8H, CH_2CH_2), 3.44 (m, 4H, CH_2), 3.68 (t, 4H, CH_2), 4.01 (d, 4H, CH_2), 6.57 (d, 2H), 7.60 (t, 2H), 8.12 (d, 2H), 8.35 (d, 2H), 8.51 (d, 2H).

A solution of bis(thiocarbonyl) disulfide (0.156 g, 0.510 mmol) and the naphthalimide–dye-labeled CTA precursor (0.213 g, 0.246 mmol) in ethyl acetate was degassed with nitrogen and heated at 80 °C for 20 h. The solvent was removed with a rotary evaporator, and the residue was purified by silica column chromatography using ethyl acetate – hexane as the eluent. Yield: 0.049 g (34%); mp 90–93 °C. ^{1}H NMR ($CDCl_3$, ppm) δ: 0.99 (d, 6H, CH_3), 1.93 (s, 3H, CH_3), 2.44–2.71 (m, 4H, CH_2CH_2), 3.54 (t, 2H, CH_2), 3.77 (t, 2H, CH_2), 4.04 (d, 2H, CH_2), 6.17 (broad, 1H, NH), 6.60 (d, 1H, naphthalic-H), 6.91 (broad, 1H, NH), 7.66 (t, 1H), 7.35 (m, 2H, m-ArH), 7.38 (t, 1H, p-ArH), 7.84 (dd, 2H, o-ArH), 8.24 (d, 1H), 8.45 (d, 1H), 8.57 (d, 1H). Elemental anal. calcd.: C 65.01, H 5.63, N 9.78; found: C 64.83, H 5.77, N 9.23.

The homopolymerization of HPMA

The polymerizations were carried out under an Argon (Ar) atmosphere using the Shlenck technique. A typical polymerization procedure is described in the following. A stock solution was prepared comprised of AIBN (140.08 mg, 0.851 mmol), CIDB (41.08 mg, 0.155 mmol), and 1,3,5-trioxane (internal standard, 449 mg, 4.98 mmol) in degassed DMF (5 mL). HPMA (0.458 g, 3.55 mmol) was evacuated and back-filled with Ar three times. The degassed *t*-BuOH (3.2 mL) was injected into a round-bottom flask containing HPMA to form a 1 mol/L solution, and a solution of AIBN, CIDB, and 1,3,5-trioxane in DMF (200 μL) was transferred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

into the same flask. The reaction was carried out at 80 °C immediately and finally quenched in an acetone – dry ice bath. Aliquots (0.1 mL) were taken out for NMR analysis throughout the reaction. The final polymer was precipitated using a mixture of anhydrous diethyl ether and anhydrous acetone (1:1 v/v), recovered by centrifugation, and then lyophilized overnight for further analysis by NMR and GPC.

The copolymerization of HPMA and NMS

The copolymerization reactions were carried out under an Argon (Ar) atmosphere on a Shlenck line. A typical copolymerization procedure (Table 1) is described in the following. A stock solution was prepared consisting of AIBN (6.6 mg, 0.040 mmol), NCTA (45.7 mg, 0.0799 mmol), and 1,3,5-trioxane (internal standard, 77.6 mg. 0.861 mmol) in degassed DMF (1 mL). The monomers were evacuated and backfilled with Ar three times. The solvents were degassed by bubbling with Ar gas. *t*-BuOH (1.9 mL) was added to a round-bottom flask containing HPMA (0.275 g, 2.13 mmol) to form a 1 mol/L solution, and then the solution of AIBN, NCTA, and 1,3,5-trioxane in DMF (200 μL) was transferred into the flask. The mixture was heated at 80 °C for 30 min, and then a solution of NMS in DMF (0.5 mol/L) was added continuously into the reaction mixture at 0.43 mL/h through an airtight syringe by a syringe pump (KD Scientific, model 780100). After the addition of the NMS solution, the reaction was kept at 80 °C for an additional 30 min and was then quenched in an acetone – dry ice bath. Aliquots (0.1 mL) were taken out for NMR analysis throughout the reaction. The final polymer was precipitated using a mixture of anhydrous diethyl ether and anhydrous acetone (1:1 v/v), recovered by centrifugation, and then lyophilized overnight. A sample for end-group analysis was subjected to a second precipitation from DMF into ether–acetone. The polymer product (26 mg) was stored at 4 °C.

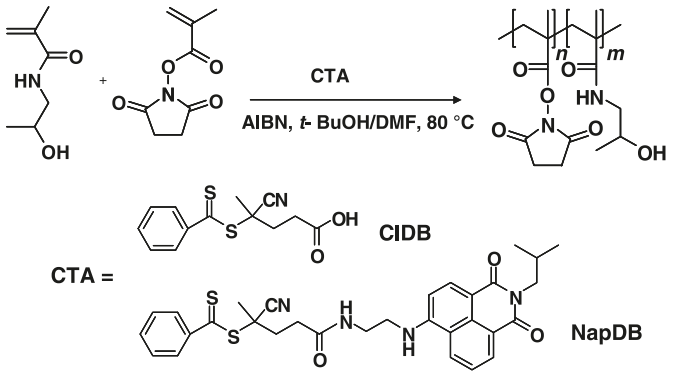
Molecular weight determination

A sample of the dye-labeled polymer was examined by UV–vis spectroscopy. A sample of the dye-labeled poly(HPMA-co-NMS) (1.134 mg) was dissolved in 1.0 mL DMF to form a 1.13 g/L solution. The calibration curve of the UV absorbance of the naphthalimide–dye was built using 9-isobutyl-4-ethylenediamino-1,8-naphthalimide (BEAN) as a model compound. A series of solutions of BEAN in DMF was prepared with accurately known concentrations. The absorbance of these solutions at 440 nm was measured by UV–vis spectrometry. For the ^{1}H NMR experiments, dye-labeled copolymers were dissolved into DMSO-d_6 to form solutions at 10 mg/mL. In the GPC experiments, dye-labeled polymers were dissolved in NMP containing 0.2 wt% LiCl to form 1 mg/mL solutions.

Results and discussion

In a RAFT polymerization employing a thiocarbonylthio compound ZC(=S)SR as a chain transfer agent, the R group will become attached to the initiating end of the chain. The –SC(=S)Z at the other end can act as a protected thiol for further transformation of the polymer. In the initial polymerization reactions described below, CIDB (see below, Scheme 1) was used as the chain-transfer agent (CTA). It

Scheme 1. Reversible addition–fragmentation chain transfer (RAFT) copolymerization of *N*-(2-hydroxypropyl)methacrylamide (HPMA) and *N*-methacryloxysuccinimide (NMS).



was synthesized as described in ref. 27. This CTA introduces a carboxylic acid into the R-group. If the R-group bears important functionality (such as a fluorescent dye) for applications in aqueous media, it is important that the attachment of the dye not involve ester groups which can slowly hydrolyze in water. In the design of the naphthalimide chain transfer agent used in these experiments, it is incorporated as an amide. The synthesis of this CTA is shown in Scheme 2. It was synthesized from bis(benzenethiocarbonyl) disulfide and the dye-containing azo-initiator in a single step. The yield was only 34% after column chromatography, but ^{1}H NMR and elemental analysis indicated that the product was pure. It showed only one spot by TLC.

We initially examined the kinetics of the polymerization of HPMA at 80 °C in the presence of CIDB as the chain-transfer agent and AIBN as the initiator. The ratio of [HPMA]–[CIDB]–[AIBN] was 320:2:1. As shown in the Supplementary data, $\ln([M]_0/[M]_t)$ increased linearly with reaction time over the first 4 h of the polymerization. Later, the rate of the polymerization became slower. The molecular weight increased monotonically but not quite linearly throughout the polymerization (see Fig. S2 in the Supplementary data), and maintained a narrow polydispersity. At 70% conversion, the sample was characterized by GPC (PMMA standards), yielding M_n = 32 000 with PDI = 1.3. These results establish that CIDB is an effective CTA for this RAFT polymerization. These results also provide information about the monomer conversion kinetics that we used to design the addition rate of NMS for the copolymerization of HPMA and NMS.

Semi-batch copolymerization of HPMA and NMS with CIDB as the CTA

Initial studies of the copolymerization of HPMA and NMS were carried out using CIDB as the RAFT agent. This reaction is shown in Scheme 1. In this copolymerization, all of the reactants except NMS (that is, AIBN, the CTA, 1,3,5-trioxane as an internal standard, and HPMA monomer, in a mixture of DMF and *tert*-butyl alcohol as the solvent) were introduced into a flask on a Schlenk line equipped with a septum and thoroughly outgassed as described in the Experimental section. The reaction was initiated by heating the solution to 80 °C and, after 30 min, a solution of NMS

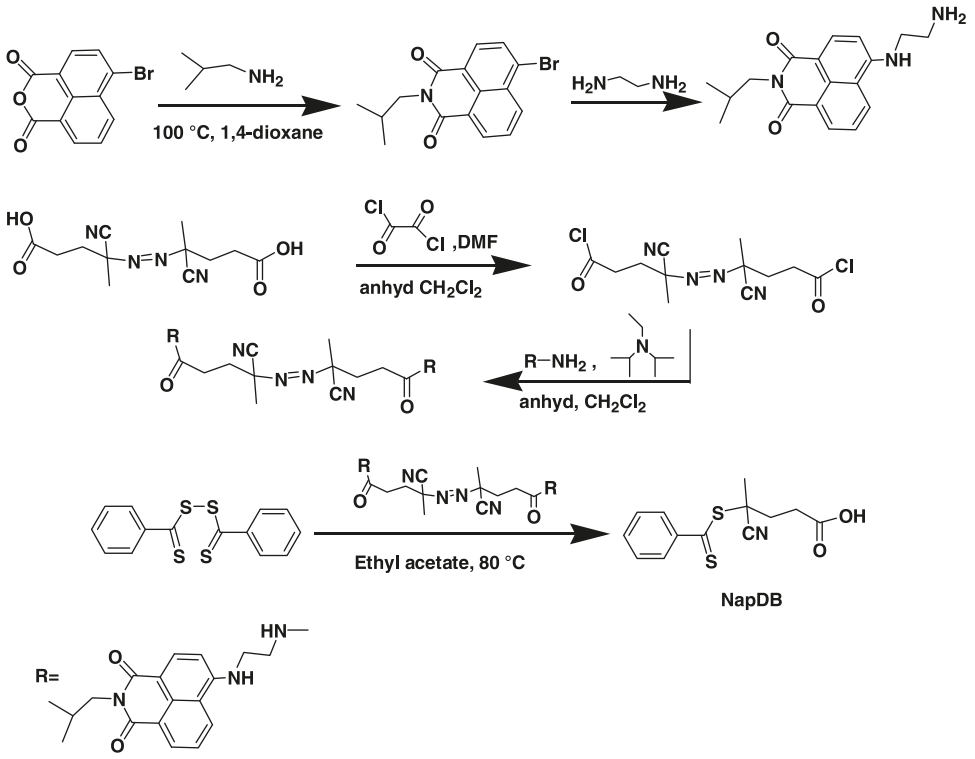

Fig. 1. ^{1}H NMR spectra for the conversion of *N*-(2-hydroxypropyl)methacrylamide (HPMA) and *N*-methacryloxysuccinimide (NMS) in reversible addition–fragmentation chain transfer (RAFT) copolymerization. The numbers in different colour zones indicate the average value of the vinyl protons of each corresponding monomer compared with the peak of the internal standard.

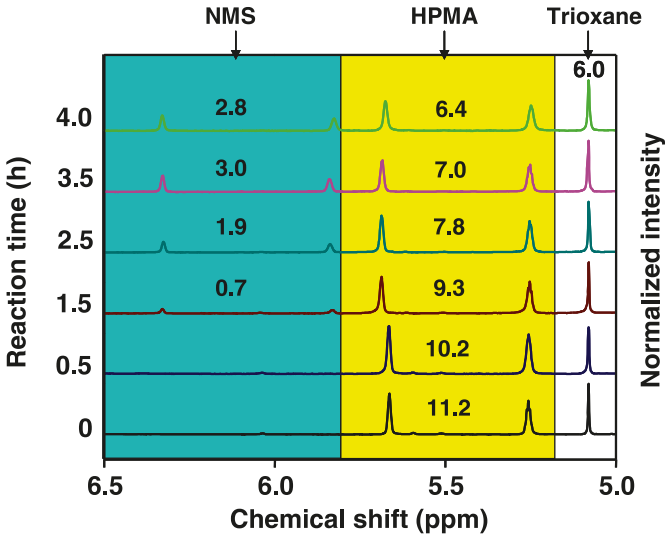


(0.5 mol/L) in DMF was added continuously into the reaction mixture at 0.43 mL/h via a syringe pump.

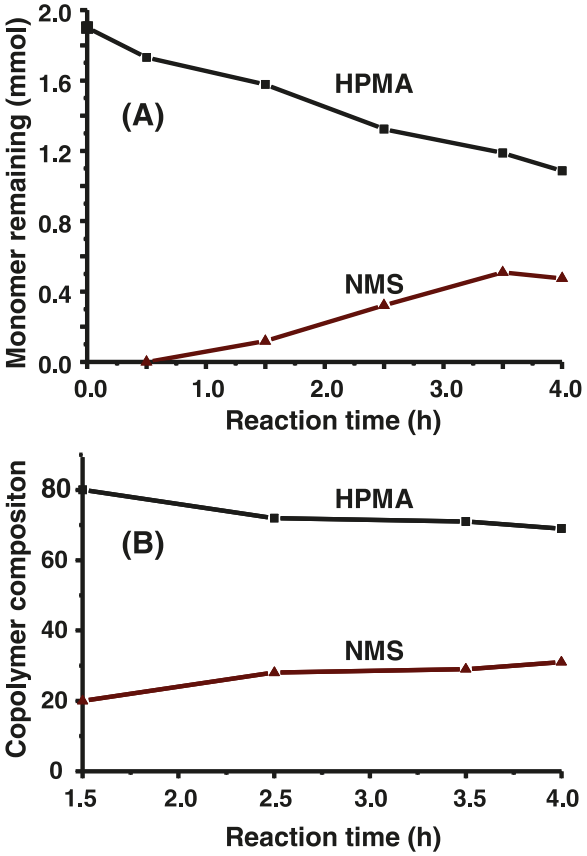
The conversion of HPMA and NMS was determined by ^{1}H NMR (in $CDCl_3$) (Fig. 1). The peaks at 5.2 and 5.7 ppm are ascribed to the vinyl protons of HPMA, and the peaks at 5.8 and 6.3 ppm are ascribed to the vinyl protons of NMS. The peak of 1,3,5-trioxane at 5.1 ppm was used as an internal standard to determine the amounts of HPMA and NMS remaining in the reaction mixture. In Fig. 1, the integral of this peak is arbitrarily assigned an integration value of 6.0. The numbers in the yellow zone of the spectra represent the average of the integrals of the two vinyl protons of HPMA, whereas the numbers in the blue zones of the spectra are the corresponding values of the two vinyl protons of NMS. These integral values indicate the amount of HPMA and NMS remaining at each point in the reaction. Over the first 30 min of the reaction, only HPMA was present. Then the addition of NMS began. Over the next 3.5 h, one can see a decrease in the concentration of HPMA in the reaction, accompanied by a slow steady build-up of NMS monomer in the reaction mixture. Even though NMS is more reactive in this copolymerization than HPMA, the consumption rate of NMS in the reaction was slower than its feed rate.

In Fig. 2A, we plot these data in terms of the time evolution of the amount of the monomers present in the system. The amount of HPMA in the reaction decreased essentially linearly with reaction time, and the amount of free NMS in the reaction mixture increased over time. After 4 h, 42% of the HPMA in the reaction and 24% of the NMS added were consumed. The composition of the poly(HPMA-co-NMS) obtained at different intervals of time was determined by ^{1}H NMR (in d_6-DMSO). Figure 2B shows that the percentage of HPMA in poly(HPMA-co-NMS) decreased slightly from 80% to 69% as the incorporation of NMS increased from 20% to 31%. The relatively high percentage of HPMA in the copolymer at 1.5 h is a consequence of the poly(HPMA) segment formed during the initial 30 min of the polymerization.

GPC measurements showed that the molecular weight of the copolymer increased over the first 3.5 h of the reaction. Individual traces were symmetrical (shown in Fig. S3B in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

Fig. 2. (A) Amounts of monomer remaining at different reaction times in the semi-batch reversible addition–fragmentation chain transfer (RAFT) copolymerization of *N*-(2-hydroxypropyl)methacrylamide (HPMA) and *N*-methacryloxysuccinimide (NMS) with 4-cyanopentanoic acid dithiobenzoate (CIDB) as the chain-trnasfer agent (CTA). (B) The composition of the copolymer at these reaction times determined by ^{1}H NMR.

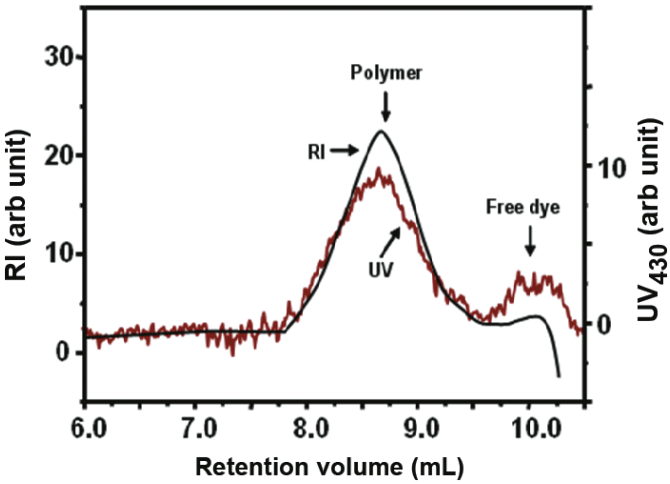


the Supplementary data), and the polydispersities were relatively narrow (PDI = 1.3–1.4). Based upon PMMA standards, M_n values increased from 10 000 g/mol after 1.5 h to 18 000 g/mol after 3.5 h, with little additional change found after 4 h, when the reaction was terminated. The poly(HPMA-co-NMS) obtained had M_n= 18 000 g/mol and PDI = 1.4. Analysis of the polymer by ^{1}H NMR revealed that the incorporation of NMS in the copolymer increased gradually as the copolymerization proceeded. We infer that the semi-batch method of synthesis enabled the formation of a polymer with a quasi-random distribution of NMS units, except for the segment of poly(HPMA) formed at the beginning of the polymerization.

Synthesis and characterization of the naphthalimide–dye end-labeled copolymer

To obtain a corresponding copolymer of HPMA and NMS with a strongly fluorescent dye at one end, the polymerization reaction was repeated using NapDB as the RAFT agent. This reaction is shown in Scheme 1. The copolymerization was carried out in the semi-batch mode at 80 °C over 4 h, with the addition of NMS (0.43 mL/h) initiated at the 30 min point of the reaction. The ratio of monomers

Fig. 3. Gel permeation chromatography (GPC) traces (UV and refractive index (RI) detectors) of the naphthalimide–dye end-labeled poly(HPMA-co-NMS) synthesized using a mol ratio ([HPMA + NMS]/[CTA]/[AIBN] = 320:2:1). The UV signal was monitored at 430 nm. HPMA, *N*-(2-hydroxypropyl)methacrylamide; NMS, *N*-methacryloxysuccinimide; CTA, chain-transfer agent; and AIBN, 2,2′-azobis(2-methylpropionitrile).



(HPMA + NMS) to NapDB to AIBN was maintained at 320:2:1. The ratio of HPMA to NMS remained 3:1. The conversion of HPMA and NMS was determined by ^{1}H NMR, using 1,3,5-trioxane as an internal standard. From GPC measurements on the dye-labeled poly(HPMA-co-NMS), using the refractive index (RI) detector in conjunction with PMMA standards, we obtained a nominal molecular weight of M_n = 21 000, M_w = 31 000, PDI = 1.5 (Fig. 3).

This sample also shows two peaks in the UV trace (λ = 430 nm) at retention times of 14.5 and 16.7 min. The former corresponds to the polymer and demonstrates that the dye is part of the polymer structure. The peak at longer retention time is due to residual CTA in the sample. The amount present is too small to give an appreciable signal in the RI detector.

The ^{1}H NMR spectrum of the purified naphthalimide–dye end-labeled poly(HPMA-co-NMS) in d_6-DMSO is presented in Fig. 4 along with the corresponding peak assignments. The characteristic resonances for the poly(HPMA-co-NMS) backbone appear at 0.4–1.4 ppm, along with the methacrylamide methyl protons and the methyl protons (k) of the HPMA unit. The peaks at 2.8 and 3.0 ppm are ascribed to the protons of the succinimide (o) and to the protons of the amide methylene (i), respectively. The signal of the alcohol methine (j) appears at 3.7 ppm. The signals of hydroxyl proton and amine proton appear at 4.7 and 7.3 ppm, respectively. The signals of the naphthalimide are also very clear and easily identified, such as the proton a at 8.6 ppm, the proton e at 8.5 ppm, and the proton c at 8.3 ppm. The peak at 3.3 ppm is due to traces of water present in the deuterated DMSO used as the NMR solvent.

For quantitative interpretation of the ^{1}H NMR signals, a spectrum was acquired with 1280 scans and a relaxation delay time of 25 s. The mean number of HPMA units per polymer (DP_{HPMA}) and of NMS units per polymer (DP_{NMS}) were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

Fig. 4. [1]H NMR spectrum of the naphthalimide–dye end-labeled poly(HPMA-co-NMS) in DMSO-d_6. The inset is an enlargement of the region from 6.8 to 8.7 ppm.

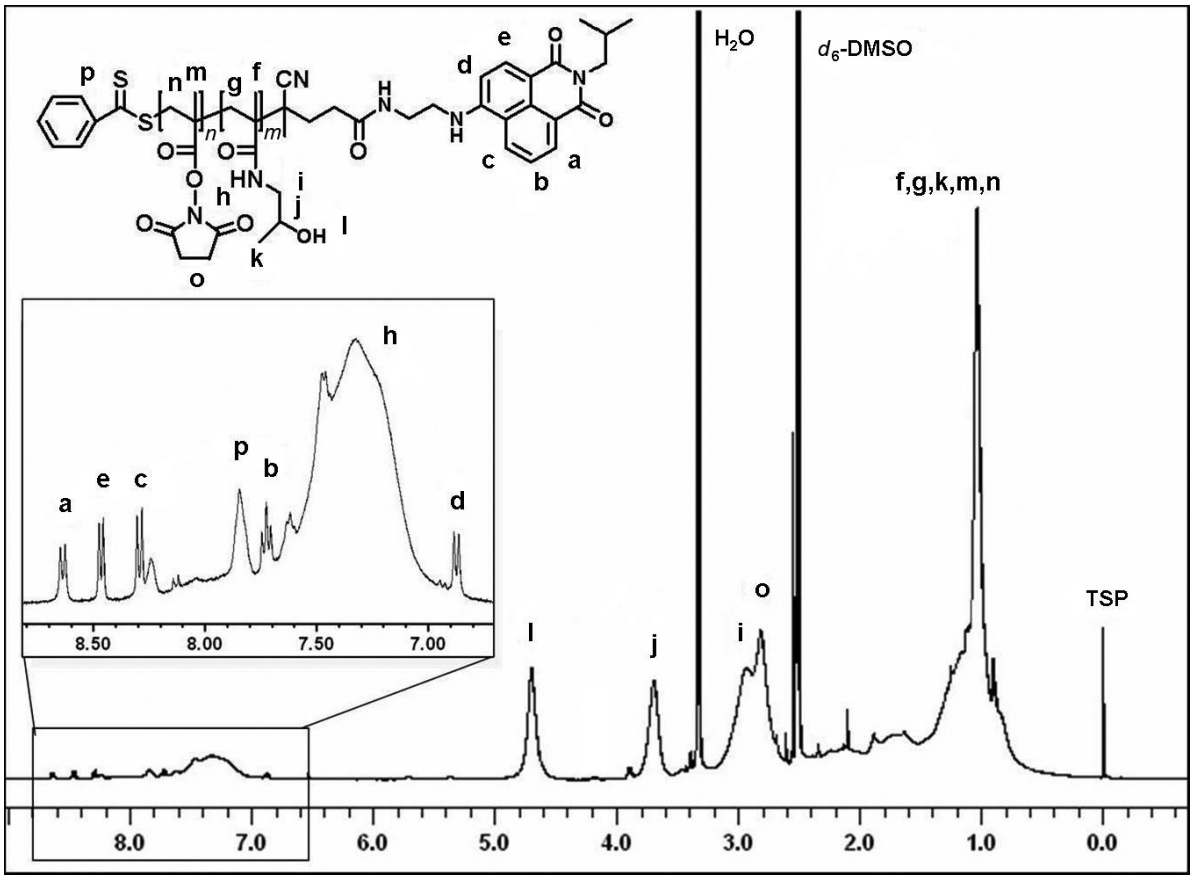


Fig. 5. UV–vis absorption spectrum of the naphthalimide–dye end-labeled poly(HPMA-co-NMS) (1.13 g/L) in *N*,*N*-dimethylformamide (DMF), with an absorbance at λ_{max} (440 nm) of 0.094.

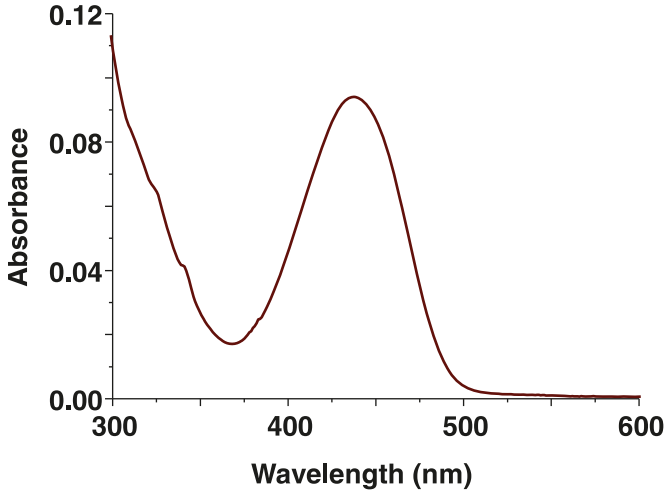

evaluated from the ratios of the peak integrals, using the signal a at 8.65 ppm as a measure of the naphthalimide end group. The signal j at 3.7 ppm represents one proton per HPMA unit. The signals i + o at 2.8–3.1 ppm represent contributions from the NMS group (4H) and 2H from the HPMA group. The desired information was calculated using eqs. [1] and [2].

$$[1] \quad DP_{HPMA} = \frac{I_j n_a}{I_a n_j}$$

$$[2] \quad DP_{NMS} = \frac{(I_{i+o} - I_j n_i / n_j) n_a}{I_a n_i}$$

Here I_a is the integral of peak a. I_i, I_j, and I_o are the integrals of peaks i, j, and o, respectively. n_a is the number of peak a protons. n_i, n_j, and n_o are the numbers of peak i, j, and o protons), respectively. The absolute number – average molecular weight of poly(HPMA-co-NMS) was calculated from the degrees of polymerization of monomers (HPMA and NMS), as well as the mass of the naphthalimide chain end assuming one dye molecule per chain.

As a check on this value of M_n, we used TSP as an external standard for the quantitative determination of M_n by NMR. In this procedure, a sample of the dye-labeled poly(HPMA-co-NMS) (6.17 mg) was dissolved in d_6-DMSO (0.6913 g), and a known amount (19.8 mg) of a solution of TSP in d_6-DMSO (1.0 mg/g) was added. The [1]H NMR spectrum was measured as described previously. The TSP signal can be seen as the peak at 0.0 ppm in Fig. 4. The integral of this signal was compared with the signal of the naphthalimide–dye at 8.65 ppm to obtain the mol ratio of the naphthalimide dye to TSP. The results obtained from [1]H NMR (d_6-DMSO) are summarized in Table 1. The M_n values determined with both methods are in good agreement. The mol ratio of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

HPMA–NMS determined by NMR (69:31) is somewhat enhanced in its NMS content compared with the 3:1 mol ratio of monomers in the feed (25 mol%) NMS.

Figure 5 presents a UV–vis spectrum of the polymer in DMF solution. The solution shows λ_{max} at 440 nm. To estimate M_n based upon this absorption, we determined a value of the molar extinction coefficient of the chromophore in DMF ($\varepsilon = 1.3 \times 10^4$ (mol/L)$^{-1}$ cm^{-1}) using 9-isobutyl-4-ethylenediamino-1,8-naphthalimide as a model compound. In this way we calculated $M_n^{UV} = 18\,000$. These M_n values are compared in Table 1 and are seen to be in good agreement with each other. The value of M_n obtained from analysis of the GPC trace with a calibration curve based on PMMA standards was 21 000. The difference between this value and those obtained by NMR and UV–vis is an indication of the different hydrodynamic volumes of poly(HPMA-co-NMS) and PMMA in NMP at 80 °C.

Summary

Copolymers poly(HPMA-co-NMS) with molecular weight of ca. 20 000 and 30 000 were synthesized by RAFT polymerization, using two different RAFT agents. In one example, we used the carboxylic acid functionalized CIDB, whereas in the second example, we used NapDB containing a naphthalimide–dye derivative with an absorption λ_{max} at 430 nm. Both polymers contained ~30 mol% NMS groups. This pair of monomers is characterized by a serious reactivity ratio mismatch ($r_{HPMA} = 0.12$ and $r_{NMS} = 3.46$).[13] To overcome this problem, we followed the example of Kane and co-workers[13,14] and fed the more reactive monomer (NMS) into the reaction slowly as the polymerization proceeded. We began the addition of NMS as a solution in DMF 30 min after initiation of the polymerization of HPMA (~15% conversion). The reaction was not run under monomer-starved conditions. By NMR, we could show that the amount of free NMS monomer in the reaction built up slowly over the 3.5 h that it was fed into the reaction. An aliquot of the polymer taken after 1 h of reaction time contained 20 mol% NMS and, after 4 h, the polymer contained 30 mol% NMS. Values of M_n determined by end-group analysis by ^{1}H NMR and by UV–vis spectroscopy were in good agreement with each other.

Effect of positively charged backbone groups on radical cation migration and reaction in duplex DNA

Sriram Kanvah and Gary B. Schuster

Abstract: A series of DNA oligomers were prepared that contain guanidinium linkages (positively charged) positioned selectively in place of and among the normal negatively charged phosphodiester backbone groups of duplex DNA. One-electron oxidation of these DNA oligomers by UV irradiation of a covalently linked anthraquinone group generates a radical cation (electron "hole") that migrates by hopping through the DNA and is trapped at reactive sites, GG steps, to form mutated bases that are detected by strand cleavage after subsequent piperidine treatment of the irradiated DNA. Analysis of the strand cleavage pattern reveals that guanidinium substitution in these oligomers does not measurably affect the charge migration rate but it does inhibit reaction at nearby guanines.

Key words: DNA oxidation, anthraquinone photosensitizer, charge transport, guanidinium backbone.

Résumé : On a préparé une série d'oligomères de l'ADN qui contiennent des liaisons guanidinium (chargées positivement) positionnées d'une façon sélective à la place de et parmi les groupes normalement chargés d'une façon négative des groupes phosphodiesters du duplex de l'ADN. L'oxydation à un électron de ces oligomères d'ADN par une irradiation UV d'un groupe anthraquinone lié d'une façon covalente provoque la formation d'un cation radical (« trou » d'électron) qui se déplace par sauts à travers l'ADN, qui est piégé à ses sites réactifs, étapes GG, avec formation de bases ayant subi une mutation qui sont détectées par une coupure des brins après un traitement subséquent avec de la pipéridine des ADN irradiés. L'analyse des patrons de clivage des brins révèle que la substitution par des groupes guanidinium dans ces oligomères n'a pas d'effet mesurable sur la vitesse de migration de la charge, mais qu'elle inhibe la réaction au niveau des guanines adjacentes.

Mots-clés : oxydation de l'ADN, anthraquinone comme photosensibilisateur, transport de charge, squelette de guanidinium.

[Traduit par la Rédaction]

Introduction

Extensive research on long-distance radical cation ("hole") transport in duplex DNA has focused on understanding its implications to the oxidative damage caused by chemical and ionizing radiation that often leads to mutagenic lesions.[1] These experiments have generated a vigorous debate on the mechanism of charge transport in DNA.[2–9] Our work in this field has focused on charge transport and on the reactions of the nucleobase radical cations.[2,10–13] In this examination, we use UV irradiation of an anthraquinone group (AQ) covalently linked to duplex DNA to initiate one-electron oxidation, which occurs when an electron is transferred from a neighboring nucleobase to the excited AQ with the concomitant formation of the AQ radical anion and a base radical cation.[14] The radical anion is subsequently consumed by reaction with O_2 (forming superoxide) and the radical cation migrates through the DNA bases via a hopping mechanism[5,15] until it is trapped by an irreversible reaction, usually with water or oxygen, that results in a damaged (mutated) nucleobase. The damaged base is typically detected by strand cleavage following chemical or enzymatic treatment of the oxidized DNA. For a long time it was thought that reaction of the radical cation occurred primarily at the sites of lowest oxidation potential,[16] for instance the 5′ G of a GG doublet or at a GGG triplet. However, recent reports of reaction at thymine in oligonucleotides that do not contain guanines reveal instead that reaction generally occurs at the nucleobase radical cation having the highest reactivity.[17–20]

The effect of nucleobase sequence on charge hopping emerges from consideration of the entire sequence of nucleobases in the oligonucleotide. That is, in one instance a particular base sequence can facilitate charge hopping and in another that sequence can be a barrier to hopping.[21] The transport of a radical cation over such a barrier is a result

of the instantaneous fluctuations in the orientation of the nucleobases[10,22] and, most importantly, in the water (solvent) and counterion environment.[10,23] In this regard, it is important to understand the effect of perturbations to the normal stacking of bases in DNA charge transport[24] and to the solvent and counterion environment that occur with changes to the sugar-phosphate backbone.[10,25,26] In particular, we assessed the effect of positively charged groups substituted for the normally neutral nucleobases and the effect of replacing the negatively charged phosphate groups of the backbone with uncharged methylphosphonate groups. For example, in one case we inserted a cationic pyridinium nucleoside mimic for a base[27] and in another we substituted formally positively charged Hg(II) metal centers[28] for protons in thymine–thymine mispairs. These experiments revealed a robust radical cation migration process. On the other hand, replacement of backbone phosphate groups with methylphosphonates causes profound changes to the solvent and counterion environment and this results in significant changes to the reaction of the radical cation at nearby guanines in the oligonucleotide.[10,29] In this work, we extend the examination of backbone perturbation to the reversal of the charge in segments of a DNA oligonucleotide from negative to positive by examining mixed backbone sequences consisting of positively charged guanidinium linkages positioned selectively among the normal negatively charged phosphodiesters of duplex DNA.

Experimental section

N′-Acetyl-*N*-(3′-deoxythymidine-3′-yl)-*N*″-(5′-deoxythymidine-5′-yl) guanidine (TgT) was prepared as described elsewhere.[30] Sodium azide, instead of lithium azide, was used in the synthetic scheme described. The TgT-containing oligomers (Fig. 1) were prepared by standard procedures. The amidite building block of TgT was obtained using a standard phosphoramidite reaction strategy. A 15 min coupling time was used for the TgT phosphoramidite in an Expedite 8909 DNA synthesizer. Similarly, the anthraquinone phosphoramidite was attached to the 5′ end of the oligomer using a 15 min coupling time. The DNA oligomers were deprotected at 60 °C by reaction with 30% ammonium hydroxide solution overnight. The protected guanidine, on treatment with ammonium hydroxide, is deprotected to yield the positively charged guanidinium linkage.[31] All oligonucleotides were purified using a Hitachi HPLC system containing a reverse-phase Dynamax C-18 column in an acetonitrile and triethylammonium acetate buffer solvent system and characterized by mass spectrometry. Electrospray ionization spectra of the modified DNA are given in the Supplementary data (Figs. S3 to S10).

Melting temperatures were determined on a Cary 1E UV–vis spectrophotometer on 2.0 μmol/L samples at 260 nm. Circular dichroism spectra were determined using a JASCO spectropolarimeter. 3′-End labeled DNA oligomers were obtained by incubation of the single-stranded DNA with [α-^{32}P]ATP and terminal deoxynucleotidyl transferase at 37 °C for 45 min. Samples were purified on a 20% denaturing polyacrylamide gel; elution and precipitation with ethanol yielded the radiolabeled DNA.

Samples for irradiation were prepared by hybridization of a mixture of radiolabeled DNA and unlabeled DNA (5 μmol/L). The samples were heated to 90 °C for 10 min and allowed to cool slowly to room temperature. Samples were irradiated at approx. 30 °C in microcentrifuge tubes in a Rayonet photoreactor (Southern New England Ultraviolet Co., Barnsford, Connecticut) containing eight 350 nm

For personal use only.

lamps, each having an intensity of 8 W. Irradiation times were adjusted by iteration to ensure single-hit conditions. After irradiation, the samples were precipitated once with ethanol, dried, and treated with piperidine at 90 °C for 30 min. After evaporation of the piperidine, the samples were dissolved in denaturing loading dye and analyzed on a 20% 19:1 acrylamide:bisacrylamide gel. The gels were dried and the cleavage sites were visualized by autoradiography. Quantification of cleavage bands was performed on a Fuji phosphorimager.

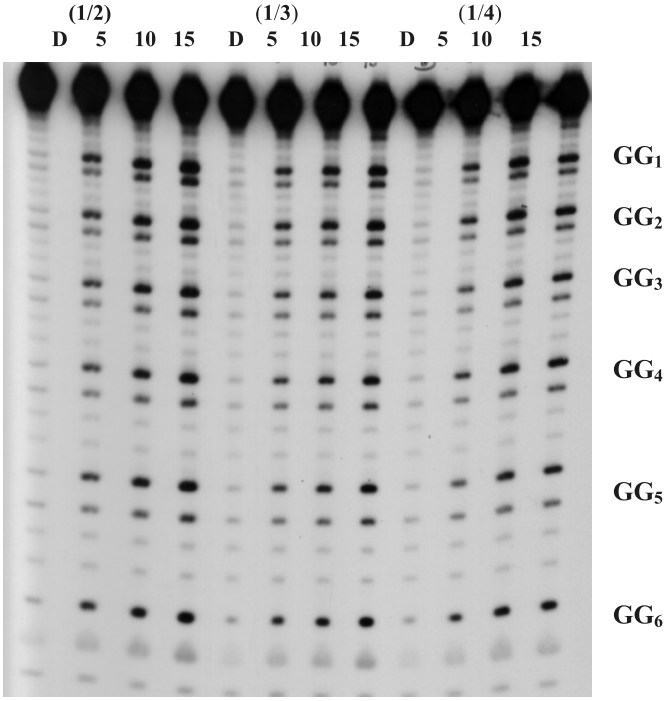
Results and discussion

Figure 1 shows the series of oligomers that were prepared to assess the effect of converting regions of the normal phosphate-linked negatively charged backbone of DNA to guanidinium-linked regions bearing positive charges. Each duplex contains a 5′-linked AQ group as photosensitizer, a 3′ ^{32}P radiolabel, and 6 GG steps that serve as traps for the radical cation, where reaction with H_2O or O_2 leads to base damage and subsequent strand cleavage after piperidine treatment. DNA(**1/2**) is a normal DNA duplex oligomer that serves as a control for analysis of DNA(**1/3**) and DNA(**1/4**), which have 1 and 3 guanidinium-containing TgT groups, respectively. DNA(**5/6**), which serves as a control for experiments with DNA(**7/8**), is similar to DNA(**1/2**) except that the nucleobase pairs separating GG_3 and GG_4 have been changed. In DNA(**1/2**), GG_3 and GG_4 are separated by an AA step, while in DNA(**5/6**) there is a TT step between GG_3 and GG_4. In DNA(**7/8**), GG_3 is surrounded by TgT groups — one is adjacent to the GG and the other is in the complementary strand.

The substitution of guanidinium groups for phosphate groups reduces the overall negative charge of the DNA duplexes by 2, 4, or 6 depending on the number of modifications. It is expected that the positively charged guanidinium groups will reduce the electrostatic repulsion of the phosphate groups of normal double-stranded DNA. However, the melting temperatures (T_m) of the TgT-containing duplexes are not greatly different from that of the normal DNA duplexes. For example, the T_m of DNA(**1/4**), which contains 3 TgT groups, is 47 °C in pH 7.0 sodium phosphate buffer solution, and DNA(**1/2**) melts at 50 °C. Likewise, the other guanidinium-containing duplexes melt at temperatures similar to their all-phosphate-containing control compounds. The first derivative melting curve profiles of these DNA duplexes are given in the Supplementary data. Circular dichroism spectra (Fig. S2 of the Supplementary data) of the guanidinium-containing duplexes are essentially indistinguishable from those of their control compounds, which indicates that the global B-DNA structure is not measurably affected by the guanidinium substitutions.

Irradiation of these AQ-containing DNA duplexes at 350 nm results in the one-electron oxidation of a nucleobase to form a radical cation. The radical cation then migrates through the DNA, encountering either normal phosphate groups or regions containing positively charged guanidinium groups in the backbone. The guanidinium modifications may affect either (or both) the rate constant for charge hopping from base to base (k_{hop}) or the rate constant for trapping (k_{trap}) of the radical cation by reaction with H_2O or O_2.

Fig. 2. Autoradiogram comparing the photocleavage of DNA duplexes (**1/2**), (**1/3**), and (**1/4**) having zero, one, and three guanidine modifications, respectively. The guanidine modifications are on the pyrimidine-dominated complementary strand. D, 5, 10, and 15 refer to irradiation times in minutes (D is "dark"; i.e., no irradiation) and GG_n refers to the GG step position (1–6) in the labeled DNA strand (see Fig. 1).



Changes to these rate constants would be reflected in the relative amounts of strand cleavage detected at GG steps in subsequent analyses. For example, if the TgT group presents an insurmountable barrier to radical cation migration, then no strand cleavage would be detected at GG steps 2–6 in DNA(**1/3**).

As shown in Fig. 2, irradiation of duplex DNA(**1/2**) leads, as expected, to similar amounts of strand cleavage at each of the 6 GG steps because the rate of hopping in this sequence is much greater than the rate of trapping.[22] Irradiation of DNA duplexes (**1/3**) and (**1/4**), which contain 1 and 3 guanidine substitutions, respectively, gives a similar result — essentially equal strand cleavage efficiency at each of the 6 GG steps. This is a surprising result that may have occurred because the path of radical cation migration is primarily through purines, which have lower oxidation potentials than pyrimidines, and the guanidinium modification is between two pyrimidines located on the complementary strand. We examined the reactions of DNA(**6/7**) and DNA(**7/8**) to address this possibility.

As indicated above, DNA(**6/7**) and DNA(**7/8**) differ from the first set of oligomers by changes in the nucleobase sequence. In these sequences a TT step separates the first three GG steps from the rest. Unlike a single T,[23] a TT step[31] between GG_3 and GG_4 of DNA(**5/6**) presents a significant barrier to radical cation migration, as is clearly seen in the relative amount of strand cleavage at each of the GG steps. Irradiation of DNA(**5/6**) at 350 nm causes essentially equivalent strand cleavage at GG_1, GG_2, and GG_3, and reduced

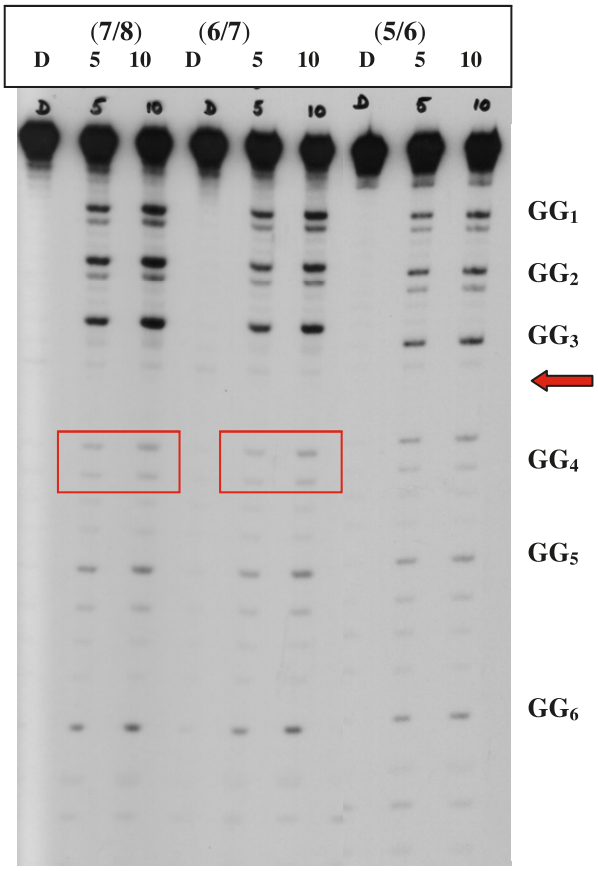
Fig. 3. Autoradiograms comparing photocleavage of DNA duplexes (**7/8**), (**6/7**), and (**5/6**). Arrow indicates position of backbone modification. D, 5, and 10 refer to irradiation times in minutes (D is "dark"; i.e., no irradiation) and GG_n refers to the GG step position (1–6) in the labeled DNA strand (see Fig. 1).

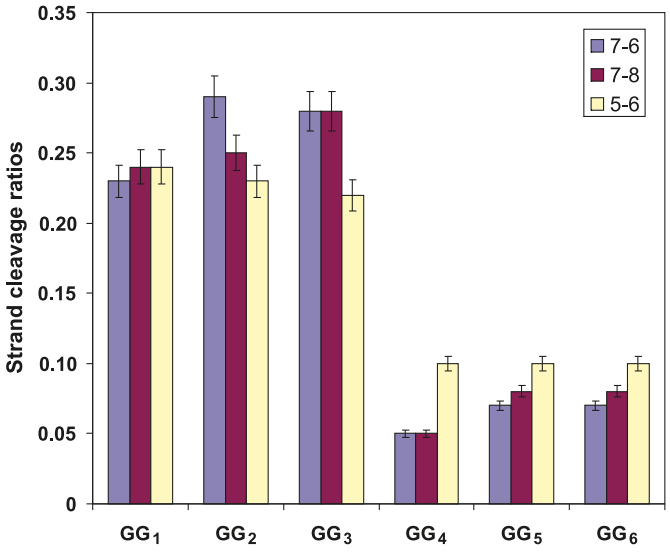


amounts of reaction at GG_4, GG_5, and GG_6 (see Fig. 3). The GG steps following the TT barrier react with similar efficiency, which can be attributed to the presence of charge transfer-facilitating purine bridges. In DNA(**6/7**), the guanidinium-containing TgT group is between GG_3 and GG_4 and the expected radical cation migration path through purines is further inhibited. In this case, substitution of the positively charged guanidinium group does reduce the amount of strand cleavage observed at GG_4, GG_5, and GG_6, as shown in Fig. 3 and in the histogram from quantitative phosphorimagery shown in Fig. 4. Similar results are obtained from the irradiation of DNA(**7/8**). The positive charge in DNA(**6/7**) leads to about 50% inhibition of reaction at GG_4, while the additional positive charge in DNA(**7/8**) has no additional influence. The positively charged backbone modification has a local effect on radical cation trapping, while there is no effect on radical cation hopping, as seen in reactions of GG_5 and GG_6 (Fig. 4).

Conclusions

We replaced portions of the phosphodiester backbone of DNA with segments containing positively charged guanidinium groups. The guanidinium groups connect thymines in a TT bridge that separates GG steps. The results of the one-electron oxidation experiments show that the presence of

Fig. 4. Histogram showing the relative amount of strand cleavage at respective GG steps for DNA duplexes (**6/7**), (**7/8**), and (**5/6**) after 10 min of irradiation at 350 nm and standard work-up with piperidine. The error bars are calculated from independent repetitions.



positively charged backbone groups does not affect the hopping rate constants for radical cations in these duplexes. This substitution does have a local effect when the positively charged backbone is introduced into the "purine pathway". This result is understood to be a consequence of radical cation ("hole") density that is localized largely on the relatively low oxidation potential nucleobase sites guanine and adenine. Apparently, although the phosphate backbone may also be involved in charge delocalization, its role is not significant enough to measurably affect the hopping of radical cations in DNA. The rate of the trapping reaction appears to be somewhat reduced at guanines adjacent to a guanidinium group.

Supplementary data

Supplementary data are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Comparison of photoenolization and alcohol release from alkyl-substituted benzoyl benzoic esters

Sivaramakrishnan Muthukrishnan, Tamara C.S. Pace, Qian Li, Brian Seok, Gerdien de Jong, Cornelia Bohne, and Anna D. Gudmundsdottir

Abstract: Photolysis of **1B** in argon-saturated solutions yields **4B** and releases methanol. Laser flash photolysis of **1B** shows formation of biradical **2B**, which has a lifetime of ~50 ns and a λ_{max} at 330 nm. Biradical **2B** undergoes an intersystem crossing to form photoenols **E-3B** and **Z-3B** with a λ_{max} at 390 nm. Laser flash photolysis shows that the lifetimes of **E-3B** and **Z-3B** are affected by the solvent. Density functional theory calculations demonstrate that the transition-state barrier for a 1,5-H atom shift from **Z-3B** to regenerate **1B** is affected by the *ortho*-alkyl substituents, whereas the stereoelectronics of the alkyl substituent affect the transition-state barrier of **E-3B** as it undergoes electrocyclic ring closure to form **4B**. The photoreactivity of **1B** was compared with its analogous methyl and isopropyl derivatives **1A** and **1C**, respectively, to better estimate the effect of the alkyl substituent on reactivity.

Key words: photoremovable protecting groups, photoenols, laser flash photolysis, 1,5 H-atom shift, electrocyclic ring closure, intramolecular lactonization.

Résumé : La photolyse de **1B** dans des solutions saturées en argon conduit à la formation de **4B** et à la libération de méthanol. La photolyse éclair au laser de **1B** conduit à la formation du biradical **2B** dont le temps de vie est d'environ 50 ns et un λ_{max} à 330 nm. Le biradical **2B** subit une transformation intersystème avec formation des photoénols **E-3B** et **Z-3B** avec un λ_{max} à 390 nm. La photolyse éclair au laser montre que les temps de vie des isomères **E-3B** et **Z-3B** sont affectés par le solvant. Des calculs selon la théorie de la fonctionnelle de la densité démontre que la barrière de l'état de transition pour un déplacement 1,5 d'atome d'hydrogène à partir de **Z-3B** et conduisant à la régénération du produit **1B** est affectée par les substituants *ortho*-alkyles alors que les effets stéréoélectroniques du substituant alkyle affectent la barrière de l'état de transition de l'isomère **E-3B** lorsqu'il subit une fermeture électrocyclique de cycle conduisant à la formation de **4B**. Dans le but de pouvoir mieux évaluer l'effet d'un substituant alkyle sur la réactivité, on a comparé la photoréactivité de **1B** à celles de ses analogues, les dérivés méthyle (**1A**) et isopropyle (**1C**).

Mots-clés : groupes protecteurs photolabiles, photoénols, photolyse éclair au laser, déplacement 1,5 d'un atome d'hydrogène, fermeture électrocyclique de cycle, lactonisation intramoléculaire.

[Traduit par la Rédaction]

Introduction

In the past few decades, various systems have been designed for use as photoremovable protecting groups, phototriggers, and photocaging groups.[1–7] Photoremovable protecting groups have potential use in a wide variety of applications, such as drug and gene delivery, release of fragrances in household products, and as an aid in multistep synthesis. Furthermore, photoremovable protecting groups have been used to release bioactive compounds in living tissue and thus make it possible to study physiological events such as enzyme activity, muscle contraction by ATP hydrolysis, and ion channel permeability. Because they have potential use in such a wide variety of applications, photoremovable protecting groups with diverse physical properties are desirable. Furthermore, detailed knowledge of the photorelease mechanism makes it easier to determine the best-suited photoremovable protecting groups for each application.

We have shown that ester **1C** releases its alcohol moiety upon irradiation, and that the release is independent of the reaction medium.[8,9] The release from **1C** is initiated by intramolecular H-atom abstraction by the triplet ketone in **1** to form 1,4-triplet biradical **2C**, which intersystem crosses to E and Z-photoenols **3C**. **Z-3C** is short-lived because it

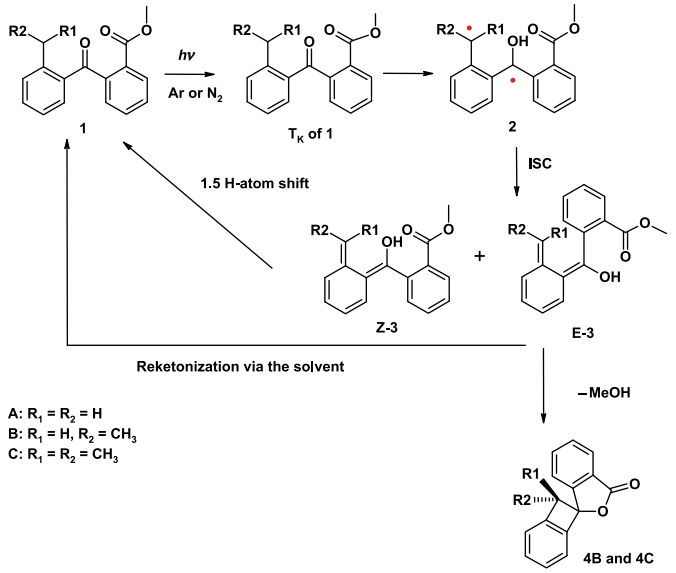
Scheme 1. Proposed reaction mechanism for photorelease from **1**.



decays by a 1,5-H shift to regenerate **1C**. The longer lived **E-3C** undergoes electrocyclic ring closure and intramolecular lactonization to release the alcohol moiety. In comparison, **1A**, which has an *ortho*-methyl group, fails to release its alcohol moiety upon irradiation (Scheme 1), even though transient spectroscopy shows that the major reactivity of **1A** involves intramolecular H-atom abstraction to form **Z-3A** and **E-3A**.[10] It was concluded that the short lifetime of **E-3A** prevented it from undergoing intramolecular lactonization and releasing its alcohol.

In this paper, we compare the photoreactivities of methyl, ethyl, and isopropyl benzoyl benzoic esters **1A**, **1B**, and **1C**, respectively, in argon- or nitrogen-saturated solutions by performing product studies, transient absorption spectroscopy, and theoretical calculations. The lifetimes of **Z-3** and **E-3** are affected by intramolecular hydrogen bonding, the steric demand, and the stereoelectronic properties of the *ortho*-alkyl groups. The yields of photorelease from **1A**, **1B**, and **1C** depend on the yields of **E-3A**, **3B**, and **3C** and, more importantly, on their lifetimes.

Experiments

Laser flash photolysis

Laser flash apparatus

Laser flash photolysis studies were performed using Excimer[11] or YAG lasers.[12,13] Rate constants were determined by fitting an average of three to eight kinetic traces. Transient absorption spectra were obtained by plotting average absorbance values collected from decays at 10 or 20 nm intervals between 300 and 600 nm.

Sample preparation for laser flash photolysis

Stock solutions of **1A**, **1B**, and **1C** in methanol and acetonitrile were prepared with spectroscopic grade solvents, such that the solutions had absorptions between 0.6 and 0.8 at 266 nm. Stock solutions of **1A**, **1B**, and **1C** in spectroscopic grade benzene and acetonitrile were prepared so that the solutions had absorptions between 0.8 and 0.6 at 308 nm. Typically, about 2 mL of the solutions was placed in 7 mm × 7 mm Suprasil quartz cells capped with prewashed septa. These solutions were purged with nitrogen or argon for 10 min. The lifetimes of **E-3C** were measured as described earlier.[13]

Preparation of 1B

To a stirred solution of phthalic anhydride (2.29 g, 15 mmol) in a 1:1 anhydrous diethyl ether – toluene mixture was added 2-ethylphenyl magnesium bromide, prepared from 2-bromoethylbenzene (3.0 g, 16 mmol) and magnesium turnings (500 mg, 17.8 mmol) in anhydrous diethyl ether.[14] The resulting mixture was refluxed for 12 h and poured onto ice – hydrochloric acid, and the resulting mixture was extracted with diethyl ether (3 × 30 mL). The mixture was washed with a 10% $NaHCO_3$ solution, and the aqueous phase was acidified with 10% aq HCl and extracted with diethyl ether (3 × 30 mL). The organic layer was dried over anhydrous magnesium sulfate and evaporated under vacuum to yield 2-(2′-ethylbenzoyl)benzoic acid (2.2 g, 8.5 mmol, 56%). Without further purification, the material was dissolved in methanol, concd H_2SO_4 (5 mL) was added, and the mixture was refluxed overnight (16 h). The resulting mixture was cooled to room temperature, neutralized with aq $NaHCO_3$, and extracted with diethyl ether (3 × 40 mL). The organic layer was dried over anhydrous magnesium sulfate and evaporated under vacuum to yield a yellow residue. The residue was purified by silica gel column chromatography to yield methyl 2-(2′-ethylbenzoyl)benzoic acid ester **1B** as a pale yellow oil (2.2 g, 8.2 mmol, 51% yield).

Photolysis of 1B in argon-saturated 2-propanol

Ester **1B** (71 mg, 0.27 mmol) was placed in a Pyrex tube and dissolved in 2-propanol (7 mL), and the resulting solution was purged with argon at room temperature for 15 min and sealed with a rubber septum. The solution was irradiated using a 450 W medium pressure mercury arc lamp immersed in a Pyrex well for 28 h at room temperature. The reaction was monitored through thin layer chromatography (10% ethyl acetate in hexane). After the majority of the starting material disappeared, the solvent was removed under vacuum, and the yellow residue was purified with a silica gel column using a 7:93 ethyl acetate – hexane mixture to yield **4B** as a yellow liquid (35 mg, 15 mmol, 56% yield) and recovered starting material (25 mg, 0.09 mmol, 35% recovery).

4B: IR (neat, cm^{-1}): 2924, 1771, 1465, 934. ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.03–7.17 (m, 2H), 7.31–7.64 (m, 5H), 7.98–8.00 (m, 1H), 4.31 (q, J = 8 Hz, 1H), 1.28 (d, J = 8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 169.8, 146.9, 141.9, 133.5, 131.1, 129.4, 128.7, 126.7, 125.6, 123.4, 123.4, 122.4, 90.3, 50.9, 14.7. MS) *m/z* calcd for $C_{17}H_{16}O_2$ [M + 1]: 237.0916; found: 237.0904.

Quantum yields

Quantum yields for the photolysis of **1B** were determined both for depletion of the starting material and for formation of product **4B**. 2-Propanol was dried over molecular sieves and distilled prior to use. The mole to area ratio response of the GC traces was calibrated for compounds **1B** and **4B** and valerophenone in 2-propanol, which was the actinometer.[15] Irradiation of 0.1 mol/L argon- and nitrogen-saturated 2-propanol solutions of **1B** on a merry-go-round apparatus using a 450 W medium pressure mercury arc lamp and potassium chromate filter to isolate the 313 nm line was performed to about 10% conversion. At least three replicates of each sample were irradiated and analyzed with a GC equipped with an FID detector. The results from all three replicates were averaged.

Theoretical calculations

Density functional theory (DFT) calculations were performed using Gaussian03 at the B3LYP level of theory and with the 6–31+G(d) basis set.[16,17] All transition states were confirmed to have one imaginary vibrational frequency by the analytical determination of the second derivative of the energy with respect to the internal coordinates. Intrinsic reaction coordinate[18] calculations were used to verify that the transition states corresponded to the correct reactant and products.[19,20] Vertical UV absorption spectra were calculated using time-dependent density functional theory (TD-DFT).[21–25] The effect of solvation was calculated using the self-consistent reaction field (SCRF) method with the integral equation formalism polarization continuum model (IEFPCM) with methanol and acetonitrile as the solvents.[26–30]

Results and discussion

Product studies

Photolysis of **1B** in an argon-saturated solution results in lactone **4B**, which is similar to the photoreactivity of **1C** (Scheme 2). Irradiation of **1B** in solvents such as benzene, toluene, chloroform, and 2-propanol yields **4B** in comparable yields, indicating that the photorelease is not strongly affected by the solvent (Fig. 1). In contrast, we have reported that photolysis of **1A** yields no products in solvents such as benzene and chloroform, which do not have easily abstractable H atoms. However, in solvents with abstractable H atoms, **1A** yields **5** (Scheme 3), presumably from intermolecular H-atom abstraction from the solvent.[10]

[b]See ref. 8.

Quantum yields

The quantum yields for the depletion of **1B** and the formation of **4B** in 2-propanol are listed in Table 1. The quantum yields for **1C**, which have been published previously, are slightly higher than those for **1B** and are listed in Table 1 for comparison.

Calculations

To better understand why **1A**, **1B**, and **1C** react differently, we calculated the stationary points on their energy surfaces. We optimized the gas-phase structures of **1A**, **1B**, and **1C** and their respective first triplet excited states of the ketone. The C=O bond in the T_K of **1** is elongated to 1.311 Å compared with 1.225 Å in the S_0. The progression of the C–O bond stretch fits well with the T_K of **1** having an (n,π*) configuration.[31–34] The calculated energies of the T_Ks of **1A**, **1B**, and **1C** are ~8 kcal/mol (1 cal = 4.184 J) lower than the measured value for the analogous benzophenone. However, we have previously shown that DFT calculations

Table 2. Intramolecular hydrogen bonds in **Z-3** and **E-3**.

	Bond vibrational frequency	Bond length
Compound	O–H (cm^{-1})	C=O H–O– (Å)
Z-3A	3479	1.783
Z-3B	3480	1.782
Z-3C	3459	1.740
E-3A	3506	1.800
E-3B	3504	1.7821
E-3C	3490	1.756

underestimate the energy of triplet ketones with an (n,π*) configuration.[35]

We optimized the structures of biradicals **2A**, **2B**, and **2C** and found that their lowest energy conformers have intramolecular hydrogen bonding between the O–H group and the C=O ester group. The hydrogen-bonded conformers are ~5–8 kcal/mol lower in energy than those that do not have intramolecular hydrogen bonding. The calculated O–H and C=O stretches in the hydrogen-bonded conformer of **2A** are located at 2996 and 1662 cm^{-1}, respectively, but the corresponding stretches are at 3742 and 1768 cm^{-1} in a conformer of **2A** that does not undergo intramolecular hydrogen bonding. Thus, the calculated IR spectra confirm the intramolecular hydrogen bonding in the lowest energy conformers of **2A**, **2B**, and **2C**.

The structures of **Z-3** and **E-3** with intramolecular hydrogen bonding were also optimized. Enols **Z-3** and **E-3** are between 35 and 40 kcal/mol higher in energy than corresponding ketones **1A**, **1B**, and **1C**. Furthermore, **Z-3** is between 1 and 3 kcal/mol more stable than the corresponding **E-3** molecule. The intramolecular hydrogen bond in **Z-3C** is shorter and has a lower vibrational frequency than that in **Z-3A** and **Z-3B** and is therefore stronger (Table 2). Similarly, the intramolecular hydrogen bond in **E-3C** is found to be stronger than that for **E-3A** and **E-3B**.

We calculated the transition state for the T_K of **1** for the H-atom abstraction to form biradical **2**. The transition-state barrier for γ H-atom abstraction of the T_K of **1A** is ~8 kcal/mol, whereas the transition-state barriers for the T_Ks of **1B** and **1C** are less by 3 and 4 kcal/mol, respectively. The stationary points on the energy surfaces of **1A**–**1C** are plotted in Figs. 2–4. These plots highlight that the intramolecular H-atom abstraction from the T_K of **1A**, **1B**, and **1C** to form biradicals **2A**, **2B**, and **2C** can be easily achieved at ambient temperature. Even though biradical **2A** is a primary radical, it is only ~3 kcal/mol less stable than **2B** and **2C**, presumably because the radical center on the *ortho*-methylene is stabilized owing to conjugation with the aromatic rings. The driving force for the reactivity of **E-3** and **Z-3** must be the re-aromatization of the benzene ring.

We calculated the transition states for **Z-3** to reform **1** via 1,5 H-atom shifts (Table 3 and Fig. 5). The transition-state barrier for **Z-3A** to reform **1A** is 7.2 kcal/mol and 6.6 kcal/mol for **Z-3B** to form **1B**. Presumably, the electron-donating effect of the ethyl groups stabilizes the transition state more than the methyl group stabilizes it. In comparison, the steric demand of the isopropyl group, which cannot rotate away as

Scheme 4. Calculated transition state barriers for **E-3**, **6**, and **7**.

	Torsion Angle	Transition state for electrocyclic ring closure (kcal/mol)	Transition state for lactonization (kcal/mol)
E-3A	28	18.6	37.4
E-3B	33	16.1	36.8
E-3C	44	15.9	42.4

	Transition state for lactonization (kcal/mol)	Torsion Angle	Transition state for electrocyclic ring closure (kcal/mol)
E-3A	43.5	33	18.6
E-3B	43.2	35	17.6
E-3C	43.0	44	17.8

the ethyl group can, causes the transition-state barrier for the 1,5 H-atom shift in **Z-3C** to increase to 7.9 kcal/mol.

The calculated transition states for electrocyclic ring closure of **E-3** show that alkyl substituents stabilize this transition state (Scheme 4). Thus, the transition-state barrier for **E-3A** is the highest, and the barriers for **E-3B** and **E-3C** are lower. The steric effect of the dimethyl substituents in **E-3C** twists its butadienyl moiety. The torsion angle between the butadienyl moiety in **E-3C** is 44°, but only 33° and 28° in **E-3B** and **E-3A**, respectively. In the electrocyclic ring closures, twisting of the butadienyl moiety to a distorted structure moves the reactant along the potential energy surface towards the transition state's twisted geometry. So the steric effect of the dimethyl substituent in **E-3C** lowers the transition-state barrier for forming **6C** by twisting the butadienyl moiety.

Furthermore, we calculated the transition-state barrier for **6** to undergo lactonization and found that the barrier for lactonization is ~40 kcal/mol, which is considerably higher than the transition-state barrier for **E-3** to undergo electrocyclic ring closure. However, it is complicated to compare these transition-state barriers because solvation is expected to affect the lactonization significantly more than the electrocyclic ring closure. The calculated transition-state barriers make it possible to evaluate the effect of the alkyl substituents on these two processes rather than to obtain their absolute values. The steric demand of the dimethyl group in **6C** makes the lactonization slightly less feasible than for **6A** and **6B**.

We calculated the transition states for lactonization of **E-3A**, **3B**, and **3C** to form **7**. The transition-state barrier is

Fig. 2. Calculated stationary points on the energy surface for **1A**. The energies are in kcal/mol (1 cal = 4.184 J) and are obtained from the singlet- (black) and triplet-optimized structures with zero point energy corrections included. Numbers in parentheses are energies calculated with a polarization continuum model (PCM) model for methanol.

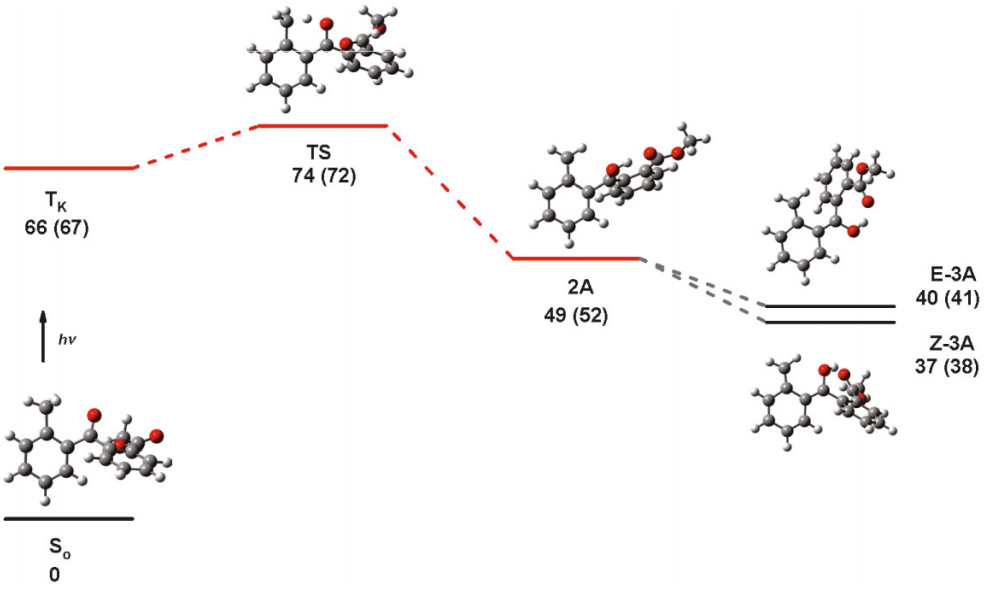

Fig. 3. Calculated stationary points of the energy surface for **1B**. The energies are in kcal/mol (1 cal = 4.184 J) and are obtained from the singlet- (black) and triplet-optimized structures with zero point energy corrections included. Numbers in parentheses are energies calculated with a polarization continuum model (PCM) model for methanol.

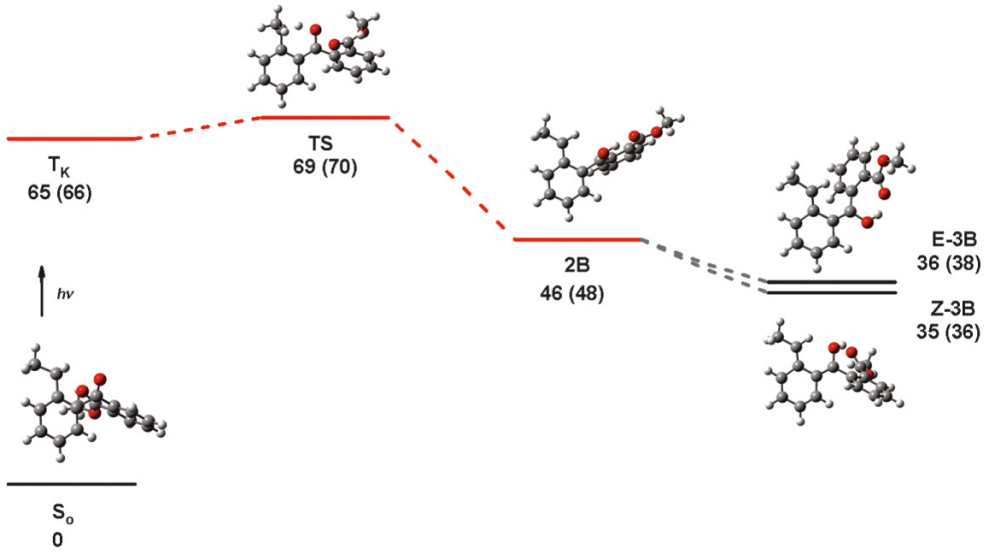

~43 kcal/mol for **E-3**. The calculations demonstrate that the *ortho*-alkyl substituent has minimal effect on the lactonization of **E-3**. In comparison, the calculated transition-state barrier for **7** to form **4** shows that ring closure of **7A** is the least favored as expected, since its butadienyl moiety is less twisted than for **7B** and **7C**.

Thus, the calculations show that the electrocyclic ring closure of **E-3** and **6** are affected by the alkyl substituents, whereas lactonization of **E-3** is not. However, the transition-state barrier for lactonization of **6C** is increased by the steric demand of the dimethyl group.

Laser flash photolysis of **1B** in nitrogen-saturated methanol produced a transient spectrum with a λ_{max} at ~330 nm with a lifetime of ~53 ns (Fig. 6) We assign this absorption to triplet biradical **2B** on the basis of its similarity to the transient spectra of the analogous 1,4-biradical **2A**.[9,10] The TD-DFT calculations support this assignment because the major calculated electronic transition for **2B** is located at 336 nm (f = 0.0871) in the gas phase and at 334 nm (f = 0.1104) in methanol. In oxygen-saturated solutions, the absorption owing to **2B** was quenched. As the absorption band for **2B** decayed, a new transient with a λ_{max} at 390 nm (Fig. 6) formed at the same rate. We assign this absorption to **Z-3B** and **E-3B**, based on comparison with the transient spectra of **3A** and **3C**.[8,10] The TD-DFT calculations also support this assignment as they revealed that the major absorption bands of **Z-3B** and **E-3B** are located at 426 nm (f = 0.1975) and 437 nm (f = 0.0699) in methanol, respec-

Z-3B	6.6
Z-3C	7.9

Note: 1 cal = 4.184 J.

Fig. 5. Transition state for 1,5 H-atom shift in **Z-3A**, **Z-3B**, and **Z-3C**.

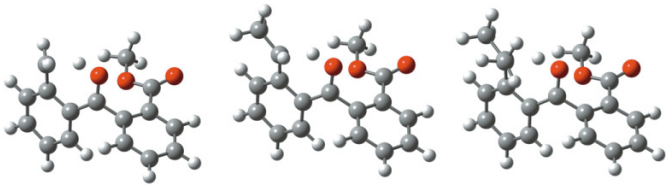

Fig. 6. Laser flash photolysis of **1B** in N_2-saturated methanol over (A) a time window of 1 μs and (B) a time window of 200 μs.

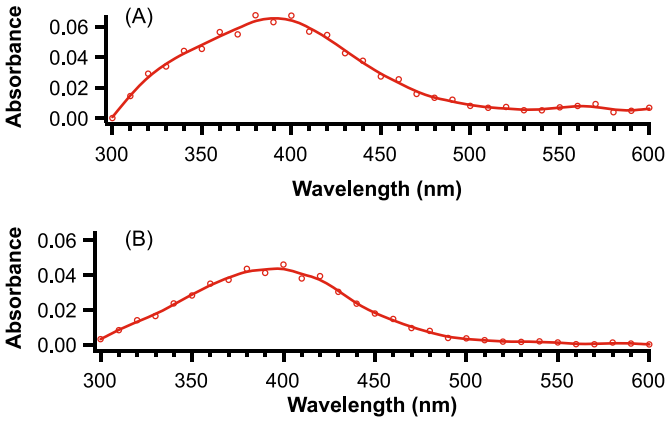

tively. The lifetimes of **Z-3B** and **E-3B** in methanol are 15 μs and >3 ms, respectively. The lifetimes for each component can be obtained by fitting the decay with a monoexponential function because the decay of **Z-E3** is complete before **E-3B** has decayed significantly (Fig. 7). In acetonitrile, the lifetime of **Z-3B** is reduced to 2.5 μs, and the lifetime of **E-3B** is >19 ms. This is in agreement with previous reports that show that the Z-photoenols from *o*-methyl benzophenone and *o*-methyl acetophenones are longer lived in solvents that can form hydrogen bonds with the photoenols.[36,37]

We have reported the laser flash photolysis of **1A** and **1C** previously;[8] however, in this paper we compare the lifetimes and yields of biradicals **2A**, **2B**, and **2C** and photoenols **3A**, **3B**, and **3C** (see Table 4). The lifetimes of biradicals **2A**, **2B**, and **2C** are similar within experimental error, which fits well with the calculations that predict that these biradicals have similar stabilities.

The ratios of **Z-3** and **E-3** in benzene (Fig. 7), which cannot form hydrogen bonds with the photoenols, are shown in Fig. 7. The ratios of Z-enol to E-enol were measured from the absorbance at 390 nm by measuring the combined absorptions of **Z-3** and **E-3** on shorter timescales and the absorption of **E-3** on longer timescales. The Z:E ratio was highest for **3A** at 1:1.2 and somewhat lower for **3C** (3.2:1) and **3B** (3.5:1). Thus, by assuming that **E-3** and **Z-3** have similar absorption coefficients, the quantum yields for enol formation from **1A** is only half that observed for **1B** and **1C** (Fig. 7). The lower yield of photoenols from **1A** is a reflection that the intramolecular H-atom abstraction is less favorable in the T_K of **1A** than in that of **1B** and **1C**. However, the **Z**:**E** ratio is the lowest for **3A**, presumably because intramolecular rotation in **2A** is less hindered than in **2B** and **2C**. We have previously shown that restricted intramolecular rotation in analogous biradicals results in less E-photoenol formation.[38]

The lifetime of **Z-3C** is the longest in all solvents (Table 4), whereas that of **Z-3B** is only somewhat shorter lived and that of **Z-3A** is considerably shorter. The lifetime

	Lifetime		
Compound	Benzene	MeCN	MeOH
2A	77 ns	57 ns	54 ns
Z-3A	0.09 μs	1.2 μs	6.5 μs
E-3A	1<τ>8 ms	10 ms	162 μs
2B	50 ns	58 ns	33 ns
Z-3B	~0.7 μs	2.5 μs	15 μs
E-3B	1<τ>8 ms	19 ms	>3 ms
2C	70 ns	83 ns	60 ns
Z-3C	1.2 μs	8 μs	17 μs
E-3C	>500 ms	>0.1 s	>0.1 s

of **Z-3A** in methanol is comparable to the analogous Z-enol from 2,4-methyl benzophenone,[37] whereas the lifetime of **Z-3A** in benzene is considerably longer. Wagner and co-workers[37] showed that the 1,5 H-atom shifts are retarded by intermolecular hydrogen bonding. Thus, we theorize that intramolecular hydrogen bonding also renders **Z-3** more stable towards a 1,5 H-atom shift. The steric factors of the alkyl substituent in **Z-3B** and **Z-3C** also retard the 1,5-hydrogen shift, and thus they are longer lived than **Z-3A**.

The lifetime of **E-3A** was shorter than for **E-3B** in acetonitrile and methanol, whereas the lifetimes in benzene are comparable. **E-3C** is longer lived than both **E-3A** and **E-3B**. Unlike the Z-photoenols, the E-photoenol reketonization is solvent-assisted. Furthermore, in competition with reketonization, **E-3B** and **E-3C** must undergo electrocyclic ring closure and intramolecular lactonization to form **4B** and **4C**, respectively. **E-3A** reketonizes faster than it undergoes electrocyclic ring closure or lactonization. Thus, we theorize that in nonpolar solvents, **E-3B** and **E-3C** decay by electrocyclic ring closure followed by lactonization. Our hypothesis is based on the observation that **E-3A** does not produce **4A** in nonpolar solvent, whereas **E-3A** has lifetimes that are similar as observed for **E-3B** and that the transition-state barrier for **E-3A** to undergo electrocyclic ring closure is larger than that for **E-3B** and **E-3C**. In comparison, the calculated transition-state barrier for lactonization of **E-3** is not affected significantly by the alkyl substituents.

Conclusion

The product studies show that **1B** and **1C** release their alcohol moiety upon irradiation via photoenolization and form **4B** and **4C**, whereas **1A** also undergoes photoenolization, but both **Z-3A** and **E-3A** decay back to the starting material. Laser flash photolysis shows that **1A**, **1B**, and **1C** all undergo H-atom abstraction to form **2**, which intersystem crosses to form **E-3** and **Z-3**. The yields of the photoenols are similar for **1B** and **1C** and slightly less for **1A** in benzene. The calculations further support this because stationary points on the energy surface of these esters are very similar. The lifetime of **E-3A** is significantly shorter in methanol than that of both **E-3B** and **E3C**. Thus, **E-3A** does not react to release its alcohol moiety but rather regenerates **1A**. In comparison, the lifetime of **E-3A** is considerably longer in benzene and acetonitrile, however, because the electrocyclic ring closure for **E-3A** is less favorable than for **E-3B**, it reketonizes faster than it undergoes electrocyclic ring closure. Thus, in designing photoprotecting groups based on intramolecular photoenolization, it is important to consider the effect of the alkyl substituent on electrocyclic ring closure and lactonization.

Investigation of ligand effects on exciton recombination in PbS nanoparticles

Jennifer M. Zemke, Thomas E. Novet, and David R. Tyler

Abstract: Multiple exciton generation (MEG) and exciton recombination were studied by femtosecond transient absorption spectroscopy in PbS nanoparticles (NPs) capped with oleic acid (PbS–OLA) and 2,3-dimercaptopropane sulfonate (PbS–DMPS) ligands. Analysis of the transient absorption data showed that the PbS–DMPS nanoparticles exhibit increased rates of multi- and single-exciton recombination compared with the PbS–OLA nanoparticles; however, the MEG yield for both sets of particles was the same within experimental error. The origin of the differences in the exciton recombination decay rates is unknown, but it is speculated that it may be due to the ionic functionality of DMPS or to the different ligating atoms of the OLA and DMPS ligands. The PbS–DMPS nanoparticles were highly sensitive to the presence of oxygen, which caused a dramatic increase in nonradiative decay pathways, which can be mistaken for multiexciton absorbance and decay. Removal of oxygen eliminated the nonradiative decay pathways. Overall, this study showed that the dynamics of MEG can be modified by changing the NP ligand shell, a result that may be useful in the development of NP-based thin-film solar devices.

Key words: multiple exciton generation, surface modification of nanoparticles, exciton recombination, nanoparticle ligand exchange.

Résumé : On a étudié le génération d'excition multiple (GEM) et la recombinaison d'exciton par spectroscopie d'absorption des espèces transitoires au niveau de la femtoseconde, dans des nanoparticules de PbS coiffées de ligands d'acide oléique (PbS–OLA) et de sulfonate de 2,3-dimercaptopropane (PbS–DMPS). L'analyse des données d'absorption des espèces transitoires montre que, par comparaison avec les nanoparticules de PbS–OLA, les nanoparticules de PbS–DMPS présentent des vitesses accrues de recombinaison d'excitons simples et multiples; toutefois, les rendements pour la GEM sont les mêmes, aux erreurs expérimentales près, dans les deux cas. L'origine des différences dans les vitesses de décroissance de recombinaison de l'exciton est inconnue, mais il est possible de spéculer qu'elle pourrait être due à la fonctionnalité ionique du DMPS ou aux atomes de ligature différents des ligands OLA et DMPS. Les nanoparticules de PbS–DMPS sont très sensibles à la présence d'oxygène qui provoque une augmentation dramatique dans les voies non radiatives de décroissance, que l'on peut attribuer à tort à de l'absorbance multiexciton et à de la décroissance. L'enlèvement de l'oxygène permet d'éliminer ces voies de décroissance non radiatives. Dans l'ensemble, cette étude montre que la dynamique de la GEM peut être modifiée par un changement de la couche de ligand de nanoparticules, un résultat qui peut être utile dans le développement de dispositifs solaires en film mince à base de nanoparticules.

Mots-clés : génération d'excition multiple, modification de la surface de nanoparticules, recombinaison d'exction, échange de ligand d'une nanoparticule.

[Traduit par la Rédaction]

Introduction

Semiconductor nanoparticles (NPs) are favorable candidates for integration into cost-effective solar devices. This is primarily due to their broad optical tunability and ease of processing. In particular, lead chalcogenide (PbS, PbSe, or PbTe) NPs provide tunability through the near-infrared (NIR) portion of the electromagnetic spectrum while exhibiting quantum-confined properties, two desirable qualities for matching the solar spectrum in photovoltaic devices.[1–5]

Because of quantum confinement, an NP has a discrete energy spectrum. In semiconductor NPs, this spectrum is split by a forbidden energy gap much like in bulk semiconductors. However, owing to the discretized energy states, NPs exhibit very different properties from the bulk.[6] Most importantly, bulk semiconductors waste excess solar energy as heat. In semiconductor NPs, however, a process called multiple exciton generation (MEG) can lead to more efficient solar energy transduction. In the MEG process, multiple excitons are created per photon absorbed, provided energy and momentum requirements are met. For semiconductor NPs, the incident photon energy required to create

multiple excitons is $2E_g$ or greater (where E_g is the NP bandgap energy).[7–11] In contrast, much greater excitation energies are needed for bulk semiconductor MEG.[12] In principle, if MEG occurs and charge separation and (or) transport is faster than or competitive with recombination, MEG can appreciably enhance the photocurrent of solar devices.

To attain efficient marketable NP-based devices, the lifetimes of single and multiple excitons, and what governs these lifetimes, must be understood. For this reason, substantial effort has gone into quantifying MEG decay times in various NP systems. It is well-documented that multiple excitons recombine through an Auger-type process much more quickly (tens to hundreds of picoseconds) than the long-lived (nanosecond to microsecond) radiative recombination of single excitons and that this process is dependent on the size, shape, and composition of the NPs studied.[7–11,13–18]

Because of the large surface-to-volume ratio inherent to NPs, it is hypothesized that the NP surface plays a significant role in the electron dynamics of the system.[19,20] Thus, a key component in designing NP-based solar cells is understanding the role of the stabilizing ligand shell. Provided that electron dynamics are not influenced by a large density of surface trap states,[21] it is hypothesized that by controlling the type of ligand on the NPs the MEG efficiency, multiexciton lifetime, and charge transport through a device can be optimized. Additionally, it was shown for PbSe that preparation techniques and post-treatment of NP films with various ligands and solvents yield very different recombination dynamics and MEG efficiencies.[22] The authors of this study suggested that the differences they observed are most likely attributable to the chemical species present on the NP surface or to the changes observed in average interparticle distance.[22] These results prompted our curiosity regarding using the structure of the ligand shell to control MEG, and we began a study to investigate ligand effects on MEG. In this paper we report the results of our first study. Specifically, oleic acid-capped PbS NPs (PbS–OLA) and 2,3-dimercaptopropanesulfonate capped PbS NPs (PbS–DMPS) were investigated with femtosecond transient absorption spectroscopy to determine if there is a ligand effect on MEG and exciton recombination dynamics.

Before presenting the results of our study, a few more introductory notes are necessary. Recently, there has been some controversy over MEG in NP systems. In particular, it has been argued that MEG is less efficient than what was previously reported[11,23–25] (Note, however, that the controversy is not about the existence of MEG). For example, a re-examination of CdSe and CdTe NPs led to the conclusion that MEG efficiency is negligible in these systems, contrary to prior results and contrary to the general idea that MEG is enhanced in quantum-confined systems.[23] In our view, much of the controversy stems from the fact that numerous experimental variables can affect the apparent MEG dynamics. For example, differences in apparent MEG efficiencies have been reported in different preparative batches of supposedly identical nanoparticles.[26,27] Because of this, controversy has developed over the existence of photocharging of the NPs leading to a misinterpretation of true MEG yields; however, stirring of the solutions to sample a fresh volume of NPs with each laser pulse greatly reduces the probability of photoionization and allows for the observation of true MEG yields.[26] Additionally, the extent of ligand coverage and oxidation of a NP surface may lead to increased carrier trapping, thus requiring additional considerations in analyzing the carrier dynamics.[27] All of these points serve to emphasize that to efficiently exploit MEG in working devices it is essential to understand the properties of the NPs, including elucidating the direct effect of the ligand shell.

Experimental section

Synthesis of PbS NPs

All reagents and solvents were obtained from Sigma-Aldrich except D_2O, which was purchased from Cambridge Isotope Laboratories. Lead sulfide NPs were synthesized by preparing a lead precursor solution according to the method of Hines and Scholes.[1] To synthesize the parent OLA-capped particles, a solution consisting of 4 mL octadecene and 4 mL OLA was prepared and 0.3 g PbO was added to the mixture. The solution was heated under vacuum to 100 °C for 30 min to dissolve the PbO and to drive off H_2O. The solution was subsequently heated to the appropriate injection temperature (100–150 °C) for the desired particle size and held at that temperature for at least 30 min.

While the lead solution was heating, a sulfur precursor solution of 0.167 mL hexamethyldisilathiane and 4 mL octadecene was degassed under nitrogen. When the lead solution reached the desired injection temperature, the sulfur precursor was quickly injected into the flask and allowed to cool to room temperature. Removal of excess ligand and octadecene was completed by repeated precipitation in acetone, centrifugation of the particles, and dispersion in small amounts of toluene.[1] NIR characterization of the particles was accomplished using a PerkinElmer Lambda 19 UV–vis–NIR spectrophotometer. Particle size and monodispersity were measured using a FEI Titan 80-300 TEM in STEM mode (PbS–OLA NP $d = 5.0 \pm 0.7$ nm).

Ligand exchange on the PbS–OLA particles was accomplished according to literature precedent.[28] D_2O was chosen as the solvent over H_2O because of its suppressed NIR absorption. Equal volumes of PbS–OLA solutions (25 mg/mL) and the 2,3-dimercaptopropanesulfonate sodium salt dissolved in D_2O (78 mmol/L) were stirred until phase transfer of the particles was complete (~1 h). The ionically functionalized NPs were centrifuged to break emulsions formed during stirring and phase transfer. The PbS–DMPS particles were then precipitated from D_2O using acetonitrile, centrifuged, and resuspended in D_2O. The particles were characterized by NIR absorbance spectroscopy and TEM imaging (PbS-DMPS NP $d = 5.2 \pm 0.9$ nm).

Transient absorption measurements

Femtosecond laser system

The optical setup used for obtaining the pump–probe transient absorption data included a passively mode-locked Ti:Sapphire oscillator (SpectraPhysics Tsunami, 750 mW) pumped by a solid-state Nd:YAG laser (SpectraPhysics Millenia Pro., 5 W). This source yielded 100 fs pulses centered at 800 nm. The pulses were seeded into a regenerative am-

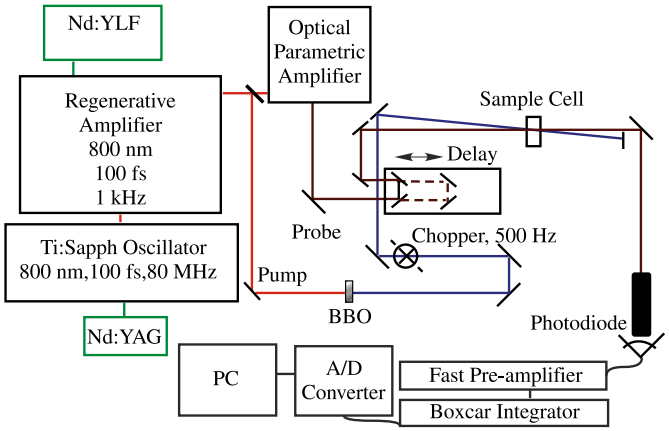
Fig. 1. Optical layout of the femtosecond laser system.



plifier (SpectraPhycics Spitfire Pro) pumped by a q-switched intracavity-doubled Nd:YLF laser (SpectraPhysics Empower, 15 W).

Optical layout

The beam from the amplifier (3.1 W, 1 kHz) was split into pump and probe components as shown in Fig. 1. The pump component was frequency doubled to 400 nm for MEG experiments (for non-MEG experiments it remained at 800 nm) and was chopped at 500 Hz, half the rate of the probe, with an optical chopper. The probe component was tuned in an optical parametric amplifier (OPA) to match the NIR first exciton absorbance of the nanoparticle samples. The probe pulses were delayed with respect to the pump by a micron resolution delay stage. The probe signal was detected on a fast biased InGaAs photodiode (Thorlabs DET 410), whereas the pump signal was indexed by a biased silicon photodiode (Thorlabs DET 210). The signal intensities were amplified and sampled using a fast preamplifier (SRS-SR445A) and boxcar integrator (SRS-SR250). The output from the boxcar integrator was connected to an analog-to-digital converter and then input into a PC. Transient absorption data was calculated using the probe pulse intensity with and without pump pulse excitation. IgorPro software was used for data analysis.

Sample preparation and handling

Solvents were degassed with nitrogen prior to use. Samples were prepared by dispersing NPs in an appropriate solvent at a desired concentration. Sample solutions were placed in cuvettes equipped with stir bars and PTFE stoppers. To ensure removal of oxygen, PbS–DMPS solutions were degassed a second time before transferring to a cuvette in the latter studies. The headspaces of all cuvettes were filled with nitrogen, and the cuvettes were taped and sealed for the duration of the femtosecond experiments.

As a special note, transients taken for stirred and static solutions of both PbS–OLA and PbS–DMPS sometimes showed an appreciable difference in the ratio of early to late population components. Also, as previously mentioned, there have been recent reports outlining the observation of ligand-dependent photocharging of NP solutions.[26] For these reasons, all of the samples used for MEG determination in this study were stirred.

Results and discussion

Choice of ligands

Because we are trying to elucidate the direct effect of the ligand on MEG, we determined that solution-phase samples were of interest primarily owing to the fact that, in solution, the effective concentration of NPs is less than in a film, which decreases the likelihood that interparticle distance is affecting MEG. During our initial investigations of NP ligand–shell substitution reactions, we found that substitution of PbS–OLA NPs by neutral organic thiol ligands led to precipitation of the NPs or to opaque solutions in a wide variety of solvents, rendering the NPs unsuitable for our transient absorption measurements. It was necessary, therefore, to find a ligand, other than one of the neutral thiols, which would allow the NPs to remain suspended in a transparent solution. A literature search revealed that substitution of OLA-capped nanoparticles by DMPS yielded stable NPs in solution, particularly under anaerobic conditions.[28] This same study suggested that, once the DMPS is coordinated to the NP, the ionic ligands repel one another, thereby maintaining a minimum interparticle distance that reduced the probability of precipitation brought on by agglomeration. Most importantly, this study determined that thin-film devices made with the PbS–DMPS NPs showed enhanced photoresponse in the NIR compared with PbS–OLA films, where no photocurrent was detected under the same conditions. This enhanced photoactivity was primarily attributed to the reduced interparticle spacing in the PbS–DMPS films over PbS–OLA films. Transient absorption studies of the PbS–OLA and PbS–DMPS NPs could reveal additional information regarding the differences in photoresponse of the films, such as enhancements of MEG quantum yields or longer exciton lifetimes. The synthetic ease of the DMPS-for-OLA substitution reaction, combined with the encouraging thin-film photocurrent results, was a strong incentive to carry out this study using the DMPS and OLA NP systems.

Transient absorption of OLA-capped NPs

Two fractions of OLA-capped NPs (from the same synthetic batch) with a first exciton absorbance at 1340 nm were excited with 800 and 400 nm laser pulses in toluene solution. In all transient absorption measurements, the probe wavelength was tuned to the maximum of the exciton absorbance in the NIR spectrum. The particles were excited under low-fluence excitation to prevent nonlinearities and to ensure that the average number of photons absorbed per NP (N_{abs}) was kept to a minimum. The value for N_{abs} is given by eq. [1].[11]

$$[1] \qquad N_{abs} = J(0)\frac{1 - e^{-\alpha L}}{cL}$$

where L is the path length of the cuvette, $J(0)$ is the photon fluence at the front face of the cuvette, c is the sample concentration, and αL = OD ln,[10] as calculated from the optical density (OD) of the NP absorbance spectrum.

Raw transient absorption traces at varied pump fluences obtained for 800 nm excitation (Fig. 2*a*) were fit using a global least-squares fitting routine. The subsequent analysis was performed according to the procedure outlined by Ellingson et al.[8] Within this analysis, the time constants for

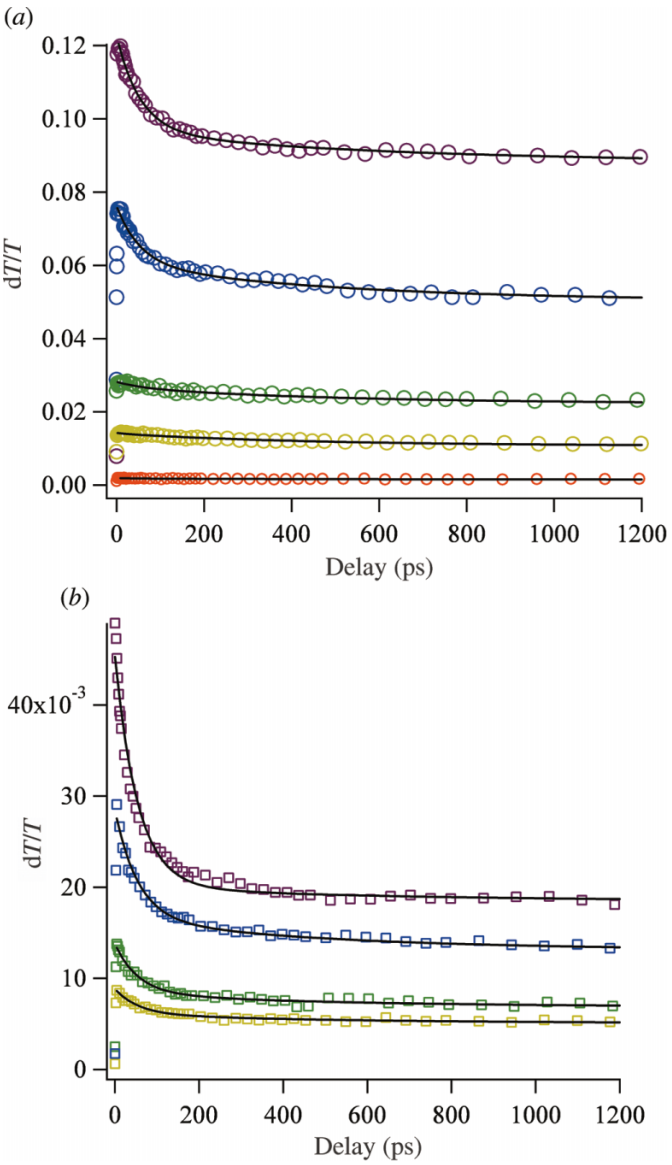
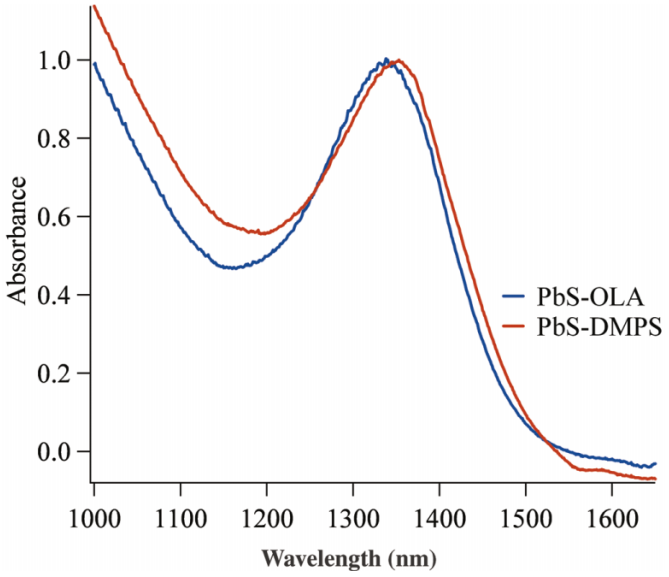
Fig. 2. Transient decay curves for PbS – oleic acid (OLA) nanoparticles (NPs) excited at (*a*) 800 nm (1.55 eV, 1.68E_g, where E_g is the NP bandgap energy) and (*b*) 400 nm (3.11 eV, 3.35E_g), with various pump intensities.



single exciton (τ_X) and biexciton (τ_{MX}) recombination were global parameters and were varied for at least four kinetic traces until the best fit results were obtained. The resulting time constants revealed a single exciton lifetime of 80 ns and a faster biexciton time constant of 436 ps. The amplitudes for these variable fluence traces at 800 nm excitation (<2E_g) are the Poisson amplitudes, which are influenced by N_{abs}. Upon extracting the amplitudes and exciton lifetimes in the case where MEG does not occur ($h\nu < 2E_g$), raw transients for MEG excitation can be analyzed. Figure 2*b* shows the variable fluence traces for the excitation of PbS–OLA at 400 nm (3.35E_g). In this case, the curves were fit by constraining τ_X and τ_{MX} to the extracted values obtained above; however, the amplitudes of these curves are no longer strictly Poissonian and now contain components of MEG. Extraction of the MEG quantum yield will be detailed later.

Fig. 3. Example NIR absorbance spectra showing the first exciton absorption ($1S_h$–$1S_e$) for parent PbS – oleic acid (OLA) (blue line) nanoparticles (NPs) vs ligand-exchanged PbS – 2,3-dimercaptopropanesulfonate (DMPS) particles (red line).



Ligand exchange and transient absorption of PbS–DMPS NPs

Ligand-exchange reactions were carried out on PbS–OLA NPs with DMPS (PbS–MPS). The PbS–DMPS NPs were characterized by TEM imaging and NIR absorption spectroscopy to confirm their size and exciton absorbance (see Experimental section). The red shift in the NIR spectrum for the PbS–DMPS NPs compared with PbS–OLA NPs (Fig. 3) is accounted for by the change in dielectric constant of the solvent[28] and not by a change in particle size, as confirmed by TEM imaging.

Ultrafast decay curves for a single batch of PbS–DMPS particles were obtained for 800 and 400 nm excitation (1.69 and 3.38 times the bandgap energy, respectively) at various pump fluences. The raw traces for both excitation wavelengths are shown in Fig. 4. It is interesting to note that the transient dynamics recorded for PbS–DMPS at 400 nm excitation (Fig. 4*b*) are very different from the OLA-capped particles under MEG conditions. At first glance, it appears that the PbS–DMPS nanoparticles excited under MEG conditions have a greatly enhanced MEG signature compared to the PbS–OLA NPs (the ratio of populations at early and late times; 2.5 and 3.4, respectively). However, experiments showed that the enhanced MEG in the PbS–DMPS NPs is likely attributable to NP decomposition leading to enhanced trapping. After 1–3 days in the sealed cuvettes, the particles precipitated out of solution. The precipitation time was loosely correlated to the care taken to remove oxygen in the samples. To investigate this phenomenon further, a second ligand exchange was performed from the same PbS–OLA parent batch but with care taken to remove O_2 from the PbS–DMPS product before sealing it in the sample cuvettes. Additionally, the PbS–DMPS and PbS–OLA NPs were monitored by NIR absorbance spectroscopy throughout the MEG laser experiments to ensure that the laser experiments were not carried out on decomposed NPs.

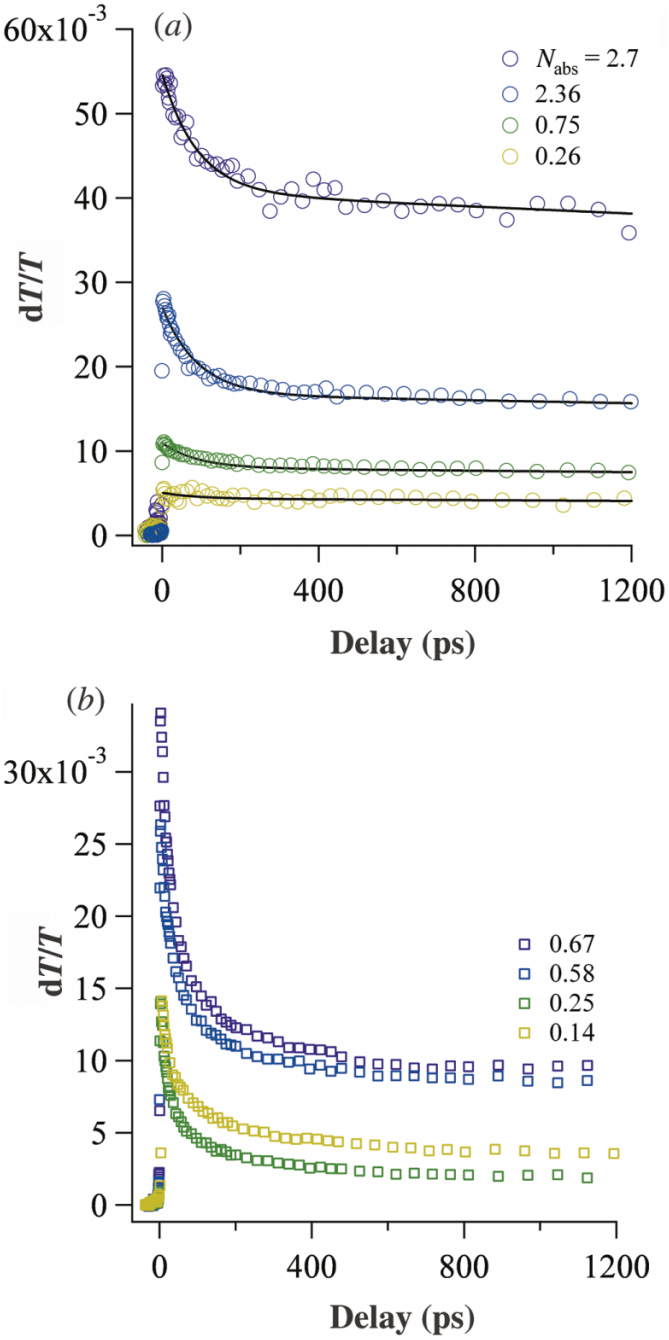
Fig. 4. Variable fluence transient curves and curve fits for PbS – 2,3-dimercaptopropanesulfonate (DMPS) under (*a*) 800 nm and (*b*) 400 nm excitation.



In the case of PbS–OLA NPs, shown in Fig. 5*a*, there is no change in the $1S_h$–$1S_e$ (first exciton) absorbance over the course of the femtosecond experiments. (It should be noted that there is a blue shift of the exciton absorbance in these NPs compared with freshly prepared NPs. This change is most likely due to some oxidation of the NP core[29] causing a change in size of the nanoparticles. Nevertheless, there is no evidence of the particles changing during the course of the MEG data collection.) In contrast to the PbS–OLA solution, the PbS–DMPS NPs do change during the MEG ex-

periment (Fig. 5*b*): the first exciton absorbance peak narrows and appears almost multimodal within 1 day.

To eliminate the effects of NP decomposition during the MEG experiments, only transient spectra taken within the first 8 h following sample preparation were used in the data analyses. Additionally, the samples were degassed a second time prior to sealing the cuvettes. Results of the MEG experiments on PbS–DMPS NPs prepared under these anaerobic conditions are shown in Fig. 6. Note there is no apparent decomposition in the spectra of the PbS–DMPS NPs.

The global fitting procedure described previously was used to fit the raw transient data for PbS–DMPS. Time constants extracted from the non-MEG curve fits are listed in Table 1 and compared with those obtained for PbS–OLA. Also shown in Table 1 are the MEG quantum yields (QYs) for the PbS–DMPS and PbS–OLA particles. In determining QY, the ratio of short and long time signal (A/B) is plotted as a function of N_{abs} (Fig. 7). Fits for the curves for 800 nm excitation assume Poisson statistics for the absorption of

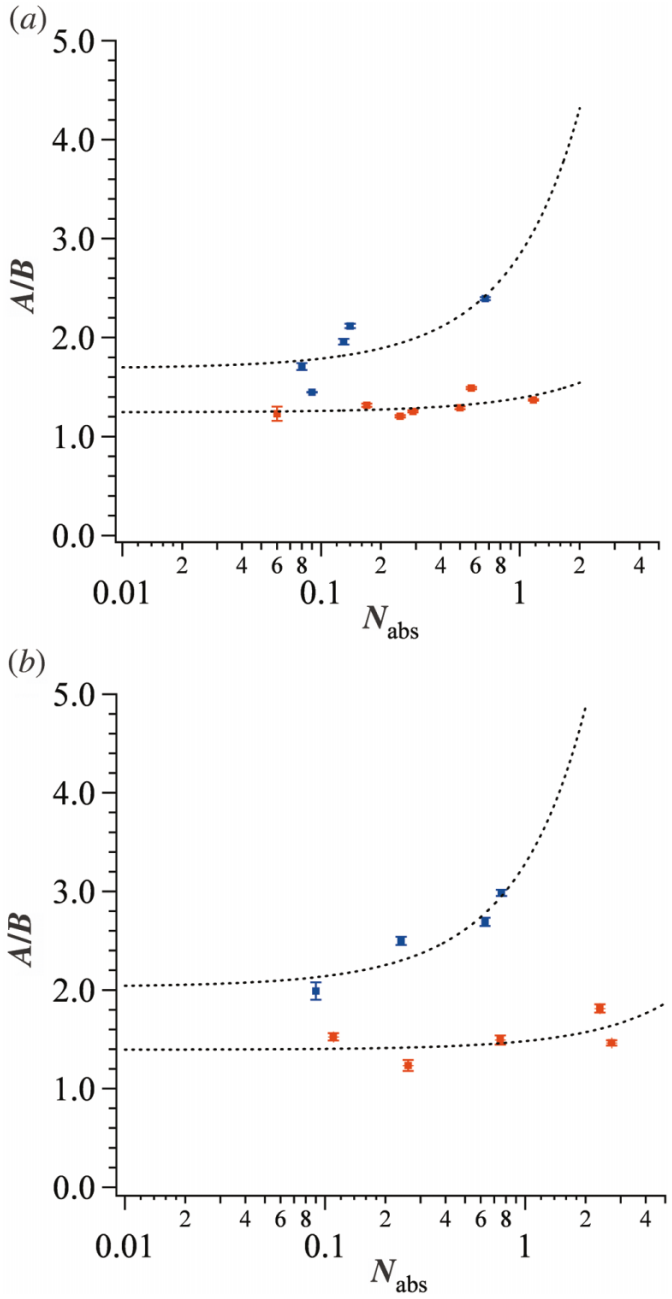
photons by the NPs. The curves for 400 nm excitation are non-Poissonian, but are fit by allowing for the adjustment of the QY, which accounts for the enhanced amplitudes owing to MEG. By extrapolating these fits back to vanishing photon fluence and dividing out the contribution of the

Fig. 7. Ratios of early to late time signals vs the average number of photons absorbed per nanoparticle at the front face of the sample cuvette (N_{abs}) for (*a*) PbS – oleic acid (OLA) and (*b*) PbS – 2,3-dimercaptopropanesulfonate (DMPS) particles.



800 nm excitation curves, the MEG QY for each particle set was determined. Note in Table 1 that even the more rigorously deoxygenated PbS–DMPS NPs experience faster decay dynamics than their PbS–OLA parent batch; however, the MEG QY for each particle set is the same within experimental error. The time constants for multi- and single-exciton decay for the PbS–DMPS particles are less than half that of the PbS–OLA particles, indicating that the ligand has an effect on MEG and exciton recombination.[30]

The origin of the ligand effect on decay dynamics is unknown. One suggestion is that the faster decay rates for exciton recombination in the DMPS system are due to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

negative charge on the ligand. It is suggested that the electron is electrostatically repelled by the anionic ligand shell. This would prevent delocalization of the electrons over the surface of the NP, spatially confining them to the core, which causes them to recombine with holes more quickly. A related hypothesis is that the ligand effect can be attributed to the different ligating atoms in the two ligands. The DMPS ligand binds through sulfur instead of oxygen. Because oxygen is more electronegative than sulfur, it is more likely to accept electron density and, therefore, more likely to delocalize the electronic wave function over the surface of the NP, which would lead to slower electron–hole recombination rates. A final suggestion is that the differences in the decay dynamics may be due to a solvent effect. Previous studies suggested that the solvent can affect electron dynamics in NPs that have significant trap state densities,[31] but does not play as significant a role in passivated NPs.[32] The NPs used in this investigation are passivated by the ligands, leading to the conclusion that solvent effects may not be of great consequence. Investigations are underway in our laboratory to further probe these ligand effects and to provide insight into their origin.

Key insights and conclusions

PbS NPs with OLA and DMPS ligands were investigated to determine how the NP ligand shell affects MEG and exciton recombination dynamics. Experiments showed striking differences between the PbS–DMPS samples prepared in the presence of oxygen and those prepared anaerobically. With oxygen present in the samples, the kinetic decay curves exhibited large false MEG-type signatures and enhanced recombination rates owing to the photooxidation and degradation of the NPs and the ensuing increase in the number of nonradiative decay pathways. Rigorous removal of oxygen from the samples produced kinetic decay curves with time constants for PbS–DMPS NPs that were significantly shorter than those of the PbS–OLA NPs. The origin of the differences in the exciton recombination decay rates is unknown, but it is speculated that it may be due to the ionic functionality of the DMPS ligand or to the different ligating atoms of the OLA and DMPS ligands. This study shows that MEG dynamics can be tuned by changing the NP ligand shell, which may have implications for the development of NP-based efficient thin-film solar devices.

(30) Whereas the PbS–OLA particles did not exhibit signs of photooxidation during the laser studies, it is possible they might have undergone oxidation prior to the laser studies and prior to ligand exchange. It is also possible that having pre-oxidized particles during the ligand exchange facilitates the oxidation of the ligand or prevents satisfactory passivation of the NPs, leading to the precipitation of the NPs. During the course of our investigation, it was reported by Klimov and co-workers[27] that oxidation of the NP core has a slight effect on MEG dynamics. In the same manner, if oligosulfide formation of the DMPS ligand occurs because of oxidation then a coordination site (or dangling bond) can open up on the surface of the particle. Both the oxidation of the NP core and the presence of dangling bonds can contribute to electron-trapping states on the NP surface. Correcting for a trapping factor in such a case provides a better assessment of true MEG yields.

Abstract: The generation of diarylmethyl carbocations within non-protic zeolites (LiY, NaY, KY, RbY, CsY, and NaX) was carried out via laser excitation (266 nm or 266 nm / 308 nm) of diarylacetic acids. Rapid loss of CO_2, followed by photochemical oxidation of the diarylmethyl radicals resulted in the formation of the diarylmethyl carbocations. The reactivity of the diarylmethyl carbocations was found to be highly dependent on the alkali metal counterion and the Si/Al ratio of the zeolite framework. Furthermore, the effect of various para-electron donating substituents (4-H, 3-CH_3, 4-CH_3, 4,4′-CH_3, and 4-OCH_3) on the diarylmethyl carbocation reactivity was investigated. Comparison of the Hammett plots constructed for the reactivity of the diarylmethyl carbocations in zeolites with those in solution (CH_3CN–H_2O (1:2) and TFE) showed decreased sensitivity of the electrophilic species towards para-electron donating substituents in the heterogeneous media. The leveling effect observed in the zeolite Hammett plots has been attributed to the presence of an isokinetic relationship, specifically, a low isokinetic temperature for the reaction of diarylmethyl carbocations with the aluminosilicate zeolite framework.

Key words: zeolites, cation-exchanged Y, reactivity, carbocation, linear free energy relationships, Hammett plots, isokinetic temperatures.

Résumé : On a procédé à la génération de carbocations diarylméthyles dans des zéolites non protiques (LiY, NaY, KY, RbY, CsY et NaX) en effectuant une excitation laser (266 nm ou 266 nm / 308 nm) d'acides diarylacétiques. La perte rapide de CO_2, suivie par l'oxydation photochimique des radicaux diarylméthyles conduit à la formation des carbocations diarylméthyles. On a trouvé que la réactivité des carbocations diarylméthyles dépend beaucoup du contre-ion du métal alcalin et du rapport Si/Al du squelette du zéolite. De plus, on a étudié l'effet de divers substituants para électrodonneurs (4-H, 3-CH_3, 4-CH_3, 4,4′-CH_3 et 4-O-CH_3) sur la réactivité du carbocation diarylméthyle. Une comparaison des courbes de Hammett obtenues à partir de la réactivité des carbocations diarylméthyles dans des zéolites avec celles obtenues en solution (CH_3CN–H_2O (1 : 2), TFE) permet d'observer une diminution de la sensibilité des espèces électrophiles vis-à-vis des substituants para électrodonneurs en milieu hétérogène. L'effet de nivellement observé dans les courbes de Hammett pour le zéolite est attribué à la présence d'une relation isocinétique, spécifiquement une température isocinétique basse pour la réaction des carbocations diarylméthyles avec le squelette aluminosilicate du zéolite.

Mots-clés : zéolites, Y à cation échangé, réactivité, carbocation, relations linéaires d'énergie libre, courbes de Hammett, températures isocinétiques.

Introduction

Zeolites are crystalline aluminosilicate materials comprised of a network of $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra arranged in a fashion that gives rise to a highly organized network of microscopic voids in the form of channels or cavities.[1–6] Because of the tetravalent character, each aluminum atom in the zeolite framework possesses a negative charge that is often counterbalanced by small monovalent[1,3,5–7] or divalent cations,[5,8–10] such as the alkali metal cations (M^+ = Li^+, Na^+, K^+, Rb^+, or Cs^+), creating a non-protic polar environment that contains both Lewis acid[1,5,7,8,11–13] and base sites.[3,8,11,14,15] The polarity of the intrazeolite environment and the ability of the framework to restrict diffusional motion are fundamental characteristics that have been exploited in the development of zeolites as a host environment for the study of short-lived reactive intermediates.

The use of zeolites to study carbocation intermediates has been well-known over the past several decades, with most cases focusing on the study of these electrophilic species in Brönsted acid zeolites (M^+ = H^+).[16–21] More recently, xanthylium,[22] cumyl,[11,23] and fluorenyl[24,25] carbocations have been generated and their reactivities studied when contained within the framework cavities of non-protic cation-exchanged

zeolites. Studying the reactivity of short-lived carbocations within the cavities of non-protic zeolites presents an opportunity to investigate how variables such as zeolite basicity/nucleophilicity affect the reactivity and decay of these species.[11] Furthermore, non-protic zeolites have been shown to exhibit enhanced Lewis base properties that are highly dependent on the framework charge-balancing cations, as well as the Si/Al ratio of the solid support.[1,3,7,8] The active Lewis base sites, which have been implicated in the decay of reactive carbocations, are attributed to the nucleophilic framework oxygens of the [Al–O–Si]$^-$ bridge.[3,11,14,26,27] Smaller alkali metal counterions (e.g., Li^+ or Na^+) strongly interact with the active Lewis base sites, reducing the nucleophilicity of the zeolite framework and resulting in increased lifetimes of zeolite-encapsulated carbocations, whereas the larger counterions (e.g., Rb^+ or Cs^+) provide for a more nucleophilic environment and enhanced reactivity.

In the present work, the reactivity of a series of diarylmethyl carbocations are studied as a function of aryl substituent and zeolite composition. The diarylmethyl carbocations were generated by laser flash photolysis of the corresponding diarylacetic acids[28,29] within the cavities of cation-exchanged zeolites (Scheme 1). The absorption properties and reactivity of the carbocations investigated in this work have been thoroughly studied in homogenous solution.[29–36]

Of particular interest is the influence of the intrazeolite environment on the substituent effects for the carbocation decay within the zeolite environment. Previous work in our group has suggested that the decay of carbocations generated within the confines of non-protic zeolites is less sensitive towards substituents effects as compared with those same carbocations when generated in polar–protic solvents.[24,37] Using a more complete series of diarylacetic acids for the generation of aryl-substituted diarylmethyl carbocations allowed for a larger range of carbocation reactivity to be studied within the zeolite framework. This larger data set, along with temperature studies, has assisted in the development of a possible rationale for the zeolite leveling effect on carbocation reactivity.

Results

Diarylmethyl carbocations in alkali-metal-cation-exchanged zeolites

Laser irradiation with 266 nm excitation of di-*p*-tolylacetic acid (4,4′-$(CH_3)_2$D(COOH)) incorporated in zeolite NaY under evacuated conditions resulted in the formation of two well-defined transient absorption bands located at 340 and 470 nm (Fig. 1*a*). These absorption bands closely resemble those for the di-*p*-tolylmethyl radical (4,4′-$(CH_3)_2D^•$) at 340 nm and the di-*p*-tolylmethyl cation (4,4′-$(CH_3)_2D^+$) at 470 nm previously identified upon laser excitation of di-*p*-tolylmethylchloride in acetonitrile[30] and di-*p*-tolylmethane in MY zeolites.[38] Further support for the identification of the 340 nm band to a carbon-centred radical is the complete quenching of the band when molecular oxygen is added to the dry zeolite – organic composite prior to laser irradiation. The transient absorption band at 470 nm, which is identified as 4,4′-$(CH_3)_2D^+$, displays characteristics typical for a reactive carbocation generated within a dry cation-exchanged zeolite cavity. The transient decay is not influenced by the addition of molecular oxygen to the zeolite sample, but the rate constant for the decay significantly accelerates upon the introduction of nucleophiles such as co-absorbed water.

The decay of 4,4′-$(CH_3)_2D^+$ in dry NaY at room temperature is shown in Fig. 2. As is typical for reactions in zeolites, the decay did not fit to a single first-order expression, reflecting the heterogeneous environments within the zeolites cavities in which the carbocations react. In the present case, the decay did fit well to a double first-order (or bi-exponential) rate expression consisting of a fast component that decayed with a rate constant of 4.8×10^4 s^{-1} and a slow component with a rate constant of 5.3×10^3 s^{-1}. The fact that the decay fit well to a bi-exponential expression suggests that the cations exist in two distinct environments within the zeolites and indicates that the simple bi-exponential model is adequate in describing the rate constants for the decay of the carbocations studied in the present work.

Similar results to those described previously were observed upon 266 nm laser excitation of 4,4′-$(CH_3)_2$(COOH) incorporated within dry evacuated LiY, KY, RbY, and CsY. In each case, the transient absorption spectra contained two strong absorption bands, one centred at 340 nm owing to 4,4′-$(CH_3)_2D^•$ and the second centred at 470 nm owing to 4,4′-$(CH_3)_2D^+$. Rate constants for the decay of the 4,4′-$(CH_3)_2D^+$ within the cation-exchanged zeolites were determined by fitting the decays to a bi-exponential rate expression, and these rate constants are summarized in Table 1. The reactivity of 4,4′-$(CH_3)_2D^+$ increased as the size of the zeolite counterion increased from Li^+ to Cs^+, which is consistent with the greater nucleophilic environment provided by CsY as compared with LiY. In addition to the larger rate constants upon going from LiY to CsY, the relative amount of carbocation compared with radical decreased. Thus, in LiY, both the carbocation and radical absorptions were similar in amplitude, but, in CsY, the radical signal dominated.

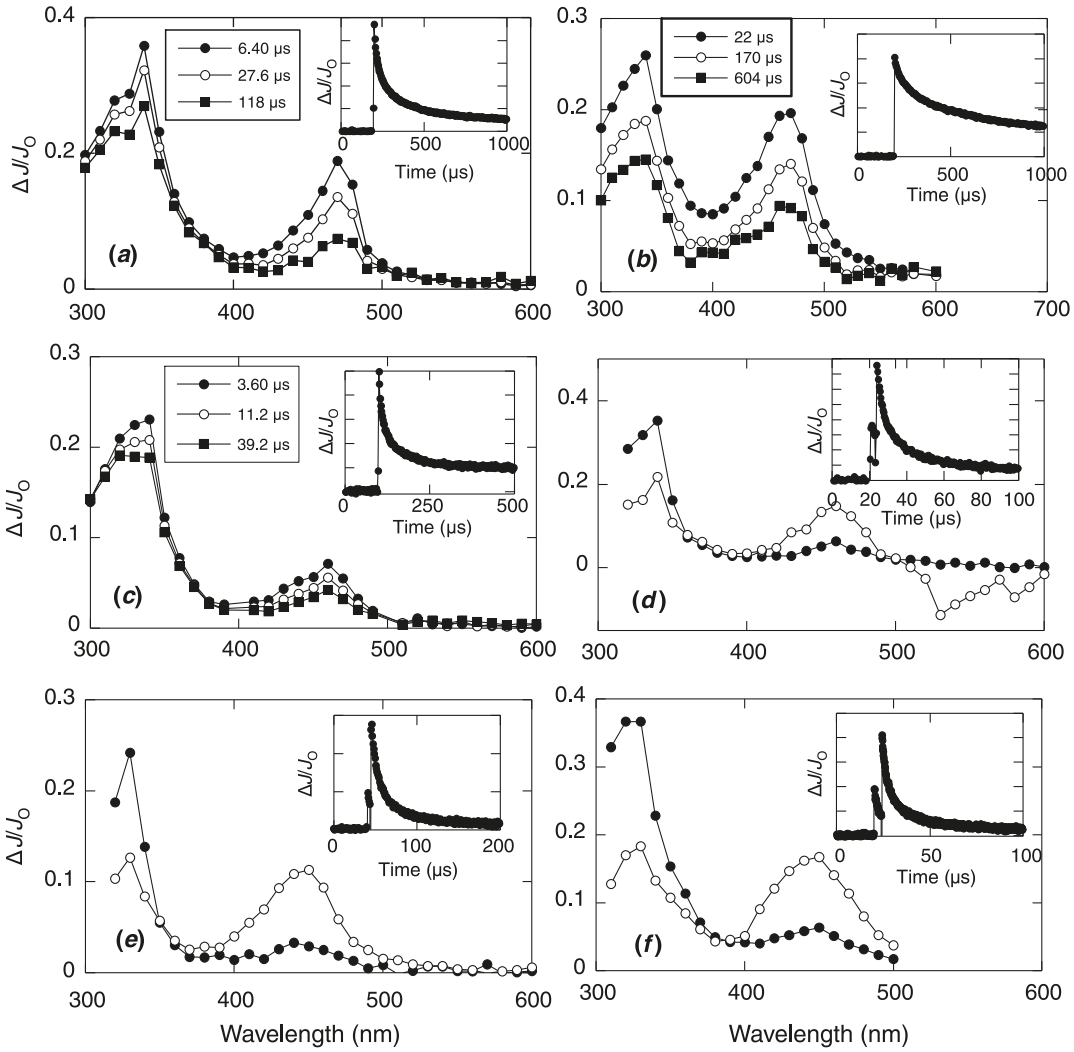
Fig. 1. Transient diffuse reflectance spectra generated following 266 nm laser flash photolysis of (*a*) di-*p*-tolylacetic acid, (*b*) *p*-anisylphenylacetic acid, and (*c*) *p*-tolylphenylacetic acid in dry NaY under evacuated conditions (1×10^{-3} Torr (1 Torr = 133.322 Pa)). Transient diffuse reflectance spectra generated following two-laser two-colour laser flash photolysis (at 266 nm (●) and at 308 nm (○)) of (*d*) *p*-tolylphenylacetic acid in evacuated KY and (*e*) diphenylacetic acid and (*f*) *m*-tolylphenylacetic acid in evacuated NaY. Insets show the decay of the respective carbocations at their absorption maximum.



Laser irradiation of *p*-anisylphenylacetic acid (4-(OCH_3)D(COOH)) in dry, evacuated NaY produced the transient absorption spectra shown in Fig. 1*b*. The spectra shows the presence of two strong absorption bands, one centred at 340 nm owing to the *p*-anisylphenylmethyl radical[30,38] (4-(OCH_3)D•) and the second centred at 460 nm owing to the *p*-anisylphenylmethyl cation[30,38] (4-(OCH_3)D^+). The band at 340 nm was rapidly quenched upon the addition of oxygen to the zeolite sample, in agreement with the identification of the transient to a radical species. In addition, the reactivity of the band at 460 nm was significantly enhanced upon co-absorption of water, consistent with the identification of the band as the carbocation. Under dry evacuated conditions at room temperature, the decay of 4-(OCH_3)D^+ fit well to a bi-exponential rate expression, giving fast and slow decay rate constants of 2.5×10^4 and 2.6×10^3 s^{-1}, respectively.

The *p*-anisylphenylmethyl cation was also readily generated in the other cation-exchanged zeolites (LiY, KY, RbY, and CsY) upon 266 nm laser excitation of 4-(OCH_3)D(COOH) under dry evacuated conditions. As was the case for the di-*p*-tolylmethyl cation, the rate constant for the decay of the *p*-anisylphenylmethyl cation increased going from LiY to CsY, as expected for a carbocation incorporated within the cavities of the cation-exchanged Y zeolites. Furthermore, the relative yield of the carbocation formation compared with radical formation decreased moving from LiY to CsY. Rate constants for the decay of 4-(OCH_3)D^+ in the cation-exchanged zeolites are given in Table 1.

Laser irradiation of *p*-tolylphenylacetic acid (4-(CH_3)D(COOH) incorporated within dry, evacuated NaY produced the transient absorption spectra shown in Fig. 1*c*. Similar to the other substrates, the transient spectrum shows the presence of two absorption bands. The transient absorption band centred at 340 nm is assigned to the *p*-tolylphenylmethyl radical (4-(CH_3)D•) on the basis of the band's close similarity to that of the known absorption spectrum for the radical, and in a similar manner the longer wavelength band

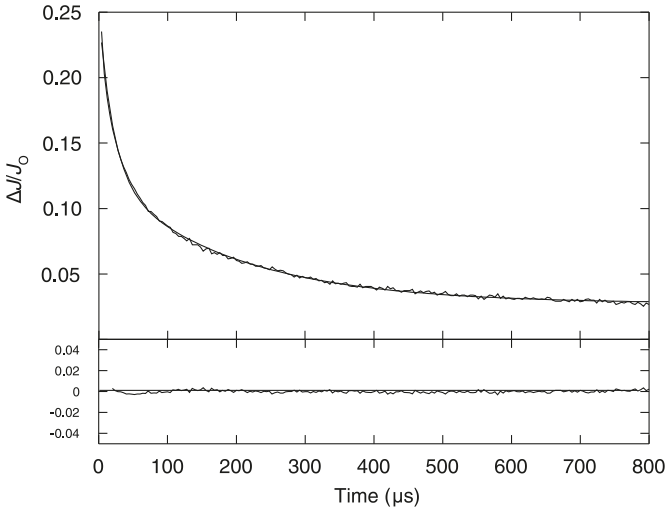
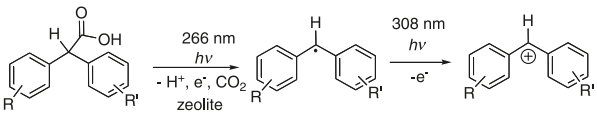
Fig. 2. Time-resolved change in absorption at 470 nm after 266 nm laser irradiation of di-*p*-tolylacetic acid in dry evacuated NaY. The experimental data and line-of-best fit obtained using a bi-exponential equation are shown in the upper segment of the graph and the lower segment shows the residuals.



centred at 460 nm is assigned to the monosubstituted *p*-tolylphenylmethyl cation (4-$(CH_3)D^+$).[30] The intensity of the carbocation band at 460 nm is considerably weaker than that for the radical at 340 nm. As well, the carbocation decayed with fast and slow components, 1.2×10^5 and 1.5×10^4 s^{-1}, respectively (Table 1), which are considerably greater than those observed for the more stabilized di-*p*-tolylmethyl and *p*-anisylphenylmethyl carbocations.

Laser irradiation of 4-$(CH_3)D(COOH)$ incorporated within dry evacuated LiY produced very similar results to those in NaY, and the rate constants for decay in LiY are listed in Table 1. However, in dry evacuated KY, RbY, and CsY, only the radical at 340 nm was observed, with little evidence for carbocation formation at 460 nm. To enhance the yield of carbocation formation within these more nucleophilic and less ionizing cation-exchanged zeolites, two-laser two-colour experiments were conducted. In these experiments, the incorporated acid was subjected to 266 nm laser excitation in the usual way. However, within a short time period, typically ~6 μs, after the initial 266 nm laser pulse a second laser pulse at 308 nm was directed onto the sample to selectively excite the diarylmethyl radical and cause a rapid photoionization to yield the corresponding carbocation (eq. [1]).

[1]



As shown in Fig. 1*d*, a 308 nm laser pulse delivered to the sample just after 266 nm irradiation of 4-$(CH_3)D(COOH)$ in KY caused bleaching of the *p*-tolylphenylmethyl radical signal at 340 nm and increased absorption at 460 nm owing to the formation of the *p*-tolylphenylmethyl carbocation by photoionization of the radical. Strong fluorescence from the excited diarylmethyl radical is also observed between 500 and 600 nm.[28,29,39,40] This fluorescence signal was short-lived and did not influence the kinetics of the carbocation decay taken at ~450 nm. In this manner the yield of 4-$(CH_3)D^+$ in all the cation-exchanged zeolites was sufficiently large for the carbocation decay within the MY zeolites to be accurately determined. Slow and fast components of the rate constants for the decay of the 4-$(CH_3)D^+$ in the cation-exchanged zeolites are given in Table 1.

Laser irradiation (266 nm) of diphenylacetic acid (D(COOH)) incorporated within dry evacuated NaY produced the transient absorption spectrum shown in Fig. 1*e* (●), which features a strong band owing to the diphenylmethyl radical ($D^\bullet$) at 330 nm and a much weaker band at 450 nm owing to the diphenylmethyl cation (D^+). Subsequent 308 nm laser irradiation strongly enhanced the cation signal (Fig. 1*e*, ○) so that reliable kinetic data could be obtained. Again, the decay of the cation fit well to a bi-exponential expression giving rate constants for fast and slow components of 3.1×10^5 and 5.1×10^4 s^{-1}, respectively. Two-colour two-laser experiments were also employed for generation of D^+ in the LiY, KY, RbY, and CsY zeolites. In each case, 308 nm laser excitation of the diphenylmethyl radical $D^\bullet$ generated by the initial 266 nm laser pulse led to the formation of the diphenylmethyl cation D^+ in sufficient yields so that rate constants could be readily obtained (Table 1).

Similar results were found upon irradiation of *m*-tolylphenylacetic acid (3-$(CH_3)D(COOH)$). Two-colour two-laser experiments were carried out in all five of the cation-exchanged zeolites to produce a high enough yield of the *m*-tolylphenylmethyl cation (3-$(CH_3)D^+$) for accurate kinetic analysis. The spectra generated upon two-colour two-laser excitation of 3-$(CH_3)D(COOH)$ in dry NaY are shown in Fig. 1*f*, where 3-$(CH_3)D^+$ at 450 nm can be readily seen. 3-$(CH_3)D^+$ decayed quickly in NaY with fast and slow components of 4.0×10^5 and 6.0×10^3 s^{-1}, respectively. Rate constants for the decay of 3-$(CH_3)D^+$ in the MY zeolites are also given in Table 1.

The five diarylacetic acids were also irradiated in NaX. In each case, the transient spectra included a band near 340 nm that is consistent with the formation of the diarylmethyl radicals. A band corresponding to a diarylmethyl cation was also observed upon irradiation of di-*p*-tolylacetic acid, *p*-anisylphenylacetic acid, and *p*-tolylphenylacetic acid in NaX, either by simple 266 nm or two-colour two-laser excitation, but no carbocation absorption was detected from diphenylacetic acid and *m*-tolylphenylacetic acid. The decays of the detectable carbocations fit well to a bi-exponential rate law, giving the rate constants included in Table 1. As expected, owing to the higher nucleophilicity of NaX, the rate constants for the decays of the carbocations in NaX are all considerably larger than those obtained in NaY.

Temperature study

Rate constants for the decay of the five substituted diarylmethyl carbocations were investigated as a function of temperature in the five cation-exchanged MY zeolites and in NaX. For each carbocation the decay rate constant was measured at a minimum of six different temperatures. In each case, the decays were fit to a bi-exponential rate expression, with attention being focused on the effect of temperature on the fast component. Representative data for the diarylmethyl carbocation in NaY are given in Table 2. As

well, lifetime distribution plots over several timescales were constructed at the various temperatures, and the rate constants for the fast component were calculated using the exponential series method (ESM).[41] This process was carried out for each of the kinetic profiles to ensure consistency in data analysis and also to confirm that the data extracted from the bi-exponential fits were comparable to the numbers collected from the ESM plots. In most cases the rate constants for the fast component calculated using the two methods were closely similar. However, at low temperatures, the ESM gave more reproducible results than the bi-exponential fit, and in these cases the rate constants determined using ESM were used.

Determination of activation parameters for the decay of diarylmethyl cations in zeolites

The activation parameters for the intrazeolite behaviour of the diarylmethyl carbocations were determined using the Eyring equation (eq. [2]).

$$[2] \qquad \ln\left(\frac{k_{decay}}{T}\right) = \ln\left(\frac{k_B}{h}\right) + \frac{\Delta S^{\neq}}{R} + \frac{\Delta H^{\neq}}{RT}$$

where k_{decay} is the decay rate constant, T is the temperature, k_B is the Boltzmann constant, h is Planck's constant, $\Delta S^{\neq}$ is the entropy of the reaction, $\Delta H^{\neq}$ is the enthalpy of the reaction, and R is the gas constant. An Eyring plot of $\ln(k_{decay}/T)$ vs $1/T$ results in a straight line, where $\Delta H^{\neq}$ and $\Delta S^{\neq}$ can be obtained from the slope and intersect of the graph, respectively. Representative Eyring plots constructed from the rate constants for the decay of the diarylmethyl carbocations in KY are given in Fig. 3. The activation parameters for the diarylmethyl carbocations studied in this work in the NaY, KY, RbY, and CsY zeolites and NaX are summarized in Table 3.

Substituent effects

Whereas the intrazeolite environment has been shown to be an important factor in determining the reactivity of encapsulated diarylmethyl carbocations, substituent effects on the diarylmethyl carbocations must also be considered to fully explain the reactivity of these species within the zeolite cavities. Hammett plots were constructed to evaluate the substituent effects experienced by the diarylmethyl carbocation in NaY, KY, RbY, CsY, and NaX at four different temperatures. Representative plots are shown in Fig. 4 for data obtained at 299 K. Data for the effect of substituents on the decay of the same carbocations in CF_3CH_2OH (TFE)[36] and CH_3CN–H_2O (1:2)[33] are also included in Fig. 4.

The slopes of these plots (ρ^+) represent the sensitivity of the reaction to substituents, and values of ρ^+ obtained for reaction of the diarylmethyl cations in the five zeolites at four different temperatures are summarized in Table 4.

Discussion

In the present work, diarylmethyl carbocations were generated by laser flash photolysis of the corresponding diarylacetic

acids. The proposed mechanism for carbocation formation is shown in Scheme 2. Upon incorporation of the carboxylic acid into the zeolite framework, the acid undergoes an equilibrium deprotonation reaction to form the corresponding carboxylate ion. This is consistent with other deprotonation reactions for similar carboxylic acids in cation-exchanged zeolites.[22] Laser flash photolysis using 266 nm excitation of the carboxylate ion then results in the photochemical generation of the acyloxy radical, which undergoes a rapid loss of CO_2 (>10^8 s^{-1}) to form the diarylmethyl radical.[42–44] A subsequent photoionization of the carbon-centred radical either with the same laser pulse (266 nm) or with a second-colour second-laser pulse (308 nm) efficiently oxidizes the diarylmethyl radical to the corresponding diarylmethyl carbocation. The presence of the fluorescence on short timescales from excited diarylmethyl radicals between 530 and 580 nm in the transient spectra also supports the proposed radical photoionization mechanism.

Sufficient amounts of the more stabilized carbocations, such as 4,4′-$(CH_3)_2D^+$ and 4-$(OCH_3)D^+$, were generated for kinetic analysis using a single 266 nm laser pulse. Presumably, the yield of ionization from the small quantity of excited radicals generated by sequential absorption of 266 nm light from a single laser pulse was high enough for the production of adequate amounts of the carbocations. On the other hand, for the less stabilized carbocations, especially those in the less ionizing zeolites like KY, RbY, and CsY, the yield of ionization from the excited radical generated in a single 266 nm laser pulse was too low for adequate formation of the carbocations. In those cases, the second, 308 nm laser pulse was able to generate a far greater quantity of excited radical so that even inefficient ionization from the excited state still led to the formation of suitable amounts of carbocation for kinetic analysis.

The effect of zeolite nucleophilicity on the decay of diarylmethyl carbocations

The results presented in Table 1 clearly show that the reactivity of diarylmethyl carbocations is strongly influenced by the nucleophilicity of the intrazeolite environment. Notably, a systematic increase in reactivity of the diarylmethyl carbocations is observed upon varying the alkali-metal counterion from Li^+ to Cs^+. The Lewis basicity, or electron-donating ability, of the zeolite framework is highly influenced by the alkali-metal counterion, in particular the ionic interactions that occur between the counterion and the framework oxygens of the $[Si–O–Al]^-$ backbone. Small hard cations, such as Na^+, have stronger interactions with the active sites in the zeolite backbone than larger soft counterions, such as Cs^+. The weaker attractive force experienced between the softer counterions and the $[Si–O–Al]^-$ sites often translates into a more basic zeolite framework and stronger nucleophilic interactions between the framework oxygens and encapsulated electrophilic guests. The enhanced reactivity of the diarylmethyl carbocations can be readily illustrated by the ~20-fold increase in the rate constant for the decay of the di-*p*-tolylmethyl carbocation in CsY as compared with in NaY. A similar trend was observed for the *p*-anisylphenylmethyl, *p*-tolylphenylmethyl, diphenylmethyl, and *m*-tolylphenylmethyl carbocations, where 18-, 12-, 6- and 3-fold increases in reactivity were noted going from NaY to CsY. The decays of the photogenerated diarylmethyl carbocations in LiY were found to be slightly faster than expected. This increase in reactivity in LiY can be attributed to increased amounts of intrazeolite water present within the highly hydroscopic LiY, which increases the reactivity of the diarylmethyl carbocations generated within this intrazeolite environment.

The Si/Al ratio also influences the reactivity of zeolite-encapsulated diarylmethyl carbocations. For example, the rate constant for the decay of the di-*p*-tolylmethyl carbocation increases by a factor of 20 on going from NaY to NaX. NaX has an increased number of $[Si–O–Al]^-$ bridges, which provides a greater number of active nucleophilic sites (as compared with NaY) and a more nucleophilic zeolite environment. The increased reactivity of the diarylmethyl carbocations in NaX is consistent with the mechanism for carbocation decay that involves nucleophilic attack of the zeolite backbone onto the electrophilic cationic centre[14,45–47] and is in agreement for the decay of other reactive carbocation within cation-exchanged zeolites.[11,24,25]

Temperature effects

The data in Table 3 show an increase in the enthalpy of activation with more electron-rich *p*-aryl substituents. For example, for the more reactive diphenylmethyl carbocation in NaY, $\Delta H^{\neq}$ is 26 kJ/mol. However, substitution of the aryl ring with an electron-donating *p*-OCH_3 group more than doubles the $\Delta H^{\neq}$ for the reaction between the carbocations to 60 kJ/mol. The entropy of activation also increases with increasing electron-donating ability of the *p*-aryl substituents in NaY. This effect is again large, with the entropy of activation increasing by almost 100 J K^{-1} mol^{-1} upon going from the unsubstituted diphenylmethyl carbocation to the 4-OCH_3 derivative, and also changing from a negative to a positive value. Similar results are observed in the other MY zeolites. In all cases, $\Delta H^{\neq}$ more than doubles upon going from D^+ to (4-OCH_3)D^+. In addition, the values for $\Delta S^{\neq}$ decrease, although the decrease is smaller in KY,

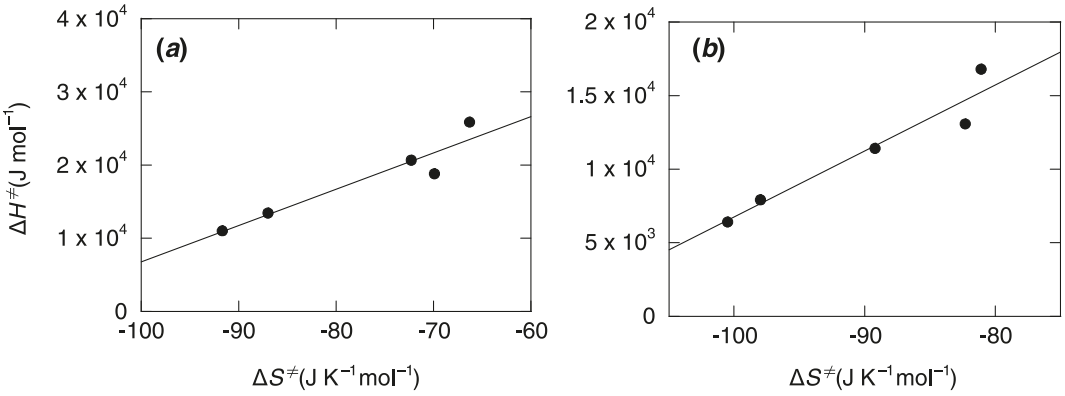
Fig. 5. Enthalpy–entropy compensation plots for the decay of di-*p*-arylmethyl carbocations in (*a*) KY and (*b*) CsY at temperatures ≤299 K.



RbY, and CsY compared with NaY, and in some cases within the sum of the standard errors in $\Delta S^{\neq}$. Thus, the data show electron-donating substituents cause an increase in both the enthalpy and entropy of activation. The increase in $\Delta H^{\neq}$ serves to slow the reaction, whereas an increase in $\Delta S^{\neq}$ causes a faster reaction. Therefore, the observation that the reaction slows in the presence of electron-donating groups indicates that the effect of the substituents on the overall reactivity of diarylmethyl carbocations is driven by changes to the activation enthalpy and not the entropy of activation.

Substituent effects and isokinetic temperatures

From the ρ^+ values listed in Table 4 for the decay of diarylmethyl carbocations in TFE, CH_3CN–H_2O (1:2) and MY zeolites at 299 K, it is evident that the decay of the carbocations is substantially more sensitive to the effects of *p*-aryl substituents when formed in TFE and CH_3CN–H_2O solvents than when encapsulated within MY zeolites. For example, the ρ^+ value obtained in TFE (ρ^+ = 4.2) is more than two times the corresponding value in NaY (ρ^+ = 1.43). Even when compared with the more nucleophilic CH_3CN–H_2O (1:2) solvent mixture (ρ^+ = 3.1), the ρ^+ values in alkali-metal cation-exchanged X and Y zeolites, ranging from a low of ρ^+ = 0.7 to high of ρ^+ = 1.4 (at 299 K), are still significantly smaller. These results indicate that the intrazeolite environment tends to cause a "leveling effect" on the sensitivity of diarylmethyl carbocations towards the *p*-aryl substituent when formed within the confines of a solid support.

One possible explanation for the leveling effect is that the confines of the zeolite cavities force the aromatic rings to rotate relative to the empty p orbital of the carbocation centre, thus reducing the influence of the substituents on the aromatic ring. However, the data in Table 4 clearly show a sizeable increase in ρ^+ with decreasing temperature, indicating that the diarylmethyl carbocations in the MY zeolites are sensitive towards the electronic effects of the *p*-aryl substituents at low temperatures. This sensitivity to substituents at low temperatures argues against reduced coplanarity of the rings with the empty p orbital as being the main source of the leveling effect, although it still may play a secondary role.

On the other hand, the observed sensitivity of ρ^+ to temperature and the shallow Hammett plots that give small ρ^+ values are results that have, for other reactions, been attributed to low isokinetic temperatures (IKT).[48–53] Thus, an alternative explanation for the leveling effect observed in the reaction of substituted diarylmethyl cations in the zeolites is the presence of an unusually low IKT.[54,55]

To explore the possibility that the reactions of the diarylmethyl cations feature a low IKT, several methods were employed to determine the presence of an isokinetic relationship and the value of an IKT. One of the simplest methods is based on a linear relationship between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ where the slope (β) is the corresponding IKT (eq. [3]).[49,54–59]

$$[3] \qquad \Delta H^{\neq} = \beta \Delta S^{\neq}$$

Figure 5 presents the enthalpy–entropy compensation plots constructed for the decay of diarylmethyl carbocations in KY and CsY. From these graphs, it is evident that the enthalpies and entropies of activation are complementary. Furthermore, analysis of the slopes of the linear fits produced values considered to be an approximation of the IKT for the reaction of the diarylmethyl carbocations with the $[Si–O–Al]^-$ framework. Table 5 presents the estimated IKTs in NaY, KY, RbY, CsY, and NaX as calculated from the linear fit. All of the values extracted from the enthalpy–entropy plots give low IKTs, ranging from lows of 333 to 360 K for reaction in NaX and NaY, respectively, to a high of 513 K for reaction in CsY.

The presence of an isokinetic relationship is also typically visible in Eyring plots, where the presence of a common point of intersection can be estimated to be the IKT for the organic reaction of interest.[60] Figures 6*a* and 6*b* depict the Eyring plots for the intrazeolite decay of the diarylmethyl carbocations in NaY and CsY. A distinct point of intersection can be seen in each plot. The Eyring plots constructed for the decay of the diarylmethyl carbocations in KY, RbY, and NaX also present a point of intersection, supporting the presence of an isokinetic relationship for the decay of diarylmethyl carbocations in non-protic zeolites. *F* value statistical calculations were also undertaken to validate the IKT (or point of intersection) observed in each Eyring plot.[60] Like the approximate IKTs obtained from the compensation plots, the values calculated from the Eyring plot / F-statistic method were also low. The average IKTs calculated using these methods are presented in Table 5. The IKTs for the decay of diarylmethyl carbocations in alkali-

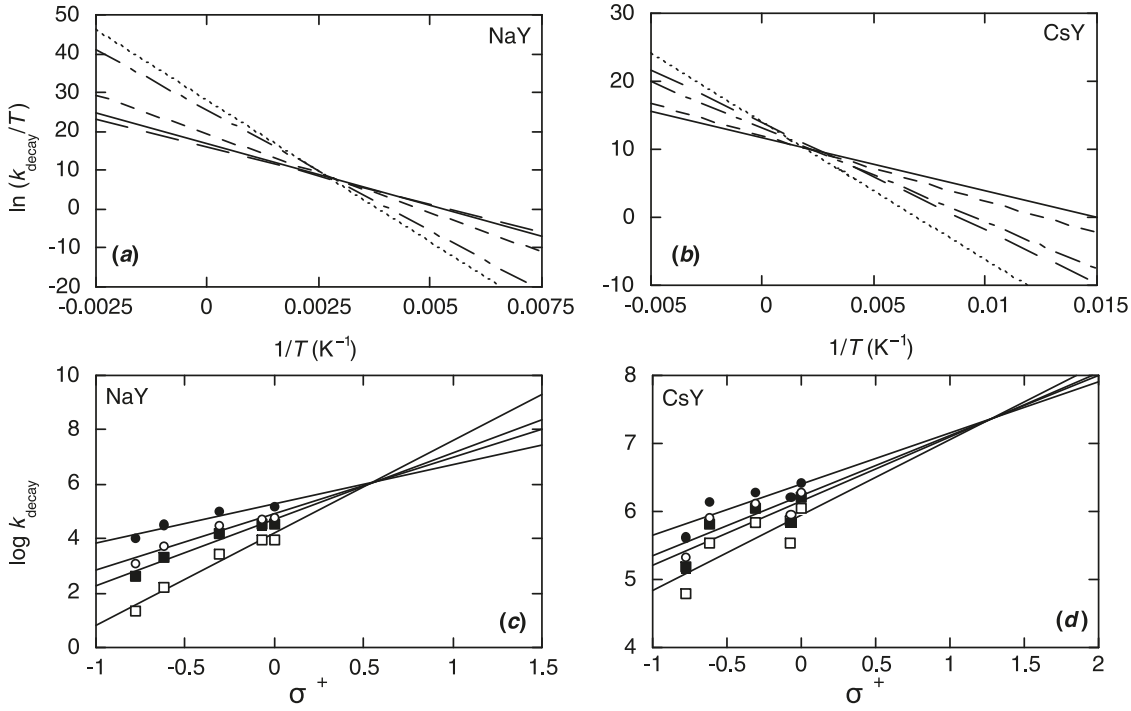
Table 5. Isokinetic temperatures (IKT) for the decay of diarylmethyl cations in alkali metal cation-exchanged X and Y zeolites.

	IKT		
Zeolite	$\Delta H^{\neq}$ vs $\Delta S^{\neq}$ (K)	Eyring/F statistic (K)	Avg. (K)[a]
NaY	360	366	363±4
KY	497	505	501±4
RbY	482	518	500±18
CsY	511	520	515±5
NaX	333	345	339±6

Note: Standard deviation ≤20%.

[a]Errors were calculated using the standard deviation of the two values collected.

Fig. 6. Extended Eyring plots for the decay of the diphenylmethyl (—), *m*-tolylphenylmethyl (– –), *p*-tolylphenylmethyl (— —), di-*p*-tolylmethyl (- — -), and *p*-anisylphenylmethyl (- -) cations in (*a*) NaY and (*b*) CsY at temperatures ≤299 K. Extended Hammett plots for the decay of di-*p*-arylmethyl carbocations in (*c*) NaY and (*d*) CsY at 299 K (●), 274 K (○), 264 K (■), and 239 K (□).



metal cation-exchanged Y zeolites were estimated to be between 345 and 518 K.

A reaction series that exhibits a common point of intersection in the Eyring plots will commonly present a common point of intersection in the Hammett plot as well.[48,49] The Hammett plots constructed for the decay of the diarylmethyl carbocations in NaY and CsY are presented in Figs. 6*c* and 6*d*. The point of intersection occurs at σ^+ = 0.58 for NaY and σ^+ = 1.23 in CsY. A carbocation possessing a substituent parameter equivalent to the point of intersection will have identical reactivity at all temperatures, commonly referred to as the isokinetic substituent. The low-temperature Hammett plots presented in Fig. 6 can also be used to illustrate the increased sensitivity of the diarylmethyl carbocations towards *p*-aryl substituents with decreasing temperature, as is reflected by the ρ^+ values presented in Table 5.

From the data presented in Table 5, it is evident that the IKTs for the decay of diarylmethyl carbocations in alkali-metal cation-exchanged Y and NaX zeolites are much lower than 1000 K and fall well within a normal experimental range. Several accounts on the reactivity of diarylmethyl carbocations towards π nucleophiles[48,61,62] can be likened to the nucleophilic attack of the diarylmethyl carbocations by the active Lewis base sites in the zeolite framework. The IKT for the reaction of diarylmethyl carbocations with various alkenes is close to 700 K higher than the IKT for the reaction of the analogous electrophilic species in non-protic X and Y zeolites.

Based on the previous publications in solution and the current results obtained in non-protic zeolites, it seems reasonable to suggest that the observed leveling effect of the *p*-aryl substituent effects in zeolite-encapsulated diarylmethyl carbocations can be explained by the lower IKT for the reaction of diarylmethyl carbocations with the [Si–O–Al]$^-$ backbone. Though no experimental or theoretical technique

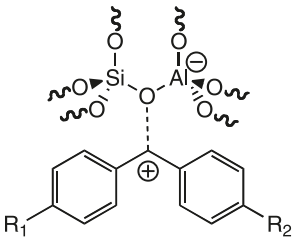
Scheme 3.



can predetermine the IKT for a given organic reaction, molecular complexation during the solvation process has been considered a determining factor for reactions with low IKTs [54]. Zeolites are commonly referred to as solid-state ionizing, solvents,[63] where co-encapsulated guest molecules undergo interactions with the aluminosilicate framework similar to solvation interactions in solution, as illustrated in Scheme 3. Thus, we propose that the solvation of the diarylmethyl carbocations in non-protic zeolites involves the formation of a framework-bound alkoxy adduct (Scheme 3).

Comparing the results obtained for the decay of the carbocations in NaY and NaX supports the solvation of the zeolite-encapsulated diarylmethyl carbocations as the potential source of the low IKTs. From the data presented in Table 5, it can be seen that the IKT for the decay of the diarylmethyl carbocations in NaX is an estimated 20 K lower than in NaY. The formation of a solvated cation would be more likely to occur within the confines of the more basic/nucleophilic environment of zeolite X based on the larger number of active base sites within this zeolite lattice.

Experimental

Materials

Diphenylacetic acid was commercially available (Sigma-Aldrich) and was used as received. The synthesis of di-*p*-tolylacetic acid,[64] *p*-tolylphenylacetic acid,[65] *p*-anisylphenylacetic,[65] and *m*-tolylphenylacetic acid[66,67] have been reported previously.

Zeolites

NaY (Si:Al = 2.4) and NaX (Si:Al = 1.3) were purchased from Sigma-Aldrich. All zeolites were activated in an oven at 450 °C for at least 12 h prior to use to ensure the removal of intrazeolite water. Alkali-metal cation-exchanged zeolites were prepared through aqueous ion exchange with the corresponding chloride salts (LiCl, KCl, RbCl, and CsCl) in the usual way.[11] The number of cations per unit cell of zeolite Y are 16 site I cations, 32 site II cations, and 8 site III cations. Only site II and site III cations are accessible to guest molecules.[7] The degree of cation exchange in Y zeolites is typically 47% for LiY, 97% for KY, 44% for RbY, and 47% for CsY. For larger cations, such as Rb^+ and Cs^+, only the Na^+ cations that occupy type II and type III sites can be readily exchanged.[68] Hydrated Li^+ does not readily exchange the type I cations, which results in a lower percent exchange. All solvents used during zeolite preparation were spectroscopic grade (99.98%, Omnisolv, BDH) and were used as received.

Sample preparation

The method of guest molecule incorporation into the zeolite was adapted from a procedure previously described.[69]

Laser flash photolysis

The computer-controlled ns laser flash photolysis system was employed in this study and has been previously described.[11] For one-laser irradiation experiments, the excitation source was the fourth harmonic (266 nm, ≤25 mJ, <8 ns/pulse) of a Nd:YAG laser. For the two-laser techniques, the first excitation source was the Nd:YAG 266 nm laser and the second was an excimer laser (308 nm, <70 mJ, 10 ns/pulse). Diffuse reflectance experiments involve measuring the fraction of reflected light absorbed by the transient, denoted as the reflectance change, $\Delta J/J_0$, where J_0 is the reflectance intensity before laser excitation and ΔJ is the change in reflectance intensity after excitation owing to absorption by photogenerated transients. Transient signals were directed into a monochromatic-photomulitipler tube system and subsequently captured using a digital oscilloscope and transferred to a computer controlled by software based on the Labview programming language. Samples contained in 3 mm × 7 mm quartz sample cells were used under reduced pressure or under oxygen-saturated conditions. Samples irradiated under an oxygen atmosphere were purged using high-purity molecular oxygen for a minimum of 20 min prior to laser flash photolysis.

Data analysis

Data analysis was based on the fraction of reflected light absorbed by the transient species, $\Delta J/J_0$. Owing to the large number of microenvironments found in the zeolite matrix, time-resolved kinetic spectra commonly contain multiple components. As such, the time-resolved decays of the transients investigated in this report fit well to bi-exponential first-order rate equations, rather than simple first-order expressions, unless otherwise reported.

The low-temperature time-resolved data was collected using a Thermo NESLAB CC-100 cooler, a NESLAB U-Tainer B thermostat, and a NESLAB Exatrol temperature control. To accurately determine the temperature conditions experienced by the solid-state samples, a sample probe was constructed that replicated the intrazeolite conditions. The temperature standard consisted of 300 mg of hydrated NaY zeolite placed into a 3 mm × 7 mm quartz sample cell. A digital thermometer was then securely placed into the heterogeneous material. The probe was placed into the cooled sample holder and allowed to equilibrate for 10–15 min, during which time the temperature reading on the thermometer stabilized. Following determination of the equilibrium experimental temperature, the sample to be studied was placed into the sample holder and allowed to equilibrate for the same amount of time as the temperature probe.

The rate constants for the decay of several of the more stable diarylmethyl carbocations were incomplete on the longest timescales of our ns laser flash photolysis apparatus, therefore, the corresponding rate constants were calculated from lifetime distribution plots. Rate constant distributions were calculated from transient decays using ESM.[41] The fitting function employed contained 200 exponential terms, which were fixed logarithmically spaced rate constants ranging

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

from 1 to 1 $\times$ 10^7 s^{-1} with variable pre-exponentials. Typically, three sets of rate constant distributions were revealed by ESM analysis of the transient decays. Each set of rate constant distributions was fit using nonlinear least-squares fitting to a Gaussian equation; the parameters from these fits were used to calculate the normalized area under each set of distributions. The rate constants were extracted from the lifetime data using a Gaussian fit.

Kinetic data used for the low-temperature Hammett plots were calculated using the Eyring activation parameters.

Supplementary data

Supplementary data (time-resolved spectral and kinetic data and low-temperature plots (enthalpy–entropy compensation, Eyring, and Hammett) are available with this article through the journal Web site (www.nrcresearchpress.com/cjc).

Fluorescence enhancement of amine-capped CdSe/ZnS quantum dots by thiol addition

Jordi Aguilera-Sigalat, Simon Rocton, Raquel E. Galian, and Julia Pérez-Prieto

Abstract: The present communication reports that while addition of alkyl thiols drastically reduces the fluorescence of CdSe core quantum dots, it actually enhances the emission properties of already highly fluorescent amine-capped CdSe/ZnS core-shell quantum dots.

Key words: CdSe/ZnS, core shell, fluorescence, ligand exchange, quantum dot.

Résumé : On montre dans ce travail que, alors que l'addition d'alkylthiols diminue d'une façon drastique la fluorescence des points quantiques d'un coeur CdSe, cette addition augmente en fait les propriétés d'émission de fluorescence déjà très élevées des points quantiques de la couche d'un coeur CdSe/ZnS chapeauté par une amine.

Mots-clés : CdSe/ZnS, couche d'un cœur, fluorescence, échange de ligand, point quantique.

[Traduit par la Rédaction]

Introduction

Quantum dots (QDs) have unique optical properties[1] that make them of interest for biological, medical, and engineering applications. They are highly fluorescent systems compared with organic dyes, though different factors, such as growth conditions, post-illumination treatment, the nature of the capping ligand, and storage conditions, seem to affect their fluorescence quantum yield (Φ_F). Some of these factors may induce the appearance of defects on the QD surface, producing an additional nonradiative pathway due to trapping of the electron or the hole generated after the absorption of light. To reduce the number of defects and, consequently, increase the Φ_F, good QD surface passivation is needed. This can be accomplished by adding an inorganic shell or using long-chain organic surfactants.[1]

With regard to using an inorganic shell as coating, a higher band gap material (ZnS, ZnSe, CdS) has been used to prepare core-shell QDs that have, in general, a much higher Φ_F.[2,3]

With respect to ligands, trioctylphosphine (TOP) and trioctylphosphine oxide (TOPO) are the most common ligands used in the synthesis of QDs.[1,2,4] However, the exchange of the phosphine ligands by fatty amines leads to an enhancement of the Φ_F of the resulting nanoparticle.[5] Functional thiol ligands have also been used as capping material to make QDs water-soluble and to add functionality to the nanoparticle.[6] Thiol ligands can replace TOPO and amine ligands and bind more strongly to the QD surface,[7,8] but such exchange decreases the Φ_F of CdSe core QDs.[5,8,9] This behavior has been attributed to the hole-trapping capacity of thiol molecules.[10]

Curiously, in the case of CdSe/ZnS core-shell QDs, where the shell should avoid the QD emission quenching by electron donors,[11] ligand exchange of TOPO by hydrophilic thiols to achieve water-soluble QDs also leads to a decrease in Φ_F. This has been explained by formation of thiolates in water, and such thiolates somehow add new hole trap states.[7,12]

To gain insight into the effect of thiols (rather than thiolates) on the fluorescence of organic-soluble core-shell QDs, we studied the QD emission in the presence of two model alkyl thiols: 11-mercapto-1-undecanol (MU) and a thiol functionalized with a benzophenone chromophore (KP-SH) (Scheme 1). For comparison purposes, studies using CdSe core QDs were also performed. We analyzed the influence of the native ligand (TOPO or TOP for CdSe and a long-chain amine for CdSe/ZnS) used as capping material, the QD size, and the thiol concentration on the variation of the QD fluorescence. Our results demonstrated that the CdSe and CdSe/ZnS QDs presented a different response to the addition of the assayed thiols.

Results and discussion

CdSe core QDs (QD-C) capped with TOPO and TOP ligands were synthesized according to the methodology reported by Peng and Peng.[4a] The size of the nanoparticles

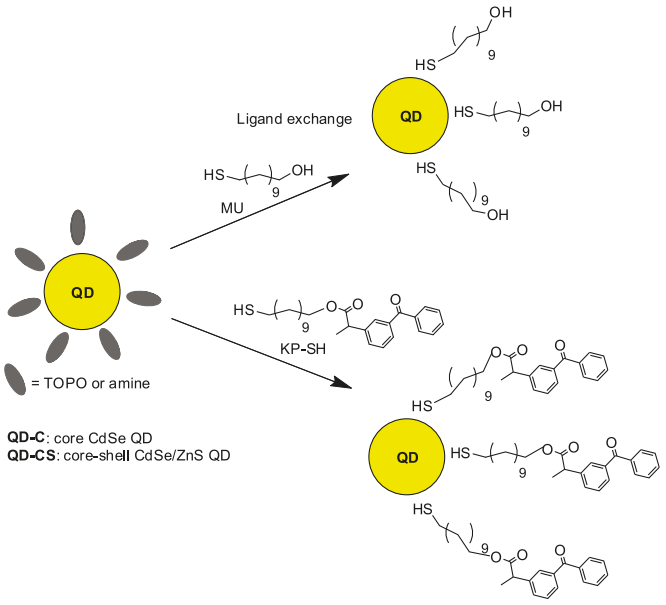
Scheme 1. Exchange of TOPO or TOP (core QDs) and amine (core-shell QDs) by thiol compounds.



was estimated using the maximum of the first exciton peak in the UV–vis spectrum[13]; thus, the maximum at 513 nm for QD-C1 was indicative of a diameter of 2.5 nm. High-resolution transmission electron microscopy images confirmed the size of the nanoparticle as well as the crystalline properties and monodispersity of QD-C1 (size 2.6 ± 0.4 nm). In addition, different commercial CdSe/ZnS core-shell QDs (QD-CS), capped with a long-chain primary amine, were used. All QDs were soluble in organic solvents such as toluene and chloroform.

The effect of different thiol (MU, KP-SH[14]) concentrations on the optical properties of the QDs was studied using steady-state absorption and fluorescence spectroscopy. The addition of thiol did not cause a significant change in either the maximum of the first exciton peak or the emission maximum of core and core-shell QDs (Table S1 in the Supplementary data). However, important fluorescence quenching was detected upon addition of MU (5 mmol/L) to a toluene solution of QD-C1 (2.9 µmol/L) with a thiol/QD concentration ratio of 1724 (Fig. 1, Table 1). Similarly, fluorescence quenching was detected after addition of KP-SH to QD-C1 ([thiol]/[QD] = 6200).

By contrast, when the MU/QD concentration ratio was as low as 540, the initial fluorescence quenching was followed by fluorescence enhancement (reaching a plateau after 90 min) and the appearance of a broad photoluminescence at a longer wavelength than the band edge luminescence (maximum approx. 700 nm, see Fig. 2). The latter luminescence could be ascribed to new surface states with emission properties.[15] Likewise, after addition of KP-SH in a KP-SH/QD molar ratio of 620, an initial fluorescence quenching was followed by a fluorescence enhancement (Fig. S2 in the Supplementary data; Table 1). Also, an emission at longer wavelengths than the band edge was observed.

Similar results were obtained for another batch of homemade CdSe core QDs, QD-C2 (λ_{max} exciton peak at 523 nm, 2.6 nm). Moreover, the sensitivity of QD-C2 fluorescence to thiol addition was higher after 6 months of aging. This result shows the increase of QD surface defects with time.

Fig. 1. Fluorescence spectra of a deaerated toluene solution of QD-C1 (2.9 µmol/L) in the absence (●) and in the presence of MU (5 mmol/L) 0 min (▼), 30 min (■), and 80 min (○) after the addition of the MU; [MU]/[QD-C1] = 1724.

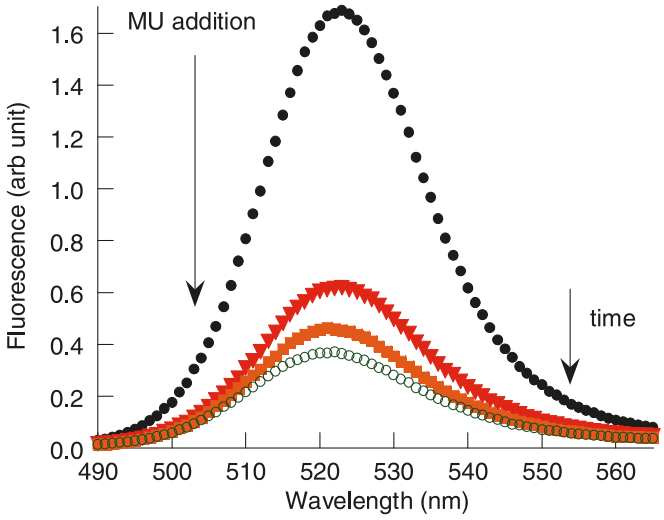


Table 1. Variation of the QD fluorescence quantum yield after the addition of MU and KP-SH, and kinetic rate constant of the ligand exchange (k_{LE}).

QD/thiol system	[Thiol]/[QD] molar ratio	$(I_{inf}–I_0)/I_0$[a]	k_{LE} (s^{-1} L mol^{-1})
QD-C1/MU	540	0.80	—
	1 724	–0.67	7.0±0.4
QD-C1/KP-SH	620	0.18	22.2±0.6
	6 200	–0.65	—
QD-CS1/MU	2 940	0.59	5.8±0.3
QD-CS1/KP-SH	3 600	1.34	11.5±0.4
QD-CS2/MU	12 500	0.93	13±1
QD-CS2/KP-SH	4 500	0.72	22±2

[a] I_0 and I_{inf}: fluorescence emission area of the QD in the absence of the thiol and 2 h after addition of the thiol, respectively.

To check whether this behavior also applied to core-shell QDs, we extended our studies to commercial core-shell QDs (QD-CS).[16] The addition of the functional thiol KP-SH to QD-CS1 (λ_{max} exciton peak at 504 nm) induced fluorescence enhancement at different concentrations; thus, an important emission increase (+1.34) with no change in the maximum was registered 2 h after the addition of KP-SH with a ligand/QD molar ratio of 3600 (Fig. 3). The same trend was detected for QD-CS2 (λ_{max} exciton peak at 565 nm) fluorescence, but it was less sensitive than that of QD-CS1 (Fig. S3 in the Supplementary data). The addition of MU to a QD-CS1 toluene solution (MU/QD concentration ratio of 2940) also produced an important fluorescence enhancement (+0.59) in a time-dependent process (Fig. S4). The fluorescence enhancement was observed even when using an [MU]/[QD] ratio in the 2 940 – 12 500 range (see Fig. S5 for a 12 500 molar ratio). This fluorescence enhancement

Fig. 2. Fluorescence spectra of a deaerated toluene solution of QD-C1 (2.9 μmol/L) before (○), immediately after (●), and 90 min after (■) the addition of MU (1.57 mmol/L); [MU]/[QD-C1]= 540.

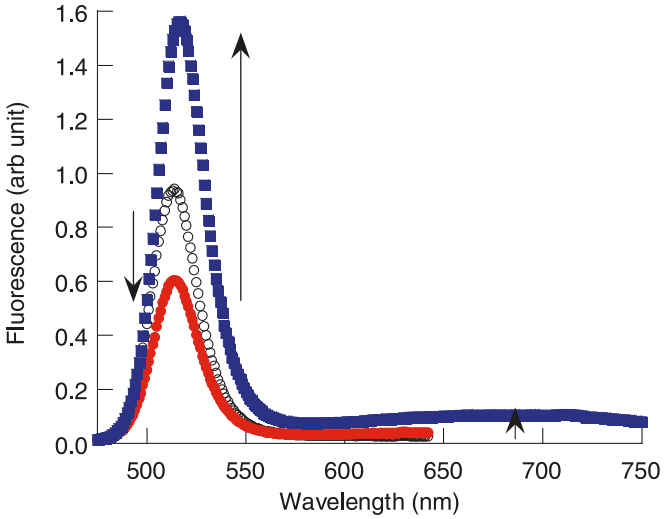

Fig. 3. Fluorescence spectra of a deaerated toluene solution of QD-CS1 in the absence (■, [QD] = 0.5 μmol/L) and in the presence of KP-SH ([KP-SH]/[QD] = 3600), the latter being registered 0 (○), 10 (▲), 30 (×), 60 (●), and 150 (□) min after the addition of the thiol.

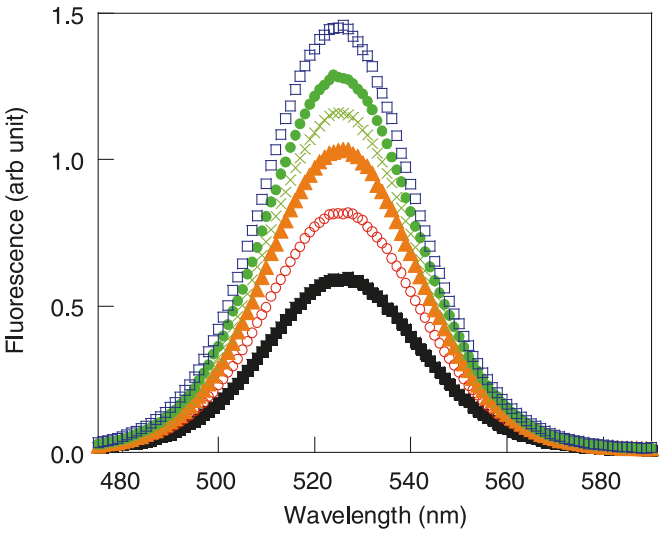
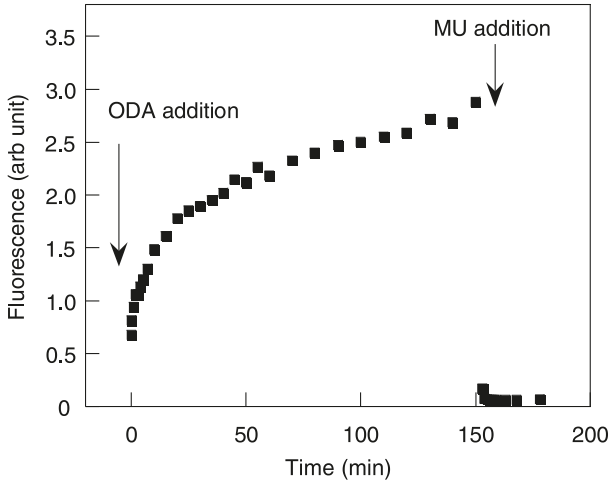


of the core-shell QDs upon thiol addition contrasts with the effect reported for the thiolates.[17,18]

Control experiments were performed to rule out the possibility that the different nature of the native ligand (TOPO in core QDs and a long-chain amine in core-shell QDs) was the origin of the different response to thiol addition of the core and core-shell QDs. So, the effect of the addition of octadecylamine (ODA), followed by MU 150 min later, on the QD-C1 fluorescence was monitored (Fig. 4). The addition of ODA to QD-C1 led to a considerable enhancement of the QD emission (+3.28) in a time-dependent process (Figs. 4 and S7). This increase was in agreement with the higher fluorescence quantum yield of amine-coated QDs compared with TOPO- or TOP-coated QDs.[4b] The exchange kinetics has been interpreted as being due to a combination

Fig. 4. Time dependence of the fluorescence intensity of QD-C1 (2.9 μmol/L) upon addition of ODA (6.5 mmol/L) followed by addition of MU (5.2 mmol/L) 150 min later; [amine]/[QD] = 2200 and [thiol]/[QD] = 1800.



of ligand binding to vacant surface sites on CdSe QDs (fast coordination) and the ligand exchange itself (a slower process). After an equilibrium was reached, addition of MU caused a drastic decrease in the fluorescence emission of the system because the amine was replaced by the thiol ligand (Figs. 4 and S8). Therefore, the presence of amine as a native capping ligand (QD-CS) instead of TOPO (QD-C) is not responsible for the different behavior produced by thiol addition to these QDs.

The time-dependent fluorescence quenching observed for CdSe has been previously used as a tool to measure the exchange kinetics of native ligands for thiols on the CdSe surface.[8] Therefore, the changes in QD emission intensities were recorded as a time function, from which the kinetic rate constants (k_{LE}, Table 1) for the ligand exchange (TOPO, CdSe; amine, CdSe/ZnS) were calculated (see details in Figs. S9–S14 in the Supplementary data). The values for the addition of KP-SH were two times higher than those for the addition of MU, which is indicative of a higher replacement of a bulkier ligand.

To gain insight into the nature of the thiol binding to the QD, we prepared two samples (A and B) containing QD-CS3 (λ_{max} exciton peak at 520 nm, 48.1 × 10^{-9} mol) and KP-SH (2.4 × 10^{-4} mol) in deaerated chloroform (50 mL). They were maintained at room temperature for 2 h (sample A) and 48 h (sample B). After almost total solvent evaporation (2 mL) and the addition of methanol (30 mL), the samples were centrifugated at 8000 rpm (20 800*g*) for 20 min at 20 °C and the supernatants were decanted. The nanoparticles were dissolved in chloroform (2 mL) and the purification process was repeated twice, finally leading to CS3@KP_{2h} and CS3@KP_{48h} nanoparticles.

Both QD-CS3/KP-SH solutions exhibited a higher fluorescence than QD-CS3, and their emission maxima shifted slightly (1 nm) towards the red compared with that of QD-CS3 (Fig. 5). Remarkably, the emission of the cleansed QDs, CS3@KP_{2h} and CS3@KP_{48h}, was lower than that of QD-CS3 (Fig. 5), and the maxima were located at 542 nm (4 nm red-shifted compared with QD-CS3).[19] Therefore,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12

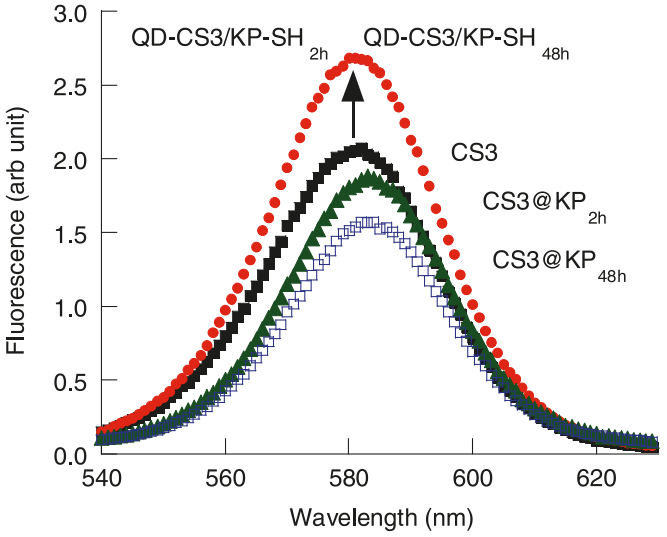
Fig. 5. Comparative fluorescence spectra of deaerated toluene solutions of QD-CS3 (■), QD-CS3/KP-SH (5×10^3 molar ratio) 2 h and 48 h after addition of the thiol (●), and cleansed CS3@KP_{2h} (▲) and CS3@KP_{48h} (□).



washing of the thiol-capped QDs resulted in a loss of the unbound (encapsulated) thiol and produced QDs with an emission lower than that of the initial core-shell QDs. The red-shifted emission exhibited by CS3@KP_{2h} and CS3@KP_{48h} indicated some thiol binding to the QD surface with time.

These results demonstrated that the replacement of amines by thiols on the core-shell QD surface resulted in better protection of the QD emission. The thiols encapsulated within the QD ligands were responsible for the fluorescence enhancement. In addition, the higher emission of CS3@KP_{48h} QDs than of CS3@KP_{2h} QDs suggested that thiolate binding to the QD surface appeared to be, at the least, nondetrimental for the QD emission.

Theoretical calculations have shown that thiol binding to ZnS surfaces is endothermic, while thiolate binding is a spontaneous process that can cause an alteration of the ZnS surface.[20] Consequently, we suggest that the replacement of amine ligands by thiols in the CdSe/ZnS QDs could benefit from the basicity of the amine ligands, allowing slow deprotonation of the thiol ligands to take place close to the nanoparticle surface and eventually resulting in thiolate binding to the shell with minimum surface alteration.

In summary, our results demonstrate that while addition of thiols drastically reduces the fluorescence of CdSe core QDs, it actually enhances the emission properties of already highly fluorescent amine-capped CdSe/ZnS core-shell QDs.

Abstract: A broadly based investigation of the effects of a diverse array of substituents on the photochemical rearrangement of *p*-hydroxyphenacyl esters has demonstrated that common substituents such as F, MeO, CN, CO_2R, $CONH_2$, and CH_3 have little effect on the rate and quantum efficiencies for the photo-Favorskii rearrangement and the release of the acid leaving group or on the lifetimes of the reactive triplet state. A decrease in the quantum yields across all substituents was observed for the release and rearrangement when the photolyses were carried out in buffered aqueous media at pHs that exceeded the ground-state pK_a of the chromophore where the conjugate base is the predominant form. Otherwise, substituents have only a very modest effect on the photoreaction of these robust chromophores.

Key words: substituent, pH, pK_a, solvent effects, photorelease.

Résumé : Une étude détaillée des effets de divers arrangements de substituants sur le réarrangement photochimique des esters de *p*-hydroxyphénacyle a démontré que les substituants communs, tel F, MeO, CN, CO_2R ou CH_3, n'ont que peu d'effet sur la vitesse et les efficacités quantiques du réarrangement de photo-Favorskii et sur la libération du groupe acide partant ou sur les temps de vies de l'état triplet réactif. On a observé que tous ces substituants provoquent des diminutions des rendements quantiques pour la libération et le réarrangement quand les réactions de photolyse sont effectuées dans un milieu aqueux tamponné à un pH supérieur à celui du pK_a de l'état fondamental du chromophore pour lequel la base conjuguée est la forme prédominante. Autrement, les substituants n'ont qu'un effet modeste sur la photoréaction de ces robustes chromophores.

Mots-clés : substituant, pH, pK_a, effets de solvant, libération photochimique.

Introduction

Among the known photoremovable protecting groups, *p*-hydroxyphenacyl (pHP, **1**, eq. [1]) has consistently provided very fast (within a few nanoseconds after excitation or even less) and efficient, high conversion release of substrates. Moreover, the photoproducts are transparent at irradiation wavelengths ≥280 nm, permitting essentially complete conversion. Since developing the pHP as a "caging group" a decade ago,[1] pHP derivatives have found several applications in neurobiology,[2] enzyme catalysis,[3] and chemistry[4–6] that have demonstrated the advantages of its rapid, efficient release properties. An intriguing aspect of pHP photochemistry is the rearrangement of the chromophore that accompanies the release of the substrate. Anderson and Reese,[7] who discovered the photorearrangement by photolysis of *p*-hydroxyphenacyl chloride, isolated ethyl *p*-hydroxyphenylacetate (HPAA), which they described as a "photo-Favorskii" rearrangement product and depicted the skeletal rearrangement as passing through a putative spirocyclohexa-2,5-dienylcyclopropyl-4,8-dione intermediate (**I_2**) (eq. [1]).

For personal use only.

Our subsequent studies using a variety of leaving groups have affirmed that the major rearrangement pathway proceeds to the *p*-hydroxyphenylacetic acid as long as the reactions are carried out in aqueous or hydroxylic solvents.[8] Recent studies have been directed toward fine-tuning the requirements for the release and for the rearrangement of the pHP group, particularly, the effects of varying the leaving group (**LG**), the substituents on pHP, and the solvent.[8]

Details regarding the timing and multiplicity requirements of the bond-making and bond-breaking events in the photo-Favorskii rearrangement have been addressed in several mechanistic and theoretical investigations.[9–11] The release rates, as well as the product distribution, are sensitive to the presence of H_2O and other hydroxylic solvent combinations.[8–10] An adiabatic triplet sequence has been proposed[10,12] that involves both the deprotonation of the phenolic OH group and the heterolytic release of the leaving group[13] prior to formation of cyclopropanone $\mathbf{I_2}$ (eq. [1]). At least one additional intermediate, an oxyallyl–phenoxy triplet biradical ($\mathbf{I_1}$), has been proposed and evidence for $\mathbf{I_1}$ was recently reported.[9] Still, the molecular events including the multiplicities of the intermediates and the pathways that form $\mathbf{I_1}$ and $\mathbf{I_2}$ and their conversions to products are not fully established.

We report here the results of our investigations of the substituent effect on the photochemistry, multiplicity, quantum yield, reaction rate, and the effects of pK_a and pH. In addition, we have evaluated the substituent effect on the rearrangement including intermediates $\mathbf{I_1}$ and $\mathbf{I_2}$ suggested for the photo-Favorskii rearrangement. A series of substituted pHP esters (Fig. 1) were examined under a variety of conditions that included changes in solvent, pH, and ionic strength of the media. The mechanistic implications of these results provide a clearer understanding of this most interesting photorearrangement reaction.

Results and discussion

The array of substituted pHP derivatives was chosen to include both electron donor and acceptor functional groups (Fig. 1). Several of these compounds were also selected for future synthetic alterations or attachment sites for modifications desired for various applications of pHP photochemistry. There were a few instances where the γ-aminobutyric acid (GABA) leaving group was not easily installed, so the alternative acetate or diethyl phosphate leaving groups were inserted. These leaving groups are also well-documented in the literature of pHP photorelease chemistry and therefore can be related to the more numerous GABA representatives through comparisons of the known photochemistry of the parent, unsubstituted pHP acetate (**24**),[9,11] or diethyl phosphate (**27**).[1,2,10,11]

Synthesis of substituted pHP derivatives

Schemes 1A and 1B describe the synthetic protocols employed for the substituted pHP esters in Fig. 1. The GABA leaving group was chosen to assure good aqueous solubility. GABA is particularly advantageous in this respect, and in our laboratories it has served as the standard leaving group for several previous studies of pHP release rates and efficiencies. In general, the synthetic strategies for substituted pHP chromophores vary according to the availability of the substituted phenol, *p*-hydroxybenzoic acid, or *p*-hydroxyacetophenone precursor. The *p*-hydroxyacetophenones, when available, are converted directly to the pHP GABA and other leaving-group analogs by any one of a number of convenient transformations that activate the α-methyl group, e.g., bromination to the α-bromomethyl ketone followed by S_N2 displacement with N-BOC protected GABA and then deprotection with TFA, e.g., **13**–**23** (Scheme 1B).

The syntheses of the GABA derivatives of pHP (**1**), 3-methoxy-pHP (**2**), and 3,5-dimethoxy-pHP (**3**) followed the published protocols developed earlier for glutamates.[2a,2b] The 3-carboxymethyl-pHP (**10**) and 3-carbamoyl-pHP (**11**) derivatives were derived by the same sequence from the commercially available methyl 5-acetylsalicylate. The 2- and 3-cyano and all of the fluoro ketones (**13d**–**23d**), were synthesized from the corresponding phenols by a sequence of bromination of the phenol (**13b**–**23b**), then benzyl protection (**13c**–**23c**), followed by acylation through Stille coupling with Pd(0) and 1-ethoxyvinyl stannane to furnish, in excellent yield, the substituted *p*-benzyloxyacetophenone. Debenzylation gave acetophenones **13d**–**23d**, which were then converted to the GABA esters **13**–**23**.

The synthesis of new acetate derivatives **25** and **26** stemmed from a protocol uniform to the GABA esters, but commencing with the *p*-hydroxyacetophenones available from the Stille coupling route mentioned above and using sodium acetate in lieu of GABA according to the method of Phillips.[10]

The synthesis of the new diethyl phosphates **30**–**32** constituted an altogether separate series of steps. For the electron-donating methoxy scaffolds **30a** and **31a**, Friedel–Crafts acylation of corresponding pivalate-protected phenols with chloroacetyl chloride, followed by chloro displacement with sodium bromide engendered α-bromo derivatives **30d**–**31d**. Facile diethyl phosphate substitution of the bromoketones

was then mediated by Ag(I) followed by pivalate deprotection using ammonium acetate in aqueous methanol to furnish **30** and **31**.

An initial Fries rearrangement of acetyl-protected *p*-hydroxybenzoic acid **32b** provided the *o*-acetylated analog **32c**, whose carboxylic acid moiety was transformed into the α-diazo ketone through the acid chloride. After deacetylation with ammonium acetate in aqueous methanol, reaction with diethyl phosphoric acid gave **32**.

UV–vis spectral properties of substituted pHPs

The UV–vis spectral properties of **1–32** in H_2O and in aqueous buffer at pH 9 and the groundstate pK_as of the corresponding *p*-hydroxyacetophenones are given in Table 1. The pK_as range from 3.9 to >8.0, indicating that at physiological pH the chromophore will be a mixture of the conjugate base (phenoxide) and the neutral, un-ionized phenol. In most cases, the un-ionized form is prevalent at pH 5.0–7, whereas at pH 9, in all cases, the conjugate base prevails. It was anticipated that the photochemistry of the two forms might differ. In fact, the photochemistry will be shown to be sensitive to the solution pH as well as to the pK_a of the chromophore.

The UV–vis spectra of unsubstituted *p*-hydroxyacetophenone (pHA, **1d**) measured at neutral pH (phosphate buffer, pH 7) and in basic media (pH 8) typify the significant shifts in the absorption maxima upon ionization of these chromophores (Fig. 2).[4a] The spectrum of pHA displays a prominent π–π* absorption band with a maximum at 275 nm. In some solvents, a weak shoulder on the red edge of the π–π* band of the *p*-hydroxyketone (not shown) has been attributed to the carbonyl n–π* transition.[10c] The absorption band centered at 330 nm is assigned to the conjugate base π–π* transition. Based on the significant contributions of both chromophores in aqueous solutions between pH 5 and 8, it was necessary to study the photochemistry and physical properties of substituted pHP derivatives under buffered conditions to assure a constant ratio of the two forms of the

chromophore. Studies were also conducted in unbuffered aqueous media for comparison.

Product studies

Two major photolysis products were obtained from each substituted pHP derivative: the leaving group, i.e., GABA, diethyl phosphate, or acetate, and the substituted *p*-hydroxyphenylacetic acid (pHPAA), which is the rearrangement product from the photo-Favorskii reaction (eq. [1]). A minor product, the substituted *p*-hydroxybenzyl alcohol, is formed

in <5% yield and is derived by decarbonylation of the putative spirodienedione intermediate $\mathbf{I_2}$, followed by hydration of the resulting *p*-quinone methide.[9] All of the products were characterized by HRMS and by comparison of their ^{1}H and ^{13}C NMR spectral properties either with authentic samples or related products from our previous pHP studies.

Photolyses carried out in aprotic organic solvents generally produced reduction products such as the substituted pHA and other radical-derived products. These studies were not pursued further, and the products were not observed in the aqueous solution photolyzates.

Quantitative determination of the products was obtained by ^{1}H NMR or by LC–MS/MS. The ^{1}H NMR spectra of pHP caged GABAs in D_2O were cleanly transformed into spectra of the two major photoproducts accompanied by complete disappearance of pHP GABA. Product studies were routinely carried out to quantitative conversion.

Triplet-state pK_a, quantum yield, and Stern–Volmer studies

The pK_a of the excited triplet state of **1d** is strongly reduced by about 4.3 pK_a units relative to pHA's ground-state pK_a of 7.9.[8] Since proton transfer plays a significant role in the mechanism of the release of the leaving group,[4,8–13] changes in the pK_a of the chromophore will provide additional insight into the mechanistic features of the reaction. Currently, there remains a controversy over the timing and importance of the proton transfer to the solvent. One suggested pathway depicts proton transfer from the chromophore in concert with leaving group departure (vide infra).[10] For this scenario, the enhanced acidity of the pHP triplet would enhance the reactivity of the chromophore toward release and rearrangement. The second scenario suggests that the phenol group is merely a spectator and does not play a pivotal role in the release or rearrangement.[10,14] Therefore,

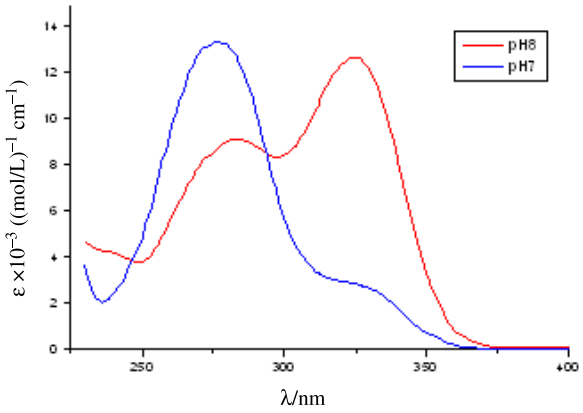
Fig. 2. UV spectral data for *p*-hydroxyacetophenone (**1d**). The absorption spectra are of a 0.13 mmol/L solution of **1d** in NaH_2PO_4 buffer (3% CH_3CN) at pH 7 and 8 showing the shift in absorption from the phenol to its conjugate base. (From Givens and Yousef 2005, in *Dynamic Studies in Biology: Phototriggers, Photoswitches, and Caged Biomolecules*, Chap. 1.3.2.2, p. 60, reproduced with permission, ©Wiley-VCH Verlag CmbH & Co. KGaA.)



a study of the effect of pK_a on the reaction efficiency and rate of release should be valuable.

The quantum yields for the disappearance of pHP esters and for the appearance of the two major products were determined by LC–MS/MS and ^{1}H NMR at low conversion (<5%) in unbuffered H_2O (Table 2) and in buffered solutions (Table 3) at acidic, neutral, and basic pH.

The quantum yields were first determined in unbuffered H_2O (Table 2). However, these must be considered less accurate because the pH changes during photolysis. The mildly acidic phenolic *p*-hydroxyphenacyl chromophore (pK_a ~ 4–8) is converted into a series of three new acids, a bifunctional *p*-hydroxyphenylacetic acid along with the leaving group, which, in several cases, is the strongest acid present, e.g., a phosphoric or sulfonic acid. The contributions of the three newly created acids decrease the pH. Since the photolysis solution for a particular chromophore is a delicate balance of the phenolic pHP ester and its conjugate base and since their ratio is dependent on the chromophore's pK_a, the changing pH of the media will affect that ratio and, therefore, the quantum yield. Furthermore, as reported earlier and amplified in this paper, the quantum yields are dramatically different for the un-ionized chromophore and its conjugate base. Taken together, the quantum yields in unbuffered media are a complex function of the pK_a, a changing pH, and the relative quantum yields. Nevertheless, the quantum yields reported in Table 2 may be considered as representative because they were derived by extrapolation to initial efficiencies at low conversions (<2%). However, they are not corrected for the relative concentrations of the un-ionized and conjugate base present.

Table 3 reveals that in buffered media the efficiencies for release decrease as the pH of the media increases for essentially every pHP ester. The decrease in efficiency is most pronounced as the increasing pH approaches the pK_a of the pHP ester, reaching its lowest when the chromophore is completely converted to its conjugate base, which is graphically depicted in Fig. 3. This normally resulted in a reduction of 60%–80% in the quantum yield.

Table 2. The effect of pK_a on the quantum yields for substituted *p*-hydroxyphenacyl (pHP) γ-aminobutyric acid (GABA) in unbuffered H_2O. Entries are arranged according to decreasing disappearance quantum yields.

[a]Quantum yield for the disappearance of pHP GABA.
[b]Quantum yield for the appearance of GABA.
[c]Quantum yield for the appearance of rearranged acid.
[d]CH_3CN–H_2O (1:1).

The lower quantum yield may be attributable to several factors including a decrease in intersystem crossing (isc) efficiency (Φ_{ST}) or in the rate constant of release relative to that of competing nonproductive pathways. One of these may simply be deprotonation to the triplet conjugate base (**1**$^-$).[3] Results in Table 4 suggest, however, that the rates for intersystem crossing are essentially insensitive to substitution for the un-ionized esters. Less is known for the rates of isc for the conjugate bases.

Two substituents of interest are cyano and methoxy. The ortho (or 2) substituted derivatives were not amenable to our synthetic strategies and difficulty was encountered in the attempts to synthesize the GABA derivatives, especially in the Boc deprotection step. However, acetate and phosphate analogs were synthetically accessible and, therefore, their photochemistries were examined. Disappearance quantum yields were measured for 2- and 3-cyano pHP OAc and for the four variations of the methoxy pHP diethyl phosphates. These are given in Table 5 along with the parent pHP OAc and diethyl phosphates reported earlier for comparison.[1,9–11]

Clearly, the cyano-substituted acetates are less efficient than the parent, which was surprising, since the GABA analog of the 3-CN pHP GABA gave an enhanced efficiency for photodeprotection. It should be noted that poorer aqueous solubility of acetate and other carboxylic esters requires cosolvents such as acetonitrile or DMSO. There is mounting evidence that the concentration of the organic cosolvent re-

duces quantum yields and rates of release.[9,11–13] This is not consistently the case, but may be a factor in the cyano acetate series.

Methoxy substitution, on the other hand, has little effect for the 3-MeO pHP phosphates but does enhance the reactivity of the 2-MeO pHP phosphates (**30** and **31**). These are among the most efficient photodeprotection efficiencies we have encountered in the phosphate series.[1,3c,4a,8,9,12] It was discovered, however, that these latter two derivatives were less soluble and less stable to aqueous hydrolysis.

Picosecond pump–probe spectroscopy on a cross section of the substituted pHP that included both electron-donating and -withdrawing derivatives and fluorinated examples showed little variation in the rate constants of triplet rise (k_1) and decay (k_2) (Table 4).

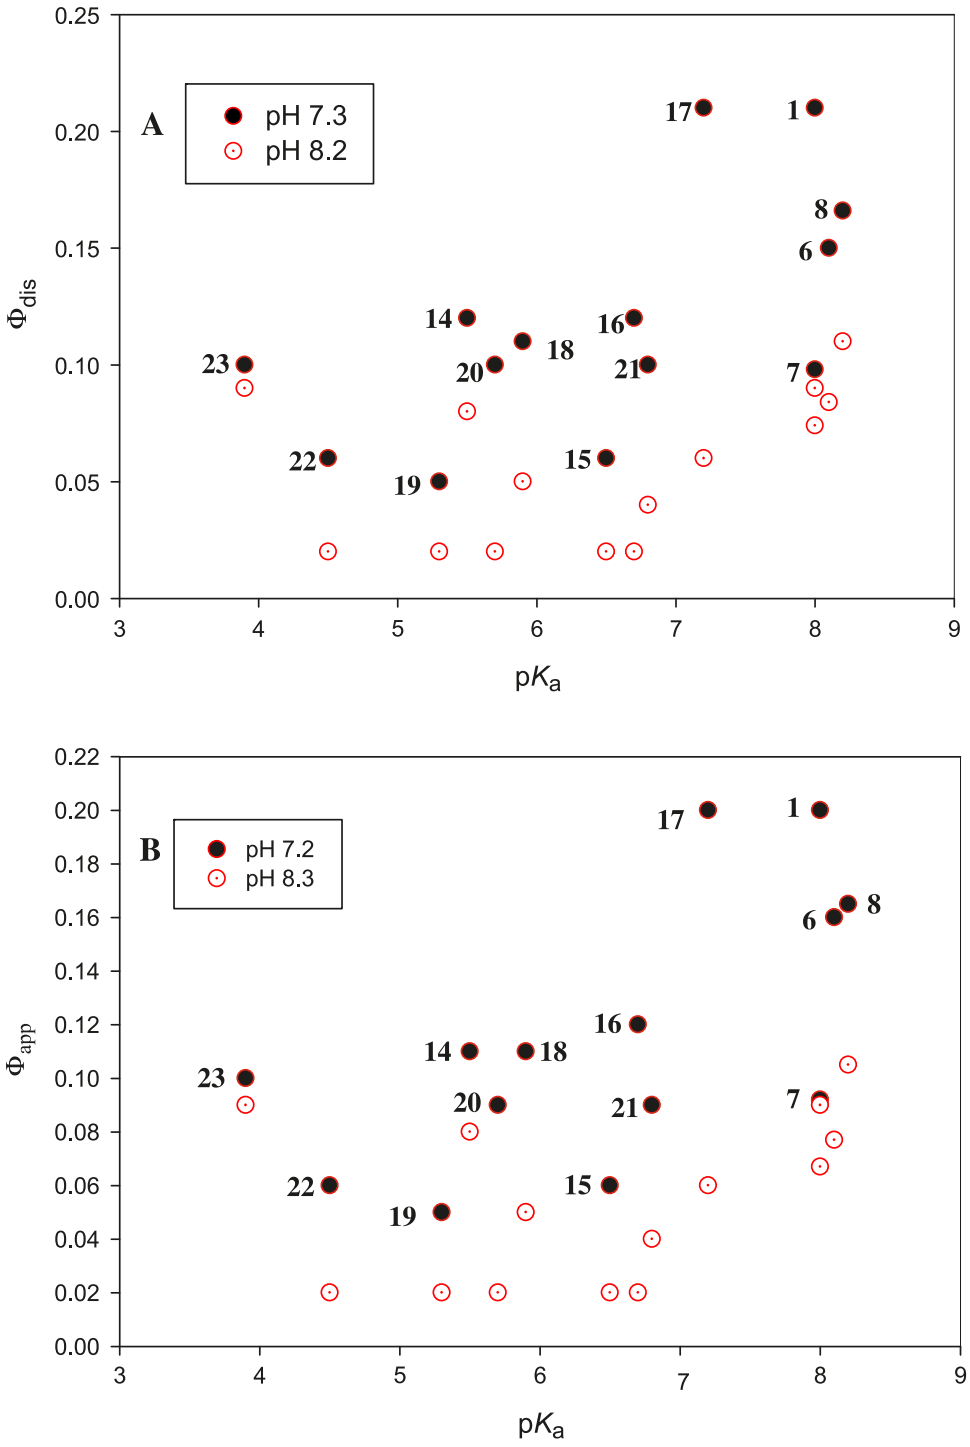
Scheme 2 summarizes a series of the parallel pathways available to the photoactivated pHP derivatives and their conjugate bases. The products are the same for both pathways, but the details concerning the excited states and the partitioning among their available decay and reaction pathways are different. We have a much less-detailed understanding of the mechanism for the reaction of the conjugate bases than the un-ionized pHP system. However, we have monitored the change in quantum yields at different pH and at a longer excitation wavelength (RPR 350 nm lamps). The values are uniformly much lower than those obtained for the un-ionized pHP analog using RPR 300 nm lamps. The conjugate bases display a weak fluorescence ($\Phi < 1 \times 10^{-4}$). Otherwise, the two forms show comparable rates of triplet formation and decay upon excitation at 350 nm. Thus, the low product quantum yields for the conjugate bases are most likely due to variations in the partitioning among the competing exit channels from the triplet excited states of the two chromophores.

Parallel studies on Stern–Volmer quenching of the ester disappearance and product appearance by sorbate for a few of the esters further indicated no significant differences in triplet lifetimes. This also suggests that there is little difference in the partitioning among the triplet decay pathways, but does not exclude the possibility of recombination of initially formed ion-triplet biradical pairs (See the Experimental section and Table 6 for details).

Heterolytic release of the leaving group generates an intermediate biradical–ion pair ([$\mathbf{I}_1{}^3$·**LG**]) raising the possibility of cage return, which might contribute to the differences in the photorelease quantum yields. Evidence for cage return was obtained by increasing the ionic strength of the aqueous solutions with $LiClO_4$, $NaClO_4$, $MgCl_2$, etc. With several derivatives, the quantum yields increased significantly, some by a factor of two or more, whereas others remained unchanged and, in a few cases, even decreased. The increased ionic strength had no effect on the LFP triplet decay rates.

Finally, the triplet energies of the pHP and its conjugate base may be a source of the differences in reactivity. The 71.6 kcal/mol (1 cal = 4.184 J) triplet energy of pHP is diminished to 61.2 kcal/mol for the conjugate base.[8] This ~10 kcal/mol decrease in energy may favor the barrierless or low-barrier processes over the more energy demanding

Fig. 3. Graphic representation of the effect of pK_a on the quantum yield of substituted *p*-hydroxyphenacyl (pHP) γ-aminobutyric acid (GABA) as a function of pH. Numerical identifications of the esters are placed adjacent to the pH 7.3 values. (A) Disappearance quantum yield of substituted pHP GABA as a function of its pK_a at pH 7.3 (●) and 8.2 (○). (B) Appearance quantum yields of GABA as a function of the pHP ester pK_a at pH 7.3 (●) and 8.2 (○). Data are from Table 3. The 3-CN derivative **13** is omitted because of a solvent change.



heterolytic release pathway of the photo-Favorskii rearrangement.

Pathways that may account for nonproductive decay of the triplet would include deprotonation to the conjugate base with subsequent rapid decay to its ground state[15] or proton tautomerization to **33**, the proton tautomer of pHP originally suggested by Wan and co-workers[11] (which was later shown to be a triplet[8]) that, following isc to the ground state, would rapidly tautomerize back to the pHP ester. Interestingly, there is a prominent, long-lived 340 nm transient that also is observed in the LFP spectra of most pHP derivatives. This band is appropriately positioned for assignment

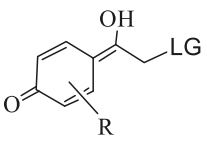
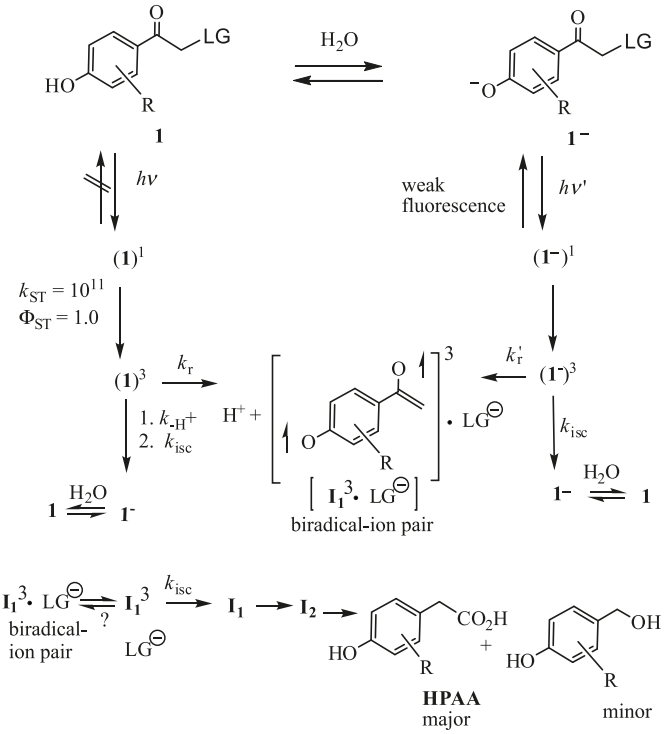
either to the ground-state conjugate base of the pHP group or to **33**.[11,14] As in the case of the conjugate base of pHP derivatives, the tautomer **33** is an unlikely candidate for room-temperature heterolysis.[9]



33

For the heterolytic pathway that proceeds on to the rearranged product, three scenarios have also been suggested.

Scheme 2. Parallel pathways for the photochemical and photophysical processes of *p*-hydroxyphenacyl (pHP) or its conjugate base.



Proton loss[14] or heterolysis could be the initial step or the two could occur in concert. Two such stepwise scenarios can be envisaged, differing by only the order of departure of two entities. Evidence that militates against proton loss preceding the departure of the leaving group comes from the poor efficiencies of the conjugate bases and from our earlier analysis of solvent kinetic isotope effects (SKIE). A "proton inventory" of the SKIE revealed that either two or three protons are "in flight" in the release process.[9,16] The partition functions are consistent with the phenolic proton and two solvent water protons associated with two carbonyls during the extrusion of $\mathbf{I_1}$.

The other stepwise construct would involve the departure of the leaving group before loss of the proton, thereby generating a triplet α-keto carbenium ion. This pathway is also unlikely based on the known photochemistry of released derivatives such as *p*-methoxyphenacyl analogs, which, even in hydroxylic solvents, do not efficiently follow a rearrangement pathway for the chromophore.[1b,17] This is in keeping with the requirement that the *para* hydroxyl function and a leaving group positioned α to the carbonyl be present on the phenacyl chromophore to ensure efficient photo-Favorskii rearrangement.

Taken together, these results are viewed as favoring the concomitant loss of the phenolic proton and the leaving group. Thus, the evidence is most consistent with the interpretation that a concerted proton and leaving group departure occurs with the resulting extrusion of a neutral triplet biradical $\mathbf{I_1}$. This process is not only a minimum energy pathway for heterolysis, but also conserves spin.[18] The oxyallyl–phenoxy triplet biradical $\mathbf{I_1}$ then relaxes to a singlet and closes to the spirobicyclohexadienedione $\mathbf{I_2}$. The fate of $\mathbf{I_2}$ as a groundstate intermediate mimics a typical Favorskii

rearrangement[19] by ring-opening hydrolysis via nucleophilic attack of solvent (water) to produce rearranged *p*-hydroxyphenylacetic acid. Decarbonylation, a minor pathway open to $\mathbf{I_2}$, yields *p*-quinone methide that hydrolyzes to *p*-hydroxybenzyl alcohol, the minor product.

The effect of structure on the photolytic reactivity of substituted pHP GABAs

There appears to be no correlation between the ground-state pK_as of the chromophores and their photochemical behavior in terms of their quantum yields or rate constants for release. The pK_a dictates the ratio of the un-ionized and conjugate base, and this ratio in turn affects the photochemical reactivity. Therefore, the photochemical and photophysical properties do not change with the introduction of most substituents. The most notable exceptions are the effect of 3-nitro and the 2- and 3-hydroxyl groups, which completely quench reactivity. Similarly unreactive were the 3-acetyl and any appended auxochromes that could quench such as naphthyl (not shown).

Conclusions

A unique rearrangement, the photo-Favorskii reaction, of pHP esters combines the accelerated release of substrate ligands with a hypsochromic shift of the pHP chromophore. The rearrangement occurs on the triplet manifold by a spin-conserved extrusion of the chromophore as a triplet biradical $\mathbf{I_1}$ followed by relaxation of the biradical and closure to yield $\mathbf{I_2}$, the "Favorskii" intermediate, merging the photochemical pathway with a ground-state Favorskii reaction.[19] With few exceptions, substituents on the chromophore do not influence the mechanics of the rearrangement sequence and cause only small variations in the quantum yields and reaction-rate constants. The release of substrate is consistently more efficient for the un-ionized chromophores. Substituents do influence the chromophore pK_a; electron-donating and -withdrawing groups both lower the pK_a and, therefore, favor the conjugate base at neutral pH. This causes lower quantum yields, since the conjugate base is much less efficient at releasing the leaving group.

4-Hydroxybenzyl alcohol, a ubiquitous minor product, serves as additional supporting evidence for the intermediacy of $\mathbf{I_2}$ through its formation by decarbonylation and hydrolysis.[9]

Finally, these results provide evidence that further modification of the chromophore is possible without decreasing its photoreactivity, enhancing the pHP physical and photochemical versatility. Carboxyl, carbonyl, ether, and amide functional groups can be introduced to enhance the solubility, binding, and other physical properties without fear of losing reactivity.

Current studies on this intriguing chromophore and on the mechanism of the unusual photochemical rearrangement are in progress.

Experimental

Methods

Melting points were conducted with open-ended capillary tubes using a noncalibrated Thomas–Hoover melting-point apparatus. Lyophilization was performed using a Labconco FreezeZone device set at –52 °C and 0.04 mbar (1 bar = 100 kPa). Solution pH values were determined using a Fisher Scientific pH 510 meter calibrated with certified Fisher buffer solutions of pH 4, 7, and 10. Products of all reactions were assessed for purity using the following instrumental techniques: For ^{1}H, ^{13}C, and ^{19}F NMR, Bruker DRX 400 and DRX 500 MHz spectrometers were utilized with trifluoroacetic acid as an internal standard (δ = –76.55 ppm). GC–MS analysis was done on an Agilent 6890N Network GC system equipped with a Quattro Micromass triple quadrupole electron impact mass spectrometer. Exact masses were performed on a Quattro Micromass triple quadrupole electrospray ionization mass spectrometer. UV–vis data were obtained on a Carey Bio100 instrument using 1.5 mL quartz cuvettes. Fluorescence data were acquired on a Carey Eclipse fluorescence spectrophotometer using a 10 mm

quartz cell. IR data were obtained using a Shimadzu FT-IR 8400 S instrument with pressed potassium bromide (KBr) pellets or a prefabricated sodium chloride (NaCl) chloroform cell for solid-phase analysis and NaCl prefabricated plates for oil analysis. Ground-state pK_as were determined through sample titration with increasing amounts of 0.0461 mol/L NaOH (standardized with potassium hydrogen phthalate), correlating pH vs [OH^-] and ascertaining the half equivalence point as the pK_a. Product separation was achieved by flash chromatography using EM Science silica gel and gradient hexanes – ethyl acetate as eluting solvents. All reactions were run under ambient conditions unless otherwise stated. ^{1}H NMR spectroscopy was utilized to monitor the progress of the photolysis of all new pHP cages. In general, a 1–10 mmol/L sample of pHP-caged GABA was prepared in 2 mL D_2O and ~2 mL was placed in an NMR tube. This was positioned in a photoreactor equipped with two 15 W, 3000 Å Rayonet lamps and a merry-go-round. Irradiation for 30 min generally led to 100% conversion as judged by the absence of the ester proton signals. Photoproduct identification was achieved through the spiking the samples of the irradiated mixture with authentic samples of the resolved GABA. Quantitative photolysis conditions for determination of quantum yields and Stern–Volmer quenching constants (K_{SV}) were as follows: The lamp light output (in mEinsteins/min) was established using the potassium ferrioxalate method.[7] Milligram quantities of caged compounds and caffeine or acetamidophenol were weighed out on a Fisher brand microbalance and dissolved in 4 mL of 18 MΩ ultrapure water salt solutions of various concentrations, buffers with or without adjusted ionic strengths, or purified organic solvents were then added to a quartz tube and vortexed, resulting in a homogenous solution of the caged compound and internal standard. Concentrations of the caged compounds ranged from 1 to 9 mmol/L. These tubes were then placed in a carousel within a Rayonet photochemical reactor equipped with two 3000 Å, 15 W Rayonet photochemical reactor RPR3000 mercury lamps as light sources. One hundred microlitre samples were removed at 30 s intervals up to 5 min using a 250 μL Hamilton microsyringe and diluted to 1 mL with water using 1 mL volumetric flasks.

Quantum efficiency determinations

Quantitative analysis was achieved by HPLC–UV or HPLC–MS/MS. The LC–MS/MS instrument was a Waters 2695 Liquid Chromatographer equipped with a Quattro Micromass triple quadrupole electrospray ionization mass spectrometer, outfitted with an autosampler. UV–vis detection consisted of a Waters 2497 type with a dual wavelength detector set at 220 and 240 nm. The reservoirs used were as follows: (*i*) 99% water, 1% methanol, 10 mmol/L ammonium formate, and 0.06% formic acid; and (*ii*) 99% methanol, 1% water, 10 mmol/L ammonium formate, and 0.06% formic acid. The column was a reverse-phase (C18), 4 μm mesh Altech Altima, 50 mm in length. Injections of 100 μL were made with an automated sampler for each run for a total of three injections per vial. A mobile phase gradient was utilized to optimize compound separation. The flow rate was set at 300 μL/min. Data analysis was performed by Mass Lynx Ultima software and Microsoft Excel. Smoothing functions were used for peak analysis of the chromatographic peaks. Calibration curves to obtain *R* values from linear least-squares regression were determined at concentrations of the reactants and products in photolyses by systematic increases of pHP-caged GABA, free GABA, and *p*-hydroxyphenylacetic acid concentrations to determine correlations with internal standards caffeine or 4-acetamidophenol. The quantum efficiencies were then calculated from the ratio of the reactant or product concentrations to the photons absorbed using the actinometer values obtains as indicated above.

Lifetime and rate measurements

The Stern–Volmer quenching technique[20] effectively distinguished the triplet lifetimes of pHP derivatives, using potassium sorbate as the quencher. Concentrations of pHP GABA solutions ranged from 0.001 to 0.01 mol/L; these were diluted with sorbate solutions of increasing concentration (0–0.1 mol/L) and subsequently photolyzed under previously indicated conditions to ascertain the change in quantum efficiencies of GABA release. Φ_0/Φ vs [*Q*], and K_{SV} were determined. To establish the triplet lifetime (τ^3), the rate of quenching (k_q) was assumed to be commensurate with the rate of bimolecular diffusion in water ($k_{diff} \sim 7.2 \times 10^9$ s^{-1}). The results are shown in Table 6.

Femtosecond pump–probe spectroscopy

Femtosecond transient absorption was measured with the pump – supercontinuum probe technique using a Ti/Sa laser system (Clark MXR CPA-2001; 775 nm, pulse energy 0.9 mJ, full width at half maximum 150 fs, and operating frequency 426 Hz). Part of the beam was fed into a Clark MXR NOPA. The output at 532 nm was frequency-doubled by a β-barium borate (BBO) crystal to 266 nm and upon compression, elicited pump pulses with an energy of 1 μJ and <150 fs pulse width. A probe beam continuum was generated by focusing the 775 nm beam in front of a CaF_2 plate with a 2 mm path length that produced a supercontinuum probe beam spanning a wavelength range of 270–690 nm. The pump and probe beams were focused to a 0.2 mm spot on the sample that was flowing in an optical cell with a thickness of 0.4 mm. The probe beam and a reference signal (passing the solution beside the pump beam) were spectrally dispersed and registered with two photodiode arrays (512 pixels). Transient absorption spectra were calculated from the ratio of the two beams. The pump–probe cross-correlation was <100 fs over the entire spectrum. Measurements on short time scales (up to 50 ps) were corrected for chirp using a program (SPAN) kindly provided by Professor N. Ernsting, Institut für Chemie, Humboldt Universität zu Berlin, Germany. To improve the signal-to-noise ratio, the data were averaged over multiple pump–probe scans (3–6 scans with 400 shots per temporal point).

Materials

Unless indicated, starting materials were obtained from Sigma-Aldrich or Matrix Scientific. Before usage, solvents were purified via simple distillation employing phosphorus pentoxide, calcium hydride, or calcium chloride and stored in containers with microwave-activated 4 Å molecular sieves. Ultrapure (18 MΩ) water was used in all instances.

Synthesis

pHP GABAs

4-(2-(4-Hydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (1)

The steps to synthesize **1** were described in the protocol by Givens et. al.[5]

4-(2-(4-Hydroxy-3-methoxyphenyl)-2-oxoethoxy)-4-oxobutan-1-amonium-2,2,2-trifluoroacetate (2)

The synthesis of **2** was accomplished by using the procedures of Givens et al.[5] and Conrad et al.[2] as reported for **1**. Under an inert atmosphere of argon, a flame-dried 100 mL round-bottom flask was charged with *N*-Boc-γ-aminobutyric acid (248 mg, 1.22 mmol), 2-bromo-1-(4-hydroxy-3-methoxyphenyl)ethanone (300 mg, 1.22 mmol), and acetonitrile (50 mL). Potassium carbonate (188 mg, 1.36 mmol) was added and the mixture was stirred at room temperature (rt) for 24 h. The solvent was removed under reduced pressure and the remaining residue was dissolved in ethyl acetate and washed with water (3 × 10 mL). The organic extract was dried with $MgSO_4$ and concentrated to afford a pink solid. The crude product was flash chromatographed on silica gel with 2:1, 1:1, and then 2:3 hexane – ethyl acetate. Collection of the appropriate fractions and removal of the solvent under reduced pressure provided 2-(4-hydroxy-3-methoxyphenyl)-2-oxoethyl-4-[(*tert*-butoxycarbonyl)amino]-butanoate as a light pink solid. Yield: 333 mg, 74%; mp 88–89 °C. The *t*-Boc group was removed by treating the 2-(4-hydroxy-3-methoxyphenyl)-2-oxoethyl-4-[(*tert*-butoxycarbonyl)amino]butanoate (281 mg, 0.76 mmol) with cold trifluoroacetic acid (TFA, 10 mL). The solution was stirred at 0 °C for 1 h. The excess TFA was removed under reduced pressure and the remaining residue was dissolved in water, and washed with ethyl acetate. The aqueous layer was collected and the water removed by lyophilization to give 4-(2-(4-hydroxy-3-methoxyphenyl)-2-oxoethoxy)-4-oxobutan-1-amonium-2,2,2-trifluoroacetate as a tan solid (**2**, 545 mg, 100% yield, mp 128–130 °C). IR (KBr, cm^{-1}): 3339, 3181, 3150, 2935, 2756, 2088, 1757, 1675, 1593, 1516, 1460, 1424, 1383, 1368, 1281, 1178, 1132, 1020. ^1H NMR (400 MHz, D_2O) δ: 1.94 (p, *J* = 7.3 Hz, 2H), 2.60 (t, *J* = 7.1 Hz, 2H), 3.00 (t, *J* = 7.7 Hz, 2H), 3.79 (s, 3H), 5.37 (s, 2H), 6.85 (d, *J* = 8.3 Hz, 1H), 7.36 (s, 1H), 7.43 (d, *J* = 8.4 Hz, 1H).

4-(2-(4-Hydroxy-3,5-dimethoxyphenyl)-2-oxoethoxy)-4-oxobutan-1-amonium-2,2,2-trifluoroacetate (3)

The synthesis of **3** was accomplished by using the procedure of Conrad et. al.[2] A solution of 2-bromo-1-(4-hydroxy-3-methoxyphenyl)ethanone[2] (600 mg, 2.18 mmol/L) was treated with 4-(*tert*-butoxycarbonylamino)butanoic acid (N-*t*-Boc-GABA; 443 mg, 2.18 mmol/L) in 10 mL of benzene at 7 °C to which was added 366 mg (2.41 mmol/L) of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in 10 mL of benzene. The mixture was allowed to reach rt and stirred overnight. The solvent was removed in vacuo and the crude product purified by silica gel chromatography (522 mg, 60% yield). The *t*-Boc protecting group was then removed by treatment with TFA (10 mL) at 0 °C for 4 h. The TFA was removed by rotary evaporation and the crude product was treated with H_2O–EA. The aqueous layer was collected and the water removed by lyophilization to give 4-(2-(4-hydroxy-3,5-dimethoxyphenyl)-2-oxoethoxy)-4-oxobutan-1-amonium-2,2,2-trifluoroacetate as a colorless oil (**3**, 100%). IR (film, cm^{-1}): 3388, 3179, 2943, 2847, 1737, 1693, 615, 1536, 1466, 1431, 1379, 1326, 1300, 1169, 1047. ^1H NMR (400 MHz, D_2O) δ: 1.94 (m, 2H), 2.58 (t, *J* = 7.1 Hz, 2H), 3.00 (t, *J* = 7.7 Hz, 2H), 3.63 (s, 6H), 5.18 (s, 2H), 6.75 (s, 2H). FAB MS (free amine) *m*/*z*: 342 (M +1). HRMS calcd for $C_{15}H_{20}NO_8$ (M + H): 342.1189; found: 342.1193.

Representative description, with 16

1-(Benzyloxy)-4-bromo-2-fluorobenzene (16b)

The general method of Frechét and co-workers[21] was followed. A solution of 4-bromo-2-fluorophenol (**16a**, 3.83 g, 20.0 mmol), benzyl bromide (2.38 mL, 20.0 mmol), and potassium carbonate (6.91 g, 50.0 mmol) in CH_3CN (30 mL) was stirred at rt for 15 h. The solution was diluted with 50 mL CH_2Cl_2, washed with water (3 × 30 mL), dried (magnesium sulfate), and concentrated to give 5.24 g (93%) of 1-(benzyloxy)-4-bromo-2-fluorobenzene (**16b**) as a white precipitate; mp 65–67 °C. IR ($CHCl_3$, cm^{-1}): 3020, 2987, 2684, 2304, 1498, 1421, 1265, 1217, 1051, 896, 738, 695. ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.41 (m, 5H), 7.27 (dd, *J* = 6.4, *J* = 2.2 Hz, 1H), 7.26 (dt, *J* = 4.3, *J* = 2.0 Hz, 1H), 6.89 (t, *J* = 8.8 Hz, 1H), 5.13 (s, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 154.23, 151.73, 146.06, 136.02, 128.88, 127.73, 120.14, 117.23, 115.86, 113.02, 71.90. ^{19}F NMR (376 MHz, $CDCl_3$ + 1 drop of CF_3CO_2H) δ (ppm): –130.78. HRMS (M+) calcd for $C_{13}H_{10}FBrO$: 279.9899; found: 279.9905.

1-(Benzyloxy)-3-fluorophenyl)ethanone (16c)

The general method of Kosugi et al.[22] was used. The experimental procedure is described with that for **23** (vide infra).[28] White precipitate; yield: 89%, mp 79–81 °C. IR ($CHCl_3$, cm^{-1}): 3053, 2987, 1679, 1610, 1514, 1498, 1421, 1265, 1217, 1052, 896, 738, 696. ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.74 (dd, *J* = 11.3, *J* = 2.4 Hz, 1H), 7.69 (dd, *J* = 9.0, *J* = 1.6 Hz, 1H) 7.44, (m, 5H), 7.04 (t, *J* = 8.4 Hz, 1H), 5.23 (s, 2H), 2.55, (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 196.05, 153.66, 151.16, 135.82, 130.92, 128.95, 127.57, 125.76, 116.36, 114.22, 71.25, 26.52. ^{19}F NMR (376 MHz, $CDCl_3$ + 1 drop of CF_3CO_2H) δ (ppm): –133.02. HRMS (M + H) calcd for $C_{15}H_{13}FO_2$: 245.0978; found: 245.0951.

1-(4-(Benzyloxy)-3-fluorophenyl)-2-bromoethanone (16d)

The method was adapted from Ohriand co-workers.[23] A 50 mL round-bottom flask was charged with **16c** (700 mg, 2.86 mmol) and phenyltrimethylammonium tribromide (PTAB) (1.07 g, 2.86 mmol). The mixture was subsequently dissolved by the addition of 40 mL of CH_2Cl_2–CH_3OH (1:1). The resultant solution was stirred at rt for 6 h, at which time full conversion was indicated by GC–MS. The solution was transferred to a separatory funnel, diluted with 50 mL of CH_2Cl_2, and washed profusely with water (3 × 50 mL). Excess solvent was removed under reduced pressure, affording an orange precipitate, 900 mg (2.58 mmol), ~95%.[24] IR ($CHCl_3$, cm^{-1}): 3055, 2988, 1679, 1615, 1511,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

1498, 1417, 1267, 1219, 1050, 891, 748, 696. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.77 (dd, J = 10.0, J = 2.4 Hz, 1H), 7.72 (dd, J = 7.0, J = 2.8 Hz, 1H), 7.42 (m, 5H), 7.07 (t, J = 8.4 Hz, 1H), 5.24 (s, 2H), 4.37 (s, 2H). ^{19}F NMR (376 MHz, $CDCl_3$ + 1 drop of CF_3CO_2H) δ (ppm): –133.12.

*2-(4-(Benzyloxy)-3-fluorophenyl)-2-oxoethyl-4-(*tert-*butoxycarbonylamino)butanoate (16e)*

The general method of Fujita and Hiyama[25] was utilized. A solution of 1-(4-(benzyloxy)-3-fluorophenyl)-2-bromoethanone (**16d**, 900 mg, 2.78 mmol), potassium carbonate (1.15 mg, 8.35 mmol), and 4-(*tert*-butoxycarbonylamino) butanoic acid (N-Boc–GABA, 678 mg, 3.33 mmol) in 50 mL of CH_3CN was stirred for 24 h at rt. The solution was washed with EtOAc, water, the aqueous phase discarded, and the resulting phase evaporated under reduced pressure. Flash column chromatography (hexanes–EtOAc, 5:1) afforded **16e** as a white precipitate. Yield: 1.10 g (89%); mp 97–99 °C. IR (KBr, cm^{-1}): 3300, 3100–2800, 1742, 1701, 1600, 1517, 1437, 1400 1309, 1200, 1165, 953, 750, 700, 668. ^{1}H NMR (400 MHz, CD_3CN) δ (ppm): 7.80 (dd, J = 7.0, J = 2.4 Hz, 1H), 7.78 (dd, J = 7.0, J = 2.0 Hz, 1H), 7.47 (dd, J = 4.4, J = 1.8 Hz, 1H), 7.42 (m, 5H), 5.31 (s, 2H), 5.25 (s, 2H), 2.97 (t, J = 6.8 Hz, 2H), 2.45 (t, J = 7.6 Hz, 2H), 1.76 (m, 2H), 1.40 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 190.67, 172.51, 155.60, 152.30, 150.80, 135.82, 128.39, 128.14, 127.68, 126.93, 125.60, 115.28, 114.82, 77.45, 70.36, 66.12, 39.64, 30.63, 28.22, 24.96. ^{19}F NMR (376 MHz, CD_3CN + 1 drop of CF_3CO_2H) δ (ppm): –133.44. HRMS (M + Na) calcd for $C_{24}H_{28}FNO_6Na$: 468.1798; found: 468.1796.

4-(2-(3-Fluoro-4-hydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (16)

The general method of Marsh and Goodman[26] was followed. To a flame-dried 50 mL round-bottom flask containing 2-(4-(benzyloxy)-3-fluorophenyl)-2-oxoethyl-4-(*tert*-butoxy-carbonylamino)-butanoate (**16e,** 850 mg, 1.91 mmol) was added 20 mL of freshly distilled TFA. Stirring continued for 24 h at rt under ambient conditions. The solution was evaporated under reduced pressure and washed with EtOAc–water. The water layer was then extracted, frozen, and then lyophilized, affording **16** as an adhesive precipitate. Yield: 550 mg (78%). IR (KBr, cm^{-1}): 3434, 3269, 3100–2800, 1741, 1693, 1610, 1553, 1420, 1201, 1050, 823, 759, 719. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 7.70 (d, J = 9.0 Hz, 2H), 7.12 (t, J = 9.9 Hz, 1H), 5.50 (s, 2H), 3.09 (t, J = 7.6 Hz, 2H), 2.66 (t, J = 7.0 Hz, 2H), 2.05 (m, 2H). ^{13}C NMR (125 MHz, MeOD) δ (ppm): 190.05, 172.06, 161.60, 152.27, 151.07, 150.33, 126.03, 125.33, 117.30, 115.33, 65.95, 38.54, 30.02, 22.48. ^{19}F NMR (376 MHz, D_2O) δ (ppm): –133.58. HRMS (M+) calcd for $C_{12}H_{15}FNO_4$: 256.0985; found: 256.0977.

The synthetic protocol for generating compounds **14** and **15**[27] and **17**–**23**[28] has been previously published. The synthesis of **13** was analogous to that for **16** and, therefore, only the spectroscopic data for this is described.

1-Benzyloxy-4-bromo-2-cyanobenzene (13b)

White solid. Yield: 87%; mp 80–81 °C. IR (KBr, cm^{-1}): 3068, 3035, 2229, 1591, 1487, 1454, 1287, 1132, 1132, 1018, 813, 742, 696. ^{1}H NMR (400 MHz, CD_3CN) δ (ppm): 5.22 (s, 2H), 7.14 (d, 1H), 7.45 (m, 5H), 7.73 (dd, 1H), 7.81 (d, 1H). ^{13}C NMR (100 MHz, CD_3CN) δ (ppm): 71.9, 104.5, 112.5, 115.9, 116.2, 128.7, 129.4, 129.7, 136.7, 136.8, 138.4, 160.6. HRMS (M+) calcd for $C_{14}H_{10}BrNO$: 286.9946; found: 286.9937.

1-(4-Benzyloxy-3-cyanophenyl)ethanone (13c)

White solid. Yield: 90%; mp 120–123 °C. IR (KBr, cm^{-1}): 3068, 3033, 2229, 1681, 1602, 1500, 1419, 1355, 1275, 1137, 977, 817, 750, 630. ^{1}H NMR (400 MHz, CD_3CN) δ (ppm): 2.53 (s, 3H), 5.31 (s, 2H), 7.26 (d, 1H), 7.44 (m, 5H), 8.17 (dd, 1H), 8.26 (d, 1H). ^{13}C NMR (100 MHz, CD_3CN) δ (ppm): 25.45, 70.79. 101.53, 112.63, 115.27, 127.50, 128.19, 128.40, 130.15, 134.20, 134.50, 1335.27, 163.02, 194.85. HRMS (M + H) calcd for $C_{16}H_{13}NO_2$: 252.1024; found: 252.1022.

1-(4-Benzyloxy)-3-cyanophenyl)-2-bromoethanone (13d)

White solid. Yield: 91%; mp 94–96 °C. IR ($CDCl_3$, cm^{-1}): 688, 833, 1037, 1247, 1280, 1600, 1735, 2115, 2258, 3091. ^{1}H NMR (400 MHz CD_3CN) δ (ppm): 4.63 (s, 2H), 5.35 (s, 2H) 7.16 (d, 1H), 7.46 (m, 5H), 8.25 (dd, 1H), 8.32 (d, 1H). ^{13}C NMR (100 MHz, CD_3CN) δ (ppm): 32.30, 71.30, 102.26, 113.31, 115.34, 117.36, 127.28, 127.88, 128.60, 128.78, 135.10, 135.46, 135.48, 163.87, 188.96. HRMS (M+) calcd for $C_{16}H_{13}BrNO_2$: 330.0130; found: 330.0140.

*2-(4-(Benzyloxy)-3-cyanophenyl-2-oxoethyl-4-(*tert-*butoxycarbonylamino)butanoate (13e)*

White solid. Yield: 81%; mp 119–120 °C. IR ($CHCl_3$, cm^{-1}): 3456, 2252, 1743, 1706, 1600, 1502, 1271, 1166. ^{1}H NMR (400 MHz, CD_3CN) δ (ppm): 1.39 (s, 6H), 1.78 (t, 2H), 2.20 (m, 2H), 3.10 (t, 2H), 5.31 (s, 4H), 7.29 (d, 1H), 7.40 (m, 5H), 8.17 (dd, 1H), 8.25 (d, 1H). ^{13}C NMR (100 MHz, CD_3CN) δ (ppm): 24.47, 25.46, 27.27, 30.34, 39.01, 65.62, 70.79, 70.93, 77.73, 101.89, 112.64, 112.97, 115.01, 117.00, 127.02, 127.53, 128.24, 133.88, 134.15, 135.13, 155.58, 163.57, 172.21, 189.92. HRMS (M + H) calcd for $C_{25}H_{29}N_2O_6$: 452.2026; found: 453.2021.

4-(2-(3-Cyano-4-hydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (13)

Waxy solid. Yield: 50%. IR (KBr, cm^{-1}): 3388, 2358, 2343, 2237, 1677 (broad), 1610, 1438, 1205, 1137, 842, 802, 723. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 1.94 (t, 2H), 2.59 (m, 2H), 3.08 (t, 2H), 5.39 (s, 2H), 7.05 (d, 1H), 8.01 (dd, 1H), 8.18 (d, 1H). ^{13}C NMR (100 MHz, D_2O) δ (ppm): 21.96, 29.43, 38.54, 66.59, 99.25, 112.76, 115.10, 117.42, 119.74, 134.87, 162.83, 172.45, 192.32. HRMS (M+) calcd for $C_{13}H_{15}N_2O_4$: 263.1032; found: 263.1023.

The synthetic course towards **4**–**9** and **12** followed the same protocol as for **13**–**23**, but commenced with the commercially available corresponding *p*-hydroxyacetophenones. Hence, only spectroscopic data for these are indicated.

1-(3,4-Bis(benzyloxy)phenyl)ethanone (4d)

White solid. Yield: 98%. *This compound is known.* ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.63 (dd, J = 8.8, J = 2.3 Hz, 1H), 7.40 (m, 11H), 6.94 (dd, J = 9.2, J = 2.0 Hz, 1H), 5.25 (s, 2H), 5.22 (s, 2H), 2.52 (s, 3H).

For personal use only.

1-(3,4-Bis(benzyloxy)phenyl)-2-bromoethanone (4e)

Oil. Yield: 96%[7]. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.68 (s, 1H), 7.41 (m, 11H), 6.96 (d, 1H), 5.24 (s, 2H), 5.22 (s, 2H), 4.46 (s, 2H).

2-(3,4-Bis(benzyloxy)phenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (4f)

White precipitate. Yield: 90%; mp 112–114 °C. IR (KBr, cm^{-1}): 3310, 3100–2800, 1743, 1700, 1658, 1601, 1436, 1400, 1200, 1165, 955, 745, 742, 700, 697, 665, 651. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.62 (dd, J = 7.2, J = 2.4 Hz, 1H), 7.56 (d, J = 1.8 Hz, 1H), 7.38 (m, 10H), 7.19 (d, J = 8.1 Hz, 1H), 6.92 (t, J = 7.2 Hz, 1H), 5.40 (s, 2H), 5.27 (s, 2H), 5.21 (s, 2H), 2.97 (t, J = 6.8 Hz, 2H), 2.40 (t, J = 7.7 Hz, 2H), 1.70 (m, 2H), 1.38 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 197.09, 171.80, 155.60, 152.85, 147.98, 136.85, 128.41, 127.94, 127.58, 126.84, 122.64, 113.04, 112.51, 77.47, 70.00, 66.07, 39.61, 30.67, 28.22, 24.54. HRMS (M + H) calcd for $C_{31}H_{36}NO_7$: 534.2492; found: 534.2484.

2-(2,4-Dihydroxyphenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (4g)

An adapted method of Theodorakis and co-workers[29] was utilized. To a stoppered round-bottom flask containing a solution of **4f** (1.20 g, 2.24 mmol) and 120 mg of 10% *w*/*w* Pd/C in 25 mL of EtOAc was added H_2 via a needle from a reinforced balloon. The reaction was deemed complete after 4 h by the absence of the reagent band on TLC (hexanes–EtOAc, 1:1). Excess solvent was removed in vacuo to afford an adhesive precipitate. Yield: 98%. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.32 (d, J = 7.2 Hz, 2H), 6.93 (s, 1H), 6.89 (t, J = 6.9 Hz, 1H), 5.39 (s, 2H), 2.98 (t, J = 6.8 Hz, 2H), 2.38 (t, J = 7.9 Hz, 2H), 1.68 (m, 2H), 1.40 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 197.34, 171.97, 155.66, 155.52, 136.92, 123.01, 113.09, 112.39, 77.55, 70.13, 39.56, 30.65, 28.19, 24.53.

4-(2-(3,4-Dihydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (4)

White precipitate. Yield: 92%; mp 56–58 °C. IR (KBr, cm^{-1}): 3432, 3274, 3100–2800, 1739, 1691, 1602, 1520, 1421, 1377, 1309, 1298, 1201, 1178, 1128, 1055, 1027, 1008, 823, 762, 717, 613. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 7.35 (s, 1H), 7.33 (s, 1H), 6.91 (d, J = 7.1 Hz, 1H), 5.36 (s, 2H), 3.07 (t, J = 6.8 Hz, 2H), 2.65 (t, J = 7.8 Hz, 2H), 2.00 (m, 2H). ^{13}C NMR (125 MHz, D_2O) δ (ppm): 194.29, 174.13, 163.06, 150.88, 144.11, 125.88, 122.69, 119.74, 117.42, 115.10, 66.56, 38.30, 30.23, 21.95. HRMS (M+) calcd for $C_{12}H_{16}NO_5$: 254.1028; found: 254.1032.

1-(2,4-Bis(benzyloxy)phenyl)ethanone (5d)

White precipitate. Yield: 97%. *This compound is known.* ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.86 (t, J = 7.6, 1H), 7.39 (m, 11H), 6.64 (dd, J = 8.7, J = 2.3 Hz, 1H), 5.12 (s, 2H), 5.10 (s, 2H), 2.57 (s, 3H).

1-(2,4-Bis(benzyloxy)phenyl)-2-bromoethanone (5e)

Waxy precipitate. Yield: 94%.[7] ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.78 (s, 1H), 7.35 (m, 10H), 6.60 (d, 2H), 5.12 (s, 2H), 5.09 (s, 2H), 4.51 (s, 2H).

2-(2,4-Bis(benzyloxy)phenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (5f)

Adhesive precipitate. Yield: 48%. IR (KBr, cm^{-1}): 3310, 3100–2800, 1743, 1700, 1658, 1601, 1436, 1400, 1200, 1165, 955, 745, 742, 700, 697, 665, 651. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.93 (t, J = 8.8 Hz, 1H), 7.43 (m, 10H), 7.14 (dd, J = 8.7, J = 2.2 Hz, 1H), 6.88 (t, J = 5.7 Hz, 1H), 6.62 (d, J = 4.7 Hz, 1H), 5.37 (s, 2H), 5.29 (s, 1H), 5.21 (s, 1H), 5.10 (s, 2H), 2.94 (t, J = 6.6 Hz, 2H), 2.37 (t, J = 7.5 Hz, 2H), 1.76 (m, 2H), 1.37 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 190.50, 172.15, 164.65, 159.78, 155.58, 135.99, 132.04, 128.35, 127.51, 118.10, 107.59, 103.90, 100.33, 77.43, 70.72, 69.19, 39.95, 30.68, 28.22, 24.88. HRMS (M + H) calcd for $C_{31}H_{36}NO_7$: 534.2492; found: 534.2504.

2-(2,4-Dihydroxyphenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (5g)

Adhesive precipitate. Yield: 97%. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 11.43, (s, 1H), 11.34 (s, 1H), 7.88 (s, 1H), 7.70 (d, 1H), 6.87 (t, 1H), 6.38 (d, 1H), 5.28 (s, 1H), 2.96 (t, 2H), 2.40 (t, 2H), 1.67 (m, 2H), 1.38 (s, 9H).

4-(2-(2,4-Dihydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (5)

White precipitate. Yield: 85%; mp 136–138 °C. IR (KBr, cm^{-1}): 3432, 3274, 3100–2800, 1739, 1691, 1602, 1520, 1421, 1377, 1309, 1298, 1201, 1178, 1128, 1055, 1027, 1008, 823, 762, 717, 613. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 7.97 (d, J = 6.8 Hz, 1H), 7.72 (d, J = 8.8 Hz, 1H), 6.53 (d, J = 7.6v, 1H), 5.48 (s, 1H), 5.43 (s, 1H), 3.14 (t, J = 7.6 Hz, 2H), 2.72 (t, J = 7.0 Hz, 2H), 2.08 (m, 2H). ^{13}C NMR (125 MHz, D_2O) δ (ppm): 193.77, 174.15, 162.75, 151.02, 144.22, 125.92, 122.70, 119.65, 117.37, 115.58, 66.60, 38.51, 30.28, 22.00. HRMS (M+) calcd for $C_{12}H_{16}NO_5$: 254.1028; found: 254.1038.

1-(4-(Benzyloxy)-3-methyl-phenyl)ethanone (6d)

White precipitate. Yield: 95%. *This compound is known.* ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.82 (s 1H), 7.80 (s, 1H), 7.40 (m, 5H), 6.90 (d, J = 8.8 Hz, 1H), 5.17 (s, 2H), 2.56 (s, 3H), 2.33 (s, 3H).

1-(4-(Benzyloxy)-3-methylphenyl)-2-bromoethanone (6e)

Oil. Yield: 97%.[7] ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.82 (d, 2H), 7.40 (m, 5H), 6.88 (d, J = 8.8 Hz, 1H), 5.19 (s, 2H), 4.33 (s, 2H), 2.33 (s, 3H).

2-(4-(Benzyloxy)-3-methylphenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (6f)

White precipitate. Yield: 94%; mp 105–106 °C. IR (KBr, cm^{-1}): 3307, 3100–2800, 1742, 1701, 1659, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.82 (d, J = 9.1 Hz, 2H), 7.40 (m, 5H), 7.14 (d, J = 8.1 Hz, 1H), 6.87 (t, J = 7.4 Hz, 1H), 5.39 (s, 2H), 5.25 (s, 2H), 2.96 (t, J = 6.8 Hz, 2H), 2.42 (t, J = 7.6 Hz, 2H), 2.24 (s, 3H), 1.70 (m, 2H), 1.38 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 191.14, 172.20, 161.40, 155.60, 136.67, 131.00, 130.10, 129.26, 128.50, 127.34, 126.45, 125.07, 111.62, 77.45, 69.55, 66.03, 39.33, 30.68, 28.18, 24.98, 16.04. HRMS (M + Na) calcd for $C_{25}H_{31}NO_6Na$: 464.2049; found: 464.2017.

2-(4-Hydroxy-3-methylphenyl)-2-oxoethyl-4-(tert-butoxycarbonylamino)butanoate (6g)

Adhesive precipitate. Yield: 98%. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 10.76 (s, 1H), 7.86 (d, J = 9.2 Hz, 2H), 7.66 (d, J = 8.0 Hz, 1H), 6.89 (t, 1H), 5.38 (s, 2H) 2.96 (t, J = 6.9 Hz, 2H), 2.42 (t, J = 7.8 Hz, 2H), 2.24 (s, 3H), 1.70 (m, 2H), 1.38 (s, 9H).

4-(2-(4-Hydroxy-3-methylphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (6)

White precipitate. Yield: 89%; mp 118–120 °C. IR (KBr, cm^{-1}): 3432, 3274, 3100–2800, 1739, 1691, 1602, 1520, 1421, 1377, 1309, 1298, 1201, 1178, 1128, 1055, 1027, 1008, 823, 762, 717, 613. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.86 (s, 3H), 7.72 (d, J = 6.2 Hz, 1H), 7.67 (dd, J = 9.0, J = 1.8 Hz, 1H), 5.39 (s, 1H), 2.88 (t, J = 7.0 Hz, 2H), 2.56 (t, J = 7.6 Hz, 2H), 2.16 (s, 3H), 1.87 (m, 2H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 190.67, 171.72, 160.98, 158.27, 130.76, 127.76, 125.10, 120.30, 117.94, 114.76, 66.11, 38.09, 30.15, 22.10, 15.80. HRMS (M+) calcd for $C_{13}H_{18}NO_4$: 252.1230; found: 252.1212.

1-(4-(Benzyloxy)2-methylphenyl)ethanone (7d)

White precipitate. Yield: 93%. *This compound is known.* GC–MS (EI): One peak; retention time, 8.24 min (initial temp 50 °C, ramp 25 °C/min until 300 °C). MS *m*/*z*: 240.0.

1-(4-(Benzyloxy)-2-methylphenyl)-2-bromoethanone (7e)

White precipitate. Yield: 92%. *This compound is known.* GC–MS (EI): One peak; retention time, 9.77 min (initial temp 50 °C, ramp 25 °C/min until 300 °C). MS *m*/*z*: 317.9, 319.9.

2-(4-(Benzyloxy)-2-methylphenyl)-2-oxoethyl-4-(tert-butoxycarbonylamino)butanoate (7f)

Adhesive precipitate.Yield: 91%. IR (KBr, cm^{-1}): 3307, 3100–2800, 1742, 1701, 1659, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.86 (d, J = 9.1 Hz, 1H), 7.47–7.40 (m, 5H), 6.97 (t, J = 6.5 Hz, 2H), 6.87 (t, J = 7.4 Hz, 1H), 5.28 (s, 2H), 5.19 (s, 2H), 2.97 (t, J = 6.7 Hz, 2H), 2.42 (m, 5H), 1.68 (m, 2H), 1.37 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 193.63, 172.21, 161.05, 155.60, 141.48, 136.40, 132.04, 128.47, 127.42, 125.06, 118.30, 111.85, 107.74, 77.45, 69.30, 67.05, 38.83, 30.68, 28.22, 24.54, 21.11. HRMS (M + Na) calcd for $C_{25}H_{31}NO_6Na$: 464.2049; found: 464.2040.

2-(4-Hydroxy-2-methylphenyl)-2-oxoethyl-4-(tert-butoxycarbonylamino)butanoate (7g)

Adhesive precipitate. Yield: 98%. IR (KBr, cm^{-1}): 3460, 3300, 3100–2800, 1740, 1699, 1662, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 10.30 (d, 1H), 7.78 (d, J = 9.1 Hz, 1H), 6.89 (t, J = 7.5 Hz, 1H), 6.71 (t, J = 6.3 Hz, 1H), 5.26 (s, 2H), 2.98 (t, J = 6.7 Hz, 2H), 2.41 (m, 5H), 1.69 (m, 2H), 1.39 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 192.91, 172.21, 160.96, 155.60, 141.83, 131.87, 125.29, 118.74, 112.51, 77.45, 66.86, 38.97, 30.46, 28.22, 24.95, 21.68. HRMS (M + Na) calcd for $C_{18}H_{25}NO_6Na$: 374.1580; found: 374.1577.

4-(2-(4-Hydroxy-2-methylphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (7)

White precipitate. Yield: 95%; mp 110–112 °C. IR (KBr, cm^{-1}): 3460, 3300, 3100–2800, 1740, 1699, 1662, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.86 (s, 3H), 7.80 (d, J = 9.0 Hz, 1H), 6.74 (t, J = 6.2 Hz, 1H), 5.28 (s, 2H), 2.96 (t, J = 6.7 Hz, 2H), 2.54 (t, J = 7.6 Hz, 2H), 2.40 (s, 3H), 1.87 (m, 2H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 192.71, 171.72, 161.19, 158.64, 141.88, 131.90, 124.55, 118.81, 117.56, 112.58, 67.02, 37.84, 30.14, 22.54, 20.34. HRMS (M+) calcd for $C_{13}H_{18}NO_4$: 252.1236; found: 252.1227.

1-(4-(Benzyloxy)-3,5-dimethylphenyl)ethanone (8d)

Oil. Yield: 95%. *This compound is known.* GC–MS (EI): One peak; retention time, 8.38 min (initial temp 50 °C, ramp 25 °C/min until 300 °C). MS *m*/*z*: 254.0.

1-(4-(Benzyloxy)-3,5-dimethylphenyl)-2-bromoethanone (8e)

White precipitate. Yield: 95%. *This compound is known.* GC–MS (EI): One peak; retention time, 9.87 min (initial temp 50 °C, ramp 25 °C/min until 300 °C). MS *m*/*z*: 331.9, 333.9.

2-(4-(Benzyloxy)-3,5-dimethylphenyl)-2-oxoethyl-4-(tert-butoxycarbonylamino)butanoate (8f)

Adhesive precipitate. Yield: 96%. IR (KBr cm^{-1}): 3307, 3100–2800, 1742, 1701, 1659, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 7.70 (d, J = 8.6 Hz, 1H), 7.50–7.40 (m, 5H), 6.89 (t, J = 7.2 Hz, 1H), 5.42 (s, 2H), 4.88 (s, 2H), 2.97 (t, J = 6.9 Hz, 2H), 2.43 (t, J = 7.8 Hz, 2H), 2.29 (s, 6H), 1.68 (m, 2H), 1.36 (s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 191.84, 172.19, 160.04, 155.60, 137.06, 131.49, 129.59, 128.68, 128.36, 128.13, 127.85, 77.45, 73.52, 66.20, 38.97, 30.50, 28.18, 24.97, 16.20. HRMS (M + Na) calcd for $C_{26}H_{33}NO_6Na$: 478.2206; found: 478.2191; (M + H) calcd for $C_{26}H_{34}NO_6$: 456.2386; found: 456.2388.

2-(4-Hydroxy-3,5-dimethylphenyl)-2-oxoethyl-4-(tert-butoxycarbonylamino)butanoate (8g)

Adhesive precipitate. Yield: 99%. IR (KBr, cm^{-1}): 3548, 3301, 3100–2800, 1739, 1702, 1661, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 9.40 (s, 1H), 7.59 (d, J = 8.6 Hz, 2H), 6.89 (t, J = 7.2 Hz, 1H), 5.36 (s, 2H), 2.98 (t, J = 7.0 Hz, 2H), 2.55 (t, J = 7.5 Hz, 2H), 2.20 (s, 6H), 1.92 (m, 2H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 190.91, 172.20, 159.67, 155.59, 128.60, 125.25, 123.74, 77.44, 65.91, 38.96, 30.90, 28.18, 24.98, 16.52. HRMS (M + Na) calcd for $C_{19}H_{27}NO_6Na$: 388.1736; found: 388.1735.

4-(2-(4-Hydroxy-3,5-dimethylphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (8)

White precipitate. Yield: 92%; mp 125–127 °C. IR (KBr, cm^{-1}): 3550, 3301, 3100–2800, 1739, 1702, 1661, 1606, 1437, 1407, 1209, 1167, 955, 743, 700, 667. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 9.36 (s, 1H), 7.86 (s, 3H), 7.62 (d, J = 8.6 Hz, 2H), 5.36 (s, 2H), 2.98 (t, J = 7.0 Hz, 2H), 2.43 (m, 5H), 2.22 (s, 6H), 1.69 (m, 2H), 1.37

For personal use only.

(s, 9H). ^{13}C NMR (125 MHz, d_6-DMSO) δ (ppm): 189.74, 170.61, 157.71, 156.71, 127.72, 124.97, 123.15, 116.95, 65.02, 37.10, 28.88, 21.48, 15.55. HRMS (M+) calcd for $C_{14}H_{20}NO_4$: 266.1392; found: 266.1389.

Benzyl 5-acetyl-2-(benzyloxy)benzoate (9d)

White precipitate. Yield: 93%; mp 98–100 °C. IR (KBr, cm^{-1}): 3325, 3100–2800, 1726, 1697, 1676, 1598, 1500, 1452, 1370, 1269, 1230, 1176, 1060, 1030, 1008, 821, 757, 721, 698. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.46 (d, J = 2.1 Hz, 1H), 8.08 (dd, J = 9.0, J = 2.4 Hz, 1H), 7.44–7.33 (m, 10H), 7.09 (d, J = 8.8 Hz, 2H), 5.38 (s, 2H), 5.25 (s, 2H), 2.58 (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 195.42, 165.04, 160.91, 135.11, 134.24, 133.04, 130.28, 129.16, 128.22, 127.81, 119.35, 117.36, 112.49, 70.08, 68.86, 25.74. HRMS (M + Na) calcd for $C_{23}H_{20}O_4Na$: 383.1259; found: 383.1262.

Benzyl 2-(benzyloxy)-5-(2-bromoacetyl)benzoate (9e)

Oil. Yield: 95%. IR (KBr, cm^{-1}): 3325, 3100–2800, 1726, 1697, 1676, 1598, 1500, 1452, 1370, 1269, 1230, 1176, 1060, 1030, 1008, 821, 757, 721, 698. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.50 (d, J = 2.2 Hz, 1H), 8.10 (dd, J = 9.0, J = 2.4 Hz, 1H), 7.44–7.33 (m, 10H), 7.10 (d, J = 8.9 Hz, 2H), 5.38 (s, 2H), 5.25 (s, 2H), 4.41 (s, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 189.39, 165.32, 162.18, 135.68, 135.48, 134.52, 133.49, 128.74, 128.26, 127.11, 126.47, 120.87, 113.44, 70.86, 67.21, 30.48. HRMS (M + Na) calcd for $C_{23}H_{19}BrO_4Na$: 461.0365; found: 461.0372.

Benzyl-2-(benzyloxy)-5-(2-(4-(*tert*-butoxycarbonylamino)butanoyloxy)acetyl)benzoate (9f)

White precipitate. Yield: 75%; mp 75–77 °C. IR (KBr, cm^{-1}): 3271, 3100–2800, 1733, 1701, 1697, 1600, 1577, 1500, 1454, 1415, 1365, 1269, 1251, 1215, 1166, 1056, 1028, 1008, 919, 875, 821, 758, 700. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 8.26 (d, J = 2.4 Hz, 1H), 8.12 (dd, J = 9.0, J = 2.3 Hz, 1H), 7.44–7.33 (m, 11H), 6.89 (t, J = 5.5 Hz, 2H), 5.45 (s, 2H), 5.33 (s, 2H), 2.97 (t, J = 7.2 Hz, 2H), 2.42 (t, J = 7.0 Hz, 2H), 1.68 (m, 2H), 1.38 (s, 9H). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 190.85, 172.13, 165.28, 161.01, 155.90, 135.82, 133.51, 130.81, 128.42, 128.04, 127.89, 127.33, 126.27, 113.95, 77.78, 70.10, 64.96, 59.73, 39.30, 30.64, 28.22, 25.24. HRMS (M + Na) calcd for $C_{32}H_{35}NO_8Na$: 584.2260; found: 584.2239.

5-(2-(4-(*tert*-Butoxycarbonylamino)butanoyloxy)acetyl)-2-hydroxybenzoic acid (9g)

Adhesive precipitate. Yield: 96%. ^{1}H NMR (400 MHz, d_6-DMSO) δ (ppm): 8.37 (d, J = 2.4 Hz, 1H), 8.08 (dd, J = 9.2, J = 2.3 Hz, 1H), 7.10 (d, J = 8.9 Hz, 2H) 6.90 (t, J = 5.5 Hz, 2H), 5.43 (s, 2H), 2.98 (t, J = 7.2 Hz, 2H), 2.44 (t, J = 7.0 Hz, 2H), 1.68 (m, 2H), 1.36 (s, 9H).

4-(2-(3-Carboxy-4-hydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (9)

Adhesive precipitate. Yield: 94%. IR (KBr, cm^{-1}): 3440, 3274, 3100–2800, 1733, 1741, 1692, 1649, 1631, 1596, 1500, 1450, 1416, 1299, 1201, 1184, 1124, 1053, 1006, 823, 800, 760, 707, 680. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 8.36 (s, 1H), 8.00 (d, J = 8.9 Hz, 1H), 7.08 (d, J = 8.1 Hz), 5.46 (s, 2H), 3.12 (t, J = 7.2 Hz, 2H), 2.68 (t, J = 7.0 Hz, 2H), 2.06 (m, 2H). ^{13}C NMR (125 MHz, D_2O) δ (ppm): 193.77, 174.11, 171.62, 165.14, 163.06, 134.87, 131.89, 119.72, 117.89, 115.09, 113.41, 66.60, 38.55, 30.45, 21.97. HRMS (M+) calcd for $C_{13}H_{16}NO_6$: 282.0978; found: 282.0967.

1-(4-(Benzyloxy)-3-nitrophenyl)ethanone (12d)

White precipitate. Yield; 96%. *This compound is known.* ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.45 (dd, J = 9.2, J = 2.4 Hz, 1H), 8.14 (dd, J = 9.2, J = 1.8 Hz, 1H), 7.42 (m, 6H), 5.34 (s, 2H), 2.60 (s, 2H).

1-(4-(Benzyloxy)-3-nitrophenyl)-2-bromoethanone (12e)

Oil. Yield: 97%.[7] ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.34 (s, 1H), 8.00 (d, 1H), 7.28 (m, 6H), 5.20 (s, 2H), 4.23 (s, 2H).

2-(4-(Benzyloxy)-3-nitrophenyl)-2-oxoethyl-4-(*tert*-butoxycarbonylamino)butanoate (12f)

White precipitate. Yield: 67%; mp 144–146 °C. IR (KBr, cm^{-1}): 3310, 3100–2800, 1740, 1700, 1655, 1603, 1433, 1400, 1204, 1170, 955, 745, 697, 665. ^{1}H NMR (400 MHz, CD_3CN) δ (ppm): 8.37 (dd, J = 7.2, J = 2.6 Hz, 1H), 8.12 (d, J = 1.5 Hz, 1H), 7.43 (m, 6H), 6.85 (t, J = 7.2 Hz, 1H), 5.34 (s, 2H), 3.09 (t, J = 6.8 Hz, 2H), 2.46 (t, J = 7.6 Hz, 2H), 1.77 (m, 2H), 1.40 (s, 9H). ^{13}C NMR (125 MHz, CD_3CN) δ (ppm): 195.22, 173.42, 160.65, 158.77, 139.23, 136.54, 135.40, 133.98, 131.78, 128.36, 125.89, 119.24, 116.82, 66.72, 38.44, 30.51, 29.11, 21.88. HRMS (M + Na) calcd for $C_{24}H_{28}N_2O_8Na$: 495.1743; found: 495.1755

4-(2-(4-Hydroxy-3-nitrophenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (12)

White precipitate. Yield: 78%; mp 76–78 °C. IR (KBr, cm^{-1}): 3441, 3265, 3100–2800, 1740, 1690, 1605, 1520, 1430, 1377, 1309, 1252, 1225, 1199, 1166, 1055, 820, 760. ^{1}H NMR (400 MHz, D_2O) δ (ppm): 8.72 (d, J = 2.2 Hz, 1H), 8.20 (d, J = 9.2 Hz, 1H), 7.32 (d, J = 8.8 Hz, 1H), 5.56 (s, 2H), 3.14 (t, J = 7.8 Hz, 2H), 2.72 (t, J = 9.2 Hz, 2H), 2.08 (m, 2H). ^{13}C NMR (125 MHz, D_2O) δ (ppm): 193.16, 174.10, 163.13, 157.81, 135.75, 134.33, 126.61, 120.50, 117.44, 115.12, 66.69, 38.54, 30.23, 21.96. HRMS (M+) calcd for $C_{12}H_{15}N_2O_6$: 283.0925; found: 283.0914.

The procedures for constructing **10** and **11** were the same as those described by Conrad et. al.;[2a,2c] therefore, only spectral data for these are indicated.

5-Bromoacetyl-2-hydroxybenzoic acid methyl ester (10b)

White solid. Yield: 73%; mp 91–92 °C. IR ($CHCl_3$, cm^{-1}): 3030, 3010, 2957, 1675, 1589, 1491, 1444, 1355, 1309, 1089, 965. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 4.01 (s, 3 H), 4.41 (s, 2 H), 7.05 (d, J = 8.8 Hz, 1H), 8.09 (dd, J = 8.8 Hz, 2.2, 1H), 8.50 (d, J = 2.2 Hz, 1H). ^{13}C NMR (74.5 MHz, $CDCl_3$) δ (ppm): 30.4, 52.8, 112.3, 118.4, 125.6, 132.2, 133.1, 136.0, 165.8, 169.9, 189.3. HRMS (M + H) calcd for $C_{10}H_{10}BrO_4$: 272.9762; found: 272.9759.

5-[4-*tert*-Butoxycarbonylaminobutyryloxy)acetyl]-2-hydroxybenzoic acid methyl ester (10c)

White solid. Yield: 46%; mp 113–114 °C. IR ($CHCl_3$, cm^{-1}): 3447, 3023, 2981, 2953, 1745, 1695, 1681, 1588, 1504, 1444, 1368, 1163, 1089, 962. ^1H (400 MHz, $CDCl_3$) δ (ppm): 1.44 (s, 9 H), 1.91 (q, J = 7.0 Hz, 2 H), 2.54 (t, J = 7.3 Hz, 2 H), 3.23 (q, J = 6.4 Hz, 2 H), 4.00 (s, 3 H), 5.32 (s, 2 H), 7.07 (d, J = 8.8 Hz, 1 H), 8.04 (dd, J = 8.8 Hz, 2.2, 1 H), 8.44 (d, J = 2.2 Hz, 1 H). ^{13}C NMR (74.5 MHz, $CDCl_3$) δ (ppm), 25.5, 28.6, 31.3, 53.0, 65.8, 112.5, 118.7, 126.0, 131.0, 135.1, 166.0, 170.0, 172.9, 190.2. HRMS (M + H) calcd for $C_{19}H_{26}NO_8$: 396.1650; found: 396.1648.

4-(2-(4-Hydroxy-3-(methoxycarbonyl)phenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (10)

Clear oil. Yield: 100%. IR (CH_2Cl_2, cm^{-1}) 3695, 3440, 3040, 2967, 1739, 1648, 1601, 1526, 1492, 1454, 1359, 1228, 1203, 773, 671. ^1H NMR (400 MHz, D_2O) δ (ppm): 2.04 (q, J = 7.0 Hz, 2H), 2.70 (t, J = 7.1 Hz, 2H), 3.10 (t, J = 7.3 Hz, 2H), 3.96 (s, 3H), 5.47 (s, 2H), 7.03 (d, J = 8.73 Hz, 1H), 8.02 (dd, J = 8.8 Hz, 2.2, 1H), 8.36 (d, J = 8.8 Hz, 2.2, 1H). ^{13}C NMR (74.5 MHz, D_2O) δ (ppm): 22.1, 30.4, 38.7, 53.0, 66.5, 112.7, 117.8, 125.1, 131.3, 134.9, 164.3, 169.4, 174.0, 193.2. HRMS (M+) calcd for $C_{14}H_{18}NO_6$: 296.1134; found: 296.1132.

5-Bromoacetyl-2-hydroxybenzamide (11b)

White solid. Yield: 29%; mp 185 °C (dec.). IR (film, cm^{-1}): 3417, 3364, 3305, 3280, 1671, 1650, 1625, 1587, 1487, 1427, 1363, 1286, 1228, 837, 592. ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 4.72 (s, 2 H), 7.03 (d, J = 8.2 Hz, 1H), 7.45 (bs, 1H), 8.12 (dd, J = 8.8 Hz, 2.20, 1H), 8.38 (bs, 1H), 8.56, (d, J = 2.0 Hz, 1H). ^{13}C NMR (74.5 MHz, $CDCl_3$) δ (ppm): 32.7, 114.6, 119.2, 126.2, 130.5, 135.8, 167.9, 173.4, 190.2. HRMS (M + H) calcd for $C_9H_9BrNO_3$ (M + H): 257.9766; found: 257.9783.

4-*tert*-Butoxycarbonylaminobutyric acid 2-(3-carbamoyl-4-hydroxyphenyl)-2-oxoethyl ester (11c)

White solid. Yield: 59%; mp 138–139 °C. IR ($CHCl_3$, cm^{-1}): 3535, 3462, 3414, 3028, 2975, 2931, 1750, 1699, 1663, 1611, 1508, 1417, 1368, 1166. ^1H NMR (400 MHz, acetone-d_6) δ (ppm): 1.4 (s, 9H), 1.85 (q, J = 7.2 Hz, 2H), 2.50 (t, J = 7.4 Hz, 2H), 3.17 (q, J = 6.6 Hz, 2H), 5.42 (s, 2H), 6.05 (bs, 1H), 7.02 (d, J = 8.7 Hz, 1H), 7.55 (bs, 1H), 8.07 (dd, J = 8.7, 1.7 Hz, 1H), 8.37 (bs, 1H), 8.51 (d, J = 1.8 Hz, 1H). ^{13}C NMR (75.4 MHz, acetone-d_6) δ (ppm): 26.3, 28.7, 31.7, 40.4, 66.7, 78.6, 114.5, 119.2, 126.2, 129.4, 134.6, 156.8, 167.7, 173.2, 173.4, 191.2. HRMS (M + H) calcd for $C_{18}H_{25}N_2O_7$: 381.1662; found: 381.1645.

4-(2-(3-Carbamoyl-4-hydroxyphenyl)-2-oxoethoxy)-4-oxobutan-1-aminium-2,2,2-trifluoroacetate (11)

Clear oil. Yield: 100%. IR ($CHCl_3$, cm^{-1}): 3415, 3219, 1728, 1692, 1665, 1629, 1497, 1432, 1377, 1238, 1200, 1144. ^1H NMR (400 MHz, D_2O) δ (ppm): 1.92 (q, J = 7.16 Hz, 2H), 2.61 (t, J = 7.4 Hz, 2H), 3.00 (q, J = 6.6 Hz, 2H), 5.40 (s, 2H), 6.94 (d, J = 8.7 Hz, 1H), 7.90 (dd, J = 8.72, 1.72 Hz, 1 H), 8.32 (d, J = 1.88 Hz, 1 H). ^{13}C NMR (75.4 MHz, D_2O) δ (ppm): 22.4, 30.6, 38.9, 66.9, 115.6, 118.2, 125.2, 130.4, 134.1, 163.2, 171.1, 174.4, 193.7. HRMS (M + H) calcd for $C_{13}H_{17}N_2O_5$: 281.1137; found: 281.1114.

The same protocol used for **13**–**23** was utilized for the synthesis of **24** and **25** up to the formation of benzyl-protected α-bromoacetophenones **13**–**23a**.

2-(4-Hydroxyphenyl)-2-oxoethyl acetate (24)

The sequence towards the synthesis of **24** conformed to that of Wan and co-workers.[30]

2-(Acetyloxy)-1-[3-cyano-4-(phenylmethoxy)phenyl]ethanone (26f)

A solution of NaOAc (175 mg, 2.13 mmol) and **25e** (470 mg, 1.42 mmol) in acetone was stirred overnight. The resulting solution was evaporated to dryness, 15 mL of water was added, and the mixture was extracted with ethyl acetate (3× 15 mL). The ethyl acetate layer was dried with anhyd $MgSO_4$. The solvent was removed and the resulting solid was further purified by column chromatography (hexanes – ethyl acetate, 1:1) to give 2-(acetyloxy)-1-[3-cyano-4-(phenylmethoxy)phenyl]ethanone (**25f**) as a white solid (250 mg, 57%); mp 122–124 °C. IR (KBr, cm^{-1}): 2225, 1735, 1701, 1595, 1321, 1222, 1078, 989, 761. ^1H NMR (400 MHz, CD_3Cl) δ (ppm): 2.20 (s, 3H), 5.17 (s, 2H), 5.27 (s, 2H), 7.21 (m, 1H), 7.37 (m, 6H), 7.87 (d, 1H). ^{13}C NMR (100 MHz, CD_3CN) δ (ppm): 19.3, 65.8, 70.3, 112.2, 118.0, 118.2, 122.2, 127.4, 127.6, 128.1, 128.3, 128.4, 128.4, 131.5, 135.5, 161.7, 169.9, 190.0. HRMS (M + Na) calcd for $C_{18}H_{15}NO_4Na$: 332.0899; found: 332.0901.

2-(3-Cyano-4-hydroxyphenyl)-2-oxoethyl acetate (26)

An adapted method from the synthesis of **4g** was employed. White solid. Yield: 80%; mp 158–160 °C. IR (KBr cm^{-1}): 3203, 2227, 1741, 1672, 1604, 1560, 1321, 1220, 1122, 1074, 896, 837, 740. ^1H NMR (400 MHz $(CD_3)_2CO$) δ (ppm): 2.13 (s, 3H), 5.37 (s, 2H), 7.23 (m, 1H), 7.25 (s, 1H), 8.10 (d, 1H). ^{13}C NMR (100 MHz, $(CD_3)_2CO$): 19.5, 65.9, 113.0, 117.2, 118.1, 122.5, 128.0, 132.1, 161.5, 169.6, 189.6. HRMS (M + Na) calcd for $C_{11}H_9NO_4Na$: 242.0429; found: 242.0417.

2-(Acetyloxy)-1-[2-cyano-4-(phenylmethoxy)phenyl]ethanone (25f)

The same procedure used for **26f** was followed. White solid. Yield: 90%; mp 92–94 °C. IR (KBr, cm^{-1}): 2231, 1741, 1691, 1604, 1377, 1284, 1224, 1085, 823, 738. ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 2.22 (s, 3H), 5.24 (s, 2H), 5.30 (s, 2H), 7.08 (d, 2H), 8.05 (m, 5H), 8.16 (d, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ (ppm): 20.6, 65.6, 71.2, 113.2, 115.1, 127.0, 127.4, 128.7, 128.9, 134.1, 134.2, 134.6, 163.8, 170.4, 189.3. HRMS (M + Na) calcd for $C_{17}H_{16}NO_4Na$: 332.0899; found: 332.0916.

2-(2-Cyano-4-hydroxyphenyl)-2-oxoethyl acetate (25)

White solid. Yield: 90%; mp 185–186 °C. IR (KBr, cm^{-1}): 3150, 2237, 1739, 1666, 1585, 1508, 1421, 1379, 1240, 1124, 1083, 941, 835. ^1H NMR (400 MHz $(CD_3)_2CO$) δ (ppm): 2.14 (s, 3H), 5.42 (s, 2H), 7.19 (d, 1H) 8.12 (dd, 1H), 8.29 (d, 1H). ^{13}C NMR (100 MHz, $(CD_3)_2CO$): 19.5, 65.8, 100.0, 115.3, 116.8, 129.9, 133.8,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

134.0, 163.1, 169.6, 189.7. HRMS (M + H) calcd for $C_{11}H_8NO_4$: 218.0453: found: 218.

pHP Diethyl phosphates

Diethyl (2-(4-hydroxyphenyl)-2-oxoethyl) phosphate (27)

The synthesis of **27** was achieved using the protocol of Givens and Park.[1]

Diethyl (2-(4-hydroxy-3-methoxyphenyl)-2-oxoethyl) phosphate (28)

The synthesis of **28** was achieved using the same protocol used for **27**.[1]

Diethyl (2-(4-hydroxy-3,5-dimethoxyphenyl)-2-oxoethyl) phosphate (29)

The procedure for synthesizing **29** has been previously published.[25]

3-Methoxyphenyl pivalate (30b)

The general method of Gorobets et al.[31] was followed with modifications. To a cooled (0 °C), stirred solution of 3-methoxyphenol (**30a**, 2.0 g, 16.1 mmol) in dry CH_2Cl_2 (10 mL), freshly distilled triethyl amine (3.350 mL, 24.2 mmol) and catalytic amount of 4-dimethylaminopyridine (20 mg, 0.16 mmol) were added under Ar. After 10 min, pivaloyl chloride (2.98 mL, 24.2 mmol) was added dropwise to the reaction mixture. The reaction mixture was allowed to stir for 30 min at 0 °C, brought to rt, and then stirred overnight. At that point, water (10 mL) and ethyl acetate (30 mL) were added to the reaction mixture and the organic phase was washed sequentially with 10% HCl (3 × 25 mL), water (2 × 25 mL), saturated $NaHCO_3$ solution (3 × 25 mL) and brine (2 × 25 mL. The organic phase was separated, dried over anhyd $MgSO_4$, filtered, and the supernatant concentrated under reduced pressure to produce 3-methoxyphenyl pivalate (**30b**) as thick yellow oil (3.335 g, 100%). IR (Teflon film, cm^{-1}) 2972–2837, 1753, 1606, 1593, 1490, 1140, 1115, 1043, 766. ^1H NMR (500 MHz, CD_3COCD_3) δ (ppm): 7.31–7.28 (1H, t, J = 8.1 Hz), 6.82–6.82 (1H, d, J = 2.3 Hz), 6.81–6.80 (1H, d, J = 2.4 Hz), 6.69–6.66 (1H, m), 3.79 (3H, s), 1.33 (9H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 177.8, 161.6, 153.4, 130.6, 114.7, 112.1, 108.7, 55.8, 39.6, 27.4. HRMS (M + H) calcd for $C_{12}H_{17}O_3$: 209.1178; found: 209.1182. The ^1H NMR data were similar to the literature values.[32]

4-(2-Chloroacetyl)-3-methoxyphenyl pivalate (30c)

The general method of Gonzalez-Gomez et al.[33] was followed with modifications. To a cooled (0 °C) stirred solution of $AlCl_3$ (4.73 g, 35.4 mmol) in chloroacetyl chloride (10 mL) under Ar was added 3-methoxyphenyl pivalate (**30b**, 3.355 g, 16.1 mmol). The reaction mixture was allowed to stir for 3 h at 0 °C under Ar. Then, water (20 mL) was added cautiously to quench the reaction and the resulting solution was extracted to EtOAc (4 × 25 mL). The organic phase was washed sequentially with saturated $NaHCO_3$ solution (3 × 25 mL) and brine (2 × 25 mL). The organic phase was separated, dried over anhyd $MgSO_4$, filtered, and the supernatant concentrated under reduced pressure to afford the crude product that was chromatographed on silica gel (EtOAc–hexanes–CH_2Cl_2, 1:2:2) to give 4-(2-chloroacetyl)-3-methoxyphenyl pivalate (**30c**) as green-white crystalline solid (2.32 g, 50%), mp 58–61 °C. IR (KBr, cm^{-1}): 2980–2854, 1757, 1686, 1606, 1420, 1271, 1186, 1117, 897, 791. ^1H NMR (500 MHz, CD_3COCD_3) δ (ppm): 7.85–7.84 (1H, d, J = 8.6 Hz), 7.01–7.00 (1H, d, J = 2.0 Hz), 6.86–6.83 (1H, d, J = 8.6 Hz), 4.90 (2H, s), 4.01 (3H, s), 1.34 (9H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 190.4, 176.7, 161.3, 157.6, 132.6, 123.4, 115.4, 107.2, 56.8, 51.8, 39.8, 27.3. HRMS (M + H) calcd for $C_{14}H_{18}O_4Cl$: 285.0894; found: 285.0912.

4-(2-Diethoxyphosphoryloxyacetyl)-3-methoxyphenyl pivalate (30e)

The general methods of Finkelstein[34] and Yoh et al.[35] were utilized with modifications. A 50 mL round-bottom flask was charged with 4-(2-chloroacetyl)-3-methoxyphenyl pivalate (**30c**, 500 mg, 1.8 mmol) and NaBr (1.08 g, 10.5 mmol). Acetone (20 mL) was added and the resulting mixture was refluxed at 60 °C for 24 h. The reaction mixture was then concentrated and the resulting residue was suspended in ethyl acetate (20 mL) and washed sequentially with brine (2 × 20 mL) and water (20 mL). The ethyl acetate layer was separated, dried over anhyd $MgSO_4$, filtered, and the supernatant concentrated under reduced pressure to afford 4-(2-bromoacetyl)-3-methoxyphenyl pivalate (**30d**) as a white solid (95% conversion to the α-bromo ketone analog according to ^1H NMR). This compound was used directly in the next step without purification. To a stirred solution of 4-(2-bromoacetyl)-3-methoxyphenyl pivalate (**30d**, 548 mg, 1.66 mmol) in CH_3CN (10 mL), diethyl phosphoric acid (641 mg, 4.16 mmol) and Ag_2O (772 mg, 3.33 mmol) were added. The resulting mixture was stirred at 60 °C and the progress of the reaction was monitored by TLC. After 16 h, the black-colored suspension was filtered through a plug of Celite, the filtrate concentrated, and EtOAc (20 mL) was added. The organic layer was washed sequentially with saturated $NaHCO_3$ (40 mL) and water (20 mL) and dried over anhyd $MgSO_4$. The solvent was evaporated to afford the crude product as a yellow-brown liquid that was chromatographed on silica gel using a gradient solvent system (EtOAc–hexanes (1:2), EtOAc–hexanes (1:1), EtOAc–hexanes (2:1), EtOAc–hexanes (3:1), EtOAc–MeOH (19:1)) to produce the 4-(2-(diethoxyphosphoryloxy)acetyl)-2-methoxyphenyl pivalate (**30e**) as a yellow-brown solid (468 mg, 76%), mp 80–84 °C. IR (KBr, cm^{-1}): 2982–2852 (br), 1747, 1686, 1605, 1261, 1124, 1028, 854, 798. ^1H NMR (500 MHz, CD_3COCD_3) δ (ppm): 7.93–7.91 (1H, d, J = 8.6 Hz), 7.01 (1H, d, J = 2.0 Hz), 6.86–6.84 (1H, d, J = 8.5 Hz), 5.18–5.16 (2H, d, J = 10.8 Hz), 4.18–4.12 (4H, m), 4.00 (3H, s), 1.34 (9H, s), 1.32–1.29 (6H, m). ^{13}C NMR (125 MHz, $CDCl_3$) δ (ppm): 193.0, 192.9, 176.7, 161.7, 157.7, 132.4, 122.8, 115.4, 107.1, 73.0, 64.4, 64.3, 56.8, 39.8, 27.3, 16.5. ^{31}P NMR (162 MHz, CD_3COCD_3) δ (ppm): –0.24. HRMS (M + H) calcd for $C_{19}H_{26}O_8PNa$: 425.1341; found: 425.1323.

Diethyl (2-(4-hydroxy-2-methoxyphenyl)-2-oxoethyl) phosphate (30)

NH_4OAc (1.435 g, 18.61 mmol) was added to a stirred solution of 4-(2-(diethoxyphosphoryloxy)acetyl)-2-methoxyphenyl pivalate (**30e**, 468 mg, 1.16 mmol) in aq MeOH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

(H_2O–MeOH, 1:4, 20 mL). The resulting mixture was warmed at 50 °C and the progress of the reaction was monitored by TLC. After 36 h, the reaction mixture was concentrated and the residue was extracted with EtOAc (5 × 10 mL). Combined organic layers were dried over anhyd $MgSO_4$ and the solvent was evaporated to afford diethyl 2-(4-hydroxy-3-methoxyphenyl)-2-oxoethyl phosphate (**30**) as a dark yellow solid that was further purified on silica gel using a gradient solvent system (EtOAc–hexanes (3:1), EtOAc–MeOH (19:1)) to isolate the pure compound as a white crystalline solid (340 mg, 92%), mp 95–98 °C. IR (KBr, cm^{-1}): 3134, 1672, 1602, 1473, 1383, 1337, 1231, 1032, 984, 849. ^{1}H NMR (400 MHz, CD_3COCD_3) δ (ppm): 9.40 (1H, s) 7.83–7.81 (2H, d, J = 8.8 Hz), 6.56 (2H, m), 5.12–5.09 (2H, d, J = 11.2 Hz), 4.20–4.13 (4H, m), 3.94 (3H, s), 1.33–1.29 (6H, m). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 191.5, 164.97, 162.9, 133.4, 117.3, 109.4, 99.7, 73.1, 73.0, 64.4, 56.1, 16.5. ^{31}P NMR (162 MHz, CD_3COCD_3) δ (ppm): –0.37. HRMS (M – H) calcd for $C_{13}H_{18}O_7P$: 317.0790; found: 317.0795.

The same protocol was used for the synthesis of **31b** and **31d** except for the final step for **31** and only spectral data are conveyed for these derivatives.

3,5-Dimethoxyphenyl pivalate (31b)

Oil. Yield: 100%. IR (Teflon film, cm^{-1}): 2968–2839, 1751, 1618, 1475, 1130, 1063, 895, 835, 681. ^{1}H NMR (500 MHz, CD_3COCD_3) δ (ppm): 6.38–6.37 (1H, t, J = 2.3 Hz), 6.29 (1H, s), 6.28 (1H, s), 3.77 (6H, s), 1.32 (9H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 176.9, 162.2, 154.0, 101.8, 98.4, 55.9, 39.6, 27.4. HRMS (M + Na) calcd for $C_{13}H_{18}O_4Na$: 261.1103; found: 261.1100.

4-(2-Bromoacetyl)-3,5-dimethoxyphenyl pivalate (31d)

White solid. Yield: 20%; mp 125–128 °C. IR (KBr, cm^{-1}): 3018–2841, 1749, 1732, 1597, 1464, 1412, 1221, 1128, 997, 892. ^{1}H NMR (500 MHz, CD_3COCD_3) δ (ppm): 6.53 (2H, s), 4.59 (2H, s), 3.81 (6H, s), 1.33 (9H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 193.9, 176.8, 158.9, 155.6, 114.9, 99.7, 56.8, 51.0, 39.7, 27.4. HRMS (M + Na) calcd for $C_{15}H_{19}O_5BrNa$: 381.0314; found: 381.0312.

Diethyl (2-(4-hydroxy-2,6-dimethoxyphenyl)-2-oxoethyl) phosphate (31)

The general methods of Knopik et al.[36] and Das et al.[37] were followed with some modifications. The potassium salt of diethyl phosphoric acid (535 mg, 2.78 mmol) and dibenzo-[18]-crown-6 (50 mg, 0.14 mmol) were added to a stirred solution of 4-(2-bromoacetyl)-3,5-dimethoxyphenyl pivalate (**31d**, 500 mg, 1.40 mmol) in CH_3CN (10 mL). The resulting mixture was stirred at 80 °C and the progress of the reaction was monitored by TLC. After 16 h, the reaction mixture was concentrated and EtOAc (20 mL) was added. The organic layer was washed sequentially with saturated $NaHCO_3$ (40 mL) and water (20 mL) and dried over anhyd $MgSO_4$. The solvent was evaporated to afford the crude product as a yellow-white solid that was chromatographed on silica gel using a gradient solvent system (EtOAc–hexanes (1:2), EtOAc–hexanes (1:1), EtOAc–hexanes (2:1), EtOAc–hexanes (3:1), EtOAc–MeOH (19:1)) to isolate the crude diethyl 2-(4-hydroxy-2,6-dimethoxyphenyl)-2-oxoethyl phosphate as a dark yellow thick oil. Several attempts were made to purify the product on silica gel, but they were unsuccessful. Therefore, the crude product was used in the deprotection step without further purification. NH_4OAc (456 mg, 5.92 mmol) was added to a stirred solution of the crude phosphate from the previous step (160 mg) in aq MeOH (H_2O–MeOH, 1:4, 10 mL). The resulting mixture was warmed at 50 °C and the progress of the reaction monitored by TLC. After 36 h, the reaction mixture was concentrated and the residue was extracted with EtOAc (5 × 10 mL). The combined organic layers were dried over anhyd $MgSO_4$, and the solvent was evaporated to afford diethyl 2-(4-hydroxy-2,6-dimethoxyphenyl)-2-oxoethyl phosphate (**31**) as a yellow-brown thick oil that was further purified by preparative TLC (hexanes–isopropanol–chloroform, 1:1:11) to produce the pure product as a thick yellow oil (10 mg, overall 2%). UV–vis [H_2O–CH_3CN (1:1)] λ_{max} (ε $(mol/L)^{-1}$ cm^{-1}): 283 (5013). IR (Teflon film, cm^{-1}): 2959–2852, 1738, 1593, 1462, 1342, 1261, 1211, 1153, 1028, 800. ^{1}H NMR (400 MHz, CD_3COCD_3) δ (ppm): 9.04 (1H, s), 6.18 (1H, s), 4.81–4.79 (2H, d, J = 9.3 Hz), 4.13–4.05 (2H, m), 3.75 (3H, s), 1.30–1.27 (6H, m). ^{13}C NMR (125 MHz, CD_3COCD_3) δ ppm 196, 162.4, 160.2, 108.8, 92.9, 72.2, 64.4, 56.2, 16.5. ^{31}P NMR (162 MHz, CD_3COCD_3) δ (ppm): –0.75. MS (ESI (–)) m/z calcd for $(C_{14}H_{21}O_8P–H)^-$: 347.0896; found: 347.0887.

3-Acetyl-4-hydroxybenzoic acid (32b)

The general method of Nagano and Matsumura[38] was followed with modifications. Aluminum chloride (2.96 g, 22.2 mmol) was added into a flame-dried three-neck round-bottom flask containing a solution of 4-hydroxybenzoic acid (**32a**; 1.0 g, 5.55 mmol) in nitrobenzene (10 mL) under Ar. The reaction mixture was kept stirring vigorously at 150 °C for 14 h in the three-neck flask fitted with a $CaCl_2$ tube. On cooling, some crushed ice and 10% HCl (50 mL) were added to the flask, and the separated nitrobenzene was removed by distillation. The aqueous phase was extracted with EtOAc (3 × 25 mL) and washed with saturated $NaHCO_3$ solution (3 × 25 mL). The alkaline aqueous phase was acidified with 10% HCl and extracted again with EtOAc (3 × 25 mL). The combined later organic layers were dried over anhyd $MgSO_4$, filtered, and the supernatant concentrated under reduced pressure to afford 3-acetyl-4-hydroxybenzoic acid (**32b**) as a pink colored solid (980 mg, 98%), mp 227–230 °C. IR (KBr, cm^{-1}): 3433, 1684, 1643, 1610, 1578, 1420, 1325, 1296, 1215, 1122, 943, 825, 771. ^{1}H NMR (400 MHz, CD_3COCD_3) δ (ppm): 12.71 (1H, s), 8.56 (1H, s), 8.17–8.15 (1H, d, J = 8.0 Hz), 7.05–7.03 (1H, d, J = 8.0 Hz), 2.77 (3H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 166.7, 166.6, 138.1, 134.6, 122.4, 120.2, 119.1, 119.0, 27.0. HRMS (M – H) calcd for $C_9H_7O_4$: 179.0344; found: 179.0323

4-Acetoxy-3-acetylbenzoic acid (32c)

Triethyl amine (1.465 mL, 10.55 mmol) followed by acetyl chloride dropwise (564 μL, 7.91 mmol) was added to a stirred solution of **32b** (950 mg, 5.27 mmol) in dry CH_2Cl_2 (15 mL) under Ar. The reaction mixture was allowed to stir for 45 min at rt. At that point, ethyl acetate (40 mL) was added to the reaction mixture, and the organic phase was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

washed with 10% HCl (3 × 25 mL) followed by saturated $NaHCO_3$ solution (3 × 25 mL). The aqueous fractions from the $NaHCO_3$ extraction were combined, acidified with 10% HCl, and extracted into EtOAc (3 × 25 mL). The EtOAc fractions were combined, dried over anhyd $MgSO_4$, filtered, and the supernatant concentrated under reduced pressure to afford the 4-acetoxy-3-acetylbenzoic acid (**32c**) as a pink solid (820 mg, 70%), mp 125–145 °C (dec.). IR (KBr, cm^{-1}) 3078–2552 (br), 1767, 1689, 1647, 1429, 1296, 1192, 918, 735; ^1H NMR (400 MHz, CD_3COCD_3) δ (ppm): 10.44 (1H, s), 8.48 (1H, d, *J* = 1.8 Hz), 8.23–8.21 (1H, d, *J* = 8.4 Hz), 7.35–7.33 (1H, d, *J* = 8.4 Hz), 2.60 (3H, s), 2.33 (3H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 197.3, 169.4, 166.4, 153.5, 138.1, 135.1, 132.3, 129.3, 125.4, 119.1, 27.0, 21.2. HRMS (M – H) calcd for $C_{11}H_9O_5$: 221.0450; found: 221.0440.

1-(3-Acetyl-4-hydroxyphenyl)-2-diazoethanone (32d)

A flame-dried 50 mL round-bottom flask was charged with **32c** (830 mg, 3.74 mmol) and freshly distilled $SOCl_2$ (20 mL) was added under Ar. The resulting mixture was refluxed at 80 °C for 8 h and concentrated under reduced pressure to afford 4-acetoxy-3-acetylbenzoyl chloride as colorless oil. This acid chloride was used in next step without further purification. To a solution of KOH (3.0 g, 53.5 mmol) in 2-methoxyethanol (17 mL) and water (5 mL), diazold (5.0 g, 23.3 mmol) in diethyl ether (75 mL) was added carefully. The resulting mixture was gently heated to reflux temperatures (40–45 °C). The ether layer was distilled into the collection flask in an ice bath at 0 °C. The ether distillate was sequentially dried over KOH pellets for 1 h at 0 °C and with Na pieces for 1 h at 0 °C. Then a solution of acid chloride (899 mg, 3.74 mmol) in dry ether (10 mL) was added dropwise to the distillate (diazomethane) with vigorous stirring at –5 °C. The reaction mixture was allowed to come to 0 °C and stirred overnight. The solvent was evaporated, and the yellowish orange thick oil was used in the deptrotection step without purification. To a stirred solution of crude 2-acetyl-4-(2-diazoacetyl)phenyl acetate (340 mg, 1.38 mmol) in aq MeOH (H_2O–MeOH, 1:4, 20 mL), NH_4OAc (852 mg, 11.05 mmol) was added. The resulting mixture was warmed at 50 °C and the progress of the reaction was monitored by TLC. After 8 h, the reaction mixture was concentrated and the residue was extracted with acetone (5 × 10 mL). The combined organic layers were dried over anhyd $MgSO_4$ and the solvent was evaporated to afford 1-(3-acetyl-4-hydroxyphenyl)-2-diazoethanone (**32d**) as a yellowish brown oil that was further purified on silica gel (hexanes–EtOAc, 1:1) to generate the pure compound as a yellow oil (254 mg, 21% overall yield). IR (Teflon film, cm^{-1}): 3364, 2112, 1761, 1690, 1614, 1418, 1362, 1196, 1150, 1011, 914, 847, 733. ^1H NMR (400 MHz, CD_3COCD_3) δ (ppm): 12.68 (1H, s), 8.40 (1H, d, *J* = 2.2 Hz), 8.04–8.01 (1H, d, *J* = 8.8 Hz), 7.03–7.01 (1H, d, *J* = 8.8 Hz), 6.69 (1H, s), 2.76 (3H, s). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 197.5, 185.0, 169.5, 153.2, 135.3, 132.2, 129.6, 125.4, 54.9, 21.2. HRMS (M – H) calcd for $C_{10}H_7N_2O_3$: 203.0457; found: 203.0452.

2-(3-Acetyl-4-hydroxyphenyl)-2-oxoethyl diethyl phosphate (32)

To a stirred solution of **32d** (240 mg, 1.18 mmol) in benzene (10 mL), diethyl phosphoric acid (362 mg, 2.35 mmol) in benzene (5 mL) was added dropwise. The resulting mixture was stirred at 60 °C and the progress of the reaction was monitored by the TLC. After 24 h, EtOAc (20 mL) was added to the reaction mixture. The organic layer was washed sequentially with saturated $NaHCO_3$ (40 mL) and water (20 mL) and then dried over anhyd $MgSO_4$. The solvent was evaporated to afford the crude product as a brownish yellow oil that was chromatographed on silica gel (with a gradient solvent system: EtOAc–hexanes (1:2), EtOAc–hexanes (1:1), EtOAc–hexanes (2:1), EtOAc–hexanes (3:1)) to produce 2-(3-acetyl-4-hydroxyphenyl)-2-oxoethyl diethyl phosphate (**32**) as a thick brown oil (306 mg, 79% yield). IR (Teflon film, cm^{-1}): 3443, 2985–2872, 1703, 1643, 1597, 1369, 1265, 1209, 1153, 1030, 820. ^1H NMR (400 MHz, CD_3COCD_3) δ (ppm): 12.81 (1H, s), 8.59–8.58 (1H, d, *J* = 2.2 Hz), 8.17–8.14 (1H, d, *J* = 8.8 Hz), 7.08–7.06 (1H, d, *J* = 8.8 Hz), 5.42–5.39 (2H, d, *J* = 10.6 Hz), 4.18–4.13 (4H, m), 2.79 (3H, s), 1.33–1.30 (6H, m). ^{13}C NMR (125 MHz, CD_3COCD_3) δ (ppm): 191.6, 167.2, 136.5, 133.3, 126.8, 120.2, 119.4, 119.3, 69.5, 64.6, 27.2, 16.5, 16.4. ^{31}P NMR (162 MHz, CD_3COCD_3) δ (ppm): –0.14. HRMS (M – H) calcd for $C_{14}H_{18}O_7P$: 329.0790; found: 329.0772.

Deposition of anionic conjugated poly(phenylenevinylene) onto silica nanoparticles via electrostatic interactions — Assembly and single-particle spectroscopy

An T. Ngo, Kai L. Lau, Jeffrey S. Quesnel, Robert Aboukhalil, and Gonzalo Cosa

Abstract: Fluorescent nanoparticles were prepared via adsorption of the conjugated polyelectrolyte poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) onto 50 and 100 nm aminosilane functionalized silica beads. The particles were investigated via ensemble and single-molecule or -particle spectroscopy techniques to quantify the effect of the silica bead core on the exciton migration efficiency within the polymer. Ensemble emission spectra and ensemble fluorescence quenching studies with methyl viologen are consistent with good exciton migration along the polymer in the polymer-coated bead. The silica nanobead scaffolding preserves the sensitivity of the free polymer and provides a controllable architecture that minimizes nonspecific interactions. Single-particle spectroscopy studies were conducted on particles immobilized onto the positively charged surface of glass cover slips. Particle immobilization enabled us to monitor the effect of oxygen scavenger solutions on individual particles by changing the surrounding solution. The intensity–time trajectories of individual beads provide a mechanism of signal transduction with potential applications in multiplexing studies. Hundreds of individual beads can be imaged in a rapid parallel fashion.

Key words: fluorescent sensor, water-soluble light-emitting polymer, energy migration, single-molecule spectroscopy, organic–inorganic nanoparticle.

Résumé : On a préparé des nanoparticules fluorescentes par adsorption du polyélectrolyte conjugué poly[5-méthoxy-2-(3-sulfopropoxy)-1,4-phénylènevinylène] (MPS-PPV) sur des billes de silice de 50 et de 100 nm fonctionnalisées avec de l'aminosilane. Afin de quantifier l'effet du coeur de la bille de silice sur l'efficacité de la migration de l'exciton dans le polymère, on a étudié les particules par des techniques de spectroscopie sur l'ensemble et sur les molécules et particules individuelles. Le spectre d'émission de l'ensemble et les études de désactivation de fluorescence par le viologène de méthyle sur l'ensemble sont en accord avec une bonne migration de l'exciton le long du polymère dans la bille couverte de polymère. L'échafaudage de la nanobille de silice permet de préserver la sensibilité du polymère libre et fournit une architecture contrôlable qui minimise les interactions non spécifiques. Des études de spectroscopie sur des particules individuelles ont été effectuées sur des particules immobilisées sur la surface chargée d'une façon positive de lamelles de verre. L'immobilisation des particules nous a permis de suivre l'effet des solutions pièges d'oxygène sur des particules individuelles par un changement de la solution environnante. Les trajectoires d'intensité et temps des billes individuelles fournit un mécanisme de transduction de signal avec des applications potentielles dans des études de multiplexage. Il est possible de faire l'image de centaines de billes individuelles d'une façon parallèle rapide.

Mots-clés : senseur fluorescent, polymère émettant de la lumière soluble dans l'eau, migration d'énergie, spectroscopie de molécule individuelle, nanoparticule organique–inorganique.

[Traduit par la Rédaction]

Introduction

Conjugated polyelectrolytes have attracted interest over the past 10 years as highly sensitive fluorescent molecules for the detection of biological and chemical analytes.[1–5] Their sensitivity stems from the delocalization of the excited state across multiple chromophore segments along the polymer backbone. Rapid exciton migration to molecular quenchers (analytes of interest) located along a polymer backbone accounts for amplified fluorescence quenching[1,2] or superquenching,[5] which gives these polymers a unique sensitivity.

A number of studies have shown that rapid exciton migration is normally encountered in polymer chains that are

highly folded and (or) aggregated, where through-space energy transfer is a viable transport mechanism, but it is not common in extended polymer chains, where through-bond energy transfer is the dominant exciton transport mechanism.[6–8] Conditions that favour the aggregation of the polymer are therefore more conducive to rapid exciton transport and highly sensitive quenching.

The deposition of conjugated polyelectrolytes onto silica beads[9–12] or other substrates[13,14] via electrostatic interaction[15] has been proposed by a number of researchers as a means of providing a well-controlled environment with increased polymer backbone interaction that would allow for faster exciton transport and thus greater sensitivity in the conjugated polymer. Whitten and co-workers have explored the use of μm-sized beads coated with a cationic poly(phenylene ethynylene) (PPE) conjugated polyelectrolyte, which is in turn coated by a lipid bilayer, to report upon the degradation of the lipid bilayer by surfactants[9] or phospholipase enzymes.[11] Schanze and co-workers[16] have exploited the singlet-oxygen-producing ability of such supported conjugated polyelectrolytes as a potential biocide. Finally, Swager and co-workers,[10,17] working on sub-μm beads and employing a layer by layer deposition strategy, have reported on the preparation of 200 nm beads with alternating quaternary ammonium polycations and negatively charged PPE. They observed that the sensitivity of the 200 nm silica-bead-supported PPE increased upon the deposition of multiple PPE layers.[10]

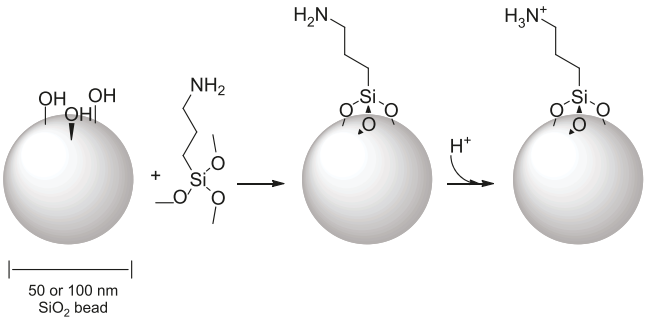
Here we report on the functionalization of silica nanobeads (50 and 100 nm in diameter) with aminosilane groups and their subsequent coating with the anionic conjugated polyelectrolyte poly(phenylene vinylene) poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV). We also describe the characterization of these particles via both ensemble and single-particle spectroscopy. Ensemble emission spectra and ensemble fluorescence quenching studies with methyl viologen are consistent with good exciton migration along the polymer in the polymer-coated bead. Single-particle studies on the nanobeads provide insight into the polymer photophysics and illustrate the use of conjugated polyelectrolytes in novel fluorescent assays, where the intensity–time trajectories of individual nanobeads provide a mechanism of signal transduction with potential applications in multiplexing studies. Hundreds of individual beads can be imaged in a rapid parallel fashion.

Results and discussion

Preparation of MPS-PPV-coated SiO_2 beads

To enable the adsorption of anionic MPS-PPV via electrostatic interactions, we first functionalized the silica beads with aminosilane groups to render them cationic. Anionic silica nanoparticles 50 and 100 nm in diameter were functionalized with 3-aminopropyltrimethoxysilane following the procedure described by Haller and co-workers.[18] 3-Aminopropyltrimethoxysilane (97%) was added to a suspension of silica nanoparticles in water. The concentration of nanobeads (stated as mol of bead/L unless otherwise specified) was 9.10×10^{-8} mol/L for 100 nm beads (5.65 wt% silica, d = 1.027 g/mL) and 3.7×10^{-6} mol/L for 50 nm beads (20–21 wt% silica). After several seconds of vortexing, 38% (12 N) HCl was added to quench the reaction. This was followed by thorough washing of the beads with distilled deionized water in various precipitation–resuspension steps. The functionalization process was verified by measuring the bead ζ potential (Figs. 1A and 1B). Prior to functionalization, and owing to the deprotonated silanol groups on the bead surface, the beads exhibited negative ζ potentials of –56 ± 13 mV (50 nm beads) and –38 ± 2 mV (100 nm beads). Functionalization introduced amine groups at an optimal ratio of three hydroxyl groups to one amine (Scheme 1). This reversed the sign of the surface potential at neutral pH, producing ζ potential values of +43 ± 9 mV (50 nm beads) and +37 ± 11 mV (100 nm beads). Functionalization did not affect the mean hydrodynamic diameter of the 50 or 100 nm beads, but produced a slight broadening in the size distribution of the 100 nm beads. The functionalized beads were used within 3 months following the aminosilanization, although the colloidal suspensions may be stable for years.[18]

Scheme 1. Amine functionalization of silica beads (drawing not to scale).[18]



The beads were next coated with the conjugated polyelectrolyte MPS-PPV by adding aliquots of bead solution slowly, with mixing,[9] to ca. stoichiometric amounts of MPS-PPV in 1 mmol/L sodium acetate buffer, pH 5.80. A number of steps consisting of bead addition to MPS-PPV solutions, mechanical agitation, centrifugation, supernatant removal, and resuspension (first in a fresh MPS-PPV solution, and after 3 cycles, in a 1 mmol/L *N*-(2-hydroxyethyl)-piperazine-*N*′-ethanesulfonic acid (HEPES, pH 7.3) buffer for the next 4 cycles) followed. Use of insufficient polymer during the initial step of the coating procedure was visually indicated by a colourless rather than an orange supernatant (which is otherwise seen and indicates a large amount of un-adsorbed polymer). The order of addition (beads to polymer) was important to prevent aggregation between partially coated beads.

The coating process was verified by ζ potential and dynamic light scattering (Fig. 1). Following coating with MPS-PPV, the 50 and 100 nm beads exhibited ζ potentials of –34 ± 19 and –37 ± 22 mV, respectively. We measured a mean hydrodynamic diameter of 140 nm ± 14 nm for the MPS-PPV-coated 100 nm silica beads ($S100^{-}NH_3^{+}PPV^{-}$) (see Fig. 1B), which was within the standard deviation of the starting amino-functionalized bead ($S100^{-}NH_3^{+}$) diameter, 122 nm ± 25 nm. We may conclude that the coated beads formed no dimers or larger aggregates. In contrast the

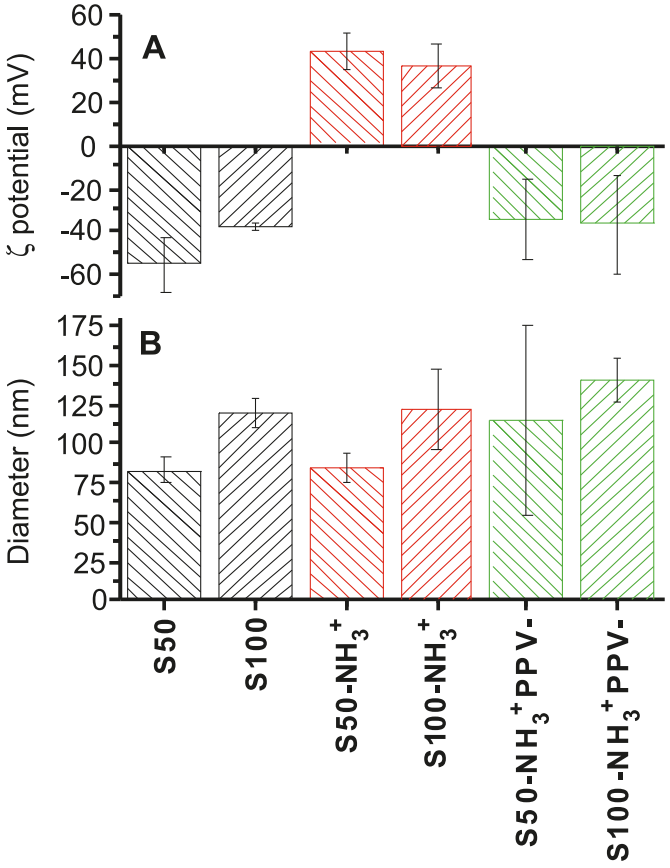
Fig. 1. Zeta (ζ) potential (A) and mean hydrodynamic diameter (B) upon functionalization and coating of silica nanobeads with the anionic conjugated polyelectrolyte poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV). Two different bead diameters (50 and 100 nm) were studied. S50, S100, anionic silica nanobeads; $S50^{-}NH_3^{+}$, $S100^{-}NH_3^{+}$, amine-functionalized silica nanobeads; and $S50^{-}NH_3^{+}PPV^{-}$, $S100^{-}NH_3^{+}PPV^{-}$, MPS-PPV coated onto amine-functionalized silica nanobeads.



50 nm silica beads had an average diameter of 83 nm ± 8 nm when bare ($S50^{-}NH_3^{+}$) and 115 nm ± 60 nm when coated ($S50^{-}NH_3^{+}PPV^{-}$) (Fig. 1B). This increase in size would indicate that particle dimerization occurred during polymer coating.

The amount of MPS-PPV coating was next quantified by UV–vis absorbance of the supernatants. A final value of 69% coverage was calculated assuming one MPS-PPV monomer per 0.36 nm^2 of bead surface.[19] Table 1 shows representative absorbance values for the supernatants in the bead-coating procedure. We may note that the first three supernatants contained polymer that did not adsorb onto the beads when the beads were exposed to free polymer solutions on three consecutive resuspension–precipitation cycles. Also, the fraction of polymer remaining in solution increased substantially in consecutive cycles, consistent with significant coating occurring in the first adsorption cycle. The last five supernatants listed in Table 1 correspond to washing cycles. These supernatants contain excess polymer that was washed off the beads after coating in the first three cycles. Here the amount of polymer washed from the beads decreases with washing cycles.

Absorption and fluorescence

Following the preparation of MPS-PPV-coated nanobeads, we characterized them via ensemble spectroscopy. We acquired UV–vis absorption spectra after subtracting the contribution owing to scattering from the beads. Given that these beads are 6- to 100-fold smaller than those silica beads previously reported by other groups,[9–12] their light scattering is less pronounced at wavelengths where MPS-PPV absorbs. No major spectral differences were observed upon comparing the absorption or emission spectra of the MPS-PPV coated beads to those of the free polymer in solution (Fig. 2). The relative emission quantum yields (Φ_f) were also determined upon 450 nm excitation; MPS-PPV adsorption to silica beads reduced its emission quantum yield by 30%–50% (Table 2).

Fluorescence quenching studies

We next conducted ensemble quenching studies on MPS-PPV-coated beads and on free MPS-PPV employing methyl viologen (MV^{2+}) as a quencher.[3,14,20,21] The results are summarized in Table 3 and illustrated in Fig. 3. Whereas MPS-PPV coated onto 100 nm beads had essentially the same Stern–Volmer fluorescence quenching constant as the free polymer, MPS-PPV coated onto 50 nm beads exhibited a threefold increase in the Stern–Volmer constant (K_{sv}) compared with free polymer, this change may be accounted for by electronic and surface effects different in each of the two beads. Electronic and surface effects upon adsorption onto beads have been shown to magnify the K_{sv} of other fluorescent polymers (with respect to nitroaromatic quenchers) by up to 200-fold.[10,17]

The upward curvature observed in the Stern–Volmer plots (Fig. 3D) likely indicates that more than one quenching mechanism is operational, such as a combination of both static and dynamic quenching.[22] For free MPS-PPV, it has been shown that deviation from linearity with increasing quencher concentration arises from MV^{2+}-mediated aggregation of the polyanionic polymer.[23] Aggregation in turn increases the probability of exciton migration to the quencher site and leads to enhanced sensitivity to the quencher.[24]

Counter ion induced aggregation should play a less significant role when MPS-PPV is coated onto aminosilanized silica beads. Whereas deviations from linearity are not significant in 100 nm beads, they are, however, observed in quenching plots of MPS-PPV coated onto 50 nm beads. This observation, together with some extent of blue shift in the emission spectra with increasing MV^{2+} (see the following) would point to either the presence of short MPS-PPV oligomers in solution or to the presence of labile, nonaggregated, fragments on the surface.

We note that following increasing additions of quencher, the free MPS-PPV exhibited a gradual blue shift (Fig. 3) from 567 to 553 (3.52×10^{-7} mol/L) to 543 nm (5.57×10^{-7} mol/L MV^{2+}) and then finally to 519 nm (9.49×10^{-7} mol/L). Such a marked shift is not observed with MPS-PPV adsorbed onto silica beads. MPS-PPV coated onto 50 nm beads exhibits a small blue shift, from 570 (no MV^{2+}) to 561 nm (2.34×10^{-7} mol/L MV^{2+}); the blue shift for MPS-PPV coated onto 100 nm beads is negligible, from 567 (no MV^{2+}) to 563 nm (5.55×10^{-7} mol/L MV^{2+}).

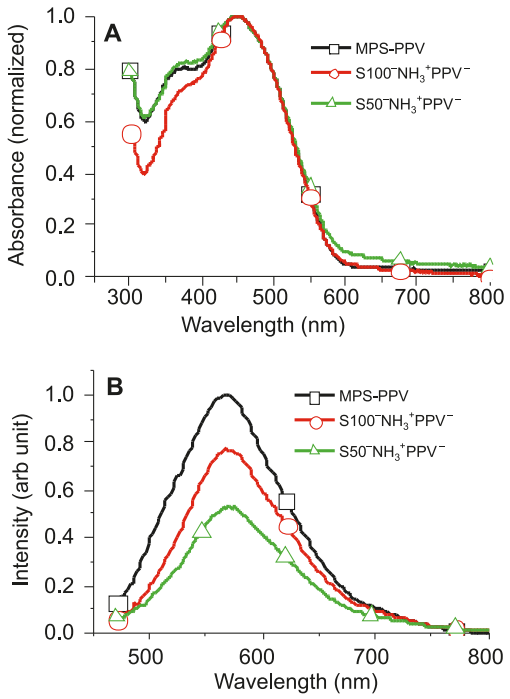
7	1.0×10^{-6}			1.0×10^{-6}	0.9
8	7.5×10^{-7}			7.5×10^{-7}	0.7

Note: MPS-PPV, poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene]. The volume of each supernatant was 900 μL; 100 nm beads = 1.3 nmol/L; [MPS-PPV] = 1.34×10^{-4} mol/L for cycles 1–3. A molar extinction coefficient value of 3460 $(mol/L)^{-1}$ cm^{-1}, calculated in terms of monomer repeat units, was utilized for MPS-PPV. Stoichiometry: 1 MPS-PPV monomer repeat unit per 0.36 nm^2 of bead surface.[19]

Fig. 2. Poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene (MPS-PPV) absorption (A) and emission (B) spectra when adsorbed to 50 and 100 nm beads and when free in solution. Fluorescence was measured upon 450 nm excitation of optically matched MPS-PPV solutions; fluorescence spectra are normalized with respect to free polymer. All spectra were taken at pH 7.3 in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES). 2.0×10^{-5} mol/L MPS-PPV (□), $S100^-NH_3^+PPV^-$, [beads] = 5×10^{-10} mol/L (○), and $S50^-NH_3^+PPV^-$, [beads] = 4.6×10^{-9} mol/L (△).



Likely, the blue shift observed in free polymer with increasing quencher concentration arises from the presence of short MPS-PPV oligomers in solution or the presence of labile, nonaggregated, fragments on the surface, which are not quenched under the sub-μmol/L quencher concentrations employed herein.

Table 2. Effect of bead support (100 and 50 nm) on the relative fluorescence quantum yield of poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) at 450 nm in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES) (pH 7.3).

Sample	Φ_f (relative)
MPS-PPV	1.0
$S100^-NH_3^+PPV^-$	0.7
$S50^-NH_3^+PPV^-$	0.5

Table 3. Stern–Volmer constants (K_{sv}) for free poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) compared with MPS-PPV coated onto beads of 50 and 100 nm diameters.

Sample	K_{sv}
MPS-PPV	$2.61(\pm0.05)\times10^6$
$S50^-NH_3^+PPV^-$	$8.3(\pm0.3)\times10^6$
$S100^-NH_3^+PPV^-$	$2.2(\pm0.04)\times10^6$

Note: All Stern–Volmer constants were measured in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES, pH 7.3). The error from the linear fit is indicated in parentheses.

Fluorescence enhancement upon nonspecific interactions with proteins

As part of the characterization of the MPS-PPV-coated silica beads we next studied the effects of nonspecific interactions with proteins on the polymer photophysics. Hydrophobic and electrostatic interactions with proteins can affect the fluorescence and quenching of conjugated polyelectrolytes free in solution.[25,26] An intensity enhancement and a blue shift in intensity, as well as a reduced Stern–Volmer fluorescence quenching constant all constitute signature features of the nonspecific interaction of conjugated polyelectrolyte

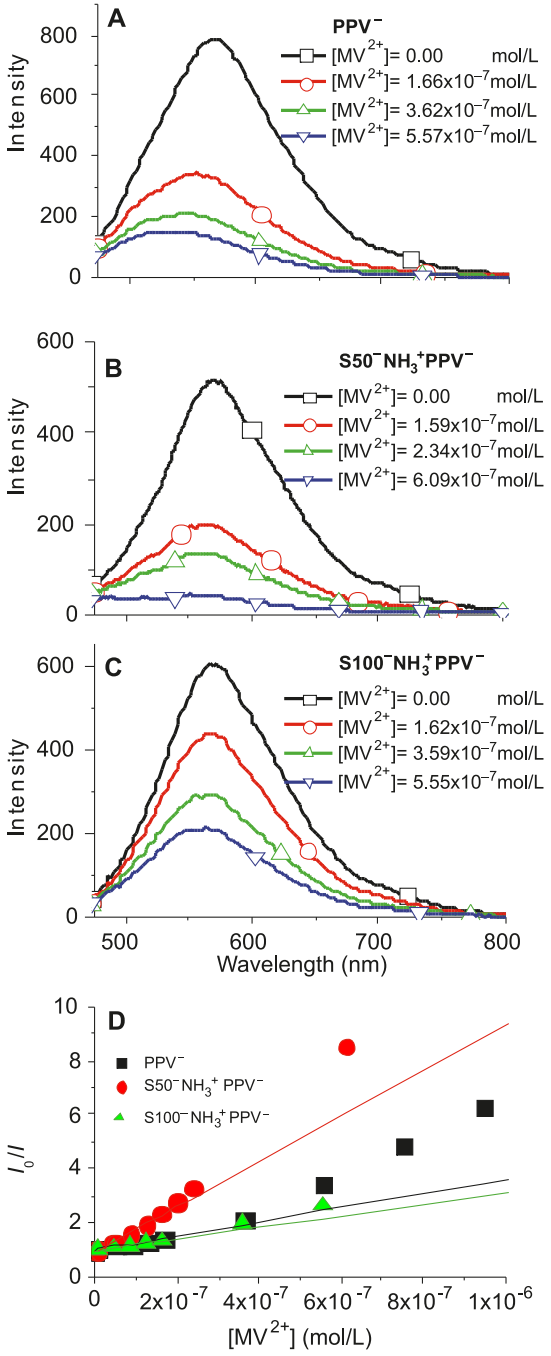
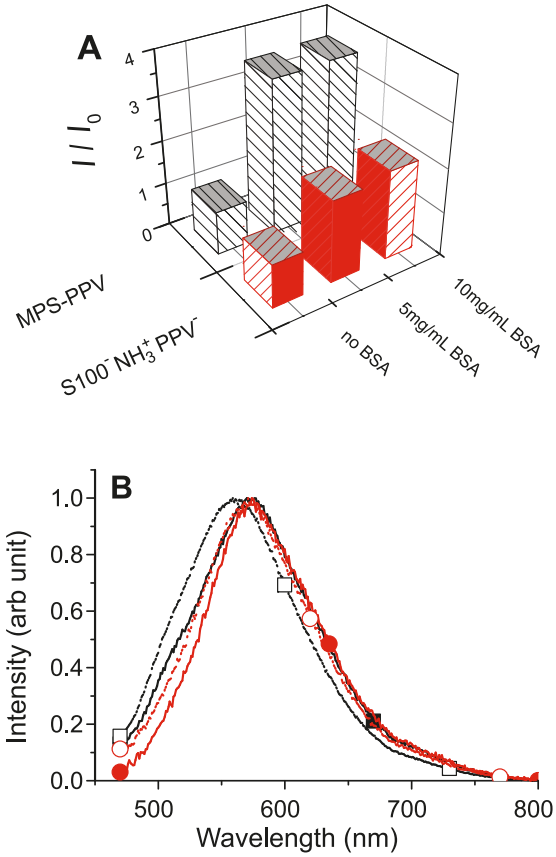
Fig. 3. Quenching of poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) by methyl viologen (MV^{2+}). (A), (B), and (C) show the fluorescence spectra under increasing [MV^{2+}] for (A) MPS-PPV 2.0×10^{-5} mol/L, (B) $S50^{-}NH_3^{+}PPV^{-}$ (the solution was 4.6×10^{-9} mol/L in beads and 2.0×10^{-5} mol/L in MPS-PPV), and (C) $S100^{-}NH_3^{+}PPV^{-}$ (the solution was 5×10^{-10} mol/L in beads and 2.0×10^{-5} mol/L in MPS-PPV). (D) The Stern–Volmer quenching plots and the linear fit to the first few experimental points for the various particles under study. Excitation was performed at 440 nm.



MPS-PPV with hydrophobic media.[27,28] The potential for these interactions must be taken into account when designing detection platforms utilizing conjugated polyelectrolytes.[29] By controlling the aggregation state of the polyelectrolyte, a silica bead support has the potential to minimize such effects.

Fig. 4. Bovine serum albumin (BSA, 69 kDa) added to 3.0×10^{-5} mol/L poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) and $S100^{-}NH_3^{+}PPV^{-}$. (A) Intensity enhancement, from integrated areas of background-subtracted peaks, for MPS-PPV (black) and for $S100^{-}NH_3^{+}PPV^{-}$ (red). (B) Normalized emission spectra at 450 nm excitation. MPS-PPV free (■), MPS-PPV plus 5 mg/mL BSA (□), $S100^{-}NH_3^{+}PPV^{-}$ (●), $S100^{-}NH_3^{+}PPV^{-}$ plus 5 mg/mL BSA (○). All solutions were in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES, pH 7.3).



We exposed $S100^{-}NH_3^{+}PPV^{-}$ beads and free MPS-PPV to bovine serum albumin (BSA), a 69 kDa protein that has known surfactant properties. The fluorescence of the free MPS-PPV was enhanced 3.5-fold and blueshifted by 12 nm (576–564 nm), whereas the fluorescence of $S100^{-}NH_3^{+}PPV^{-}$ beads underwent only a twofold enhancement and no blue shift (Fig. 4). The bead-support configuration thus minimizes the fluorescence effects of nonspecific interactions on conjugated polyelectrolytes. It is also foreseeable to decorate the beads with suitable receptors for the specific (and sensitive) detection of analytes of interest.

Single-particle studies

We next used single-particle total internal reflection fluorescence microscopy (TIRF) to examine the initial intensity distribution and the evolution of intensity over time for $S50^{-}NH_3^{+}PPV^{-}$ and $S100^{-}NH_3^{+}PPV^{-}$ beads. Our imaging experiments were conducted both in air-saturated buffered solution and in a buffered solution containing an oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

Fig. 5. Poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) coated 100 nm beads ($S100^{-}NH_3^{+}PPV^{-}$) in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES, pH 7.3), imaged in the absence (A) and presence (C) of glucose oxidase oxygen scavenger. Initial intensity histograms ((B) and (D)) are also shown for both conditions. Samples were illuminated via 488 nm excitation at 6.0 mW laser power, 500 ms exposure time, and a flow rate of 1 μL/min.

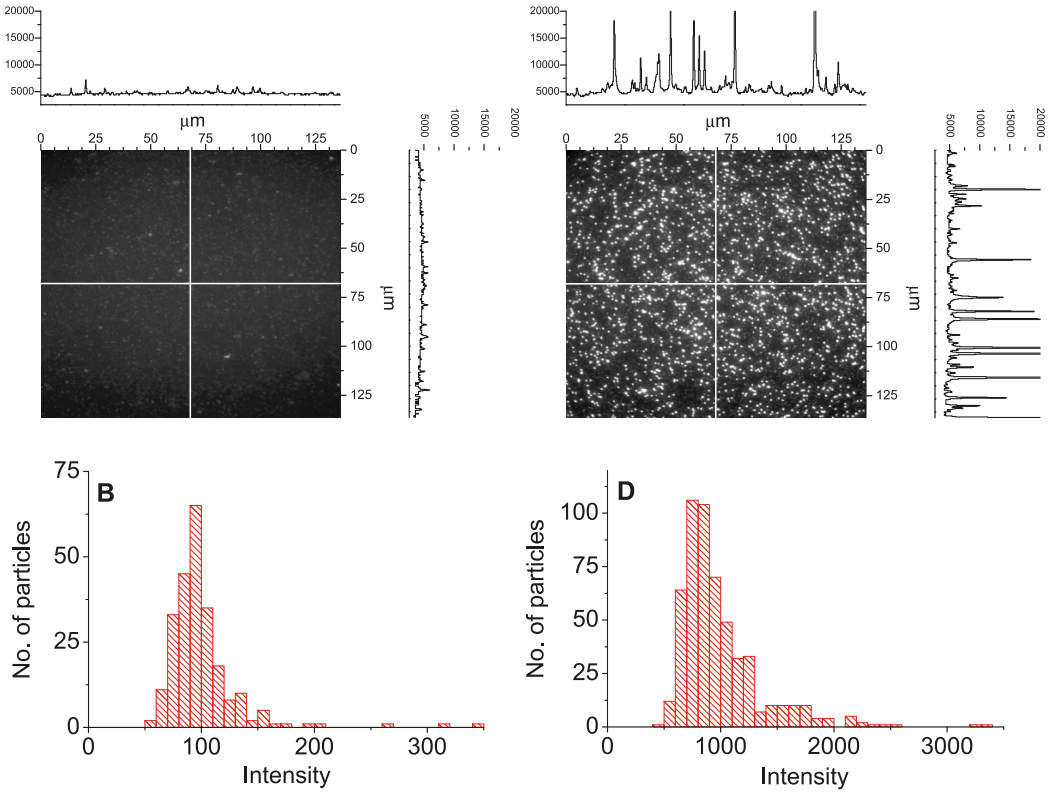


Fig. 6. Effect of oxygen scavenger on the photobleaching of poly[5-methoxy-2-(3-sulfopropoxy)-1,4-phenylenevinylene] (MPS-PPV) coated 50 nm beads ($S50^{-}NH_3^{+}PPV^{-}$). Samples were imaged at 500 ms integration time, at 6.0 mW ± 0.2mW laser power, in 1 mmol/L *N*-(2-hydroxyethyl)piperazine-*N*′-ethanesulfonic acid (HEPES, pH 7.3), and at a flow rate of 1 μL/min, in the presence and absence of glucose oxidase oxygen scavenger. (A)–(B) $S50^{-}NH_3^{+}PPV^{-}$ beads imaged in buffer, no oxygen scavenger (EMCCD gain = 3200). (C)–(D) $S50^{-}NH_3^{+}PPV^{-}$ beads imaged in oxygen scavenger (EMCCD gain = 1700). Examples of stepwise photobleaching behaviour are shown in (A) buffer and (C) oxygen scavenger. Examples of exponential decay are shown in (B) buffer and in (D) oxygen scavenger.

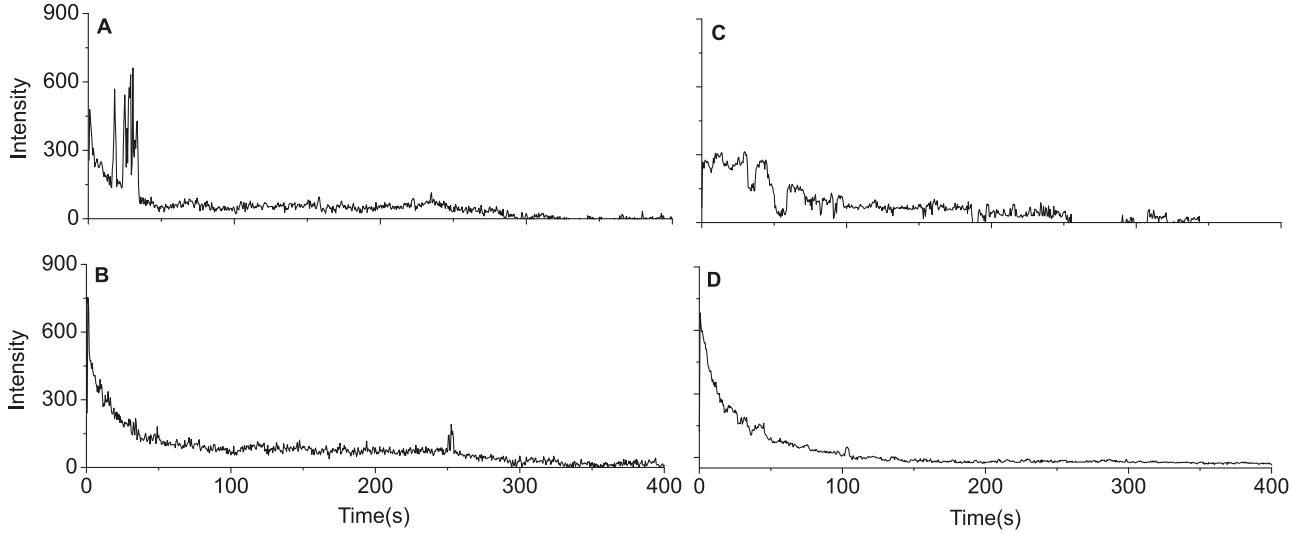

scavenger mixture consisting of α-D-glucose, glucose oxidase, catalase, and β-mercaptoethanol.[30]

We observed that when immersed in the oxygen scavenger solution the emission intensity and the photostability of the MPS-PPV-coated beads increased dramatically when compared with air-saturated solutions. We noted a ca. fourfold

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

increase in the survival time and an eightfold intensity increase over the air-saturated solution (Figs. 5 and 6). When the particles were monitored in a solution of glucose oxidase and catalase, with no glucose oxidase substrate α-D-glucose, no difference was observed vs air-saturated solutions (not shown). The glucose oxidase – catalase effect on the emissive properties of the particles thus arises from the oxygen-scavenging activity of the mixture rather than nonspecific protein-conjugated polyelectrolyte interactions. Ensemble experiments conducted with BSA (vide supra) further show that nonspecific interactions with proteins have only a minor effect on the photophysical properties of MPS-PPV-coated silica nanoparticles.

Oxygen in the solution is known to quench the emission of PPV-based conjugated polymers, where both reversible and irreversible quenching pathways may take place. For poly[2-methoxy-5-(2'ethyl-hexyloxy)1,4-phenylene-vinylene] (MEH-PPV) it has been shown that singlet-oxygen mediated photo-oxidation leads to the formation of carbonyl groups at the vinyl bond that turn the polymer irreversibly nonemissive.[31,32] Likely, a similar quenching phenomenon is observed with the closely related polymer MPS-PPV utilized in our studies. The glucose oxidase – catalase system,[30] widely used in single-molecule spectroscopy,[33] decreases the amount of oxygen in the solution, preventing oxidative damage to the fluorophore and lengthening its lifetime. The addition of β-mercaptoethanol further reduces the possibility of singlet-oxygen sensitization by the conjugated-polymer triplet states, since β-mercaptoethanol is a well-known triplet quencher.[34] The combined effect of the triplet quenching by β-mercaptoethanol and the oxygen depletion by glucose oxidase – catalase ultimately leads to a ca. 40-fold increase in the number of photons recorded per particle prior to their irreversible photobleaching. Preliminary experiments further show that β-mercaptoethanol on its own can also affect the fluorescence quantum yield. We are currently investigating the source of this effect.

Single-particle spectroscopy allows for the detection of multiple populations within a given sample.[35] Intensity–time trajectories report upon the extent of interchromophore communication in conjugated polymers[7,36], where on–off single-step transitions, characteristic of single chromophores, will indicate good electronic contact and (or) efficient exciton transport,[8,36,37] and intensity–time trajectories showing an exponential drop in emission over time will reflect on poor exciton transport and the presence of a large number of unrelated chromophores.[7]

Upon analyzing more than 500 intensity–time trajectories recorded for either $S50^{-}NH_3^{+}PPV^{-}$ or $S100^{-}NH_3^{+}PPV^{-}$, we observed that most beads exhibited a gradual photobleaching with time both in an oxygen scavenger solution[30] containing glucose oxidase and in an air-saturated solution (buffer only, no glucose oxidase). Given the time resolution of our experiments, where frames were acquired every 500 ms, the occasional stepwise photobleaching behaviour that we noticed, particularly in air-saturated solutions (see Figs. 6A and 6C) may be ascribed to rapid photobleaching of a number of chromophores in the particle within a given 500 ms frame. Indeed, in oxygen-scavenger-containing solutions we observed virtually no steps in the intensity photobleaching.

We note that there is no evidence that the particles behave as a single quantum state (i.e., particles undergoing one-step photobleaching much like single chromophores do) neither for 50 nor 100 nm MPS-PPV-coated beads. Such behaviour is, however, observed in single MPS-PPV polymer particles in solution or in MEH-PPV particles spin cast in a polymer matrix. The amount of polymer material required to coat the silica beads is likely too large for the exciton to explore the whole bead surface during the excited-state lifetime.

Conclusion

In conclusion, the anionic light-emitting poly(phenylene vinylene) MPS-PPV was adsorbed onto silica nanobeads of 50 and 100 nm diameter towards the creation of a novel material for fluorescence detection and imaging. The increased K_{SV} and decreased quantum yield in PPV-coated beads indicate that the bead support promotes interchain contact, as has been observed for poly(phenylene-ethynylene). The PPV-coated beads were further resistant to fluorescence modifications induced by nonspecific binding to serum proteins. Particle immobilization enabled us to monitor the effect of oxygen scavenger solutions on individual particles by changing the surrounding solution. Hundreds of individual beads can be imaged in a rapid parallel fashion. Glucose oxidase – catalase oxygen scavenger caused an eightfold increase in fluorescence intensity and a fourfold increase in the emissive time prior to photobleaching, which is consistent with reducing the possibility of permanent oxidative damage to the fluorophore. The intensity–time trajectories of individual beads provide a mechanism of signal transduction with potential applications in multiplexing studies. Our results provide new insights into the development of fluorescent sensors based on immobilized silica nanoparticles coated with water-soluble poly(phenylene vinylene) derivatives.

Experimental

Materials

Silica beads 100 nm (±30 nm) in diameter and 5.65 wt% in water were purchased from Polysciences Inc. (Warrington, Pennsylvania). Silica beads 40–50 nm in diameter and 20–21 wt% in water were generously provided free of charge from Nissan Chemical Industries Ltd. (Houston, Texas). Methyl viologen (MV^{2+}), 3-aminopropyltrimethoxysilane (97%), β-mercaptoethanol (14.3 mol/L), D-(+)-glucose (minimum 99.5%), and a 0.25 wt% solution of MPS-PPV in distilled deionized water were purchased from Sigma-Aldrich (Oakville, Ontario). Acetone, HPLC grade, 99.5% was obtained from ACP Chemicals Inc. (Montreal, Quebec). Vectabond was acquired from Vector Laboratories (Burlingame, California). Catalase (beef liver) and glucose oxidase were obtained from Roche Diagnostics (Indianapolis, Indiana). HEPES buffer (1 mol/L, pH 7.3, for molecular biology), acetic acid (99.7%), and sodium acetate (99.3%) were purchased from Fisher Scientific Canada (Ottawa, Ontario).

Functionalization of silica beads

Amino-silanized 100 nm silica beads ($S100^{-}NH_3^{+}$)

To 100 μL of 100 nm (±30 nm) silica beads, 5.65 wt% in water (9.1×10^{-8} mol/L beads), was added 0.16 mL of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

3-aminopropyltrimethoxysilane (97%). The sample was vortexed for several seconds and incubated at room temperature for 5 min. 0.5 mL of 38% HCl was then added to protonate the amine groups. The sample was again vortexed thoroughly and centrifuged at 16 060*g* (13 000 rpm on a Fisher Accuspin microcentrifuge) for 5 min. 0.5 mL of the supernatant was replaced with 1 mL of MilliQ water. The beads were resuspended by brief sonication and then centrifuged. One millilitre of the supernatant was replaced with 1 mL of water; this wash step was repeated two additional times or until the pH of the supernatant was between 5 and 7. The samples were stored at 4 °C for up to 6 months. Yield: ~1 mL of 7.2×10^{-9} mol/L amino-silanized beads of 100 nm diameter ($S100^{-}NH_3^{+}$) in water.

Amino-silanized 50 nm silica beads ($S50^{-}NH_3^{+}$)

To 100 μL of 50 nm (±10 nm) silica beads, 20–21 wt% in water (3.65×10^{-6} mol/L beads), was added 0.05 mL of 3-aminopropyltrimethoxysilane (97%). The procedure for functionalizing 50 nm beads was otherwise identical to the procedure for the functionalization of 100 nm beads.

Amino-silanized PPV-coated 100 nm silica beads ($S100^{-}NH_3^{+}PPV^{-}$)

Aliquots of beads in water were added slowly, dropwise with agitation, to a solution of 1.4×10^{-4} mol/L MPS-PPV for a final bead concentration of 1.3×10^{-9} mol/L. The sample was vortexed for 1 h, incubated at room temperature for 1 h, and centrifuged at 16 060*g*. The supernatant was replaced with 1.4×10^{-4} mol/L MPS-PPV; the beads were resuspended by brief sonication and vortex, vortexed for 1 h and incubated at room temperature for 30 min, then centrifuged at 16 060*g*. The supernatant was replaced with 1.4×10^{-4} mol/L MPS-PPV; after resuspension the beads were vortexed for 10 min and incubated at room temperature for 15 min. The sample was then centrifuged, and the supernatant replaced with 1 mmol/L HEPES (pH 7.3) buffer. After resuspension in HEPES buffer, the beads were vortexed for 10 min and incubated at room temperature for 15 min. The sample was then centrifuged and the supernatant replaced with fresh buffer solution. This washing step was repeated four times.

Amino-silanized PPV-coated 50 nm silica beads ($S50^{-}NH_3^{+}PPV^{-}$)

The procedure was identical to that employed with 100 nm beads other than a final bead concentration of 1.3×10^{-8} mol/L was achieved when aliquots of beads were added to MPS-PPV solutions.

Dynamic light scattering

Aliquots of sample were added to buffer that had been filtered through 0.45 μm hydrophilic syringe filters. The intensity – intensity time correlation of scattered 532 nm laser light was measured at 25 °C, perpendicular to the incident beam, using a Brookhaven BI-9000 AT digital correlator and BI-200SM goniometer system. The optical density filter and detector slit were adjusted to yield a scattered intensity of 10–100 kcps. The normalized intensity – intensity time correlation function was transformed to the normalized electric field time correlation function via the Siegert relation and evaluated via the CONTIN regularization algorithm.

Zeta potential studies

Bead samples were diluted to a final concentration of 2.6×10^{-10} mol/L in 1 mmol/L HEPES buffer (pH 7.3) ($S100^{-}NH_3^{+}PPV^{-}$ and $S50^{-}NH_3^{+}PPV^{-}$) or 1 mmol/L sodium acetate buffer (pH 5.8) ($S100^{-}NH_3^{+}$ and $S50^{-}NH_3^{+}$). Several trials consisting of 10 cycles (i.e., 10 individual measurements) were taken for each sample on a ZetaPlus ζ potential analyzer (Brookhaven Instruments Corp.) at room temperature.

Absorption and fluorescence

Absorption and emission spectra were recorded on Cary 5000 UV–VIS–NIR and Cary Eclipse fluorescence spectrophotometers, respectively. The amount of MPS-PPV coating the beads was estimated by subtracting the bare-bead scattering from the absorbance spectrum of coated beads. A solution of MPS-PPV in 1 mmol/L HEPES (pH 7.3) buffer was prepared to match the amount of MPS-PPV coating the beads, within 5% and at an absorbance between 0.05 and 0.1. The fluorescence emission of both samples was recorded at 450 nm excitation with 10 nm excitation and emission slits and a scan range of 470–800 nm.

For quenching of MPS-PPV-coated silica beads with MV^{2+}, aliquots of MV^{2+} in 1 mmol/L HEPES (pH 7.3) buffer were added to the samples of free MPS-PPV or MPS-PPV-coated beads, and fluorescence spectra were recorded after mixing well. The final concentrations of MV^{2+} ranged from 1×10^{-10} to 1×10^{-5} mol/L.

TIRF microscopy imaging

Cover slips were cleaned with piranha solution (30% $H_2O_2 - H_2SO_4$, 1:3 (cc)) and rinsed with autoclaved deionized water until the pH of the rinse water was 6–7. Residual water was removed by three repeated washes with acetone. Vectabond, (0.5 mL) collected under argon gas, was added to the cover slips immersed in 25 mL of acetone. The cover slips were then incubated for 5 min. The reaction was quenched by replacing the acetone with water and rinsing twice. Cover slips were rinsed with HydroClone HyPure molecular biology grade water and dried via blown argon prior to fitting with flow chambers. Flow chambers were prepared with a predrilled polycarbonate film (Grace Biolabs) assembled on top of the cover slips, yielding a final volume of 10 μL. Silicone ports were glued on top of the chamber with double-sided tape.

Up to 40 μL of a 10 pmol/L bead solution was first flowed into the chambers; subsequently 20 μL of buffer were flowed at 5 μL/min to remove any beads not bound to the surface. Images were recorded during the flowing of buffer at a rate of 1 μL/min. Following imaging in buffer conditions, 20 μL of glucose oxidase oxygen scavenger solution were flowed over the sample. Images were then recorded while flowing oxygen scavenger at a rate of 1 μL/min. The oxygen scavenger solution consisted of β-mercaptoethanol (1% *v*/*v*), β-D-(+)-glucose (3% *w*/*v*), glucose oxidase (0.1 mg/mL), and catalase (0.02 mg/mL), where the glucose oxidase was added just prior to use. All experiments were conducted at room temperature (22–25 °C).

For personal use only.

The experimental setup consisted of an Olympus IX 71 microscope adapted with a commercial turnkey TIRF module IX2-RFAEVA-2 by Olympus. The excitation involved objective-based TIRF. The samples were illuminated at the critical angle[38] using the 488 nm output of a cw Ar+ laser from SpectraPhysics at 6.0 mW ± 0.2 mW (measured at the nosepiece). The laser beam was introduced via a single mode fiber optic and directed by a dichroic beamsplitter (z488rdc; Chroma, Rockingham, Vermont) to the sample via a high numerical aperture (N.A. = 1.45) oil immersion objective (Olympus PLAN APO 60X). Fluorescence emission was collected through the same objective and then transmitted through an emission filter HQ530 LP (640DCXR Chroma) into a Cascade 512B EMCCD camera (Roper Scientific, Inc.) operated with Image Pro software. Images were recorded at exposure times of 500 ms for over 350 s. Individual beads in a series of images acquired over time were identified using software developed in our laboratory and based on MATLAB and IDL routines by T. Ha.[39]

Abstract: The complexation dynamics of the triplet excited state of xanthone with β-cyclodextrin were studied at various temperatures between 10 and 50 °C. Association and dissociation rate constants were determined using the laser flash photolysis quenching methodology with Cu^{2+} as a quencher. The rate constants for the association and dissociation of triplet xanthone with β-cyclodextrin increased with temperature, while the equilibrium constant for the triplet excited state remained relatively constant. Equilibrium constants for the ground-state complexation of xanthone with β-cyclodextrin were determined from fluorescence studies at various temperatures. The ground-state binding efficiency decreased with temperature and was markedly greater than that of the triplet excited state at all temperatures. The enthalpy and entropy for the β-cyclodextrin complex formation of the ground and triplet excited states fall on the enthalpy–entropy compensation relationship previously established for cyclodextrin complexes. The activation enthalpies for the association and dissociation rate constants for triplet xanthone are similar. The activation entropy is favorable for the association process, whereas a negative activation entropy was measured for the dissociation process, suggesting that solvation plays a key role in the complex formation between xanthone and β-cyclodextrin.

Key words: xanthone, β-cyclodextrin, binding dynamics, temperature, excited states.

Résumé : Opérant à diverses températures en 10 et 50 °C, on a étudié la dynamique de la complexation de l'état excité triplet de la xanthone avec la β-cyclodextrine. Les constantes de vitesse d'association et de dissociation du triplet de la xanthone avec la β-cyclodextrine augmente avec la température alors que la constante d'équilibre pour l'état excité triplet demeure relativement constante. Les constantes d'équilibre pour la complexation de l'état fondamental de la xanthone avec la β-cyclodextrine ont été déterminées à partir d'études de fluorescence à diverses températures. L'efficacité de fixation de l'état fondamental diminue avec la température et sa valeur est beaucoup plus grande que celle de l'état excité triplet, à toutes les températures. L'enthalpie et l'entropie de formation du complexe avec la β-cyclodextrine des états fondamental et excité triplet se retrouvent tous sur la relation de compensation enthalpie-entropie établie antérieurement pour les complexes de la cyclodextrine. Les enthalpies d'activation pour les constantes de vitesse d'association et de dissociation pour l'état triplet de la xanthone sont semblables. L'entropie d'activation est favorable pour le processus d'association alors qu'on a mesuré une entropie d'activation négative pour le processus de dissociation, ce qui suggérerait que la solvatation joue un rôle clé dans la formation de complexe entre la xanthone et la β-cyclodextrine.

Mots-clés : xanthone, β-cyclodextrine, dynamique de fixation, température, états excités.

Introduction

Cyclodextrins (CDs) are cyclic oligosaccharides with relatively rigid hydrophobic internal cavities in which a number of organic and inorganic guest molecules can be incorporated. The size of the CD cavity is determined by the number of glucose units in the molecule (6, 7, or 8 for α, β, and γ-CD).[1,2] There is much thermodynamic information available for the complexation of guests to CDs. The efficiency of complex formation is largely determined by the hydrophobicity of the guest, as well as size complementarity between the guest and the CD cavity.[3,4] There is much less known about the binding dynamics of guests with CDs,[5–7] because in general the binding dynamics are fast. Early temperature jump[8] and stopped-flow experiments[9,10] showed that the association and dissociation rate constants for a series of azo dyes varied by three orders of magnitude, whereas changes in the equilibrium constants were much smaller. These results showed that the changes in the kinetics do not necessarily parallel changes in the thermodynamics of the guest complexation to CDs. Very little temperature-dependent kinetic data has been determined because fast kinetic techniques are required. In the case of a complex between the trinitrophenylated Meisenheimer complex of adenosine and γ-CD, the kinetics could be studied by NMR because of the unusually high equilibrium constant for this complex.[11] However, for the lower equilibrium constants usually seen for CD complexes with 1:1 stoichiometry, techniques with time resolution in the ns to μs time domain are required.

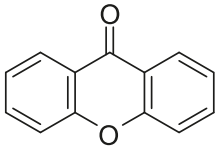
Chart 1. Structure of xanthone.



Dynamics studies using triplet excited states are suitable for this time domain.[6,7]

The size of the guest molecule contributes greatly to the binding efficiency of the guest–CD complex. In the case of xanthone (Chart 1) the highest equilibrium constant was for binding to β-CD, whereas binding to α-CD and γ-CD was less efficient because the cavities are, respectively, too small and too large.[12] Theoretical studies, combined with induced circular dichroism measurements, showed that xanthone binds to the rim of the CD cavity and is not deeply included in the cavity.[13]

In our previous work on the binding of xanthone to β-CD, we studied the binding dynamics at 20 °C directly[12,14,15] or using Cu^{2+} as a quencher.[16] These studies found quite different equilibrium constants for the ground state and triplet excited state of xanthone,[14] attributed to the higher basicity and greater dipole moment of the xanthone triplet excited state compared with the ground state.[16]

In this current work, we examined the effect of temperature on the triplet-excited-state binding dynamics of xanthone with β-CD, as well as the temperature effects on the equilibrium constants for the ground and excited states.

Results

Ground-state complexation

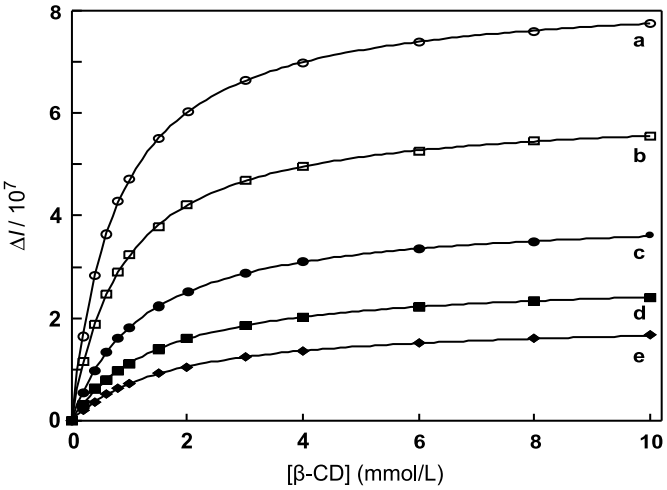
Equilibrium constants (K_{eq}) for ground-state guest molecules with a host can be determined when a spectroscopic observable of the guest changes upon complexation to the host. Addition of β-CD resulted in a decrease in xanthone fluorescence intensity and a small blue shift in the fluorescence emission maximum. The xanthone fluorescence intensity was also seen to decrease with increasing temperature.

The equilibrium constants (K_{eq}) for the binding of ground-state xanthone to β-CD were obtained at various temperatures from analysis of the change in xanthone fluorescence intensity (ΔI) with increasing β-CD concentrations ($[CD]_T$; eq. [1] and Fig. 1),

$$[1] \qquad \Delta I = \frac{[G]_T \Delta\phi K_{eq}[CD]_T}{1 + K_{eq}[CD]_T}$$

where $\Delta\phi$ is related to the difference in quantum yields for the free and bound guests and $[G]_T$ is the total guest concentration. This equation is valid for formation of a 1:1 host–guest complex when the concentration of CD exceeeds the guest concentration.[17] The nonlinear equation is preferable for the determination of K_{eq} values because it gives proper weight to the experimental data; however, a double reciprocal plot (eq. [2]) can be used to check the assumption of a 1:1 complex stoichiometry, because a linear relationship is expected if the correct stoichiometry is assumed. Linear double reciprocal plots were obtained at all temperatures studied (Fig. S1 in the Supplementary data).

Fig. 1. Changes in xanthone (25 μmol/L) fluorescence intensity with β-cyclodextrin (β-CD) concentration at (a) 10 °C (○), (b) 20 °C (□), (c) 30 °C (●), (d) 40 °C (■), and (e) 50 °C (◆). The solid lines correspond to the fit of the experimental data to eq. [1].



$$[2] \qquad \frac{1}{\Delta I} = \frac{1}{[G]_T \Delta\phi} + \frac{1}{[G]_T \Delta\phi K_{eq}[CD]_T}$$

The K_{eq} values determined for the xanthone–β-CD complex at various temperatures (Table 1) decreased with increasing temperature. The 20 °C data is in agreement with the previously determined value of 1100 ± 200 $(mol/L)^{-1}$.[14]

The change in K_{eq} with temperature was analyzed using the van't Hoff equation (eq. [3]). The enthalpy (ΔH^0) and entropy changes (ΔS^0) for the 1:1 complex formation between xanthone and β-CD were calculated from the van't Hoff plot (Fig. 2). Values of –14 ± 2 kJ mol^{-1} and +11 ± 4 J mol^{-1} K^{-1} were recovered for ΔH^0 and ΔS^0, respectively.

$$[3] \qquad \ln K_{eq} = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R}$$

Triplet-excited-state complexation

The binding dynamics of triplet xanthone to CDs[12,14,16] can be studied using the direct or the quenching methods.[6,18] The direct method takes advantage of the large shift in the triplet–triplet absorption spectra for xanthone in environments of different polarity.[19,20] When kinetic decays are monitored at wavelengths away from the isosbestic point, the decay is a sum of two exponentials, with a fast component attributed to relocation of xanthone from β-CD into the bulk solution. As the temperature was increased, the observed rate constant for the fast component increased. Unfortunately, the signal-to-noise ratio also increased at the higher temperatures, and the error in the direct kinetic measurements was too high for recovery of association and dissociation rate constants.

In the case of the quenching methodology, the triplet-excited-state kinetics of xanthone were measured at 600 nm. This monitoring wavelength corresponds to the isosbestic point for the triplet–triplet absorption spectra for xanthone in water and xanthone bound to β-CD.[12] The decays followed a mono-exponential function and the triplet

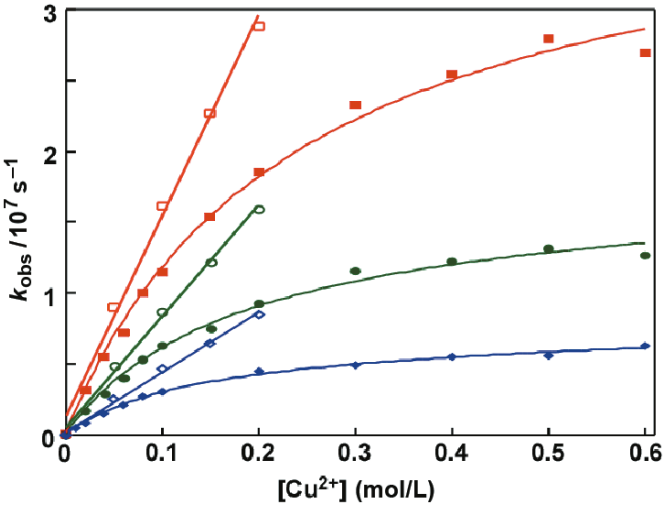
lifetimes for xanthone in water were in excess of 10 μs at all temperatures studied. The triplet lifetimes were somewhat longer in the presence of β-CD, and the lifetimes in the absence and presence of β-CD were shortened somewhat as the temperature was increased.

Quenchers for triplet excited states, such as Cu^{2+} or NO_2^-,[12,21] which reside primarily in the aqueous phase, can be employed to determine the values for the association (k_+^*) and dissociation (k_-^*) rate constants for triplet xanthone with β-CD. This quenching methodology has been previously used in the determination of the complexation dynamics of guest molecules with CDs.[6,22] For example, the binding dynamics of triplet chromone with β-CD was studied using Cu^{2+} or NO_2^- as quenchers, whereas the binding dynamics of triplet flavone could only be studied using Cu^{2+}.[16] In the present study Cu^{2+} was used as the quencher because preliminary experiments showed that with NO_2^- the qualitative trends with changes in temperature were the same as those observed with Cu^{2+}, but the rate constants recovered had larger errors.

The values for the quenching rate constant in water (k_q) were determined from quenching plots for xanthone in water in the absence of cyclodextrin. The observed triplet decay rate constant (k_{obs}) was obtained at several quencher concentrations, and the data were fit to eq. [4], where k_0 is the decay rate constant for xanthone in water in the absence of quencher. The plots for the quenching of triplet xanthone by Cu^{2+} in water were linear at all temperatures (Fig. 3).

Fig. 3. Quenching plots for the triplet-excited-state quenching of xanthone by Cu^{2+} in water (open symbols) and in the presence of 6 mmol/L β-cyclodextrin (β-CD; filled symbols) at 10 °C (◆), 30 °C (●), and 50 °C (■). The solid lines for the quenching plots in water correspond to the fit to eq. [4]. The solid lines for the quenching plots in the presence of β-CD correspond to the fit to eq. [5] when the decay rate constant for xanthone in water in the absence of cyclodextrin (k_0) and the quenching rate constant in water (k_q) are fixed to the values obtained in water, the decay rate constant for xanthone in the presence of β-CD without quencher (k_0^H) is fixed to the value for the decay in β-CD in the absence of quencher, and the quenching rate constant for the host (k_q^H) is fixed to 1 × 10^6 (mol/L)$^{-1}$ s^{-1}.



The quenching efficiencies in water increased with temperature and were two orders of magnitude smaller (Table 2) than the diffusion-controlled rate constant for a bimolecular reaction, e.g., 6.5 × 10^9 (mol/L)$^{-1}$ s^{-1} at 20 °C.[23]

$$[4] \qquad k_{obs} = k_0 + k_q[Cu^{2+}]$$

In the presence of β-CD, the plots for quenching triplet excited xanthone by Cu^{2+} were curved (Fig. 3). The curvature is due to less-efficient quenching of the triplet excited states bound to the CD cavity. Generally, quenchers that reside primarily in the aqueous phase are employed so that the quenching efficiency of excited-state guests in water is higher than that for guests bound to the host, k_q^H. At higher quencher concentrations, the rate-limiting step for quenching becomes the exit of the guest from the host or its intrinsic decay within the host, resulting in downward curvature in the quenching plots. Qualitatively, the larger the difference between the linear quenching plots obtained in aqueous solution and the curved quenching plots obtained in the presence of the host, the slower the binding dynamics in the host–guest system. If the concentration of free guest is small in comparison with the amount of bound guest, then the kinetics are pseudo-first-order and follow a mono-exponential decay, and k_{obs} is given by eq. [5],[22,24]

$$[5] \qquad k_{obs} = k_0^H + k_-^* + k_q^H[Cu^{2+}] - \frac{k_-^* k_+^* [CD]}{k_0 + k_q[Cu^{2+}] + k_+^*[CD]}$$

where k_0^H is the decay rate constant for xanthone in the pre-

Note: The errors in k_q correspond to the statistical errors for the fit of the data to eq. [4], the ranges for k_q^H are the values for which the fit of the data to eq. [5] was acceptable and the errors in k_+^*, and k_-^* correspond to the average deviation for the maximum and minimum values recovered when k_q^H was fixed in the quoted range.

[a]Bracketed numbers correspond to the number of times experiments were performed.

[b]K_T values were calculated from k_+^*/k_-^*.

sence of β-CD, but without quencher. The k_0 and k_q values were fixed to those determined from quenching studies in the absence of cyclodextrin. A concentration of 6 mmol/L β-CD was used for these quenching studies. At too low a concentration of β-CD, the assumption that the concentration of free guest is less than that of the bound guest is no longer valid. Employing the highest host concentration may also not be ideal, because the curvature of the plot is defined by fewer points when host concentration is increased.[18]

When the quenching plots were fit to eq. [5] adequate fits were observed for a wide range of values for k_q^H, k_+^*, and k_-^*. The possible values for k_q^H range from complete protection from the quencher ($k_q^H = 0$) to no protection from the quencher ($k_q^H = k_q$). Fits were performed by fixing k_q^H to zero, then with incrementally larger values, until the fit was no longer adequate. The association and dissociation rate constants in Table 2 correspond to the average of the minimum and maximum values recovered for the range of k_q^H values that resulted in adequate fits (see Fig. S2 in the Supplementary data for adequate and inadequate fits over a range of k_q^H values at 10 °C). The equilibrium constant for triplet xanthone and β-CD (K_T) was calculated from the association and dissociation rate constants. The K_T values did not change significantly with temperature and were much smaller than the equilibrium constants for ground-state xanthone (see above). The values for k_+^*, k_-^*, and K_T at 20 °C were the same within experimental error as those determined previously in quenching experiments with Cu^{2+}.[16]

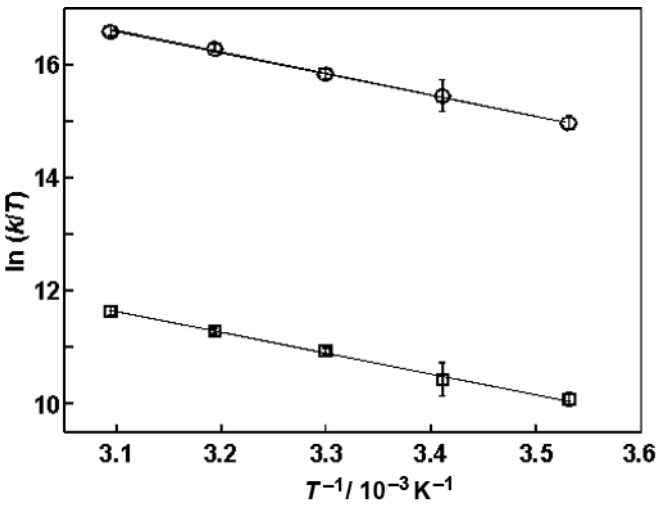
The changes in the association and dissociation rate constants were analyzed using the Eyring equation (eq. [6]) to obtain activation parameters,

$$[6] \qquad \ln\frac{k}{T} = -\frac{\Delta H^{\neq}}{RT} + \frac{\Delta S^{\neq}}{R} + \ln\frac{k_B}{h}$$

where $\Delta H^{\neq}$ is the activation enthalpy, $\Delta S^{\neq}$ is the activation entropy, k_B is the Boltzmann constant, h is Planck's constant, T is the temperature, and R is the gas constant.

$\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the dissociation process recovered from the Eyring plot (Fig. 4) were +31 ± 1 kJ mol^{-1} and –7.1 ± 0.1 J mol^{-1} K^{-1}, respectively, whereas values of +30 ± 1 kJ mol^{-1} and +36 ± 1 J mol^{-1} K^{-1} were recovered for the association process.

Fig. 4. Eyring plots for the association (○) and dissociation (□) rate constants for triplet xanthone binding to β-cyclodextrin (β-CD).



Discussion

Theoretical studies combined with spectroscopic validation using induced circular dichroism measurements showed that xanthone binds to the rim of β-CD with one of the rings included within the cavity.[6,13] Formation of the complex is enthalpically (ΔH^0 = –14 ± 2 kJ mol^{-1}) and entropically driven (ΔS^0 = +11 ± 4 J mol^{-1} K^{-1}). The gain in enthalpy is related to the hydrophobic interactions between the aromatic ring of xanthone included in the cavity and the CD. The structure of the complex was calculated to have the xanthone tilted towards one side of the CD cavity to gain further stabilization by the interaction of xanthone with the rim containing the secondary hydroxyl groups.[13] However, no specific hydrogen bonds were identified in these calculations. In addition, the structure of β-CD is significantly different from that determined in its crystal structure, suggesting that the CD is flexible enough to adapt to the guest so that the interactions between the guest and the CD are enhanced.[13] From the entropic point of view, the inclusion of xanthone within the CD cavity and the distortion of the CD to maximize interactions lead to a lowering of the degrees of freedom and a decrease of entropy. However, water molecules released from inside the CD cavity and from solvating the parts of the guest included in the com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

plex increase the entropy of the system.[4] Therefore, the positive ΔS^0 value observed for the formation of the xanthone β-CD complex is dominated by the release of water.

An analysis of over 1000 values for the equilibrium constants between guests and CDs showed that an enthalpy–entropy compensation occurs for the binding of guests with CDs.[4] For each increment in enthalpic gain for complex formation, some of this gain is lost in the form of a less favorable entropy. In the case of β-CD, 20% of the enthalpic gain is translated into a free-energy gain (eq. [7] derived from 488 equilibrium constant values). When ΔH^0 is equal to zero, the formation of host–guest complexes with β-CD are favored entropically by 11 kJ mol^{-1} (298.15 K) owing to the liberation of water molecules.[4] The $T\Delta S^0$ value calculated for the complexation of xanthone with β-CD from the experimentally determined ΔH^0 value is –0.2 ± 0.1 kJ mol^{-1}, which is comparable to the experimental $T\Delta S^0$ value of 3 ± 1 kJ mol^{-1}, considering the scatter of the enthalpy–entropy compensation plot (r = 0.89) used to derive eq. [7].[4] This comparison shows that the complexation of xanthone follows the same pattern as observed for other guests.

$$[7] \qquad T\Delta S^0 = 0.8\Delta H^0 + 11 \ \ (\text{kJ mol}^{-1})$$

The complexation dynamics of the triplet state of xanthone, determined in laser flash photolysis experiments, are faster than for the ground state, measured in laser temperature jump experiments.[14] The faster dynamics are due to the increase in the dissociation rate constant for the triplet state when compared with the dissociation rate constant for the ground state. This faster dissociation was attributed[14] to the higher dipole moment of triplet ketones with π,π* configuration[25] and (or) the high basicity of the excited state of triplet xanthone.[26] The equilibrium constants for the triplet excited state, calculated from the k_+^* and k_-^* values, were constant with the increase in temperature and were always smaller than the equilibrium constants for the ground state. The smaller equilibrium constant for the excited state is due to the faster dissociation process, whereas the lack of dependence of the triplet-state equilibrium constant on temperature indicates that the enthalpy change is negligible. Therefore, the β-CD complex formation for the triplet state of xanthone is exclusively driven by entropy owing to the release of solvation water molecules. The enthalpic component for complex formation was mainly attributed to the hydrophobic interaction of the portions of the guest that were desolvated with the walls of the CD with some contribution from possible hydrogen bonds between the guest and the hydroxyl groups of the CD.[4] The increase of ΔH^0 to ca. 0 for the triplet state compared with the ΔH^0 value of –14 kJ mol^{-1} for the ground state suggests that either a smaller area of the guest interacts with the CD, leading to the location of triplet xanthone further away from the CD cavity, or weaker hydrogen bonds are formed at the rim of the CD. In contrast, the $T\Delta S^0$ value for the triplet state (12.8 ± 0.3 kJ mol^{-1}, calculated from the activation parameters determined from the Eyring plots) is higher than the value for the ground state. This difference is either related to the formation of a more flexible triplet xanthone–CD complex or owing to the release of a larger number of water molecules for complex formation with the triplet state compared with the complex for ground state xanthone. The ΔH^0 and $T\Delta S^0$ values for triplet xanthone fall onto the enthalpy–entropy compensation relationship defined by eq. [7]. This result shows that the binding of the electronically excited state follows the same trends as for ground states. Finally, for an equilibrium constant, which is primarily determined by a gain in entropy, one would expect an increase in K_T at higher temperatures. However, such a trend was not observed owing to the narrow temperature range that could be employed in the current study.

In the case of the excited state, the enthalpy and entropy of activation for the association and dissociation processes were determined from the Eyring plots. The same enthalpies of activation for the association and dissociation processes are probably coincidental, since no apparent reason exists from the structural point of view why the $\Delta H^{\neq}$ values should be the same. The entropy of activation for the dissociation process is negative, showing that solvation by water of the separated CD and triplet xanthone molecules is the major contributor to this parameter. The positive $\Delta S^{\neq}$ for the association process is also consistent with the release of water molecules from the host and guest being the driving force for the complex formation. Indeed the large value for $\Delta S^{\neq}$ suggests that desolvation of the guest and host is the rate-limiting process for the formation of the complex.

Conclusions

The temperature-dependence studies showed that the binding of the ground state of xanthone with β-CD was enthalpically and entropically driven, whereas in the case of the triplet excited state only entropy played a role in the formation of the complex. The sign for $\Delta S^{\neq}$ for the association and dissociation rate constants of triplet xanthone further suggested that changes in solvation between the separated host and guest are a major determinant for complex formation with CDs. The ΔH^0 and ΔS^0 values for both the ground and triplet states of xanthone follow the enthalpy–entropy compensation dependence determined for other guest molecules with β-CD. This result showed that the binding of the electronically excited state follows the same trends as for ground states, and changes observed between the binding of ground and excited states of guests is dictated by changes in shape or electronic properties between the two states.

Experimental

Equipment

Fluorescence spectra were collected using a PTI QM-2 fluorimeter. Experiments were carried out on aerated solutions in 10 mm × 10 mm quartz cells, and the temperature was kept constant using a Haake water bath. Solutions were kept at the correct temperature in the water bath prior to measurement and were equilibrated at least 10 min in the sample holder before spectra were collected. The excitation wavelength was 345 nm, and emission was collected between 355 and 575 nm. Fluorescence spectra were corrected for the baseline emission of water, so that Raman emission from the solvent was subtracted from the spectra. Fluorescence intensities were determined by integration of the spec-

For personal use only.

tra between 365 and 450 nm. The slits for the excitation and emission monochromators were set with a bandpass of 3 nm.

The laser flash photolysis system used to measure triplet decay kinetics has been described previously.[27] Samples were excited at 355 nm using a Spectra Physics Quanta Ray Lab 130–4 Nd:YAG laser. The sample holder was modified to incorporate a Unisoku USP-203 cryostat, which can be used to achieve temperatures from –150 to 100 °C. Each sample was allowed to equilibrate at least 10 min in the cryostat before measurements were made.

The cryostat was mounted on a home-built stage that can be moved in three dimensions to allow alignment with both the laser beam and the Xe-lamp monitoring beam, which are orthogonal to each other. The cryostat was fitted with four windows; the two windows in the laser path have AR coating for the laser wavelengths. A pinhole was fitted to the window on which the Xe lamp was incident to ensure that the size of the monitoring beam was smaller than the size of the incident laser beam.

All solutions for laser flash photolysis were placed in 10 mm × 10 mm quartz cells and deaerated with N_2O for at least 20 min prior to use. Ketones such as xanthone are easily photoionized in aqueous solutions, and N_2O acts as an efficient solvated electron trap.[28]

Materials

β-Cyclodextrin (Cargill) and $CuSO_4 \cdot 5H_2O$ (Sigma-Aldrich) were used as received. Xanthone (Sigma-Aldrich) was recrystallized from 95% ethanol prior to use. Deionized water (Sybron-Barnstead) was employed for all samples.

Solution preparation

Solutions for triplet-excited-state quenching experiments with Cu^{2+}

A solution of xanthone in water (25 μmol/L) was prepared by injection from a methanol stock solution (1 mmol/L). Xanthone (25 μmol/L) in β-CD (6 mmol/L) was prepared by dissolving β-CD in the aqueous xanthone solution. The solution was then heated to 60 °C for 30 min. The high Cu^{2+} concentrations used in the quenching experiments necessitated that each quencher concentration be prepared as a separate solution. The highest Cu^{2+} concentration solution (0.6 mol/L) was prepared by dissolving copper(II) sulfate in the xanthone–β-CD solution. Solutions with lower Cu^{2+} concentrations were prepared by dilution with the xanthone–β-CD solution. The solutions were left to shake for 12 h.

Solutions for fluorescence binding isotherms

A solution of xanthone in water (25 μmol/L) was prepared by injection from a methanol stock solution (1 mmol/L). The highest concentration xanthone–β-CD solutions (10 mmol/L) was prepared by dissolving β-CD in the aqueous xanthone solution. Solutions with lower β-CD concentrations were prepared by dilution with the aqueous xanthone solution. The solutions were left to shake for 12 h.

Supplementary data

Supplementary data (double reciprocal plots for ground-state xanthone binding to β-CD and fits with different parameters for the triplet xanthone quenching plots) for this article are available on the journal Web site (canjchem.nrc.ca).

Abstract: The exposure of DNA to radiation and chemical insults leads to damage and disease. Thus, detection and understanding of DNA damage is important for elucidating molecular mechanisms of disease. However, current methods of DNA damage detection are either time-consuming, destroy the sample, or are too specific to be used for generic detection of damage. In this paper, we examine the sensitivity of different locked nucleic acid (LNA) hairpin probes for detecting UV-induced oligonucleotide damage to LNA composition, target concentration, and ionic strength. We also compare the selectivity of the LNA hairpin probe with a DNA molecular beacon (MB) hairpin probe for detecting DNA damage. Our results show that the selectivity of the LNA hairpin probe to UV-induced nucleic acid damage increases with increasing ionic strength of the buffer and decreases with increasing target concentration and with increasing LNA ratio.

Key words: locked nucleic acids, fluorescence, nucleic acids, DNA damage, molecular beacons, sensors.

Résumé : L'exposition de l'ADN à des radiations et à des insultes chimiques provoque des dommages et des maladies. La détection et la compréhension des dommages à l'ADN sont donc des opérations importantes pour l'élucidation des mécanismes moléculaires des maladies. Toutefois, les méthodes actuelles courantes de détection des dommages à l'ADN demandent beaucoup de temps, détruisent l'échantillon ou sont trop spécifiques pour être utilisées par la détection générique des dommages. Dans ce travail, on examine la sensibilité des différentes sondes en épingle à cheveux d'acide nucléique bloqué (ANB) pour la détection de dommages dans l'oligonucléotide induits par l'UV à la composition de l'ANB, à la concentration de la cible et de la concentration ionique. On compare aussi la sélectivité de la sonde en épingle à cheveux d'ANB à une sonde en épingle à cheveux d'un faisceau moléculaire (FM) d'ADN pour la détection des dommages à l'ADN. Les résultats obtenus montrent que la sélectivité de la sonde en épingle à cheveux d'ANB aux dommages à l'acide nucléique induits par l'UV augmente avec une augmentation de la force ionique du tampon et qu'elle diminue avec une augmentation de la concentration de la cible et avec une augmentation du rapport d'ANB.

Mots-clés : acides nucléiques bloqués, fluorescence, acides nucléiques, dommages à l'ADN, faisceaux moléculaires, senseurs.

Introduction

Absorption of light by DNA produces molecular-scale lesions in the DNA and RNA, which can subsequently lead to cancer and other diseases.[1–4] Absorption of UVB (290–320 nm) and UVC (200–290 nm) light leads to the formation of thymidine cyclobutyl photodimers (CPD) as the primary photoproduct.[5] Other photoproducts with UV irradiation are pyrimidine pyrimidinone [6–4]-photoproducts, dewar pyrimidinones, and uracil and thymine photohydrates. All these photoproducts are localized on the pyrimidine nucleobases near the C5=C6 double bond, opposite to the site of base pairing. Other damage agents, such as oxidative conditions and ionizing radiation, lead to other DNA lesions, such as single- and double-strand breaks, 8-oxoguanosine and other oxidation products, and cross-links.

A number of techniques have been used to detect nucleic acid damage previously, either in vivo or in vitro. Most of these techniques isolate the DNA, melt it to obtain single-stranded DNA fragments, separate the fragments, and detect the lesions.[6–9] Such techniques include gel electrophoresis,[6] capillary electrophoresis,[7] electrochemistry,[7] HPLC,[8] and mass spectrometry.[9] While useful, these techniques are destructive and time-consuming. In addition, the electrophoretical and chromatographical techniques require prefiltering, which may itself introduce lesions.

Other spectroscopic-based techniques have recently been used to characterize nucleic acid damage. Differences in the fluorescence lifetime of a dye intercalated in undamaged and damaged DNA have been used to detect DNA damage.[10] Fluorescently labeled antibodies provide an exquisitely selective probe of particular damage photoproducts, such as thymine CPDs.[11] Most recently, molecular beacons (MBs) have been used as a broad-spectrum sensor of DNA and RNA damage[12] (A. Mah, S. Yarasi, and G. R. Loppnow,

manuscript in preparation). MBs are DNA hairpins labeled with a quencher on one end and a fluorophore on the other. In the hairpin form, the quencher and fluorophore are in close proximity and the fluorescence is quenched. However, binding of target DNA or RNA, which is complementary to the loop of the MB, separates the fluorophore and quencher, and the fluorescence is detectable. The inherent sensitivity of fluorescence makes the MBs sensitive probes of nucleic acid damage.

We have previously shown[12] (A. Mah, S. Yarasi, and G. R. Loppnow, manuscript in preparation) that the binding of the molecular beacon is sufficiently destabilized upon the occurrence of a single UV-induced, ionizing radiation-induced, or oxidation-induced damage site such that the hairpin configuration has a much lower melting temperature (i.e., free energy) than the hybridized probe. This condition results in lower fluorescence from the damaged target-loop hybrid and, consequently, a maximum discrimination of damaged vs undamaged oligonucleotide.

Fluorescently labeled locked nucleic acid (LNA) hairpins have the potential to detect UV-induced DNA damage. LNAs are nucleic acids containing ribonucleosides in which a methylene group connects the $C_{4'}$ and $O_{2'}$ atoms of the ribose sugar, locking it into the 3′ endo (North) conformation.[13] Such DNA probes appear to be more selective towards base pair mismatches[13] and have been used to enhance the specificity of probes for fluorescence in situ hybridization (FISH) assays, DNA microarrays, and real-time polymerase chain reaction (RT-PCR).[14–17] In this paper, we show that fluorescently labeled LNA hairpins can indeed detect UV-induced DNA damage, albeit with lower selectivity for damaged DNA than conventional MBs. The results show that the sensitivity of LNA MBs depends on ionic strength, target concentration, and the LNA composition of the hairpin. These results are discussed in the context of the conformation dynamics of LNA hairpins.

Experimental

Materials

The single-strand dT_{17} and dT_{24} oligonucleotide targets and the MBs were obtained from Integrated DNA Technologies Inc. (Coralville, Iowa) and are listed in Table 1. The target oligonucleotides were purified by standard desalting, whereas the MBs were purified by HPLC. The magnesium chloride ($MgCl_2$) and sodium chloride (NaCl) were both obtained from EMD Chemicals Inc. (Gibbstown, New Jersey). Tris and ethylenediaminetetraacetic acid (EDTA) were obtained from ICN Biomedicals, (Aurora, Ohio) and BDH Inc. (Toronto, Ontario), respectively. All chemicals were used as received. Nanopure water from a Barnsted Nanopure (Boston, Massachusetts) system was used for all solutions. The oligonucleotide samples and MBs were each dissolved in 1 mmol/L EDTA in nanopure water and kept frozen at –20 °C until needed.

UV irradiation

Nitrogen-purged solutions of 4 μmol/L dT_{24} in one of two buffers, either 10 mmol/L Tris, 1 mmol/L EDTA, and 3 mmol/L $MgCl_2$ adjusted to pH 7.5 or 20 mmol/L Tris, 1 mmol/L EDTA, 5 mmol/L $MgCl_2$, and 50 mmol/L NaCl adjusted to pH 7.5, were irradiated in sealed, UV-transparent 1 cm path length cuvettes. The cuvettes were placed in a water bath also contained in a UV-transparent water dish. The temperature, which was monitored by means of a Cole-Parmer DiGi-SENSE thermocouple (Niles, Illinois), was kept constant throughout the irradiation by the water bath. Oligonucleotide samples were irradiated in a Luzchem (Ottawa, Ontario) DEV photoreactor chamber with UVC light from lamps emitting principally at 254 nm. The samples were constantly stirred during irradiation, and the photoreactor was purged with nitrogen throughout the irradiation to flush out oxygen and any ozone subsequently generated from the UVC lamps. Control samples were handled identically, but were not exposed to UV radiation. The UVC lamps were turned on ~20 min before the start of irradiation to stabilize the lamp output.

Absorption and fluorescence measurements

Absorption spectra were recorded at intervals throughout the irradiation period on a Hewlett-Packard (Sunnyvale, California) 8452A diode array spectrophotometer by placing the irradiated cuvettes containing the target oligonucleotide solutions directly into the spectrophotometer. For the room-temperature fluorescence measurements, a 20 μL aliquot of each irradiated solution was taken at various time intervals and was later mixed with appropriate amounts of the probe and buffer solution to give final concentrations of 200 nmol/L oligonucleotide and 200 nmol/L probe for the MB–target (1:1) experiments and final concentrations of 1 μmol/L oligonucleotide target and 200 nmol/L probe for the MB–target (1:5) experiments. These solutions were then incubated in the dark at room temperature for about 24 h. Room-temperature fluorescence spectra of 200 μL aliquots of the incubated hybridization mixtures were measured using a Photon Technologies International (Birmingham, New Jersey) fluorescence system. The spectra were recorded between 500 and 700 nm with excitation at 495 nm. A 10 mm path length Suprasil quartz fluorescence cuvette was used for these measurements. The melting curves were baseline-corrected[19] to obtain accurate melting temperatures.

Results and discussion

The design and optimization of MBs to probe nucleic acid damage have been described previously in detail.[12] We use the same principles here for designing and optimizing the LNA MBs to ensure that these probes can selectively discriminate single damage sites in oligonucleotides. A representative melting curve of one of the MBs, both alone and in the presence of undamaged target, is shown in Fig. 1. In the absence of target DNA or RNA, the MB stem is closed and exhibits minimal fluorescence. In the presence of undamaged oligonucleotide, the MB opens and forms a stable target-loop hybrid with maximum fluorescence. Subsequently, the binding should be sufficiently destabilized upon the occurrence of a single damage site such that the hairpin configuration has a much lower melting temperature (i.e., free energy) than the hybridized probe. This condition results in lower fluorescence from the damaged target-loop hybrid and, consequently, a maximum discrimination of damaged vs undamaged oligonucleotide.

MB_{26}-5	5′-(6-FAM)-*CACAAAA*(+A)AA(+A)AA(+A)AA(+A)*TTTGTG*-(3-BHQ_1)-3′	51.6	—	42.0	32.9
MB_{26}-6	5′-(6-FAM)-*TCCAAAA*(+A)A(+A)A(+A)A(+A)A(+A) AA*TTTGGA*-(3-BHQ_1)-3′	54.4	—	43.1	40.1

[a]The subscript represents the total number of bases comprising the oligonucleotide sample and the number at the end represents the number of locked nucleic acids (LNAs) in the structure.
[b]"+" denotes the locked nucleotide, 6-FAM is 6-carboxyfluorescein, 3-DAB is 4-(4′-dimethylaminophenylazo)-benzoic acid) and 3-BHQ_1 is the black hole quencher-1.[20] The bases in italic typeface represent the stem of the molecular beacon (MB).

Fig. 1. Melting curve of 200 nmol/L molecular beacon $(MB)_{26}$-5 alone (○) and in the presence of 200 nmol/L target poly-dT_{17} (●) in 20 mmol/L Tris buffer containing 1 mmol/L EDTA, 5 mmol/L $MgCl_2$, and 50 mmol/L NaCl. Both curves were generated at a rate of 1.0 °C/min. This is a representative melting curve of the MBs alone and with targets, which all showed similar shapes.

The melting curves (Fig. 1) show that the MB stem melts at a slightly higher temperature than that of the target-loop hybrid, which is an important criterion for the optimal performance of the MB in the detection of damage.[12] To ensure this criterion is met, we performed thermal denaturation profiles of MBs in equilibrium with their targets and obtained the melting curves for the MBs alone and with the targets. The results are shown in Table 1. In all cases, the difference in melting temperature (T_m) between the hairpin and hybrid forms of the LNA MBs is similar to the difference in the T_m between the same forms of the non-LNA MB. This result suggests that both sensors may have similar selectivity to oligonucleotide damage.[12]

Target dT_{17} and rU_{17} were chosen for this study because of their well-known photochemistry. CPDs are the primary form of UV-induced damage in dT_{17}, in addition to the formation of small amounts of the pyrimidine–pyrimidinone [6–4] photoproduct.[5,20] In rU_{17} approximately equal amounts of the CPD and photohydrates are formed.[5,20] The quantum yields (Φ) for such processes are Φ = 0.044 for CPD formation in poly-dT and Φ = 0.012 and Φ = 0.015 for photohydrate and CPD formation, respectively, in poly-rU.[20] Therefore, comparing the MB hybridization with UV-damaged rU_{17} and dT_{17} will allow for a determination of the relative destabilizing effect of CPD and photohydrates on duplex formation. In addition, poly-dT and poly-rU targets exclude complications owing to other processes, such as spontaneous depurination because of thermal effects, UV-induced depurination of guanosine residues, and UV-induced oxidative damage for guanine bases.

The fluorescence of the LNA MBs with targets dT_{17} and rU_{17}, which have been irradiated with UVC, are shown in Fig. 2 as a function of irradiation time. As damage accumulates on the target oligonucleotide strand, the MB–target hybrid becomes less stable than the hairpin form at the

Fig. 2. Fluorescence intensity at 520 nm as a function of irradiation time for the targets. Only the 200 nmol/L (A) dT_{17} and (B) rU_{17} targets were irradiated (●) and the damage was detected by molecular beacon $(MB)_{26}$-5. Aliquots of the irradiated target were mixed with 200 nmol/L MB in buffer containing 200 mmol/L Tris, 5 mmol/L $MgCl_2$, 50 mmol/L NaCl, and 1 mmol/L EDTA at pH 7.5, and the fluorescence of this mixture was then measured. The control (○) is the unirradiated target sequences hybridized with the MB_{26}-5 in the same buffer. The black solid line through the irradiated sample points is a single exponential fit (eq. [1]) to the fluorescence intensity of the irradiated sample with (A) $I_0 = 0.3$, $A = 3.8$, and $\tau = 1.98$ min and (B) $I_0 = 0.2$, $A = 6.7$, and $\tau = 0.79$ min. The straight line through the control sample points is a linear fit drawn by eye.

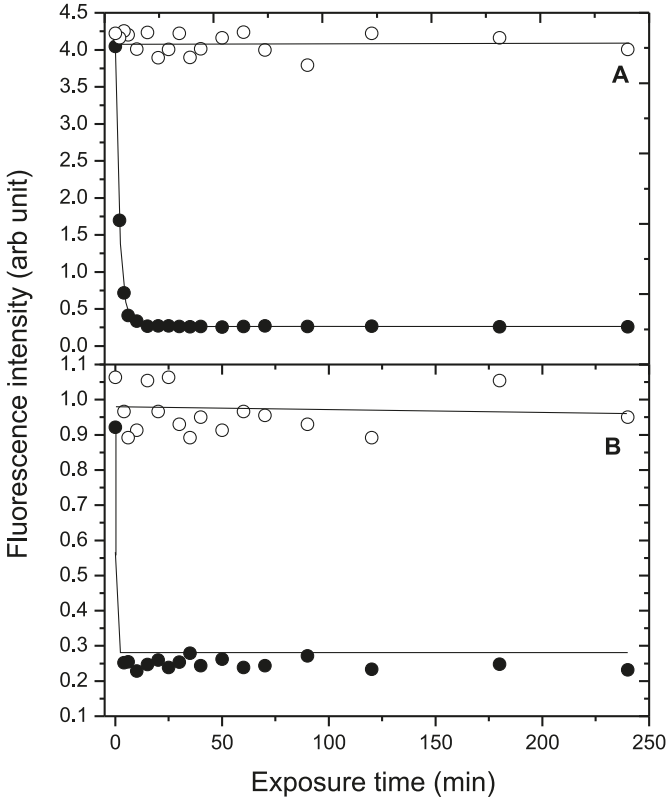

Fig. 3. Fluorescence intensity at 520 nm as a function of irradiation time for dT_{24} (●). Only the 1 μmol/L dT_{24} target was irradiated and the damage was detected by molecular beacon $(MB)_{33}$-4. Aliquots of the irradiated target were mixed with 200 nmol/L MB in buffer containing (A) 10 mmol/L Tris, 3 mmol/L $MgCl_2$, and 1 mmol/L EDTA at pH 7.5 and (B) 20 mmol/L Tris, 50 mmol/L NaCl, 5 mmol/L $MgCl_2$, and 1 mmol/L EDTA at pH 7.5. The fluorescence of this mixture was then measured. The control (○) is the unirradiated dT_{24} target sequence hybridized with MB_{33}-4 in the same buffer. The black solid line through the irradiated sample points is a single exponential fit (eq. [1]) to the fluorescence intensity of the irradiated sample with (A) $I_0 = 0.4$, $A = 1.3$, and $\tau = 8.4$ min and (B) $I_0 = 0.5$, $A = 3.5$, and $\tau = 5.6$ min. The straight line through the control sample points is a linear fit drawn by eye.

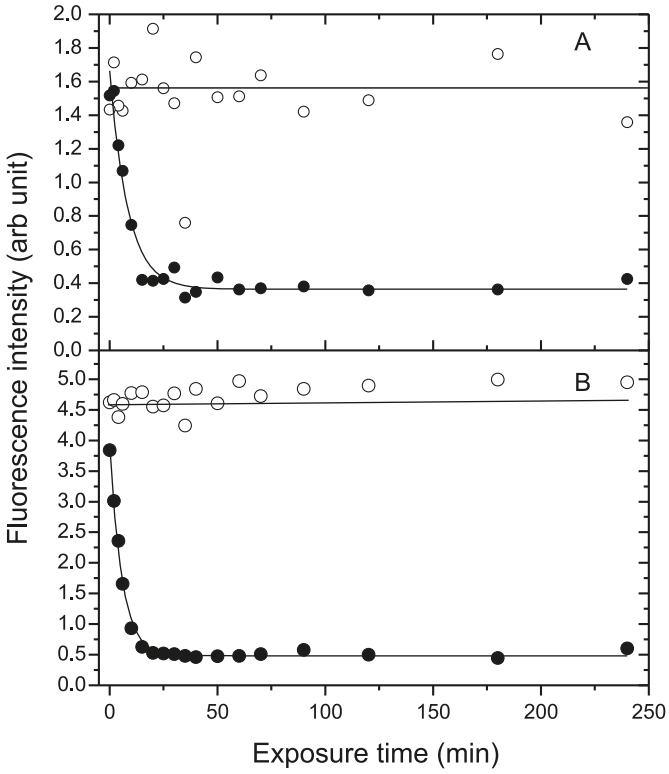

temperature used in the assay, effectively decreasing the fluorescence intensity. In Figs. 2–5, such a decrease with fluorescence is observed as the irradiation time increases. This result demonstrates that LNA MBs can detect DNA and RNA damage.

The damage curves shown in Figs. 2–5 have been fit with a single exponential function:

$$[1] \qquad I = I_0 + Ae^{-t/\tau}$$

where I is the fluorescence intensity at time t, I_0 is the fluorescence intensity at time 0, A is the amplitude, and $e^{-t/\tau}$ is the exponential decay. This fit allows us to determine the rate of decrease of fluorescence intensity with irradiation time. This decay in the fluorescence intensity represents the instability of the damaged target–MB hybrid. Therefore, the faster the rate of the fluorescence intensity decrease, the more selective the MB is at detecting UV-induced oligonucleotide damage under identical irradiation conditions for the same target. Because all of the target solutions were irradiated under the same conditions, with the same rate of oligonucleotide damage accumulation, the comparison of the rates of fluorescence intensity decrease provides a direct comparison of the selectivity of the different probes with oligonucleotide damage. We studied the effect of ionic strength, target–MB concentration ratios, and the LNA–DNA composition of the MB to determine the optimal conditions for the LNA MB to detect UV-induced damage with high selectivity.

Ionic strength of the medium

As shown previously,[12] MBs detect DNA damage at $[Mg^{2+}]$ of 1 mmol/L or higher. Tan and co-workers[13] showed that higher ionic strength buffers than that used for MBs may improve the LNA MB detection of single base pair mismatches. Figure 3 shows the fluorescence intensity decrease for the LNA MB as a function of target UVC irradiation time at two different conditions, one of low ionic

Fig. 4. Fluorescence intensity at 520 nm as a function of irradiation time for dT_{17} (●). Only (A) 1 μmol/L dT_{17} target and (B) 200 nmol/L dT_{17} target were irradiated and the damage was detected by molecular beacon $(MB)_{26}$-4. Aliquots of the irradiated target were mixed with 200 nmol/L MB in buffer containing 20 mmol/L Tris, 5 mmol/L $MgCl_2$, 50 mmol/L NaCl, and 1 mmol/L EDTA at pH 7.5, and the fluorescence of this mixture was then measured. The control (○) is the unirradiated dT_{17} target sequence hybridized with MB_{26}-4 in the same buffer. The black solid line through the irradiated sample points is a single exponential fit (eq. [1]) to the fluorescence intensity of the irradiated sample with (A) $I_0 = 0.2$, $A = 5.4$, and $\tau = 5.79$ min and (B) $I_0 = 0.2$, $A = 2.9$, and $\tau = 1.67$ min. The straight line through the control sample points is a linear fit drawn by eye.

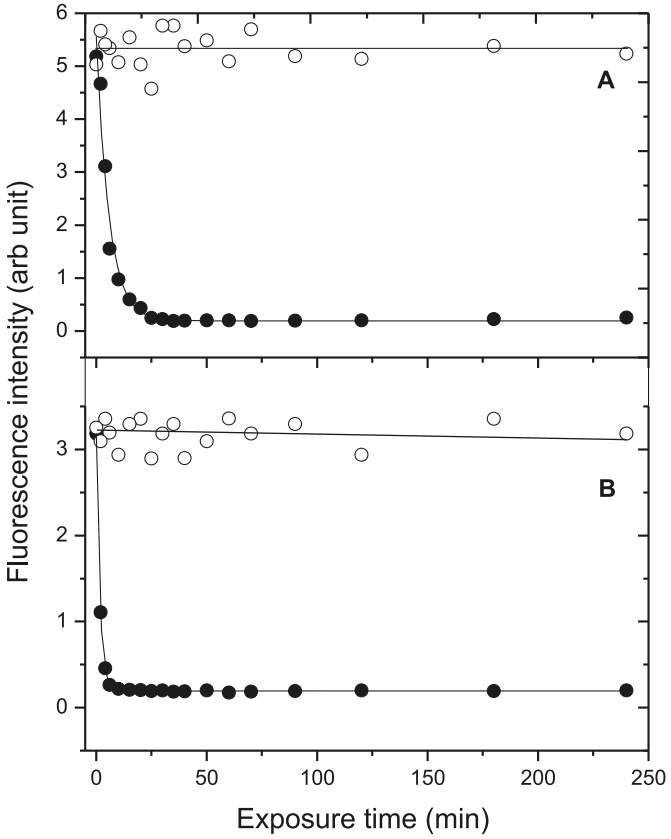

Fig. 5. Fluorescence intensity at 520 nm as a function of irradiation time for dT_{17}. Only the 200 nmol/L dT_{17} target was irradiated (●) and the damage was detected by (A) molecular beacon $(MB)_{26}$-4, (B) MB_{26}-5, and (C) MB_{26}-6. Aliquots of the irradiated target were mixed with 200 nmol/L MB in buffer containing 200 mmol/L Tris, 5 mmol/L $MgCl_2$, 50 mmol/L NaCl, and 1 mmol/L EDTA at pH 7.5, and the fluorescence of this mixture was measured. The control (○) is the unirradiated dT_{17} target sequence hybridized with the MBs in the same buffer. The black solid line through the irradiated sample points is a single exponential fit (eq. [1]) to the fluorescence intensity of the irradiated sample with (A) $I_0 = 0.2$, $A = 2.9$, and $\tau = 1.67$ min, (B) $I_0 = 0.3$, $A = 3.8$, and $\tau = 1.98$ min, and (C) $I_0 = 0.1$, $A = 3.3$, and $\tau = 2.13$ min. The straight line through the control sample points is a linear fit drawn by eye.

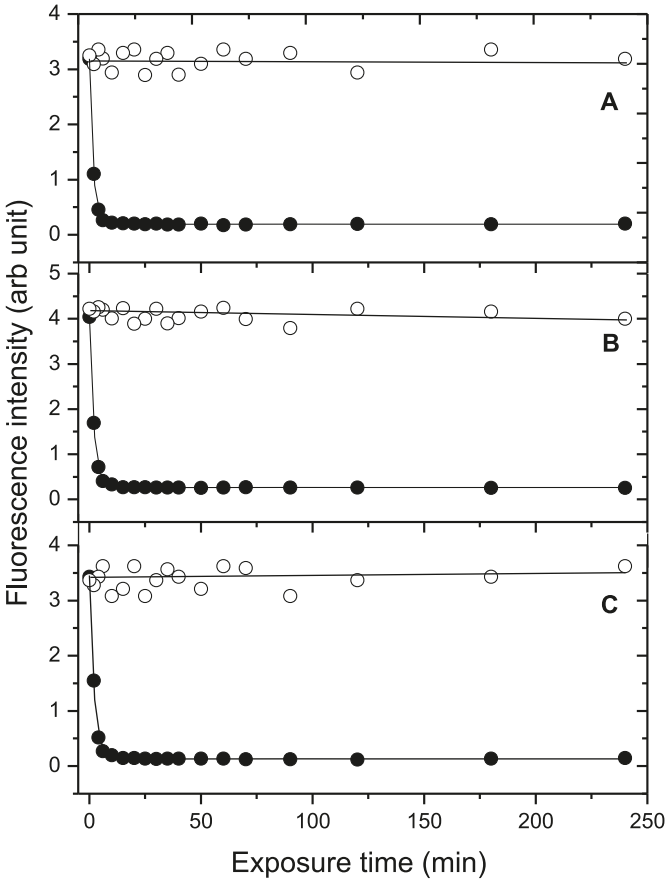

strength, having 1 mmol/L [Mg^{2+}], and the other is of higher ionic strength, incorporating both Na^+ and Mg^{2+} counterions. Table 2 presents the damage time constants for the decrease in fluorescence intensity when fit to eq. [1]. Results show that higher ionic strength increases the selectivity of the LNA MB probe to DNA damage (i.e., shows a more rapid decrease in MB fluorescence with irradiation time). With the conditions used here, a 1.5 times higher selectivity to damage is observed than with the lower ionic strength conditions. This result indicates the importance of ionic strength in determining the stability, structure, and binding behavior of MB probes.

The oligonucleotide target concentration

To study the effect of the target concentration in the presence of the high ionic strength medium on the selectivity of the LNA MBs to detect UV damage, we performed two experiments, one in which the MB_{26}-4 was incubated with UV-damaged dT_{17} target present in a 1:1 concentration ratio and one in which the concentration ratio is 1:5 for the MB–target. The results are shown in Table 2 and Fig. 4. These results show that high relative target concentration and high ionic strength yield longer damage constants than lower relative target concentrations. This result may suggest the formation of triplexes of two targets and one MB instead of the formation of a duplex hybrid between the target and the MB. Damage to one target of the triplex and subsequent dehybridization would still yield a stable MB–target duplex with high fluorescence. Not until both targets are damaged would the MB form a closed hairpin and exhibit fluorescence quenching. This scheme would yield longer damage constants than a system of only duplexes.

Table 2. Time constants of the first-order exponential decay of different samples.

Sample[a]	Ratio of MB:T	Ionic strength[b]	Regression coefficient	Time constant (min)
MB_{33}-4 + dT_{24}	1:5	Low	0.959	8.42
MB_{33}-4 + dT_{24}	1:5	High	0.993	5.61
MB_{33}-0 + dT_{24}	1:1	Low	0.996	1.34
MB_{26}-4 + dT_{17}	1:5	High	0.977	5.79
MB_{26}-4 + dT_{17}	1:1	High	1.000	1.67
MB_{26}-5 + dT_{17}	1:1	High	0.999	1.98
MB_{26}-6 + dT_{17}	1:1	High	0.997	2.13
MB_{26}-4 + rU_{17}	1:1	High	0.983	3×10^{-3}
MB_{26}-5 + rU_{17}	1:1	High	0.993	0.79
MB_{26}-6 + rU_{17}	1:1	High	0.997	1.54

[a]The subscript represents the total number of bases comprising the molecular beacon and the number at the end represents the number of locked nucleic acids (LNAs) in the structure.

[b]Low ionic strength, 10 mmol/L Tris + 3 mmol/L $MgCl_2$ + 1 mmol/L EDTA; and high ionic strength, 20 mmol/L Tris + 50 mmol/L NaCl + 5 mmol/L $MgCl_2$ + 1 mmol/L EDTA.

LNA–DNA ratio in the MB design

Previous studies[14] showed that the incorporation of LNA bases in the MB stem sequence significantly increases the stability of the hairpin structure. This increased stability greatly increases the energy barrier of opening the LNA–MB stem and, consequently, slows down its hybridization kinetics. In this work, we used MBs with LNA bases only in the loops, in different ratios, and with stems composed only of DNA bases. This design allows the study of the effect of LNA bases on the selectivity of the MB to detect UV damage in oligonucleotides and avoid the long hybridization kinetics of LNA bases in the MB stem.[13] Table 1 shows the four MBs used in this experiment, MB_{33}-0 (complement to dT_{24}), MB_{26}-4 (complement to dT_{17}), MB_{26}-5 (complement to dT_{17}), and MB_{26}-6 (complement to dT_{17}), with incorporation ratios of LNA bases in the MB loop of 0%, 24% (4/17), 29% (5/17), and 36% (6/17), respectively. The results after irradiating the target dT_{17} with UVC light and separately hybridizing aliquots of the damaged target with these four MBs are shown in Fig. 5 and Table 2. It is clear that the damage constants increase with increasing proportion of LNA bases in the loop, reflecting a decrease in selectivity of the LNA MB to detect UV damage with an increasing LNA ratio. Similar trends were obtained upon irradiating the rU_{17} target (Table 2). However, the damage constants of the single exponential decay fit (eq. [1]) are much lower for the rU_{17} target than for the dT_{17} one (Fig. 2). This result agrees with a previously published study,[12] which showed that the MB detection of UV-induced damage to poly-rU is much more selective than that to poly-dT, owing to a lower overall stability of damaged RNA–DNA hybrids compared with damaged DNA–DNA hybrids.

These results conclusively show that incorporation of LNA bases in the MB loop do not improve the sensitivity of the MBs to UVC-induced oligonucleotide damage. This is surprising in light of previous reports of LNA's greater sensitivity to single base pair mismatches.[13–16] Indeed, LNAs have been shown to be more sensitive than ssDNA probes in detecting single base pair mismatches.[13–16] However, these previous studies utilized LNA MBs that contained a greater proportion of locked nucleotides, up to a fully modified LNA MB loop.[14] The results presented here suggest that the difference in recognition sites for single base pair mismatches compared with UV-damage products (CPD and photohydrates) in the oligonucleotide target strand is significant enough to preclude the use of LNA MBs for selective detection of DNA damage.

A possible molecular explanation for this difference between damage and mismatch detection by the LNA MBs may lie in differences in the recognition site for single base mismatch (at the site of hydrogen bonding) compared with the recognition site of UV-damage products (at the C_5=C_6 bond, on the opposite side of the molecule from the base-pairing site). Although damage is known to disrupt the local DNA structure, such a perturbation may not be as large as the proximal change in hydrogen bonding that occurs upon single base-pair mismatch. Thus, damage may not destabilize the LNA MB as much as single base-pair mismatches. Future experiments should provide a more well-defined model for the detection of damage by the LNA MB and an explanation for the lower sensitivity of such detection by LNA MBs compared with MBs.

Conclusion

The results presented in this paper demonstrate the factors affecting the specificity of LNA MBs to detect UV-induced nucleic acid damage. High ionic strength and low target concentration improves the performance of these MBs in detecting UV-induced damage in dT and rU polynucleotides, as demonstrated by the shorter damage constants. Increasing the LNA ratio in the MB design leads to longer damage constants, reflecting a decrease in the selectivity of these MBs to detect damage. In conclusion, the results presented here show that, although LNA hairpin probes have greater selectivity to single base-pair mismatches than regular MB probes, they have lower specificity for detecting nucleic acid damage.

Density functional theory computational study on Diels–Alder reactions of cyclopentadiene with selected vinylsilanes and methylenecyclopropane

Nick Henry Werstiuk and Wojciech Sokol

Abstract: Aimed at predicting relative reactivities, density functional theory (DFT) calculations were carried out on a series of Diels–Alder reactions involving silylvinyl derivatives reacting with cyclopentadiene as part of a synthetic research project. Using three reactions for which experimental rate data are available to calibrate our calculations, we computationally pinpointed the best synthetic route to bicyclo[2.2.1]hept-5-ene-2,2-diylbis(trimethylsilane) (**1**). The synthesis begins with the Diels–Alder reaction of cyclopentadiene (**2**) with commercially available (1-bromovinyl)trimethylsilane (**6**).

Key words: DFT calculations, Diels–Alder reactions, bicyclic trimethylsilanes, activation parameters.

Résumé : Dans le cadre d'un projet de recherches en synthèse et dans le but de prédire les réactivités relatives, on a effectué des calculs de théorie de la fonctionnelle de la densité (TFD) sur une série de réactions de Diels–Alder impliquant des dérivés silylvinyles réagissant avec du cyclopentadiene. Utilisant trois réactions pour lesquelles des données expérimentales sur les vitesses sont disponibles pour calibrer nos calculs, on a précisé par calcul la meilleure voie de synthèse pour obtenir le bicyclo[2.2.1]hept-5-ène-2,2-diylbis(triméthylsilane) (**1**). La synthèse implique une réaction de Diels–Alder du cyclopentadiène (**2**) avec du (1-bromovinyl)triméthylsilane (**6**) disponible commercialement.

Mots-clés : calculs d'après la théorie de la fonctionnelle de la densité (TFD), réactions de Diels–Alder, triméthylsilanes, paramètres d'activation.

[Traduit par la Rédaction]

Introduction

Our interest in crystallizing the 6,6-trimethylsilyl- and 6,6-spirocyclopropyl-2-norbornyl cations — **6,6-diTMS-2-nbc** and **6,6-spirocyclo-2-nbc** — for low-temperature high-resolution X-ray determination of their electron densities as part of a quantum theory of atoms in molecules (QTAIM) study[1,2] led us to develop a new synthesis of bicyclo[2.2.1]-hept-5-ene-2,2-diylbis(trimethylsilane) (**1**); we reasoned that 2-bromo-bicyclo[2.2.1]heptane-6,6-diylbis(trimethylsilane) prepared from **1** would serve as a suitable precursor of **6,6-diTMS-2-nbc** at low temperature. To that end we undertook a density functional theory (DFT) study to assist us in pinpointing a new synthesis of **1** by utilizing a Diels–Alder (D–A) reaction for the first step (Scheme 1). The previously described route involved a two-stage process — the second step required 35 days to complete — from dicyclopentadiene (**2**) and 1,1-bis(trichlorosilyl)ethane (**3**).[3,4] In addition to the fact that the second step of the previous synthesis (**4** to **1**) required 35 days with frequent additions of MeMgI, **3** is not commercially available and its synthesis is not straightforward.[5,6] We considered three alternative D–A reactions summarized in Scheme 1: the reaction of ethene-1,1-diylbis(trimethylsilane) (**5**), commercially available (1-bromovinyl)trimethylsilane (**6**), and trichloro[1-(trimethylsilyl)vinyl]silane (**8**) with cyclopentadiene (**2**). To establish the best route, we carried out DFT calculations on the D–A reaction of **2** with **5**, **6**, and **8** to compute activation energies for the forward and reverse processes and, where possible, to determine the diastereoselectivities. We also studied the dimerization of **2** to **10N** and **10X**, its reaction with methylenecyclopropane (**11**) and with **3** to calibrate our calculations because activation energies for these reactions are available in the literature.[7–9] In this paper we report our computational results that pointed to the sequence of reactions **2** + **6** → **7X** + **7N** → **1** as the route of choice to **1**.

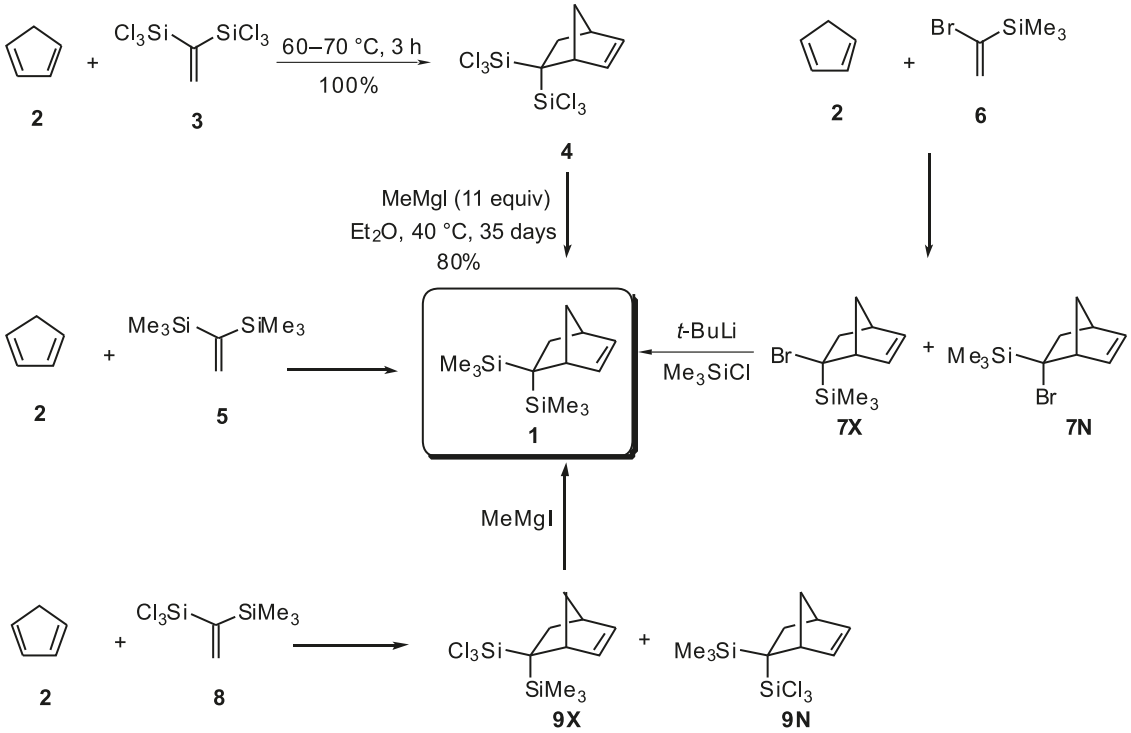
Scheme 1. Synthetic routes to bicyclo[2.2.1]hept-5-ene-2,2-diylbis(trimethylsilane) (**1**).



Computational methods

DFT calculations were performed with GAUSSIAN 03 (G03).[10] Geometries of all structures including transition states (TSs) were optimized at the MPW1PW91/6–31+G(d) level of theory as implemented in G03. The Cartesian coordinates and total energies of all structures are collected in the Supplementary data. We chose to use the MPW1PW91 functional because it was developed by Adamao and Berone[11] to better account for van der Waals forces. Frequency analyses, carried out at the same level of theory on the reactants, TSs, and products at 298.15 K for all species, confirmed that the transition states, as required, possessed one imaginary frequency. Calculations at the MPW1PW91/6–31+G(d) and B3PW91/6–31+G(d) levels on the dimerization of **2** yielded the results we reported previously.[12] Whereas calculations (the results are collected in the Supplementary data) at the B3PW91/6–31+G(d) level on the reactions of **2** with **3**, **5**, **6**, and **8** yielded results similar to those obtained at MPW1PW91/6–31+G(d), only the MPW1PW91/6–31+G(d) results are discussed in this paper. Frequency analyses were also carried out 463.15 K for selected molecules (the D–A synthesis of spiro[bicyclo[2.2.1]heptane-2,1′-cyclopropane]-5-ene is usually carried out at this temperature),[7a,7b] but the data are not reported. Energies of TSs were also corrected with basis set superposition error (BSSE)[13] calculations as implemented in G03. Thermochemical data for the forward and retro D–A reactions are collected in Table 1 and Table 2, respectively.

Results and discussion

To verify the accuracy of our calculations for the reaction of **2** with **5**, **6**, and **8**, we calibrated our approach by studying three reactions for which the experimental energies of activation are available, including the dimerization of **2**. As was found previously,[12,14] **10N-TS** exhibits C_2 symmetry. TSs **10N-TS** and **10X-TS** for formation of **10N** and **10X** are displayed in Fig. 1 along with the lengths (Å) of the incipient C–C bonds. It is seen that **10N-TS** exhibits a significantly larger asynchronicity (0.87 Å) than **10X-TS** (0.06). The key point is that our computed $\Delta H^{\ddagger}$ is in excellent agreement with the experimental value. The experimental Arrhenius activation energy (E_a) for the dimerization of **2** is 16.7 ± 0.6 kcal/mol (1 cal = 4.184 J).[9] Consequently, $\Delta H^{\ddagger}$ ($\Delta H^{\ddagger} = E_a - RT$, where R is the gas constant and T is the temperature) is estimated to be 16.1 kcal/mol at 298 K; our computed $\Delta H^{\ddagger}$ for endo dimerization is 17.0 kcal/mol ($\Delta G^{\ddagger}$ = 31.0 kcal/mol). That we found $\Delta H^{\ddagger}$ to be 20.3 kcal/mol ($\Delta G^{\ddagger}$ = 34.2 kcal/mol) for formation of **10X** — 3.3 kcal/mol higher than the endo reaction — is in keeping with the fact that **10N** is the kinetic product in the dimerization of **2**; experimentally, endo/exo > 49 ($\Delta\Delta G^{\ddagger}$ > 3.3 kcal/mol). We also found that $\Delta\Delta H$ for **10X** and **10N** is –1.1 kcal/mol at 298 K, in keeping with the fact that **10X** is the thermodynamic product in the dimerization of **2**. These results validate our computational studies.
