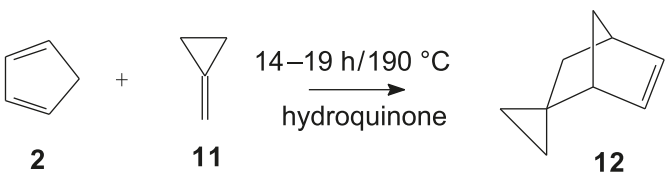
Scheme 2. Synthesis of spiro[bicyclo[2.2.1]heptane-2,1′-cyclopropane]-5-ene.



pentadiene[7a,7b] in the presence of hydroquinone (Scheme 2). Transition state **12-TS** for the reaction is displayed as Fig. 2 along with the incipient bond lengths. The asynchronicity is 0.10 Å — in this case the C1–C6 bond is shorter that the C4–C5 bond.

At 298 K the calculated $\Delta G^{\ddagger}$ was 34.0 kcal/mol, only 3.0 kcal/mol higher than $\Delta G^{\ddagger}$ for the endo dimerization of **2**. At 463 K, the temperature at which this reaction is typically carried out, $\Delta G^{\ddagger}$ was 41.5 kcal/mol, 3.3 kcal/mol higher than for the formation of **10N** at 463 K. The retro reaction of **12** has a much higher $\Delta G^{\ddagger}$ (52.6 kcal/mol) than the forward process, in keeping with the fact the **12** is the thermodynamic product.

We also studied the D–A reaction for the formation of **4** to calibrate our calculations. Kirmse and Söllenböhmer[3,4] showed that **4** is obtained quantitatively from **2** and **3** under relatively mild conditions at 333–343 K in 3 h, implying that the barrier for the reaction is lower than the barrier for dimerization of **2**. This reaction has a much lower computed

Fig. 1. Transition states (TS) (*a*) **10N-TS** and (*b*) **10X-TS** and incipient C–C bond lengths (Å) at MPW1PW91/6–31+G(d).

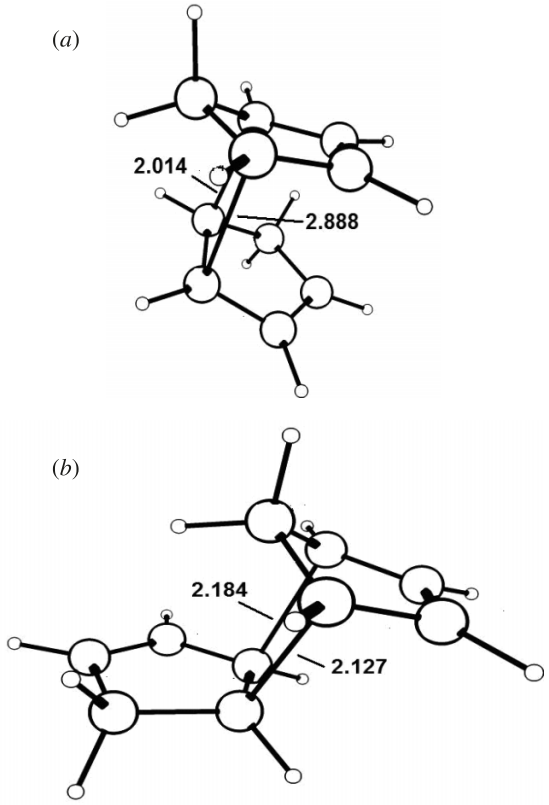

Fig. 2. Transition state (TS) **12-TS** and incipient C–C bond lengths (Å) at MPW1PW91/6–31+G(d).

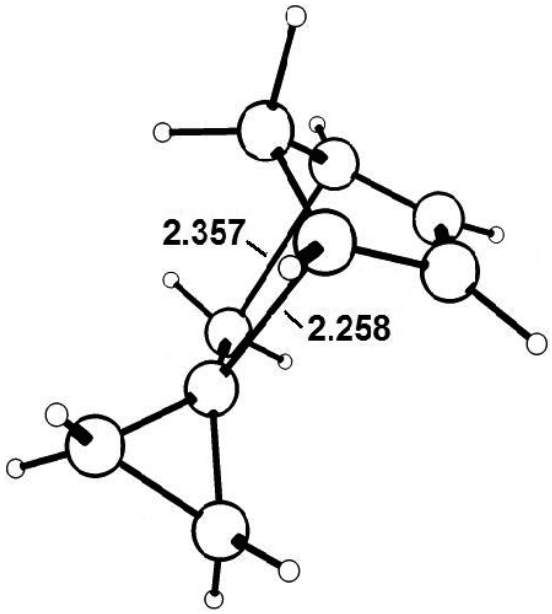
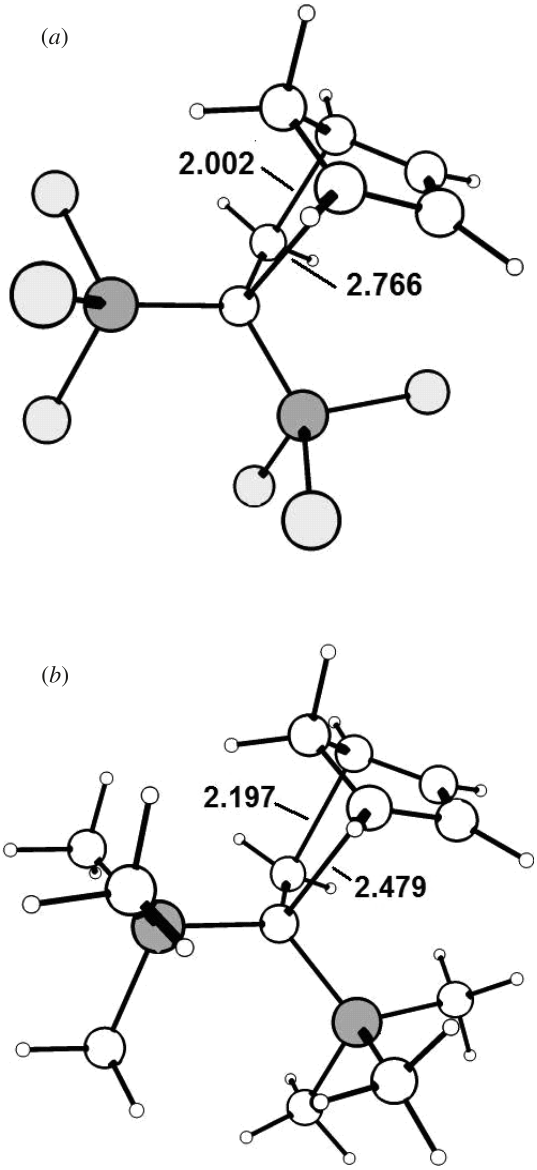


$\Delta H^{\ddagger}$ than endo dimerization of **2** (13.5 vs 17.0 kcal/mol) at 298 K. This is also seen in the relative free energies of activation (28.1 vs 31.0 kcal/mol). Of the six D–A reactions we studied, the formation of **4** has the lowest barrier, nicely in keeping with the experimental results. Transition state **4-TS** for the reaction of **2** + **3** is displayed as Fig. 3*a* along with

Fig. 3. Transition states (TS) (*a*) **4-TS** and (*b*) **1-TS** and incipient C–C bond lengths (Å) at MPW1PW91/6–31+G(d).



the incipient C–C bonds. In this case, the asynchronicity is large (0.76Å) with the incipient C1–C6 bond being much longer than the C4–C5 bond.

Given that our computational results on the formation of **10N**, **12**, and **4** correlated well with experimental studies documented in the literature, we expect the computed thermochemical parameters for the other D–A reactions included in this study to be of comparable accuracy and thereby assist us in selecting the best route to **1**; we proceeded to study alternative D–A reactions to **1** computationally. It should be pointed out that the BSSE corrections for the dimerization of **2** and its reactions with **11** and **3** did not significantly alter the differences in activation energies based on the uncorrected total energies ($\Delta\Delta E_{elec}^{\ddagger}$s) even though the BSSE-corrected $\Delta E_{elec}^{\ddagger}$ values (column 3 of Tables 1 and 2) were 2–3 kcal/mol higher than the uncorrected values. We expect that the same situation holds for the reactions of **2** with **5**, **6**, and **8**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12

Fig. 4. Transition states (TS) (*a*) **9X-TS** and (*b*) **9N-TS** and incipient C–C bond lengths (Å) at MPW1PW91/6–31+G(d).

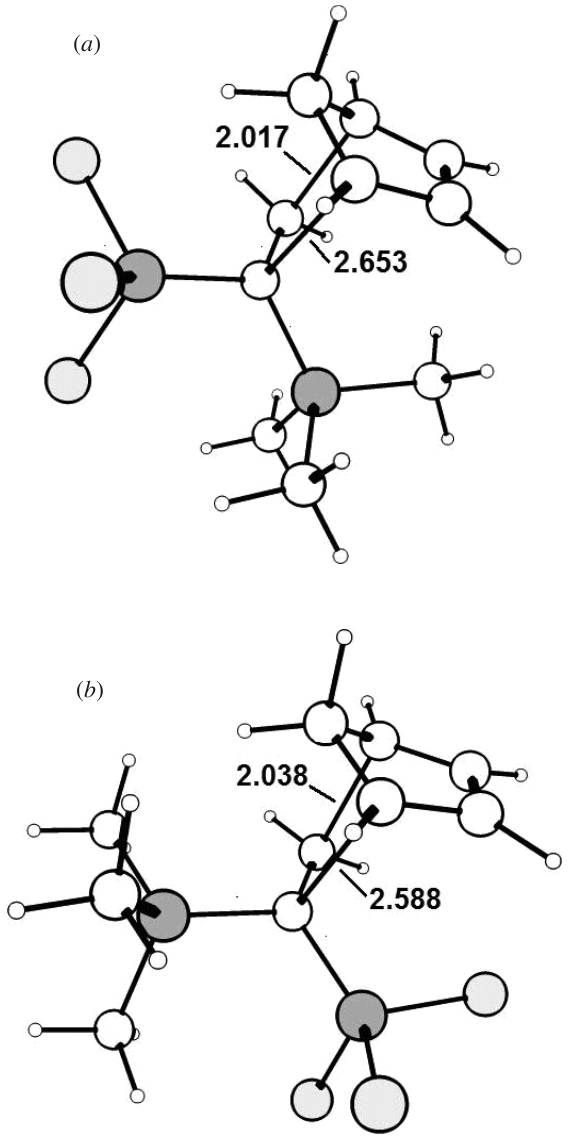

Fig. 5. Transition states (TS) (*a*) **7X-TS** and (*b*) **7N-TS** and incipient C–C bond lengths (Å) at MPW1PW91/6–31+G(d).

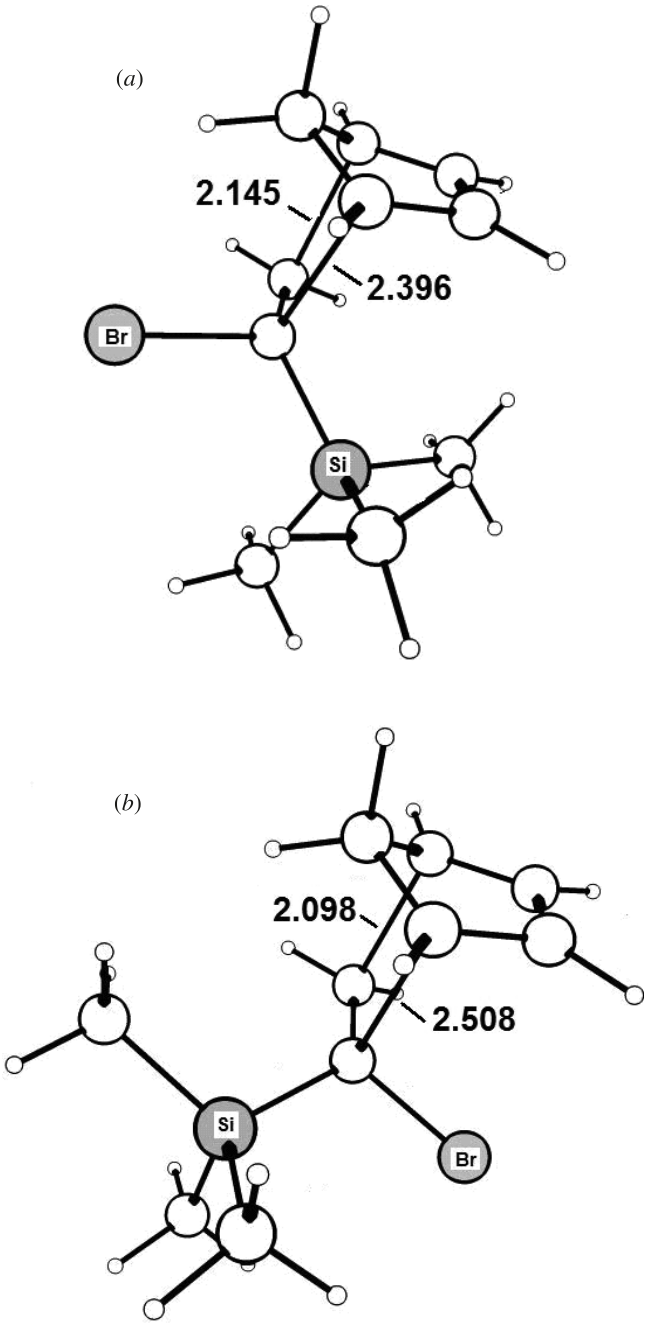

An alternative route directly to **1** involves the reaction of **2** with **5**. In this case, the asynchronicity (0.28 Å) is considerably smaller than in the case of the formation of **4**, with the C1–C6 incipient bond being longer than the C4–C5 bond even though the two trimethylsilyl groups are the largest pair of substiutents investigated at C6. At 298 K, $\Delta G^{\ddagger}$ is 40.1 kcal/mol, 12.0 and 9.1 kcal/mol higher than the $\Delta G^{\ddagger}$s for the formation of **4** and **10N**, respectively. Moreover, $\Delta G^{\ddagger}$ for the reverse reaction is 33.7 kcal/mol, 6.4 kcal/mol lower than $\Delta G^{\ddagger}$ for the forward reaction. At 463 K, the forward and reverse $\Delta G^{\ddagger}$s are 48.4 and 32.7 kcal/mol, respectively. This means that only trace amounts of **1** will be present when the reaction is attempted. Clearly, the **2** + **5** route to **1** is not a viable one.

The second alternate route we studied involved the reaction of **2** with **8**. The exo and endo TSs **9X-TS** and **9N-TS** are displayed in Fig. 4 along with the incipient C4–C5 and C1–C6 bond lengths. In this case diastereomeric products are possible. The asynchronicity indexes are relatively high; 0.64 for the **9X-TS** and 0.55 for **9N-TS**. That the $\Delta G^{\ddagger}$s for formation of *exo*-trichloro[2-(trimethylsilyl)bicyclo[2.2.1]-hept-5-en-2-yl]silane (**9X**) and *endo*-trichloro[2-(trimethylsilyl)bicyclo[2.2.1]hept-5-en-2-yl]silane (**9N**) at 298 K are 34.8 kcal/mol 34.5 kcal/mol, respectively, indicates that a small kinetic diastereoselectivity is expected. The barriers for the retro reactions of **9X** and **9N** were 29.8 and 32.7 kcal/mol, respectively. That the retro barriers are lower than the barriers for the forward reactions established that the reaction of **2** with **8** is also not a viable route to **1** via **9X** and **9N**. At 463 K the $\Delta G^{\ddagger}$s for the forward reactions for formation of *exo*- and *endo*-trichloro[2-(trimethylsilyl)bicyclo[2.2.1]hept-5-en-2-yl]silane are 42.7 and 43.1 kcal/mol,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

respectively, 15.5 and 11.2 kcal/mol higher than the $\Delta G^{\ddagger}$s for the retro reactions. Clearly, the sequence **2** + **8** → **9X** + **9N** → **1** is not a viable route to **1**.

The third alternate route we explored computationally involved the reaction of (1-bromovinyl)trimethylsilane (**6**) with **2** to yield **7X** and **7N**, which would yield **1** via standard lithiation and silylation steps. Transition states **7X-TS** and **7N-TS** for the reaction of **2** + **6** are displayed in Figs. 5*a* and 5*b* along with the lengths of the incipient C–C bonds. The TSs exhibit asynchronicities of 0.25 and 0.41 Å, respectively. The computed $\Delta G^{\ddagger}$s for the formation of **7X** and **7N** are 31.0 and 31.8 kcal/mol at 298 K (importantly, the ΔGs are fairly large and negative (–10.1 for **7X** and –9.9 for **7N**)) with the retro barriers being 42.0 and 41.1 kcal/mol, respectively. Even at 463 K, the barriers for retro reactions remained higher (40.5 and 41.1 kcal/mol) than the forward reactions (28.4 and 38.2 kcal/mol) and, consequently, **7X** and **7N** will be the thermodynamic products in both cases. Based on the fact that (*i*) **6** is commercially available, (*ii*) the D–A reaction with **2** to yield **7X** and **7N** is expected to proceed readily based on the computed barriers, and (*iii*) **7X** and **7N** are the thermodynamic products, it is clear the pathway that includes the preparation of **7X** and **7N** is the sequence of choice for the synthesis of **1**.

Conclusion

This study demonstrated the advantage of using DFT calculations in a synthetic research project. We successfully used DFT calculations at the MPW1PW91/6–31+G(d) level to define the route of choice for the synthesis of bicyclo[2.2.1]hept-5-ene-2,2-diylbis(trimethylsilane) (**1**) beginning with a Diels–Alder reaction.

Luminescence and decay properties of the $^1D_2$ level of Pr^{3+}-doped YPO_4

J. Collins, M. Bettinelli, and B. Di Bartolo

Abstract: This investigation reports on the spectroscopic properties of trivalent Pr in YPO_4. In particular, we show how the luminescence from the $^1D_2$ level depends on the polarization of the emission and on the temperature of the sample. We also report on the decay kinetics of the $^1D_2$ level, which show the lifetime decreasing as temperature is increased. Our observed lifetime of 440 μs is at low temperature and is significantly longer than that reported by other workers. We explain the temperature dependence of the $^1D_2$ emission by considering the population redistribution in the $^1D_2$ level, without invoking the existence of multiphonon relaxation. Finally, we estimate the radiative decay rates of individual crystal field levels within the $^1D_2$ manifold.

Key words: luminescence, praseodymium, yttrium phosphate, $^1D_2$, radiative decay, lifetime, temperature dependence.

Résumé : On rapporte les propriétés spectroscopiques du Pr trivalent dans du YPO_4. En particulier, on a cherché à établir quelle est la dépendance de la luminescence du niveau $^1D_2$ sur la polarisation de l'émission et sur la température de l'échantillon. On a aussi déterminé la cinétique de décroissance du niveau $^1D_2$; elle montre que le temps de vie diminue avec une augmentation de la température. Le temps de vie observé dans cette étude à basse température, 440 μs, est beaucoup plus long que celui rapporté par d'autres auteurs. On explique cette dépendance de l'émission $^1D_2$ sur la température par une considération de la redistribution de la population dans le niveau $^1D_2$ sans invoquer l'existence d'une relaxation multiphoton. Enfin, on a évalué les vitesses de décroissance radiative des niveaux individuels du champ cristallin dans la voie $^1D_2$.

Mots-clés : luminescence, praséodyme, phosphate d'yttrium, $^1D_2$, décroissance radiative, temps de vie, dépendance sur la température.

[Traduit par la Rédaction]

Introduction

Pr^{3+}-doped insulators have been investigated for potential use in a variety of applications such as scintillators and phosphors. An energy level diagram of trivalent Pr in solids is shown in Fig. 1. The levels of primary interest for luminescence applications are the $^3P_0$ and $^1D_2$ levels. The $^1D_2$ level has been of recent interest for possible phosphor applications because of its strong emission in the red and because it is efficiently fed from the upper levels.[1,2] Pr-doped YPO_4 also shows efficient feeding of the $^1D_2$ level, and so it represents a system of potential interest.

Previous work on Pr-doped YPO_4 shows that the maximum phonon energies are greater than 1000 cm^{-1}, and that the multiphonon decay is very strong.[3,4] These factors often lead to weak luminescence from the $^3P_0$ level, and correspondingly low quantum efficiencies. The strong multiphonon relaxation from the $^3P_0$ level, however, results in favorable conditions for luminescence from the $^1D_2$ level. The reason for this is that when the system is pumped into the more strongly absorbing ^3P_J (J = 0, 1, 2) levels, efficient multiphonon relaxation leads to the vast majority of the ions ending up in the metastable $^1D_2$. The question that remains open at this point is whether the $^1D_2$ emission is an efficient one or whether nonradiative decay processes, such as multiphonon decay, compete effectively with radiative decay. This is the central question addressed in this paper.

The decay of the $^1D_2$ has been shown to involve several processes. In addition to radiative decay and multiphonon relaxation, the $^1D_2$ decays via a cross-relaxation process that tends to quench the emission at high concentrations. These processes are shown in Fig. 1. This cross-relaxation is observed in many samples, especially a high Pr doping.[5,6] In some systems, Pr^{3+} has also exhibited upconversion, but this has not been observed in the YPO_4 system.[7,8] In this work we study the decay from the $^1D_2$ level in Pr-doped YPO_4 and attempt to understand which processes are responsible for the decay.

Several workers have studied this system, and have come to varying conclusions regarding the decay of the $^1D_2$ level.

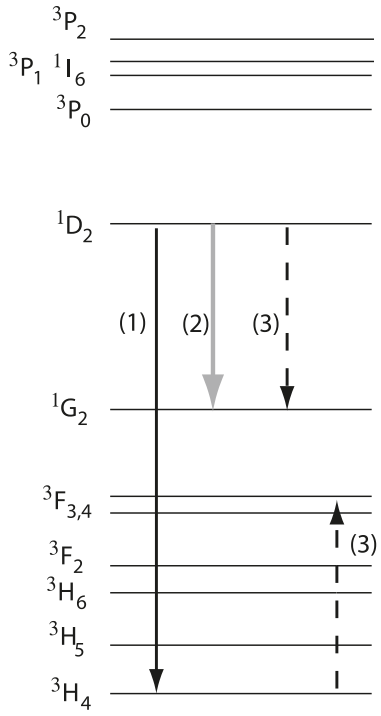
Fig. 1. Energy level diagram of the Pr^{3+} in YPO_4. Decay processes shown are (1) radiative decay, (2) multiphonon decay, and (3) nonradiative cross-relaxation.



The literature contains conflicting values for the $^1D_2$ lifetime. Also, whereas some workers conclude that multiphonon relaxation is a prominent decay process, others conclude that there is no multiphonon decay and that cross-relaxation is the dominant nonradiative decay mechanism. We will discuss these results in more detail later. In this paper we present evidence showing that in low-doped systems the decay is overwhelmingly radiative. We demonstrate this by examining both the luminescence spectra and the response of the system to pulsed excitation in the temperature range from 30 to 300 K. The temperature dependence of the radiative lifetime closely follows the results as predicted from the luminescence data at all temperatures, so that there is no reason to invoke the presence of any nonradiative decay processes.

Experimental method

Single crystals of YPO_4 doped with 0.1 mol% Pr^{3+} (substituting for Y^{3+}) were grown by spontaneous nucleation from a $PbO–P_2O_5$ flux (1:1 molar ratio).[9] The reagents employed for the growths were $NH_4H_2PO_4$ (reagent grade), PbO (reagent grade), Y_2O_3 (99.99%), and Pr_6O_{11} (99.999%). The batch was put in a covered Pt crucible with a tightly fitting lid and heated up to 1300 °C inside a horizontal furnace. After a soaking time of about 15 h, the temperature was lowered to 800 °C with a rate of ≈1.8 °C/h; the crucible was then drawn out from the furnace and quickly inverted to separate the flux from the crystals grown at the bottom of the crucible. The flux was dissolved using hot diluted nitric acid. Single crystals of good optical quality were obtained in the form of platelets having sizes up to $10 \times 4 \times 0.5$ mm^3 elongated in the direction of the *c* axis of the xenotime crystal structure.

YPO_4 crystallizes in the tetragonal $I4_1/amd$ space group (No. 141) with $Z = 4$, $a = b = 6.8817(5)$, $c = 6.0177(6)$ Å, and $\alpha = \beta = \gamma = 90°$.[10] The xenotime structure is characterized by chains of alternating edge-sharing VO_4 (tetrahedral) and YO_8 (dodecahedral) units, which develop along the crystallographic *c* axis. The Pr^{3+} doping ions replace Y^{3+} in their eightfold coordinated sites having D_{2d} point symmetry.

Absorption measurements on the sample were taken at room temperature with a PerkinElmer model 750 UV–vis–NIR absorption spectrophotometer. For all luminescence measurements, the sample was excited with a Molectron model DL-II dye laser pumped by a Molectron model UV-400 nitrogen laser. The laser produces pulses having ~1 mJ of energy and a width of 8 ns. The luminescence from the sample is dispersed by a 1 m McPherson monochromator and detected with a Hamamatsu photomultiplier tube type R1387, which was cooled by a Products for Research TE-cooled housing. A filter was placed at the entrance slit of the monochromator to eliminate scattered light from the laser, and a polarizer was also placed at the entrance slit when required. For luminescence spectra, the signal from the photomultiplier was sent to an EG&GPARC model 4121B boxcar averager. So as to maximize the signal, we used the input having 1 MΩ of impedance; no attempt was made to do time-resolved studies. The signal was averaged over 30 pulses and stored on the computer using LabVIEW. For lifetime studies, the signal from the phototube was sent directly into an oscilloscope (Tektronix model TDS3052B) and averaged over 512 pulses. The sample was cooled using a Janis model RD closed-cycle He refrigerator connected to an Oerlikon Leybold Vacuum Coolpack 2200 compressor unit. The temperature was varied from 28 to 300 K using a Lake Shore model 805 temperature controller.

Experimental results

Absorption measurements at room temperature were taken between 800 and 300 nm and display the narrow peaks associated with the Pr ion, as well as a broad-band absorption beginning near 500 nm and continually increasing in strength. This band did not seem to affect the emission from the $^1D_2$ level of the Pr ion, which is the main focus of this paper, and so will not be discussed further.

Emission spectra were taken from 470 to 800 nm and show emission lines originating from both the $^1D_2$ and the $^3P_0$ levels. The red emission near 600 nm, corresponding to the $^1D_2 \rightarrow {}^3H_4$ transition, is the most prominent set of lines at all temperatures. Figure 2 shows the crystal field levels of the excited $^1D_2$ manifold and of the ground $^3H_4$ manifold. Emission from the $^3P_0$ level is very weak in YPO_4.

Emission spectra owing to the $^1D_2 \rightarrow {}^3H_4$ transitions in the red were taken at several temperatures between 30 and 300 K. For these measurements, the sample was pumped into the $^3P_2$ level, near 450 nm. Following excitation, the Pr ion underwent a fast nonradiative decay to the $^1D_2$ level. At each temperature, we took three spectra in the range from 590 to 620 nm: one spectrum for σ-polarized emission, one for π-polarized emission, and one with no polarizer. Sample results of these spectra at 90, 150, and 300 K are shown in

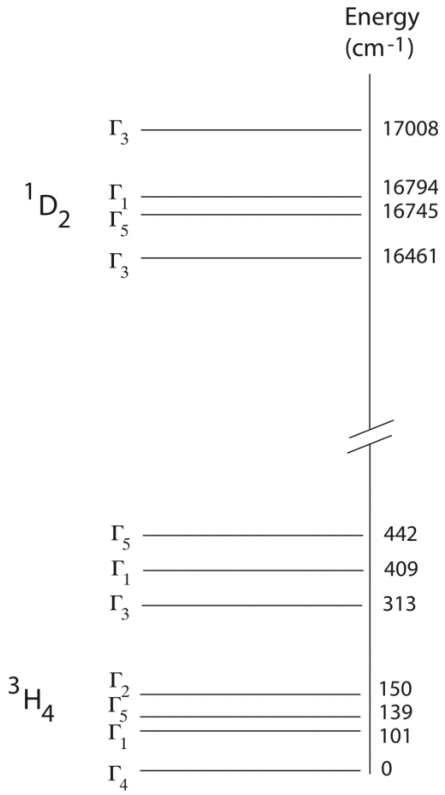
Fig. 2. Crystal field levels of the $^1D_2$ and $^3H_4$ manifolds of Pr^{3+} in YPO_4. Energy values are taken from Moune et al.[3]



Figs. 3, 4, and 5, respectively. We note that as the temperature increases, the upper levels of the manifold become populated; consequently, more lines appear in the spectrum. The lines also broaden as temperature increases.

Before turning our attention to the luminescence spectra, we note that the crystals had some small cracks and other scattering centers in its bulk. The sides of the crystal, through which the luminescence was observed, were mostly smooth but not polished, and so scattered some of the emitted light. Because of this scattering, the σ-polarized spectra contain small amounts of π-polarized emission, and vice versa. The spectra in Figs. 3–5 all show the effects of these scattering centers.

Figures 3–5 exhibit four prominent lines between 595 and 605 nm, as seen in the emission spectra without the polarizer. In the σ-polarized spectra the lines at 597.2 and 600.4 nm dominate, whereas the lines at 595.5 and 602.2 nm are suppressed. In the π-polarized spectra the opposite occurs: the lines at 595.5 and 602.2 nm dominate, whereas the lines at 597.2 and 600.4 nm are suppressed. Comparing the emission spectra for different polarizations and knowing the energies of each transition (see Fig. 2), it is straightforward to assign transitions to the various lines. The assignments, shown in Figs. 3–5 and in Table 1, are in good agreement with those given by Reid and Moos.[4]

The response of the system to pulsed excitation was measured by monitoring emission from the $^3P_0$ level (at 500 nm) and the $^1D_2$ level (at 613 nm). For these measurements, excitation was into the $^3P_2$ level near 450 nm. The $^3P_0$ decay curve was a pure exponential with a lifetime of

0.65 μs at 30 K and 0.62 μs at 300 K, in general agreement with previous work.[3] Decay curves of the $^1D_2$ level were recorded at temperatures between 28 and 300 K. Plots of sample decay curves at 28 and 150 K are shown in Fig. 6. All of the decay curves were very nearly exponential. They displayed a slight nonexponential behavior only for the first 50 μs or so. The lifetime values were determined by taking the inverse of the slope of the ln(intensity) vs time curves at times >100 μs. Figure 7 shows the $^1D_2$ lifetime at temperatures between 30 and 300 K.

Discussion

The decay of the $^1D_2$ level of Pr^{3+} in YPO_4 is governed by three processes: radiative decay, multiphonon relaxation, and energy transfer via a cross-relaxation to the $^1D_2$. These three processes are shown in Fig. 1. The cross-relaxation process tends to quench the luminescence from the $^1D_2$ level and introduces a nonexponential component into the decay curve. The process becomes more probable as the concentration of Pr increases and can sometimes act as the dominant

*The $^1D_2$(2) level is doubly degenerate. All other levels have a degeneracy of 1.

decay process. In such systems the decay curve is highly nonexponential. In a system with Pr ions doped to a low level, however, it contributes only very little to the decay, as only those atoms near one another are likely to undergo such a process. The low doping concentration and the very nearly exponential shape of the decay patterns at all temperatures suggest that though some cross-relaxation is likely occurring in this sample, it can be neglected to a good approximation. Thus, the lifetimes plotted in Fig. 7 most closely represent the lifetime of Pr ions that are isolated from one another.

We note that the measured lifetime of 440 μs in the 0.1% sample at low temperature represents a much longer lifetime than that reported elsewhere. The $^1D_2$ lifetime has been measured at low temperatures by other workers and was found to be as short at 70 μs[11] and as long as 225 μs.[3] Judd–Ofelt calculations have also been referred to in the literature, and the calculated value of the lifetime of the $^1D_2$ level was 490 μs, close to the lifetime we observed.[12] Though we offer no specific reason as to why the low-temperature lifetime differs so widely sample to sample, it is sometimes the case that during crystal growth there can be centers formed that contribute to the nonradiative decay. The fact that our measured lifetime is greater than that of others leads us to believe that 440 μs is a more accurate value of the lifetime of an isolated Pr ion in YPO_4 in the absence of any unwanted centers.

As shown in Fig. 7, we observed a decrease in the $^1D_2$ lifetime as the temperature increases. This behavior is consistent with the observations of others. The fact that the lifetime decreases from ~440 μs at 30 K to 187 μs at 300 K suggests the possibility of multiphonon relaxation to the $^1G_4$ level as a high probability decay channel. Other workers have seen similar decreases in the lifetime with temperature, though there is no agreement as to the process responsible. Work by Reed and Moos[4] attributes the decrease in lifetime to an increase in the multiphonon decay rate as temperature increases. They constructed a model that allowed for phonons of different frequencies to bridge the gap to the $^1G_4$. Moune et al.[3] were inclined to the same conclusion. Zheng and Meltzer,[12] using Judd–Ofelt calculations of the radiative rate and a measured decay time, estimated the nonradiative decay rate to be 4.4×10^3 s^{-1} and pointed to multiphonon decay as the nonradiative mechanism. Naik et al.,[5] on the other hand, estimated the multiphonon decay rate to be negligible compared with the radiative decay. They noted that the energy gap between the $^1D_2$ and the next lowest $^1G_4$ level was 6500 cm^{-1}, and since it would take seven phonons to bridge the gap, such a process was unlikely. They concluded that the decrease in the lifetime as temperature increases was due to the increase in the rate of decay via cross-relaxation. Here we propose a different simpler mechanism to explain the temperature dependence of the $^1D_2$ level.

Before beginning our analysis, we calculated the temperature dependence of the population of the various levels of the $^1D_2$ manifold between 30 and 300 K. Using the energies of the levels of the $^1D_2$ manifold shown in Fig. 2, we calculated the fractional occupancy of each level at various temperatures. We noted that the Γ_5 crystal field level $^1D_2$ level was doubly degenerate, whereas the other levels were singly degenerate. We assumed that the $^1D_2$ manifold was thermalized, so that the fractional populations were determined by the Boltzmann distribution according to

$$[1] \qquad f_i(T) = \frac{g_i e^{-\Delta E_i/kT}}{\sum_i g_i e^{-\Delta E_i/kT}}$$

where f_i is the fraction of ions in the *i*th level of the $^1D_2$ manifold, T is the temperature, g_i is the degeneracy of the

Note: A_i is the area under the emission lines associated with transitions from the ith level of the $^1D_2$ manifold and is proportional to the number of photons collected at the detector, τ_i is the "radiative lifetime" associated with the ith level of the $^1D_2$ manifold, and τ is the lifetime of the $^1D_2$ level.

ith level of the $^1D_2$ manifold, and $e^{-\Delta E_i/kT}$ is the Boltzmann factor. The results are shown in Table 2.

Considering the results of Table 2 together with the luminescence spectra at various temperatures, we notice a process that may account, in part or in whole, for the decrease in the lifetime at temperature increases. Though the spectrum is not shown, at 30 K the emission originates completely from the lowest energy level of the $^1D_2$ manifold, and a single line at 612.8 nm dominates the spectrum. At 90 K (Fig. 3*a*), additional lines appear that represent transitions originating from the next two highest excited $^1D_2$ levels (Γ_5 and Γ_1). By integrating the area under the various lines in Fig. 3*a*, we conclude that the lines associated with the higher $^1D_2$ levels account for approximately one-quarter of the emission intensity at 90 K. According to Table 2, however, only about 2% of the Pr ions reside in these higher energy states at 90 K. At 150 K (Fig. 4*a*), >50% of the $^1D_2$ emission intensity originates from these upper levels, though only about 15% of the Pr ions occupy those upper $^1D_2$ levels. These results are possible only if the radiative decay rates of the upper $^1D_2$ levels are higher than that of the lowest level. These observations suggest that as temperature increases and the higher energy states are populated, the $^1D_2$ lifetime should decrease because the radiative decay rates of these upper levels of the $^1D_2$ manifold are higher than the radiative rate of the lowest level of the manifold. Let us follow this lead more carefully, as we attempt to quantify how much of the decrease in the $^1D_2$ lifetime might be due to the thermal occupation of the higher $^1D_2$ levels.

In our analysis, we will be using luminescence data to estimate the ratio of the intensity of emission from the lowest level to the intensity of emission from the upper energy levels. An exact treatment would require us to consider all emission lines from the $^1D_2$ level to all lower energy states. This was not practical experimentally for us, since many of the emission lines fall outside of the range of the photomultiplier, and because our system is not corrected to give meaningful relative intensity values. Thus, we make the following two assumptions. The first assumption is that the $^1D_2 \rightarrow {}^3H_4$ emission is the dominant radiative decay channel, so that a reasonable estimate of the relative emission from the various $^1D_2$ levels can be obtained simply by observing transitions between these two manifolds. The second assumption is that the response of our system is reasonably flat over the range of wavelengths between 590 and 620 nm, where the bulk of the $^1D_2 \rightarrow {}^3H_4$ emissions occur. Though neither of these assumptions is completely valid, it is known that the $^1D_2$ level is as a strong emitter in the red and that in many systems the $^1D_2 \rightarrow {}^3H_4$ transitions dominate the emission spectrum. According to our observations, the lines corresponding to $^1D_2 \rightarrow {}^3H_4$ emission are much stronger than lines representing transitions to other lower levels, at least for emission lines from 600 to 850 nm. Our second assumption is validated by the fact that we are examining the luminescence in a rather narrow wavelength range, roughly between 593 and 615 nm.

Using the luminescence spectra of the $^1D_2 \rightarrow {}^3H_4$ emission at various temperatures, we first plotted the luminescence data as a function of energy instead of wavelength. We then fit the spectra to a sum of Lorentzian peaks and found the area under the various peaks. (This was done using the Origin software program in which the data were plotted.) This gives a value that is proportional to the total energy under each peak. We then divided that number by the photon energy for each peak to obtain a value that is proportional to the number of photons emitted by the various lines. As we move from 30 to 300 K, we go from a situation where the emission is from only one level ($^1D_2(1)$) to where the emission originates from up to four levels: $^1D_2(1)$, $^1D_2(2)$, $^1D_2(3)$, and $^1D_2(4)$). The uppermost $^1D_2(4)$ level was negligibly populated for most temperatures (only 4% at 300 K), so we did not consider this an important contributor to the emission. Emission from this level is neglected in the following treatment, representing yet another approximation. The emission lines we focused on are the five lines shown in Figs. 3–5. Specifically, they are the following lines: 612.8 nm from $^1D_2(1)$, 602.2 and 597.2 nm from $^1D_2(2)$, and 600.8 and 595.5 nm from $^1D_2(3)$. Other transitions do occur in that same spectral region between 590 and 615 nm, but most are weak and it was impossible to discern all the peaks. We limited our analysis to these transitions because they appeared to be considerably stronger than the other emission lines.

At 30 and 60 K, the area under the peaks owing to the $^1D_2(2)$ and $^1D_2(3)$ levels were too small to be considered reliable, so our estimates of the relative fraction of photons emitted from the various levels begin at 90 K and continues

For personal use only.

through 300 K. The results of these calculations are shown in Table 3.

To relate these data to the temperature dependence of the lifetime, we define the following terms:

N_i is the number of Pr ions in the ith level of the $^1D_2$ manifold.

N is the total number of Pr ions in the $^1D_2$ manifold.

$f_i = N_i/N$ is the fraction of ions in the ith $^1D_2$ level. These are given in Table 2.

τ_i is the "radiative lifetime" associated with the ith level of the $^1D_2$ manifold, i.e., $1/\tau_i$ is the probability per unit time that a Pr ion in the ith level undergoes radiative decay to a lower level.

τ is the lifetime of the $^1D_2$ level.

A_i is the area under the emission lines associated with transitions from the ith level of the $^1D_2$ manifold and is proportional to the number of photons collected at the detector.

The number of photons emitted per unit time by the ith $^1D_2$ level is given by N_i/τ_i. Thus, the ratio of the number of photons per unit time emitted from the ith level to that emitted from the jth level is

$$[2] \qquad \frac{A_i}{A_j} = \frac{N_i/\tau_i}{N_j/\tau_j} = \frac{f_i\tau_j}{f_j\tau_i}$$

The A_i are known from the experimental data (see Table 3), and the f_i are given in Table 2. We assume that τ_1 = 440 ms, the lifetime of the $^1D_2$ level at low temperature, so we can use eq. 2 to find the lifetime associated with the ith level.

$$[3] \qquad \tau_i = \frac{A_1 f_i}{A_i f_1}\tau_1$$

The values of τ_i can be calculated at each temperature. The results are shown in Table 3. The data show significant variation in the inherent radiative lifetime of each of the upper levels, which is perhaps unsurprising given the assumptions involved. One would expect that inherent lifetime to be nearly temperature-independent, especially if there are no nonradiative processes. The average value of these lifetimes are τ_2 = 92 μs and τ_3 = 28 μs.

Again under the assumption that the $^1D_2$ level is thermalized, τ is given by:

$$[4] \qquad \frac{1}{\tau} = \sum_i \frac{f_i(T)}{\tau_i}$$

Values of τ as a function of temperature are shown in Fig. 7 and in Table 3. The results labeled "calculated (A)" in Fig. 7 were calculated using the lifetime values associated with different temperatures, as given in Table 3. The results labeled "calculated (B)" in Fig. 7 were calculated using the average lifetimes of the $^1D_2(2)$ and $^1D_2(3)$ level. For both calculated curves, the temperature dependence of the lifetime as determined from the luminescence data decreases with increasing temperature. Although the calculated results do not follow the experimentally measured lifetimes precisely, the match is reasonably good considering the assumptions involved. Our results give too large an estimate of the radiative transition rates from the upper levels, so that the predicted lifetimes are shorter than the measured lifetimes. We speculate this can be largely attributed to the fact that not all the transitions from the $^1D_2$ manifold were monitored.

Given these results, we conclude that the temperature dependence of the $^1D_2$ levels of Pr between 30 and 300 K can be adequately explained by the fact that the upper levels within the $^1D_2$ manifold have a radiative decay rate that is higher than that of the lowest $^1D_2$ level. We see no evidence to indicate that nonradiative decay owing to multiphonon relaxation is taking place, so that at least in low-doped systems, the emission from the $^1D_2$ should be very efficient.

Conclusions

The decay from the $^1D_2$ level of Pr in YPO_4 was considered in some detail. At low temperatures we find a lifetime of 440 μs, which is roughly twice as long as that reported previously. Using polarization emission spectra at various temperatures, we were able to identify the most prominent transitions from the $^1D_2$ level. By monitoring these main emission lines of the $^1D_2 \rightarrow {}^3H_4$ transition, we estimated the lifetime of each of the upper $^1D_2$ levels. Using this data and knowing the thermal distribution of ions among the energy levels of the $^1D_2$ manifold, we were able to estimate the temperature dependence of the lifetime of the $^1D_2$ level and compare it with the experimentally measured values. The reasonable fit between the experimental and calculated values of the lifetime allow us to conclude that, contrary to the conclusion of previous workers, there is no significant contribution of multiphonon relaxation to the lifetime of the $^1D_2$ level.

A Förster resonance energy transfer (FRET) approach for enhancing fluorescence contrast in phase-separated membranes

Daniel M. Carter Ramirez, Jason Ding, Jack Guan, Dusan Vobornik, Anna Carnini, William W. Ogilvie, Zygmunt J. Jakubek, and Linda J. Johnston

Abstract: The partitioning of the dye-labeled lipid probe, NBD-DHPE (1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (ammonium salt)), was examined by fluorescence microscopy in phase-separated lipid bilayers with mixtures of coexisting liquid-ordered and fluid phases. This probe shows slightly higher fluorescence intensity in the ordered domains but undergoes a contrast reversal to give a more strongly fluorescent fluid phase in the presence of >0.2% Texas red-DHPE (TR-DHPE). The change in contrast is shown to result from Förster resonance energy transfer between the NBD donor and TR acceptor in the fluid phase, which has a TR concentration that is approximately 3 times higher than in the domains. An alternate approach using a nitroxide-substituted lipid that partitions into the fluid phase as a quencher, was also examined as a means to enhance the contrast; however, the quencher modified the behaviour of the bilayer. The energy transfer method for enhancing the contrast between ordered and fluid phases was used to examine the morphology of enzyme-treated bilayers.

Key words: fluorescence microscopy, lipid bilayers, vesicles, ceramide.

Résumé : Faisant appel à la microscopie de fluorescence, on a étudié la partition de la sonde de lipide marquée d'un colorant, la 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl, NBD-DHPE, dans des bicouches de lipides séparés par phases coexistentes de fluide ou de liquide ordonné. Cette sonde présente une intensité de fluorescence qui n'est que légèrement supérieure dans le domaine ordonné, elle subit un renversement de contraste qui conduit à une phase fluide beaucoup plus fluorescente en présence de plus de 0,2 % de Texas Rouge-DHPE (TR-DHPE). On a démontré que le changement de contraste résulte d'un transfert d'énergie de résonance de Förster entre le donneur NBD et l'accepteur TR dans la phase fluide qui comporte une concentration de TR qui est approximativement 3 fois plus élevée que dans les autres domaines. Dans le but d'obtenir une augmentation du contraste, on a fait appel à une autre approche impliquant un lipide substitué par un groupe nitroxyde qui se partitionne entre la phase fluide comme désactivant; toutefois, le désactivant a modifié le comportement de la bicouche. La méthode d'énergie de transfert pour augmenter le contraste entre les phases fluides et ordonnées a donc été utilisée pour examiner la morphologie des bicouches traitées par un enzyme.

Mots-clés : microscopie de fluorescence, bicouches de lipide, vésicules, céramide.

Introduction

The compartmentalization of the plasma membrane into functional microdomains provides an important mechanism for regulating biological processes. Lipid or membrane rafts are defined as small, dynamic, heterogeneous microdomains that are enriched in cholesterol, sphingolipids, and certain proteins.[1–5] They are believed to exist in a liquid-ordered (L_o) phase that is surrounded by the bulk fluid or liquid-disordered (L_d) membrane. Rafts are postulated to have an important functional role in modulating cell signaling by spatial and temporal control of the organization of membrane proteins. The direct visualization of rafts in cell membranes is challenging because of their small size (10–200 nm, below the optical diffraction limit) and their relatively short lifetime.[6] These limitations have prompted many studies of lipid-phase behavior in model membranes such as small unilamellar vesicles, giant unilamellar vesicles, and supported lipid bilayers. Coexisting liquid phases have been observed for a variety of lipid mixtures

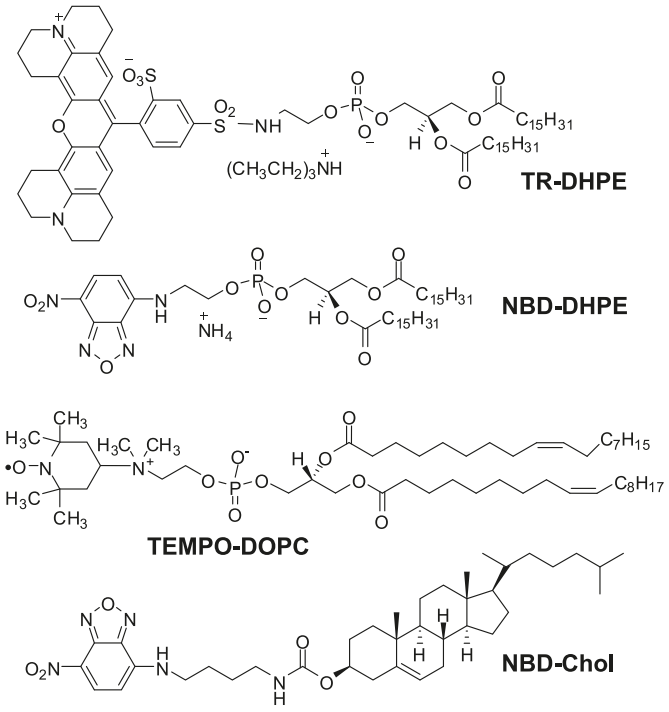
Scheme 1.



with at least three components, a low melting unsaturated phospholipid, a high melting saturated phosphatidylcholine or sphingomyelin, and cholesterol (Chol),[7–9] thus confirming one of the key concepts of the lipid raft hypothesis.

Despite the widespread use of fluorescence microscopy to study coexisting L_d and L_o phase separation in supported membranes and in giant unilamellar vesicles, there are relatively few dyes or dye-labeled lipids that can be used to selectively label the L_o phase. For example, the partitioning of more than 25 different fluorophores was assessed by fluorescence microscopy in giant unilamellar vesicles using a standard protocol for two different ternary lipid mixtures.[10] This study examined phospholipid probes with both saturated and unsaturated acyl chains and with fluorophores attached to either the acyl chain or polar headgroup. Based on relative fluorescence intensities, all fluorophore-labeled phospholipids partitioned more strongly into the disordered phase, including several headgroup-labeled lipids with saturated acyl chains that would be expected to cause the least disturbance to lipid packing in the L_o phase.[10] Although cholestatrienol partitioned into the L_o phase, other studies have demonstrated that dye-labeled cholesterol analogs show slight preferences for either L_o or L_d phases, depending on the fluorophore polarity and the method and location (hydroxyl vs alkyl chain) of its attachment to the sterol.[11–14] Several aromatic hydrocarbons show stronger fluorescence in the L_o phase, whereas dialkylcarbocyanine dyes have a preference for either the L_o or L_d phase, depending on the chain length and saturation or unsaturation of the hydrocarbon chain of the dye and the lipid composition for DOPC/SM/Chol (dioleolylphosphatidylcholine/sphingomyelin/cholesterol) and DOPC/DSPC (distearoylphosphatidylcholine)/Chol mixtures. Despite the clear preference of most lipid probes to partition into L_d phases in model membranes, NBD-DHPE (1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl); headgroup labeled) partitions strongly into L_o domains in vesicles (POPC (1-palmitoyl-2-oleoyl-*sn*-glycerophosphocholine)/C_{16}-SM/Chol, K_p (L_o/L_d partition coefficient) = 3.7)) and fluoresces more strongly in the L_o phase in supported planar bilayers prepared from POPC / brain SM / Chol mixtures.[15,16] Interestingly, this probe has also been reported to partition into the L_o phase in giant plasma membrane vesicles, although many other common lipid probes partition into the L_d phase in this system.[17]

As part of our investigations of the enzymatic generation of ceramide in bilayers with coexisting L_o and L_d phases, we had attempted to use NBD-DHPE to label L_o domains in supported bilayers prepared from DOPC/ESM (egg sphingomyelin)/Chol mixtures. Although this probe showed a slight preference for partitioning into the disordered phase based on relative fluorescence intensity measurements, we observed that a combination of NBD-DHPE and Texas red-DHPE (TR-DHPE) resulted in stronger NBD fluorescence in L_o domains. Here, we show that this apparent reversal of contrast for NBD-DHPE is caused by Förster resonance energy transfer (FRET) between NBD-DHPE and TR-DHPE in the fluid phase. TR-DHPE partitions strongly into the L_d phase, leading to efficient FRET, as expected from the strong overlap of donor NBD emission with absorption of the TR acceptor. Energy transfer was characterized in detail using a combination of fluorescence microscopy experiments for supported bilayers and measurements of FRET efficiencies based on donor fluorescence lifetimes in vesicle solution. We also examined an alternate approach using a nitroxide quencher, TEMPO-DOPC (1,2-dioleoylphosphatidyl-*N*,*N*-dimethyl-*N*-(2,2,6,6-tetramethyl-1-oxyl-piperidinyl)-ethanolamine), that partitions strongly into the disordered phase, to enhance the contrast for NBD in the L_o domains. Finally, we demonstrate that the double labeling strategy can be used to visualize the complex morphologies obtained during enzyme restructuring of supported membranes

Experimental section

Materials

DOPC, ESM (chicken), Chol, TEMPO-DOPC, and *N*-NBD-DHPE were purchased from Avanti Polar Lipids and were used as received. Texas red 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine triethylammonium salt (TR-DHPE) was obtained from Invitrogen. NBD-Chol was synthesized as described previously.[13] Sphingomyelinase (SMase) isolated from *Staphylococcus aureus* was obtained from Sigma-Aldrich. All aqueous solutions were prepared using 18.3 MΩ/cm Milli-Q water. SMase buffer: 125 mmol/L NaCl, 10 mmol/L $CaCl_2$, 2 mmol/L $MgCl_2$, and 10 mmol/L HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), pH 7.4. Structures of the lipid probes are shown in Scheme 1.

Preparation of supported bilayers

Small unilamellar vesicles (SUVs) were prepared as described previously.[18] Briefly, chloroform solutions of phospholipids and dye-labeled lipids were mixed in the appropriate ratios and the lipid films obtained after evaporating the solvent were hydrated in water. The samples were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

then sonicated in a bath sonicator to clarity to form SUVs with a final lipid concentration of 0.5 mg/mL. All vesicle solutions were sonicated at temperatures above the melting temperature (T_m) of the constituent lipids and were used immediately or stored at 4 °C for up to 1 week prior to use.

Planar supported bilayers were formed via vesicle fusion. Vesicle solution (60 μL) and 750 μL $CaCl_2$ (15 mmol/L) were added to freshly cleaved mica (15–25 μm thick for fluorescence imaging) clamped in a liquid cell. After incubation at 45 °C for 60 min, bilayers were gradually cooled to room temperature over a period of 2 h, and then washed with Milli-Q water to remove unattached vesicles before imaging.

Atomic force microscopy

Atomic force microscopy (AFM) images were obtained on a PicoSPM atomic force microscope (Molecular Imaging) in MAC mode using magnetic coated silicon tips with spring constants of ~0.5 N/m and resonance frequencies between 8 and 35 kHz in aqueous solutions. Either a 30 μm × 30 μm or 5 μm × 5 μm scanner was used with a scan rate between 0.7 and 1.3 Hz. All images shown are flattened raw data. Two independently prepared samples were imaged for each bilayer composition, and several areas were scanned for each sample. Domain heights were measured as the difference between the condensed-phase domains and the fluid phase.

Fluorescence microscopy

Fluorescence images of bilayers were measured in a total internal reflection fluorescence (TIRF) mode on an Olympus IX81 microscope equipped with a high- resolution charge-coupled device (CCD) camera (CoolSNAP, Photometrics) and a 60×/1.45 NA Plan Apochromat TIRF objective. Fluorescence was excited with a 488 nm Ar ion laser (NBD-labeled probes) or a 543 nm Kr ion laser beam (TR-DHPE). NBD and TR fluorescence were recorded through FF01-536/40 and FF01-624/40 emission filters (Semrock), respectively. For comparison of the effects of laser polarization, images were recorded using TIRF and epifluorescence geometries; the linearly polarized emission from the laser results in ~70% axial polarization for TIRF as compared with in-plane polarized excitation for epifluorescence. For SMase treatment, the bilayers were washed with SMase buffer and imaged. The effect of enzyme on the bilayer was followed in time by imaging the same area before and after the addition of buffered enzyme solution at room temperature.

The fluorescence intensity analysis was done using ImagePro software (MediaCybernetics). The intensities of adjacent L_d fluid phase and L_o domains were measured from intensity cross sections of the area of interest. These values were corrected for background fluorescence before calculating the L_d/L_o intensity ratio (I_{L_o}/I_{L_d}). The background fluorescence count was obtained by either completely bleaching an area immediately adjacent to the area of interest or by using a bilayer defect in the region of interest. Care was taken to ensure that background, domain, and fluid-phase intensities were measured within a small area (2–4 μm) with uniform excitation intensity to minimize effects owing to variation in excitation intensity across the field of view. A minimum of 10 corrected I_{L_o}/I_{L_d} values were collected per region (~100 μm^2), and multiple samples were measured for each experiment to check for reproducibility.

Fluorescence spectroscopy

Absorption spectra were measured with a Cary 5000 UV–vis–NIR spectrophotometer (Varian, Inc.) at 22 °C using a 1 cm path length quartz cuvette. Emission spectra and fluorescence lifetimes were recorded at 22 °C using a Fluorolog Tau-3 (Horiba Jobin Yvon) spectrofluorometer. Fluorescence quantum yields for TR-DHPE in vesicle solutions were measured with reference to rhodamine 101 ($\Phi = 1.0$)[19] at an excitation wavelength of 550 nm and absorbance < 0.2. Fluorescence lifetimes were measured using the frequency domain method with modulation frequencies in the 2–80 MHz range.

Results and discussion

Fluorescence microscopy of supported bilayers

Figure 1 illustrates a representative fluorescence image of a supported lipid bilayer prepared from DOPC/ESM/Chol (2:2:1) vesicles containing 0.3 mol% NBD-DHPE. The small slightly darker domains are analogous to those observed in previous fluorescence microscopy studies of similar supported bilayers using TR-DHPE to visualize phase separation; AFM showed that the dye-excluded domains were thicker than the surrounding membranes, consistent with assignment to a cholesterol- and sphingomyelin-enriched liquid-ordered phase.[20] Contrary to our expectations based on literature data for POPC mixtures,[15,16] NBD-DHPE has a slight preference for the L_d phase, based on relative fluorescence intensities. However, bilayers containing both NBD-DHPE and TR-DHPE showed an apparent reversal in contrast for the NBD channel, as illustrated in Figs. 1B and 1C. In this case, the NBD channel indicates significantly stronger fluorescence in the domains, whereas TR-DHPE shows a strong preference for the L_d phase, as previously observed. Qualitatively similar results were obtained for DOPC/ESM/Chol (1:1:1) bilayers; bilayers with NBD alone showed slightly darker domains, and the contrast was reversed for bilayers prepared with a mixture of 0.5 mol% NBD-DHPE and 0.3 mol% TR-DHPE. A change from the apparent L_d preference of the probe was also observed for Oregon green in the presence of TR-DHPE in 2:2:1 DOPC/ESM/Chol bilayers.

The change in intensity for NBD-DHPE in the L_o and L_d phases was examined as a function of TR-DHPE concentration ([TR-DHPE]). Bilayers containing 0.1 mol% TR-DHPE showed similar images (data not shown) to that for NBD-DHPE alone (Fig. 1A). However, the contrast is reversed at higher dye loadings (≥0.2 mol%). A matched experiment (same excitation intensity and exposure time) for bilayers containing 0, 0.2, and 0.5 mol% TR-DHPE is presented in Fig. 2. Note that the images in Fig. 2 are all displayed on a fixed intensity scale so that the NBD-DHPE image appears to have lower contrast compared with that shown in Fig. 1. The overall intensity for NBD fluorescence decreases significantly in the L_d phase at 0.5 mol% TR-DHPE as shown in Fig. 2D. The large decrease in NBD intensity (to ~24% of the initial value) in the L_d phase contrasts with the relatively modest decrease (to ~80% of the initial value) for the L_o

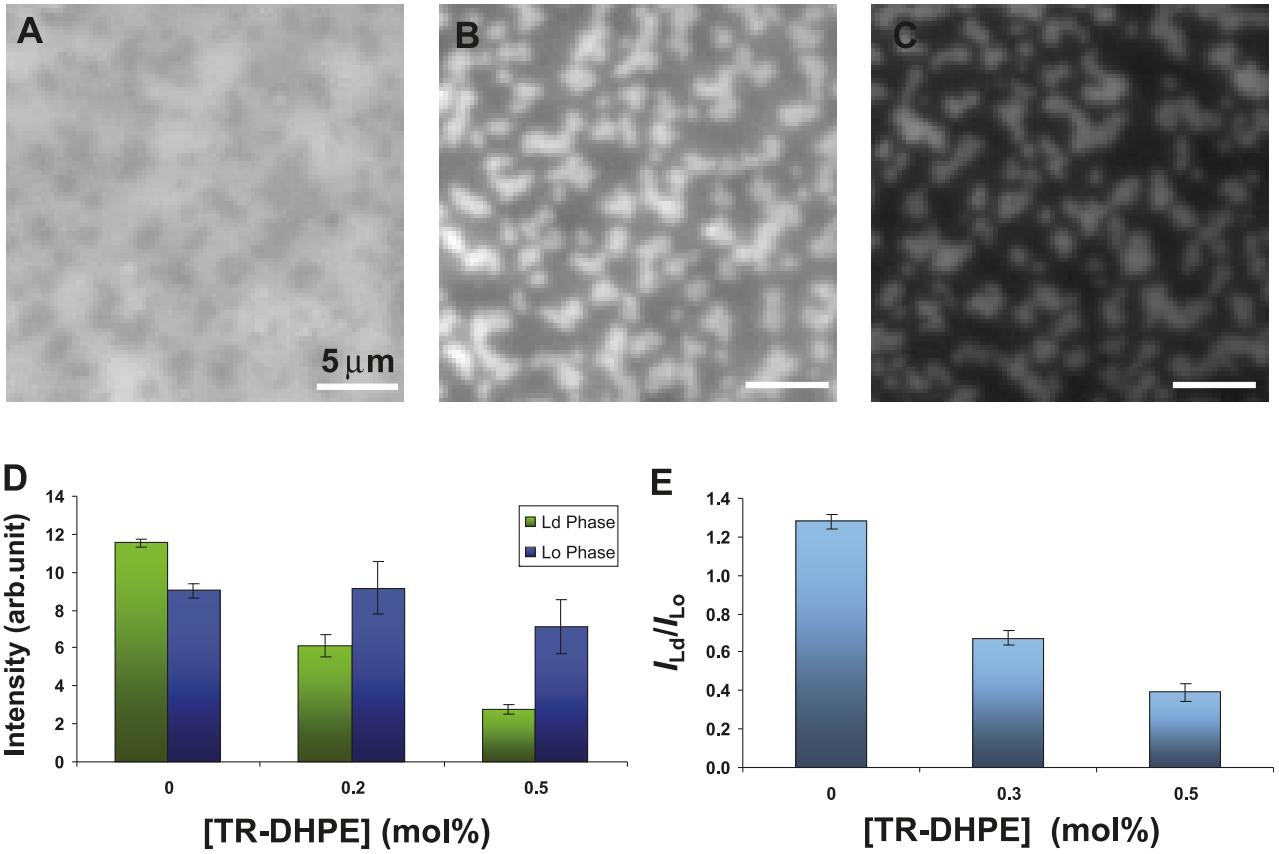
All three images are displayed on the same intensity scale. The column charts in (D) and (E) illustrate the change in NBD intensities for the L_o and L_d phases and the L_d/L_o intensity ratios, respectively, as a function of [TR-DHPE].



domains. The variation in the relative intensities of the L_o and L_d phases are displayed in Fig. 2E.

One possible explanation for the reversal in contrast for NBD in the presence of TR-DHPE is that FRET from NBD (donor) to TR (acceptor) occurs with a much higher efficiency in the fluid phase as compared with the ordered domains for the DOPC/ESM/Chol bilayers. This explanation is consistent with both the strong overlap of donor NBD emission with absorption of the TR acceptor and pronounced reduction in NBD emission in the L_d phase with increasing [TR-DHPE]. More efficient FRET in the L_d phase requires either a more favorable relative orientation of the transition

For personal use only.

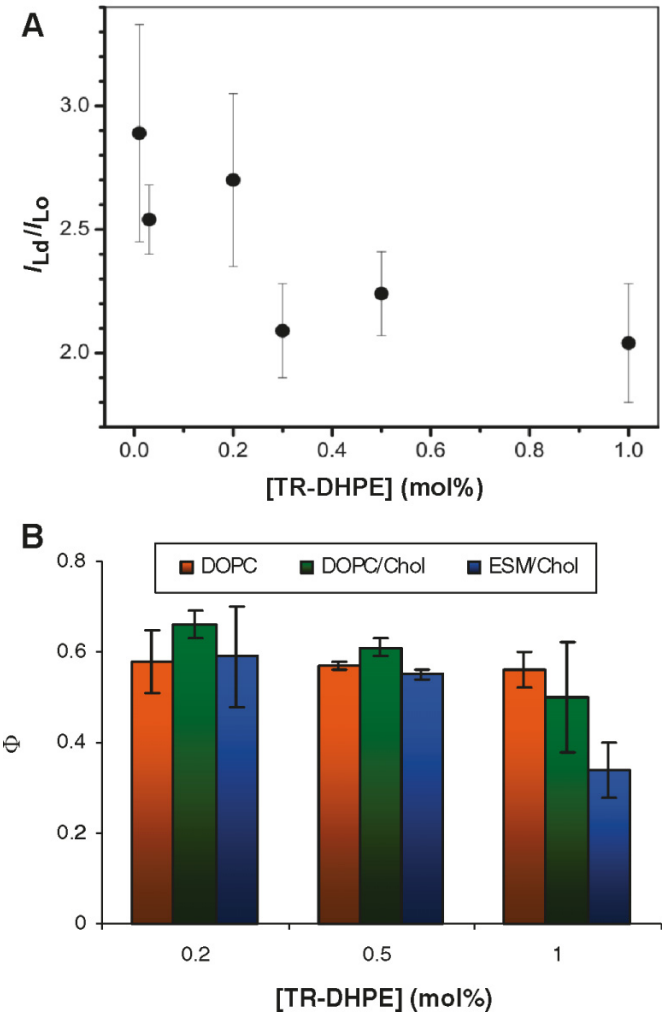
dipoles of the donor and acceptor in this phase or a significantly higher concentration of TR. Several additional experiments with DOPC/ESM/Chol bilayers and vesicles labeled with only TR-DHPE were carried out to investigate this in more detail.

First, images of bilayers with [TR-DHPE] between 0.01 and 1 mol% all showed significantly stronger fluorescence from the L_d phase, providing qualitative evidence for a higher probe concentration in this phase. The relative fluorescence intensity ratios for several concentrations are shown in Fig. 3A and indicate that the I_{L_d}/I_{L_o} ratio is ~2.7 for probe concentrations below ~0.2 mol%, but shows a modest decrease at higher concentrations (to 2.2 at 1 mol%). The fluorescence intensity ratios do not give a direct measure of the partition coefficient (K_p) between the two phases and, thus, cannot be directly related to the ratio of concentrations in L_o and L_d phases. Changes in quantum yield in the two lipid phases, differences in self-quenching between the two phases, and effects of probe orientation on the absorption efficiency all contribute to the measured intensity ratios. Fluorescence quantum yields were measured for several concentrations of TR-DHPE in DOPC, DOPC/Chol (2:1), and ESM/Chol (2:1) vesicles for comparison with the fluorescence microscopy results and to test for the effect of lipid composition on fluorescence efficiency. The data are shown in Fig. 3B and indicate that the fluorescence quantum yield at low [TR-DHPE] is the same (Φ = 0.6) within experimental error for DOPC and ESM/Chol and is only slightly higher for DOPC/Chol (Φ = 0.66). Comparison of quantum yields at 0.2, 0.5, and 1 mol% TR for each of the vesicle compositions shows a decrease in quantum yield with increased concentration for vesicles containing Chol, with self-quenching increasing with increased lipid order (DOPC < DOPC/Chol < ESM/Chol). Assuming that results in vesicles can be extrapolated to supported bilayers, the modest changes in quantum yield and the low self-quenching indicate that the fluorescence intensity ratio for the supported bilayers at the lowest [TR-DHPE] do not reflect differences in fluorescence efficiency or self-quenching between the two phases. Finally, images obtained with in-plane and axial polarization for the excitation laser had the same I_{L_d}/I_{L_o} ratio within experimental error; this indicates that the transition dipole moment for TR must be oriented similarly in the two phases, since in-plane polarization will favor excitation of fluorophores with dipoles oriented parallel to the membrane surface, whereas axial polarization will preferentially excite molecules oriented perpendicular to the membrane. Thus, we conclude that the concentration of TR-DHPE is approximately 3 times higher in the L_d phase than in the L_o domains.

FRET in vesicle solution

FRET between NBD-DHPE and TR-DHPE in vesicle solution was investigated by measuring NBD-DHPE lifetime distributions in the frequency domain.[21] First, the fluorescence lifetime of NBD-DHPE was evaluated in methanol solution and in DOPC, DOPC/Chol, and ESM/Chol vesicles. In methanol, the fluorescence intensity decay fits well to a single exponential function, with a lifetime of 6.2 ns. By contrast, NBD decays in vesicle solution were clearly not single exponential but gave adequate fits to a Lorentzian

Fig. 3. (A) I_{L_d}/I_{L_o} ratios for dioleolylphosphatidylcholine (DOPC) / egg sphingomyelin (ESM) / cholesterol (Chol) bilayers containing variable concentrations of Texas red 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine triethylammonium salt (TR-DHPE). (B) The dependence of TR-DHPE fluorescence quantum yield on concentration in dioleolylphosphatidylcholine (DOPC), DOPC/Chol, and ESM/Chol vesicles.



lifetime distribution. Fits with a Gaussian lifetime distribution were also statistically acceptable. The amplitude-weighted lifetimes were 6.9, 7.4, and 9.5 ns in DOPC, DOPC/Chol, and ESM/Chol vesicles, respectively, longer than the lifetime measured in methanol. These data are consistent with the increased quantum yields with increasing bilayer order: quantum yields of 0.18, 0.16 and 0.26 for ~0.5 mol% NBD-DHPE in DOPC, DOPC/Chol, and ESM/Chol vesicles, respectively.[13] The increased quantum yields reflect a less polar environment, which is related to the positioning of the fluorophore in the polar head group region of the bilayers; the longer lifetimes and increased quantum yields indicate a decrease in the nonradiative rate constant in more ordered environments.

The non-single-exponential decay kinetics and the amplitude-weighted lifetimes are consistent with previous fluorescence data for several NBD-phospholipid probes (head group labeled) in vesicle solution.[22–24] For example,

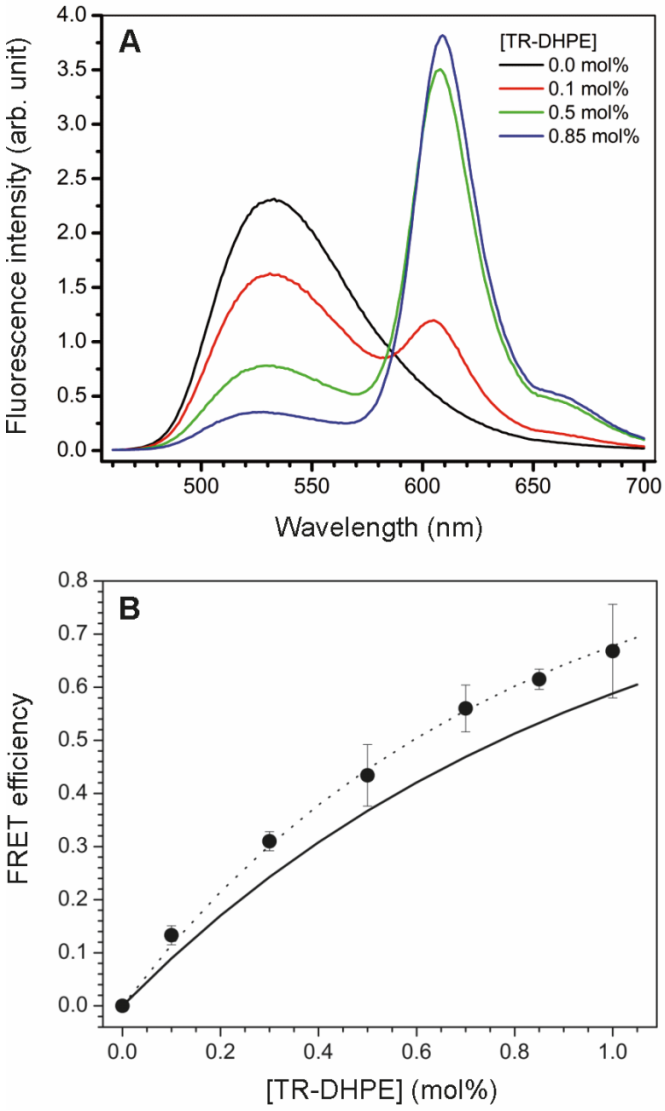
fluorescence decays with long and short components were measured for *N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-dimyristoylphosphatidylethanolamine (NBD-DMPE) in dimyristoylphosphatidylcholine (DMPC) vesicles with 0–0.4 mol fraction Chol (10–12 ns and 1.9–2.2 ns)[23] and for NBD-DHPE in dipalmitoylphosphatidylglycerol (DPPG) vesicles (6.0 and 12.6 ns).[24] Similarly, lifetimes of 9.2–10.5 ns were measured for NBD-DHPE in POPC/SM/Chol mixtures with varying fractions of L_o phase.[22] By contrast, monoexponential decay kinetics with a lifetime of 7.9 ns were reported in an earlier study for NBD-DHPE in egg phosphatidylcholine (PC) vesicles.[25] The differences in probe structure and concentration and lipid environment account for the variation in lifetimes for the various NBD-labeled lipids. There is no evidence for changes in emission properties that would be indicative of probe aggregation.

Figure 4A shows fluorescence spectra obtained by 450 nm excitation of 0.5 mol% NBD-DHPE in DOPC vesicles with 0, 0.1, 0.5, and 0.85 mol% [TR-DHPE], clearly illustrating energy transfer from the NBD donor to TR acceptor with efficiency increasing with increasing TR fractional concentration. The fluorescence lifetime for NBD in DOPC vesicles was measured as a function of TR-DHPE concentration using the frequency-domain method and modeled with a Lorentzian distribution function. The resulting decay curves and lifetime distributions are shown in Figs. S1 and S2 in the Supplementary data. For each distribution we calculated the amplitude-weighted lifetime, which is proportional to the total NBD fluorescence and which, therefore, we could subsequently use to calculate energy transfer efficiencies (E) as a function of the TR fractional concentration ($E = 1 - \frac{\bar{\tau}_{DA}}{\bar{\tau}_D}$, where $\bar{\tau}_{DA}$ is the amplitude-weighted lifetime for the donor in the presence of the acceptor and $\bar{\tau}_D$ is the amplitude-weighted lifetime for the donor in the absence of acceptor. The amplitude-weighted lifetimes and FRET efficiencies are shown in Table 1. FRET efficiencies are also plotted against the TR fractional concentration in Fig. 4B. Energy transfer occurs with similar efficiency in cholesterol mixtures, based on the comparison of measured values of 0.36 and 0.29 FRET for 0.3 mol% TR in DOPC/Chol and ESM/Chol vesicles, respectively, compared with 0.30 FRET for DOPC (see Fig. 4B and Table 1) at the same TR concentration.

The NBD to TR energy transfer efficiencies measured in DOPC vesicle membranes were compared with values calculated assuming a random distribution of acceptors in the membrane (see Fig. 4B, solid and broken lines).[26] The solid line represents energy transfer efficiencies calculated with a Förster distance of R_0 = 42.7 Å, which, in turn, was calculated using a quantum yield of NBD in DOPC equal to 0.18, a refractive index of donor and acceptor environment equal to 1.33, an overlap integral obtained from measured absorption and emission intensities of TR and NBD in DOPC, respectively, and assuming the orientation factor κ^2 = 2/3, which corresponds to transition dipole moments randomized in three dimensions. As seen in Fig. 4B, the calculated efficiencies are systematically smaller than the measured values. A possible reason for this disagreement could be underestimation of κ^2. In fact, our preliminary observations of NBD and TR interactions in supported bilayers indicate that κ^2 should be >2/3 as orientation randomization

Fig. 4. (A) Fluorescence spectra measured after 450 nm excitation of 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl (NBD-DHPE) in dioleolylphosphatidylcholine (DOPC) vesicles containing various concentrations of Texas red 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine triethylammonium salt [TR-DHPE]. (B) Förster resonance energy transfer (FRET) efficiency as a function of [TR-DHPE] in DOPC vesicles (●). The error bars indicate maximum error. The solid and broken lines represent calculated energy transfer efficiencies with Förster distances (R_0) of 42.7 and 48 Å, respectively, assuming random acceptor distribution.



of the transition dipole moments of both NBD and TR results in nonvanishing components along the direction normal to the bilayers.[27] As shown in Fig. 4B (broken line), should the Förster distance be somewhat longer, $R_0 \approx 48$ Å, the calculated efficiencies would agree with the observation very well. This longer value of R_0 could be calculated using $\kappa^2 \approx 1.35$. A κ^2 significantly >1 indicates a large contribution from energy transfer between dyes in opposite leaflets of the bilayer.

As shown in Table 1, the widths of the Lorentzian lifetime distributions do not vary systematically with TR fractional

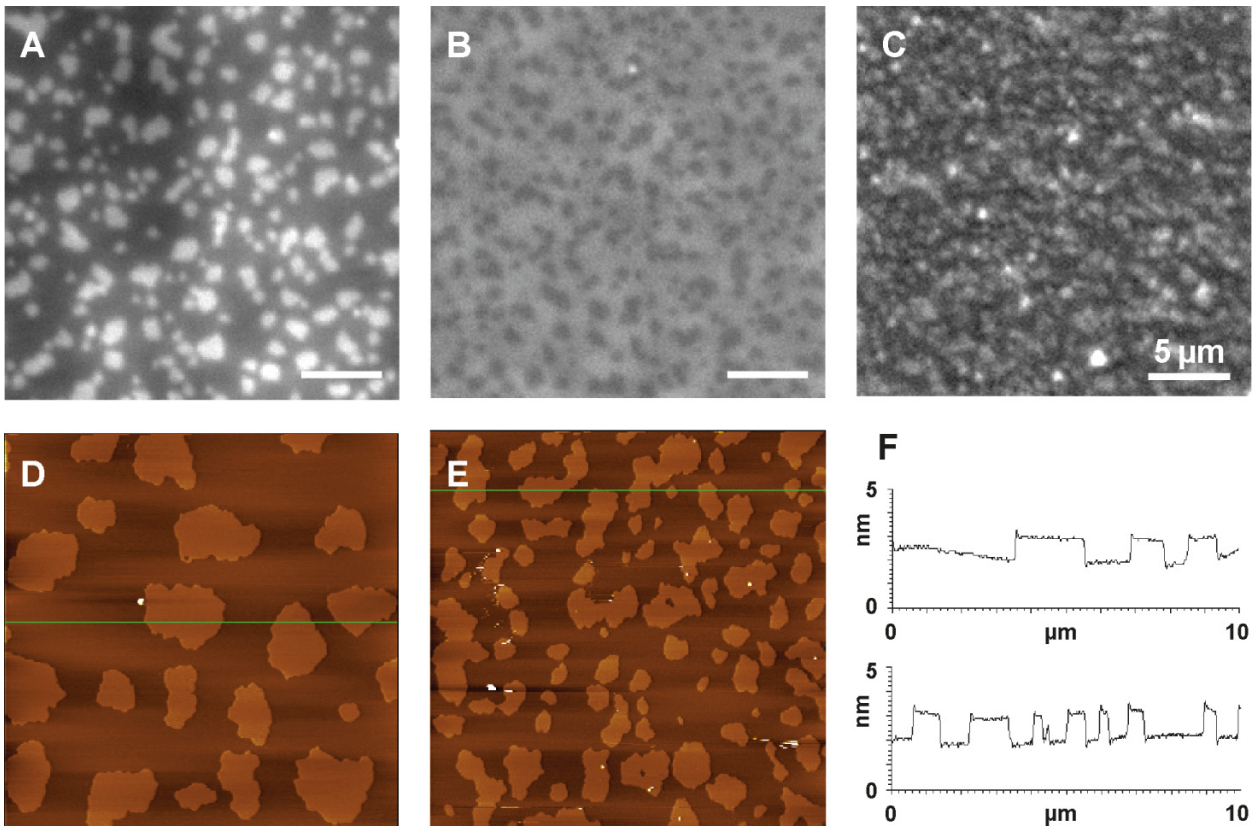
(A) 0.3 mol% TR-DHPE, (B) 3 mol% TEMPO-DOPC, (C) 6 mol% TEMPO-DOPC, (D) 0.3 mol% TR-DHPE, (E) 6 mol% TEMPO-DOPC.



concentration and are approximately equal to or only slightly greater than the width for 0.0 mol% TR. This suggests that the distributions are primarily defined by variation in the NBD environment rather than by a distribution of NBD-TR energy transfer distances.

Fluorescence quenching by TEMPO-DOPC in supported bilayers

To test whether the I_{L_d}/I_{L_o} ratio for NBD-DHPE could be tuned using a nonluminescent quencher, bilayers containing NBD-DHPE and variable concentrations of TEMPO-DOPC (Scheme 1) were examined by fluorescence microscopy. Several nitroxide-labeled unsaturated phosphatidylcholines have been shown to localize in disordered-membrane phases and have been used in fluorescence quenching assays to assess phase separation in multicomponent vesicles.[28,29] Figure 5 shows fluorescence images for bilayers labeled with 0.5 mol% NBD-DHPE and containing either 0.3 mol% TR-DHPE or 3 or 6 mol% TEMPO-DOPC; a fraction of the DOPC has been replaced by TEMPO-DOPC in the latter two mixtures while keeping the ESM/Chol ratio constant. With 3 mol% TEMPO-DOPC, the domains are still visible but the contrast between L_o and L_d is lower than in the absence of TEMPO-DOPC. The addition of 3 mol% TEMPO-DOPC also

For personal use only.

modifies the domain size and morphology, suggesting that it may not be completely excluded from the L_o phase. At higher TEMPO concentrations, the bilayer morphology is further modified by the TEMPO with smaller and more irregular-shaped domains detected by AFM and with a slight increase in the height difference between the domain and surrounding fluid phase (0.8–1.0 nm and 1.0–1.2 nm for 0 and 6 mol% TEMPO, respectively). However, the domains are still visible in fluorescence images and are now brighter than the fluid phase, indicating more efficient quenching of NBD by TEMPO-DOPC in the L_d phase than in the domains. The relatively high concentration of TEMPO required to see the same contrast reversal achieved with low [TR-DHPE] and the significant effects of TEMPO on the bilayer morphology indicate that TEMPO quenching is not a generally useful strategy for fluorescence microscopy.

Contrast-enhanced imaging to follow the dynamics of enzyme-mediated bilayer restructuring

Our previous studies have used correlated fluorescence and AFM to characterize morphological changes in supported bilayers of DOPC/ESM/Chol following in situ enzymatic generation of ceramide.[13,20,30] Ceramide is a small hydrophobic sphingolipid that has been implicated in the regulation of lipid raft-associated signaling processes; the enzymatic hydrolysis of sphingomyelin by sphingomyelinases (SMases) is a physiologically important pathway for generating ceramide.[31] The high spatial resolution of AFM coupled with the superior temporal resolution of fluorescence microscopy provides detailed information on the complex membrane restructuring that occurs. These changes include the formation of heterogeneous L_o domains with ceramide-enriched subdomains, a new dye-excluded membrane phase, and occasional defects.[20] A novel NBD-labeled cholesterol probe (NBD-Chol; Scheme 1) with a carbamate linker was synthesized and shown to partition more strongly into the L_o phase than a commercially available ester-linked probe;[13] NBD-Chol was used to identify regions of a highly ordered, cholesterol-depleted phase in SMase-treated bilayers and to show that cholesterol is depleted from the raft-like domains following ceramide generation.[13] However, the NBD-Chol partitioned almost equally between ordered- and disordered-membrane phases and did not adequately resolve the heterogeneity in ceramide-containing domains that can be observed by AFM. Here, we show that a labeling strategy using a NBD-Chol/TR-DHPE FRET pair has some advantages for resolving the complex changes that occur during enzymatic generation of ceramide in supported bilayers.

Figure 6 illustrates a representative time course experiment recording the evolution of a DOPC/ESM/Chol (7:9:4) supported bilayer following SMase treatment. The bilayer has been labeled with 0.5% NBD-Chol and 0.2% TR-DHPE, and incubated with 0.33 U/mL of enzyme. Figure 6A shows the bilayer before enzyme addition. The L_o

domains appear bright relative to the L_d phase; this is in contrast to bilayers labeled with NBD-Chol alone for which the fluid phase is brighter, but is consistent with contrast reversal owing to FRET, as described above for NBD-DHPE and TR-DHPE in membranes of similar composition. In an image (Fig. 6B) of the same sample region taken 3 min after SMase addition, the domains now appear slightly darker than the surrounding membrane. Control experiments confirmed that this change was not due to accelerated NBD photobleaching in the domain relative to the fluid phase. In our previous work, we reported that as ceramide is generated in the domains, NBD-Chol is gradually ejected from these features into the fluid phase.[13] The domain darkening observed here is consistent with this earlier observation. Recorded 9 min after enzyme addition, Fig. 6C reveals domains that exhibit two levels of fluorescence intensity. Although the features retain their overall rounded shape and can be matched to domains in the initial untreated bilayer, they now appear as dark rings enclosing bright regions at their centers. Over time, these rings continue to darken and thicken, and the bright regions at the domain centers decrease in size (see Fig. 6D, 16 min; note that the intensities are weaker in both phases owing to probe bleaching).

Based on previous correlated fluorescence–AFM imaging of similar SMase-treated bilayers, the dark border and bright central regions that appear in the domains correspond to a raised, fencelike gel-phase perimeter and a liquid-ordered core that is lower in height. The taller gel-phase regions have been assigned to ceramide-enriched regions that are depleted in cholesterol,[18,32] and so should exclude a probe for cholesterol. The dark domain perimeters in Figs. 6C and 6D show that this is in fact the case with the NBD-Chol. The domain centers remain bright indicating that they retain the probe and therefore also a significant cholesterol content, consistent with previous AFM results.[13] Such heterogeneity within domains was not observed by fluorescence with the NBD-Chol probe in the absence of TR-DHPE, illustrating the advantage of the FRET method for enhancing fluorescence contrast.

Conclusions

The probe NBD-DHPE shows stronger fluorescence in the fluid phase in DOPC/ESM/Chol mixtures, but contrast reversal to give more strongly fluorescent liquid-ordered domains is observed in the presence of >0.2% TR-DHPE. This observation is explained by the occurrence of efficient FRET between NBD and TR in the fluid phase, consistent estimates of a threefold higher concentration of TR-DHPE in the L_d phase relative to the L_o domains, and with a detailed study of fluorescence lifetimes for NBD-DHPE in the presence of 0.0–1.0 mol% TR-DHPE in homogeneous DOPC vesicles. FRET efficiencies of ~0.30 at 0.3 mol% TR were measured for vesicles of several different compositions. The utility of the FRET approach for enhancing contrast between phases in complex lipid mixtures was demonstrated by imaging bilayers during enzyme-mediated bilayer restructuring. Labeling the bilayers with an NBD-TR combination allowed us to resolve domain heterogeneity owing to ceramide-enriched subdomains that was not evident when using either of the two dyes independently.

FRET methodologies have been used to detect and characterize phase separation in a variety of lipid mixtures of varying complexity and quantitative approaches have been devised to determine phase boundaries, probe partition coefficients, and domain size.[33] However, energy transfer between donor and acceptor fluorophores, as examined here, has not been utilized as a means for improving fluorescence contrast or visualizing liquid-ordered domains for which most lipid probes show a relatively low partition coefficient. It is important to note that significant FRET efficiencies are measured even at the relatively low dye concentration of 0.2%. Similar (or higher) concentrations are widely used in fluorescence microscopy studies of both supported membranes and giant unilamellar vesicles (GUVs), frequently in double labeling experiments with dyes that have a significant overlap of donor emission and acceptor absorption. Thus, it is important to ensure that results for the partitioning of components into a specific phase in doubly labeled membranes are correctly interpreted and do not reflect a FRET component.

Abstract: 1-Hydroxypyrene (**1**) shows unusual acid–base chemistry in its singlet excited state. Whereas most hydroxyarenes experience a marked enhancement in their acidity when excited, and rapidly deprotonate to give the corresponding phenolate anion, this is not an important pathway for **1**, despite theoretical predictions that **1** should experience enhanced acidity as well. In this work, we demonstrate that **1** undergoes a competing excited state intramolecular proton transfer from the OH to carbon atoms at the 3, 6, and 8 positions of the pyrene ring to give quinone methide intermediates. When the reaction is carried out in D_2O, reversion of these quinone methides to starting material results in replacement of the ring hydrogens with deuterium, providing a convenient handle to follow the reaction with NMR spectroscopy and mass spectrometry. The quantum yield for the reaction is 0.025 and appears to not be strongly dependent on the water content when aqueous acetonitrile solutions are used. 1-(2-Hydroxyphenyl)pyrene (**19**) was prepared and studied and shows similar reactivity to **1**.

Key words: 1-pyrenol, 1-hydroxypyrene, excited state intramolecular proton transfer, quinone methide, photoprotonation, photochemistry.

Résumé : Dans son état excité singulet, le 1-hydroxypyrène (**1**) présente une chimie acide–base inhabituelle. La plupart des hydroxyarènes présentent une augmentation marquée de leur acidité dans leur état excité et ils se déprotonent rapidement pour conduire à l'anion phénolate correspondant; ce n'est pas une voie importante pour **1** même si les prédictions théoriques indiquent que **1** devrait aussi voir son acidité augmentée. Dans ce travail, on démontre que dans son état excité **1** subit aussi une réaction compétitive de transfert intramoléculaire de proton à partir du groupe OH vers les atomes de carbone dans les positions 3, 6 et 8 du noyau pyrène qui conduisent à des intermédiaires quinone-méthides. Quand on effectue la réaction dans du D_2O, la réversion de ces quinone-méthides vers le produit de départ conduit au remplacement des atomes d'hydrogène du cycle par du deutérium qui fournit un moyen utile de suivre la réaction à l'aide de la spectroscopie RMN et de la spectrométrie de masse. Le rendement quantique pour la réaction est de 0.025 et il ne semble pas dépendre beaucoup du contenu d'eau lorsqu'on utilise des solutions aqueuses d'acétonitrile. On a aussi préparé et étudié la réaction du 1-(2-hydroxyphényl)pyrène (**19**) et il présente la même réactivité que le **1**.

Mots-clés : 1-pyrénol, 1-hydroxypyrène, transfert intramoléculaire de proton dans l'état excité, quinone-méthides, photoprotonation, photochimie.

[Traduit par la Rédaction]

Introduction

It is well-known that a large variety of aromatic alcohols experience enhanced acidity when excited to S_1.[1] For example, the hydroxyl group of 2-naphthol increases in acidity by nearly 7 orders of magnitude on excitation from its ground state ($pK_a(S_0) \approx 9.5$) to its first excited state ($pK_a(S_1) \approx 2.8$). The enhancement of acidity on excitation is even more pronounced for 1-naphthol, whose pK_a changes from 9.2 in the ground state to 0.4 in S_1.[2] Excited phenols will usually deprotonate adiabatically within picoseconds in water via a process known as excited state proton transfer (ESPT), and observation of fluorescence emission from the resultant excited-state phenolate is generally taken as a diagnostic sign of ESPT.

The excited-state acidity of 1-hydroxypyrene (**1**) has been a source of interest because unlike most other phenols, it is difficult to discern the existence of ESPT from fluorescence spectroscopy. Milosavljevic and Thomas[3] used Förster cycle calculations to predict that **1** should possess a $pK_a(S_1)$ value of 4.5, indicating that ESPT in neutral water should be thermodynamically favourable. They then explored the photophysics of **1** in water and concluded that "no discernable equilibrium exists between the excited state [of **1**] and its excited ionic forms", which is at variance with the Förster cycle predictions. This prompted the authors to question the validity of Förster cycle calculations, and indeed the "concepts of acidity of excited states". By comparing steady-state emission spectraof **1** in pH 4–7 unbuffered water with those in low pH (<2) solution, Kombarova and Il'ichev[4]

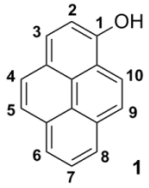
were able to detect emission from the pyrenolate arising from ESPT, although only a small fraction of the excited phenol appears to dissociate. Using time-resolved fluorescence data, the authors are able to confirm that the pyrenolate emission indeed arises from excited-state dissociation of the pyrenol hydroxyl group, and they estimate a $pK_a(S_1)$ of 3.8 for **1**, which is in good agreement with the value obtained by the Förster cycle calculations. However, the calculated rate constant for ESPT was only 4×10^6 s^{-1}, which is exceptionally slow for a proton transfer reaction. For comparison, pyranine, the 3,6,8-trisulfonated derivative of **1**, undergoes ESPT to water with a rate constant $>10^{10}$ s^{-1}.[5]



Over the past decade, we have shown that several simple aromatic alcohols can undergo efficient excited state intramolecular proton transfer (ESIPT) from the OH group to aromatic carbon atoms to yield quinone methide (QM) intermediates. For example, ESIPT in 1-naphthol (**2**) from the hydroxyl group to the 5 or 8 position leads to formation of QMs **3** or **4**, which then undergo reverse proton transfer to refurnish starting material (eq. [1]).[6] Evidence for the ESIPT pathway was provided by monitoring deuterium incorporation at the 5 and 8 positions (when the solvent contained D_2O), and by nanosecond laser flash photolysis (LFP) studies that allowed direct observation of QM **3**. Whereas ESIPT in **2** requires water to mediate the proton transfer, an intrinsic or "direct" ESIPT that does not require water was discovered to be available for 2-phenylphenol (**5**) to give QM **6** (eq. [2]).[7] Since these discoveries, we have also found that similar ESIPT processes can occur in naphthylphenols[8] and hydroxyphenylanthracenes,[9] and in these cases, products in addition to deuterium-labeled starting material were obtained. Irradiation of **7**–**9** resulted in ESIPT from the OH to the 7′ carbon atom on the attached naphthalene ring to give quinone methides **10**–**12**, which underwent electrocyclic ring closure to give benzopyran products **13**–**15** (eq. [3]).[8] ESIPT from the OH to the 10 position of **16** gave QM **17**, which reacted with water to give the isolable hydration product **18** (eq. [4]).[9] Discovery of these elementary photochemical pathways in these relatively simple aromatic alcohols piqued our curiosity as to whether a similar process might be available for **1**, which would shed some light on its apparently anomalous ESPT behavior and may help explain why ESPT to water (to yield $\mathbf{1}^-$) is inefficient. In addition, biaryl derivative **19** was prepared and examined for ESIPT reactivity via possible deuterium exchange, photocyclization, or photohydration. We present results that indicate that ESIPT can occur in **1** and **19** from the OH to the 3, 6, and 8 positions of the pyrene ring in both compounds to give rise to QM intermediates, which undergo exclusive reverse proton transfer to give starting material (labeled with deuterium when D_2O is used).

Experimental

General

All fine chemicals were purchased from Sigma-Aldrich Canada and used as received. Solvents were purchased as spec. grade or better, acetonitrile was dried over CaH_2 and distilled prior to use, and water was distilled and deionized. ^{1}H NMR spectra were recorded on a Bruker AVANCE 500 MHz instrument. MS were recorded on a Kratos Concept H spectrometer (EI). UV–vis were recorded on a Varian CARY 50 or CARY 100 spectrometer.

Materials

1-(2′-Hydroxyphenyl)pyrene (19)

1-Bromopyrene (1.00 g, 3.56 mmol), *o*-methoxyphenylboronic acid (0.684 g, 4.5 mmol), K_2CO_3 (4 g), $Pd(PPh_3)_4$ (0.20 g), and DME (50 mL, N_2 purged prior to addition) were combined and refluxed under N_2 for 20 h and allowed to cool. Sixty millilitres of 1 mol/L NaOH were added to the reaction mixture, which was then extracted with two portions of CH_2Cl_2 totaling 70 mL. The combined organics were dried with $MgSO_4$, filtered, and the solvent was removed by rotary evaporation. The crude 1-(2′-methoxyphenyl)pyrene was redissolved in 40 mL of diethyl ether, which was passed through a 1 cm plug of silica gel and a 2 cm plug of celite to remove catalyst. The silica and celite were flushed with an additional 100 mL of diethyl ether, and solvent was removed from the combined ethers by rotary evaporation. The resulting material was redissolved in 50 mL of CH_2Cl_2 and placed in an ice bath. To this cooled solution was added a solution of BBr_3 (10 mmol) in CH_2Cl_2 (60 mL) via a dropping funnel over a period of 30 min, after which the mixture was allowed to stir for 1 h. The reaction was quenched by the addition of 100 mL of H_2O, 10 mL of 10% HCl, and 10 mL of brine. The organic layer was removed and the aqueous layer was washed with an additional 30 mL of CH_2Cl_2. The organics were combined, dried with $MgSO_4$, filtered, and the solvent was removed by rotary evaporation. The resulting solid was recrystallized from methanol to yield **19** as white crystals. ^{1}H NMR (500 MHz,

$CDCl_3$, ppm) δ: 4.842 (1H, s, OH), 7.118 (1H, ddd, J = 7.4, 7.4, 1.2 Hz), 7.128 (1H, dd, J = 8.4, 1.2 Hz), 7.387 (1H, dd, J = 7.4, 1.6 Hz), 7.423 (1H, ddd, J = 8.4, 7.4, 1.6 Hz), 7.894 (1H, d, J = 9.2 Hz), 7.984 (1H, d, J = 7.8 Hz), 8.032 (1H, t, J = 7.6 Hz), 8.053 (1H, d, J = 9.2 Hz), 8.108 (1H, d, J = 8.9 Hz), 8.135 (1H, d, J = 8.9 Hz), 8.190 (1H, dd, J = 7.6, 0.9 Hz), 8.224 (1H, d, J = 7.6, 0.9 Hz), 8.267 (1H, d, J = 7.8 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 115.68, 120.72, 124.67, 124.69, 125.05, 125.21, 125.38, 125.52, 126.29, 126.81, 127.27, 128.02, 128.26, 128.37, 129.37, 129.66, 130.96, 131.03, 131.33, 131.42, 131.60, 153.25.

1-Methoxypyrene

To a 10 mL flask was added **1** (35 mg, 0.16 mmol), DMSO (10 mL), crushed KOH (1 g), and methyl iodide (2.85 g, 20 mmol). The mixture was stirred at room temperature for 16 h and then diluted by the addition of 50 mL of water to dissolve remaining KOH. The resulting mixture was extracted with 50 mL of CH_2Cl_2, and the organic layer was washed with 1 mol/L NaOH (50 mL) and water (2 × 150 mL), and then dried over $MgSO_4$, and the solvent was removed by rotary evaporation. The crude reaction mixture was purified by preparatory TLC (1000 μm silica gel) using 15:85 *v*/*v* ether–hexanes as the elutant, and yielded **20** as a white solid (90% yield). ^{1}H NMR (500 MHz, acetone-d_6, ppm) δ: 4.189 (3H, s, OCH_3), 7.706 (1H, d, J = 8.4 Hz), 7.935 (1H, d, J = 9.0 Hz), 7.990 (1H, t, J = 7.6 Hz), 8.025 (1H, d, J = 9.0 Hz), 8.097 (1H, d, J = 9.2 Hz), 8.152 (1H, dd, J = 7.6, 0.9 Hz), 8.173 (1H, dd, J = 7.6, 0.9 Hz), 8.208 (1H, d, J = 8.4 Hz), 8.425 (1H, d, J = 9.2 Hz). the ^{1}H NMR datamatches a previous report.[10] ^{13}C NMR (125 MHz, acetone-d_6) δ: 56.67, 109.43, 120.90, 121.97, 125.12, 125.27, 125.79, 126.16, 126.57, 126.84, 127.21, 127.24, 128.30, 132.69, 132.82, 154.70.

Product studies

Solutions were prepared in a quartz reaction vessel and purged with argon or oxygen for 10 min prior to and continuously during irradiation in a Rayonet RPR 100 or Luz-Chem LZC-Org photochemical reactor using 350 nm lamps. The photolysate was extracted with CH_2Cl_2, dried with anhyd $MgSO_4$, and solvent was removed under reduced pressure, and the resulting material analyzed by ^{1}H NMR spectroscopy and MS. For quantum yields, four such runs were carried out for each of **1** and **5** (both in D_2O–CH_3CN (1:9) solution), and the total amount of deuterium incorporation was determined based on peak integrations in the respective ^{1}H NMR spectra. Quantum yields were calculated according to eq. [5]:

$$[5] \qquad \Phi_{\mathbf{1}} = \Phi_{\mathbf{5}} \frac{\%\mathrm{conv}(\mathbf{1})}{\%\mathrm{conv}(\mathbf{5})}$$

where $\Phi_{\mathbf{1}}$ and $\Phi_{\mathbf{5}}$ are the quantum yields of the deuterium incorporation of **1** and **5**, respectively, and %conv(**1**) and %conv(**5**) are the percents of conversion as measured by ^{1}H NMR. The reported quantum yields are the average of the four runs.

Fluorescence and laser flash photolysis measurements

Solutions for fluorescence spectroscopy were purged with argon for 5 min before analysis. Spectra were obtained using a Photon Technology International (PTI) A-1010 Quanta-Master luminescence spectrometer. All transient absorption spectra and lifetimes were obtained using a Nd:YAG laser (Spectra Physics Quanta-Ray, GCR, <30 mJ/pulse) with a pulse duration of ~10 ns and an excitation wavelength of 355 nm. Flow cells were used (7 mm path length) and solutions were purged with nitrogen or oxygen for 10 min prior to excitation. Solution concentrations were adjusted to achieve an optical density of 0.3 at the excitation wavelength.

Results and discussion

Our primary evidence for the ESIPT pathway in **2** came from the observation of H–D exchange at the 5 and 8 positions when the substrate was irradiated in D_2O–CH_3CN solvent mixtures.[6] The same strategy was employed for **1** in an attempt to observe the deuterated products that would arise if a similar ESIPT process as that of **2** was available for **1**. Irradiation of **1** in D_2O–CH_3CN (1:1, *v*/*v*) (~5 × 10^{-4} mol/L, 16 × 350 nm lamps, argon saturated, 2 h) gave starting material with deuterium incorporated at the 3 position (7%), and to the 6 and 8 positions (34% for both positions combined) to give **1**-*3D*, **1**-*6D*, and **1**-*8D*, respectively (eq. [6]). The deuterium exchange is evident in the ^{1}H NMR spectrum (Fig. 1) where irradiation led to a decrease in the areas of the peaks at 8.10, 8.12, and 8.14 ppm assigned to the protons at the 3, 6, and 8 positions, respectively.[11] A broad doublet is observed to grow in under the doublet of doublets at 7.96 ppm assigned to the proton at the 7 position. This reduced coupling is consistent with deuterium incorporation at one of the adjacent sites. Similarly, a small broad singlet has grown in under the doublet at 7.62 ppm assigned to the 2 position, consistent with a lesser amount of deuterium incorporation at the 3 position. The overall extent of exchange was confirmed by MS, which showed a distribution of 65.8% undeuterated, 29.8% monodeuterated, and 4.2% dideuterated starting material, giving an overall deuterium exchange of 39% (NMR measurements indicate a total of 41%). No other photoproducts were observed in the photolysate. Irradiation of 1-methoxypyrene, the methyl ether of **1**, under the same conditions led to no observable deuterium incorporation by NMR, confirming that the reaction requires the OH functional group, consistent with an ESIPT mechanism.

[6]

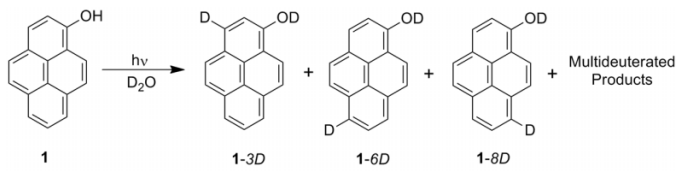

Fig. 1. [1]H NMR spectrum (500 MHz) of **1** before (bottom) and after (top) irradiation in D_2O–CH_3CN (1:1; 2 h), showing decreases in the areas of the peaks at 8.14, 8.12, and 7.99 ppm assigned to ring protons at the 8, 6, and 3 positions, respectively.

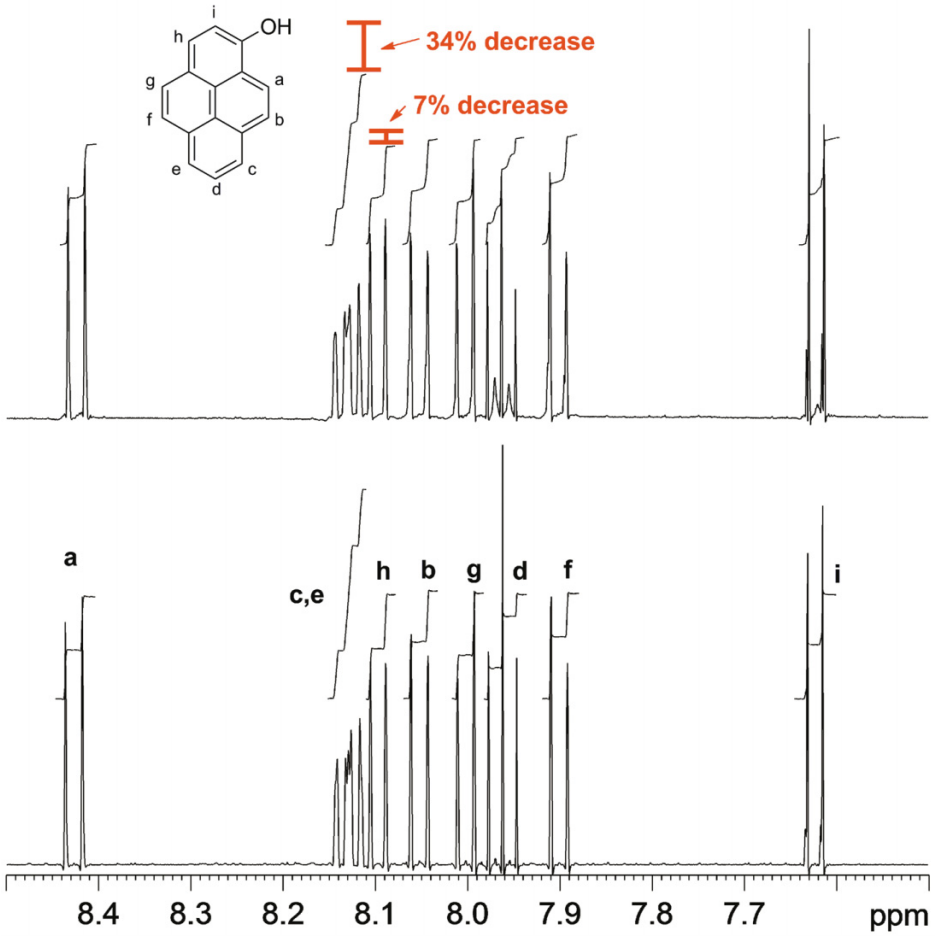

Fig. 2. Plot of the sum of the % deuterium exchange at the 3, 6, and 8 positions of **1** as a function of [D_2O] (in CH_3CN) as determined by MS.

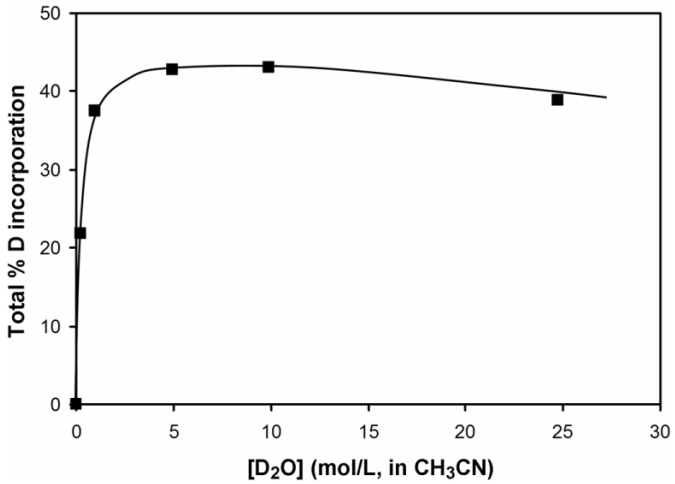

By irradiating solutions of **2** in CH_3CN containing varying amounts of D_2O and analyzing the photolysate by [1]H NMR, it was found that the ESIPT efficiency for this compound relied heavily on the composition of the solvent mixture.[6] Only residual reaction was observed at D_2O concentrations less than ~2 mol/L. Also, less water was apparently required for ESIPT to the 8 position than for ESIPT to the 5 position, which we rationalized to be a consequence of the different distances between the acidic OH and aromatic ring sites; the closer the phenol OH is to the site that receives the proton, the less water is required to mediate the proton transfer. To probe the dependence on water of the deuterium exchange reaction of **1**, irradiations were carried out in which the concentration of D_2O (in CH_3CN) was varied. The photolysate (after evaporation in vacuo) was examined by [1]H NMR and MS for deuterium incorporation at aromatic ring positions, and the total deuterium exchange at the three positions (as determined by MS) is presented in Fig. 2. Very different behaviour is observed for this derivative than was observed for **2** when the D_2O content is lowered: the total deuterium exchange did not decrease significantly until very small D_2O concentrations were reached, suggesting that very little water (or possibly none at all) is required to mediate the process. An intrinsic ESIPT (such as that observed for **5**)[7] seems unlikely, since the hydroxyl functionality is located a significant distance from the sites of deuterium exchange, particularly the 6 and 8 positions, preventing the ground-state hydrogen bonding interaction that is thought to be a prerequisite.

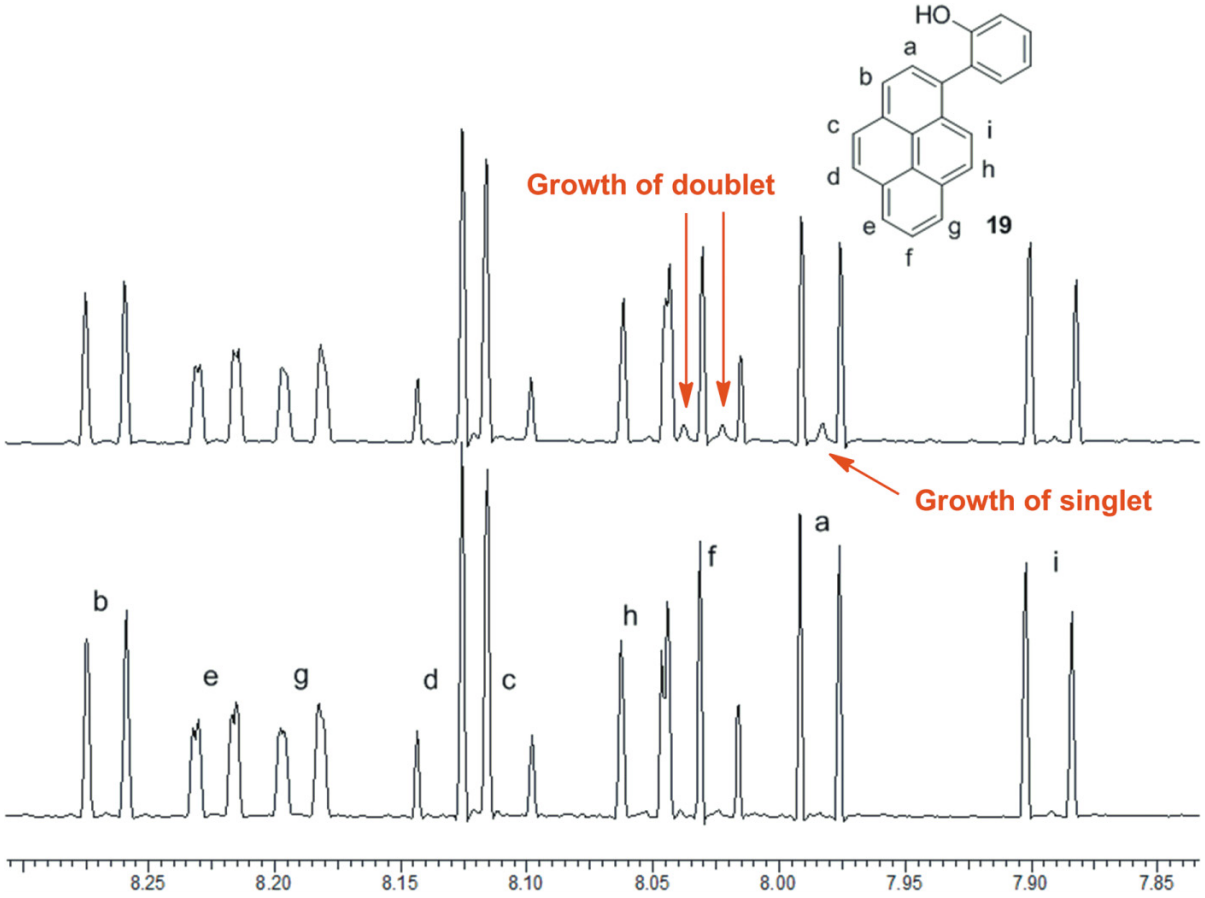
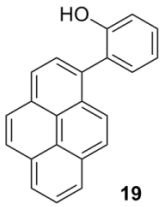
Fig. 3. ^{1}H NMR spectra (500 MHz), 7.8–8.3 ppm region, of **19** before (bottom) and after (top) irradiation in D_2O–CH_3CN (1:1; 30 min), highlighting the changes in peaks at 7.98 and 8.03 ppm that are consistent with loss of vicinal coupling with adjacent hydrogens because of deuterium exchange. Resonances owing to the phenolic ring appear between 7.0 and 7.5 ppm and are not included in this figure.



The relative extents of deuterium exchange at the 3, 6, and 8 positions were monitored by ^{1}H NMR at the different D_2O concentrations. If the deuterium exchange reaction is the result of a water-mediated ESIPT, deuterium incorporation at the 3 position should require far less water (or D_2O) than at the 6 and 8 positions, because of the smaller distance between the 3 position and the OH moiety that the water would have to span. The efficiency of exchange at the 6 and 8 positions was expected to show a much stronger dependence on D_2O concentration with significantly larger D_2O concentrations needed. The ratio of deuterium exchange at the 3 position to the 6 and 8 positions was completely unchanged as the D_2O content of the solution was reduced. This result argues against a water-mediated ESIPT such as that observed for **2**,[6] indicating water is likely not acting as a "bridge" to mediate the proton (deuteron) transfer.

The quantum yield of deuterium exchange for **1** was measured by ^{1}H NMR in CH_3CN–D_2O (9:1, *v*:*v*) solutions using the deuterium exchange reaction of **5** as a secondary reference standard.[7b] The quantum yield for exchange was measured to be 0.021 at the 6 or 8 positions and 0.004 for the 3 position, for a total quantum yield of deuterium incorporation at any one of these sites of 0.025. This value is somewhat lower than the other examples of ESIPT to aromatic carbon reported by us.[6–9] The ESIPT is expected to be more than twice as efficient in CH_3CN–H_2O (9:1, *v*/*v*), assuming a primary isotope effect of 2 or greater.

Irradiation of **19** was carried out in a similar manner as for **1** in D_2O–CH_3CN (1:1, *v*/*v*) (~5 × 10^{-4} mol/L, 16 × 350 nm lamps, argon saturated, 30 min), and the photolysate was examined by ^{1}H NMR spectroscopy (peak assignments were made with the aid of COSY and NOESY NMR spectra, included in the Supplementary data). Deuterium exchange was observed at the 3, 6, and 8 positions of the pyrene ring, the same positions as observed for **1**. The ^{1}H NMR spectra of **19** before and after irradiation are shown in Fig. 3. The areas of the peaks at 8.27, 8.22, and 8.19 ppm are reduced following irradiation, consistent with replacement of the hydrogens at these positions with deuterium. A broad singlet is observed to have grown beneath the doublet at 7.98, which is assigned to the proton on carbon 2 of the pyrene ring, which is consistent with loss of coupling to the adjacent proton (Fig. 3). Similarly, a doublet has grown beneath the triplet at 8.03 ppm, consistent with loss of coupling to an adjacent proton at position 6 or 8. The overall quantum yield for exchange of these three sites is similar to that of **1**. No other products, such as photocyclization or photohydration products, were observed, indicating that this derivative does not show chemistry similar to **7**, **8**, **9**, or **16**.



19

Fluorescence measurements

Fluorescence spectroscopy was used to study **1** to confirm the lack of significant observable emission from the pyrenolate (**1**$^-$) that would result from an adiabatic ESPT to water. Excitation of **1** (λ_{ex} = 345 nm) in neat CH_3CN or in neat water gave strong and structured emission with maxima at 383, 405, and 427 nm. Excitation of an authentic sample of **1**$^-$ (formed by dissolving **1** in 0.01 mol/L NaOH solution, λ_{ex} = 400 nm) gave strong, broad, and unstructured fluorescence emission at 450 nm. The fluorescence yield of **1** was not noticeably diminished on moving from CH_3CN to water, and no phenolate emission was observed under neutral conditions, confirming that ESPT to water is at best a very minor pathway for **1** under these conditions. These observations mirror previous fluorescence studies carried out for **1** by others.[3,4]

Solutions of **1** in water with the same concentration as those employed in the product studies (~5 × 10^4 mol/L) were also examined by fluorescence spectroscopy to monitor for excimer formation. No long wavelength band assignable to excimer emission was observed at these concentrations, indicating that excimer formation does not contribute to the observed photochemistry.

Nanosecond laser Fflash photolysis (LFP)

Milosavljevic and Thomas[4] studied the photophysics of **1** using LFP in cyclohexane, methanol, and methanol–NaOH. In cyclohexane and methanol solutions, three transients were observed and assigned to the triplet excited state of **1** (^{3}**1***, λ_{max} = 430 nm), the radical cation of **1** (**1**$^{\bullet+}$, λ_{max} = 515 nm), and the pyrenyloxyl radical (**PyO**$^\bullet$, λ_{max} = 430 nm). In methanol, the solvated electron that accompanies formation of **1**$^{\bullet+}$ is also observed, and its yield was observed to vary with the square of the laser power, indicating that the solvated electron (and the accompanying radicals **1**$^{\bullet+}$ and **PyO**$^\bullet$) are formed via a two-photon process and are therefore not likely to be important species at low light intensities such as those used in the product studies in this work. The pyrenolate anion (generated by deprotonating **1** with NaOH in methanol) was also studied and gave ^{3}**1***, **PyO**$^\bullet$, and solvated electrons (via a one-photon process), but no **1**$^{\bullet+}$. No data was reported in aqueous solution, which is the relevant solvent for the deuterium exchange reaction that we report in the present work. An ESIPT reaction to the 3, 6, and 8 positions of **1** would give QM intermediates **20**–**22**, respectively (eq. [7]). QMs **20** and **22** are non-Kekule structures, and thus were expected to have short lifetimes that would be inaccessible by LFP.[12] QM **21** was anticipated to have a much longer lifetime, and so we made an attempt to detect it with LFP. LFP of a solution of **1** in CH_3CN–H_2O (1:1), nitrogen purged, gave rise to a transient absorption with maxima at 440 and 510 nm. The signal at 510 nm was assigned to the radical cation (**1**$^{\bullet+}$), which was previously reported in methanol.[3] This transient completely decayed within ~3 μs to leave a long-lived transient with λ_{max} = 440 nm, whose absorption profile and lifetime strongly resemble that of **PyO**$^\bullet$ reported in methanol solution.[3] **PyO**$^\bullet$ can presumably be readily generated by deprotonation of **1**$^{\bullet+}$, which in turn can be generated by photoejection of an electron. In our experiments, the solvated electron was not visible, so laser power dependence studies were not carried out. No additional transients were observed, so direct evidence for the formation of QMs **20**–**22** in this solvent could not be obtained by this method. Our inability to detect these species likely stems from their low quantum yield of formation, although it is also possible that they are too short-lived for the time resolution of the instrumentation (i.e., τ < 20 ns).

Scheme 1.

20 21 22

Mechanism

The relevant photophysical and photochemical processes for **1** in aqueous solution are summarized in Scheme 1. Excitation of **1** produces the singlet excited state (^{1}**1***), which has a lifetime of approximately 16 ns.[4] The dominant relaxation pathway for this excited state is fluorescence emission (Φ_F ~ 0.66)[12] at 380 nm.[3] A small fraction of the singlet excited state undergoes ESPT of the phenolic OH to the solvent (water) adiabatically to give the pyrenolate anion in its singlet excited state (**1**$^{-*}$), which has a lifetime of 3 ns,[4] and returns to the ground-state pyrenolate anion (**1**$^-$) via fluorescence emission with λ_{max} 450 nm. The triplet state of **1** (^{3}**1***) is observed in LFP experiments and absorbs at 430 nm.[3] The radical cation (**1**$^{\bullet+}$) and pyrenoxyl radicals (**PyO**$^\bullet$) are also observed in LFP experiments and are proposed to arise via two-photon processes that are only relevant under conditions of high photon flux (i.e., under laser irradiation), as was the case for these transients previously reported in cyclohexane and methanol.[4]

In addition to these photophysical properties that have been previously reported for **1** in water and in other solvents,

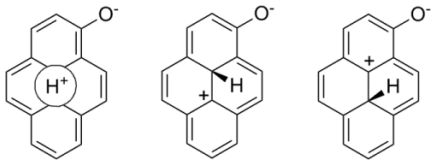
we propose an additional deactivation pathway that is available to $^1\mathbf{1}^*$ in water that is an ESIPT from the OH to carbon atoms on the pyrene ring to give quinone methides **20**–**22**, which revert to **1** via reverse proton transfer (resulting in deuterium labeling when the solvent is D_2O). Classification of the observed deuterium exchange reaction as an ESIPT process is consistent with recent literature on related compounds[6–9] and is supported by the absence of deuterium incorporation observed for the methyl ether analogue under the same conditions. An unexpected dependence on water content was observed with very little or no water required to mediate the proton transfer between the OH and the 3, 6, and 8 positions. Such behaviour was only previously observed for 2-phenylphenol and 2,2′-bisphenol that have an intrinsic ESIPT mechanism available to them because of the close proximity of the phenolic OH to the site of exchange.[7] An intrinsic ESIPT from the OH to the 6 or 8 positions would be difficult to envisage for **1** because of their considerable distance from the OH. Also of interest is that the ratio of exchange efficiencies for the three sites remains constant over wide variations of D_2O concentration, suggesting the formation of **20**–**22** from the excited state of **1** is independent of the degree of aqueous solvation of the excited state. A possible mechanism to account for these observations involves the existence of an intermediate prior to QM formation that is common to all three QMs that are formed (**20**–**22**). One such possibility involves an initial proton transfer occurring from the OH to the pyrene π system to form a ''protonated π complex'' such as **23**. This proton transfer might occur without solvent assistance or with the help of a small amount of a hydroxylic solvent. The acidic proton in **23** may then rearrange to form **20**–**22** via a solvent-independent process. The relative efficiencies for protonation at these three sites would simply be a function of the electron density at each position and the mobility of the proton. It would be expected that the most favourable destination of the proton in an intermediate such as **23** would be the oxygen atom, an overall process that would not lead to observable deuterium incorporation. If this is the case, the quantum yield of this initial ESIPT would be considerably higher than the quantum yield of deuterium exchange ($\Phi = 0.025$) ESIPT from the OH to one of the central (ipso) carbons might also be possible, and would give rise to QM intermediates **24** or **25**, which could undergo reverse proton transfer to regenerate starting material (without deuterium labeling) or rearrange to QMs **20**–**22**. The exact nature, and indeed the existence of an intermediate prior to QM formation, remains speculative at the moment, and the relatively low efficiency of these processes complicates their study via time-resolved absorption techniques, especially in light of the strong signals produced by the other absorbing transient species.

The deuterium exchange reaction of **19** is proposed to proceed via a related pathway — ESIPT from the phenol to the pyrene ring gives QMs that undergo reverse proton transfer to regenerate starting material, labeled with deuterium when D_2O is used in place of H_2O as the solvent. The same positions in **1** and **19** undergo exchange, indicating that the regiochemistry of the ESIPT is controlled solely by the electronics of the 1-substituted pyrene ring in S_1 and that the 3, 6, and 8 positions are the sites with the highest electron density in S_1. This is an interesting result, given that when the 3, 6, and 8 positions of **1** are substituted with the electron-withdrawing sulfonate groups (to make pyranine), ESPT to water becomes rapid ($\tau = 87$ ps)[5] and the acidity in S_1 becomes much greater ($pK_a(S_1) = 0.4–1.4$).[14] The substitution pattern of the sulfonate groups in pyranine is ideal for promoting photoacidity considering the localization electron density on the 3, 6, and 8 carbons in S_1. Tolbert et al.[2a] successfully employed the strategy of substituting aromatic carbon–hydrogen bonds of phenols with electron-withdrawing groups at positions that are electron-rich in S_1 to create phenols with very low values of $pK_a(S_1)$, a class of compounds known as ''super photoacids''. The lack of photocyclization or photohydration products for **19** (or **1** in fact) similar to those observed on irradiation of **7**–**9** and **16** is probably a consequence of the high resonance energy associated with the cyclic array of 14 π electrons that make up the periphery of the pyrene ring,[15] since photocyclization or photohydration would necessarily disrupt this aromaticity.



23 **24** **25**

The discovery of this ESIPT pathway provides additional evidence that **1** becomes more strongly acidic in S_1, supporting earlier findings based on fluorescence spectroscopy[4] and Forster calculations.[3] However, the ESIPT is not particularly efficient ($\Phi = 0.025$), especially when compared with fluorescence ($\Phi_F = 0.66$),[12] the dominant photophysical process from S_1. The ESIPT pathway has a similar efficiency to ESPT to water, indicating that it is a major photoprototropic reaction of **1** and provides a competitive pathway that would reduce the yield of $\mathbf{1}^{-*}$. Discovery of this ESIPT reaction and the related process for **19** provides further evidence that ESIPT is a very general reaction for hydroxyaromatic compounds and that this process must be considered in any serious investigation of the photophysics of hydroxyarenes.

Abstract: Two new cyclopropanoic fatty acid glycosides, named parisveroside A (**1**) and parisveroside B (**2**), were isolated from a MeOH extract of the roots of *Paris verticillata* (Liliaceae) together with three other known compounds, salicin (**3**), 3-(β-D-glucopyranosyloxymethyl)-2-(4-hydroxy-3-methoxyphenyl)-5-(3-hydroxypropyl)-7-methoxy-(2*R*,3*S*)-dihydrobenzofuran (**4**), and allantoin (**5**). Their structures were elucidated on the basis of spectroscopic data, including 1D and 2D NMR, HR-FAB-MS, and chemical evidence. To investigate the antineuroinflammatory effects of the isolated compounds (**1**–**5**), nitric oxide (NO) production was evaluated in the lipopolysaccharide-activated microglia cell line, BV-2. Compounds **2** and **4** significantly inhibited NO production with IC_{50} values of 74.8 and 60.5 μmol/L, respectively.

Key words: Paris verticillata, Liliaceae, fatty acid glycosides, parisveroside A, parisveroside B, neuroinflammation.

Résumé : Utilisant comme produit de départ le mélange obtenu par extraction des racines de *Paris verticillata* (Liliacée) à l'aide de méthanol, on a isolé deux nouveaux glycosides dérivés de l'acide gras cyclopropanoïque, soit le parisvéroside A (**1**) et le parisvéroside B (**2**), ainsi que trois autres produits connus, la salicine (**3**), le 3-(β-D-glucopyranosyloxyméthyl)-2-(4-hydroxy-3-méthoxyphényl)-5-(3-hydroxypropyl)-7-méthoxy-(2*R*,3*S*)-dihydrobenzofurane (**4**) et l'allantoïne (**5**). On a élucidé les structures en se basant sur des preuves chimiques et des données spectroscopiques, dont celles des RMN 1D et 2D et de la spectrométrie de masse à haute résolution avec bombardement avec des atomes rapides (SM-HR-BAR). Pour étudier les effets anti-neuroinflammatoires des composés isolés, on a évalué la production d'oxyde d'azote (NO) dans des cellules BV-2 de la lignée cellulaire de microglie activée par un lipopolysaccharide. Les composés **2** et **4** inhibent d'une façon significative la production de NO avec des valeurs de IC_{50} de 74,8 et 60,5 μmol/L respectivement.

Mots-clés : Paris verticillata, Liliacée, glycosides d'acides gras, parisvéroside A, parisvéroside B, neuroinflammation.

Introduction

The genus *Paris* consists of less than two dozen herbaceous plants that have 4- to 11-merous flowers.[1] Some *Paris* species are used in traditional Chinese medicine for their analgesic and anticoagulant properties, most notably as an ingredient of Yunnan Baiyao.[2] In Korea, the perennial herb *Paris verticillata* (Liliaceae) is widely distributed in valleys and its root has been used as a Korean traditional medicine against asthma, boils, and chronic bronchitis.[3] Few phytochemical and biological investigations on this plant have been previously conducted. The presence of several constituents, including saponins, sterols, and flavonoids, was reported from the aerial parts of *P. verticillata*.[4] In our continuing search for bioactive constituents from Korean medicinal plants, we investigated a MeOH extract from the roots of *P. verticillata*, which is in use as traditional medicine. The investigation led to the isolation of a phenolic amide, phenolics, and pyrrolizidine alkaloids with cytotoxic activity.[5,6] In our continuing investigation of bioactive constituents from the roots of *P. verticillata*, we further isolated two new cyclopropanoic fatty acid glycosides, named parisveroside A (**1**) and parisveroside B (**2**), together with three previously reported compounds (**3**–**5**). Compounds **3**–**5** were characterized for the first time from this plant. Here, we also investigated the antineuroinflammatory effects of isolated compounds (**1**–**5**) in lipopolysaccharide (LPS)-activated BV-2 cells, a microglia cell line.

Results and discussion

The 80% MeOH extract of the roots of *P. verticillata* was subjected to repeated column chromatography on silica gel to afford two new cyclopropanoic fatty acid glycosides (**1**–**2**), together with three known compounds (**3**–**5**) (Fig. 1). Their structures were elucidated by 1D and 2D NMR and HR-FAB-MS and compared with published data.

Parisveroside A (**1**) was isolated as a colorless gum with a molecular formula of $C_{17}H_{30}O_8$ on the basis of the $[M + H]^+$ peak at *m*/*z* 363.2021 (calcd. for $C_{17}H_{31}O_8$: 363.2019) in the

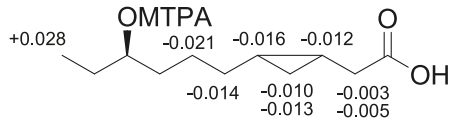
HR-FAB-MS. The IR spectrum of **1** indicated the presence of hydroxyl groups (3390 cm^{-1}) and a carbonyl group (1698 cm^{-1}). The ^{1}H NMR spectrum of **1** showed an anomeric proton at δ 4.34 (1H, d, J = 8.0 Hz, H-1′), which is a characteristic signal for a β-glucopyranosyl unit, and six oxygenated protons attributed to a sugar at δ 3.86–3.26. It also displayed signals for one methyl at δ 0.93 (3H, t, J = 6.5 Hz, H-11), 10 methylenes at δ 2.34–2.24 (2H, m, H-2), 1.62–1.33 (8H, m, H-6, 7, 8, 10), and one oxygenated methine at δ 3.75 (1H, m, H-9), as well as a cyclopropane ring at δ 1.08 (1H, m, H-3), 0.82 (1H, m, H-5), 0.73 (1H, m, H-4a), and –0.11 (1H, q, J = 5.5 Hz, H-4b). The ^{13}C NMR and DEPT spectra of **1** showed signals of 11 carbons of an aglycone attributable to one methyl, six methylenes, three methines (one oxygenated), and one quaternary carbon (carboxyl), along with signals for a β-glucopyranosyl unit (δ 102.3, 77.0, 76.5, 74.1, 70.6, and 61.7). These data suggested that compound **1** was a glycosidic fatty acid with a cyclopropane ring.[7,8] The glucose unit obtained after hydrolysis gave a positive optical rotation, $[\alpha]_D^{25}$ +48.6 (c 0.05, H_2O), indicating that it was D-glucose.

The proton and protonated carbon NMR signals of **1** were assigned unambiguously by the HSQC experiment. The cyclopropanoic fatty acid was further confirmed by the ^{1}H–^{1}H COSY correlations from H-2 to H-11 and the HMBC correlations H-2/C-5, H-3/C-1, H-4/C-2, 6, H-9/C-7, and H-11/C-9 (Fig. 2), together with their chemical shift values. The HMBC correlation of the anomeric proton H-1′ (δ 4.34) with C-9 (δ 80.7) indicated that the β-D-glucopyranosyl unit is located at C-9. The stereochemistry, including the absolute configuration at C-9, was established by a combination of analyses, including correlations in the NOESY experiment and the modified Mosher's method.[9] The proton signals for cyclopropylmethylene at δ 0.73 and –0.11 revealed the presence of a cis-1,2-disubstituted cyclopropane ring.[7,8] In the trans form, there are no signals for the cyclopropane proton above δ 0. The *cis*-cyclopropylmethine protons were also confirmed by the NOESY correlation H-3/H-5. On enzymatic hydrolysis of **1** with β-glucosidase, a new fatty acid, 9-hydroxy-*cis*-cascarillic acid (**1a**) was obtained. Compound **1a** was treated with (+)- and (–)-α-methoxy-α-trifluoromethylphenyl acetyl (MTPA) chlorides in NMR tubes to afford (*R*)-MTPA ester (**1r**) and (*S*)-MTPA ester (**1s**), respectively.[9] Diagnostic ^{1}H NMR chemical-shift differences between the MTPA esters of **1** ($\Delta\delta = \delta_S - \delta_R$) (Fig. 3) indicated the 9*R* configuration of **1**. Thus, the structure of **1** was determined as 9*R*-(β-D-glucopyranosyloxy)-*cis*-cascarillic acid, and it was named parisveroside A (Fig. 1).

Parisveroside B (**2**) was isolated as a colorless gum. Its molecular formula was determined to be $C_{18}H_{32}O_8$ from the $[M + Na]^+$ peak at m/z 399.2012 (calcd. for $C_{18}H_{32}NaO_8$: 399.1995) in the HR-FAB-MS spectrum. Its IR spectrum revealed similar absorption bands to **1**. The ^{1}H and ^{13}C NMR spectra of **2** were almost identical to those of **1**, except for the resonance of one additional methoxy signal. On the basis of the ^{1}H–^{1}H COSY and HSQC spectra, all protons and carbons could be assigned. The HMBC correlation between the methoxy proton at δ 3.69 and C-1 at δ 174.9 indicated that the methoxy group was located at C-1. Enzymatic hydrolysis of **2** yielded a new fatty acid, methyl-9-hydroxy-*cis*-cascarillate (**2a**) and glucose as the sugar component, having a β-D-configuration from the ^{1}H and ^{13}C NMR data and optical rotation analysis. The glycosidic linkage was determined from the HMBC correlation H-1′/C-9. The stereochemistry of **2** was assigned to be the same as that of **1** on the basis of the comparison of the NMR data and optical rotation values: $[\alpha]_D^{25}$ +26.6 (c 0.10, MeOH) of **2** with those of **1**. Thus, the structure of **2** was determined as methyl-9*R*-(β-D-glucopyranosyloxy)-*cis*-cascarillate, and it was named parisveroside B (Fig. 1).

Three other known compounds obtained in this investigation were identified as salicin (**3**),[10] 3-(β-D-glucopyranosyloxymethyl)-2-(4-hydroxy-3-methoxyphenyl)-5-(3-hydroxypropyl)-7-methoxy-(2*R*,3*S*)-dihydrobenzofuran (**4**),[11] and allantoin (**5**)[12] by comparison of their spectroscopic data with those published in the literature (Fig. 1). The known compounds **3**–**5** are reported from this plant source for the first time.

Fig. 3. Δδ Values ($\delta_S - \delta_R$) in ppm of the two α-methoxy-α-trifluoromethylphenyl acetyl (MTPA) esters derived from **1a**.



Microglia, the unique population of central nervous system resident immune cells, have been implicated in the pathogenesis of a variety of neurodegenerative diseases including Parkinson's disease and Alzheimer's disease.[13,14] Excessive production of nitric oxide (NO) and proinflammatory cytokines from activated microglia play an important role in neurodegenerative disorders. Therefore, regulation of the microglial activation will be an important strategy to prevent the progressive damage of the neurodegenerative diseases. Here, the antineuroinflammatory activities of the isolated compounds (**1**–**5**) were evaluated by assessing NO production in the BV-2 cells. BV-2 cells were pretreated with or without compounds **1**–**5** for 30 min prior to the addition of LPS (100 ng/mL). As shown in Fig. 4, compounds **2** and **4** significantly inhibited the NO production in LPS-stimulated BV-2 cells. Among tested compounds, compound **4** was the most potent. Pretreatment of BV-2 cells with compound **4** inhibited LPS-induced NO production in a dose-dependent manner with an IC_{50} value of 60.5 μmol/L. It revealed effective ratios of 23.9% ± 5.7%, 30.2% ± 6.2%, and 44.9% ± 3.5% at concentrations of 10, 20, and 50 μmol/L, respectively, in comparison with the control. The IC_{50} value of compound **2** was also 74.8 μmol/L. On the other hand, none of the compounds showed any cytotoxicity at concentrations used in the present study (data not shown).

Microglial cell activation plays a key role in mediating inflammatory processes in the CNS, which are associated with various neurodegenerative diseases. NO is one of the main proinflammatory mediators produced by activated microglia.[15] Therefore, compounds **2** and **4** from *P. verticillata* might be of therapeutic interest with respect to the treatment of neurodegenerative disease mediated by neuroinflammation.

Experimental

General experimental procedures

Optical rotations were measured on a Jasco P-1020 polarimeter in MeOH or $CHCl_3$. IR spectra were recorded on a Bruker IFS-66/S FT-IR spectrometer. FAB and HR-FAB mass spectra were obtained on a JEOL JMS700 mass spectrometer. NMR spectra, including ^1H–^1H COSY, HSQC, HMBC, and NOESY experiments, were recorded on a Varian UNITY INOVA 500 NMR spectrometer operating at 500 MHz (^1H) and 125 MHz (^{13}C) with chemical shifts given in ppm (δ). Preparative HPLC was conducted using a Gilson 306 pump with a Shodex refractive index detector and an Apollo silica 5 μ column (250 mm × 10 mm). Silica gel 60 (Merck, 70–230 mesh and 230–400 mesh) and RP-C_{18} silica gel (Merck, 230–400 mesh) were used for column chromatography (CC). Merck precoated silica gel F_{254} plates and RP-18 F_{254s} plates were used for TLC. Spots were detected on TLC under UV light or by heating after spraying with 10% H_2SO_4 in C_2H_5OH (*v*/*v*).

Plant material

The roots of *P. verticillata* were collected at Mount O-Dae, Gangwon Province, Korea, in August 2002, and the plants were identified by one of the authors (K.R.L.). A voucher specimen (SKKU 2002-08) was deposited in the herbarium of the School of Pharmacy, Sungkyunkwan University, Suwon, Korea.

Extraction and isolation

The roots of *P. verticillata* (1.5 kg) were extracted using 80% aq MeOH at room temperature over a period of 3 days three times. The solvent was evaporated under reduced pressure to give a crude extract (180 g). The crude extract was dissolved in distilled water (800 mL) and successively extracted with *n*-hexane, CH_2Cl_2, EtOAc, and *n*-BuOH to provide *n*-hexane (5.2 g), CH_2Cl_2 (3.5 g), EtOAc (4.4 g), and *n*-BuOH extracts (20 g). The EtOAc-soluble fraction (4.4 g) was subjected to normal-phase CC over a silica gel using $CHCl_3$–MeOH of increasing polarity (5:1–1:1) to give five fractions (E1–E5). Fraction E3 (1.2 g) was subjected to reversed-phase CC over a RP-C_{18} silica gel using MeOH–H_2O (2:3) to provide four subfractions (E31–E34). Subfraction E33 (120 mg) was separated by preparative normal-phase HPLC using a solvent system of *n*-hexane–$CHCl_3$–MeOH (3:5:1) over 30 min at a flow rate of 2.0 mL/min (Apollo silica 5 μ column; Shodex refractive index detector) to obtain parisveroside B (**2**, 7 mg). The *n*-BuOH-soluble fraction (10 g) was subjected to CC over HP-20 resin using 100% H_2O and 100% MeOH to give two fractions (B1, 100% H_2O, and B2, 100% MeOH). The B1 fraction (2 g) was washed using MeOH and recrystallized to give allantoin (**5**, 200 mg). The B2 fraction (3 g) was subjected to normal-phase CC over silica gel using $CHCl_3$–MeOH–H_2O (10:10:0.5) to give six fractions (B21–B26). The B21 fraction (180 mg) was further separated using silica gel CC with $CHCl_3$–MeOH–H_2O (10:4:0.5) and purified by preparative normal-phase HPLC using a solvent system of $CHCl_3$–MeOH–H_2O (9:4:0.5) to afford salicin (**3**, 6 mg) and 3-(β-D-glucopyranosyloxymethyl)-2-(4-hydroxy-3-methoxyphenyl)-5-(3-hydroxypropyl)-7-methoxy-dihydrobenzofuran (**4**, 4 mg). The B22 fraction (70 mg) was purified using silica gel CC with $CHCl_3$–MeOH–H_2O (9:4:0.5) to yield parisveroside B (**1**, 5 mg).

Parisveroside A (1)

Colorless gum; $[\alpha]_D^{25}$ +36.5 (*c* 0.05, MeOH). IR (KBr, cm^{-1}) ν_{max}: 3390, 2949, 1698, 1522, 1450, 1026, 674. ^1H NMR (CD_3OD, 500 MHz) δ: 4.34 (1H, d, *J* = 8.0 Hz, H-1′), 3.86 (1H, dd, *J* = 11.0, 1.0 Hz, H-6′a), 3.77 (1H, dd, *J* = 11.0, 3.5 Hz, H-6′b), 3.75 (1H, m, H-9), 3.46–3.35 (3H, m, H-2′, 3′, 4′), 3.26 (1H, m, H-5′), 2.34–2.24 (2H, m, H-2), 1.62–1.58 (4H, m, H-8, 10), 1.43–1.33 (4H, m, H-6, 7), 1.08 (1H, m, H-3), 0.93 (3H, t, *J* = 6.5 Hz, H-11), 0.82 (1H, m, H-5), 0.73 (1H, m, H-4a), –0.11 (1H, q, *J* = 5.5 Hz, H-4b). ^{13}C NMR (CD_3OD, 125 MHz) δ: 177.5 (C-1), 102.3 (C-1′), 80.7 (C-9), 77.0 (C-3′), 76.5 (C-5′), 74.1 (C-2′), 70.6 (C-4′), 61.7 (C-6′), 34.1 (C-2), 33.1 (C-8), 28.8 (C-6), 27.4 (C-10), 25.2 (C-7), 15.4 (C-5), 11.7 (C-3), 10.2 (C-4), 8.8 (C-11). HR-FAB-MS *m*/*z* 363.2021 $[M + H]^+$ (calcd. for $C_{17}H_{31}O_8$: 336.2019).

Parisveroside B (2)

Colorless gum; $[\alpha]_D^{25}$ +26.6 (*c* 0.10, MeOH). IR (KBr, cm^{-1}) ν_{max}: 3395, 2948, 1702, 1515, 1455, 1026, 674. ^1H NMR (CD_3OD, 500 MHz) δ: 4.33 (1H, d, *J* = 8.0 Hz, H-1′), 3.86 (1H, dd, *J* = 11.5, 1.5 Hz, H-6′a), 3.69 (3H, s, OCH_3), 3.68 (1H, dd, *J* = 11.5, 3.5 Hz, H-6′b), 3.65 (1H, m, H-9), 3.38–3.33 (3H, m, H-2′, 3′, 4′), 3.25 (1H, m, H-5′), 2.39–2.30 (2H, m, H-2), 1.64–1.56 (4H, m, H-8, 10), 1.50–1.35 (4H, m, H-6, 7), 1.08 (1H, m, H-3), 0.93 (3H, t, *J* = 6.5 Hz, H-11), 0.83 (1H, m, H-5), 0.73 (1H, m, H-4a), –0.10 (1H, q, *J* = 5.5 Hz, H-4b). ^{13}C NMR (CD_3OD, 125 MHz) δ: 174.9 (C-1), 102.4 (C-1′), 80.7 (C-9), 77.1 (C-3′), 76.6 (C-5′), 74.2 (C-2′), 70.7 (C-4′), 61.8 (C-6′), 50.9 (OCH_3), 33.3 (C-2), 33.1 (C-8), 28.8 (C-6), 27.5 (C-10), 25.1 (C-7), 15.4 (C-5), 11.4 (C-3), 10.2 (C-4), 8.9 (C-11). HR-FAB-MS *m/z* 399.2012 $[M + Na]^+$ (calcd. for $C_{18}H_{32}NaO_8$: 399.1995).

Enzymatic hydrolysis of 1 and 2

Compounds **1** and **2** (3 mg each) were dissolved in H_2O (3 mL) and β-glucosidase (emulsin, 9 mg) was added to the solution and kept at 37 °C for 3 days, in each case. The reaction mixtures were extracted with $CHCl_3$, and the aqueous phases compared with an authentic sugar sample using co-TLC (MeCN–H_2O, 6:1, R_f 0.33 for glucose). Identification of D-glucose in the aqueous layer was carried out by comparing the optical rotation of the liberated glucose ($[\alpha]_D^{25}$ +48.6 (*c* 0.05, H_2O) from **1** and $[\alpha]_D^{25}$ +45.3 (*c* 0.05, H_2O) from **2**) with that of an authentic sample of D-glucose.[16] The $CHCl_3$ layers of **1** and **2** were followed by purification on a silica gel Waters Sep-Pak Vac 6cc ($CHCl_3$–MeOH, 15:1) to afford new compounds **1a** (1.4 mg) and **2a** (1.1 mg). **1a**: colorless gum; $[\alpha]_D^{25}$ –12.5 (*c* 0.04, $CHCl_3$). ^1H NMR (C_5D_5N, 500 MHz) δ: 3.95 (1H, m, H-9), 2.62–2.48 (2H, m, H-2), 1.64–1.57 (4H, m, H-8, 10), 1.30 (2H, m, H-7), 1.24 (2H, m, H-6), 1.17 (1H, m, H-3), 1.06 (3H, t, *J* = 6.5 Hz, H-11), 0.85 (1H, m, H-5), 0.76 (1H, m, H-4a), –0.03 (1H, q, *J* = 5.5 Hz, H-4b). HR-FAB-MS *m/z* 201.1485 $[M + H]^+$ (calcd. for $C_{11}H_{21}O_3$: 201.1491). **2a**: colorless gum; $[\alpha]_D^{25}$ –20.7 (*c* 0.03, $CHCl_3$). ^1H NMR (C_5D_5N, 500 MHz) δ: 3.91 (1H, m, H-9), 3.70 (3H, s, OCH_3), 2.65–2.47 (2H, m, H-2), 1.65–1.58 (4H, m, H-8, 10), 1.28 (2H, m, H-7), 1.23 (2H, m, H-6), 1.19 (1H, m, H-3), 1.05 (3H, t, *J* = 6.5 Hz, H-11), 0.87 (1H, m, H-5), 0.77 (1H, m, H-4a), –0.01 (1H, q, *J* = 5.5 Hz, H-4b). HR-FAB-MS *m/z* 215.1652 $[M + H]^+$ (calcd. for $C_{12}H_{23}O_3$: 215.1647).

Preparation of the Mosher ester derivatives of 1a

Compound **1a** (0.7 mg) was transferred to a clean and completely dry NMR tube. Deuterated pyridine (0.7 mL) and (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride, (*S*)-MTPA-Cl, (5 μL) were added immediately to the NMR tube and then the NMR tube was shaken carefully to mix the sample and (*S*)-MTPA-Cl evenly. The reaction NMR tube was then permitted to stand at room temperature overnight. The completed reaction afforded the (*R*)-MTPA ester derivative (**1r**) of **1a**. The (*S*)-MTPA ester derivative (**1s**) of **1a** was obtained in the same manner as described for **1r**. The ^1H NMR spectra for **1r** and **1s** were directly measured with the reaction NMR tubes. **1s**: ^1H NMR (C_5D_5N, 500 MHz) δ: 5.184 (1H, m, H-9), 2.537 (1H, m, H-2a), 2.485 (1H, m, H-2b), 1.762–1.559 (4H, m, H-8, 10), 1.257 (2H, m, H-7), 1.200 (2H, m, H-6), 1.156 (1H, m, H-3), 1.042 (3H, t, *J* = 6.5 Hz, H-11), 0.801 (1H, m, H-5), 0.686 (1H, m, H-4a), –0.078 (1H, q, *J* = 5.5 Hz, H-4b). **1r**: ^1H NMR (C_5D_5N, 500 MHz) δ: 5.192 (1H, m, H-9), 2.540 (1H, m, H-2a), 2.490 (1H, m, H-2b), 1.772–1.560 (4H, m, H-8, 10), 1.278 (2H, m, H-7), 1.214 (2H, m, H-6), 1.168 (1H, m, H-3), 1.014 (3H, t, *J* = 6.5 Hz, H-11), 0.817 (1H, m, H-5), 0.696 (1H, m, H-4a), –0.065 (1H, q, *J* = 5.5 Hz, H-4b).

Measurement of NO production and cell viability

The BV-2 mouse microglial cell line was maintained in Dulbecco's modified Eagle medium (DMEM) supplemented with 5% fetal bovine serum (FBS) and 1% penicillin–streptomycin (PS). To measure NO production, BV-2 cells were plated into a 96 well plate (3×10^4 cells/well) and treated with 100 ng/mL LPS in the presence or absence of chrysin for 24 h. Nitrite, a soluble oxidation product of NO, was measured in the culture media using the Griess reaction. The supernatant (50 μL) was harvested and mixed with an equal volume of Griess reagent (1% sulfanilamide and 0.1% *N*-1-napthylethylenediamine dihydrochloride in 5% phos-

phoric acid). After 10 min, the absorbance at 540 nm was measured using a microplate reader. Sodium nitrite was used as a standard to calculate the NO_2^- concentration. Cell viability was assessed by a 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl-tetrazolium bromide (MTT) assay.[17] N^G-Monomethyl-L-arginine (L-NMMA, Sigma-Aldrich), a well-known NOS inhibitor, was tested as a positive control. The IC_{50} value for the positive control, L-NMMA, was 18.0 μmol/L.

Abstract: The relationships between ion yield(s) as a function of desorption alone and (or) ionization was investigated using two model systems. In the first model system, a carbohydrate (2,3,6-tri-*O*-methyl-β-cyclodextrin, TMBCD), which could be directly laser desorbed, was analyzed with and without a silicon-based heat sink compound (HSC). The HSC allowed heat to pass through but obstructed the flow of charge. In the second model system, a peptide (substance P), which ccould not be laser desorbed, was analyzed under similar conditions. The ion yield of TMBCD under either system of heat conductivity was similar, whereas the ion yield of the peptide with the heat sink was negligible. Compounds that are predominately cationized either in the gas phase or preformed in solution give an ion yield that is not dependent upon the surface conditions, whereas compounds that are not ordinarily cationized are affected by the emission of electrons from the metal surface.

Key words: heat sink, matrix-assisted laser desorption (MALD), matrix-assisted laser desorption/ionization (MALDI), electron emission.

Résumé : Faisant appel à deux systèmes modèles, on a étudié les relations entre les rendements ioniques en fonction de la désorption seule et (ou) de l'ionisation. Dans le premier système modèle, on a analysé un hydrate de carbone, la 2,3,6-tri-*O*-méthyl-β-cyclodextrine, TMBCD, qui peut être désorbée avec et sans composé dissipateur thermique (CDT) à base de silicone. Le CDT permet la libre circulation de la chaleur, mais obstrue les déplacements de la charge. Dans le deuxième système modèle, on a analysé dans les mêmes conditions un peptide (substance P) qui ne peut pas être désorbé par le laser. Le rendement ionique en TMBCD est semblable quel que soit le système de conductivité thermique alors que le rendement ionique du peptide avec le dissipateur thermique est négligeable. Les composés qui sont d'une façon prédominante cationisés en phase gazeuse ou préformés en solution donnent un rendement ionique qui ne dépend pas des conditions superficielles alors que les composés qui ne sont habituellement pas cationisés sont affectés par l'émission d'électrons par la surface métallique.

Mots-clés : dissipateur thermique, désorption laser assistée par la matrice (DLAM), désorption/ionisation assistée par la matrice (DILAM), émission d'électron.

[Traduit par la Rédaction]

Introduction

Matrix-assisted laser desorption/ionization (MALDI) has become an important analytical technique in the study of a range of compounds,[1] including peptides[2,3] and synthetic polymers,[4,5] from which accurate end-group analysis and molecular weight determination, including both whole mass and sequence information, can be obtained.[6–11] Recently, Spengler et al.[12] reported that fragment analysis of a variety of compounds generated by the MALDI process can allow linkage information to be obtained by post-source delay (PSD), whereas others have extended this to in-source decay (ISD),[13] electron-capture dissociation,[14] or terminal sequenc-

ing[15], thereby furthering the utility of the MALDI technique.[16]

Since Karas and Hillenkamp's[17] initial report on MALDI, the physio-chemical processes that underlie the MALDI process are still not entirely known.[18] There are a number of models that attempt to explain the MALDI process. Vertes et al.[19] proposed a mechanical expansion model in which the matrix, following laser irradiation, converts its electronic excitation energy via radiationless transitions into vibrational energy that causes the matrix to expand. This rapid expansion leads to the sublimation of the matrix, which aids in the desorption of the analyte molecules.[19] Additionally, the laser interacts with the MALDI matrix and also with the metal probe tip, which would therefore pass heat back into the sample by conduction.[20] Several processes may contribute to the expansion and ionization of a laser-induced plume, including the thermal-spike model as proposed by Vertes and Gijbels,[21,22] in which a bottleneck in energy transfer is created from the hot matrix molecules to the analyte molecules by a *mismatch* in vibrational coupling. A pressure-pulse model, which has also been described,[23] is derived from plasma desorption. A pressure gradient is created perpendicular to the surface by energy deposition, resulting in molecular ejection by momentum transfer.[24] Analysis of the physical laser–matter interaction zone suggests that the excitation profile is essentially two-dimensional,[20] based on the penetration depth (85 nm) of a typical nitrogen laser.

There are a variety of additional desorption/ionization mechanisms[25–41] that have been postulated to account for the MALD/MALDI phenomena. The "ionization" theory[25] is based on a two-step ionization process in which the primary ionization refers to the production of ions directly from neutral molecules and mainly produces excited analyte molecules after the laser shot.[26] The secondary ionization process occurs through the collision of excited matrix molecules with each other and analyte molecules during the expansion of the plume. The "multi-photon excitation" theory[27] considers that the matrix molecule is directly ionized by the laser pulse. Typical ionization potentials of a matrix in the solid state are in the range of 8–10 eV.[28] Taking into consideration that photons of two commonly used UV lasers have 3.68 eV (for nitrogen) and 4.66 eV (for Nd:YAG),[29] it is understood that two or three photons are required to produce an excited matrix molecule.[30] Two photons, though, appear in most cases to contribute insufficient energy to overcome the ionization potential (IP) and a three-photon mechanism does not seem plausible under the low laser irradiation used in MALDI.[27] "Excited state proton transfer (ESPT)" theory[31,32] proposes an intramolecular proton transfer after a single photon excitation.[42] However, salicylic acid and salicylamide are matrices known to have ESPT behavior, but 2,5-dihydroxybenzoic acid (2,5-DHB), which is widely used and complies with the IP requirement, is not efficient in ESPT, nor are other matrices. "Energy pooling"[25] suggests a model in which more than one excited matrix molecule is required to excite an analyte molecule. The two excited matrix molecules collide with each other to produce a radical anion[43] or cation. The hypothesis is that in the laser fluences available in MALDI, it is more likely that a second photon will not interact with the same matrix molecule as the first photon, but the one next to it. So a matrix ion should be produced from two or more not fully excited matrix molecules. The "crystal size and analyte incorporation" theory[33] suggests that there is no universal explanation for the processes under MALDI. The authors experimented by changing sample preparation, sample deposition, and droplet drying rate methods as well as laser parameters. The results of these variations were significantly different depending on crystal size, analyte–matrix incorporation, and laser fluence. Finally, the "desorption"[34] step in the MALDI process is just as important as the ionization process. Desorption is believed to be a combination of thermal contribution and photomechanical stress, as well as Coulombic forces from the applied potential to the "early" charged particles that underline this process. Desorption is highly dependent upon the heat that is transferred to the sample as well as the laser fluence, the laser spot, and the duration of the pulse. In addition, desorption is influenced by the size and the density of the matrix–analyte crystals. Other theories propose that ablation from hydrodynamic pressure increases under the laser pulse;[35] ablation is caused by spallation under strong mechanical stress;[36] ablation is caused by phase explosion;[37] thermal desorption of individual molecules;[38] and layer by layer sublimation.[39] A more appealing theory, however, is the formation of big clusters that are ejected from the surface with high velocities owing to phase explosion.[40] Phase explosion occurs in the sample when the rate of laser energy deposition exceeds that of the phase transitions by melting, evaporating, or sublimating the system, producing high-energy electrons[41] and both positive and negative ions.[44]

In this paper, we investigate the effect of a heat sink compound (HSC) on the MALDI process. The HSC is used in electronics to allow high thermal conduction while eliminating electrical contact, thereby safeguarding electrical components from excessive heat damage (cf. Table S1 in the Supplementary data). The heat sink would thereby "short circuit" the MALD process if local heating is the major mechanism. Although the heat sink has a macroscopic impact on the MALD process, it also exhibits microscopic effects in that the heat transfer and electrical conductivity are separated. This separation is based on the design of the layered surface; metal surface – heat sink – matrix/analyte. Consequently, the laser photons most likely interact with only the matrix–analyte layer. Additionally, heat conduction from the metal MALDI slide to the sample would be unaffected, but electrical contact would be prohibited.

Experimental method

A general experimental design is summarized in the following section followed by a description of various instrument parameters to assess standard errors in the measurement of the time-of-flight of substance P (Sub P; Error and standard deviation measurement section), the effect of shielding section, followed by a description of chemicals utilized, with an overview of the sample preparation method. An alternative "masking" technique is also described for comparison, with a section summarizing the various techniques.

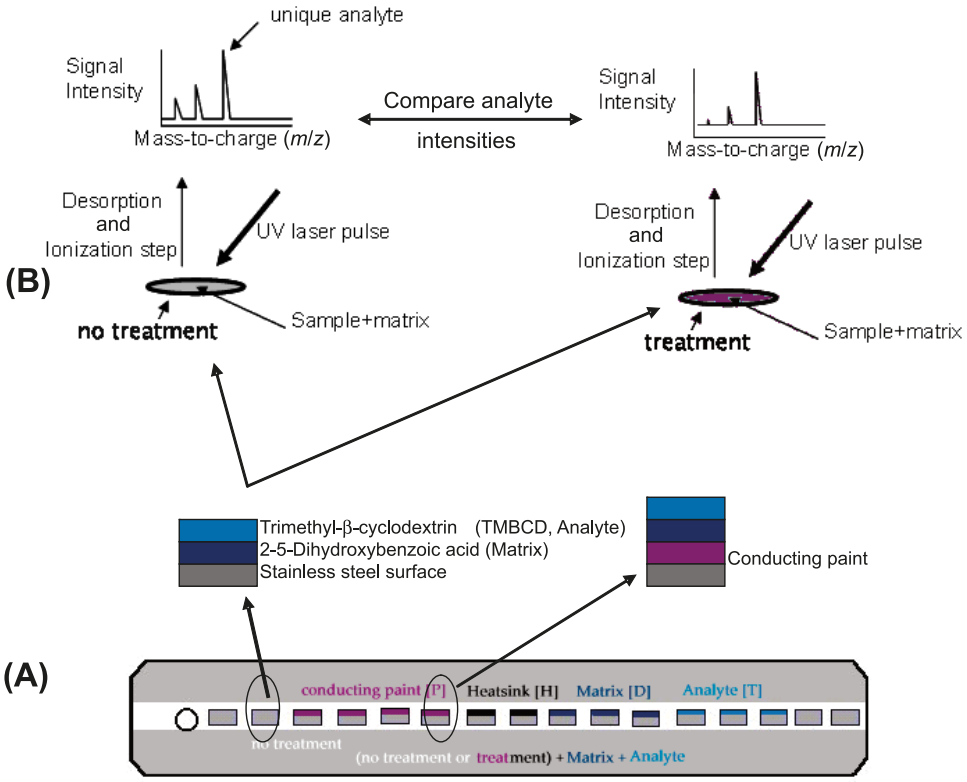
Scheme 1. Schematic of the experimental design illustrating the various formulations, use of atomic force and optical microscopy for visual or morphological examination, and mass spectrometry to determine ion yields.



Experimental design

The rationale for the layering was that the effect of "no treatment" (–HSC, summarizing MALDI) to "treatment" (+HSC, summarizing LDI, MALD, or MALDI) would give an indication of which parameters were paramount. Comparison of the different formulations that comprise the application of the heat sink (H), or the conducting paint (P), or the heat sink followed by conducting paint (H + P), would give an indication of whether MALD or MALDI was more important and whether this was analyte specific for analytes that are predominately protonated ($C_{63}H_{98}N_{18}O_{13}S$, Sub P) or cationized (2,3,6-tri-*O*-methyl-β-cyclodextrin). A number of instrument parameters were adjusted to obtain the highest ion intensity and then applied to experiments in which the heat sink was utilized. These adjustments are described in the Supplementary data (cf. *Adjustment of Instrument Parameters*) including three-dimensional profiling of the surface to determine surface roughness (cf. *Surface Profiling Procedure*).

Error and standard deviation measurement

Standard errors for the flight times were determined to evaluate the presence of a voltage lag owing to the application of the heat sink. These results are summarized in Tables S2 and S3 in the Supplementary data in full. Briefly, no lag was observed, confirming earlier calculations that indicated that the voltage drop, if any, would be a fraction of the applied extraction of 20 kV (also see *Expressions used to determine ion flight time in the Kratos III MALDI-TOF mass spectrometer*, *Expression used to determine signal-to-noise ratio*, and *MALDI reproducibility and accuracy assessment* in the Supplementary data for equations used to determine flight times).

Shielding effect measurement

To determine whether the "surface-shielding" effect could result in a change in the analyte peak intensity, a number of analytical systems were compared and are presented in the work-flow process as illustrated in Scheme 1. Comparison of the analyte peak intensity under normal conditions (no treatment, –HSC) to conditions in which the heat sink had been applied (treatment, +HSC) indicated a diminished analyte peak intensity. A follow-up experiment was performed to determine whether the results could be reversed by use of a conductive additive. The role of the conductive layer is twofold: (*i*) to supply an ample amount of charge to the system and (*ii*) to separate the effects of charge and temperature. The conductive layer enables us to short circuit the effect of the heat sink (+HSC), and restores the analyte peak intensities to almost 100% of their initial readings.

General chemicals and layering procedure

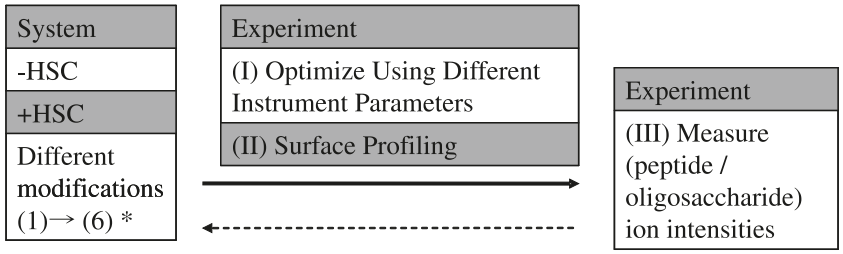
The peptides, solvents, and chemicals, unless otherwise stated, were analytical purity grade purchased from Sigma-Aldrich (Dorset, UK). The matrices (Fig. S2 for the respective structures), α-cyano-4-hydroxy-cinnamnic acid (CHCA),[45] 2,5-dihydroxybenzoic acid (2,5-DHB[46]), and analytes, trimethyl-β-cyclodextrin (TMBCD, $C_{63}H_{112}O_{35}$, average molecular mass = 1429.54 Da) and Sub P ($C_{63}H_{98}N_{18}O_{13}S$, average molecular mass = 1347.63 Da)

Table 1. Summary of the experimental conditions.

System annotation	Sequence of layering	Experimental condition (evaluation of desorption (MALD) or ionization (MALDI) or a combination thereof (group I–IV))
T	Stainless steel – TMBCD	LDI
H + D	Stainless steel – matrix	LDI
H + T	Stainless steel – heat sink – TMBCD	LDI
H + P + T	Stainless steel – heat sink – conducting paint – TMBCD	LDI
D + T	Stainless steel – matrix – TMBCD	Matrix-assisted laser desorptionionization (group I)
H + D	Stainless steel – heat sink – matrix	Matrix-assisted laser desorption/ionization (MALD)
H + P + D	Stainless steel – heat sink – conducting paint	Matrix-assisted laser desorption/ionization (MALDI)
P + D + T	Stainless steel – conducting paint – matrix – TMBCD	Matrix-assisted laser desorption/ionization (group II)
H + D + T	Stainless steel – heat sink – matrix – TMBCD	Matrix-assisted laser desorption/ionization (group III)
H + P + D + T	Stainless steel – heat sink – conducting paint – matrix – TMBCD	Matrix-assisted laser desorption/ionization (group IV)

Note: TMBCD, trimethyl-β-cyclodextrin; LDI, laser desorption ionization.

Scheme 2. Schematic of the work flow illustrating how the heat sink compound would be used to determine the mode of sample ionization (preformed ions vs ions formed during secondary reactions in the gas phase).



(*cf. Table 3, Scheme 2, Supplemental Tables 2 and 3, and Supplemental Figure 1)

were purchased from Sigma-Aldrich and were used with no further purification. CHCA was chosen as a matrix because of the good analyte-to-noise ratio that it provides when used with peptides and its high IP potential.[47] Three additional peptides were initially used for the calibration of the instrument. Bradykinin fragment 1-5 ($C_{27}H_{40}N_8O_6$, MW = 572.66), Sub P fragment 1-7 ($C_{41}H_{65}N_{13}O_{10}$, MW = 900.04), and Alytesin ($C_{68}H_{106}N_{22}O_{17}S$, MW = 1535.77). Only Bradykinin 1-5 and Sub P 1-7 were further analysed in the series of experiments (see Supplemental spectra (SS) 1–14 presented in the Supplementary data for some representative MALDI-TOF spectra).

The HSC was manufactured by Dow Corning (CD340 (CAS – 6850-01-127-6826) and is a nonmelting silicone (optimum temperature 200 °C) with high thermal conductivity (0.42 W/m·K) and a high dielectric strength (21 kV/mm), Midland, Michigan). The HSC was dissolved in tetrahydrofuran (THF). The matrix (0.1 mol/L CHCA or 2,5-DHB) was dissolved in acetonitrile–water (1:1 *v*/*v*). The sample consisted of 0.5 μL HSC that was air-dried and upon which 0.5 μL of CHCA (or 2,5-DHB) was added and dried. To this bilayer a 0.5 μL aliquot of analyte (TMBCD or Sub P) was added and dried in a stream of nitrogen. Cations were not added. The ratio of matrix:analyte was 1:1000–3000.

In preparing the peptide samples for deposition via masking and spraying, the peptides were diluted separately in water. The resulting concentration was 0.1 μmol/L. The matrix was diluted in a water–methanol (1:1 *v*/*v*) solution until precipitation occurred. Both the peptide samples and the matrix were stored below –20 °C. A droplet of 1 μL of the peptide solution was deposited on the target and dried under a flow of air at room temperature. A droplet of 1 μL of the matrix solution was deposited on the same target and dried in the same way.

The peptides were analysed under several laser powers above the threshold to achieve the best analyte-to-noise ratio. At a power of 101 (arbitrary units), the best analyte-to-noise ratio was achieved for both peptides on a simple steel substrate with no modifications. Higher analyte-to-noise ratios were observed for the insulators at higher laser powers. For the normal substrate at powers of 112, there were signs of fragmentation and consequently reduced peptide peaks.

Sample preparation method: overview

The general preparative approach used is illustrated in Scheme 2, and the various formulations utilized are summarized in Table 1. Briefly, the following three systems were evaluated: (*a*) determination of the protonated or sodiated pseudomolecular ion under laser desorption/ionization (LDI) conditions on stainless steel that has (*i*) not been modified, (*ii*) has been modified with an HSC, and (*iii*) has been modified with a bilayer of HSC followed by a conducting paint; (*b*) determination of the protonated or sodiated pseudomolecular ion under MALDI conditions on stainless steel that has not been modified in the same manner as for the LDI system; and (*c*) repeating the process in system (*b*) with a number of experimental permutations. In each case, one component of the sample was deposited (0.5 μL) and allowed to dry before the next component was deposited.

Chemicals used for the masking procedure

The green-coloured polyvinylchloride (PVC) nonconductive tape (Wilco) was purchased from Wilkinson, Chatsworth, California, and the transparent tape was purchased from Niceday (purchased from Viking-Direct, Leicester, UK). Dow Corning 340 silicon HSC (white) and Electrolube silver conductive paint were purchased from RS Components, Ltd. (Corby, Northants, UK). The electron-capture compound,[48] trifluoromethylundecafluoro-cyclohexane ($C_6F_{11}CF_3$),[49] also known as perfluoromethylcyclohexane (PFMC), reagent[50]) was purchased from Sigma-Aldrich and was of technical grade. PFMC is a highly volatile liquid with high dielectric strength that captures free electrons by collision. The most commonly used electron-capture compound is sulfur hexafluoride (SF_6), but it could not be used in this experiment because it is in the gas phase at room temperature and the application of it in the MALDI-TOF (Kratos) mass spectrometer, or on a target exposed in an open room, would not be plausible.

The slides for the MALDI-TOF (Kratos IV) mass spectrometer were purchased from Kratos Analytical (Manchester, UK). They are stainless steel substrates with 20 separate target locations. The SIMair Focus airbrush with a 0.2 mm nozzle tip was purchased from Ziggy Art (Coventry, UK). The air was pumped from a 10 mol/L compressor (Air Products PLC, Crewe, Cheshire, UK). The semisolid state of the silicon HSC meant that its surface was distorted by the touch of a light brush applying the silver paint. This problem was overcome by the use of an airbrush. Another application involved the spraying of the electron-capture compound directly onto the substrate surface.

Masking procedure

To prepare the modified slides, the heat sink layer (mask) was created from transparent tape, which restrained the silicon-based semifluid paste that was subsequently applied to the surface of the slide with a metal spatula. With the use of a microscopic slide, the excess silicon was removed and the surface of the layer was smoothed. The length, width, and thickness of the layer were adjusted from the mask. A continuous layer of 2 cm $\times$ 6 mm tape was applied to the slide and was cut to fit on the targets precisely. A silver paint mask, similar to the heat sink, was also constructed. The paint was sprayed with the airbrush over the layers. The paint was applied in such a way that it was touching the edges of the metal substrate to create an electric field.

Every slide was modified in a different way, taking into account the limitations and the special handling that each of the materials required because of those limitations. This resulted in differences in the thickness of the layers, which could have affected the resulting spectra. (cf. Table S4 for a summary of the measurements of individual and combined layers). The target was considered to be flat (average of the low and high points) for the calculations, but the actual morphology is as shown in Fig. S3, which is slightly concave.

Sample preparation: summary

1. Both peptides were analyzed on a normal slide and the six modified slides (see Supplementary data, Fig. S1, for pictorial depcitions of the modified slides) at laser power 101 with CHCA as the matrix.
2. Both peptides were analyzed on modified slides (1) and (4) at laser power 106 with CHCA matrix.
3. Both peptides were analyzed on modified slide (2) at laser power 112 with CHCA matrix.

Analogously, the following control experiments were also conducted.

1. CHCA matrix was analyzed on a normal slide at several laser powers with no peptide. The experiment took place to verify the purity of the matrix and identify any unknown peaks.
2. 2,5-DHB matrix was analyzed on a normal slide with and without peptides. The experiment took place to identify any unknown peaks in comparison with the results from CHCA matrix.
3. Both peptides were analyzed on a normal slide at several laser powers with no matrix. The experiment took place to certify that neither peptide has any absorbance at the wavelength of the laser pulse, verifying that nonmatrix-assisted LDI was not occurring. No peaks were observed.
4. An additional modified slide was created. The slide carried a single layer of continuous PVC tape. The purpose of this control experiment was to observe if and how the electrical field was influenced by a layer of nonconductive material and if the was any relationship to the amount applied. The measurements on this slide were compared with the ones from the modified slide (2). No significant differences were observed. (Also see Figs. S4 and S5, which are bar graphs summarizing the measured ion intensities under different surface modification conditions).

Results and discussion

Experimental rationale

In this paper the model presented examines two parameters that could possibly affect desorption and ionization processes; they are the electron and thermal contributions induced by the laser pulse. In the model discussed, the energy pooling and multi-photon theories have been adopted and modified by introducing an additional energy parameter. Taking into consideration that the IP of the matrix cannot be overcome by one or two photons, it is necessary to take into account the energy given from the photoelectrons produced at the surface of the substrate after the laser pulse. Even though the normal stainless steel substrate does not have a significant photoelectron emission under the laser pulse in MALDI, the metal undergoes reduction when in contact with the matrix–analyte system.[51] Free electrons are possibly created in two processes of MALDI. Firstly, electrons may be produced after the laser pulse from the substrate surface. Secondly, electrons could be produced during ionization owing to collision between excited matrix molecules and matrix or analyte molecules.[52] This project examines the plausibility of a free electron[41] from the substrate surface and single or multiple photon co-excitation of the matrix.[26]

The thermal contribution parameter is considered to be necessary and is expected to have a significant influence in MALDI. There are many indications that a thermal factor is

†Not significant.

responsible for a thermally induced ionization. This is based on a sample being rapidly heated during desorption, then rapidly cooled during plume expansion, and then heated again owing to collisions between molecules. This makes a thermal contribution during ionization extremely unlikely. Thus, thermal contribution effects will be taken into account mainly for the desorption process.

To evaluate the validity of these considerations one needs to isolate the thermal and electron contribution to the sample. Different insulating, conductive and semiconductive materials were used to facilitate these conditions. Specially modified targets were produced that (*i*) allow thermal diffusion to the substrate and electron production, (*ii*) allow thermal diffusion but prohibit electron production, and (*iii*) prohibit both thermal diffusion to the substrate and electron production. The values of thermal and electrical conductivity were relatively different among the materials used; therefore, the variability of the applied conditions on the slides is taken into account. This process was continued until all of the layers of the sample were deposited (as shown in Fig. S1. Also see Supplemental spectra (SS) 1–14 for some representative MALDI-TOF spectra).

Results

The peak intensity of the protonated form of CHCA (nominal mass 190 Da, matrix species), Sub P (nominal mass 1348 Da, analyte species), and the sodiated form of trimethyl-β-cyclodextrin (TMBCD+Na, nominal mass 1430 Da, analyte species) were measured either under LDI or MALDI conditions. The peak intensities (in mV) were normalized to the analyte (analyte peak / matrix peak) such that any variations in the spectra would be taken into account (and plotted in arbitrary units, arb units). Table 2 shows the relationship between the peak intensity of the matrix and the analyte with (+HSC) and without (–HSC) the heat sink compound.

Table 2 shows that the TMBCD pseudomolecular peak intensity is ~56.69% (general expression 1: 100 – [(+HSC value]/(–HSC value)]100] or, for this example, 100 – [(column b)/(column B)]100) more intense without the HSC than with the HSC under MALDI conditions (Table 2, column E). This is reflected in the ratio of the analyte peak without the HSC compared with the ratio with the HSC. The peaks were then normalized where the analyte peak intensity was divided by the matrix peak, such that any ionization factors were cancelled out (Table 2, columns D and d). The normalized peak difference drops from 53.92% to ~6.03% (see general expression 1). The relationship between the matrix peak intensity without the heat sink (Table 2, column A) to the corresponding peak with the heat sink (Table 2, column a) is also shown. The matrix peak is ~53.92% (see general expression 1) higher without the HSC than with the HSC. It can also be noted that TMBCD can be laser desorbed (Table 2, column C). The pseudomolecular peak intensities of TMBCD without and with the heat sink under MALDI conditions relative to the corresponding measurements under LDI conditions are 99.72% (general expression 2: 100 – [(LDI value)/(MALDI value)]100 or, for this example, 100 – [(C)/(B)]100) (Table 2, column B vs column C) higher under MALDI conditions (i.e., $MALDI_{HSC–TMBCD} >> LDI_{HSC–TMBCD}$) and 99.36% (see gen-

Fig. 1. (A) MALDI-TOF mass spectrum of the protonated sodiated forms of trimethyl-β-cyclodextrin (TMBCD) with α-cyano-4-hydroxycinnamic acid (CHCA) as the matrix (upper spectrum). The matrix-to-trimethyl-β-cyclodextrin ratio was 1500:1 and ~100 laser shouts were summed. A 0.5 μL aliquot of matrix (0.1 mol/L in acetonitrile) was deposited onto a stainless steel slide and allowed to dry. Once dry, 0.5 μL of peptide (dissolved in acetonitrile–water (2:1) with 0.01% trifluoroacetic acid) was deposited and allowed to dry. The mass spectrum is annotated as (CHCA + TMBCD). (B) MALDI-TOF mass spectrum of the protonated sodiated forms of TMBCD with CHCA as the matrix (lower spectrum). The matrix-to-trimethyl-β-cyclodextrin ratio was 1500:1 and ~100 laser shouts were summed. A 0.5 μL aliquot of matrix (0.1 mol/L in acetonitrile) was deposited onto a heat sink compound (+HSC) that had previously (using a stock solution of 1 mg/mL in tetrahydrofuran) been applied onto a stainless steel slide and allowed to dry. Once dry, 0.5 μL of peptide (dissolved in acetonitrile–water (2:1) with 0.01% trifluoroacetic acid) was deposited and allowed to dry. The mass spectrum is annotated as (HSC + CHCA + TMBCD).

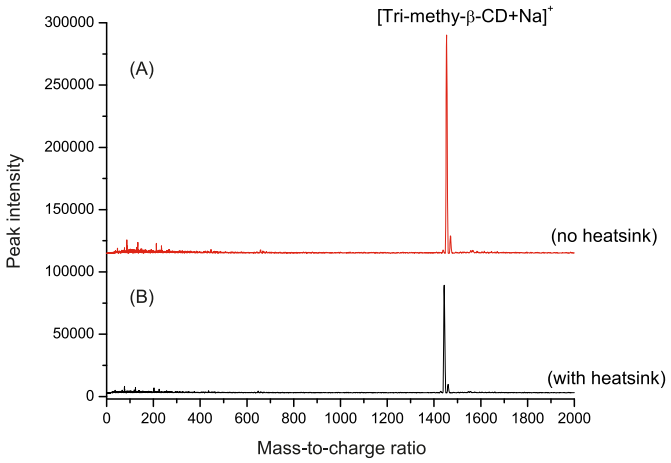

Fig. 2. (A) MALDI-TOF mass spectrum of the protonated form of substance P (Sub P) with α-cyano-4-hydroxycinnamic acid (CHCA) as the matrix. The matrix-to-Sub P ratio was 1000:1 and ~100 laser shouts were summed. A 0.5 μL aliquot of matrix (0.1 mol/L in acetonitrile) was deposited onto a stainless steel slide and allowed to dry. Once dry, 0.5 μL of peptide (dissolved in acetonitrile–water (2:1) with 0.01% trifluoroacetic acid) was deposited and allowed to dry. The mass spectrum was annotated as (CHCA + Sub P) [A]. (B) MALDI-TOF mass spectrum of the protonated form of Sub P with CHCA as the matrix. The matrix-to-Sub P ratio was 1000:1 and ~100 laser shouts were summed. A 0.5 μL aliquot of matrix (0.1 mol/L in acetonitrile) was deposited onto a heat sink compound (+HSC) that had previously (using a stock solution of 1 mg/mL in tetrahydrofuran) been applied onto a stainless steel slide and allowed to dry. Once dry, 0.5 μL of peptide (dissolved in acetonitrile–water (2:1) with 0.01% trifluoroacetic acid) was deposited and allowed to dry. The mass spectrum was annotated as (HSC + CHCA + Sub P) [B].

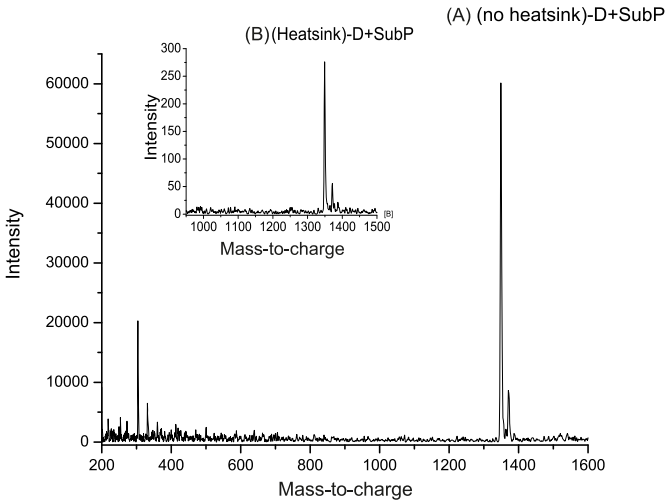

eral expression 2) (Table 2, column b vs column C) with the heat sink, respectively (i.e., $MALDI_{HSC+TMBCD} >> LDI_{HSC-TMBCD}$). The comparisons were also subjected to an analysis of variance and an ad hoc Sheffé's test pairwise comparison at the 95% confidence level,[53] and were mostly insignificant (the insignificant pairwise comparisons are noted in Tables 2 and 3). The accuracy and reproducibility of the instrument is presented in Table 3. The data in Table 3A were obtained on the Kratos MALDI-TOF mass spectrometer III and the data in Table 3B were collected on the Kratos MALDI-TOF mass spectrometer IV. The effect of the heat sink upon the MALD process will be discussed shortly.

For Sub P we see a more pronounced difference between the peak intensities with and without the HSC. The Sub P peak intensity without the HSC is 99.48% higher than with the HSC (Table 2, column G vs column g). Although there seemed to be no difference with and without the HSC for TMBCD, (Table 2, column e), we see a 190-fold difference in the relative peak intensities of Sub P and +HSC vs –HSC (Table 2, column J). It can be seen that the heat sink may influence the desorption process under MALDI conditions (i.e., the MALD process) in this case (Table 2, column J, as opposed to MALDI (or Table 2, column e). When the peak intensities are normalized, this difference decreases from 99.5% to 99.25% (Table 2, column I vs column i). The peak ratio drops from 190-fold (Table 2, column J) to ~130-fold (Table 2, column j), a drop of 30.37% . Also, Sub P cannot be laser desorbed (Table 2, column H) irrespective of the surface treatment (Table 2, column h). On the contrary, TMBCD can be laser desorbed (Table 2, column C), even though the signal intensity with the HSC was almost negligible (Table 2, column c), indicating that the molecule was potentially desorbed or ions had preformed prior to desorption.

Figure 1 is a MALDI-TOF mass spectrum of the sodiated form of TMBCD without (Fig. 1*a*) and with the HSC (Fig. 1*b*). For clarification, the mass spectrometer software integrates the peaks in mV; however, upon conversion of the data into an *x*–*y* table and subsequently graphed, the *y* axis is plotted in arb units, whereas the *x* axis maintains its charge-to-mass units. Analysis of the spectra did not reveal any major peaks <100 Da. The main matrix species observed were the protonated matrix (which was greatly diminished with the heat sink), the dehydrated matrix species (exhibiting a loss of 18 Da), and the matrix dimer, which has also been observed for liquid matrices.[54] Comparison of the matrix peaks obtained from the untreated (stainless steel) and treated (stainless steel with HSC) indicated that the application of the heat sink does not drastically affect the frag-

For personal use only.

mentation pattern of the matrix,[55] except that the intensity of some species was diminished for a surface treated with a HSC. Figure 2 depicts the corresponding MALDI-TOF mass spectra of the protonated form of Sub P without (Fig. 2*a*) and with the heat sinks (Fig. 2*b*). Comparison of Figs. 2*a* and 2*b* (and columns A and a in Table 2) illustrate a decrease in the intensity of the matrix peak for the matrix – heat sink bilayer. This phenomenon is similar to the MALDI suppression effect, in which low-mass matrix-ion peaks are suppressed.[20] However, in Fig. 2 the matrix peaks (and columns F and f in Table 2) are seen and thus are not totally diminished, indicating that the matrix suppression may partly be dependent upon the analyte species that is characterized.[56] Alternatively, there may be a different physical process occurring that results in lower intensity matrix peaks that are commonly observed under matrix suppression conditions.

In summary, the main utility of applying the HSC is to facilitate efficient heat transport between the analyte crystals and the surface, although the thermal conductivity of HSC is less than that of stainless steel (Table S1); however, comparisons of the same peptide under both conditions gave different ion intensities (cf. Tables 2 and 3 and Figs. S4 and S5) indicating a role for the heat sink.

The rationale for the use of the HSC is to determine if heat conductance from the metal slide to the matrix is a major pathway in the MALD process. If the contribution of metal-to-matrix or metal-to-analyte heating was minimal in the overall desorption of the matrix or analyte, then it can be expected that no difference should be seen in the –HSC vs +HSC system. This was not the case. The heat sink is thought to operate as a capacitor, storing charge. Consequently, if the pressure–pulse model is used to describe the MALD process, the desorption of the matrix–analyte system will occur only if an inordinately large number of collision events create the molecular momentum necessary for the desorption process to take place.[57] The model predicts that the number of molecules varies as a function of molecular mass (assuming a constant binding energy), which can be described by a power function ($f(M^{5/3})$, where M = molecular mass).[58] Soft expansion of the matrix by low-energy secondary electron excitation may be partially blocked by the heat sink.[59] Additional experiments using an electron donor in the Fourier transform ion cyclotron resonance (FTICR) mass spectrometer were conducted that support our conclusion[60] that photoelectrons are also involved in the ionization process.[3,47,61] Therefore, if the MALD process is dominant, and not the heat conduction from the metal to the matrix, then the result may be observed as two contradictory trends. In cases where MALD is more efficient, more ions would be generated, leading to an increase in the molecular ion signal intensity even though a larger standard deviation may be expected owing to uneven layering resulting in varied flight times (cf. *Error and Standard Deviation Measurement* and *MALDI reproducibility and accuracy assessment* in the Supplementary data). This deviation can be compensated for by the reflectron, (assuming the kinetic energy is not too dispersed for the ion of the same mass-to-charge ratio[62]), which can be negligible if the sample layers are thin. The other process ion generation (i.e., the ionization of the neutral matrix through thermal induction from the metal slide) through heat conduction in this scenario would generate zero ions and the overall sum may decrease in spite of the improved efficiency of the MALD process.

Our preliminary thickness measurement indicates that all layers are <50 μm thick (cf. *Surface Profiling Procedure* in the Supplementary data). These observations can lead to a number of possible conclusions (i.e., the change in analyte signal intensity as a function of heat sink deposition could be due to mechanisms (*a*) or (*b*) as follows), which describe how heat sink deposition can affect the analyte signal intensity. Plausible conclusions can be summarized as (*a*) a large voltage drop owing to the possible "capacitance"-related voltage drop attributed to the heat sink, thus, resulting in delayed ionizations, and (*b*) formation of meta-stable peaks,[63] owing to incomplete extraction and acceleration. However, the (*b*) phenomenon was not observed.

The calculation of the voltage drop in the presence of the HSC utilizes equations commonly seen in any traditional university physics course.[64] The parallel-plate capacitor consists of plates that possess dimensions of 2.0 mm × 100 μm that are separated by a distance of 5.0 mm, and exhibit a surface charge density (σ) of 3.5×10^{-5} C/m^2. Based on the 20 kV accelerating voltage of the Kratos III, the capacitance of the system in a vacuum is calculated using

$$[1] \qquad C_0 = \frac{\varepsilon_0 A}{d}$$

where ε_0 is permittivity in a vacuum, A is the area of the plates, and d is the distance separating the plates. Without the HSC, the capacitance of the system was 3.54×10^{-16} F. Therefore, in the absence of an insulator the charge carried by the capacitor was calculated ($Q = VC_0$, where V = 20 kV) to be $Q = 7.1 \times 10^{-12}$ C. The insertion of the heat sink (+HSC) into the system creates a bilayer capacitor that can be addressed mathematically as two capacitors in series, such that

$$[2] \qquad \frac{1}{C_{eq}} = \frac{1}{C_{vac}} + \frac{1}{C_{+HSC}}$$

where C_{eq} is the equivalent capacitance, C_{vac} is the capacitance in a vacuum, and C_{+HSC} is the capacitance of the system including the HSC. The value for C_{vac} was determined as above, except that d = 0.00495 m and C_{+HSC} was calculated using

$$[3] \qquad C_{+HSC} = \frac{\kappa \varepsilon_o A}{d}$$

where κ is the dielectric constant (κ = 5, Dow Corning product information) and $d = 50 \times 10^{-6}$ m (see text). The resulting C_{eq} corresponds to an increase of ~0.85% of the initial capacitance of the system. Assuming that the charge of the system remains constant, the potential difference between the plates owing to the insertion of heat sink (+HSC) is calculated to be 199 kV. Consequently, we predict the voltage drop to be on the order of $\sim 1.0 \times 10^2$ V (a decrease of 0.50% in the effective accelerating voltage), which we deem as being negligible. Alternatively, if the voltage is not fixed, it can be concluded ($Q = VC_0$) that as the capacitance increases, so does the charge, which in turn will give greater ion yield for the measured analyte ion intensities. However,

this phenomenon was not observed because the measured intensities of both analytes under regular MALDI conditions were higher than the intensities with the heat sink or under LDI conditions, emphasizing the importance of the heat transfer and energy transfer processes involved in MALDI.

An initial look into the analysis of the charge and photon excitation effects focuses on the space charge effect. The space charge effect is the consequence of the mutual repulsion (owing to Coulombic forces) between particles of similar charge and, in our case, mostly influences the nonconductive material. It is based on the principle that static electricity is generated by unbalancing the molecular construction of relatively nonconductive insulators, such as plastics and paper. If one considers that a static electric field is created on the nonconductive material from the laser pulse, then the similarly charged ion beam can be repulsed and consequently defocused.[65]

To assess if the target is still "in focus" one needs to calculate the beam waist of the laser beam (cf. Fig. S6). Beam waist is the location along the propagation direction where the beam radius has a minimum, which in theory is located at $x = 0$ and is normal to the substrate in MALDI experiments where the laser beam is ideally focused.

For Gaussian beams: the governing equations of a Gaussian beam are the e^{-2} radius $w(x)$ eq. [4] and the wave front curvature $R(x)$ eq. [5].

$$[4] \qquad w(x) = w_0^2\left[1 + \left(\frac{\lambda x}{\pi w_0^2}\right)^2\right]$$

$$[5] \qquad R(x) = x\left[1 + \left(\frac{\pi w_0^2}{\lambda x}\right)^2\right]$$

where λ is the laser wavelength, x is the distance from the source, w_0^2 is the radius of the beam waist at $x = 0$, and $2w_0$ is the beam waist. The beam waist at $x = 0$ (focal point) was calculated using eq. [6].

$$[6] \qquad 2w_0 = \left(\frac{4\lambda}{\pi}\right)\left(\frac{F}{D}\right)$$

where $F(S_2)$ is the focal length (4 cm) and D is the diameter of the beam illuminated on the lens (1 cm). Therefore, $2w_0 = 1.72$ μm. Equation [6] is valid only when the depth of focusing (DOF) is smaller than the focal length. DOF was calculated using eq. [7].

$$[7] \qquad \mathrm{DOF} = \left(\frac{8\lambda}{\pi}\right)\left(\frac{F}{D}\right)^2$$

Therefore, DOF = 13.7 μm.

It was observed that the beam waist is really small compared with the thickness of the layers; therefore, one may assume that the results are affected. However, in laser beam profile measurements carried out on a laser used in a MALDI-TOF (Kratos IV) mass spectrometer, it was shown that the laser beam of the LSI lasers is not Gaussian in profile. The beam was TEM_{mn} (transverse electromagnetic mode, where $m, n \neq 0$; Gaussian beams are TEM_{00}) shaped, which increases the beam waist significantly. From the indices, m refers to the number of intensity minima in the direction of the electric field oscillation and n refers to the number of minima in the direction of the magnetic field oscillation.[24] At $x = 0$, the beam waist is approximately equal to the diameter of the laser pulse, which is estimated to be 100 μm.

For a real beam, the concept of M^2, which is known as the propagation constant, is introduced to describe the relationship between a real beam and an ideal Gaussian beam. M^2 was calculated using eq. [8].[25]

$$[8] \qquad d = M^2\left(\frac{4\lambda}{\pi}\right)\left(\frac{F}{D}\right) \Leftrightarrow M^2$$

where d is the the diameter of the laser beam ($\approx$100 μm) or the real beam waist at $x = 0$. Therefore, $M^2 = 58.26$. The real beam waist (W_0) is given by eq. [9].

$$[9] \qquad 2W_0 = M^2 2w_0$$

Therefore, $2W_0 \approx 100$ μm. Now, eq. [4] becomes eq. [10] for a real beam.

$$[10] \qquad W(x) = W_0^2 + M^4\left(\frac{\lambda x}{\pi W_0}\right)^2$$

The comparison of $W(x)$ (eq. [10]) and $w(x)$ (eq. [4]) can be clearly seen (Figs. S7 and S8 in the Supplementary data). To evaluate the importance of these calculations, one must take into consideration the 45° angle of the laser beam to the target. The Gaussian beam waist is very narrow and can be easily defocused even with a small change in thickness to which the slides have been subjected (cf. Figs. S6–S8). The real beam waist for $x = 115$ μm presents a beam waist $W(x) = 104.05$ μm, which shows that the beam is slightly defocused but still within the beam waist; therefore, no significant result alteration should be expected.

The third control experiment (see the Sample preparation: summary section) utilized tape on the targets and a continuous layer of tape on targets that were analyzed under the same conditions. The results from both slides were similar. In theory, the slide with the continuous layer should present increasing electric field phenomena with the increase of the shots on the layer.[66] Furthermore, comparison of the results from the heat sink and the PVC tape on target slides shows that the analyte-to-noise ratio for PVC was higher than that of the silicon (Si) (cf. Figs. S4 and S5). Taking into account the thickness of each layer, one can see that the PVC layer is double in thickness. That should mean a higher space-to-charge ratio because the target comes closer to both the focal lens and the plate with the 20 kV potential (the potential difference increases when the same potential is applied in a smaller space). The experiments that took place prove that a significant charge-to-space ratio did not take place.

It is also necessary to evaluate the applicability of the proposition made in the Introduction that electron contribution by collisions with matrix molecules, after one- or two-photon excitation, completes the primary ionization process.[27] The calculation will take place for a nitrogen laser with photon energy 3.68 eV[25] and a matrix molecule with IP = 10 eV. Since 10 eV IP is considered to be high, and the nitrogen photon laser energy low, the calculations should

$(analyte/matrix)_{heatsink}$:$(analyte/matrix)_{paint}$ (III/II)			68.75
$(analyte/matrix)_{heatsink+paint}$:$(analyte/matrix)_{paint}$ (IV/II)			0.54

Note: D = protonated 2,5-dihydroxybenzoic acid (2,5-DHB, $[M + H]^+$, 155.4 Da, and dehydrated 2,5-DHB $[M - 18]^+$, 138.2 Da); T = protonated 2,3,6-tri-*O*-methyl-β-cyclodextrin (TMBCD, $[M + H]^+$, 1430.6 Da); H = heat sink compound (HSC; Dow Corning 097); P = conductive paint (Ag-based). Analysis of variance (ANOVA) indicates all comparisons were significant at the 95% confidence level and for the ad hoc Scheffé's test, except where indicated.

*Not significant.

Fig. 3. Representation of the "normalized" signal intensity of the protonated sodiated forms of trimethyl-β-cyclodextrin (TMBCD) under matrix-assisted laser desorption/ionization conditions (MALDI) without (TMBCD/Matrix–HSC) and with (TMBCD/Matrix+HSC) the heat sink compound (HSC). A minimum of 10 experiments were conducted, and the mean peak intensity with the corresponding standard deviation was calculated.

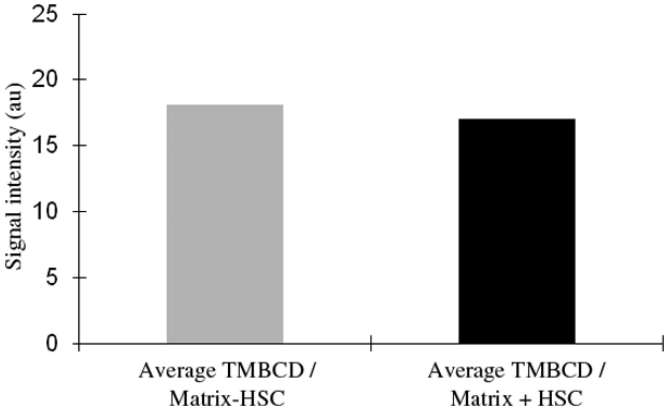

Fig. 4. Representation of the "normalized" signal intensity of the protonated forms of substance P ($C_{63}H_{98}N_{18}O_{13}S$, Sub P) under matrix-assisted laser desorption/ionization (MALDI) conditions without (Sub P/Matrix–HSC) and with (Sub P/Matrix+HSC) the heat sink compound (HSC). A minimum of 10 experiments were conducted, and the mean peak intensity with the corresponding standard deviation was calculated. The values were also calculated for the protonated sodiated forms, which were within 5% of the values determined for the protonated form. This observation is based on the fact that Sub P is predominately in the protonated form.

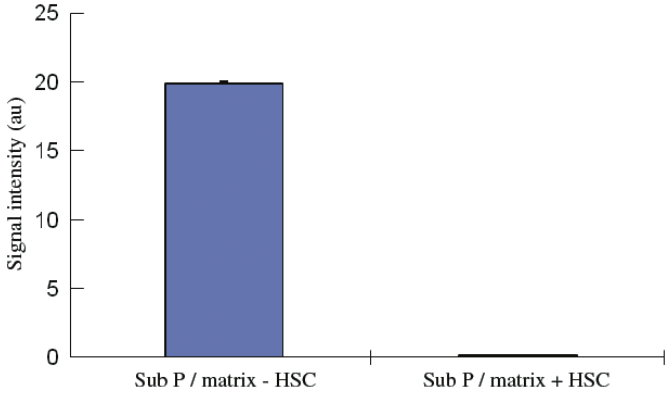

cover a large range of lasers and matrices.[67] The potential is considered to increase linearly with distance from the substrate until it reaches 20 kV. The distance between the plates is 5 mm, and the elementary charge of an electron is 1.6×10^{-19} C. To excite a matrix molecule, the additional required energy is 10 eV – 3.68 eV = 6.32 eV. Therefore, an electron needs to obtain an energy of at least 6.32 eV. The distance from the target surface that the electron must be to be located in the potential difference of 6.32 eV is given by eq. [11]

$$[11] \qquad \text{Distance} = \frac{H\text{NP}}{\text{FP}} = \frac{5 \times 6.3}{20} = 1.57$$

giving Distance = 1.57 μm, where H is the distance (in mm) between the plates, NP is the needed potential (in V) in calculated distance, and FP is the final potential (in kV) applied in distance H. But this begs the question as to whether or not the electron can be removed from the surface.[41,47,60,61] Between the positively charged metal targets, the electron-attracting Coulombic force exists. To overcome those forces, work must be consumed. The work needed is given by eq. [12].

$$[12] \qquad W = \text{NP}q$$

where W is the work required to remove the charge (q). This gives $W = 6.3\ \text{V} \times 1.6 \times 10^{-19}\ \text{C} = 1.08 \times 10^{-18}$ J.

In the case of the two-photon single electron excitation,[68] the same calculation employed with the previous case predicts the additional energy needed, 10 eV – 2×3.68 eV = 2.64 eV from eqs. [11] and 12, where the Distance = 0.59 μm and $W = 4.22 \times 10^{-19}$ J. Several other combinations could exist with one or two photons and one or more

For personal use only.

electrons. The work needed for the electrons to travel at this distance is negligible when compared with the rapid expansion of the plume from 200 m/s to ultrasonic velocities depending on the molecule (ion or neutral).[69] It can therefore be said that electrons can travel the distance required for contribution in the matrix excitation, which in turn would present a different threshold for analyte desorption or dissociation.[70]

Also, no delayed flight times were observed and the standard deviation[53] was within the range observed for samples under normal conditions, suggesting that the layers were not too thick or uneven to cause defocusing of the laser (data not shown). The defocusing process would be attributed to the short focal distance, which creates a shallow field depth. Therefore, if the target is not exactly positioned at the laser focal point, a decrease in peak intensity would be observed. In the follow-up experiment, TMBCD (T) was used as the analyte because it was shown (in this study) to possess a large desorption cross section relative to Sub P, which would also presumably be observed under IR MALDI conditions.[63] The ratio of the signal intensity to analyte intensity is shown in Table 4.

It can be seen by comparing the ratio of the analyte signal peak to the matrix signal peak that there is very little difference (7.50 vs 7.07 arb units, $P > 0.05$) in having metal slide – matrix – analyte (Table 4, group I) vs metal slide – conductive paint – matrix – analyte (Table 4, group II), where the paint acts as a second control (P + D + T). Comparing this with the system with the heat sink (Table 4, group III), we see a 37-fold (from approximately 7 to 260 arb units, $P < 0.05$) increase in the ratio of the analyte–matrix peak (Table 4, group III vs group II). Comparing this (Table 4, group II) to the composite system with the heat sink, followed by conducting paint coating (Table 4, group IV), we see a drop in the ratio to ~54% (3.82 vs 7.07 arb units, $P < 0.05$) of the initial group II value, indicating that the "charging and shielding" effect of the heat sink is not significant enough to account for the reductions in signal intensity observed for Sub P. The reductions seen for TMBCD are less than what is seen in this experiment, indicating that this is a maximum value. Therefore, the largest drop in peak intensity, which can account for the charging effect of the heat sink, is at best 54%.

Discussion

The heat sink could allow heat conduction from the metal surface of the slide to the MALDI matrix, but would not allow any charge conduction. Any excited matrix molecules formed at the heat sink – matrix interface would "experience" a lower extraction potential (set at +20 kV) than a system without the heat sink. This may lead to a lowering of the matrix peak intensity, although our calculations indicate any voltage drop is on the order of 100 V and the defocusing of the ion beam to be minimal at best. The difference in matrix peak intensities, therefore, cannot be accounted for entirely by the heat sink – matrix interactions alone, in that the thermal conductivities are too low in comparison with stainless steel. For TMBCD, no difference was observed (Fig. 3). We have determined that TMBCD can itself be minimally desorbed (Table 2, column C). Consequently, when TMBCD is the analyte the majority of the molecules undergo desorption partly by laser desorption and by MALDI processes, such as matrix sublimation,[19] pressure–pulse model,[23] or by soft expansion by secondary electrons.[38] The heat sink may interact with these secondary electrons,[41] thereby minimizing their influence in the MALD process[71] and leading to a lowering of peak signal intensity.

In the system where Sub P is the analyte, the contributions to MALD by matrix sublimation may not in itself be sufficient to cause all the molecules to desorb (Fig. 4). In this system, contributions from soft expansion by secondary electrons may also be required in the MALD processes to yield efficient desorption. When TMBCD is the analyte, matrix sublimation may be a MALD pathway, which in itself is sufficient to cause the majority of analyte molecules to desorb. However, when Sub P is the analyte, this pathway may be insufficient and an alternative pathway concurrent to, or consecutive to, matrix sublimation may be required to cause efficient desorption. The heat sink would interfere with this pathway and limit the efficiency of desorption compared with the system without the heat sink. If there is a contributory pathway via heat conduction from the metal slide in the Sub P system, it is insufficient to cause desorption.

In the experiment carried out to test this idea, it could be seen that the drop in signal intensity solely owing to shielding of the heat sink was 54%. That was based on comparing the analyte–matrix ratios of (P + D + T, or group II in Table 4) and comparing them with the corresponding system with the heat sink (H + P + D +T, or group IV in Table 4). If one were to look at total analyte (TMBCD) signal intensity, then the ratio ((H + P + D + T)/(P + D + T)) drops to 32.5%. The drop in signal intensity cannot be totally accounted for by heat-sink shielding, and the follow-up experiment would tend to support that observation. It is therefore more likely that the drop can be attributed to "blocking or short-circuiting" one of the MALD pathways. Recently, Allwood et al.[72] proposed that more than one mechanism may play an important part in the MALD process, both thermal and photoprocesses, which may have different contributions to the phenomenological event of MALD. If both matrix sublimation and soft expansion (the so-called "popcorn" model),[58] are processes that contribute to MALD, it can be seen that inhibiting one system may affect the desorption yield. In the TMBCD case, laser(s) desorption and matrix sublimation processes are sufficient to desorb the majority of the molecules. Additionally, the presence of the heat sink was observed to have a negligible effect on the desorption yield (Fig. 3). Sub P, which does not undergo laser desorption, shows a marked difference in the presence and absence of the heat sink (Fig. 4). It seems unlikely that metal–matrix heat conduction plays a major role because Sub P peak intensity varies according to the presence or absence of the heat sink and, as previously stated, the thermal conductivities of the heat sink are less than that of stainless steel (cf. Table S1 in the Supplementary data). It can also be assumed that the bulk of the laser energy is absorbed by the (<100) monolayers; therefore, is seems likely that direct interaction with the heat sink is minimal because of the two-dimensional nature of laser desorption.[20] Additionally, slow heat diffusion in solid organic samples,[73] owing to a mismatch

in the time scale in the sample heating desorption/ionization in MALDI, leads to minimal direct heat dissipation via conduction. On the contrary, the laser-induced conductive thermal heating depth is much greater than radiative absorption heating depth (defined as $1/a$, where a is the absorption cross section, which for pure silicon is $\sim 1 \times 10^6$ cm^{-1})[74] at the end of the laser pulse. The temperature difference can be estimated to be 142 K ($\Delta T_{surface} = \frac{2I}{K}\sqrt{\frac{\kappa t}{\pi}}$, where I is the laser irradiance that is determined from the measured fluence (F) and laser pulse time (ns); ($F/t \sim 15 \times 10^{-3}$ mJ/cm^2 / 3×10^{-9} s = 5 MW/cm^2) and K is the thermal conductivity (0.42 WK cm^{-1} (see Table S1), and κ is the thermal diffusivity = $K/C_p \sim 0.42/2 = 0.21$ cm^{-1}, where C_p is the specific heat capacity estimated to be 2 J/K/cm^3 for pure silicon).[75] The temperature is sufficient for the evaporation or decomposition of the physioabsorbed solvent molecules surrounding the analytes, leading to emission of preformed ions at a threshold temperature, which is easily within reach of the HSC relative to pure silicon.

Conclusion

In summary, there are strong indications that emissions of photoelectrons close to the surface enhance the ion yield and improves the reproducibility of the resulting spectra.[67] Photoelectrons could provide the additional energy to overcome the ionization potential of the matrix without significantly influencing the ion yield, since the attractive Coulombic forces (between substrate and photoelectrons) increase with a decrease in the distance and attract the electrons back to the surface. Even if the forces exerted by the expanding plume are higher than the attractive Coulombic force, the photon and photoelectron co-excitation of the matrix is not excluded.[25] Further enhancement of the photoemission phenomenon can be attributed to the topology of the heat sink layer. The uneven surface can lead to the creation of electron-holes that under certain conditions can lead to photoemission. This photoemission may also enhance the ionization process through the generation of radical species that have been observed in our and other studies. The uneven layering of the heat sink can aid in the recycling of new analyte species post-UV radiation, which has been observed under SALDI conditions.[76] Under SALDI-like conditions local charge separation at the surface could be increased. This charge separation could indicate desorption of preformed analyte ions (e.g., highly charged ions) by restricting ion-to-ion recombination in the early formation of the desorption plume. The charge separation on the uneven surface could be facilitated by the electric field of the laser pulse, (in tandem with local surface heating). The phenomena of local heating and charge separation has also been observed by surface-enhanced Raman spectroscopy for other surfaces[77] where the local electric field component can lead to ion emission.[78] Thermal diffusion, on the other hand, provides insufficient thermal contribution to the matrix–analyte system. Consequently, since the MALD process occurs only partially, a subsequent decrease in the ion yield is anticipated and in fact observed.[79] There is no indication that the thermal contribution directly influences the ionization.

The TMBCD ions can exist based on solution thermodynamics.[20] In the case of Sub P, ionization processes involving cluster ejection and breakdown result in a singly charged protonated peptide[80] in the selvedge region,[81] or in the gas-phase reactions with or without solvation[30]; however, some analytes in either the monomeric or multimeric form[45] may be analyzed via charge-transfer processes from the matrix.[40,82] It can be thought of as a multistep process, in which solvent evaporation is followed by ion desolvation and eventually ion desorption of the preformed ions. This is a phenomenon that has been observed for other surface desorption techniques.[83]

Another parameter to take into account is the substrate surface and its mechanical characteristics. The HSC facilitated thermal diffusion but may also have influenced the mechanical stress and pressure increase during desorption, since its semisolid state would absorb more stress than a solid target. This can also be supported by the differences in thermal conductivities (see Table S1 presented in the Supplementary data section for conductivity data), in that stainless steel and silver metal or alloy have higher values of thermal conductivity than the heat sink, but the ion yields are not decreased as would be expected, which indicates that even though thermal diffusion takes place there are other processes occurring that compensate for the decrease in thermal transfer to the sample. Another mechanism for ionization is cation attachment,[26] which is characterized by the carbohydrate that is preferentially sodiated. Under these conditions, the preformed ions may negate any analyte yield reduction[81] that may result from the interaction of the heat sink.

The present results for MALD from a regular metal surface and from a composite with an intervening heat sink material (allowing for electrical conductance but no heat transfer) indicates that the measured ion yield is highly analyte-dependant. When the analyte was a carbohydrate, the differences in measured ion yield for the sodiated species were similar, although greater yields were measured under regular MALDI-TOF conditions, strongly indicating that the ions were formed in solution (via a physioadsorbed solvent)[84] or were preformed in bulk solution prior to desorption.[85] Conversely, with Sub P a negligible ion yield was detected for the protonated peptide, indicating that the fraction of preformed ions was negligible and that the peptide absorbed on the surface as a neutral species with subsequent protonation either at the surface or in the gas phase with a solvating environment. The solvating medium can possibly be described as highly charged state clusters in which ion desorption is assisted via local charge pair separation, desolvation, and laser-induced heating that is assisted by localized electric fields promoted by some intrinsic proton source (e.g., acid, either from the matrix species, the acidic side group, or the free acid). This ion separation would be aided by electron emission from the lower surfaces, or "active sites", in which the analyte is turned over and exposes a fresh analyte between laser pulses. A side indicator would be the population of the radical cation of the matrix [M$^{\bullet+}$], which was observed (under MALDI-TOF and FTICR conditions, data not shown, although no radical analyte was observed under the current conditions of the experiment. Other instrument parameters were investigated to determine whether the measured differences in the ion yields were dependent upon instrumental effects. It was shown that the effect of voltage drop, beam width, or surface profile (affecting the kinetic

energy spread) were not adequately significant to account for the differences. In addition, many of the differences observed with the peptide could be mitigated by the addition of electron capture agents (lowering ion intensities) or silver (increasing ion intensities) indicating that the affect of the heat sink was to decouple the desorption and ionization events under MALDI-TOF conditions. For optimal ion yields, an acidic environment, an uneven surface, and localized heating are the necessary prerequisites.

Supplementary data

Abstract: Phytochemical investigation of *Garcinia prainiana*'s leaves led to the isolation of prainianonide (**1**), a new flavanone glucuronide, together with six known compounds: (2*S*)-eriodictyol 7-*O*-β-D-glucuronide (**2**), naringenin 7-*O*-β-D-glucuronide (**3**), (–)-GB-1a (**4**), (+)-morelloflavone (**5**), amenthoflavone (**6**), and friedelin (**7**). Their structures were elucidated by spectroscopic methods. The absolute configuration of **1** was determined by circular dichroism spectroscopy. Compounds **4** and **5** showed significant antioxidant activity.

Key words: Garcinia prainiana, Guttiferae, flavanone glucuronide, biflavonoid, antioxidant.

Résumé : Une étude phytochimique des feuilles de *Garcinia prainiana* a permis d'isoler le prainianonide (**1**), un nouveau glucuronide de flavanone ainsi que six nouveaux composés : le 7-*O*-β-D-glucuronide du (2*S*)-ériodictyol (**2**), le 7-*O*-β-D-glucuronide du de la naringénine (**3**), le (–)-GB-1a (**4**), la (+)-morelloflavone (**5**), l'amenthoflavone (**6**) et la friedéline (**7**). Leurs structures ont été élucidées par des méthodes spectroscopiques. La configuration absolue du composé **1** a été déterminée par spectroscopie de dichroïsme circulaire. Les composés **4** et **5** présentent une activité antioxydante significative.

Mots-clés : Garcinia prainiana, Guttiferae, glucuronide de flavanone, biflavonoïde, antioxydant.

[Traduit par la Rédaction]

Introduction

Plants in the genus *Garcinia* are known to be a rich source of bioactive compounds such as xanthones,[1–3] biflavonoids,[4,5] benzophenones,[5] benzoquinones,[6] and triterpenes.[7,8] Some of them have shown a wide range of biological activities including antibacterial,[1,6] antifungal,[9] antioxidant,[3,10] and cytotoxic[5,11] effects. In our ongoing effort to search for biologically active substances from *Garcinia* plants, we found that the crude methanol extract from the leaves of *G. prainiana* showed significant antioxidant activity. *Garcinia prainiana*, locally named Chu-pu, is distributed in the southern part of Thailand. This plant is a small tree with a berrylike fruit. Its ripe fruits are edible and used for lowering blood pressure.[12] In this paper, we describe the isolation and structural elucidation of one new flavanone glucuronide together with six known compounds and their antioxidant activity.

Results and discussion

The crude methanol extract from the leaves of *G. prainiana* was subjected to chromatographic techniques to yield one new flavanone glucuronide, prainianonide (**1**), as well as two known flavanone glucuronides, (2*S*)-eriodictyol 7-*O*-β-D-glucuronide (**2**)[13] and naringenin 7-*O*-β-D-glucuronide (**3**),[14] three biflavonoids, (–)-GB-1a (**4**),[15] (+)-morelloflavone (**5**),[16] and amenthoflavone (**6**),[17] and friedelin (**7**) (Chart 1).[18] The structure of **1** was determined by analysis of one- and two-dimensional NMR spectroscopic data, while the known compounds were identified by comparison of the NMR data, especially ^{1}H and ^{13}C NMR data, with previously reported data (see Supplementary data). The absolute configurations of **1** and **2** were assigned by circular dichroism (CD) spectroscopy. This is the first report on the isolation of a flavanone glucuronide from the genus *Garcinia*.

Prainianonide (**1**) was isolated as a pale yellow gum. Its molecular formula, $C_{22}H_{22}O_{11}$, was deduced by high-resolution electron impact mass spectrometry (HR-EI-MS) (*m*/*z* 462.1144 $[M]^+$ (calcd. 462.1162)). The UV spectrum showed characteristic absorption bands of a flavanone chromophore at 283 and 337 nm.[19] The IR spectrum showed absorption bands for a hydroxyl group (3422 cm^{-1}), an ester carbonyl group (1716 cm^{-1}), and a flavanone carbonyl group (1644 cm^{-1}). The ^{1}H NMR spectrum (Table 1) displayed AA′BB′ signals at δ 7.33 and 6.82 (2H each, d, J = 8.4 Hz), two meta-coupled signals at δ 6.16 and 6.17 (1H each, brs), an oxymethine proton signal at δ 5.39 (1H, dd, J = 13.2, 2.7 Hz), and methylene proton signals at δ 3.18 (1H, dd, J = 17.1, 13.2 Hz) and 2.75 (1H, dd, J = 17.1, 2.4 Hz). These data indicated that **1** had a 4′,5,7-trihydroxyflavanone

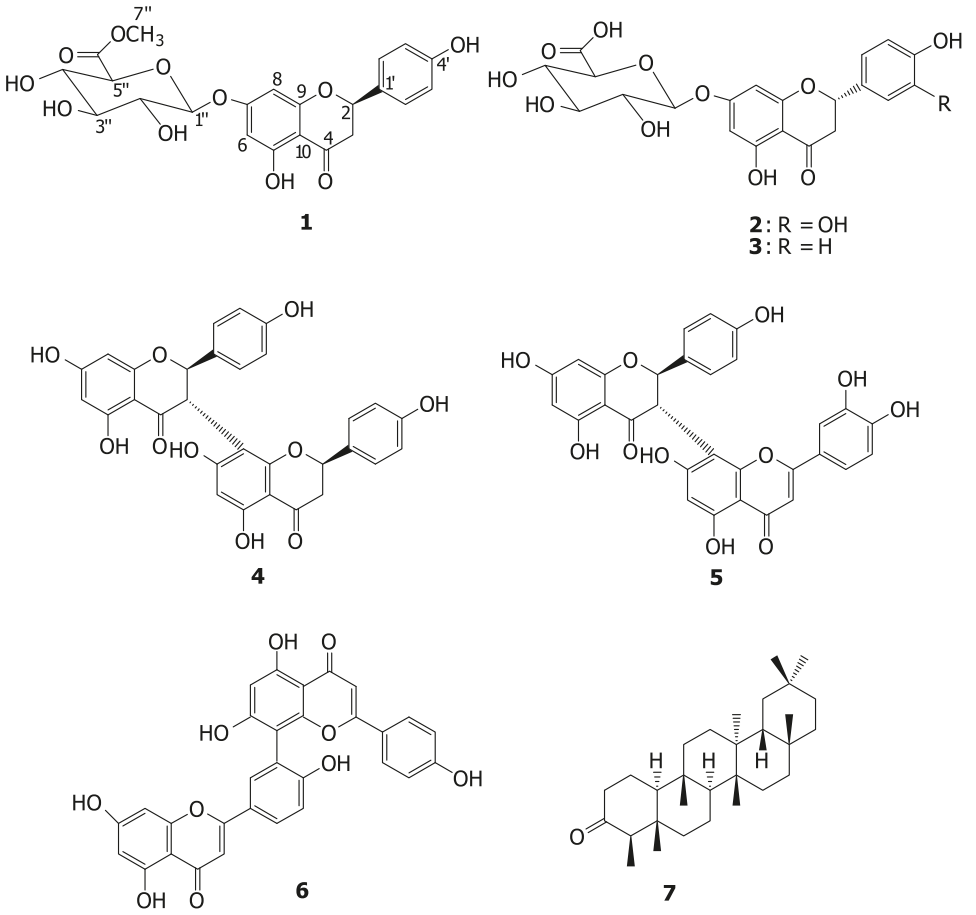
Chart 1.



skeleton.[20] In addition, the ^{1}H NMR data (Table 1) showed signals of a sugar unit (δ 5.07 (1H, d, J = 7.2 Hz), 4.09 (1H, d, J = 9.6 Hz), 3.60 (1H, t, J = 9.6 Hz), 3.49 (1H, dd, J = 9.6, 7.2 Hz), 3.47 (1H, t, J = 9.6 Hz)) and a methoxyl signal at δ 3.76 (3H, s). The ^{13}C NMR spectrum (Table 1) showed the presence of one ester carbonyl carbon (δ 169.4). A heteronuclear multiple bond correlation (HMBC) between the methoxy protons (δ 3.76) and the ester carbonyl carbon (δ 169.4) indicated the presence of a methyl ester group. This methyl ester group was connected to C-5″ (δ 75.2) of a sugar moiety, which was determined by HMBC of H-5″ (δ 4.09) / C-6″ (δ 169.4). From these results, the sugar moiety was identified as a methyl ester of glucuronic acid.[13] The anomeric proton of the glucuronic acid at δ 5.07 with a large coupling constant of 7.2 Hz implied that this unit must have a β-glucuronide form.[13] Irradiation of H-5″ affected signal intensities of both H-1″ (δ 5.07) and H-3″ (δ 3.47), supporting the assigned stereochemistry of the glucuronide unit. A cross peak in the HMBC spectrum between H-1″ of the glucuronide unit and C-7 (δ 165.1) of the flavanone skeleton indicated the attachment of the glucuronide unit to the 7-hydroxyl group of the flavanone moiety. The absolute configuration of **1** was assigned by CD spectroscopy. Its CD spectrum showed positive Cotton effects (249 (Δε –5.84), 290 (Δε +2.35) nm), indicating that the absolute configuration of the 2-position is an *R* orientation, which was supported by comparison with positive (252 (Δε –1.00), 292 (Δε +3.66) nm) and negative Cotton effects (250

(Δε +1.43), 293 (Δε –3.48) nm) of (2*R*)-eriodictyol 7-*O*-β-D-glucuronide and (2*S*)-eriodictyol 7-*O*-β-D-glucuronide (**2**), respectively.[13] Therefore, **1** was characterized as (2*R*)-4,5-dihydroxyflavanone 7-*O*-β-glucuronide methyl ester, a new flavanone glucuronide.

Compounds **1**–**6** were examined for their antioxidant activity against DPPH (diphenylpicrylhydrazyl) radicals, while compound **7** was not tested owing to the lack of phenolic moiety. Compounds **4** and **5** showed higher radical scavenging potency than the standard (butylated hydroxyanisole), with IC_{50} values (concentration required to reduce DPPH radicals by 50%) of 148 and 72 μmol/L, respectively (Table 2). Compound **2** was much less active, with an IC_{50} value of 841 μmol/L. The radical trapping potency of morelloflavone (**5**), which was twofold higher than that of GB-1a (**4**), was mainly due to the presence of *ortho*-dihydroxy groups in its B ring, a structural feature required for effective radical scavenging.[21] Compound **5**, however, has been shown to be a potent antioxidant in various studies.[22,23] In comparison with the biflavonoids (**4** and **5**), the flavanone glucuronide (**2**) seemed to be a poor scavenger. As the 5,7-dihydroxy moiety in the A ring is known to have a strong influence on the total antioxidant activity of flavonoids,[21] thus blocking the 7-position by glycosylation and containing only a single hydroxyl substituent at position 5 in the A ring, compound **2** became an ineffective hydrogen donor in this chemical arrangement.

Table 2. Antioxidant activity of compounds **1**–**6**.

Experimental

General

The infrared (IR) spectra were recorded neat using a PerkinElmer 783 FTS165 FTIR spectrometer. The ultraviolet (UV) absorption spectra were measured on a SHIMADZU UV-160A spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a 300 MHz Bruker FTNMR Ultra Shield spectrometer in deuterochloroform solution with tetramethylsilane as an internal standard. The EI and HR-EI mass spectra were obtained on a MAT 95 XL mass spectrometer (Thermofinnigan). Optical rotation was measured on a JASCO P-1020 polarimeter. CD spectra were recorded on a JASCO J-810 spectropolarimeter. Thin-layer chromatography was performed on silica gel 60 GF_{254} (Merck). Column chromatography (CC) was carried out on Sephadex LH-20, silica gel (Merck) type 60 (230–400 mesh ASTM) or type 100 (70–230 mesh ASTM), or reverse phase C-18 silica gel. Light petroleum had a bp of 40–60 °C.

Plant material

The leaves of *G. prainiana* were collected in Narathiwat Province, Thailand. The voucher specimens (K.Maneenoon2010-001-003) were deposited in the Herbarium at the Department of Biology, Faculty of Science, Prince of Songkla University, Hat Yai, Songkhla, Thailand.

Extraction and isolation

The leaves of *G. prainiana* (0.80 kg), cut into small segments, were extracted with MeOH three times over a period of 7 days at room temperature. After filtration, the filtrate was evaporated to dryness under reduced pressure to give a crude methanol extract as a dark brown gum (56.2 g). The resulting residue was subjected to CC over Sephadex LH-20 with MeOH to afford four fractions (G1–G4). Fraction G3 (1.01 g) was dissolved with CH_2Cl_2 to provide soluble (G3D) and insoluble (G3N) fractions. Fraction G3D (399.6 mg) was subjected to CC over silica gel with a gradient of CH_2Cl_2/petroleum ether (1:1) to provide **7** (73.4 mg). Fraction G4 (2.7 g) was subjected to CC over reverse phase silica gel with a gradient of MeOH/H_2O (1:1) to provide five subfractions (G4A–G4E). Subfraction G4A (260.2 mg) was chromatographed using CC over reverse phase silica gel with a gradient of MeOH/H_2O (1:4) to produce **2** (14.1 mg). Subfraction G4B (31.2 mg) was separated by CC over reverse phase silica gel with a gradient of MeOH/H_2O (2:3) to provide four subfractions (G4B1–G4B4). Subfraction G4B1 (15.6 mg) was further subjected to CC over reverse phase silica gel with a gradient of MeOH/H_2O (1:4) to provide **3** (4.3 mg). Subfractions G4B3 (25.9 mg) and G4B4 (34.7 mg) were chromatographed using CC over Sephadex LH-20 with MeOH/CH_2Cl_2 to produce **1** (3.9 mg) and **4** (8.7 mg), respectively. Subfraction G4D (69.5 mg) was purified by CC over reverse phase silica gel with a gradient of MeOH/H_2O (6:4) to afford **5** (25.3 mg). Subfraction G4E (67.1 mg) was subjected to CC over reverse phase silica gel with a gradient of MeOH/H_2O (6:4) followed by CC over Sephadex LH-20 using MeOH/CH_2Cl_2 to produce **6** (4.0 mg).

Prainianonide (1)

Pale yellow gum. $[\alpha]_D^{26}$ –26.0° (*c* 0.20, MeOH). UV (MeOH) (nm, log ε): 337 (2.14), 283 (3.63), 224 (3.81). FTIR (neat, cm^{-1}): 3422, 1716, 1644. CD (MeOH) (nm, Δε): 249 (–5.84), 290 (+2.35). ^1H NMR (300 MHz, CD_3OD) and ^{13}C NMR (75 MHz, CD_3OD) data: see Table 1. EI-MS *m*/*z*: 462 $[M]^+$ (3), 272 (100), 254 (7), 179 (27), 166 (36), 153 (86), 120 (57), 107 (23). HR-EI-MS *m*/*z*: 462.1144 $[M]^+$ (calcd. for $C_{22}H_{22}O_{11}$: 462.1162).

Determination of antioxidant activity

DPPH radical scavenging assay

The DPPH radical scavenging assay was carried out in triplicate, based on the method used by Hutadilok-Towatana et al.[24] BHA (butylated hydroxyanisole), a positive control, gave an IC_{50} value of 167 μmol/L. The DPPH radical scav-

enging ability was calculated based on the concentration of sample required to reduce DPPH radicals by 50% (IC_{50}).

Supplementary data

Supplementary data are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: The present work reports the efficient synthesis of oligonucleotides bearing metallacarborane complexes containing iron (3,3′-iron-1,2,1′,2′-dicarbollide) on a solid support via the H-phosphonate method. This versatile methodology can be applied to the synthesis of DNA oligomers bearing various metallacarborane units.

Key words: metallacarborane, oligonucleotide, modified oligonucleotide, H-phosphonate chemistry.

Résumé : Dans ce travail, on rapporte la synthèse efficace d'oligonucléotides portant des métallacarboranes contenant du fer (3,3′-fer-1,2,1′2′-dicarbollide) sur un support solide en faisant appel à la méthode du H-phosphonate. Cette méthodologie versatile peut être appliquée à la synthèse d'oligomères de l'ADN portant diverses unités métallacarboranes.

Mots-clés : métallacarborane, oligonucléotide, oligonucléotide modifié, chimie du H-phosphonate.

[Traduit par la Rédaction]

Introduction

Metal- and metalloid-containing nucleic acids exhibit a wide range of biological and physicochemical activities, some of which have been employed in molecular medicine, diagnostics, and technology, providing a variety of advantages. The applications of metal-labelled nucleic acids include electrochemically detectable probes, fluorescent probes, artificial "chemical nucleases", probes for DNA-mediated electron transfer, and "molecular wires" in bioelectrochemical devices.[1,2] Among several types of nucleic acid modifications with metals, two general classes can be distinguished. In the first class, metal ions form a complex directly with DNA; in the second class, the metal is attached to the DNA as part of a metal carrier, usually a metal complex or a metallo-organic substituent.[2]

We have focused on the second class of metal-containing DNAs, using metallacarboranes as the metal carriers. Metallacarboranes are a family of metallocene-type complexes consisting of at least one carborane cage and one or more metal atoms. Carborane clusters are versatile and efficient ligands for metals such as Co, Fe, Ni, Cr, Mn, Re, Au, Cu, Ir, and Pt and can be used to incorporate a wide variety of other metals with different properties into nucleic acids, nucleic acid components, and other biomolecules.[3,4]

The rationale for this study of the synthesis of DNA oligomers labelled with a metal complex bearing iron was the potential use of this type of modification as redox-active probes for electrochemical DNA detection and the central component of DNA biosensors. The number of metal complexes tested for this purpose is limited, with the best-known example being ferrocene, a metallocene-type complex.[5,6] The only other examples of a nucleoside–metallocene conjugate reported so far are nucleoside–metallacarborane modifications.[2] In the present work, a metallacarborane label containing iron was selected because of its analogy to ferrocene and because of the favorable electrochemical characteristics of iron. The study of metallacarborane redox labels bearing other metals is ongoing in our laboratory.

Results and discussion

A modified nucleoside derivative of 2′-deoxyadenosine was used as a monomer. 5′-*O*-Dimethoxytrityl-6-*N*-{5-[(3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl]-3-oxa-pentoxy}-2′-deoxyadenosine (**6**) was obtained as described (Scheme 1).[7]

Briefly, the 5′- and 3′-hydroxyl groups of 2′-deoxyadenosine (**1**) were protected. For that purpose, *tert*-butyldimethylsilyl (TBDMS) protection was used for both hydroxyl groups, providing 3′,5′-*O*,*O*-di(*tert*-butyldimethylsilyl)-2′-deoxyadenosine (**2**).[8] In the second step, **2** was activated with a 2.5-fold molar excess of sodium hydride and then treated with a 1.5-fold molar excess of the 8-dioxane-(3,3′-iron-1,2,1′,2′-dicarbollide) adduct [8-O(CH_2CH_2)$_2$O-1,2-$C_2B_9H_{10}$-3,3′-Fe-1′,2′-$C_2B_9H_{11}$] (**3**).[7,9] Compound **3**[10] can be easily prepared from 3,3′-iron-1,2,1′,2′-dicarbollide[11] and dioxane. In the third step, the TBDMS protective groups in **4** were removed with tetrabutylammonium fluoride (TBAF), providing the metallacarborane–nucleoside conjugate 6-*N*-{5-[(3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl]-3-oxa-pentoxy}-2′-deoxyadenosine (^{BEFeC}A, **5**). Finally, the 5′-hydroxyl group in **5** was protected with a dimethoxytrityl group (DMT) under standard conditions,[12] yielding 5′-*O*-dimethoxytrityl 6-*N*-{5-

[(3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl]-3-oxa-pentoxy}-2′-deoxyadenosine (**6**).

A sequence complementary to a fragment of the UL55 gene of human cytomegalovirus was selected as a model oligonucleotide. The modified oligomer containing the 3,3′-iron-1,2,1′,2′-dicarbollide at the 5′ end, ^{BEFeC}ACGAGTCTTCGGCTCCGGA-3′, was prepared by solid-phase synthesis (Scheme 2).

The unmodified part of the oligonucleotide was synthesized using phosphoramidite chemistry, a β-cyanoethyl cycle,[13] and an automated DNA synthesizer. A manual step and H-phosphonate chemistry were used to add the modified monomer bearing the (3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl group.[7,14] Phosphoramidite chemistry was originally designed for the incorporation of conjugate **5** into an oligonucleotide according to the methodology developed by us for the analogous modification with cobalt.[15] Unfortunately, the phosphitylation of **6** with (β-cyanoethoxy)(*N*,*N*-diisopropylamino)chlorophosphine under standard conditions proved to be more challenging than expected and the reaction produced several unidentified phosphorus-containing products. Therefore, H-phosphonate chemistry, which has been used previously for the solution-phase synthesis of metallacarborane-containing dinucleotides,[7] was employed.

The key intermediate, 5′-*O*-dimethoxytrityl 6-*N*-{5-[(3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl]-3-oxa-pentoxy}-2′-deoxyadenosine 3′-*O*-(H-phosphonate) (**7**), was obtained using the PCl_3–triazole method.[16] After cooling a solution of imidazole, triethylamine, and phosphorus trichloride in methylene chloride to –40 °C, a solution of **6** in the same solvent was added. After the reaction was complete, a solution of triethylammonium bicarbonate (TEAB) buffer was added, and the mixture was allowed to warm to room temperature. After a standard work-up, the product was isolated by silica gel column chromatography.

The modified oligonucleotide **8** was prepared as follows. After completion of the synthesis of the unmodified part of the oligonucleotide, the column was detached from the DNA synthesizer and the oligomer was manually detritylated.

H-phosphonate-modified **7** was dissolved in a mixture of anhydrous pyridine–acetonitrile, activated with pivaloyl chloride (PvCl), and then applied to the column. The coupling step was repeated three times, and each coupling reaction was performed for 10 min. Owing to the limited stability of **7** bearing the 3,3′-iron-1,2,1′,2′-dicarbollide modification in the presence of the PvCl present in the solution containing pyridine, a fresh solution of the activated monomer was prepared for each subsequent coupling reaction. The final oxidation step was performed using an oxidizing solution containing 10% H_2O in CCl_4, triethylamine, and *N*-methylimidazole.[14] Cleavage of the completed oligomer from the support was performed according to the standard procedure. The deprotection with 30% aqueous ammonia solution was shortened to 2 h at 50 °C without any adverse effect on the deprotection efficacy. Deprotected metalated oligonucleotide **8** was characterized by reverse-phase HPLC

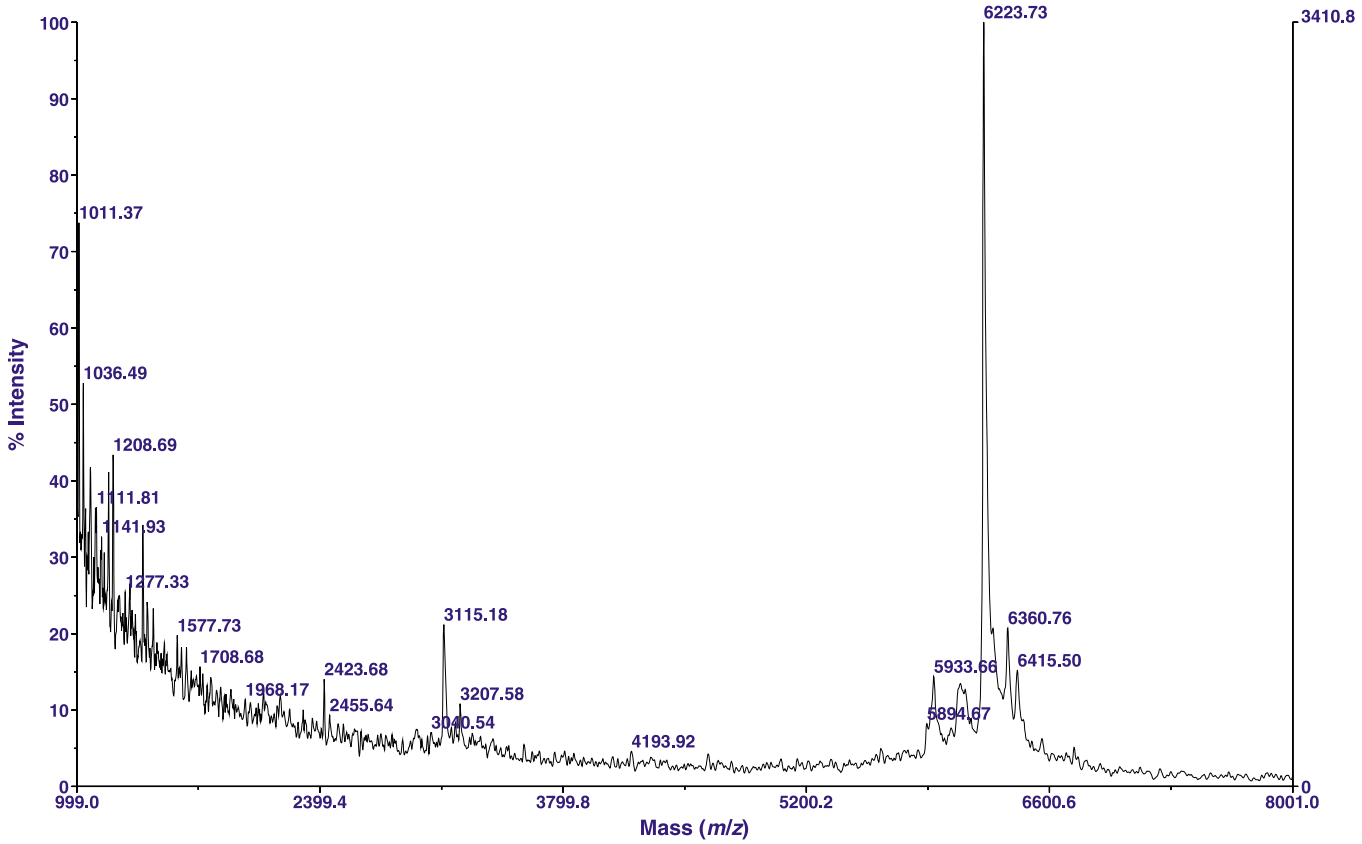
Fig. 1. MALDI-TOF for modified oligonucleotide **8** bearing a metallacarborane group.



(RP-HPLC), MALDI-TOF (Fig. 1), and UV spectrophotometry.

Because of the presence of the amphiphilic metallacarborane group, oligonucleotide **8** showed highly increased lipophilicity as measured by the retention time on the RP-HPLC column. The usefulness and diagnostic value of UV spectra in the case of nucleoside conjugates bearing metallacarboranes should be noted. UV detection during HPLC analysis can be conducted at λ = 268 nm (for oligonucleotides) and at λ = 310 nm, the characteristic wavelength for the metallacarborane modification.

Enzymatic digestion of oligomer **8** with snake venom phosphodiesterase (CVPD) was performed. RP-HPLC analysis of the digestion products showed the presence of unmodified nucleosides at the expected ratio and modified nucleoside **5** (Fig. 2).

The purity of oligomer **8** was confirmed additionally by electrophoresis using 20% polyacrylamide gel containing 7 mol/L urea (PAGE) (Fig. 3). The PAGE analysis showed the expected diagnostic spot corresponding to the modified oligonucleotide **8**.

In summary, we have developed a new type of modified oligonucleotide bearing a metallacarborane complex containing iron. The usefulness of the H-phosphonate method for the synthesis of DNA oligomers bearing metallacarborane modifications on a solid support was shown. Enzymatic digestion of the modified oligonucleotide **8** fully confirmed the expected nucleoside composition and presence of the metallacarborane modification. This study expands the available range of metallacarborane-modified oligonucleotides and opens the way for further design and use of novel biopharmaceuticals and molecular probes bearing metallacarborane complexes.

Experimental section

2′-*O*-Deoxyadenosine was purchased from Pharma Waldhof GmbH. *tert*-Butyldimethylsilyl chloride was obtained from ABCR GmbH & Co. KG, 1 mol/L tetrabutylammonium fluoride solution in THF was from Sigma-Aldrich (Steinheim, Germany), and dimethoxytrityl chloride was from Avocado Research Chemicals. Imidazole was purchased from Merck, phosphorus trichloride was from Sigma-Aldrich, and pivaloyl chloride was from Fluka Chemie AG. Crude dried venom from *Crotalus atrox* (EC 3.1.4.1) was purchased from Sigma-Aldrich. Column chromatography was performed on 230–400-mesh silica gel obtained from Sigma-Aldrich. A reverse-phase Econosil C18 column (5 µm, 4.6 mm × 250 mm) was obtained from Alltech Associates, Inc. Thin-layer chromatography was performed on silica gel F254 plates purchased from Sigma-Aldrich. All solvents were of the highest available quality. CPG (500 Å pore size) 0.2 µmol columns loaded with the DMT-on, base-protected, unmodified oligonucleotide 5′-CGAGTCTTCGGCTCCGGA-3′ were obtained from Genomed. Acrylamide and urea were purchased from Serva (Heidelberg, Germany).

Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra were obtained on a Voyager-Elite mass spectrometer (PerSeptive Biosystems, Framing-

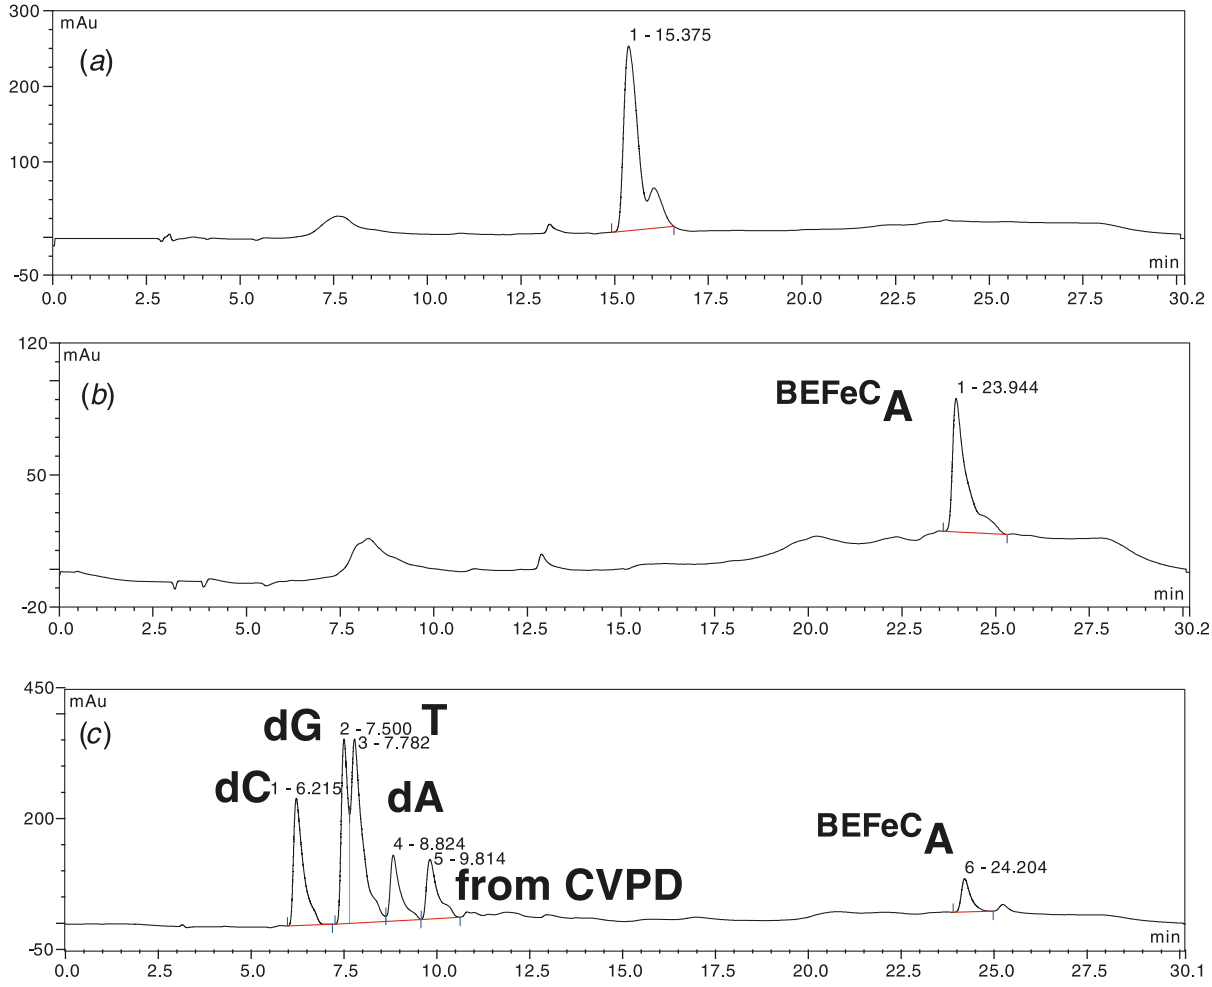
Fig. 2. Enzymatic digestion (CVPD) of oligonucleotide 5′-^{BEFeC}ACGAGTCTTCGGCTCCGGA-3′ (**8**): (*a*) oligonucleotide **8**, (*b*) 6-*N*-{5-[(3,3′-iron-1,2,1′,2′-dicarbollide)-8-yl]-3-oxa-pentoxy}-2′-deoxyadenosine (**5**) (^{BEFeC}A), (*c*) products of oligonucleotide **8** digestion.



ham, Massachusetts, USA). The ratio of 3-hydroxypicolinic acid to diammonium citrate was 8:1. The masses are those of the negative ions.

UV spectroscopy measurements were performed on a GBC Cintra 10 UV–vis spectrometer (Dandenong, Australia). Samples were dissolved in purified deionized water. The measurements were performed at ambient temperature.

RP-HPLC analysis and purification were performed using a Hewlett-Packard 1050 system equipped with a UV detector and an Alltech Econosil C18 column (5 μm, 4.6 mm × 250 mm). UV detection was conducted at λ = 268 nm and λ = 310 nm. The flow rate was 1 mL/min. All analyses were performed at ambient temperature.

Polyacrylamide gel electrophoresis was performed using a Sigma-Aldrich apparatus for vertical electrophoresis. Stains-All staining dye for slab gels was purchased from Sigma-Aldrich.

Synthesis of the nonadecanucleotide ^{BEFeC}ACGAGTCTTCGGCTCCGGA-3′ bearing a (3,3′-iron-1,2,1′,2′-dicarbollide) modification

The unmodified part of the oligonucleotide was synthesized using an ABI 3900 DNA synthesizer. A column loaded with controlled pore glass functionalized with 5′-*O*-dimethoxytrityl-6*N*-benzoyl-2′-deoxyadenosine (0.2 μmol) was used as the solid support. Elongation of the oligomer was performed using a standard 0.2 μmol-scale β-cyanoethyl DNA synthesis cycle without changing the condensation time. The coupling of the modified monomer **7** using H-phosphonate chemistry and the oxidation step were performed manually. After completion of the synthesis of the unmodified part of the oligonucleotide, the column was detached from the DNA synthesizer. The oligomer was next detritylated manually with 3% dichloroacetic acid (DCA) in dichloromethane (2 × 5 mL). The column was then washed with dichloromethane (10 mL) followed by pyridine–acetonitrile (1:3 *v*/*v*, 4 mL) and was dried using an argon stream (10 min). Monomer **7** (5 mg) (0.005 mmol) was co-evaporated twice with anhydrous pyridine under reduced pressure. Next, **7** was dissolved in a mixture of anhydrous pyridine–acetonitrile (1:3 *v*/*v*, 40 μL), to which was added PvCl (1.8 μL) in pyridine–acetonitrile (1:3 *v*/*v*, 40 μL). A solution of activated **7** was applied to the column, and the coupling reaction was allowed to proceed for 10 min. The coupling step was repeated three times, each time with a freshly prepared solution of activated **7**. The column was then washed with pyridine–acetonitrile (1:3 *v*/*v*, 4 mL) and dried with a stream of argon. The oxidation step was performed using an oxidizing solution containing

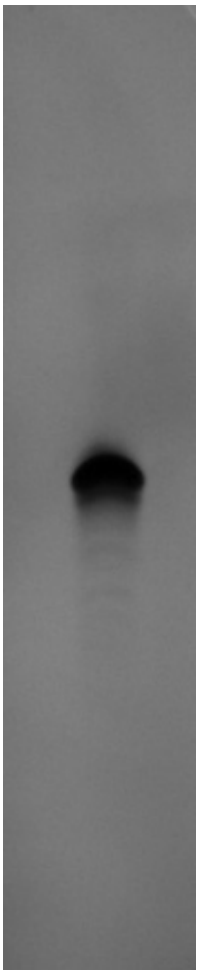
Fig. 3. PAGE analysis of modified oligonucleotide **8**; 20% polyacrylamide denaturing gel containing 7 mol/L urea. The oligonucleotide sample was visualized by staining with Stains-All.



10% H_2O in CCl_4, triethylamine, and *N*-methylimidazole (9.0:0.5:0.5) for 35 min. The column was washed with pyridine–acetonitrile (1:3 *v*/*v*, 4 mL) and dried with a stream of argon. The oligonucleotide was then cleaved from the support with 30% aqueous ammonia (1 mL) at ambient temperature for 1 h. The deprotection of the bases was achieved by incubation of the oligonucleotide solution at 50 °C for 2 h. The solution of base-deprotected, DMT-on oligonucleotide was degassed with a stream of argon, evaporated to dryness under vacuum, and then redissolved in water, yielding crude product with an optical density of 23.5 units (ODU) at 260 nm. The crude DMT-on oligomer was purified by RP-HPLC. For each run, 5 ODU of the DMT-on oligonucleotide was used. The following conditions were used for the RP-HPLC purification of the DMT-on oligonucleotide: 0 min 100% A, 20 min from 0% D to 100% D, 5 min 100% D, and 5 min from 100% D to 0% D. Buffer A contained 0.1 mol/L TEAB (triethylammonium bicarbonate) (pH 7.0) in a mixture of acetonitrile and water (2:98, *v*/*v*), and buffer D contained 0.1 mol/L TEAB (pH 7.0) in a mixture of acetonitrile and water (40:60, *v*/*v*). The flow rate was 1 mL/min. UV detection was conducted at λ = 268 nm. The fractions containing the desired product were collected, and the buffer was evaporated under vacuum. The residue was co-evaporated with 95% ethanol to remove the TEAB, and then detritylation was performed using 80% acetic acid (1 mL) at ambient temperature for 20 min, yielding crude **8**. Next, the acetic acid solution was evaporated to dryness under vacuum, and the completely deprotected **8** was purified by RP-HPLC. The same HPLC conditions as described above for the DMT-on oligomer were used for the purification and analysis of the completely deprotected oligonucleotide **8**. The fractions containing the desired product were collected, and the buffer was evaporated under vacuum. The residue was co-evaporated with 95% ethanol to remove the buffer. The oligonucleotide was redissolved in water and lyophilised. Yield: 10.2 ODU (A_{260}). UV (H_2O) λ_{min}: 235 nm; λ_{max}: 264 nm. RP-HPLC Rt: 15.4 min. MALDI-TOF MS *m/z* (%): 6223.73 [M+12] (100%); calcd. for $C_{192}H_{261}B_{18}FeN_{71}O_{115}P_{18}$: 6211.32 (100%).

Enzymatic digestion of 8 with snake venom phosphodiesterase

Tris–HCl buffer (100 mmol/L containing $MgCl_2$ (20 mmol/L)) was added to an aqueous solution of oligonucleotide **8** (0.75 ODU, 40.5 μL). The resulting solution was treated with 1.9×10^{-2} units (15 μL) of phosphodiesterase (crude dried venom from *Crotalus atrox* dissolved in water) and incubated at 38 °C. After 10 and 20 min, aliquots were withdrawn, heated at 80 °C, and then stored at –70 °C prior to analysis by RP-HPLC.

PAGE analysis

The sample of modified oligonucleotide **8** (0.2 ODU in 7 μL formamide containing bromophenol blue and xylene cyanol) was analyzed by electrophoresis using 20% polyacrylamide denaturing gel containing urea (7 mol/L) for 5 h at 500 V. The sample was visualized by staining with Stains-All.

Abstract: An efficient, experimentally simple, and convenient procedure for the C–O coupling of organic halides with phenols and alcohols in a PEG_{1000}-DAIL[$CdCl_3$]–toluene temperature-dependent biphasic system has been developed. The product can be easily isolated by a simple decantation, and the catalytic system can be recycled and reused without loss of catalytic activity.

Key words: C–O coupling, organic halide, ionic liquid, thermoregulated ionic liquid biphasic system.

Résumé : On a mis au point une méthode commode, efficace et expérimentalement simple de faire un couplage C–O d'halogénures organiques avec des phénols et des alcools dans un système biophysique PEG_{1000}-DAIL[$CdCl_3$]–toluène qui varie avec la température. Les produits peuvent être facilement isolés par une simple décantation et le système catalytique peut être recyclé et réutilisé dans perte d'activité catalytique.

Mots-clés : couplage C–O, halogénure organique, liquide ionique, système biphasique de liquide ionique soumis à une thermorégulation.

Introduction

The carbon–oxygen bond-forming reaction is one of the most fundamental transformations because of the large number of applications of the resulting compounds (ethers) in organic, pharmaceutical, and polymer chemistry.[1,2] The usual synthetic methods for such a conversion include the Williamson ether synthesis,[3,4] Ullmann coupling,[5,6] palladium-catalyzed couplings of aryl halides,[7–10] C–O couplings of arylboronic acids with phenols,[11,12] iron-catalyzed couplings,[13,14] and other coupling reactions.[15–17] However, these protocols, are generally associated with one or more disadvantages, such as long reaction times, high reaction temperatures, high catalyst loading, tedious work-up procedures, poor substrate scope, moisture sensitivity, costly metal catalysts, difficulty of catalyst recovery, and environmental toxicity. To overcome these limitations, some significant modifications have been made for the Ullmann ether synthesis during the past few years. It has been observed that certain additives, such as 8-hydroxyquinoline,[18] *N*,*N*-dimethyl glycine,[19] 1-naphthoic acid,[20] 2,2,6,6-tetramethylheptane-3,5-dione,[21] tripod ligands,[22] Schiff base,[23] PPAMP,[24] triphenylphosphine,[25] neocuproine,[26] nitrogen-based multidentate ligands,[27] phosphorus dendrimer ligands,[28] and some copper(I) complexes,[29] can accelerate the rate of the reactions, and therefore, the reactions can be performed under milder conditions. Whilst these remarkable advances in the field of Ullmann coupling are exceedingly beneficial, most of the reactions still require long reaction times of more than 24 h, elevated reaction temperatures, and high catalyst loading, and entail difficulties in recycling of the catalyst. Therefore, the introduction of new and environmentally benign procedures that address these drawbacks continues to be of value and interest.

The room-temperature ionic liquid, a kind of environmentally friendly solvent and catalyst because of its adjustable physical and chemical properties, got broad attention from scholars in various fields such as synthesis, catalysis, separation, and electrochemistry.[30,31] In view of both the advantages and disadvantages of homogeneous and heterogeneous catalysis, and to improve catalyst recovery, some novel temperature-dependent ionic liquid biphasic catalytic systems have been reported recently,[32–34] and in our research project group, Luo and co-workers very recently reported a new PEG_{1000}-based dicationic ionic liquid (PEG_{1000}-DAIL) exhibiting temperature-dependent phase behavior with toluene, and applied it successfully in a one-pot synthesis of

benzopyrans.[35] They found that the ionic liquid showed some advantages such as high conversions and selectivity, stability at high temperatures, and reusability in the reaction, and it provides a novel route for the separation and recycling of catalysts. Herein, we report a convenient and efficient procedure for the C–O coupling of organic halides with both phenols and alcohols to synthesize aryl ethers catalyzed by PEG$_{1000}$-based dicationic ionic liquid (PEG$_{1000}$-DAIL[$CdCl_3$]) under ligand-free conditions (Scheme 1).

Results and discussion

The investigation was initiated by using the coupling of 4-iodonitrobenzene with phenol as a model reaction (Table 1). At first, catalysts of different types of ionic liquids were tested in this model reaction (Table 1, entries 1–11) with K_2CO_3 as base, and the results showed that PEG$_{1000}$-DAIL[$CdCl_3$] demonstrated the best performance (Table 1, entry 3). No product was detected in the absence of ionic liquid as a catalyst (Table 1, entry 12). For comparison on the efficiency of different bases in the couplings (Table 1, entries 3 and 14–18), both K_2CO_3 and Cs_2CO_3 were found to be effective bases for this aryl ether formation (Table 1, entries 3 and 15). Other bases, including K_3PO_4, Na_2CO_3, and some organic bases such as Et_3N and pyridine, gave lower yields (Table 1, entries 14 and 16–18). The bases had a large effect on the reaction and were crucial for achieving high yields because a much lower yield (65%) was obtained in the absence of a base (Table 1, entry 13). Therefore, the combination of less expensive base K_2CO_3 and PEG$_{1000}$-DAIL[$CdCl_3$] was chosen as the optimal condition for further exploration.

In addition, the catalytic system could be typically recovered and reused for subsequent reactions with no appreciable decrease in yields and reaction rates (Fig. 1). The recycling process involved the removal of the top oil layer (toluene, containing product) by decantation. The bottom aqueous layer (PEG$_{1000}$-DAIL[$CdCl_3$]) was concentrated under vacuum and then filtered. Fresh substrates and toluene were then recharged with the residual PEG$_{1000}$-DAIL[$CdCl_3$] and the mixture was heated to react once again.

With these optimized reaction conditions in hand, we employed a variety of organic halides in an attempt to synthesize different aryl ethers, as shown in Table 2. Various types of aryl, benzylic, allylic, and aliphatic halides were successfully converted to the corresponding ethers with phenol (Table 2, entries 1–24), whereas the aliphatic halides were less reactive, and higher reaction temperature and longer reaction time were needed to reach good yields (Table 2, entries 16 and 17). Aryl halides with electron-withdrawing substituents (Table 2, entries 6–10, 12, 13, and 15) were more reactive than those with or without electron-donating substituents (Table 2, entries 1–5, 11, and 14). It was also observed that the reactions were faster with benzylic and allylic halides (Table 2, entries 18–24) than with aryl halides (Table 2, entries 1–15). Moreover, the halogen sources greatly influenced the reaction. Taking aryl halides as an example, the reaction activity decreased in the order iodobenzene > bromobenzene > chlorobenzene (Table 2, entries 1, 11, and 14). In addition, to examine a greater range of hydroxy substrates to better illustrate the scope and limitations of this protocol, we investigated the reactions with phenols and alcohols using 4-iodonitrobenzene as a representative organic halide (Table 2, entries 25–30). The experimental

results indicated that substituents on the phenol ring have a great influence on the reaction. For example, substitution of a methyl or methoxy group at the position of phenol incurs a reduction in both yield and reaction rate (Table 2, entries 25 and 26). Finally, the reactions are faster with phenols (Table 2, entries 25–28) than with alcohols (Table 2, entries 29 and 30).

The excellent reaction results of the catalytic system suggest that the coupling among organic halides, phenols, or alcohols, K_2CO_3, toluene, and PEG_{1000}-DAIL[$CdCl_3$] has a particular catalytic process, which is schematically depicted in Fig. 2. Before the coupling, there exists an obvious biphasic system, and the bottom layer consists of PEG_{1000}-DAIL[$CdCl_3$] and K_2CO_3, and the top layer consists of toluene and substrates. During the process of coupling, the biphasic system disappears and a homogeneous reaction medium is formed. After the completion of the reaction, a complete phase separation is formed again after being cooled to room temperature. The next process involves the removal of the oil layer by decantation; the bottom aqueous layer is concentrated by removing the water produced in the reaction under vacuum and then filtered. Fresh substrates and toluene are then recharged to the recovered PEG_{1000}-DAIL[$CdCl_3$] and then recycled. The PEG_{1000}-DAIL[$CdCl_3$] plays a very important role in the coupling process to locally concentrate the reacting species by exhibiting a temperature-dependent phase behavior with methylcyclohexane (i.e., the thermoregulated biphasic behavior of monophase under high temperature and biphase under room temperature), which leads to a large increase in the effective reactant concentration and excellent results of the coupling.

Conclusion

In conclusion, we have developed an experimentally simple and efficient protocol for the C–O coupling of organic halides with phenols and alcohols in a PEG_{1000}-DAIL[$CdCl_3$]–toluene temperature-dependent biphasic system. A wide range of aryl, benzylic, allylic, and aliphatic halides were found to be applicable to the catalytic system. Advantages of our procedure include simplicity of operation, high yields, easy isolation of products, good thermoregulated biphasic behavior of the ionic liquid, and excellent recyclability of the catalyst. Efforts to define the coupling mechanism and expand the utility of the environmentally benign catalytic system to other organic synthesis are currently under study in our laboratory.

Experimental

All the chemicals were obtained from commercial sources without any pretreatment. All reagents were of analytical grade. The ionic liquids were synthesized according to liter-

For personal use only.

Abstract: A series of novel 1,9-diazodipyrrins (**4**) were readily synthesized by reacting aryldiazonium salts with 5-aryldipyrromethanes under both acidic and basic conditions. The zinc complex of 1,9-diphenylazodipyrrin (**5aZn**) was confirmed by X-ray crystallographic analysis, and 1,9-diazodipyrrins and their zinc and nickel complexes (**5M**) were characterized by ^{1}H and ^{13}C NMR, IR, UV–vis, and MS. All of the metal complexes absorb almost all colours of the rainbow; the absorption maximums are >650 nm and the half-band widths are over 100 nm. The fluorescence of the zinc complexes of 1,9-diphenylazodipyrrin (**5aZn**) and 1,9-di(2-iodophenylazo)dipyrrin (**5cZn**) were also explored.

Key words: dipyrrin, dipyrromethane, azo dye, boron-dipyrromethene (BODIPY), fluorescence.

Résumé : On a facilement réalisé la synthèse d'une série de nouvelles 1,9-diazodipyrrines (**4**) en faisant réagir des sels d'aryldiazonium avec des 5-aryldipyrrométhanes dans des conditions acides ou basiques. On a confirmé la structure du complexe de zinc de la 1,9-diphénylazodipyrrine (**5aZn**) par diffraction des rayons-X alors que les 1,9-diazodipyrrines et leurs complexes avec le zinc et le nickel (**5M**) ont été caractérisés par leurs spectres RMN du ^{1}H et du ^{13}C, leurs spectres IR, UV–vis et leurs spectres de masse. Tous les complexes métalliques absorbent pratiquement toutes les couleurs de l'arc-en-ciel; les maxima d'absorption sont supérieurs à 650 nm et les largeurs des bandes à demi-hauteur s'etalent sur 100 nm. On a aussi examiné la fluorescence des complexes de zinc de la 1,9-diphénylazodipyrrine (**5aZn**) et de la 1,9-di(2-iodophénylazo)dipyrrine (**5cZn**).

Mots-clés : dipyrrine, dipyrrométhane, colorant azo, bore-dipyrrométhène (BODIPY), fluorescence.

[Traduit par la Rédaction]

Introduction

Dipyrrins are well-known as important building blocks in supramolecular chemistry and as subunits of porphyrins (Fig. 1).[1] Owing to the fluorescent characteristics of their BF_2 complexes (boron-dipyrromethene (BODIPY) dyes), publications related to dipyrrins have increased dramatically during the past two decades.[2] In comparison with their bridged nitrogen analogues, azadipyrromethenes,[3] dipyrrins have smaller absorption maxima, which has limited their potential use as photosensitizers for photodynamic therapy.[4] The design and synthesis of dipyrrin derivatives with longer wavelength absorption has been a challenge in this field. Nucleophilic substitutions and catalyzed coupling reactions on 1,9-dichloro-BODIPY have been adapted to produce BODIPYs with greater absorption maxima (**1**), but their absorption maxima are still <620 nm.[5,6] Until now, among the numerous known dipyrrin derivatives, only a few 1,9-distyryldipyrrin-BF_2 (**2**)[7] and rigid 1,5,9-triaryldipyrrin-BF_2 (**3**)[8] complexes with strong electron-donating substituents (OR and NR_2) have absorption maxima >650 nm. Herein, we report the synthesis, X-ray crystallographic, and spectral characterization of novel 1,9-diazodipyrrins (**4**) and their zinc and nickel complexes (**5M**).

Results and discussion

Synthesis of 1,9-diazodipyrrins

In our initial studies, we employed the use of dipyrromethanes[9] to react with diazonium salts to form the desired 1,9-diazodipyrrins. Unfortunately, the reaction of dipyrromethanes with phenyldiazonium chloride did not afford 2,2′-di(phenylazo)dipyrromethane (**6**) but rather 2,5-diphenylazopyrrole (**7**) was isolated in a 61% yield (Scheme 1). This is the same product that would result from reacting diazonium salts with pyrrole.[10] The degradation reactions between dipyrromethanes and aryldiazonium salts leading to monopyrrollic products are known in the literature and can be assumed to be the result of the strong electrophilic nature of pyrrole.[11,12] Depraetere and Dehaen[12] reported the structure

of 1,9-diphenylazo-5,5-dipropyl-dipyrromethane in 2003, but did not provide any supporting analytical data.

While dipyrrins are relatively electron deficient, they can also act as nucleophiles in the presence of Lewis acids to form porphyrins.[13] This characteristic prompted us to investigate the reaction between 5-phenyldipyrrin and phenyldiazonium salt (Scheme 2). 5-Phenyldipyrrin was readily prepared by the reaction of trimethyl orthobenzoate with pyrrole and an excess of dichloroacetic acid.[14] The phenyldiazonium salt was formed by reacting aniline with sodium nitrite – aqueous dichloroacetic acid at temperatures <5 °C.[10] After neutralization with triethylamine and treatment with 0.5 equiv. of 5-phenyldipyrrin in methanol, a red mixture was formed. Chromatography on a silica gel column provided a small amount of purple product that was identified as 1,9-diazodipyrrin **4a** by NMR and MS. When an acidic solution of the phenyldiazonium salt was added directly to the methanol solution of 5-phenyldipyrrin, the same purple compound was isolated in a 15% yield. Further reaction of **4a** with zinc acetylacetonate provided the complex **5aZn**. With the growth of diffraction-quality crystals of **5aZn** by the slow evaporation of a dichloromethane–hexane solution

Scheme 2. The reaction between 5-phenyldipyrrin and phenyldiazonium dichloroacetic salt.

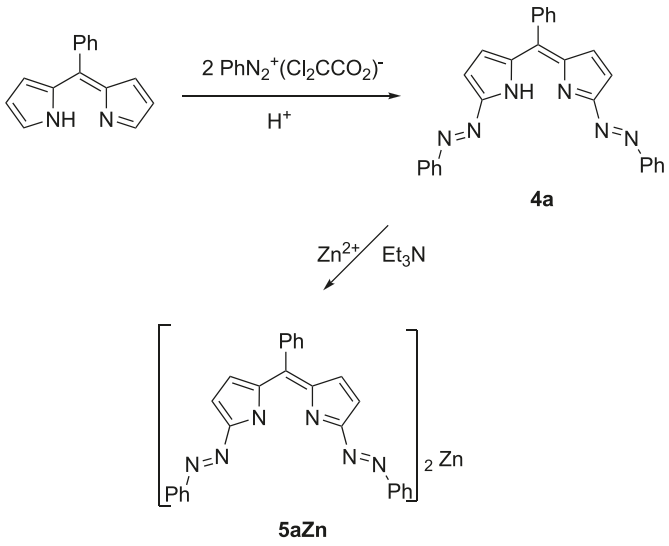

Fig. 2. ORTEP view of **5aZn** (hydrogen atoms are not shown).

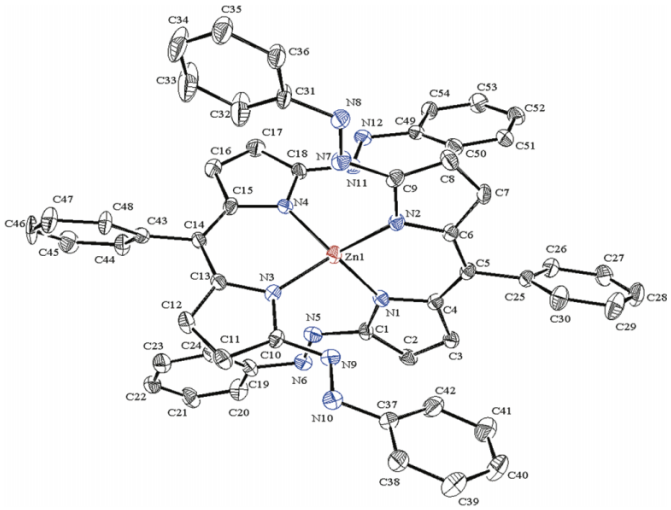

at –5 °C, the structure of complex **5aZn** was confirmed by X-ray crystallographic analysis (Fig. 2; also see the Supplementary data).

With the confirmed structure of the 1,9-diazodipyrrin in hand, we turned our attention to exploration of an alternate synthetic method to improve the yield of 1,9-diazodipyrrins. Interestingly, in contrast to the dipyrromethane, 5-(4-iodophenyl)dipyrromethane[15] was found to react with phenyldiazonium chloride under basic conditions to form 1,9-di(phenylazo)-5-(4-iodophenyl)dipyrromethane (**6d**) (route 1 in Scheme 3). When air was bubbled into an ethyl acetate solution of **6d** for several hours, **6d** was converted into 1,9-(diphenylazo)-5-(4-iodophenyl)dipyrrin (**4d**). Following this method, the reaction of 5-(2,4,6-trimethoxyphenyl)dipyrromethane[16] with phenyldiazonium chloride afforded 1,9-(diphenylazo)-5-(2,4,6-trimethoxyphenyl)dipyrrin (**4e**) in a moderate yield. Furthermore, when the reactions between 5-phenyldipyrrin with aryldiazonium dichloroacetic salts were carried out under acidic conditions, 1,9-diazodipyrrins (**4b**:

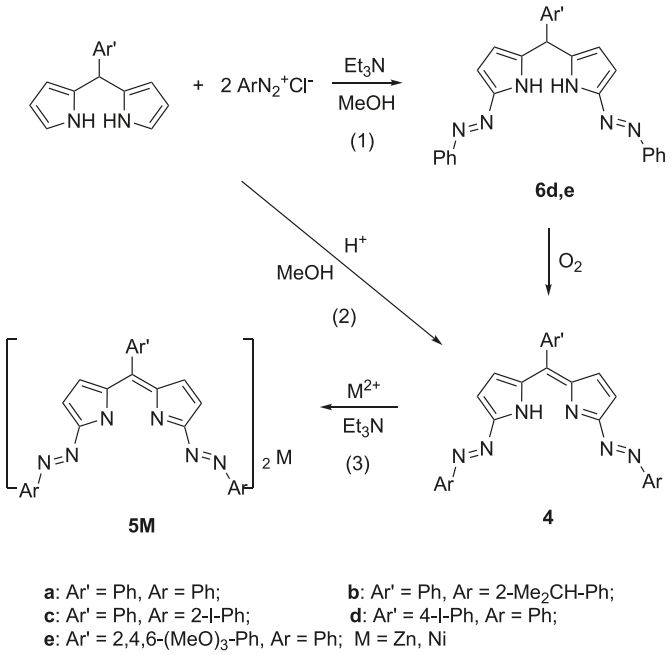
Scheme 3. Synthesis of 1,9-diazodipyrrin complexes starting from 5-aryldipyrromethane and aryldiazonium dichloroacetic salt.



Ar′ = Ph, Ar = 2-Me_2CH-Ph; **4c**: Ar′ = Ph, Ar = 2-I-Ph) were formed directly in a one-pot synthesis (route 2 in Scheme 3). All of the 1,9-diazodipyrrins (**4**) reacted with a zinc salt to form complexes (**5aZn**, **5bZn**, **5cZn**, **5dZn**, and **5eZn**) and **4a** reacted with nickel acetate to form the nickel complex **5aNi** (route 3 in Scheme 3). Whereas complexes **5aZn**, **5aNi**, **5bZn**, **5cZn**, and **5dZn** are fully characterized by NMR, MS, and UV–vis spectra, complex **5eZn** was unstable even when stored at low temperature.

X-ray crystal structure of 5aZn

The structure of **5aZn** was determined by X-ray crystallography and is shown in Fig. 2. Data were collected at –170.0 ± 0.1 °C with maximum 2θ values of 45.1° on a Bruker APEX II diffractometer with graphite-monochromated Mo Kα radiation. The structures were solved by direct methods.[17] The material crystallizes with one disordered phenyl ring (C43–C48), which was modeled in two orientations with restraints to maintain the hexagonal character of the phenyl ring. All refinements were performed using the SHELXL-97[18] via the WinGX[19] interface. Crystal data and structure refinements are summarized in Table 1, and selected bond lengths and angles are listed in Table 2.

Complex **5aZn** has a tetrahedral structure around the central zinc ion. The Zn–N(pyrrole) bond distances are 1.983(4), 1.984(4), 1.981(4), and 1.981(4) Å, respectively, but the N–Zn–N angles within the same diazodipyrrin ligand (92.2(2)° and 91.8(2)°) are smaller than those between two ligands (116.2(2)°, 117.5(2)°, 123.4(2)°, and 117.8(2)°). **5aZn** exhibits N=N bond distances between 1.262 and 1.265 Å, which are slightly longer than that of free 2-phenylazopyrrole (1.253(2) Å) and shorter than those of 2,5-diazopyrroles (1.283–1.293 Å).[10]

Figure 3 shows the top and side view representations of **5aZn**. Whereas 2,5-diazopyrroles have the trans–cis form for their N=N–C(pyrrole) configurations,[10] all N=N–C(pyrrole) configurations in structure **5aZn** are in the trans–trans form as a result of the coordination to the central zinc ion. The diazodipyrrin ligands are slightly distorted, where the dihedral angles between the dipyrrin planes and phenyl planes are 18° and 16° for the ligand of C5 and 19° and 23° for the ligand of C14, respectively. The 5-phenyl groups are not perpendicular to their dipyrrin planes, thus, not parallel to the dipyrrin planes of the other ligands. The 5-phenyl group C25–C30 has angles of 63° to the parent dipyrrin plane and 33° to that of the other ligand; the 5-phenyl group C43–C48 has angles of 63° and 56° to the parent dipyrrin

plane and 33° and 29° to that of the other ligand, respectively. Furthermore, the mean deviations of carbon and nitrogen atoms from the π-delocalized skeletons of the diazodipyrrin ligands are 0.14 and 0.16 Å, respectively.

^{1}H NMR spectra

1,9-Diazodipyrrin (**4a** and **4c**–**4e**) and their complexes (**5aZn**, **5aNi**, **5cZn**, and **5dZn**) exhibit symmetric proton signals in their ^{1}H NMR spectra, but the bulky *ortho*-isopropyl substituents of **4b** and **5bZn** distort their ligand planes and result in distinct proton signals for the two arylazo and two pyrrole groups.

^{1}H NMR spectra were generated at various temperatures between 25 and –80 °C for **4a**, **5aZn**, and **5cZn**, and their pyrrolic proton signals are shown in Fig. 4. Azo dyes have cis and trans isomers, which exist in an equilibrium specific to the solvent and temperature. Upon decreasing the temperature, the equilibrium between the cis and trans isomers shifts toward the cis isomer.[20] The planar 1,9-diazodipyrrin **4a** has two pyrrolic proton signals at 7.05 and 6.78 ppm at room temperature. No significant change was observed for the chemical shift difference of the two pyrrolic protons (0.27 ppm) from 25 to –80 °C (0.25 ppm). This suggests the phenylazo groups have little influence on the pyrrolic proton signals in the same 1,9-diazodipyrrin ligand regardless of whether the cis or trans configuration dominates. However, the chemical shift difference of two pyrrolic protons of **5aZn** increases from 0.00 ppm at 25 °C to 0.31 ppm at –80 °C. This phenomenon suggests that the trans–trans form of the N=N–C(pyrrole) configuration in structure **5aZn** at room temperature shifts toward the cis–trans form at –80 °C, so that the phenylazo group is further away from the pyrrolic groups in an adjacent 1,9-diazodipyrrin ligand and has less influence on their pyrrolic proton signals. Interestingly, the chemical shift difference of the two pyrrolic protons of **5cZn** shows little change from 0.28 ppm at 25 °C to 0.31 ppm at –80 °C. This may be explained by the large radius of the iodo substituent at the ortho position of the –N=N–, which restricts the azo cis/trans isomerization.

UV–vis spectra

Table 3 lists the UV–vis absorption data of **4** and complexes **5M**. Figure 5 shows the UV–vis absorption spectra of **4a**, **5aZn**, and **5aNi**. **4a** has its visible absorption maximum at 528 nm and a half-band width of 119 nm that reflects the overlap of absorptions between the arylazo and dipyrrin chromophores. Complexation with the zinc ion in **5aZn** shifts the absorption maximum bathochromically and forms two distinct and sharper absorptions at 613 and 659 nm with a total half-band width of 108 nm. The absorption on the blue side should be attributed to the azo chromophore as it is less affected by the metal ion; correspondingly, the lower energy absorption can be assigned to the dipyrrin chromophore. With the introduction of the iodo atom, the corresponding absorptions of **5cZn** shift further to 631 and 683 nm. In contrast, complexation with nickel in **5aNi** shifts the absorption maximum to 655 nm and produces a half-band width of 155 nm. As the analogue of **4a**, the 1,9-distyryldipyrrin–BF_2 complex has its absorption maximum at 630 nm.[21]

Fig. 4. The partial ^{1}H NMR spectra of **4a**, **5aZn**, and **5cZn** at temperatures between 25 and –80 °C.

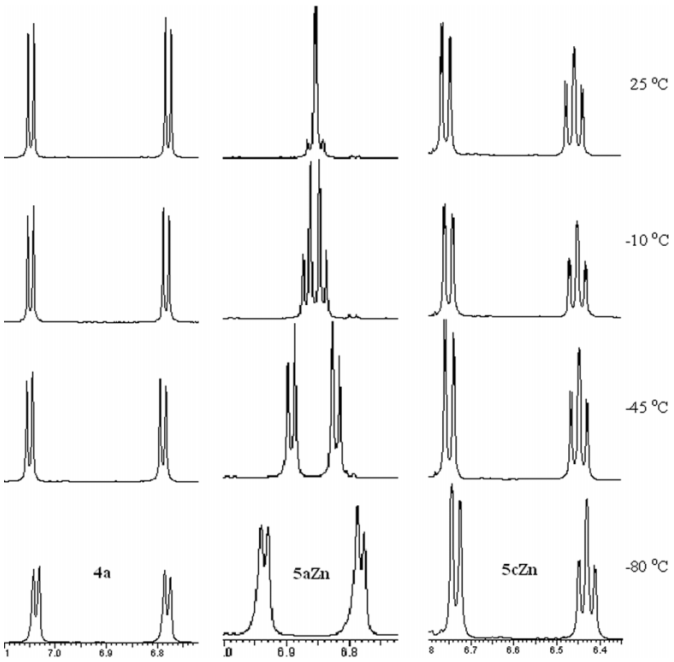

Table 3. The UV–vis absorption data of 1,9-diazodipyrrins (**4**) and their complexes (**5M**) in $CHCl_3$.

5eZn	628, 674	128

Fluorescence

Since the zinc complexes of dipyrrins are reported to be fluorescent,[22] the fluorescence of complexes **5aZn** and **5cZn** were examined at room temperature. When **5aZn** was excited at a wavelength of 630 nm, a weak but noticeable emission was detected with a maximum wavelength of 690 nm (Fig. 6). Complex **5eZn** might have better emission because of the restricted rotation of the bulky 5-(2,4,6-trimethoxy)phenyl group,[22,23] but it decomposed during the detection process. Interestingly, **5cZn**, which is stable, did not fluoresce when excited at 650 nm, which is consistent with the heavy atom effect of the iodines.[4,24]

Conclusion

In this work, we report the facile synthesis of 1,9-diazodipyrrins and select metal complexes as novel dipyrrin and azo dye derivatives. Along with only a few 1,9-distyryldipyrrin–BF_2 and rigid 1,5,9-triaryldipyrrin–BF_2 complexes

Fig. 5. Absorption spectra of **4a** (black line) and complexes **5aZn** (purple line) and **5aNi** (blue line) in chloroform.

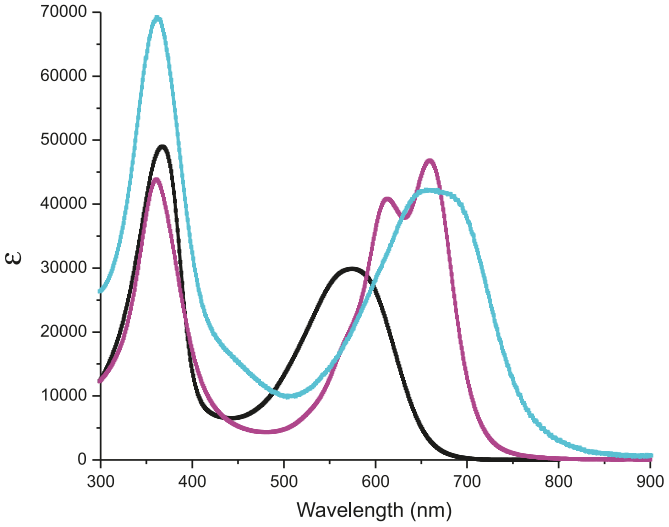

Fig. 6. Fluorescence spectrum of **5aZn** in chloroform with excitation at 630 nm.

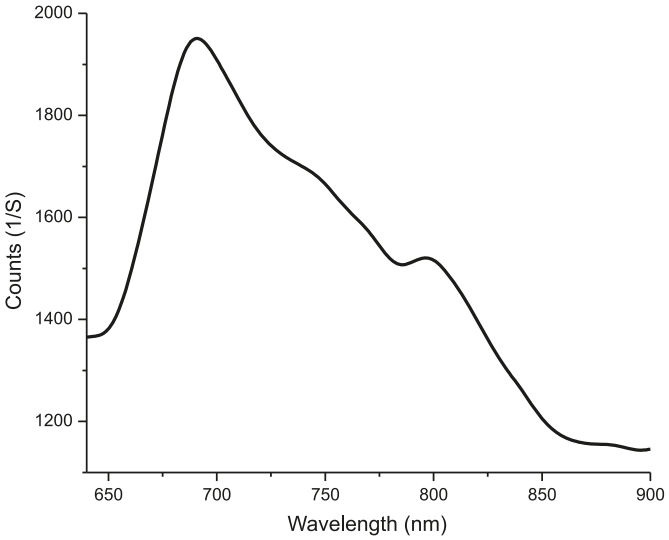

with strong electron-donating substituents, these compounds constitute a rare group of dipyrrin derivatives with absorption maxima >650 nm, an important feature for potential photodynamic therapy (PDT) agents. As well, initial studies show the **5aZn** complex exhibits weak fluoresence. Future work entails the introduction of π-conjugated substituents (SR, OR, I, Br, and NO_2) to the two ortho positions of the arylazo group to restrict cis/trans isomerization of the –N=N– bond. These changes, as well as complexation with BF_2, should enhance fluorescence efficiency.

Experimental

All starting materials, reagents, and solvents were commercially available and used as received. Column chromatography was performed using 230–400 mesh silica gel. Melting points are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ with a 400 MHz spectrometer (J in Hz); the chemical shifts (δ, ppm) are quoted relative to the residual nondeuterated solvent ($CHCl_3$). UV–vis spectra were measured in $CHCl_3$. IR spectra were measured as solid samples and N=N stretching vibrations were designated referring to the literature.[25] Mass spectra were measured using ESI and MALDI-TOF.

General procedure for the preparation of 1,9-diazodipyrrins 4a–4c

To a suspension of the aromatic amine (4.0 mmol) in water (8 mL) was added dichloroacetic acid (12 mmol, 1.0 mL). The solution was cooled and kept at 0–5 °C in an ice bath and diazotized by addition of a solution of sodium nitrite (4.1 mmol, 0.283 g) in water (3 mL), followed by stirring for 30 min at 0–5 °C. To a solution of the dipyrrin (2 mmol) and dichloroacetic acid (2 mmol, 0.17 mL) in methanol (80 mL) was slowly added a solution of the diazonium salt at 0–5 °C. The resulting mixture was stirred for 5 h and then evaporated under vacuum to dryness. The residues were purified by column chromatography, eluting with a gradient mixture of ethyl acetate and hexane (1:20 to 1:10) for **4a** and dichloromethane and hexane (2:3) for **4b** and **4c**.

1,9-Diphenylazo-5-phenyldipyrrin (4a)

General procedure for the preparation of 1,9-diazodipyrrins 4d and 4e

To a suspension of the aromatic amine (4.0 mmol) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

water (8 mL) was added dichloroacetic acid (12 mmol, 1.0 mL). The solution was cooled and kept at 0–5 °C in an ice bath and diazotized by addition of a solution of sodium nitrite (4.1 mmol, 0.283 g) in water (3 mL), followed by stirring for 30 min at 0–5 °C. To a solution of the dipyrrin (2 mmol) and triethylamine (25 mmol, 3.5 mL) in methanol (80 mL) was slowly added a solution of the diazonium salt at 0–5 °C. The resulting mixture was stirred for 5 h and then evaporated under vacuum to dryness. The residues were dissolved in ethyl acetate and washed with water. Air was bubbled into the organic phase for 4 h and then evaporated and purified by column chromatography, eluting with a mixture of ethyl acetate and hexane (1:20).

1,9-Diphenylazo-5-(4-iodophenyl)dipyrrin (4d)

Yield: 43%; mp 164–166 °C. UV–vis (1.03×10^{-5} mol/L, $CHCl_3$) λ_{max}: 372 (4.63), 573 (4.50). IR (N=N, cm^{-1}) ν: 1044. ^1H NMR (CD_2Cl_2) δ: 8.06 (d, 4H, J = 6.8), 7.91 (d, 2H, J = 8.3), 7.64–7.57 (m, 6H), 7.35 (d, 2H, J = 8.3), 7.07 (d, 2H, J = 4.4), 6.77 (d, 2H, J = 4.4). ^{13}C NMR (CD_2Cl_2) δ: 163.3, 153.4, 142.7, 137.4, 135.7, 132.8, 132.1, 130.2, 129.4, 129.2, 123.4, 122.1, 115.6. ESI MS $(M + H)^+$ m/z: 555.2. Anal. calcd for $C_{27}H_{19}IN_6 \cdot 2/5C_6H_{14}$ (solvent of crystallization determined by NMR): C 59.97, H 4.21, N 14.27; found: C 60.24, H 3.78, N 14.09.

1,9-Diphenylazo-5-(2,4,6-trimethoxyphenyl)dipyrrin (4e)

Yield: 40%; mp 180–181 °C. UV–vis (1.06×10^{-5} mol/L, $CHCl_3$) λ_{max}: 351 (4.60), 573 (4.54). IR (N=N, cm^{-1}) ν: 1050. ^1H NMR (CD_2Cl_2) δ: 12.78 (b, 1H), 8.04 (d, 4H, J = 7.4), 7.59 (t, 4H, J = 7.5), 7.54 (t, 2H, J = 7.2), 6.99 (d, 2H, J = 4.5), 6.69 (d, 2H, J = 4.4), 6.30 (s, 2H), 3.92 (s, 3H), 3.74 (s, 6H). ^{13}C NMR (CD_2Cl_2) δ: 162.2, 162.0, 158.9, 152.9, 143.8, 136.1, 131.2, 128.8, 128.7, 122.7, 114.8, 105.3, 90.1, 55.5, 55.0. ESI MS $(M + H)^+$ m/z: 519.4. Anal. calcd for $C_{30}H_{26}N_6O_3 \cdot 1/5C_6H_{14}$ (solvent of crystallization determined by NMR): C 69.94, H 5.42, N 15.68; found: C 69.78, H 5.33, N 15.33.

General procedure for the preparation of zinc complexes of 1,9-diazodipyrrins (5Zn)

The solution of 1,9-diazodipyrrin (0.06 mmol), zinc acetylacetonate hydrate (0.03 mmol, 8 mg), and triethylamine (0.2 mmol, 28 μL) in dry dichloromethane (30 mL) was refluxed for 1 h and then evaporated under vacuum to dryness. The residue was purified by column chromatography, eluting with a mixture of ethyl acetate and hexane (1:20) for **5aZn**, **5dZn**, and **5eZn** and dichloromethane and hexane (2:3) for **5bZn** and **5cZn**.

Zinc complex of 1,9-diphenylazo-5-phenyldipyrrin (5aZn)

Yield: 90%. UV–vis (1.03×10^{-5} mol/L, CH_2Cl_2) λ_{max} (log ε): 361 (4.64), 613 (4.61), 659 (4.67). IR (N=N, cm^{-1}) ν: 1043. ^1H NMR ($CDCl_3$) δ: 7.56 (t, 1H, J = 7.4), 7.50 (t, 2H, J = 7.5), 7.43 (dd, 6H, J = 7.6, 1.3), 7.32 (t, 2H, J = 7.2), 7.25 (t, 4H, J = 7.55), 6.83 (d, 2H, J = 4.5), 6.79 (d, 2H, J = 4.5). ^{13}C NMR ($CDCl_3$) δ: 166.4, 153.8, 149.4, 143.2, 138.4, 133.9, 131.4, 131.0, 129.2, 129.0, 127.6, 123.3, 111.8. MALDI-TOF MS $(M)^+$ m/z: 918. Anal. calcd for $C_{54}H_{38}N_{12}Zn \cdot 1/2H_2O \cdot 1/2C_6H_{14}$ (solvents of crystallization determined by NMR): C 70.40, H 4.77, N 17.28; found: C 70.08, H 4.62, N 16.90.

Zinc complex of 1,9-di(2-isopropylphenylazo)-5-phenyldipyrrin (5bZn)

Yield: 88%. UV–vis (1.06×10^{-5} mol/L, $CHCl_3$) λ_{max} (log ε): 367 (4.66), 615 (4.66), 674 (4.68). IR (N=N, cm^{-1}) ν: 1047. ^1H NMR (CD_2Cl_2) δ: 7.67–7.59 (m, 10H), 7.34–7.31 (m, 8H), 7.02 (d, 4H, J = 8.0), 6.95–6.88 (m, 8H), 6.79 (d, 4H, J = 4.5), 3.93–3.86 (m, 4H), 1.19 (s, 12H), 1.17 (s, 12H). ^{13}C NMR (CD_2Cl_2) δ: 167.4, 150.7, 149.0, 148.6, 142.8, 138.2, 133.9, 131.7, 131.4, 129.3, 127.7, 126.4, 126.2, 115.1, 108.4, 27.6, 23.6. ESI MS $(M + H)^+$ m/z: 1087.8. Anal. calcd for $C_{66}H_{62}N_{12}Zn \cdot 2/3C_6H_{14}$ (solvent of crystallization determined by NMR): C 73.36, H 6.27, N 14.67; found: C 73.53, H 6.22, N 14.68.

Zinc complex of 1,9-di(2-iodophenylazo)-5-phenyldipyrrin (5cZn)

Yield: 92%. UV–vis (1.50×10^{-5} mol/L, $CHCl_3$) λ_{max} (log ε): 370 (4.69), 631 (4.80), 683 (4.83). IR (N=N, cm^{-1}) ν: 1051. ^1H NMR (CD_2Cl_2) δ: 7.93–7.92 (dd, 2H, J = 7.0, 2.0), 7.66–7.57 (m, 10H), 7.15–7.12 (dt, 4H, J = 8.1, 1.3), 7.08–7.04 (m, 4H), 6.94–6.93 (dd, 2H, J = 6.4, 2.5), 6.91–6.88 (q, 4H, J = 9.9), 6.76–6.75 (dd, 4H, J = 8.0, 1.4), 6.47–6.44 (dt, 4H, J = 7.9, 1.5). ^{13}C NMR (CD_2Cl_2) δ: 167.1, 153.0, 144.0, 140.4, 139.4, 134.8, 132.9, 131.8, 129.9, 128.3, 120.2, 117.7, 115.1, 110.4, 103.9. MALDI-TOF MS m/z: 1421.8. Anal. calcd for $C_{54}H_{34}I_4N_{12}Zn \cdot 1/2CH_2Cl_2$ (solvents of crystallization determined by NMR): C 44.64, H 2.41, N 11.46; found: C 44.23, H 2.63, N 11.42.

Zinc complex of 1,9-diphenylazo-5-(4-iodophenyl)dipyrrin (5dZn)

Yield: 85%. UV–vis (9.42×10^{-6} mol/L, $CHCl_3$) λ_{max} (log ε): 369 (4.68), 615 (4.63), 662 (4.67). IR (N=N, cm^{-1}) ν: 1040. ^1H NMR (CD_2Cl_2) δ: 7.90 (d, 4H, J = 8.6), 7.42 (d, 8H, J = 7.1), 7.38 (t, 4H, J = 7.3), 7.29 (t, 8H, J = 7.7), 7.19 (d, 4H, J = 8.4), 6.89 (d, 4H, J = 4.6), 6.83 (d, 4H, J = 4.4). ^{13}C NMR (CD_2Cl_2) δ: 166.9, 154.1, 148.5, 143.2, 138.1, 137.3, 134.2, 133.4, 131.8, 129.5, 123.5, 112.6, 95.9. ESI MS $(M + H)^+$ m/z: 1171.1. Anal. calcd for $C_{54}H_{36}I_2N_{12}Zn \cdot 4/7C_6H_{14}$ (solvent of crystallization determined by NMR): C 56.47, H 3.63, N 13.76; found: C 56.01, H 3.62, N 13.38.

Zinc complex of 1,9-diphenylazo-5-(2,4,6-trimethoxyphenyl)dipyrrin (5eZn)

Yield: 76%. UV–vis ($CHCl_3$) λ_{max}: 356, 628, 674. IR (N=N, cm^{-1}) ν: 1048. MALDI-TOF MS $(M + H)^+$ m/z: 1099.4.

Preparation of the nickel complex of 1,9-diphenylazo-5-phenyldipyrrin (5aNi)

A solution of **4a** (0.06 mmol, 25.7 mg), nickel acetate tetrahydrate (0.03 mmol, 7.5 mg), and triethylamine (0.2 mmol, 28 μL) in dry dichloromethane (30 mL) was refluxed for 1 h and then evaporated under vacuum to dryness. The residue was purified by column chromatography, eluting with a mixture of ethyl acetate and hexane (1:20) to give the product. Yield: 92%. UV–vis (1.10×10^{-5} mol/L, $CHCl_3$) λ_{max} (log ε): 361 (4.84), 655 (4.62). IR

(N=N, cm^{-1}) ν: 1054. ^1H NMR (CD_2Cl_2) δ: 7.64 (9H), 7.50 (4H), 6.89 (6H). ^{13}C NMR ($CDCl_3$) δ: 170.0, 146.1, 141.8, 138.1, 132.9, 131.3, 130.0, 129.7, 129.1, 128.7, 122.9, 121.7, 104.2. ESI MS $(M + Na)^+$ *m/z*: 935.3. Anal. calcd for $C_{54}H_{38}N_{12}Ni \cdot 1/2H_2O$: C 70.29, H 4.26, N 18.22; found: C 70.11, H 4.24, N 17.93.

Supplementary data

Supplementary data (^1H NMR, ^{13}C NMR, and UV–vis spectra) are available with this article through the journal Web site (www.nrcresearchpress.com/cjc). CCDC 784639 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Abstract: Diisopropyl 8-bromo-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine was used as a starting material for the synthesis of the 8-*C*-substituted 2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (PMEDAP) analogues. A systematic screening of diverse cross-coupling reactions was carried out. Stille, Suzuki–Miyaura, Negishi, and Sonogashira cross-couplings, as well as Pd-catalysed reactions with trialkylaluminiums, were employed for the introduction of various alkyl, alkenyl, alkynyl, aryl, and hetaryl substituents to the C-8 position of the 2,6-diaminopurine moiety. In contrast to the potent parent compound PMEDAP, which exhibits potent antiretroviral and antitumor activity, none of the sixteen newly synthesized 8-*C*-substituted analogues of PMEDAP showed any specific antiviral activity.

Key words: acyclic nucleoside phosphonates, PMEDAP, cross-coupling, antiviral, antitumor.

Résumé : On a réalisé la synthèse d'analogues substitués en 8-*C* de la 2,6-diamino-9-[2-(phosphonométhoxy)éthyl]purine (PMEDAP) en utilisant le dérivé diisopropyle de la 8-bromo-2,6-diamino-9-[2-(phosphonométhoxy)éthyl]purine comme produit de départ. On a effectué une évaluation systématique de diverses réactions de couplages croisés. On a utilisé les couplages croisés de Stille, Suzuki–Miyaura, Negishi et Sonogashira ainsi que les réactions catalysées par le palladium avec des dérivés de type trialkylaluminium pour effectuer l'introduction de substituants alkyle, alkényle, alkynyle, aryle et hétaryle dans la position C-8 de la portion 2,6-aminopurine. Par opposition au composé fondamental PMEDAP qui présente une activité antirétrovirale et antitumorale importante, aucun des seize nouveaux analogues de synthèse du PMEDAP portant un substituant en position C-8 ne présente d'activité antivirale spécifique.

Mots-clés : phosphonates de nucléoside acycliques, PMEDAP, couplage-croisé, antiviral, antitumoral.

[Traduit par la Rédaction]

Introduction

Acyclic nucleoside phosphonates[1] (ANPs) are nucleotide analogues with a wide range of biological activities, especially antiviral,[2] antiparasitic,[3] cytostatic,[4] and immunomodulatory.[5] Extensive structure–activity relationship (SAR) studies of ANPs have been conducted to increase their potential for biological properties, leading to potential drug candidates and approved drugs.[2c,6]

Analogues with a 2,6-diaminopurine (DAP) base occupy a special place among ANPs, as their antiviral activity and potency is comparable to that of their adenine counterparts.[2c] For its remarkable biological and therapeutic properties, 2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (PMEDAP) constitutes an attractive candidate for the treatment of both retrovirus and herpesvirus infections.[2c] Furthermore, N^6-substituted PMEDAP derivatives, and especially N^6-cyclopropyl-PMEDAP, possess promising cytostatic and tumour-cell differentiation-inducing properties.[7] A novel prodrug of the cytostatic agent 9-[2-(phosphonomethoxy)ethyl]guanine (PMEG), GS-9219, has potential for the treatment of non-Hodgkin lymphoma (NHL).[8] It has been shown that the N^6-substituted PMEDAP derivatives act as prodrugs of PMEG,[7] and that the enzymes that catalyse their conversion to PMEG are human abacavir monophosphate (hABC-MP) deaminase[9] and the recently identified N^6-methyl-AMP aminohydrolase.[10]

The SAR studies of ANPs involve various modifications of the phosphonate moiety, of the aliphatic linker, and of the purine and pyrimidine bases. A C-8 position of the purine ring is a clear option for the base modification of the purine derivatives. A number of ANPs substituted at the C-8 position of the purine have previously been prepared by nucleophilic substitution from the corresponding 8-bromopurine derivatives.[11] Various cross-coupling techniques have recently been developed for the syntheses of purines bearing carbon substituents at the C-8 position,[12] although the cross-coupling reactions were studied more extensively at the C-6 position of the purine moiety.[13]

Within the SAR studies of ANPs and also from the synthetic point of view, we decided to prepare a series of PMEDAP derivatives substituted at the C-8 position of the purine

moiety with carbon substituents using various cross-coupling reactions. Since some ANPs substituted at the C-8 position of the purine moiety displayed pronounced biological properties (antiviral and immunomodulatory),[14] the antiviral activity of the final C-8 modified PMEDAP analogues has been evaluated.

Results and discussion

Diisopropyl 8-bromo-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (**1**, Scheme 1) was prepared by alkylation of 2,6-diaminopurine with 2-[(diisopropoxyphosphoryl)methoxy]ethyl chloride followed by bromination with the bromine solution in a DMF/CCl_4 mixture according to the previously described procedure.[15]

At first, a series of 8-alkyl- and 8-aryl-substituted PMEDAP derivatives were prepared by Stille cross-coupling[16] of **1** with tetraalkyl and alkyltributyl stannanes under a catalysis of $Pd(PPh_3)_4$ in NMP (1-methyl-2-pyrrolidone) (Scheme 1 and Table 1). Cross-coupling with more reactive unsaturated stannanes (phenyl and vinyl) proceeded in short reaction times (2 h) at 100 °C and yielded the desired 8-substituted products (**2c** and **2d**) in ~40% yields (Table 1, entries 3 and 4). On the other hand, saturat7ed stannanes afforded only low yields of the 8-substituted products **2a** (17%; Table 1, entry 1) and **2b** (22%; Table 1, entry 2). It was caused by the lower reactivity of aliphatic stannanes and by the undesirable deprotection of diisopropyl esters by alkylstannanes (good Lewis acids) at higher temperatures (>100 °C) during longer reaction times. When more reactive alkyltributyl stannanes and the Pd_2dba_3/Ph_3As catalytic system[17] were used, compounds **2d**, **2e**, and **2f** were obtained in 84%, 50%, and 59% yields, respectively (Table 1, entries 5, 7, and 8). Compounds **2a**–**2f** were deprotected by the standard procedure (Me_3SiBr, CH_3CN, room temperature (rt)) to yield phosphonic acids **3a**–**3f** (Scheme 1 and Table 1).

Suzuki–Miyaura[18] cross-coupling was used for the introduction of various aryl, hetaryl, and alkenyl substituents to the C-8 position of the 2,6-diaminopurine moiety (Scheme 1 and Table 2).[19] The 8-bromo derivative **1** reacted smoothly with aryl-, hetaryl- and alkenylboronic acids. The reaction was catalysed with $Pd(PPh_3)_4$ (5 mol%) and potassium carbonate was used as a base. To improve the solubility of potassium carbonate, a mixture of DMF and water was used as a solvent. The corresponding 8-substituted derivatives **2c** and **2g**–**2k** were obtained in very good yields (65%–79%; Table 2) and the subsequent removal of the ester groups yielded free phosphonic acids **3g**–**3k** (Scheme 1 and Table 2).

The third approach used for the introduction of the *C*-substituent to the C-8 position of the purine ring was Negishi cross-coupling employing alkylzinc halides (Scheme 1 and Table 3).[20] The reactions with benzyl-, allyl-, trifluoromethyl-, and cyclopropylzinc halides in DMF were catalysed with $Pd(PPh_3)_4$ at 50 °C and gave the products **2l**–**2n** in satisfactory 49%–71% yields (Table 3). The starting benzyl- and allylzinc bromides were obtained by transmetalation of the appropriate organomagnesium Grignard reagent with $ZnBr_2$ in THF. Trifluoromethylzinc iodide was prepared by the sonication of trifluoromethyl iodide in THF with activated zinc on cooling. Finally, cyclopropylzinc chloride was prepared by lithiation of cyclopropyl bromide with *n*-BuLi

Table 2. Suzuki–Miyaura cross-coupling to produce compounds **2** (reagents: $RB(OH)_2$, $Pd(PPh_3)_4$, K_2CO_3, DMF/H_2O, 90 °C, 2–4 h); deprotection to produce compounds **3** (reagents: $(CH_3)_3SiBr$, CH_3CN, room temperature).

followed by transmetalation with $ZnBr_2$. Ethyl (2,6-diaminopurine-8-yl)acetate **2o** was prepared by Negishi cross-coupling of **1** with the Reformatsky reagent $BrZnCH_2COOEt$ prepared in situ by the sonication of 2-bromoethyl acetate with zinc in THF. In this case, the best yield of 57% was obtained using the catalytic system Pd_2dba_3/dppf (diphenylphosphinoferrocene) (Table 3, entry 5).[21] The coupling with zinc cyanide proceeded well under the catalysis of the Pd_2dba_3/dppf catalytic system and gave the 8-cyano derivative **2p** in an 81% yield (Table 3, entry 6), whereas the reaction using $Pd(PPh_3)_4$ as a catalyst gave an unsatisfactory 27% yield (data not shown).[22] The compounds **2l**–**2n** and **2p** were deprotected by the standard procedure to afford free phosphonic acids **3l**–**3n** and **3p** (Scheme 1 and Table 3). Compound **2o** is unstable under the reaction conditions and decomposes.

Trialkylaluminium was used for the introduction of the methyl and ethyl substituents. The reaction in THF was catalysed by $Pd(PPh_3)_4$ and proceeded smoothly to give the desired products **2a** and **2b** in 54% and 48% yields, respectively (Scheme 1 and Table 4).[23] This method proved to be more suitable for the introduction of a simple alkyl substituent to the C-8 position of the purine moiety than Stille cross-coupling with tetraalkyl stannanes.

The ethynyl group can be introduced by Sonogashira cross-coupling of compounds **1** with trimethylsilylacetylene. The reaction was performed under standard conditions ($PdCl_2(PPh_3)_4$, CuI, Et_3N, DMF) and gave the product **4** in a 67% yield (Scheme 2).[24] Free phosphonic acid **5** was obtained in a 31% yield after the removal of the TMS group with methanolic ammonia followed by the standard deprotection of the phosphonate moiety (Me_3SiBr, CH_3CN). The

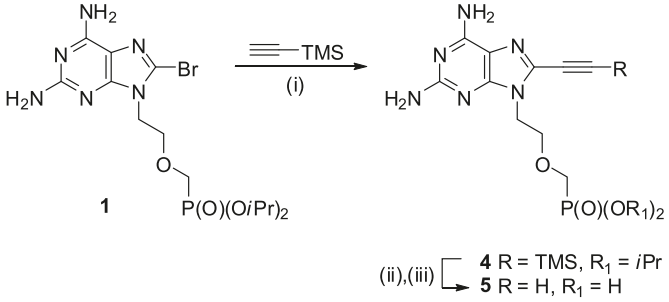
Scheme 2. Sonogashira cross-coupling of **1** with trimethylsilylacetylene. Reagents: (*i*) $PdCl_2(PPh_3)_2$, CuI, Et_3N, DMF, room temperature; (ii) NH_3, CH_3OH, r.t.; (iii) $(CH_3)_3SiBr$, CH_3CN, rt.



final step was conducted at 0 °C owing to the instability of the ethynyl group under the reaction conditions.

All final compounds **3a**–**3n**, **3p**, and **5** were tested for cytostatic and antiviral activities. Although certain C-8 substituted purine nucleotide analogues are known to exhibit pronounced antiviral activity, none of the C-8 substituted PMEDAP derivatives prepared displayed any appreciable biological activity. Nevertheless, this work constitutes an important partial result of a broader SAR study of acyclic nucleoside phosphonates, compounds of an enormous medicinal importance.

Conclusions

In conclusion, various cross-coupling reactions of diisopropyl 8-bromo-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (**1**) with diverse types of organometallic reagents were employed for the preparation of a series of 2,6-diamino-8-*C*-substituted purine derivatives. Although various Pd-catalysed cross-coupling reactions on halopurines have appeared in the literature over the last decade or so, this work first describes a comprehensive and systematic study of various cross-coupling methods on 8-bromopurine derivatives. Stille and Suzuki cross-coupling reactions of stannanes and boronic acids, respectively, were used for the introduction of aryl, hetaryl, and alkenyl substituents. Alkylzinc halides and trialkylaluminium reagents were used for the introduction of suitable alkyl groups. Sonogashira cross-coupling was efficiently used for the preparation of the 8-ethynylpurine derivative **4**. All of the organometallic reagents used tolerated the presence of the unprotected amino group at the C-2 position of the purine ring well. The cleavage of the phosphonate esters **2a**–**2n**, **2p**, and **4** with Me_3SiBr/MeCN afforded the target acyclic nucleotide analogues **3a**–**3n**, **3p**, and **5**. The deprotection of the compound **2o** was not successful owing to its instability under the reaction conditions. All 16 of the final compounds **3a**–**3n**, **3p**, and **5** were tested for cytostatic and antiviral activities, but none of them displayed any appreciable activity against the viruses tested. It can be concluded that the substitution at the C-8 position of a PMEDAP analogue with the *C*-substituents leads to the loss of biological activity of the potent parent compound.

Experimental

General

The solvents were dried by standard procedures. Tetrahydrofuran (THF) was freshly distilled from sodium/benzophenone under argon. The NMR spectra were recorded with Bruker Avance 500 (500 MHz for ^1H and 125.8 MHz for ^{13}C) and Bruker Avance 400 (^1H at 400, ^{13}C at 100.6 MHz) spectrometers in $CDCl_3$, DMSO-d_6, or D_2O. The chemical shifts (in ppm, δ scale) were referenced to TMS (for the ^1H NMR spectra in $CDCl_3$) and (or) to the solvent signal ($CDCl_3$ δ = 7.26 ppm for the ^1H NMR and δ = 77.0 ppm for the ^{13}C NMR; DMSO-d_6 for the ^1H NMR δ = 2.5 ppm and for the ^{13}C NMR δ = 39.7). The chemical shifts in D_2O were referenced to 1,4-dioxane for ^1H NMR δ = 3.75 and for ^{13}C NMR δ = 67.19. The melting points were determined on a Büchi melting point B-545 apparatus and are uncorrected. The TLC was performed on plates of Kieselgel 60 F254 (Merck). The mass spectra were measured on a ZAB-EQ (VG Analytical) spectrometer using FAB (ionization by Xe, accelerating voltage 8 kV, glycerol matrix) or on a LCQ classic spectrometer using electrospray ionization (ESI). Preparative HPLC purification was performed on a column packed with 10 μm C_{18} reversed phase (Luna) (250 mm × 21 mm.

Stille cross-coupling with organostannanes

Method A (general procedure)

8-Bromopurine **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in NMP (4 mL) were treated with the appropriate stannane (3 mmol) under an argon atmosphere, and the reaction mixture was heated at 100 °C until the complete consumption of the starting material (monitored by TLC). The solvent was evaporated under reduced pressure and the residue was taken to EtOAc and washed with brine and EDTA and dried over $MgSO_4$. The product was purified by column chromatography (SiO_2; EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized from EtOH.

Method B (general procedure)

8-Bromopurine **1** (475 mg, 1 mmol), Pd_2dba_3 (23 mg, 0.025 mmol) and $AsPh_3$ (31 mg, 0.1 mmol) in NMP (4 mL) were treated with the appropriate stannane (3 mmol) under an argon atmosphere, and the reaction mixture was heated at 100 °C until the complete consumption of the starting ma-

Diisopropyl 2,6-diamino-8-vinyl-9-[2-(phosphonomethoxy)ethyl]purine (2d)

Method A afforded a pale yellow crystalline product; yield: 171 mg (43%); mp 179–181 °C. Method B gave yellowish crystals; yield: 334 mg (84%); mp 179 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.23 and 1.28 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 3.70 (d, $J_{H,P}$ = 8.3, 2H, CH_2P), 3.88 (t, J_{vic} = 5.2, 2H, CH_2O), 4.25 (t, J_{vic} = 5.2, 2H, CH_2N), 4.66 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.2, 2H, $(CH_3)_2CH$), 5.14 (bs, 2H, NH_2-2), 5.51 (d, J_{cis} = 4.5, 1H, CH_2-2′$_{trans}$) 6.08 (bs, 2H, NH_2-6), 6.30 (d, J_{trans} = 17.5, 1H, CH_2-2′$_{cis}$), 6.78 (dd, J_{trans} = 17.5, J_{cis} = 4.5, 1H, CH-1′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.80 and 23.90 (d, $J_{C,P}$ = 4, $(CH_3)_2CH$), 41.82 (CH_2N), 65.96 (d, $J_{C,P}$ = 167, CH_2P), 71.04 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 71,32 (d, $J_{C,P}$ = 11, CH_2O), 113.79 (C-5), 120.68 (C-2′), 123.51 (C-1′), 146.22 (C-8), 152.76 (C-4), 155.64 (C-6), 159.77 (C-2) ppm. MS (FAB) *m/z* (%): 399 (100) $[M + H]^+$. Anal. calcd for $C_{16}H_{27}N_6O_4P$ (398.4): C 48.24, H 6.83, N 21.09; found: C 48.20, H 6.92, N 21.27.

Diisopropyl 8-allyl-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (2e)

Method A afforded a white crystalline product; yield: 33 mg (8%); mp 185–187 °C. Method B afforded white crystals; yield: 206 mg (50%); mp 186–188 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.20 and 1.27 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 3.38 (d, J_{vic} = 6.3, 2H, CH_2-1′), 3.65 (d, $J_{H,P}$ = 8.5, 2H, CH_2P), 3.89 (t, J_{vic} = 5.5, 2H, CH_2O), 4.27 (t, J_{vic} = 5.5, 2H, CH_2N), 4.65 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.2, 2H, $(CH_3)_2CH$), 5.21 (bs, 2H, NH_2-2), 5.28 (dq, $J_{3'cis,1'} = J_{gem}$ = 1.5, J_{cis} = 8.1, 1H, CH_2-3′$_{trans}$), 5.35 (dq, $J_{3'cis,1'} = J_{gem}$ = 1.5, J_{trans} = 17.2, 1H, CH_2-3′$_{cis}$), 6.11 (bs, 2H, NH_2-6), 6.05 (ddt, J_{trans} = 17.2, J_{cis} = 8.1, J_{vic} = 6.3, 2H, CH-2′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.78 and 23.88 (d, $J_{C,P}$ = 4, $(CH_3)_2CH$), 40.33 (C-1′), 41.76 (CH_2N), 66.15 (d, $J_{C,P}$ = 168, CH_2P), 71.22 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 71,39 (d, $J_{C,P}$ = 10, CH_2O), 113.79 (C-5), 116.46 (C-3′), 138.21 (C-2′), 148.65 (C-8), 151.72 (C-4), 156.39 (C-6), 159.54 (C-2) ppm. MS (ESI): *m/z* (%): 435 (45) $[M + Na]^+$, 413 (100) $[M + H]^+$. Anal. calcd for $C_{17}H_{29}N_6O_4P$ (412.4): C 49.51, H 7.09, N 20.38; found: C 49.56, H 7.13, N 20.25.

Diisopropyl 2,6-diamino-8-(thien-2-yl)-9-[2-(phosphonomethoxy)ethyl]purine (2f)

Method B gave a pale yellow oil; yield: 268 mg (59%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.19 and 1.25 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 3.73 (d, $J_{H,P}$ = 8.5, 2H, CH_2P), 4.01 (t, J_{vic} = 5.5, 2H, CH_2O), 4.42 (t, J_{vic} = 5.5, 2H, CH_2N), 4.63 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.2, 2H, $(CH_3)_2CH$), 5.31 (bs, 2H, NH_2-2), 6.36 (bs, 2H, NH_2-6), 7.13 (dd, $J_{4',5'}$ = 5.1, $J_{4',3'}$ = 3.7, 1H, H-4), 7.44 (dd, $J_{5',4'}$ = 5.1, $J_{5',3'}$ = 0.8, 1H, H-5′), 7.69 (dd, $J_{3',4'}$ = 3.7, $J_{3',5'}$ = 0.8, 1H, H-3′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.60 and 23.75 (d, $J_{C,P}$ = 4, $(CH_3)_2CH$), 42.91 (CH_2N), 65.73 (d, $J_{C,P}$ = 167, CH_2P), 70.64 (d, $J_{C,P}$ = 12, CH_2O), 70.97 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 113.55 (C-5), 127.60 (CH-5′), 127.65 (CH-4′), 128.07 (CH-3′), 131.64 (CH-2′), 142,7 (C-8), 153.34 (C-4), 155.38 (C-6), 159.59 (C-2) ppm. MS (ESI) *m/z* (%): 477 (35) $[M + Na]^+$,

455 (100) $[M + H]^+$. Anal. calcd for $C_{18}H_{27}N_6O_4PS$ (454.4): C 47.57, H 5.99, N 18.49; found: C 47.68, H 6.03, N 18.31.

Suzuki–Miyaura cross-coupling with boronic acids

Method C (general procedure)

$Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added to a mixture of 8-bromopurine **1** (475 mg, 1 mmol), boronic acid (3 mmol) and K_2CO_3 (331 mg, 3 mmol) in a DMF/H_2O mixture (4:1, 10 mL) under an argon atmosphere. The mixture was heated at 90 °C for 4 h. The solvents were evaporated, and the residue in EtOAc was washed with H_2O and dried over $MgSO_4$. The product was isolated by column chromatography (SiO_2; EtOAc/acetone/EtOH/H_2O, 18:3:1:1).

Diisopropyl 2,6-diamino-8-phenyl-9-[2-(phosphonomethoxy)ethyl]purine (2c)

Method C afforded **2c** as a yellowish oil; yield: 321 mg (72%).

Diisopropyl 2,6-diamino-8-[4-(trifluoromethyl)phenyl]-9-[2-(phosphonomethoxy)ethyl]purine (2g)

Method C afforded a colourless oil; yield: 351 mg (68%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.17 and 1.25 (2 × d, J_{vic} = 6.3, 12H, $(CH_3)_2CH$), 3.68 (d, $J_{H,P}$ = 8.6, 2H, CH_2P), 4.04 (t, J_{vic} = 5.3, 2H, CH_2O), 4.29 (t, J_{vic} = 5.3, 2H, CH_2N), 4.63 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.3, 2H, $(CH_3)_2CH$), 4.73 (bs, 2H, NH_2-2), 5.38 (bs, 2H, NH_2-6), 7.75 (d, J = 8.1, 2H, H-3′, H-5′), 8.00 (d, J = 8.1, 2H, H-2′, H-6′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.38 and 23.74 (d, $J_{C,P}$ = 4.2 $(CH_3)_2CH$), 42.89 (CH_2N), 65.85 (d, $J_{C,P}$ = 162, CH_2P), 70.21 (d, $J_{C,P}$ = 12, CH_2O), 70.84 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 112.73 (C-5), 126.79 (CH-m-Ph), 127.60 (CH-o-Ph), 130.57 (CF_3), 131.59 (CH-i-Ph), 153.96 (C-8), 157.43 (C-4), 158.94 (C-6), 162.87 (C-2) ppm. MS (ESI) *m*/*z* (%): 539 (25) $[M + Na]^+$, 517 (100) $[M + H]^+$. Anal. calcd for $C_{21}H_{28}F_3N_6O_4P$ (516.4) calcd.: C 48.84, H 5.46, N 16.27; found: C 49.01, H 5.39, N 16.31.

Diisopropyl 2,6-diamino-8-(2,4-difluorophenyl)-9-[2-(phosphonomethoxy)ethyl]purine (2h)

Method C afforded a colourless oil; yield: 367 mg (76%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.17 and 1.25 (2 × d, J_{vic} = 6.3, 12H, $(CH_3)_2CH$), 3.58 (d, $J_{H,P}$ = 8.6, 2H, CH_2P), 3.84 (t, J_{vic} = 5.3, 2H, CH_2O), 4.17 (t, J_{vic} = 5.8, 2H, CH_2N), 4.60 (dh, $J_{H,P}$ = 7.8, J_{vic} = 6.3, 2H, $(CH_3)_2CH$), 4.72 (bs, 2H, NH_2-2), 5.35 (bs, 2H, NH_2-6), 6.96 (ddd, $J_{3',F}$ = 8.3, $J_{3',5'}$ = 1.5, $J_{3',F}$ = 8.1, 1H, H-3′), 7.04 (ddd, $J_{5',F}$ = 8.3, $J_{5',6'}$ = 7.5, $J_{3',5'}$ = 1.5, 1H, H-5′), 7.70 (ddd, $J_{5',6'}$ = 7.5, $J_{6',F}$ = 5.0, $J_{6',F}$ = 5.0, 1H, H-6′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.47 and 23.94 (d, $J_{C,P}$ = 4.3 $(CH_3)_2CH$), 43.15 (CH_2N), 65.43 (d, $J_{C,P}$ = 162, CH_2P), 70.74 (d, $J_{C,P}$ = 13, CH_2O), 71.30 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 102.74 (C-3′), 112.32 (C-5), 113.68 (C-5′), 119.65 (C-1′), 132.78 (C-6′), 154.58 (C-8), 156.47 (C-4), 156.59 (C-6), 159.49 (C-2′), 162.75 (C-4′), 163.29 (C-2) ppm. MS (ESI): *m*/*z* (%): 507 (30) $[M + Na]^+$, 485 (100) $[M + H]^+$. Anal. calcd for $C_{20}H_{27}F_2N_6O_4P$ (484.5): C 49.59, H 5.62, N 17.35; found: C 49.65, H 5.51, N 17.38.

Diisopropyl 2,6-diamino-8-(thien-3-yl)-9-[2-(phosphonomethoxy)ethyl]purine (2i)

Method C gave a colourless oil; yield: 290 mg (64%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.17 and 1.26 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 3.57 (d, $J_{H,P}$ = 8.7, 2H, CH_2P), 3.96 (t, J_{vic} = 5.6, 2H, CH_2O), 4.34 (t, J_{vic} = 5.6, 2H, CH_2N), 4.58 (dh, $J_{H,P}$ = 7.4, J_{vic} = 6.2, 2H, $(CH_3)_2CH$), 4.85 (bs, 2H, NH_2-2), 5.51 (bs, 2H, NH_2-6), 7.22 (dd, $J_{5',4'}$ = 7.5, $J_{5',1'}$ = 1.5, 1H, H-5′), 7.74 (dd, $J_{4',5'}$ = 7.5, $J_{4',1'}$ = 2.9, 1H, H-4′), 8.01 (ddd, $J_{5',6'}$ = 2.9, $J_{2',4'}$ = 5.0, $J_{2',5'}$ = 1.5, 1H, H-2′) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.17 and 23.64 (d, $J_{C,P}$ = 4.2 $(CH_3)_2CH$), 42.95 (CH_2N), 66.21 (d, $J_{C,P}$ = 165, CH_2P), 70.26 (d, $J_{C,P}$ = 12, CH_2O), 71.35 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 113.47 (C-5), 126.38 (C-2′), 127.60 (C-4′), 128.19 (C-5′), 135.51 (C-1′), 154.28 (C-8), 157.74 (C-4), 160.19 (C-6), 164.86 (C-2) ppm. For personal use only.

dine under an argon atmosphere. The reaction mixture was stirred at rt until the complete consumption of magnesium, cooled to –78 °C, and a solution of $ZnCl_2$ in THF (1 mol/L, 5 mL, 5 mmol) was added. The resulting mixture was stirred at rt for 1 h and subsequently added to the solution of compound **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in dry DMF (5 mL), and the mixture was stirred at rt for 3 h. The solvent was evaporated and the residue in EtOAc was washed with water and the solvent was evaporated. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized from EtOH to give **2l** (328 mg, 71%) as colourless crystals; mp 185–187 °C. MS (ESI): *m/z* (%): 485 (100) $[M + Na]^+$. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.17 and 1.26 (2 × d, J_{vic} = 6.4, 12H, $(CH_3)_2CH$), 3.63 (d, $J_{H,P}$ = 8.6, 2H, CH_2P), 4.01 (s, 2H, H-1′), 4.05 (t, J_{vic} = 5.5, 2H, CH_2O), 4.31 (t, J_{vic} = 5.5, 2H, CH_2N), 4.60 (dh, $J_{H,P}$ = 7.8, J_{vic} = 6.4, 2H, $(CH_3)_2CH$), 5.25 (bs, 2H, NH_2-2), 6.38 (bs, 2H, NH_2-6), 7.34–7.42 (m, 3H, H-o,p-Ph), 7.58 (m, 2H, H-m-Ph) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.52 and 23.68 (d, $J_{C,P}$ = 4.0 $(CH_3)_2CH$), 32.11 (CH_2-1′), 43.72 (CH_2N), 66.82 (d, $J_{C,P}$ = 164, CH_2P), 71.92 (d, $J_{C,P}$ = 11, CH_2O), 72.08 (d, $J_{C,P}$ = 7, $(CH_3)_2CH$), 113.37 (C-5), 128.53 (CH-m-Ph), 128.97 (CH-o-Ph), 134.74 (C-i-Ph), 150.12 (C-8), 153.82 (C-4), 156.92 (C-6), 161.35 (C-2) ppm. MS (ESI) *m/z* (%): 485 (100) $[M + Na]^+$. Anal. calcd for $C_{21}H_{31}N_6O_4P$ (462.5): C 54.54, H 6.76, N 18.17; found: C 54.63, H 6.62, N 18.10.

Diisopropyl 8-allyl-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (2e)

1,2-Dibromoethane (15 μL, 0.1 mmol) was added to a zinc (326 mg, 5 mmol) suspension in THF (2 mL) under an argon atmosphere, and the resulting mixture was sonicated for 15 min. Allylbromide (105 μL, 1.2 mmol) in DMF (1.5 mL) was added and the mixture was sonicated for a further 45 min. After zinc sedimentation, the supernatant was added to a mixture of compound **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in dry DMF (5 mL) under an argon atmosphere. The reaction mixture was stirred at rt for 2 h. The solvent was evaporated and the residue in EtOAc was washed with water and the solvent was evaporated. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized from EtOH to give **2e** (263 mg, 64%) as colourless crystals.

Diisopropyl 2,6-diamino-8-trifluoromethyl-9-[2-(phosphonomethoxy)ethyl]purine (2m)

1,2-Dibromomethane (15 μL, 0.1 mmol) was added to a zinc suspension (326 mg, 5 mmol) in dry THF (2 mL) under an argon atmosphere, and the mixture was sonicated for 15 min, cooled to –78 °C, and trifluoromethyl iodide (105 μL, 1.2 mmol) was added. The resulting mixture was sonicated and cooled until the complete dissolution of zinc (30 min). The solution was then added to compound **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in dry DMF (5 mL), and the reaction mixture was stirred at rt for 2 h. The solvent was removed and the residue in EtOAc was washed with H_2O and the solvent was evaporated. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) to give **2m** (212 mg, 55%) as a colourless solid. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.23 and 1.29 (2 × d, J_{vic} = 6.3, 12H, $(CH_3)_2CH$), 3.43 (d, $J_{H,P}$ = 8.5, 2H, CH_2P), 3.81 (t, J_{vic} = 5.4, 2H, CH_2O), 4.13 (t, J_{vic} = 5.4, 2H, CH_2N), 4.36 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.3, 2H $(CH_3)_2CH$), 4.64 (bs, 2H, NH_2-2), 5.38 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.75 and 23.92 (d, $J_{C,P}$ = 4.0, $(CH_3)_2CH$), 41.47 (CH_2N), 64.01 (d, $J_{C,P}$ = 164, CH_2P), 71.89 (d, $J_{C,P}$ = 7.0, $(CH_3)_2CH$), 72.04 (d, $J_{C,P}$ = 4.0, CH_2O), 113.93 (C-5), 117.85 (CF_3), 148.76 (C-8), 152.95 (C-4), 154.90 (C-6), 160.37 (C-2). MS (ESI) *m/z* (%): 463 (25) $[M + Na]^+$, 441 (100) $[M + H]^+$. Anal. calcd for $C_{15}H_{24}F_3N_6O_4P$ (440.4): C 40.91, H 5.49, N 19.08; found: C 41.02, H 4.38, N 19.05.

Diisopropyl 8-cyclopropyl-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (2n)

n-BuLi (2 mol/L solution in hexanes, 1.2 mL, 3 mmol) was added to cyclopropyl bromide (362 mg, 242 μL, 3 mmol) in THF (4 mL) at –78 °C under an argon atmosphere and stirred at –78 °C for 15 min. Anhydrous $ZnCl_2$ in THF (1 mol/L solution, 3 mL, 3 mmol) was added, and the mixture was stirred at rt for 1 h. The resulting mixture was added to compound **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in dry DMF (5 mL), and the reaction mixture was stirred at rt for 2 h. The solvent was evaporated and the residue in EtOAc was washed with water and the solvent was evaporated. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized from EtOH to give **2n** (200 mg, 49%) as colourless crystals, mp 178–180 °C. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.11 (d, J_{vic} = 7.2, 4H, H-2′,3′), 1.18 and 1.24 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 1.59 (d, J_{vic} = 7.2, 1H, CH-1′), 3.60 (d, $J_{H,P}$ = 8.5, 2H, CH_2P), 4.12 (t, J_{vic} = 5.3, 2H, CH_2O), 4.40 (t, J_{vic} = 5.3, 2H, CH_2N), 4.53 (dh, $J_{H,P}$ = 7.7, J_{vic} = 6.2, 2H $(CH_3)_2CH$), 4.98 (bs, 2H, NH_2-2), 5.56 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 3.69 (C-1′), 8.24 (C-2′,3′), 23.56 and 23.74 (d, $J_{C,P}$ = 4.0, $(CH_3)_2CH$), 41.48 (CH_2N), 66.03 (d, $J_{C,P}$ = 167, CH_2P), 70.59 (d, $J_{C,P}$ = 12.0, CH_2O), 71.36 (d, $J_{C,P}$ = 7.0, $(CH_3)_2CH$), 113.89 (C-5), 134.58 (C-8), 152.91 (C-4), 155.78 (C-6), 163.04 (C-2). MS (ESI) *m/z* (%): 435 (60) $[M + Na]^+$, 413 (100) $[M + H]^+$. Anal, calcd for $C_{17}H_{29}N_6O_4P$ (412.4): C 49.51, H 7.09, N 20.38; found: C 49.71, H 6.98, N 20.34.

Diisopropyl 2,6-diamino-8-(2-ethoxy-2-oxoethyl)-9-[2-(phosphonomethoxy)ethyl]purine (2o)

1,2-Dibromomethane (15 μL, 0.1 mmol) was added to a zinc (326 mg, 5 mmol) suspension in freshly distilled THF (2 mL) under an argon atmosphere, and the mixture was sonicated for 15 min. Ethyl 2-bromoacetate (654 μL, 4 mmol) in dry DMF (2 mL) was added and the mixture was sonicated for 45 min. After zinc decantation, the supernatant was added to a mixture of compound **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in dry DMF (5 mL) under an argon atmosphere. The reaction mixture was stirred at rt for 3 h. The solvent was evaporated and the residue in EtOAc was washed with water and the solvent was evaporated. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) to give **2o**

Diisopropyl 8-cyano-2,6-diamino-9-[2-(phosphonomethoxy)ethyl]purine (2p)

Compound **1** (400 mg, 0.84 mmol), $Zn(CN)_2$ (295 mg, 2.5 mmol), Pd_2dba_3 (87 mg, 0.15 mmol), and dppf (92 mg, 0.16 mmol) in dry NMP (5 mL) were stirred under an argon atmosphere for 3 h. The solvent was evaporated and the residue suspended in $CHCl_3$ (30 mL), filtered through Celite, and washed with water (3 × 20 mL). The organics were dried over $MgSO_4$, purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1), and crystallized from EtOH to give **2p** (260 mg, 81%) as a white crystalline product, mp 164–166 °C. ^{1}H NMR (500 MHz, MeOD) δ: 1.19 and 1.24 (2 × d, J_{vic} = 6.2, 12H, $(CH_3)_2CH$), 3.78 (d, $J_{H,P}$ = 8.3, 2H, CH_2P), 3.92 (t, J_{vic} = 5.0, 2H, CH_2O), 4.34 (t, J_{vic} = 5.0, 2H, CH_2N), 4.55 (dh, $J_{H,P}$ = 7.4, J_{vic} = 6.2, 2H $(CH_3)_2CH$), 4.73 (bs, 2H, NH_2-2), 5.45 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.86 and 23.98 (d, $J_{C,P}$ = 4.0, $(CH_3)_2CH$), 43.20 (CH_2N), 64.67 (d, $J_{C,P}$ = 141, CH_2P), 69.28 (d, $J_{C,P}$ = 7.0, $(CH_3)_2CH$), 72.36 (d, $J_{C,P}$ = 5.0, CH_2O), 111.43 (C-5), 113.24 (CN), 129.62 (C-8), 154.93 (C-4), 156.74 (C-6), 162.15 (C-2) ppm. MS (ESI) *m/z* (%): 420 (100) $[M + Na]^+$, 398 (91) $[M + H]^+$. Anal. calcd for $C_{15}H_{24}N_7O_4P$ (397.4): C 45.34, H 6.09, N 24.67; found: C 45.48, H 6.04, N 24.31.

Reactions with trialkylaluminum reagents

Method D (general procedure)

Trialkylaluminum (3 mmol) was added to smixture of 8-bromopurine **1** (475 mg, 1 mmol) and $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) in THF (5 mL) under an argon atmosphere and the reaction mixture was stirred at reflux for 5 h. The solvent was evaporated, washed with brine and saturated aqueous EDTA solution, and dried over $MgSO_4$. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized from EtOH.

Diisopropyl 2,6-diamino-8-methyl-9-[2-(phosphonomethoxy)ethyl]purine (2a)

Treatment of **1** with trimethylaluminum using Method D afforded **2a** as colourless crystals; yield: 221 mg (54%).

Diisopropyl 2,6-diamino-8-ethyl-9-[2-(phosphonomethoxy)ethyl]purine (2b)

Treatment of **1** with triethylaluminum using Method D gave **2b** as colourless crystals; yield: 203 mg (48%).

Deprotection of Diisopropyl esters 2 to free phosphonic acids 3

Method E (general procedure)

Diisopropylesters **2a**–**2p** (0.5 mmol) in CH_3CN (10 mL) were treated with Me_3SiBr (2 mL, 15.2 mmol), and the reaction mixture was stirred at rt overnight. The volatiles were removed under reduced pressure, the residue was co-distilled with toluene (5 mL) and TEAB (tetrabutylammonium bicarbonate, 0.5 mol/L, 2 mL) was added and the solvent was evaporated. The residue in H_2O (5 mL) was applied onto a column of Dowex 50 × 8 (H^+). The column was washed with water and the product was eluted with 2.5% aqueous ammonia. The crude product was then applied to a column of Dowex 1 × 2 (AcO^-), the column was then washed with water, and the product was eluted with a linear gradient of AcOH (0–2 mol/L). The product-containing fractions were evaporated and co-distilled with water (2 × 10 mL), and the crude product was crystallized from the H_2O/EtOH mixture.

2,6-Diamino-8-methyl-9-[2-(phosphonomethoxy)ethyl]purine (3a)

Method E afforded a colourless solid; yield: 67%; mp > 250 °C. ^{1}H NMR (500 MHz, D_2O) δ: 2.45 (s, 3H, CH_3-8), 3.26 (d, $J_{H,P}$ = 8.6, 2H, CH_2P), 3.85 (t, J_{vic} = 5.2, 2H, CH_2O), 4.11 (t, J_{vic} = 5.2, 2H, CH_2N) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 15.66 (CH_3-8), 44.99 (CH_2N), 70.29 (d, $J_{C,P}$ = 155, CH_2P), 73.27 (d, $J_{C,P}$ = 4.0, CH_2O), 112.98 (C-5), 152.62 (C-8), 154.05 (C-4), 155.30 (C-6), 159.75 (C-2) ppm. MS (ESI) *m/z* (%): 303 (100) $[M + H]^+$. Anal. calcd for $C_9H_{15}N_6O_4P$ (302.2): C 35.77, H 5.00, N 27.81; found: C 35.82, H 4.92, N 27.95.

2,6-Diamino-8-ethyl-9-[2-(phosphonomethoxy)ethyl]purine (3b)

Method E afforded a colourless solid; yield: 81%; mp > 250 °C. ^{1}H NMR (500 MHz, D_2O) δ: 1.32 (t, J_{vic} = 7.5, 3H, CH_3CH_2), 2.84 (q, J_{vic} = 7.5, 2H, CH_3CH_2), 3.50 (d, $J_{H,P}$ = 8.3, 2H, CH_2P), 3.84 (t, J_{vic} = 5.7, 2H, CH_2O), 4.16 (t, J_{vic} = 5.7, 2H, CH_2N) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 13.09 (CH_3CH_2), 22.83 (CH3CH_2), 44.61 (CH_2N), 70.58 (d, $J_{C,P}$ = 152, CH_2P), 72.89 (d, $J_{C,P}$ = 10.0, CH_2O), 114.12 (C-5), 154.67 (C-4), 156.73 (C-8), 157.22 (C-6), 161.68 (C-2) ppm. MS (ESI) *m/z* (%): 317 (100) $[M + H]^+$. Anal. calcd for $C_{10}H_{17}N_6O_4P$ (316.2): C 37.98, H 5.42, N 26.57; found: C 38.12, H 5.48, N 26.41.

2,6-Diamino-8-phenyl-9-[2-(phosphonomethoxy)ethyl]purine (3c)

Method E afforded a colourless solid; yield: 78%; mp > 250 °C. ^{1}H NMR (400 MHz, D_2O) δ: 3.65 (d, $J_{H,P}$ = 8.4, 2H, CH_2P), 4.00 (t, J_{vic} = 5.6, 2H, CH_2O), 4.18 (t, J_{vic} = 5.6, 2H, CH_2N), 7.48–7.53 (m, 3H, H-m, p-Ph), 7.81 (m, 2H, H-o-Ph) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 43.15 (CH_2N), 71.47 (d, $J_{C,P}$ = 151, CH_2P), 72.34 (d, $J_{C,P}$ = 12.0, CH_2O), 113.75 (C-5), 128.51 (CH-m-Ph), 129.26 (CH-o-Ph), 129.29 (C-i-Ph), 149.07 (C-8), 153.16 (C-4), 155.23 (C-6),

2), 6.49 (bs, 2H, NH_2-6), 7.35–7.44 (m, 3H, H-o, p-Ph), 7.59 (m, 2H, H-m-Ph) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 32.46 (CH_2-1′), 43.15 (CH_2N), 67.23 (d, $J_{C,P}$ = 167, CH_2P), 72.59 (d, $J_{C,P}$ = 11.0, CH_2O), 113.32 (C-5), 128.45 (CH-m-Ph), 129.03 (CH-o-Ph), 134.56 (C-i-Ph), 150.88 (C-8), 154.27 (C-4), 156.13 (C-6), 159.90 (C-2) ppm. MS (ESI) *m/z* (%): 379 (100) $[M + H]^+$.

2,6-Diamino-8-(trifluoromethyl)-9-[2-(phosphonomethoxy)ethyl]purine (3m)

Method E gave a colourless solid; yield: 81%; mp > 250 °C. ^{1}H NMR (500 MHz, D_2O) δ: 3.48 (d, $J_{H,P}$ = 8.2, 2H, CH_2P), 3.78 (t, J_{vic} = 5.4, 2H, CH_2O), 4.40 (t, J_{vic} = 5.4, 2H, CH_2N), 4.68 (bs, 2H, NH_2-2), 5.32 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 41.48 (CH_2N), 64.12 (d, $J_{C,P}$ = 165, CH_2P), 72.02 (d, $J_{C,P}$ = 4.0, CH_2O), 114.78 (C-5), 117.91 (CF_3), 148.54 (C-8), 153.06 (C-4), 155.32 (C-6), 160.26 (C-2) ppm. MS (ESI) *m/z* (%): 357 (100) $[M + H]^+$. Anal. calcd for $C_9H_{12}F_3N_6O_4P$ (356.2): C 30.35, H 3.40, N 23.59; found: C 30.51, H 3.34, N 23.51.

2,6-Diamino-8-(cyclopropyl)-9-[2-(phosphonomethoxy)ethyl]purine (3n)

Method E afforded a colourless solid; yield: 74%; mp > 250 °C. ^{1}H NMR (500 MHz, D_2O) δ: 1.13 (d, J_{vic} = 7.1, 4H, H-2′,3′), 1.61 (d, J_{vic} = 7.1, 1H, CH-1′), 3.58 (d, $J_{H,P}$ = 8.4, 2H, CH_2P), 4.10 (t, J_{vic} = 5.5, 2H, CH_2O), 4.45 (t, J_{vic} = 5.5, 2H, CH_2N), 5.04 (bs, 2H, NH_2-2), 5.51 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: = 3.63 (C-1′), 8.27 (C-2′,3′), 41.38 (CH_2N), 66.12 (d, $J_{C,P}$ = 161, CH_2P), 70.47 (d, $J_{C,P}$ = 12.0, CH_2O), 113.24 (C-5), 134.63 (C-8), 152.74 (C-4), 156.72 (C-6), 163.89 (C-2) ppm. MS (ESI) *m/z* (%): 351 (50) $[M + Na]^+$, 329 (100) $[M + H]^+$.

2,6-Diamino-8-(cyano)-9-[2-(phosphonomethoxy)ethyl]purine (3p)

Method E gave a colourless solid; yield: 65%; mp > 250 °C. MS (ESI): *m/z* (%): 314 (100) $[M + H]^+$. ^{1}H NMR (500 MHz, D_2O) δ: 3.82 (d, $J_{H,P}$ = 8.4, 2H, CH_2P), 3.84 (t, J_{vic} = 5.3, 2H, CH_2O), 4.38 (t, J_{vic} = 5.3, 2H, CH_2N), 4.62 (bs, 2H, NH_2-2), 5.48 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 43.96 (CH_2N), 64.50 (d, $J_{C,P}$ = 131, CH_2P), 73.03 (d, $J_{C,P}$ = 5.0, CH_2O), 111.96 (C-5), 113.22 (CN), 130.75 (C-8), 154.24 (C-4), 156.48 (C-6), 162.27 (C-2) ppm. MS (ESI) *m/z* (%): 314 (100) $[M + H]^+$.

Diisopropyl 2,6-diamino-8-[(2-trimethylsilyl)ethynyl]-9-[2-(phosphonomethoxy)ethyl]purine (4)

Triethylamine (0.2 mL, 1.5 mmol) was added to amixture of the compound **1** (475 mg, 1 mmol), CuI (10 mg, 0.05 mmol), and $Pd(PPh_3)_2Cl_2$ (35 mg, 0.05 mmol) in dry DMF (4 mL) under an argon atmosphere at rt, and the resulting mixture was stirred for 15 min at rt. Trimethylsilylacetylene (160 μL, 1.15 mmol) in THF (1 mL) was added and the reaction mixture was stirred at rt for 3 h. The solvent was evaporated and the residue in EtOAc was washed with water and dried over $MgSO_4$. The crude product was purified by column chromatography (SiO_2, EtOAc/acetone/EtOH/H_2O, 18:3:1:1) and crystallized form EtOH to give **4** (350 mg, 67%) as a pale yellow crystalline product; mp 146–148 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.30 (s, 9H, CH_3Si), 1.24 and 1.28 (2 × d, J_{vic} = 6.2, 12H, (CH_3)$_2$CH), 3.77 (d, $J_{H,P}$ = 8.6, 2H, CH_2P), 3.98 (t, J_{vic} = 5.8, 2H, CH_2O), 4.31 (t, J_{vic} = 5.8, 2H, CH_2N), 4.48 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.2, 2H (CH_3)$_2$C*H*), 5.73 (bs, 2H, NH_2-2), 7.28 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: –0.48 (CH_3Si), 23.86 and 24.00 (d, $J_{C,P}$ = 4.0, (CH_3)$_2$CH), 42.36 (CH_2N), 65.73 (d, $J_{C,P}$ = 167, CH_2P), 70.28 (d, $J_{C,P}$ = 11.0, CH_2O), 71.13 (d, $J_{C,P}$ = 7.0, (CH_3)$_2$*C*H), 93.26 (C-1′), 101.53 (C-2′), 114.06 (C-5), 131.93 (C-8), 151.84 (C-4), 155.65 (C-6), 160.43 (C-2) ppm. MS (ESI) *m/z* (%): 469 (100) $[M + Na]^+$. Anal. calcd for $C_{19}H_{33}N_6O_4PSi$ (468.6): C 48.70, H 7.10, N 17.94; found: C 48.75, H 7.00, N 18.06.

2,6-Diamino-8-(ethynyl)-9-[2-(phosphonomethoxy)ethyl]purine (5)

Compound **4** (261 mg, 0.5 mmol) was stirred in methanolic ammonia (10 mol/L, 5 mL) at rt overnight. The volatiles were evaporated and the crude product was recrystallized from an EtOAc – light petroleum (1:1) mixture to give 197 mg (94%) of 8-ethylnyl derivative as a colourless crystalline product; mp 192–194 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.23 and 1.28 (2 × d, J_{vic} = 6.2, 12H, (CH_3)$_2$CH), 3.41 (s, 1H, CH-2′), 3.75 (d, $J_{H,P}$ = 8.5, 2H, CH_2P), 3.97 (t, J_{vic} = 5.8, 2H, CH_2O), 4.33 (t, J_{vic} = 5.8, 2H, CH_2N), 4.48 (dh, $J_{H,P}$ = 7.6, J_{vic} = 6.2, 2H (CH_3)$_2$C*H*), 4.82 (bs, 2H, NH_2-2), 5.48 (bs, 2H, NH_2-6) ppm. ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.88 and 24.00 (d, $J_{C,P}$ = 4.0, (CH_3)$_2$CH), 42.57 (CH_2N), 65.83 (d, $J_{C,P}$ = 167, CH_2P), 70.40 (d, $J_{C,P}$ = 11.0, CH_2O), 71.15 (d, $J_{C,P}$ = 7.0, (CH_3)$_2$*C*H), 73.30 (C-1′), 82.66 (C-2′), 114.20 (C-5), 131.25 (C-8), 151.91 (C-4), 155.71 (C-6), 160.60 (C-2) ppm. MS (ESI) *m/z* (%): 397 (100) $[M + H]^+$. Anal. calcd for $C_{16}H_{25}N_6O_4P$ (396.4): C 48.48, H 6.36, N 21.20; found: C 48.42, H 6.45, N 21.27.

Deprotected 8-ethynylpurine derivative **5** was prepared by GP3, isolated by preparative HPLC (eluted with 1% MeOH in H_2O), and crystallized from an EtOH/H_2O mixture to give pale yellow crystals; yield: 31%; mp > 250 °C. ^{1}H NMR (500 MHz, D_2O) δ: 3.64 (d, $J_{H,P}$ = 8.4, 2H, CH_2P), 3.94 (t, J_{vic} = 5.0, 2H, CH_2O), 4.08 (bs, 1H, CH-2′), 4.29 (t, J_{vic} = 5.0, 2H, CH_2N) ppm. ^{13}C NMR (125.8 MHz, D_2O) δ: 45.48 (CH_2N), 69.76 (d, $J_{C,P}$ = 156, CH_2P), 72.82 (d, $J_{C,P}$ = 10.0, CH_2O), 74.28 (C-1′), 88.30 (C-2′), 114.96 (C-5), 134.94 (C-8), 153.12 (C-4), 157.53 (C-6), 161.99 (C-2) ppm. MS (ESI) *m/z* (%): 313 (100) $[M + H]^+$. Anal. calcd for $C_{10}H_{13}N_6O_4P$ (312.2): C 38.47, H 4.20, N 26.92; found: C 38.42, H 4.26, N 27.04.

Acknowledgments

This study was performed as a part of research project OZ40550506 of the Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic, Prague. It was supported by the Centre for New Antivirals and Antineoplastics 1M0508 by the Ministry of Education, Youth, and Sports of the Czech Republic and by the Gilead Sciences and IOCB Research Centre, Prague, Czech Republic.

Abstract: This study presents the synthesis and physical characterization of a series of structurally well-defined star-shaped poly(lactic acids). Polymer stars are prepared from a series of multifunctional alcohol cores including flexible polyols pentaerythritol and dipentaerythritol (four-armed and six-armed cores, respectively) and rigid substituted arenes tri(hydroxymethyl)benzene and hexa(hydroxymethyl)benzene. Utilizing a tin(II) octanoate catalyst, arms of 10 monomer units long are built from *rac*-lactide and L-lactide to form atactic and isotactic star polymers. Polymers were subsequently characterized by means of NMR spectroscopy, gel permeation chromatography, differential scanning calorimetry, and thermogravimetric analysis. Our results support previous work that suggests that the length of the individual arms, not the total molecular weight, correlates to physical characteristics including glass, melt, crystallization, and decomposition temperatures. In addition, differences between core molecules suggest that the chemical nature of the core can significantly alter the physical properties of the star polymer. Trends in crystallization and glass transition temperatures relative to the core used merit further study and correlate closest to the molecular weight and the number of arms emanating from the star core. It is also clear that the rigidity provided by aromatic cores has a significant effect on the melting temperatures of these macromolecules.

Key words: Polymer star, lactide, poly(lactic acid), ring opening polymerization.

Résumé : On a réalisé la synthèse et effectué la caractérisation physique d'une série d'acides poly(lactique) bien définie et en forme étoilée. Les polymères étoilés ont été préparés à partir d'une série l'alcools de base multifonctionnels, dont les polyols flexibles pentaérythritol et dipentaérythritol (respectivement les alcools de base à quatre et à six branches) et des arènes substitués rigides, tels le tri(hydroxyméthyl)benzène et l'hexa(hydroxyméthyl)benzène. Faisant appel à l'octanoate de zinc comme catalyseur et les *rac*-lactide et L-lactide comme monomères, on prépare des bras comportant 10 unités monomères de longueur dans les formes atactique et isotactique des polymères étoilés. On a subséquemment caractérisé ces polymères par spectroscopie RMN, par chromatographie par perméation de gel, par calorimétrie à balayage différentiel et par analyse thermogravimétrique. Les résultats obtenus sont en accord avec ceux obtenus antérieurement d'après lesquels c'est avec le nombre total de bras individuels, et non le poids moléculaire total, qu'il existe une corrélation avec les caractéristiques physiques, dont les températures de transition vitreuse, de fonte, de cristallisation et de décomposition. De plus, les différences entre les molécules de base suggèrent que la nature chimique de la base peut altérer les propriétés physiques d'un polymère étoilé d'une façon significative. Les tendances dans les températures de cristallisation et de transition vitreuse par rapport à celles des molécules de base méritent des études ultérieures et donne la meilleure corrélation avec le poids moléculaire et le nombre de bras émanant de la base étoilée. Il est aussi clair que la rigidité fournit par les molécules de base aromatiques provoque un effet significatif sur les températures de fusion de ces macromolécules.

Mots-clés : polymèrer étoilé, lactide, acide poly(lactique), polymérisation par ouverture de cycle.

[Traduit par la Rédaction]

Introduction

Poly(lactic acid) (PLA) has become an essential green material as it is derived from renewable feedstocks, is biodegradable and bioassimilable, and has found many niche applications across a broad sweep of commercial fields.[1] Of particular interest is the role these and other aliphatic polyesters have to play in the biomedical industry.[2] Whereas linear PLA homo- and co-polymers have been used in sutures and stents since 1960,[3] the physical properties of the macromolecules can be refined by incorporating PLA into more complex macrostructures like polymer stars[4] and brushes.[5] In particular, PLA polymer stars have found utility as matrices for controlled-release drug delivery and other biomedical applications.[6]

The core-first approach dominates star polymer synthesis for PLA, where a multifunctional initiator promotes the ring-opening polymerization of the lactide monomer from alcohol or amine functionalities. When catalyzed by tin(II) octanoate ($Sn(Oct)_2$), the reaction transforms *rac*- or L-lactide into atactic PLA (a-PLA) and isotactic PLA (L-PLA) stars,

respectively. Previous studies have focused on the role of molecular weight[7] or polymer tacticity[8] in shaping polymer properties, whereas others have examined the incorporation of PLA stars into miktoarm[9–11] and dendritic frameworks[12–14] or examined the application of these materials in self assembly and drug delivery.[15,16] The initiator is also a key differentiator between polymer stars. A diverse array of simple multifunctional polyols have been used as initiators for PLA polymer stars[4] including three-armed stars prepared from trimethylolpropane and glycerol; four-armed stars from pentaerythritol, ditrimethylolpropane, and erythritol; five-armed stars from xylitol; six-armed stars from dipentaerythritol, inositol, and sorbitol; and eight-armed stars from tripentaerythritol. Less clear is the effect of these cores on polymer star synthesis or properties, but some key trends have been observed. The macromolecular structure dependence of thermal properties were investigated for three- to six-armed L-PLA stars.[17] Increasing molecular weights of six-armed sorbitol polymers correlated to concomitant increases in thermal decomposition (T_d) and melting (T_m) temperatures, a trend exacerbated by the different reactivities between primary and secondary alcohol functionalities in the sorbitol core. For polymer stars with similar theoretical absolute molecular weights ($M_{n,th}$), structures with fewer arms exhibited higher T_m values, suggesting that physical properties correlate with the length of the polymer arm emanating from the star core rather than the absolute molecular weight of the star.[17]

There is a surprising lack of chemical diversity in the choice of simple discrete initiators for this ring-opening polymerization because of an expected focus on flexible sugar alcohols. Cores with more rigidity include β-cyclodextrins,[18] modified perylenes,[19] hexahydroxytriphenylene,[20] and dibenzoylmethane- and bipyridine-ligated metal complexes.[21] Whereas these cores impart photochemical, spectroscopic, and supramolecular properties to the stars, no correlation between core structure and properties has been made.

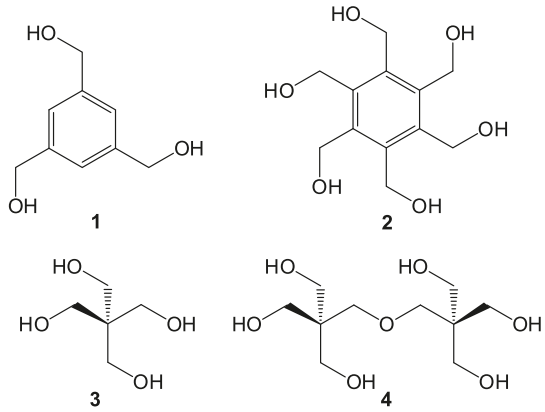
In this vein we endeavoured to develop synthetic methodologies to prepare three-, four-, and six-armed star polymers of *rac*- and L-lactide with variable core structures with a focus on simple rigid cores. Specifically, we targeted PLA stars built from 1,3,5-tri(hydroxymethyl)benzene (THMB, **1**), hexa(hydroxymethyl)benzene (HHMB, **2**), pentaerythritol (PE, **3**), and dipentaerythritol (DPE, **4**) (Fig. 1) and characterized the star polymers with gel permeation chromatography (GPC), ^{1}H NMR spectroscopy, thermogravimetric analysis (TGA), and differential scanning calorimetry (DSC).

Experimental

Materials

HPLC-grade toluene, THF, methanol, and dichloromethane were purchased from Fisher Scientific and deuterated solvents were purchased from Cambridge Isotopes. Anhydrous toluene was obtained by passing the solvent through an Innovative Technologies solvent purification system consisting of columns of alumina and a copper catalyst. Anhydrous solvents were tested with addition of a toluene solution of sodium benzophenone ketyl prior to use. $Sn(Oct)_2$ was purchased from Sigma-Aldrich Chemical Co. and distilled prior to use. Dipentaerythritol and pentaerythritol were purchased from Sigma-Aldrich Chemical Co. and purified by recrystallization from methanol and vacuum sublimation three times, respectively, before being dried in vacuo for 48 h prior to use. 1,4-Dioxane was dried over CaH_2 and distilled prior to use. Benzene-1,3,5-tricarboxylic acid (98%) was purchased from Sigma-Aldrich Chemical Co. and used as received. The monomers *rac*- and L-lactide were purchased from PURAC Biomaterials and purified by three successive vacuum sublimations of the material prior to use.

Fig. 1. Core molecules for poly(lactic acid) star polymers.



General considerations

All experiments involving moisture- and air-sensitive compounds and catalysts were performed under a nitrogen atmosphere using an MBraun LABmaster sp. glovebox system equipped with a –35 °C freezer and [H_2O] and [O_2] analyzers. GPC was carried out in THF (flow rate: 1 mL min^{-1}) at 50 °C with a Polymer Labs PL–GPC 50 Plus integrated GPC system using three 300 mm × 7.5 mm Resipore columns. Polystyrene standards were used for calibration and corrected for PLA.[22] ^{1}H NMR spectra were recorded with a Bruker Avance spectrometer (300 MHz) in $CDCl_3$ or D_2O. TGA was performed on a TA instruments TGA Q500 under an inert nitrogen atmosphere with a flow rate of 60 mL min^{-1} and a heating rate of 10 °C min^{-1}. DSC was performed on a TA instruments DSC Q100 using a heating rate of 5 °C min^{-1} and a flow rate of 50 mL min^{-1}. Guelph Analytical Laboratories conducted the CHN elemental analyses.

Core syntheses

1,3,5-Tri(hydroxymethyl)benzene

This procedure was modified from an existing literature procedure.[23] In a glovebox, lithium aluminum hydride (2.505 g, 6.60 mmol) was added to a 250 mL round bottom Schlenk flask and suspended in 10 mL of anhydrous THF. The vessel was sealed and removed from the glovebox. Trimethyl 1,3,5-benzene-tricarboxylate (5.002 g, 1.98 mmol) was dissolved in 50 mL of anhydrous THF in a 250 mL Schlenk tube. The carboxylate solution was added via cannula dropwise to the $LiAlH_4$, and the dark grey lithium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

suspension turned to a deep orange colour that quickly dissipated. Upon completion of the carboxylate addition, the mixture was a deep green colour. The mixture was allowed to reflux for 5 h after which the vessel was cooled in an ice–water bath and stirred. Three solutions (5 mL H_2O, 5 mL 15% (*w*/*w*) NaOH in H_2O, and 15 mL H_2O) were sequentially added in a dropwise fashion to quench any remaining $LiAlH_4$ and hydrolyze the Al salts. Filtration and washing with three 20 mL portions of THF provided a colourless filtrate. Organics were removed under reduced pressure, yielding a colourless crude oil in 92% yield. Purification of this material by recrystallization from ethyl acetate and column chromatography gave an analytically pure white powder (0.934 g, 0.56 mol, 28.2%). Improved yields were obtained by forgoing recrystallization and purifiying the material by silica gel column chromatography. ^{1}H NMR data (300 MHz, MeOD, 298 K) δ: 7.25 (s, 3H, Ar*H*), 4.60 (s, 6H, ArCH_2). ^{13}C NMR data (75 MHz, MeOD, 298 K) δ: 141.41 (s, *Ar*-CH_2), 126.00 (s, *Ar*-H), 64.04 (s, *C*H_2). Elemental anal. calcd (%): C 65.27, H 7.19, N 0.00; found (%): C 65.41, H 7.22, N 0.00.

Hexa(hydroxymethyl)benzene

This synthesis was modified from an existing literature procedure.[24] In a glovebox, 2-butyne-1,4-diol (6.008 g, 6.98 mmol) was dissolved using 50 mL anhydrous dioxane in a 250 mL round bottom flask. Cyclopentadienylcobalt dicarbonyl (2.06 g, 1.05 mmol) was added, along with 50 mL dioxane, to a 500 mL Strauss flask, to which the alkyne solution was added in a dropwise fashion. The vessel was sealed and removed from the glovebox where it was left to react in a 130 °C oil bath for 4 days. The formation of an orange precipitate was evident after 1 day. After the allotted reaction time, the mixture was filtered using a fine glass filter frit, the solid was collected, washed three times using 25 mL THF, and dried in vacuo (3.73 g, 1.44 mmol, 62.0%). ^{1}H NMR data (300 MHz, d_6-DMSO, 298 K) δ: 4.86 (s, 6H, ArCH_2), 4.69 (s, 12H, O*H*). ^{13}C NMR data (75 MHz, d_6-DMSO, 298 K) δ: 138.79 (s, Ar), 56.75 (s, *C*H_2). Elemental anal. calcd (%): C 55.81, H 7.02, N 0.00; found (%): C 56.06, H 6.88, N 0.00.

Polymerization experiments

Polymerization procedures were modified from previously reported protocols.[25] All polymerization reactions were performed in sealed 25 mL round bottom ampoules under an inert atmosphere, at 125 °C, with a molar ratio of monomer – alcohol functionality – catalyst of 10:1:0.04. The catalyst employed in each instance was $Sn(Oct)_2$. Monomers employed included *rac*-lactide and L-lactide and core initiators **1**–**4**. Experiments were also conducted with a benzyl alcohol initiator to prepare a standard material for comparative purposes. The reaction proceeded for ~8 h and was then quenched with 10 mL of a 9:1 *v*/*v* solution of CH_2Cl_2–MeOH for 30 min at room temperature. The resulting mixture was precipitated from cold methanol, collected via filtration, washed with 50 mL H_2O and 50 mL MeOH, and dried in vacuo prior to analysis.

For example, *rac*-lactide (0.545 g, 3.86 mmol) and hexa(hydroxymethyl)benzene (0.0162 g, 6.83 mmol) were added to a dry 25 mL round bottom ampoule equipped with a magnetic stirring bar. The ampoule was connected to a Schlenk line, sealed, and evacuated for 10 min before being filled with N_2. This evacuation/refill procedure was repeated three times. A 7.33 mmol/L $Sn(Oct)_2$ solution in toluene (2.1 mL, 6.24 mg, 0.0154 mmol) was syringed into the vessel that was then sealed and put under vacuum to remove the toluene. The ampoule was then placed into a preheated oil bath at 125 °C for 8 h. After the allotted time, the vessel was cooled to room temperature, opened to the atmosphere, and quenched with 10 mL of a 9:1 *v*/*v* solution of CH_2Cl_2 and methanol. The solution was stirred for 30 min and then added dropwise to 100 mL of cold methanol to precipitate the polymer. The resultant white polymer was collected via filtration, washed with 50 mL MeOH and 50 mL H_2O, and dried in vacuo for 12 h. Monomer conversion was determined gravimetrically to be 89.7% (0.5033 g).

Results and discussion

Core and polymer synthesis

Whereas PE and DPE are commercially available polyols, the rigid THMB and HHMB cores had to be synthesized. The reduction of 1,3,5-benzene-tricarboxylate with excess lithium aluminum hydride provided the crude desired aromatic **1** in high yields. Purification substantially lowered

Fig. 2. Differential scanning calorimetry (DSC) profile for hexa(hydroxymethyl)benzene (HHMB) poly(lactic acid) (PLA) star **2-L**.

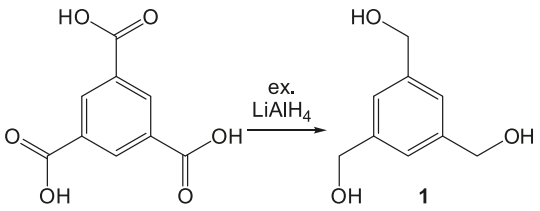
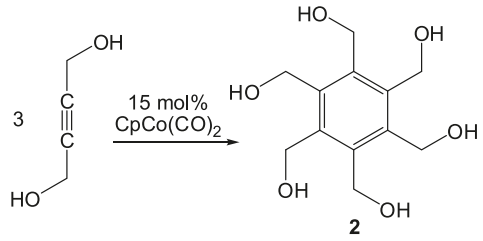
yields, but enough product was isolated from this effort that optimization of this step was not pursued. For the hexa-substituted core initiator, the $CpCo(CO)_2$ catalyzed cyclotrimerization of 2-butyne-1,4-diol afforded **2** in moderate yields. Attempts to synthesize **1** via a cobalt-catalyzed cyclotrimerization of 1-propyn-3-ol were unsuccessful, accessing a mixture of aromatic isomers with various substitution patterns arising from head-to-tail additions and an insoluble polymeric material resulting from thermal polymerization of the propargyl alcohol. These reactions are shown in eqs. [1] and [2], respectively.

[1]



[2]



PLA stars with 10 monomer units per alcohol functionality were synthesized. Oligomeric arm lengths were chosen because their low overall molecular weights accentuate the structural differences.[4] A molar ratio corresponding to 0.04 $Sn(Oct)_2$ units and 10 lactide monomer units per alcohol functionality was used (ie. 0.25:1:60 using one DPE molecule). Higher catalyst loadings, up to the one catalyst unit per growing arm expected for living ring-opening polymerizations, gave consistent bimodal product distributions. This suggests self-initiation behavior by the $Sn(Oct)_2$ or a reaction impurity while also increasing the propensity for

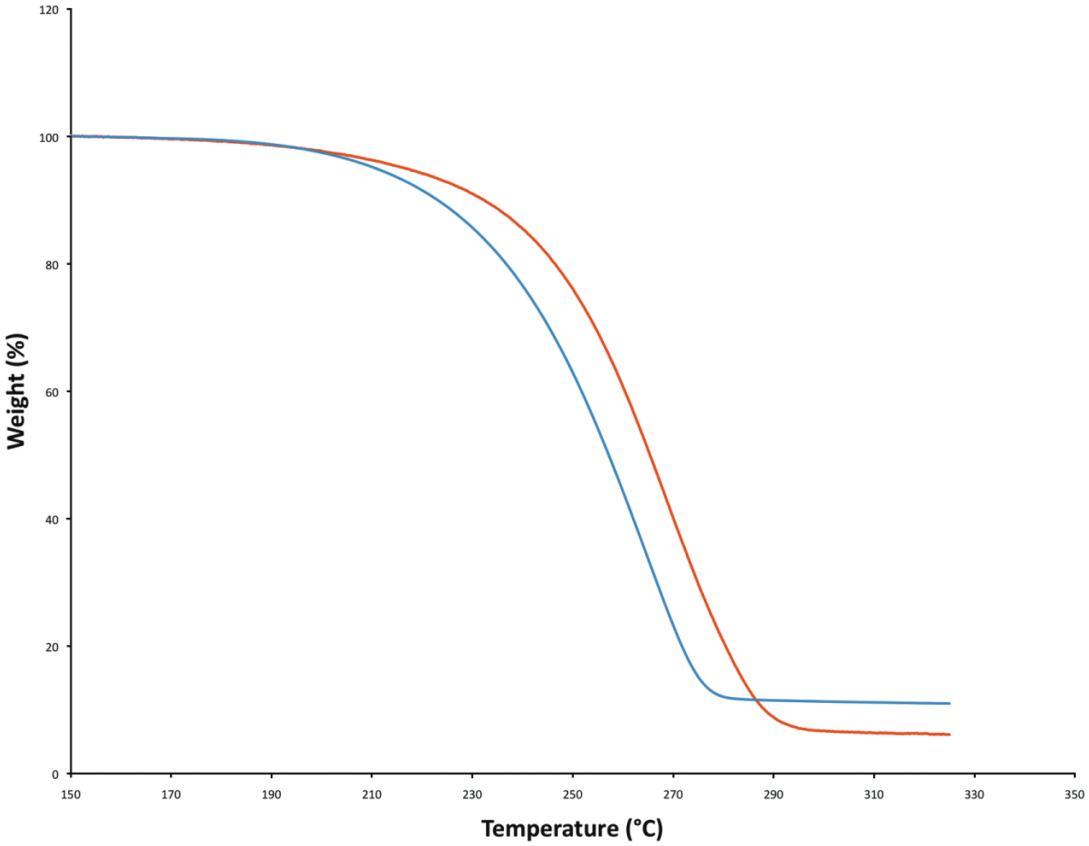
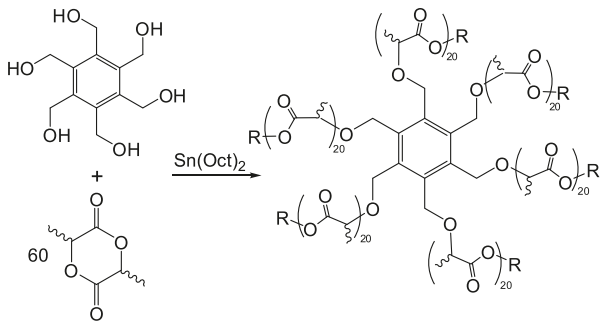
Fig. 3. Thermogravimetric analysis (TGA) profile for **2-r** (gray line) and **2-L** (black line).



transesterification reactions leading to reduced molecular weights for long reaction times. Additionally, the efficacy of low catalyst loadings suggests some immortal behavior for the tin catalyst under these reaction conditions.[26] As an example, the synthesis of the resultant star polymer for an HHMB core is shown in eq. [3].

[3]



^{1}H NMR analysis in $CDCl_3$ of the resultant PLA macromolecules shows that all alcohol functionalities associated with the parent core molecules disappear, suggesting activation of all arms in the formation of the star polymers. In addition, each sample exhibits a shift in the methylene (CH_2) resonances towards higher ppm owing to the deshielded environment of the polymer chain. For example, HHMB-initiated PLA displays the loss of the O*H* peak present at 4.86 ppm and shifts the CH_2 peak from 4.69 to 5.16 ppm. Because of peak overlap, end-group analysis of the terminal alcohol functionalities after polymer isolation could not assist in further polymer characterization, although the uniformity of the spectral resonances is suggestive of arms of similar lengths. Characterization by GPC is collected in Table 1. Percent conversions, measured gravimetrically, are shown along with the determined polydispersity and molecular weight values calculated relative to polystyrene standards and corrected for linear PLA, but remain uncorrected for the differences in star hydrodynamic volumes. Polymerization times of 8 h were chosen as shorter reaction times and led to inefficient initiation and broadened polydispersities, whereas reaction times of 24 h led to significant transesterification.

Low to moderate polydispersities (PDIs) imply good control over the polymerization reactions. Slightly higher PDIs for aromatic initiators **1** and **2** may be due to longer initiation times, as expected from comparative benzyl alcohol and isopropanol initiations of linear PLA.[1] Deviations from expected molecular weights are likely due to significant differences in effective hydrodynamic volume between linear and star-shaped polymers, affecting size-exclusion chromatographic techniques,[4] with six-armed stars built from **2** and **4** showing, as expected, the highest M_n deviations.

Physical properties of polymer stars

The six polymer stars in question were then characterized by TGA and DSC to assess the effect of core initiator on polymer properties. These data are collected in Table 2. T_g, T_c, and T_m values refer to glass, crystallization, and melting transitions, respectively, whereas T_d refers to the onset temperature for polymer decomposition and X_c refers to the percent crystallinity of the star samples.

The variation of core initiator was shown to influence the chemical properties of the resulting polymeric material in both atactic and isotactic PLA. Differences in T_g depended predominantly on the number of polymer arms, not the core molecule. Additionally, differences in T_g may also be due to changes in molecular weight between the different samples.[25] In the case of initiators **2**, **3**, and **4**, the isotactic samples exhibited higher T_g values than their atactic partners. Owing to the lower molecular weights ($M_{n,th}$ = 4.5 vs 5.8–8.8 kDa), the stars formed from initiator **1** do not follow this trend. For samples of the same or similar molecular weight and number of arms little difference is observed in comparing rigid to flexible cores. While we expected the rigidity present in the aromatic initiator to restrict the movement of the polymer arms and potentially prevent energy distribution throughout the macromolecule, the low energy process associated with the glass transition is unaffected. Similarly, crystallization characteristics observed for stereoregular stars derived from L-lactide (T_c and X_c) are unaffected by core rigidity. Crystallization temperatures appear to have an inverse relationship to percent crystallinity, with THMB-derived samples exhibiting a low T_c and the highest X_c, whereas PE-derived samples had the highest T_c and the lowest X_c.

As expected, melting signals were only observed for isotactic polymer stars.[4] In agreement with previous work, the presence of two melting points is characteristic of semicrystalline PLA.[27] Here, clear differences exist between rigid and flexible core initiators: **1** and **2** possess the two highest T_m values, suggesting increased order and rigidity throughout the star. The thermal stability imparted by the rigid core is especially apparent when comparing two six-armed polymer stars of similar molecular weights, with an increase of ~20 °C in the T_m for the hexa-substituted benzene versus the flexible dipentaerythritol. Comparing **1** with **2** and **3** with **4** also shows that a greater number of arms in PLA star polymers may induce higher melting temperatures, but this trend may be an artifact of molecular weight differences between the samples. A representative DSC profile for sample **2-L** is shown in Fig. 2.

Finally, thermal stability was measured by TGA and reported as the onset temperature (T_d) of rapid thermal decomposition. In each case, the isotactic samples showed higher thermal stability, as high as a 25 °C difference for DPE stars. Six-armed stars also possessed higher decomposition points, but few obvious trends existed between the nature of the initiating core and the thermal stability. For aromatic rigid cores, drawn out decomposition profiles were observed, with larger decomposition ranges noted in both isotactic and atactic samples with cores **1** and **2**. Two representative TGA profiles are shown in Fig. 3 for HHMB-initiated atactic (black line) and isotactic (gray line) star polymers. Small weight percentages that remain intact in each case may be due to persistence of the HHMB core, as pure HHMB has a T_d of ~320 °C.

Current efforts are focused on expanding the range of rigid and flexible polymer cores to other numbers of arms, including three-armed flexible, four-armed rigid, and five-armed flexible and rigid cores based upon hydroxybenzyl and polyol frameworks.

Conclusions

Eight PLA polymer stars were prepared from four multifunctional core initiators. Whereas good control over the reaction, in general, is offered by the $Sn(Oct)_2$ catalyst, the benzyl functionalities in hexa- and tri-(hydroxymethyl)benzene initiators are more challenging to initiate and lead to minor deviations from ideal living characteristics. Physical properties of the stars correlate well with established markers including molecular weight and the number of polymer arms. A striking effect of the rigidity of the core was noted in the melting temperatures of the star polymers, with increased core rigidity correlating with higher T_m values. Efforts to examine whether the core initiator has an effect on polymer degradation and to expand the range of core initiators accessible for star polymer synthesis continue.

One-pot domino synthesis of polyvicinalamine monomers

Cem B. Kilic and Alpay Taralp

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: Imidazole was generated in situ via a domino reaction between glyoxal, formaldehyde, and two units of aqueous ammonia. Aqueous bicarbonate and a carboxylic anhydride or dialkyl dicarbonate were added, yielding the corresponding *N*,*N*′-diacyl or *N*,*N*′-dicarbalkoxy-2-hydroxyimidazoline. A Bamberger ring cleavage ensued, affording *cis*-1,2-di(acetamido)-ethene, *cis*-1,2-di(propylamido)ethene, *cis*-1,2-di(ethoxyamido)ethene, *cis*-1,2-di(*tert*-butoxyamido)ethene, or *cis*-1,2-di(benz-amido)ethene as easily isolable solids. The convenience and generality offered by this one-pot approach implied a cost-effective route to the routine synthesis of oligo- and polyvicinalamine precursors.

Key words: Bamberger ring cleavage, domino reaction, one-pot reaction, multicomponent reaction, polyvicinalamine monomers.

Résumé : On a généré de l'imidazole par une réaction de type domino in situ entre le glyoxal, le formaldéhyde et deux unités d'ammoniac aqueux. L'addition de bicarbonate aqueux et d'un anhydride carboxylique ou d'un dicarbonate de dialkyle conduit à la formation de la *N*,*N*′-diacyl- ou *N*,*N*′-dicarbalkoxy-2-hydroxyimidazoline correspondante. Il s'ensuit une réaction de clivage de cycle de Bamberger qui permet d'isoler facilement le *cis*-1,2-di(acétamido)éthène, le *cis*-1,2-di(propylamido)éthène, le *cis*-1,2-di(éthoxyamido)éthène, le *cis*-1,2-di(*tert*-butoxyamido)éthène ou le *cis*-1,2-di(benzamido)éthène sous la forme de solides. La facilité et la généralité offerte par cette approche monotope implique une voie efficace du point de vue des coûts en vue de la synthèse de routine de précurseurs d'amines oligo- et polyvicinales.

Mots-clés : clivage de cycle de Bamberger, réaction de type domino, réaction monotope, réaction à plusieurs composants, amine vicinale.

[Traduit par la Rédaction]

Introduction

Polyamines have received much interest in view of their high amino group content, multi-interaction modes, facile tailorability, and widespread applicability in products ranging from commodity chemicals for pulp processing or water treatment to specialty chemicals intended for use in pharmacy and biotechnology.[1–3]

Recently, oligo- and polyvicinalamines with an impressive 1:1 nitrogen–carbon ratio were prepared (Scheme 1). Of the three approaches portrayed (Scheme 2), the monomers utilized have been based on butenedioic acid, *cis*-1,2-diamidoethene, and 1,3-diacetyl-4-imidazolin-2-one.[1–13] The use of commercial butenedioic acid-type monomers (Scheme 2, top left) introduces inconveniences related to halogenation, corrosion control, and waste management. The use of *cis*-1,2-diamidoethene monomers (Scheme 2, top right) permits a relatively simpler, greener industrial process. Still, neither approach has enabled the formation of high molecular weight polyvicinalamines.[2–5] The polymerization of 1,3-diacetyl-4-imidazolin-2-one (Scheme 2, bottom left) has yielded comparatively higher molecular weight materials.[2,4] This last monomer, a cyclic analogue of *cis*-1,2-di(acetamido)ethene (**1a**, entry 1 in Table 1), is

highly reactive by virtue of the ring structure, which limits steric clutter about the double bond, and the acetyl groups, which overcome limitations inherent to polymerizing 4-imidazolin-2-one.[3] Still, the high hydrolytic stability of the polymeric intermediate formed demands harsh conditions to generate the free polyvicinalamine.[3]

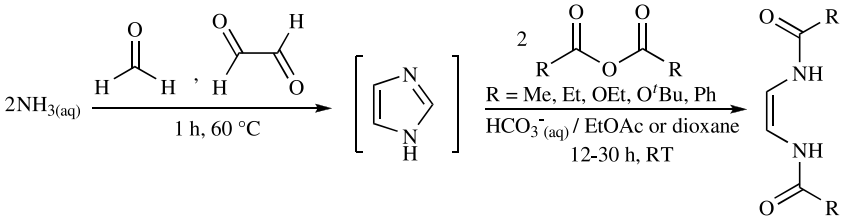
Some other factors, which influence the production feasibility of these polyamines, include the cost and commercial availability of the starting materials. Whereas the butenedioic acid-based monomers are readily available, the *cis*-1,2-diamidoethene monomers are inevitably prepared using commercial imidazole. An even more inconvenient starting material, 1,3-diacetyl-4-imidazolin-2-one, is prepared from 4-imidazolin-2-one, a synthon that is commercially unavailable.[5] Interestingly, the related monomer 1,3-diethoxy-4-imidazolin-2-one has been prepared directly from *cis*-1,2-di(ethoxyamido)ethene (**2a**, entry 2 in Table 1) by treatment with phosgene.[4] As this route bypassed 4-imidazolin-2-one, it seemed reasonable to assume that a suitable source of imidazole, prepared very cost effectively, could serve as a raw material of both the *cis*-1,2-diamidoethene type monomers and heterocyclic variants such as 1,3-diacetyl-4-imidazolin-2-one. This prospect was also attractive in that it seemed extendable to the preparation and conversion of 4-substituted and 4,5-disubstituted imidazoles.

In this work, a simple approach was envisaged to generate and utilize imidazole, affording the *cis*-1,2-diamidoethene monomers. The rationale was to prepare imidazole in situ via a domino synthesis,[7,13,14] and to continue directly with a Bamberger reaction (Schemes 3 and 4).[1] As implied, a key advantage of this approach was to bypass the inconveniences normally associated with isolating imidazole.[7,13] Integrating the two processes into a one-pot strategy appeared technically feasible, given that each reaction has traditionally been conducted in aqueous media. In a typical in-house procedure (Scheme 3), a small excess of ammonia and stoichiometric amounts of glyoxal and formaldehyde, were heated in a slightly oversized vessel, yielding imidazole. Unlike the classic 3 h domino synthesis,[7] the generation of imidazole was restricted to 1 h; time-course trials confirmed that the yields of *cis*-1,2-di(acetamido)ethene (**1a**, entry 1 in Table 1) were not improved by further incubation. The conditions to achieve ring cleavage were subsequently established in the same pot by modifying the solvent system and temperature. The workup was facilitated by spontaneous crystallization or selective organic-phase partitioning of the *cis*-1,2-diamidoethene products. Recrystallization was conceivably optional, as the "crude" lyophilized products revealed a purity, which implied their suitability as monomers.[1,2]

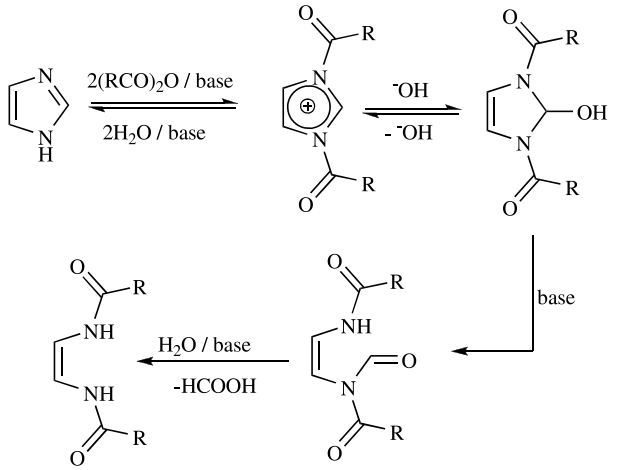
Results and discussion

The one-pot process proved easy to implement and amenable to a broad selection of acylating agents (**1**–**5**, Table 1). The yields, while modest, were offset by the extremely cheap starting materials and ease of product isolation. The

Scheme 3. One-pot domino reaction scheme to afford *cis*-1,2-di(alkylamido)ethene, *cis*-1,2-di(alkoxyamido)ethene, and *cis*-1,2-di(benzamido)ethene from commodity materials.



Scheme 4. Bamberger ring cleavage pathway in aqueous bicarbonate. Imidazole is activated via carboxylic anhydride or dialkyl dicarbonate.[1] The *N*,*N*′-diacyl or *N*,*N*-dicarbalkoxy imidazolium species formed is attacked by hydroxide at the C-2 center, affording an *N*,*N*′-diacyl or *N*,*N*′-dicarbalkoxy-2-hydroxyimidazoline. Ring fission ensues, producing a *cis*-1,2-diamido-*N*-formylethene. Hydrolytic *N*-deformylation follows, yielding the end product.



facility of the overall process was best illustrated by the example of acetic anhydride (**1**, entry 1 in Table 1), which upon gradual addition smoothly afforded **1a** via spontaneous crystallization.[1] The process was readily upscaled to 30 L, further implying its industrial merit. The approach also served to confirm the general utility of acid anhydrides, as all work on the Bamberger reaction had been focused, until recently,[1] on the use of benzoyl chloride, alkyl and aryl chloroformates, and **2**.[2,6,8–11] This validation was particularly encouraging, as one of the two reported attempts to prepare a *cis*-1,2-di(alkylamido)ethene, specifically **1a**, had failed using **1**.[12] Lastly, the stereo-electronic diversity among **1a**–**5a** (Table 1) was attractive, as it could potentially serve to extend the utility of this monomer class. For instance, a copolymer prepared from **1a**, **2a**, and **3a** could likely be prompted to selectively deblock under the appropriate conditions.

Prior studies[6,9] on the Bamberger reaction provided a mechanistic basis to relate product yield to the conversion of a 2-hydroxyimidazoline intermediate. As shown in Scheme 4, ring fission is initially prompted by the stepwise *N*,*N*′-diacylation or *N*,*N*′-dialkoxy formylation of imidazole in aqueous base, forming an activated imidazolium species. Hydroxide attack ensues at the C-2 carbon, reversibly forming a *N*,*N*′-diacyl or *N*,*N*′-dicarbalkoxy-2-hydroxy-imidazoline. A general or specific base-catalyzed cleavage of the ring follows, yielding a *cis*-1,2-diamido-*N*-formylethene. The formyl group is hydrolyzed via base catalysis, affording the *cis*-1,2-diamidoethene product. Hydrolytic pathways are also known to resist the activation of imidazole. These act to quench reagents and to hydrolyze any *N*-substituted and *N*,*N*′-disubstituted imidazoles. By probing the interaction of imidazole and **2** at low concentrations, Grace et al.[6] described a kinetic scenario, characterizable by the rapid accumulation of 2-hydroxy-*N*,*N*′-dicarbethoxyimidazoline, the slow cleavage of the ring, and the pH-dependent and typically rate-determining deformylation of the carbon at position C-2. As all reactants of the current study were utilized at much higher initial concentrations, it was safe to conclude that the *N*,*N*′-disubstituted 2-hydroxyimidazoline intermediate derived from each of **1**–**5** would be rapidly formed. In the mechanistic assessment of Grace et al.,[6] it was also clear that given enough time, the yield of *cis*-1,2-di(ethoxyamido)ethene would not reflect the deformylation rate of *cis*-1,2-diethoxyamido-*N*-formylethene. Rather, it would reflect the committed conversion of 2-hydroxy-*N*,*N*′-dicarbethoxyimidazoline to *cis*-1,2-diethoxyamido-*N*-formylethene. Thus, achieving a good yield ultimately rested on establishing an extended and sufficiently high steady-state concentration of the imidazoline, a task realized by discouraging hydrolytic deactivation and optimizing the availability of **2**. A similar kinetic view applied to the current work. Namely, the yield of each of **1a**–**5a** (Table 1) reflected the extent to which an effective and prolonged conversion of the corresponding *N*,*N*′-disubstituted 2-hydroxyimidazoline could be realized. Hence, the yield discrepancies amongst **1a**–**5a** not only reflected inherent stereoelectronic differences acting along the reaction coordinate, but presumably also some variations related to the addition of **1**–**5**. The literature yields (in parentheses in Table 1) were generally superior to the corresponding in-house process. No attempt was made to derive insight from this discrepancy, as the protocols differed notably.[2]

From a practical viewpoint, the yields were generally improved by both strong stirring, which served to disperse **1**–**5**, and by the moderately prolonged addition of sufficient **1**–**5**, which prompted the steady *N*,*N*′-diacylation or *N*,*N*′-dicarbalkoxylation of imidazole (Scheme 4). While the influence of pH on the course of the reaction had not been systematically characterized at large reactant concentrations, the Bamberger reaction was reported to proceed best within the pH range of 6–7.[6] Increasing the alkalinity further was discouraged, as the half-life of the *N*,*N*′-diacyl or *N*,*N*′-dicarbalkoxy imidazolium species would drop accordingly, detracting from the accumulation and turnover of the corresponding 2-hydroxyimidazoline. Still, the findings obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

herein using alkaline bicarbonate implied a rather flexible working pH range of reaction.

As a final point, the elusive *cis*-1,2-di(formamido)ethene was targeted in view of its potential to serve as an easily polymerizable monomer.[1] Just as with prior attempts, however, no product was isolated when formic acetic anhydride was added to the in situ-generated imidazole or to commercially produced imidazole as per the established method.[1] The fact that imidazole was recovered unchanged was attributed to the high accessibility and electropositive nature of the formyl carbonyl center, which presumably served to speed the hydrolytic deactivation of reagent and formylated imidazole species.

To summarize, several *cis*-1,2-diamidoethene monomers were prepared by manipulating glyoxal, formaldehyde, ammonia, and an acylating agent in one pot. The process precluded the purification of intermediates, the deployment of relatively expensive or volatile compounds like imidazole and chloroformate, and any laborious workup. The fact that an industrially applicable end product was prepared and readily isolable, following a four-component transformation in the presence of many potentially interfering by-products,[7] further attested to the facility and robustness of this strategy. Finally, whereas *cis*-1,2-diamidoethene can serve as a monomer, this class of compound may also be converted to the corresponding *N*,*N*′-disubstituted 4-imidazolin-2-one heterocycle,[4] which is known to have a much greater propensity to polymerize.[3] All in all, it would appear that the cost efficiency and conveniences imparted by this one-pot approach could promote the routine preparation and use of oligo- and polyvicinalamines.

Experimental

Technical grade starting materials were obtained from local suppliers and were used without further purification.

Typical experimental procedure

To a stirred solution of ammonium hydroxide (6.0 g, 22–25 wt%), a mixture of glyoxal (4.35 g, 30.0 mmol, 40 wt%) and formaldehyde (2.25 mL, 30.2 mmol, 37 wt%) was cautiously added. The mixture was allowed to stir (60 °C, 1 h), generating imidazole. Subsequently, distilled water (150.0 mL), ethylacetate (30.0 mL), and sodium bicarbonate (25.0 g) were added to the reaction. Acetic anhydride (12.0 mL, 127.0 mmol, 4.23 equiv with respect to glyoxal) was slowly added (30 min) under vigorous stirring during which time effervescence was noted. The reaction vessel was lightly capped after **1** was fully added and stirring was continued (13 h, room temperature (RT)) to promote full deformylation. The precipitated solid was recovered by filtration, washed with distilled water (3 × 5.0 mL), optionally triturated in distilled water (20.0 mL, 80 °C, 15–30 min), and lyophilized to yield **1a** (1.50 g, 35% with respect to glyoxal) as a white solid. Di-*tert*-butyl dicarbonate (**3**) was gently warmed prior to use and administered dropwise as in the case of acetic anhydride. Unlike **1**–**3** and **5**, benzoic anhydride (**4**) was finely pulverized and added in one shot. For **3a** and **4a**, 1,4-dioxane (75.0 mL) was used in place of ethylacetate (Entries 3–4). Precipitation of **4a** (Entry 4) was facilitated by adding water (250 mL) during the workup. Product **5a** (Entry 5) was directly isolated by evaporating the ethylacetate layer. To ascertain the in situ yield of imidazole, an aliquot of the domino reaction (48.0 μL) was dissolved in deuterium oxide (600 μL) spiked with sodium acetate (24.0 μg). The sample was immediately analyzed using ^{1}H NMR (RT, D_2O/DHO presaturation, 10 s interpulse delay, and 256 scans). The signal corresponding to the three C–H protons of imidazole was compared with the three protons of acetate, permitting a yield calculation of the former compound.

Parameters used for characterization

NMR: Inova 500; ATR-FTIR: Bruker Equinox 55; GC–MS: gas chromatography, Agilent 6890N; GC column: J&W, DB5, 30 m, i.d. = 0.25 mm; film thickness: 0.25 μm; carrier gas: He; injection: 50 ng / 1 μL MeOH; injection temp.: 270 °C; aux. temp.: 240 °C; temp. progr.: 100/5–5–260; mass spectrometry: Sensi-TOF, Five Technologies, Munich; mass range: 40–500 amu; ionization energy: 70 eV; DSC: Netzsch 204 Phoenix; temp. ramp rate: 5 K/min; atmosphere: N_2. A chemical shift of 2.5 ppm (^{1}H NMR) and 39.4 ppm (^{13}C NMR) was applied to reference DMSO-d_6.[15] The melting onset temperature (T_{onset}) was estimated from the DSC profile as per ASTM standard test procedure E794.[16] The peak melting temperature (T_m) was obtained by direct inspection. Both values have been expressed for clarity. In **1a**–**5a**, the TLC runs showed one spot under UV light. All GC–MS profiles yielded one peak.

Abstract: The production of gas-phase singly charged ruthenium chloride anionic complexes by laser desorption ionization of $RuCl_3 \cdot 3H_2O$ is reported. The $[Ru_xCl_y]^-$ clusters could only be detected in the absence of the matrix component in the negative mode. The cluster compositions observed were $[RuCl_4]^-$, $[RuCl_5]^-$, $[Ru_2Cl_6]^-$, $[Ru_2Cl_7]^-$, $[Ru_3Cl_9]^-$, $[Ru_4Cl_{11}]^-$, and $[Ru_5Cl_{12}]^-$. With the aid of density functional theory calculations, we proposed feasible structures for each ruthenium chloride cluster, in which Ru–Ru bonds and Cl bridges were a common characteristic.

Key words: ruthenium, laser desorption ionization, metal clusters, $RuCl_3 \cdot 3H_2O$, density functional theory, mass spectrometry.

Résumé : Faisant appel à la technique d'ionisation par désorption au laser du $RuCl_3 \cdot 3H_2O$, on a réalisé la production en phase gazeuse de complexes anioniques du chlorure de ruthénium portant une seule charge. Dans le mode négatif, on ne peut détecter la présence des agrégats de $[Ru_xCl_y]^-$ qu'en l'absence de la composante matricielle. On a pu observer les cations de composition $[RuCl_4]^-$, $[RuCl_5]^-$, $[Ru_2Cl_6]^-$, $[Ru_2Cl_7]^-$, $[Ru_3Cl_9]^-$, $[Ru_4Cl_{11}]^-$ et $[Ru_5Cl_{12}]^-$. En se basant sur des calculs selon la théorie de la fonctionnelle de la densité, on propose des structures plausibles pour chacun des agrégats de chlorure de ruthénium dans lesquels des liaisons Ru–Ru et des ponts Cl sont des caractéristiques communes.

Mots-clés : ruthénium, ionisation par désorption au laser, agrégats métalliques, $RuCl_3 \cdot 3H_2O$, théorie de la fonctionnelle de la densité, spectrométrie de masse.

[Traduit par la Rédaction]

Introduction

Part of our research program focuses on the development of new methods for the structural characterization of complex bacterial polysaccharides (PSs). We envisaged that the coupling of ruthenium to PSs, especially those expressing amine moieties, may help us obtain less convoluted NMR spectra of the PSs and possibly yield compounds suitable for crystallographic analysis. The coordination of monosaccharide units to transition metals, especially those of the platinum group, is well-documented.[1] Other investigations into the mechanisms of coordination, with characterization of the resulting products, have also been carried out with metals such as iron,[2] platinum,[3] palladium,[3] and copper.[4] X-ray crystallography and spectroscopic data has shown that monosaccharides coordinate to the metal through vicinal hydroxyl or amine functional groups.

For comparison with the matrix-assisted laser desorption ionization – time of flight – mass spectrometry (MALDI-TOF-MS) spectra of putative products from reactions in which $RuCl_3 \cdot 3H_2O$ was a starting material, a MALDI-TOF-MS spectrum of $RuCl_3 \cdot 3H_2O$ was sought. The results afforded by the MALDI-TOF-MS and LDI-TOF-MS experiments carried out on $RuCl_3 \cdot 3H_2O$ are described.

Materials and methods

Mass spectrometry

For MALDI-TOF-MS, $RuCl_3 \cdot 3H_2O$ was mixed directly with a matrix solution composed of 2 mg of 3,4-dihydroxybenzoic acid in 20% of ethanol. An analyte–matrix 1:2 ratio (*v*/*v*) and 1 μL was spotted on the MALDI sample target and allowed to dry at room temperature. For LDI-TOF-MS, a few crystals of analyte were deposited on the sample target and gently pressed toward the target. The analyses were performed using a MALDI-TOF-MS instrument (model Reflex III, Bruker) equipped with a 337 nm nitrogen laser. Samples were analyzed in reflectron and negative ion modes. Ion sources 1 and 2 were held at 20 and 16.35 kV, respectively. The guiding lens voltage was set at 9.75 kV. The reflector detection gain was set at 5.3 with pulsed ion extraction at 200 ns. The nitrogen laser power was set to the minimum level necessary to generate a reasonable signal and avoid possible degradation of analytes. Typically, 15% of laser energy was used, which was calculated to be 4 mJ. In the case of high laser energy experiments, 45% of laser energy was used, which equalled 12.5 mJ. The pulse duration was 9 Hz, the spot size was 2 mm, and the calculated energy density was 100 μJ/0.1 mm^2. A two-point external calibration was

performed, using the $[M - H]^{-1}$ (153.01 Da) and $[2M - H]^{-2}$ (447.12 Da) peaks of dehydroxybenzoic acid and the dimer of sinapinic acid, respectively, prepared in acetonitrile–water solution (10 pmol/μL). Ruthenium(III) trichloride trihydrate was purchased from Pressure Chemicals (Pittsburgh, Pennsylvania).

Computations

All geometry optimization and vibrational frequency analysis density functional theory (DFT) calculations were performed using Gaussian09.[5] All calculations used the PBE0 exchange-correlation functional[6] with a dual basis set; SDD[7] was used for the Ru atoms and 6–311G(2d) was used for the Cl atoms. The composition of molecular orbitals and overlap population analysis, to determine bond orders and bonding of all species, were calculated using AOMix.[8,9]

Results and discussion

Our first attempt, using a matrix solution of 3,4-dihydroxybenzoic acid in 20% of ethanol, yielded no easily understood *m/z* ions, and no ions representative of the molecular weight of $RuCl_3 \cdot 3H_2O$ or related species were observed. Subsequently, we attempted the same experiment with no matrix (LDI-TOF-MS). The LDI-TOF-MS experiment in the negative mode also showed no *m/z* ions attributable to $RuCl_3 \cdot 3H_2O$ or associated residues, but afforded a series of low and high *m/z* ions of defined compositions with an isotope pattern that suggested the presence of ruthenium- and chloride-containing species (Fig. 1).

The most intense *m/z* ion at 243.69 was attributed to a complex containing one Ru atom and four Cl atoms, $[RuCl_4]^-$. Dominant species containing two Ru atoms were observed at *m/z* 415.42 for $[Ru_2Cl_6]^-$ and at *m/z* 450.32 for $[Ru_2Cl_7]^-$. Two other intense ions containing three and four Ru atoms were observed at *m/z* 621.88 for $[Ru_3Cl_9]^-$ and at 793.47 for $[Ru_4Cl_{11}]^-$. Although of low intensity, *m/z* ions attributable to $[RuCl_5]^-$ and $[Ru_5Cl_{12}]^-$ complexes were also observed at *m/z* 278.61 and 930.11, respectively. Computer-generated isotopic distribution profiles for the described compositions matched the observed experimental data (Fig. 2). However, that of $[RuCl_4]^-$ suggested that this *m/z* peak could also contain $[RuCl_3{:}2OH]^-$. Within the limits of detection, no other higher mass ions were observed.

Based on computational studies, a structure is proposed for each cluster, and, in particular, we suggest cyclic conformations for the larger complexes, $[Ru_3Cl_9]^-$, $[Ru_4Cl_{11}]^-$, and $[Ru_5Cl_{12}]^-$. Figure 3 shows the proposed cluster structures with their respective total energy values. DFT calculations showed that the proposed noncyclic structures of $[RuCl_4]^-$ and $[Ru_2Cl_6]^-$ favoured a planar and tetrahedral-like geometry, respectively (Fig. 3). As $[RuCl_4]^-$ and $[Ru_2Cl_6]^-$ are both doublet species, an unrestricted PBE0 method was used for the calculations, with the S^2 values for $[RuCl_4]^-$ and $[Ru_2Cl_6]^-$ being 0.7503 and 0.7547, respectively, after annihilation of the first-order spin contaminant. A square pyramidal geometry was attributed to the $[RuCl_5]^-$, a closed shell singlet species with an S^2 value of 0.0000.

The proposed $[Ru_2Cl_7]^-$ cluster contains two Ru atoms bonded together with a single bond and three chloride bridges (Fig. 3). Two terminal chlorides extended from each Ru atom. As a singlet species, the $[Ru_2Cl_7]^-$ cluster optimization had an S^2 value of 0.0000.

For the $[Ru_3Cl_9]^-$ complex, one of the most intense *m/z* ions, the structure is composed of a series of three-membered

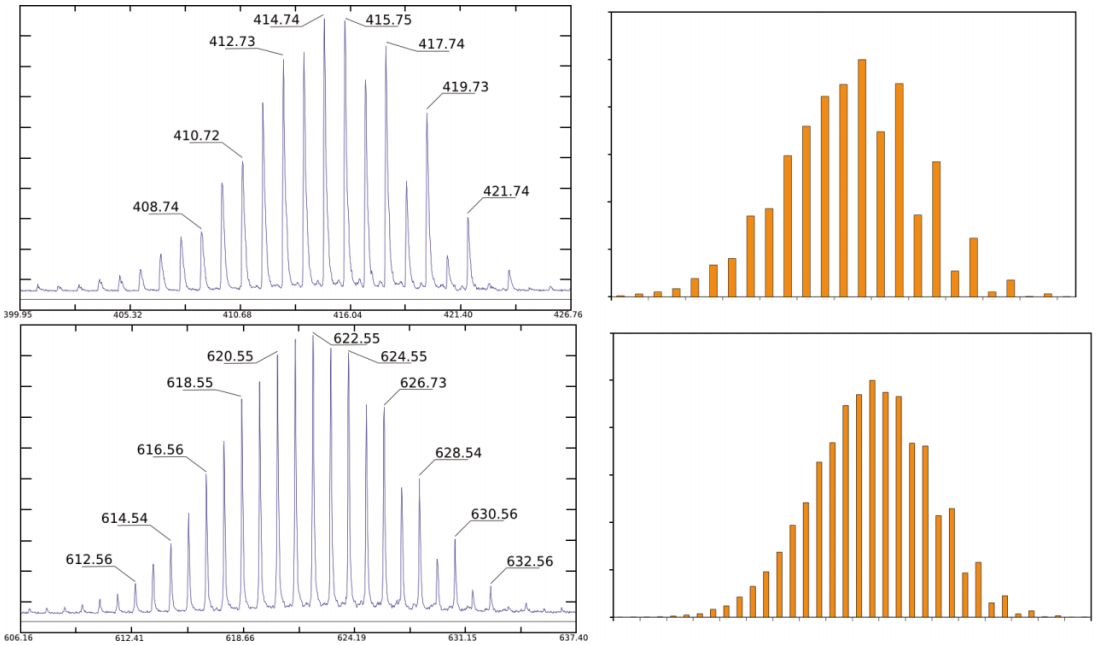
For personal use only.

Fig. 2. Mass spectral profile of the isotopic pattern of $[Ru_2Cl_6]^-$ (top) and $[Ru_3Cl_9]^-$ (bottom). The experimental spectrum is at the left and the computed isotopic pattern is at the right.



rings lying on a single plane (Fig. 3). The proposed structure of the $[Ru_3Cl_9]^-$ cluster bares a strong resemblance to the DFT geometry optimizations of $[Re_3(\mu\text{-}Cl)_3Cl_9]^{-3}$ described by Psaroudakis et al.[10] Both molecules contain a three-membered ring of metal atoms with each metal atom being connected to two in-plane bridging chlorides and two out-of-plane terminal chlorides. The optimization of the $[Ru_3Cl_9]^-$ cluster gave an S^2 value of 0.0000 (singlet species).

For the $[Ru_4Cl_{11}]^-$ cluster, we first envisaged a bicyclo[3.3.1]nonane-like structure; however, a molecular orbital overlap population analysis to determine bonding suggested the cyclic structure presented in (Fig. 3). As a singlet species, the $[Ru_4Cl_{11}]^-$ cluster optimization had an S^2 value of 0.0000. For $[Ru_5Cl_{12}]^-$, we hypothesized a tetracyclic[3.3.3.1.1]tridecane-like structure, in which all Ru atoms were connected to each other through Cl bridges. However, the computational calculations afforded the structure shown in Fig. 3. To obtain convergence, the optimization and frequency calculations on the $[Ru_5Cl_{12}]^-$ cluster were performed with loose convergence criteria (1×10^{-6}) for the self-consistent field (SCF) energy. The optimization showed that $[Ru_5Cl_{12}]^-$ is a highly symmetric molecule with Ru atoms in both planar and tetrahedral configurations. An S^2 value of 0.9106 resulted for this unrestricted calculation and one virtual frequency was reported from the vibrational analysis. Geometry optimization and vibrational analysis of the neutral $[Ru_5Cl_{12}]$ cluster was also performed and was successful under the default convergence criteria with no virtual frequencies reported. A comparison between the optimized neutral $[Ru_5Cl_{12}]$ and anionic $[Ru_5Cl_{12}]^-$ clusters showed they were visually similar. The observed difficulties in the convergence of the anionic $[Ru_5Cl_{12}]^-$ cluster under default criteria is thought to arise from the highly delocalized HOMO, which contains the unpaired electron for this doublet species. Except for $[Ru_5Cl_{12}]^-$, no imaginary frequencies were reported for the optimized geometries, indicating that an energy minimum was reached for the aforementioned cases.

We suggest that the cyclic $[Ru_3Cl_9]^-$, $[Ru_4Cl_{11}]^-$ and $[Ru_5Cl_{12}]^-$ clusters may be in part formed through intranucleophilic substitutions in the gas phase, and, to some extent, the presence of *m/z* 35 $[Cl^-]$ in the LDI-TOF-MS spectrum (Fig. 1) lends support to this hypothesis. In addition to the structures shown in Fig. 3, other structural arrangements for $[Ru_2Cl_7]^-$, $[Ru_3Cl_9]^-$, and $[Ru_4Cl_{11}]^-$ were also observed to minimize, but at higher total energies (Fig. 4).

As mentioned, we suggested that the *m/z* ions at 622.30 and 794.30 corresponded to cyclic clusters of $[Ru_3Cl_9]^-$ and $[Ru_4Cl_{11}]^-$, respectively; but, the possibility exists that these *m/z* ions could be adduct compounds in the form of $[Ru_3Cl_8 + Cl]^-$ and $[Ru_4Cl_{10} + Cl]^-$. Similarly, $[RuCl_5]^-$ could exist in the form of a $[RuCl_4 + Cl]^-$ adduct. However, neutral clusters of $[RuCl_4]$, $[Ru_3Cl_8]$, and $[Ru_4Cl_{10}]$ were not converged in the SCF during optimization. Thus, we suggest that there is a low probability that these adductlike clusters exist. In the proposed structures (Figs. 3 and 4), there were no data that would suggest the presence of double or triple bonds between the Ru atoms.

Neighbouring the high-intensity *m/z* ions, ions of much lower intensity could be observed that differed by *m/z* 35. These could be generated by loss of Cl atoms from the described clusters or could represent other species. Although of very low intensity, other ions at *m/z* 208.77, 224.72, 278.64, 844.12, and 874.51 might be attributed to $[RuCl_3]^-$, $[RuCl_3{:}OH]^-$, $[RuCl_4{:}2OH]^-$, $[Ru_4Cl_{10}{:}OH]^-$, and $[Ru_5Cl_9{:}2OH]^-$, respectively.

Conclusions

We have shown that gas-phase Ru_xCl_y clusters may be synthesized by the laser ablation of $RuCl_3{\cdot}3H_2O$ in the

negative ion mode. Based on computational calculations, Figs. 3 and 4 show proposed structures for the ruthenium chloride clusters. However, other structural isomers may be possible. Cluster formation was found to be inhibited when 3,4-dihydroxybenzoic acid was used as the matrix. The MS data showed that the Ru–Cl ratio decreases as the number of Ru atoms increase and that the higher order clusters contain a mixed oxidation state. Other examples of cluster formations by LDI containing various transition metals have been described.[11–13] Also, a wide range of metal clusters have

been produced by LDI of metal oxides, metal phosphides, metal chalcogenides, and metal carbonyls.[11] Similarly to the results obtained here, it has been reported that the use of a matrix prevented the formation of these types of metal-containing clusters.[11,12] Large rhenium chloride clusters have also been observed to be generated by LDI of rhenium trichloride,[12] with cluster formation only being afforded under negative mode ionization.[12]

Although reports describing the production of gas-phase transition-metal clusters are typically limited to laser ablation methods, work by Wang and Wang[14] showed that electrospray ionization (ESI) of alkali and alkali – earth metal halide solutions lead to the generation of various metal cluster dianions. However, they were unable to observe cluster formation from metal halide solutions of any of the 3d transition-metal elements. Although gas-phase clusters may not have a solution or solid-state counterpart, O'Hair and Khairallah[13] produced gas-phase metal clusters in a MALDI-TOF-MS apparatus that could be employed as catalysts, and thus the ruthenium chloride clusters described in this work could prove to be useful chemical compounds.

Abstract: A simple and efficient solid-phase extraction – spectrofluorimetric method has been developed to determine glutathione (GSH). Fluorescent probe *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-yl)methyl)iodoacetamide (BODIPY Fl-C_1-IA) was used as the derivatization reagent. The procedure was based on a BODIPY Fl-C_1-IA selective reaction with GSH to form the highly fluorescent product BODIPY Fl-C_1-IA–GSH, using a solid-phase extraction column and spectrofluorimetric determination. The variables affecting analytical performance were studied and optimized. The calibration graph using the preconcentration system for GSH was linear over the range of 1–200 nmol/L with a limit of detection of 0.05 nmol/L (signal-to-noise ratio = 3). The relative standard deviation for six replicate determinations of GSH at the 100 nmol/L concentration level was 3.9%. The method was applied to water samples and average recoveries between 87.5% and 111.5% were obtained for spiked samples.

Key words: spectrofluorimetry, glutathione, solid-phase extraction, *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-yl)methyl)iodoacetami-de.

Résumé : On a développé une méthode simple et efficace d'extractoin spectrofluorimétrique en phase solide pour déterminer le glutathion (GSH). On a utilisé la sonde fluorescente *N*-(4,4-difluoro-5,7-diméthyl-4-bora-3a,4a-diaza-*s*-indacène-3-yl)méthyl)iodoacétamide (BODIPY F1-C_1-1A) comme réactif pour obtenir des dérivés. La méthode repose sur le fait que le BODIPY F1-C_1-1A donne une réaction sélective avec le GSH conduisant à la formation du produit hautement fluorescent BODIPY F1-C_1-1A–GSH qui peut être isolé par extraction en phase solide sur colonne et soumis à une détermination spectrofluorimétrique. On a étudié et optimisé les variables qui affectent la performance analytique. Le graphique de calibration à l'aide du système de préconcentration du GSH est linéaire sur la plage de 1 à 200 nmol/L, avec une limite de détection de 0,05 nmol/L (rapport signal à bruit = 3). La déviation relative standard pour six déterminations de GSH en duplicata, à un niveau de concentration de 100 nmol/L, est de 3,9 %. On a appliqué la méthode à des échantillons d'eau et on a obtenu des taux de récupérations moyens variant de 87,5 % à 111,5 % pour les échantillons ensemencés.

Mots-clés : spectrofluorimétrie, glutathion, extraction en phase solide, *N*-(4,4-difluoro-5,7-diméthyl-4-bora-3a,4a-diaza-*s*-indacène-3-yl)méthyl)iodoacétamide.

[Traduit par la Rédaction]

Introduction

The tripeptide glutathione (L-γ-glutamyl-L-cysteine-glycine, GSH) is the most abundant low molecular mass thiol in the cells of many organisms.[1] It is the major compound containing the –SH group produced by animals, plants, phytoplankton, and bacteria.[2,3] GSH is recognized as a key physiological antioxidant that not only detoxifies reactive oxygen species directly, but also enhances the functional ability of other crucial antioxidants such as vitamins E and C.[4,5] Many studies have pointed out the importance of GSH homeostasis during human diseases or intoxication by toxins, particularly in the liver,[6–9] kidney,[10] and the central nervous system.[11] Therefore, the quantitative measurement of low levels of GSH is desirable.

Currently available methods for determining GSH are generally based on chromatography and immunoassays. For example, Griffith[12] reported the determination of the total glutathione content in mouse plasma with an enzymatic recycling assay based on glutathione reductase; Guo et al.[13] developed a high-performance liquid chromatographic method based on a derivatizing reagent, 1,3,5,7-tetramethyl-8-phenyl-(4-iodoacetamido)difluoroboradiaza-*s*-indacene, for measuring low molecular weight thiol-containing compounds, including GSH, coenzyme A, *N*-acetylcysteine, cysteine, homocysteine, and 6-mercaptopurine in human plasma

samples; Sakhi et al.[14] reported the detection of glutathione in human plasma using a two-dimensional chromatographic system with parallel porous graphitized carbon columns coupled with fluorescence and coulometric electrochemical detection; Guo et al.[15] developed a spectrofluorimetric method for the determination of GSH in human blood and pig liver based on a fluorescence probe (1,3,5,7-tetramethyl-8-phenyl-(2-maleimide)-difluoroboradiaza-*s*-indacene).
Although these methods are currently available for GSH determination, most of them are time-consuming, complicated, and inconvenient to operate. Therefore, a rapid, selective, and sensitive method for the analysis of GSH is still desired.

In the spectrofluorimetric method, GSH is either chemically reactive or a catalyst for several types of chemical reactions on products, with a subsequent effect on the fluorescence properties (development, inhibition, or enhancement) in either a direct or an indirect way. Difluoroboradiaza-*s*-indacenes (BODIPY, Fig. 1*a*) are a class of highly rigidized and polymethine-like fluorescent dyes that have found numerous applications in biochemistry and molecular biology because of their high extinction coefficients, high fluorescence quantum efficiency, and stability in light. *N*-(4,4-Difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-yl)methyl)iodoacetamide (BODIPY Fl-C_1-IA) has been used for derivation and determination of GSH. It has almost no fluorescence before it reacts with thiols. When it reacts with GSH to produce BODIPY Fl-C_1-IA–GSH, the fluorescence of the fluorophore is strongly increased. This gives it good sensitivity and selectivity in the determination of GSH. Compared with other GSH derivatization reagents,[16,17] BODIPY Fl-C_1-IA exhibits the highest fluorescence enhancement. Therefore, it is favorable for the determination of trace GSH in real samples.

Direct determination of GSH at low concentration in complex matrices is often difficult because of the insufficient sensitivity of this technique as well as the matrix interferences occurring in real samples. So a pretreatment step for sample enrichment and cleanup is necessary. Solid-phase extraction (SPE) is usually used to purify various samples and preconcentrate the analytes to improve the analytical sensitivity because of its advantages in simplicity, rapidness, and less consumption of organic solvents.[18–21] However, to the best of our knowledge, there is no report on the application of SPE coupled with spectrofluorimetry to determine GSH in environmental waters.

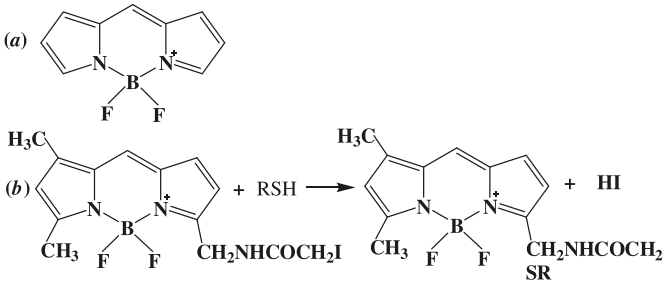
In this paper, a method for the detection and quantification of GSH using BODIPY Fl-C_1-IA derivatization followed by SPE and spectrofluorimetry is presented. The derivatization conditions and the parameters affecting the SPE procedure are discussed and optimized. The proposed method permits the analysis and quantification of GSH in different water samples using a simple spectrofluorimetric method.

Experimental

Apparatus

All fluorescence measurements were performed using a Cary Eclipse fluorescence spectrophotometer (Varian) with 1 cm path length quartz cells. Both the instrument excitation and emission slits were adjusted to 5 nm. The pH value of the solution was measured using a pHS-3C meter (Shanghai Leici Equipment Factory, China). A Waters OAsis MCX (SPE) cartridge column (3 mL) was purchased from Waters Corporation.

Fig. 1. (*a*) The structure of difluoroboradiaza-*s*-indacene (BODIPY) and (*b*) the derivatization reaction of *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-yl)methyl)iodoacetamide (BODIPY Fl-C_1-IA) and thiols.



Reagents

BODIPY Fl-C_1-IA was purchased from Sigma-Aldrich (St. Louis, Missouri), and a 5×10^{-3} mol/L stock solution was prepared with pretreated acetonitrile (dried with P_2O_5). GSH was purchased from Shanghai Chemicals (Shanghai, China). A 1.0×10^{-3} mol/L standard solution of GSH was prepared with water daily. Dilution of these stock solutions to appropriate concentrations was performed before use. KH_2PO_4–$Na_2B_4O_7$ buffer solution was obtained by mixing 0.1 mol/L KH_2PO_4 solution and 0.05 mol/L $Na_2B_4O_7$ solution to the required pH. $Na_2B_4O_7$–H_3BO_3–KCl was obtained by mixing 0.05 mol/L $Na_2B_4O_7$, 0.20 mol/L H_3BO_3, and 0.20 mol/L KCl solutions to the required pH. Unless otherwise specified, all reagents were of analytical reagent grade and used without further purification, and all solutions were prepared from double-distilled water

Sample preparation

Three water samples were selected for validating the developed method. These include tap, rain, and Shi River waters. Tap water was collected from our own laboratory after flowing for 10 min. The rain and Shi River water samples were collected from the city of XinYang in Henan Province (China).

General procedure

Derivative procedure

Twenty microlitres of BODIPY Fl-C_1-IA (5×10^{-5} mol/L), 20 μL H_3BO_3–KCl–Na_2CO_3 buffer (pH 9.0), and an appropriate volume of GSH solution were transferred into a 1 mL tube. Then the well-mixed solution was incubated at 35 °C for 35 min, and the derivatization (Fig. 1*b*) was completed.

Solid-phase extraction

A SPE column was first preconditioned by methanol and water. The appropriate volume of sample solutions was passed through the cartridge by an injector. Subsequently, analytes retained on the SPE column were eluted with an optimal volume of acetone. The eluate was evaporated under a stream of nitrogen at 40 °C, and the residue was reconstituted

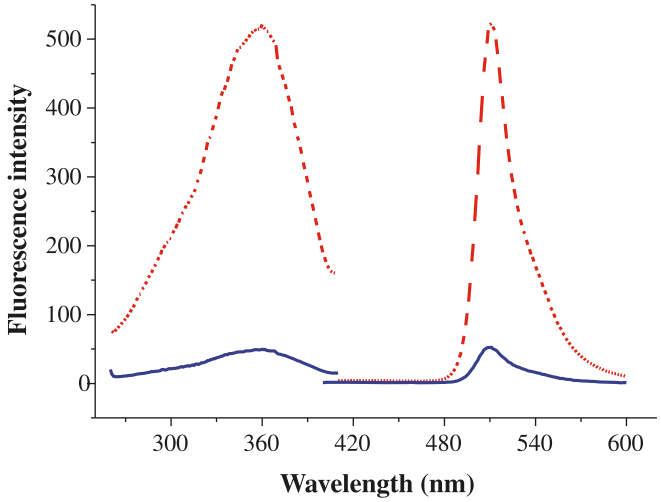
Fig. 2. Fluorescence spectra of *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-yl)methyl)iodoacetamide (BODIPY Fl-C_1-IA) and BODIPY Fl-C_1-IA – glutathione (GSH). BODIPY Fl-C_1-IA (solid line) and BODIPY Fl-C_1-IA–GSH (dashed line). Fluorescence intensities: $C_{\text{BODIPY Fl-C1-IA}} = 3.3 \times 10^{-6}$ mol/L and $C_{\text{BODIPY Fl-C1-IA-GSH}} = 6.7 \times 10^{-7}$ mol/L. Spectral bandpass: 5 and 5 nm for excitation and emission spectra, respectively.



with 300 μL of water. Finally, 250 μL of the resultant solution was measured at excitation wavelength (λ_{ex})/emission wavelength (λ_{em}) = 360/510 nm.

Results and discussion

Fluorescence characteristics

The fluorescence spectra of BODIPY Fl-C_1-IA and its derivatization product BODIPY Fl-C_1-IA–GSH are shown in Fig. 2. The maximum excitation wavelength for BODIPY Fl-C_1-IA–GSH was at 360 nm and the maximum emission wavelength was at 510 nm. The fluorescent characteristics of BODIPY Fl-C1-IA and other reagents are compared in Table 1. The results show that the fluorescent characteristics of BODIPY Fl-C1-IA are comparable to those probes, especially for the photostability of the derivatization product.

The experiments showed that the fluorescence intensity of BODIPY Fl-C_1-IA–GSH at $\lambda_{ex}/\lambda_{em}$ = 360/510 nm could be stable for at least 24 h at room temperature with a change of 5%, which was long enough to complete the determination of GSH. The experimental results indicated that BODIPY Fl-C_1-IA–GSH had excellent stability. The adding sequence of buffer, BODIPY Fl-C_1-IA, and GSH solutions had no evident influence on the fluorescence signal.

Optimization of derivatization

The chemical structure of BODIPY Fl-C_1-IA and its reaction with thiols are shown in Fig. 1*b*. To achieve the maximum derivatization yield, the derivatization conditions including the buffer type, pH of the buffer, the volume of the buffer, the concentration of BODIPY Fl-C_1-IA, the reaction temperature, and the reaction time were carefully optimized.

The effect of the buffer on the derivatization was studied. Three different buffers (H_3BO_3–KCl–Na_2CO_3, $Na_2B_4O_7$–H_3BO_3–KCl, and KH_2PO_4–$Na_2B_4O_7$) were tested at a pH range of 7.50–9.50 (Fig. 3*a*). The maximum signal was achieved at pH 8.50 in H_3BO_3–KCl–Na_2CO_3 buffer, which is suitable for further study. The influence of the buffer amount was also estimated. The signal of the derivatives reached the maximum at 20 μL of H_3BO_3–KCl–Na_2CO_3 buffer (pH 8.50) (Fig. 3*b*). Thus, 20 μL of H_3BO_3–KCl–Na_2CO_3 buffer (pH 8.50) was selected in the derivatization reaction.

The effect of BODIPY Fl-C_1-IA concentration was evaluated in the concentration range of 1.7×10^{-6} to 7.5×10^{-6} mol/L (Fig. 3*c*). It was observed that the maximum and the constant fluorescence intensities were obtained with a concentration between 3.3×10^{-6} and 7.5×10^{-6} mol/L. Then, 3.3×10^{-6} mol/L of the reagent was selected.

The effect of the temperature on derivatization yield was also studied in the range of 20–55 °C (Fig. 3*d*). The results show that the fluorescence intensity reached a maximum at 35 °C. Therefore, 35 °C was selected as the optimum temperature value for the derivatization.

With respect to the reaction time, optimization was performed in the range of 25–50 min (Fig. 3*e*). The results show that fluorescence intensity reached its maximum and was invariable when the reaction time was 35 min. Thus, 35 min was selected for this work.

Optimization of SPE conditions

The goal of the present study was to use the SPE method coupled with spectrofluorimetry to sensitively determine GSH. To obtain the maximum enrichment yield, the type of eluent, its volume, and the extraction time were carefully optimized.

Effect of type of the eluent

Choosing the most suitable eluent was important for SPE. Desorption of the analyte from the SPE column was investigated using different kinds of organic solvents including acetone, methanol, acetonitrile, and ethanol. The experimental results show that the desorption ability of acetonitrile and acetone was better than that of methanol and ethanol (Fig. 4*a*). However, boiling point and toxicity of acetone were lower than that of acetonitrile, and the time of extraction process was shortened with acetone. Therefore, acetone was selected for the elution of analytes from the SPE column.

Effect of the volume of the eluent

During a SPE procedure, the volume of eluent is an essential factor that can affect the enrichment performance. The effect of acetone volume was evaluated in the range of 200–500 μL. As shown in Fig. 4*b*, the fluorescence intensity of the derivative increased along with acetone volume in the range of 200–300 μL and then remained constant when the volume was continuously enhanced. Therefore, 300 μL of acetone was selected for further study.

Effect of extraction time

SPE is a type of equilibrium extraction, and the optimal extraction efficiency is achieved when equilibrium is established. Hence, extraction time is one of the most important parameters in the extraction process, which is regarded as the interval time between entering sample solutions and

before washing. The effect of extraction time on extraction efficiency was researched in the range of 1–6 min (Fig. 4*c*). The fluorescence intensity of the derivative increased along with extraction time in the range of 1–3.5 min and then remained constant when the time was continuously lengthened. Thus, 3.5 min was selected as the extraction time.

Interference

Under the above selective conditions, the effects of some coexisting substances on the determination of GSH (6.7×10^{-8} mol/L) were investigated. The results are shown in Table 2 (relative error ≤±5%). The interference study of common metal ions and inorganic anions existing at high levels showed that the presence of these ions had a negligible interference to the determination. This indicates that the proposed method has good selectivity.

Analytical curve, sensitivity, and precision

Under optimum conditions, a calibration graph was constructed. Table 3 shows the analytical characteristics of the method. The calibration graph was linear between 1 and 200 nmol/L, with a correlation coefficient of 0.996. The limit of detection, calculated as three times the standard deviation (SD) of the blank signal, was 0.05 nmol/L for the preconcentration sample solution. The relative SD (RSD) resulting from the analysis of six replicates was 3.9%. These values were better than that for the spectrofluorimetry without SPE procedure in water (Table 3).

Table 3. Analytical characteristics of the method.

Analytical parameters	Without preconcentration	With preconcentration
Linear range (nmol/L)	60–7000	1–200
Regression equation[a]	$Y = 0.8736X + 10.439$	$Y = 3.3601X + 132.06$
Detection limit[b] (nmol/L)	4	0.05
Correlation coefficient	0.992	0.996
Relative RSD	2.4	3.9

Note: RSD, relative standard deviation.

[a]X is the concentration of the mercapto compounds (nmol/L) and Y is the fluorescence intensity of the mercapto compound derivatives.

[b]Calculated as three times the SD of the blank signal.

Table 4. Analytical results for the samples.

Samples	GSH added (μmol/L)	GSH found (μmol/L)	Recovery (%)	RSD (%)
Tap water	0	0		
	0.4	0.43	107.5	3.6
	2	1.94	97	4.9
	20	20.18	100.9	2.7
Shi River water	0	0		
	0.4	0.38	95	5.2
	2	1.85	92.5	3.8
	20	17.64	88.2	2.6
Rain water	0	0		
	0.4	0.35	87.5	5.5
	2	2.23	111.5	3.7
	20	20.69	103.4	3.2

Note: GSH, L-γ-glutamyl-L-cysteineglycine; RSD, relative standard deviation.

Sample analysis

The proposed method was applied for the determination of GSH in water samples. GSH concentrations in different water samples were measured according to the methods mentioned in the General procedure section. The results are summarized in Table 4. No GSH was found in three water samples. The accuracy of the sample analysis was validated by spiking a known amount of standard GSH with the sample and calculating its recovery. Recoveries were obtained from 87.5% to 111.5% with a satisfactory RSD of 2.6%–5.5%, which verifyed the feasibility and reliability of the present method.

Conclusions

The proposed method outlined the successful development and application of SPE combed with spectrofluorimetry for the sensitive determination of GSH in environmental water samples. It permited the analysis and quantification of GSH at nmol/L levels in different water samples with a simple and low-cost spectrofluorimetric method. This methodology offers a simple, rapid, sensitive, and inexpensive alternative to other separation–preconcentration techniques with the concomitant benefits from the use of SPE (safety, cost, high separation yield, versatility, and nonpolluting aspect). The proposed method gave low LOD, good RSD, and recovery of the GSH from its initial matrix without previous treatment. The method was verified with real samples and applied satisfactory to the determination of GSH in different water samples.

Abstract: Infrared absorption and Raman spectra were calculated by using the molecular dynamics method for water clusters with chlorine and bromine ions in a medium of water and either ozone or oxygen molecules. The intensity of IR absorption spectra of clusters with absorbed oxygen increased and that of clusters with absorbed ozone decreased as the number of chlorine ions grew. When Br^- were present in the system the inverse behaviour was observed. An increase in the number of ions weakened the intensity of the Raman spectra when either oxygen or ozone was absorbed; for ozone this weakening was more noticeable. A stronger reduction of the integrated intensity of the Raman spectrum with an increase in the number of Br^- was observed in the presence of ozone molecules in the system. Cl^- ions caused an amplification of the emission power of the IR radiation for both systems in the presence of oxygen and ozone, and Br^- strengthened the emission of IR radiation for systems containing ozone, and weakened it for systems with oxygen molecules.

Key words: absorption, chlorine and bromine ions, IR and Raman spectra, oxygen, ozone, water clusters.

Résumé : Faisant appel à la méthode de la dynamique moléculaire, on a calculé les spectres d'absorption IR et Raman d'agrégats d'eau avec des ions chlorure et bromure dans un milieu aqueux contenant des molécules d'ozone ou d'oxygène. L'intensité des spectres d'absorption IR des agrégats comportant de l'oxygène absorbé augmente alors que celle des agrégats comportant de l'ozone absorbé diminue avec une augmentation du nombre d'ions chlorures. Dans les systèmes comportant des ions bromures, on a observé un comportement inverse de cette amplitude. En présence d'oxygène ou d'ozone absorbé, une augmentation du nombre d'ions chlorures diminue l'intensité des spectres Raman; avec l'ozone, cette diminution est plus importante. Une réduction encore plus forte de l'intensité intégrée du spectre Raman est observée avec une augmentation du nombre d'ions bromures, en présence de molécules d'ozone dans le système. Les ions chlorures provoquent une amplification de la puissance de l'émission du rayonnement IR pour les deux systèmes en présence d'oxygène ou d'ozone et les ions bromures augmentent l'émission du rayonnement IR des systèmes contenant d'ozone alors que les molécules d'oxygène l'affaiblissent.

Mots-clés : absorption, ions chlorures et bromures, spectres IR et Raman, oxygène, ozone, agrégats d'eau.

Introduction

The stratospheric ozone (O_3) layer contains 90% of the atmosphere's ozone and thus is responsible for the majority of the absorption of solar UV radiation. Halogen atoms are released by the degradation of long-lived halocarbon species (CH_3Cl, $CFCl_3$, CH_3Br, etc.), which are emitted either naturally or anthropogenically in the troposphere and then transported into the stratosphere. Halogen atoms (X = F, Cl, Br, or I), which are released in the degradation processes, react quickly with O_3 to form halogen oxides. In addition, halogen atoms can react with O_2 by association reactions to form halogen peroxide radicals. These radicals are unstable and dissociate by the reverse of their formation reaction, therefore, under atmospheric conditions the XO_2 species exist in equilibrium with X and O_2. The stability of XO_2 decreases in the series F > Cl > Br > I. One of the main causes of formation of the ozone hole is the increase in stratospheric chlorine and bromine levels because of the release of man-made chlorofluorocarbons (CFCs) such as CF_3Cl and CF_2Cl_2. The ClO dimer plays a major part in the catalytic destruction of ozone occurring in the polar lower stratosphere during wintertime, which leads to the formation of the ozone hole over Antarctica. On the other hand, BrO is lost by BrCl production. The behaviour of halogen oxides in the stratosphere is strongly influenced by the chemistry of temporary reservoir species containing chlorine and bromine. The combined Br–Cl catalytic cycles are very efficient in depleting ozone, and can therefore cause equal or even larger ozone destruction than chlorine alone in the lower stratosphere. Although there are significant human sources of Br, the contemporary abundance of total stratospheric Br is only ~0.5% of that of Cl.[1] Owing to the much shorter atmospheric lifetimes of iodine-containing compounds (e.g., CH_3I emitted from the oceans) compared with

their Cl^-- and Br^--containing analogues, iodine does not reach the stratosphere in significant quantities.

In the chemistry of atmospheric particles, halogen activation, which describes the liberation of halogen containing components from sea salt particles, must be considered. These components undergo subsequent photolysis to release exceedingly reactive Cl and Br atoms. Photochemical reactions in clouds occur in the liquid phase with the participation of $HO^\bullet$ and $HO_2^\bullet$ radicals and other oxidizing components (H_2O_2 or O_3) supplied from the gas phase. Dense small aggregates of molecules are conventionally called clusters. Water clusters are present in clouds and can also exist in a cloudless atmosphere.[2] Atoms and molecules in the atmosphere experience ionization from the action of cosmic rays, from the radiation of radioactive rocks, and from radon in the air itself. The ionization of molecules releases electrons. Chlorine and bromine atoms easily attract free electrons to produce negatively charged ions. Chlorine or bromine ions interact with ozone and split it into oxygen molecules and atoms (possibly into three oxygen atoms). This reaction is facilitated by the presence of water. In other words, the reaction has its highest rate on the surfaces of water clusters. Fast chlorine or bromine ions are the first to reach the surface of water clusters.

The purpose of this work was to study the interaction of halide-containing electrically charged water clusters with ozone and oxygen molecules, and to determine the character of the changes in the dielectric properties of these aggregates that occur as a result of such interactions.

Model

Water is among the most studied of chemicals, owing in part to its ubiquity and its necessity for all life. In addition to these "natural" reasons, water is an interesting compound because it has unique physical properties and is a model hydrogen-bonded liquid. Most of the available water interaction potentials are parameterized to reproduce the thermodynamic and structural properties of bulk water. The polarizable model allows us to examine the changes in the dipole moment of the individual water molecules as a function of their environment. This can provide insight into many body effects in water clusters at a molecular level. Dang and Chang[3] developed a polarizable potential model for water that behaves reasonably well with changes in the environment (i.e., for clusters, liquid, and liquid–vapor). The simulation of water clusters was performed using a modified transferable intermolecular potential 4 points (TIP4P) interaction potential for water and the rigid four-centre model of the H_2O molecule.[4] The modification of the interaction potential for water by Dang and Chang[3] concerned variation of the parameters of the Lennard–Jones part of the potential and localization of negative charge. As a result, the value of the permanent dipole moment for the water molecule is taken to be equal to its experimentally obtained value of 1.848 D. The geometry of this molecule corresponds to the experimentally obtained parameters of the molecule in the gas phase: r_{OH} = 0.09572 nm and angle HOH = 104.5°.[5] Fixed charges (q_H = 0.519e and q_M = –1.038e, where e is electronic charge) are assigned to H atoms and to a point M lying on the bisector of angle HOH at a distance of 0.0215 nm from the oxygen atom. The values of the charges and the position of point M are selected so as to reproduce the experimentally obtained values of the dipole and quadrupole moments[6,7] as well as the ab initio calculated energy of the dimer and the typical distances in the dimer.[8]

The total interaction energy of the system can be written as

$$[1] \qquad U_{tot} = U_{pair} + U_{pol}$$

where the pairwise additive part of the potential is the sum of the Lennard–Jones and Coulomb interactions,

$$[2] \qquad U_{pair} = \sum_i \sum_j \left\{ 4\varepsilon^{(LJ)} \left[\left(\frac{\sigma_{ij}^{(LJ)}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}^{(LJ)}}{r_{ij}} \right)^{6} \right] + \frac{q_i q_j}{r_{ij}} \right\}$$

Here r_{ij} is the distance between sites i and j, q is the charge, and $\sigma^{(LJ)}$ and $\varepsilon^{(LJ)}$ are the Lennard–Jones parameters.

The nonadditive polarization energy is given by

$$[3] \qquad U_{pol} = -\frac{1}{2} \sum_i \mathbf{d}_i \cdot \mathbf{E}_i$$

where $\mathbf{d}_i$ is the induced dipole moment at the centre of mass of the ith molecule, $\mathbf{E}_i$ is the total electric field at this centre, and $\mathbf{E}_i^0$ is the electric field at site i produced by the fixed charges in the system,

$$[4] \qquad \mathbf{E}_i^0 = \sum_{j \neq i} \frac{q_j \mathbf{r}_{ij}}{r_{ij}^3}$$

where $\mathbf{r}_{ij}$ is the vector from the centre of mass of the jth molecule to the centre of mass of the ith molecule,

$$[5] \qquad \mathbf{d}_i = \alpha_i \mathbf{E}_i$$

where α_i is the atomic polarizability and

$$[6] \qquad \mathbf{E}_i = \mathbf{E}_i^0 + \sum_{j \neq i} \mathbf{T}_{ij} \cdot d_j$$

where $\mathbf{T}_{ij}$ is the dipole tensor,

$$[7] \qquad \mathbf{T}_{ij} = \frac{1}{|r_{ij}|^3} (3\hat{\mathbf{r}}_{ij}\hat{\mathbf{r}}_{ij} - \mathbf{1})$$

where $\hat{\mathbf{r}}_{ij} = \mathbf{r}_{ij}/r_{ij}$ is the unit vector and $\mathbf{1}$ is the 3 × 3 unit tensor.

The stabilization of short-range order in water clusters is largely attained because of the short-range Lennard–Jones potential with the centre of interaction ascribed to the oxygen atom. Related to point M, in addition to the electric charge, is the polarizability, which is required for the description of nonadditive polarization energy. The standard iterative procedure is used at every time step for calculating induced dipole moments.[3] The accuracy of determination of $\mathbf{d}_i$ was in the range 1×10^{-5} to 1×10^{-4} D.

The additive part of the oxygen–oxygen and oxygen–water interactions is described by an atom–atom potential calculated by the Gordon–Kim approximation with the application of the spherical average of electronic densities,[9,10]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[8] \qquad \Phi(r_{ij}) = b_i b_j \exp[-(c_i + c_j)r_{ij}] - a_i a_j r_{ij}^{-6} + \frac{q_i q_j}{r_{ij}}$$

where the parameters a_i, b_i, and c_i of the potential describing these interactions were borrowed from Spackman.[9,10] The $q_+ = 0.19e$ positive charge was set on the central atom of the O_3 molecule and the $q_- = -0.095e$ negative charge on each of its side atoms.[11] The O_3 molecule was electrically neutral as a whole. Atoms in the O_2 molecule had no electric charges.

The Coulomb interaction of Cl^- and Br^- ions with water was determined by their electric charge ($q = -1e$, where e is the elementary charge unit). The ion–H_2O non-Coulomb interaction was included as a Lennard–Jones Cl^-–O or Br^-–O interaction with the parameters from refs. 11 and 12. We also considered atom–atom interaction between Cl^- or Br^- ions described by eq. [8] with the parameters from ref. 10. The nonadditive contribution to interactions between water, oxygen, ozone, chlorine, and bromine was caused by polarization and was taken into account in calculations according to eqs. [3]–[7].

Here, we consider flexible models of molecules. Flexibility was created using the procedure developed in terms of Hamilton dynamics in refs. 13 and 14. Let us consider a diatomic molecule and let atoms a and b in it be separated by the distance

$$[9] \qquad R = \| \mathbf{r}_a - \mathbf{r}_b \|$$

where $\mathbf{r}_a$ and $\mathbf{r}_b$ are the vectors that determine the positions of the atoms. Let $\mathbf{v}_a$ and $\mathbf{v}_b$ be the corresponding velocities and let the reduced mass have the form

$$[10] \qquad \mu = \frac{m_a m_b}{m_a + m_b}$$

The size of the molecule consisting of atoms a and b is determined by the equality of the total potential force $\mathbf{f}(\mathbf{R}) = -\frac{\partial \mathbf{r}}{\partial R} \bigtriangledown \Phi(\mathbf{r})$ to the centrifugal force $-\mu R\omega^2$, that is,

$$[11] \qquad -\mu R\omega^2 - \mathbf{f}(\mathbf{r})\frac{\partial \mathbf{r}}{\partial R} = 0$$

where vector $\mathbf{R} = \mathbf{r}_a - \mathbf{r}_b$, $\mathbf{r}$ is the vector determining distance from atoms a or b up to the external centre interacting with them, and $\omega = \| \mathbf{v}_a - \mathbf{v}_b \| /R$ is the angular velocity. The minimization of contributions to the potential energy U of each generalized coordinate yields

$$[12] \qquad \frac{\partial}{\partial q_i} U(\mathbf{r}, \mathbf{v}) = \frac{\partial}{\partial R_i}\left[\frac{1}{2}\mu_i R_i^2 \omega_i^2 + \Phi(\mathbf{r})\right] = 0$$

This method is applicable to molecules with arbitrary compositions.[15] The use of the flexible model of molecules allowed us to expand the range of frequencies under study.

The simulation of the interaction of $(Cl^-)_i(H_2O)_{50-i}$ or $(Br^-)_i(H_2O)_{50-i}$ clusters with a gas medium containing iH_2O molecules and six O_2 or O_3 molecules began with creating the configuration of the equilibrium cluster of water $(H_2O)_{50}$ with the kinetic energy corresponding to 250 K in the molecular dynamics calculations. The positions of Cl^- or Br^- in the cluster were determined using a system of coordinates fixed at the centre of mass of the cluster. The cluster was approximated by a sphere and water molecules situated most closely to the coordinate axes from this sphere were found. These molecules (their number was from one to six) were displaced outside along the coordinate axes through distances of 0.6–0.7 nm from the former positions of their centres of mass, into which Cl^- or Br^- were introduced. The number of ions equaled the number of displaced molecules. The interaction of the newly formed $(Cl^-)_i(H_2O)_{50-i}$ or $(Br^-)_i(H_2O)_{50-i}$ cluster with water and O_2 or O_3 molecules was studied in an ensemble with an external thermostat[16] at 250 K. The cutoff radius for intermolecular interactions was 0.9 nm in our model. Six O_2 or O_3 molecules were situated predominantly on the lower side of the cluster. The fairly compact arrangement of these molecules facilitated studies of their influence on the behavior of Cl^- or Br^-. The time instant at which ions were incorporated into the water cluster and O_2 (or O_3) molecules approached this aggregate was taken as time $t = 0$. The calculation of spectral characteristics started with time instant $10^5\Delta t$ (1 ps), where Δt is the integration time step, and the complete duration of the calculation was $2.5 \times 10^6 \Delta t$ time steps.

The Gear method[17] of the fourth order was used for determining the trajectories of the centres of mass of the molecules. The integration time step was 10^{-17} s. The Rodriguez–Hamilton parameters[18] were used to derive the analytical solution of equations of motion for molecular rotation, and the scheme of integration of the equations of motion in the presence of rotations corresponded to the approach suggested by Sonnenschein.[19]

Dielectric propeties

It was assumed that a cluster containing i molecules of oxygen or ozone and n molecules of water has the statistical weight

$$[13] \qquad W_{i,n} = \frac{N_{i,n}}{N_{i,\Sigma}} \quad i = 1, ..., n$$

where $N_{i,n}$ is the number of clusters with i molecules (ions) of impurity and n molecules of water per 1 cm^3 and $N_{i,\Sigma} = \sum_{i=1}^{n} N_{i,n}$. The value of $N_{i,n}$ was estimated as follows. We considered the case of the scattering of nonpolarized light where the molecular free path l is much less than the wavelength of light λ. The extinction (attenuation) coefficient η of the incident beam may be determined on the one hand by the Rayleigh formula[20] and on the other hand in terms of the scattering coefficient ρ[21] in the approximation of the scattering at an angle of 90°. In view of the fact that η is $\alpha + \rho$, where α is the absorbance, we have

$$[14] \qquad N_{i,n} = \frac{2\omega^4}{3\pi c^4}\frac{(\sqrt{\varepsilon} - 1)^2}{\alpha}\left(1 - \frac{3}{16\pi}\right)$$

Here c is the velocity of light, ε is the permittivity of the medium, and ω is the incident wave frequency. The spectral characteristics of the systems were calculated in view of the adopted statistical weights $W_{i,n}$. The procedure of forming the systems of clusters provided for the uniform distribution of these formations and is valid at a low concentration of clusters, which means that they do not interact with one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

another. The average value of the concentrations of the clusters of each type in the systems under investigation was 12–13 orders of magnitude lower than the Loschmidt number.

The total dipole moment of the cluster $\mathbf{d}_{cl}$ was calculated by the formula

$$[15] \qquad \mathbf{d}_{cl}(t) = q_+^{(k)} \sum_{i=1}^{N_{tot1}} \mathbf{r}_i(t) + q_-^{(k)} \sum_{j=1}^{N_{tot2}} \mathbf{r}_j(t)$$

where $\mathbf{r}_i(t)$ is the vector indicating the location of nucleus i or point M at the instant of time t, q is the electric charge located at the centre under consideration, the index k specifies the type of nucleus (or point M), the subscript + relates to the nucleus carrying a positive electric charge, the subscript – to the nucleus carrying a negative charge, and N_{tot1} and N_{tot2} are the numbers of positively and negatively charged nuclei in the cluster, respectively.

The permittivity $\varepsilon(\omega)$ as a function of frequency is given by the complex quantity $\varepsilon(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega)$ (where ε' is the real part and ε'' is the imaginary part of permittivity), which was determined using the equation[22,23]

$$[16] \qquad \frac{\varepsilon(\omega) - 1}{\varepsilon - 1} = -\int_0^\infty \exp(-i\omega t)\frac{\mathrm{d}F}{\mathrm{d}t}\mathrm{d}t = 1 - i\omega\int_0^\infty \exp(-i\omega t)F(t)\mathrm{d}t$$

where the function $F(t)$ is the normalized autocorrelation function of the total dipole moment of the cluster,

$$[17] \qquad F(t) = \frac{\langle \mathbf{d}_{cl}(t)\cdot\mathbf{d}_{cl}(0)\rangle}{\langle \mathbf{d}_{cl}^2\rangle}$$

The cross section of IR radiation absorption is given by

$$[18] \qquad \sigma(\omega) = \frac{2}{\varepsilon_v c\hbar n}\omega\tanh\left(\frac{\hbar\omega}{2kT}\right)\mathrm{Re}\int_0^\infty \mathrm{d}t e^{i\omega t}\langle \mathbf{d}_{cl}(t)\cdot\mathbf{d}_{cl}(0)\rangle$$

where ε_v is the permittivity of the vacuum, $\hbar = h/2\pi$, h is Planck's constant, and n is the refractive index.

The Raman and IR spectra of the clusters were calculated via the autocorrelation functions of polarizability and dipole moment, respectively. A polar molecule is characterized by a permanent (gas phase) dipole moment $\mathbf{d}_{i,0}$ and polarizability tensor $\boldsymbol{\alpha}_{i,0}$. Interaction with neighbouring molecules creates the induced dipole moment and polarizability of molecule i. Each model molecule was treated as a polarizable point dipole situated in the centre of mass of the molecule. The $\mathbf{d}_i$ dipole moment of molecule i and its polarizability α_i are related because of molecule interactions with the environment.[24]

$$[19] \qquad \mathbf{d}_i = \mathbf{d}_{i,0} + \boldsymbol{\alpha}_{i,0}\sum_{j\neq 1}\mathbf{T}_{ij}\mathbf{d}_j$$

$$[20] \qquad \boldsymbol{\alpha}_i = \boldsymbol{\alpha}_{i,0} + \boldsymbol{\alpha}_{i,0}\sum_{j\neq 1}\mathbf{T}_{ij}\boldsymbol{\alpha}_j$$

We used the anisotropic gas-phase polarizability tensor $\boldsymbol{\alpha}_{xx,yy,zz} = \{1.495, 1.626, 1.286\}$ Å^3 for the water molecule.[24] O_3 and O_2 molecules were characterized by the isotropic experimental polarizability values 2.85 and 0.793 Å^3, respectively.[25] The atomic polarizabilities for Cl^- (3.25 Å^3) and Br^- (3.1 Å^3) were taken from ref. 25.

Equations [19] and [20] for $\mathbf{d}_i$ and $\boldsymbol{\alpha}$ were solved by inverting the matrix and using the $\mathbf{d}_{i,0}$ and $\mathbf{a}_{i,0}$ values on the right-hand side.

For depolarized light, the Raman spectrum is given by the equation[24]

$$[21] \qquad J(\omega) = \frac{\omega}{(\omega_L - \omega)^4}(1 - \mathrm{e}^{-\hbar\omega/kT})\,\mathrm{Re}\int_0^\infty \mathrm{d}t e^{i\omega t}\langle \Pi_{xz}(t)\Pi_{xz}(0)\rangle$$

where

$$[22] \qquad \Pi(t) \equiv \sum_{j=1}^{N}[\boldsymbol{\alpha}_j(t) - \langle\boldsymbol{\alpha}_j\rangle]$$

where ω_L is the exciting laser frequency, Π_{xz} is the xz component of $\Pi(t)$, the x axis is directed along the molecular dipole, and xy is the molecular plane. Simulations were performed for ω_L = 19 436.3 cm^{-1} (the argon laser green line, λ = 514.5 nm).

In liquid water the interaction of Cl^- and Br^- with H_2O molecules is limited to the electrostatic attraction of water dipoles to anions. In a small water cluster Cl^- and Br^- experience mutual repulsion and cannot be held close to water molecules for long. We performed calculations for six $(Cl^-)_i(H_2O)_{50-i}$ + iH_2O + $6O_2$, systems and six $(Cl^-)_i(H_2O)_{50-i}$ + iH_2O + $6O_3$ systems, with i = 1–6. The same calculations were carried out for the corresponding systems containing Br^-. Systems with i = 1–6 are denoted by I–VI in the presence of oxygen and by VII–XII in the presence of ozone. We put one stroke at the number of the system containing Cl^- and two strokes at the system number including Br^-. The criterion for the addition of O_3 or O_2 molecules to a water cluster was the establishment of $r_{o-o} \leq$ 0.35 nm distances.

The frequency dispersion of permittivity defines the frequency dependence of dielectric loss $P(\omega)$ in accordance with the expression[21]

$$[23] \qquad P = \frac{\varepsilon'' < E^2 > \omega}{4\pi}$$

where $< E^2 >$ is the average value of the square of the electric field strength and ω is the frequency of the emitted electromagnetic wave.

Motions with a frequency of <1200 cm^{-1} correspond to the liberation of molecules and those with a frequency >1200 cm^{-1} largely describe intramolecular vibrations.[26]

Results and discussion

Chlorine-containing systems

Because of Coulomb repulsion from negatively charged oxygen ions and mutual repulsion, the Cl^- in $(Cl^-)_i(H_2O)_{50-i}$ clusters rushed to the outside of the cluster. The ions leaving a cluster pushed water molecules apart. This and the interaction with the environment molecules (H_2O and either O_2 or O_3) heated the $(Cl^-)_i(H_2O)_{50-i}$ + iH_2O + $6O_3$ (or $6O_2$) system.

The strongest heating, to 311 K (at time $t \sim 3$ ps), was observed when the cluster of water with six chlorine atoms was surrounded by O_3 molecules. The algorithm that we used allowed for the decomposition of O_3 molecules with energies of 1.3 eV or higher. This energy is sufficient for splitting an ozone molecule surrounded by water molecules. However, in reality there was no decomposition of ozone. As a rule, in 2 ps, that is by the time that $t = 5$ ps, the system was cooled because of velocity scaling and reached its initial temperature of ~250 K. Two Cl^- leave the $(Cl^-)_6(H_2O)_{44}$ cluster in both O_2- and O_3-containing systems by the time $t = 1.2$ ps (Fig. 1). One of the Cl^- hit an O_2 molecule (Fig. 1A). In the same system with ozone, two ions directly interacted with O_3 molecules (one of these ions interacted with two O_3 molecules at once), one ion was "bound" to a water molecule, and one ion was almost free (Fig. 1B). By $t = 2.8$ ps all Cl^- ions had left the cluster and, conversely, O_3 molecules had approached it. Clusters with four and two Cl^- lost these ions in 2.8 and 2.2 ps, respectively. A similar interaction picture was observed when O_2 rather than O_3 molecules approached the cluster. The system was then free of ions in 2.8 ps (six Cl^-), 2.4 ps (four Cl^-), and 2.2 ps (two Cl^-).

The IR absorption spectra are determined by the behaviour of the autocorrelation function of the total $\mathbf{d}_{cl}$ of a cluster. When O_2 molecules without permanent dipole moments are added to a water cluster, they weakly influence the $\mathbf{d}_{cl}$ value determined by the aqueous component of the cluster. For this reason, the perturbation force introduced by Cl^- is approximately proportional to the number of ions (N_{Cl^-}). The integral intensities of the IR absorption spectra (I_{tot}s) therefore grow as N_{Cl^-} increases (Fig. 2A). The opposite situation arises if O_3 molecules are absorbed. When O_3 molecules, whose permanent dipole moment (0.12 D) is lower than that of water, are added to a cluster they create additional "beats" during the evolution of the $\mathbf{d}_{cl}$ value.

The action of Cl^- on the cluster strengthens these oscillations with different frequencies and phases. The larger the number of Cl^- in the cluster, the stronger the beats created by the O_3 molecules. As a result, the ability of the system to absorb IR radiation decreases (I_{tot} decreases) as the number of ions increases (Fig. 2B). The I_{tot} values for systems I′–VI′ increase nonmonotonically and those for systems VII′–XII′ decrease as the number of Cl^- grows. The I_{tot} ratios are 1:0.80:1.22:1.10:2.83:1.83 for systems I′–VI′ and 1:1.04:0.86:0.79:0.99:0.94 for systems VII′–XII′. In all cases the absorption peak is in the vicinity of the frequency $\omega = 960 \pm 20$ cm^{-1}. The main absorption of liquid water is observed at 690 cm^{-1},[27] and that of ozone–oxygen gas mixtures in the vicinity of 996 cm^{-1}.[28]

The Raman spectra of aqueous systems containing oxygen or ozone are differ more than the IR spectra (Fig. 3). The Rayleigh line at $\omega = 0$ is excluded from the spectra. The positions of the first peaks coincide (26 cm^{-1}), but there is no correspondence between the other peaks. In addition, the integral intensities of Raman spectra are noticeably higher with oxygen than with ozone in aqueous systems. The Raman spectrum for liquid water is characterized by low-frequency peaks at 60 cm^{-1} as well as by a peak near 170 cm^{-1}.[29] The peak at 60 cm^{-1} is caused by the bending of hydrogen bonds between water molecules; the peak at

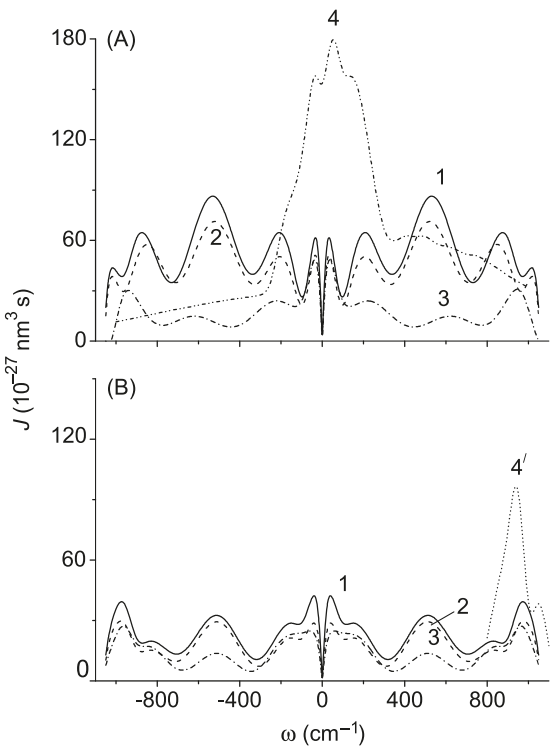
Fig. 3. Raman spectra of systems with (A) oxygen and (B) ozone: (1) systems I′ and VII′, (2) III′ and IX′, (3) VI′ and XII′, (4) liquid water experimental,[29] and (4') a solution of OClO in water, experimental.[30]



170 cm^{-1} appears because of bond stretching.[24] The position of the newly formed last peak at 950 cm^{-1} in the spectrum of the system with six O_2 molecules and six Cl^- is close to the position of the peak in the Raman spectrum of an aqueous solution of chlorine dioxide (945 cm^{-1}) determined experimentally.[30] The peak observed in femtosecond measurements of a solution of OClO in water was assigned to a fundamental transition to a new energy level with symmetrical dilatation of the OClO molecule.

A study of the photolysis of OClO in aqueous solution showed the possibility of separation of dielectric relaxation related to solvent (water) libration modes and mechanical solvation caused by low-frequency translational motion.[31] The mechanical response of a solvent is usually provided by one or two molecules in its first solvation shell. According to the computer simulation results, 80% of water solvation that follows OClO photoexcitation occurred during a 2×10^{-14} s time interval, whereas the remaining 20% of the response was diffusive in nature and could be observed on a picosecond time scale.[31]

Two characteristic times can also be identified for excitation related to the removal of Cl^- from a water cluster. A short time interval (~3 ps) corresponds to the excitation or interaction of ions with water and O_3 (or O_2) molecules. The dielectric relaxation interval is ~10 ps. During this time, the cluster "forgets" the value and direction of its dipole moment at time $t = 0$. The dissociation of the free O_3 molecule (in the vacuum) usually occurs when energy of 4–5.5 eV is imparted to it. Chlorine ions moving out of the cluster do not possess such energy. For this reason, we did not observe the decomposition of ozone molecules.

As the strength and duration of perturbation caused by the "bombardment" of molecules (H_2O and O_3 or O_2) by Cl^- increased, the integral intensity of the IR absorption spectrum decreased in the presence of ozone and increased with the addition of oxygen. The main absorption frequency remained constant. The Raman spectra substantially changed their shape and intensity when absorbed oxygen was replaced with ozone. Irrespective of the number of Cl^- initially contained in a water cluster and the molecules it absorbs (O_3 or O_2), the main Raman spectrum frequency remains unchanged. The absorption of ozone causes a more rapid decrease in the intensity of Raman spectra compared with the absorption of oxygen.

IR emission $P(\omega)$ spectra for oxygen-containing systems are characterized by the presence of a principal band in the $800 \le \omega \le 1000$ cm^{-1} frequency range (Fig. 4A). The integral intensity (I_{rad}) of the emission spectra of the systems under consideration increased significantly in the presence of Cl^-. The ratio of I_{rad} values for the $P(\omega)$ spectra of the $(O_2)_6(H_2O)_{50}$ cluster and systems II′, IV′, and VI′ is 1:1.45:1.09:1.70. The intensity of IR radiation emission by the $(O_3)_6(H_2O)_{50}$ cluster increases as a result of the action of chlorine ions (Fig. 4A). The ratio of I_{rad} in the $P(\omega)$ spectra of the $(O_3)_6(H_2O)_{50}$ cluster and systems VIII′, X′, and XII′ is 1:1.34:1.16:1.07. In the presence of ions, Cl^- displacement of the main maximum of the $P(\omega)$ spectrum in the area of low frequencies occurs more strongly for the systems containing oxygen. The increase in the number of Cl^- acting on the cluster results in a better resolution of the second and third peaks of the $P(\omega)$ spectrum.

Bromine-containing systems

Differences in the behaviour of Br^- in water clusters, when interacting with O_2 or O_3 molecules, can appear because of their greater weight than that of Cl^- (m_{Br}/m_{Cl} = 2.25). Configurations of the $6Br^-(H_2O)_{44}$+ $6H_2O$ + 6X cluster systems, obtained up to t = 25 ps, are shown in Fig. 5. Here, X refers to O_2 molecules (Fig. 5A) or O_3 molecules (Fig. 5B). In both cases six free water molecules have joined the $6Br^-(H_2O)_{44}$ cluster. Three of six Br^- have abandoned the cluster in the presence of oxygen in the system. One of these ions is depicted in the bottom part of Fig. 5A. Three O_2 molecules also evaporated with the left ions that left the cluster, while three other molecules of oxygen joined the cluster. The effect of the presence of ozone molecules produced a different result. All six O_3 molecules were adsorbed by cluster. Thus, six Br^- have left the cluster surface, but they have are not at such a great distance that we could consider them as evaporated ones. We consider ions or molecules for which non-Coulomb interaction with other molecules vanishes at a distance of 0.9 nm as evaporated ones. These types of ions or molecules do not come back to the cluster.

Frequencies and intensities of normal vibrations are defined by the weight and kind of atoms, the bonding force, and the spatial arrangement of the atoms (lengths and corners of the bond). Absorbed ions change the cluster structure and influence the intensity of the IR spectrum and to a smaller degree the intensity of the Raman spectrum.

Absorption IR spectra of some systems containing bromine are depicted in Fig. 6. The addition of six O_2 molecules

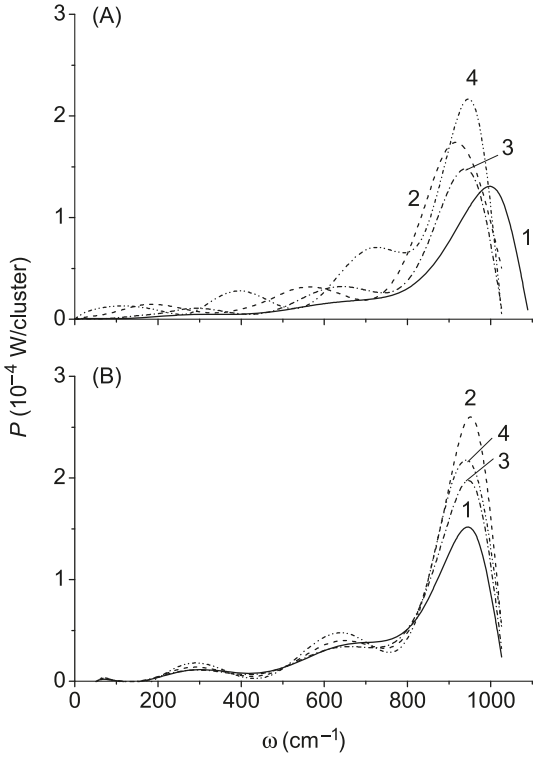
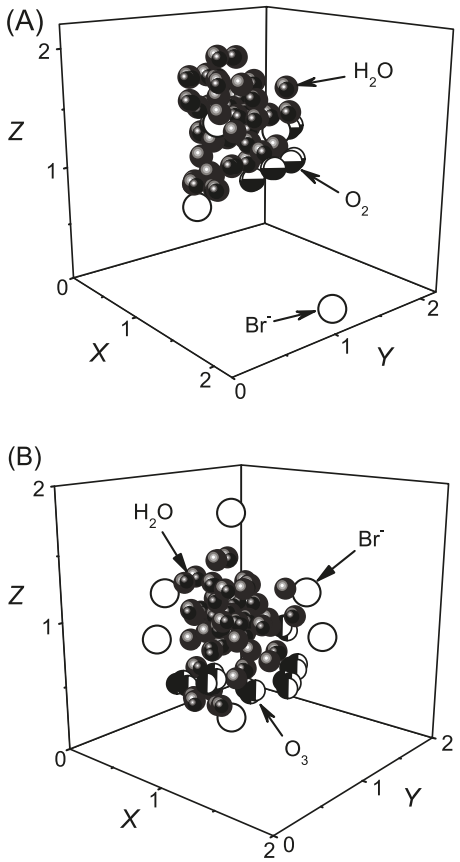
Fig. 4. IR emission spectra of systems $(Cl^-)_i(H_2O)_{50-i} + iH_2O + 6X$ for (A) X = O_2 and (B) X = O_3. (1) i = 2, (2) i = 4, (3) i = 6, (4) the $P(\omega)$ function of the $(O_3)_6(H_2O)_{50}$ cluster.



to the $(H_2O)_{50}$ cluster resulted in an increase of the integrated I_{tot} of IR radiation absorption by a factor of 2.3. However, if a water cluster initially absorbed Br^- ions (at the equivalent desorption of water molecules), then such an amplification of I_{tot} value was not observed, and the I_{tot} magnitude in the presence of four or more Br^- and the absorption of oxygen, decreases. The position of the main peak of the IR spectrum of the dispersed water system with molecular oxygen did not change, and the next highest intensity peak is deformed into a shoulder. The location of the basic peak shifted (by ~100 cm^{-1}) in the of low-frequency area with respect to the position of the main peak of an experimental IR spectrum of liquid bulk water.[27] Localization of the minimum between two peaks of the $\sigma(\omega)$ spectra of the cluster systems falls within an interval of the maximal intensity of an experimental IR spectrum of gaseous bromine hydride,[32] and the fast rise in spectrum intensity of the systems under consideration corresponds to the position of the main maximum of an experimental IR spectrum of a gaseous $O_2 + O_3$ mix.[28]

Opposite transformations of the $\sigma(\omega)$ spectrum occur with a change in the number of Br^- in the cluster with ozone present in the system. The addition of O_3 molecules to the cluster gives a reduction in the I_{tot} magnitude by a factor of 7.3. This decrease is less observed with the growth of the number of Br^- in the cluster. In other words, adsorption of ozone follows the increase of the I_{tot} values if the water cluster consistently attaches Br^-. Therefore, with two Br^- the intensity of the IR spectrum on adsorption of ozone decreases by a factor of 2.1, and when four Br^- are in the cluster the I_{tot} magnitude is reduced by only a factor of 1.07.

Fig. 5. Configurations of the systems $(Br^-)_i(H_2O)_{44} + 6H_2O + 6X$ corresponding to time (t) = 25 ps: (A) X = O_2 and (B) X = O_3. Coordinates of the molecules are presented in nanometers.



The increase of intensity of the $\sigma(\omega)$ spectra stops when the number of Br^- ions exceeds four.

The position of the main peak of the IR spectrum hardly changes and approximately corresponds to the frequency 3300 cm^{-1} during the change of the number of Br^- within a cluster. Here (as well as in the presence of oxygen in the system), a red shift of the position of the main maximum of the spectrum concerning localization of the basic peak of the experimental IR spectrum of liquid water was observed. The minimum dividing peak of the $\sigma(\omega)$ spectra of the cluster systems falls into an area of the greatest intensity of the IR spectrum of gaseous bromine hydride. The fast increase in intensities of the $\sigma(\omega)$ spectra of these systems occurs in the frequency range where the peak of the IR spectrum of gaseous ozone[33] is located.

Nonpolar O_2 molecules create a "dilution" effect owing to the decrease in the total dipole moment magnitude. The Br^- perturb an internal electric field of the cluster, accelerating the attenuation of the autocorrelation function of $\mathbf{d}_{cl}$ magnitude. As a result the intensity of the IR spectrum decreases with an increase in the number of bromine ions. The grouped polar O_3 molecules create a poorly varying electric field that orders the dipole moments of the water molecules. As a result the $\mathbf{d}_{cl}$ magnitude is increased, and the intensity of the IR spectrum grows with the increase in the number of Br^- in the system. Amplification of the perturbation owing to the addition to the cluster of more than

four Br^- results in faster attenuation of the autocorrelation function of the $\mathbf{d}_{cl}$. As a consequence, the intensity of the IR spectrum in an aqueous–ozone system at $i = 4$ starts to lessen.

Raman spectra for bromine-containing systems (I″, VI″, VII″, and XII″) are shown in Fig. 7. Adsorption of six oxygen molecules resulted in an increase in the integrated intensity of the Raman spectrum (J_{tot}) for the $(H_2O)_{50}$ cluster by a factor of 1.6. In the presence of oxygen, the $J(\omega)$ spectrum poorly changed the intensity and the shape with variation in the number of Br^- in a cluster. When absorption of six Br^- by the aqueous–oxygen system occurred, the J_{tot} magnitude decreased by only 7.1%. In the systems containing up to six Br^-, a red shift of the basic peak at ~110 cm^{-1} relative to the main peak in the experimental Raman spectrum of liquid water[34] was observed. This peak has blue shift on quantity ~130 cm^{-1} with respect to the localization of the expressed peak in the similar experimental spectrum of the Br_2 clathrate hydrates.[35] The addition of six ozone molecules resulted in a decrease in the J_{tot} of the Raman spectrum for the $(H_2O)_{50}$ cluster by a factor of 1.5. The quantity of Br^- within the clusters is essentially reflected in the shape of the $J(\omega)$ spectra of the cluster systems containing ozone. $J(\omega)$ spectra considerably reduced the intensity with an increase in the number of Br^-. The J_{tot} magnitude of the aqueous–ozone system in the presence of six Br^- is lower by a factor of 4.3 than the J_{tot} value of this system in the absence of Br^-.

Red and blue (~170 and 20 cm^{-1}, respectively) shifts of the maximum position of the Raman spectra of cluster systems with respect to the corresponding peaks of the experimental spectra for water and bromine clathrate hydrates were observed. The position of the first (less intense) peak in the $J(\omega)$ spectra of cluster systems containing ozone lies in the interval between the two peaks of the experimental spectrum of gaseous ozone.[36]

The average polarizability per molecule ($\bar{\alpha}$) goes down in comparison with the designated α magnitude for water clusters with the addition of nonpolar molecules having a lower α (0.793 Å^3) than the α magnitude for molecules of liquid water (1.49 Å^3). In this case the presence of bromine ions exerts a weak influence on chaotization of the dipole moments of water molecules. Thus, fluctuations of α magnitude and behaviour of the appropriate correlation function poorly change. It results in minor alterations of the Raman spectrum at a variation in the number of Br^- in the system. Another situation arises for the systems containing ozone. The polar molecules of ozone have a higher polarizability (α = 2.7 Å^3) than water molecules. Therefore, the $\bar{\alpha}$ magnitude in the ozone system is higher than α for the water cluster. Disordering of the dipole moments was amplified with an increase in the number of Br^- and the polarizability values were smoothly reduced. Fluctuations of the α magnitude were lower than those for systems with oxygen. As a result, the intensities of the $J(\omega)$ spectra for the systems containing ozone was reduced with an increase in the number of Br^-.

Adsorption of molecules of both oxygen and ozone by the $(H_2O)_{50}$ cluster strengthens the integrated intensities of the emission spectra of IR radiation (P_{tot}). As a result of the

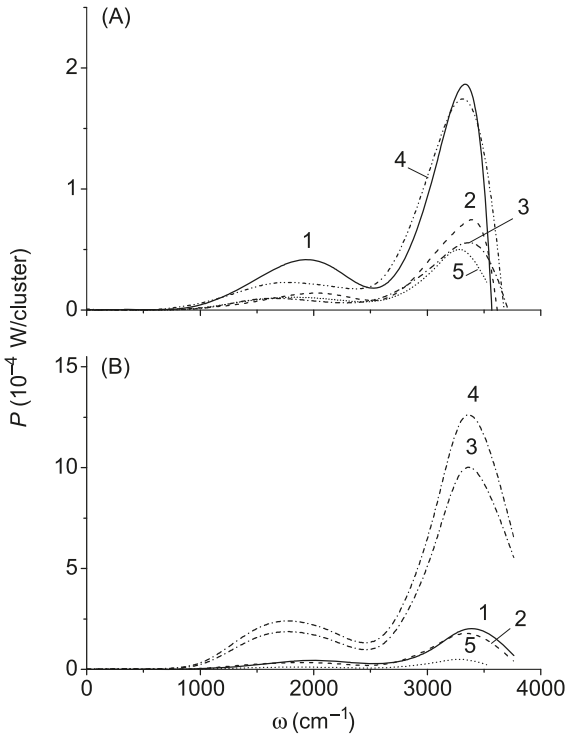
Fig. 8. IR emission spectra of systems $(Br^-)_i(H_2O)_{50-i}+ iH_2O + 6X$. (A) X = O_2, and (B) X = O_3 (1) i = 0. (2) i = 2. (3) i = 4. (4) i = 6. (5) The $P(\omega)$ function of the $(H_2O)_{50}$ cluster.



addition of six O_2 molecules, the P_{tot} magnitude increased by a factor of 3.8, and with the addition of six O_3 molecules to the cluster by a factor of 4.1 (Fig. 8). Emission spectra of cluster systems essentially change in intensity with a variation of the number of Br^- in the cluster. As a rule, the intensities of emission spectra are reduced in the presence of oxygen in the system and grows when the clusters adsorb ozone. For example, with six Br^- the $P(\omega)$ spectrum P_{tot} was reduced by a factor of 1.1 on adsorption of oxygen and it was increased by a factor of 6.4 when ozone joins. When bromine ions are added into an oxygen-containing system, the main peak of the emission spectrum, on average, is displaced by 20 cm^{-1} aside high frequencies. But addition of Br^- into ozone-containing systems results in a shift of the main peak up to 35 cm^{-1} aside low frequencies. The maximal reduction of the intensities of emission spectra for systems with oxygen occured in the presence of four Br^- in the cluster, and the maximal increase of this characteristic was observed for systems with ozone in the presence of six Br^- in the aggregate.

Conclusion

Ozone depletion occurs when the natural balance between the production and destruction of stratospheric ozone is tipped in favour of destruction. Although natural phenomena can cause temporary ozone loss, chlorine and bromine released from man-made compounds such as CFCs are now accepted as the main cause of this depletion. Emissions of CFCs have accounted for roughly 80% of total stratospheric ozone depletion. CFCs are photolyzed by UV radiation that breaks the weakest bond, usually a C–Cl or C–Br bond. Naturally occurring chlorine has the same effect on the ozone layer, but has a shorter life span in the atmosphere.

The present work demonstrates that water clusters are capable of adsorbing ozone and of detaining its molecules on the cluster surface over a significant time. Clusters consisting of polar molecules can hold Cl^- and Br^-. Thus, on the surface of a water cluster favourable conditions are created for the reaction of chlorine or bromine with ozone to proceed, which results in the destruction of the latter. The time that Br^- remain in water clusters is at least 10 times more than the time that Cl^- remain. Therefore, bromine ions destroy ozone more effectively. The intensities of IR absorption spectra essentially increase as the number of Br^- per cluster increases. Raman spectra of dispersed aqueous–ozone systems considerably reduce intensities with an increase in the number of Br^- contained in them. Emission spectra of IR radiation essentially have an increase in their intensities only at significant concentrations of Br^- in clusters.

In summary, the more massive Br^- are held in water clusters much longer than Cl^-, allowing the addition of ozone molecules to the cluster. At the same time absorption of oxygen molecules, as a rule, leads to evaporation of some of the Br^- from the cluster and to a loss of some oxygen molecules from its environment.

Abstract: Allylic cyanohydrins were subjected to Dauben–Michno oxidation at low temperatures to provide β-cyanoenones in good to excellent yields. The potential of this oxidative transposition as a means of an enantiomeric switch of enones containing a latent plane of symmetry was tested by conversion of (–)-carvone to its enantiomer.

Key words: Dauben–Michno reaction, oxidative 1,3-transposition of allylic alcohols, cyanoenones, enantiomeric switch of carvone.

Résumé : On a soumis des cyanohydrines allyliques à une oxydation de Dauben–Michno, à basse température, pour obtenir des β-cyanoénones avec des rendements allant de bons à excellents. Dans le but d'évaluer le potentiel de cette transposition oxydante comme méthode de réaliser une transposition énantiomère dans les énones contenant un plan de symétrie latent, on a transformer la (–)-carvone en son énantiomère.

Mots-clés : réaction de Dauben–Michno, transposition oxydante 1,3 d'alcools allyliques, cyanoénones, transposition énantiomère de la carvone.

[Traduit par la Rédaction]

Introduction

The Dauben–Michno oxidation constitutes a reliable protocol for oxidative transposition of tertiary allylic alcohols substituted with electron-donating groups.[1,2] The reaction proceeds by a [3,3] sigmatropic rearrangement of the initially formed chromate ester followed by further oxidation of the rearranged chromate ester to the final enone. The process is analogous to the well-known chromium(VI) oxidations of olefins to enones that proceed via an ene reaction of the chromium oxide followed by oxidation. The initially formed chromate ester is either oxidized to an enone or undergoes [3,3] sigmatropic rearrangement prior to the final oxidation. Thus, mixtures of regioisomeric enones are frequently encountered in the oxidation of cyclic olefins.[3,4] Because only one product can arise from the rearrangement of a tertiary allylic alcohol, the Dauben–Michno reaction does not suffer from regiochemical issues. Although well-documented for allylic alcohols flanked by electron-donating groups, this reaction has not been reported for allylic alcohols substituted with esters or nitriles. To our knowledge the first example of such oxidation was the conversion of allylic alcohol **1** to enone **2** during our recently completed synthesis of oseltamivir (**3**) (Tamiflu), Fig. 1.[5]

To establish whether the reaction is general for allylic alcohols substituted with other electron-withdrawing groups we investigated a series of cyanohydrins as means of synthesis of β-cyanoenones. In this paper we report the results of this investigation, along with a procedure for an enantiomeric switch of (–)-carvone to (+)-carvone.

Results and discussion

We began the investigation with a series of cyclic enones (Table 1, entries 1–3) and their conversion to cyanohydrins following a recently published procedure that uses proline catalysis for the formation of the intermediate trimethylsilyl ethers of cyanohydrins.[6] Following the hydrolysis, the free cyanohydrins were obtained in essentially quantitative yield and used without purification in the Dauben–Michno oxidation. The proline-catalyzed protocol is exceedingly efficient and cleanly affords the cyanohydrins, thus obviating any

separation issues prior to subsequent reactions. In the case of cyclopentenone, the cyanohydrin was obtained in 60% yield at the expense of the competing 1,4-addition of the cyanide to the enone. Similarly, cyanohydrins were obtained from methylvinyl ketone (Table 1, entry 4), 3-penten-2-one (Table 1, entry 5), 4-phenylbutenone (Table 1, entry 6), acetophenone (Table 1, entry 7), and (–)-carvone (Table 1, entry 8).

The Dauben–Michno procedure required the treatment of CrO_3 with acetic anhydride at 80 °C before cooling and addition of the cyanohydrin at or below 0 °C. The best results were obtained by performing the oxidation below 0 °C to avoid competing reactions at the site of the double bond that may result from the generation of peroxyacetic acid during the reaction. Such competition is absent when the oxidation is performed at –40 °C or below. The yields of transposed cyanoenones were in the range of 70%–80% except in the case of cyclopentenone, where the conversion was excellent and essentially quantitative (vide NMR); however, the volatility of the product contributed to low isolated yields (Table 1).

With acyclic enones the results were different; in the case of methylvinyl ketone the corresponding unsaturated aldehyde **15** (a consequence of the oxidation of a primary chromate ester formed by the sigmatropic rearrangement) was isolated as a mixture of *Z*- and *E*-isomers in the ratio of 7:1. (Note: On repetition of these experiments at higher temperatures or on a larger scale only the *Z*-isomer was detected.) The volatility of the product made the accurate determination of yield difficult. It was somewhat surprising that little or no over-oxidation took place whether 1 equiv or up to 3 equiv of the oxidant were used. We did not detect the corresponding acid even after careful repetition of the experiments; however, over-oxidation of an aldehyde to an acid requires the formation of a hydrate, which cannot take place under the conditions of the reaction. If the corresponding acid is desired, a simple dilution of the reaction with water and addition of an additional equivalent of chromium oxide should provide the corresponding carboxylic acid in high yield.

With pent-3-en-2-one (**16**) the corresponding cyanohydrin **17** was isolated in 76% yield and rearranged cleanly to the β-cyanoenone **18** in 84% yield (66% over two steps); only the *Z*-isomer **18a** was observed. In the case of 4-phenylbutenone (**19**), the rearrangement of the corresponding cyanohydrin **20** produced only traces of the transposed enone **21**, and the major product isolated was benzaldehyde (**22**). The formation of benzaldehyde may be rationalized by the oxidative cleavage of the intermediate 1,2-chromate diester formed from the styrene double bond in competition with the Dauben–Michno reaction.

For acetophenone (**23**) and the oxidation of its cyanohydrin **24**, only the formation of an intractable polymer was observed at prolonged reaction times or at higher temperatures. The cyanohydrin derived from acetophenone was still present in the reaction mixture after 16 h at room temperature. We expected the Dauben–Michno to proceed with disruption of aromaticity to provide **25**, in analogy with reported cases of reactivity of this type;[7] however, attempts at trapping intermediates of type **25** with external dienophiles such as maleic anhydride proved unsuccessful.

The oxidative 1,3-transposition could, in principle, be used

to provide enantiomers of homochiral enones that contain a latent plane of symmetry, as shown in Fig. 2 with carvone. To test this idea we applied the Dauben–Michno protocol to carvone with the expectation that further manipulations of the β-cyanoenone **28** would lead to the formation of *ent*-carvone, as depicted in Fig. 2.

The Dauben–Michno oxidation of cyanohydrin **27** derived from carvone provided the corresponding β-cyanoenone **28** in 75% yield. At 0–4 °C, considerable amount of side products, such as the methyl ketone **29** and epoxide **30**, were isolated. The former compound is likely a result of the oxidative cleavage of the 1,2-diol, formed by the addition of CrO_3 to the isopropylidine double bond, whereas the latter is probably formed by epoxidation mediated by peroxyacetic acid generated by in situ oxidation of acetic acid. When the reaction was performed at –40 to –50 °C, only oxidative rearrangement took place, and no side products arising from over-oxidation were observed.

Fig. 3. Synthesis of *ent*-dihydrocarvone from enone **28**.

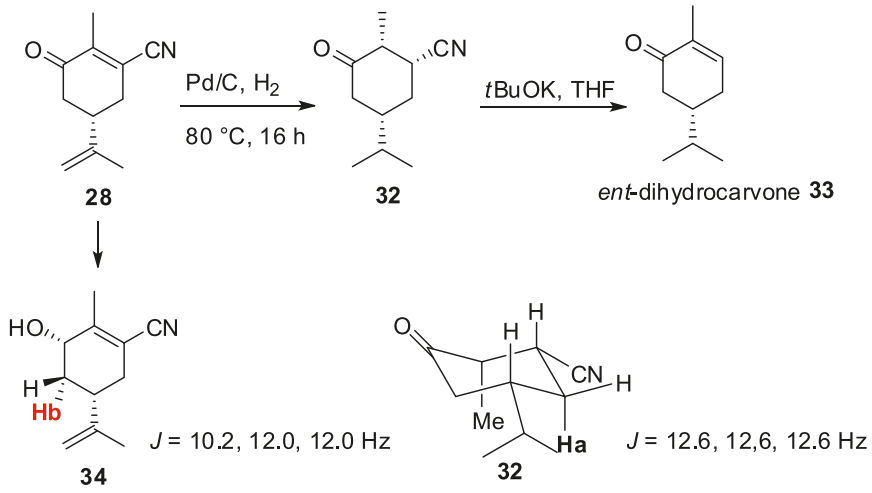

Fig. 4. Enantiomeric switch of (–)-carvone.

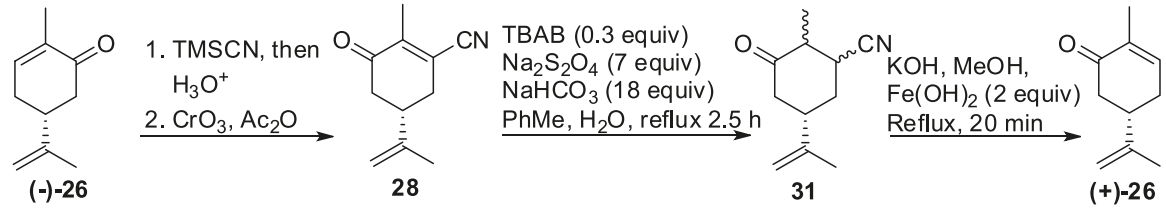

Fig. 5. Djerassi's assignment of diastereomeric dihydrocyanocarvone **31**.

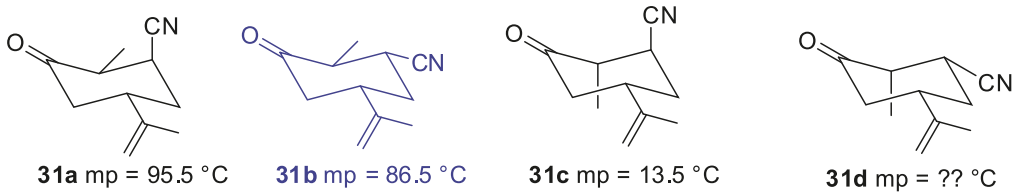

The proof of principle for the enantiomeric switch was demonstrated on a small scale by the conversion of cyanoenone **28** to the fully saturated β-cyano ketone **32** as shown in Fig. 3. Hydrogenation of **28** at 1 atm (1 atm = 101.325 kPa) produced ketone **32** (34% yield), whose structure was assigned by the analysis of coupling constants of H_a, as shown in Fig. 3.

The low yield of the hydrogenation was attributed to the formation of a by-product (2-methyl-3-cyano-5-isopropylphenol) resulting from full aromatization under the conditions of the hydrogenation. Treatment of **32** with *t*-BuOK in THF provided *ent*-dihydrocarvone (**33**). Enone **28** was also reduced under Luche conditions to the allylic alcohol **34** in anticipation of a possible rhodium-catalyzed isomerization[8] ($RhCl_3$, EtOH) to the saturated ketone **31**; however, this isomerization proved unsuccessful. The stereochemistry assignment of **34** was evident from the large coupling constants of the axial H_b, as shown in Fig. 3.

For the direct conversion of cyanoenone **28** to *ent*-carvone (**26**) several methods were investigated, among them hydrolysis to the corresponding acid and thermal decarboxylation,[9] and Birch reduction,[10] as shown in Fig. 2. Neither method proved very efficient in our hands.

The enantiomeric switch of carvone was accomplished in two steps via a reduction–elimination sequence as shown in Fig. 4. The cyanoenone **28** was reduced with sodium dithionite[11] to a mixture of the saturated cyanoketones **31**. All four diastereomers of **31** are known compounds, generated over the years in investigations of various reactions of enones[12–14] that utilized carvone as a convenient starting material. The major product from the dithionite reduction turned out to be the diastereomer **31b** (Fig. 5), as evidenced by melting point as well as by detailed NMR analysis.

In the early 1900s Lapworth[15–17] studied the addition of cyanide to *ent*-carvone and isolated two diastereomers of **31**, one from the reaction of potassium cyanide in ethanol, water, and acetic acid conducted at room temperature, and the other from a reaction performed in refluxing ethanol without acetic acid. (These two compounds would later be identified as **31a** and **31b**, respectively; Fig. 5) When Djerassi et al.[18] repeated Lapworth's experiments in 1963 with (–)-carvone, they found that the physical constants of the two diastereomers matched Lapworth's results. They then studied the equilibration of the two isomers and isolated a third when **31a** was treated with *p*-TsOH in EtOAc at room temperature for 1 week. The third isomer, a much lower melting compound, was later assigned as structure **31c**, Fig. 4.

Fig. 6. Assignment of stereochemistry of **31b** by NMR methods. (A) Resolution enhanced ^{1}H spectrum. (B) Resolution enhanced ^{1}H spectrum selectively decoupled from H7 methyl.

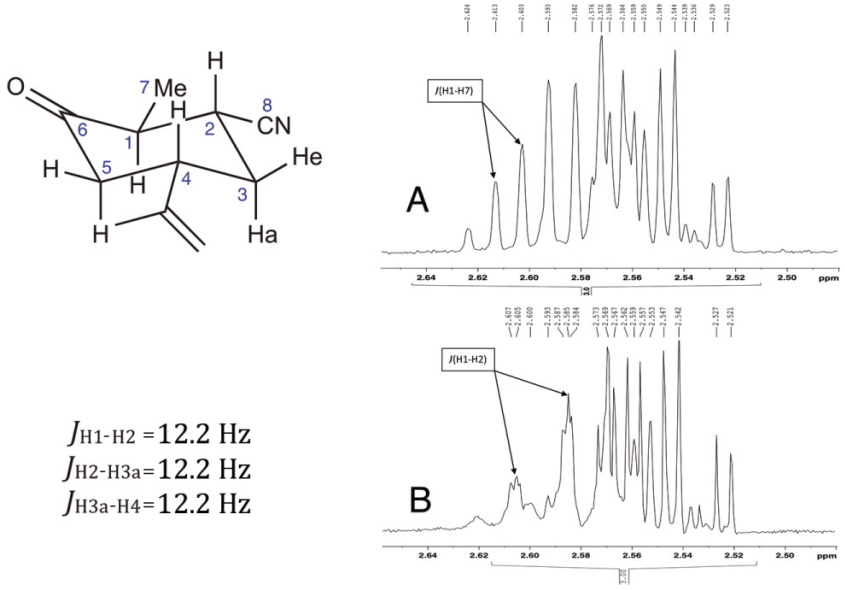

Fig. 7. Attempted Dauben–Michno synthesis of (+)-carvone from (–)-carvol **35**.

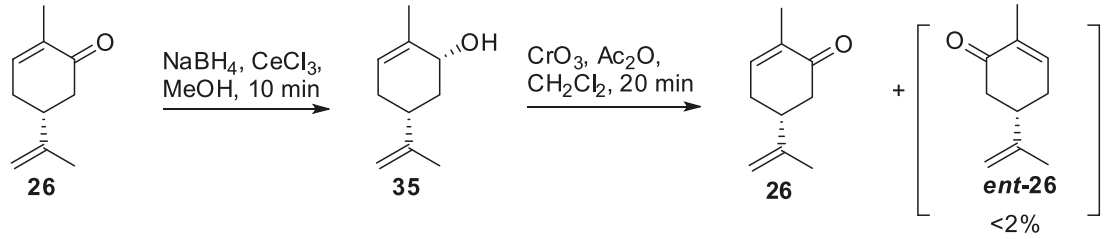

Attempted equilibration of **31b** was unsuccessful save for a trace amount of a new compound tentatively assigned as **31d**. Djerassi et al.[18] assigned the stereochemistry of the four diastereomers of **31** by use of detailed conformational analysis and optical rotary dispersion. In addition, they proved by simple yet ingenious experiments that the equilibration of **31a** occurs at C-2 and not at C-3 by conversion of nitriles to benzamides and equilibration of C-2 positions. The stereochemistry of **31b** was evident by matching the melting point with the compound identified by Djerassi et al.[18]

The assignment of **31b** by NMR methods proved to be nontrivial because of overlapping signals of the key protons and required the dispersion field of a 600 MHz spectrometer with advanced methods to separate the overlapping signals. The assignment of stereochemistry is shown in Fig. 6. In the normal proton spectrum, the six protons from the ring are all grouped at 1.9–2.6 ppm with one proton at 2.03 ppm, a multiplet at 2.37 ppm corresponding to three protons, and another multiplet at 2.57 ppm also corresponding to three protons. The proton at 2.03 ppm shows a d–d–d splitting pattern with three equal coupling constants (J = 12.2 Hz). Given the ring structure of cyclohexane there is only one possible case for the assignment of this proton, H3a. It is the only possible case with two large vicinal couplings (axial–axial) and one large geminal coupling. This also establishes that protons H4a and H2a are axial protons, implying that both the CN group and the propylene are in equatorial positions on the ring.

For the assignment of the H1 proton two-dimensional NMR methods had to be employed. From the H–C HSQC and COSY spectra, the locations of the other ring protons were determined. H1, H5, (H2a or H4a) are grouped at 2.6 ppm and H5 and H3e (H4a or H2a) are grouped at 2.37 ppm. H1 is identified from the coupling to the H7 methyl group in the COSY spectrum as being located on the left side of the multiplet, as shown in Fig. 6A. To increase spectral resolution, Gaussian line broadening was employed with a shift of 0.5 and a line-broadening factor of –1 Hz. From the proton spectrum a coupling constant of 6.2 Hz, corresponding to the vicinal coupling of H1 to H7 protons, was determined. This coupling alone would generate a quartet splitting pattern for H1. However, a more complicated pattern is observed for H1, therefore, the coupling H1 to H2 cannot be extracted directly from the proton 1-D NMR spectrum.

A homonuclear proton experiment was employed to measure the H1–H2 vicinal coupling constant. A proton spectrum was acquired selectively decoupling the H7 methyl group protons at 1.30 ppm from H1. As a result the H1 coupling pattern was simplified and reduced to H1–H2 vicinal coupling, as shown in Fig. 6B. By overlapping the normal proton spectrum with the selectively decoupled spectrum, the H1–H2 coupling constant of 12.2 Hz was extracted. This corresponds to an axial position for H1, confirming that the C-1 methyl group occupies an equatorial position. At this point the right side of the 2.57 ppm multiplet can be assigned as

For personal use only.

H2a showing the d–d–d pattern expected for H2a, as H4a would generate a d–d–d–d pattern. As this spectral assignment for **31b** would, of course, not have been possible in the 1960s, one must admire the brilliant deductive logic employed by Djerassi et al.[18] in accurately assigning all four diastereomers of **31**.

In preliminary experiments the treatment of **31b** with NaOEt in ethanol provided (+)-carvone, identical in all respects to (–)-carvone except for the sign of optical rotation, thus accomplishing the intended enantiomeric switch. Under these conditions, however, the yields of carvone were low (~35%) at the expense of condensation products. The conditions that employ $Fe(OH)_2$ (shown in Fig. 4) provided the much improved yield of 79% for (+)-carvone.

Finally, we subjected carvol (**35**), obtained by Luche reduction of carvone according to literature protocol,[19] to the Dauben–Michno conditions at –50 °C to investigate the possibility of competition between chromate ester re-oxidation to (–)-carvone versus the Dauben–Michno transposition–oxidation to (+)-carvone (Fig. 7). The rate-determining step in chromium(VI) oxidation of alcohols is the collapse of the chromate ester[20] and not its formation. We speculated that at low temperature, the sigmatropic rearrangement of the initially formed chromate ester required for the transposition may compete with the oxidation even for secondary allylic alcohols.

If the transition state of the [3,3] rearrangement is not symmetrical along the latent plane of symmetry in carvone, then the Dauben–Michno protocol applied to carvol would provide the enantiomer directly. The initial experiment, performed at –55 °C, indeed provided a scalemic mixture of carvone with an optical rotation lower than that of the (–)-enantiomer, indicating that the two processes may indeed compete.

We performed three experiments at different temperatures (–55, –78, and –100 °C) and noted some decrease in the value of rotation for the (–)-enantiomer. However, verification of true *er* by HPLC (Daicel Chiralcel OB-H; flow = 0.6 mL/min (hexane–*i*-PrOH, 95:5; retention time for (*R*)-(–)-carvone = 9.56 min and for (*R*)-(–)-carvone = 10.41 min)[21] provided at best an indication of an ~1%–2% increase in the (+)-enantiomer. Thus, no conclusion can be drawn from these experiments. For now, the three-step high-yielding protocol for the enantiomeric switch via Dauben–Michno oxidation of cyanohydrins should suffice.

Conclusions

We have developed a reliable procedure for the conversion of enones to the corresponding β-cyanoenones with the attendant 1,3-functional transposition of the carbonyl group of the original enone. The possibility of using this transposition to generate enantiomers of enones that possess a latent plane of symmetry was tested and reduced to practice with the enantiomeric switch of (–)-carvone. Future attention should be given to a more detailed study of the Dauben–Michno oxidation of other allylic alcohols, including secondary ones, and the dependence of the outcome of such oxidation on conformational bias and stereochemical features of the substrates.

Experimental section

General procedure for the synthesis of cyanohydrins[6]

To a vial charged with the lithium salt of L-proline (0.1 mmol) was added the enone (1.0 mmol) followed by trimethylsilyl cyanide (1.0 mmol, 133 μL). After the suspension was stirred at room temperature for 12 h, an additional portion of trimethylsilyl cyanide (1.0 mmol, 133 μL) was added, and the reaction mixture was subsequently stirred for another 12 h. Upon completion, THF (2 mL) and 1 mol/L aq HCl (2 mL) were added, and the resulting solution was stirred for 1 h. Following the hydrolysis, the reaction mixture was washed with diethyl ether (30 mL) and water (5 mL), and the aqueous layer was re-extracted with diethyl ether (2 × 15 mL). The combined organic layers were dried over magnesium sulfate with a spatula tip of sodium bicarbonate, then filtered and concentrated under reduced pressure to afford the essentially pure cyanohydrin, which was used without further purification.

General procedure for the Dauben–Michno oxidations[5]

Acetic anhydride (5.3 mmol, 0.5 mL) was added to a vial charged with chromium(VI) oxide (2.5 mmol). The mixture was stirred at 80 °C until complete dissolution (5 min). After cooling to room temperature, the solution was diluted with dichloromethane (2 mL) and added dropwise to a solution of cyanohydrin (1.0 mmol) in dichloromethane (3 mL) at 4 °C. The resulting solution was stirred for 10 min before addition of ethanol (3 mL). The solution was allowed to stir for 30 min at room temperature before concentration under reduced pressure and co-evaporated with toluene. The crude mixture was passed through a column of silica gel using dichloromethane as a solvent to yield β-cyanoenone.

3-Oxocyclohept-1-enecarbonitrile (12)[27]

^{1}H (300 MHz, $CDCl_3$) δ: 6.56 (s, 1H), 2.63–2.67 (m, 4H), 1.82–1.93 (m, 4H). ^{13}C (300 MHz, $CDCl_3$) δ: 201.17, 142.81, 127.36, 118.95, 42.96, 32.14, 25.36, 21.14.

2-Hydroxy-2-methylbut-3-enenitrile (14)

^{1}H (300 MHz, $CDCl_3$) δ: 5.95 (dd, 1H, J = 10.2, 17.1 Hz), 5.67 (d, 1H, J = 16.8 Hz), 5.35 (d, 1H, J = 10.2 Hz), 1.67 (s, 3H). ^{13}C (300 MHz, k$CDCl_3$) δ: 137.49, 120.45, 116.77, 68.76, 28.06.

(Z)-2-Methyl-4-oxobut-2-enenitrile (15a) *(major)*

IR (film, cm^{-1}) ν: 2925, 2222, 1688, 1618, 1448, 1381, 1227, 1171, 1095, 1041, 1019, 861, 787, 665. ^{1}H (300 MHz, $CDCl_3$) δ: 10.02 (d, 1H, J = 7.8 Hz), 6.52 (dq, 1H, J = 1.5, 7.8 Hz), 2.25 (d, 3H, J = 1.5 Hz). ^{13}C (300 MHz, $CDCl_3$) δ: 189.62, 141.64, 129.26, 115.41, 21.68. MS (EI+) *m/z* % 94 (M^+ – H): 83 (15), 68 (63), 52 (29), 44 (100).

(E)-2-Methyl-4-oxobut-2-enenitrile (15b) *(minor)*

IR (film, cm^{-1}) ν: 2925, 2222, 1688, 1618, 1448, 1381, 1227, 1171, 1095, 1041, 1019, 861, 787, 665. ^{1}H (300 MHz, $CDCl_3$) δ: 10.07 (d, 1H, J = 7.8 Hz), 6.52 (dq, 1H, J = 1.5, 7.8 Hz), 2.38 (d, 3H, J = 1.5 Hz). ^{13}C (300 MHz, $CDCl_3$) δ: 189.62, 141.64, 129.26, 115.41, 21.68. MS (EI+) *m/z* % 94 (M^+ – H): 83 (15), 68 (63), 52 (29), 44 (100).

(E)-2-Hydroxy-2-methyl-3-pentenenitrile (17)

R_F = 0.76 (hexanes–EtOAc, 5:1). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.10 (dq, J = 15.3, 6.6 Hz, 1H), 5.55 (dd, J = 15.4, 1.7 Hz, 1H), 3.08 (brs, 1H), 1.76 (dd, J = 6.6, 1.7 Hz, 3H), 1.64 (s, 3H); –OH signal confirmed by D_2O exchange. ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 130.81, 129.02, 120.80, 68.42, 28.27, 17.26; NMR data are in agreement with those previously reported.[28]

(Z)-2-Methyl-4-oxopent-2-enenitrile (18)

R_F = 0.15 (hexanes–EtOAc, 5:1); mp 37–38 °C (white crystals, pentane–Et_2O). IR (KBr, cm^{-1}) ν: 2359, 1732, 1637, 1385. ^{1}H NMR (600 MHz, $CDCl_3$, ppm) δ: 6.60 (d, J = 1.5 Hz, 1H), 2.39 (s, 3H), 2.16 (d, J = 1.5 Hz, 3H). ^{13}C NMR (151 MHz, $CDCl_3$, ppm) δ: 194.25, 140.10, 119.64, 117.12, 30.06, 22.18. MS (+EI) *m/z* (%): 109 (22), 94 (100), 66 (15), 43 (40). HRMS (+EI) calcd for C_6H_7NO: 109.05276; found: 109.05246.

1-Hydroxy-2-methyl-5-(prop-1-en-2-yl)cyclohex-2-enecarbonitrile (27)

^{1}H (300 MHz, $CDCl_3$) δ: 5.70 (dd, 1H, J = 1.2, 3.0 Hz), 4.79 (d, 2H, J = 12.3 Hz), 3.24 (bs, 1H), 2.49–1.90 (m, 5H), 1.86 (s, 3H), 1.74 (s, 3H). ^{13}C (300 MHz, $CDCl_3$) δ: 146.85, 131.76, 128.40, 121.09, 110.18, 70.21, 41.27, 38.96, 30.67, 20.57, 17.01.

β-Cyanocarvone (28)

To a solution of crude cyanohydrin **27** (352 mg, 1.99 mmol) in dichloromethane (3 mL) cooled to –55 °C was added a solution of CrO_3 (499 mg, 4.99 mmol) and Ac_2O (2 mL) in dichloromethane (6 mL). After 30 min the reaction was quenched by the addition of methanol (10 mL) and allowed to warm to room temperature. The mixture was then concentrated and co-evaporated three times with toluene (10 mL). Chromatography of the residue (silica, 20 mL; dichloromethane–hexane, 1:1) afforded enone **28** as a light yellow solid; yield: 260 mg (75%). R_F = 0.6 (dichloromethane–hexane, 1:1). $[\alpha]_D^{20}$ = 82.8 (*c* 1, $CHCl_3$); mp 25–26 °C (neat). IR (KBr, cm^{-1}) ν: 3747, 30.85, 2970, 2925, 2218, 1688, 1648, 1439, 1383, 1318, 1295, 1140, 1108, 1070, 900. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 4.81 (s, 1H), 4.72 (s, 1H), 2.73–2.53 (m, 3 H), 2.45 (ddq, 1H, J = 3 × 2.4, 12.3, 17.4 Hz), 2.37 (dd, 1H, J= 12.9, 16.2 Hz), 2.00 (dd, 3H, J = 1.8, 2.4 Hz), 1.70 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.66, 146.31, 144.74, 124.58, 116.95, 111.86, 42.60, 41.26, 33.07, 20.40, 14.86. MS (+FBA) *m/z* (%): 176 (100). HRMS could not be obtained; the compound proved to be too labile. Structure was confirmed by HRMS after reduction of the keto group.

Oxidation of 27 at elevated temperature

To a solution of crude cyanohydrin **27** (235 mg, 1.33 mmol) in dichloromethane (5 mL) cooled to 0 °C was added a solution of CrO_3 (332 mg, 3.33 mmol) and Ac_2O (0.78 mL) in dichloromethane (2.5 mL). After 20 min at 0 °C a new portion of CrO_3 (332 mg, 3.33 mmol) and Ac_2O (0.78 mL) in dichloromethane (2.5 mL) was added. After an additional 70 min, the reaction was quenched by the addition of ethanol (2 mL) and allowed to warm to room temperature over 45 min. The mixture was then concentrated. Chromatography of the residue (silica, 25 mL; Et_2O–hexane, 1:1) afforded diketone **29** (yield: 17.6 mg), epoxide **30** (yield: 73.2 mg), and a mixed fraction (yield: 61 mg).

5-Acetyl-2-methyl-3-oxocyclohex-1-enecarbonitrile (29)

$[\alpha]_D^{20}$ = 25.1 (*c* 1, $CHCl_3$). IR (film, cm^{-1}) ν: 3022, 2964, 2220, 1685, 1416, 1358, 1314, 1265, 1216, 1104, 752, 668, 629. ^{1}H (600 MHz, $CDCl_3$) δ: 3.23 (dddd, 1H, J = 4.2, 7.2, 10.5, 10.5 Hz), 2.82–2.78 (m, 3H), 2.65 (dd, 1H, J = 11.4, 16.8 Hz), 2.25 (s, 3H), 2.10 (s, 3H). ^{13}C (600 MHz, $CDCl_3$) δ: 205.98, 194.49, 146.66, 122.89, 116.56, 46.69, 38.99, 29.71, 27.88, 14.97. MS (EI+) *m/z* % 177 (M^+): 135 (45), 107 (6), 79 (7), 43 (100), HRMS calcd for $C_{10}H_{11}NO_2$: 177.1998; found: 177.0790.

2-Methyl-5-(2-methyloxiran-2-yl)-3-oxocyclohex-1-enecarbonitrile (30)

$[\alpha]_D^{20}$ = 57.5 (*c* 1, $CHCl_3$). IR (film, cm^{-1}) ν: 2927, 2218, 1686, 1436, 1386, 1313, 1140, 1070, 894, 820, 682, 622. ^{1}H (300 MHz, $CDCl_3$) δ: 2.70 (dd, 1H, J = 4.1, 14.2 Hz), 2.66–2.57 (m, 3H), 2.50–2.43 (m, 1H), 2.33–2.26 (m, 1H), 2.26–2.14 (m, 1H), 2.04 (s, 3H), 1.32 (d, 3H, J = 8.4 Hz). ^{13}C (300 MHz, $CDCl_3$) δ: 195.81, 146.45, 124.28, 116.78, 57.39, 52.64, 40.13, 39.41, 29.85, 18.82, 14.87. MS (EI+) *m/z* % 176 (M^+ – CH_3): 148 (51), 134 (100), 122 (53), 58 (81), 43 (96). HRMS calcd for $C_{11}H_{13}NO_2$: 191.2264; found: 176.0712.

(1R,2R,5S)-2-Methyl-3-oxo-5-(prop-1-en-2-yl) cyclohexanecarbonitrile (32)

A solution of enone **28** (0.1g, 0.57 mmol) with Pd/C (20 mg, 10%) in ethanol (3 mL, 95%) was hydrogenated in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

an H_2 atmosphere at 80 °C for 16 h. The reaction mixture was then filtered through Celite and concentrated. Chromatography (silica, 8 mL; dichloromethane–hexane, 1:1) of crude product afforded 35 mg (34%) of fully saturated ketone **32** as a white solid. The remaining mass balance consisted of fully aromatized material identified as 2-methyl-3-cyano-5-isopropylphenol. R_F = 0.5 (dichloromethane–hexane, 1:1). $[\alpha]_D^{20}$ = –49.26 (*c* 1, $CHCl_3$); mp 77 °C (hexane). IR (KBr, cm^{-1}) *v*: 3412, 2979, 2959, 2938, 2916, 2874, 2241, 1713, 1477, 1469, 1448, 1429, 1381, 1369, 1346, 1313, 1245, 1231, 1218, 1147, 1076, 870, 628. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 2.58–2.44 (m, 3 H), 2.27 (dddd, 1H, *J* = 2.4, 2.7, 2.7, 13.5 Hz), 2.14 (dd, 1H, *J* =13.2, 12.9 Hz), 1.81 (ddd, 1H, *J* = 12.6, 12.6, 12.6 Hz), 1.63 (dd, 1H, *J* = 12.6, 14.1 Hz), 1.61 (m, 1H), 1.25 (d, 3H, *J* = 6.0 Hz), 0.93 (d, 3H, *J* = 6.6 Hz), 0.92 (d, 3H, *J* = 5.4 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 207.54, 120.28, 46.35, 44.53, 43.71, 36.13, 32.78, 32.36, 19.28, 19.06, 12.71. MS (+EI) *m/z* (%): 179 (100). HRMS (+EI) calcd for $C_{11}H_{17}N_1O_1$: 179.13101; found: 179.13136.

(3S,5S)-3-Hydroxy-2-methyl-5-(prop-1-en-2-yl)cyclohex-1-enecarbonitrile (34)

To the cooled (4 °C) solution of enone **28** (50 mg, 29 mmol) in methanol (2 mL) was added $CeCl_3{\cdot}7H_2O$ (106 mg, 29 mmol). After 5 min of stirring, $NaBH_4$ (11 mg, 29 mmol) was added portionwise. After an additional 10 min stirring, the reaction was quenched by the addition of a citric acid solution (0.5 mL, 5% *w*/*w*) and concentrated. The residue was dissolved in dichloromethane (25 mL) and washed with citric acid (5 mL, 5% *w*/*w*). The aqueous layer was re-extracted with additional dichloromethane (5 mL), the combined organic layers were dried over $MgSO_4$, and then concentrated to yield essentially pure product. Chromatography (silica, 5 mL, dichloromethane) yielded 48 mg (95%) of the allylic alcohol **34** as a colourless oil. R_F = 0.2 (dichloromethane). $[\alpha]_D^{20}$ = 40.42 (*c* 1, $CHCl_3$). IR (KBr, cm^{-1}) *v*: 3446, 3084, 2926, 2859, 2215, 1646, 1441, 1378, 1288, 1261, 1071, 1056, 1025, 895. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 4.81 (s, 1H), 4.76 (s, 1H), 4.24 (m, 1H), 2.36–2.13 (m, 5 H), 2.11 (s, 3H), 1.75 (s, 3H), 1.55 (ddd, 1H, *J* = 10.2, 12.0, 12.0 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 154.69, 146.75, 118.34, 110.52, 108.08, 70.25, 39.28, 36.62, 32.71, 20.43, 18.33. MS (+EI) *m/z* (%): 177 (3), 159 (100), 144 (33), 134 (59). HRMS (+EI) calcd for $C_{11}H_{15}N_1O_1$: 177.11536; found: 177.11525. HRMS (+EI) calcd for $C_{11}H_{13}N_1$: 159.10480; found: 159.10496.

Reduction of 28 to 31a, 31b, and 31c

To a round-bottomed flask containing water (5 mL) and tetrabutylammonium bromide (100 mg, 0.3 mmol) was added a solution of enone **28** (175 mg, 1.0 mmol) in toluene (5 mL). The emulsion was degassed in an ultrasonic bath for 20 min. A condenser was attached, and the system was flushed with nitrogen. Sodium bicarbonate (1.52 g, 18 mmol) was added, and the reaction mixture was heated to reflux. Sodium dithionite (7 × 200 mg, 85%, 6.95 mmol) was added in seven portions over 2 h. After an additional 30 min of stirring at reflux, the reaction mixture was allowed to cool to room temperature. The reaction mixture was diluted with CH_2Cl_2 (50 mL) and water (10 mL). The aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic extracts were washed with 0.5 N HCl (5 mL), then water (5 mL), and dried over magnesium sulfate. After filtration and evaporation of the solvent, the crude mixture was purified via flash column chromatography (EtOAc in hexanes, 10%–25%) to yield 145 mg (82%) of the mixture consisting of three of the four isomers of cyanoketone **31**. This mixture was suitable for use in the elimination to (+)-carvone.

Identification of isomers 31a, 31b, and 31c

To a round-bottomed flask containing water (60 mL), sodium bicarbonate (4.31 g, 51.30 mmol), and tetrabutylammonium bromide (275 mg, 0.855 mmol) was added a solution of enone **28** (500 mg, 2.85 mmol) in toluene (60 mL). The reaction mixture was heated to reflux, and sodium dithionite (6 × 875 mg, 4.28 mmol) was added in six portions over 3 h. After an additional 1 h of stirring at reflux, the reaction mixture was allowed to cool to room temperature. The organic layer was separated from the aqueous layer and then dried over magnesium sulfate. After filtration and evaporation of solvent, the crude mixture was purified via flash column chromatography (hexane – diethyl ether, 7:1) to provide 75 mg (15%) of saturated ketone **31b** as a white solid. Further separation provided the remaining isomers **31a** and **31c**.

(1S,2S,5S)-2-Methyl-3-oxo-5-(prop-1-en-2-yl) cyclohexanecarbonitrile (31a)

R_F = 0.17 (hexanes–EtOAc, 5:1). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.86 (s, 1H), 4.80 (s, 1H), 3.34 (dt, *J* = 6.0, 3.7 Hz, 1H), 2.86–2.72 (m, 1H), 2.66–2.47 (m, 2H), 2.36–2.18 (m, 2H), 2.05–1.86 (m, 1H), 1.77 (s, 3H), 1.25 (d, *J* = 6.6 Hz, 3H).

^{1}H NMR data are in agreement with the literature.[14]

(1R,2S,5S)-2-Methyl-3-oxo-5-(prop-1-en-2-yl) cyclohexanecarbonitrile (31b)

White solid. R_F = 0.42 (hexane – ethyl acetate, 5:1). $[\alpha]_D^{20}$ = –56 (*c* 1, $CHCl_3$). mp 82–84 °C (first crystallization: hexanes – diethyl ether; second crystallization: mp 85–86 °C (lit.[18] mp 86.5). IR ($CHCl_3$, cm^{-1}) *v*: 2244, 1719, 1648, 1452, 901. ^{1}H NMR ($CDCl_3$, 600 MHz, ppm) δ: 4.85 (s, 1H), 4.78 (s, 1H), 2.61–2.52 (m, 3 H), 2.40–2.36 (m, 3H), 2.01 (ddd, 1H, *J* = 10.9, 11.9, 12.4 Hz), 1.75 (s, 3H), 1.28 (d, 3H, *J* = 6.4 Hz). ^{13}C NMR ($CDCl_3$, 150 MHz, ppm) δ: 206.66, 145.27, 119.98, 111.30, 46.28, 44.14, 36.00, 34.25, 20.23, 12.67. MS (+EI) *m/z* (%): 177 (12), 95 (55), 82 (54), 68 (100), 67 (74), 41 (41). HRMS (+EI) calcd for $C_{11}H_{15}NO$: 177.11536; found: 177.11509.

(1S,2R,5S)-2-Methyl-3-oxo-5-(prop-1-en-2-yl) cyclohexanecarbonitrile (31c)

Viscous oil; assignment is tentative (**31c** has a mp of 13 °C). IR (KBr, cm^{-1}) *v*: 2359, 1650, 1385, 1088. ^{1}H NMR (600 MHz, $CDCl_3$, ppm) δ: 4.87 (s, 1H), 4.79 (s, 1H), 3.14 (td, *J* = 5.1, 2.5 Hz, 1H), 2.64 (t, *J* = 12.8 Hz, 1H), 2.40 (dt, *J* = 12.8, 2.3 Hz, 1H), 1.87–1.80 (m, 1H), 1.78 (s, 1H), 1.61–1.49 (m, 1H), 1.45 (d, *J* = 6.8 Hz, 1H). MS (+EI) *m/z* (%): 177 (27), 95 (72), 82 (52), 69 (29), 68 (100), 67 (70), 41 (42).; HRMS (+EI) calcd for $C_{11}H_{15}NO$: 177.11536; found: 177.11498.

ent-Carvone

The mixture of saturated ketones **31a**, **31b**, and **31c** obtained (445 mg, 2.5 mmol) was dissolved in MeOH (15 mL). The solution was degassed in an ultrasonic bath for 5 min (to avoid oxidation of Fe(II) by air). A condenser was attached, and $FeSO_4 \cdot 7H_2O$ (1.39 g, 5.0 mmol) was added. KOH (2.25 g, 35 mmol, 10 + 4 equiv) was added to a vigorously stirred suspension to generate $Fe(OH)_2$. The reaction flask was placed in a preheated oil bath, and the mixture heated at reflux for 20 min. The resulting dark black mixture was quickly cooled to room temperature and diluted with EtOAc (100 mL) and water (10 mL). The organic layer was washed with 0.2 N HCl (3 × 10 mL) and dried over magnesium sulfate. After filtration and evaporation of solvent, the crude product was filtered through a short pad of silica gel (eluted with 10% EtOAc in hexanes) to yield *S*-(+)-carvone (296 mg, 79%).

S-(+)-Carvone

$[\alpha]_D^{19} = +54.2$ (*c* 1, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$) δ: 6.82–6.65 (m, 1H), 4.80 (s, 1H), 4.75 (s, 1H), 2.78–2.51 (m, 2H), 2.51–2.37 (m, 1H), 2.37–2.19 (m, 2H), 1.85–1.76 (m, 3H), 1.75 (s, 3H). (Commercially available (+)-carvone is 96% optically pure; (–)-carvone is 98% optically pure).

Abstract: NaZSM-5 zeolite was found to be an efficient heterogeneous catalyst for the synthesis of dimethyl carbonate (DMC), which can serve as a building block, an additive to fuel oil, and an electrolyte in batteries, via the transesterification of ethylene carbonate (EC) with methanol. Notably, 77% DMC yield and 97% selectivity were achieved under mild reaction conditions. Furthermore, the effects of various reaction parameters such as catalyst loading, reaction time, and methanol/EC molar ratio on the catalytic performance were investigated in detail. This protocol was found to be applicable to a variety of alcohols, producing the corresponding dialkyl carbonates with moderate yields and selectivities. Moreover, the catalyst can be recovered by simple filtration with retention of catalytic activity; a stable crystal configuration and a slight alteration of its superficial structure were observed by X-ray diffraction and BET measurements.

Key words: ethylene carbonate, zeolite, transesterification, dimethyl carbonate.

Résumé : On a trouvé que la zéolite NaZSM-5 est un catalyseur hétérogène efficace pour la synthèse, par le biais d'une transestérification du carbonate d'éthylène (CE) avec du méthanol. du carbonate de diméthyle (CDM) qui peut être utilisé produit de départ en synthèse, comme additif pour les huiles à chauffage et comme électrolyse dans les batteries. Il est remarquable que le rendement de 77 % en CDM avec une sélectivité de 97 % ait été obtenu dans des conditions réactionnelles douces. De plus, on a étudié en détail les effets de divers paramètres réactionnels, comme la charge de catalyseur, le temps de réaction et le rapport molaire méthanol/CE. On a trouvé que ce protocole peut être appliquer à une variété d'alcools conduisant à la production des carbonates de dialkyle correspondants, avec des rendements et des sélectivités modérées. De plus, le catalyseur peut être récupéré par simple filtration avec rétention de son activité catalytique; des mesures de BET et de diffraction des rayons-X indiquent que la configuration cristalline est stable, mais qu'elle subit de légères altérations de sa structure superficielle.

Mots-clés : carbonate d'éthylène, zéolite, transestérification, carbonate de diméthyle.

[Traduit par la Rédaction]

Introduction

Dimethyl carbonate has been drawing much attention as a safe, non-corrosive, and environmentally friendly building block for the production of polycarbonate and other chemicals.[1] Most promisingly, DMC could be of interest as an additive to fuel oil owing to a high octane number, reducing particulate emission from diesel engines.[2] In addition, it has been used as an electrolyte in lithium batteries owing to its high dielectric constant.[3] Therefore, the development of green and efficient DMC production technology and investigation of its fuel properties have attracted much more attention in the oil and chemical industries. From the viewpoint of green chemistry, the two-step transesterification process (steps 1 and 2) utilizing CO_2 as a raw material, as illustrated in Scheme 1, is more promising than other commercial processes[4] including methanolysis of phosgene, carbon monoxide–nitrite process, and gas-phase oxidative carbonylation of methanol using toxic, corrosive, flammable, and explosive gases.

In past decades, numerous homogeneous catalysts have been developed for the transesterification of alkylene carbonates with methanol, such as alkali metals,[5] quaternary ammonium salts,[6] and ionic liquids.[7] However, these catalysts are difficult to recover from the reaction mixture in homogeneous catalysis. In this context, easily recovered heterogeneous catalysts would be more desirable. Indeed, the transesterification reaction also proceeds very efficiently with heterogeneous catalysts including molecular sieves,[8] basic metal oxides,[9] metal cyanides,[10] basic salts,[11] dawsonites,[12] hydrotalcites,[13] smectites,[14] basic anion-exchange resin,[15] functionalized chitosan,[16] and silica.[17] Although great advances have been seen,[5–17] most catalytic processes suffer from low catalytic activity, and high reaction temperature and (or) the use of expensive metallic compounds are often required. So development of efficient, cost-effective, and easily recycled catalysts for DMC synthesis is still highly desired.

In the framework of our continuous effort to synthesize organic carbonates from CO_2,[16,18,19] we would like to report herein that DMC synthesis via a transesterification reaction of ethylene carbonate (EC) and methanol was achieved by

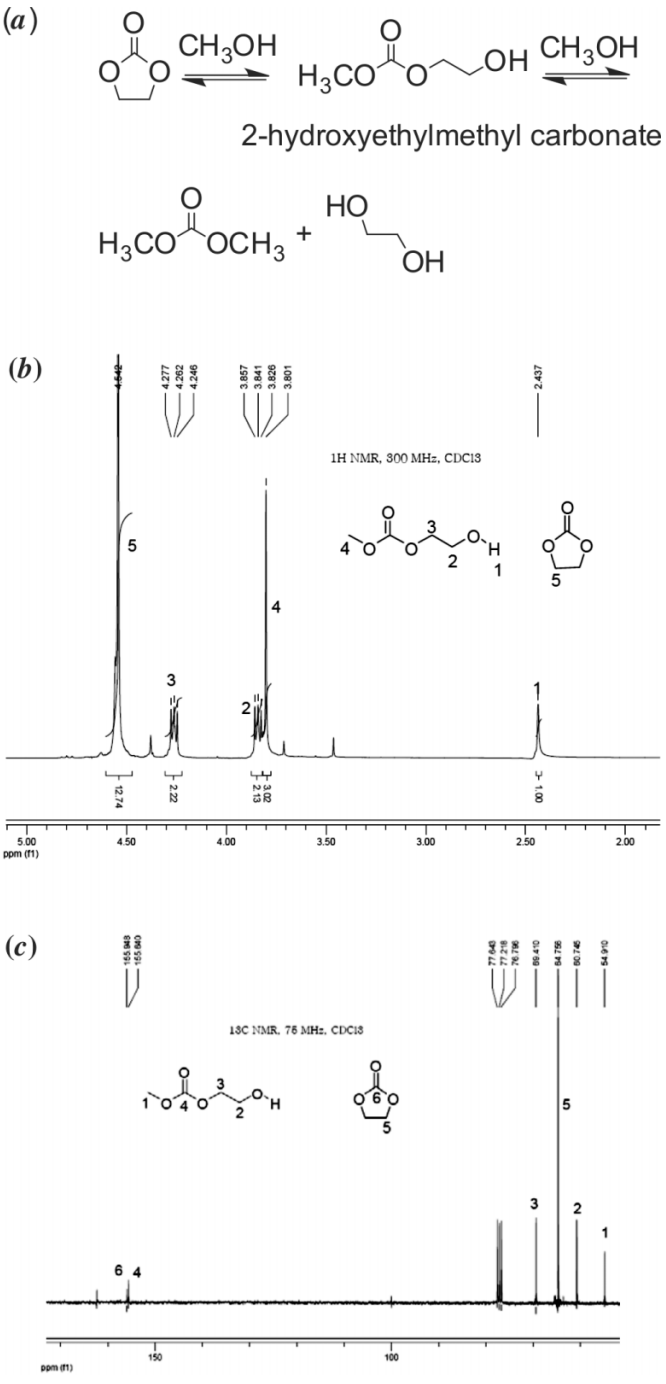
employing a commercially available NaZSM-5 zeolite as an efficient and recyclable catalyst. Perfect catalyst performance in this process was obtained under mild conditions.

Results and discussion

In the initial study, the transesterification of EC with methanol was conducted in the presence of various homogeneous organic and inorganic bases. Experiments were carried out under identical operating conditions (Table 1). A small amount of DMC could be detected even without any catalyst (entry 1), but basic catalysts could greatly improve the reaction (entries 2–6, 8–9). In particular, NaZSM-5 zeolite (entry 2) showed higher catalytic activity than alkali metal compounds (NaOH, K_2CO_3, CH_3ONa; entries 3–5), an alkali earth metal oxide (MgO; entry 6), and organic bases such as tributylamine, triethylamine, and tetramethylguanidine (entries 7–9). A transition metal oxide (ZnO) and aluminum oxide (entries 10 and 11) also showed much lower activity than NaZSM-5 zeolite. It is worth mentioning that 2-hydroxyethyl methyl carbonate (HEMC), regarded as the intermediate of

Fig. 1. (*a*) Formation of 2-hydroxyethyl methyl carbonate. (*b*) ^1H NMR spectrum of the reaction mixture after removing DMC and MeOH under reduced pressure. (*c*) ^{13}C NMR spectrum of the mixture.



DMC formation (Fig. 1*a*),[7b] was detected by ^1H NMR (Fig. 1*b*) and ^{13}C NMR (Fig. 1*c*). A 77% DMC yield with 97% selectivity was attained by using NaZSM-5 as the catalyst at 70 °C for 3 h.

Subsequently, the influence of catalyst loading on DMC yield and selectivity was investigated under otherwise identical reaction conditions. As shown in Fig. 2, the catalyst amount had a considerable influence on DMC yield. It is worth noting that lower catalyst loadings such as 0.1 g and

Fig. 2. Influence of catalyst loading on DMC yield and selectivity using NaZSM-5 as catalyst. Reaction conditions: EC (30 mmol), methanol (240 mmol), 70 °C, 3 h.

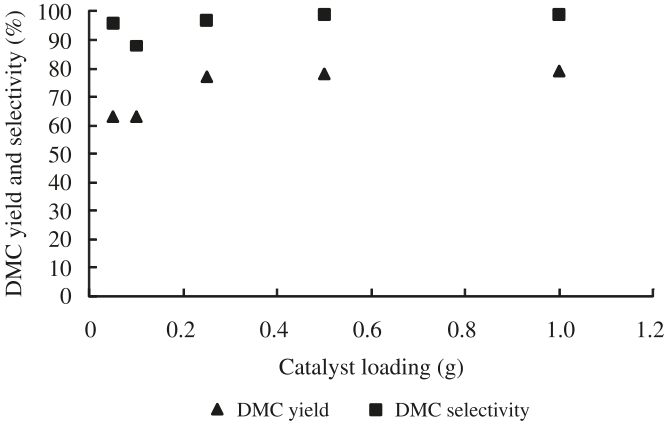

Fig. 3. Effect of reaction time on DMC yield and selectivity using NaZSM-5 as catalyst. Reaction conditions: EC (30 mmol), methanol (240 mmol), NaZSM-5 (0.25 g), 70 °C.

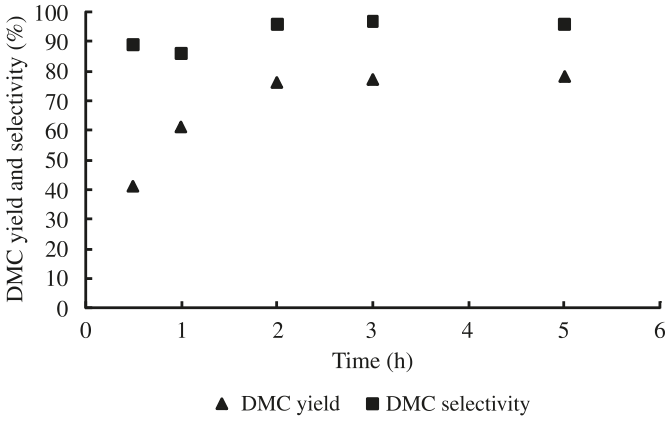
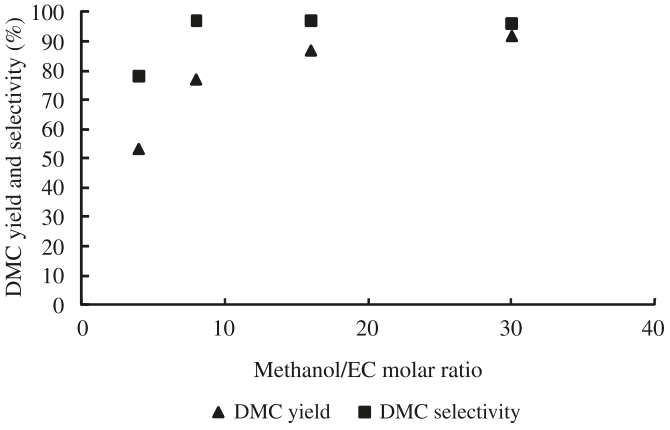


0.05 g gave lower DMC yield and selectivity, probably owing to facile formation of HEMC at low catalyst concentration, whereas higher catalyst loadings would be required for further transesterification of HEMC with methanol to form DMC. A 77% yield and 97% selectivity of DMC were obtained at 0.25 g of catalyst loading. However, further increasing the catalyst loading to 0.5 g and 1 g produced almost no change in DMC yield and selectivity. Therefore, a catalyst loading of 0.25 g is enough for this transformation within 3 h.

The dependence of DMC yield and selectivity on reaction time was also evaluated. It was found that the reaction time had a strong influence on the yield and selectivity of DMC. As shown in Fig. 3, the reaction rate was fast at the initial stage and remained almost invariant after 2 h. This hints that the transesterification reaction reached equilibrium after approximately 2 h under the reaction conditions. Notably, the selectivity of DMC was slightly lower within the first hour of reaction, probably owing to the facile formation of HEMC at the initial stage, whereas a longer reaction time led to further transesterification of HEMC with methanol for DMC formation. Therefore, we conclude that a reaction time of 2 h is appropriate for DMC synthesis under the reaction conditions used in this study.

The influence of the methanol/EC ratio on the reaction outcome was investigated under identical reaction conditions. As shown in Fig. 4, the methanol/EC ratio had a significant impact on the transesterification reaction. As the molar ratio of methanol/EC varied from 4:1 to 16:1, both DMC yield and selectivity increased gradually, presumably because of the reversible nature of the transesterification step.[18] In addition, much lower selectivity of DMC with a 4:1 molar ratio of methanol/EC was probably due to the prior formation of HEMC. Nevertheless, further increasing the methanol/EC molar ratio to 30 did not result in a significant change, probably owing to a dilution effect, which would cause a low concentration of EC in the vicinity of the catalyst and retard the interaction between EC and the catalyst. To overcome the thermodynamic limitation of the transesterification and to realize the complete conversion of EC, the reaction was continued for another hour after it reached equilibrium and the

Fig. 4. The dependence of DMC yield and selectivity on the methanol/EC ratio using NaZSM-5 as catalyst. Reaction conditions: EC (30 mmol), catalyst loading (0.25 g), 70 °C, 3 h.



product was simultaneously removed through distillation under atmosphere pressure. Indeed, EC was completely converted to DMC with a methanol/EC molar ratio of 30:1, as determined by GC analysis.

Various alcohols including methanol, ethanol, and propan-2-ol were also tested for the synthesis of dialkyl carbonates (DACs) through the present process for the transesterification of various alcohols with EC and propylene carbonate (PC). As shown in Table 2, the yield and selectivity of DACs decreased with increasing alkyl chain length of alcohols (entries 1–3, 4–6) and increasing steric hindrance of alkylene carbonates (entry 1 vs. 4, 2 vs. 5, 3 vs. 6).[15] The reaction of EC with methanol under the reaction conditions gave 77% yield and 97% selectivity of DMC (entry 1). The reactivity decreased sharply when the substrate changed from EC to PC, while the selectivity remained high (entry 1 vs. 4). This is due to the steric effect of the bulky methyl group in PC as compared with symmetrical EC. Moreover, the reactions with ethanol and propan-2-ol appeared to be more sluggish (entry 1 vs. 2–3). It was observed that an increase in the number of carbon atoms of the alcohol led to a decrease in the yield and selectivity of the DAC, presumably because of increasing steric hindrance. On the other hand, ethoxylate

[a]Determined by GC.

[b]NaOH (5 mol% relative to EC) was used as a catalyst instead of NaZSM-5.

[c]Recovered catalyst, second run.

[d]Recovered catalyst, third run.

and propan-2-ol anions were more difficult to form in comparison with methanol, probably because of the electronic effect. It is worth mentioning that ZSM-5 zeolite contains straight channels, and a large substrate like ^{i}PrOH almost loses reactivity (entry 6), presumably owing to diffusional restriction as previously reported.[20] The pore diffusion limitation induced by the large molecular size of the reactants could play an important role in the transesterification reaction when using a zeolite catalyst. Furthermore, comparison of heterogeneous catalysis with its homogenous counterpart (entry 1, Table 2 vs. entry 3, Table 1; entry 6 vs. 7, Table 2; entry 4 vs. 8, Table 2) also supports this hypothesis.

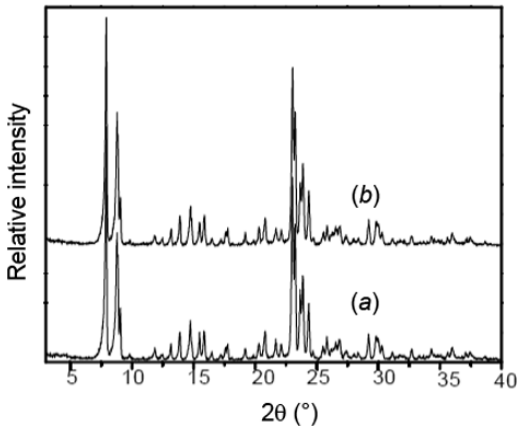
To better understand the present catalysis, both fresh catalyst and recovered catalyst were characterized using X-ray diffraction (XRD) and BET.[21] The solid catalyst can be easily recovered from the reaction mixture simply by filtration, washing with methanol, and drying at 60 °C. As shown in Fig. 5, the XRD patterns of the fresh catalyst and the recovered catalyst did not show appreciable differences, indicating the stable crystal configuration of the catalyst. In addition, based on the BET measurement, the surface area and the pore size of the zeolite changed from 281 m^2/g, 0.66 nm to 273 m^2/g, 0.66 nm, indicating slight changes of the catalyst superficial structure after reaction. To further test catalyst reusability, the reaction was carried out under the same conditions (30 mmol EC, 240 mmol methanol, reaction temperature 70 °C, reaction time 3 h) with the recovered NaZSM-5. The solid catalyst was found to be recyclable and showed retention of activity in 3 recycles (entries 9 and 10, Table 2).

Experimental section

Chemical reagents

Methanol (99.5%) was purified using magnesium and stored under a nitrogen atmosphere. Other reagents were of analytical grade and were used without further purification.

Fig. 5. X-ray diffraction pattern of fresh (*a*) and recovered (*b*) catalyst.



Characterization

The crystalline phase of the as-prepared sample was characterized at room temperature by X-ray diffraction using a Rigaku D/MAX-2500 powder diffractometer in a 2θ range from 3° to 40° equipped with graphite-monochromatized Cu Kα radiation (λ = 1.541874 Å). The powder samples were mounted on a silicon plate for X-ray measurement. Pore size distributions, BET surface areas, and pore volumes were measured by nitrogen adsorption/desorption at –196 °C using a BELSORP-mini gas adsorption analyzer (BEL Japan, Inc.) according to the standard IUPAC recommendations. Prior to measurement, the sample was degassed for 3 h at 300 °C to 0.1 Pa. The specific surface area, S_{BET}, was calculated by applying the BET equation.[21] Average pore diameter was estimated by the average method from the relation $4V_p/S_{BET}$, where V_p is the total pore volume (at $P/P_0 = 0.975$). Pore width distribution over the mesopore range was generated by Barrett–Joyner–Halenda (BJH) analysis of the adsorption branches and the average pore width was also estimated from the BJH distribution.

The analysis of products was performed with a gas chromatograph (Shimadzu 2014 chromatograph) equipped with a capillary column (RTX-5, 30 m × 0.25 mm) using a flame ionization detector. The intermediate was characterized by NMR spectra recorded on a Bruker 300 MHz spectrometer in $CDCl_3$. ^{1}H and ^{13}C NMR chemical shifts (δ) in ppm are downfield from tetramethylsilane ($CDCl_3$: $\delta_C = 77.0$ ppm; residual $CHCl_3$ in $CDCl_3$: $\delta_H = 7.26$ ppm).

Typical procedure for DMC synthesis via transesterification of EC with methanol

A mixture of ethylene carbonate (2 mL, 30 mmol), methanol (9.7 mL, 240 mmol), NaZSM-5 (0.25 g), and biphenyl (60 mg, an internal standard for GC analysis) was added to a 50 mL flask and refluxed for 3 h. The vessel was then cooled to room temperature. The products were analyzed by GC and further identified by GC-MS (HP G1800A) by comparing retention times and fragmentation patterns with those of authentic samples.

Conclusions

Commercially available NaZSM-5 zeolite was found to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

a highly efficient catalyst for DMC synthesis through the transesterification reaction of EC with methanol under mild reaction conditions. A 77% yield and 97% selectivity of DMC were obtained under optimal reaction conditions. It is worth mentioning that EC was completely converted to DMC when the product was simultaneously removed through distillation under atmospheric pressure. This catalytic system can be used with various alcohols and alkylene carbonates, obtaining the corresponding dialkyl carbonates. Variation of catalytic activity towards different substrates is correlated with steric effect, electronic effect, and pore diffusion limitation of the NaZSM-5 zeolite. In addition, the catalyst can be recovered by simple filtration with retention of catalytic activity. These characteristics make it an ideal catalyst system for DMC production in terms of green process and potential industrial applications. Further applications of NaZSM-5 zeolite towards other reactions are currently under investigation in our laboratory.

Biaryl crosslinkers. I. Crosslinking of a bisazidobiaryl with poly(3-hexylthiophene)

Jaya Lohani, V.R. Balakrishnan, Manoj Gaur, P. Raghunathan, and S.V. Eswaran

Abstract: A new biaryl-based bisazide has been used to crosslink poly(3-hexylthiophene), a conducting polymer useful for organic electronics. Crosslinking was monitored using infrared spectroscopy and film morphology was studied using scanning electron microscopy. Hole mobility studies of the devices prepared from pristine and crosslinked polymer show an increase in hole mobility of one order of magnitude for the latter devices.

Key words: crosslinkers, 2D NMR, bisazide, poly(3-hexylthiophene), hole mobility.

Résumé : On a utilisé un nouveau biazide à base de biaryle pour effectuer une réticulation du poly(3-hexylthiophène), un polymère conducteur utile en électronique organique. On a suivi la réticulation par spectroscopie infrarouge et on a étudié la morphologie du film par microscopie électronique à balayage. Des études de mobilité du trou sur des dispositifs préparés à partir de polymère vierge et réticulé ont permis de démontrer que la mobilité du trou est d'un ordre de grandeur plus grande pour les dispositifs à base de polymère réticulé.

Mots-clés : coupleur de réticulation, RMN-2D, bisazide, poly(3-hexylthiophène), mobilité du trou.

Introduction

Polythiophenes and their derivatives, especially poly(3-alkylthiophenes), have been investigated extensively owing to their relatively good environmental stability[1,2] and interesting electrical and electronic properties.[3] Among this class of polythiophenes, poly(3-hexylthiophene) (P3HT) is the most widely studied material because of its good film-forming properties, strong absorption, and high hole mobilities, making it one of the foremost candidates for large-area device applications. P3HT has been used for fabrication of photovoltaic devices,[4–8] memory devices,[9] and thin-film transistors,[10,11] for lithographic purposes,[12–14] and for biosensors.[15,16] Polymer-based diodes are typically fabricated using a "vertical stack architecture" in which the active polymer material is sandwiched between two electrodes having a desired difference in work function.[17] Hole mobility is an important parameter, especially for photovoltaic applications. Hole mobilities of regioregular polythiophene (Fig. 1) as calculated by the space charge limited current (SCLC) method are of the order of 10^{-5} cm^2 V^{-1} s^{-1}.[18–22] However, field-effect mobilities in the range of 0.1 to 1 cm^2 V^{-1} s^{-1} have been achieved using highly ordered films.[23]

To use conducting polymers in organic electronics, materials with good hole mobilities are required. Only a few methods are available to increase the hole mobility. Besides synthesizing new materials, some of the approaches employed in this respect involve increasing molecular weight and decreasing polydispersivity,[24,25] introducing conjugated bridges in the polymer backbone,[26] doping,[27] and using high-boiling solvents.[28]

Recently, we have shown the use of a biaryl natural product as a material for device fabrication.[29] In this paper, we report the synthesis and use of a new biaryl-based bisazide to crosslink P3HT. Hole mobility studies of devices fabricated using pristine and crosslinked polymer were carried out using the SCLC method, and film morphology was studied using scanning electron microscopy (SEM).

Materials and methods

Chemicals and solvents were purchased from Merck or S.D. Fine-Chem Ltd. Regioregular P3HT was purchased from Spectrochem Pvt. Ltd. and used without additional purification. Reactions were monitored by thin-layer chromatography on fluorescent indicator coated plates purchased from Merck. Purification of compounds was done by column chromatography over silica gel (60 to 120 mesh) with a gradient elution using hexane with increasing proportions of ethyl acetate. Melting points were measured on an electrothermal melting-point apparatus and are uncorrected. IR spectra were recorded on a Spectrum BX series spectrophotometer using KBr. ^1H and ^{13}C NMR spectra were recorded on a Bruker AVANCE 300 MHz spectrometer and 2D NMR spectra were recorded on a Bruker 400 MHz instrument. TMS was used as the internal standard in all cases. Mass spectra were recorded on a Waters Microanalysis LCT mass spectrometer (model No. KC455). Film thickness was measured by a

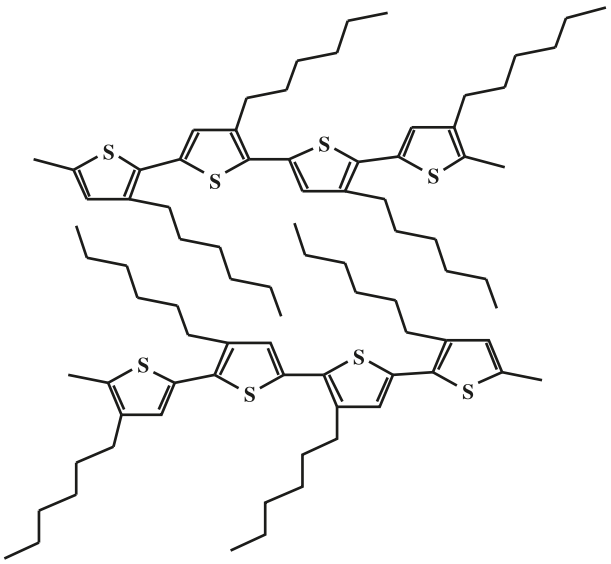
Fig. 1. Structure of head-to-tail regioregular P3HT.



SENTECH SE 500 ellipsometer. SEM investigations were carried out on a LEO 1430 instrument using films coated over indium tin oxide (ITO) coated glass.

Device fabrication

Devices were prepared on glass substrates coated with a thin layer of ITO, which were patterned by an etching process using a mixture of HNO_3–HCl–H_2O in a 1:12:12 ratio. The coated and etched substrates were cleaned by a standard wet process with detergent, followed by boiling acetone, isopropanol, and deionized water, with sonication at each step. Solutions of regioregular P3HT in chlorobenzene (2 wt %) were spin-coated at 2000 rpm, resulting in films with a thickness of about 175 nm. The solutions were prepared with different concentrations of the crosslinker and were filtered through a 0.2 μm pore size PTFE membrane syringe filter before spin coating. The solvent was removed in vacuo and metallic electrode contacts were formed by thermal evaporation of the metal, aluminum (~200 nm), in a vacuum coating unit using a base pressure of 2×10^{-6} mbar (1 bar = 100 kPa) in the evaporation chamber and a deposition rate of >1 Å s^{-1} over the film through a shadow mask. To avoid any doping by oxygen, the devices were kept in vacuum till measurements were done. Current–voltage (I–V) characteristics were recorded under normal class 10 000 clean room environmental conditions (temperature 25 °C and relative humidity ~45% to 50%) using a Keithley 2410 SourceMeter.

Results and discussion

Figure 2 shows the reaction sequence used to synthesize the crosslinker. 1,2,4-Trimethoxybenzene **(I)** was synthesized by Thiele's acetylation of *p*-benzoquinone followed by methylation with dimethyl sulfate in aqueous alkali. Lithiation of 1,2,4-trimethoxybenzene using *n*-butyllithium in diethyl ether gave the lithium salt, which on subsequent iodination gave compound **II**. The iodo-derivative, on Ullmann coupling in the presence of activated copper, yielded **III**, which on further nitration gave the corresponding dinitro compound (**IV**). The dinitro derivative, on reduction with stannous chloride in HCl, gave the corresponding diamino derivative **(V)**, which on diazotization followed by displacement by sodium azide yielded the crosslinker **(VI)**.

2D NMR studies of 2,2′,3,3′,6,6′-hexamethoxy-5,5′-dinitrobiphenyl (IV)

Previously we reported an aromatic nitro ipso substitution leading to a molecule belonging to a rare space group, $P4_2$.[30] Synthesis of compound **IV** was taken up to determine whether it too would belong to the rare space group $P4_2$. 2D NMR studies were then undertaken to establish its structure. The nuclear Overhauser effect (NOE) spectrum (see Fig. S1 in the Supplementary data) of the compound shows that the assignment from ^{1}H-3 at δ 7.59 corresponds to a peak at δ 3.94 (CH_3-10), indicating this methyl is ortho to C-3. In this NOE spectrum, cross peaks are observed between CH_3-8 at δ 3.77 and both of the other methyl groups, i.e., CH_3-10 at δ 3.94 and CH_3-14 at δ 3.62. ^{13}C NMR assignments from heteronuclear multiple bond coherence (HMBC) spectra (Fig. 3) were based on the magnitude of the observed coupling constants for C-4 (5.93 Hz) and C-6 (none resolved). However, it cannot be ruled out that these assignments could be reversed. The signal for C-4 appears at 137.7 ppm. From this, C-6 can be calculated and placed as being extremely shielded at 88.9 ppm. The observance of a four-bond coupling ($^4J_{HC}$) only for CH_3-8 may be the result of this being the only methyl group with the OCH_3 aligned in the plane with the aromatic ring. The other two methoxy groups exhibit an angle of ~125° from the plane of the ring. Complete NMR assignments for the compound are given in Table 1.

Crosslinking with poly(3-hexylthiophene)

In regioregular P3HT, inter-chain interactions are enhanced by π-stacking of the polymer chains, and the formation of a lamellar stacking of the polymer chains with good π-orbital overlap between neighboring chains is promoted by the regular arrangement of the alkyl side chain in P3HT.[18] With better control of the structural order, the efficiency of charge transport is expected to improve with stronger π–π interactions. This π-overlap can be further improved by crosslinking the polymer chains, which in turn will improve the electronic communication between them. For this purpose a biaryl-based bisazide was synthesized and crosslinked with the polymer. Crosslinking was achieved in a Rayonet photoreactor fitted with eight UV tubes (λ = 254 nm) of 12 W each. To avoid the effect of heat, the fan of the instrument was kept on during the experiment. Photolysis of the azide generates highly reactive nitrenes that can insert into a single bond (C–H) or double bond (thiophene ring) of the polymer. IR spectroscopy was used as a tool to determine the progress of crosslinking in the polymer film. The disappearance of the characteristic peak (20 min) for the azide group at ~2100 cm^{-1} in the IR spectrum indicated the completion of crosslinking (Fig. 4).

To determine the effect of crosslinking on the hole mobility of P3HT, devices with a glass/ITO/polymer/Al structure were prepared. Pristine P3HT films were prepared from a 2 wt % solution of polymer in chlorobenzene after stirring for 24 h in the dark. For the crosslinking experiments, the crosslinker was mixed in an appropriate ratio, namely 10 or

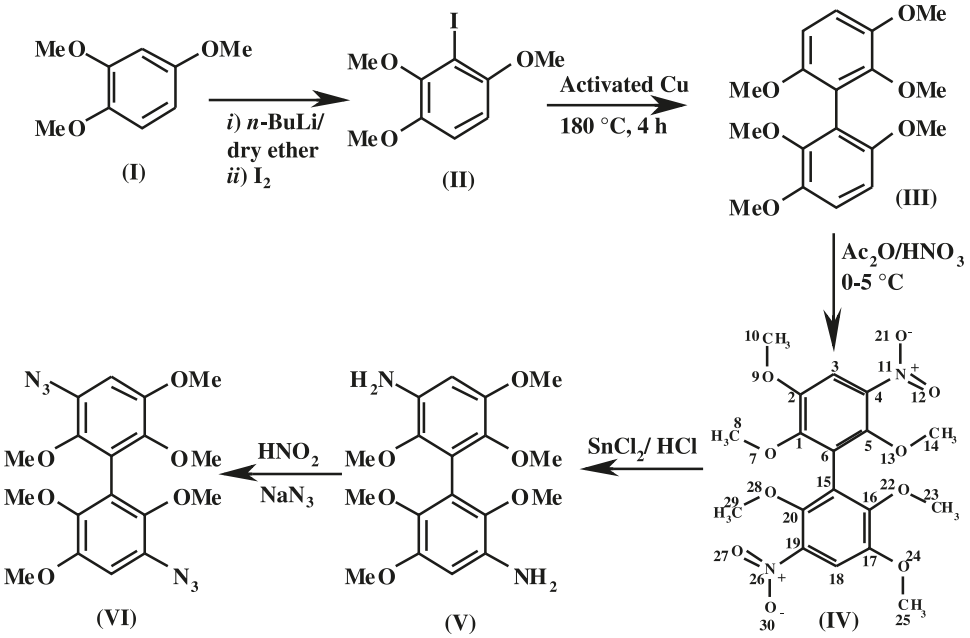

Fig. 3. HMBC spectrum of compound **IV**. In the expanded inset view appearing as the inner box, the $^{2}J_{HC}$ and $^{3}J_{HC}$ values are optimized for digital resolution of 4 Hz (black) and 2.5 Hz (red), respectively.

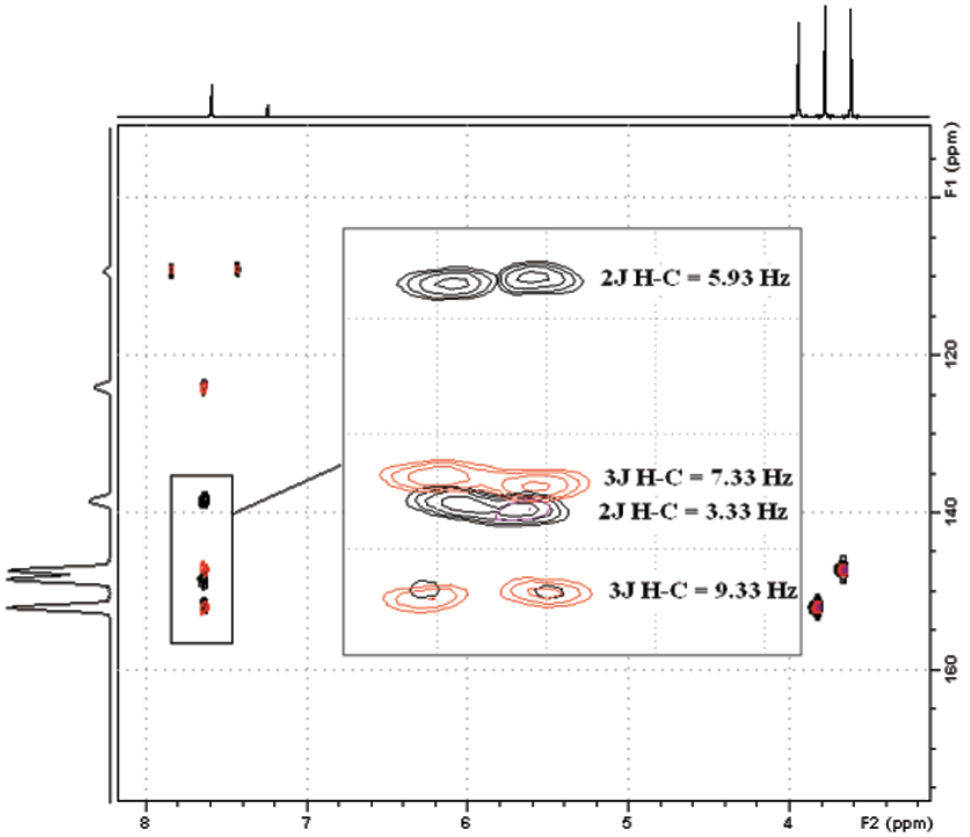

20 wt % of the polymer. The prepared films were protected from light until crosslinking was complete. As a control, pristine P3HT films were also studied after being subjected to similar conditions. The hole mobility can be described by the Mott and Gurney model of space charge limited current, considering the current flow in the trap-free limit.[31] Figure 5 shows a linear rise in current with voltage and a subsequent transition at high voltages to the region towards V^2 dependence. The field-independent mobility, μ, can be calculated by applying Child's Law,

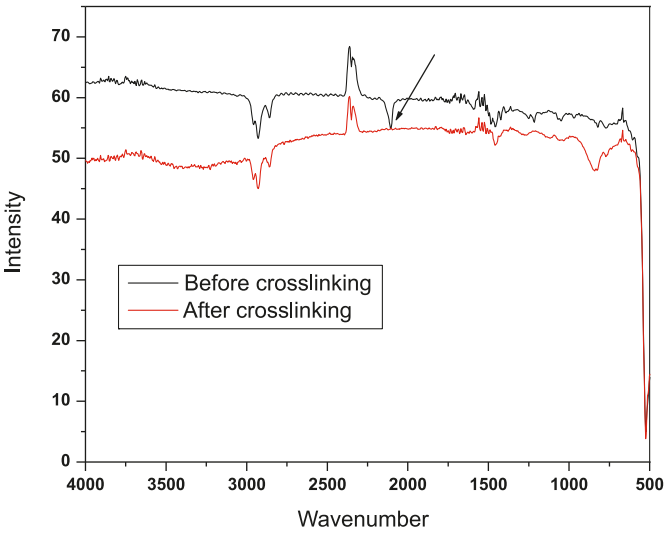
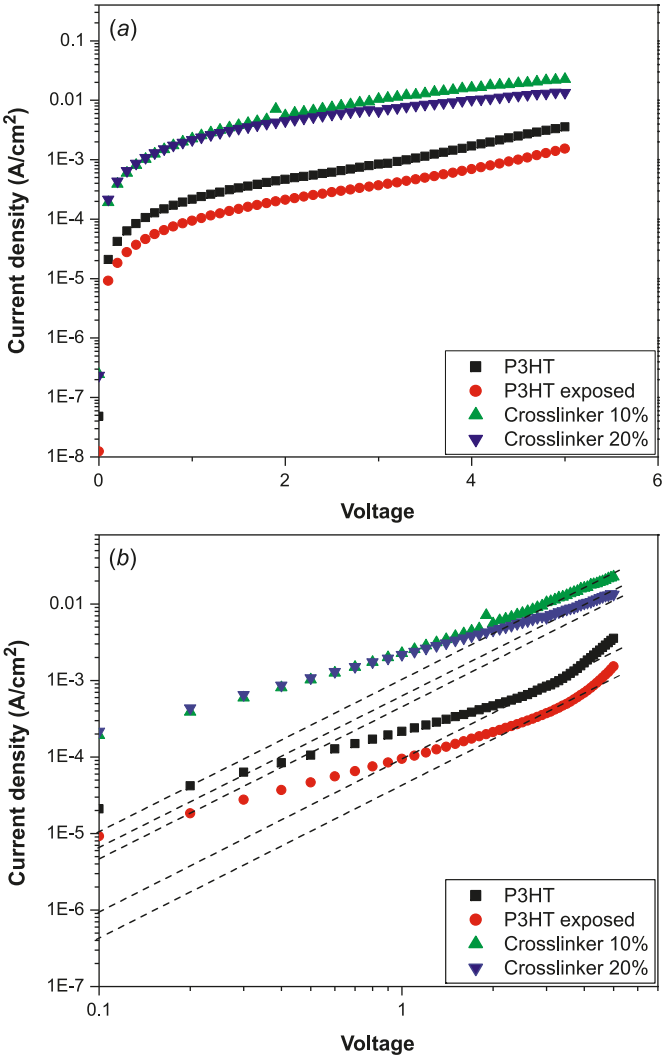
Fig. 4. IR spectrum of the P3HT film before (upper trace) and after (lower trace) crosslinking with 20 wt % crosslinker (disappearance of the azide is shown by the arrow).



$$[1] \qquad J = \frac{9}{8}\mu\varepsilon\varepsilon_0\frac{V^2}{d^3}$$

where J is the current density, μ is the free carrier hole mobility, ε is the dielectric constant (taken to be 3), ε_0 is the permittivity in a vacuum, V is the applied voltage, and d is the film thickness. The hole mobility was calculated from the intercept of the corresponding lines on the axis of current density. Using the above J–V relationship, the SCLC mobility (Fig. 5) of P3HT and the blank was calculated to be of the order of $\sim 10^{-5}$ cm^2 V^{-1} s^{-1}, which is in accordance with values reported earlier.[18–22] Hole mobility values for the crosslinked polymer, as compared with pristine P3HT (4.5×10^{-5} cm^2 V^{-1} s^{-1}), increased by an order of magnitude of one, reaching 5×10^{-4} cm^2 V^{-1} s^{-1} and 3×10^{-4} cm^2 V^{-1} s^{-1} for devices fabricated after crosslinking with 10 wt % and 20 wt % crosslinker, respectively. A slight decrease in hole mobility was observed in devices fabricated using pristine P3HT exposed to UV as a control. The increase in hole mobility after crosslinking may be a result of better molecular ordering due to better π-overlap of the polymer chains. When a higher concentration of crosslinker is used, there is formation of an amorphous region due to twisting and bending of the polymer chains, resulting in a decrease in hole mobility.

Fig. 5. Comparison of current–voltage characteristics of the glass/ITO/polymer/Al devices. (*a*) Semi-log plot and (*b*) logarithmic plot. The hole mobilities were found to be 4.5×10^{-5} cm^2 V^{-1} s^{-1} for P3HT, 2×10^{-5} cm^2 V^{-1} s^{-1} for UV-exposed P3HT, 5×10^{-4} cm^2 V^{-1} s^{-1} for 10 wt % crosslinker, and 3×10^{-4} cm^2 V^{-1} s^{-1} for 20 wt % crosslinker.



The film morphology was studied using SEM. Film morphology for P3HT, both pristine and exposed, is smooth (Figs. 6*a* and 6*b*). After crosslinking a change in film morphology is seen. Films with a crosslinker concentration of 10 wt % show granular morphology (Fig. 6*c*) and those with a higher crosslinker concentration show fibrous structure (Fig. 6*d*), possibly due to excessive crosslinking.

To conclude, a new biaryl-based bisazide has been synthesized and evaluated as a crosslinker. Devices fabricated using crosslinked P3HT show an increase in hole mobility, as determined by the SCLC method, by a factor of one order of magnitude. This study could be useful for fabrication of devices, especially thin-film transistors and solar cells.

Abstract: A series of *N*,*N*′-alkylidene bisamides were prepared via a green and environmentally friendly synthetic protocol from the reaction of phenyl acetylene or hex-1-yne, aromatic aldehyde, and benzamide or acetamide. Silica-supported barium chloride (SiO_2–$BaCl_2$) catalyzes the process of the reaction. The prepared catalysts were characterized by X-ray diffraction, and the products were obtained with high conversions and yields.

Key words: SiO_2–$BaCl_2$, heterogeneous catalyst, environmentally friendly synthesis, *N*,*N*′-alkylidene bisamides.

Résumé : On a préparé une série de *N*,*N*′-alkylidène bisamides par un protocole de synthèse écologique impliquant la réaction du phénylacétylène ou de l'hex-1-yne, d'un aldéhyde aromatique et du benzamide ou de l'acétamide. Du chlorure de baryum déposé sur de la silice (SiO_2–$BaCl_2$) catalyse la réaction. Les catalyseurs préparés ont été caractérisés par diffraction des rayons-X et les produits ont été obtenus avec des taux de conversion et des rendements élevés.

Mots-clés : SiO_2–$BaCl_2$, catalyse hétérogène, synthèse écologique, *N*,*N*′-alkylidène bisamides.

[Traduit par la Rédaction]

Introduction

The development of simple, efficient, and environmentally benign chemical processes or methodologies for widely used pharmacophores from readily available reagents and catalysts are the major challenges for chemists throughout the world.[1] To plan and manage chemical reactions with "green" experimental protocol is an enormous challenge that chemists have to confront to improve the quality of the environment for present and future generations.[2] Over the past, chemists have been aware of the environmental implications of their chemistry. Nowadays, they are trying to develop new synthetic methods, reaction conditions, and uses of chemicals that reduce risks to humans and the environment. Organic solvents are high on the list of damaging chemicals because they are employed in huge amounts and are usually volatile liquids that are difficult to store.[3]

One important aspect of clean technology is the use of environmentally friendly catalysts — typically a solid catalyst that can be recovered easily when the reaction is complete. Heterogeneous organic reactions have proven useful to chemists in the laboratory as well as in an industrial context. These reactions are affected by the reagents immobilized on the porous solid supports and have advantages over the conventional solution-phase reactions because of the good dispersion of active reagent sites, associated selectivity, and easier work-up.[3]

Compounds bearing amide and bisamide groups are important intermediates in organic synthesis, since these groups can be easily transformed into other functionalities (such as *gem*-diaminoalkyl and aminoalkyl groups) and are of considerable interest in the synthesis of pharmacological materials such as peptidomimetic compounds.[4] Therefore, preparation of amides has attracted considerable attention in the past and in recent years.

The common approach for the synthesis of bisamides is the direct reaction of aldehydes with the corresponding amides or nitriles.[5–10]

In this paper various acidic catalysts such as sulfuric acid (85%; also as solvent),[5] sulfonic acid,[6] triflic acid,[8] sulfamic acid,[10a] or chlorosulfonic acid[10b] were examined.

Considering that most of the organic reagents involved in fine chemical synthesis are sensitive to harsh conditions, it is desirable to choose catalysts that can catalyze organic transformations under mild conditions.

The aim of the present protocol was to summarize the data for the one-pot preparation of *N*,*N*′-alkylidene bisamide derivatives in high yield using a three-component condensation of an alkyne, aromatic aldehydes, and amides in the presence

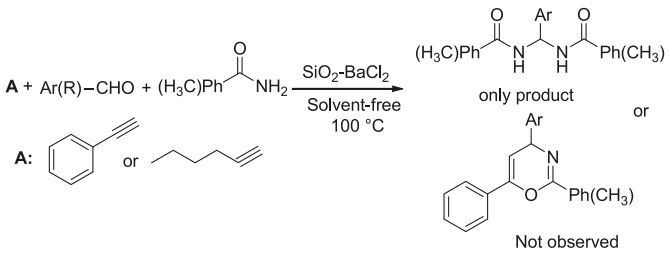
Scheme 1.



of silica-supported barium chloride (SiO_2–$BaCl_2$) as the catalyst under thermal, solvent-free conditions (Scheme 1).

Results and discussion

Hung et al.[11] reported that the condensation of phenyl acetylene, aromatic aldehyde, and urea with acetic acid / trifluoroacetic acid as the catalyst and acetonitrile as the solvent lead to the formation of 4*H*-[1,3]oxazines. In continuation of this theme, we are trying to develop new synthetic methods, reaction conditions, and uses of heterogeneous catalysts that reduce risks to humans and the environment. Thus, the reaction of phenyl acetylene, benzaldehydes, and benzamide in the presence of a catalytic amount of SiO_2–$BaCl_2$ as the catalyst under thermal, solvent-free conditions was investigated (Scheme 1). As can be seen from Scheme 1 we did not observe 2-phenyl(methyl)-4*H*-1,3-oxazine derivatives, and a series of *N*,*N*′-alkylidene bisamides formed.

Within our plan to investigate the structures of bisamide and needing an alkyne or a catalyst for the formation of bisamides, the reaction including benzaldehyde, benzamide, and a catalytic amount of SiO_2–$BaCl_2$ under heating at 100 °C failed to give the correlative product in the absence of phenyl acetylene, which indicated that phenyl acetylene plays an important role in the reaction (Scheme 2). Chromatographic studies (TLC) confirmed that the alkyne was completely disappearing when the product was formed.

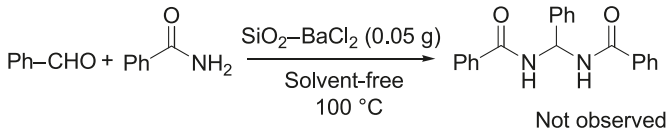
As a result the mentioned reaction failed to give any products in the absence of the catalyst.

To improve the yield and optimize the reaction conditions, the reaction was carried out using phenyl acetylene, benzaldehyde, and benzamide in the presence of SiO_2–$BaCl_2$ as the catalyst (Scheme 3). Initially, the effect of temperature on the rate of the reaction was investigated (Table 1). At 80 °C, the reaction proceeded smoothly and almost complete conversion of the product was observed. A further increase in temperature to 100 °C increased the rate of the reaction. Therefore, the reaction temperature was kept at 100 °C (giving a short reaction time and high yield).

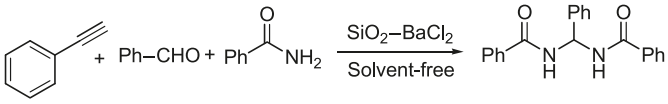
We then tried to optimize the amount of catalyst for this reaction. It should be noted that 0.025 g of SiO_2–$BaCl_2$ was efficient enough to catalyze the reaction, and increasing the amount of catalyst did not significantly improve the yield (Table 1). Finally, an optimimal set of conditions was achieved using 0.025 g of SiO_2–$BaCl_2$ as the catalyst and 100 °C. The results are summarized in Table 1.

Using these optimized reaction conditions, the scope and efficiency of these procedures were explored for the synthesis of a wide variety of substituted bisamides (Scheme 1). The results are summarized in Table 2.

Scheme 2.



Scheme 3.



As expected, this reaction proceeded smoothly, and the desired products were obtained in good to excellent yields. A series of aromatic aldehydes with either electron-donating or electron-withdrawing groups attaching to aromatic rings were investigated (Table 1, entries 1–9). However, when aromatic aldehydes with electron-withdrawing groups (such as nitro-) were reactants, the reaction time was shorter than that with electron-donating groups (such as methoxy-). Although meta- and para-substituted aromatic aldehydes gave good results, ortho-substituted aromatic aldehydes (such as 2-nitrobenzadehyde) gave lower yields and longer reaction times because of the steric effects. These good results were also obtained in the case of the hex-1-yne (Table 1, entries 14 and 15).

As a result the reaction of butyraldehyde with phenyl acetylene and benzamide failed to give any product (Table 1, entry 10).

Encouraged by the results obtained with benzamide, we turned our attention to acetamide (Table 1). As shown in Table 1, the reactions of phenyl acetylene and aryl aldehyde with acetamide under the mentioned reaction conditions progressed smoothly but with longer reaction times, and the desired products were obtained in good yields. (Table 1, entries 11 and 12). However, ortho-substituted aromatic aldehydes (such as 2-nitrobenzadehyde) failed to give any product (Table 1, entry 13).

To explain the formation of bisamides via the one-pot multicomponent reaction, we have proposed a plausible reaction mechanism, which is illustrated in Scheme 4. Firstly, the interaction of aldehyde with an empty π orbital of the Lewis acid occurs to form a cation intermediate. Therefore, the formation of **A** resulting from the cyclocondensation of an activated aldehyde with phenyl acetylene is established. The second step is the addition of amide to **A** to yield β-amido ketones (**B**) that protonate and convert to the bisamide as the product by an attack of the amide (Scheme 4).

Conclusion

In conclusion, a rapid and environmentally benign protocol for the preparation of *N*,*N*′-alkylidene bisamides in a one-pot procedure wasn developed. The work-up procedure is very clear-cut; that is, the products were isolated and purified by simple filtration and crystallization from aqueous ethanol (or diethyl ether). Our protocol avoids the use of dry media during the reaction process, making it superior to the reactions that use solvent.

[a]Isolated yield (based on phenyl acetylene (1 mmol), benzaldehyde (1.1 mmol), and benzamide (2.5 mmol)).

Experimental

All reagents were purchased from Merck and Sigma-Aldrich and used without further purification. All yields refer to isolated products after purification based on the amount of aldehyde. Products were characterized by comparison of spectroscopic data (IR and ^{1}H NMR spectra) and melting points with authentic samples. The NMR spectra were recorded on a Bruker Avance DPX 300 MHz instrument. The

Scheme 4. Proposed mechanism for the formation of *N*,*N*′-alkylidene bisamides.

spectra were measured in DMSO-d_6 relative to TMS (0.00 ppm). IR spectra were recorded on a PerkinElmer 781 spectrophotometer. Melting points were determined in open capillaries with a BUCHI 510 melting point apparatus. TLC was performed on silica gel polygram SIL G/UV 254 plates.

Preparation of SiO_2–$BaCl_2$

In a 250 mL flask, barium chloride dihydrate ($BaCl_2 \cdot 2H_2O$, 1 g) was dissolved in water (50 mL) and silica gel (10 g) (Silica gel 60 for column chromatography, 230 mesh) was added to this mixture, which was vigorously stirred under rotary evaporation until the water was completely evaporated. This powder was kept in an oven at 100 °C for 1 h to give the active catalyst.

X-ray diffraction (XRD)

Powder X-ray diffraction measurements were performed using a D_8 Advance diffractometer made by Bruker AXS, Germany. Scans were taken with a 2θ step size of 0.02 and a counting time of 1.0 s using a Cu Kα radiation source generated at 40 kV and 30 mA. Specimens for XRD were prepared by compaction into a glass-backed aluminum sample holder. Data were collected over a 2 u range from 48° to 70°, and phases were identified by matching experimental patterns to entries in the Diffract^{plus} version 6.0 indexing software. The fresh catalyst was characterized by XRD and its pattern is presented in Fig. 1. As shown in Fig. 1, the actual phases were silicon oxide (silica) – SiO_2 (cubic) and $BaCl_2$.

General procedure for the synthesis of *N*,*N*′-alkylidene bisamides

To a mixture of aryl aldehyde (1.1 mmol), benzamide or acetamide (2.5 mmol), and phenyl acetylene or hex-1-yne (1 mmol) was added SiO_2–$BaCl_2$ (0.025 g) and the mixture was heated at 100 °C in an oil bath for the appropriate time (Table 1). The progress of the reaction was monitored by TLC. After completion of the reaction, the mass was cooled to 25 °C, and the mixture was dissolved in boiling ethanol. The catalyst was removed by simple filtration. The solvent was concentrated and the solid product was purified by a recrystallization procedure in the appropriate solvent (ethanol 40% or diethyl ether).

All products were characterized by IR, ^{1}H NMR, and ^{13}C NMR spectra.

Abstract: The interaction of a calix[4]arene-based species containing two 8-oxyquinoline chromophore pendants with hazardous metal ions has been investigated using optical absorption and fluorimetric techniques. In the presence of Hg^{2+}, Cd^{2+}, and Pb^{2+} ions, there is only a small decrease of the calixarene absorption band at 283 nm. The main changes are associated with the absorption band of the 8-oxyquinoline group at 315 nm, undergoing a systematic bathochromic shift to above 350 nm. In addition, a systematic decrease of the oxyquinoline emission at λ_{em} = 392 nm (λ_{exc} = 315 nm) has been observed. These observations are consistent with the coordination of the metal ions to the quinoline groups attached to the calixarene ligand, providing a useful fluoroinophore species for analytical purposes.

Key words: 8-oxyquinoline, calix[4]arene, hazardous metal ions.

Résumé : Faisant appel aux techniques d'absorption optique et fluorimétrique, on a étudié les réactions d'interaction entre des ions métalliques dangereux et des espèces à base de calix[4]arène contenant deux chromophores pendants 8-oxyquinoléine. En présence des ions Hg^{2+}, Cd^{2+} et Pb^{2+}, on n'observe qu'une faible diminution de la bande l'absorption du calixarène à 283 nm. Les principaux changements sont associés à la bande d'absorption du groupe 8-oxyquinoléine à 315 nm qui subit un déplacement bathochrome systématique au-dessus de 350 nm. De plus, on observe une diminution systématique de l'émission de l'oxyquinoléine à $\lambda_{ém}$ = 392 nm (λ_{exc} = 315 nm). Ces observations sont en accord avec une coordination des ions métalliques par les groupes quinoléines attachés au ligand calixarène, fournissant une espèce fluoroionophore pour des besoins analytiques.

Mots-clés : 8-oxyquinoléine, calix[4]arène, ions métalliques dangereux.

[Traduit par la Rédaction]

Introduction

Ionophores are becoming important selective agents for the detection and extraction of hazardous metal ions, allowing many applications in environmental chemistry and biology.[1] Recently, a new chemosensor species that signals Hg^{2+}, Cu^{2+}, and Zn^{2+} ions in acetonitrile has been published.[2] In particular, functionalized calixarenes have been extensively employed in molecular recognition of metal ions, because of their unique structural features. They can be chemically modified in the upper or lower rim positions, providing suitable architectures exhibiting improved solubility in organic solvents, and binding ability and selectivity for guest molecules or ions.[3] In fact, most analytical publications on calixarenes have focused on the extraction of alkali ions,[4] actinides, lanthanides,[5] and hazardous metals, including toxic metals from nuclear waste. Calixarenes bearing a crown-6 group[6] can selectively extract Hg^{2+} and Pb^{2+} ions, whereas those involving a crown-5 group are able to extract smaller cations, such as Zn^{2+} and Cd^{2+}. Successful extraction of Hg^{2+}, Ag^{+}, Pd^{2+}, and Au^{3+} ions has been performed[7] using the 25,26,27,28-(2-*N*,*N*-dimethyldithiocarbamoylethoxy)calix[4]arene and 25,26,27,28-(2-methylthioethoxy)calix[4]arene species. On the other hand, a high Ba^{2+} selectivity has been reported for calix[4]arene-1,2-crown-4 ethers[8] in the competitive extraction of alkaline earth metal cations.

The chemical characteristics of calixarenes can be conveniently exploited in combination with analytical techniques such as chromatography, spectrophotometry, spectrofluorimetry, and atomic absorption spectrometry for the determination of metal ions. In particular, it has been reported that spectrofluorimetry using fluorescent probes exhibits many advantages in terms of sensitivity and selectivity in the detection of metal ions such as Cr(VI),[9] Tl(I), and Cs(I).[10]

To extend the use of calix[4]arenes as fluorescent probes, we have successfully attached hydroxyquinoline groups to lower rim positions leading to species **1** (5,11,17,23-tetra(*tert*-

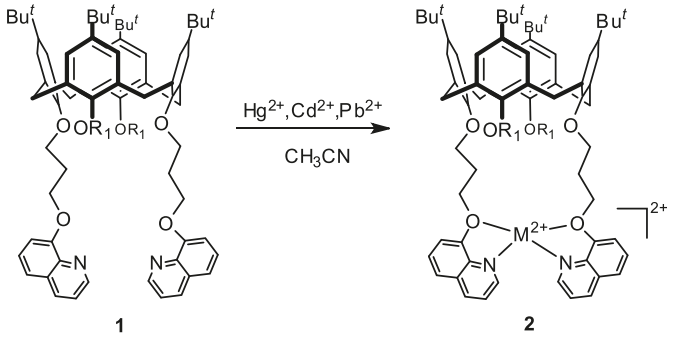
Fig. 1. Complexation scheme of Hg^{2+}, Pb^{2+}, and Cd^{2+} by ligand **1** (5,11,17,23-tetra(*tert*-butyl)-25,27-bis[(quinoline-8-oxy)propyloxy]-26,28-dihydroxy-calix[4]arene).



butyl)-25,27-bis[(quinoline-8-oxy)propyloxy]-26,28-dihydroxy-calix[4]arene)[11,12] (Fig. 1). It should be noticed that hydroxyquinoline (HQ) has been extensively used in the form of [Al $(HQ)_3$] complexes in commercial organic light-emitting devices because of its high luminescent properties. As a matter of fact, we have already shown that species **1** exhibits a remarkable performance in tunable light-emitting devices.[13] However, when attached to the calix[4]arene species, in addition to their luminescent role, the hydroxyquinoline groups also allow the selective binding of metal ions,[12,13] giving rise to many interesting applications as fluoroionophore agents. This type of application has not yet been explored for the detection of the hazardous Hg^{2+}, Pb^{2+}, and Cd^{2+} metal ions. For this reason, the investigation of this new relevant aspect is dealt with in this paper.

Experimental

General

Electronic spectra were recorded on a Hewlett-Packard model 8453 diode array spectrophotometer. Photoluminescence spectra were recorded on a Photon Technology International (PTI) fluorescence spectrophotometer equipped with a xenon pulsed lamp, using 1 cm quartz cells, at room temperature.

The solvents employed for the syntheses were dried, freshly distilled, and kept under nitrogen. TLC was performed on alumina plates (neutral Al_2O_3 60 F_{254}).

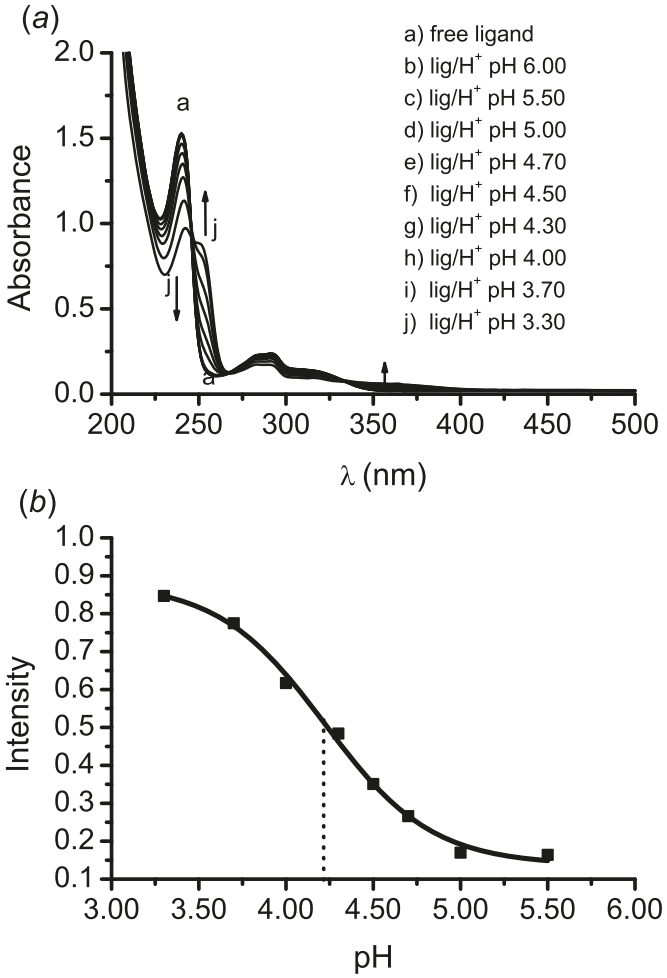
Species **1** was synthesized as previously described.[11,12]

The solutions of metal ions were prepared from their corresponding nitrate or chloride salts. The acid solution of HCl was freshly prepared with milliQ water (18.2 mΩ cm at 298 K). All reagents and solvents were purchased from Merck (Darmstadt, Germany).

Analytical procedure

For the determination of the acid dissociation constant of **1**, a 1×10^{-5} mol dm^{-3} solution was prepared in previously deaerated CH_3CN–H_2O (1:1 *v/v*) mixed solvent. The formal pH was varied, in the range of 6.00 to 3.30, by adding small aliquots (μL) of 1×10^{-3} mol dm^{-3} HCl directly into the spectrophotometric quartz cell.

Fig. 2. (*a*) Spectral variation for ligand **1** as a function of pH in CH_3CN–H_2O (1:1 *v/v*). (*b*) Sigmoidal plots of intensity as a function of pH at $\lambda = 253$ nm. $R^2 = 0.99$.



Stoichiometry and determination of the formation constants

For the evaluation of the composition and equilibrium constants of the complexes, the experiments were carried out in deaerated acetonitrile. By starting with a solution containing 1×10^{-5} mol dm^{-3} of **1**, and varying the concentrations of the Hg^{2+}, Pb^{2+}, and Cd^{2+} ions, as expressed in terms of the metal–ligand ratios: 0.3:1, 0.6:1, 1:1, 1.5:1, 2:1, 3:1, 5:1, 8:1, 10:1, 12:1, 15:1, 18:1, and 20:1. The solutions were monitored by means of absorption and fluorescence measurements. The binding constants were calculated using the data corresponding to $[M]/[L] \geq 3$. Nonlinear regression analysis using the simplex minimization method and Benesi–Hildebrand and Scatchard methods[14] were used for the determination of the binding constants.

Results and discussion

The oxyquinoline–calixarene species (ligand **1**) exhibits characteristic absorption bands at 283 and 292 nm (ε = 38 000 cm^{-1} mol^{-1} dm^3, for both bands) ascribed to $\pi \rightarrow \pi^*$ transitions in the calixarene groups, and at 320 nm (ε = 20 000 cm^{-1} mol^{-1} dm^3) ascribed to $\pi \rightarrow \pi^*$ transitions in the

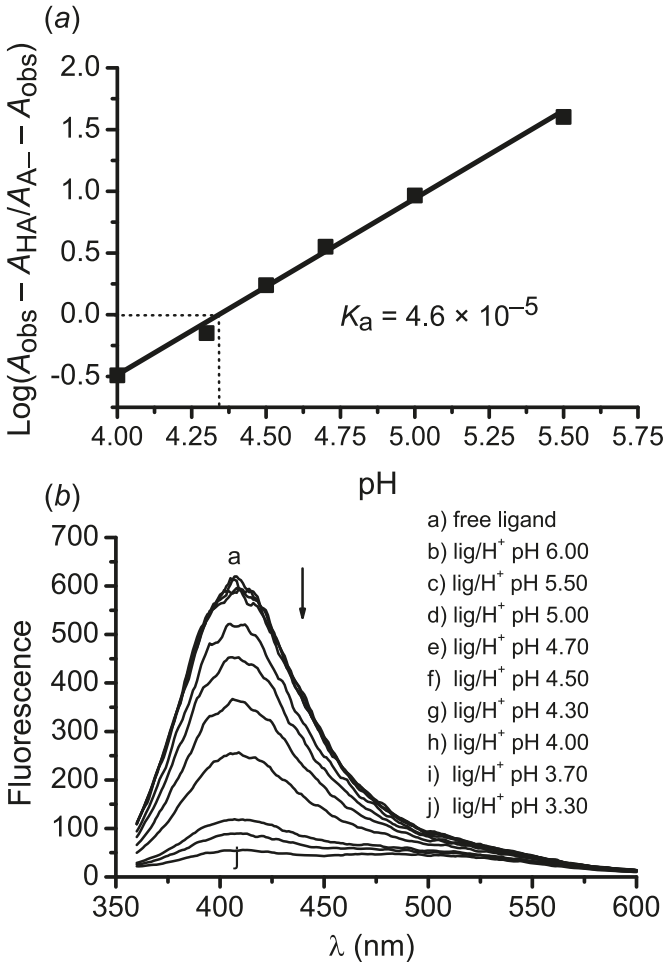
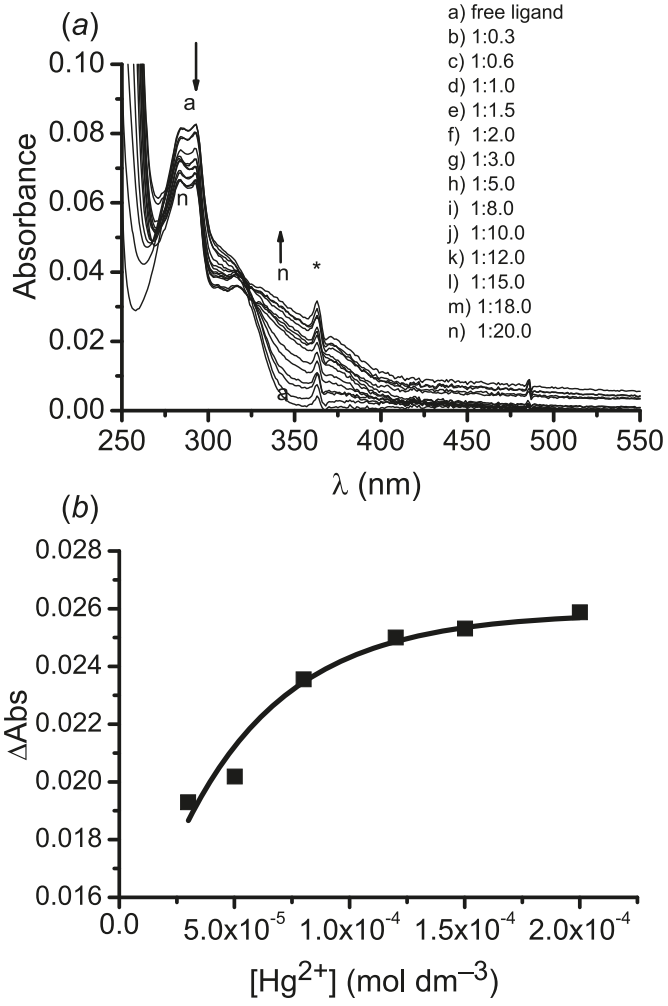
Fig. 3. (*a*) Linear logarithmic plot of ligand **1** as a function of pH, $R = 0.99$. (*b*) Variation of the emission intensity of **1** as a function of pH.



8-oxyquinoline groups. Fluorescence emission is observed at 392 nm ($\lambda_{exc} = 315$ nm) associated with the 8-oxyquinoline group. The emission quantum yield of **1** was previously determined in acetonitrile as $\phi_{q313} = 0.039$,[11] which is one order of magnitude higher than that of the 8-hydroxyquinoline group[15] ($\phi = 0.0038$). It was observed that the substitution of the –OH group by $–OCH_3$ in the quinoline group increases the quantum yield of this group.[16] In the absence of metal ions, this species exists predominantly in neutral form. In acidic $CH_3CN–H_2O$ (1:1 *v*/*v*) solutions, (pH range 3.30–6.00), the quinoline nitrogen atom is protonated (Fig. 2*a*) according to a well-behaved equilibrium process, exhibiting well-defined isosbestic points in the absorption spectra. The plot of intensity versus pH (Fig. 2*b*) shows a typical sigmoidal curve. For a monoprotonated species, the plots of log $[(A - A_{HA})/(A_A - A)]$ (where A is the absorbance, A_{HA} is the absorbance of all protonated ligand, and A_A is the absorbance of nonprotonated ligand) vs pH are expected to be linear, with a unitary slope; however, as shown in Fig. 3*a*, the observed slope is practically 2, indicating simultaneous protonation of the two quinoline groups in **1**. The pK_a was calculated as 4.34 (±0.05) ($K_a = 4.6 \times 10^{-5}$ mol^{-1} dm^3) ($\lambda = 353$ nm), and is consistent to the p$K_a = 4.9$ observed for the *N*-pyridine

Fig. 4. Titration of ligand **1** with Hg^{2+} in acetonitrile. (*a*) Evolution of the absorption spectrum as a function of Hg^{2+} concentration. (*b*) Plot of ΔAbs, where ΔAbs is Absorbance – initial Absorbance, as a function of $[Hg^{2+}]$ at $\lambda = 350$ nm. $R^2 = 0.97$. Instrumental artifact (*).



ring[17] in 8-hydroxyquinoline; the difference reflects the replacement of –OH by the –OR group (R = $CH_2CH_2CH_2$calix) in ligand **1**.

Calculation of the charge-transfer excited state pK_a* for this ligand was carried out by using eq. [1][18,19]

$$[1] \qquad pK_a^* = pK_a(gs) + 2.86(\nu_1 - \nu_2)/2.303\,RT$$

where pK_a(gs) is the ground-state pK_a, ν_1 is the frequency in wavenumbers of the charge-transfer absorption maxima band of the unprotonated form, ν_2 is the frequency of the corresponding absorption in the protonated form, $R = 1.9872$ cal mol^{-1} K^{-1} (1 cal = 4.184 J), and 2.86 is a conversion factor to energy. The calculated pK_a* of **1** was 11.50, indicating a basicity increase of seven orders of magnitude with respect to the ground-state p$K_a = 4.34$.

Protonation of **1** can also be monitored by the decrease of the emission band at 410 nm upon excitation at 315 nm, as shown in Fig. 3*b*. The pK_a calculated in this way is consistent with that obtained spectrophotometrically (p$K_a = 4.25$).

The interaction of hazardous metal ions with ligand **1** has

Fig. 5. (*a*) Evolution of the emission spectrum of ligand **1** with increasing concentrations of Hg^{2+} at λ_{em} = 392 nm. (*b*) Plot of F_0/F vs [Hg^{2+}], R = 0.98.

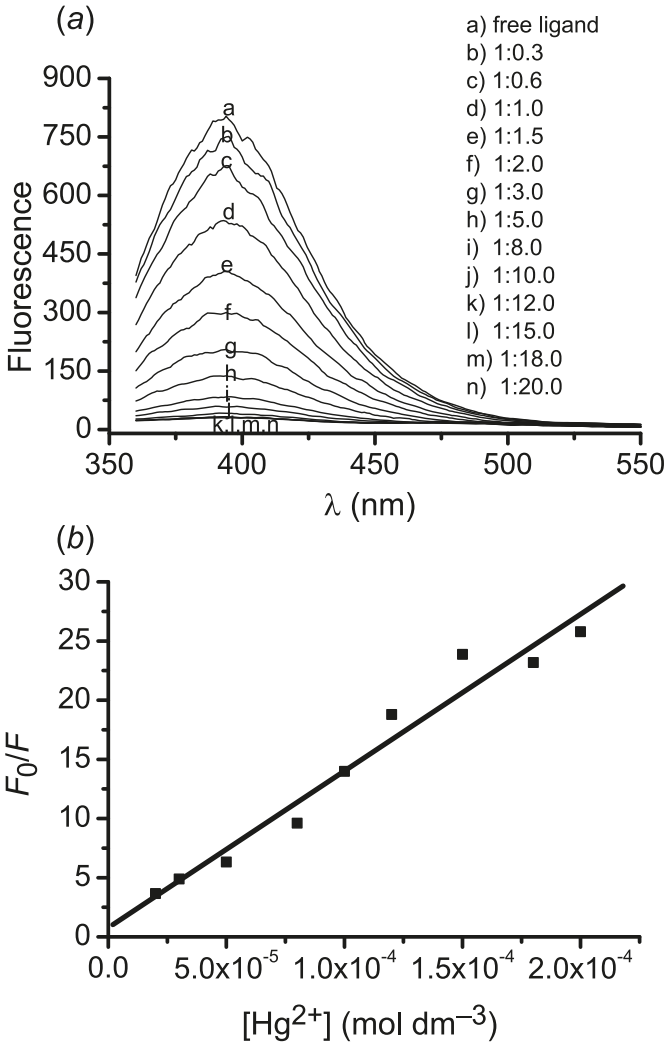

Fig. 6. Titration of ligand **1** with Pb^{2+} in acetonitrile. (*a*) Evolution of the absorption spectrum as a function of Pb^{2+} concentrations, (*b*) Plot of ΔAbs, where ΔAbs is Absorbance – initial Absorbance, as a function of [Pb^{2+}] at λ = 350 nm. R^2 = 0.94.

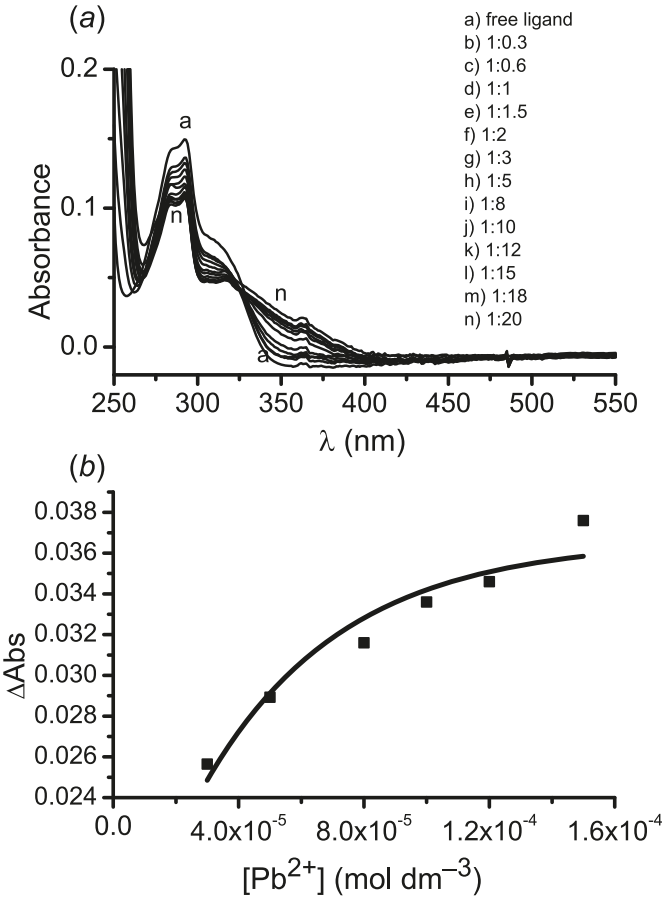

been investigated in acetonitrile, by monitoring the changes in the UV–vis absorption spectra and in the corresponding fluorescence spectra.

In the presence of Hg^{2+} ions, there is only a small decrease of absorbance in the region of the calixarene band (283 nm; Fig. 4*a*). The main changes are associated with the absorption band of the 8-oxyquinoline group at 315 nm, which undergoes a systematic bathochromic shift to about 350 nm, generating an isosbestic point at 322 nm. This result is consistent with the selective binding of the Hg^{2+} ions to the 8-oxyquinoline chromophore.

The titration plot, monitoring ΔAbs vs the concentration of metal ion ([M]), is shown in Fig. 4*b*. It was treated by nonlinear regression analysis, yielding a good fitting for a 1:1 stoichiometry, according to eq. [2]

$$[2] \qquad \Delta A = \frac{L K_{11} \Delta\varepsilon [M]}{1 + K_{11}[M]}$$

where $\Delta A = A_t - A_0$, A_t is the total absorbance, L = ligand, M = metal ion ([M] = [Mt], where [M] >> [L] and [Mt] = total concentration of metal ion), $\Delta\varepsilon$ = molar absorptivity ($\Delta\varepsilon = \varepsilon - \varepsilon_M - \varepsilon_L$, where ε = molar absorptivity of complex, ε_M = molar absorptivity of metal ion, and ε_L = molar absorptivity of ligand), and K_{11} = binding constant.

The calculated binding constant for the Hg^{2+} ions was K_{11} = 6.4 (±0.70) × 10^4 mol dm^{-3}. Similarly, the binding constant was also calculated based on the Benesi–Hildebrand method, assuming a 1:1 stoichiometry, yielding K_{11} = 7.3 (±0.7) × 10^4 mol dm^{-3}, and also by the Scatchard method, yielding K_{11} = 3.1 (±0.5) × 10^4 mol dm^{-3}. The Scatchard method led to a binding constant of the same magnitude as the preceding methods, but yielded a smaller absolute value because of the larger oscillation of R^2 = 0.76 associated with the experimental data.

The binding of the Hg^{2+} ions to the oxyquinoline–calixarene species was also monitored by the changes in the emission profiles, as shown in Fig. 5*a*. One can see that there is a systematic decrease of the luminescence of free ligand **1** at 392 nm. This fact contrasts with the results previously reported for the binding of ligand **1** to Zn^{2+} ions.[12] In this case, a new emission band has been observed at 440 nm, ascribed to the Zn^{2+}-coordinated ligand **1** complex. The lack of this band in the corresponding Hg^{2+} complex indicates that the metal ion is acting as a powerful quencher, in contrast with the Zn^{2+} ions.

In this case, the binding constants can be evaluated from

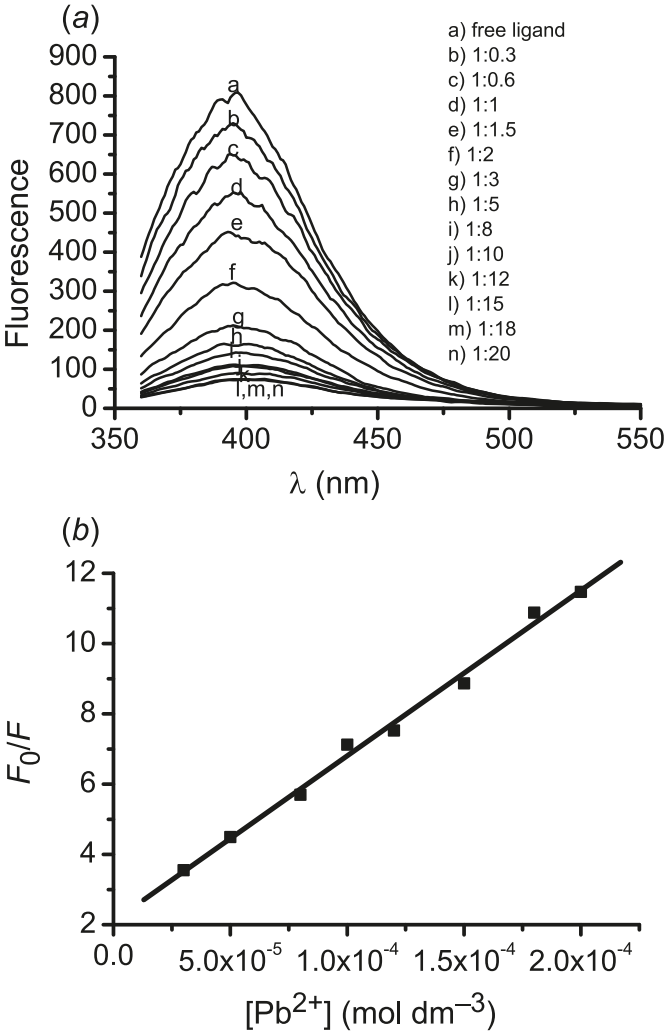
Fig. 7. (*a*) Evolution of the emission spectrum of ligand **1** with increasing concentrations of Pb^{2+} at λ_{em} = 392 nm. (*b*) Plot of F_0/F (where F_0 is the fluorescence in the absence of metal ion and F is the fluorescence) vs [Pb^{2+}], R = 0.99.



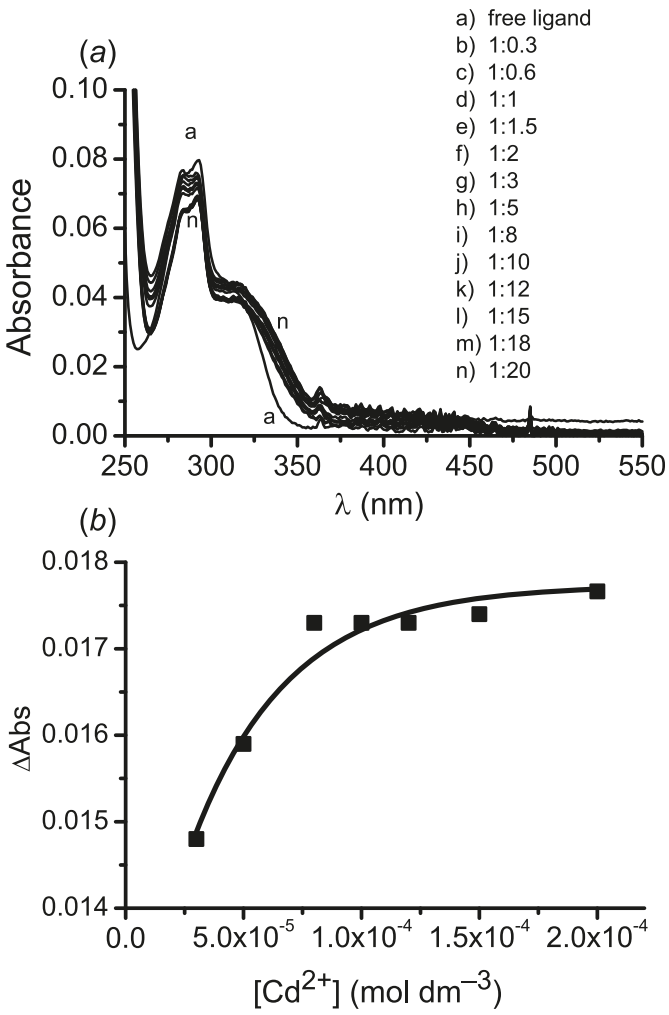
the fluorescence data according to the Stern–Volmer equation (eq. [3]),

$$[3] \qquad \frac{F_0}{F} = 1 + K_{11}[\mathrm{M}]$$

where F_0 = fluorescence in the absence of metal ion, F = fluorescence, and K_{11} = Stern–Volmer constant. Under the conditions of [M] >> [L], the plot of F_0/F vs [M] was linear, as shown in Fig. 5*b*, yielding K_{11} = 13.2 (±0.8) × 10^4 mol dm^{-3}. The equilibrium constant based on the Stern–Volmer plot is two times higher than that determined spectrophotometrically. Presumably, this constant should also involve additional contributions of outer sphere or collisional complexes generated with Hg^{2+} ions, which are effective in suppressing the fluorescence of the ligand, but leading to minor changes in the absorption spectra.

Similar experiments have been carried for Pb^{2+} ions, as shown in Figs. 6 and 7. The changes observed in the absorption and emission spectra, as a function of the amount of

Fig. 8. Titration of ligand **1** with Cd^{2+} in acetonitrile. (*a*) Evolution of the absorption spectrum as a function of Cd^{2+} concentrations. (*b*) Plot of ΔAbs, where ΔAbs is Absorbance – initial Absorbance, as a function of [Cd^{2+}] at λ = 350 nm, R^2 = 0.96.



Pb^{2+} ions, are very similar to those found in the case of the Hg^{2+} ions. The corresponding binding constants are collected in Table 1, for comparison purposes. In this case, however, a good agreement can be observed for the absorption and fluorescence data, indicating negligible quenching from the outer-sphere complexes.

In the case of the Cd^{2+} ions, the results shown in Figs. 8 and 9 depart from those observed for the Hg^{2+} and Pb^{2+} ions, and resemble those previously reported for Zn^{2+} ions. The estimated binding constants based on the spectrophotometric data were in the range of 11.6 × 10^4 to 13.8 × 10^4 mol dm^{-3}. The binding of the Cd^{2+} ions leads only to a partial quenching of the oxyquinoline emission at 392 nm, leading to a less intense emission band of the Cd^{2+}-coordinated species at 440 nm, as for the Zn^{2+} system.[12] In this case, the calculation of the equilibrium constant from the Stern–Volmer plots is no longer valid.

Conclusion

The fluoroionophore species **1** provides an interesting optical sensor for the determination of Hg^{2+}, Cd^{2+}, and Pb^{2+}

Abstract: The gypsy moth, *Lymantria dispar*, uses pheromones, such as (+)-disparlure, for communication. These pheromones are detected by the sensitive antennae of the male moth and travel through their aqueous environment to the sensory neuron, possibly with assistance from pheromone binding proteins (PBPs). The hydrophobicity of disparlure, which is of primary importance for its interactions with PBPs, can be measured by its partition coefficients. These coefficients for heptane/water and chloroform/water interfaces were obtained in this work experimentally and using molecular dynamics (MD) simulations. The agreement between the experimental and calculated values validates the choice of the force field parameters, which can thus be used in future MD simulations of the PBP–pheromone interactions.

Key words: gypsy moth, disparlure, partition coefficients, hydrophobicity, epoxide, OPLS parameters, molecular dynamics simulations.

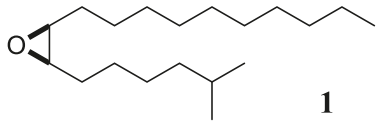
Résumé : La lymantride spongieuse, mite gitane, *Lymantria dispar*, fait appel à des phéromones, tel le (+)-disparlure, pour ses communications. Ces phéromones sont détectées par des antennes sensibles des lymantrides mâles et elles circulent dans leur environnement aqueux vers le neurone sensoriel, peut-être avec l'aide de protéines fixatrices de phéromones (PFP). Le caractère hydrophobe du disparlure qui est d'importance capitale pour ses interactions avec les PFP peut être mesuré par ses coefficients de partition. Dans ce travail, on a mesuré expérimentalement ces coefficients pour les systèmes heptane/eau et chloroforme/eau et on les a aussi calculés par la méthode de la dynamique moléculaire (DM). L'accord entre les valeurs calculées et celles obtenues expérimentalement valide le choix des paramètres de champ de force qui pourront être utilisés dans des simulations ultérieures de DM des interactions PFP/phéromone.

Mots-clés : lymantride spongieuse, disparlure, coefficients de partition, caractère hydrophobe, époxyde, paramètres des potentiels optimisés pour des simulations de liquides, simulations de dynamiques moléculaires.

[Traduit par la Rédaction]

Introduction

(7*R*,8*S*)-*cis*-7,8-Epoxy-2-methyloctadecane (**1**) is the main sex pheromone of the gypsy moth, *Lymantria dispar*.[1]



1

This pheromone, commonly known as (+)-disparlure, is released by the female moth and detected by the very sensitive antennae of the male. These antennae are covered with hollow sensory hairs, which contain the target olfactory nerve cells (see Fig. 1). The pheromone is thought to access the interior of the hair through a system of pore tubules.[2] Inside the hair is an aqueous protein-rich environment containing pheromone-binding proteins (PBPs),[3] one possible role of which is to transport hydrophobic molecules, such as disparlure, through the aqueous environment to the receptors of the olfactory nerve cell,[4] where the pheromone itself is believed to activate the receptors.[5] A study with expressed odorant receptors[6] has shown that the receptors can be activated by direct addition of pheromone to the incubation medium. In contrast, another recent study has proposed that a conformer of the PBP–pheromone complex plays a role in activating the receptor,[7] and other studies have suggested that the PBP–pheromone complex works in conjunction with the sensory neuron membrane protein in regulating the ion conductance of the olfactory nerve cell.[8]

The hydrophobicity of disparlure must be of primary importance in its interactions with PBPs. Experimental studies of these interactions and their kinetics have recently been reported.[9] Further insight could be achieved through molecular modeling and molecular dynamics (MD) simulations. With

Fig. 1. The suggested route[2] disparlure takes through the sensillum lymph on its way to the olfactory nerve. A moth antenna (A) is highly branched, and the branches are covered with sensory hairs (sensilla). The sensilla are hollow cuticular structures that are innervated by a few olfactory neurons (1 in panel B). The cuticle of the hair (4) is traversed by pores (5). The dendrite of an olfactory neuron (3) protrudes into the space of the hair and is bathed by an electrolyte, the sensillum lymph (panel C). The sensillum lymph contains the pheromone-binding protein (triangles) and ions (Na^+, K^+, Cl^-, phosphate). The dendritic membrane (8) houses the olfactory receptors (7) and the sensory neuron membrane protein (6). recent advances in computer technology, MD has become an excellent companion and a viable alternative to often costly and difficult experiments.[10] The quality of the MD results depends on the quality of the force field used in the simulations. The OPLS (optimized potentials for liquid simulations) force field[11] is often used to study reactions and processes in solutions. Unfortunately, to the best of our knowledge, the epoxy ring parameters have never been reported in the literature. In the present work we propose such parameters and test their quality in describing hydrophobic properties of disparlure. For that purpose, we have measured experimentally the partition coefficients of racemic disparlure at *n*-heptane/water and chloroform/water interfaces (*n*-heptane and chloroform were chosen because of their different hydrophobicities) and compared the experimental results with the MD values calculated using the augmented OPLS parameters.

Experimental procedures

Synthesis and purification of disparlure

Racemic disparlure, (±)-*cis*-7,8-epoxy-2-methyloctadecane, was prepared by *meta*-chloroperoxybenzoic acid epoxidation of (*Z*)-2-methyl-7-octadecene, which was obtained in 96:4 diastereoselectivity by partial hydrogenation of 2-methyl-7-octadecyne using Lindlar's catalyst under a hydrogen atmosphere. The 2-methyl-7-octadecyne was synthesized by an acetylide coupling reaction between 1-dodecyne and 1-bromo-5-methylhexane using *n*-butyllithium as a base and tetramethylethylenediamine as a co-solvent in tetrahydrofuran under gentle reflux. This three-step synthesis gave an overall yield of 17% (limiting reagent 1-bromo-5-methylhexane) with high *cis*-epoxide configuration (96%; see ^{1}H NMR spectra of (*Z*)-2-methyl-7-octadecene[12] and the racemic disparlure, Supplementary data). Also, the method avoided using carcinogenic hexamethylphosphoramide during the acetylide coupling reaction.

The *cis*- and *trans*-disparlure were easily distinguished by ^{1}H NMR. H-7 and H-8[13] of *cis*-disparlure showed a multiplet signal at δ 2.90 ppm, whereas in *trans*-disparlure these two methine protons gave a broad triplet at δ 2.38 ppm.[12] However, the signals of H-7 and H-8 of (*Z*)- and (*E*)-2-methyl-7-octadecene overlapped at δ 5.30 ppm[13] and therefore could not be used to distinguish these two isomers. The *Z* and *E* alkene isomers and the *cis* and *trans* disparlure isomers also ran at different retention times in gas chromatography with an SPB-5 (Supelco) column.

Determination of partition coefficients

The purest available organic solvent (2.00 mL heptane or chloroform, HPLC grade) and 2.00 mL of double-distilled water were pipetted into a 4 mL glass vial using 2.00 mL glass pipettes. The system was allowed to equilibrate for 20 min. Then 2.0 μL of purified racemic disparlure was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

added to the organic phase using a 10 μL glass syringe from a 50 mg mL^{-1} stock solution in distilled *n*-hexane. Once the disparlure was added, the vial was capped and the system was equilibrated for 30 min before a sample was extracted from each phase.[14] A portion (0.40 mL) of the organic phase was removed from the incubation mixture, using a 2.00 mL glass pipette, and added to a 1 mL glass vial with 4 μL of 1.3 mg mL^{-1} *n*-hexadecane in distilled *n*-hexane, as an internal standard, and ~10 mg Na_2SO_4. The internal standard was added to compensate for evaporation. It was allowed to dry for 1 min before the volume was measured using a 100 μL glass syringe. An aliquot (1 μL) of the organic sample was analyzed using gas chromatography mass spectrometry (GC-MS). Spectra were recorded on a Varian Saturn 2000 mass spectrometer coupled to a CP 300 gas chromatograph equipped with an SPB-5 GC column (Supelco, 30 m, 0.25 mm i.d., 0.25 μm film). MS conditions were as follows: collection period, 4–14 min; *m/z* range, 50–500; ionization mode, electron impact; ion preparation technique, selected ion storage (49–501 *m/z*). For analysis of the aqueous layer, 0.50 mL was retrieved from the aqueous phase of the incubation system with a 0.50 mL glass pipette. Internal standard (0.20 mL of 9.6 μg mL^{-1} *n*-hexadecane in distilled ethyl acetate/hexane (1:1)) was added to the extract in a silicon-coated glass vial, the vial was shaken, and the organic layer was removed using a 100 μL glass syringe (Hamilton). The extraction was repeated with another 0.20 mL of solvent with internal standard. The two organic phases were pooled and dried in a 1 mL glass vial with ~10 mg Na_2SO_4 for 1 min, and the volume was measured using a 100 μL glass syringe. An aliquot (1 μL) was analyzed using GC. All experiments were performed at 25 °C. The partition coefficient P was calculated as the ratio of the disparlure concentrations in organic solvent (C_s) and the aqueous phase (C_w): $P = C_s/C_w$.

Molecular dynamics calculations

MD simulations were performed using the GROMACS program suite[15] at a constant temperature of 298 K (Berendsen thermostat, $\tau_T = 0.01$ ps), a constant pressure of 100 kPa (Berendsen barostat, $\tau_P = 0.1$ ps), and periodic boundary conditions[10] for the systems containing a single molecule of disparlure in solvents that consisted of either 320 molecules of *n*-heptane, 375 molecules of chloroform, or 2500 molecules of water. The 1 ns MD trajectories were obtained by leap-frog integration with a step size of 1 fs. The total interaction energy of the system was calculated as the sum of five terms:[11]

$$[1] \quad U = U_{\text{bond}} + U_{\text{angle}} + U_{\text{torsion}} + U_{\text{Coulomb}} + U_{\text{LJ}}$$

The first three terms represent the intramolecular energy associated with bond stretching, angle bending, and torsions:

$$[2] \quad U_{\text{bond}} = \sum_{\text{bonds}} \frac{1}{2} k_r (r - r_0)^2$$

$$[3] \quad U_{\text{angle}} = \sum_{\text{angles}} \frac{1}{2} k_\theta (\theta - \theta_0)^2$$

$$U_{\text{torsions}} = \sum_{\text{dihedrals}} \sum_{n=0}^{3} C_n (\cos \phi)^n$$

No cross-terms were taken into account. The intermolecular and through-space intramolecular interactions were described by the pairwise Coulomb potential

$$[4] \quad U_{\text{Coulomb}} = \sum_{\text{atom pairs}} K \frac{q_i q_j}{r_{ij}}$$

representing charge–charge electrostatic interactions and the Lennard Jones (LJ) potential

$$[5] \quad U_{\text{LJ}} = \sum_{\text{atom pairs}} 4\varepsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{6} \right]$$

representing van der Waals interactions. Standard combination rules were used for the LJ parameters ε and σ:

$$[6] \quad \varepsilon_{ij} = \sqrt{\varepsilon_i \varepsilon_j}$$

$$[7] \quad \sigma_{ij} = \frac{1}{2}(\sigma_i + \sigma_j)$$

The particle mesh Ewald method[16] was used to calculate coulombic energy, with $r_{\text{coul}} = 1.4$ nm. The LJ cutoff radius was 1.4 nm.

OPLS parameters[11,17] were used for disparlure, *n*-heptane, and chloroform, and the SPC model[18] was used for water. The atomic, bond, and angle parameters for the epoxy group of disparlure were missing from the standard OPLS set and thus we augmented the set with the parameters listed in Table 1. The atomic (non-bonded) parameters for the epoxy group were assumed to be the same as the corresponding OPLS parameters for ether.[19] The values of r_0 and θ_0 were obtained by B3LYP/6-31G(d,p) geometry optimization using Gaussian 03.[20] The bond and angle force constants, k, as well as all torsion parameters were assumed to be the same as the OPLS parameters for cyclopropane.[19]

The Gibbs energies of solvation of disparlure in water (ΔG_w) and organic solvent (ΔG_s) were found by thermodynamic integration.[10] To avoid singularities at small values of the scaling parameter λ, the solvent–disparlure interaction U_{sd} was scaled as λ^n:[21]

$$[8] \quad U(\lambda) = U_{\text{solvent}} + U_{\text{disparlure}} + \lambda^n U_{\text{sd}}$$

For $n = 9$, the convergence was achieved with 40-point integration. Each point was obtained by averaging over a 1 ns trajectory. The partition coefficients P were then calculated as

$$[9] \quad P = \exp\left(\frac{\Delta G_w - \Delta G_s}{RT} \right)$$

Results and discussion

The values of the logarithms of the partition coefficients calculated for (+)-disparlure (**1**) at chloroform/water and *n*-heptane/water interfaces are compared with the experimentally obtained values in Table 2 and demonstrate a very good fit. As expected, disparlure appears to prefer *n*-heptane to chloroform, and either organic solvent to water. This is consistent with the structure of the pheromone, which is dominated

by two long hydrocarbon chains. However, the impact of the more polar epoxy group cannot be ignored. Thus, *n*-nonane, with fewer than half the number of carbon atoms of disparlure, appears to be much more hydrophobic, with a log P value at the chloroform/water interface of 6.57.[22]

The reported results validate the parameter set listed in Table 1 as a reliable tool for assessing the hydrophobic properties of disparlure. The high hydrophobicity of the pheromone seems to imply that PBPs may indeed play an important role in the transport of disparlure through the aqueous environment of the antenna lymph to the olfactory nerve dendrite. However, our preliminary calculations suggest that diffusion of disparlure in water is fast enough to allow the independent migration of this pheromone through aqueous medium, which is consistent with observations made with expressed receptors.[7] This result is in agreement with the experimental fact that the diffusion constants of such hydrophobic molecules as toluene, cyclohexane, and propene in dilute aqueous solutions are comparable to those of hydrophilic methanol.[23] Further experimental and computational studies are therefore needed to obtain a definitive answer to the question of disparlure transport and the role of PBPs in it.

Chemical bond and hardness of M-,W-type hexagonal barium ferrites

Zhiping Li and Faming Gao

Abstract: Using the chemical bond theory of dielectric description, the chemical bond parameters of the M-, W-type hexagonal barium ferrites were calculated. The hardness of $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$ were calculated. The calculated hardness of $BaFe_{12}O_{19}$ is 5.9 GPa, which is in agreement with the experimental values. The calculated hardness of planes parallel to the *c* axis of $BaFe_{18}O_{27}$ is 5.5 GPa, which is smaller than that of $BaFe_{12}O_{19}$.

PACS Nos: 62.20.Qp, 71.10.2w

Key words: bonding, hardness, ferrites.

Résumé : Faisant appel à la théorie de la liaison chimique de la description diélectrique, on a calculé les paramètres de la liaison chimique des ferrites de baryum de type-M et W. On a calculé la dureté du $BaFe_{12}O_{19}$ et du $BaFe_{18}O_{27}$. La dureté calculée du $BaFe_{12}O_{19}$ est de 5,9 GPa, qui est en accord avec les valeurs expérimentales. La dureté des plans parallèles à l'axe *c* du $BaFe_{18}O_{27}$ est de 5,5 GPa qui est inférieure à celle du $BaFe_{12}O_{19}$.

Mots-clés : liaison, dureté, ferrites.

Introduction

Ferrite materials are particularly excellent in wear resistance and chemical stability. Therefore, the protective layer on the surface of medium is dispensable, leading to a great advantage for high-density recording.[1–3] The best known of these structures is the hexagonal M structure of $BaFe_{12}O_{19}$, an isotype to the mineral magnetoplunbite, which is built up from the S block with a spinel structure and Ba^{2+} containing a R block perpendicular to the *c* axis and alternating in the *c* direction. The W-type hexaferrite $BaFe_{18}O_{27}$ has a structure that is closely related to that of M. The R block is identical to that in M, but the spinel block is thicker. This makes the Fe_2-W structure more complicated, resulting in seven nonequivalent sites for the Fe^{2+} and Fe^{3+} ions. To understand their high mechanical hardness and chemical stability, we studied the origin of their hardness by using chemical bond theory.

Theory and calculations

According to the chemical bond theory for complex crystals,[4,5] the "crystal formula," and is a combination of subformulas of chemical bonds. Because any chemical bond is binary, the bond subformula is therefore also binary, and Levine's[6] model may be reasonably applied to calculate these binary bond subformulas.

The subformula of any kind of chemical bond A–B in the multibond crystal $A_aB_bD_dG_g\ldots$ can be expressed by the following formula

$$[1] \qquad \left[\frac{N(\mathrm{B}-\mathrm{A})a}{N_{\mathrm{CA}}}\right]\mathrm{A}\left[\frac{N(\mathrm{A}-\mathrm{B})b}{N_{\mathrm{CB}}}\right]\mathrm{B}$$

where A, B, D, G,… represent different elements or different sites of the same element in the crystal formula, *a*, *b*, *d*, *g*,… represent numbers of the corresponding element, *N*(B–A) represents the number of B ions in the coordination group of the A ion, *N*(A–B) represents the number of A ions in the coordination group of the B ion, N_{CA} represents the nearest coordination number of the A ion, and N_{CB} represents the nearest coordination number of the B ion.

The macroscopic linear susceptibility χ can be resolved into the contributions χ^{μ} from the various types of bonds or from the various binary crystals

$$[2] \qquad \chi = \varepsilon - 1 = \sum_{\mu} F^{\mu}\chi^{\mu} = \sum_{\mu} N_{\mathrm{b}}^{\mu}\chi_{\mathrm{b}}^{\mu}$$

where ε is the dielectric constant, χ^{μ} is the total macroscopic susceptibility of a binary crystal composed of only one type of μ bond, F^{μ} is the fraction of the binary crystal composed within the actual crystal complex, χ_{b}^{μ} is the susceptibility of a single bond of type μ in the corresponding binary crystal, and N_{b}^{μ} is the number of bonds per cubic centimetre.

$$[3] \qquad \chi^{\mu} = (4\pi)^{-1}[(h\Omega_{\mathrm{p}}^{\mu})^2/(E_{\mathrm{g}}^{\mu})^2]$$

where E_{g}^{μ} is the average energy gap for the type μ bond, $\Omega_{\mathrm{p}}^{\mu}$ is the plasma frequency obtained from the numbers of valence electrons of type μ per cubic centimetre (N_{e}^{μ}), using

Fe(7)O(7)	12k	12k	0.933	2.023	7.781	9.054	0.425	9.089	33.038

Note: N_e^μ is the number of valence electrons of type μ per cubic centimetre, k_F^μ is the Fermi wavenumber of the valence electron, E_h^μ is the homopolar part of the average energy gap, C^μ is the heteropolar part of the average energy gap, f_c^μ is the covalency of a chemical bond, χ^μ is the total macroscopic susceptibility of a binary crystal composed of only one type of μ bond, and H_v^μ (in GPa) are the calculated Vickers hardness for pseudobinary crystals.

$$[4] \qquad (h\Omega_p^\mu)^2 = (4\Pi N_e^\mu e^2/m)D^\mu A^\mu$$

where D^μ and A^μ are the correction factors for the order of unity and m is the electron mass. N_e^μ is expressed as follows

$$[5] \qquad \begin{aligned} N_e^\mu &= (n_e^\mu)^*/v_b^\mu \\ (n_e^\mu)^* &= [(Z_A^\mu)^*/N_{CA}^\mu + (Z_B^\mu)^*/N_{CB}^\mu] \\ (k_F^\mu)^3 &= 3\Pi^2 N_e^\mu \end{aligned}$$

where $(n_e^\mu)^*$ is the number of effective valence electrons per μ bond, $(Z_A^\mu)^*$ is the number of effective valence electrons of the A ion, k_F^μ is the Fermi wavenumber of the valence electron, and v_b^μ is the bond volume,

$$[6] \qquad v_b^\mu = (d^\mu)^3/\sum_\nu [(d^\nu)^3 N_b^\nu]$$

where d^μ is the bond length. According to the Phillips – Van Vechten theory, the E_g^μ for every μ bond can be separated into homopolar (E_h^μ) and heteropolar (C^μ) parts.

$$[7] \qquad (E_g^\mu)^2 = (E_h^\mu)^2 + (C^\mu)^2$$

The ionicity and covalency of any type of chemical bond is defined as follows

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[8]\quad \begin{aligned} f_i^\mu &= (C^\mu)^2/(E_g^\mu)^2 \\ f_c^\mu &= (E_h^\mu)^2/(E_h^\mu)^2 \end{aligned}$$

where

$$[9]\quad E_h^\mu = 39.74/(d^\mu)^{2.48} \quad \text{(eV)}$$

For any binary crystal AB_n-type compounds, the heteropolar C^μ part is defined as

$$[10]\quad C^\mu = 14.4b^\mu[(Z_A^\mu) + \Delta Z_A^\mu - n(Z_B^\mu)]e^{-k_s^\mu r_0^\mu}/r_0^\mu \quad \text{(eV)}$$

where

$$[11]\quad \begin{aligned} r_0^\mu &= d^\mu/2 \\ k_s^\mu &= (4k_F^\mu/\Pi a_B)^{1/2} \end{aligned}$$

where a_B is the Bohr radius, n is the ratio of element B to element A in the subformula, ΔZ_A^μ is the correction factor for d electron effects such as the crystal field stable energy and the Janh–Teller effect, etc.,[7] and b^μ is proportional to the square of the average coordination number N_c^μ

$$[12]\quad \begin{aligned} b^\mu &= \beta(N_c^\mu)^2 \\ N_c^\mu &= N_{CA}^\mu/(1+n) + nN_{CB}^\mu/(1+n) \end{aligned}$$

where b^μ depends on a given crystal structure. If the dielectric constant of the crystal is known, the value of β can be deduced by using the above equations. The bond parameters of a crystal for which the dielectric constant is not known may also be estimated by using the β value of its isostructural crystals.

Results and discussion

The crystal structure data of $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$ are taken from refs. 8 and 9. In the hexagonal structure of $BaFe_{12}O_{19}$, the Fe^{3+} ions occupy five different crystallographic sites. Three of the Fe^{3+} sites are octahedral (12k, 4f2, and 2a), one is tetrahedral (4f1), and one is trigonal bipyramidal (2b). In the hexagonal structure of $BaFe_{18}O_{27}$, the Fe^{3+} ions occupy seven different crystallographic sites. According to their detailed structural data and eq. [1], we can write their bond-valence equations as

$$[13]\quad \begin{aligned} BaFe_{12}O_{19} &= BaFe(1)Fe(2)Fe(3)_2Fe(4)_2Fe(5)_6O(1)_2O(2)_2O(3)_3O(4)_6O(5)_6 \\ &= 1/2BaO(3)_{12/5} + 1/2BaO(5)_3 + Fe(1)O(4)_{3/2} + 2/5Fe(2)O(1)_{5/4} + \\ &\quad 3/5Fe(2)O(3) + 1/2Fe(3)O(2) + 3/2Fe(3)O(4) + Fe(4)O(3)_{6/5} + \\ &\quad Fe(4)O(5)_{3/2} + Fe(5)O(1)_{3/2} + Fe(5)O(2)_{3/2} + Fe(5)O(4)_{3/2} + Fe(5)O(5)_{3/2} \end{aligned}$$

$$\begin{aligned} BaFe_{18}O_{27} &= BaFe(1)Fe(2)_2Fe(3)_3Fe(4)_2Fe(5)_2Fe(6)_2Fe(7)_6O(1)_2O(2)_2O(3)_2O(4)_3O(5)_6O(6)_6O(7)_6 \\ &= 1/2BaO(4)_{12/5} + 1/2BaO(7)_3 + 2/5Fe(1)O(3)_{5/4} + 3/5Fe(1)O(4) + Fe(2)O(5)_{3/2} + \\ &\quad Fe(2)O(6)_{3/2} + Fe(3)O(2)_{3/2} + 2Fe(3)O(6)_{3/2} + 1/2Fe(4)O(1) + 3/2Fe(4)O(6) + \\ &\quad 1/2Fe(5)O(2) + 3/2Fe(5)O(5) + Fe(6)O(4)_{6/5} + Fe(6)O(7)_{3/2} + Fe(7)O(1)_{3/2} + \\ &\quad Fe(7)O(3)_{3/2} + 2Fe(7)O(5)_{3/2} + 2Fe(7)O(7)_{3/2} \end{aligned}$$

Using the $\beta = 0.097$ for the isostructrual crystal $LaMgAl_{11}O_{19}$,[10] the chemical bond parameters for each type of chemical bond were calculated, and are listed in Tables 1 and 2.

Using the obtained chemical bond parameters we can calculate the hardness of $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$ crystals. The average hardness H_v of complex crystals may be calculated by a geometric average of the hardness of the pseudobinary compound composed of a μ-type bond as follows:[10]

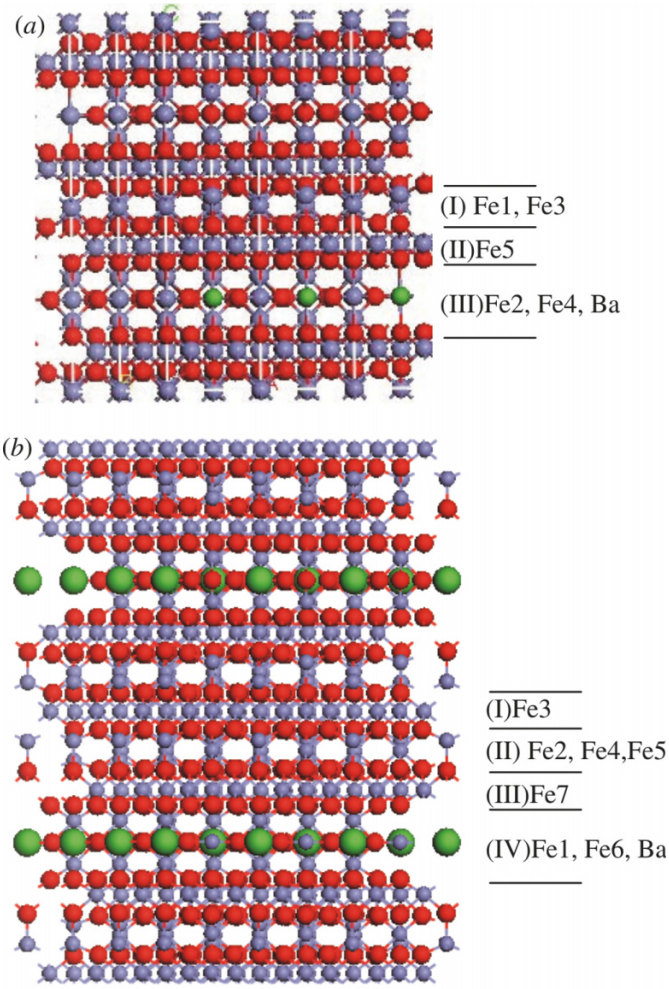
$$[14]\quad H_v = [\prod_{\mu}^{\mu}(H_v^\mu)^{n^\mu}]^{1/\Sigma n^\mu}$$

$$[15]\quad H_v^\mu = 350(N_e^\mu)^{2/3}e^{-1.191f_i^\mu}/(d^\mu)^{2.5}$$

where n^μ is the number of type-μ bonds within the actual crystal complex.

From Fig. 1, we observe the layer structure along the c axis in the $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$ crystals. There are three different bonding layers along the c axis in $BaFe_{12}O_{19}$: (I), (II), and (III). In the (I) layer, Fe(1) and Fe(3) are contained. Thus, the hardness of the (I) layer should equal the geometric average of the hardness of the pseudobinary compounds $Fe(1)O(4)_{3/2}$, Fe(2)O(3), Fe(3)O(2), and Fe(3)O(4). In the (II) layer, Fe(5) is only contained. The hardness of the (II) layer should equal the geometric average of the hardness of the pseudobinary compounds $Fe(5)O(1)_{3/2}$, $Fe(5)O(2)_{3/2}$, $Fe(5)O(4)_{3/2}$, and $Fe(5)O(5)_{3/2}$. In the (III) layer, there are Fe(2), Fe(4), and Ba ions. So the hardness of the (III) layer should equal the geometric average of the hardness of the pseudobinary compounds $BaO(3)_{12/5}$, $BaO(5)_3$, $Fe(2)O(1)_{5/4}$, Fe(2)O(3), $Fe(4)O(3)_{6/5}$, and $Fe(4)O(5)_{3/2}$. Using eq. [13], the calculated hardness of the (I) layer, (II) layer, and (III) layer areas are 27.1, 16.5, and 5.9 GPa, respectively. Therefore, the (III) layer area could be the easiest slip area, and plays a determinative role in the hardness of planes parallel to the c axis. In other words, the calculated hardness of planes parallel to the c axis of $BaFe_{12}O_{19}$ should be 5.9 GPa, which is in good agreement with the experimental value of 6.0 GPa.[3]

Fig. 1. (*a*) Crystal structure of $BaFe_{12}O_{19}$. (*b*) Crystal structure of $BaFe_{18}O_{27}$.



In $BaFe_{18}O_{27}$, there are four different bonding layers along the *c* axis: (I), (II), (III), and (IV). In the (I) layer, Fe(3) is only contained. Thus, the hardness of the (I) layer should equal the geometric average of the hardness of the pseudobinary compounds $Fe(3)O(2)_{3/2}$ and $Fe(3)O(6)_{3/2}$. In the (II) layer, Fe(2), Fe(4), and Fe(5) are contained. The hardness of the (II) layer should equal the geometric average of the hardness of pseudobinary compounds $Fe(2)O(5)_{3/2}$, $Fe(2)O(6)_{3/2}$, Fe(4)O(1), Fe(4)O(6), Fe(5)O(2), and Fe(5)O(5). In the (III) layer, Fe(7) is contained. The hardness of the (III) layer should equal the geometric average of the hardness of pseudobinary compounds $Fe(7)O(1)_{3/2}$, $Fe(7)O(3)_{3/2}$, $Fe(7)O(5)_{3/2}$, and $Fe(7)O(7)_{3/2}$. In the (IV) ayer, there are Fe(1), Fe(6), and Ba ions. So the hardness of the (IV) layer should equal the geometric average of the hardness of pseudobinary compounds $BaO(4)_{12/5}$, $BaO(7)_3$, $Fe(1)O(3)_{5/4}$, Fe(1)O(3), $Fe(6)O(4)_{6/5}$, and $Fe(6)O(7)_{3/2}$. Using eq. [13], the calculated hardness of the (I) layer, (II) layer, (III) layer, and (IV) layer areas are 15.0, 24.4, 17.7, and 5.5 GPa, respectively. Therefore, the (IV) layer area could be the easiest slip area, and plays a determinative role in the hardness of the planes parallel to the *c* axis. In other words, the calculated hardness of the planes parallel to the *c* axis of $BaFe_{18}O_{27}$ should be 5.5 GPa.

Conclusion

Using the chemical bond theory of dielectric description, the chemical bond parameters of M-, W-type hexagonal barium ferrites were calculated. The hardness of $BaFe_{12}O_{19}$ and $BaFe_{18}O_{27}$ were calculated. The calculated hardness of $BaFe_{12}O_{19}$ is 5.9 GPa, which is in agreement with the experimental value. The calculated hardness of the planes parallel to the *c* axis of $BaFe_{18}O_{27}$ is 5.5 GPa, which is less than that of $BaFe_{12}O_{19}$.

Postsynthetic modification of an imine-based microporous organic network

Phillip A. Kerneghan, Shira D. Halperin, David L. Bryce, and Kenneth E. Maly

Abstract: A highly cross-linked microporous organic network with imine linkers was prepared by condensation of tetrakis(4-aminophenyl)methane with terephthaldehyde. Gas adsorption studies indicate that the material exhibits permanent microporosity, and guest exchange experiments demonstrate that small molecules can diffuse into the network. Postsynthetic modification of this microporous network was achieved by treatment with borane in THF, which reduced the imine groups to the corresponding amines as shown by IR and ^{13}C CP-MAS solid-state NMR spectroscopy. The resulting material showed enhanced resistance to acidic hydrolysis compared with the imine precursor, and retained its ability to absorb guest molecules. The amine network was amenable to further postsynthetic modifications. Specifically, acetylation of this network using acetic anhydride was demonstrated.

Key words: imines, synthesis, microporous polymers, postsynthetic modification.

Résumé : On a préparé un réseau organique microporeux très réticulé à l'aide de coupleurs imines par condensation du tétrakis(4-aminophényl)méthane avec du téréphtaldéhyde. Des études d'adsorption de gaz indiquent que le matériau comporte une microporosité permanente alors que des expériences d'échange de molécule invitée démontrent que les petites molécules peuvent diffuser dans le réseau. On a réalisé des modifications postsynthétiques de ce réseau microporeux par un traitement avec du borane dans le THF qui a permis de réduire les groupes imines en amines correspondantes, tel que démontré par la spectroscopie infrarouge et la RMN du ^{13}C à l'état solide dans le mode de la rotation à l'angle magique avec polarisation croisée (RAM-PC). Le matériau qui en résulte présente une résistance accrue à l'hydrolyse acide par comparaison avec le précurseur imine et il conserve sa facilité à absorber des molécules invitées. Le réseau amine peut être amené à d'autres modifications postsynthétiques. On a démontré, en particulier, la possibilité d'acyler ce réseau à l'aide d'anhydride acétique.

Mots-clés : imines, synthèse, polymères microporeux, modification postsynthétique.

Introduction

Microporous solids are an important class of materials because their small pore sizes and high surface area make them potentially useful for chemical separation, catalysis, or gas storage.[1] Metal–organic frameworks (MOFs), which are crystalline three-dimensional coordination polymers, have been extensively studied, and show large surface areas and well-defined channels and pores.[2] In addition to coordination polymers, recent studies have focused on covalently linked microporous solids derived entirely from organic building blocks.[3] These materials, which include highly cross-linked polymers,[4] polymers of intrinsic microporosity (PIMs),[5] other amorphous polymers,[6] and covalent organic frameworks (COFs),[7] also exhibit large surface areas that make them potentially suitable for applications.

An important challenge in the field of microporous solids is the control of the properties of these materials, and, in particular, the incorporation of specific functional groups into the materials. The incorporation of any desired functionality into microporous solids often requires that desired groups be attached to the molecular building blocks prior to network formation and that these groups be compatible with the reaction conditions for network formation. An alternative strategy for incorporating desired functional groups involves covalent "postsynthetic" modification of the microporous material. Covalent postsynthetic modification of a porous coordination polymer was first reported by Seo et al.,[8] who showed that a network bearing uncoordinated and exposed pyridine groups could be methylated using iodomethane. More recently, Cohen and co-workers[9,10] demonstrated that covalent postsynthetic modification of MOFs can be used effectively to incorporate functionality into these microporous solids while maintaining a desired network topology. Similarly, postsynthetic modification of a permeable organic hydrogen-bonded network by reaction of thiols with exposed allyl groups has also been demonstrated.[11] Although postsynthetic modification of polymers such as polyolefins is well-established,[12] comparable postsynthetic transformations of organic microporous materials has not been reported, in part because many microporous polymers do not have the requisite functional groups for further reactions. In other cases, microporous

organic solids such as COFs are linked by readily hydrolyzed groups such as boroxines or boronates that make them sensitive to further synthetic transformations. Postsynthetic modification of microporous organic materials therefore requires networks that are robust enough to withstand further reaction conditions, as well as functional groups that are accessible to reagents that can diffuse into the porous network.

Recently, Yaghi and co-workers[7d] introduced a new class of COFs based on imine linking groups. Schwab et al.[13] also used Schiff base formation for the preparation of microporous polymer networks. The presence of imine groups as linkers for organic microporous materials presents a unique opportunity for postsynthetic modification of the organic framework by reduction of these imines to the corresponding amines. Although imines are susceptible to hydrolysis, the corresponding amine networks are expected to display increased chemical stability. Moreover, the amine groups provide a functional handle for further synthetic transformations. Such an approach could provide access to new microporous organic solids with diverse functionality and controllable properties. Herein we report the postsynthetic modification of an imine-based microporous network by reduction and show that it can produce a network with enhanced resistance to hydrolysis. We also demonstrate that the reduced network can undergo further synthetic transformations, such as acetylation of the amino groups.

Results and discussion

Imine network **1** was prepared as outlined in Scheme 1 using terephthaldehyde and tetrakis(4-aminophenyl)methane[14] under solvothermal conditions in a mixture of dioxane and aqueous acetic acid, as described by Yaghi and co-workers.[7d]

The formation of the imine network was confirmed by IR spectroscopy (Fig. 1) and ^{13}C CP-MAS solid-state NMR spectroscopy (Fig. 2); the results are consistent with the previously reported data[7d] as well as the spectroscopic data from model compounds (See Supplementary data). Further investigation by powder X-ray diffraction showed that in contrast to Yaghi's[7d] crystalline and multiply interpenetrated COF, network **1** diffracted very weakly, showing broad reflections consistent with largely amorphous material (see Supplementary data). Despite the amorphous nature of **1**, nitrogen adsorption studies showed a sharp uptake at low pressure, indicating that the material was indeed microporous (Fig. 3).

Fig. 2. ^{13}C CP-MAS spectra of imine network **1**, reduced network **2**, and acetylated network **3**. Signals marked with * indicate spinning side bands, and the two signals marked with # for the spectrum of **2** correspond to included THF.

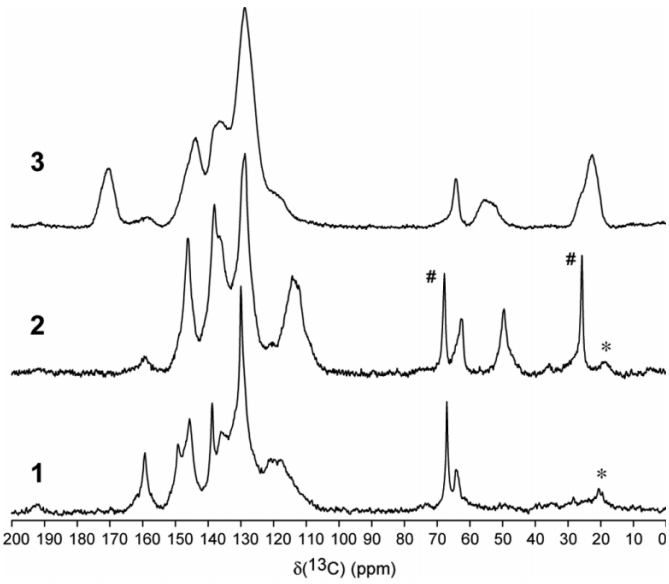

Fig. 3. Nitrogen adsorption isotherm for **1** measured at 77 K.

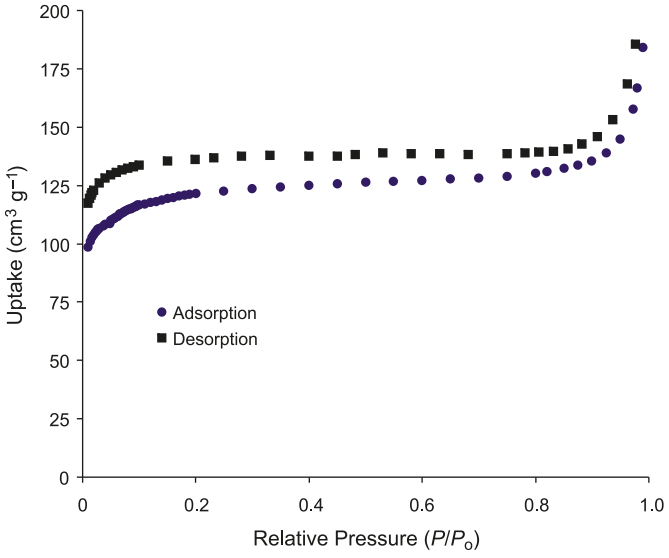
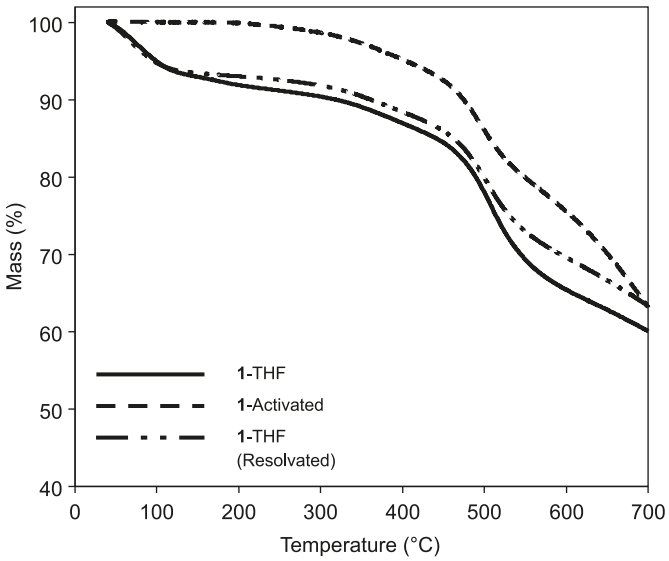


From the adsorption data, the Brunauer–Emmett–Teller (BET) surface area was determined to be 416 m^2/g. This value is significantly lower than that reported by Yaghi and co-workers (1360 m^2/g)[7d], but is comparable to some other microporous networks. We attribute these differences in the properties of our material compared with Yaghi's to the sensitivity of COF network formation to slight variations in the reaction conditions. It is noteworthy that some hysteresis is observed in comparing the adsorption and desorption isotherms. This observation is consistent with the results of Yaghi and co-workers[7d] and indicates some flexibility of the framework. Thermogravimetric analysis of **1** solvated with THF showed ~7% mass loss below 100 °C, corresponding to the loss of the solvent (Fig. 4), with substantial mass loss above 450 °C, corresponding to decomposition of the network.

Fig. 4. Thermogravimetric analysis traces of **1** with THF, activated, and resolvated with THF.



Subsequent activation by heating at 100 °C under vacuum overnight, followed by resolvation with THF showed a similar uptake compared with the original solvated network, providing further support for the porosity of the material and evidence that it can take up small molecules. Further solvent-exchange experiments and subsequent analysis by TGA showed that the guest molecules can be exchanged (see Supplementary data). These thermal analysis experiments demonstrate that **1** is permeable to guest molecules, and therefore may be suitable for postsynthetic modification by allowing reactants to diffuse into the porous network.

Network **1** was suspended in anhydrous THF and treated with an excess of borane–THF (Scheme 2). After standing for 24 h, the solid was collected and washed with water, followed by THF. The IR spectrum of **2** showed a substantial attenuation of the C=N stretching band at 1615 cm^{-1} and a concomitant increase in the N–H stretching band at ~3200 cm^{-1} (Fig. 1). These results are consistent with the reduction of the imine linkages of **1** to the corresponding amines. Further confirmation of the reduction was provided by ^{13}C CP-MAS spectroscopy, which showed a disappearance of the signal at 159 ppm and the appearance of a signal at 50 ppm, corresponding to the benzylic carbon of the reduced product (Fig. 2). Based on integration of the aromatic region and comparison with the remaining imine signal, the conversion is estimated to be ~83%. These chemical shifts are consistent with those of *N*-benzylideneaniline and the corresponding *N*-benzylaniline model compounds (see Supplementary data). These results, which show reduction of the imines, indicate that the reducing agent is able to penetrate the porous network and react with interior imine sites.

Nitrogen adsorption measurements on **2** show showed negligible uptake and gave a BET surface area of 10 m^2/g, indicating that the material no longer exhibited microporosity (see Supplementary data). We attribute this observation to the increased flexibility of the network upon reduction, allowing it to collapse upon evacuation. Thermogravimetric analysis showed that reduced network **2** shows comparable thermal stability to **1** with substantial decomposition at

Scheme 2.

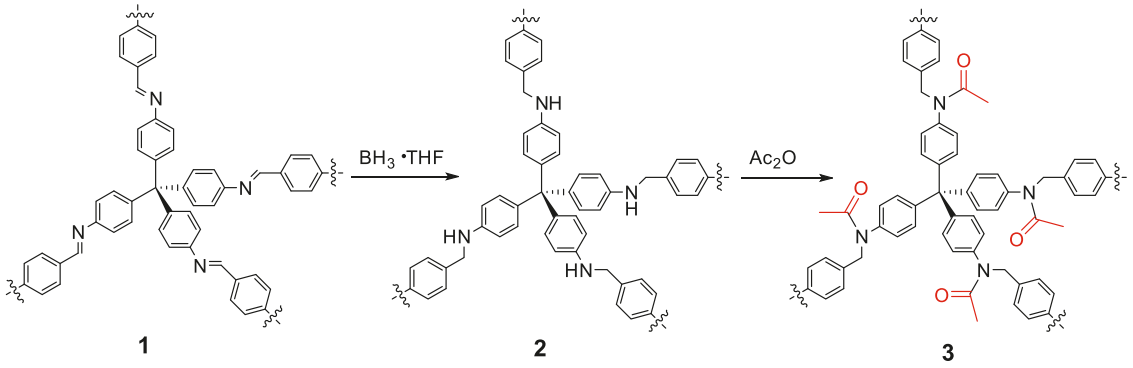


Fig. 5. Thermogravimetric analysis traces of **2** with THF, activated, and resolvated with THF.

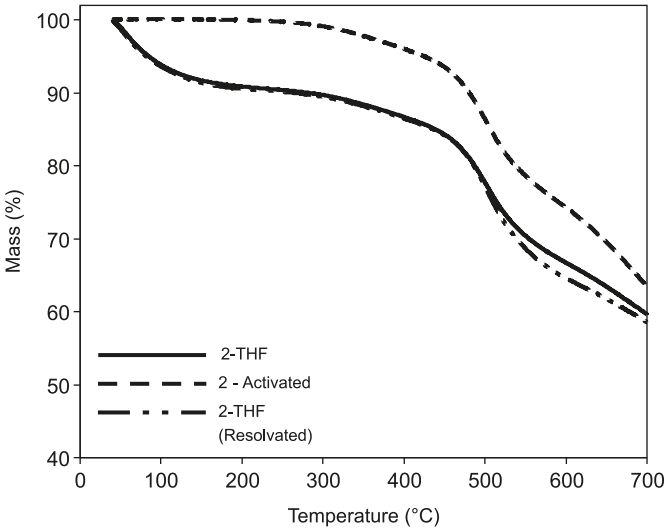

temperatures >400 °C. Activation resulted in complete loss of solvent, as demonstrated by TGA, and subsequent resolvation showed solvent uptake very similar to the original solvated material, suggesting that although **2** does not exhibit permanent microporosity, it retains its ability to uptake guest molecules (Fig. 5). The stability of networks **1** and **2** to acidic hydrolysis was evaluated by heating at reflux in 2 mol/L HCl. Imine network **1** is readily hydrolyzed to its corresponding starting materials, as shown by dissolution of the material after only a few minutes of gentle heating. In contrast, network **2** remained insoluble after heating at reflux for 3 h.

The IR spectrum of the material recovered after acid digestion of **2** shows a very broad N–H stretching band that is characteristic of ammonium salts (see Supplementary data), suggesting that **2** has been protonated and that these materials may ultimately be used to prepare novel permeable ionic networks.

The amine groups present in **2** not only increase the chemical stability of the network, but also provide an opportunity for further synthetic transformations. To demonstrate that subsequent postsynthetic transformations are possible, we decided to explore acetylation using acetic anhydride. Network **2** was immersed in acetic anhydride, and allowed to stand at room temperature overnight to ensure complete exchange of the solvent for acetic anhydride. The reaction mixture was subsequently heated at 100 °C in a sealed tube for 24 h. After cooling to room temperature, the solid was collected by filtration and washed thoroughly with THF to yield acetylated network **3**. Evidence for acetylation was provided by IR spectroscopy, which showed a substantial decrease in the intensity of the N–H stretching band and the appearance of a band at 1658 cm^{-1}, which is consistent with the amide C=O stretching. It is noteworthy that the observed C=O stretching is not consistent with the absorbance bands of either acetic acid (1714 cm^{-1}) or remaining acetic anhydride (1755 cm^{-1}), providing evidence for amide formation. The ^{13}C CP-MAS NMR spectrum of **3** shows a change in the aromatic region of the spectrum, as well as the diagnostic appearance of two new signals at 22 and 170 ppm, which are consistent with the incorporation of acetamide methyl and carbonyl carbons, respectively, into the structure. Indeed, these signals are consistent with the solution ^{13}C NMR spectrum of model compound *N*-benzyl-*N*-phenylacetamide (see Supplementary data.)

In summary, we have demonstrated postsynthetic modification of a microporous organic network for the first time. Network **2**, prepared by reduction of imine **1**, loses its permanent microporosity, presumably because the framework is more flexible and collapses upon removal of guests. However, **2** retains high thermal stability and the ability to uptake guest molecules, and also shows enhanced resistance to acid hydrolysis, suggesting that this may ultimately provide a route to more chemically robust microporous organic solids. In addition, we have shown that further synthetic transformations are possible, which may offer an approach for preparing new microporous organic solids with controlled properties for potential applications in gas storage, molecular separations, and heterogeneous catalysis.

Experimental

General

All starting materials and solvents were obtained from commercial sources and used without purification, unless otherwise specified. Anhydrous and oxygen-free THF was dispensed from a custom-built solvent purifier that used purification columns packed with activated alumina and supported copper catalyst (Glasscontour, Irvine, California). Tetrakis(4-aminophenyl)methane was prepared according to published procedures and recrystallized from DMSO–H_2O prior to use,[14] and terephthaldehyde (99%) was purchased

from Sigma-Aldrich and recrystallized from water prior to use. IR spectra were recorded as KBr disks using a PerkinElmer Spectrum BX FT-IR spectrometer.

Samples for ^{13}C CP-MAS NMR spectroscopy were ground into fine powders and packed into 4 mm o.d. zirconia rotors. NMR spectra were acquired with high-power proton decoupling at 9.4 T ($\nu_0(^{13}C)$ = 100.6 MHz) using a Bruker Avance III console and a 4 mm triple-resonance Bruker MAS NMR probe. The magic angle was set by maximizing the number of rotational echoes in a ^{79}Br MAS NMR experiment on powdered KBr. Carbon-13 CP-MAS NMR pulse calibrations and chemical shift referencing were performed using adamantane (δ = 38.55 ppm for the high-frequency peak, relative to the primary standard TMS). Ninety degree ^1H pulse widths were 3.45 μs, contact pulses were 1.5 or 2.0 ms, acquisition times were 40–50 ms, and recycle delays were 20–50 s. Approximately 1000 to 2000 scans were averaged for each of the COF samples. MAS rates were chosen to eliminate the overlap of spinning sidebands with resonances of interest, and ranged from 11 111 to 13 600 Hz. FIDs were processed with zero-filling, 15–20 Hz exponential apodization, and Fourier transformation.

Gas adsorption isotherms were measured volumetrically using a Micromeritics ASAP 2010 automated adsorption analyzer. Samples were degassed at room temperature for 7 h prior to measurement. A liquid nitrogen bath (77 K) was used for the N_2 isotherms. The N_2 gas used was UHP grade. Brunauer–Emmett–Teller (BET) method was used to determine the specific surface areas (ABET, $m^2\ g^{-1}$) using the adsorption data over 0.05–0.20 relative pressure (P/P_0).

Synthesis of network 1[7d]

A pyrex glass tube with a 6 mm i.d. and an 8 mm o.d. was charged with tetrakis(4-aminophenyl)methane (20 mg, 0.052 mmol), terephthaldehyde (12 mg, 0.089 mmol), and a mixture of dioxane (0.8 mL) and 2 mol/L AcOH (0.2 mL). The tube was flash-frozen in liquid nitrogen, evacuated to a pressure of 150 mTorr (1 Torr = 133.322 Pa), and flame-sealed at a length of 12 cm. The contents of the tube were allowed to warm to room temperature and then heated at 100 °C for 72 h. The yellow solid formed was collected via filtration and washed repeatedly with THF. The yellow precipitate was collected and dried under vacuum at 100 °C for 24 h to evacuate the pores of all solvent guest molecules. Yield: 48 mg.

Synthesis of network 2

An oven-dried flask was charged with **1** (104 mg) and purged with N_2(g) for 15 min. Borane–THF (15 mL, 1 mol/L) was then added to the flask and the mixture was allowed to stir for 24 h at room temperature. The solid was collected by filtration and washed with THF to yield 97 mg of **2** as a beige solid.

Synthesis of network 3

Network **2** (96 mg) was submerged in Ac_2O for 18 h to allow Ac_2O to exchange into the pores of the network. This mixture was then placed into a sealed glass tube, heated to 100 °C, and stirred for 24 h. The solid was collected via filtration, washed with THF, and submerged in THF for 24 h to remove any remaining Ac_2O. The solid was collected via filtration and washed with THF to give **3** (109 mg) as a beige solid.

Supplementary data

Supplementary data (synthesis and characterization, details of spectroscopic characterization, powder X-ray diffraction studies, characterization of model compounds, and representative thermogravimetric analysis) are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: Copper and chromium oxide nanocomposite materials with different Cu/Cr ratios were prepared by impregnation of a conventional silica support with toluene solutions of the corresponding acetylacetonate precursors and characterized by X-ray diffraction, Fourier transform infrared spectroscopy, UV–vis spectroscopy, X-ray photoelectron spectroscopy, and temperature-programmed reduction–thermogravimetric methods. Their catalytic behaviour in the total oxidation of CO and different oxygenate VOCs (methanol, dimethyl ether, and ethyl acetate) was tested. The relation between the phase composition and catalytic properties of the materials was also analyzed. It was established that materials with a 1:2 CuO/Cr_2O_3 molar ratio exhibit high catalytic activity for dimethyl ether oxidation, those with 2:1 and 1:1 ratios are suitable for CO and methanol oxidation, respectively, and both of the latter, but at much higher temperatures, are good for ethyl acetate elimination. A catalyst with an optimal composition of 1:1 (mol/mol) CuO/Cr_2O_3, working in a reactor with three temperature zones of 490–500 K, 570–580 K, and 620–630 K, is proposed for the effective simultaneous elimination of CO, methanol, ethyl acetate, and dimethyl ether in toxic emissions.

Key words: copper chromium oxide nanocomposites, total oxidation, CO, methanol, dimethyl ether, ethyl acetate.

Résumé : On a préparé des matériaux nanocomposites d'oxydes de cuivre et de chrome, avec divers rapports Cu/Cr, en procédant à l'imprégnation d'un support de silice conventionnel avec une solution de toluène des précurseurs acétylacétonates correspondants et on les a caractérisés par des méthodes de diffraction des rayons-X, de spectroscopie infrarouge à transformée de Fourier, UV-visible, de spectroscopie photoélectronique des rayons-X et par thermogravimétrie par réduction thermoprogrammée. On a évalué leur comportement catalytique pour l'oxydation totale du CO et de divers composés organiques volatils oxygénés (méthanol, oxyde de diméthyle, acétate de méthyle). On discute de la relation entre la composition de la phase et les propriétés catalytiques des échantillons. Il a été établi que les matériaux comportant un rapport molaire de 1 : 2 de CuO/Cr_2O_3 présentent l'activité catalytique la plus élevée pour l'oxydation de l'oxyde de diméthyle et que ceux avec des rapports de 2 : 1 et 1 : 1 sont appropriés pour l'oxydation respectivement du CO et du méthanol alors que les deux sont bons, à des températures beaucoup plus élevées, pour l'élimination de l'acétate d'éthyle. Pour l'élimination simultanée efficace du CO, du méthanol et de l'acétate d'éthyle d'émissions toxiques, on propose l'utilisation du catalyseur de composition optimale, avec un rapport molaire de 1 : 1 de CuO/Cr_2O_3, opérant dans un réacteur comportant trois zones de température à 490–500 K, 570–580 K et 620–630 K.

Mots-clés : nanocomposites d'oxydes de cuivre et de chrome, oxydation totale, CO, méthanol, oxyde de diméthyle, acétate d'éthyle.

[Traduit par la Rédaction]

Introduction

In the last decades, CO and volatile organic compounds (VOCs), generally emitted from automotive devices and a variety of industrial processes, have been a subject of strong monitoring and legislation. Catalytic incineration has been reported as one of the most appropriate methods for their elimination, but the development of highly effective catalysts for stationary and mobile installations is still a matter of intensive investigation.[1–6] This problem is more complicated by the fact that real emissions are often a mixture of different toxic compounds (CO, alcohols, aldehydes, esters, ethers, hydrocarbons etc.). Noble metals have been reported as typical catalysts for VOC elimination, but they are costly and have low stability in the presence of chloride compounds. Transition metal oxide materials are a cheaper alternative to noble metals and recently much attention has been paid to the development of supported catalysts, using a paired metal oxide system as the active ingredient.[7] The possibility of specific interaction between the loaded metal oxides as well as between them and the support provides a great potential for development of materials with tunable composition and variable catalytic properties. A copper and chromium oxide combination has been considered one of the most effective

non-precious metal catalysts for CO oxidation,[8–12] but its behaviour in VOC incineration is less studied.[11,13,14] Moreover, the mechanism of the catalytic processes and the role of different active ingredients have often been subjects of intensive discussion. The Mars–van Krevelen mechanism, including release of oxygen from the metal oxide lattice and its further recovery from the oxidized agent,[15] is usually reported for hydrocarbon oxidation, while both the Langmuir–Hinshelwood mechanism, involving adsorption of CO molecules and oxygen atoms,[9,16] and the Mars–van Krevelen mechanism[17,18] have been discussed for CO oxidation. For monocomponent chromium materials supported on silica, formation of surface-grafted chromium-containing species as well as crystalline Cr_2O_3 has been observed.[19] Higher catalytic activity in total oxidation of organic compounds has been reported for the latter. It was assumed that the complete oxidation of ethyl acetate is determined by the efficiency of the redox cycle of surface Cr(III) → Cr(IV) ions.[20] For monocomponent copper oxide materials supported on silica, higher catalytic activity for methane oxidation was observed for isolated copper species than for interacting copper species.[21] In the case of bi-component copper–chromium materials, copper species are usually reported as the main active centers for CO oxidation, while the role of chromium is thought to be limited copper reduction via formation of $CuCr_2O_4$.[22] It was reported also that Cu(II) species and higher chromium content in copper–chromium materials favour deep oxidation of methanol to CO_2, while metallic Cu generates active sites for the partial oxidation of methanol.[14] In contrast, a decrease in the rate of CO oxidation with increasing copper oxidation state was found in other studies.[9,23,24] A mechanism of CO oxidation where the catalyst surface was considered as a thin layer of Cu_2O and oxygen vacancies, allowing CO adsorption on exposed Cu(I) sites or on the Cu_2O/Cu interface, was proposed.[16] Formation of a mixture of CuO, $CuCr_2O_4$, and $Cu_2Cr_2O_4$ compounds was considered for catalysts with higher activity in CO and propene oxidation.[11,12] Higher catalytic activity of $CuCr_2O_4$ in comparison with CuO in CO oxidation has also been demonstrated.[9] The observed synergetic effect of copper–chromium systems during CO oxidation has been associated with facilitated electron transfer between the components with stabilization of Cr(VI) and Cu(I) ions[25] and with increased metal oxide dispersion via formation of mixed copper–chromium oxides.[11] It was also suggested that chromium particles suppress copper aggregation by acting as a barrier between the copper particles ("barrier restricting" effect).[25]

The aim of the present paper is to investigate the effect of the composition of copper and chromium oxide nanocomposites supported on conventional silica on their catalytic behaviour in the total oxidation of CO and various oxygenate VOCs (alcohols, ethers, esters). CO, methanol, and dimethyl ether (DME) are used as model compounds, as they are the most important pollutants emitted during formaline production. For comparison, oxidation of ethyl acetate, which is a typically emitted pollutant in the printing industry and generally reported as one of the most difficult to oxidize among VOCs, is also studied. Special attention is paid to optimization of the catalyst composition for the simultaneous elimination of a mixture of different model pollutants.

Experimental

Materials

Conventional SiO_2 (Cab-O-sil M-5, Aldrich) with a BET surface area of 202 m^2/g was used as a support. Copper (Cu/silica) and chromium (Cr/silica) oxides were loaded using the incipient wetness impregnation technique from the corresponding acetylacetonate precursors in toluene. Bi-component materials were prepared by simultaneous deposition of precursors in the desired ratio using the same procedure. After impregnation the samples were dried and the precursors were decomposed in air at 773 K for 2 h. Samples with a total metal oxide loading of 10 wt % were prepared. The CuO/Cr_2O_3 molar ratio in bi-component materials was 1:1 for 1Cu1Cr/silica, 1:2 for 1Cu2Cr/silica, and 2:1 for 2Cu1Cr/silica.

Methods of investigation

Powder X-ray diffraction (XRD) was carried out on a STADI P diffractometer (STOE & Cie GmbH) configured in transmission geometry and equipped with a germanium primary monochromator (Johann-type) and a linear position sensitive detector (Cu $K\alpha_1$ radiation, 40 kV, 30 mA). For data processing the software WinX^{POW} v. 1.10 (STOE & Cie GmbH) was used. The UV–vis spectra were recorded on the powder samples using a PerkinElmer Lambda 900 UV/VIS/NIR spectrometer equipped with a diffuse reflectance unit. X-ray photoelectron spectroscopy (XPS) measurements were performed with a Physical Electronics Quantum 2000 instrument equipped with a monochromatic Al Kα X-ray source. An operating power of 25 W was used with a spot diameter of 100 μm. An electron flood gun and a low-energy ion gun were used for charge compensation. The detector was positioned at an angle of 45° in relation to the sample surface. The low and high resolutions of pass energy in spectral acquisition were 117.4 and 23.5 eV, respectively. Surface concentrations were determined with MultiPak 6.1 software (Physical Electronics), using peak areas to give surface concentrations in atom percent. The binding energies were referenced to that of the Si 2p signal of silica at 103.5 eV. In Ar^+ ion sputtering, a focused beam with a current of 50 μA, a raster area of 2 mm × 2 mm, and an acceleration voltage of 4 kV was used.

The TPR–TG (temperature-programmed reduction–thermogravimetric) analyses were performed in a Setaram TG92 instrument. Typically, 40 mg of the sample was placed in a microbalance crucible and heated in a flow of 50 vol % H_2 in Ar (100 cm^3/min) up to 773 K at 5 K/min with a final hold of 1 h.

Catalytic experiments

CO, DME, and methanol oxidation was studied under isothermal conditions using 0.5 mL catalyst diluted with 0.5 mL pumice. A flow mixture of 2.0 wt % CO in air, flow velocity of 20 000 h^{-1}, and contact time of 0.18 s were used in CO oxidation experiments. A mixture of 1 wt % DME in air, flow velocity of 20 000 h^{-1}, and contact time of 0.18 s were used in DME oxidation experiments. For methanol oxidation experiments, 2 wt % methanol in air, a flow velocity of 20 000 h^{-1}, and a contact time of 0.18 s were used. Ethyl acetate oxidation was performed with 0.5 mL catalyst and a

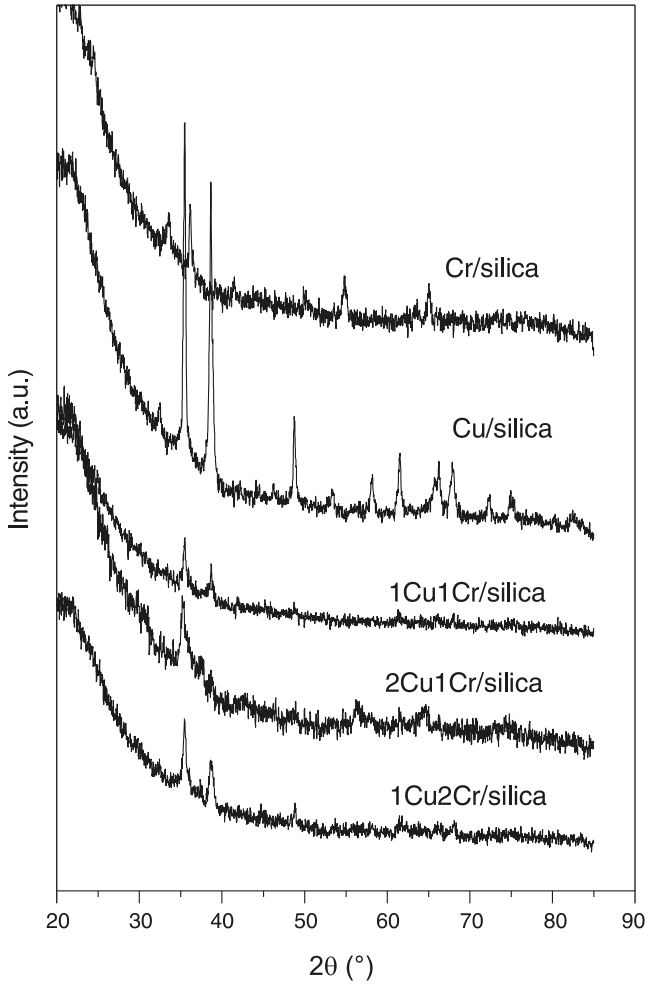
Fig. 1. XRD patterns of copper- and chromium-modified silica.



mixture of 1.21 wt % ethyl acetate in air under an isothermal or temperature-programmed regime.

Before the catalytic experiments the samples were pretreated in air at 773 K for 2 h. Gas chromatography analyses were done on a Varian 3700 apparatus using carbon-based calibration. The activation energy was determined using the Arrhenius equation. According to this equation, the slope of a plot of $\ln k$ versus $1/T$ is $-E_a/R$, where k is the rate constant, E_a is the activation energy, R is the ideal gas constant, and T is the temperature.

Results and discussion

Physicochemical characterization

In Fig. 1 are presented XRD patterns for all modified silica materials, and the corresponding data of phase composition are listed in Table 1. In the case of monocomponent materials, intense and well-defined reflections of CuO (powder diffraction file (PDF) 80-0076) are registered in the XRD pattern of Cu/silica, while wider and less intense reflections corresponding to Cr_2O_3 (PDF 85-0730) are observed in the case of Cr/silica. The average particle size, calculated by Scherer formulae, is about 35 and 26 nm for Cu/silica and Cr/silica, respectively, indicating relatively high dispersion of the loaded metal oxide nanoparticles. A mixture of CuO and

Table 1. XRD data for all copper and chromium modifications, including phase composition, average particle size (D), and relative proportion of each component.

Sample	Phase composition	D (nm)	wt %
Cu/silica	CuO	35	100
Cr/silica	Cr_2O_3	26	100
1Cu1Cr/silica	CuO	17	79
	Cr_2O_3	11	21
2Cu1Cr/silica	CuO	16	17
	$CuCr_2O_4$	12	83
1Cu2Cr/silica	CuO	15	44
	Cr_2O_3	12	56

Cr_2O_3 metal oxide phases is registered for 1Cu1Cr/silica and 1Cu2Cr/silica. We should point out the increased metal oxide dispersion in both cases in comparison with the corresponding monocomponent samples (Table 1). It is interesting to mention also the higher CuO/Cr_2O_3 ratio elucidated on the basis of XRD reflections as compared with the expected ratio (see Experimental section). We ascribe this observation to the formation of copper- and chromium-containing species with higher dispersion, which could not be detected by the XRD method. The phase composition of the sample with higher copper content (2Cu1Cr/silica) differs significantly from that of the other bi-component materials (Table 1). Here a new $CuCr_2O_4$ phase (PDF 88-0110) with an average particle size of about 12 nm is predominantly registered.

To describe the loaded metal oxide species more precisely, various spectroscopic methods were applied. Fourier transform infrared spectra of all modifications represent all absorption bands typical of silica skeletons (not shown). The intense broad band centered at about 3400 cm^{-1} is typically assigned to hydrogen-bonded vicinal pairs of silanol groups.[26] The decrease in the intensity of this band for modified materials in comparison with the parent ones indicates the existence of interactions between the loaded metal oxide species and the surface silanol groups. The high intensity of the band at about 1050 cm^{-1}, which is more pronounced in the case of Cr/silica and 1Cu2Cr/silica samples, is probably due to stretching vibrations of the terminal Cr=O group in polymeric hexavalent chromia species.[25] The bands at 571 and 624 cm^{-1} in the spectra of Cr/silica could be ascribed to crystalline Cr_2O_3 nanoparticles.[27] The relatively high intensity of the band at about 600 cm^{-1} for Cr/silica and the broadening of this band for the bi-component materials could be due to the presence of amorphous, highly dispersed Cr_2O_3 species,[27] which seem to be more abundant in the case of the latter materials.

The presence of various chromium-containing species is also confirmed by XPS spectra. The Cr $2p_{3/2}$ peaks in the spectra (the one for 1Cu1Cr/silica is presented in Fig. 2*a*) could be fitted to two components with binding energies of approximately 576.3 and 579.6 eV, which generally are attributed to Cr(III)- and Cr(VI)-containing species, respectively.[19,28–32] At the same time, the Cu $2p_{3/2}$ peak (Fig. 2*b*) is positioned at about 933 eV, with a shake-up satellite peak between ~940–945 eV and ~960–965 eV, which could be attributed to Cu(II) ions in different environments.[14,33]

Selected UV–vis spectra of copper- and chromium-modified

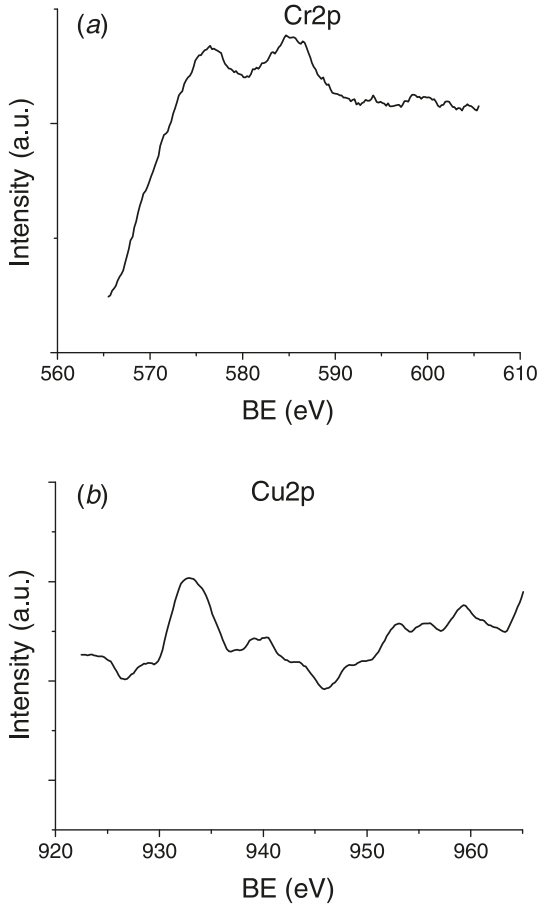

Fig. 3. UV–vis spectra of selected copper- and chromium-modified silica materials. *R*, reflectance.

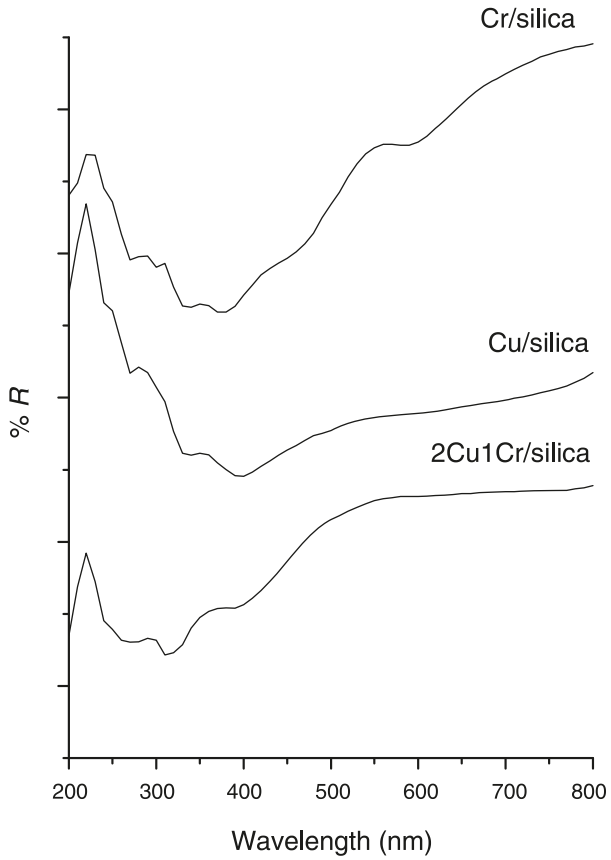

silica materials are shown in Fig. 3. The spectrum of Cr/silica presents bands at approximately 260–280, 370–380, and 470 nm, which could be assigned to O → Cr(VI) charge transfer (CT) in mono- and polychromate species, respectively.[30,34–37] The absorption at about 300, 450, and 600 nm is generally ascribed to transitions of Cr(III) ions in octahedral coordination in Cr_2O_3.[34–37] The spectrum of Cu/silica consists of absorption bands in the 230–265 nm and 330–390 nm regions. The first band could be attributed to CT transitions between surface oxygen and isolated Cu(II) ions and the second one originates from Cu-O-Cu clusters in a highly dispersed state.[38] The broad band centered at 670–750 nm is usually assigned to d-d transitions of Cu(II) in octahedral coordination in CuO.[38] The spectra of bi-component materials represent superposition of the spectra of both monocomponent materials. Taking into account the XRD data (see above), we ascribe the observed increase of absorption at about 270 nm and 330 nm for all bi-component materials to the formation of highly dispersed chromium- and copper-containing species, probably interacting with each other.[38]

Temperature-programmed reduction–differential thermogravimetric (TPR–DTG) profiles of all copper- and chromium-modified silica materials are presented in Fig. 4. The main reduction peak for Cu/silica is centered at 484 K and the registered mass loss corresponds to about 68% reduction of CuO to Cu. In agreement with the UV–vis data, the observed result could be attributed to the presence of finely dispersed, difficult to reduce copper oxide species strongly interacting with the silica support. In comparison, no significant mass loss was observed for the Cr/silica sample, indicating negligible reduction transformations of the active ingredient in this case, most probably due to the predominant presence of Cr_2O_3 nanocrystallites. The TPR profiles for all bi-component materials are characterized by broader reduction peaks, and in some cases these peaks are shifted to higher temperatures. A new high-temperature peak at about 656 K is registered in the case of the 2Cu1Cr/silica sample. At the same time, the observed mass loss for all bi-component materials is about 15%–22% lower than that expected for the corresponding mechanical mixtures of bulk copper and chromium oxides. In accordance with the spectroscopic and XRD data (see above), we assign this effect to increased dispersion of copper and chromium species and to step-wise reduction of $CuCr_2O_4$ species.[11,12]

Catalytic study

CO oxidation

Data for CO oxidation on various samples with increasing temperature are presented in Fig. 5*a*. All modifications exhibit catalytic activity above 423 K and CO_2 is the only registered carbon-containing product in the whole investigated temperature interval. Higher catalytic activity is observed for the monocomponent copper modification than for the chromium one. Among the bi-component materials, higher activity is registered only for the 2Cu1Cr/silica sample, where the

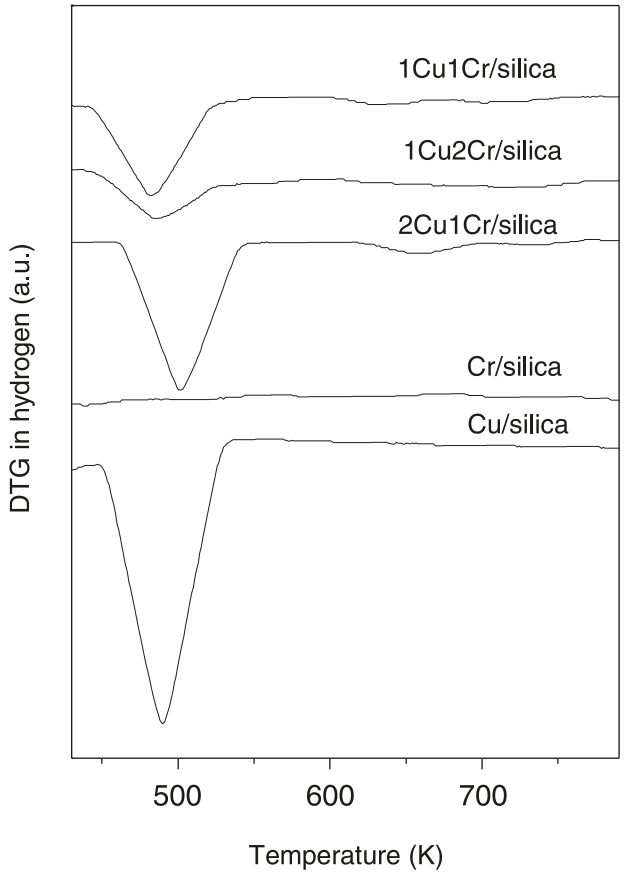
Fig. 4. TPR–DTG profiles of copper and chromium oxide modifications.



conversion curve is shifted to the lower temperatures by about 50 K in comparison with that of Cu/silica. These observations are supported by the calculated turnover frequency (TOF) values (Table 2), as the highest TOF was found for 2Cu1Cr/silica. We should also emphasize the lower values of the activation energy (E_a) for this sample (5 kcal/mol) in comparison with Cu/silica (9 kcal/mol), which could be attributed to the presence of different catalytic active sites in these materials. In accordance with the XRD data (Table 1, Fig. 1), the observed higher activity of 2Cu1Cr/silica is probably due to the formation of $CuCr_2O_4$ spinel nanoparticles, and this assumption correlates well with the data reported in other studies.[9,12] On the other hand, it seems that the increased dispersion of copper and chromium oxide nanoparticles, which is observed mainly for 1Cu2Cr/silica and 1Cu1Cr/silica, does not significantly improve the catalytic activity (Table 2). Taking into account the TPR–DTG data (Fig. 4), we suggest that the formation of Cu(I) ions, stabilized in a $Cu_xCr_yO_4$ spinel structure, facilitates the catalytic process via better CO adsorption.[24]

Methanol oxidation

Figure 5*b* illustrates total oxidation of methanol under the same experimental conditions. Here, the catalytic activity was observed above 473–523 K and again CO_2 is the only registered product. Copper and chromium monocomponent materials exhibit similar but lower catalytic activity in comparison with all bi-component materials. We draw attention to the high activity of 1Cu1Cr/silica. Here, the conversion curve was shifted to the lower temperatures by about 100 K, and the calculated TOF is 3–4 times higher than that for the other samples (Table 2). Taking into account the physicochemical data (see above), this extremely high catalytic activity could not be ascribed simply to the increased dispersion of the metal oxide nanoparticles or to the formation of new mixed oxide compounds. In our opinion, the observed synergetic effect can be assigned to the formation of a new type of catalytic active site at the copper and chromium species interface. We propose a mechanism consisting of methanol dehydrogenation on the chromium species with the formation of surface methoxide intermediates[39,40] and their further transformation to CO_2 via formation of carbonate intermediates by oxygen insertion from the copper oxide species.[39]

DME oxidation

The temperature dependencies of DME total oxidation are shown in Fig. 5*c*. As can be seen, DME oxidation occurs at a much higher temperature in comparison with CO and methanol oxidation (Figs. 5*a*, 5*b*). Moreover, the conversion curve of Cu/silica is shifted to higher temperatures in comparison with that of Cr/silica, indicating its lower catalytic activity. The calculated values of E_a for both materials are 26 and 20 kcal/mol, respectively, which could be evidence for changes in the mechanism of DME oxidation on these materials. We assume the facilitated DME oxidation on Cr/silica to be a complex step-wise process of DME hydration to methanol on the Cr_2O_3 species[41] and its further oxidation to CO_2 via the mechanism described for methanol oxidation (see above).

As a whole, all bi-component materials exhibit higher catalytic activity than the corresponding monocomponent ones, which is also well demonstrated by TOF values, presented in Table 2. No significant increase in catalytic activity is observed for 2Cu1Cr/silica, where CuO and $CuCr_2O_4$ are the main registered phases (Fig. 1, Table 1). At the same time, the catalytic activity of bi-component systems increases with chromia content. These results provide further evidence of the important role of chromia species in DME oxidation. Thus, the higher catalytic activity of bi-component materials could be related both to the increased dispersion of copper and chromium oxide species and to the appearance of a synergetic effect at the interface of copper and chromium oxide nanoparticles.

Ethyl acetate (EA) oxidation

The conversion curves of EA oxidation versus temperature for all modified materials are shown in Fig. 5*d*. Like DME oxidation, EA oxidation occurs at higher temperatures (above 500 K). Ethanol, acetaldehyde, and acetic acid are registered as by-products below 570 K. The shifting of the conversion curves with the temperature (Fig. 5*d*) and the calculated TOF values (Table 2) strongly indicate that Cr/silica has the lowest activity and the bi-component materials with copper content have increased catalytic activity. The similarity in the course of the conversion curves for various materials reveals the similarity in the mechanism of EA oxidation, which according to Gandhe et al.[42] includes hydrolysis of EA to acetic acid and ethanol and further oxidation to acetaldehyde with the participation of oxygen from the solid. According to the

Fig. 5. Temperature dependencies of CO (*a*), methanol (*b*), DME (*c*), and EA (*d*) oxidation for various silica modifications.

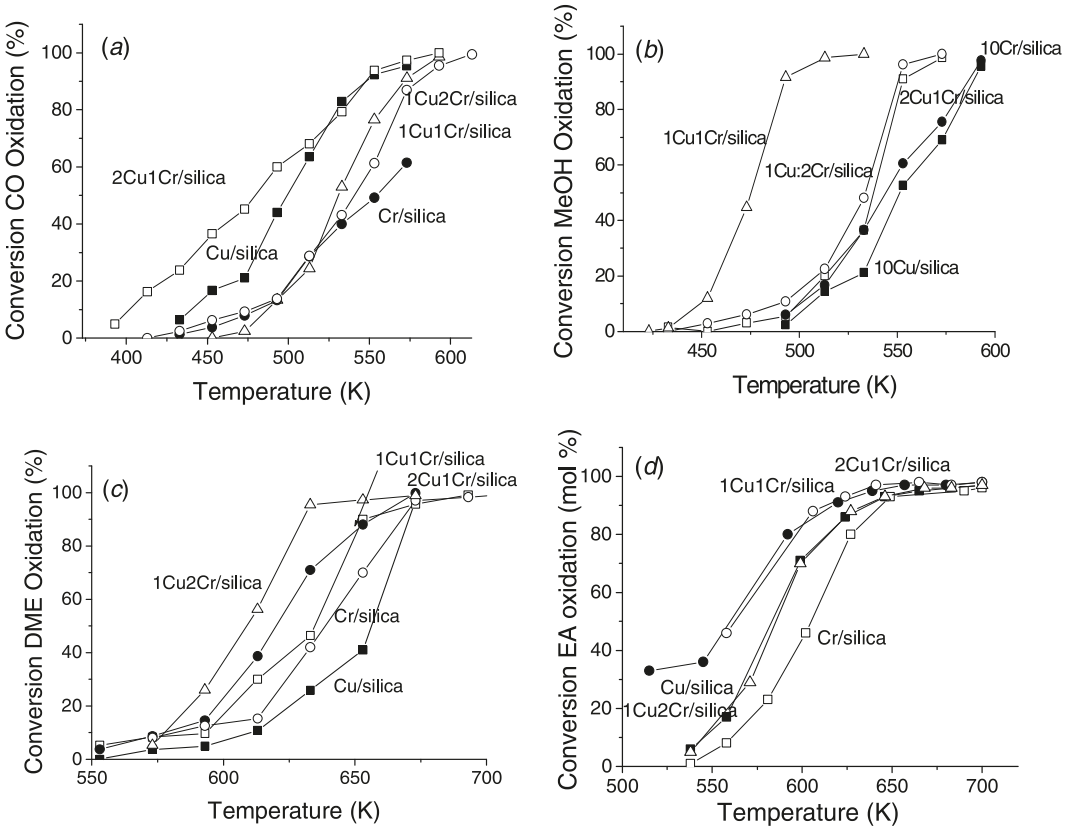

Table 2. TOF (conversion per metal site) for total oxidation of CO, methanol, DME, and ethyl acetate over various samples at selected temperatures.

Sample	CO (473 K)	Methanol (523 K)	DME (613 K)	Ethyl acetate (576 K)
Cu/silica	5.57	4.58	2.92	10.61
Cr/silica	2.02	6.73	9.62	4.81
1Cu1Cr/silica	0.62	25.60	14.51	16.84
2Cu1Cr/silica	11.78	7.38	11.78	15.96
1Cu2Cr/silica	3.59	9.12	17.74	9.25

Table 3. The lowest temperature (K) at which 90% conversion is achieved for various reactions and catalyst compositions.

Sample	CO	Methanol	DME	Ethyl acetate
Cr/silica	604	586	655	645
Cu/silica	549	590	670	639
1Cu1Cr/silica	573	492	630	619
2Cu1Cr/silica	549	552	633	619
1Cu2Cr/silica	560	550	627	639

XRD data (Fig. 1, Table 1), the increased activity of the bicomponent materials could be mainly related to the increased dispersion of chromium and copper metal oxide nanoparticles and also to the formation of spinel $CuCr_2O_4$ species (sample 2Cu1Cr/silica).

Therefore, catalysts with different copper/chromium ratios seem to be suitable for oxidation of CO and various oxygenate VOCs with high efficiency. However, under real industrial conditions, when toxic gas emissions represent a mixture of different oxygenates, the problem of their simultaneous elimination becomes much more complex. A catalyst for the deep oxidation of each component, working at relatively low temperature with high catalytic activity and selectivity, is needed. Obviously, optimization of the catalyst composition and its working regime requires detailed investigation of the formation of the active ingredients and their role in catalysis. It could be expected that the final phase composition of the samples is strongly affected not only by the initial Cu/Cr ratio but also by the reaction medium as well. Analyzing the relation between the sample composition and the temperature at which 90% conversion is achieved for each component (Fig. 5, Table 3), we propose 1Cu1Cr/silica (CuO/Cr_2O_3 in a 1:1 molar ratio) as the most effective catalyst for simultaneous elimination of a complex mixture of CO, methanol, DME, and EA. However, a reactor with a temperature layer gradient with at least three temperature zones (490–500 K, 570–580 K, and 620–630 K) seems to be most effective in this case.

Conclusion

Higher dispersion is observed for all silica-supported bicomponent copper–chromium materials in comparison with the corresponding monocomponent ones. The final phase composition of the samples (a mixture of CuO, Cr_2O_3, and (or) $CuCr_2O_4$), which significantly affects their catalytic behaviour in CO, methanol, DME and ethyl acetate oxidation, is strongly affected by the Cu/Cr ratio. The materials with a 1:2 molar ratio of CuO/Cr_2O_3 exhibit high catalytic activity for deep oxidation of DME, while those with 2:1 and 1:1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

ratios are suitable for total oxidation of CO and methanol, respectively, and both of the latter, but at much higher temperatures, are good for EA elimination. The effective simultaneous elimination of CO, methanol, ethyl acetate, and dimethyl ether in toxic gas emissions seems to be facilitated by a catalyst with an optimal composition of 1:1 CuO/Cr_2O_3 (mol:mol) and a reactor with a temperature layer gradient consisting of three temperature zones of 490–500 K, 570–580 K, and 620–630 K.

Antibiotic-inspired zinc oxide with morphology-dependent photocatalytic activity

Shuyan Gao, Xiaoxia Jia, Zhengdao Li, Yanli Chen, and Kai Jiang

Abstract: ZnO materials with different morphologies (hexahedron, coneflowerlike, cauliflowerlike, and nanorods) have been synthesized via a bioinspired method, which is effective and facile for the controlled synthesis of ZnO. Zinc acetate and ammonia were used as growth precursors, and ampicillin was used as the morphology-directing agent. X-ray diffraction (XRD) data showed that the obtained ZnO with different morphologies displayed different crystal growth habits. Photodegradation of Orange G was used as a model reaction to test the photocatalytic activity of ZnO samples. Different morphologies exhibited different activities to Orange G degradation. The cauliflowerlike ZnO sample showed the best photocatalytic performance compared with the others. The influence of the morphology-directing agent and pH on the morphology of ZnO samples and the effect of the morphologies on the photocatalytic activity are tentatively discussed.

Key words: bioinspired method, formation mechanism, ZnO, morphologies, nanostructures, photocatalytic activity.

Résumé : Faisant appel à une méthode d'inspiration biologique, on a effectué la synthèse de divers matériaux à base de ZnO, avec des morphologies différentes (en forme d'hexaèdre, d'échinacée, de chou-fleur ou de nanobâtonnet); c'est une méthode efficace et facile d'effectuer des synthèses contrôlées de ZnO. On a utilisé de l'acétate de zinc et de l'ammoniac comme précurseurs de croissance et l'ampicilline comme agent pour orienter la morphologie. Des données de diffraction des rayons X (DRX) montrent que les ZnO obtenus avec diverses morphologies présentes des habitudes de croissance cristalline différentes. On a utilisé la photodégradation du colorant Orange G comme modèle réactionnel pour évaluer l'activité photocatalytique des échantillons de ZnO. Les diverses morphologies présentent des activités différentes vis-à-vis de la dégradation de l'Orange G. L'échantillon de ZnO en forme de chou-fleur présente une meilleure activité photocatalytique que les autres. On discute d'une façon préliminaire de l'influence de l'agent d'orientation de la morphologie et du pH sur la morphologie des échantillons de ZnO et de l'effet des morphologies sur l'activité photocatalytique.

Mots-clés : méthode d'inspiration biologique, mécanisme de formation, ZnO, morphologies, nanostructures, activité photocatalytique.

Introduction

Zinc oxide (ZnO) is a direct, wide band-gap semiconductor material with many promising properties for blue/UV optoelectronics, transparent electronics, spintronic devices, and sensor applications.[1–6] Recently, a number of nanostructured ZnO materials with morphologies such as rods, belts, cables, combs, wires, tetrapods, and hierarchical nanostructures with high symmetries have been synthesized.[7–13] Nevertheless, the synthesis methods to obtain controlled nanostructures often involve tedious processes.[14] Generally, morphology control in metal oxide nanostructures requires chemical methods using highly alkaline solutions,[15,16] or physical methods performed at high temperatures.[17–19]

It is well-known that the photocatalytic properties of ZnO are related primarily to the amount of surface catalytically active sites, which depend on (*i*) the surface area of the catalyst, (*ii*) the mass of the catalyst, or (*iii*) the number of surface OH groups on a photocatalyst. Other factors affecting degradation rates include structural properties (such as phase composition, crystalline quality, particle size, size distribution, and band-gap energy) and various parameters including temperature, pH, initial concentration of the pollutant, light intensity, the reactor geometry, agglomeration, stirring, etc.[20] Therefore, the morphology of one catalyst, which determines both surface area and the structural properties mentioned above, plays a key role in catalytic activity.[21–23] To tailor electronic, optical, and catalytic properties of ZnO, much effort has been made to control its structure.[24–31] However, much more research is still needed in this area. Controlling the morphologies of nanomaterials via green methods is of great interest in many fields. Herein, we recently developed a bioinspired method to synthesize ZnO materials with different morphologies (hexahedron, coneflowerlike, cauliflowerlike, and nanorods) and investigated the influence of the morphology-directing agent and pH on the morphology and the effect of the morphologies on the photocatalytic activity. In this paper, biomolecule ampicillin was used as the morphology-directing agent to synthesize ZnO.

Experimental section

Preparation of pure ZnO

Ampicillin trihydrate ($C_{16}H_{19}N_3O_4S \cdot 3H_2O$) was purchased from Zhengzhou Biosail Biotechnology Co. Ltd., and all other analytical grade chemicals were supplied by Beijing Chemicals Co. Ltd. and used as received. The synthesis procedure for ZnO is quite straightforward. Briefly, a 25.4 mmol/L aqueous solution of ampicillin (calculated by the repeating unit) and 5.0 mmol/L of zinc acetate dihydrate were mixed with agitation in a beaker. Then, a 28 wt% aqueous solution of ammonia was added dropwise to the above mixture. The resulting solution was transferred into a 50 mL Teflon-lined autoclave and heated at 373 K for 7 h. When the reactions were completed, the precipitates were collected, washed with deionized water and ethanol several times, and finally dried in air. The detailed methods for preparing samples 1–4 are listed in Table 1.

Sample characterizations

The phase and purity of the sample was determined by X-ray diffraction (XRD) on a Bruker D8A X-ray diffractionmeter with Cu Kα radiation ($\lambda = 0.154\,056$ nm). The morphologies of the as-prepared samples were observed by a field emission scanning electron microscope (FESEM, Hitachi S-4800). The surface property of all as-prepared samples was determined by X-ray photoelectron spectroscopy (XPS) measurements using a PerkinElmer PHI 5600ci X-ray source (1486.6 eV). The C 1sESCA System, with a monochromatized Al Kα peak of hydrocarbon contamination was used as an internal reference (284.5 eV). Raman spectra were recorded on a Raman 960 FT-Raman spectrometer using a laser beam with an excitation wavelength of 1064 nm and a resolution of 8 cm^{-1}.

Photocatalytic test

Orange G (OG; formula, $C_{16}H_{10}N_2O_7S_2Na_2$; molecular weight, 452), a widely used anionic azo dye, was employed as a representative dye pollutant to evaluate the photocatalytic performance of ZnO samples. A cylindrical photoreactor surrounded by a circulating water jacket to cool the reaction solution was used and the UV light was provided by a 250 W high-pressure fluorescent Hg lamp (Institute of Electrical Light Source, Beijing; the strongest emission at 365 nm). For a typical procedure, a mixture of 100 mL of a 10 ppm aqueous solution of OG and 100 mg of each ZnO photocatalyst was agitated in the dark for 1 h in the photoreactor to ensure establishment of an adsorption equilibrium of the dye on the surface of the catalyst. After the initiation of the reaction by irradiation of the reactor, 5 mL samples of the suspension were withdrawn at regular intervals and were immediately centrifuged and then filtered to remove the catalyst particles completely. The degradation of OG was determined by measuring the absorbance of the solution samples on a TU-1810 UV–vis spectrophotometer (Beijing Purkinje General Instrument Co., Ltd.).

Crystal structure and microstructure of the as-prepared ZnO samples

FESEM images

Figure 1 shows the FESEM images of the samples obtained under different preparation conditions. Sample 1 (Fig. 1a) displays a hexagonal structure. The planes on each crystal are smooth. The height of the hexahedron is ~1 μm, and the side length of the hexagonal face is ~3 μm. A few hexahedrons were joined across the basal plane. Figure 1b is coneflowerlike assembled by seven or eight cones in all directions. Figure 1c has well-defined cauliflowerlike microstructures, assembled by many densely arranged nanosheets as "petals". ZnO nanorods with uniform diameters of ~100 nm were obtained, with an open cavity at the end (Fig. 1d). These show that the preparation conditions have an evident effect on the product morphologies, which can in turn guide the fabrication technologies to service materials synthesis.

It is well-known that shape control of the crystals can be achieved by manipulating the growth kinetics.[32–34] First, ZnO nuclei generally evolve into nanorods by preferential *c*-axis ([001] direction) oriented growth. Second, when the crystal growth along the [001] direction is suppressed, a hexahedron can be obtained because of the growth along the sixfold symmetric directions, which are normal to the [001] direction.[35] Third, petal-interlaced growth results in a cauliflower. Connecting all the "petal" frameworks leads to a larger piece of cauliflower. Finally, cone-interlaced growth results in a coneflower. Therefore, the synthetic conditions therein favour the structure control. Based on the above observations, the schematic illustration of the formation process of the obtained different ZnO microstructures is presented in Fig. 2.

XRD patterns

Typical XRD patterns of all four samples are shown in Fig. 3 to investigate the phase purity. All of the diffraction peaks from the samples corresponded to those of wurtzite-structure ZnO (The Joint Committee on Powder Diffraction Standards (JCPDS): 36-1451; *a*, 3.249 Å; *c*, 5.206 Å) with high crystallinity. No impurity peaks were observed for the other impurities such as $Zn(OH)_2$. Interestingly, compared with the XRD patterns of samples a and d, the intensity of

the (002) peak in the patterns of the ZnO coneflower (sample b) and the cauliflower (sample c) is relatively weaker.

Raman spectroscopy

Raman scattering is very sensitive to the lattice microstructure. Phonon frequencies and scattering intensities determined by Raman spectroscopy can lead to conclusions concerning microscopic parameters such as bonding and structure as well as deviations from the ideal crystalline counterpart.[36] ZnO belongs to the wurtzite space group. On the basis of group theory, the correlation of the site group to the factor group is constructed in Table 2.

There are eight sets of optical phonon modes at the Γ point of the Brillouin zone in single-crystalline ZnO, in which the $A_1 + E_1 + 2E_2$ modes are Raman-active and expected in Raman spectra. Moreover, the A_1 and E_1 are polar and hence split into transverse optical (TO) and longitudinal optical (LO) phonon components. Figure 4 shows a typical Raman spectrum of the sample. The sharp, strong Raman peak at 438 cm^{-1} is attributed to the ZnO nonpolar optical phonon (E_2) modes,[37] which is one of the characteristic peaks of wurtzite ZnO.[38,39] The less prominent peak at 381 cm^{-1} corresponds to the A_1(TO) mode, which is caused by the

formation of oxygen vacancies, zinc interstitials, and a free carrier in ZnO[40], and indicates that a few defects exist in the sample, which is in agreement with the XPS results. The bands at 332 cm^{-1} are assigned to A1 s-order overtones.

XPS characterizations

The surface components and chemical states of the as-prepared ZnO samples were investigated by XPS analysis, and the corresponding results are shown in Fig. 5. Figure 5a shows the scan survey spectra for the representative ZnO sample. All of the peaks on the curve can be ascribed to Zn, O, and C elements and no peaks of other elements were observed. The presence of C mainly comes from the hydrocarbon contaminants that commonly exist for XPS. Therefore, it can be concluded that the sample is composed of Zn and O only, which is in agreement with the XRD results. A strong peak at ~1022.6 eV can be attributed to Zn 2p3/2 (Fig. 5b), which is slightly larger than the value 1022.0 eV of Zn in the bulk ZnO. This indicates that Zn is in the 2+ valence state within an oxygen-deficient environment. The curve-fitting patterns of O1s are shown in Fig. 5c. The hollow circles denote the original data, and the solid lines represent the fitted

Fig. 5. (a) A representative X-ray photoelectron spectroscopy (XPS) survey spectrum of a ZnO sample. XPS full spectra of (b) Zn 2p3/2 and (c) O1s.

curves and the deconvoluted individual peaks of the two different oxygen species present on the surface. The deconvoluted peak marked with "α" is closely associated with the lattice oxygen (O_L) of ZnO and its position is at ~529.7 eV, while the other peak marked with "β" is attributed to the oxygen of surface hydroxyl (OH) and its position is at ~531.1 eV.

OG photodegradation

ZnO has been used as a photocatalyst for the photodegradation of water pollutants, the photoreduction of halogenated benzene derivatives, the photoreduction of toxic metal ions, and photocatalytic water splitting. To understand the relationship between the structure and photocatalytic performance of ZnO samples, the photocatalytic activities of as-synthesized ZnO with different morphologies were studied using OG degradation as a model system. The UV–vis absorption spectra and degradation profile of all of the ZnO samples are shown in Fig. 6.

Figure 6a shows the UV–vis absorption spectra of OG in the presence of cauliflowerlike ZnO as the photocatalyst. It can be seen that the absorbance peaks at 331 and 477 nm were reduced significantly, indicating the degradation of the dye molecules. To demonstrate the morphology-induced enhancement of the photocatalytic performance of ZnO, a further experiment was performed using other samples as photocatalysts for the photodegradation of OG under the same conditions. The results of the OG degradation in a series of experimental conditions are summarized in Fig. 6b. The time-dependent photoactive performance of ZnO catalysts for phenol degradation was recorded. Degradation (y axis) is defined as $(C/C_0) \times 100\%$, and the x axis is reaction time (min), in which C_0 and C are the initial concentration after the equilibrium adsorption and the reaction concentration of OG, respectively. As can be clearly seen in Fig. 6b, the residual concentration of the OG aqueous solution at 100 min UV irradiation is as follows: ZnO coneflower (22.0%), cauliflower (5.2%), hexahedron (14.4%), and nanorods (12.5%). After 100 min of irradiation, the OG in aqueous solution was almost completely eliminated by the cauliflowerlike ZnO sample. These observations demonstrate that the photocatalytic activity depends on the morphology of the ZnO samples, which are decided on by their growth behaviors.

Reaction mechanism

Reaction mechanism of ZnO

In the ammonia system solution, the growth process of ZnO nanocrystals at room temperature is as follows:

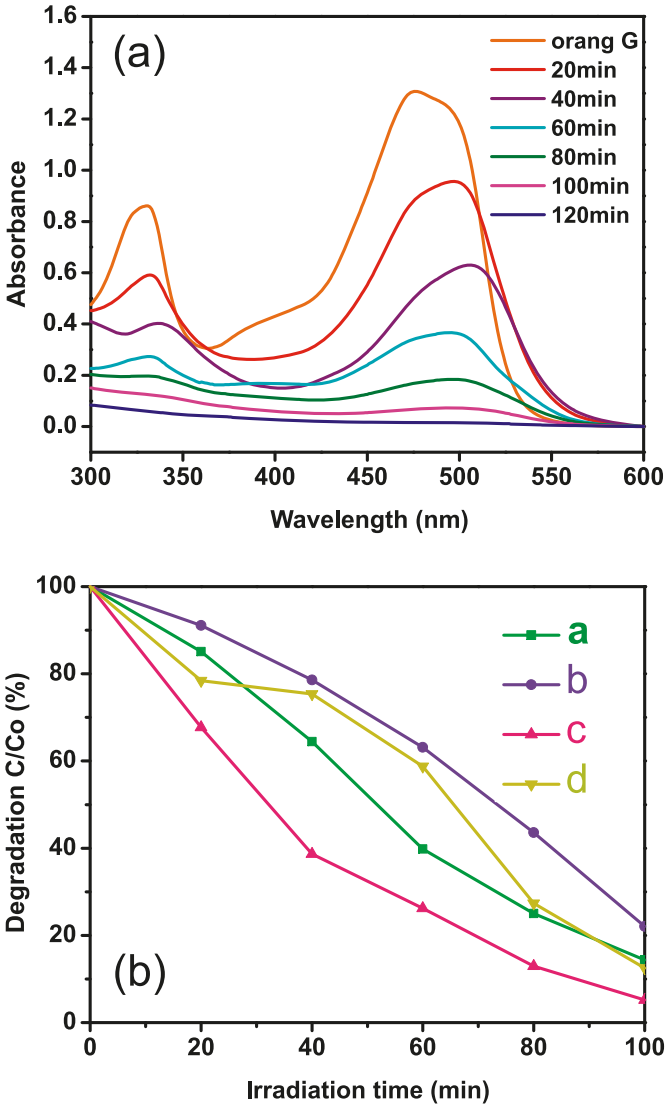
$$[1] \quad NH_3{\cdot}H_2O \rightarrow NH_4^+ + OH^-$$

$$[2] \quad Zn^{2+} + NH_3{\cdot}H_2O \rightarrow [Zn(NH_3)_4]^{2+} + H_2O$$

$$[3] \quad [Zn(NH_3)_4]^{2+} \rightarrow [Zn(OH)_n]^{(n-2)-} \rightarrow ZnO$$

Thereinto, $n = 2$ or 4. At room temperature, in the saturated solution of $Zn^{2+}/NH_3{\cdot}H_2O$, Zn is mainly in the form of

Fig. 6. (a) The time-dependent UV–vis absorbance spectra of Orange G (OG) in the presence of ZnO with a cauliflowerlikepattern. (b) The reaction concentration of OG (C) / the initial concentration after the equilibrium adsorption (C_o) vs time curves of the photodegradation of OG in the presence of four kinds of samples.



$[Zn(NH_3)_4]^{2+}$ and $[Zn(OH)_n]^{(n-2)-}$. When the temperature increases, $[Zn(NH_3)_4]^{2+}$ begins to decompose and forms saturated liquid, and the content of the hydroxy-aggregates $[Zn(OH)_n]^{(n-2)-}$ in zinc solution exceeds its saturation. Hence, $[Zn(OH)_n]^{(n-2)-}$ forms ZnO after dehydration. The whole process is shown in eqs. [1]–[3].[41]. The supersaturated degree of solution is expressed by the supersaturation, which refers to the ratio of quality and degree that is over the saturation of solution. As the layer of crystal seed and the product of growth are the same composition, and the lattice matches well, ZnO gives priority to heterogeneous nucleation between the substrate and the electrolyte interface, and prefers to epitaxialy grow along the c-axis polar surface, which has a relatively high surface energy. When the supersaturation of the solution is too large, $[Zn(OH)_n]^{(n-2)-}$ easily undergoes polymerization through dehydration, and homogeneous nucleation precipitation occurs as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

[4] $$2[Zn(OH)_n]^{(n-2)^-} \rightarrow [Zn_2O(OH)_{2n-2}]^{(2n-4)^-} + H_2O$$

[5] $$[Zn_{x+1}O_x(OH)_{(x+1)n-2x}]^{(x+1)n-2(x+1)^-} + [Zn(OH)_n]^{(n-2)^-}] \rightarrow [Zn_{x+2}O_{x+1}(OH)_{(x+2)n-2(x+1)}]^{(x+2)n-2(x+2)^-} + H_2O$$

The subscript x represents the number of Zn^{2+} in the congeries. When the congeries are large enough, ZnO sediment begins to separate out.

Formation mechanisms of different morphologies

According to the FESEM observations, different amounts of ampicillin lead to different morphologies. First, the theory of Israelachvili[42] tells us that (*i*) surfactants will spontaneously form aggregates when their concentration is above a certain "critical" value and (*ii*) the aggregate morphology depends on the well-known packing parameter P

[6] $$P = v/I_c a_o$$

where v and I_c are the volume and chain length of the hydrophobic group, respectively, and a_o is the cross-sectional area of the headgroup dictated by the electrostatic repulsion between adjacent headgroups in the associates. Alternatively, reducing the electrostatic repulsion between adjacent headgroups can increase P. pH, temperature, and salinity[43] can all alter the electrostatic repulsion and thus the aggregation morphology. At the high pH value, only a few vesicles are formed. With the decrease of pH value, more and bigger vesicles are formed, and the vesicle diameter increases with the decrease of pH value at a fixed surfactant concentration. In our experiment, when the amount of ampicillin is the same, particles more easily aggregate with a decrease in pH value, and petals and cones can easily self-assemble to cauliflower and coneflower, respectively, whereas nanorods cannot further self-assemble into a hierarchical microstructure. Why cannot hexahedron further self-assemble into a hierarchical microstructure? The formation of a hexahedron rests with too much ampicillin (3 mL, pH 10.95), which is a morphology-directing agent. The steric hindrance effect with a larger volume should cause the rejection of the micelle and influence the micelle aggregates.[44] These phenomena indicate that different pH values and relative amount of morphology-directing agent will result in dissimilar morphologies of the product and the formation of diverse and novel assemblies of the ZnO nanostructures. More studies and work are underway to further understand the mechanisms for the assembly process induced by this new driving action.

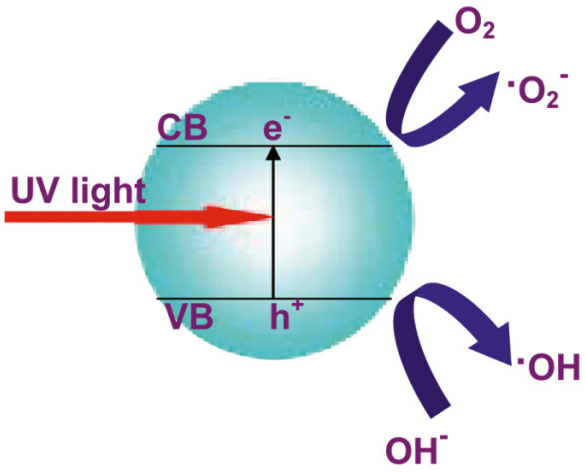
Influence of the morphologies on the catalytic performance of the ZnO samples

In terms of the previously proposed mechanism for the photocatalytic degradation for organic dye,[45,46] which occurs by an indirect pathway involving hydroxyl radicals as the oxidizing intermediate as follows:

[7] $$ZnO + h\upsilon \rightarrow ZnO(e_{CB}^- + h_{VB}^+)$$

[8] $$H_2O + h_{VB}^+ \rightarrow H^+ + \cdot OH$$

Scheme 1. The charge separation process and the photocatalytic mechanism of ZnO samples under UV irradiation.



[9] $$\text{Dye} + \cdot OH \rightarrow \text{Oxidation products}$$

The conduction-band electrons (e_{CB}^-) and valence-band holes (h_{VB}^+) are generated on the surfaces of ZnO nanostructures when they are illuminated by UV light with an energy greater than the band-gap energy. Holes can react with water adhering to the surfaces of ZnO nanostructures to form highly reactive hydroxyl radicals (·OH), which have a powerful oxidation ability to degrade organic dye. The charge separation process and the photocatalytic mechanism of ZnO samples under UV irradiation are shown in Scheme 1.

Usually, a high specific surface area has a beneficial effect on the activity for catalysts. Thus, the morphologies of ZnO catalysts play an important role in the photocatalytic activity.[47,48] According to the above photocatalytic results, cauliflower > hexahedron > nanorod > coneflower ZnO, which may be attributed to their special structural features. The size of the surface areas of ZnO samples is cauliflower > hexahedron > nanorod, which can be roughly judged from the FESEM images. Cauliflower is assembled by many densely arranged nanosheets, hexahedron is suppressed 1-D growth, and nanorod is 1-D growth. The surface photochemical reaction of OG degradation occurs in the sequence of dispersion, diffusion, adsorption, surface reaction, and final desorption, and each of these elementary processes affects the surface reaction rate. The large surface area and capacious interspaces in the cauliflowerlike ZnO nanostructures offer more opportunity for the diffusion and mass transportation of OG molecules and hydroxyl radicals in the photochemical reaction of OG degradation. However, the photocatalytic activity of the coneflower is inferior, probably because the photocatalytic activity of ZnO is also strongly dependent on the surface orientation of the nanocrystals, which could result in orientation-dependent charge-transfer processes, and the type and concentration of oxygen vacancies on the surface, which needs to be verified by further work.

Conclusion

In this work, biomolecule ampicillin was used as a morphology-directing agent for the first time to construct ZnO without any metal catalysts under ambient conditions. This demonstrates that the bioinspired green method is an

efficient approach for the preparation of ZnO with different morphologies. ZnO samples with different morphologies exhibited different activities to OG degradation probably because of the morphology and growth habit. The underlying formation mechanism and catalytic mechanism were discussed. The as-synthesized ZnO samples are also expected to be useful for other applications such as gas sensing. Moreover, this work further hints that this green and economical approach can be extended to synthesize other metal oxide materials with a novel morphology.

Abstract: The primary goal of a quantitative structure–property relationship study is to identify a set of structurally based numerical descriptors that can be mathematically linked to a property of interest. In this work, two main groups of descriptors have been used to predict ^{13}C NMR chemical shifts of ipso, ortho, meta, and para positions in a series of 113 monosubstituted benzenes. First, two groups of descriptors — original molecular descriptors (constitutional, topological, electronic, and geometrical) and multivariate image analysis (MIA) descriptors — were calculated. Then, calculated descriptors were subjected to principal component analysis and the most significant principal components were extracted. Finally, more correlated principal components were used as inputs of artificial neural networks. The results obtained using the rank correlation–principal component–artificial neural network (RC–PC–ANN) modeling method show high ability to predict ^{13}C NMR chemical shifts. Also, comparison of the results indicates that MIA descriptors show better ability to predict ^{13}C NMR chemical shifts than the original molecular descriptors.

Key words: multivariate image analysis (MIA), quantitative structure–property relationship (QSPR), principal component–artificial neural network (PC–ANN), ^{13}C NMR chemical shift, monosubstituted benzenes.

Résumé : Le but principal d'une étude de relation quantitative structure-propriété est d'identifier un ensemble des descripteurs numériques à base de structure que peuvent être liés d'une façon mathématique à une propriété intéressante. Dans ce travail, deux groupes principaux de descripteurs pour prédire les déplacements chimiques, en RMN du ^{13}C, des positions ipso, ortho, méta et para dans une série de 113 dérivés monosubstitués du benzène. Dans un premier temps, on a calculé deux groupes de descripteurs, incluant des descripteurs moléculaires originaux (constitutionnels, topologiques, électroniques et géométriques) et on a procédé à une analyse d'image multivariable (AIM). Dans un deuxième temps, on a soumis les descripteurs calculés à une analyse du composant principal et on en a extrait les composants principaux les plus significatifs. Enfin, on a utilisé d'autres composants principaux apparentés comme données pour des réseaux neuraux artificiels. Les résultats obtenus à l'aide de la méthode modelage par corrélation des rangs de Spearman avec un composant principal appliqué à un réseau neural artificiel (« CR-CP-RNA ») montrent une grande habilité à prédire les déplacements chimiques en RMN du ^{13}C. De plus une comparaison des résultats indique que les descripteurs d'AIM possèdent une plus grande habilité à prédire les déplacements chimiques en RMN du ^{13}C que les descripteurs moléculaires originaux.

Mots-clés : analyse d'image multivariable (AIM), relation quantitative structure-propriété (RQSP), composant principal appliqué à un réseau neural artificiel (« CP-RNA »), déplacement chimique en RMN du ^{13}C, benzènes monosubstitués.

[Traduit par la Rédaction]

Introduction

At the present time the methods of studying quantitative structure–property relationships are increasingly developed in various areas of chemistry, biology, and pharmacy. Quantitative structure–activity/structure–property relationship (QSAR/QSPR) studies, one of the most important areas in chemometrics, give information that is useful for molecular design and medicinal chemistry.[1–4] QSAR/QSPR models are mathematical equations relating chemical structure to a wide variety of physical, chemical, biological, and technological properties. In general, development of a QSPR model involves three steps: structural encoding, feature selection, and model building. Structural encoding involves the use of numerical descriptors to encode the structural features of a compound. Feature selection is then employed to determine which subset of the descriptors indicates the best relation with the property of interest. Models built from the best subset

of descriptors form a direct link between descriptors and the property of interest. Finally, validation determines the level of the model's predictive capabilities for unknown compounds.

The most frequently applied computational methods for QSPR are based on 3D or multidimensional approaches,[5–11] which provide information about the relation between physicochemical parameters and the property of interest. A 2D image-based methodology has recently been developed (MIA-QSPR, multivariate image analysis applied to QSPR),[12,13] which avoids conformational screening and 3D alignment steps. MIA-QSPR has also been shown to be nicely predictive with some operational advantages.

Geladi and Esbensen[14] have demonstrated that image analysis may provide useful information in chemistry, though the descriptors do not have a direct physicochemical meaning, since they are binaries. In MIA-QSPR studies, images (2D chemical structures) have been shown to contain chemical information,[12,13] allowing the correlation of chemical structures and properties.

Goodarzi et al. have reported a QSPR study of the ^{13}C NMR chemical shifts of methoxy flavonol derivatives using the MIA-QSPR method.[15] They revealed that the predictive ability of MIA descriptors is comparable or even superior to that of the well-known gauge-included atomic orbital procedure for ^{13}C NMR chemical shift calculation. Garkani-Nejad and Poshteh-Shirani have used the MIA-QSPR method to predict ^{13}C NMR chemical shifts of naphthalene derivatives.[16] The obtained results indicated high predictive ability of MIA descriptors in predicting ^{13}C NMR chemical shifts of naphthalene derivatives.

The main aim of the present work was to reveal the capabilities of the rank correlation–principal component–artificial neural network (RC–PC–ANN) modeling method in predicting ^{13}C NMR chemical shifts of a series of 113 monosubstituted benzenes using two kinds of descriptors: original

molecular descriptors and MIA descriptors. The results obtained using the two kinds of descriptors were compared.

Experimental

Data set

The ^{13}C NMR chemical shifts of 113 monosubstituted benzenes (in ppm relative to TMS) for ipso, ortho, meta, and para positions were obtained from the literature.[17] During this study, attention was paid to collecting ^{13}C NMR chemical shift data under similar experimental conditions. The chemical structures of the different substituted compounds used in this study and their ^{13}C NMR chemical shifts are shown in Table 1.

Descriptors

Original molecular descriptors

All structures were generated with HyperChem software (version 7) and optimized by the AM1 semi-empirical method.[18] The selection and calculation of the structural descriptors as numerically encoded parameters is regarded as an essential step in every QSPR study. In this work, some QSPR descriptors were calculated using the HyperChem package. Then the HyperChem files were transferred into Dragon software[19] to calculate different kinds of descriptors. Constitutional, topological, and geometrical descriptors calculated with Dragon software have been successfully used in various QSPR studies.[20,21] Also, MOPAC software[22] was used to calculate electronic and quantum chemical descriptors. Then, descriptors with constant or almost constant values for all molecules were eliminated. In addition, pairs of variables with a correlation coefficient greater than 0.90 were classified as intercorrelated and only one of them was considered in developing the models. A total of 146 descriptors were considered for further investigations.

Multivariate image analysis (MIA) descriptors

The structures of studied compounds (Table 1) were systematically drawn in ACD/ChemSketch[23] and saved in PaintStar[24] as bitmap files. The bitmap windows were cut to a 215 × 210 pixels size to minimize memory and the drawn molecules were systematically fixed in a given coordinate by a common point among them. For instance, position 1 (Fig. 1) was manually fixed at the 100 × 100 pixels coordinate. Each 2D image was read and converted into binaries (double array in MATLAB[25]). Each image of 215 × 210 pixels was unfolded to a 1 × 45 150 pixels row and then the 113 images were grouped to form a 113 × 45 150 pixels matrix (Fig. 1). Columns with zero variance were removed to minimize memory, reducing the size of matrices to 113 × 817 pixels.

Principal component regressions

In QSAR/QSPR studies, a regression model of the form $y = Xb + e$ may be used to describe a set of predictor variables (X) with a predicted variable (y) by means of a regression vector (b). However, the collinearity that often exists between independent variables creates a severe problem in certain types of mathematical treatments such as matrix inversion.[26] A better predictive model can be obtained by orthogonalization of the variables by means of principal component analysis (PCA), and the consequent method is called principal component regression (PCR).[27–29] To reduce the dimensionality of the independent variable space, a limited number of principal components (PCs) are used. Selection of significant and informative PCs is the main problem in almost all PCA-based calibration methods.[30–32] Different methods have been used to select the significant PCs for calibration purposes. In the simplest and most common one, the factors are ranked in order of decreasing eigenvalue and introduced into the calibration model one after the other. In another method, called correlation ranking, the factors are ranked by their correlation coefficient with the property to be correlated (a dependent variable).[32] Better results are often achieved by this method. Therefore, in this study, the correlation ranking method was used to select significant PCs obtained from original molecular descriptors and MIA descriptors.

In the present work, the first PCA was carried out on two data matrices using Minitab.[33] After acquiring PCs, PCR analysis including correlation ranking (CR–PCR) was employed. In the CR–PCR procedure, the PCs were entered into the PCR model consecutively based on their decreasing correlation with the ^{13}C NMR chemical shifts. The coefficient of determination $R^2 \geq 0.5$ was used to select the optimum number of factors in the PCR models. The obtained models are summarized in Tables 2 and 3 for original molecular descriptors and MIA descriptors, respectively. In all CR–PCR equations, the factor with the highest correlation with the ^{13}C NMR chemical shift is considered the most significant and, subsequently, the factors are introduced into the calibration model until $R^2 \geq 0.5$ is achieved. PCs with higher correlations have greater information about the variation in the ^{13}C NMR chemical shifts.

Artificial neural network modeling

Because of the complexity of the relationships between the

cent years.[34,35] Multilayer feed-forward neural networks trained with back-propagation learning algorithms have become increasingly popular.[34–37] The flexibility of ANN for discovering a more complex relationship has resulted in this method finding wide application in QSAR/QSPR studies (reviewed by Duch et al.[38]).

The principal component–artificial neural network (PC–ANN) was proposed by Gemperline et al. to improve the training speed and decrease the overall calibration error.[39] PC–ANN combines the PCA with ANN and models the nonlinear relationships between the PCs and the dependent variable.

A feed-forward neural network with a back-propagation of error algorithm was constructed to model the structure–property relationship. Our network had an input layer, a hidden layer, and an output layer. The input vectors were the set of PCs selected by correlation ranking (Tables 2 and 3). The number of nodes in the input layer depended on the number of PCs introduced to the network. The number of nodes in the hidden layer was optimized through the learning procedure. There was only one node in the output layer. The data set was separated into three subsets: a training set including 71 compounds, a validation set including 16 compounds, and a test set including 16 compounds. The training, validation, and test data sets were used to optimize the network performance. The training set was used for model generation, the test set was used to control the overtraining, and the validation set was used to evaluate the generated model. The ANN program was coded in MATLAB 7.1 for Windows.[25] The network was then trained using the training set by the back-propagation strategy for optimization of the weight values. The proper number of nodes in the hidden layer was determined by training the network with different numbers of nodes in the hidden layer. The standard error (SE) measures how good the outputs are in comparison with the target values. It should be noted that for evaluating the overfitting, the training of the network for the prediction of ^{13}C NMR chemical shifts must stop when the SE of the test set begins to increase while the SE of the training set continues to decrease. Therefore, training of the network was stopped when overtraining began.

The results obtained using the RC–PC–ANN method for PCs extracted from original molecular descriptors and MIA descriptors are shown in Tables 4 and 5.

Results and discussion

Table 1 lists the structures of monosubstituted benzenes used in this study and their corresponding experimental ^{13}C NMR chemical shift values for four different positions: ipso, ortho, meta, and para. After elimination of the constants and one of the collinear descriptors, 146 original molecular descriptors and 817 MIA descriptors remained. After the application of PCA to the two descriptor data matrices, 112 PCs were extracted for each group of descriptors. Then, separate PCR models were obtained for each position (ipso, ortho, meta, and para). The models obtained by the correlation ranking procedure are shown in Tables 2 and 3. The QSPR models for all positions resulted in high statistical qualities. Comparison of these models indicates that the number of PCs is lower for the original molecular descriptors than for the MIA descriptors. This shows that the PCs obtained from

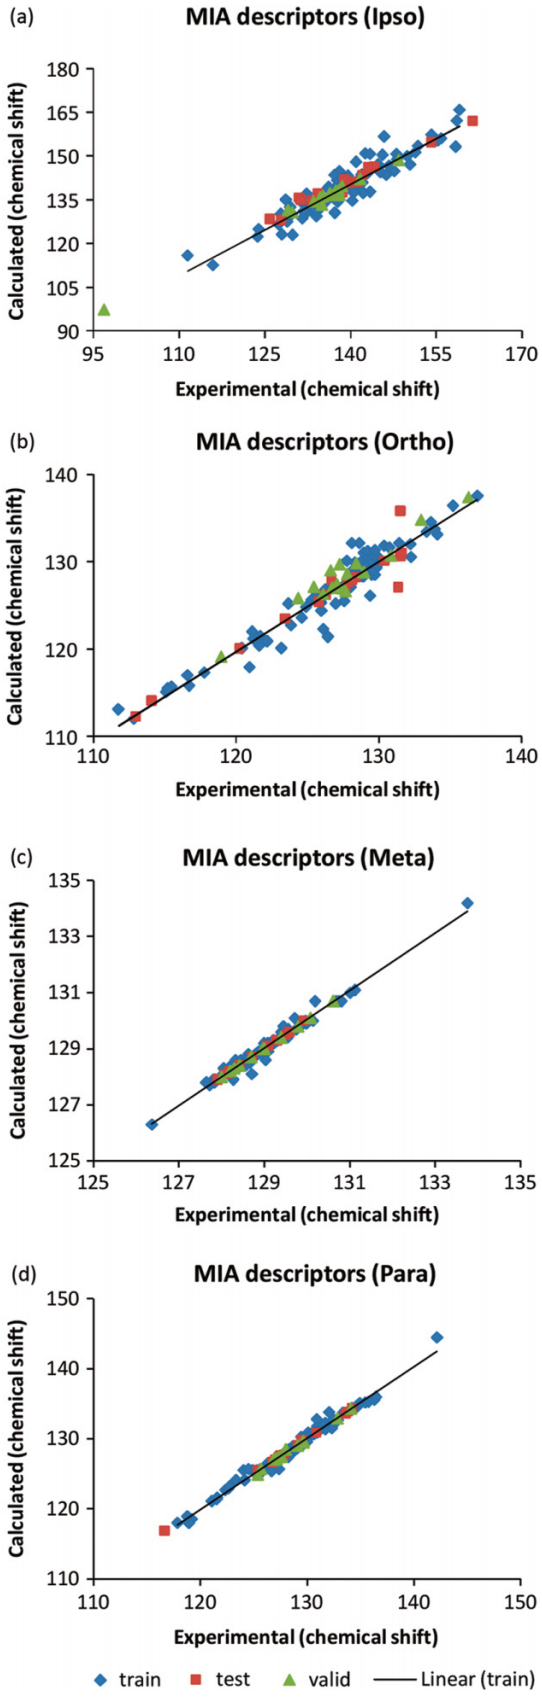
Fig. 3. Plots of experimental ^{13}C chemical shifts of monosubstituted benzenes against values calculated using RC–PC–ANN models based on MIA descriptors for C1–C4 (*a–d*, respectively).



the original molecular descriptors provide greater information about the variations of ^{13}C NMR chemical shifts.

To increase the ability of the obtained models to predict ^{13}C NMR chemical shifts, a nonlinear modeling method was employed. Typically, superior models can be found using ANNs because they implement nonlinear relationships and because they have more adjustable parameters than linear models. Therefore, in this study we used ANN as the nonlinear model. Correlation ranking was used to select the most relevant set of PCs as inputs of the ANN. The results of the RC–PC–ANN method are presented in Tables 4 and 5 for the training, validation, and test sets, respectively.

For comparison, R^2 and SE values of RC–PC–ANN models for original molecular descriptors and MIA descriptors are summarized in Table 6. As can be seen from this table, the QSPR models obtained from the two main groups of descriptors indicate good performance for different carbon positions and could predict the ^{13}C NMR chemical shifts of the related molecules with low error. Also, comparison of the results indicates that the RC–PC–ANN models based on PCs extracted from the MIA descriptors are more accurate and show better predictive ability than the RC–PC–ANN models based on PCs extracted from the original molecular descriptors.

Finally, ^{13}C NMR chemical shifts of the studied compounds were calculated using ChemDraw;[40] these values are shown in Table 7. Also, statistical parameters of these values are indicated in Table 6.

The results obtained in the present work indicate that though MIA descriptors do not have a direct physicochemical meaning, they may provide useful information and are capable of predicting the ^{13}C NMR chemical shifts of studied compounds with a good predictive ability.

Plots of experimental ^{13}C NMR chemical shifts versus those calculated using RC–PC–ANN modeling methods for ipso, ortho, meta, and para positions are shown in Figs. 2*a*–2*d* for the original molecular descriptors and Figs. 3*a*–3*d* for the MIA descriptors.

Conclusion

The QSPR modeling of ^{13}C NMR chemical shifts of monosubstituted benzenes was studied using the RC–PC–ANN method. A comparison was made between the original molecular descriptors and MIA descriptors. The results showed that both groups of descriptors are capable of predicting ^{13}C NMR chemical shifts of benzene derivatives. Also, it was found that RC–PC–ANN models based on PCs extracted from MIA descriptors are more accurate and show better predictive ability than RC–PC–ANN models based on PCs extracted from original molecular descriptors.

Abstract: A robust method for functionalizing poly(cyclic olefin) surfaces comprised of Zeonor 1060R was developed. These surfaces were first oxidized using two separate methods, ozonolysis and oxygen plasma treatment, to increase their hydrophilic properties and produce carboxylic acids on the surface. The resulting acids enabled direct amide coupling with various amines containing azide or alkyne moieties onto the surface. These modified surfaces were further functionalized via copper-catalyzed azide–alkyne cycloadditions (CuAAC) on the surface and the method was optimized for this material. Surface modifications were characterized by water contact angle measurements, fluorescence microscopy, atomic force microscopy, and X-ray photoelectron spectroscopy. Our data demonstrates a robust method for generating "clickable" Zeonor 1060R surfaces as demonstrated through attachment and subsequent detection of a triazole-linked fluorophore. The method developed enables the systematic modification of any poly(cyclic olefin) surface for functionalization using the click reaction.

Key words: "click" chemistry, Zeonor, ozone, oxygen plasma.

Résumé : On a mis au point une méthode puissante pour fonctionnaliser les surfaces de poly(oléfines cycliques), dont le Zeonor 1060R. Afin d'augmenter leurs propriétés hydrophiles et de produire des acides carboxyliques à leur surfaces, on a procédé dans une première étape à l'oxydation de ces surfaces à l'aide de deux méthodes distinctes, l'ozonolyse et un traitement à l'aide d'un plasma d'oxygène. Les acides qui en résultent permettent de réaliser un couplage amide direct avec diverses amines contenant des portions azoture ou alcyne à leur surface. On a soumis ces surfaces modifiées à d'autres fonctionnalisations par le biais de cycloadditions azoture–alcyne catalysées par le cuivre (AACCu) sur la surface et on a optimisé la méthode pour ce matériau. Les modifications de la surface ont été caractérisées par des mesures de l'angle de contact avec l'eau, par microscopie de fluorescence, par microscopie des forces atomiques et par spectroscopie photoélectronique des rayons X. Les données démontrent qu'il s'agit d'une méthode puissante pour générer des surfaces de Zeonor 1060R cliquables tel que démontré en attachant, puis en détectant un fluorophore lié par un triazole. La méthode développé permet une modification systématique de toute surface de poly(oléfines cycliques) en vue d'une fonctionnalisation à l'aide d'une réaction par cliquage.

Mots-clés : chimie par cliquage, Zeonor, ozone, plasma d'oxygène.

Introduction

Microcrofluidic technologies are used in the fields of medical diagnostics, drug discovery, genomics, and proteomics for providing rapid, reliable, sensitive, and simultaneous processing and detection of many different analytes present in a biological mixture.[1–6] There is increased interest in developing plastic microfluidic- and microarray-based technologies for modification of surfaces and immobilization of biomolecules onto the surfaces. Amorphous thermoplastics, specifically Zeonor and Zeonex, have attracted a great deal of attention in recent years owing to their favorable chemical

properties such as high transition temperature, low fluorescence background, high transparency, resistance to organic solvents, low water uptake, and moldability.[7–11] From a commercial point of view, Zeonor and Zeonex materials exhibit other desirable properties such as low cost, micromachining abilities, and mass producibility.[11] Surface functionalization on plastic surfaces represents a simple, robust, and industrially scalable alternative to conventional inorganic substrates such as silica, glass, silicon nitride, and epoxy-based polymers.[10]

Poly(cyclic olefins) are typically hydrophobic, comprised purely of hydrocarbons with no functional groups amenable for covalent functionalization. These Zeonor surfaces can be rendered hydrophilic via photografting,[12] oxygen plasma,[13–15] or ozonolysis.[16] Poly(cyclic olefin) Zeonor materials have been successfully employed for DNA immobilization,[15] purification of nucleic acids,[17] microarrays,[16] and immunoassays.[18,19] In these examples, hydrophilic Zeonor surfaces were functionalized via 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) – *N*-hydroxysuccinimide (NHS) mediated couplings of surface carboxylic acids with terminal amino groups[15–17] or through Schiff's base formations from (3-aminopropyl)triethoxysilane (APTES)-functionalized surface amino groups with terminal aldehydes.[19] These coupling procedures for functionalizing oxidized surfaces are typically hampered by lack of specificity, difficulty introducing the functional groups at a range of pH, or low yields.

In our search for versatile chemistry and functional groups to modify Zeonor surfaces, naturally we were attracted to Sharpless's "click" chemistry,[20] particularly the copper-catalyzed azide–alkyne cycloaddition (CuAAC).[21] Azides and alkynes are convenient to introduce, are mutually reactive, and show extraordinary tolerance to other functionality. Furthermore, the regioselective Cu(I) catalyst used in CuAAC reactions is tolerant to solvent and pH, and the triazole products are formed irreversibly and often quantitatively. Although the CuAAC reaction has been employed for functionalizing other polymers[22] and surfaces,[23,24] to our knowledge this is the first report of CuAAC reactions on the surface of a poly(cyclic olefin) leading to a "clickable" surface.

Herein we describe CuAAC reactions on commerically available Zeonor 1060R surfaces that were first oxidized by plasma or ozone treatment. Covalent modification of oxidized plastic surfaces with either azide or alkyne groups enables specific and efficient modular functionalization of Zeonor 1060R surfaces with virtually any organic monolayer. This method presents a distinct advantage for fabricating different devices and for processing and evaluating biological samples because click chemistry is uniform and reproducible regardless of what functional groups are incorporated onto the surface.

Results and discussion

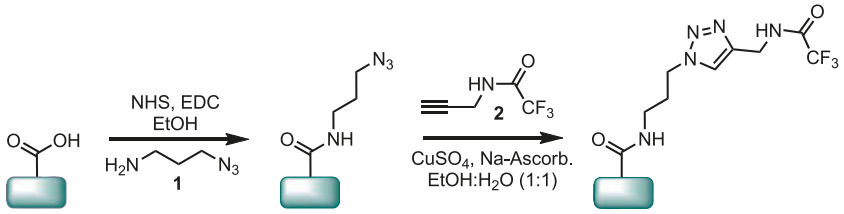
Surface modification

Several approaches are available that allow the hydrophilization of cyclic olefin polymer and copolymer surfaces. Oxygen plasma treatment is rather aggressive and significantly increases the hydrophilicity of the surface through the introduction of numerous polar groups, such as hydroxyl and carboxylic acids. Carboxylic acids offer an efficient means to connect other molecules to the surface via amide or ester bond-forming reactions. Oxygenation of these surfaces via oxygen plasma treatment has been shown not to result in deleterious effects on biological compatibility,[16] providing opportunities for experimentation and analysis directly on the plastic surface. Oxygen plasma is a robust method for modifying poly(cyclic olefin) surfaces, but for use on an industrial scale, it will require specialized equipment that is appropriate for large manufacturing facilities only. Alternatively, ozone treatment of cycloolefin polymer surfaces is known to generate hydroxyls, esters, ketones, and carboxylic acid groups on the surface.[16] Whereas the mechanism for this process is not precisely known, studies have shown the presence of intermediates containing hydroperoxides, hydrotrioxides, and peroxyl radicals that generate the various functional groups.[25,26] It has been demonstrated that aggressive oxygen plasma or UV–ozone treatment of plastic surfaces dramatically alters the surface topography and background fluorescence.[16] Simple ozone treatment of plastic surfaces has been shown not to increase background fluorescence as required for fluorescence studies,[16] as well as being an economical, industrially scalable, and environmentally friendly alternative.

We chose an amide bond to append the clickable group for its chemical stability and general ease of formation from a surface carboxylic acid, amine, and carbodiimide coupling agent.[16] Solvent compatibility was a major factor to consider and negated numerous reactions from surface functionalization. For example, reacting the polymeric surface with highly reactive intermediates such as free radicals,[27] nitrenes,[28–30] or carbenes[31,32] is an effective method to attach molecules through C–H insertion, but these reactions are typically carried out within hydrocarbon solvents systems that are not compatible with the Zeonor scaffold. Generally, polar aprotic and polar protic solvents provide optimal surface compatibility. Several carbodiimides are available and effective at generating the desired amide bond, but since Zeonor is hydrocarbon-based, we wanted to avoid reagents derived from aromatic or hydrocarbon side chains from being embedded within the surface. For that reason, we chose EDC because it is water-soluble and known to be compatible with Zeonor coupling procedures.[16] Generally, immobilization of the clickable functionality was accomplished by standard NHS–EDC coupling of oxidized Zeonor surface carboxylic acids with a primary amine containing the azide or alkyne functionality. Control reactions demonstrated that neither the NHS group nor the amine could be attached without the presence of EDC (X-ray photoelectron spectroscopy (XPS) data not shown).

After exploring possible linking reagents for establishing the azide moiety onto the surface, a short, easily synthesized linker azido-propyl amine **1** was chosen.[33] Preparation of the azide-terminated surface was performed as depicted in Scheme 1 and surface incorporation of the azide was confirmed through XPS, described in more detail (vide infra). To test the feasibility of the click reaction on the poly(cyclic olefin) surface, a small clickable tag **2**,[34] possessing a trifluoro carboxamide group was synthesized and used for monitoring the CuAAC reaction by XPS. The trifluoromethyl group is rarely present or incorporated into Zeonor or most other molecules and was ideally suited for demonstrating

Scheme 1. Preparation of alkyne-terminated Zeonor 1060R and subsequent copper(I)-catalyzed [3 + 2] azide–alkyne cycloaddition.



CuAAC reactions on the surface. Any fluorine present on the surface results from reactions of the alkyne and azide directly; this is supported because there was no fluorine incorporation in the absence of copper catalyst. This shows that the copper catalyst was indeed required and that nonspecific adsorption did not occur between the oxidized Zeonor surface and **2**.

There have been reports of catalytic rate enhancements and copper(I) stabilizing effects for CuAAC reactions when conducted in the presence of tris((1-benzyl-1*H*-1,2,3-triazol-4-yl) methyl)amine (TBTA),[35] sulfonated bathophenanthroline (SBP),[36] and tris(2-benzimidazolylmethyl)amine[37,38] ligands. We conducted CuAAC reactions on the surface using stoichiometric equivalents of $CuSO_4$ in the absence of these heterocyclic ligands, since it was found that some of the ligands induced nonuniform surface functionalization as measured by XPS (data not shown). We found that aqueous ethanol in the presence of Cu(I) was an effective medium for direct [3 + 2] cycloadditions on the surface.

After functionalizing the oxidized Zeonor surface with the azide linker **1**, we investigated the immobilization of an alkyne onto the polymer (cyclic olefin) surface to determine if there were surface compatibility issues or reaction preferences between the azide or alkyne moieties. It was not known how the polymer would tolerate a purely hydrocarbon-based linker or how this would affect the [3 + 2] cycloaddition, since the oxidized poly(cyclic olefin) surface is essentially hydrocarbons imparted with oxygen functional groups from either ozone or oxygen plasma oxidation. Using NHS–EDC conditions for coupling **1** to the oxidized surface, we reacted propargyl amine **3** and propargyl tetraethylene glycol amine **4**.[39] It is well-known that pegylated surfaces have greater biocompatibility and increased water solubility, and can inhibit surface-induced denaturation of biomolecules.[40] Zeonor plates were functionalized using both native and ozonated surfaces that were exposed to either **3** or **4** in the presence of NHS–EDC. Incorporation of **3** or **4** terminal alkyne groups was monitored through XPS measurements of signals arising from nitrogen. XPS spectra for surfaces functionalized with **3** or **4** were found to exhibit the expected elemental compositions for the respective reactions. To further confirm click functionalization, we conducted the reaction of **3** and **4** terminated surfaces with derivative **5** (Scheme 2). The resulting fluorine signal in the XPS spectra clearly demonstrated successful CuAAC reactions on the surface.

Contact angle measurements

Poly(cyclic olefins) with unmodified surfaces exhibit a high contact angle (>90°). These pristine surfaces have poor surface wettability, rendering them hydrophilic requires high energy modifications. It is well-established that ozone or oxygen plasma treatments generate various polar functional groups on the surface (e.g., alcohols, ethers, carboxylic acids, ketones, hydroperoxides, or peroxides)[11] and impart a great degree of wettability onto the surface. It was found that ozone treatments of the plastic surface provided a marginal improvement based on contact angles, a decrease to 50°–55°, which was maintained for up to 2 weeks without any change.[41] It is known that oxygenated plastic surfaces rearrange from their treated polar morphology back to a form resembling their original state.[42] The exact mechanism for this rearrangement is not known, but is thought to proceed through incorporation of the polar groups within the polymer.[43–45] Samples treated with oxygen plasma showed the greatest contact angle decrease, reaching essentially 0° with a 15 min exposure. A 5 or 10 min exposure to oxygen plasma provided contact angles of 5°. It was noted that prolonged exposure times resulted in significant alterations of the surface topography and distorted the optical properties of the surface. Since these alterations were undesired, a shorter reaction time was used to preserve the necessary optical properties of Zeonor.

Upon surface oxidation, the Zeonor plates were converted into the azide- and alkyne-terminated surfaces, as described in Schemes 1 and 2, prior to measuring surface contact angles (see Table 1). The measured contact angles from Table 1 show that there is a significant difference between the advancing and receding contact angles, where advancing is the largest possible angle and receding is the smallest angle from the sample. Differences between the advancing and receding contact angles, or the hysteresis, can be used to describe characteristics about the surface.[46] Contact angles from freshly oxygenated samples were found to be <5° for oxygen plasma treatment and about 55° for ozone treatment. From these reference points, functionalization of the surface with the different alkyl and pegylated linkers was found to influence the resulting contact angles for the samples. As shown in Table 1, both oxygenation methods and ensuing surface chemistry were found to significantly decrease the receding contact angle, indicating an enhanced wettability of the surface. Substantial differences in oxygen plasma-treated surfaces were found between initial treatment with the plasma and the functionalization of the clickable surface. This is expected to some degree because the functional groups being attached (mostly alkyl or perfluoroalkyl groups) are more hydrophobic than the expected functional groups present after oxidation, such as carboxylic acids that would be ionized at neutral pH. A possible contributing factor may also be the scission of the polymer during the oxidation process, resulting in highly oxygenated defects on the surface. Initial contact angle measurements would include surfaces that might contain microscopic defects, and upon solution-based functionalization the small defects and (or) the washing away of

Scheme 2. Preparation of azide-terminated Zeonor 1060R surfaces and subsequent copper(I)-catalyzed [3 + 2] azide–alkyne cycloaddition.

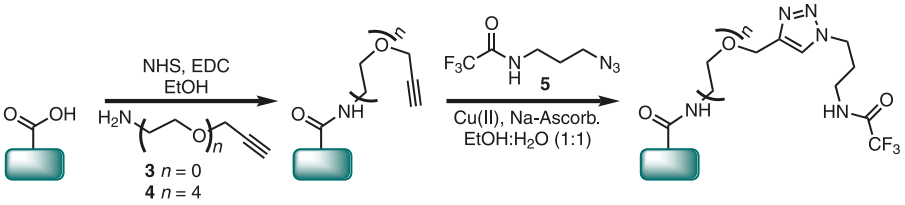

Table 1. Contact angle measurements for azide- and alkyne-terminated Zeonor 1060R surfaces before and after copper-mediated [3 + 2] cycloadditions (CA = contact angle, adv. = advancing and rec. = receding).

Entry	Terminated surface	Oxygen source	Ca[a] (adv.)	Ca[a] (rec.)
1		O_3	73.0	21.9
2		O_3	77.7	25.1
3		O_2	72.8	20.5
4		O_3	82.4	15.5
5		O_2	65.7	17.8
6		O_3	72.2	42.4
7		O_3	81.5	41.0

[a]Values are an average of five measurements for each plate and generally have a standard deviation of 1°–2° for the advancing contact angle and a deviation of 2°–5° for the receding contact angle.

fragments might contribute to a greater change in contact angle and a more hydrophobic surface.[11]

Contact angles for surfaces functionalized with **4** (Table 1, entries 4 and 5) were found to possess the smallest receding contact angles, for both oxygen plasma and ozone treatments; this result was expected because pegylated derivatives are useful for increasing water solubility. Ozone-treated surfaces possessing either alkyne or azide motifs appended via hydrocarbon linkers (Table 1, entries 1–3) were found to exhibit the greater receding contact angles. In comparing entries 2 and 3 in Table 1, there is a significant difference between oxygen plasma and ozone treatment on surfaces terminated with **3**. Entries 6 and 7 demonstrate that once the CuAAC reaction has been carried out, a significant increase in receding contact angle occurred because of the hydrophobic nature of the linker.

Surface hysteresis can be influenced by a number of factors including surface roughness, chemical heterogeneity, surface deformation, surface configurational change, and adsorption and desorption. Surface roughness and deformation of the samples were found to have little influence on the contact angles based on AFM (results not shown), since the average deviation on surfaces was determined to be 90 Å. Oxygenated Zeonor surfaces are known to revert to their original surface environment over time through molecular reorganization,[47] but reorganization will not occur once surface functional groups are converted to the corresponding amides. Chemical heterogeneity, where the surface functionalization randomly occurs across the surface, may have some contribution to the observed hysteresis because it is known that ozonolysis produces some chemical heterogeneity on the surface.[16]

Surface functionalization by CuAAC and XPS

To unequivocally prove that the surfaces were functionalized through amide bond formation and not by nonspecific binding, a series of experiments were measured by XPS. For all samples, the binding energy (BE) was calibrated to 285 eV for the C1s signal. The XPS spectrum for native Zeonor surface (Fig. 1*a*) displays a predominant peak from C1s (98.78%; Table 1, entry 1) and a small O1s signal (1.22%; Table 1, entry 1). XPS analysis of surfaces treated by ozonolysis demonstrated that a significant degree of oxygenation had occurred (Fig. 1*b*), where the elemental oxygen on the surface rose to 11.43% (Table 2, entry 2). Determining an effective surface coverage of oxygen from the XPS data requires knowledge of the inelastic mean free path for C1s photoelectrons in Zeonor. In the absence of this quantity, a value of ~3.5 nm can be assumed based on calculations for other polymers such as polystyrene and PMMA.[48] Using this value along with the density of Zeonor (1 g/cm^3), and assuming that all the oxygen is incorporated at the surface of the polymer, the observed oxygen signal corresponds to ~1.25 oxygen atoms per surface carbon atom. NHS–EDC coupling of **1** to the surface resulted in a signal for N1s (Fig. 1*c*). The observation of a N1s peak clearly indicated that the azide had been covalently attached to the surface via an amide linkage, since control experiments conducted in the absence of NHS–EDC found that nonspecific binding of **1** did not occur (data not shown). The percentage of nitrogen was shown to increase on the surface to 6.44% (Table 3, entry 3). Since each grafted azide will contribute four nitrogen atoms, the observed nitrogen signal corresponds to a surface coverage of ~0.1 ML (~10% of a monolayer) of azide groups. Having an azide grafted to ~10% of surface carbons is a useful amount in terms of immobilizing probe biomolecules on the surface.

After subjecting the azide-terminated surface to CuAAC reaction with fluorinated alkyne **2**, the XPS spectrum (Fig. 1*d*) showed incorporation of fluorine (2.72%; Table 3, entry 4) at a BE of 686 eV and of copper at a BE of 932 eV. Control experiments without the presence of copper did not provide a signal from fluorine, which indicated that nonspecific adsorption of **2** had not occurred on the surface and, as well, that copper was indeed necessary for the CuAAC reaction (data not shown).

Analogously, modification of the ozone-treated Zeonor 1060R surface with alkyne **3** and subsequent CuAAC reaction with **4** were analyzed by XPS (Fig. 2). XPS spectra were obtained for the alkyne-terminated surface (Fig. 2*a*)

Table 2. X-ray photoelectron spectroscopy (XPS) analysis of the azide- and alkyne-terminated Zeonor surfaces before and after performing copper-catalyzed azide–alkyne cycloaddition (CuAAC) reactions.

Entry	Terminated surface	C–O ratio	C–N ratio	O–N ratio	N–F ratio
1	**1** (before)	7.1	12.8	1.8	na
2	**1** (after)	6.1	15.0	2.4	1.9
3	**3** (before)	6.1	26.8	4.4	na
4	**3** (after)	5.1	19.4	3.8	2.2

and triazole-linked surface (Fig. 2*b*). NHS–EDC coupling with **3** resulted in 3.10% nitrogen incorporation (Table 3, entry 5) with a BE of ca. 400 eV. As expected, the peak intensity of the N1s signal for the alkyne-terminated surface was much lower than for the previous azide-terminated surface, since there was only one nitrogen being incorporated, not four. The fact that the nitrogen signal is only two times higher (and not four) for the azide is likely due to the fact that some of the observed nitrogen signal arises from unreacted NHS-activated groups on the surface. CuAAC of the alkyne-terminated Zeonor 1060R surface with fluorinated azide **5** was confirmed with the incorporation of fluorine (1.88%; Table 3, entry 6) at a BE of 686 eV. As in Fig. 1*d*, some copper catalyst remains on the surface as indicated by the 931 eV feature. Nitrogen features around 400 eV represented an increase of nitrogen from the formation of the triazole cycloadduct. The copper feature at 931eV could be minimized by washing the surface with an ethanol–imidazole solution (Fig. 2*c*). Control experiments conducted in the absence of CuSO4 – sodium ascorbate did not show nonspecific adsorption of **5** onto the surface.

Additional analysis of the surfaces that underwent click reactions was performed to compare the different ratios of incorporated elements (Table 2). Investigating either azide **1** or alkyne **3** terminated surfaces before and after click reactions provides information regarding CuAAC reaction efficiency on the surface. Under ideal conditions, where incorporation of the CF_3 label results from triazole formation, N and F should be found in a 5:3 ratio. The observed N–F ratios for reactions of **1** and **3** terminated surfaces with **5** were found to be 1.9 and 2.2, respectively (Table 2, entries 2 and 4), which are quite close to the expected value. This close correspondence between expected and measured N–F ratios indicates that the CuAAC coupling reactions proceed quite efficiently with most of the initial azide or alkyne groups leading to triazole formation. Coupling with the azide-terminated surface yields a slightly greater amount of fluorine incorporation suggesting a greater overall grafting efficiency for this route. The expected O–N ratios for **1**-and **3**-terminated surfaces are 0.25 and 1, respectively. Upon triazole formation, the ratio should change to 0.4. The observed O–N ratios for the initial azide and alkyne surfaces are significantly larger than expected. The azide-terminated surface exhibits 14% of the expected nitrogen content, whereas the alkyne-terminated surface has 22% of the expected nitrogen (assuming all of the initial oxygen is the form of acid groups). Several factors contribute to the excess oxygen (or lower nitrogen content): not all oxygen induced by the ozone treatment is in the form of carboxylic acids; it is likely that not all carboxylic acids are NHS activated; and finally not all NHS-activated acids lead to amide formation. Unreacted NHS activated groups yield a O–N ratio of 4. Because the initial surfaces have excess oxygen, it is not surprising that the surfaces after CuAAC reaction also exhibit larger O–N ratios than expected. However, the trends upon triazole formation are as expected with coupling to the azide surface increasing the O–N ratio, whereas coupling to the alkyne surface decreases the O–N ratio. The observed C–N and C–O ratios are also clearly larger than expected based on the grafted molecules alone, since much of the carbon signal comes from several layers of "bulk" Zeonor. However, the changes after the CuACC reaction are in accord with expectations, with the C–N ratio increasing upon coupling to the azide-terminated surface and decreasing upon addition to the alkyne.

CuAAC reactions of alkyne-terminated cycloolefin polymer surfaces with tetramethylrhodamine azide

Having demonstrated CuAAC reactions on the surface of alkyne- or azide-terminated Zeonor surfaces using fluorinated chemical handles, we wanted to investigate the generation of a thin fluorescent film by reacting alkyne-terminated Zeonor surfaces with a fluorescent chemical handle (Fig. 3), tetramethylrhodamine azide (TAMRA-N_3).[49] We also wanted to evaluate the dependence of alkyne linker length and whether the presence of a TBTA ligand would result in more efficient CuAAC reactions within shorter timeframes.

As expected, **3**- and **4**-terminated Zeonor 1060R surfaces underwent CuAAC reactions with TAMRA-N_3, and the course of the reaction was monitored by fluorescence. After 1 h of reaction, a significant increase in fluorescence on the surface was observed for both alkyne-terminated surfaces, indicating successful formation of the 1,4-substituted triazole

Table 3. Elemental composition percentages of Zeonor 1060R, ozone-treated Zeonor 1060R, and **1**-and **3**-terminated surfaces before and after copper-catalyzed azide–alkyne cycloaddition (CuAAC) with **2** and **5**, respectively.

			Elemental composition (%)[a]			
Entry	Terminated surface	Oxidant	C1s	O1s	N1s	F1s
1	Native	na	98.78	1.22	0	0
2	Oxidized	O_3	88.17	11.43	0	0
3	**1** (before)	O_3	82.25	11.66	6.44	0
4	**1** (after)	O_3	79.10	12.88	5.28	2.72
5	**3** (before)	O_3	82.94	13.65	3.10	0
6	**3** (after)	O_3	78.42	15.37	4.05	1.88

[a]Values were determined by background subtraction and applying a sensitivity-factor correction using the Casa XPS software. Values represent the average of at least three measurements from two independent samples.

Fig. 2. X-ray photoelectron spectroscopy (XPS) analysis of surface modification through ozonolysis and functionalization with **3** followed by copper-catalyzed azide–alkyne cycloaddition (CuAAc) with **5**. (*a*) Functionalization through EDC–NHS and **3**. (*b*) CuAAC reaction of **3**-terminated surface with **5**. (*c*) Removal of copper through ethanol–imidazole washing.

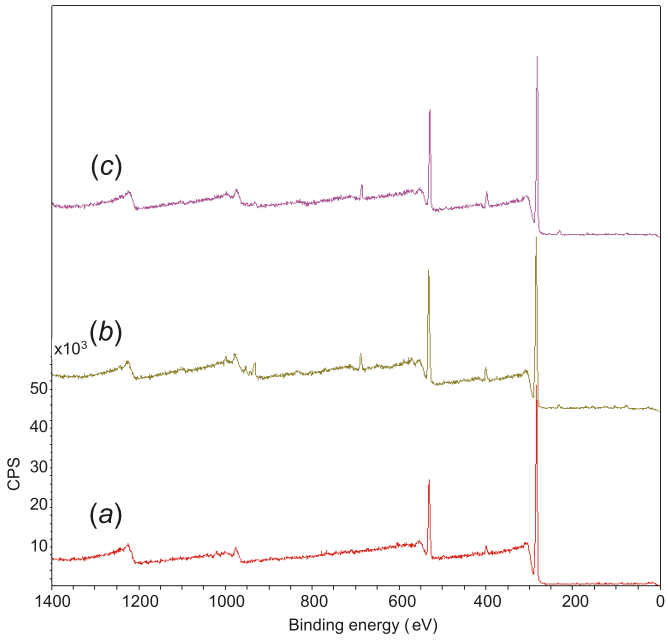

Fig. 3. Generation of a fluorescent thin film on **3**- and **4**-terminated Zeonor surfaces via copper-catalyzed azide–alkyne cycloaddition (CuAAC) reactions with tetramethylrhodamine azide (TAMRA-N_3).

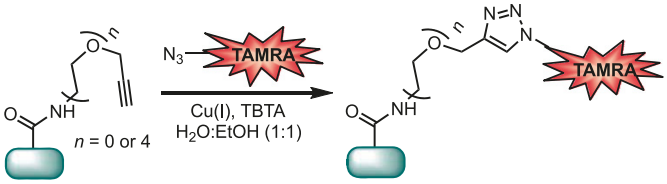
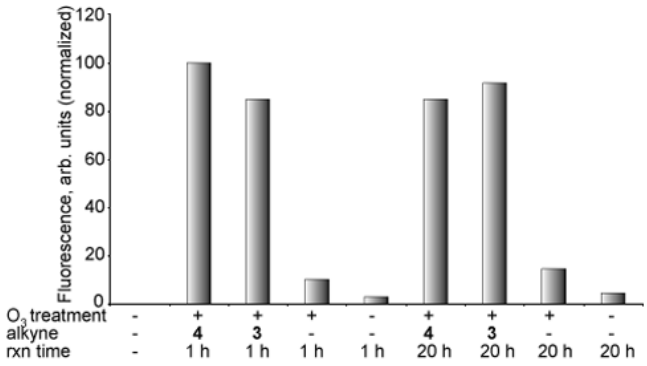


product (Fig. 4, lanes 2 and 3). The negative controls after 1 h of reaction (Fig. 4, lanes 4 and 5) and 20 h of reaction (Fig. 4, lanes 8 and 9) resulted in negligible increases in fluorescence, indicating minimal nonspecific binding of

Fig. 4. Fluorescence from copper-catalyzed azide–alkyne cycloaddition (CuAAC) reactions of **3**- and **4**-terminated surfaces with tetramethylrhodamine azide (TAMRA-N_3).



TAMRA-N_3 to the surface. This background fluorescence could be minimized by washing the surface with KOH–EtOH solution.

After 20 h of CuAAC reaction, fluorescence signals from reactions of **3**- and **4**-terminated surfaces displayed the expected changes owing to successful functionalization (Fig. 4, lanes 6 and 7), whereas the negative controls demonstrated a small increase of nonspecific binding of TAMRA-N_3 to the surface (Fig. 4, entries 8 and 9). Based on the fluorescence experiments, **3**- and **4**-terminated Zeonor surfaces underwent successful CuAAC reactions within 1 h in the presence of TBTA. The added pegylated linker length of **4** displayed slightly more efficient CuAAC reactions in the 1 h reaction times; this can likely be attributed to the added flexibility and solubility of this alkyne linker under the CuAAC reaction conditions.

Conclusion

We investigated the oxidation of Zeonor 1060R surfaces using both ozone and oxygen plasma and found both techniques to provide viable routes for attaching the unique azide or alkyne clickable groups via amide couplings. From our data, ozone and oxygen plasma were comparable in binding efficacy for identical amines, and ozone would be the preferred choice based on convenience and cost. Zeonor surfaces were found to support a clickable surface that reacted in

aqueous ethanol for either azide or alkyne moieties, but azide surfaces were found to be ideal based on yields estimated by multiple XPS experiments. Fluorescence experiments with TAMRA-N3 provided a visual means of monitoring the CuAAC reactions of **3** and **4** on the oxidized Zeonor 1060R surface. With these proof-of-principle approaches that we have shown for clickable surfaces, it is now possible to apply modular chemistry to incorporate numerous different reporter groups onto Zeonor-based slides or devices. We are currently conducting such experiments and the results will be reported in due course.

Materials and methods

Materials

Zeonor 1060R pellets were obtained from Zeon Chemical (Louisville, Kentucky). The plates weree formed by injection moulding using a Boy 30A injection tool (Dr. Boy GmbH & Co. KG, Germany) at a temperature of 250–260 °C, an injection speed of 40 mm/s, and a pressure of 132 bar (1 bar = 100 kPa). All chemicals were purchased from Sigma-Aldrich and were used without further purification. The following reagents were prepared according to literature procedures: 3-azidopropylamine (**1**),[33,34] *N*-trifluoroacetylpropargylamine (**2**),[50,51] 3,6,9,12-tetraoxopentadec-14-yn-1-amine (**4**),[39] 1-azido-3-(trifluoroacetamido)propane (**5**),[34] and TAMRA-N_3.[49]

XPS

The XPS analyses were performed using a PHI 5500 XPS instrument with a monochromated Al Kα source at an angle 45° from the wafer normal. (The X-ray source is Al 1486.6 eV mono at 350.0 W.) The PHI model 10-360 precision energy analyzer consists of an input lens, a spherical capacitor analyzer (SCA), and a detector. All experimental data were obtained within a vacuum of 10^{-9} Torr (1 Torr = 133.322 Pa). Quantitative analysis of the spectra reported in Tables 2 and 3 was carried out using CasaXPS version 2.3.14.

Preparation of Zeonor 1060R plates

Ozone treatment of Zeonor 1060R plates

Surfaces of Zeonor 1060R were treated for 1 h in an OZO-2VTT (O_3 Zomax, Canada) ozone generator that produces 3% ozone (by weight).

Oxygen plasma treatment of the Zeonor 1060R plates

Plates were exposed to an oxygen plasma (Plasma-lab 80Plus, Oxford Instruments, UK) for 10 min at a pressure of 100 mTorr, a gas flow of 20 cm^3/min, and a power of 200 W.

Contact angle measurements

Advancing and receding contact angle measurements were obtained from a Ramé-Hart Instrument Co. goniometer (model 200-F1, Netcong, New Jersey) using deionized water as the probe liquid.

General procedure for azide–alkyne functionalization of oxygenated Zeonor 1060R

To a 50 mL round bottom flask were added EtOH (30 mL), NHS (158 mg, 1.37 mmol), and EDC–HCl (570 mg, 2.74 mmol), and the mixture was stirred until a homogeneous solution was obtained. Then, oxygenated Zeonor 1060R was introduced into the solution and stirring was continued for 2 h, after which time the samples were removed and washed with EtOH (two times) and dried under purified nitrogen. The samples were then added to a solution containing either azide (**1**) or alkyne (**3** or **4**) in DMSO (30 mL) and stirred for 16 h. After 16 h, samples were removed and washed with EtOH and again dried under a stream of nitrogen gas.

General procedure for CuAAC reactions on the plastic surface

In a 20 mL screw cap vial were added EtOH (5 mL), dH_2O (5 mL), and $CuSO_4{\cdot}5H_2O$ (2.2 mg, 0.088 mmol) and the vial was covered with aluminum foil and cooled to 0 °C. Sodium ascorbate (3 equiv, 5.0 mg, 0.252 mmol) was added and the solution was stirred for 20 min, at which time either **2** or **5** was added followed by the functionalized plastic surface. After stirring overnight, samples were washed with EtOH, H_2O, and EtOH and dried with purified nitrogen or argon. Samples were examined by XPS. Samples were placed into a solution of imidazole in EtOH (0.11 mol/L (113 mg, 1.66 mmol in 15 mL)) for 30 min, followed by two successive EtOH washes and then dried with purified nitrogen. Samples were re-examined by XPS to confirm the presence or absence of copper.

General procedure for CuAAC reactions of alkyne-terminated surfaces with TAMRA-N_3

In a 20 mL screw cap vial in the dark was added 10 mL of EtOH–H_2O (1:1), the solution was cooled to 0 °C, and then 0.5 mL of a $CuSO_4{\cdot}5H_2O$ solution (3.8 mg in 4.0 mL of water) and 0.5 mL of a sodium ascorbate solution (30.7 mg in 4 mL of water) were added. The solution was stirred for 20 min at which time 0.25 mL of a TBTA solution (16.2 mg in 2.0 mL DMSO) and 0.25 mL of TAMRA-N_3[49] (3.9 mg in 4.0 mL EtOH) were added, followed by a Zeonor plate (**3**-terminated, **4**-terminated, ozone treated, and native Zeonor 1060R). After the desired reaction time, the plates were removed, then briefly washed for 2 min with a freshly prepared solution of KOH in EtOH, then washed with EtOH, H_2O, and EtOH, and then dried with purified nitrogen. Plates were scanned for fluorescence using the Typhoon 9410 (GE Healthcare, Piscataway, New Jersey) and analyzed using ImageJ software.

Abstract: The Suzuki–Miyaura cross-coupling reaction provides a useful method for the synthesis of methyl 2-(2-chloropyridyl or 2-methoxypyridyl)phenylacetates. The 2-chloropyridyl or 2-methoxypyridyl ring system can be readily elaborated to N-substituted (OH, Me, CHF_2, H) 1,2-dihydropyrid-2-one ring systems that are useful synthons for use in bioorganic and medicinal chemistry applications.

Key words: Suzuki–Miyaura cross-coupling reaction, 1,2-dihydropyrid-2-ones, cyclooxygenase (COX) and 5-lipoxygenase (5-LOX) inhibition.

Résumé : La réaction de couplage croisé de Suzuki–Miyaura est une méthode utile pour la synthèse d'esters 2-(2-chloropyridyl)- ou de 2-(méthoxypyridyl)phénylacétates. Ce système cyclique, portant des groupes 2-chloropyridyle ou 2-méthoxypyridyle, peut facilement être transformé en systèmes cycliques à base de 1,2-dihydropyrid-2-one N-substituée (OH, Me, CHF_2, H), des synthons utiles dans des applications de chimie bioorganique ou médicinale.

Mots-clés : réaction de couplage croisé de Suzuki–Miyaura, 1,2-dihydropyrid-2-ones, inhibition de la cyclooxygénase (COX) et de la 5-lipoxygénase (5-LOX).

[Traduit par la Rédaction]

Introduction

Biotransformation of arachidonic acid gives rise to prostaglandin and leukotriene inflammatory mediators that are produced via their respective cyclooxygenase (COX) and lipoxygenase (LOX) pathways.[1] Dual inhibition of the LOX and COX enzymatic pathways[2] provides a rational approach for the design of superior anti-inflammatory agents with a better safety profile relative to ulcerogenic nonsteroidal anti-inflammatory drugs (NSAIDs) or selective COX-2 inhibitors that increase the incidence of adverse cardiovascular thrombotic effects.[3,4] The most successful effort to develop 5-LOX inhibitors was focused on *N*-hydroxyureas such as zileuton (**1**, see structure in Fig. 1), which is believed to chelate iron present in the 5-LOX enzyme.[5,6] In earlier studies, we showed that linear acetylenes possessing cyclic hydroxamic acid, *N*-hydroxy-1,2-dihydropyrid-2-one (**2**),[7] or *N*-difluoromethyl-1,2-dihydropyrid-2-one (**3**,[8] **4**[9]) 5-LOX pharmacophores exhibited dual COX and 5-LOX inhibitory activities. In a continuation of our ongoing program to design novel anti-inflammatory agents and acquire additional structure–activity relationship data, we now describe the synthesis of a group of arylacetic acids possessing an N-substituted (OH, Me, CHF_2, H) 1,2-dihydropyrid-2-one moiety, and their evaluation as inhibitors of the COX-1, COX-2, and 5-LOX enzymes.

Results and discussion

Reaction of methyl 2-iodophenylacetate (**5**)[9] with a 4- or 5-pyridineboronic acid (**6a**–**6c**) using a Suzuki–Miyaura[10,11] cross-coupling reaction in the presence of the tetrakis(triphenylphosphine)palladium (0) catalyst and 2 mol/L aqueous sodium carbonate furnished the respective diaryl products **7a**–**7c** in good yields (58%–77%) (Scheme 1). Oxidation of **7a** and **7c** using *m*-chloroperbenzoic acid (*m*-CPBA) in dichloromethane afforded the target methyl 2-(1-oxido-2-chloropyridin-4-yl)phenylacetate (**8a**, 42%) or methyl 2-(1-oxido-2-methoxypyridin-5-yl)phenylacetate (**8c**, 59%). Hydrolysis of the methyl ester **8a** using 2 N sodium hydroxide at reflux for 24 h afforded the target phenylacetic acid product **9a** in 41% yield. Reaction of the *N*-oxide **8c** with acetyl chloride at reflux, and then methanolysis, afforded the *N*-hydroxy-1,2-dihydropyrid-2-one **9c** in 96% yield.[12] Subsequent depro-

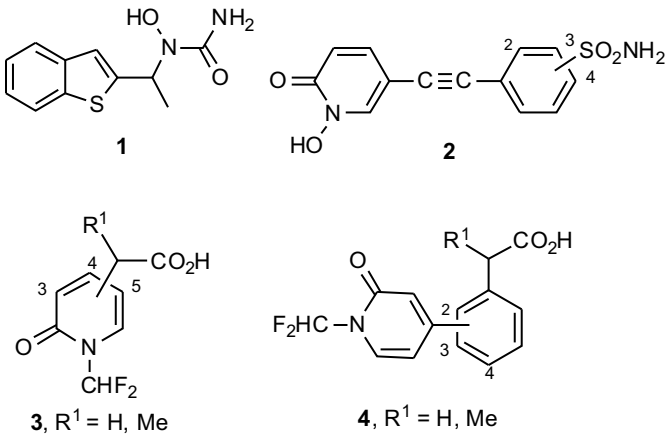
Fig. 1. Structures of the iron-chelating 5-LOX inhibitor zileuton (**1**) and dual inhibitors of the COX and LOX enzymes that possess an *N*-hydroxy-1,2-dihydropyrid-2-one (**2**) or *N*-difluoromethyl-1,2-dihydropyrid-2-one (**3**, **4**) 5-LOX pharmacophore.



tection of the methyl ester group present in **9c** using lithium hydroxide in MeOH and tetrahydrofuran (THF) at reflux temperature afforded the target phenylacetic acid product **10c** in 74% yield.

The 2-chloropyridine compounds **7a** and **7b** were converted to their respective *N*-methylpyridinium methylsulfate salts (**11a** and **11b**) upon reaction with dimethyl sulfate at reflux in acetonitrile (see Scheme 2).[13] Subsequent treatment of the salts **11a** and **11b** with 2 N aqueous lithium hydroxide at reflux proceeded smoothly, resulting in simultaneous hydrolysis of the methyl ester and conversion of the *N*-methyl-2-chloropyridinium ring to an *N*-methyl-1,2-dihydropyrid-2-one ring, to furnish the corresponding target products **12a** and **12b** in 70%–89% yield.[14] Alternatively, reaction of the 2-chloropyridyl compound **7b** with $FSO_2CF_2CO_2H$[15] in the presence of $NaHCO_3$ afforded the *N*-difluoromethyl-1,2-dihydropyrid-2-one product **13** in 53% yield. Selective hydrolysis of the methyl ester group in **13** using 2 N LiOH in a MeOH–THF–H_2O (1:1:1, *v*/*v*/*v*) solvent system afforded the phenylacetic acid product **14**.[14] In contrast, hydrolysis of **13** under more basic reaction conditions using aqueous 2 N NaOH and a longer reaction time of 5 h resulted in concomitant cleavage of the methyl ester substituent and removal of the *N*-difluoromethyl substituent to afford 2-(2-oxo-1,2-dihydropyridin-5-yl)phenylacetic acid (**15**) in 65% yield.

The *N*-hydroxy-1,2-dihydropyrid-2-one cyclic hydroxamic acid mimetics **9a** and **10c** were designed with the expectation[7] that they would act as iron chelators to inhibit the 5-LOX enzyme. Although the C-5 regioisomer **10c** did exhibit weak COX-2 inhibition (IC_{50} = 10.1 μmol/L), **9a** and **10c** were both inactive as inhibitors of the 5-LOX enzyme (see data in Table 1). Similar enzyme inhibition studies showed that the C-4 (**12a**) and C-5 (**12b**) *N*-methyl-1,2-dihydropyrid-2-one regioisomers were inactive as inhibitors of the 5-LOX and COX-2 enzymes (IC_{50} > 100 μmol/L), but the C-4 regioisomer **12a** exhibited weak inhibition (IC_{50} = 52.4 μmol/L) of the COX-1 enzyme. In spite of its weak in vitro COX-1 inhibitory activity, **12a** showed good in vivo anti-inflammatory activity in a rat model, where a 45% reduction in inflammation was observed for a 100 mg/kg oral dose relative to the reference drug ibuprofen, which furnished a 50% reduction in inflammation for a 67 mg/kg oral dose. The structurally related *N*-difluoromethyl-1,2-dihydropyrid-2-one **14** and 1,2-dihydropyrid-2-one **15** compounds, which failed to inhibit the COX-1 and 5-LOX enzymes (IC_{50} > 100 μmol/L), showed weak inhibition of the COX-2 enzyme relative to the reference drugs aspirin and ibuprofen. In view of their weak COX-2 inhibitory potency and failure to inhibit 5-LOX, the anti-inflammatory activities for **14** and **15** were not determined. These enzyme inhibition structure–activity data show that none of the compounds investigated in this study exhibited the desired dual inhibition of the COX-2 and 5-LOX enzymes.

Scheme 1. Synthesis of *N*-hydroxy-1,2-dihydropyrid-2-one derivatives of phenylacetic acid. Reagents and conditions: (*a*) $Pd(PPh_3)_4$, 2 mol/L Na_2CO_3 (**6a** and **6b**, reflux in THF for 16 h; **6c**, reflux in 1,4-dioxane for 4 h); (*b*) *m*-CPBA, CH_2Cl_2, 25 °C, 48 h; (*c*) 2 N NaOH, reflux, 24 h (**8a**); (*d*) (*i*) AcCl, reflux, 1 h, (*ii*) MeOH, 25 °C, 16 h (**8c**); (*e*) 2 N LiOH, MeOH–THF–H_2O (1:1:1, *v*/*v*/*v*), reflux, 3 h.

[a]The in vitro test compound concentration required to produce 50% inhibition of ovine COX-1 or human recombinant COX-2. The result (IC_{50}, μmol/L) is the mean of two determinations acquired using an enzyme immunoassay kit (catalog No. 560131, Cayman Chemicals Inc., Ann Arbor, Michigan), and the deviation from the mean is <10% of the mean value.

[b]The in vitro test compound concentration required to produce 50% inhibition of potato 5-LOX (Cayman Chemicals Inc. catalog No. 60401). The result (IC_{50}, μmol/L) is the mean of two determinations acquired using a LOX assay kit (catalog No. 760700, Cayman Chemicals Inc.), and the deviation from the mean is <10% of the mean value.

[c]Data taken from a previous report (ref. 16). COX-2 inhibition was determined using ovine COX-2.

boronic acid provides a useful method for the synthesis of methyl 2-(pyridinyl)phenylacetates. The 2-chloropyridyl and 2-methoxypyridyl ring systems present in this group of compounds can be readily elaborated to *N*-hydroxy-1,2-dihydropyrid-2-one (a cyclic hydroxamic acid), *N*-methyl-1,2-dihydropyrid-2-one, and 1,2-dihydropyrid-2-one ring systems that may serve as useful synthons in bioorganic and medicinal chemistry applications.

Experimental

Instrumentation, analysis, and starting material

Melting points were determined on a Thomas Hoover capillary apparatus and are uncorrected. IR spectra were recorded as films on NaCl plates using a Nicolet 550 Series II Magna FT–IR spectrometer. ^1H NMR spectra were measured on a Bruker AM-300 spectrometer in $CDCl_3$ or DMSO-d_6 with TMS as the internal standard. Compounds **7**–**8**, **9c**, **10c**, **11**, and **13** showed a single spot on Macherey–Nagel Polygram Sil G/UV254 silica gel plates (0.2 mm) using a low, medium, or highly polar solvent system; no residue remained after combustion, indicative of high purity. Microanalyses for all other compounds were performed for C, H, and N (Micro Analytical Service Laboratory, Department of Chemistry, University of Alberta) and were within 0.4% of theoretical values. Silica gel column chromatography was performed using Merck silica gel 60 ASTM (70–230 mesh). All reagents were purchased from the Sigma-Aldrich Chemical Company (Milwaukee, Wisconsin), with the exception of 2-chloropyridine-4-boronic acid, purchased from Combi-Blocks Inc., and were used without further purification.

General Suzuki–Miyaura cross-coupling synthesis of 7a–7c

Methyl 2-iodophenylacetate (**5**, 1.20 g, 4.35 mmol) and a pyridineboronic acid (**6a**–**6c**, 4.35 mmol) were dissolved in a polar solvent (THF, 50 mL for **6a** and **6b** or 1,4-dioxane, 50 mL for **6c**). Aqueous 2 mol/L Na_2CO_3 (6.5 mL, 13.05 mmol) and then $Pd(PPh_3)_4$ (115 mg, 0.10 mmol) were added. The reaction was allowed to proceed at reflux under argon (16 h for **6a** and **6b** and 4 h for **6c**) and then cooled to 25 °C; water (50 mL) was added, and the mixture was extracted with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water (2 × 30 mL), the organic

fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The residue obtained was purified by silica gel column chromatography using hexanes–EtOAc (3:1, *v*/*v*) as eluent to afford the respective products **7a**–**7c**. Some spectroscopic data for **7a**–**7c** are listed below.

Methyl 2-(2-chloropyridin-4-yl)phenylacetate (7a)

Yield, 74%; yellow oil. IR (film): 2920, 1736, 1536 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.72 (s, 2H, C*H*$_2$), 3.73 (s, 3H, O*Me*), 7.39–7.55 (overlapping multiplets, 6H total, phenyl H-3, H-4, H-5, H-6, pyridyl H-3, H-5), 8.44 (d, J = 5.5 Hz, 1H, pyridyl H-6). ^{13}C NMR ($CDCl_3$) δ: 41.0, 52.2, 120.5, 122.1, 125.8, 128.0, 129.5, 130.6, 135.1, 137.2, 150.0, 151.2, 152.2, 171.5.

Methyl 2-(2-chloropyridin-5-yl)phenylacetate (7b)

Yield, 58%; pale yellow oil. IR (film): 2918, 1734, 1590 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.56 (s, 2H, C*H*$_2$), 3.64 (s, 3H, O*Me*), 7.24 (d, J = 6.1 Hz, 1H, phenyl H-6), 7.36–7.41 (overlapping multiplets, 3H, phenyl H-3, H-4, H-5), 7.37 (d, J = 8.5 Hz, 1H, pyridyl H-3), 7.68 (dd, J = 8.5, 2.4 Hz, 1H, pyridyl H-4), 8.37 (d, J = 2.4 Hz, 1H, pyridyl H-6). ^{13}C NMR ($CDCl_3$) δ: 38.6, 52.1, 123.7, 127.6, 128.7, 130.3, 130.7, 132.1, 135.6, 137.3, 139.5, 149.7, 150.5, 171.7.

Methyl 2-(2-methoxypyridin-5-yl)phenylacetate (7c)

Yield, 77%; pale yellow syrup. IR (film): 2919, 1736, 1086 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.60 (s, 2H, C*H*$_2$), 3.65 (s, 3H, O*Me*), 3.99 (s, 3H, pyridyl-O*Me*), 6.80 (d, J = 8.5 Hz, 1H, pyridyl H-3), 7.23–7.39 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.57 (dd, J = 8.5, 1.8 Hz, 1H, pyridyl H-4), 8.12 (d, J = 1.8 Hz, 1H, pyridyl H-6). ^{13}C NMR ($CDCl_3$) δ: 38.7, 52.0, 53.5, 110.2, 127.2, 127.4, 127.9, 129.7, 130.4, 132.3, 138.7, 139.6, 146.6, 163.3, 172.0.

General procedure for the synthesis of methyl 2-(1-oxido-2-chloropyridin-4-yl)phenylacetate (8a) and methyl 2-(1-oxido-2-methoxypyridin-5-yl)phenylacetate (8c)

m-Chloroperoxybenzoic acid (77% maximum purity) (12 mmol) was added to a stirred solution of a pyridine (**7a** or **7c**, 3.0 mmol) in CH_2Cl_2 (30 mL), and the reaction was allowed to proceed with stirring at 25 °C for 48 h. The solvent was washed with a saturated solution of aqueous $NaHCO_3$ (2 × 20 mL), then washed with water (40 mL) and brine, and the organic fraction was dried ($MgSO_4$). Removal of the solvent from the organic fraction in vacuo gave a residue that was purified by silica gel column chromatography using methanol–EtOAc (10:1, *v*/*v*) as eluent to afford the respective product **8a** or **8c**. Some physical and spectroscopic data for **8a** and **8c** are listed below.

Methyl 2-(1-oxido-2-chloropyridin-4-yl)phenylacetate (8a)

Yield, 42%; pale yellow oil. IR (film): 3060, 3030, 2955, 1741, 1461, 1267 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.59 (s, 2H, C*H*$_2$), 3.69 (s, 3H, O*Me*), 7.26 (dd, J = 6.7, 2.4 Hz, 1H, pyridyl H-5), 7.27–7.55 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.55 (d, J = 2.4 Hz, 1H, pyridyl H-3), 8.40 (d, J = 6.7 Hz, 1H, pyridyl H-6). ^{13}C NMR ($CDCl_3$) δ: 38.5, 52.3, 124.7, 127.6, 127.9, 129.3, 129.5, 131.1, 131.5, 137.1, 139.5, 139.9, 141.6, 171.5.

Methyl 2-(1-oxido-2-methoxypyridin-5-yl)phenylacetate (8c)

Yield, 59%; pale yellow oil. IR (film): 2961, 1740, 1438, 1257 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.58 (s, 2H, C*H*$_2$), 3.67 (s, 3H, O*Me*), 4.14 (s, 3H, pyridyl-O*Me*), 6.96 (d, J = 8.5 Hz, 1H, pyridyl H-3), 7.23–7.39 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.32 (dd, J = 8.5, 1.8 Hz, 1H, pyridyl H-4), 8.29 (d, J = 1.8 Hz, 1H, pyridyl H-6). ^{13}C NMR ($CDCl_3$) δ: 38.5, 52.2, 57.4, 107.3, 127.7, 128.8, 129.0, 130.1, 130.8, 132.1, 136.0, 139.9, 157.8, 171.6.

2-(1-Hydroxy-2-oxo-1,2-dihydropridin-4-yl)phenylacetic acid (9a)

A mixture of methyl 2-(1-oxido-2-chloropyridin-4-yl)phenylacetate (**8a**, 0.75 mmol) and 2 N NaOH (3.0 mL, 6.0 mmol) was refluxed for 24 h. The reaction mixture was cooled to 25 °C and washed with CH_2Cl_2 (30 mL). The water phase was then acidified to pH 2 by addition of 3 N hydrochloric acid prior to extraction with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water and then brine, the organic fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The crude product was purified by flash silica gel column chromatography using EtOAc–MeOH (9:1, *v*/*v*) as eluent to furnish **9a** in a 41% yield as an off-white solid, mp >335 °C. IR (film): 3084, 3018, 2922, 1722, 1651, 1575, 1229 cm^{-1}. ^1H NMR (DMSO-d_6) δ: 3.56 (s, 2H, C*H*$_2$), 6.63 (dd, J = 6.7, 1.8 Hz, pyridone H-5), 6.85 (dd, J = 6.7, 1.8 Hz, 1H, pyridone H-3), 7.18–7.34 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 8.02 (d, J = 6.7 Hz, 1H, pyridone H-6), 8.65 (br s, 2H, NO*H* and COO*H*). Anal. Calcd for $C_{13}H_{11}NO_4 \cdot 1/8H_2O$: C, 63.03; H, 4.55; N, 5.65. Found: C, 63.21; H, 4.64; N, 5.62.

Methyl 2-(1-hydroxy-2-oxo-1,2-dihydropridin-5-yl) phenylacetate (9c)

Acetyl chloride (5 mL) was added to methyl 2-(1-oxido-2-methoxypyridin-5-yl)phenylacetate (**8c,** 82 mg, 0.30 mmol) and the reaction was allowed to proceed at reflux for 1 h. The reaction mixture was cooled to 25 °C, and excess acetyl chloride was removed in vacuo. The residue was dissolved in methanol prior to stirring at 25 °C for 16 h. Methanol was removed in vacuo to afford **9c**; yield, 96%; pale yellow oil. IR (film): 3026, 2961, 2921, 1746, 1656, 1582, 1168 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.61 (s, 2H, C*H*$_2$), 3.68 (s, 3H, O*Me*), 6.87 (d, J = 9.1 Hz, 1H, pyridyl H-3), 7.23–7.37 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.49 (dd, J = 9.1, 2.4 Hz, 1H, pyridyl H-4), 7.90 (d, J = 2.4 Hz, 1H, pyridyl H-6), 8.67 (br s, 1H, *N*-O*H*). ^{13}C NMR ($CDCl_3$) δ: 38.7, 52.2, 116.8, 119.8, 127.7, 128.7, 130.4, 130.6, 130.7, 132.4, 136.3, 139.5, 156.7, 171.9.

2-(1-Hydroxy-2-oxo-1,2-dihydropridin-5-yl)phenylacetic acid (10c)

A mixture of **9c** (0.75 mmol) and 2 N LiOH (3.0 mL, 6.0 mmol) in THF (3.0 mL) and MeOH (3.0 mL) was stirred at reflux temperature for 3 h. The reaction mixture was cooled to 25 °C and washed with CH_2Cl_2 (30 mL). The water phase was acidified to pH 2 by addition of 3 N hydrochloric acid prior to extraction with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water and then brine, the organic fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The crude product was purified

by flash silica gel column chromatography using EtOAc–MeOH (9:1, *v*/*v*) as eluent to yield **10c**; yield, 74%; pale yellow solid, mp 147–149 °C. IR (film): 3081, 3041, 2924, 2859, 1703, 1663, 1562 cm^{-1}. ^1H NMR (DMSO-d_6) δ: 3.70 (s, 2H, CH_2), 6.57 (d, J = 6.7 Hz, pyridone H-3), 7.24–7.39 (overlapping multiplets, 5H total, phenyl H-3, H-4, H-5, H-6 and pyridone H-4), 7.88 (d, J = 2.4 Hz, 1H, pyridone H-6), 12.22 (br s, 2H, NO*H* and COO*H*). Anal. Calcd for $C_{13}H_{11}NO_4 \cdot 1/10H_2O$: C, 63.21; H, 4.57; N, 5.67. Found: C, 63.25; H, 4.55; N, 5.61.

General procedure for the synthesis of 2-(1-methyl-2-oxo-1,2-dihydropyridyl)phenylacetic acids (12a–12b)

Dimethyl sulfate (420 mg, 3.33 mmol) in MeCN (10 mL) was added to a solution of **7a** or **7b** (290 mg, 1.11 mmol) in MeCN (10 mL). The mixture was stirred at reflux for 6 h. Removal of excess dimethyl sulfate and MeCN in vacuo afforded the respective 1-methylpyridinium methylsulfate salt **11a** or **11b**. Compound **11a**, ^1H NMR (DMSO-d_6) δ: 3.62 (s, 3H, *Me*SO_4^-), 3.67 (s, 2H, CH_2), 3.68 (s, 3H, O*Me*), 4.53 (s, 3H, N*Me*), 7.41–7.47 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.98 (dd, J = 6.7, 1.8 Hz, 1H, pyridyl H-5), 8.09 (d, J = 1.8 Hz, 1H, pyridyl H-3), 9.19 (d, J = 6.7 Hz, 1H, pyridyl H-6). Compound **11b**, ^1H NMR (DMSO-d_6) δ: 3.65 (s, 3H, O*Me*), 3.67 (s, 3H, *Me*SO_4^-), 3.68 (s, 2H, CH_2), 4.46 (s, 3H, N*Me*), 7.34–7.50 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 8.07 (d, J = 8.5, Hz, 1H, pyridyl H-3), 8.48 (dd, J = 8.5, 1.8 Hz, 1H, pyridyl H-4), 9.12 (d, J = 1.8 Hz, 1H, pyridyl H-6). A solution of the 1-methylpyridinium methylsulfate **11a** or **11b** in THF (3.0 mL) and MeOH (3.0 mL) was added to 2 N LiOH (3.0 mL, 6.0 mmol), and the mixture was stirred at reflux temperature for 2 h. The reaction mixture was cooled to 25 °C and washed with CH_2Cl_2 (30 mL). The water phase was then acidified to pH 4 by addition of 3 N hydrochloric acid prior to extraction with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water and then brine, the organic fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The crude product was purified by flash silica gel column chromatography using EtOAc–MeOH (9:1, *v*/*v*) to yield the respective product **12a** or **12b**. Some physical and spectral data of **12a** and **12b** are listed below.

2-(1-Methyl-2-oxo-1,2-dihydropridin-4-yl)phenylacetic acid (12a)

Yield, 89%; off-white solid, mp 182–184 °C. IR (film): 3068, 2943, 1723, 1658, 1558 cm^{-1}. ^1H NMR ($CDCl_3$ + DMSO-d_6) δ: 3.52 (s, 3H, N*Me*), 3.53 (s, 2H, CH_2), 6.22 (dd, J = 6.7, 1.8 Hz, 1H, pyridone H-5), 6.52 (d, J = 1.8 Hz, 1H, pyridone H-3), 7.15–7.33 (overlapping multiplets, 5H total, phenyl H-3, H-4, H-5, H-6, pyridone H-6), 9.98 (br s, 1H, COO*H*). Anal. Calcd for $C_{14}H_{13}NO_3$: C, 69.12; H, 5.39; N, 5.76. Found: C, 68.64; H, 5.42; N, 5.66.

2-(1-Methyl-2-oxo-1,2-dihydropridin-5-yl)phenylacetic acid (12b)

Yield, 70%; pale yellow solid, mp 171–173 °C. IR (film): 3075, 2941, 1719, 1659, 1564 cm^{-1}. ^1H NMR ($CDCl_3$ + DMSO-d_6) δ: 3.47 (s, 3H, N*Me*), 3.48 (s, 2H, CH_2), 6.46 (d, J = 9.2 Hz, 1H, pyridone H-3), 7.12–7.28 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.34 (dd, J = 9.2, 2.4 Hz, 1H, pyridone H-4), 7.46 (d, J = 1.8 Hz, 1H, pyridone H-6), 10.1 (br s, 1H, COO*H*). Anal. Calcd for $C_{14}H_{13}NO_3$: C, 69.12; H, 5.39; N, 5.76. Found: C, 68.78; H, 5.51; N, 5.55.

Methyl 4-(1-difluoromethyl-2-oxo-1,2-dihydropyridin-5-yl) phenylacetate (13)

To a solution of **7b** (522 mg, 2.0 mmol) in acetonitrile (15 mL) was added $FSO_2CF_2CO_2H$ (1.12 g, 6.0 mmol) followed by $NaHCO_3$ (186 mg, 2.2 mmol). This mixture was heated at reflux under argon for 12 h and cooled to 25 °C; a saturated solution of aqueous $NaHCO_3$ (40 mL) was added and the mixture was extracted with CH_2Cl_2 (3 × 40 mL). The organic fraction was washed with water (50 mL) and then brine, and the organic fraction was dried ($MgSO_4$). Removal of the solvent from the organic fraction in vacuo afforded **13** in 53% yield; pale yellow oil. IR (film): 3010, 2966, 1744, 1694, 1619, 1153 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.60 (s, 2H, CH_2), 3.67 (s, 3H, O*Me*), 6.61 (d, J = 9.1 Hz, 1H, pyridone H-3), 7.23–7.39 (overlapping multiplets, 4H, phenyl H-3, H-4, H-5, H-6), 7.43 (dd, J = 9.1, 2.4 Hz, 1H, pyridone H-4), 7.48 (d, J = 2.4 Hz, 1H, pyridone H-6), 7.74 (t, J = 60.4 Hz, 1H, C*H*F_2). ^{13}C NMR ($CDCl_3$) δ: 38.7, 52.2, 107.5 (t, J = 250 Hz), 120.4, 121.1, 127.8, 128.5, 128.8, 130.0, 130.8, 132.4, 136.3, 143.3, 160.2, 171.8.

2-(1-Difluoromethyl-2-oxo-1,2-dihydropyridin-5-yl) phenylacetic acid (14)

A mixture of methyl 2-(1-difluoromethyl-2-oxo-1,2-dihydropyridin-5-yl)phenylacetate (**13**, 0.75 mmol) and 2 N LiOH (3.0 mL, 6.0 mmol) in THF (3.0 mL) and MeOH (3.0 mL) was stirred at reflux temperature for 2 h. The reaction mixture was cooled to 25 °C and washed with CH_2Cl_2 (30 mL). The water phase was then acidified to pH 2 by addition of 3 N hydrochloric acid prior to extraction with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water and then brine, the organic fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The crude product was purified by flash silica gel column chromatography using EtOAc–MeOH (9:1, *v*/*v*) as eluent to furnish **14** in 90% yield; pale yellow gum. IR (film): 3063, 2948, 1737, 1692, 1592, 1152 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.64 (s, 2H, CH_2), 6.68 (dd, J = 7.3, 1.8 Hz, 1H, pyridone H-3), 7.25–7.42 (overlapping multiplets, 4H total, phenyl H-3, H-4, H-5, H-6), 7.47 (dd, J = 7.3, 2.4 Hz, 1H, pyridone H-4), 7.56 (d, J = 2.4 Hz, 1H, pyridone H-6), 7.75 (t, J = 60.4 Hz, 1H, C*H*F_2), 10.2 (br s, 1H, COO*H*). Anal. Calcd for $C_{14}H_{11}F_2NO_3$: C, 60.22; H, 3.97; N, 5.02. Found: C, 59.94; H, 4.30; N, 4.79.

2-(2-Oxo-1,2-dihydropyridin-5-yl)phenylacetic acid (15)

A mixture of **13** (0.75 mmol) and 2 N NaOH (3.0 mL, 6.0 mmol) was heated at reflux for 5 h. The reaction mixture was cooled to 25 °C and washed with CH_2Cl_2 (30 mL). The water phase was then acidified to pH 2 by addition of 3 N hydrochloric acid prior to extraction with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with water and then brine, the organic fraction was dried ($MgSO_4$), and the solvent was removed in vacuo. The crude product was purified by flash silica gel column chromatography using EtOAc–MeOH (9:1, *v*/*v*) as eluent to afford **15**;

yield, 56%; pale yellow solid, mp 242–244 °C. IR (film): 3060, 2981, 1663, 1614 cm^{-1}. ^1H NMR (DMSO-d_6) δ: 3.46 (s, 2H, CH_2), 6.43 (d, J = 9.1 Hz, 1H, pyridone H-3), 7.18–7.33 (overlapping multiplets, 5H total, phenyl H-3, H-4, H-5, H-6 and pyridone H-6), 7.38 (dd, J = 9.1, 2.4 Hz, 1H, pyridone H-4), 7.60 (s, 1H, N*H*), 10.1 (br s, 1H, COO*H*). Anal. Calcd for $C_{13}H_{11}NO_3$: C, 68.11; H, 4.84; N, 6.11. Found: C, 68.23; H, 4.86; N, 5.98.

Cyclooxygenase inhibition assays

The ability of the test compounds listed in Table 1 to inhibit ovine COX-1 and human recombinant COX-2 (IC_{50} value, μmol/L) were determined using an enzyme immunoassay kit (catalog No. 560131, Cayman Chemical, Ann Arbor, Michigan, USA) according to our previously reported method.[17]

5-Lipoxygenase inhibition assay

The ability of the test compounds listed in Table 1 to inhibit potato 5-LOX (catalog No. 60401, Cayman Chemical, Ann Arbor, Michigan, USA) (IC_{50} values, μmol/L) were determined using an enzyme immunoassay kit (catalog No. 760700, Cayman Chemical) according to our previously reported method.[18]

Abstract: Three-component cyclocondensation of β-naphthol, aldehydes, and 5,5-dimethylcyclohexane-1,3-dione (dimedone) was catalyzed efficiently by ruthenium chloride hydrate under mild reaction conditions to afford 12-aryl or alkyl-8,9,10,12-tetrahydrobenzo[*a*]xanthen-11-one derivatives in good to excellent yields.

Key words: ruthenium, one-pot synthesis, tetrahydrobenzo[*a*]xanthen-11-one.

Résumé : La cyclocondensation à trois composants du β-naphtol, d'aldéhydes et de 5,5-diméthylcyclohexane-1,3-dione (dimédone) est catalysée d'une façon efficace par l'hydrate du chlorure de ruthénium, dans des conditions douces, pour conduire à la formation de dérivés 12-aryl- ou 12-alkyl- de la 8,9,10,12-tétrahydrobenzo[*a*]xanthén-11-one, avec des rendements allant de bons à excellents.

Mots-clés : ruthénium, synthèse monotope, tétrahydrobenzo[*a*]xanthén-11-one.

[Traduit par la Rédaction]

Introduction

In recent years, multicomponent reactions (MCRs) have attracted great attention from research groups working in medicinal chemistry, drug discovery, and materials science as they furnish the desired products in a single operation without isolating the intermediates. Simple procedures, facile execution, atom economy, and high selectivity are among the described advantages of multicomponent reactions.[1–5]

Developing ways to synthesize xanthenes and benzoxanthenes has been of considerable interest because these compounds possess antiviral,[6] antibacterial,[7] and anti-inflammatory properties.[8] Such compounds are also utilized for antagonism of the paralyzing action of zoxazolamine,[9] and can also be employed as dyes,[10] as pH-sensitive fluorescent materials for the visualization of biomolecules,[11] and in cancer therapy.[12] In addition, these heterocyclic compounds are structural key units in several natural products.[13] Xanthone derivatives are also found abundantly in a variety of natural products and exhibit various biological properties.[14,15] Synthetic tetrahydrobenzo[*a*]xanthen-11-ones have been prepared through three-component reaction of β-naphthol, aldehydes, and 1,3-dicarbonyl compounds in the presence of catalysts such as $BF_3{\cdot}Et_2O$,[16] $NaHSO_4{\cdot}SiO_2$,[17] strontium triflate ($Sr(OTf)_2$),[18] *p*-toluenesulfonic acid (pTSA),[19] indium trichloride ($InCl_3$),[20] phosphorous pentoxide (P_2O_5),[20] I_2,[21] tetrabutylammonium fluoride (TBAF),[22] HBF_4-SiO_2,[23] dodecatungstophosphoric acid ($H_3PW_{12}O_{40}$),[24] ceric ammonium nitrate (CAN),[25] 2,4,6-trichloro-1,3,5-triazine (TCT),[26] and $HClO_4$-SiO_2.[27] Several of these methodologies, however, suffer from severe drawbacks including long reaction times and toxic solvents,[16–18,22] the use of expensive reagents,[19] drastic conditions for catalyst preparation,[27] the use of a toxic catalyst,[21] and the requirement of a large or stoichiometric amount of catalysts.[20] Therefore, to avoid these limitations, the discovery of a new and efficient catalyst for preparation of these important molecules is of prime interest.

Recently, we have been involved in the study of the catalytic activity of ruthenium towards organic reactions such as the condensation of indoles and aldehydes,[28] oxidation of aromatic and heteroaromatic compounds,[29] double-conjugate 1,4-addition to enones,[30] nucleophilic addition to epoxides,[31] oxidative trimerization of indoles,[32] and Michael addition of indoles to hormone steroids.[33] As a matter of fact, many organic transformations that involve ruthenium species as catalyst are known and well-documented.[34–36] In continuation of our investigation in this context, hereby, we introduce a simple and efficient method for the synthesis of tetrahydrobenzo [*a*]xanthen-11-ones from one-pot condensation of β-naphthol, aldehydes, and dimedone in the presence of ruthenium chloride hydrate under mild reaction conditions.

Results and discussion

Typical results of the ruthenium-catalyzed cyclocondensation of β-naphthol, aldehydes, and 5,5-dimethylcyclohexane-1,3-dione are shown in Table 1. In an optimized procedure, with respect to the catalyst concentration, choice of solvent,

temperature, and time, the treatment of benzaldehyde (1 mmol), β-naphthol (1 mmol), and dimedone (1.2 mmol) in the presence of $RuCl_3 \cdot nH_2O$ catalyst (5 mol%) in ethanol (2.5 mL) at 80 °C for 30 min gave the corresponding tetrahydrobenzo[*a*]xanthen-11-one as a precipitate, which was easily purified (see Experimental) (product **4a**, 88% yield).

To evaluate the generality of the process, we also examined the reaction of β-naphthol and 5,5-dimethylcyclohexane-1,3-dione with a variety of aromatic aldehydes (Table 1, entries 2–12). Both aromatic aldehydes bearing electron-withdrawing and electron-donating groups afforded corresponding tetrahydrobenzo[*a*]xanthen-11-one derivatives in high yields (82%–92%). It is also noteworthy that the electronic properties of the aromatic ring have an effect on the time of this nucleophilic addition reaction. Aromatic aldehydes with electron-withdrawing groups reacted, somehow, faster than the aromatic aldehydes with electron-donating groups. An aliphatic aldehyde (Table 1, entry 13), however, showed a longer reaction time and lower yield. Although the precise mechanism of the reaction awaits further studies, a plausible mechanism for this transformation, which rationalizes the formation of products, is outlined in Scheme 1. By referring to the literature,[16,17] we proposed that after prior activation of the carbonyl group of aldehyde by Ru^{III} (intermediate **1**), nucleophilic attack from C_1 of β-naphthol provides an *ortho*-quinone methide intermediate (*o*-QM, intermediate **2**). After subsequent attack of dimedone to the *o*-QM and loss of water, intermediate **3** undergoes dehydration to afford the desired product **4**.

A comparison between the present results and other reported methods in this context is shown in Table 2.

As it is shown, operational simplicity and higher efficiency of our protocol covers the expensive cost of ruthenium chloride hydrate. Moreover, reusability of the catalyst was also studied to minimize costs and inorganic waste. As it is shown in Table 3, after four times, the reused catalyst showed only a 4% decrease in the yield of desired product.

To improve efficiency, we carried out this reaction under microwave irradiation. As it is shown in Table 4, this method affords the desired products in excellent yields in rather short times.

Conclusion

In brief, we have reported a convenient synthesis of tetrahydrobenzo[*a*]xanthen-11-ones by using $RuCl_3 \cdot nH_2O$ as a homogeneous catalyst. The unique feature of the reaction is that the corresponding tetrahydrobenzo[*a*]xanthen-11-ones are insoluble in the reaction solvent and this leads to an easy workup along with high yields (75%–92%). In all cases, simple filtration of the reaction mixture and rinsing with cold ethanol provided spectroscopically pure products. Several merits, such as efficiency, mild reaction conditions, short reaction times, high yields of products, easy workup procedure, low catalyst loading, reusability of the catalyst, and use of ethanol as an eco-friendly solvent, make this protocol a useful and attractive process for the synthesis of tetrahydrobenzo [*a*]xanthen-11-ones.

Experimental

General

All products were characterized by spectroscopic data (IR, ^1H NMR, ^{13}C NMR). IR spectra were recorded on a Shimadzu

Scheme 1. Proposed mechanistic pathway for the formation of tetrahydrobenzo[*a*]xanthen-11-one derivatives under ruthenium catalysis.

FTIR-8400S spectrophotometer. ^{1}H NMR spectra were measured on a Bruker DRX-400 Avance spectrometer. ^{13}C NMR spectra were obtained on a Bruker DRX-100 Avance spectrometer. Chemical shifts of ^{1}H and ^{13}C NMR spectra were expressed in parts per million downfield from trimethylsilane (TMS) as the internal standard. Melting points were measured on a BÜCHI Melting Point B-540 and are uncorrected.

Elemental analyses were made by a Carlo-Erba EA1110 CNNO-S analyzer and agreed with the calculated values. Microwave irradiation was performed in a LBP125 microwave oven.

Materials

All the reagents were purchased from Merck and used without further purification.

Typical experimental procedure

To a mixture of β-naphthol (144.17 mg, 1 mmol), benzaldehyde (106.13 mg, 1 mmol), and dimedone (168.22 mg, 1.2 mmol) in ethanol (2.5 mL), $RuCl_3 \cdot nH_2O$ (10.71 mg, 0.05 mmol) was added and the mixture was refluxed in an oil bath at 80 °C for 30 min, which yielded a precipitate. The progress of the reaction was monitored by thin-layer chromatography (TLC). After completion of the reaction, as

Table 2. Comparison of our results with those obtained by other groups in the reaction of β-naphthol, benzaldehyde, and dimedone.

1	C_6H_5	4	**4a**	88
2	4-$NO_2C_6H_4$	2	**4b**	90
3	4-ClC_6H_4	3	**4d**	93
4	4-$CH_3C_6H_4$	5	**4g**	87
5	$(CH_3)_2CH$	7	**4m**	78

indicated by TLC, the precipitate was filtered off and rinsed with cold ethanol. The solid was dried under vacuum to afford the desired compound in pure form (311.78 mg, 88%). The same procedure was also used for the other products listed in Table 1. To reuse the catalyst, after filtration, substrates were added into solution and the same procedure was repeated. For microwave reactions, irradiation was conducted in an open vessel at 50 °C in a 500 W microwave oven (Table 4).

12-(3,4-Dimethoxyphenyl)-9,9-dimethyl-8,9,10,12-tetrahydrobenzo[*a*]xanthen-11-one (4k)

Solid; mp 201–204 °C. IR (KBr, cm^{-1}) ν: 3070, 2960, 1644, 1590, 1371, 1260, 1220, 1140, 1020, 817. ^1H NMR (400 MHz, $CDCl_3$, 25 °C, ppm) δ: 7.93 (d, 1H, J = 8.8 Hz), 7.78 (d, 1H, J = 8.0 Hz), 7.62 (d, 1H, J = 8.4 Hz), 7.48 (t, 1H, J = 7.2 Hz), 7.36 (t, 1H, J = 7.2 Hz), 7.18 (d, 1H, J = 8.8 Hz), 6.69 (d, 1H, J = 7.6 Hz), 6.59 (d, 1H, J = 7.6 Hz), 6.50 (s, 1H), 5.64 (s, 1H), 3.68 (s, 3H), 3.57 (s, 3H), 2.54 (s, 2H), 2.42 (d, 1H, J = 16.4 Hz), 2.27 (d, 1H, J = 16.4 Hz), 1.09 (s, 3H), 0.98 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, ppm) δ: 196.2, 162.8, 153.6, 142.1, 136.0, 133.5, 130.2, 129.0, 128.2, 127.1, 126.8, 125.4, 124.3, 123.5, 116.9, 116.4, 115.8, 113.2, 112.4, 53.7, 53.4, 49.6, 40.2, 32.7, 31.2, 27.8, 26.0. Abstract: The reaction of 5-aminosalicylic acid (5-ASA) with nitrous acid has been studied at low pH under conditions that simulate a gastric environment. The course of the reaction was followed by UV–visible and fluorescence spectroscopy and the products were analyzed by high performance liquid chromatography (HPLC) with UV–visible and mass spectroscopic detectors. In addition, the formation of nitric oxide (NO) was estimated electrochemically. 5-ASA was readily consumed in a process catalyzed by chloride and thiocyanate, whose rate is first order in 5-ASA and second order in nitrous acid. 2-Hydroxy-5-diazonium benzoic acid (diazonium derivative) and NO were detected as products of the reaction. From the NO formation profiles, it is concluded that NO is produced as a minor product in a process parallel to the path that leads to generation of the diazonium derivative. While the formation of NO could be beneficial for the protection of the stomach, the generation of the diazonium derivative could be considered a potentially toxic process.

Key words: 5-aminosalicylic acid, mesalazine, nitrous acid, nitrite, diazonium derivative, nitric oxide.

Résumé : On a étudié la réaction de l'acide 5-aminosalicylique (5-AAS) avec l'acide nitreux, à un pH faible, dans des conditions qui simulent un environnement gastrique. On a suivi l'évolution de la réaction par spectroscopies UV-visible et de fluorescence et on a analysé les produits par chromatographie liquide à haute performance (CLHP) avec des détecteurs par spectroscopie UV-visible et de masse. De plus, on a fait appel à une méthode électrochimique pour évaluer la formation d'oxyde nitrique (NO). L'acide 5-aminosalicylique est rapidement consommé dans un processus catalysé par les ions chlorure et thiocyanate et pour lequel la vitesse est du premier ordre en 5-AAS et du second ordre en acide nitreux. On a détecté de l'acide 2-hydroxy-5-diazoniumbenzoïque (dérivé diazonium) et du NO comme produis de la réaction. D'après les profils de formation du NO, on en conclut que le NO se forme comme produit mineur dans un processus parallèle à la voie qui conduit à la formation du dérivé diazonium. Alors que la formation du NO pourrait être bénéfique pour la protection de l'estomac, la formation du dérivé diazonium peut être considérée comme un processus potentiellement toxique.

Mots-clés : acide 5-aminosalicylique, mésalazine, acide nitreux, nitrite, dérivé diazonium, oxyde nitrique.

Introduction

Chronic inflammatory bowel pathologies such as ulcerative colitis and Crohn's disease cause inflammatory changes and ulcers of different types in the gastrointestinal mucosa.[1] 5-Aminosalicylic acid (5-ASA), the active moiety of azosalicylic drugs such as sulfasalazine and olsalazine, is currently used in the treatment of these pathologies and in the maintenance of their clinical remission.[2–4] The mechanism of action of 5-ASA has been related to the inhibition of the production of mediators of the lipooxygenase and cyclo-oxygenase pathways as well as platelet activating factor, which are elevated in the colonic tissue of patients with inflammatory bowel disease.[4] In addition, 5-ASA inhibits the production of interleukin and other cytokines, including tumor necrosis factor alpha.[4]

Besides the inhibition of inflammatory pathways, 5-ASA has additional protective effects, being an efficient scavenger of peroxyl radicals and a highly effective molecule in protecting membranes against lipid peroxidation.[5–8] Furthermore, after its oxidation by peroxyl radicals, 5-ASA can be regenerated by endogenous compounds such as ascorbic acid, cysteine, and glutathione.[9] In addition, 5-ASA delays the

oxidation of low density lipoprotein[10] and reacts with hypochlorous acid,[11] singlet oxygen,[12] and hydroxyl radicals.[13,14]

The beneficial action of 5-ASA in the treatment of bowel diseases is exerted from the luminal side. For this reason, different pharmaceutical formulations (e.g., Salofalk, Pentasa, Asacol) have been developed to allow orally ingested 5-ASA to reach the inflamed distal intestine without being absorbed and (or) decomposed in the stomach. Nevertheless, it has been shown, using in vitro dissolution tests, that a fraction of 5-ASA can be released from Pentasa tablets even at low pH (1.2).[15]

Owing to the reactivity of 5-ASA towards oxidants, it appears to be a potential substrate of nitrite in acidic medium. The steady-state concentration of nitrite in the human body is regulated by different sources, with ingested nitrate being the most important nutritional source of nitrite. Nitrate derived from foods such as green leaves, cereals, and meat is reduced by commensal bacteria in the oral cavity, generating high nitrite concentrations in saliva (1–2 mmol L^{-1}) and the stomach.[16–18] In stomach conditions, nitrite (pK_a = 3.2–3.4) is present as nitrous acid (eq. [1]) in equilibrium with nitrogen oxides, according to eqs. [2]–[5]:[19]

$$[1] \quad NO_2^- + H^+ \rightleftharpoons HNO_2$$

$$[2] \quad HNO_2 + H^+ \rightleftharpoons NO^+ + H_2O$$

$$[3] \quad 2HNO_2 \rightleftharpoons N_2O_3 + H_2O$$

$$[4] \quad N_2O_3 \rightleftharpoons NO + NO_2$$

$$[5] \quad HNO_2 + H^+ + X^- \rightleftharpoons NOX + H_2O$$

where X^- corresponds to a thiocyanate or chloride ion.

Thus, nitrite in the gastric environment (or its derived nitrogen species) could react with xeno- or endobiotics that, depending on their structure, could generate nitroso, nitro, or nitrosamine derivatives.[19–21] In particular, nitrosamines (generated from the interaction of nitrous acid with amines) have been directly related to an increased carcinogenic risk.[22] Many drugs with an amine moiety in their structure could form nitrosamine compounds by their interaction with acidic nitrite.[22]

Nonetheless, the interaction of nitrite with xenobiotics does not always lead to toxic metabolites (nitrosamines), as in some cases this interaction is associated with the release of nitric oxide (NO), thus contributing to vasodilation, mucosal blood flow, and mucus thickness.[23–26] It has been shown that the interaction of ascorbic acid[23] and phenols such as chlorogenic acid,[24] quercetin,[24,25] and caffeic acid[26] with nitrite in stomach conditions leads to NO release. Furthermore, it has been reported both in vitro and in vivo that foods and beverages such as wine,[26,27] apple extracts,[28] and coffee melanoidins[29] generate NO from their interaction with nitrite in acidic medium.

Considering that 5-ASA, a drug whose chemical structure has an aromatic amine and a phenol group, is partially released from Pentasa tablets in simulated gastric medium, in the present work a systematic study of the reaction between 5-ASA and nitrite in acidic conditions (nitrous acid) was performed. The time course of decomposition and the formation of reaction products were studied both by spectroscopic techniques (UV–visible and fluorescence) and by high performance liquid chromatography (HPLC), with diode array (DAD) and mass spectroscopy (MS) detection. In addition, the generation of NO during the reaction was evaluated by an electrochemical technique.

Experimental

Chemicals

5-Aminosalicylic acid (5-ASA), diethylenetriaminepentaacetic acid (DTPA), sodium nitrite, resorcinol, quercetin, catechol, pyrogallol, phloretin, and sodium hydrosulfite were purchased from Sigma-Aldrich (St. Louis, Missouri, USA). Potassium sulfate and potassium thiocyanate (KSCN) were purchased from Applichem (Darmstadt, Germany). Potassium iodide was supplied by Acros Organics (New Jersey, USA).

Solutions

Unless otherwise indicated, experiments were carried out in simulated gastric fluid (SGF), consisting of sodium chloride (34 mmol L^{-1}) adjusted to pH 2.0 with concentrated hydrochloric acid. Stock solutions of 5-ASA (10 mmol L^{-1}) were prepared daily in DMSO. Stock solutions of nitrite (10 mmol L^{-1}) and KSCN (10 mmol L^{-1}) were prepared daily in double-distilled water.

UV–visible and fluorescence studies

The reaction mixture, containing 5-ASA (1–300 μmol L^{-1}) and nitrite (10–500 μmol L^{-1}) in SGF, was incubated at 25 °C in the thermostated cuvette of either a Hewlett Packard 8453 (Palo Alto, California, USA) or a Varian Cary 50 (Mulgrave, Victoria, Australia) UV–visible spectrophotometer. A similar procedure was carried out to follow the reaction by fluorescence, except the reaction mixture was incubated in the thermostated cuvette of a PerkinElmer LS-55 spectrofluorimeter (Beaconsfield, UK). Fluorescence measurements were carried out using 303 nm and 430 nm as the excitation and emission wavelengths, respectively. During the reaction of 5-ASA with nitrous acid, no significant changes in the shape of the fluorescence band of 5-ASA were observed. Also, control 5-ASA solutions, incubated in the absence of nitrous acid, revealed no changes in the initial absorbance or fluorescence intensity. The addition of DTPA (0.1 mmol L^{-1}) to SGF had no effect on the reactions. Therefore, no special precautions were taken against transition metal ion contamination in the water and salts used for the preparation of SGF. In some experiments, a 5-ASA (500 μmol L^{-1}) plus nitrite (500 μmol L^{-1}) solution was incubated in SGF at 25 °C, and at different times (15, 40, and 60 min) aliquots of 100 μL were taken and added to 2.9 mL of either SGF, phosphate buffer (pH 7.0), or NaOH (0.1 N). UV–visible spectra of these solutions were registered (pH was rigorously controlled after the addition of aliquots). In addition, in the experiments carried out at pH 7.0, the effect of sodium hydrosulfite (100 μmol L^{-1}) on the UV–visible spectra was evaluated. Reaction order and rate constant determinations were conducted in acidic medium (either SGF or $HClO_4$) with $[5\text{-ASA}]_0$ = 50 μmol L^{-1} and variable concentrations of $NaNO_2$ (0.65–50 mmol L^{-1}), NaCl ($[Cl^-]_0$ = 0–1.8 mol L^{-1}),

and KSCN (0–2 mmol L^{-1}), following the absorbance increase at 340 nm.

The reaction of the final product of the reaction between 5-ASA and nitrous acid (in SGF) with phenols was carried out at alkaline (pH = 12) or neutral (pH = 7.3) pH. Briefly, the diazonium product was obtained by incubating a solution of 5-ASA (5 mmol L^{-1}) plus nitrite (10 mmol L^{-1}) in SGF at 25 °C for 30 min. The solution was diluted 20-fold and an aliquot was added to a solution containing phenols (0.2–1.0 mmol L^{-1}) in NaOH (20 mmol L^{-1}). The time course of the reaction was followed by the changes in the UV–vis spectra up to 3 h.

Electrochemical detection of NO

NO release was followed using an ISO–NO electrode (WPI, Inc., Sarasota, Florida, USA) under nitrogen atmosphere at 25 °C. Solutions of KI–H_2SO_4 (0.1 mol L^{-1}) plus nitrite (0.7–10 μmol L^{-1}) were used to calibrate the electrode. Working solutions containing 5-ASA (5 μmol L^{-1} – 1 mmol L^{-1}) in SGF were incubated in a thermostated cell. After stabilization of the baseline, a nitrite bolus (20–200 μmol L^{-1}) was added. In some experiments, 5-ASA (50 μmol L^{-1}) was co-incubated with KSCN (200 μmol L^{-1}) before nitrite addition.

HPLC studies

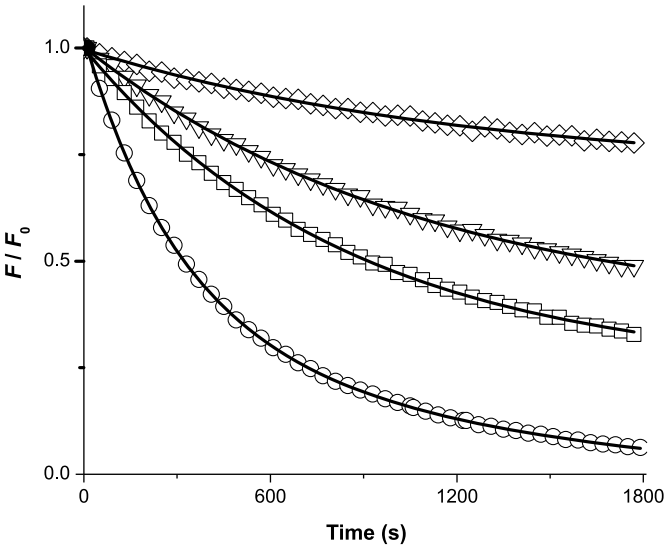
Time course of the reaction of 5-ASA with nitrous acid followed by HPLC–DAD

Chromatograms were obtained using a PerkinElmer HPLC system (pump 410) equipped with a Supelco C-18 column (25 cm × 4.6 mm) and a diode array detector (PerkinElmer 235C). A 95:5 mixture of phosphate (KH_2PO_4, 0.1 mol L^{-1}, adjusted to pH 4.4 with orthophosphoric acid) and methanol was used as the mobile phase. The flow rate was 1.0 mL min^{-1}. Solutions of 5-ASA (50–100 μmol L^{-1}) were incubated in the absence and presence of nitrite (100–200 μmol L^{-1}) in SGF. At different times, aliquots were taken through an autosampler system (PerkinElmer ISS 200) and immediately injected into the HPLC system. The reaction was followed at 220, 305, and 340 nm. All experiments were carried out in duplicate or triplicate.

HPLC–MS studies

HPLC measurements were performed using an 1100 Series liquid chromatograph (Agilent Technologies) coupled to an ion trap mass spectrometer (Esquire 4000, Bruker Daltonics, Inc., Massachusetts, USA). MS analyses were performed in the positive electrospray ionization mode with a desolvation temperature of 325 °C. A C-18 chromatography column (150 mm × 4.6 mm, Luna, Phenomenex Inc., Torrance, California, USA) was used. A 95:5 mixture of 0.1% acetic acid and methanol was used as the mobile phase and the flow rate was 1.0 mL min^{-1}. Briefly, 20 μL of the samples, 5-ASA (50 μmol L^{-1}) in the absence or presence of nitrite (200 μmol L^{-1}) in SFG, were injected into the HPLC–MS system at different reaction times. All experiments were carried out in duplicate or triplicate.

Fig. 1. Decay of the fluorescence of 5-ASA induced by nitrite in acidic medium. 5-ASA (50 μmol L^{-1}) was incubated in simulated gastric fluid (SGF) at 25 °C in the presence of the following concentrations of nitrite: 20 μmol L^{-1} (◇), 50 μmol L^{-1} (▽), 75 μmol L^{-1} (□), and 150 μmol L^{-1} (○). The excitation and emission wavelengths were 303 nm and 430 nm, respectively.



Results

UV–visible and fluorometric studies

Exposure of 5-ASA to nitrite in SGF (nitrous acid) led to a progressive decrease in its fluorescence intensity, as shown in Fig. 1. The data depicted in this figure imply that 5-ASA (50 μmol L^{-1}) reacts efficiently with nitrous acid. In fact, nearly 68% of 5-ASA was consumed after 20 min of reaction with nitrous acid (75 μmol L^{-1}). The UV–visible spectrum of 5-ASA was recorded as a function of time to further assess the characteristics of its reaction with nitrous acid. The results obtained with 50 μmol L^{-1} 5-ASA and 200 μmol L^{-1} nitrous acid are presented in Fig. 2A. As can be seen in this figure, a significant increase in the absorbance at λ = 303 nm with time was observed. This increase was due to the presence of a new strong band at λ = 340 nm, the wavelength that was chosen to follow the time course of the reaction. Typical results (presented in Fig. 2B) show that the addition of increasing concentrations of nitrite (10–500 μmol L^{-1}) to a 5-ASA solution (50 μmol L^{-1}) in SGF leads to higher rates of the absorbance increases in a nitrite concentration dependent way. The absorbance at 340 nm reaches a plateau at nearly 0.86 absorbance units (AU), which is clearly evident at the highest nitrite concentration employed (500 μmol L^{-1}), where the plateau is reached after approximately 20 min of reaction.

Considering that chloride can act as a nitrosonium carrier, the reaction was also studied in perchloric acid ($HClO_4$) solution (Fig. 3). As shown in Fig. 3A, the time course of the absorbance at 340 nm corresponding to the reaction of 5-ASA (50 μmol L^{-1}) with an excess of nitrite in $HClO_4$ (0.65 mol L^{-1}) follows pseudo-first-order kinetics, adjusting in all cases to a mono-exponential function. Pseudo-first-order rate constants were obtained from these data and plotted

Fig. 2. Kinetics of the reaction of 5-ASA with nitrite followed by UV–visible spectroscopy. (A) Changes in the UV–visible spectra of 5-ASA during the reaction with nitrous acid. 5-ASA (50 μmol L^{-1}) was incubated with nitrite (200 μmol L^{-1}) in SGF at 25 °C. Lines a–n are the spectra taken every 3 min from 0 to 42 min of incubation. (B) Kinetic profiles (followed at λ = 340 nm) of the reaction of 5-ASA with nitrous acid. 5-ASA (50 μmol L^{-1}) was incubated in SGF with the following concentrations of nitrite: 10 μmol L^{-1} (△), 50 μmol L^{-1} (◇), 100 μmol L^{-1} (▽), 200 μmol L^{-1} (□), and 500 μmol L^{-1} (○).

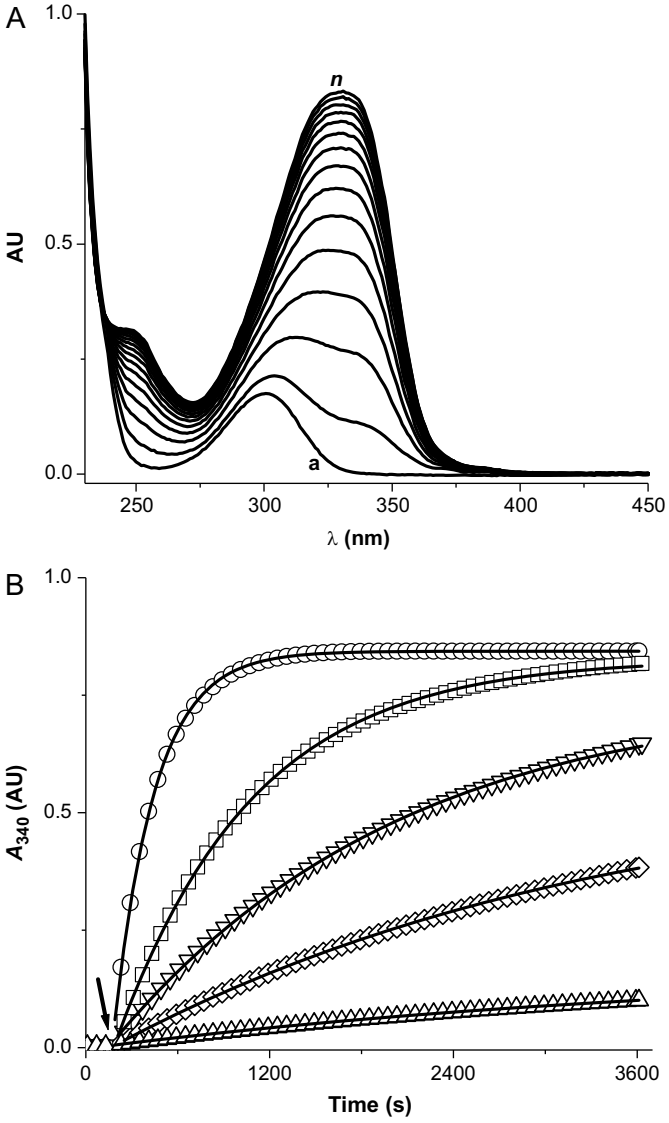

Fig. 3. Kinetic parameters of the 5-ASA–nitrous acid reaction. (A) First-order linearization of the absorbance units at λ = 340 nm associated with the time course of the reaction. 5-ASA (50 μmol L^{-1}) was incubated in 0.65 mol L^{-1} $HClO_4$ with an excess of nitrite ([nitrite] = 2.5 (line a), 3.9 (line b), 12.5 (line c), 16.7 (line d), and 43 mmol L^{-1} (line e)). Data were adjusted to a monoexponential equation (A = Amp × e^{-kt} + A_∞), where amplitude (Amp) is the difference of the absorbance at zero time and the absorbance at infinity ($A_0 - A_\infty$). (B) Dependence of the pseudo-first-order rate constant for 5-ASA consumption on the nitrite concentration. The points were fitted to a second-order polynomial function. Best fit values: k_{obs} = 1.54[NO_2^-] + 146[NO_2^-]^2.

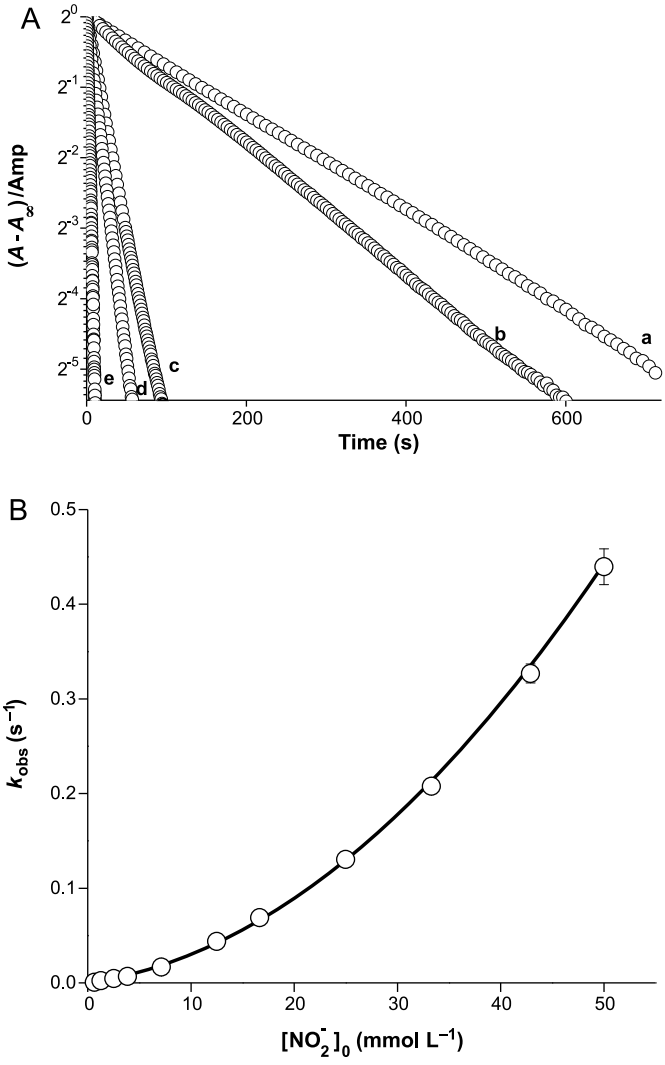

against the total nitrite concentration (Fig. 3B). In agreement with previous knowledge of amine nitrosation reactions,[30] the data depicted in Fig. 3B show a second-order polynomial dependence. These data indicate parallel reactions that are first- and second-order in nitrous acid with rate constants (under these conditions) of 1.5 L mol^{-1} s^{-1} and 146 L^2 mol^{-2} s^{-1}, respectively. This implies similar contributions of both processes at 10 mmol L^{-1} nitrous acid.

In view of the catalytic activity of chloride and thiocyanate (SCN^-) in nitrosation reactions, the reaction of 5-ASA with nitrous acid was studied in the presence of both nitrosonium carriers (in $HClO_4$). The results depicted in Fig. 4 show that the reaction was first-order in each nitrosonium carrier (chloride or SCN^-). As expected, SCN^- (k = 136 L mol^{-1} s^{-1}) was a better catalyst than chloride (k = 0.39 L mol^{-1} s^{-1}).[30]

The influence of the pH of the medium on the initial rate of reaction (assessed from the time courses at 340 nm) and the UV–visible spectra of the product(s) was studied. As shown in Fig. 5, the dependence of the initial rate of reaction on pH follows the trend expected for a single-ionization process. The data were adjusted to the Henderson–Hasselbach equation, obtaining a pK_a of 3.6. This value is very close to that of nitrous acid, suggesting that the reactive species is the

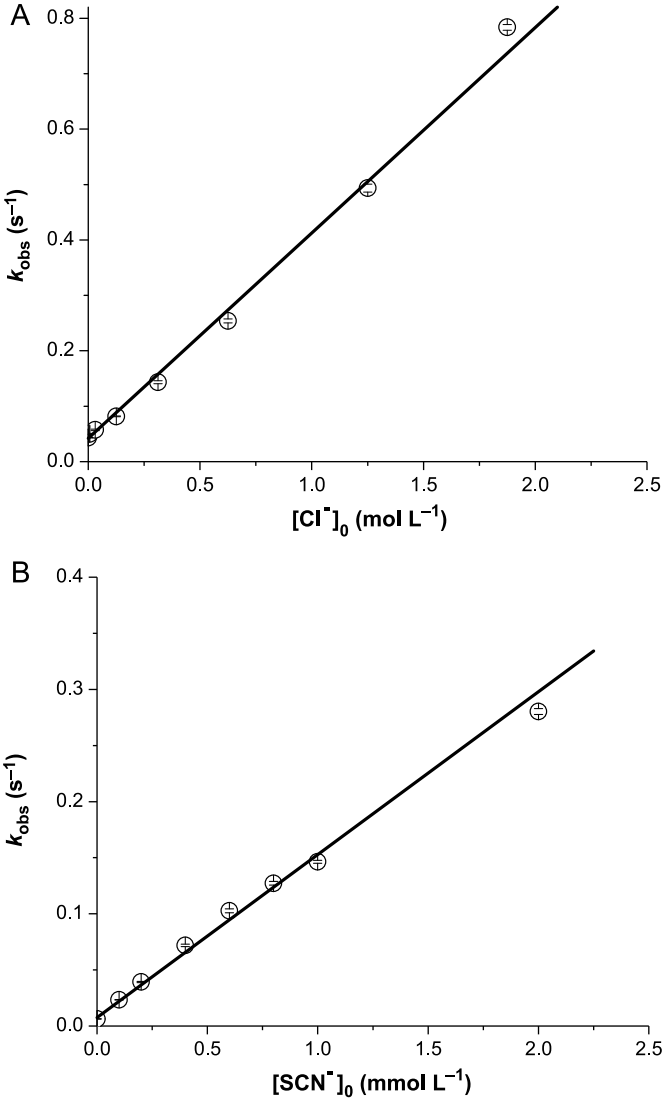
Fig. 4. Effect of chloride and thiocyanate on the 5-ASA–nitrous acid reaction. (A) Dependence of the observed reaction rate constant (k_{obs}, s^{-1}) on the initial chloride (Cl^-) concentration. $[5\text{-ASA}]_0$ = 50 μmol L^{-1}; $[HClO_4]$ = 0.65 mol L^{-1}; $[NO_2^-]_0$ = 16.7 mmol L^{-1}. (B) Dependence of the observed reaction rate constant (k_{obs}, s^{-1}) on the initial thiocyanate (SCN^-) concentration. $[5\text{-ASA}]_0$ = 25 μmol L^{-1}; $[HClO_4]$ = 10 mmol L^{-1}; $[NO_2^-]_0$ = 1 mmol L^{-1}. Best linear fits: $k_{obs} = 0.37[Cl^-] + 0.04$ and $k_{obs} = 145[SCN^-] + 0.008$.



monoprotonated acid (nitrous acid) and that there is no relevant role for other species, such as nitrite (NO_2^-) or $H_2NO_2^+$. The UV–vis spectra of the products of the reaction (obtained by incubating 5-ASA (500 μmol L^{-1}) plus nitrite (500 μmol L^{-1}) in SGF for 40 min) were studied in SGF, phosphate buffer (pH = 7.0), and 0.1 mol L^{-1} NaOH. As shown in Fig. 6, the maximum wavelength in SGF (330 nm, line a) was displaced to 355 nm at pH 7.0 (line b). Similar results were obtained in 0.1 mol L^{-1} NaOH (data not shown). In addition, the maximum absorption band of the spectrum obtained at pH 7.0 shifted to 332 nm when sodium hydrosulfite (100 μmol L^{-1}) was added to the solution (dashed line in Fig. 6). These results imply that the product generated at pH 2.0 and absorbing at 340 nm shifts its absorption to 355 nm at neutral pH.

Fig. 5. Influence of pH on the initial rate of the 5-ASA–nitrous acid reaction. 5-ASA (50 μmol L^{-1}) was incubated with nitrite (1 mmol L^{-1}) at 25 °C. The pH of the medium (SGF, acetic acid/sodium acetate buffer, K_2HPO_4, or phosphate buffer) was adjusted with HCl or NaOH. The time course of the reaction was followed at 340 nm.

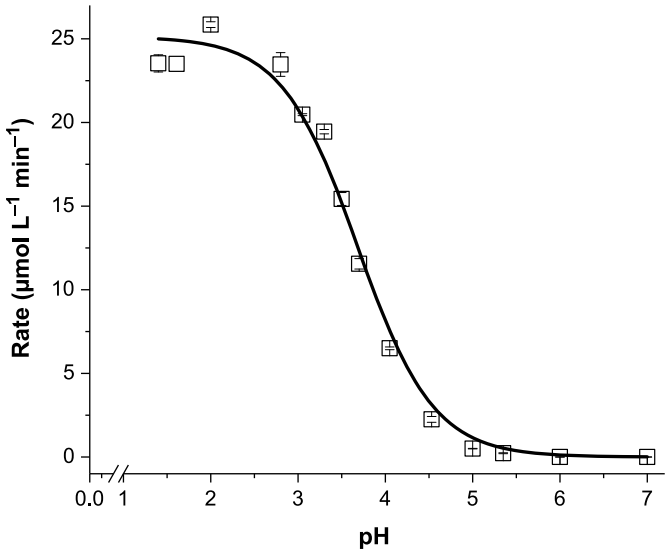


Fig. 6. Effect of pH and sodium hydrosulfite on the UV–visible spectra obtained after the reaction of 5-ASA with nitrous acid. 5-ASA (500 μmol L^{-1}) was incubated with nitrite (500 μmol L^{-1}) at 25 °C in SGF for 1 h. Afterwards, 100 μL of the solution was added to 2.9 mL of SGF (curve a) or phosphate buffer at pH 7.0 (curve b). Dashed line: solution of curve b plus sodium hydrosulfite (100 μmol L^{-1}).

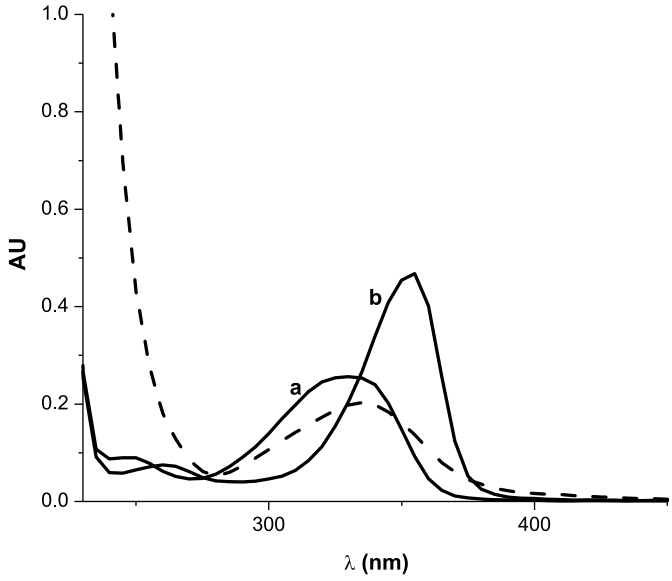


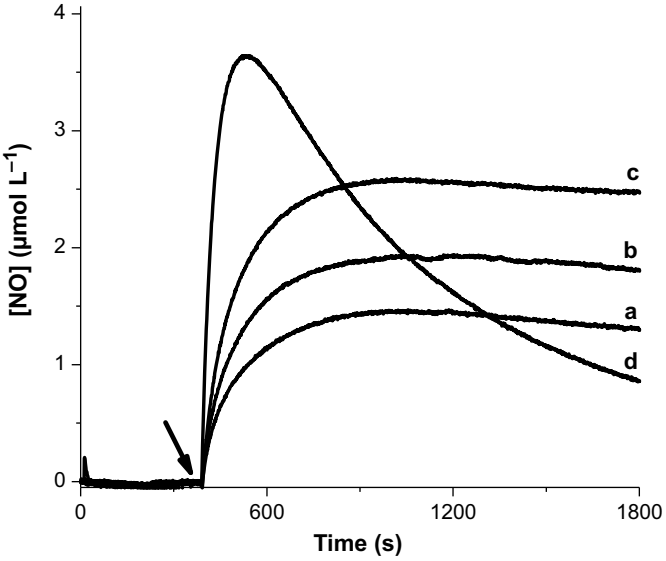
At this pH the product can be reduced by sodium hydrosulfite.

Electrochemical detection of nitric oxide (NO)

Figure 7 shows the time course of the production of NO during the reaction of 5-ASA with nitrite in SGF. The release of NO was studied in the presence of an excess of nitrite or 5-ASA. A steady-state concentration of NO was observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

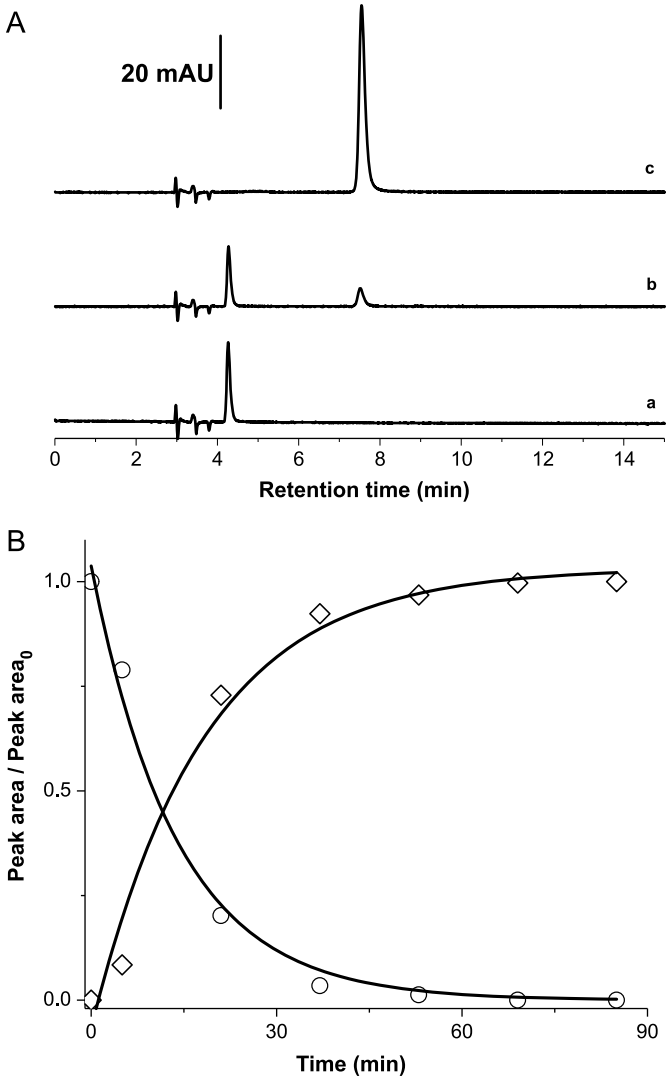
Fig. 7. Production of NO during the reaction of 5-ASA with nitrous acid. Time course of the production of NO upon addition of 200 μmol L^{-1} nitrite (arrow) in the absence (line a) and presence of 5-ASA: 10 μmol L^{-1} (line b), 50 μmol L^{-1} (line c), and 1 mmol L^{-1} (line d). The solutions were incubated in SGF at 25 °C.



when 5-ASA (10 and 50 μmol L^{-1}) was incubated with excess nitrite (200 μmol L^{-1}). This steady-state concentration was higher than that observed in the absence of 5-ASA (1.5 μmol L^{-1}) and was dependent on the 5-ASA concentration. The maximum NO concentrations were near 1.9 and 2.6 μmol L^{-1} for 10 and 50 μmol L^{-1} 5-ASA, respectively (Fig. 7). Interestingly, the steady state of NO was registered after 12 min of reaction, at which time 5-ASA is still reacting with nitrous acid, as can be observed in Fig. 2. This, and the maximum rate observed at zero reaction time (Fig. 7), implies that the release of NO is due to a direct reaction between 5-ASA and nitrous acid, without the formation of long-lived intermediates. In addition, the initial rate of NO formation increased linearly with 5-ASA concentration, suggesting its formation with first-order kinetics in 5-ASA. The steady-state concentration of NO observed in Fig. 7 at low 5-ASA concentrations suggests that NO is being generated and consumed at similar rates. A different behavior of NO release was observed in the excess 5-ASA condition. When 250 μmol L^{-1} – 1 mmol L^{-1} 5-ASA was incubated with 200 μmol L^{-1} nitrite, a clear decrease in NO concentration was observed after the maximum NO concentration had been reached. After the maximum NO concentration is reached, the slope becomes dependent on the 5-ASA concentration, being maximal at the highest 5-ASA concentration used (1 mmol L^{-1}). This could indicate NO consumption by 5-ASA or by the initial products.[31–33] In fact, it is well known that NO and (or) its nitrosating derivatives can react with aromatic amines, in particular with aminosalicylates.[33]

Since thiocyanate (SCN^-) acts as a nitrosonium carrier[19,30] and is a normal salivary component reaching physiological concentrations close to 1 mmol L^{-1} in the stomach,[34] we investigated a possible effect of SCN^- on NO formation during the reaction of 5-ASA and nitrite in SGF. For this purpose, a nitrite bolus (200 μmol L^{-1} final concentration) was added to

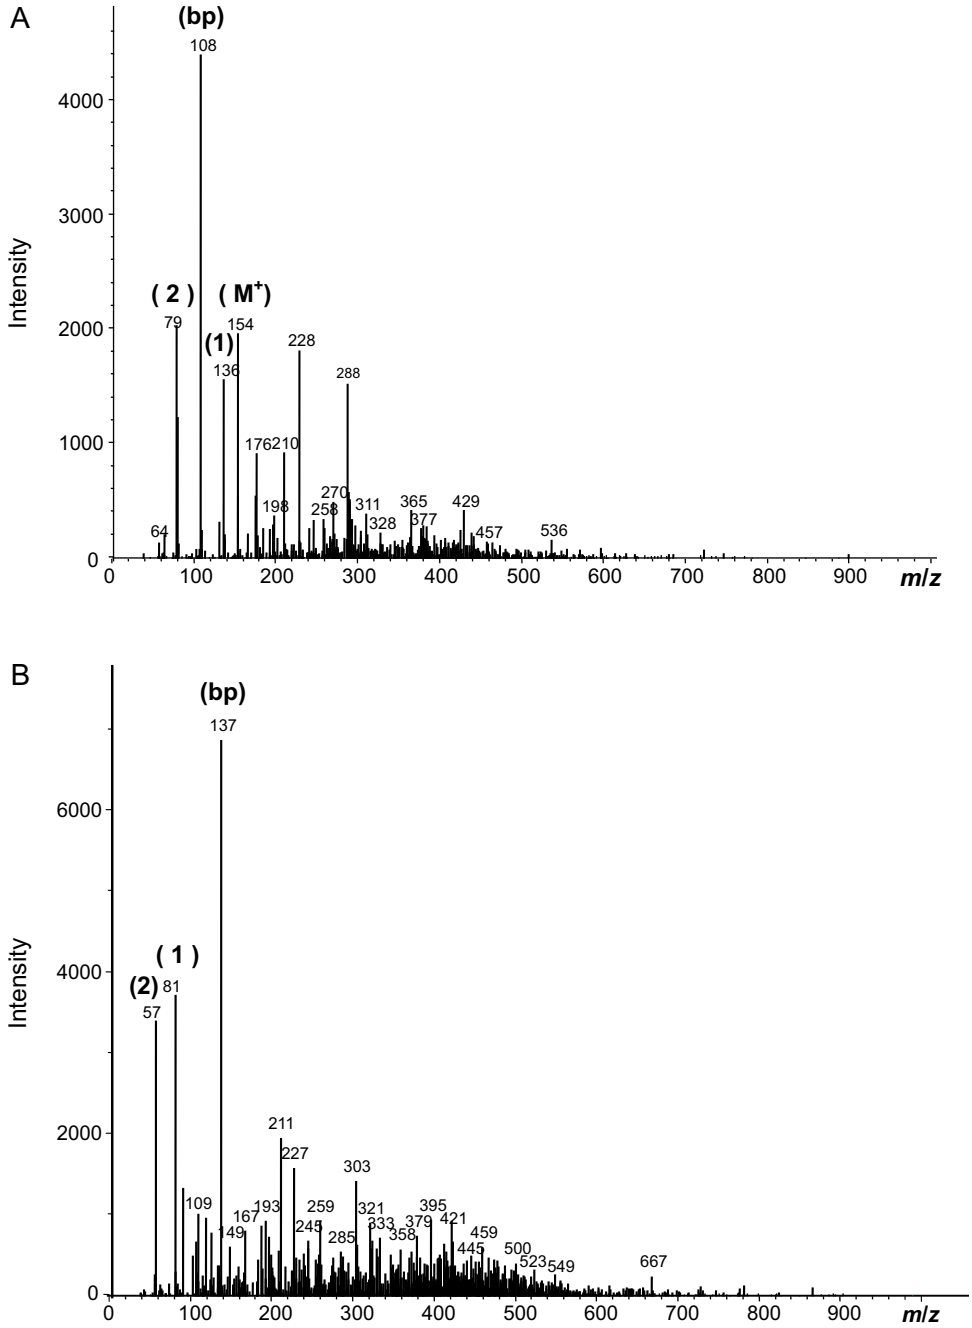
Fig. 8. Time course of the reaction of 5-ASA with nitrous acid followed by HPLC. 5-ASA (50 μmol L^{-1}) was incubated with nitrite (200 μmol L^{-1}) in SGF. (A) Chromatograms obtained from the reaction of 5-ASA plus nitrite at different incubation times. Line a, 0 min; line b, 5 min; and line c, 50 min. (B) Dependence of the area of the chromatographic peaks at 4.3 min (○) and 7.5 min (◇) on the incubation time.



a solution of 5-ASA (1 mmol L^{-1}) plus KSCN (200 μmol L^{-1}) in SFG. The results showed that the presence of KSCN increased the maximum NO concentration from 3.6 to 4.8 μmol L^{-1} (data not shown). These results could be explained by the formation of NOSCN, a species that has been implicated as a nitrosating agent[19] able to generate NO in the presence of reductants such as ascorbic acid.[28,34]

Independently of the experimental conditions employed (excess of either nitrite or 5-ASA, or presence of KSCN), it is remarkable that under our experimental conditions the yield of the detected NO in the system is small. In fact, at the time at which the maximum NO concentration is observed (at 1 mmol L^{-1} 5-ASA), all the limiting reactant (nitrous acid, HNO_2) has been consumed. This implies that approx. 200 μmol L^{-1} nitrite in SGF produces less than

Fig. 9. Extracted mass spectrum (HPLC–MS) obtained during the reaction of 5-ASA and nitrous acid. 5-ASA (50 μmol L^{-1}) was incubated with nitrite (200 μmol L^{-1}) in SGF. After 10 min an aliquot of the reaction mixture was injected into the HPLC–MS system. (A) Mass spectrum of the HPLC–MS peak (2.8 min) corresponding to 5-ASA. (B) Mass spectrum of the HPLC–MS peak (6.6 min) corresponding to the final product of the reaction.



3.6 μmol L^{-1} NO (in the absence of KSCN), rendering a yield of less than 2%. In this context, it is important to consider that NO is formed with a very fast initial rate, implying that the NO is generated as a primary product, probably in parallel with the main reaction of 5-ASA and nitrous acid. In fact, the initial slope of NO release is 6 times lower than the initial slope of 5-ASA consumption assessed by fluorescence.

Studies aimed at characterizing the final product(s) of the 5-ASA–nitrous acid reaction

To characterize the product(s) generated during the reaction of 5-ASA and nitrous acid, HPLC measurements were carried out. Solutions of 5-ASA (50–100 μmol L^{-1}) plus nitrite (100–200 μmol L^{-1}) were incubated in SGF and injected into the HPLC system at different reaction times. As can be seen in Fig. 8A, 5-ASA (50 μmol L^{-1}) in the absence of nitrous acid showed a single chromatographic peak with a retention time of 4.3 min. When nitrite was added to a 5-ASA solution in SGF, in parallel with a decrease of the peak at 4.3 min, a new peak at 7.5 min was registered (line b in Fig. 8A). The intensity of both peaks was dependent on the incubation time and after 60 min of reaction, only the peak

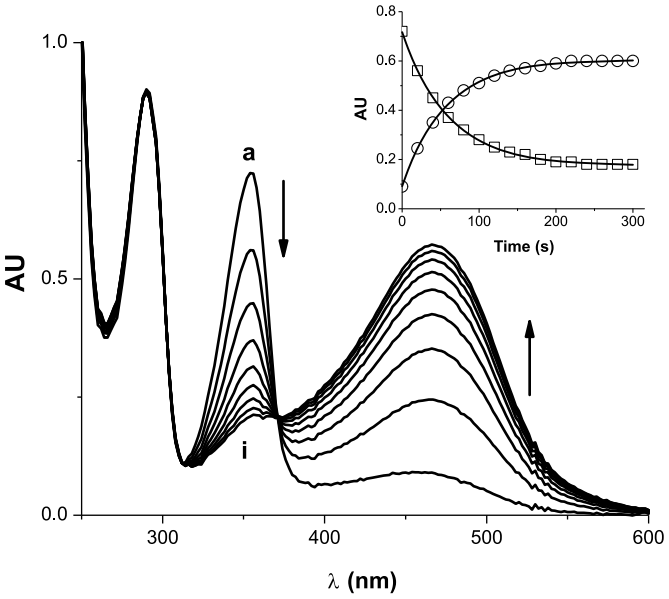
Fig. 10. Time course of the reaction between the final product of the 5-ASA–nitrous acid reaction (diazonium derivative) and resorcinol. The diazonium product was obtained by incubating a solution containing 5-ASA (5 mmol L^{-1}) and nitrite (10 mmol L^{-1}) in SGF at 25 °C for 30 min. Afterwards, the solution was diluted 20-fold. An aliquot of this solution was added to a solution containing resorcinol (250 μmol L^{-1}) in NaOH (20 mmol L^{-1}). The time course of the reaction was followed by the changes in UV–visible spectra registered in the range 250–700 nm. Lines a–i represent spectra taken every 3 min. Inset: time course of the reaction followed at 355 nm (□) and 466 nm (○).



at 7.5 min was detected. The time course of the reaction assessed by HPLC (Fig. 8B) is similar to the kinetic profiles registered by UV–visible or fluorescence spectroscopy. These results showed that only one product is formed in the main reaction of 5-ASA with nitrous acid. To identify this product, HPLC–MS studies were carried out. For this purpose, a solution containing 5-ASA (50 μmol L^{-1}) plus nitrite (200 μmol L^{-1}) was incubated for 30 min in SGF and injected into the HPLC–MS system. The registered HPLC–MS chromatograms showed two chromatographic peaks at 2.8 and 6.6 min (data not shown). The mass spectrum of the peak at 2.8 min is in agreement with the structure of 5-ASA (Fig. 9A), according to the following fragmentation pattern: ion molecular peak (M^+) of 5-ASA, m/z = 154; base peak (bp), m/z = 108, corresponding to the loss of the C-1 substituent (COOH) of 5-ASA; peak (1), m/z = 136, related to the loss of the amine group of 5-ASA; peak (2), m/z = 79, related to the loss of C-1, C-2, and C-5 substituents.

The fragmentation pattern of the peak detected at 6.6 min (product of the reaction) is shown in Fig. 9B and gave the following ions: base peak (bp) with m/z = 137, corresponding to the loss of the N_2^+ fragment; peak (1) with m/z = 81 and peak (2) with m/z = 57, according with the fragmentation pattern of salicylic acid.[35]

The analysis of this fragmentation pattern indicated the formation of the diazonium derivative (2-hydroxy-5-diazonium benzoic acid) as a product of the reaction of 5-ASA and nitrous acid. To corroborate this finding, we assayed a number of reactions expected from a diazonium compound with phenols. A solution containing the final product of the reaction between 5-ASA (5 mmol L^{-1}) and nitrite (10 mmol L^{-1}) in SGF was diluted 20-fold and mixed with a solution of resorcinol in 20 mmol L^{-1} NaOH (pH = 12) or 50 mmol L^{-1} Tris buffer (pH 7.3). Figure 10 shows the changes in the UV–visible spectra upon the reaction of the diazonium derivative of 5-ASA (2-hydroxy-5-diazonium benzoic acid, approx. 25 μmol L^{-1}) with resorcinol (250 μmol L^{-1}) at pH 12. As can be seen in this figure, in the presence of resorcinol a clear decrease in the absorbance at 355 nm (associated with the diazonium derivative) was observed. In parallel with this decrease, a new absorption band at 466 nm was generated. This band can be associated with the formation of diazo derivatives.[36] This behavior, observed in the first 30 min of incubation (see inset of Fig. 10), was characterized by the presence of a neat isosbestic point at 370 nm. In addition, UV–visible studies allowed us to postulate that the final product of the reaction between 5-ASA and nitrous acid (diazonium derivative) also reacts with phenols such as phloretin, catechol, pyrogallol, and quercetin at pH 7.3 (data not shown).

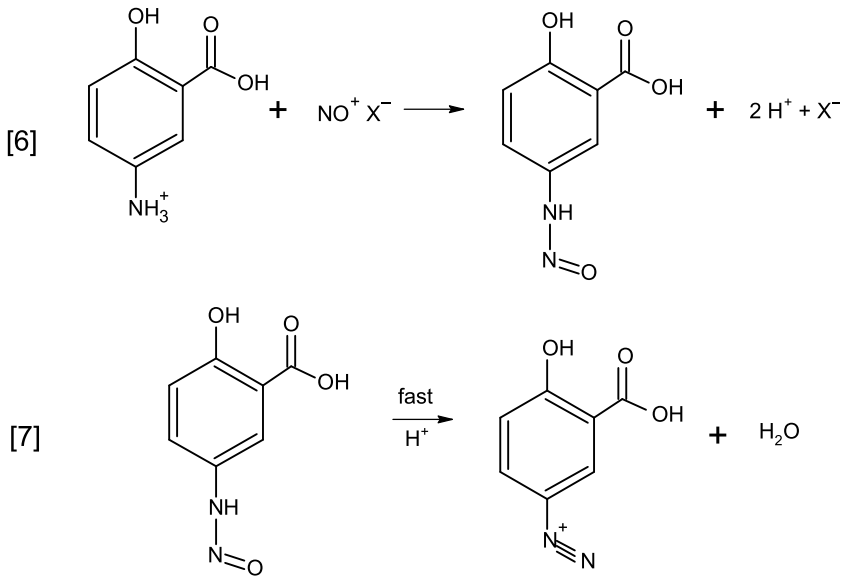
Discussion

The interaction of xenobiotics with nitrite in acidic media (nitrous acid) and the possible release of NO during the reaction is currently a matter of study[20–28,37,38] Here, we investigated the interaction of 5-ASA, a drug widely employed in the treatment of bowel diseases, with nitrous acid. The structure of 5-ASA (Scheme 1), characterized by an aromatic amine and a hydroxyl group, makes 5-ASA a plausible substrate to react with nitrous acid. In fact, our findings demonstrate that 5-ASA reacts efficiently with nitrous acid to form the diazonium derivative (2-hydroxy-5-diazonium benzoic acid). In addition, NO was detected as a minor product of the reaction (~16% of the consumed 5-ASA). This value is higher than the yield estimated from the maximum NO concentration observed in Fig. 7 (2% of the initial nitrous acid concentration). This difference is due to the consumption of the NO formed by 5-ASA or its derivatives.

The reaction of 5-ASA and nitrous acid was evidenced by the decrease of 5-ASA fluorescence and by the generation of new bands in the UV–visible spectrum (Figs. 1 and 2, respectively). The reaction was dependent on the pH of the medium in a way that indicated a single-ionization process with a pK_a of 3.6 (Fig. 5). This pK_a value is very close to that of nitrous acid, implying that nitrous acid is a necessary precursor in the reaction. The reaction order, first in 5-ASA and first and second in nitrous acid (Fig. 3), points to a classical nitrosation reaction, which in the case of primary amines is followed by a rapid dehydration to yield the diazonium compound. In addition, the results presented in Fig. 4 demonstrate that the reaction is catalyzed by chloride and thiocyanate in similar ways, as has been reported for others compounds containing amine moieties.[19]

The UV–visible spectrum obtained after the reaction between 5-ASA and nitrous acid was dependent on the pH of the medium (Fig. 6). The maximum band of the UV–visible spectrum was displaced from 340 nm to 355 nm when the pH changed from 2.0 to 7.0. Also, the addition of sodium hydrosulfite (dithionite) to the solution at pH 7.0 shifted the

Scheme 1.



absorbance maximum to 332 nm. The latter could be explained by the known reductive effect of hydrosulfite on azo compounds.[39]

The present data reveal that in addition to 2-hydroxy-5-diazonium benzoic acid, NO was generated (as a minor product) during the reaction of 5-ASA and nitrous acid in SGF (Fig. 7). The kinetic profiles of NO release indicate that NO (at low concentration) was formed as a primary product, probably in a minor parallel reaction. Similar NO concentrations have been detected in the reaction of phenols such as caffeic acid and coumaric acid with nitrite in SGF.[26] However, even low concentrations of NO could be significant, giving some protection to the stomach and probably contributing to vasodilation, mucosal blood flow, and mucus thickness.[23–26] In this context, an NO-releasing 5-ASA derivative has been proposed as a plausible alternative with improved efficacy in the treatment of bowel disease.[40]

From the obtained results, we propose that 2-hydroxy-5-diazonium benzoic acid and NO are formed through parallel mechanisms, according to Scheme 1 and Scheme 2. 5-ASA would react with nitrous acid to form 2-hydroxy-5-diazonium benzoic acid (Scheme 1) as the main product and in a parallel way (minor) to form NO (Scheme 2). As low NO concentrations were detected during the reaction, the final product(s) generated by the NO pathway were probably not detected in the HPLC experiments.

As eq. [6] shows (Scheme 1), the first step of the reaction is the formation of the *N*-nitrosamine derivative to form the diazonium salt (eq. [7]), as expected for the reaction between primary aromatic amines and nitrosonium carriers.[19,30] In this context, a methodology based on the formation of diazonium salts from the reaction of 5-ASA with nitrous acid has recently been proposed as a simple assay to estimate 5-ASA concentration in pharmaceutical formulations.[41]

The mixed first- and second-order kinetics in nitrous acid arises from the identity of the NOX species. In the absence of external nitrosonium carriers the reaction proceeds via HNO_2 and N_2O_3, which can be interpreted as nitrosonium hydroxide and nitrosonium nitrite, respectively. The generation of these nitrosating species (eqs. [1] and [3]) implies first- and second-order kinetics in nitrous acid, respectively.[19] In the presence of chloride and thiocyanate, additional NOX species are present that catalyze reaction [6].

NO is in turn produced by a combination of reactions. Acidic nitrite is in equilibrium with N_2O_3 via eq. [3], and N_2O_3 is in equilibrium with NO and NO_2 (eq. [4]). This equilibrium is displaced to the left ($K = 2 \times 10^{-5}$),[42] but $\cdot NO_2$ also has an alternative escape route via dimerization and dismutation:[43]

$$[8] \qquad 2\cdot NO_2 \rightleftharpoons N_2O_4 + H_2O \rightarrow NO_2^- + NO_3^- + 2H^+$$

Reaction [8] would displace equilibrium [4] to the right, thus explaining the spontaneous NO evolution in the absence of 5-ASA (Fig. 7, trace a). Two additional possibilities appear likely, both involving the reduction of intermediates. First, 5-ASA or 2-hydroxy-5-diazonium benzoic acid (or both) could be oxidized by $\cdot NO_2$, a strong oxidant known to react quickly with aminophenols (eq. [9] in Scheme 2). The reaction would not produce NO directly but would sequester NO_2 from equilibrium [4], thus making more NO available for detection. Alternatively, either aromatic substrate could react with NO^+ (or NOX), which is also a strong one-electron oxidant with a redox potential ($E°$) of 1.24 V (eq. [10] in Scheme 2). This reaction has been proposed to explain how phenols such as caffeic acid and coumaric acid (among others) generate NO in their interaction with nitrite in stomach conditions.[26]

Additionally, the fact that thiocyanate increases NO production indicates that reaction [10] is occurring and its rate depends on the identity of NOX. This does not rule out the possibility of reaction [9] occurring concomitantly. Nevertheless, the reactions proposed in Scheme 2 imply that final products corresponding to the oxidation of 5-ASA should be generated. However, these products were not detected in our HPLC studies. Furthermore, we estimate that the initial rate of NO formation represents close to 16% of the consumption

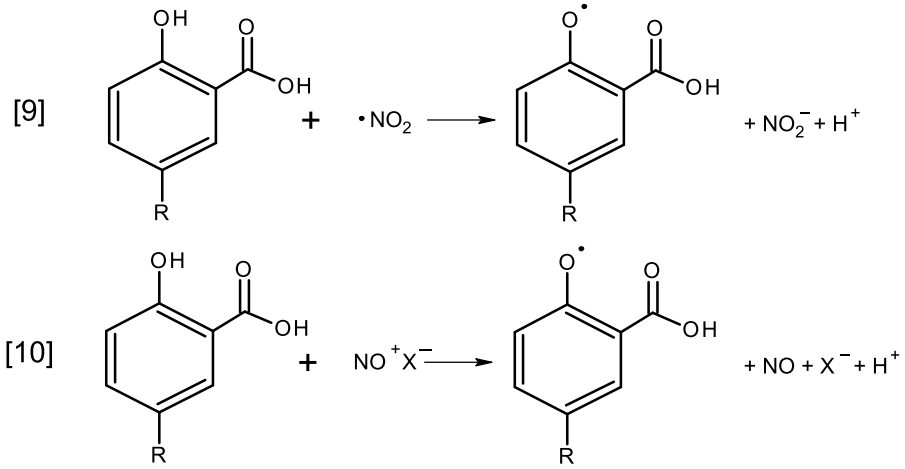
Scheme 2.



of 5-ASA, leading to concentrations of the final products in the micromolar range.

The detected diazonium derivative (Fig. 9) would be stable under stomach conditions, but upon neutralization of the medium (as in the small intestine or at alkaline pH) would be able to react with phenols to form diazocompounds.[44,45] Our results showed that the diazonium derivative generated from the reaction of 5-ASA with nitrite in SGF reacted with resorcinol, giving the characteristic visible absorption band of diazo derivatives (Fig. 10).

Conclusion

The present in vitro studies indicate that 5-ASA reacts with nitrous acid, generating the diazonium derivative as the main product with minor amounts of nitric oxide. While the formation of nitric oxide could be beneficial for the protection of the stomach, the generation of the diazonium salt could be considered a potentially toxic process.

Amine and thiazole substituted γ-butyrolactones from naturally occurring limonene

Pushpinder Kaur, Pralay Das, Abha Chaudhary, and Bikram Singh

Abstract: Substituted γ-butyrolactones are important structural motifs in several natural products and pharmaceuticals. In this paper, we report the synthesis of novel γ-butyrolactone amine and thiazole derivatives from naturally occurring limonene. Regioselective bromination followed by nucleophilic substitution with different amines and thiourea gave desired products in moderate yield.

Key words: regioselectivity, bromination, amination, thiazole, γ-butyrolactone.

Résumé : Les γ-butyrolactones substituées sont d'importants motifs structuraux dans plusieurs produits naturels et pharmaceutiques. Dans ce travail, on a synthétisé de nouveaux dérivés amine et thiazole de la γ-butyrolactone à partir du limonène qu'on peut obtenir de sources naturelles. La bromation régiosélective, suivie d'une substitution nucléophile avec diverses amines et thiourées permet d'obtenir les produits désirés avec des rendements modérés.

Mots-clés : régiosélectivité, bromation, amination, thiazole, γ-butyrolactone.

Introduction

The amine derivatives of γ-butyrolactone are important motifs found in several biologically active natural products and pharmaceuticals. These structural units are very common in antiallergic,[1] antineoplastic,[2] and antifungal[3] compounds, in antimalarial alkaloids[4] and gastroprotective drugs,[5] and in new inhibitors of phosphodiesterase and HIV-1 protease.[6] Moreover, these amino derivatives have been used as building blocks of other important molecules.[7]

In recent years, significant attention has been focused on the synthesis of amine derivatives of γ-butyrolactone. Different research groups have started with an α-halo-γ-butyrolactone derivative and a C-protected amino acid in the presence of base,[8] oxazolone with α-haloketones in the presence of potassium bicarbonate and a phase transfer reagent,[9] aza-Michael-type addition using $NsONHCO_2Et$,[10] and amino hydroxylation of diesters.[11] Roos and Effenberger first prepared amino alcohols and then proceeded with stepwise amino protection, ozonolysis, and oxidation.[12] All the research groups have either synthesized N-protected derivatives or used starting materials that contain nitrogen functionality. Also, they have prepared amine derivatives substituted in the lactone ring. In our case, a new type of butyrolactone derivative (**3**) having a side chain with a carbonyl group has been synthesized from naturally occurring limonene (**1**).

Thiazole and its derivatives are very useful compounds in various fields of chemistry including medicine and agriculture. For example, the thiazolium ring present in vitamin B_1 serves as an electron sink, and its coenzyme form is important for the decarboxylation of α-keto acids.[13] This heterocyclic system has found broad application in drug development for the treatment of several diseases.[14] To the best of our knowledge, γ-butyrolactones with different substituted amine and thiazole moieties are very rare entries in organic synthesis. In the last few years we have been engaged in the development of limonene to γ-butyrolactone chemistry. Herein we report the regioselective bromination of the side chain of **3** followed by nucleophilic substitution with different amines and thiourea. Amide and sulfonamide derivatives of thiazolobutyrolactone have also been synthesized.

Results and discussion

Limonene (**1**) was isolated from citrus peel essential oil (extracted with a Clevenger apparatus) using column chromatography. Limonene was identified by gas chromatography – mass spectrometry and with the reference sample procured from Sigma-Aldrich (Germany). α-Terpineol (**2**) was prepared by selective oxymercuration-demercuration of the external double bond in limonene (Scheme 1). α-Terpineol was subjected to oxidative cleavage using different oxidizing agents such as CrO_3,[15] $KMnO_4$,[16] and $RuCl_3$.[17] $RuCl_3$–$NaIO_4$ was found to be the best oxidizing agent, giving the highest yield of **3**.

We were interested in introducing amine and sulfur atoms in the side chain of **3** to enhance its activity. But when **3** was treated with primary amine, ring opening was taking place. So we decided to first introduce a halogen atom in the side chain and then carry out the substitution with different amines.

The α-halogenation of carbonyl compounds is the step for introducing a heteroatom, generating a stabilized carbon radical

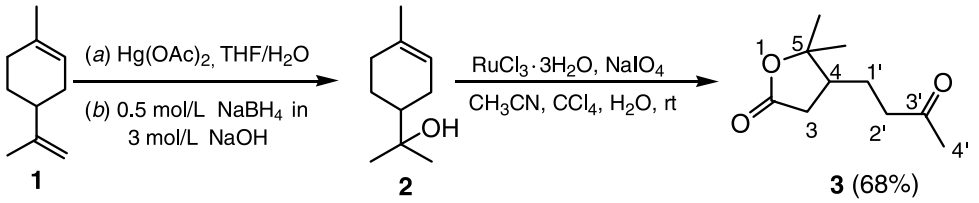
Scheme 1. Synthesis of γ-butyrolactone (**3**) from limonene.



or carbanion and providing conjugation to carbonyl groups. Aldehydes and ketones can be halogenated at the α-position with bromine, chlorine, and iodine. Various α-bromination methods for carbonyl compounds have been reported, including the basic method using Br_2, *N*-bromosuccinimide, dioxane/dibromide, and a hexamethylenetetramine–bromine complex under microwave irradiation.[15]

For unsymmetrical ketones the preferred order of halogenation is typically CH > CH_2 > CH_3, but mixtures are frequently encountered.[18] In basic conditions the reaction goes through an enolate mechanism where the C-4′ group is attacked preferably over the C-2′ group to stabilize the enolate (Scheme 1). With acid catalysts, the reaction goes through enol formation, and for enol stabilization an internal carbon (C-2′) is brominated rather than the terminal C-4′ (Scheme 1). The quantity of brominating reagent is an important factor in controlling consecutive bromination at the same position.[18] The purpose of the catalyst is to provide a small amount of enol or enolate. The reaction can also be carried out without addition of catalyst, as traces of catalyst are always present and these are enough to catalyze enol formation.

We have developed a milder, selective, and controlled bromination of **3** at the C-2′ position. In this procedure, 1 mol/L Br_2 in dichloromethane (DCM) was added dropwise to **3** in a 1:1 ratio at room temperature. In situ formation of **4** was monitored and identified by thin layer chromatography (TLC) and liquid chromatography – mass spectrometry (LC-MS). Bis-brominated product was observed with increasing molar concentrations of bromine in DCM. The molar ratio (1:1) is an important factor for selective monobromination at the C-2′ position. Isolation of **4** is very difficult owing to the unstable C–Br bond under moist and basic conditions. After the addition of bromine the reaction mixture was immediately dried on a rotary evaporator to remove unreacted bromine and HBr produced under the reaction conditions.

Bromo-substituted γ-butyrolactone (**4**) was used for amination reactions without further purification. Compounds **5a**–**5g** were prepared (Table 1) through selective bromination and nucleophilic substitution by different amines in a consecutive manner at the C-2′ position of **4**. Aminations of **4** using primary aliphatic amines like cyclohexylamine, benzylamine, and ethylenediamine occurred very rapidly with the γ-butyrolactone ring, and ring-substituted products (A and B) were observed simultaneously as major by-products along with the expected minor product C (Scheme 2). The mixture of products was observed by TLC and LC-MS.

For steric reasons, *tert*-butylamine (entry 3) and isopropylamine (entry 9) remained unreacted even on addition of higher equivalents of amine for a longer time. Primary aromatic amines such as aniline and *p*-toluidine (entries 1 and 2) participated in selective bromine substitution and produced **5a** and **5b** in 58% and 61% yield, respectively.

Primary aromatic amines are less reactive than primary aliphatic amines and the expected products were formed in greater quantity (entry 1, 58%; entry 2, 61%) than the ring-opened product. It is clear from the results that the bromine substitution rate is much faster than the rate of ring cleavage of the γ-butyrolactone **4**.

Secondary amines were found to be more suitable and selective for aminations of **4**. No ring cleavage product was observed. The reactions were carried out with acyclic as well as cyclic (five- and six-member) amines. Compound **5c** was obtained in good yield (84%) by the reaction of diethylamine (entry 4) with **4**.

Using morpholine and piperidine (entries 5 and 6), the yields obtained for **5d** and **5e** were 69% and 63%, respectively. For piperazine (entry 7) there was the possibility of substitution by both nitrogen atoms, but as one equivalent of **4** and one equivalent of piperazine were used, only monosubstituted product was obtained. The yield obtained with pyrrolidine (entry 8) was less than that obtained with six-member cyclic amines.

Intermediate **4** was further used for the synthesis of another heterocyclic molecule containing both sulfur and nitrogen atoms by Hantzsch thiazole synthesis (Scheme 3). In this reaction, **4** was refluxed with thiourea to give the thiazole-containing butyrolactone derivative **6** in 68% yield.

As the thiazole derivative **6** contains a free amino group in its skeleton, it can be further substituted to introduce other functional groups that can lead to enhanced biological activity. Therefore, we substituted the amino group of **6** with different amides and sulfonamides (Scheme 4). Acetyl and benzyl amide derivatives (**6a** and **6b**) were prepared by refluxing **6** with one equivalent of acetyl or benzoyl chloride, respectively, in the presence of a catalytic amount of pyridine. Product **6** was refluxed with the acid chlorides of acetic acid, benzoic acid, and *p*-toluenesulfonic acid in the presence of pyridine to yield **6a** (72%), **6b** (68%), and **6c** (75%), as shown in Scheme 4.

Conclusion

In summary, methods to introduce a diverse set of amino groups onto γ-butyrolactone have been developed. The key intermediate for all of these transformations is γ-butyrolactone bromide derivative **4**, obtained from γ-butyrolactone derivative **3** in a selective bromination reaction. To this intermediate were introduced a variety of substituted amines to produce amino-functionalized γ-butyrolactones.

Experimental section

General

All reactions were conducted using oven-dried glassware.

9	**4**		30/60	No reaction		—

[a]All products were characterized by IR, ^{1}H NMR, ^{13}C NMR, and HRMS (ESI) spectral data.
[b]Isolated yields were calculated from **4**.

Commercial-grade reagents were used without further purification. Solvents were dried and distilled following usual protocols. Column chromatography was carried out using silica gel (60–120 mesh). TLC was performed on aluminum-backed plates coated with silica gel 60 with F_{254} indicator.

The ^{1}H NMR and ^{13}C NMR spectra were recorded with a 300 MHz spectrometer using $CDCl_3$. ^{1}H NMR chemical shifts are expressed in parts per million (δ) relative to $CHCl_3$ (δ = 7.26); ^{13}C NMR chemical shifts are expressed in parts per million (δ) relative to the $CDCl_3$ resonance (δ = 77.0). High-resolution mass spectra (HRMS) were obtained using positive electrospray ionization (*m*/*z* values are given). Infrared spectra were recorded as thin films on sodium chloride plates. Optical rotation was measured with a HORIBA SEPA-300 polarimeter.

Synthesis of dihydro-5,5-dimethyl-4-(3-oxobutyl)furan-2(3*H*)-one (3)

To 20 mL of water, $NaIO_4$ (56.39 g, 0.263 mmol) followed by acetonitrile (10 mL) and carbon tetrachloride (10 mL) was

added and stirred for 5 min. $RuCl_3 \cdot 3H_2O$ (1.299 mmol) was added and stirred for 10 min. To the reaction mixture, **2** (10 g, 0.064 mmol) was added dropwise at 0 °C. It was stirred at 0 °C for 20 min and then at room temperature for 5–6 h until the reaction was complete. The reaction mixture was partitioned with water and ethyl acetate in a separatory funnel and the water layer was washed with ethyl acetate (3 × 30 mL). The combined ethyl acetate layer was dried over sodium sulfate. The solvent was evaporated under vacuum to give **3**, which was purified by column chromatography over silica gel using hexane – ethyl acetate (41:9), providing **3** as an oily liquid (8 g, 68%). $[\alpha]_D^{27}$ –43.2° (c = 0.01, MeOH). R_f 0.65 (1:1 hexane – ethyl acetate). IR ($CHCl_3$) υ_{max} (cm^{-1}): 1781, 1722, 1549, 1251, 1004, 977. ^1H NMR (300 MHz, $CDCl_3$, δ): 2.48–2.40 (m, 1H), 2.37–2.35 (m, 2H), 2.20–2.15 (m, 1H), 2.10–2.07 (m, 1H), 2.05 (s, 3H), 1.65–1.60 (m, 1H), 1.45–1.35 (m, 1H), 1.30 (s, 3H), 1.13 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 207.2 (1C), 174.9 (1C), 86.4 (1C), 44.8 (1C), 41.8 (1C), 34.1 (1C), 29.7 (1C), 27.1 (1C), 22.9 (1C), 21.6 (1C). Representative procedure for the synthesis of dihydro-5,5-dimethyl-4-(2-(phenyl amino)-3-oxobutyl)furan-2(3*H*)-one (5a)

To compound **3** (200 mg, 1.08 mmol) dissolved in 1 mL dichloromethane, 0.1 mL of 1 mol/L Br_2 in dichloromethane was added dropwise and stirred at room temperature for 5 min. The completion of the reaction was monitored by TLC and LC-MS. The reaction mixture was dried in a rotary evaporator to remove extra bromine and HBr present in the reaction mixture. To the resulting brominated product, aniline (1.08 mmol) and 1–2 drops of triethylamine were added and stirred at 55–60 °C in a water bath. After the completion of the reaction, the reaction mixture was extracted with ethyl acetate. The ethyl acetate layer was washed with a minimum amount of $NaHCO_3$ solution and then with water. It was dried over sodium sulfate and concentrated in a rotary evaporator. Purification was performed by silica gel column chromatography using hexane : ethyl acetate (95:5 to 80:20) to give **5a** as an oily liquid (173 mg, 58%); $[\alpha]_D^{27}$ +61.7° (c = 0.01, MeOH). R_f 0.90 (1:1 hexane – ethyl acetate). IR ($CHCl_3$) υ_{max} (cm^{-1}): 3622, 3018, 2975, 1758, 1712, 1513, 1476, 1420, 1229, 1046, 723. ^1H NMR (300 MHz, $CDCl_3$, δ): 7.20–6.53 (m, 5H), 3.98 (br s, NH), 2.62–2.54 (dd, J = 8.05, 7.08 Hz, 1H), 2.50–2.43 (m, 1H), 2.32–2.28 (m, 1H), 2.23–2.19 (m, 1H), 2.16 (s, 3H), 1.80–1.78 (m, 1H), 1.54–1.49 (m, 1H), 1.45 (s, 3H), 1.26 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 207.2 (1C), 175.0 (1C), 146.2 (1C), 129.6 (2C), 118.7 (1C), 113.2 (1C), 86.7–85.9 (1C), 62.4–61.8 (1C), 45.2 (1C), 42.6–41.8 (1C), 34.8–35.1 (1C), 31.4–31.2 (1C), 30.0–29.7 (1C), 27.4–26.3 (1C), 23.3–21.9 (1C). HRMS (ESI) data (*m/z*): $[M + H]^+$ calcd. for $C_{16}H_{22}NO_3$, 276.3508; found, 276.1692.

Dihydro-5,5-dimethyl-4-(2-(*p*-tolylamino)-3-oxobutyl) furan-2(3*H*)-one (5b)

The compound was purified by column chromatography over silica gel using hexane – ethyl acetate (41:9), providing **5b** as an oily liquid (191 mg, 61%). R_f 0.53 (1:1 hexane – ethyl acetate). IR ($CHCl_3$) υ_{max} (cm^{-1}): 3622, 3018, 2975, 1759, 1722, 1513, 1476, 1420, 1229, 1046, 723. ^1H NMR (300 MHz, $CDCl_3$, δ): 6.98 (d, J = 7.87, 2H), 6.49 (d, J = 7.87, 2H), 3.91 (br s, NH), 2.74–2.53 (m, 1H), 2.49–2.42 (m, 1H), 2.40–2.31 (m, 2H), 2.22 (s, 3H), 2.18–2.12 (m, 3H), 1.69–1.84 (m, 1H), 1.44–1.36 (m, 4H), 1.26–1.24 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 209.9 (1C), 175.2 (1C), 144.1–143.9 (1C), 129.9–129.2 (3C), 113.2–113.1 (2C), 86.6–86.3 (1C), 62.6–62.0 (1C), 45.0 (1C), 42.6–41.6 (1C), 35.0–34.7 (1C), 31.2–31.0 (1C), 27.2–27.0 (1C), 21.9–21.7 (1C), 20.2 (1C). HRMS (ESI) data (*m/z*): $[M + H]^+$ calcd. for $C_{17}H_{24}NO_3$, 290.3774; found, 290.3773.

Dihydro-5,5-dimethyl-4-(2-(diethylamino)-3-oxobutyl) furan-2(3*H*)-one (5c)

The compound was purified by column chromatography over silica gel using hexane – ethyl acetate (17:3), providing **5c** as an oily liquid (231 mg, 84%). R_f 0.50 (1:1 hexane – ethyl acetate). IR ($CHCl_3$) υ_{max} (cm^{-1}): 3616, 3019, 2975, 2400, 1756, 1720, 1514, 1417, 1203, 1046, 928. ^1H NMR (300 MHz, $CDCl_3$, δ): 2.77–2.61 (m, 2H), 2.57–2.51 (m, 2H), 2.46–2.39 (m, 2H), 2.30–2.28 (m, 1H), 2.28 (s, 3H), 1.82–1.77 (m, 1H), 1.72–1.60 (m, 1H), 1.51 (s, 3H), 1.33 (s, 3H), 1.27–1.13 (m, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 201.2 (1C), 174.9 (1C), 86.9–86.4 (1C), 60.6 (1C), 52.6–51.0 (2C), 45.4–42.1 (1C), 35.1–34.3 (1C), 33.7 (1C), 32.7 (1C), 27.7–27.1 (1C), 23.5–22.1 (1C), 14.4 (2C). HRMS (ESI) data (*m/z*): $[M + H]^+$ calcd. for $C_{14}H_{26}NO_3$, 256.3611; found, 256.3689.

Dihydro-5,5-dimethyl-4-(2-morpholino-3-oxobutyl)furan-2 (3*H*)-one (5d)

The compound was purified by column chromatography over silica gel using hexane – ethyl acetate (8:17), providing **5d** as an oily liquid (200 mg, 69%). $[\alpha]_D^{27}$ –46.4° (c = 0.01, MeOH). R_f 0.19 (1:1 hexane – ethyl acetate). IR ($CHCl_3$) υ_{max} (cm^{-1}): 3616, 3019, 2975, 2400, 1758, 1720, 1514, 1423, 1217, 1046, 1031, 928. ^1H NMR (300 MHz, $CDCl_3$, δ): 3.70–3.69 (4H), 3.13–2.97 (1H), 2.63–2.59 (3H), 2.52–2.51 (3H), 2.33–2.29 (1H), 2.25–2.21 (s, 3H), 2.18–2.17 (1H), 1.90–1.70 (1H), 1.46 (s, 3H), 1.26 (s 3H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 210.5 (1C), 175.2 (1C), 85.6 (1C), 71.3 (1C), 66.3–66.1 (2C), 49.0–48.8 (2C), 42.1–41.8 (1C), 33.8 (1C), 28.6 (1C), 27.5 (1C), 26.4 (1C), 20.9 (1C). HRMS (ESI) data (*m/z*): $[M + H]^+$ calcd. for $C_{14}H_{24}NO_3$, 270.3447; found, 270.3448.

Dihydro-5,5-dimethyl-4-(2-(piperidin-1-yl-3-oxobutyl) furan-2(3*H*)-one (5e)

The compound was purified by column chromatography over silica gel using hexane – ethyl acetate (8:17), providing **5e** as an oily liquid (182 mg, 63%). $[\alpha]_D^{27}$ –55.3° (c = 0.01, MeOH). R_f 0.50 (hexane – ethyl acetate, 1:1). IR ($CHCl_3$) υ_{max} (cm^{-1}): 3620, 3089, 2975, 2400, 1759, 1730, 1519, 1423, 1227, 1046, 928. ^1H NMR (300 MHz, $CDCl_3$, δ): 2.75–2.46 (m, 4H), 2.32 (s, 3H), 2.25–2.09 (m, 4H), 1.75–1.71 (m, 1H), 1.55–1.36 (m, 10H), 1.20 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 208.7–207.6 (1C), 175.5–174.9 (1C), 86.9–86.4 (1C), 71.4 (1C), 52.5–51.2 (2C), 43.7–42.1 (1C), 35.2–34.3 (1C), 32.7 (1C), 29.9–29.2 (1C), 27.7–27.3 (1C), 26.1–25.6 (2C), 25.1–24.9 (1C), 22.8–22.2 (1C). 4-(2-Amino-4-methyl-thiazol-5-ylmethyl)-5,5-dimethyl-dihydro-furan-2-one (6)

Thiourea (82.6 mg, 1.08 mmol) was dissolved in 20 mL of distilled water with heating in a round-bottomed flask equipped with a reflux condenser. Compound **4** (200 mg, 1.08 mmol) dissolved in 2 mL of methanol was added dropwise to the thiourea solution and the reaction mixture was refluxed till the reaction was complete. The reaction mixture was cooled and made alkaline with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. The ethyl acetate layer was washed twice with distilled water, dried over Na_2SO_4, and concentrated in a rotary evaporator. Purification was performed by recrystallization with hot dichloromethane to give **6**. Crystalline powder (137.4 mg, 68%); mp 152–

A simple and efficient copper-catalyzed amination of aryl halides by aqueous ammonia in water

Yefeng Zhu and Yunyang Wei

Abstract: The copper(I) iodide/1,4-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)piperazine (CuI–L2) system catalyzed the cross-coupling reactions between aryl halides and aqueous ammonia in water to produce primary aromatic amines in good yields. The protocol was simple and efficient, avoiding the need for inert atmosphere, additional base, or other additives.

Key words: copper, catalysis, cross coupling, water chemistry, aqueous ammonia, primary arylamine.

Résumé : Le système iodure de cuivre(I)/1,4-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)pipérazine (CuI–L2) catalyse les réactions de couplages croisées entre les halogénures d'aryles et une solution aqueuse d'ammoniaque pour conduire à la formation d'amines aromatiques primaires avec de bons rendements. Le protocole est simple et efficace, il ne nécessite pas d'atmosphère inerte, de base additionnelle ou d'autres additifs.

Mots-clés : cuivre, catalyse, couplage croisé, chimie dans l'eau, solution aqueuse d'ammoniaque, arylamine primaire.

Introduction

Ammonia is an attractive source of nitrogen in organic synthesis owing to its great abundance and low cost.[1] In recent years, the palladium- or copper-catalyzed coupling of aryl halides with ammonia has attracted increasing attention because of the value of primary aromatic amines in the preparation of natural products, agrochemicals, dyes, polymers, and medicinal compounds.[2] While palladium catalysts developed by Buchwald and Hartwig[3] proved most useful for this reaction, less progress has been achieved with copper catalysts. Recently, Kim and Chang[4] reported a proline-derived copper complex catalyzed arylation of ammonium chloride or aqueous ammonia with aryl iodides. Following these pioneering works, a lot of catalytic systems have been reported,[5] such as CuI/diketone ligands,[5a] CuI/2-pyridinyl-β-ketone ligands,[5b] CuI/4-hydroxy-L-proline,[5c] etc. Furthermore, Rao et al.[6a] also introduced a ligand-free copper-catalyzed arylation of aqueous ammonia with aromatic boronic acids at room temperature. These reactions are generally performed in organic solvents, which lead to environmental problems.[7] It is highly desirable to find a procedure to carry out these coupling reactions in cheap, nontoxic, and nonflammable "green" solvents. Obviously, water is the most cheap and environmentally benign solvent.[8] However, to the best of our knowledge, there are only a few well-established methods to effectively synthesize anilines from aryl halides and aqueous ammonia in water.[9] More recently, Wu et al.[9b] reported the coupling reactions of aryl halides with aqueous ammonia by a sulfonato–Cu(salen) complex in water, but an additional base was essential.

We have identified Mannich bases[10] (Fig. 1) as efficient ligands for the Cu-catalyzed N-arylation of imidazoles in water.[11] We now report a ligand-assisted copper(I)-catalyzed method for the coupling of aryl halides with aqueous ammonia in water. This method utilizes inexpensive CuI as the catalyst and simple synthesized Mannich bases as ligands and tolerates a wide range of functional groups. Inert atmosphere and additional base were not needed. The use of aqueous ammonia makes the reaction easier to handle than the cases where gaseous ammonia or ammonia in organic solvent was used.

Results and discussion

We initially selected iodobenzene as a model substrate for optimization of the reaction conditions. The standardized protocol was carried out by using iodobenzene (1 equiv.), CuI (10 mol%), L2 (10 mol%), and aqueous ammonia (2 mL) in water at 120 °C for 12 h. The results are summarized in Table 1.

It can be seen from Table 1 that the CuI–L combination successfully promoted the coupling reaction with yields from 75% to 90% (Table 1, entries 1–4), whereas no product was detected without the ligand under similar conditions (Table 1, entry 5). Among the ligands used, 1,4-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)piperazine (L2) displayed the best catalytic activity (Table 1, entry 2). Thus, L2 was chosen as the ligand for further optimization of the reaction conditions. Different copper sources have also been examined, the catalysis by CuI, CuCl, and $CuSO_4$ with L2 afforded the aniline product in good yields of 90%, 85%, and 87%, respectively (Table 1, entries 2, 7, and 8, respectively). However, the use of the $CuCl_2$–L2 combination resulted in a moderate yield of 51% (Table 1, entry 9). It must be pointed out that in the absence of copper catalysis, no aniline derivative was obtained

14	CuI	L2	2	<5[d]

Note: Unless otherwise noted, the reactions were carried out with iodobenzene (1 mmol), 25%–28% aqueous ammonia (2 mL) at 120 °C for 12 h.

[a]Isolated yields.

[b]H_2O (1 mL) was added.

[c]Reaction time was 8 h.

[d]Reaction temperature was 100 °C.

(Table 1, entry 6). Further investigation revealed that 2 mL aqueous ammonia was needed for the reaction to take place. When we decreased the amount or the concentration of aqueous ammonia, the reaction rate decreased (Table 1, entries 10–12). In addition, a lower temperature decelerated the reaction rate and led to a lower yield (Table 1, entry 14). In summary, the proper conditions for amination of aryl halides by aqueous ammonia in water consist of the combination of CuI (10 mol %), L2 (10 mol %), and aqueous ammonia (2 mL) at 120 °C for 12 h in air.

With this practical procedure in hand, we explored the scope of this reaction and screened a wide range of aryl iodides and bromides. As shown in Table 2, most of the aryl iodides with either electron-donating or electron-withdrawing substituents afforded aniline derivatives in water in excellent yields, and the highest yield was obtained by using 4-iodoacetophenone. However, when the highly activated 4-nitroiodobeneze was used, a slightly lower yield (61%; Table 2, entry 3) was obtained because of the formation of a small amount of unidentified byproduct.

Next, we were intrigued by the possibility of using aryl bromides as coupling partners, which are less reactive substrates but of much greater interest for industrial applications. It can be seen from Table 2 that all the electron-deficient aryl bromides afforded the aniline products with excellent yields ranging from 72% to 92% under the optimized conditions (Table 2, entries 5–9). The reactions with the electron-rich aryl bromides were slower, but the products could be isolated in good yields by extending the reaction time to 24 h (Table 2, entries 10–14). It is noteworthy that the catalytic system displayed a great tolerance for multiple groups including the nitro, acetyl, and ether groups. However, the steric hin-

drance has a huge influence on the coupling reaction. When 2-methylbromobenzene was aminated with this catalytic system, only a 27% isolated yield was obtained (Table 2, entry 11). Fortunately, when the reaction was performed with *o*-methoxybromobenzene, the corresponding *o*-methoxyaniline was obtained in an 85% isolated yield (Table 2, entry 13). Furthermore, attempts to use chlorobenzene as an aryl source failed (Table 2, entry 15). When 4-nitrochlorobenzene, an activated aryl chloride, was used as the arylating agent, only a 5% yield of the corresponding coupling product was detected (Table 2, entry 16).

Conclusion

In summary, we have developed a ligand-assisted copper (I)-catalyzed method for coupling aryl halides with aqueous ammonia in water. This protocol avoids the use of toxic organic solvents and eliminates the need for an inert atmosphere, additional base, or other additives, which greatly facilitates operations. Excellent yields are obtained with a wide range of aryl bromides and aryl iodides as substrates in the catalytic system.

Experimental

General method

All reactions were carried out in a Teflon septum screw-capped tube under air atmosphere. All chemicals were obtained from a commercial source (Sinopharm Chemical Reagent Company, Ltd., Shanghai, China, and Aladdin Reagent, Shanghai, China) and used without further purification. Ligands L1–L4 were synthesized according to the literature.[10] Column chromatography was performed on silica 200–300 mesh. ^{1}H NMR and ^{13}C NMR spectra was recorded on a Bruker Avance 300, 400, or 500 and 125 spectrometer at ambient temperature in $CDCl_3$ or DMSO-d_6. Chemical shifts are reported in parts per million relative to TMS.

Typical procedure for the coupling

Aryl halides (1 mmol), CuI (0.1 mmol), 1,4-bis(2-hydroxy-3,5-di-*tert*-butylbenzyl)piperazine (0.1 mmol), and aqueous ammonia (2 mL) were added to a Teflon septum screw-capped tube. The reaction mixture was stirred at 120 °C for 12 h and then cooled to room temperature and extracted with ethyl acetate. The organic layer was then dried with anhydrous Na_2SO_4, and the solvent was removed under reduced pressure. The aniline product was finally obtained by column chromatography on silica gel.

Abstract: The quasi-classical trajectory (QCT) calculations for the title reaction were carried out using the recently developed, accurate potential energy surface (PES) of the $1^1A'$ singlet state of the OHF system The integral cross section and the product rotational alignment factor $\langle P_2(\mathbf{j}' \cdot \mathbf{k})\rangle$ were calculated as a function of collision energy. In addition, I discovered the effect of isotopic substitution on stereodynamics for the title reaction, and the influence of the rotation excitation of the reagent on stereodynamics is also presented. Both the scalar and vector properties of the reaction $O(^1D) + HF \rightarrow OH + F$ (^2P) are studied in this paper. It was found that the reaction is mainly controlled by an indirect reaction mechanism, and that the deep noncollinear insertion HOF well has a great impact on the dynamics of the reaction. The conclusions drawn in this paper will draw from references to similar reactions, and provide a theoretical foundation for related experiments.

Key words: scalar and vector properties, O + HF reaction, isotope effect, rotation excitation of the reagent, quasi-classical trajectory.

Résumé : On a effectué des calculs de trajectoire quasi-classique (TQC) pour la réaction mentionnée dans le titre en faisant appel à la surface d'énergie potentielle (SEP) précise développée récemment de l'état singulet $1^1A'$ du système OHF. On a calculé la section droite intégrale et le facteur d'alignement rotationnel du produit $\langle P_2(\mathbf{j}' \cdot \mathbf{k})\rangle$ en fonction de l'énergie de collision. De plus, on a découvert un effet de substitution isotopique pour la réaction mentionnée dans le titre et on présente aussi l'influence de l'excitation de rotation du réactif sur la stéréodynamique. Dans ce travail, on étudie aussi les propriétés scalaires et les propriétés vectorielles de la réaction $O(^1D) + HF \rightarrow OH + F(^2P)$. On a trouvé que la réaction est principalement contrôlée par un mécanisme réactionnel indirect et que l'important puits d'insertion non colinéaire du HOF affecte beaucoup la dynamique de la réaction. Les conclusions tirées de ce travail serviront de référence à des réactions semblables et fourniront des bases théoriques pour des expériences apparentées.

Mots-clés : propriétés scalaires et vectorielles, réaction OHF, effet isotopique, rotation et excitation du réactif, trajectoire quasi-classique.

[Traduit par la Rédaction]

Introduction

Recently, the reactions of atomic oxygen with hydrogen halides (HX, where X refers to halogens) have received considerable attention for their importance in the studies of molecular reaction dynamics.[1–5] By disentangling the relative contributions in high-resolution angular and velocity distribution measurements at different collision energies, the dynamics of both O(^{3}P) and O(^{1}D) reactions have been investigated, and the effect of electronic excitation on the reaction dynamics of atomic oxygen and the possible role of intersystem crossing between triplet and singlet potential energy surfaces have also been explored directly. Examples of these studies include the reactions of O(^{1}D) with hydrogen halides (HF, HCl, HBr, and HI) to give the halogen oxides (FO, ClO, BrO, and IO),[1,3,6–9] and the reaction of O(^{1}D) with CF_3Br to give BrO,[10] etc. The halogenated compounds are currently of interest and the subject ofrecent studies, owing to their abundance in nature and their importance for human health and environmental protection.[11–30]

Among the halogenated compounds, the OHF system is considered to be one of the model systems for open shell reactions because of its relatively simple electronic structure. There have been several recent reports on the accurate potential energy surfaces (PESs) of the OHF reactive system. In 2004, based on multireference configuration interaction (MRCI) electronic calculations, Gómez-Carrasco et al.[12] fitted 8069 ab initio points, and obtained a high quality global PES for the ground triplet state of the OHF reactive system. Running the quasi-classical trajectory (QCT) calculations in this PES for the F + HO reaction, they[12] got similar results that are in good agreement with existing kinetic and dynamic experiments. In addition, using the aug-cc-pVTZ extended basis sets of Dunning[13,14] for the ab initio calculations, Gómez-Carrasco et al.[15] obtained a new global PES of the ground $^3A''$ adiabatic electronic state. Based on this PES, they performed the wave packet (WP) and QCT calculations for the reactive collision F + OH, and found that the reaction presented a dynamic barrier, essentially due to the zero-point energy (ZPE) for the bending vibration near the saddle point

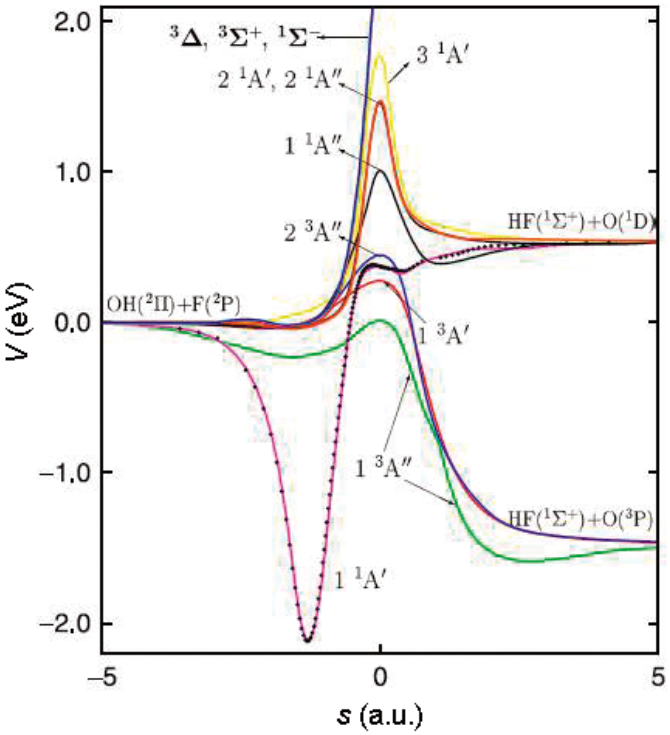
that determines two different reaction mechanisms.[15] In the same year, González-Sánchez et al.[16] reported a quantum WP study on the reagent **k**–**j** vector correlations for the reaction of F + OH on the $1^3A''$ state and the rate constants at nearly room temperature. Later, on the global three-dimensional adiabatic PESs for the excited $2^3A''$ and $1^3A'$ triplet states of the OHF system, Gómez-Carrasco et al.[17] studied the reaction dynamics of $F(^2P) + OH(^2\Pi) \rightarrow O(^3P) + HF(^1\Sigma^+)$ using a WP treatment within a centrifugal sudden approach. In 2007, they calculated the angle-resolved photodetachment spectra for the first five adiabatic singlet states $2^1A'$, $3^1A'$, $1^1A''$, $1^1A'$, and $2^1A''$ of the OHF system,[18] and calculated about 20 000 MRCI single point energies for the $O(^1D) + HF \rightarrow OH + F(^2P)$ reaction and obtained the highly accurate $1^1A'$ PES.[19] The minimum energy path of $1^1A'$ PES is shown in Fig. 1.[19] In the figure, *s* is defined as the sum of the displacements d*s* between two consecutive points of the surface, in terms of the three internuclear distances. By convention, *s* is positive (negative) from the saddle point toward O + HF (OH + F) channel, being $s = 0$ at the saddle point for the PES. Thus the sign of *s* distinguishes both chemical channels. In Fig. 1, one can see a very deep well in the product channel, which is the most noteworthy characteristic of this PES. This deep well locates the F + HO channel with energy $V \approx 2.111$ eV (including ZPE). In addition, there is a shallow well (energy of 0.323 eV) located at the O + HF channel, and the transition state of the PES has an energy of 0.375 eV over the F + HO channel. Based on this PES, Gómez-Carrasco et al.[19] investigated the dynamic and kinetic properties of reaction $O(^1D) + HF \rightarrow OH + F(^2P)$ using quantum WP and QCT methods, and the results agreed well with each other. More recently, Chu[20] has studied the chemical stereodynamics of reactions H/D + FO → OH/OD + F, HF/DF + O using three PESs of the $1^1A'$, $1^3A'$, and $1^3A''$ states by the time-dependent quantum WP and QCT method, and Zhao et al.[21] have investigated the H + OF → OH + F, HF + O reaction stereodynamics on $1^3A'$ PES using the QCT method.

To date, our work has mainly focused on the scalar and vector properties of the reactions based on $1^3A''$ PES of OHF system,[22–27] and only one paper has reported the effect of reagent vibration on the stereodynamics of the reaction $O(^1D) + HF \rightarrow OH + F(^2P)$ based on $1^1A'$ PES.[28] For a better understanding of the dynamic properties of the $O(^1D) + HF$ reaction on $1^1A'$ PES with a very deep well in the product channel, I have studied not only the scalar (vector) properties, but also its isotope variant, using QCT.

Theoretical method

The QCT calculation method used here is the same as used in other studies.[29–34] Classic Hamilton's equations are numerically integrated in three dimensions. First, I have calculated the integral cross section and the product rotational alignment factor. Setting the initial rovibrational conditions of the HF reagent to be $v = 0$, $j = 0$, the collision energy was chosen from 0.02 to 0.6 eV; second, I have studied the effect of isotope substitution O + HF/DF/TF ($v = 0$, $j = 0$) on stereodynamics at the different collision energies; and third, I have investigated the effect of rotation excitation O + HF ($v = 0$, $j = 1, 2, 3$) on the product polarization at the same collision energy. For each reaction, a batch of 10 000 trajectories was run, the integration step size in the trajectories was chosen to be 0.1 fs, and the initial distance from the O atom to the center of mass of HF was 20.0 Å, which can guarantee conservation of the total energy and angular momentum.

Fig. 1. Global minimum-energy path for the three-dimensional ground single state $1^1A'$ for $O(^1D) + HF > OH + F(^2P)$ reaction. (From Gómez-Carrasco et al.[19], reproduced with the kind permission of Chemical Physics Letters © Elsevier 2007).



I have used standard product rotational polarization theory,[23–40] but I only summarize the details relevant to the present work. The QCT calculation was performed in the center-of-mass (CM) frame where the reagent relative velocity vector **k** is parallel to the *z* axis, and the *x*–*z* plane is the scattering plane containing the initial and final relative velocity vectors, **k** and **k**′. The angle θ_t is the so-called scattering angle between the reagent relative velocity and the product relative velocity. θ_r and ϕ_r are the polar and azimuthal angles of the final rotational angular momentum **j**′.

The $P(\theta_r)$ distribution describes the $\mathbf{k} - \mathbf{j}'$ vector correlation with $\mathbf{j}' \cdot \mathbf{k} = \cos\theta_r$, it can be expanded in a series of Legendre polynomials,

$$[1] \qquad P(\theta_r) = 2\sum_k k(2k+1)a_0(k)P_k(\cos\theta_r)$$

the expanding coefficients $a_0(k) = \int_0^\pi P(\theta_r)P_k(\cos\theta_r)\sin\theta_r d\theta_r = \langle P_k(\cos\theta_r)\rangle$ are called orientation (*k* is odd) and alignment (*k* is even) parameters, and *k* is the integer to ensure the convergent results of $P(\theta_r)$. Because only the rotational alignment of the product is measured in most experiments, in this study we mainly discuss the average rotational alignment factor $\langle P_2(\mathbf{j}' \cdot \mathbf{k})\rangle$.

The dihedral angle distribution function $P(\phi_r)$ describing the $\mathbf{k} - \mathbf{k}' - \mathbf{j}'$ correlation can be expanded in a Fourier series as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[2] \qquad P(\phi_{jr}) = \frac{1}{2\pi}(1 + \sum_{\text{even},n\geq 2} a_n \cos n\phi_r + \sum_{\text{odd},n\geq 1} b_n \sin n\phi_r)$$

where $a_n = 2\langle \cos n\phi_r \rangle$ and $b_n = 2\langle \sin n\phi_r \rangle$. Using θ_r and ϕ_r to define the direction of $\mathbf{j}'$, the space distribution of the product's rotation angular momentum can be written as

$$[3] \qquad P(\theta_r, \phi_r) = \frac{1}{4\pi}\sum_{kq}[k]a_q^k C_{kq}(\theta_r, \phi_r)$$

$$= \frac{1}{4\pi}\sum_{k}\sum_{q\geq 0}(a_{q\pm}^k \cos q\phi_r - a_{q\mp}^k i \sin q\phi_r)C_{kq}(\theta_r, 0)$$

where $a_{q\pm}^k = 2\langle C_{k|q|}(\theta_r, 0)\cos q\theta_r \rangle$ (k is even) and $a_{q\mp}^k = 2i\langle C_{k|q|}(\theta_r, 0)\sin q\theta_r \rangle$ (k is odd).

In this calculation, $P(\theta_r)$, $P(\phi_r)$, and $P(\theta_r, \phi_r)$ are expanded up to $k = 18$, $n = 24$, and $k = 7$, respectively, which shows a good convergence.

Results and discussion

The dynamics of reaction O + HF OH + F

The QCT reaction probability as a function of collision energy for $O(^1D) + HF \rightarrow OH + F(^2P)$ ($J = 0$) reaction has been reported by Gómez–Carrasco et al.,[19] and the QCT result is in good accord with the WP result.

Figure 2 shows the QCT results of the integral reaction cross section. It is clear that the value of integral cross section is very large at the low collision energies, and rapidly decreases with increase in relative translational energy. The biggest impact parameter b_{max} at different collision energies is shown in Table 1. As can be seen in Table 1, b_{max} is large and rapidly decreases when the collision energy is <0.1 eV, but is small and decreases very slowly when the collision energy is >0.1 eV. Considering the integral cross section and b_{max}, it can be concluded that the value of orbital angular momentum, **L**, plays an important role in the reaction. Additionally, there is a shallow well in the reagent channel and no barrier in the reaction profile, which also affects the integral reaction cross section, as shown in Fig. 2.

To further investigate the dynamics of this reaction, I have also studied the vector properties of the title reaction. Figure 3 shows the dependence of the product rotational alignment factor $\langle P_2(\mathbf{j}' \cdot \mathbf{k}) \rangle$ on the collision energy. It can be seen from this figure that the value of $\langle P_2(\mathbf{j}' \cdot \mathbf{k}) \rangle$ is about –0.1 in the whole collision energy range, which indicates that there are weak product rotational alignments, and the degree of alignment is almost invariant when the collision energy increases. This could be due to the heavy–light–heavy (H–L–H) mass combination: much angular momentum transfers from the reagent orbit to the product orbit, $\mathbf{L} - \mathbf{L}'$, and little to rotation. Instead, in my calculations, the rotation number, j', of product molecule OH is large, which is shown in Fig. 4. It is easy to figure out that the rotational excitation of the product is quite strong, with the most probable population appearing at a high rotation number. The distribution changes towards higher j' value while the translational energy of the reactant increases. That is to say, much more energy goes into rotation than into translation, which is consistent with the result reported in by Gómez-Carrasco et al.[19] In that paper, the authors have ascribed their result to the noncollinear deep insertion well in the product channel. In view of my work, the reason for weak product rotational alignment can also be the deep well, which induces the complex to rotate for a long time. In Fig. 5, the internuclear distances of OH, HF, and OF as a function of propagation time are shown. It can be observed from this figure that the life of the "complex" is very long, whether the collision energy is low (0.02 eV) or

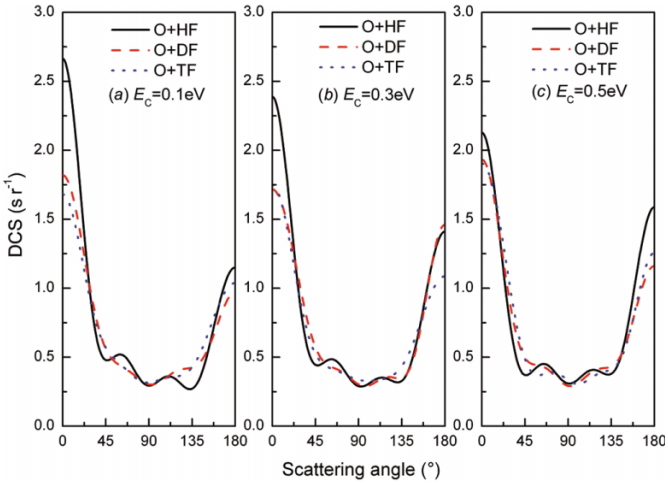
high (0.6 eV). Hence it is not difficult to conclude that this reaction is mainly controlled by an indirect reaction mechanism.

The dynamics of reactions O + HF/DF/TF ($v = 0, j = 0$) → OH/OD/OT + F

In this section, I consider the isotopic effect of the reactions O + HF/DF/TF (v = 0, j = 0) → OH/OD/OT + F at different collision energies, on dynamics.

Figures 6*a*–6*c* represent the differential cross sections (DCSs), which reflect the angular distribution for the reactions O + HF/DF/TF (v = 0, j = 0) → OH/OD/OT + F at the collision energy of 0.1 eV, 0.3 eV, and 0.5 eV. As is seen in Figs. 6*a*–6*c*, at the different collision energies, the reaction O + HF/DF/TF is dominated by strongly forward–backward scattering; at the same collision energy, forward scattering is always stronger than backward scattering. When the collision energy increases, the backward scattering becomes stronger

Fig. 6. The angular distributions for O + H/DF/TF (v = 0, j = 0) → OH/OD/OT + F reactions.



and the products trend to forward–backward symmetrical scattering. The reason for these results may be the two wells in PES, and that the title reaction is mainly controlled by an indirect reaction mechanism. Increase in collision energy speeds up the complex rotation, which makes the products trend to forward–backward symmetrical scattering. At the same collision energy, when the target molecule HF is substituted by DF and TF, the same qualitative markedly forward–backward distribution is given. These results are consistent those discussed by Gómez-Carrasco et al.[19] Of course, if hydrogen is substituted by its deuterium (tritium) isotope, there appears to be some divergence among the three DCSs for each collision energy, i.e., the trend of forward–backward scattering becomes weaker. It is obvious that the relative velocity of the product molecule of the O+DF/TF → OD/OT + F reaction is lower at the same initial collision energy, which may make forward–backward scattering weaker.

From the above statements, it is not clear what the isotopic effect is on the scalar properties of the title reaction, at the same collision energy. To consider isotopic effect fully, we have studied the isotopic effect on vector properties. Figures 7 and 8 show the distributions of $P(\theta_r)$ and $P(\phi_r)$ of the reactions O + HF/DF/TF → OH/OD/OT + F at collision energies of 0.1 eV and 0.4 eV, respectively. In Figs. 7*a* and 7*b*, it is clear that the peaks of $P(\theta_r)$ are at $\theta_r = 90°$ and are symmetric around 90°, which indicates that the product rotational angular momentum vector is strongly aligned along a direction at right angles to the relative velocity direction, and one can conclude that the three reactions are mainly governed by the "in plane" mechanism. Obviously, there is a discrepancy among the three $P(\theta_r)$ distributions after H is substituted by D and T. For E_c = 0.1 eV, the peak of the $P(\theta_r)$ distribution becomes lower and lower, which indicates that the product molecule alignment becomes weaker and weaker. According to other studies (Zhao et al.,[24] Wang and He,[30] and Wang et al.,[32]) $P(\theta_r)$ is sensitive to two factors: the character of the PES, and the mass factor (i.e., $\cos^2\beta = m_A m_c/(m_A + m_B)(m_B + m_C)$ for the reaction A + BC → AB + C). With respect to adiabatic approximation, the influence of isotopic substitution on the PES is not considered here. Therefore, the difference in the $P(\theta_r)$ distribution is probably attributable to the difference

Fig. 7. The distribution of $P(\theta_r)$ for the product molecule from the reaction O + HF/DF/TF → OH/OD/OT + F.

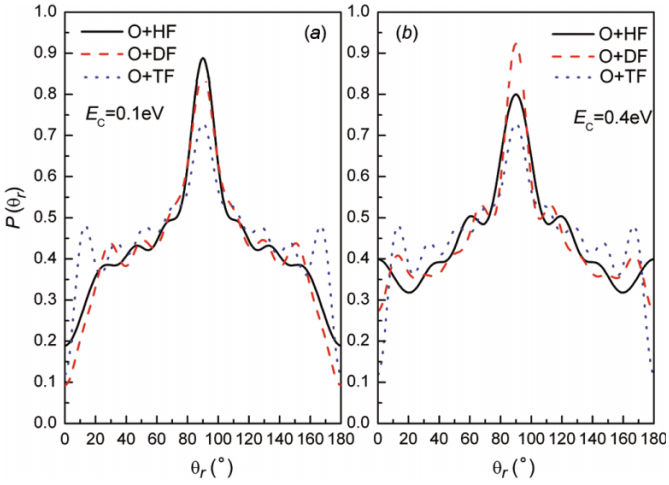

Fig. 8. The distribution of $P(\phi_r)$ for the product molecule from the reaction O + HF/DF/TF → OH/OD/OT + F.

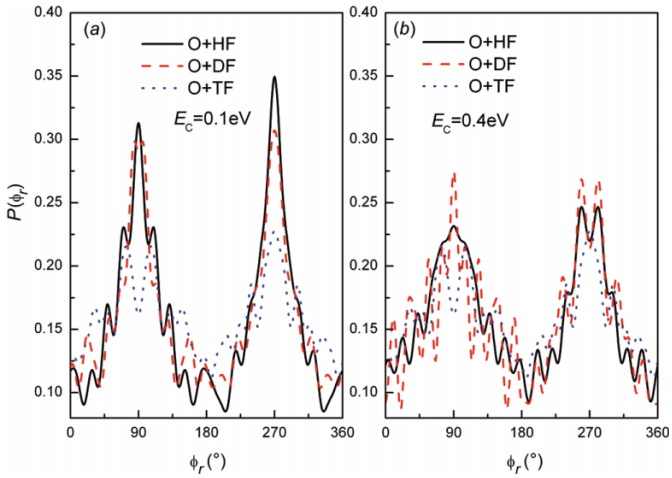
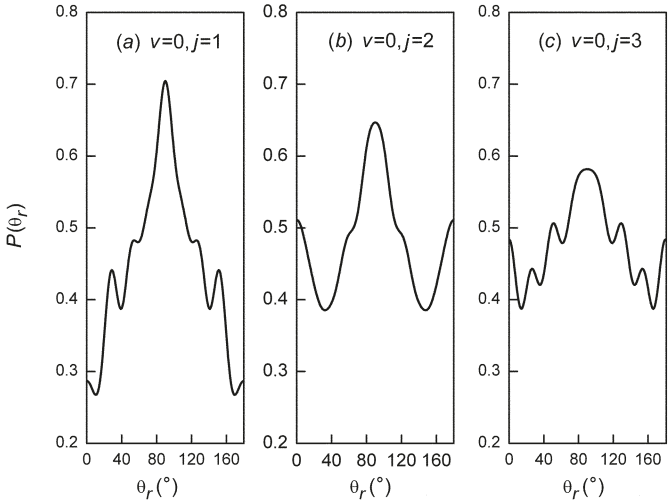


in the mass factor among the reactions O + HF/DF/TF → OH/OD/O, the values for mass factor being 0.893, 0.803, and 0.726, respectively. From Fig. 7*a*, it can be seen that that larger the mass factor, the stronger the product molecule alignment. To achieve a much clearer understanding of the isotopic effect, I have also calculated the $P(\theta_r)$ distribution at the higher collision energy, 0.4 eV, and presented it in Fig. 7*b*. As is shown in Fig. 7*b*, the result is different from the one in Fig. 7*a*. In Fig. 7*b*, the peak of the $P(\theta_r)$ distribution for O + HF is lower than that for O + DF, while higher than that for O + TF, which indicates that the degree of alignment of OH is weaker than that of OD, while stronger than that of OT. The calculations show that the isotopic effect on $P(\theta_r)$ distribution is irregular for our reactions at different collision energies. Although the O + HF/DF/TF reactions are occurring on the same PES, considering the most salient feature of $1^1A'$ PES, the very deep noncollinear insertion HOF well, we can attribute the results for $P(\theta_r)$ to this well, which may make $P(\theta_r)$ vary in relation to changes in mass factor.

Similarly, the dihedral angle distributions $P(\phi_r)$ describing the $\mathbf{k} - \mathbf{k}' - \mathbf{j}'$ correlations for E_c = 0.1 eV and 0.4 eV are depicted in Figs. 8*a* and 8*b*. The $P(\phi_r)$ tends to be asymmetric with respect to the $\mathbf{k} - \mathbf{k}'$ scattering plane, directly reflecting the polarization of angular moment. As is seen in Figs. 8*a* and 8*b*, the main peaks of six $P(\phi_r)$ distributions all appear at ϕ_r = 90° and 270°, which indicates that the rotational angular momentum vectors of the product molecule are mainly aligned along the *y*-axis in the CM frame, and the isotope effect on $P(\phi_r)$ distribution is noticeable for the same collision energy. Seen in Fig. 8*a*, the peaks of $P(\phi_r)$ at ϕ_r = 270° are slightly higher than the ones at ϕ_r = 90°, which indicates that the rotational angular momentum vector of the product molecule OH/OD/OT is not only aligned, but also slightly oriented along the negative *y*-axis. In addition, it can be seen that the product molecule orientation becomes weaker after H is substituted by D and T, and that the orientation of the OT molecule is the weakest. However, for E_c = 0.4 eV in Fig. 8*b*, the trend of $P(\phi_r)$ is inconsistent when H is substituted by D and T. For O + HF/TF → OH/OT + F reactions, the product rotational angular momentum is oriented along the negative *y*-axis, whereas, for O+DF → OD + F, the product rotational angular momentum is oriented along the positive *y*-axis. As stated previously, the isotope effect on $P(\phi_r)$ distribution is also irregular. Other studies (Zhao et al.,[24] Lin et al.,[39] Chu et al., [40] Han et al.,[41] and Li et al.[42]) have shown that the difference in orientation is due to the different harmonic ZPE of the reactant molecules HF (DF/TF). For our reactions, however, the reason for the irregular isotope effect on $P(\phi_r)$ is not the difference in ZPE, but rather because of the particular character of $1^1A'$ PES, the deep well.

Fig. 9. The distribution of $P(\theta_r)$ for the product molecule from the reaction O + HF (v = 0, j = 1, 2, 3) → OH + F at E_c = 0.4 eV.

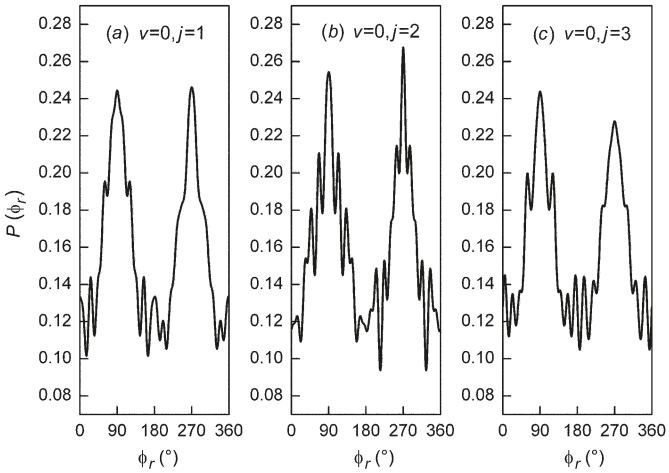


The stereodynamics of reactions O + HF (v = 0, j = 1, 2, 3) → OH + F

In this section, I have studied the effect of reagent rotational excitation on the stereodynamics of the O + HF → OH + F reaction. Figures 9 and 10 show the distributions of $P(\theta_r)$ and $P(\phi_r)$ for the reaction O + HF (v = 0, j = 1, 2, 3) → OH + F, respectively.

In Fig. 9, it is clear that the peak of $P(\theta_r)$ distribution becomes lower with the increase of rotational quantum number, which indicates that the larger the rotational quantum number, the weaker the degree of alignment of OH. This result is different from the findings of Meng et al.,[23] where the reaction

Fig. 10. The distribution of $P(\phi_r)$ for the product molecule from the reaction O + HF ($v = 0$, $j = 1, 2, 3$) → OH + F at $E_c = 0.4$ eV.



H + FO ($v = 0$, $j = 1, 2, 3$) → HO + F proceeds to $1^3A''$ PES. The reason for this discrepancy may be the difference between $1^1A'$ and $1^3A''$ PESs. For the reaction H + FO ($v = 0$, $j = 1, 2, 3$), there is a barrier in the $1^3A''$ PES; while for the reaction O + HF ($v = 0$, $j = 1, 2, 3$) based on $1^1A'$ PES, there is no barrier other than a deep well in the product channel.

From Fig. 10, which shows the $P(\phi_r)$ distribution, one can find that for the reaction O + HF ($v = 0$, $j = 1$), $\mathbf{j}'$ has no evident orientation, but for $j = 2$, $\mathbf{j}'$ tends to be oriented along the negative direction of the y-axis, and for $j = 3$, $\mathbf{j}'$ tends to be oriented along the positive direction of the y-axis. In both latter cases, the degree of orientation is very weak. That is to say, the reagent rotational excitation influences the orientation of the products, but the impact is not great. The reason for this is the deep noncollinear insertion HOF well in the PES. Whether or not the reagent rotational quantum number is large, the complex will rotate for a long time in the well, and the product molecule OH will not have a predictable rotational orientation.

Conclusion

This paper has presented a QCT study of the scalar and vector properties of the $O(^1D) + HF$ reaction, and discussed the effect of isotope substitution as well as the influence of the rotation excitation of the reagent on stereodynamics for the title reaction. Owing to the deep noncollinear insertion HOF well and the barrierless exoergic reaction profile, some interesting results have been obtained: the reaction cross section rapidly decreases with increasing relative translational energy and then flattens out, the angular momentum polarization of the product molecule is weak, the angular distribution of products is markedly forward–backward, and both the effects of isotope substitution on stereodynamics and the reagent rotation excitation on stereodynamics are indistinctive. These conclusions could also be applied to similar reactions (e.g., $O(^3P) + HCl$),[43] and provide a theoretical foundation for related experiments.

Fast computation of DFT nuclear gradient with multiresolution*

Nicholas J. Russ, Chun-min Chang, and Jing Kong

Abstract: We present an efficient algorithm for evaluating the exchange-correlation contribution to the nuclear gradients of density-functional theory calculation within the local spin-density approximation. The algorithm is an extension of the multiresolution exchange-correlation (mrXC) method, which treats smooth and compact parts of the electron density separately. The nuclear gradient of the smooth density is calculated on the even-spaced grid while the compact part of the density is handled on the normal atom-centered grid (ACG). The overall formulism is still formally based on the ACG, and thus does not change the results of the existing ACG-based algorithms for all-electron density-functional theory (DFT) calculations. The variation of the positions and weights of ACG owing to the nuclear perturbation is also handled rigorously. Benchmark calculations with different basis sets and sizes of ACG show that mrXC reduces the computational cost by several times without loss of accuracy. It also lessens the impact on the CPU time when the size of the ACG is increased.

Key words: density-functional theory, exchange-correlation, planewaves, quantum chemistry.

Résumé : On a développé un algorithme efficace pour évaluer la contribution échange-corrélation aux gradients nucléaires pour des calculs selon la théorie de la fonctionnelle de la densité, dans les limites de l'approximation de la densité de spin locale. L'algorithme est une extension de la méthode de l'échange-corrélation à multirésolution (ECmr) qui traite séparément des parties lisses et compactes de la densité électronique. Le gradient nucléaire de la densité lisse est calculé sur une grille à espaces réguliers alors que la partie compacte de la densité est traitée sur la grille normale centrée sur l'atome (GCA). Le formalisme global est malgré tout basé sur une grille normale centrée sur l'atome et ne change donc par les résultats des algorithmes existants basés sur les GCA pour les calculs selon la TFD pour tous les électrons. La variation des positions et des poids de la GCA due à une perturbation nucléaire est traitée d'une façon rigoureuse. Des calculs repères avec divers ensembles de base et diverses tailles de GCA montrent que la méthode ECmr réduit de beaucoup les coûts de calcul sans perte de précision. Elle réduit aussi l'impact que pourrait avoir une augmentation de la taille de la GCA sur le temps requis de l'unité centrale.

Mots-clés : théorie de la fonctionnelle de la densité (TFD), échange-corrélation, ondes planes, chimie quantique.

Introduction

Numerical integration of the exchange-correlation (XC) terms is one of the major bottlenecks in a density-functional theory (DFT) calculation. We have recently devised a novel scheme called multiresolution XC (mrXC) and showed its ability to speed up the calculation of the energy with local spin density approximation (LSDA) by three to five times.[1,2] The essence of mrXC is to divide the XC terms into *smooth* (low resolution) and *compact* (high resolution) categories, and treat the former more efficiently. In this paper, we will present the mrXC algorithm for the calculation of analytical gradients of the LSDA energy with respect to the nuclear coordinates, which is fundamental to nearly all types of applications.

Tremendous progress has been made to enhance the performance of DFT since the 1990s, with most of the effort on the reduction of the computational cost for Coulomb and Hartree–Fock (HF) exchange interactions. One of the most recent examples is the development of the Fourier transform Coulomb (FTC) method,[3] of which we have made a new implementation in combination with other latest efficient Coulomb algorithms.[4] FTC replaces the most expensive part of the Coulomb interaction, namely the computation of four-index electronic repulsive integrals of diffuse basis functions with small exponents, with an accurate numerical evaluation using planewaves as the auxiliary basis. The computational cost of FTC scales as $O(N^2)$ with respect to the size of the basis set and as $O(V \log V)$ with respect to the size of the molecule (V), versus $O(N^4)$ and $O(V^2)$, respectively, for the conventional approach. Prior to FTC, the most efficient way of calculating the Coulomb energy was the combination of the continuous fast multipole method (CFMM) and the J-engine method. CFMM[5] is the first linear-scaling method for the calculation of Coulomb interaction, which reduces the computational cost of the calculation of Coulomb interaction among the well-separated Gaussians from quadratic scaling to linear. The J-engine technology[6] that reduced the calculation time of the Coulomb interaction in short range by 5–10 fold was developed some time later. We showed that FTC ac-

celerates the Coulomb calculation further, by up to six times, by replacing the most time-consuming part of the J-engine calculation of the integrals containing three and four diffuse basis functions with an efficient numerical integration. The combination of FTC, CFMM, and J-engine represents the state-of-the-art in accurate Coulomb calculation with Gaussian basis functions while maintaining rigorous control of the error. Other efficient but approximating methods exist, such as the resolution-of-the-identity scheme that has been shown to have significant errors in total energy, but small errors in relative energy.[7] Much progress has also been made for the linear-scaling calculation of HF exchange,[8,9] required for hybrid DFT methods.

The other computational bottleneck besides the Coulomb and HF exchange energies, is the XC energy, and its share of the computational cost of a DFT calculation has increased significantly with the improvement of the performance of the others. A typical numerical quadrature for XC is the superposition of atom-centered grids (ACGs).[10] In such a grid, the density of the grid points is very high near nuclei because the electron density changes rapidly in this region, and becomes increasingly lower away from the nucleus as the electron density changes more slowly. While this is necessary for functions with high resolutions such as compact basis functions, it is not necessary for smooth functions with low resolutions. FTC has shown that accurate and efficient numerical integration can be done on a quite sparse even-spaced cubic grid (ESCG) for quantities related to smooth functions. It is, however, impossible to mix the ACG and the ESCG directly without loss of accuracy because the XC functional has a complicated nonlinear dependency on the total electron density that cannot be separated into smooth and compact terms without significant approximation. MrXC overcomes this difficulty by the introduction of two fast transformations between the ESCG and the ACG, which ensures accuracy while maintaining maximum efficiency.

Algorithm

An LSDA functional, f, is a nonlinear function of electron spin densities ρ_α and ρ_β. The integration of f yields the XC energy, and is done numerically on an ACG grid in a standard DFT calculation:

$$[1] \qquad E_{\mathrm{XC}} = \sum_i w_i f[\rho_\alpha(\bar{r}_i), \rho_\beta(\bar{r}_i)] \equiv \sum_i \varepsilon_{\mathrm{XC}}(i)$$

where i is the index for each point on the ACG, and w_i is the weight for that point. The computation of the density is as follows:

$$[2] \qquad \rho_{\sigma i} \equiv \rho_\sigma(\bar{r}_i) = \sum_{\mu\nu} P^\sigma_{\mu\nu}\phi_\mu(\bar{r}_i)\phi_\nu(\bar{r}_i) \equiv \sum_{\mu\nu} P^\sigma_{\mu\nu}\phi_{\mu\nu}(\bar{r}_i), \qquad \sigma = (\alpha, \beta)$$

in which $\mathbf{P}^\sigma$ is the spin density matrix and ϕ_μ and ϕ_ν are atomic basis functions. We use the two-indexed symbol $\phi_{\mu\nu}$ to denote the product of two basis functions or the basis function pair (BFP). The contribution of the XC energy to the nuclear gradient of the total DFT energy is to take the derivative of the XC energy with respect to the nuclear coordinates while the density matrix remains constant.[11] Denoting it as $E^{\bar{A}}_{\mathrm{XC}}$ with $\bar{A}$ being the coordinates of atom A, one obtains from eq. [1] through chain rule:

$$[3] \qquad E^{\bar{A}}_{\mathrm{XC}} \equiv \frac{\partial E_{\mathrm{XC}}}{\partial \bar{A}}\Big|_{\mathbf{P}} = \sum_i \left[w_i (f_i^{\rho_\alpha}\rho^{\bar{A}}_{\alpha i} + f_i^{\rho_\beta}\rho^{\bar{A}}_{\beta i}) + w_i^{\bar{A}} f_i \right] \equiv \sum_i \varepsilon^{\bar{A}}_{\mathrm{XC}}(i)$$

with the following definitions:

$$[4] \qquad f_i \equiv f[\rho_\alpha(\bar{r}_i), \rho_\beta(\bar{r}_i)], \qquad f_i^{\rho_\sigma} \equiv \frac{\partial f_i}{\partial \rho_\sigma}$$
$$\rho^{\bar{A}}_{\sigma i} \equiv \sum_{\mu\nu} P^\sigma_{\mu\nu} \frac{d}{d\bar{A}}[\phi_{\mu\nu}(\bar{r}_i)], \qquad \sigma = (\alpha, \beta)$$

The nuclear gradient of a BFP on the ACG has two components. One is the derivative of each basis function with respect to its atomic position, or the *explicit* nuclear derivative. The other is the derivative of each ACG point with respect to the position of the atom that originates the point, or the *implicit* nuclear derivative. Those two derivatives, denoted as $\rho^{(\bar{A})}_{\sigma i}$ and $\rho^{[\bar{A}]}_{\sigma i}$, respectively, are defined below:

$$[5] \qquad \rho^{\bar{A}}_{\sigma i} = \sum_{\mu\nu} \left(P^\sigma_{\mu\nu} \frac{\partial \phi_{\mu\nu}(\bar{r}_i)}{\partial \bar{A}} + P^\sigma_{\mu\nu} \frac{\partial \bar{r}_i}{\partial \bar{A}} \cdot \frac{\partial \phi_{\mu\nu}(\bar{r}_i)}{\partial \bar{r}_i} \right) \equiv \rho^{(\bar{A})}_{\sigma i} + \rho^{[\bar{A}]}_{\sigma i}$$

The evaluation of eq. [3] is dominated by calculating the nuclear gradient of the electron density, $\rho_{\sigma i\bar{A}}$, as it involves loops over BFPs and atomic coordinates at each ACG point. The calculation of the nuclear gradient of the weight involves only the loop over the atomic coordinates. The electron density value at each ACG point required for the calculation of the derivative of the functional, $f_i^{\rho_\sigma}$, is identical to the last iteration of SCF, which precedes the nuclear gradient calculation.

In the context of mrXC, the electron spin density is separated into smooth and compact parts, with the calculation of the smooth part done on an ESCG, while the compact part is calculated directly on the ACG. The motivation for an ESCG comes from two observations. First, the calculation associated with the smooth part of the density is the computational bottleneck with the ACG as it has large spatial extent and covers many more grid points than the compact part of the density. Second, the ESCG has been used for DFT calculations with pseudopotentials with high efficiency. In a calculation with pseudopotentials, only the smooth part of the density is optimized, and the Coulomb and XC terms are calculated on the ESCG. This procedure has been applied successfully for the studies of solids, especially when combined with Car–Perrilleno-type of molecular dynamics.[12] Efforts have been made to combine the ACG and the ESCG for the full electron calculation by separated integrations.[13] This scheme however involves significant approximation and numerical imprecision, as the XC functional is not a linear function of density. By contrast, mrXC keeps the integration formally on the ACG and thus maintains the full accuracy. The actual calculation associated with smooth density is done on the ESCG for the time-consuming components,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

namely the density and the XC matrix elements. The values calculated on the ESCG are projected onto the ACG grid through accurate interpolations.

The mrXC algorithm classifies each BFP as either smooth or compact. A smooth pair meets the condition that its value at any point in space can be interpolated accurately from those on an ESCG within a tight tolerance:

$$[6] \qquad \widetilde{\phi}_{\mu\nu i} = \sum_{\overline{m}} C_{i\overline{m}} \widetilde{\phi}_{\mu\nu}, \qquad \overline{m} \equiv (m_x, m_y, m_z)$$

In the above equation, $\overline{m}$ is a 3-dimensional index for the points on the ESCG, and $C_{i\overline{m}}$ the interpolation coefficient. $C_{i\overline{m}}$ is a function of the position of the point i and the positions of a small number of ESCG points surrounding that point. The sparsity of $C_{i\overline{m}}$ allows for very fast transformation of numerical values between the two grids. We use a tilde (~) to denote a smooth function and a caret (^) to denote a compact function. It then follows that the smooth density $\widetilde{\rho}$ on the ACG can be calculated as

$$[7] \qquad \widetilde{\rho}_{\sigma i} = \sum_{\overline{m}} C_{i\overline{m}} \widetilde{\rho}_{\sigma\overline{m}}$$

and its explicit nuclear gradient as

$$[8] \qquad \widetilde{\rho}^{(\overline{A})}_{\sigma i} = \sum_{\overline{m}} C_{i\overline{m}} \widetilde{\rho}^{\overline{A}}_{\sigma\overline{m}}, \ \widetilde{\rho}^{(\overline{A})}_{\sigma i} = \sum_{\overline{m}} C^{\overline{A}}_{i\overline{m}} \widetilde{\rho}_{\sigma\overline{m}}$$

Two ESCGs with different grid densities are used in the calculation of the smooth density for the XC energy with mrXC. First, the smooth density is calculated on the less dense grid that is sufficiently accurate for a Fourier expansion of the density. Then, it undergoes a Fourier transform to the more dense ESCG. The latter allows an accurate local interpolation onto an ACG using eqs. [6] and [7]. One could follow the same procedure to produce the nuclear gradient of the smooth density on the ACG, which would be accurate. However, it will not be efficient as it will require many Fourier transformations, owing to the number of nuclear perturbations involved. Instead, one would wish to calculate directly on the coarse ESCG grid the nuclear gradient of E_{XC} contributed from the nuclear gradient of the smooth density. This can be achieved through a reverse interpolation by combining eqs. [7] and [3] for the contribution of the explicit nuclear derivative of the smooth density to E_{XC}:

$$\begin{aligned}[9] \qquad \widetilde{E}^{(\overline{A})}_{\mathrm{XC}} &\equiv \sum_i w_i (f_i^{\rho_\alpha} \widetilde{\rho}^{(\overline{A})}_{\alpha i} + f_i^{\rho_\beta} \widetilde{\rho}^{(\overline{A})}_{\beta i}) \\ &= \sum_i \sum_{\overline{m}} w_i (f_i^{\rho_\alpha} C_{i\overline{m}} \widetilde{\rho}^{\overline{A}}_{\alpha\overline{m}} + f_i^{\rho_\beta} C_{i\overline{m}} \widetilde{\rho}^{\overline{A}}_{\beta\overline{m}}) \\ &\equiv \sum_{\overline{m}} [(\sum_i w_i f_i^{\rho_\alpha} C_{i\overline{m}}) \widetilde{\rho}^{\overline{A}}_{\alpha\overline{m}} + (\sum_i w_i f_i^{\rho_\beta} C_{i\overline{m}}) \widetilde{\rho}^{\overline{A}}_{\beta\overline{m}}] \\ &\equiv \sum_{\overline{m}} (\widetilde{f}^{\rho_\alpha}_{\overline{m}} \widetilde{\rho}^{\overline{A}}_{\alpha\overline{m}} + \widetilde{f}^{\rho_\beta}_{\overline{m}} \widetilde{\rho}^{\overline{A}}_{\beta\overline{m}}) \end{aligned}$$

In the above equation, evaluation of $\widetilde{f}^{\rho_\sigma}_{m}$ takes little time, as only a few neighboring points of the ESCG are involved in the interpolation of each ACG point. We should also note that $\widetilde{f}^{\rho_\alpha}$ is not equal to f^{ρ_α} on the ESCG. The latter is a function of total electron spin densities, which include the smooth and compact parts.

In a DFT energy calculation with mrXC,[1] the smooth density is first calculated on an ESCG that is less dense than the one needed for the local interpolation, i.e., eq. [9]. Such a transformation between two ESCGs can be expressed as

$$[10] \qquad \widetilde{\rho}_{\sigma m} = \sum_{|k_{\bar{j}}| \le \frac{1}{2} D_m} \widetilde{\rho}_\sigma(k_{\bar{j}}) \, \mathrm{e}^{2\pi i k_{\bar{j}} \cdot r_{\overline{m}}} = \sum_{|k_{\bar{j}}| \le \frac{1}{2} D_n} \widetilde{\rho}_\sigma(k_{\bar{j}}) \mathrm{e}^{2\pi i k_{\bar{j}} \cdot r_{\bar{n}}},$$

$$k_{\overline{j+1}} - k_{\bar{j}} = (L_x^{-1}, L_y^{-1}, L_z^{-1})$$

In the above equation, D_m and D_n are the grid densities of the dense and coarse ESCGs, respectively, L_x, L_y, and L_z the dimensions of the ESCG. $\widetilde{\rho}_\sigma(\overline{k})$ is the Fourier transformation of the smooth density calculated on the coarse ESCG according to eq. [2]:

$$[11] \qquad \widetilde{\rho}_\sigma(k_{\bar{j}}) = \sum_{\bar{n}} \widetilde{\rho}_{\sigma\bar{n}} \, \mathrm{e}^{-2\pi i k_{\bar{j}} \cdot r_{\bar{n}}}$$

The computation of the density on an ESCG (eq. [2]) involves a loop over BFPs and is computationally more expensive than the fast Fourier transformations (FFTs) required in eqs. [10] and [11]. The transformation from the coarse grid to the dense grid, shown in eq. [10], provides a significant gain in efficiency as the number of the ESCG points, and thus the computational cost of the smooth density on the grid, scale cubically with respect to the grid density. A BFP is judged as smooth when it is represented on the coarse grid within a tight threshold of error, a scheme developed and implemented by Fusti-Molnar in Q-Chem Program:[14]

$$[12] \qquad 1 - \frac{\int_{-\frac{1}{2}D_n}^{\frac{1}{2}D_n} |\widetilde{\phi}_{\mu\nu}(\overline{k})| d^3k}{\int_{-\infty}^{\infty} |\widetilde{\phi}_{\mu\nu}(\overline{k})| d^3k} < \text{threshold}$$

This screening process takes little CPU time as it is done analytically for each BFP.

To apply mrXC for the calculation nuclear gradient, it is evident from the first few equations that one needs to obtain $\widetilde{\rho}_{\sigma m\overline{A}}$ on the dense ESCG. While one can do so with the same procedure as above starting from $\widetilde{\rho}_{\sigma n\overline{A}}$ on the coarse ESCG, it would require one FFT for each atomic coordinate within the molecular framework. We will instead calculate $\widetilde{E}^{\overline{A}}_{\mathrm{XC}}$ directly on the coarse ESCG by the following reformulation with the help of eqs. [9] and [10]:

$$\begin{aligned}[13] \qquad \sum_{\overline{m}} \widetilde{f}^{\rho_\sigma}_{\overline{m}} \widetilde{\rho}^{\overline{A}}_{\sigma\overline{m}} &= \sum_{|k_{\bar{j}}| \le \frac{1}{2} D_m} \widetilde{\rho}^{\overline{A}}_\sigma(k_{\bar{j}}) \sum_{\overline{m}} \widetilde{f}^{\rho_\sigma}_{\overline{m}} \mathrm{e}^{2\pi i k_{\bar{j}} \cdot r_{\overline{m}}} \\ &\equiv \sum_{|k_{\bar{j}}| \le \frac{1}{2} D_m} \widetilde{\rho}^{\overline{A}}_\sigma(k_{\bar{j}}) \widetilde{f}^{\rho_\sigma}(k_{\bar{j}}) \\ &= \sum_{\bar{n}} \widetilde{\rho}^{\overline{A}}_{\sigma\bar{n}} \sum_{|k_{\bar{j}}| \le \frac{1}{2} D_n} \widetilde{f}^{\rho_\sigma}(k_{\bar{j}}) \mathrm{e}^{-2\pi i k_{\bar{j}} \cdot r_{\bar{n}}} \\ &\equiv \sum_{\bar{n}} \widetilde{\rho}_{\sigma\bar{n}} \widetilde{f}^{\rho_\sigma}_{\bar{n}} \end{aligned}$$

with the following:

$$[14] \qquad \widetilde{\rho}^{\overline{A}}_{\sigma n} = \sum_{\mu\nu} P^\sigma_{\mu\nu} \phi^{\overline{A}}_{\mu\nu n}, \qquad \widetilde{\rho}^{\overline{A}}_\sigma(\overline{k}_j) = \sum \widetilde{\rho}^{\overline{A}}_{\sigma n} \mathrm{e}^{-2\pi i \overline{k}_j \cdot \overline{r}_n}$$

Equation [13] leads to the calculation of the contribution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

of the explicit nuclear derivative of the smooth density to the XC energy gradient as follows:

$$[15]\qquad \widetilde{E}_{\mathrm{XC}}^{(\overline{A})} = \sum_n (\widetilde{f}_n^{\rho_\alpha}\widetilde{\rho}_{\alpha n}^{\overline{A}} + \widetilde{f}_n^{\rho_\beta}\widetilde{\rho}_{\beta n}^{\overline{A}}) = \sum_n \sum_{\mu\nu} (\widetilde{f}_n^{\rho_\alpha} P_{\mu\nu}^{\alpha} + \widetilde{f}_n^{\rho_\beta} P_{\mu\nu}^{\beta}) \phi_{\mu\nu n}^{\overline{A}}$$

We should note that the formulism in eq. [15] resembles the calculation of nuclear gradients of Coulomb energy with FTC if one replaces $(\widetilde{f}_n^{\rho_\alpha} P_{\mu\nu}^{\alpha} + \widetilde{f}_n^{\rho_\beta} P_{\mu\nu}^{\beta})$ with the Coulomb potential. Thus, further reduction of CPU time can be realized when these two methods are applied in concert.

We have shown hitherto how to apply mrXC to the calculation of the nuclear gradient of the DFT energy without the consideration of perturbations of ACG points with the atoms. This perturbation arises when the ACG point is centered on the perturbing atom and accounts for a small but numerically significant correction. In the current Q-Chem Program, such a correction is done through a simple procedure utilizing translational invariance of the nuclear gradients of a molecule. When an ACG point is centered on atom A, its contribution to the nuclear gradient of XC energy is calculated as

$$[16]\qquad E_{\mathrm{XC}}^{\overline{A}}(i) = -\sum_{B\neq A} E_{\mathrm{XC}}^{\overline{B}}(i), \qquad i \in A$$

This formulism is, however, not applicable to mrXC as it requires the nuclear gradient of the smooth density at every ACG point, which we have intentionally avoided. Instead, we start from eq. [5] and recognize that $\frac{\partial \overline{r}_i}{\partial \overline{A}}$ is the identity matrix when i is originated from A and zero otherwise, which leads the following expression for this correction from each spin:

$$[17]\qquad w_i f_i^{\rho_\sigma} \rho_{\sigma i}^{[\overline{A}]} = w_i f_i^{\rho_\sigma} \sum_{\mu\nu} P_{\mu\nu}^{\sigma} \frac{\partial \phi_{\mu\nu}(\overline{r}_i)}{\partial \overline{r}_i} \equiv w_i f_i^{\rho_\sigma} \nabla \rho_{\sigma i}, \qquad i \in A$$

We use ∇ to denote the partial derivative with respect to the electronic coordinate $\overline{r}_i$.

Finally, we arrive at the expression of the mrXC contribution to the nuclear gradients as

$$[18]\qquad E_{\mathrm{XC}}^{\overline{A}} = \widetilde{E}_{\mathrm{XC}}^{(\overline{A})} + \sum_{i\in A}\Big(w_i f_i^{\rho_\alpha} (\nabla \widetilde{\rho}_{\alpha i} + \nabla \widehat{\rho}_{\alpha i}) + w_i f_i^{\rho_\beta} (\nabla \widetilde{\rho}_{\alpha i} + \nabla \widehat{\rho}_{\alpha i}) \Big) + \sum_i \Big(w_i f_i^{\rho_\alpha} \widehat{\rho}_{\alpha i}^{(\overline{A})} + w_i f_i^{\rho_\beta} \widehat{\rho}_{\beta i}^{(\overline{A})} + w_i^{\overline{A}} f_i \Big)$$

with the nonsmooth density, $\widehat{\rho}$, and its nuclear derivatives calculated directly on the ACG.

Performance of mrXC

We have implemented the above algorithm to calculate mrXC energy gradients within the quantum chemistry package Q-Chem.[14] Its performance is tested with the DFT energy and gradient calculations using two different basis sets and two choices of ACG. Taxol ($C_{47}NO_{14}H_{51}$), a natural cancer drug with a globular structure, was chosen as the test molecule. The two sizes of ACG are SG-1[15] and unpruned (100, 302) grid. SG-1 is a pruned (50, 94) grid with about 3000 points per atom. The (100, 302) grid has 100 radial points,[16] and 302 angular points,[17] resulting in 30 200 points per atom. The accuracy of the former is considered moderate, and accuracy of the latter is high. The threshold of the smoothness is set at 10^{-6}, and the grid densities of the coarse and fine ESCGs are 3.8 and 5.7, respectively. The benchmarks are run on a 2.5 GHz quad-core Pentium processor.

Table 1 lists the results of the calculations. The third column shows the percentage of BFPs that are classified by mrXC as smooth. The fourth column shows the accuracy of mrXC in total DFT energy with the error per atom listed in the parentheses. The mean-absolute-errors (MAEs) and the maximum errors of the nuclear gradient with mrXC are listed in columns five and six. The errors are calculated using the full ACG calculations as the reference. One can see that mrXC classifies more than 90% of BFPs as smooth but yields errors less than one micro-Hartree (10^{-6} au) per atom in total energy, and about 10^{-5} au in gradient. These errors are well within the tolerance of numerical precision for a typical DFT calculation.

The calculation associated with smooth BFPs can be done more efficiently on the ESCG than on the ACG. Column seven in Table 1 shows the CPU time directly on the ACG, with and without mrXC, for the computation of the electron density and its nuclear gradients. Column eight in Table 1 shows the CPU time for the same computation on the ESCG. The calculation of these two quantities takes the vast majority of the CPU (>95%) for the calculation of the nuclear gradient of the XC energy. One can see that it only took 12 s to do the calculation with smooth BFPs with SG-1 grid and 6–311G(df,pd) basis, in comparison with 357 s (405 – 48) that it takes on the ACG for the same calculation. The transformation steps — FFT and divided-difference — between the ACG and ESCG take a relatively small amount of CPU time and are listed in column nine. From those numbers, we can calculate the speedups mrXC provides, and they are listed in Table 1, column 10. As one can see, mrXC provides speed-up of 6–10 times for the gradient part of the calculation. Further gain of efficiency can be achieved when the calculation on the ESCG is combined with the Coulomb calculation with FTC, and thus becomes "free." The speedups for this scenario are listed in Table 1, column 11.

Table 1 also lists the results with different basis sets and sizes of ACG. One can see from the numbers that there is more efficient gain with cc-pVTZ basis than with 6–311G (df,pd). This is due to the fact that the former has more functions in the valence region than the latter. Smooth BFPs are more likely formed with those valence basis functions than core functions as the former have smaller exponents. MrXC also provides better performance gain as the grid size increases, because the computational cost on ACG increases with the ACG grid size, but the cost on the ESCG remains unchanged. By reducing the workload on the ACG, mrXC minimizes the impact of enlarging the ACG on CPU time. A large ACG is often desirable due to increased accuracy, and has even been shown necessary for a numerically reliable description of intermolecular interactions.[18]

Table 1. The performance of mrXC for the calculation of the nuclear gradients of taxol with LSDA functional.

Basis (no. of BFs)	Method	Compact BFPs (%)	Error in energy (micro-Hartree)	Error in gradient (au)		CPU time (s)			Speed-up	
				MAE	Max.	ACG	ESG	Interpolation		with FTC
ACG SG-1										
6–311G(df,pd)	ACG only					405				
2111	MrXC	10.00	37.79 (0.33)	6.36E-06	6.21E-05	48	12	6	6.19	7.58
cc-pVTZ	ACG only					698				
2574	MrXC	8.60	8.27 (0.07)	3.09E-06	2.77E-05	72	28	6	6.59	8.96
ACG (100, 302)										
6–311G(df,pd)	ACG only					2715				
	MrXC	10.00	49.34 (0.44)	1.19E-06	1.38E-05	265	12	34	8.73	9.08
cc-pVTZ	ACG only					5204				
	MrXC	8.60	13.20 (0.12)	7.68E-07	7.36E-06	424	28	29	10.83	11.50

Note: The numbers in parenthesese in the 4th column (Error in energy) are errors per atom. MrXC, multiresolution exchange-correlation method; LSDA, local spin density approximation; ACG, atom-centered grid; BF, basis function; BFP, basis function pair; MAE, mean absolute error; ESG, even-spaced grid; FTC, Fourier transform Coulomb method; SG-1, pruned grid (50, 94) with ca. 3000 points per atom.

Conclusions

We have shown how to seamlessly combine the ESCG and the ACG for the numerical integration of the nuclear gradient of the XC part of the DFT energy with LSDA functionals. The algorithm is the extension of the mrXC method, which treats the smooth and the compact parts of the electron density separately. The nuclear gradient of the smooth density is calculated on the ESCG, while the compact part of the density is handled on the ACG. The overall technique is still formally based on the ACG, and thus does not change the results of the existing ACG-based algorithms for all-electron DFT calculations. The variation of the positions and weights of ACG owing to the nuclear perturbation is also handled rigorously. The benchmark calculations on the drug molecule taxol with different basis sets and sizes of ACG show that mrXC reduces the computational cost without loss of accuracy. MrXC also lessens the impact of increase in the size of the ACG on the CPU time. We are working on extending the method to all common types of DFT functionals.

Abstract: A cost-effective and efficient solid Brønsted acid catalyst was synthesized by loading methanesulfonic acid (MSA) on silica and was used for the acid-catalyzed Pechmann reaction to test the catalytic activity and its reusability. Derivatives of 4-methylcoumarin were synthesized in good yields within short reaction times in the presence of environmentally friendly higher *n*-alkanes as solvents. The regeneration study of the spent catalyst showed satisfactory results.

Key words: silica supported solid acids, methanesulfonic acid, Brønsted acidity, Pechmann reaction, derivatives of 4-methylcoumarin.

Résumé : On a synthétisé un catalyseur acide de Brønsted efficace et rentable d'un point de vue coût en recouvrant de la silice avec de l'acide méthanesulfonique (AMS) et on l'a utilisé catalyseur acide pour la réaction de Pechmann dans le but d'évaluer son activité catalytique et la possibilité de le réutiliser. On a synthétisé des dérivés de la 4-méthylcoumarine avec de bons rendements, avec des temps de réaction relativement courts, dans des solvants à base d'alcanes supérieurs écologiques. L'étude de régénération du catalyseur utilisé a donné des résultats satisfaisants.

Mots-clés : acides solides supportés par de la silice, acide méthanesulfonique, acidité de Brønsted, réaction de Pechman, dérivés de la 4-méthylcoumarine.

[Traduit par la Rédaction]

Introduction

Methanesulfonic acid (CH_3SO_3H; MSA) is a strong Brønsted acid ($pK_a = -1.9$) and has been reported as a potential acid catalyst for various acid-catalyzed reactions.[1–3] MSA is very cheap, has a lower tendency to oxidize organic compounds, is far less corrosive and toxic than widely used fluoro-substituted alkanesulfonic acids, like triflic acid and 1,1,2,2-tetrafluoroethanesulfonic acid, and the mineral acids. The problems associated with recovery and reuse of MSA from homogeneous conditions makes its application limited. To overcome these problems, a supported form of MSA could be the best alternative. The supported fluoro-substituted alkanesulfonic acids (triflic acid, 1,1,2,2-tetrafluoroethanesulfonic acid, etc.) have been synthesized and used for various acid-catalyzed organic transformations.[4–10] However, supported MSA, which could be a cost-effective and eco-friendly solid acid catalyst, and an attractive alternative to supported fluoro-substituted alkanesulfonic acids for acid-catalyzed transformations, has not been reported in the literature. The present work was aimed at developing silica-supported MSA as a cost-effective, eco-friendly, and reusable solid acid catalyst. The synthesized catalyst was used for the Pechmann reaction to synthesize derivatives of 4-methylcoumarin.

Coumarins are heterocyclic natural products finding applications as pharmacologically and biologically active compounds.[11,12] Coumarins are usually synthesized by acid-catalyzed Pechmann reaction of activated phenols and α-keto esters[13] using homogeneous Brønsted[14–16] and Lewis[17,18] acid catalysts. It is to be noted that the homogeneous acids are corrosive, required in excess, and nonreusable, sometimes result in the formation of side products, and generate acidic waste. Various solid acid catalysts such as Amberlyst ion-exchange resins,[19] zeolites,[20] montmorillonite K-10,[21] sulfated zirconia,[22] benzylsulfonic acid functionalized mesoporous Zr-TMS,[23] metal ion-exchanged ZAPO-5,[24] W/ZrO_2,[25] Nafion resin / silica nanocomposites,[26] polyaniline sulfate salt,[27] etc., have been found to be the best alternatives to homogeneous acids. However, most of the solid acids require either a longer reaction time[20–25,27] or a higher reaction temperature[22,24,27] to achieve maximum yield. The syntheses using some of the solid acids are not cost-effective because of either tedious methods of synthesizing the catalysts[27] or the use of large amounts of catalysts.[19,20,26] In addition, the solid acid catalyzed Pechmann reactions are usually carried out using nonpolar solvents like tetrahydrofuran (THF), toluene, etc.,[19,20] which are volatile, hazardous, and nonrecoverable. To the best of our knowledge, there is no report

available on the application of higher *n*-alkanes as nonpolar solvents in heterogeneous catalysis. Hence, an attempt was also made in the present work to use higher *n*-alkanes as environmentally friendly nonpolar solvents for Pechmann reactions.

Experimental

Chemicals

Tetraethylorthosilicate, ethyl acetoacetate, and pyrogallol were procured from s.d. Fine Chemicals, India. Hydrochloric acid, methanol, *n*-hexadecylamine (HDA), resorcinol, nitrobenzene, petroleum ether, *n*-butylamine, and acetonitrile were from Merck, USA. *n*-Octadecane, *n*-hexadecane, *n*-dodecane, phloroglucinol, methoxyphenol, and *m*-cresol were procured from National Chemicals, India. Methanesulfonic acid was procured from Loba Chemie, India.

Synthesis of silica-supported methanesulfonic acid (SiO_2–MSA) solid acid catalyst

The silica support was synthesized by hydrolysis of tetraethylorthosilicate (TEOS) using HDA as the template. The pH of the TEOS (20 g) and methanol (50 mL) solution was adjusted in the range of 2–3 by adding a few drops of concentrated hydrochloric acid. Water (7.2 mL) was then added to the acidic TEOS solution with stirring and the solution was kept for 30 min. The HDA solution, prepared by dissolving HDA (2.4 g, 0.01 mol) in methanol (50 mL), was added to the TEOS solution with vigorous stirring and the solution was aged for 5 days at room temperature. The gel was filtered and washed with methanol to remove surfactant template, which was confirmed by FT-IR analysis of the dried silica. The gel was dried at room temperature for 24 h and then at 120 °C for 12 h. To load a nominal amount of MSA (~1 mmol MSA / g of silica) on the silica support, 10 g of dried silica gel was treated with MSA solution (5 mL of MSA in 50 mLof carbon tetrachloride) at room temperature with stirring for 24 h. The gel was filtered and washed with methanol and then with petroleum ether to remove free MSA. The gel was dried at room temperature for 24 h and later at 120 °C for 6 h.

Characterization of SiO_2–MSA catalyst

The catalyst was characterized by N_2 adsorption–desorption isotherm, FT-IR, FT-IR of the pyridine-adsorbed sample, potentiometric titration, thermal analysis (TGA-DTA), and CHNS/O elemental analysis. The Brunauer–Emmett–Teller (BET) surface area and average pore diameter of the samples were measured by N_2 adsorption–desorption isotherm studies using a Quantachrome NOVA 1000e surface area analyzer. The sample was degassed under vacuum at 120 °C for 4 h prior to adsorption measurement, to evacuate the physisorbed moisture. The surface area was determined by using the BET equation, and the average pore diameter of the samples was measured by the Barrett, Joyner, and Halenda method (BJH).[28] The loading of MSA over the silica support was confirmed by FT-IR study using a FT-IR spectrophotometer (Shimadzu IRPrestige-21) with a diffuse reflectance scanning disc technique by mixing the sample with dried KBr (in a 1:20 wt ratio) in the range of 400–4000 cm^{-1} with a resolution of 4 cm^{-1}. The type of surface acidity (Brønsted or Lewis) in the samples was characterized by FT-IR study of the pyridine-adsorbed samples. For this the sample (0.2 g) was activated at 120 °C for 2 h. The activated sample was cooled in a desiccator under vacuum and was exposed to pyridine (25 mL) vapor for 12 h. The pyridine-adsorbed sample was degassed under vacuum for 15 min to remove physically adsorbed pyridine from the sample. The FT-IR spectra of the samples adsorbed with pyridine (mixed with KBr in a 1:20 wt ratio) were recorded in the range of 400–4000 cm^{-1}. The amount of acidity and the strength of the acid sites in the samples were measured by potentiometric titration.[8] The sample (0.05 g) was suspended in acetonitrile and stirred for 3 h. The suspension was titrated with 0.05 N *n*-butylamine in acetonitrile at 0.05 mL/min. The electrode potential variation was measured using a potentiometric titrator (Chemito, India). The TGA-DTA of the samples was carried out by a Shimadzu DTG-60H, by heating the sample in the range of 50–1000 °C with a heating rate of 10 °C/min under nitrogen flow (30 cm^3/min). The amount of MSA loaded on the silica was calculated from the TGA results (W_{MSA}) using the following equation:[8]

$$[1] \qquad W_{MSA} = (W_{SiO-MSA})/FW_{MSA}$$

where $W_{SiO-MSA}$ = weight loss (mg/g) of SiO_2–MSA catalyst from 25 to 500 °C, W_{SiO} = weight loss (mg/g) of SiO_2 support from 25 to 500 °C, and FW_{MSA} = molecular weight of CH_3SO_3H. Percentage of sulfur in the catalysts was also analyzed by CHNS/O elemental analysis (PerkinElmer 2400) to estimate the amount of methanesulfonic acid loaded on the silica.

Catalytic activity of SiO_2–MSA for synthesis of 4-methylcoumarin derivatives by the Pechmann reaction

The derivatives of 4-methylcoumarin were synthesized by the SiO_2–MSA catalyzed Pechmann reaction of a phenol (resorcinol, phloroglucinol, pyrogallol, *m*-methylphenol, *m*-methoxyphenol, or phenol) and ethyl acetoacetate (Scheme 1). The reaction was carried out by adding preactivated (at 120 °C for 1 h) catalyst to the mixture of phenol and ethyl acetoacetate, with or without solvent, at constant temperature under stirring. After the completion of reaction, the reaction mixture was cooled and methanol (~10 mL) was added to dissolve the product. The reaction mixture was filtered to separate the catalyst and the product was crystallized by cooling the filtrate.

Characterization of the products

The products were recrystallized in ethanol–water (95:1) solution and the isolated yields were calculated. The products were characterized by melting point and by FT-IR and ^1H NMR spectroscopy, and the data were matched with those reported in the literature. Melting points were measured by a melting point apparatus (Choudhary Instruments, India) and are uncorrected. Infrared spectra were recorded on a FT-IR spectrophotometer (Shimadzu IRPrestige-21) in KBr with transmittance in cm^{-1}. ^1H NMR spectra were determined on a NMR spectrometer (Bruker Avance DPX, 200 MHz) as dimethyl sulfoxide (DMSO-d_6) solutions. Chemical shifts (δ) were expressed in ppm downfield from the internal standard tetramethylsilane.

Results and discussion

Characterization of SiO_2–MSA

The physicochemical characteristics of the silica and the supported catalyst are given in Table 1. The average pore diameter for the samples was 31 Å. The SiO_2–MSA had a slightly lesser BET surface area (362 m^2/g) compared with the silica support (373 m^2/g), which is attributed to the loading of MSA on the silica surface (Table 1).

The FT-IR spectrum (Fig. 1) of SiO_2 exhibits a broad band in the range of 2800–3750 cm^{-1} ($\nu_{O–H}$, for –OH groups of silica and adsorbed water) including small peaks at 3650 ($\nu_{O–H}$, for free silanols ≡Si–OH) and 1630 cm^{-1} ($\delta_{O–H}$, for adsorbed water). In the FT-IR spectrum of SiO_2–MSA the peak for silanols (3650 cm^{-1}) disappeared and the broadness of the band in the –OH region increased. This spectral change indicates that MSA is bonded with free silanols of silica by the reaction of MSA and silanols. A similar observation was also reported for silica-supported triflic acid.[4] The FT-IR spectrum of SiO_2–MSA shows a peak at 1337 cm^{-1} for the $\nu_{S=O}$ stretching mode of the $–SO_3H$ group and a small peak at 1425 cm^{-1} for the $\delta_{C–H}$ bending mode of the $–CH_3$ group.[31] A peak for SO_2 deformation was found at 554 cm^{-1}. The FT-IR spectrum of pyridine-adsorbed catalyst (Fig. 2) shows peaks at 1489, 1554, 1620, and 1635 cm^{-1}. The peak at 1554 cm^{-1} is a characteristic peak of adsorbed pyridine on Brønsted acid sites, showing the presence of a significant amount of Brønsted acidity. There is no peak in the range of 1440–1450 cm^{-1} for adsorbed pyridine on Lewis sites. Thus, the catalyst has predominantly Brønsted acidity showing 5.3 A/cm peak area of the band at 1554 cm^{-1} (Table 1). The reaction of the $–SO_3H$ group of MSA and silanols results in

Scheme 2. Interaction of methanesulfonic acid (MSA) with the silanol of silica and generation of Brønsted acid sites.

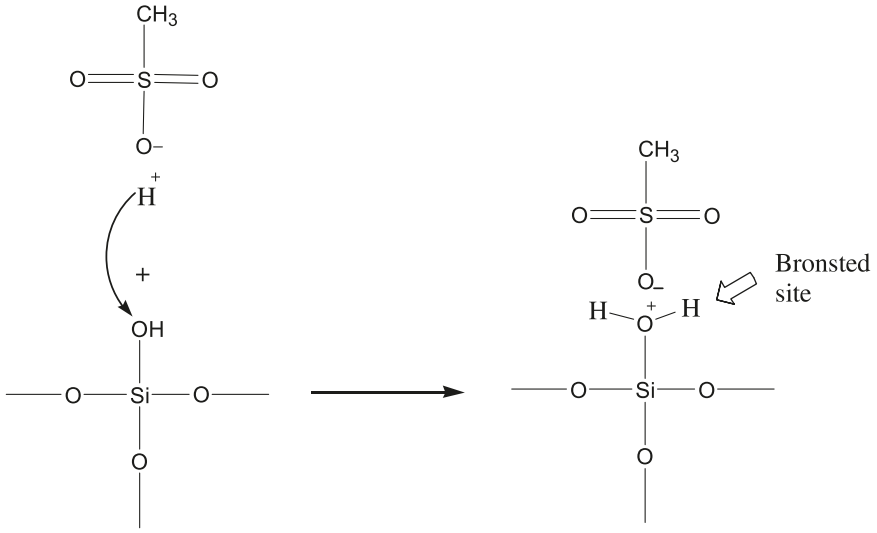

Fig. 1. FT-IR spectra of silica support and SiO_2 – methanesulfonic acid (MSA) catalyst.

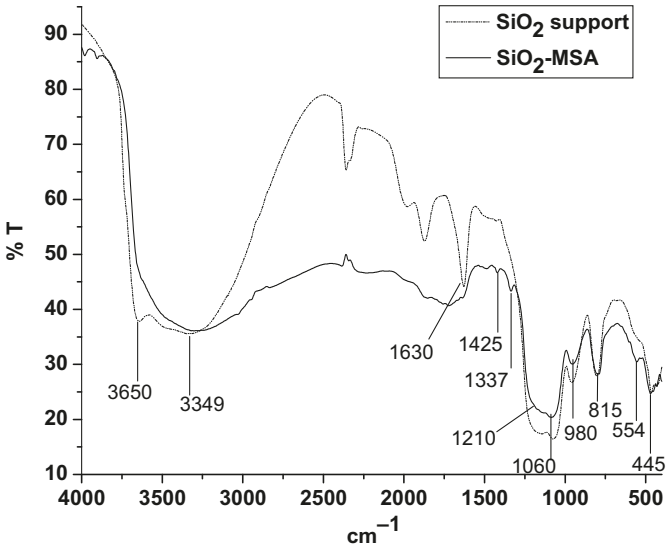

Fig. 2. FT-IR spectrum of pyridine adsorbed SiO_2 – methanesulfonic acid (MSA) catalyst.

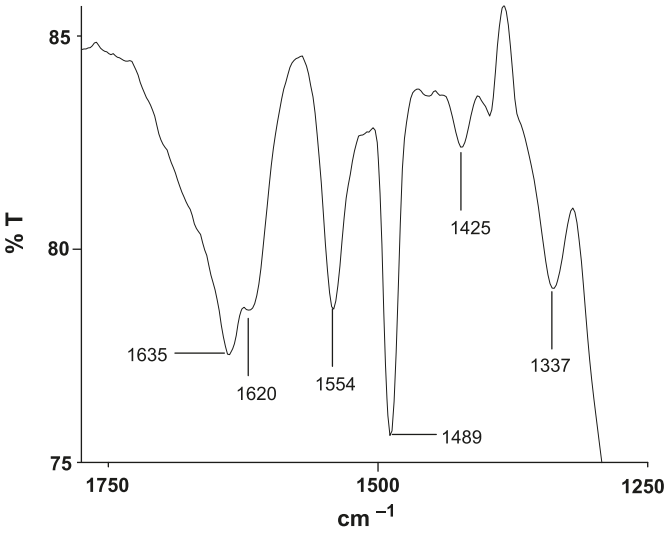

formation of protonated silanols, which hold methanesulfonate ions on the silica surface (Scheme 2). The protonated silanols bonded with methanesulfonate ions on the silica surface act as Brønsted acid sites.

The initial electrode potential (E_i), obtained by potentiometric titration with *n*-butylamine, indicates that the catalyst possesses very strong acid sites (E_i = 612 mV)[25] compared with those of the silica support (Fig. 3). The total number of acid sites in the catalyst was found to be 1200 mmol *n*-butylamine / g of catalyst (Table 1).

TGA-DTA profiles of SiO_2 support and SiO_2–MSA catalyst are given in Figs. 4*a* and 4*b* showing two-stage weight loss in SiO_2–MSA. The weight loss that occurred from 50 to 150 °C corresponds to the removal of adsorbed water. The second stage weight loss in the range of 300–450 °C is attributed to the decomposition of loaded MSA. The amount of MSA loaded on silica, calculated from TGA analysis (W_{MSA}),[8] was 1200 μmol/g (Table 1). The amount of MSA loaded over silica (N_{MSA}), calculated from the sulfur content (3.2 wt %, obtained from CHNS/O elemental analysis), corresponds to 1000 μmol/g (Table 1), which is in close agreement with W_{MSA}.

The characterization results confirmed that a significant amount of MSA was loaded over silica by surface reaction of MSA with silanols, generating predominantly Brønsted acidity. This catalyst can be used as a solid Brønsted acid for acid-catalyzed reactions.

Catalytic activity of SiO_2–MSA for the Pechmann reaction to synthesize 4-methylcoumarin derivatives and the effect of reaction parameters

SiO_2–MSA catalyst was found to be active for the Pechmann reaction giving 94% yield of 7-hydroxy-4-methylcoumarin at 160 °C after 12 h (Table 1). No product formation was observed with pure silica without loading MSA. The reaction temperature was optimized by carrying out the reaction in

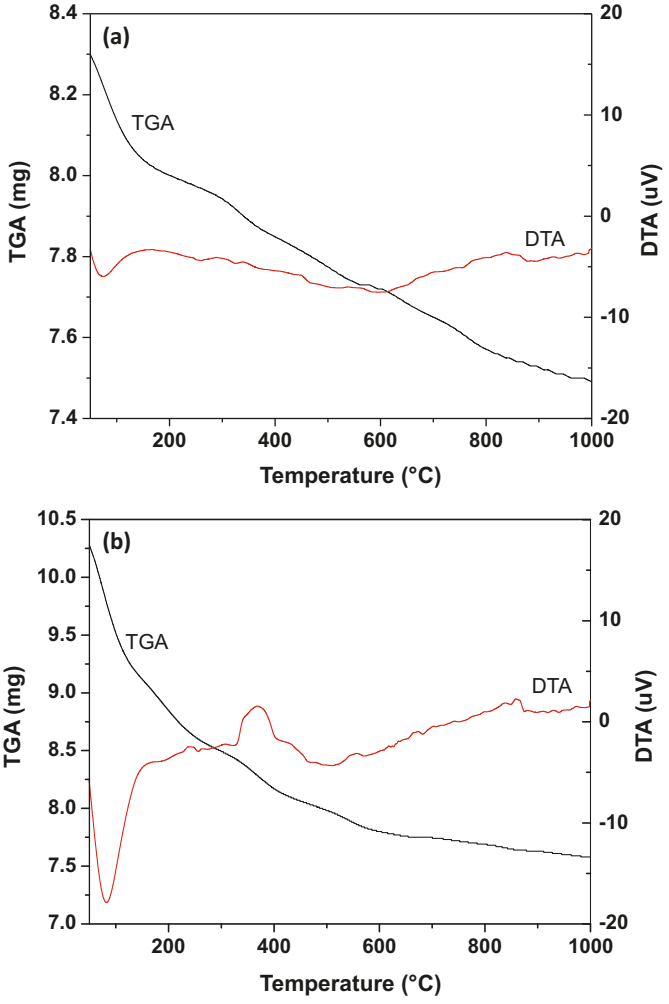

Fig. 5. Yield (wt %) of 7-hydroxy-4-methylcoumarin at different catalyst loading (6.5–1.3 wt %). (Reaction conditions: resorcinol – ethyl acetoacetate molar ratio = 2, 0.25 g catalyst, 160 °C, 12 h)

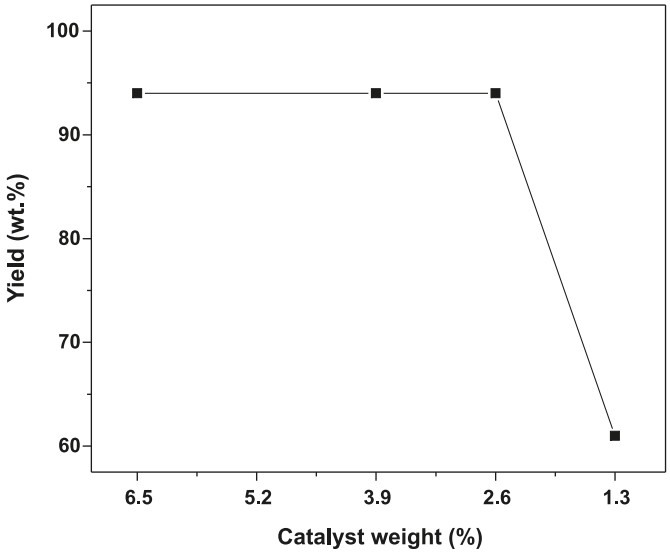

Fig. 6. Yield (wt %) of 7-hydroxy-4-methylcoumarin with time in solvent-free conditions and in the presence of various solvents. (Reaction conditions: 10 mmol resorcinol, 20 mmol ethyl acetoacetate, 3 mL solvent, 0.25 g catalyst, 160 °C)

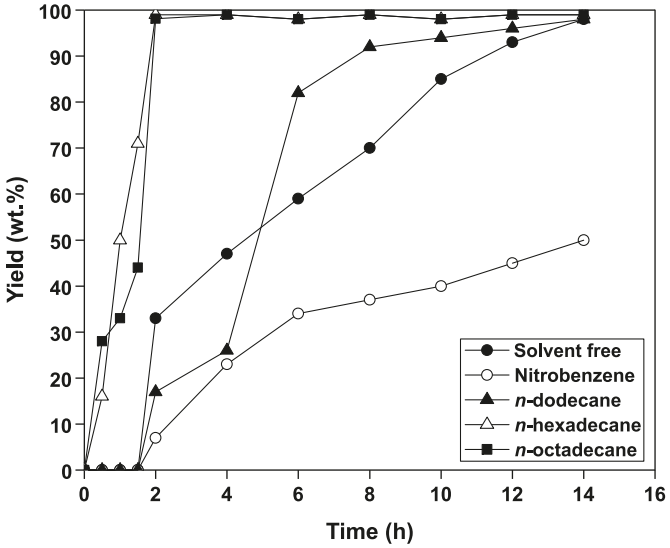

the range of 90–180 °C keeping all other parameters the same (see Supplementary data, Fig. S1). The maximum yield of 7-hydroxy-4-methylcoumarin (94%) was obtained after 12 h at 160 °C. The yield was observed to be slightly decreased (90% after 12 h) at 180 °C. Therefore, 160 °C was selected as the optimized reaction temperature.

To demonstrate the efficiency of the catalyst, the reaction was carried out by varying the catalyst loading (6.5, 3.9, 2.6, and 1.3 wt %) under similar reaction conditions. The yield of 7-hydroxy-4-methylcoumarin was observed to be steady (94%) up to a catalyst loading of 2.6 wt % (Fig. 5). It shows that the catalyst is very efficient and required in only a small quantity to achieve the maximum yield. However, the reaction kinetics were affected by the catalyst loading. It was

also observed that the higher the catalyst amount, the faster the initial rate (see Supplementary data, Fig. S2.

Nitrobenzene and higher *n*-alkanes (*n*-dodecane, *n*-hexadecane, and *n*-octadecane) were used as polar and nonpolar solvents, respectively, to study the effect of solvent on SiO_2–MSA catalyzed synthesis of 7-hydroxy-4-methylcoumarin. In nitrobenzene, the yield was significantly reduced (50% after 14 h) compared with the yield (94% after 14 h) obtained in solvent-free synthesis (Fig. 6). The lesser yield in the polar medium has been attributed to cleavage of the product[19] and the reduction in the number of available active sites owing to bonding of nitrobenzene molecules with active sites.[22] Nonpolar solvents such as toluene, cumene, THF, etc.,[19,20] have been widely used for synthesis of 7-hydroxy-4-methylcoumarin and toluene has been found to be one of the best nonpolar solvents.[19] However, toluene is a hazardous, nonseparable, nonreusable, and volatile aromatic, which limits its high-temperature applications. In the present work, higher *n*-alkanes (*n*-dodecane, *n*-hexadecane, and *n*-octadecane) were used as nonpolar solvents, which are nonhazardous, less volatile, and easily recoverable. The higher *n*-alkanes improved the activity of the catalyst by decreasing the reaction time (2–8 h) to achieve a maximum yield (>94%). *n*-Hexadecane and *n*-octadecane were more effective than *n*-dodecane, giving the maximum yield within 2 h. The enhanced activity of the catalyst in higher *n*-alkanes may be attributed to the higher nonpolar nature of the medium and the insolubility of reactant molecules in *n*-alkanes, which drives polar reactant molecules towards the catalyst surface for adsorption and chemical reaction. As the chain length of the *n*-alkane chain is increased, the reaction time to achieve maximum yield of the product was observed to be reduced as it enhances the catalytic activity of the SiO_2–MSA. This effect was explained on the basis of increasing nonpolar behavior of the *n*-alkanes with increasing chain length. The longer chain *n*-alkane molecules (*n*-hexadecane and *n*-octadecane) have strong van der Waals interactions, which does not allow the polar reactant molecules to stay in the bulk of the solvent. This forces the reactant molecules to come out from the bulk of *n*-alkane towards the catalyst surface, facilitating the adsorption of the reactant molecules on the catalyst surface for the reaction. It appears that the bulk diffusion of the reactants from solvent to catalyst surface and the surface adsorption are made easier by higher *n*-alkanes. After the surface reaction, the product (7-hydroxy-4-methylcoumarin) formed on the surface is desorbed and tends to come into the *n*-alkane (the nonpolar solvent) as the solubility of the product is significant in the nonpolar solvent. The solubilization of product in *n*-alkane facilitates the removal (desorption) of the product molecules from the catalyst surface, making surface sites free, as well as the bulk diffusion of the product molecules from the catalyst surface to the bulk of the solvent. The lesser yield in the polar medium (nitrobenzene) may also be attributed to the higher solubility of the polar reactants in the solvent, which reduces the bulk diffusion rate of the reactant molecules from solvent to catalyst surface.

The yield of 7-hydroxy-4-methylcoumarin and the reaction conditions reported with the other solid acid catalysts were compared with the SiO_2–MSA catalyst (Table 2). It can be observed that SiO_2–MSA in the presence of higher *n*-alkanes as solvents gives the highest yield (99%) in the shortest time (2 h) at relatively lower temperature in comparison with the other catalysts.

The SiO_2–SA catalyst showed significant activity for the synthesis of derivatives of 4-methylcoumarin (Table 3). However, the activated phenols (resorcinol, phloroglucinol, and pyrogallol) were found to be more reactive, giving 99%, 78%, and 70% yields of the corresponding coumarin derivatives. No product formation was observed under the given reaction conditions with less reactive phenols (*m*-methoxyphenol, *m*-methylphenol, and phenol). The reactivity of various phenols for the Pechmann reaction has already been reported.[12]

Regeneration study of spent SiO_2–MSA

The spent catalyst, recovered from the reaction mixture (in *n*-octadecane) was regenerated by washing with methanol

 *m*-methyl phenol	Not obtained	—
 Phenol	Not obtained	—

[a]Phenol substrate (10 mmol), ethyl acetoacetate (20 mmol), *n*-octadecane (3 mL; solvent), catalyst (0.25 g), 160 °C, 2 h.

(2 × 10 mL) then with petroleum ether (10 mL), followed by drying at 120 °C for 2 h (see Supplementary data, Fig. S3). The regenerated catalyst was reused for three cycles under similar reaction conditions as with fresh catalyst. The regenerated catalysts showed similar activity to fresh catalyst giving 94%–96% yield (Table 4). The CHNS/O elemental analysis of regenerated catalyst showed a slight loss of MSA, giving 984 μmol MSA/g catalyst (Table 4).

In conclusion, a cost-effective, efficient, and reusable SiO_2–MSA solid acid catalyst was synthesized and used for the synthesis of 4-methylcoumarin derivatives by the Pechmann reaction. The higher *n*-alkanes were used as nonpolar solvents for the Pechmann reaction and found to be the best alternative to conventional nonpolar solvents.

Abstract: The structures and stabilities of chainlike $(CO_2)_n$ (n = 2–6) polycarbonates, where adjacent C atoms are linked by C–O–C bonds, were investigated at the density functional theory (DFT) level (B3PW91/6–311G(2d,p)), including dicarboxylic dianions, $[C_nO_{2n+1}]^{2-}$, and the corresponding acids, $[C_nO_{2n+1}]H_2$, and Li salts, $[C_nO_{2n+1}]Li_2$. At equilibrium, the most stable systems have C_s, C_2, or C_{2v} symmetries. In the gas phase, these dianions are generally metastable with respect to spontaneous ejection of one electron, yet in the presence of counterions they become stabilized, for example, as $[C_nO_{2n+1}]^{2-}(Li^+)_2$ ion pairs. $[C_nO_{2n+1}]^{2-}$ linkages are also stabilized as dicarboxylic acids, $[C_nO_{2n+1}]H_2$; we find the latter to have equilibrium conformations of higher symmetry than previously reported in the literature. To the best of our knowledge, none of the $[C_nO_{2n+1}]X_2$ (X = Li or H) compounds with $n \geq 2$ have been reported in the experimental literature (albeit, the alkyl esters $C_2O_5R_2$ and $C_3O_7R_2$ are commercially available). All CO bonds in $C_2O_5X_2$ to $C_6O_{13}X_2$ have single- to double-bond character (≈140–118 pm), indicating that the $[C_nO_{2n+1}]$ moieties are held together by strong chemical forces (in contrast to the weakly bound complexes $(CO_2)_n$ and $(CO_2)_n^-$, $n > 1$). Vibrational frequencies were calculated to ensure all conformations were true minima. The IR and Raman intensities show that the high intensity C=O stretching modes (1750 ± 100 cm^{-1}) will help in the spectral characterization of these compounds. Solvation calculations using the polarizable continuum model (PCM) find that $C_2O_5^{2-}$ can be formed via $CO_3^{2-} + CO_2$ as well as $CO_3^- + CO_2^-$, each reaction having $\Delta G^{298} < 0$ in practically all solvents. This result confirms the experimentally observed large solubility of CO_2(g) in molten carbonates, CO_3M_2 (M = Li, Na, or K). In contrast, starting with $n = 2$, the reactions $[C_nO_{2n+1}]^{2-} + CO_2$ do not proceed spontaneously in any solvent ($\Delta G^{298} > 0$).

Key words: dicarboxylic acids, Li salts, equilibrium geometries, vibrational frequencies, density functional theory, solvent effects.

Résumé : Opérant au niveau (B3PW91/6–311G(2d,p)) de la théorie de la fonctionnelle de la densité (TFD), on a étudié les structures et les stabilités des polycarbonates $(CO_2)_n$ (n = 2–6) similaires à des chaînes dans lesquels les atomes de carbone sont liés par des liaisons C–O–C, ainsi que les dianions dicarboxylates $[C_nO_{2n+1}]^{2-}$ et les acides correspondants $[C_nO_{2n+1}]H_2$ et les sels de lithium $(C_nO_{2n+1}]Li_2$. À l'équilibre, les systèmes les plus stables présentent des symétries C_S, C_2 ou C_{2v}. En phase gazeuse, ces dianions sont généralement métastables par rapport à l'éjection spontanée d'un électron; toutefois, en présence de contre-ions, ils sont stabilisés, par exemple sous la forme de paires d'ions $[C_nO_{2n+1}]^{2-}(Li^+)_2$. Les liaisons $[C_nO_{2n+1}]^{2-}$ sont aussi stabilisées sous la forme d'acides dicarboxyliques $[C_nO_{2n+1}]H_2$; on a trouvé que ces derniers possèdent des conformations d'équilibre de symétrie plus élevée que celles rapportées antérieurement dans la littérature. Au meilleur de nos connaissances, aucun des composés $[C_nO_{2n+1}]X_2$ (X = Li ou H) avec $n \geq 2$ n'a été rapporté dans la littérature (même si les esters portant des groupes alkyles, $C_2O_5R_2$ et $C_3O_7R_2$ sont disponibles commercialement). Toutes les liaisons CO des composés allant de $C_2O_5X_2$ à $C_6H_{13}X_2$ possèdent des caractères allant de simple à double liaison (≈ 140 à 118 pm) indiquant que les portions $[C_nO_{2n+1}]$ sont liées entre elles par de fortes forces chimiques (en opposition aux complexes faiblement liés des entités $(CO_2)_n$ et $(CO_2)_n^-$, $n > 1$). On a calculé les fréquences vibrationnelles afin de s'assurer que toutes les conformations sont de véritables minima. Les intensités des spectres IR et Raman montrent l'intensité élevée des modes d'élongation C=O (1750 ± 100 cm^{-1}) sera très utile pour une caractérisation spéciale de ces composés. Des calculs de solvatation à l'aide du modèle du continuum polarisable (MCP) montrent que le $C_2O_5^{2-}$ peut être formé aussi bien par $CO_3^{2-} + CO_2$ que par $CO_3^- + CO_2^-$, le ΔG^{298} pour chaque réaction dans chaque solvant étant inférieur à zéro. Ces calculs confirment la grande solubilité observée expérimentalement du CO_2(g) dans les carbonates fondus CO_3M_2 (M = Li, Na ou K). Par ailleurs, à partir de $n = 2$, les réactions des $[C_nO_{2n+1}]^{2-} + CO_2$ ne peuvent se produire spontanément dans aucun solvant ($\Delta G^{298} > 0$).

Introduction

The ground state of gaseous $CO_2(X^1\Sigma_g^+)$ has a charge density distribution where C is partially positive and both O centres are negative.[1–4] Linear CO_2 is able to accommodate one or two electrons in excess to form bent anions CO_2^- and CO_2^{2-}. Although the latter are unstable in the gas phase, they are stabilized by counterions, e.g., as in the crystals $[CO_2^-]M^+$ and $[CO_2^{2-}](M^+)_2$, M = alkali metal.[5–8]

The positively charged C in CO_2 behaves as an electrophilic agent, avid for electron pairs.[1–4] Typical examples of CO_2-attack reactions are (*i*) at the N lone pair of NH_3 to form urea (HCO_2NH_2); (*ii*) at the N atom of amines to form carbamic acid or derivatives ($RNH_2 + CO_2 \rightarrow RNHCO_2H$), a process widely used at an industrial scale for CO_2(g) capture; (*iii*) in aqueous solutions at the O centre of OH^- to form bicarbonate (HCO_3^-); and (*iv*) in solids at the negatively charged O^{2-} centre in crystalline oxides (e.g., CaO or Li_2O) to form stable carbonates (CO_3Ca or CO_3Li_2, respectively) widely found in nature.

In all the above reactions, CO_2 plays a passive role, since they actually take place owing to the presence of strongly nucleophilic centres (NH_3, RNH_2, OH^-, or O^{2-}) that attract, or bind, CO_2(g) molecules. Indeed, neutral clusters $(CO_2)_n$ are weakly bound van der Waals complexes[9] of little relevance in chemistry. Experimental[10] and theoretical[11] studies have found that gaseous $(CO_2)_n^-$ is more stable than gaseous $(CO_2)_n$ ($n > 1$). The anionic clusters have either $CO_2^-(CO_2)_{n-1}$ or $(C_2O_4)^-(CO_2)_{n-2}$ structures where CO_2^- or $C_2O_4^-$ are "solvated" by $(CO_2)_x$ molecules, i.e., C–O–C bonds are not formed. However, under extreme conditions ($P = 40$ GPa and $T = 1800$ K), a new and extended solid phase of $(CO_2)_n$ with a polymeric, quartz-like structure called CO_2-V was synthesized by Iota et al.,[12] who assigned an intense band at 790 cm^{-1} to the symmetric stretching of a C–O–[C] single bond.

At this point, one interesting question can be put forward: what simple starting *nucleophilic* moiety X that by successive addition of CO_2s will form $X(CO_2)_n$ with strong CO bonds throughout? More precisely, one expects all *R*(CO)s and ν(CO) in $X(CO_2)_n$ to be close to those measured for standard single and double CO bonds. A positive answer to this question can be inferred right away, as several experimental works have dealt with stable polycarbonate esters (odourless liquids at room temperature), e.g., CO_3X_2,[13,14] $C_2O_5X_2$,[15,16] and $C_3O_7H_2$[15,17–19] (X = alkyl group or H). The next member, $C_4O_9H_2$, is only briefly mentioned in one patent citation.[20] These esters (of mono-, di-, tri-, and tetra-carbonic acids) have the structures shown in Scheme 1.

As seen above, the formation of stabilized chainlike $(CO_2)_n$ units with alternating double C=O and single C–O–C bonds is evident. To the best of our knowledge, nothing has been reported experimentally on similar compounds such as polycarbonic acids, $[C_nO_{2n+1}]H_2$, or alkalipolycarbonates, $[C_nO_{2n+1}]M_2$, except for the simple representatives, CO_3H_2 and CO_3M_2 (M = Li, Na,…).[21,22] No X-ray studies have been reported for any solid system with $n \geq 2$; however, IR–Raman spectra in the liquid phase have been recorded for esters such as $CO_3(CH_3)_2$[23] and $C_2O_5(CH_3)_2$.[24]

From the theoretical side, we are aware of the existence of three papers dealing with chainlike $(CO_2)_n$ systems. The first study, carried out by Lewars[25] at the AM1 and HF/3–21G levels, reported structures, vibrational frequencies, and stabilities for the (mostly of low symmetry C_1) acyclic dicarboxylic acids, $HO(CO_2)_nH$ with $n = 2–6$ (equivalent to our $[C_nO_{2n+1}]H_2$ series). In the second article, also by Lewars,[26] the $HO(CO_2)_nH$ ($n = 2–4$) compounds were reinvestigated at a higher level of computation (B3LYP/6–31G(d)); their possible decomposition mechanisms were also briefly discussed. The third study, done by Frapper and Saillard[27] at the B3LYP/6–31G(d,p) level, focused on the structures and energetics of $[C_nO_{2n-1}]H_2$ molecules from HC_2O_3H to HC_5O_9H. Each member of this series was derived from the corresponding dicarboxylic acid by replacing the two terminal OH groups by one H atom each. In summary, these theoretical studies found the CO_2 chains (alternating C=O and C–O–C bonds) to have standard double and single CO bonds, i.e., the investigated structures are held together by relatively strong chemical bonds.

The information available on $[C_nO_{2n+1}]^{2-}$ dianions is practically restricted to carbonate CO_3^{2-}. Indeed, the next member, $C_2O_5^{2-}$ (dicarbonate or pyrocarbonate), seems to be the only one of this family to have been mentioned in the literature. Claes et al.[28,29] studied the solubility and solvation of CO_2(g) in a molten eutectic mixture of $CO_3Li_2/CO_3Na_2/CO_3K_2$ at 973 K. They found CO_2(g) to be extremely soluble, well beyond what is expected from Henry's law (physical absorption). The authors concluded that chemical absorption was taking place, most probably $CO_3^{2-}{}_{molten} + CO_2(g) \rightarrow C_2O_5^{2-}{}_{molten}$. Because they could not prove the formation of $C_2O_5^{2-}$ directly (via vibrational or NMR spectroscopy, for example), QCISD/6–31+G(d) calculations[29] were carried out to gain insight about the reaction energetics. The calculated values for ΔH^{973} and ΔG^{973} (–223 and –119 kJ/mol, respectively) indicate favourable gas-phase energetics, and solvation should not hinder the formation of the postulated $C_2O_5^{2-}$ in the molten mixture. Furthermore, another article[30] reported crossover ^{13}C NMR experiments between [^{13}C] and [^{18}O] carbonates in aqueous solutions of CO_3Na_2. The complex kinetic problem was interpreted as giving evidence for the existence of the equilibrium $CO_3^{2-} + CO_2 \leftrightarrow C_2O_5^{2-}$ under these experimental conditions.

The main goal of this work was to study the structures and energetics of $[C_nO_{2n+1}]X_2$ compounds having polymeric $(CO_2)_n$ chains ($n = 2–6$). The species investigated included the free dianions $[C_nO_{2n+1}]^{2-}$ and two classes of neutral molecules, namely those with ionic bonding, $[C_nO_{2n+1}]Li_2$, and

Scheme 1.

others with terminal COOH groups, the dicarboxylic acids $[C_nO_{2n+1}]H_2$. From the start, we focused on systems having C_s, C_2, and C_{2v} symmetries. Vibrational frequencies are reported to assist the experimental characterization of these novel compounds. Finally, the energetics of $[C_nO_{2n+1}]^{2-}$ species in different solvents were analyzed using the polarizable continuum model (PCM).

Technical details

All calculations were carried out with Gaussian 03;[31] auxiliary software helped to visualize structures and vibrational frequencies (ChemCraft).[32] The theoretical method employed was the B3PW91 model of density functional theory (DFT); two basis sets were used, 6–311G(2d,p) for all systems, as well as 6–311++G(2d,p) for neutral molecules. As explained in the following, some comparative calculations were carried out using other methods (B3LYP and CCSD(T)) and basis sets.

Vibrational frequencies were systematically calculated to ensure that all geometry-optimized structures were true minima; the frequencies reported here are those directly calculated with Gaussian 03[31] (i.e., no scaling factors). Vast experience from the literature indicates that the equilibrium geometries and frequencies in the solid state are, in general, satisfactorily mimicked by ab initio calculations on the gas-phase species as long as the basis sets are compact (without semidiffuse atomic orbitals (AOs),[33] as done here).

Thermodynamic properties like enthalpy (ΔH^{298}) and Gibbs free energy (ΔG^{298}) were taken from the Gaussian 03[31] outputs. Reaction energies (ΔH^{298} and ΔG^{298}) were derived by combining data in the gas phase with the corresponding solvation energies in different solvents. The solvent calculations were carried out using the PCM method.[34]

Results and discussion

Equilibrium geometries and ν(CO) stretching frequencies

A standard procedure to identify newly synthesized compounds is to record IR and Raman vibrational spectra. This procedure is relevant as long as strongly absorbing chromophoric groups exist inside the whole molecule, and the vibrational spectrum is not too congested (which usually happens below 900 cm^{-1} because of the superposition of bending, rocking, and torsional modes). Intense bands should appear at ν(C=O) $\approx$ 1750 $\pm$ 50 cm^{-1} and ν(C–O) $\approx$ 1350 $\pm$ 50 cm^{-1}.[35] In a carboxylic C(=O)OH group, the ν(C–OH)-stretch and δ(COH)-bending modes are heavily coupled;[35] this group also strongly absorbs at ν(OH) $\approx$ 3700 $\pm$ 100 cm^{-1}. The situation is even more complex for dicarboxylic acids because of the in- and out-of-phase couplings between pairs of terminal C=O, C–OH, and OH bonds.[35]

The R(CO) distances and frequencies in CO_2^{m-} and CO_3^{m-} (m = 0, 1, or 2) species, which are the basic units of the more complex $[C_nO_m]^{2-}(X^+)_2$ oligomers, are discussed in the next sections. The same information on reference compounds

with single and double CO bonds and the novel $[C_nO_{2n+1}]X_2$ systems is presented afterwards.

CO_2^{m-} series (m = 0, 1, or 2)

The calculated data are displayed in Table 1. CO_2 is linear in its $X^1\Sigma_g^+$ ($4\sigma_g^2 3\sigma_u^2 1\pi_u^4 1\pi_g^4$) ground state. The $2\pi_u$ lowest unoccupied molecular orbital (LUMO) is CO antibonding; the addition of up to two electrons increases R(CO) and lowers ν(CO), i.e., electron attachment results in the CO bond being shifted from a double to a single bond. The equilibrium geometry changes from linear ($D_{\infty h}$) for CO_2 to bent (C_{2v}) for $CO_2^-(X^2A_1)$ and $CO_2^{2-}(X^1A_1)$. Note that gaseous CO_2^- and CO_2^{2-} are unstable upon electron detachment, but they stabilize in solutions and crystals (spatial confinement keeps the extra electrons bound). The experimentally known properties of CO_2^- and CO_2^{2-} mostly stem from studies on $CO_2^-M^+$ and $CO_2^-(M^+)_2$ crystals, with M = alkali atom.[5–8]

In going from CO_2 (linear) to CO_2^- to CO_2^{-2} (bent), the data in Table 1 show that R(CO) increases stepwise by about 8 pm, from ~116 to 124 to 132 pm. In several discussions to follow, these R(CO) distances will be considered as simple representatives of the bond character: a double bond with $R \approx 116$–120 pm, a strong single bond (or a mixed double and single bond) with $R \approx 125$–130 pm, and a weak single bond with $R \approx 130$–140 pm (definitively well below 150 pm).

Such bond elongation results from the successive addition of one electron to the $6a_1$ molecular orbital (MO) (correlating with the $2\pi_u$-LUMO of CO_2). Taking z as the symmetry axis in C_{2v} symmetry, the in-plane $6a_1$ MO is mainly p_z(C), with minor contributions from ($p_z(O^1) + p_z(O^2)$); note that $6a_1$ is CO antibonding but O–O bonding (leading to bent CO_2^- and CO_2^{2-}). These geometrical trends give valuable clues about the bonding strength of a newly formed C′–O bond when an extra *linear* O′–C′–O′ molecule combines with a terminal O_t atom of $[C_nO_m]^{2-}$ to form $[C_{n+1}O_{m+2}]$.$^{2-}$ More precisely, a strong bond is obtained only when (*i*) the attached O′–C′–O′ group becomes *bent*, indicating its share of the negative charge in excess and (*ii*) the new C′–O_t single bond has R(CO) << 150 pm.

The increase in CO distance is accompanied by a total decrease of ≈1200 cm^{-1} in the asymmetrical ν(CO) stretch, from ~2440 (CO_2) to 1730 (CO_2^-) to 1230 cm^{-1} (CO_2^{2-}), in line with the change from double to single bond along the series. Contrastingly, the symmetric ν(CO) stretch decreases by only ≈150 cm^{-1} between CO_2 and CO_2^{2-}. Worth noting is the small increase in the bending frequency δ(OCO), <50 cm^{-1}, in passing from linear CO_2 to the strongly bent CO_2^{2-} ($\alpha \approx 116°$). Interestingly, the two ν(C–O)s in CO_2^{2-} are found to be accidentally degenerate (≈1230 cm^{-1}).

The intensity data (in square brackets, Table 1) show that the IR spectra are dominated by the intense asymmetric ν(C–O) mode in all three CO_2 species. In the bent anions, all vibrational bands have significant Raman intensities, albeit with stretching modes dominating.

Thus, a given CO_2 moiety within $[C_nO_{2n+1}]$ is generally expected to give rise to three characteristic IR absorption bands, near 1700 (ν_{as}(CO)), 1300 (ν_s(CO)), and 750 cm^{-1} (δ_{bend}(OCO)). The low-frequency mode may be superimposed by other low-lying vibrational motions.

CO_3^{m-} series (m = 0, 1, or 2)

These planar species are studied for a common D_{3h} geometry, with z being the threefold perpendicular symmetry axis. Two MOs composed *exclusively* by p AOs on the oxygen atoms are relevant: 1e″ (out-of-plane $p_z(p_\pi)$ AOs) and $1a_2'$ (in-plane MO made up of p_x,p_y(p_σ) contributions). In neutral CO_3, 1e″ and $1a_2'$ are, respectively, the highest occupied molecular orbital (HOMO) and LUMO, i.e., the latter becomes successively singly and doubly occupied in CO_3^- and CO_3^{2-}.

A R(CO) = 124.5 pm in CO_3 is almost as large as R(CO) = 123.9 pm in CO_2^-. Electron attachment slightly increases R(CO) by ~6 pm between CO_3 and CO_3^{2-}. Interestingly, CO_2^{2-} and CO_3^{2-} are found to have quite similar values of R(CO) (≈131 pm) and $\alpha(CO_2)$ (≈120°). In general, the ν(CO) stretching frequencies in CO_2 and CO_2^- are invariably larger (from 200 to 500 cm^{-1}) than in CO_3 and CO_3^-. When comparing the CO_2^{2-} and CO_3^{2-} dianions, one notes that the asymmetric ν(CO) mode in CO_3^{2-} is ~200 cm^{-1} larger than in CO_2^{2-}, where the opposite situation holds for the symmetric ν(CO) (Table 1). The bending frequency in CO_3 is less than one-half the CO_2 value (≈300 cm^{-1} vs 680 cm^{-1}), but they are not too much apart in CO_3^{2-} and CO_2^{2-} (≈675 cm^{-1} vs 725 cm^{-1}).

Single- and double-CO bond compounds as reference

A comparison between experimental and theoretical ν(CO) s for known single- and double-CO bond compounds allows us to get insight about the accuracy of the B3PW91/6–311G (2d,p) method. Four compounds were selected: (*i*) dimethyl ether $(H_3C)_2O$, with two single C–O bonds; (*ii*) acetic anhydride $(H_3C–C=O)_2O$, with two C–O and C=O bonds each; (*iii*) oxalic acid $C_2O_4H_2$, the simplest dicarboxylic compound with two CO_2^- groups; and (*iv*) ethylene oxide C_2H_2O, an epoxy compound with a C–O–C ring. Relevant data are listed in Table 2.

Dimethyl ether has large R(C–O)s of 140.3 pm, resulting in relatively low stretching frequencies of 1210 and 960 cm^{-1}. Our unscaled frequencies agree with previous calculations,[36] both being about 4% higher than the experimental data.[37,38]

Acetic anhydride (C_2 symmetry) is a prime example of the $[C_nO_{2n+1}]X_2$ species: two C=O bonds interconnected via a C–O–C bridge. A short R(C=O) = 119.0 pm compares with R = 115.9 pm in CO_2 (Table 1). We calculated two close lying ν(C=O)s at 1898 and 1828 cm^{-1} (Table 2). Experimentally,[39] these bands lie at ≈1837 and 1779 cm^{-1} (about 4% lower than our DFT data).

The two single R(C–O)s in acetic anhydride (139.0 pm) are even larger than in CO_2^{2-} (131.9 pm, Table 1). The symmetric O–C(–O) mode of the anhydride is placed at 1235 cm^{-1}, in agreement with experiments (1230 cm^{-1}).[39] The asymmetric counterpart lies ~100 cm^{-1} lower (≈1150 cm^{-1}), in a region where mixing with other modes is prevalent (Table 2).

For oxalic acid ($C_2O_4H_2$, C_{2h}), two close-lying frequencies (1867 and 1842 cm^{-1}, Table 2) are the out- and in-phase coupling between C=O bonds; only one of these modes is IR or Raman active. The ν(C–O) and δ(COH) motions are strongly coupled; these four bands lie in the 1450–1200 cm^{-1} region. Our calculated frequencies are ~5% larger than the experimental values.[40]

In ethylene oxide with R(C–O) = 142.2 pm (indeed, a rather long single bond) we calculated the ν(C–O)s at 1312

*Fixed D_{3h} symmetry for comparison purposes.

and 871 cm^{-1}, with the latter demonstrating how low a single bond ν(C–O) can be shifted in a particular molecule. In fact, the bending mode δ(C–O–C) in this strained ring lies even higher (910 cm^{-1}). The theoretical values are slightly larger than those in the literature[41] (cf. Table 2).

In summary, our directly calculated frequencies for the various types of CO bonds at the B3PW91/6–311G(2d,p) level overestimate the experimental (gas phase) results by no more than 5%, and the same accuracy is expected for the vibrational data presented in the following for the new molecules.

Novel compounds with C_2O_5 to C_6O_{13} chainlike units

Table 3 lists CO distances and relevant frequencies for $[C_nO_{2n+1}]^{2-}$, $[C_nO_{2n+1}]Li_2$, and $[C_nO_{2n+1}]H_2$ species containing C_nO_{2n+1} units from C_2O_5 to C_4O_9 and Table 4 gives the same information for those with C_5O_{11} and C_6O_{13} chains. All systems are assumed to be in the gas phase. The different structures are shown in Figs. 1–5. Detailed information on the calculated geometries, vibrational frequencies, and IR–Raman intensities can be found in the Supplementary data.

All Li polycarbonates $[C_nO_{2n+1}]Li_2$ exhibit ion-pair structures already in the gas phase, i.e., the metal Li centres are mostly positively charged and the $[C_nO_{2n+1}]$ units carry up to two negative charges in excess. In fact, M^+ counterions stabilize the intrinsically unstable $[C_nO_{2n+1}]^{2-}$ fragment in the gas phase. The third compound of each group is a dicarboxylic acid, $[C_nO_{2n+1}]H_2$; because both C=O and O–H bonds are highly polarized (all having $O^{\delta-}$), their IR intensities are expected to be strong.

The parameter $p = 3n$ (first column in Tables 3 and 4) gives quick information about the total number of CO bonds, or equivalently, the total number of ν(CO) modes expected (starting with $p = 6$ for C_2O_5 and up to $p = 18$ for C_6O_{13}). Clearly, CO_2 addition increases the total number of CO bonds (or corresponding stretch frequencies) by three: two terminal COs plus the newly formed single CO bond.

In Tables 3 and 4, the R(C=O) and R(C–O) columns list R distances up to and beyond 125 pm, respectively (R = 125 pm is taken here as the upper limit for a double bond). Each R(CO) is followed by an [n] number counting how many times such a distance appears in the molecule. In both tables, those R values out of range in the dianions (i.e., with *too large* CO bonds) are italicized; they are associated with the outermost single C–O bonds connecting terminal CO_2 groups to the main (inner) frame.

As mentioned, there are as many ν(CO) stretching frequencies as CO bonds (i.e., p in total). The assignment of such ν(CO)s, experimentally and theoretically, is straightforward as long as they do not mix heavily with other normal modes (of the same symmetry). According to the literature,[35] double-bond ν(C=O)s typically lie in the 1700–1900 cm^{-1} region, whereas single-bond ν(C–O)s appear at lower frequencies, from 1500 to 900 cm^{-1}. Fortunately, CO bonds are strong IR–Raman absorbers and their contributions to the vibrational spectra are easily identifiable. Actually, that is true for the higher frequency part of the spectrum: for these systems, there are no other normal modes absorbing in the same 1700–1900 cm^{-1} region as the ν(C=O) motion characteristically does. Particularly for long chains with $n \geq 3$, the characterization of C–O single bonds (1350–800 cm^{-1}) is more complex for several reasons: (*i*) the number of ν(C–O–C)

*Experimental/calculated frequencies. The band at 1189/1173 cm^{-1} is reassigned here to ν(C–O) instead of CH_3 torsion (b_2) in the original paper.

†6–311++G(2d,p) basis. The last four frequencies are mixtures of ν(C–OH) and δ(COH). Because of H bonding, the ν(O–H)s lie at lower frequencies (cm^{-1}): 3657 (b_u) / 3654 (a_g) (TW) vs 3472 (b_u) / unknown (a_g), where subscripts a and s stand for asymmetric and symmetric stretching mode, respectively.[40]

frequencies lying close together, which is equal to $2(n - 1)$, increases rapidly, from just 2 in C_2O_5 to 6 in C_4O_9 to 10 in C_6O_{13}. These internal motions couple together to give in-phase and out-of-phase resultants; (*ii*) in the case of the dicarboxylic acids $C_nO_{2n+1}H_2$, there exist differences between the ν(C–O)s for inner C–O–C links versus ν(C–O)s for terminal C–OH groups (with unlike absorption patterns as well); and (*iii*) mixing with other normal modes (mostly bending motions). For example, the δ(COC) and δ(OCO) bending modes in $C_nO_{2n+1}^{2-}$ and $C_nO_{2n+1}Li_2$ lie at 1000–800 cm^{-1}, so they can mix with the low-lying ν(C=O)s in the same region. In summary, the best candidates for IR characterization of the present compounds is via all available double-bond ν(C=O)s.

Analysis of the data in Tables 3 and 4 lead to the following observations: (*i*) For either the R(C=O) or R(C–O) column, the equilibrium distance invariably decreases from D^{2-} to DLi_2 to DH_2, with D standing for a general $[C_nO_{2n+1}]$ fragment. This trend is more noticeable for single C–O bonds, particularly as n increases from $n = 2$ to 6. Furthermore, $C_3O_7^{2-}$ has a short R(C–O) of 133.1 pm and a large R(C–O) of 153.9 pm, with the latter lying well above 145 pm, which is perhaps an acceptable upper bound for a (relatively weak) single bond. However, in passing from $C_3O_7^{2-}$ to

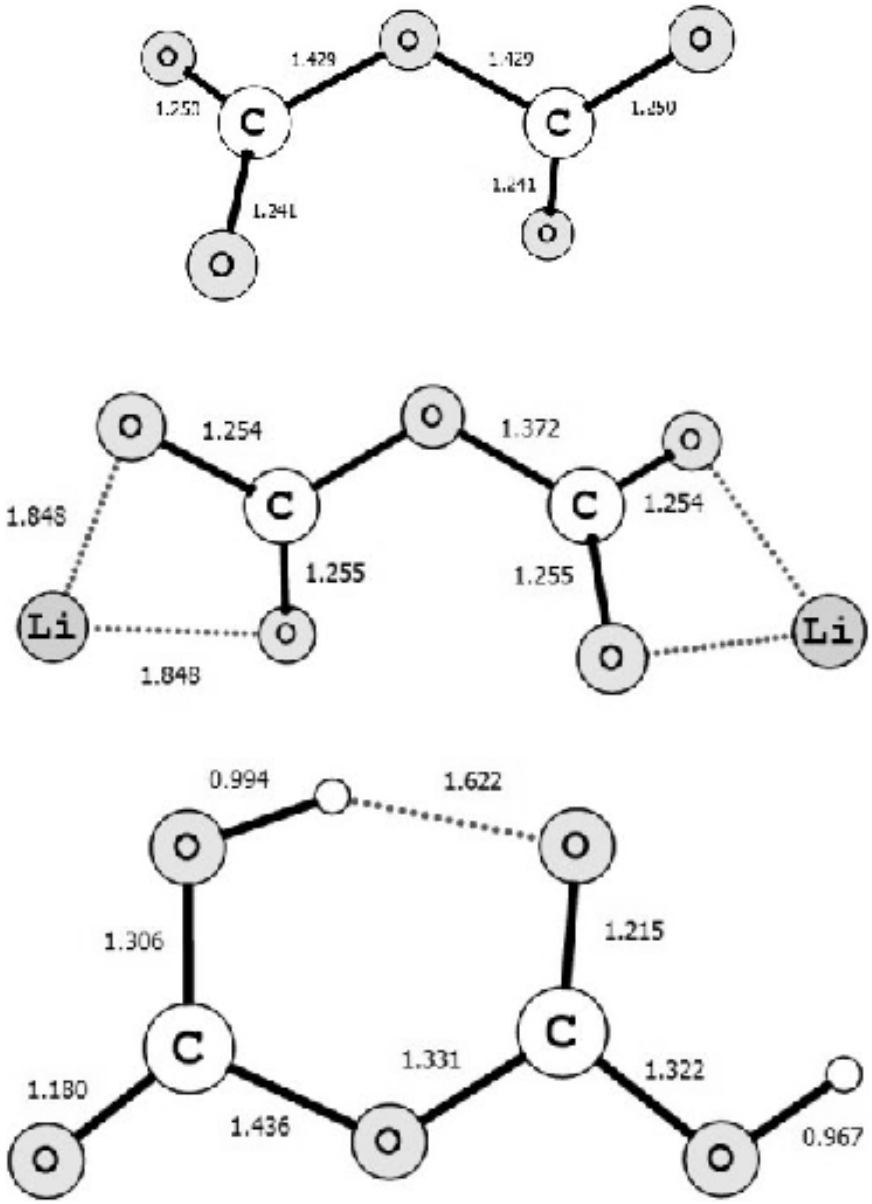
Fig. 1. Equilibrium geometries of $C_2O_5^{2-}$, $C_2O_5Li_2$, and $C_2O_5H_2$.



$C_3O_7Li_2$, the two most elongated *R*(C–O)s in the Li salt, at 133.8 and 140.9 pm, can be considered normal distances (Table 3). Clearly, the formation of ion pairs [i.e., $(C_3O_7)^{2-}(Li^+)_2$] already in the gas phase helps to shrink and stabilize the electronic charge distribution of the otherwise spatially expanded and metastable isolated $C_3O_7^{2-}$. Further, in passing to the corresponding acid $C_3O_7H_2$, all six single C–O bonds (132.7–138.2 pm) are even shorter than in the ion pair $C_3O_7Li_2$, which points out that the formation of two covalent OH bonds is a rather effective mechanism for stabilizing the dianionic core. (*ii*) In connection with point (*i*), as the dianion cluster becomes bigger and bigger, the aforementioned large *R*(C–O)s become anomalously larger and larger, about 166, 219, and 278 pm for $C_4O_9^{2-}$, $C_5O_{11}^{2-}$, and $C_6O_{13}^{2-}$, respectively. In reality, these dianions are extremely weakly bound with respect to the liberation of CO_2. However, the corresponding Li salts contain a more compact dianionic unit with all C–O bonds being shorter than 145 pm (Tables 3 and 4). (*iii*) Regarding the ν(CO)s, the theoretical values are collected in two sets, with frequencies above 1600 cm^{-1} and below 1500 cm^{-1}, respectively. The structure of the high-frequency region is simple: it contains as many ν(C=O)s as the number of C atoms (from $n = 2$ to 6), all of them appearing as strong IR bands. For the weakly bound $C_5O_{11}^{2-}$ and $C_6O_{13}^{2-}$, our calculations find extremely high ν(CO)s at $\approx$2350 cm^{-1}. This anomaly is easy to explain: the two terminal CO_2 groups share very little of the negative charge so they essentially retain a neutral CO_2 character (quasilinear frame, short *R* and high ν(CO), as shown in Table 1 for isolated CO_2).

The low ν(CO)s region (<500 cm^{-1}) is less helpful for structure determinations because of mixings with several low-lying normal modes, as pointed out earlier. In Tables 3 and 4, each low-frequency region lists *all* calculated values in decreasing order, without distinction between stretching, bending, or rocking modes. Since we expected ($p - n$) CO-

stretching modes in total in this region, we counted the number of modes and marked the (arbitrary) boundary with a left square bracket ([).

Relative stabilities upon CO_2 uptake

Calibration reaction — $CO_3X_2 + CO_2 \rightarrow C_2O_5X_2$ (X = Li or H)

Table 5 lists the gas-phase reaction energy (ΔE_{rxn}) for $CO_3X_2 + CO_2 \rightarrow C_2O_5X_2$ (X = Li or H) and $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$ as calculated with DFT (B3PW91 and B3LYP) and ab initio (MP4SDTQ and CCSD(T)) methods. Four basis sets were used: cc-pVTZ, 6–311G(2d,p), 6–311++G(2d,p), and 6–311++G(3df,p), labeled from A to D. Note that ΔE_{rxn} is the difference between directly calculated total electronic energies (no zero-point corrections); all electrons are correlated with DFT, but only valence electrons are correlated with the ab initio methods.

Carbon dioxide capture by CO_3X_2 (which is found to be *endothermic* for X = Li and H) depends weakly on the composition of the basis set. For the Li series, the DFT data with B (6–311G(2d,p)) differ by not more than 1 kJ/mol from those obtained with the extended set D (6–311++G(3df,p)). For the H series, however, the endothermicity increases by 7.5 ± 1 kJ/mol in passing from B to C (6–311++G(2d,p)), suggesting the compact basis B does not properly describe the mostly covalent but $C^{\delta-}H^{\delta+}$ polarized bonds in both carbonic and dicarbonic acids. In that regard, the existence in the gas phase of well-defined ion pairs $CO_3^{2-}(Li^+)_2$ and $C_2O_5^{2-}(Li^+)_2$ is consistent with the little influence diffuse functions have on their ΔE_{rxn}s.

For the Li compounds, the median $<\Delta E_{rxn}>$ amounts to 42.9 and 52.5 kJ/mol with B3PW91 and B3LYP, respectively, whereas for the H series, the corresponding values are 56.9 and 65.3 kJ/mol. This comparison indicates that the predicted $<\Delta E_{rxn}>$s are about 9 ± 1 kJ/mol larger with B3LYP than with B3LYP, but not necessarily more accurate. In fact, ab initio calculations at the coupled-cluster level CCSD(T) (and correlating valence electrons only) lead to $<\Delta E_{rxn}>$s that generally lie between both DFT sets (and much closer to the lower B3PW91 values).

The situation is different for isolated dianions because of their unbound character *with respect to spontaneous electron detachment*. The reaction $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$ is found to be largely *exothermic* ($|\Delta E_{rxn}| \geq 200$ kJ/mol), but the actual value depends strongly on the composition of the basis set. With basis C (i.e., adding a semidiffuse subset *sp* to basis B), we find that ΔE_{rxn} changes from –295 to –231 kJ/mol with B3PW91 or from –291 to –224 kJ/mol with B3LYP (on average, a 22% decrease). As seen in Table 5, a similar degree of destabilization is found with the valence-only CCSD(T) treatment.

In summary, this brief comparison between methods and basis sets indicates that reasonable descriptions are expected to be obtained with (*i*) B3PW91 and basis B for the $C_nO_mLi_2$ series, (*ii*) B3PW91 and basis C for the carbonic acids $C_nO_mH_2$, and (*iii*) the average value between the possibly extreme B3PW91 results calculated with bases B and C.

General energetics for $C_nO_m^{2-} + CO_2 \rightarrow C_{n+1}O_{m+2}^{2-}$

Table 6 summarizes thermodynamic data for CO_2 uptake by several dianions, starting with O^{2-} to form CO_3^{2-} and end-

ing with the most complex case studied here, $C_5O_{11}^{2-} + CO_2 \rightarrow C_6O_{13}^{2-}$. The tabulated properties comprise changes in internal energy, ΔE_{rxn} (0 K), as well as enthalpy (H), entropy (S), and Gibbs free (G) energies at normal conditions (T = 298 K and P = 1 atm (1 atm = 101.325 kPa)). The calculations were carried out with the standard B3PW91/6–311G (2d,p) method as codified in Gaussian 03;[31] the corresponding H, S, and G data were obtained from vibrational frequency calculations at the optimized geometries. Note that $|\Delta H^{298}|$ and $|\Delta E_{rxn}|$ differ by <10 kJ/mol. Similar information for the general neutral reactions $C_nO_mX_2 + CO_2 \rightarrow C_{n+1}O_{m+2}X_2$ (X = H, Li, Na, or K) is discussed elsewhere.[42]

Gas-phase results

As seen in Table 6, CO_2 uptake in the gas phase from the simplest (O^{2-}) to the most complex dianion ($C_2O_{11}^{2-}$) is exothermic throughout, from an impressive ΔH^{298} of –1075.5 kJ/mol for the first case to a modest –21 kJ/mol in the last one (sixth reaction). Quite interestingly, the decrease in ΔS for each uptake reaction (a *disorder* → *order* reorganization owing to volume contraction) remains more or less constant along the whole series with a median of 35 ± 6 kJ/mol for $-(T\Delta S)^{298}$.

According to the ΔG (= ($\Delta H - T\Delta S$)) data in Table 6, in the gas phase only the first four uptake reactions can proceed forward as written: ΔS is unfavourable for all six, but only for the last two does this outweigh the favourable ΔH (<0) to give a positive ΔG.

For the general reaction $[C_nO_{2n+1}]^{2-} + CO_2 \rightarrow [C_{n+1}O_{2n+3}]^{2-}$, two single C–O bonds are gained and one C=O broken. In a rather simple model, ΔE_{rxn} ($\approx \Delta H_{rxn}$) can be assumed to result from three contributions: bonds gained ($\Delta E < 0$) + bonds broken ($\Delta E > 0$) + charge delocalization (ΔE_d). Taking 358 and 805 kJ/mol for C–O and C=O, respectively, as reference bond dissociation energies,[43] it follows that $\Delta E_d \approx \Delta E_{rxn} = -89$ (kJ/mol). Using the data in Table 6, one obtains $\Delta E_d \approx$ –1166, –384, and –219 kJ/mol for CO_2 uptake by O^{2-}, CO_3^{2-}, and $C_2O_5^{2-}$, respectively. Clearly, delocalization of the negative charge in excess ($2e^-$) decreases in passing from O^{2-} to CO_3^{2-} to $C_2O_5^{2-}$, as the corresponding molecular volumes increase in the same order. Further, formation of $C_4O_9^{2-}$, $C_5O_{11}^{2-}$, and $C_6O_{13}^{2-}$ is accompanied by ΔE_d values of approx. –147, –121, and –117 kJ/mol, respectively.

Solvent results

It is well-known experimentally that dianions, which are unstable (upon electron detachment) in the gas phase, become stabilized when spatially confined, as in solutions or crystals. Thus, our gas-phase results have been supplemented by others taking account solvent effects as calculated with the PCM of Tomasi et al.[34] Five different solvents were selected, with dielectric constants from 7.58 (THF) to 78.39 (water), which should give a broad picture about changes in ΔG under different conditions (solvents). The free-energy change, ΔG_X, in a given solvent (X) is given by the relationship

$$\Delta G_X = \Delta G_{gas} + [\Delta G_X(\text{solvation, products}) - \Delta G_X(\text{solvation, reactants})]$$

The theoretical treatment becomes physically more realistic when considering solvation effects, whereby dianions are generally stabilized upon electron detachment, and thus these solvation calculations are more realistic for the description of reaction energies. Now, only the first two model reactions in Table 6 are predicted to take place at room temperature (independent of the solvent), that is for the processes $O^{2-} + CO_2 \rightarrow CO_3^{2-}$ and $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$ (see the following, however). Equivalently, in liquid media O^{2-} is able to capture two CO_2 molecules to form the symmetrical dianion $[O_2C–O–CO_2]^{2-}$. At this point, the following comments are worth noting. First, the nature of the counterions present in solution is of great relevance for the overall reaction mechanism. Although this topic will be discussed in more detail in future articles,[42] one example should clarify our statement: assuming that Li_2O is well soluble in solvent X to give O^{2-} and Li^+ ions, the uptake reaction $O^{2-} + CO_2 \rightarrow CO_3^{2-}$ concurs with another thermodynamically favoured reaction, i.e., the formation of ion pairs, $CO_3^{2-} + Li^+ \rightarrow CO_3Li^-$. Thus, a formal uptake of a second CO_2 by O^{2-} may be hampered by the presence of such a stable CO_3Li^- intermediate (Note: this point is indirectly supported by the endothermicity of the

Note: Dielectric constants: 7.38 (THF), 20.7 (acetone), 36.64 (acetonitrile), 46.7 (DMSO), and 78.39 (water), as listed in Gaussian 03.[31]

* ΔE_{rxn} is the energy difference between surface minima (i.e., without any type of corrections).

gas-phase reaction $CO_3Li_2 + CO_2 \rightarrow C_2O_5Li_2$ discussed earlier). Second, aprotic solvents should be considered for experimentally studying the first two reactions in Table 6. When protic solvents are used (e.g., water), the reaction $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$ may not be observed because of the dominance of the solute–solvent interaction, $CO_3^{2-} + H_2O \rightarrow CO_3H^- + OH^-$. Under these conditions, a second uptake of another CO_2 molecule will preferably form CO_3H^- via the reaction $CO_2 + OH^- \rightarrow CO_3H^-$. Third, the reactions $O^{2-} + CO_2 \rightarrow CO_3^{2-}$ and $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$ are not just of academic interest. Electrochemical studies carried out in molten salts[28] have discussed the occurrence of the reaction $O^{2-} + CO_2 \rightarrow CO_3^{2-}$ at the electrode surface. Also, it was experimentally found that molten CO_3M_2 salts (M = Li, Na, or K) near 1000 K, indeed an aprotic solvent itself, absorbed a large amount of CO_2(gas), possibly owing to the process $CO_3^{2-}{}_{molten} + CO_{2\ gas} \rightarrow C_2O_5^{2-}{}_{molten}$. Indeed, our ΔG calculations for different solvents indicate the reaction above proceeds as written at normal temperatures.

The last four rows in Table 6 are devoted to reactions of general interest. Those involving monoanions, $O^{2-} + CO_2 \rightarrow CO_3^{2-}$ and $CO_3^{2-} + CO_2 \rightarrow C_2O_5^{2-}$, are not favoured in the gas phase ($\Delta G > 0$) because of the Coulomb repulsion between singly charged reactants. However, the solvent calculations provide a different view: formation of CO_3^{2-} or $C_2O_5^{2-}$ should proceed to a large extent, but with reservations, depending on the type of both the solvent (aprotic or not) and counterion present.

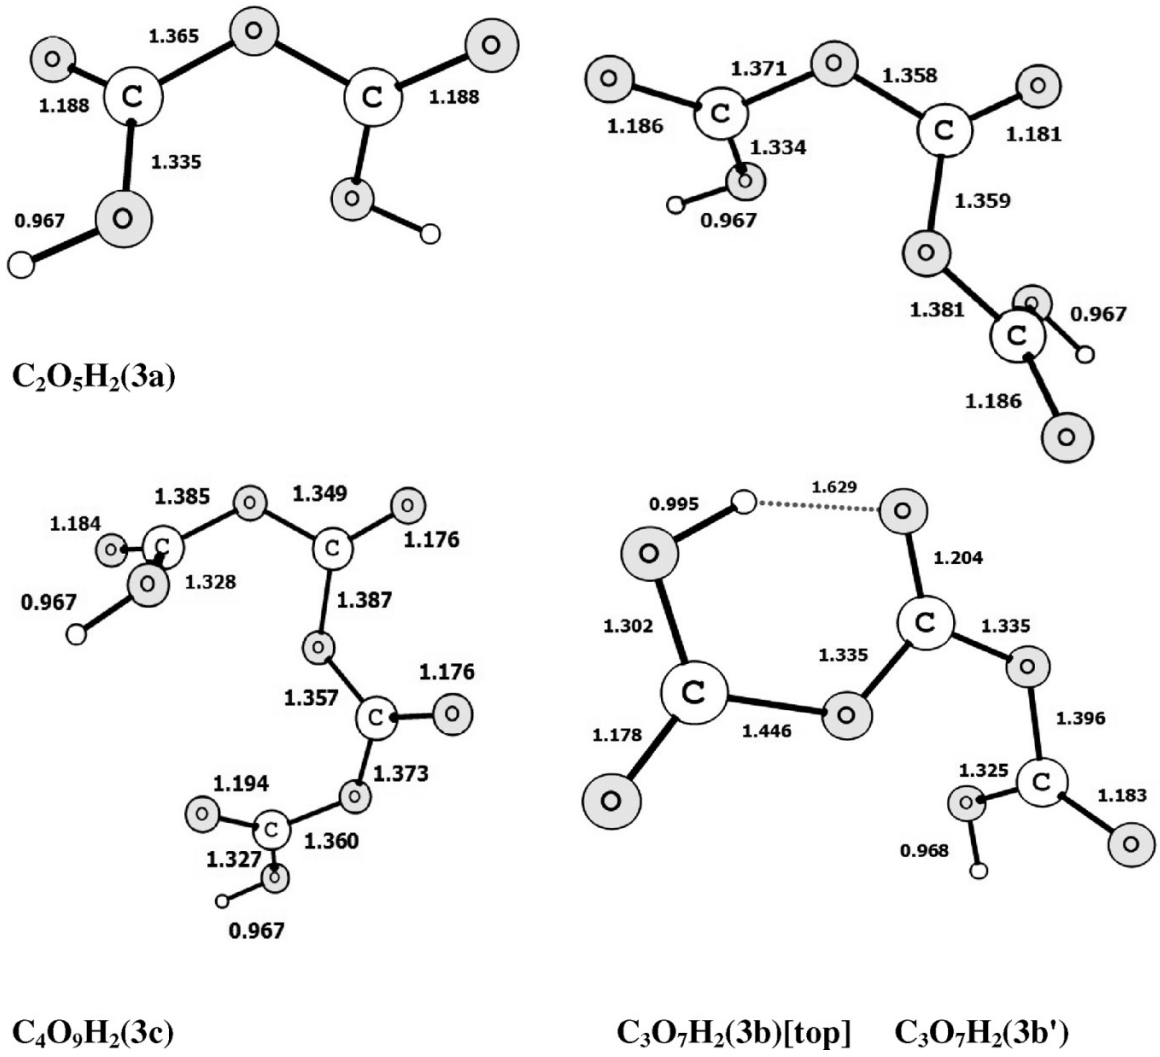
Polycarbonic acids, $C_2O_5H_2$, $C_3O_7H_2$, and $C_4O_9H_2$ — High versus low symmetry

As stated earlier, the only works known to us dealing with polycarbonic acids $C_nO_{2n+1}H_2$ (n = 2–6) are the two theoretical studies carried out by Lewars.[25,26] In the 1996 paper,[25] his main results (energetics, equilibrium geometries, and vibrational frequencies) were obtained at a low level of theory (HF/3–21G). In the second article from 2008,[26] an improved treatment was used (B3LYP/6–31G(d)); Lewars stated that the $C_nO_{2n+1}H_2$ geometries shown in both articles were not necessarily the lowest energy conformations. In fact, the isomers previously reported[25,26] *have different equilibrium geometries* (C_1 symmetry, in general) *than those found in this work* (C_s, C_2, or C_{2v}), and it is therefore of interest to reinvestigate some of Lewars polycarbonic acids at the B3PW91/6–311G(2d,p) level. Three acid isomers were chosen: $C_2O_5H_2$ (**3a**), $C_3O_7H_2$ (**3b**), and $C_4O_9H_2$ (**3c**), with Lewars'[25] labelling in parentheses (ref. 25 does not report all equilibrium parameters, so the reoptimization procedure was started using trial geometries after visual inspection of the figures in this reference). Apart from the simple case of $C_2O_5H_2$, it could be that our optimized **3b** and **3c** isomers do not have *exactly* the same spatial conformation as in the original paper, but that is not a substantial drawback as the results below will show. The presently optimized "look-alike" **3a**, **3b**, and **3c** geometries are depicted in Fig. 6, which also includes a third $C_3O_7H_2$ isomer called **3b′** (not reported in ref. 25); according to our calculations, all these species are stationary minima (no imaginary frequencies).

$C_2O_5H_2$ (3a)

Seven different rotational isomers of $C_2O_5H_2$ (dicarbonic

Fig. 6. Equilibrium geometries calculated in this work for low-symmetry (C_1) isomers, including $C_2O_5H_2$ (**3a**), $C_3O_7H_2$ (**3b**), and $C_4O_9H_2$ (**3c**), as reported in ref. 25. $C_3O_7H_2$ (**3b′**) is a new isomer optimized in this work.



acid) were studied; details of their properties will be the subject of a future article.[42] As discussed previously, we found the most stable $C_2O_5H_2$ conformation to have a planar geometry (C_s), with one H-atom bridge bonded to a carbonyl O atom (dashed lines in Fig. 1) and the second H at a cis position relative to the same O. Energetically, the next isomer, also of C_s symmetry and with the second H at a trans position (not shown in Fig. 6), lies just 2 kJ/mol higher (with both bases B and C: Table 5).

None of the seven isomers look like the $C_2O_5H_2$ (**3a**) species discussed by Lewars.[25] Our calculations find a C_2 structure for **3a** (Fig. 6), in visual agreement with refs. 25 and 26; interestingly, the new CO and OH distances differ by <1 pm from the older ones. The energetics, however, is quite different: the present $C_2O_5H_2$ (**3a**) species lies $\Delta E \approx 28$ kJ/mol above the most stable (C_s) conformation found here (Table 3 and Fig. 1). Basis C, with semidiffuse AOs, leads to $\Delta E \approx 26$ kJ/mol. Taking these findings into account, a ΔE_{rxn} of ≈83 kJ/mol calculated by Lewars[26] for the (gas phase) process $C_2O_5H_2 \rightarrow 2CO_2 + H_2O$ appears to have been overestimated by about 27 kJ/mol.

$C_3O_7H_2$ (3b)

In ref. 25, the C_1 isomer $C_3O_7H_2$ (**3b**) relates to $C_2O_5H_2$ (**3a**) by replacing one H by CO_2H (i.e., the geometry of the C_2O_5 unit is practically the same in both $C_3O_7H_2$ (**3b**) and $C_2O_5H_2$ (**3a**)). Our simulation of **3b** (Fig. 6) reproduces such features; also, the R(CO) distances are close to those given in ref. 25. But again, our calculated relative energies do not support the previous assignment: the present C_1 isomer $C_3O_7H_2$ (**3b**) lies ≈30 kJ/mol higher than the minimum C_{2v} structure assigned here for $C_3O_7H_2$ (Table 3 and Fig. 2). Note that our optimal C_{2v} isomer is strongly stabilized because of the formation of two H bonds relative to the central carbonyl oxygen (Fig. 2).

The new isomer $C_3O_7H_2$ (**3b′**) of C_1 symmetry (Fig. 6) is derived from our $C_3O_7H_2$ (C_{2v}) minimum by keeping one H bond intact and rotating the remaining $-OCO_2H$ to destroy the C_{2v} symmetry. The stabilizing effect of the H bond is clear: the **3b′** isomer lies ≈10 kJ/mol above our most stable C_{2v} conformation (two H bonds), but ~20 kJ/mol lower than the previous $C_3O_7H_2$ (**3b**) structure[25] with no H bonds (the same applies to the 4-CO_2 conformation shown in ref. 26).

$C_4O_9H_2$ (3c)

Our simulation of this nonsymmetric (C_1) isomer also has R(CO)s similar to those given by Lewars,[25] but the B3PW91/6–311G(2d,p) calculations find $C_4O_9H_2$ (**3c**) to be less stable, by ~30 kcal/mol (1 cal = 4.184 J), than the minimum C_2 structure assigned here to $C_4O_9H_2$ (Table 3 and Fig. 4).

In summary, geometry reoptimizations of the first $C_nO_{2n+1}H_2$ acids (n = 2, 3, or 4) support the findings that our high-symmetry polycarbonic acids are more stable than those of low symmetry previously reported.[25,26] Since the energy gaps between them lie well above 10 kJ/mol, it is quite improbable that other (C_1) isomers not scanned here may be more stable than our recommended high-symmetry structures. However, a note of caution: the spatially more compact, low symmetry **3a**–**3c** isomers (and similar higher species (n = 5 or 6) studied earlier[25,26]) may play a more relevant role when dealing with *solid* $C_nO_{2n+1}H_2$ systems than the present gas-phase simulations would suggest.

Another point worth noting regarding the equilibrium geometries is as follows: although not so obviously emerging from the (two-dimensional) structures shown in Figs. 2–6, the relative positions of consecutive C=O groups can be seen as generating helicoid-like frameworks (such a behaviour is more clearly discernible by the acyclic isomers depicted in Fig. 11.1 of ref. 26).

Summary and concluding remarks

This study finds a positive answer to the question posed in the Introduction: the dianion CO_3^{2-} is a simple nucleophilic system that can successively bind several CO_2s to form $CO_3^{2-}(CO_2)_n$ compounds with strong CO bonds throughout. Indeed, one factor contributing to the stability of these systems is delocalization of the extra electronic charge upon an increase in molecular size. Stabilization is additionally attained by capping both terminal $-COO^-$ groups by counterions (forming ion pairs) or H atoms (forming polycarbonate – dicarboxylic acids).

Our B3PW91/6–311G(2d,p) study on $[C_nO_{2n+1}]^{2-}$ and $[C_nO_{2n+1}]X_2$ (X = Li or H), with n = 2–6, finds several (C_s, C_2, C_{2v}) species containing chainlike $[C_nO_{2n+1}]$ moieties to be structurally stable, as pointed out by standard single and double CO bond distances and real frequencies throughout. (No attempts were made to calculate dissociation barriers of the present compounds, but the existence of relatively short C–O bonds, and correspondingly high stretching frequencies, would suggest the existence of sizeable dissociation barriers. See also ref. 26.) Similar findings regarding bond distances and frequencies were reported by Lewars[25,26] for dicarboxylic acids $[C_nO_{2n+1}]H_2$ (n = 2–6), and by Frapper and Saillard[27] for $[C_nO_{2n-1}]H_2$ (n = 2–5) molecules with fixed trans O′=C–O–C=O′ units. In general, the higher symmetry compounds studied here are more stable than those discussed in refs. 25 and 26.

Although the gaseous dianions are unstable upon electron detachment, this study shows that they stabilize in the presence of Li^+ ions, without substantial changes in their geometrical structures for n = 2, 3, or 4 (the same feature holds for $[C_nO_{2n+1}]X_2$, X = Na or K).[42] The reported geometries, frequencies, and IR–Raman intensities should help in the future characterization of these $[C_nO_{2n+1}]X_2$ ionic crystals.

To the best of our knowledge, none of these chainlike CO_2 compounds have been synthesized in the laboratory, although $C_2O_5X_2$ and $C_3O_7X_2$ esters are well-known commercially available liquid compounds at room temperature and widely used in biochemistry studies and the food industry.[13–19] We hope experimental chemists will be able to find ways to replace these X–alkyls groups by X = H or alkali-metal to synthesize some of the compounds presented here. Indeed, as is also pointed out by Lewars,[26] these CO_2 chainlike compounds could be potential candidates for high-energy density materials, as, for example, $C_nO_{2n+1}H_2$ compounds decompose *exothermically* into $nCO_2 + H_2O$ products, but they are locally stable because of the existence of substantial dissociation barriers.

In general, as the index n increases, the bond distances in $[C_nO_{2n+1}]X_2$ (X = Li or H) approximately approach three characteristic <R(CO)> values: (*i*) 118 (±1), (*ii*) 122 (±2), and (*ii*) 136 (±4) pm. By comparing these R values with the information in Tables 1 and 2, the short distances in group (*i*) can be associated with a C=O double bond (e.g., R = 115.9 and 119.0 pm in CO_2 and acetic anhydride, respectively). The intermediate R values (group (*ii*)) are close to R(CO) = 123.9 pm in CO_2^-, which can be considered a weakly CO double bond. Finally, the group (*iii*) values (132–140 pm) may be roughly correlated with the (singlelike) bonds in CO_3^{2-} (130.3 pm) and CO_2^{2-} (131.9 pm), to the extreme case of $O(CH_3)_2$ with R(CO) = 140.3 pm. Clearly, the various CO bonds in all present neutral $[C_nO_{2n+1}]X_2$ compounds are strong. The situation is somewhat less clear-cut for the isolated higher dianions (n = 5 or 6) where anomalously larger R(CO) distances are predicted (>145 pm and up to ≈280 pm; Tables 3 and 4). Clearly, the presence of X^+ counterions, or the formation of OH bonds, strongly stabilizes such floppy dianionic structures in the gas phase.

Our vibrational calculations indicate that the strong absorptions owing to C=O double bonds should help in the experimental characterization of these species, noting that $[C_nO_{2n+1}]X_2$ has as many C=O bonds as C atoms. On the other hand, C–O stretching modes associated with the C–O–C groups appear at lower frequencies and have moderately high intensities (Supplementary data). They lie in a congested area, owing to the larger number of C–O–C bonds as well as their mixing with other modes (e.g., δ(C–O–C) bending in all species as well as ν(C–OH) and δ(COH) modes in dicarboxylic acids).

Recently, spectroscopic studies[44] have been able to analyze the rovibrational spectrum of gas-phase carbonic acid (CO_3H_2) after many years of having been declared as nonexistent by traditional chemistry textbooks, which is close to the truth when dealing with the overall reaction $CO_2(g) + H_2O(l) \leftrightarrow CO_3H_2(aq)$, since the concentration of the latter has been estimated to be small.[45] According to the literature,[46] gaseous carbonic acid may play a relevant role in astrophysics, mostly in those regions where CO_2 and ice (water) are abundant, as, for example, in comets and, particularly, the planet Mars. Under those conditions, it could be possible that dicarbonic acid ($C_2O_5H_2$) also exists.

Our solvation calculations find that the CO_2 uptake reactions by O^{2-} and CO_3^{2-} (to form CO_3^{2-} and $C_2O_5^{2-}$, respec-

tively) are the only ones to proceed spontaneously ($\Delta G < 0$) in any type of solvent, although protic solvents should be avoided. These theoretical results agree with the experimental observations that CO_3Li_2(molten), for example, is an optimal absorber of CO_2(g). As well, it is also possible that the formation of solid polycarbonates $C_nO_{2n+1}R_2$ (R = large-size group) can be used for large-scale CO_2(g) uptake, which is a topic under current investigation in our laboratory.[42]

Supplementary data

Supplementary data (B3PW91/G–311G(2d,p) total energies, equilibrium geometries, and vibrational frequencies (including IR and Raman intensities) for the compounds discussed in the text) are available with the journal article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: We report the synthesis, crystal structure, and electrochemical properties of new Fe-doped $Ba_2(Ca_{1-x-y}Fe_xNb_y)(Nb_{1-z}Fe_z)O_{6-\delta}$ (Fe–BCN). The Fe–BCN was synthesized by a solid-state method in air using corresponding metal oxides and salts at elevated temperature. All of the observed powder X-ray diffraction (PXRD) peaks of the investigated Fe–BCN were indexed as cubic *Fm*-3*m* (space group No. 225) double perovskite-type structure with cell constants $a \sim 8.4$ Å and is consistent with selected area electron diffraction (SAED). Rietveld analysis suggested the distribution of Fe was at both *4a* and *4b* sites, supported the proposed chemical formula $Ba_2(Ca_{1-x-y}Fe_xNb_y)(Nb_{1-z}Fe_z)O_{6-\delta}$. This was further verified by bond valence sum (BVS) analysis of the cations. The Fe–BCN showed superior chemical stability in pure CO_2 and boiling H_2O confirmed by PXRD and FTIR. The electrical conductivity was determined by AC impedance spectroscopy. Among the samples investigated, $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.71}Fe_{0.29})O_{6-\delta}$ showed the highest total (bulk + grain-boundary) conductivity of 1.1×10^{-2} S cm^{-1} in humidified (3%) N_2 at 600 °C with activation energy of 0.43 eV in the temperature range 200–800 °C.

Key words: protonic conductors, perovskites, Fe–BCNs, mixed ionic and electronic conductors (MIECs), solid oxide fuel cells (SOFCs), anodes, Rietveld refinement, AC impedance spectroscopy, selected area electron diffraction (SAED), powder X-ray diffraction (PXRD).

Résumé : On a effectué la synthèse, déterminé la structure cristalline et mesuré les propriétés électrochimiques de nouveaux $Ba_2(Ca_{1-x-y}Fe_xNb_y)O_{6-\delta}$ dopés au fer (Fe–BCN). Les Fe–BCN ont été synthétisés par une méthode à l'état solide, dans l'air, en utilisant les oxydes et des sels des métaux correspondants, à des températures élevées. Toutes les raies des spectres de diffraction des rayons-X de poudres (DRXP) des Fe–BCN étudiés ont été indexées comme des structures cubiques *Fm-3m* (groupe d'espace No. 225) de type perovskite double avec des constantes de maille de $\alpha \sim 8{,}4$ Å qui est en accord avec la diffraction électronique d'une surface choisie (DESC). Une analyse de Rietveld suggère que la distribution du Fe se fait tant sur les sites *4a* que *4b* qui est en accord avec la formule chimique proposée $Ba_2(Ca_{1-x-y}Fe_xNb_y)O_{6-\delta}$. Cette hypothèse a aussi été confirmée par une analyse de la somme des valences de liaison (SVL) des cations. La stabilité chimique supérieure du Fe–BCN dans le CO_2 pur et dans l'eau bouillante a été confirmée par DRXP et par infrarouge à transformée de Fourier (IR-TF). On a déterminé la conductivité électrique par spectroscopie d'impédance en courant alternatif (CA). Parmi les échantillons étudiés, le $Ba_2(Ca_{0,79}Fe_{0,21})(Nb_{0,71}Fe_{0,29})O_{6-\delta}$ présente la conductivité totale (ensemble + limite des grains) la plus élevée, $1{,}1 \times 10^{-2}$ S cm^{-1}, dans de l'azote humidifié (3 %), à 600 °C, avec une énergie d'activation de 0,43 eV dans la plage de température allant de 200 à 800 °C.

Mots-clés : conducteurs protoniques, perovskite, Fe–BCN, conducteurs mixtes ionique et électronique (CMIE), piles à combustible à oxyde solide (PCOS), anodes, affinement de Rietveld, spectroscopie d'impédance à courant alternatif, diffraction électronique d'une surface choisie (DESC), diffraction des rayons X de poudres (DRXP).

[Traduit par la Rédaction]

Introduction

Proton conduction in the perovskite-type (ABO_3 A = divalent or trivalent metal ions; B = trivalent or tetravalent metal ions) oxide was pioneered by Iwahara et al.[1] in 1981. The acceptor-doped $SrCe_{0.95}Yb_{0.05}O_{3-\delta}$ compound exhibited an appreciably high proton conductivity of 5×10^{-2} S cm^{-1} at 800 °C in humidified H_2.[1] The proton conduction arises because of the partial occupation of oxide vacancy sites ($V_O^{\bullet\bullet}$) by H_2O; the subsequent formation of hydroxyl protons ($OH_O^{\bullet}$) and can be described using Kröger–Vink notation:[2,3]

$$[1] \qquad H_2O + V_O^{\bullet\bullet} + O_O^{x} \rightarrow 2OH_O^{\bullet}$$

where O_O^x represents the lattice oxygen in the perovskite lattices. The hydroxyl protons are highly mobile and can hop from one O^{2-} ion site to the adjacent site through the Grotthuss mechanism.[4] Commonly, AC impedance and DC polarization methods were used to measure the proton conductivity,[5] and neutron diffraction (ND),[6] Fourier transform infrared (FTIR) spectroscopy, and thermogravimetry (TG) were employed to characterize the crystal structure and chemical stability.[7] Among the perovskite-type oxides, rare-earth-doped $BaCeO_3$ was found to be chemically unstable in CO_2 or H_2O at elevated temperatures,[8,9] whereas B-site ordered double perovskite $Ba_3Ca_{1+x}Nb_{2-x}O_{9-\delta}$ (BCN) showed superior chemical tolerance.[10,11]

Recently, we investigated the effect of Ta substitution for Nb in BCN on proton conductivity and chemical stability under pure CO_2 and boiling H_2O.[12] Among the double perovskites reported in the literature, $Ba_3Ca_{1.18}Nb_{1.82}O_{9-\delta}$ (BCN18), is one of the most representative compounds because of its high proton conductivity of 1.8×10^{-2} S cm^{-1} at 600 °C in humidified atmospheres.[11,13] In the present work, an attempt was made to convert the proton-conducting BCN into mixed proton and electronic conductors (MPECs) through the partial substitution of Ca and Nb by transition metal ions, such as Fe, at low oxygen partial pressures (pO_2), for application as anodes for solid oxide fuel cells (SOFCs).

Experimental section

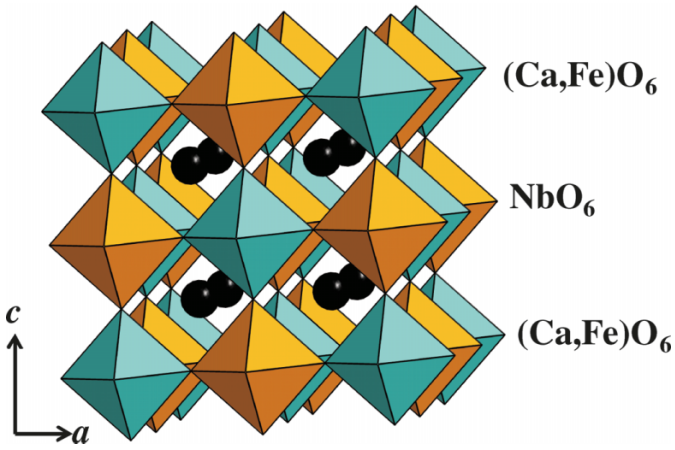
Synthesis

All Fe–BCNs were prepared by the solid-state method in air using stoichiometric amounts of ACS grade $Ba(NO_3)_2$ (99+%, Alfa Aesar), $CaCO_3$ (99%, Fisher Scientific Company), Nb_2O_5 (99.5%, Alfa Aesar), and Fe_2O_3 (98+%, Alfa Aesar). The precursors were ball-milled (Pulverisette, Fritsch, Germany) in 2-propanol using ZrO_2 balls for 6 h at 200 rpm and then dried in an oven at 100 °C. Subsequently, it was calcinated at 900 °C for 14 h at a 5–10 °C/min ramp rate in a clean alumina crucible. The resultant powdery samples were first ball-milled for another 6 h and then pressed into pellets (~1 cm in diameter and ~2 cm long) using isostatic pressure (1.2×10^8 Pa for ~2 min). The pellets were finally sintered at 1300–1500 °C for 14 h in air.

Characterization

Solid phases were identified by powder X-ray diffraction (PXRD) (Bruker D8 Advance powder X-ray diffractometer Cu Kα, 40 kV, 40 mA) from $2\theta = 10°$ to 80° at a count rate of 15 s per step of 0.02° at room temperature. The PXRD was refined by the Rietveld method using the GSAS package with the EXPGUS interface.[14] Background, scale factors, zero-point positions, cell parameters, atomic positions, and profile coefficients for the Pseudo-Voight/FCJ asymmetric peak-shape function were refined until the convergence was achieved. The displacement parameters (temperature factors) for the *4a* and *4b* sites were not refined meaningfully, possibly because of the disorder. Alternatively, the parameter for *4a* was fixed to $U_{iso} = 0.015$ Å^2 and *4b* was fixed to $U_{iso} = 0.01$ Å^2. Those values are comparable to Ca and Nb atoms in other perovskites in the literature.[15,16] Bond lengths were obtained with the DISAGL Version Win32 crystal structure distance and angle program in the GSAS packet on XRD data sets.[14] Bond valence sums (BVS) of cations were calculated with the Bond Valence Calculator Version 2.[17,18]

Fig. 2. Idealized structure of Fe-doped $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$.



A Philips XL 30 conventional scanning electron microscope equipped with an energy dispersive X-ray spectrometer (EDX) was used to study the morphology of the investigated Fe–BCN. Images were recorded at 20 kV with a secondary electron detector. Selected area electron diffraction (SAED) was performed on a FEI Tecnai F20 FEG-TEM (FEI, Eindhoven, The Netherlands) equipped with a Gatan imaging filter and a Gatan 860 GIF 2001 CCD of 1024 pixel × 1024 pixel resolution. Ex-situ PXRD, FTIR, and SEM were used to access the chemical stability of the samples in pure CO_2 at 800 °C for 14–20 h and boiling H_2O for at least 72 h. Prior to the FTIR measurements, samples were grounded with dried KBr and pressed into pellets. The pellets were measured in a NEXUS 470 FTTR spectrometer.

The sintered pellets were cut into smaller pellets (1.5 mm thickness and ~10 mm in diameter) for the electrical conductivity measurements using AC impedance spectroscopy (Solartron Electrochemical Impedance Spectroscopy; SI model No. 1260, 100 mV, 0.01 Hz to 7 MHz). The pellets were painted with Pt paste (LP A88-11S, Heraeus Inc., Germany) on both sides at room temperature and subsequently heated to 900 °C for 1 h to remove the organic binders. The pellets were connected with Pt wires using spring-loaded contact. The temperatures of the electrochemical cells were controlled by a Barnstead tubular furnace (model No. 21100) in a range of 200–800 °C. The cells were stabilized at constant temperature for 1 h prior to each AC impedance measurement and were made upon heating and cooling cycles to ensure the reproducibility.

Results and discussion

Structural analysis

The parent phase $Ba_3CaNb_2O_9$ was found to exhibit as hexagonal *P-3m1* (space group No. 164) with 1:2 ordering on B sites (*1b* and *2d*),[11,19] as cubic *Fm-3m* (space group No. 225) with 1:1 ordering on B sites (*4a* and *4b*),[19,20] and as B-site disordered simple cubic *Pm3m* (space group No. 221) structures.[21] We indexed all diffraction peaks of Fe–BCN

Table 1. Comparison of Rietveld refinement results of $Ba_2(Ca_{1-x-y}Fe_xNb_y)(Nb_{1-z}Fe_z)O_{6-\delta}$ using *Fm*-3*m* (No. 225) as the space group for all structural models.

based on the *Fm-3m* space group, and the atomic positions of the Fe dopant were further analyzed by Rietveld analysis (Fig. 1). A structural model was constructed in which the lower charge cations (Ca^{2+} and Fe^{3+}) were mainly located on the *4a* site and the higher charged cations (Nb^{5+}) were on *4b* site (Fig. 2).[19,22,23] The detailed structural models and the corresponding refinement results are summarized in Table 1. The proposed structural models were supported by good fits (R_p) on the refinements. The structural models were further verified by BVS (Table S1; see Supplementary data) and SAED (Fig. 3). BVS calculations for cations on the specific positions in *Fm-3m* were found to be in good agreement with the assigned normal oxidation states of the cations. The small discrepancy can be explained by the presence of covalent character on the bonding in the Fe–BCN, which is opposite to the pure ionic assumption used in the BVS. Brown[24] also pointed out that many highly symmetric double perovskites in the ICSD database were not verified commonly by BVS. Shown in Fig. S1 (see Supplementary data) are the typical SEM images of Fe-doped BCN. All the investigated samples showed uniform contrast and support the absence of a potential second phase. SEM analysis was mainly used to determine the elemental analysis by energy dispersive spectroscopy (EDS) and confirmed the formulas of all Fe–BCN (Table 2) (Fig. S2; see Supplementary data).

Chemical stability

The chemical stability of the investigated Fe–BCN was accessed in pure CO_2 at 800 °C for 14–20 h and boiling H_2O for 72 h. PXRD showed that the double perovskite structure of $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**) was well maintained upon the chemical stability tests (Fig. 4). Furthermore, carbonate and hydroxyl groups were not observed from the FTIR spectra (Fig. 5). All other Fe–BCN (Supplementary data Figs. S3–S5) were also found to be chemically stable under the same environments, except for $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.71}Fe_{0.29})O_{6-\delta}$ (**V**), where additional peaks were observed after the chemical treatments (Supplementary data Fig. S6). The degradation mechanism was not clear to us but it could be similar to the $Ba(Co,Fe,Nb)O_{3-\delta}$ system.[25] In fact many barium containing oxides, such as barium cerates and rare earth-doped barium cerates, are reactive with CO_2 and H_2O.[26,27] Substitution of a small amount of foreign ions into the lattice is one of the most effective and common methods to improve the stability and performance.[28,29]

Electrical properties

AC impedance plots of $Ba_2(Ca_{0.67}Fe_{0.167}Nb_{0.167})(Nb)O_{6-\delta}$ (**II**) at 300 °C in air are shown in Fig. 6. The semicircles can be interpreted as different regions of a ceramic such as bulk, grain–boundary, and electrolyte–electrode, based upon

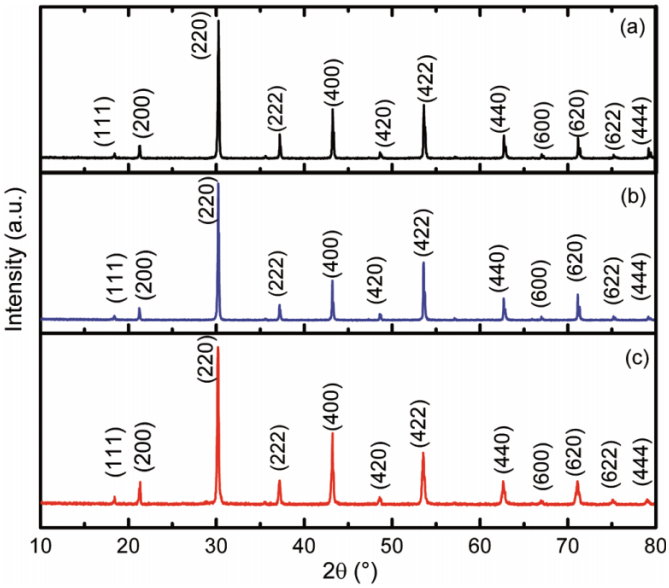
Measured atom ratio	4.09	1.46	1	1.30
Expected atom ratio	4.00	1.58	1	1.42

Fig. 4. Powder X-ray diffraction (PXRD) patterns of $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**) sintered at 1500 °C for 14 h: (*a*) as-prepared sample, (*b*) post-treatment of the as-prepared sample in 100% CO_2 for 14 h, and (*c*) post-treatment of the as-prepared sample in boiling H_2O for 72 h.



$$[3] \qquad Z_{CPE} = \frac{1}{Q(j\omega)^n}$$

where Q is the pseudo-capacitance, $j = \sqrt{1}$, and n is the empirical constant that can be any arbitrary value between 0 and 1. The actual capacitance can be calculated by[30,31,33,34]

$$[4] \qquad C = R^{\frac{1-n}{n}} Q^{\frac{1}{n}}$$

The fitting AC impedance analysis (Table 3) of the sample in air indicated that the capacitances for the high- and low-frequency semicircles were in the order of 10^{-11} and 10^{-6} F, respectively, which are characteristic values for the bulk and grain–boundary effects in ceramic materials.[30] Since all Fe–BCN were well-sintered (>90% theoretical density), the impedance owing to the grain–boundary was found to be less significant (roughly a one-sixth contribution to the total)

Fig. 5. FTIR spectra of $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**): (*a*) as-prepared, (*b*) post-treatment of the as-prepared sample in 100% CO_2 for 14 h, and (*c*) post-treatment of the as-prepared sample in boiling H_2O for 72 h. The C=O vibration band around 1700 cm^{-1} and the O–H vibration at 3500 cm^{-1} were not observed under experimental conditions.

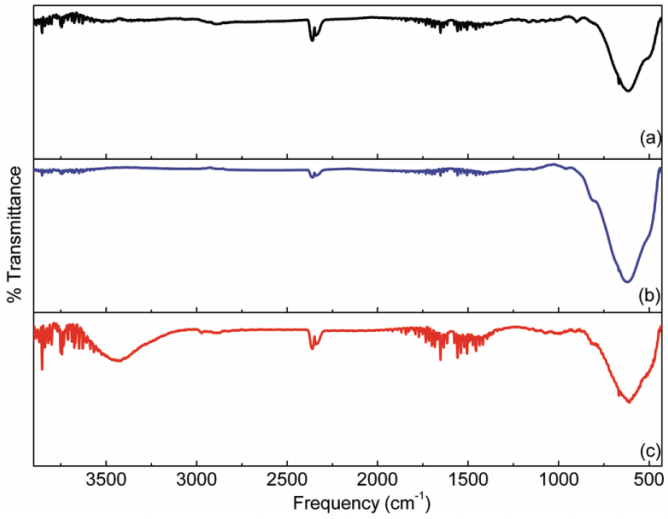


Fig. 6. Typical electrochemical impedance plot with equivalent circuits fitting of $Ba_2(Ca_{0.67}Fe_{0.165}Nb_{0.165})(Nb)O_{6-\delta}$ (**II**) at 300 °C in air and N_2 + 3% H_2O. The equivalent circuits used to fit the experimental data are shown in top right corner. The solid line passing through data points represents the best-fit line. Inset shows expanded view of high frequency region of impedance plot.

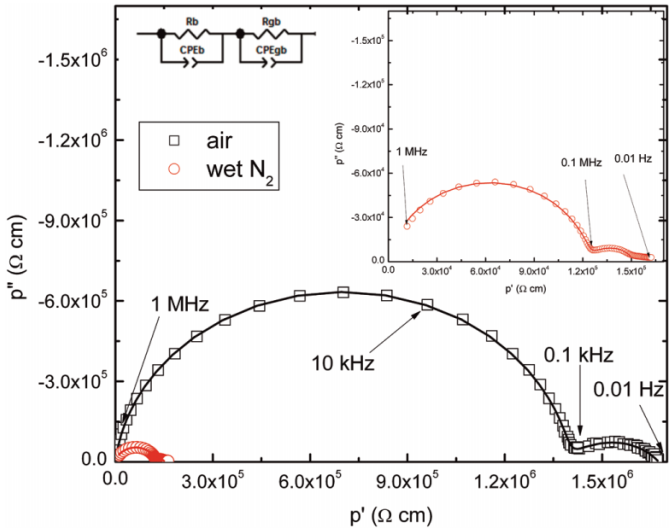

even at 300 °C. At a high-temperature regime (500–800 °C), the semicircles were highly deformed and overlapped; hence, separation of the bulk and grain–boundary contributions was not possible. Alternatively, the low-frequency intercept was used as total impedance, which included bulk and grain–boundary impedances. Such consideration was widely used in our group and in other groups.[31,32,35] Therefore, the total conductivities (bulk and grain–boundary) were used to study the doping effect on all Fe–BCN.

The Arrhenius plots for the total electrical conductivities of all Fe–BCNs, including $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**),

Fig. 7. The Arrhenius plot of $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**), $Ba_2(Ca_{0.67}Fe_{0.165}Nb_{0.165})(Nb)O_{6-\delta}$ (**II**), $Ba_2(Ca_{0.79}Fe_{0.16}Nb_{0.05})(Nb)O_{6-\delta}$ (**III**), $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.98}Fe_{0.02})O_{6-\delta}$ (**IV**), and $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.71}Fe_{0.29})O_{6-\delta}$ (**V**) in air and hydrated N_2.

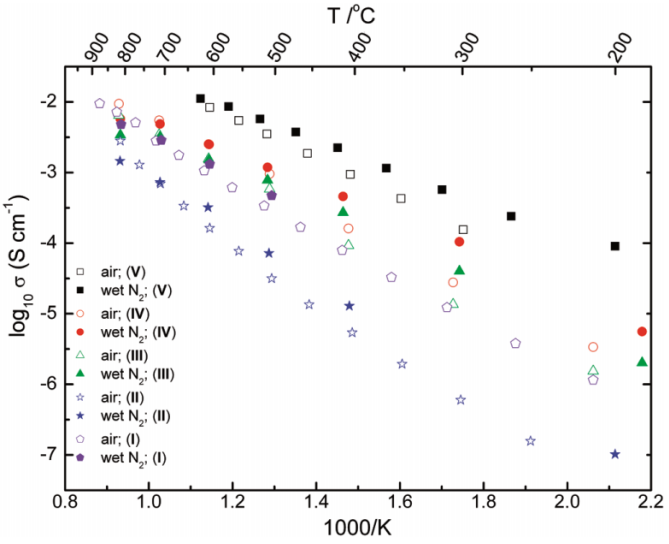

Fig. 8. Electrical conductivity of $Ba_2(Ca_{0.67}Fe_{0.33})(Nb)O_{6-\delta}$ (**I**) in air, dry N_2, dry H_2, N_2 + 3% H_2O, and H_2 + 3% H_2O.

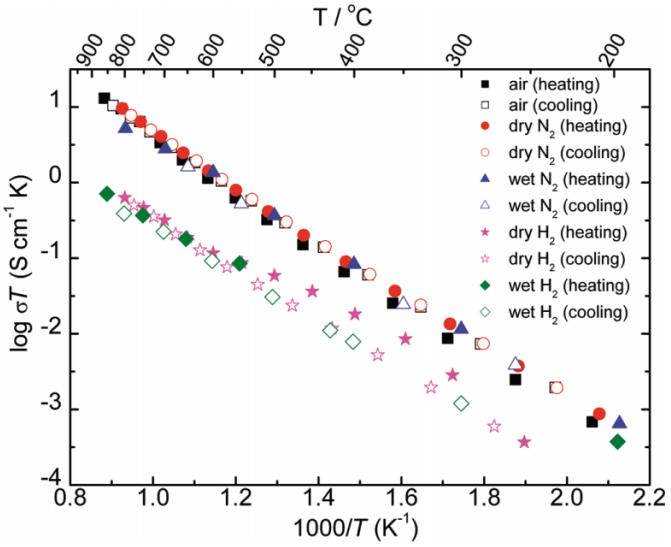

$Ba_2(Ca_{0.67}Fe_{0.165}Nb_{0.165})(Nb)O_{6-\delta}$ (**II**), $Ba_2(Ca_{0.79}Fe_{0.16}Nb_{0.05})(Nb)O_{6-\delta}$ (**III**), $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.98}Fe_{0.02})O_{6-\delta}$ (**IV**), and $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.71}Fe_{0.29})O_{6-\delta}$ (**V**), in air and hydrated N_2 are shown in Fig. 7. Interestingly, the conductivity of **IV** and **V** were found to be higher than that of **I**, **II**, and **III** in both air and hydrated N_2. The increase in electrical conductivity in wet N_2 may appear because of proton conduction. In wet N_2, the activation energies of all Fe–BCNs were found to be ~0.5 eV (200–800 °C). Typically, ceramic proton conductors exhibit smaller activation energies (ca. 0.3–0.6 eV) than that of oxide ion electrolytes (ca. 0.9 eV) and electron-holes (ca. 0.8 eV).[8,36,37] A slight variation in activation energy can be anticipated with different structures and dopant levels. Furthermore, additional electronic carriers could be created under the low oxygen partial pressure (pO_2) because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

of the reduction of Fe and Nb in Fe–BCN at elevated temperatures.

To study the effect of electrical conduction at low pO_2 (in fuel H_2), compound **I** was chosen as a case study. The Arrhenius plot of **I** in air, wet N_2, wet H_2, and dry H_2 are shown in Fig. 8. Surprisingly, the conductivities in wet and dry H_2 were lower than those for wet N_2 and air. The origin of the dramatic reduction in conductivity could be attributed to the formation electron-holes ($h^\bullet$) according to the proposed defect equilibrium reaction:

$$[5] \qquad V_O^{\bullet\bullet} + 0.5O_2 \Leftrightarrow O_O^x + 2h^\bullet$$

The detail analysis on the oxidation states of the Fe ions in Fe–BCN is important for understanding the electronic properties and the amount of oxygen vacancy in the lattices. A combination of TGA and Mössbauer spectroscopy studies will be conducted in the future to understand the electrical properties of Fe–BCN in H_2.

Conclusions

Our preliminary studies on the non-stoichiometric ordered double perovskites $Ba_2(Ca_{1-x-y}Fe_xNb_y)(Nb_{1-z}Fe_z)O_{6-\delta}$ (Fe–BCN) indicate all the prepared compounds exhibited cubic *Fm*-3*m* with cell constant $a \sim 8.4$ Å. Fe–BCN showed good chemical stability in CO_2 at elevated temperatures and in boiling water. The highest total (bulk + grain–boundary) conductivities of 2.23×10^{-3} and 1.11×10^{-2} S cm^{-1} in hydrated N_2 at 400 and 600 °C, respectively, with an activation energy of 0.43 eV (200–800 °C) were found for $Ba_2(Ca_{0.79}Fe_{0.21})(Nb_{0.71}Fe_{0.29})O_{6-\delta}$.

Abstract: An electrochemical sensor based on a cationic surfactant cetyltrimethylammonium bromide (CTAB) – dispersed graphene (Gr) system for sensitive detection of caffeine is presented. The electrochemical behavior of caffeine on the modified glassy carbon electrode was investigated by cyclic voltammetry and differential pulse voltammetry. The results showed that the modified electrode exhibited good electrocatalytic activity to the oxidation of caffeine. Under the optimized experimental conditions, caffeine was detected in the concentration range from 0.3 to 100 μmol L^{-1} with a detection limit of 91 nmol L^{-1} at a signal-to-noise ratio = 3. The biosensor exhibited some advantages over other electrochemical sensors, such as long-term stability, satisfactory recovery (98.1%–102.3%), and good reproducibility (RSD = 5.1%). The practical application of the developed method was verified in soft-drink sample analysis.

Key words: caffeine, cetyltrimethylammonium bromide, graphene, electrochemical sensor.

Résumé : On a mis au point un senseur électrochimique, à base d'un système formé de l'agent de surface bromure de cétyltriméthylammonium (BCMA) dispersé sur du graphène, comme détecteur sensible de la caféine. On a étudié les comportements électrochimiques de la caféine sur une électrode de carbone vitreuse modifiée par voltampérométrie cyclique et par voltampérométrie pulsée différentielle. Les résultats montrent que l'électrode modifiée présente une bonne activé catalytique pour l'oxydation de la caféine. Dans des conditions expérimentales optimisées, il est possible de détecter de la caféine dans la plage de concentration allant de 0,3 à 100 μmol L^{-1}, avec une limite de détection de 91 nmol L^{-1}, pour un rapport de signal à bruit égal à 3. Le biosenseur présente quelques avantages, telle sa stabilité à long terme, une récupération satisfaisante (98,1 % à 102,3 %) et une bonne reproductibilité (déviation standard de la reproductibilité = 5,1 %). On a vérifié l'application pratique de la méthode développée par l'analyse d'échantillons de liqueurs douces.

Mots-clés : caffeine, bromure de cétyltriméthylammonium, graphène, senseur électrochimique.

[Traduit par la Rédaction]

Introduction

Caffeine (3,7-dihydro-1,3,7-trimethyl-1*H*-purine-2,6-dione) is an active alkaloid. It has some important physiological effects, such as stimulating gastric acid secretion, diuresis, and the central nervous system.[1,2] However, it can cause adverse mutation effects when excessively consumed,[3] including inhibition of DNA repair and cyclic AMP phosphodiesterase activity,[4] resulting in the occurrence of cancer and heart diseases.[5] Therefore, the determination (quantification) of caffeine has great significance for both biosciences and clinical diagnosis, and even criminology.

Several techniques have been developed for the determination of caffeine, including HPLC,[6] UV spectrophotometry,[7] mass spectroscopy,[8] capillary electrophoresis, and gas chromatography.[9–12] Although these methods are sensitive, complicated instruments and time-consuming sample pretreatment are required. Compared with these methods, an electrochemical technique is attractive due to its high sensitivity, inherent simplicity, miniaturization, and low cost, and thus some electrochemical methods have been developed for the determination of caffeine.[13–15] One key area of electrochemical sensor research is in the use of various materials with nanoparticle-like physical and chemical properties, because they provide a large surface area and improve the biocompatibility, stability, and immobilization of biomolecules on the electrode surface.[16,17]

Graphene (Gr), a single layer of carbon atoms in a closely packed honeycomb two-dimensional lattice, is a novel and fascinating carbon material. Recently, it has attracted considerable attention from both the experimental and theoretical scientific communities owing to its many unique and excellent properties.[18–20] It exhibits extremely high thermal conductivity, good mechanical strength, high mobility of charge carriers, high specific surface area, quantum hall effect, and outstanding electric conductivity.[21–23] Much research effort has been put into exploring the fascinating possibilities for applications with Gr, such as the fabrication of various electrical devices, e.g., batteries,[24] field-effect transistors,[25] ultra-

sensitive sensors,[26] electromechanical resonators,[27] and electrochemical biosensors.[28] Some studies have demonstrated that Gr possesses excellent electrochemical catalytic activity, and should be considered as a modified material for a novel electrode with excellent performance.

Herein, a simple and sensitive method for the determination of caffeine was developed based on the surfactant cetyltrimethylammonium bromide (CTAB) dispersed Gr system modified glassy carbon electrode (GCE). The surfactant is a special compound with amphiphilic groups, which has been widely used in electroanalytical chemistry. It can improve the peak shape and sensitivity, and possesses antifouling capacity via inhibiting direct contact of the substrates with the electrode surfaces.[29–31] Gr is easier to disperse in a surfactant solution. This can improve the dispersion and homogeneity of the Gr. The CTAB–Gr composite film was characterized with electrochemical methods. Based on the unique properties of graphene, the fabricated modified electrode facilitated the electron transfer of caffeine, resulting in the increase of oxidation signals. The method proved to be simple, reliable, and inexpensive for the determination of caffeine in the soft-drink samples at low levels.

Experimental

Reagents

Caffeine was purchased from Beijing Shuanghuan Weije Reagent Co. (Beijing, China), and the stock solution of caffeine (1.0×10^{-2} mol L^{-1}) was prepared with doubly distilled water, and diluted with 0.01 mol L^{-1} H_2SO_4 (pH 2.0) before use. CTAB was purchased from Jing Wei Chemical Co., Ltd (Shanghai, China). The Gr used in this study was synthesized according to the reported method of Hummers et al.[32] Ultrapure water (18.2 MΩ) was obtained from a Milli-Q water purification system and used throughout. All other reagents were of analytical reagent grade and used as received.

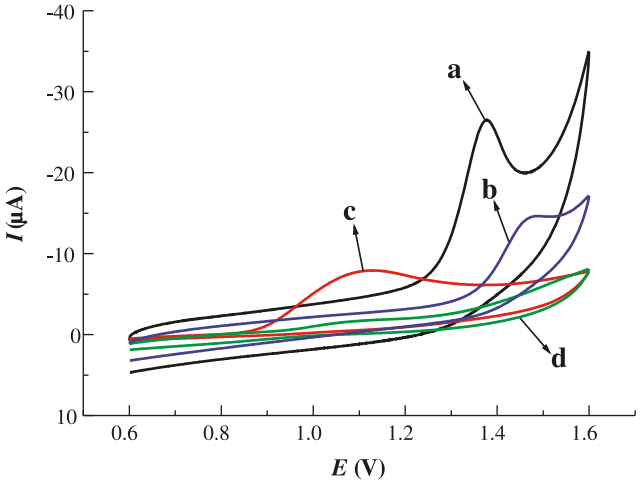
Instrumentation

Electrochemical measurements were carried out at a CHI660D electrochemistry workstation (CH Instrumental Co., ShangHai, China). A conventional 3-electrode system was employed, including a bare glassy carbon electrode (GCE) (d = 3 mm) and the modified GCE as working electrode, a platinum wire as a counter electrode and a saturated calomel reference electrode as the reference electrode. All the pH values were measured using a PHS-3C precision pH meter (Leici Devices Factory of Shanghai, China).

Preparation of modified electrode

For electrode preparation, 2 mg of graphene was dispersed in 1 mL of DMF using an ultrasonic bath to give a black suspension. CTAB–Gr suspension was accomplished as follows: 2.0 mg CTAB and 2.0 mg Gr were sonicated in 1.0 mL doubly distilled water for about 2 h. Before modification, the GCE was polished to a mirror-like surface with 0.3 and 0.05 μm alumina slurry, then washed successively with ultrapure water, anhydrous alcohol, and ultrapure water in an ultrasonic bath and dried in blowing N_2. The cleaned GC electrode was treated by dropping 5 μL of CTAB–Gr suspension and then dried in air. The obtained electrodes were noted as CTAB–Gr/GCE. For contrast, the CTAB/GCE and Gr/GCE was prepared with the same procedure, but without Gr and CTAB, respectively.

Fig. 1. Cyclic voltammograms of (*a*) the CTAB–Gr modified GCE, (*b*) Gr modified GCE, (*c*) CTAB modified GCE, and (*d*) the bare GCE in a medium containing 2.0×10^{-5} mol L^{-1} caffeine in 0.01 mol L^{-1} H_2SO_4 (pH 2.0); scan rate 100 mV s^{-1}.



Results and discussion

Electrochemical response of the CTAB–Gr/GCE electrode to caffeine

The effective surface areas of different modified electrodes were obtained by cyclic voltammetry (CV) with 1 mmol L^{-1} $K_3Fe(CN)_6$ as a probe at different scan rates. For a reversible process, the following equation applies:

$$[1] \qquad i_p = 2.69 \times 10^5 A n^{3/2} D^{1/2} c \upsilon^{1/2}$$

where i_p refers to the peak current, and A is the electrode area (cm^2). For 1 mmol L^{-1} $K_3Fe(CN)_6$, n = 1, $D = 7.6 \times 10^{-6}$ cm^2 s^{-1} (0.1 mol L^{-1} KCl), where n is the number of electrons transferred, D is the diffusion coefficient, c is the concentration of $K_3Fe(CN)_6$, and υ is the scan rate.[33] The surface areas of the bare GCE and CTAB–Gr/GCE electrodes were calculated from the slope of the i_p versus $\upsilon^{1/2}$ plot to be 0.054 cm^2 and 0.168 cm^2, respectively.

Fig. 1 shows the cyclic voltammograms (CVs) of 2.0×10^{-5} mol L^{-1} caffeine in 0.01 mol L^{-1} H_2SO_4 (pH 2.0) on the CTAB–Gr modified GCE (Fig. 1*a*), Gr modified GCE (Fig. 1*b*), CTAB modified GCE (Fig. 1*c*), and the bare GCE (Fig. 1*d*) at a scan rate of 100 mV s^{-1}, respectively. No anodic peak of caffeine was observed at the bare GCE. Compared with the Gr/GCE, the anodic peak potentials at the CTAB–Gr/GCE and CTAB/GCE shifted negatively to 1.378 and 1.112 V, respectively, indicating an electrocatalytic oxidation process. The oxidation peak current significantly increased at the modified electrodes, especially the CTAB–Gr/GCE, indicating enhanced electrocatalytic activity towards the oxidation of caffeine. By adding caffeine, the enhancement of the current density obtained using CTAB–Gr/GCE was about 9.6 times higher than that achieved at the bare GCE. Obviously, the CTAB–Gr composite film exhibited enhanced electrocatalytic activity towards the oxidation of caffeine. This performance can be ascribed to CTAB, which

Fig. 2. Cyclic voltammograms of the CTAB–Gr modified GCE in the presence of 2.0×10^{-5} mol L^{-1} caffeine in 0.01 mol L^{-1} different supporting electrolytes ($a \rightarrow d$): H_2SO_4, HNO_3, HCl, CH_3COOH; scan rate 100 mV s^{-1}.

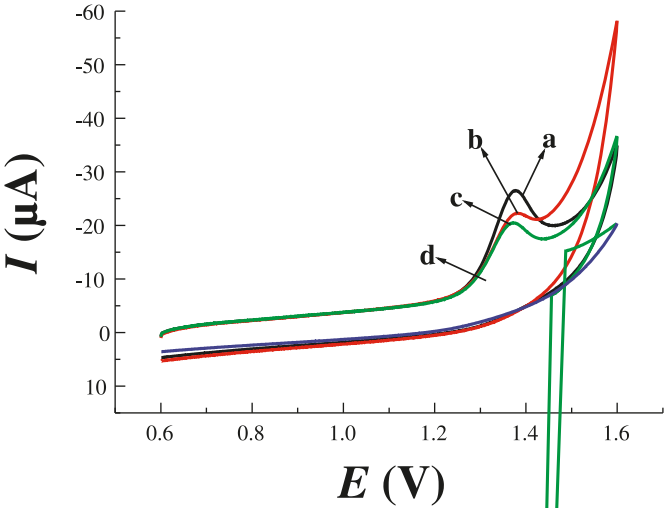

Fig. 3. Cyclic voltammograms of the CTAB-Gr modified GCE in the presence of 2.0×10^{-5} mol L^{-1} caffeine with different pH of 0.01 mol L^{-1} H_2SO_4 mediums ($a \rightarrow f$): 0.5, 1.0, 1.5, 2.0, 2.5, 3.0; scan rate 100 mV s^{-1}. Insert: plot pf pH versus oxidation peak current.

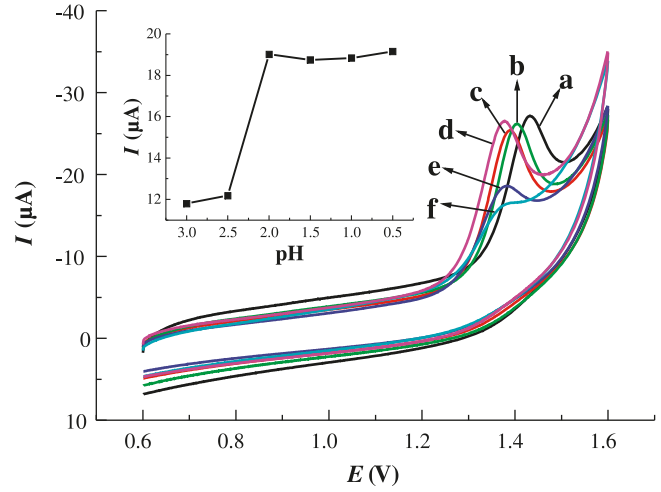

acts as a good substrate for Gr deposition on the electrode, as well as the unique characters of Gr. This composite film greatly increased the effective surface of the electrode and therefore enhanced the peak current of caffeine.

Effect of electrolytes and pH on sensor response

A number of different electrolyte solutions influence the electrochemical behavior of caffeine. Electrolyte solutions including H_2SO_4, HNO_3, CH_3COOH, and HCl are typically used in electrochemical analysis, especially in the electrochemical oxidation of caffeine.[34–37] To investigate the effect of the supporting electrolyte system on the sensor response, CV measurements of the CTAB–Gr/GCE in the presence of 2.0×10^{-5} mol L^{-1} caffeine were carried out in 0.01 mol L^{-1} H_2SO_4, HNO_3, CH_3COOH, and HCl, respectively, as depicted in Fig. 2. The highest current response was obtained in 0.01 mol L^{-1} H_2SO_4. Thus 0.01 mol L^{-1} H_2SO_4 was chosen.

Fig. 4. Cyclic voltammograms of CTAB–Gr modified GCE in the presence of 2.0×10^{-5} mol L^{-1} caffeine at different scan rate: (*a*) 20, (*b*) 100, (*c*) 180, (*d*) 260, (*e*) 340, (*f*) 420, (*g*) 500 mV s^{-1}, respectively. Insert: plot of i_p versus $\upsilon^{1/2}$.

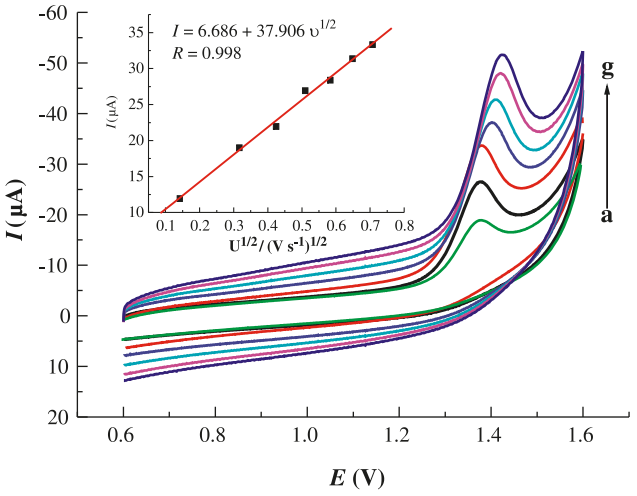

Fig. 5. Differential pulse voltammograms of CTAB–Gr modified GCE in different concentrations of caffeine ($a \rightarrow h$): 5.0×10^{-7}, 1.0×10^{-6}, 2.0×10^{-6}, 5.0×10^{-6}, 8.0×10^{-6}, 3.0×10^{-5}, 7.0×10^{-5}, 1.0×10^{-4} mol L^{-1}. Insert: plot of i_p versus $c_{caffeine}$.

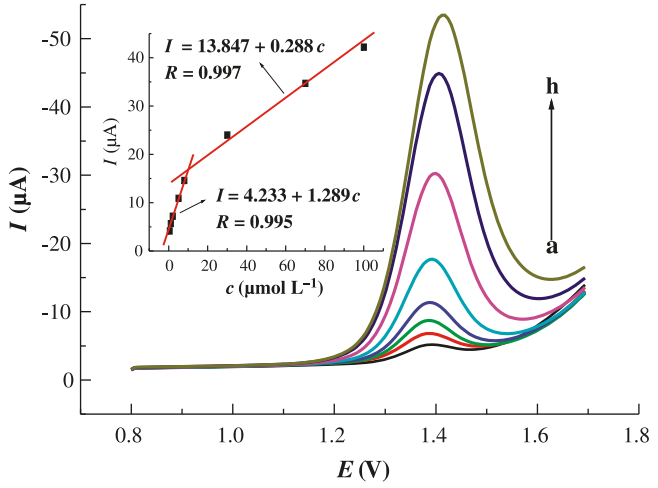

The effect of buffer pH on the electrooxidation of caffeine was investigated in the pH range 0.5–3.0. As shown in Fig. 3, the peak potential decreases with increasing pH. In addition, the peak current changed little in the pH range from 0.5 to 2.0, while it noticeably decreases at a higher pH. Therefore, pH 2.0 was chosen for the subsequent analytical experiments.

Effect of the amount of CTAB–Gr suspension

Generally speaking, the thickness of the CTAB–Gr film on GCE surface, which was determined by the amount of CTAB–Gr suspension, affected the reponse of the analytes to current. The results showed that the oxidation peak currents of caffeine reached the maximum when 5 μL of CTAB–Gr

suspension was used. The oxidation peak currents of caffeine decreased when the amount of CTAB–Gr suspension was less or higher than 5 μL. So for this study, 5 μL of CTAB–Gr suspension was selected for fabrication of the sensors.

Effect of scan rate

To obtain the kinetic parameters of caffeine redox at CTAB–Gr/GCE, the scan rate effect was investigated by cyclic voltammetry (Fig. 4). Only oxidation peaks were observed, indicating that the oxidation of caffeine was a totally irreversible electrode process. Along with the increase of the scan rate, the oxidation peak currents of caffeine increased gradually, and the relationship of the oxidation peak current with the square root of the scan rate were established with linear regression equations as I (μA) = 6.686 + 37.906 $\upsilon^{1/2}$ (R = 0.998) in the range of 20 to 350 mV s^{-1}, which indicated that the electrooxidation of caffeine was a diffusion-controlled process. With increasing scan rate, the anodic peak potential at the CTAB–Gr/GCE slightly shifted positively. For an irreversible system, at a higher scan rate the relationship between E_{pa} (absolute potential at the oxidation peak) and ln υ should submit to the equation:[38]

$$E_{pa} = (E + RT)/(1 - \alpha)nF \times \{0.78 + \ln(D_R^{1/2}/K^0) + \ln[(1 - \alpha)nF\upsilon/RT]^{1/2}\}$$

In this work, the linear regression equation was expressed as follows: $E = 1.441 + 0.0279 \ln \upsilon$ (E is absolute potential in V, υ is in V s^{-1}, and R = 0.997), thus $RT/2(1 - \alpha)nF$ = 0.0279, where T is absolute temperature (K), α is the electron transfer coefficient, and nF is the number of electrons × Faraday constant). Letting n = 2,[1,35] α was estimated to be 0.77.

Determination of caffeine at the CTAB–Gr/GCE

Differential pulse voltammetry (DPV) is often used to make electrochemical measurements, owing to its high sensitivity and rejection of background current. The preparatory experiments were performed to choose the best parameters, such as pulse increment, pulse amplitude, pulse width, and pulse period. The optimized conditions were recorded as follows: pulse increment was 6 mV, pulse amplitude was 49 mV, pulse width was 20 ms, and pulse period was 60 ms.

Under the optimized conditions, the variation of peak currents with different concentrations of caffeine was measured by DPV (Fig. 5). The peak currents of caffeine were linearly related to the concentration over the range of 3.0 × 10^{-7} to 8.0 × 10^{-6} mol L^{-1} and 8.0 × 10^{-6} to 1.0 × 10^{-4} mol L^{-1}, and the regression equations were I (μA) = 4.233 + 1.289 c (μmol L^{-1}) (R = 0.995) and I (μA) = 13.847 + 0.288 c (μmol L^{-1}) (R = 0.997), respectively. According to the following equation: LOD = 3.3 × ($s_{y/x}/b$),[39] where $s_{y/x}$ is the residual standard deviation, and b is the slope of the calibration plot, the limit of detection was calculated to be 9.1 × 10^{-8} mol L^{-1} (signal-to-noise ratio = 3). A comparison of the different electrochemical methods for the determination of caffeine is summarized in Table 1. The method for the determination of caffeine proposed herein shows high sensitivity and a wide linear range, and is suitable to be the most commonly used analytical method for detecting low concentrations of caffeine.

Stability and reproducibility of the CTAB–Gr/GCE

To examine the stability and repeatability of the developed method, the direct electrochemistry of CTAB–Gr/GCE was investigated by CV. The peak current of CTAB–Gr/GCE stayed almost unchanged when the electrode undergone successive potential scans between 600 and 1500 mV in the presence of 2.0 × 10^{-5} mol L^{-1} caffeine in 0.01 mol L^{-1} H_2SO_4. After 100 cycles of potential scanning, the anodic peak current decreased by 4.9%. When storing in a refrigerator (4 °C) for 20 days, 95.1% of its initial current response was obtained, indicating that the CTAB–Gr/GCE has long-term stability. Moreover, under the same preparing conditions, the relative standard deviation (RSD) of the peak current was 5.1% for 5 different CTAB–Gr/GCEs. This indicated good reproducibility for the method of construction of the sensor.

Interference

We investigated interference from glucose, glycine, citric acid, sucrose, fructose, aminoacetic acid, L-tyrosine, and catechin, which may be present in the soft-drink samples. The electrochemical sensor was separately exposed to two different incubating solutions of 20 μmol L^{-1} caffeine: one with interference and the other without. The results were shown in Table 2, which indicated that the selectivity of the as-prepared sensor was acceptable within experimental error.

Analysis of real samples

To evaluate the validity of the proposed method, CTAB–Gr/GCE was applied to determine the caffeine content of the soft-drink samples. Table 3 shows a comparison of the detection performance of sensor developed here and the other methods. Data were presented as the average of 4 trial replicates ± SD. The results are in agreement with the value achieved by using UV–vis spectrophotometry and HPLC, as well as the regulation of I (μA) = 13.847 + 0.288 c (μmol L^{-1}) ($R = 0.997$). According to the results, it was obvious that caffeine in the soft-drink samples could be measured using the present sensor.

To test the reliability of the measurements, a standard addition method was adopted to determine the caffeine levels in cola beverage samples spiked with caffeine standard solution. The results are listed in Table 4. The recoveries were in the range of 98.1%–102.3%. It was in accordance with the result obtained by using UV–vis absorption spectrophotometry and HPLC, which indicated good accuracy of the developed method.

Conclusions

In this work, a novel electrochemical sensor was fabricated based on a CTAB–Gr/GCE modified GCE for the sensitive determination of caffeine. The developed sensor shows an excellent electrocatalytic activity towards the oxidation of caffeine. The CTAB–Gr/GCE obviously improves the sensitivity of the electrode towarts caffeine, and has a low detection limit. The results were attributed to the specific characteristics of Gr. The developed biosensor exhibited a wide linear detection range, acceptable reproducibility, high sensitivity, long-term stability, and a low detection limit. The proposed method was further used for the detection of caffeine in soft-drink samples with satisfactory results. This work demonstrated that the proposed CTAB–Gr modification was highly useful for bioelectrochemical and biosensing applications.

Résumé : Dans ce travail, nous avons réalisé une étude théorique concernant les réactions d'addition de l'ozone sur les doubles liaisons des molécules des terpènes tels que le terpinolène **1**, le β-phellandrène **2** et le limonène **3**. En nous basant sur la méthode de calcul DFT (« density functional theory ») avec la base standard 6–31G(d) et les deux fonctionnelles BPW91 et B3LYP, nous avons discuté, du point de vue thermodynamique et orbitalaire, la possibilité et la stéréosélectivité de ces réactions. Les états de transition des réactions entre la molécule de l'ozone et les molécules des terpènes **1**, **2** et **3** ont été déterminés.

Mots-clés : terpènes, limonène, β-phellandrène, terpinolène, méthode DFT (density functional theory).

Abstract: In this work, we conducted a theoretical study on the addition reactions between ozone and double bonds of terpene molecules such as terpinolene **1**, β-phellandrene **2**, and limonene **3**. Based on the DFT (density functional theory) calculation method with the standard basis set 6–31G(d) and the two functional bases such as BPW91 and B3LYP, we discuss, from thermodynamic and orbital points of view, the possibility and the stereoselectivity of these reactions. The transition states of reactions between the ozone molecule and the terpene molecules **1**, **2**, and **3** have been calculated and discussed.

Key words: terpenes, limonene, β-phellandrene, terpinolene, DFT (density functional theory) method.

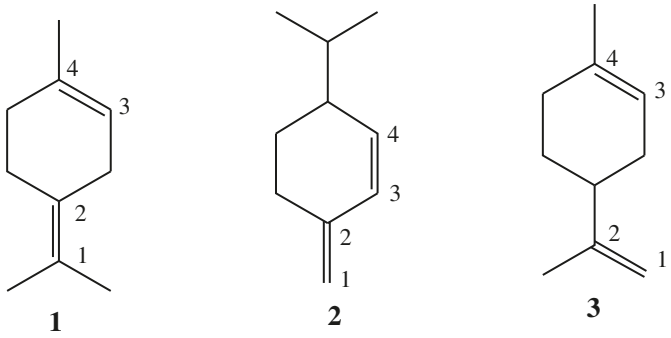
[Journal translation]

Introduction

Les terpènes sont des hydrocarbures de formule brute $(C_5H_8)_n$. Ces hydrocarbures se trouvent généralement dans les végétaux. Plusieurs études expérimentales et théoriques ont été réalisées sur l'ozonolyse des molécules des terpènes.[1–3] Les réactions des terpènes avec l'ozone ont pour première étape l'addition d'ozone sur la double liaison. Ce qui entraîne la formation d'un intermédiaire appelé le molozonide. Ce molozonide s'ouvre pour conduire à la formation d'un composé carbonylé et d'un intermédiaire biradicalaire dit de Criegee.[3] Ensuite par réarrangement interne de l'intermédiaire de Criegee, on observe la formation des composés tels que des aldéhydes, des cétones et des acides carboxyliques. À titre d'exemples, ces différentes étapes se trouvent dans la réaction de l'α-pinène avec l'ozone.[2]

Nous avons trouvé intéressant d'effectuer une étude théorique sur les réactions d'addition de l'ozone sur les doubles liaisons des molécules de terpènes. Pour mettre cette étude en évidence, nous avons choisi des molécules de terpènes de formule brute $C_{10}H_{16}$ qui possèdent chacune deux doubles liaisons, une première double liaison C1=C2 se trouve à l'extérieur du cycle à 6 carbones et une deuxième double liaison C3=C4 se trouve dans le cycle (fig. 1). Ces molécules sont appelées le terpinolène **1**, le β-phellandrène **2**, le limonène **3**.

Figure 1.



Dans ce travail, nous avons comparé la réactivité de ces deux doubles liaisons C1=C2 et C3=C4 appartenant à une même molécule de terpène vis-à-vis de la molécule de l'ozone **4** (fig. 2). Dans chaque cas de ces réactions, nous avons vérifié que ces réactions sont sous le contrôle des orbitales frontières. Enfin, nous avons étudié du point de vue thermo-

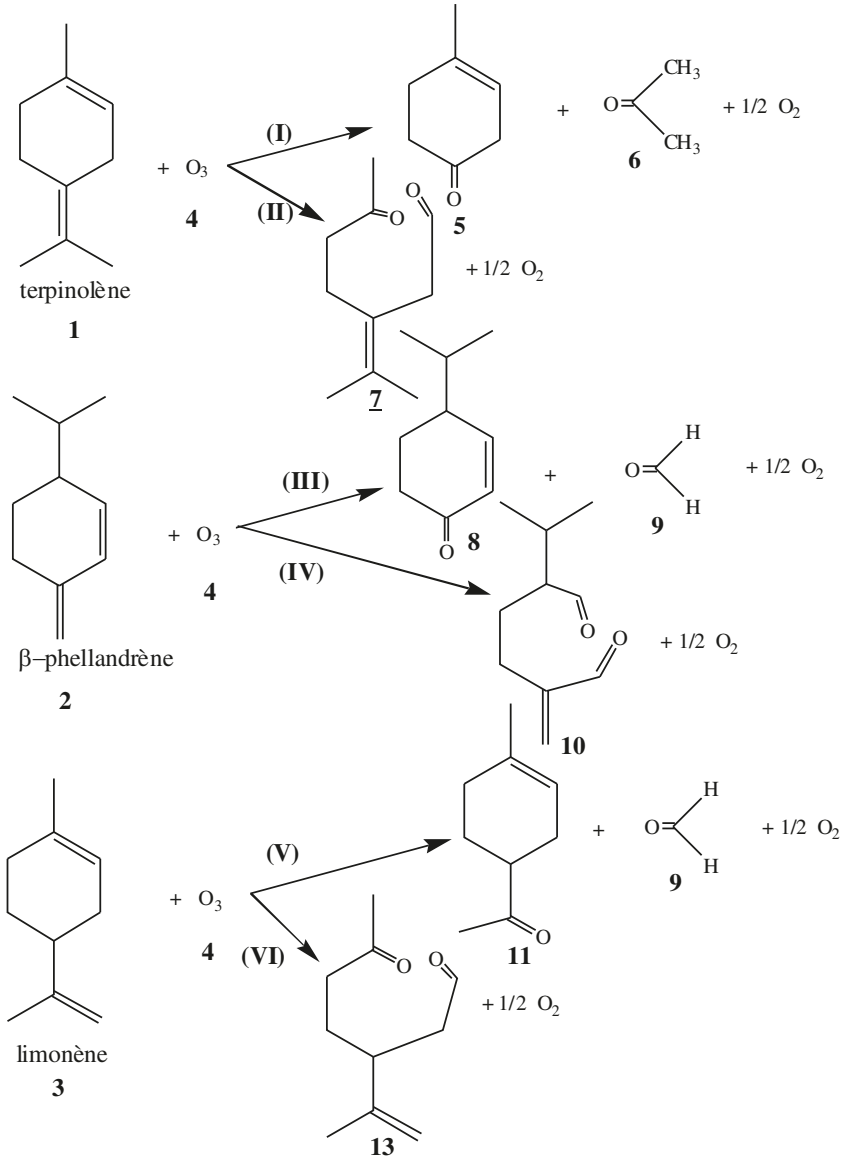
Figure 2.



dynamique et cinétique la possibilité et la stéréosélectivité de ces réactions.

Les méthodes de calcul

Cette étude a été réalisée en utilisant le programme GAUSSIAN 03.[4] Les calculs ont été effectués au niveau DFT (« density functional theory ») avec la base standard 6–31G(d). Nous avons utilisé deux types de fonctionnelles : une de type GGA tels que BPW91[5,6] et l'autre de type hybride tels que B3LYP.[5,7] En effet, il a été établi que cette méthode de calcul DFT est une des plus performantes pour ce type de molécules organiques.[8] Les calculs de fréquences vibrationnelles harmoniques ont été exécutés pour vérifier la nature des points stationnaires. Dans le cas d'absence de fréquence imaginaire, les points fixes sont classés comme des minima. Pour chaque état de transition, nous avons trouvé une seule fréquence imaginaire.[9] Afin de nous assurer que les états de transition sont corrects, nous avons déterminé (l'IRC « intrinsic reaction coordinate ») à chaque état de transition de réaction.[10]

Résultat et discussion

Étude thermodynamique

Nous avons étudié du point de vue thermodynamique la possibilité et la stéréosélectivité des réactions d'additions de l'ozone **4** sur les molécules de terpène tels que le terpinolène **1**, le β-phellandrène **2**, le limonène **3** (fig. 2). Dans le but de comparer la réactivité de ces molécules de terpènes vis-à-vis de la molécule de l'ozone **4**, nous avons déterminé dans les conditions standard de température et de pression (T = 298,15 K; P = 1 atm (1 atm = 101,325 kPa)) les variations d'énergie réactionnelle ΔEr, les variations d'enthalpie réactionnelle ΔHr, les variations d'enthalpie libre réactionnelle ΔGr et le ZPE (« zero point energy ») qui correspond aux réactions I, II, III, IV, V et VI.

Comme le montre le tableau 1, les variations d'enthalpie

libre réactionnelle ΔGr sont toutes négatives, par conséquent ces réactions sont possibles et favorisées thermodynamiquement. De plus, nous avons remarqué que les valeurs de la variation d'enthalpie libre réactionnelle ΔGr qui correspond aux réactions I, III et V sont respectivement supérieures en valeur absolue aux valeurs de la variation d'enthalpie libre réactionnelle qui correspond aux réactions II, IV et VI. Ce qui nous a permis de dire que les réactions I, III et V sont respectivement plus stables thermodynamiquement que les réactions II, IV et VI. Par conséquent, les doubles liaisons de type C1=C2 des molécules des terpènes **1**, **2** et **3** sont respectivement plus réactives que les doubles liaisons de type C3=C4 appartenant à ces mêmes molécules. De plus, nous avons remarqué que la réaction I est plus favorisée thermodynamiquement que les autres réactions II, III, IV, V et VI, puisque nous avons trouvé une valeur d'enthalpie libre réactionnelle plus importante en valeur absolue que celle qui correspond aux réactions II, III, IV, V et VI.

De la même manière, nous avons trouvé que les valeurs de la variation de l'énergie ΔEr qui correspondent aux réactions I, III et V sont respectivement supérieures en valeur absolue aux valeurs de la variation de l'énergie ΔEr qui correspondent aux réactions II, IV et VI. Ce qui confirme de nouveau que la liaison C1=C2 des molécules des terpènes **1**, **2** et **3** est plus réactive que la double liaison C3=C4 de ces mêmes molécules de terpènes. Par conséquent, les réactions I, III et V sont respectivement plus stables thermodynamiquement que les réactions II, IV et VI.

Étude des orbitales frontières

Nous avons déterminé les énergies de la LUMO (moléculaires inoccupées les moins élevés) et de la HOMO (moléculaires occupées les plus élevés) de l'ozone **4** ainsi que les énergies de la LUMO et de la HOMO des molécules des terpènes tels que le terpinolène **1**, le β-phellandrène **2**, le limonène **3** (voir tableau 2). D'après la théorie des orbitales frontières, lors de l'intéraction entre deux molécules, les orbitales frontières à considérer sont la HOMO de l'une et la LUMO de l'autre, choisies de telle sorte que l'écart énergétique ΔE qui les sépare soit le plus faible possible.[11] Comme le montre la fig. 3, le diagramme orbitalaire donne une bonne

Tableau 2. Les énergies (eV) de la moléculaires inoccupées les moins élevés (LUMO) et de la moléculaires occupées les plus élevés (HOMO) des molécules des terpènes **1**, **2** et **3** et de la molécule de l'ozone **4**.

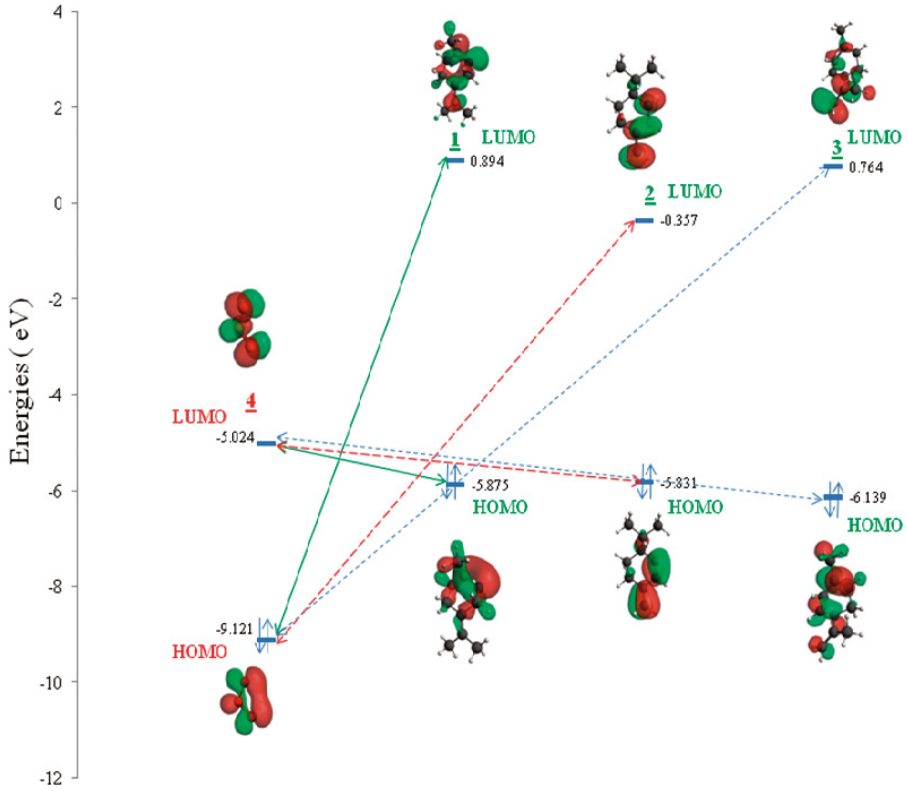
Produit	LUMO	HOMO	μ^{12}	η^{12}	ω^{12}
B3LYP/6–31G(d)					
O_3	–5,024	–9,121	–7,072	4,096	6,105
1	0,894	–5,875	–2,490	6,769	0,458
2	–0,357	–5,831	–3,094	5,474	0,874
3	0,764	–6,139	–2,687	6,903	0,523
BPW91/6–31G(d)					
O_3	–5,830	–7,489	–6,659	1,659	13,367
1	0,014	–4,965	–2,475	4,979	0,615
2	–1,183	–5,019	–3,101	3,836	1,253
3	–0,143	–5,218	–2,681	5,074	0,708

indication qualitative quant à la réactivité de notre système. Nous avons remarqué que l'intéraction principale se fait entre l'énergie de la LUMO de l'ozone et l'énergie de la HOMO des molécules des terpènes **1**, **2** et **3**, puisque nous avons observé un recouvrement favorable entre les orbitales de la LUMO de l'ozone et les orbitales de la HOMO de ces molécules **1**, **2** et **3**. De plus, nous avons remarqué que la variation d'énergie ΔE entre la LUMO de l'ozone **4** et la HOMO de terpinolène **1** est inférieure à la variation d'énergie ΔE entre la LUMO de l'ozone **4** et la HOMO de limonène **3**. Ce qui explique bien que la réaction entre l'ozone **4** et le terpinolène **1** est plus favorisée que dans le cas des réactions entre l'ozone **4** et le limonène **3**.

Nous avons par la suite déterminé les valeurs de l'électrophilicité global $\omega = \mu^2/(2\eta)^{12}$ de ces molécules de terpènes **1**, **2** et **3** (tableau 2). Pour déterminer cet électrophilicité, nous avons calculé le potentiel chimique ($\mu \approx (E_{HOMO} + E_{LUMO})/2$) qui est une valeur négative[12] et la dureté chimique $\eta \approx (E_{LUMO} - E_{HOMO})^{12}$ pour ces molécules.

Comme le montre le tableau 2, nous avons trouvé une valeur importante de l'électrophilicité pour la molécule de l'ozone **4** (ω = 6,105°; au niveau de calcul B3LYP/6–31G(d)). Par contre, les valeurs de l'électrophilicité des molécules de terpènes **1**, **2** et **3** sont moins importantes que celle de l'ozone

Figure 3. Diagramme orbitalaire des molécules des terpènes **1**, **2** et **3** et la molécule de l'ozone **4**. Énergies en eV, la valeur de l'isocontour = (0,002 unités atomiques).



4. De plus, la valeur de l'électrophilicité du terpinolène **1** est moins importante que la valeur de l'électrophilicité du limonène **3** qui est moins importante que celle du β-phellandrène **2**.

Ces résultats, nous ont permis de dire que la réaction d'addition de l'ozone **4** sur le terpinolène **1** est plus favorisée que la réaction entre l'ozone **4** et le limonène **3**, qui est plus favorisée que la réaction entre l'ozone **4** et le β-phellandrène **2**. Ces résultats confirment bien les résultats trouvés précédemment par l'étude thermodynamique.

Calcul des états de transition

Nous avons optimisé les états de transition de la réaction d'addition de l'ozone **4** sur le terpinolène **1**. Nous avons obtenu quatre conformations des états de transitions **5***(endo), **5***(exo), **7***(endo) et **7***(exo) : Les états de transitions **5*** (endo) et **5***(exo) obtenus respectivement avec une approche de l'ozone en endo de la double liaison C1=C2 de la molécule de terpinolène **1** et avec une approche de l'ozone en exo de la double liaison C1=C2 de terpinolène **1**; Les états de transitions **7***(endo) et **7***(exo) obtenus respectivement avec une approche de l'ozone en endo de la double liaison C3=C4 de terpinolène **1** et avec une approche de l'ozone en exo de la double liaison C3=C4 de terpinolène **1** (fig. 4).

Les calculs théoriques montrent que la formation des composés (**5** + **6**) est favorisée par rapport à la formation du composé **7** (fig. 4). En utilisant les méthodes de calculs DFT/B3LYP et DFT/BPW91 avec la base standard 6–31G(d), nous avons trouvé pour la formation du composé **7** une grande énergie d'activation respectivement de 3,57 et 8,36 kcal mol^{-1} aux niveaux du calcul cités précédemment. Ces valeurs sont plus grandes que celles trouvées pour les états de transition conduisant à la formation des composés (**5** + **6**) (tableau 3). Ce qui confirme de nouveau que la double liaison C1=C2 de la molécule du terpinolène **1** est plus réactive que la double liaison C3=C4 de cette même molécule **1**. De la même manière, nous avons optimisé les états de transition des réactions d'addition de l'ozone **4** sur les molécules de β-phellandrène **2** et de limonène **3**. Comme le montre le tableau 3, nous avons obtenu quatre conformations des états de transitions dans chaque cas de ces réactions. Nous avons obtenu les états de transitions **8***(endo) et **8***(exo) respectivement par une approche de l'ozone **4** en endo et en exo de la liaison C1=C2 du β-phellandrène **2**. Les états de transitions **10***(endo) et **10***(exo) sont obtenus respectivement par une approche de l'ozone **4** en endo et en exo de la liaison C3=C4 du β-phellandrène **2**. Nous avons aussi obtenu les états de transitions **11***(endo) et **11***(exo) respectivement par une approche de l'ozone **4** en endo et en exo de la liaison C1=C2 de la molécule du limonène **3**. Nous avons obtenu les états de transitions **13***(endo) et **13***(exo) respectivement par une approche de l'ozone **4** en endo et en exo de la liaison C3=C4 de la molécule du limonène **3**. Comme le montre le tableau 3, nous avons remarqué que la valeur de l'énergie de l'état de transition **5***(endo) est moins importante que les valeurs des états de transitions qui correspondent aux **8***(endo) et **11***(endo). Ce qui explique que la formation du composé **5** est plus favorisée que la formation des composés **8** et **11**. Nous avons aussi remarqué que dans chaque cas de ces réactions, les états de transitions de la forme endo sont toujours inférieurs aux états de transitions de la forme exo. De plus les valeurs des états de transitions **8***(endo) et **8***(exo) sont inférieures à celles des états de transitions **10***(endo)

et **10***(exo). Les valeurs des états de transitions **11***(endo) et **11***(exo) sont aussi inférieures à celles des valeurs des états de transitions **13***(endo) et **13***(exo). Ceci confirme bien que la double liaison C1=C2 des molécules **1**, **2** et **3** est respectivement plus réactive que la double liaison C3=C4 de ces mêmes molécules vis-à-vis de la molécule de l'ozone **4**.

Nous avons comparé nos résultats théoriques avec des études antérieures.[3,13] Ces études ont été réalisées sur l'oxydation des flavonoïdes et l'ozonolyse du limonène. Nous avons remarqué que nos résultats sont très proches des résultats trouvées par Jiang et al.[3]

La géométrie des états de transition **5***(endo) et **7***(exo) est présentée sur la fig. 5.

Nous avons comparé les longueurs de liaisons en formation; on constate que la liaison C_2–O_2 est plus courte que la liaison C_1–O_1. Nous avons aussi trouvé que les longueurs de liaisons en formation C_4–O_2 sont plus courtes que les liaisons C_3–O_1 (tableau 4). Ces distances sont assez proches de celle trouvée par Jiang et al.[3] pour la réaction entre l'ozone **4** et le limonène **3**.

Conclusion

Dans ce travail, nous avons étudié théoriquement les réactions d'addition de l'ozone **4** sur les deux doubles liaisons C1=C2 et C3=C4 appartenant à une même molécule de ter-

pène, tels que le terpinolène **1**, le β-phellandrène **2** et le limonène **3**.

Les résultats de calculs théoriques par les méthodes DFT/B3LYP et DFT/BPW91 avec la base standard 6–31G(d) montrent que ces réactions sont possibles et favorisées thermodynamiquement. De plus, nous avons trouvé que la réaction entre l'ozone **4** et le terpinolène **1** est plus stable thermodynamiquement que les réactions entre l'ozone **4** et les autres molécules de terpène, tels que le β-phellandrène **2** et le limonène **3**.

Les résultats théoriques montrent aussi que dans chaque cas des molécules de terpènes **1**, **2** et **3**, la double liaison C1=C2 est toujours plus réactive que la double liaison C3=C4 vis-à-vis de la molécule de l'ozone **4**. Les calculs des états de transition montrent que les produits cinétiques des réactions d'addition de l'ozone 4 sur les molécules **1**, **2** et **3** sont les produits provenant de l'addition de l'ozone **4** sur la double liaison C1=C2 et non pas les produits provenant de l'addition de l'ozone **4** sur la double liaison C3=C4. De plus, pour chaque molécule des terpènes **1**, **2** et **3**, les produits provenant par une approche de l'ozone **4** en endo de la double liaison C1=C2 sont plus favorisés que ceux obtenus par une approche en exo de l'ozone sur la double liaison C1=C2.

Abstract: Formal total synthesis of *ent*-codeinone and *ent*-codeine was accomplished via the total synthesis of *ent*-neopinone attained in 14 steps from β-bromoethylbenzene. The key steps included (*i*) enzymatic dihydroxylation of β-bromoethylbenzene with *E. coli* JM109 (pDTG601a), an organism that overexpresses toluene dioxygenase, (*ii*) a Heck reaction to establish C-13 stereogenic center, (*iii*) aldol condensation, and (*iv*) 1,6-conjugate addition of the ethylamino side chain to C-9. Several other modes of construction of the C-9 and C-14 centers were also investigated: Mannich cyclization, and aza-Prins reaction. The synthesis of *ent*-codeinone was formalized by intersecting Fukuyama's recently published approach. Experimental and spectral data are provided for all new compounds.

Key words: synthesis of morphine alkaloids, *ent*-codeinone synthesis, *ent*-neopinone synthesis, enzymatic dihydroxylation of aromatics, Heck reaction.

Résumé : On a réalisé une synthèse totale formelle de l'*ent*-codéinone et de l'*ent*-codéine par le biais d'une synthèse totale de l'*ent*-néopinone qui a été obtenue en quatorze étapes à partir du β-bromoéthylbenzène. Les étapes clés comportent (*i*) une dihydroxylation enzymatique du β-bromoéthylbenzène à l'aide d'*E. coli* JM109 (pDTG601a), un organisme qui imite la dioxygénase du toluène, (*ii*) une réaction de Heck pour établir le centre stéréogénique en C-13, (*iii*) une condensation aldolique et (*iv*) une addition 1,6-conjuguée de la chaîne latérale éthylamino sur le site C-9. On a aussi examiné plusieurs autres modes de construction des centres C-9 et C-14, dont une cyclisation de Mannich et une réaction aza-Prins. La synthèse de l'*ent*-codéinone a été formalisée en procédant à une intersection avec la méthode de Fukuyama publiée récemment. Les données expérimentales et spectrales pour tous les nouveaux produits.

Mots-clés : synthèse d'alcaloïdes de la morphine, synthèse de l'*ent*-codéinone, synthèse de l'*ent*-néopinone, dihydroxylation enzymatique de produits aromatiques, réaction de Heck.

[Traduit par la Rédaction]

Introduction

There has not been a shortage of interest in new synthetic approaches to morphine (**1**) in the last decade. The most recent review, published in 2011,[1] summarized all published syntheses of morphine and its congeners (there were nine syntheses in total, including the most recent synthesis of codeine (**2**)[2]), (Fig. 1), since the last major review on this topic, which appeared in 2005.[3] Altogether, more than 25 total and formal syntheses of the opiate alkaloids have been reported since the first milestone total synthesis by Gates in 1952.[4,5]

Given the rich chemical[6–8] as well as societal[9–11] history of morphine and the impact that this molecule has had on the human condition, it should not be surprising that the interest in designing a practical synthesis of this unique compound has not waned. Two hundred years after its isolation by Serturner,[12,13] chemists are still designing new and imaginative routes to this challenging molecule.[14–19]

In 2009 we published the enantiodivergent synthesis of codeine that originated in the enzymatically derived *cis*-diol **3** produced from β-bromoethylbenzene by the whole-cell fermentation with the recombinant organism *E. coli* JM109 (pDTG601a), capable of over-expressing toluene dioxygenase.[20] In that particular approach, a series of Heck reactions and a hydroamination were used to complete the synthesis of codeine (**1**) and its enantiomer.[21,22] One of the advanced intermediates used in that synthesis was aldehyde **5**.

This aldehyde was also easily converted to a homologue **6**

via a Wittig reaction and transketalization. We envisioned three different approaches, shown in Fig. 2, emanating from this compound, which was prepared on intermediate scale in eight steps from diol **3**.

In the first approach we considered a C-9 and C-14 closure by an aza-Prins reaction of the iminium salt **7** derived from the condensation of the ethylamino side chain with the masked aldehyde in **6**. Similarly, the oxidized version of this compound, enone **8** (depicted in its enolized form in Fig. 2), was expected to undergo a γ-Mannich closure to the iminium species. The third approach assumed the formation of the dienone **9** from the aldehyde and the C-ring enone, to be followed by a 1,6-conjugate addition of the amine at C-9, which closure would yield the more energetically favored enone. This type of strategy was used by Fuchs to access the natural enantiomer of morphine.[23–26] In this paper, we report the outcome of these approaches and the total synthesis of *ent*-neopinone, as well as formal total synthesis of *ent*-codeinone and *ent*-codeine via the intermediate dienone **9**.[27]

Results and discussion

The inspiration for the approach to codeine depicted in Fig. 2 came from Wiesner's zizanoic acid synthesis published in 1972.[28] In one of his many ingenious solutions to the synthetic problems of that particular era, he conceived the construction of tricyclic enone **12**, the key intermediate in his synthesis of zizanoic acids, from the β,γ-deconjugated enone

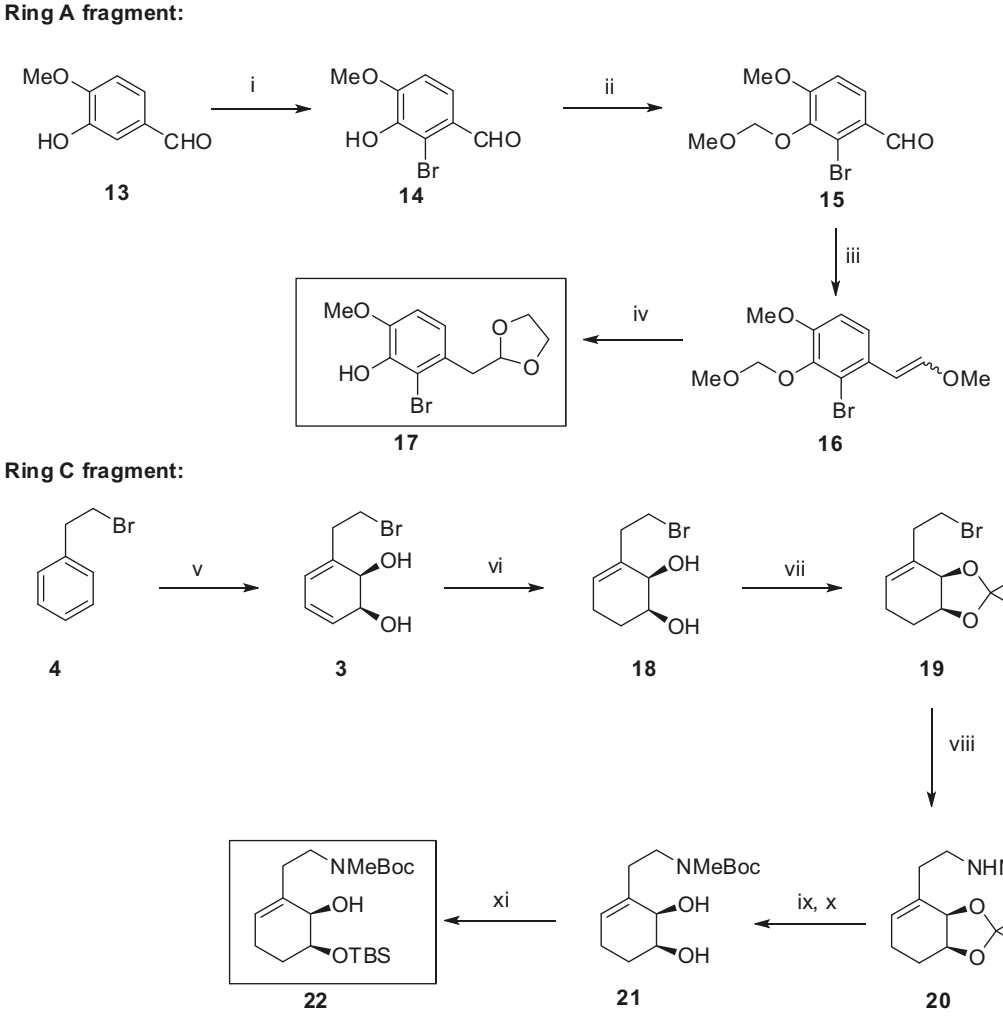
Scheme 1. Reagents and conditions: (*i*) NBS, $CHCl_3$, reflux, 68%; (*ii*) MOM-Cl, *i*Pr_2NEt, CH_2Cl_2, 4 °C; (*iii*) $ClPh_3PCH_2OCH_3$, *t*BuLi, THF, –78 °C to 4 °C; (*iv*) $(CH_2OH)_2$, *p*TsOH, THF, reflux, 76% from **14**; (*v*) *E. coli* JM109 (pDTG601a), 10–15 g L^{-1} h^{-1}; (*vi*) potassium azodicarboxylate, AcOH, MeOH, 0 °C, 83%; (*vii*) 2,2-dimethoxypropane, acetone, *p*TsOH, 80%; (*viii*) NH_2Me, K_2CO_3, THF, sealed tube, 90%; (*ix*) 3 mol L^{-1} HCl, EtOH; (x) Boc_2O, $NaHCO_3$, EtOH, 72% (2 steps); (*xi*) TBSCl, imidazole, CH_2Cl_2, –78 °C to 25 °C, 80%–88%.



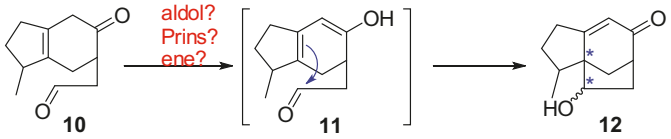
10 under both acid- and base-catalyzed conditions, as shown in Fig. 3 in an abbreviated manner.

Whereas the stereochemical outcome of these closures differed slightly depending on the conditions of the reaction, the mechanism of the closure could be interpreted in a number of ways, each of which would lead to the same product.[29,30] Thus, whether the closures proceeded via equilibrating aldol reactions in the enolized version **11**, the Prins reaction in **10**, or an ene reaction between the aldehyde and the olefin in **10**, in each case the final outcome would be enone **12**.

When we noticed the similarity in connectivity of the two asterisked carbons in **12** (Fig. 3) with C-9 and C-14 of the morphine skeleton, we saw the opportunity to explore the reactive options of intermediates such as **7** and **8**, whose functional disposition closely resembles the compounds used by Wiesner.[28]

The synthesis of the key protected aldehyde **6** required the connection of ring A and ring C fragments via Mitsunobu reaction, followed by Heck cyclization, to establish the C-13 stereogenic center. The synthesis of both fragments, adopted from our previous synthesis of codeine and its enantiomer,

Fig. 3. Wiesner's strategy toward the construction of a tricyclic core of zizanoic acid.

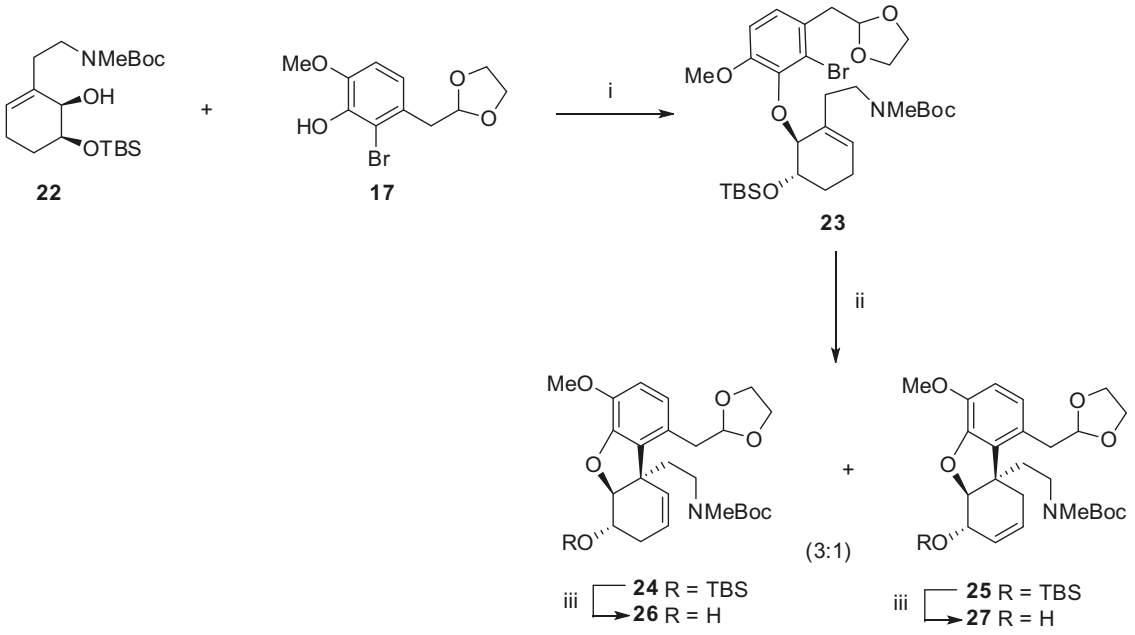


proceeded at medium scale as shown in Scheme 1 and was subjected to a moderate degree of optimization.

The A-ring derives from the isovanillin (**13**), which was brominated with *N*-bromo-succinimide (NBS) to provide bromoisovanillin **14**. Subsequent protection of the hydroxy group as its MOM ether furnished **15**, which was converted to the enol ether **16** by a Wittig reaction using the ylide generated from (methoxymethyl)triphenylphosphonium chloride. Treatment of the resulting crude mixture of (*E*)- and (*Z*)-enol ethers with ethylene glycol under acidic conditions furnished phenol **17** in 48% overall yield from **13**.

The synthesis of the intermediate comprising the C-ring started from (2-bromoethyl)benzene (**4**), which was converted

Scheme 2. Reagents and conditions: (*i*) DIAD, Bu_3P, THF, 0 °C to 25 °C, 76% (10 g scale); (*ii*) $Pd_2(dba)_3$, $(tBu)_3P$, K_2CO_3, toluene, 110 °C, 85%–95%; (*iii*) TBAF, THF, –78 °C to 25 °C, 83%–85%.



to diol **3** by microbial dihydroxylation using *E. coli* JM109 (pDGT601A) in space-time yields of 10–15 $g\,L^{-1}\,h^{-1}$ on 15 L fermentor scale, as described previously.[21] Diimide reduction of the sterically less hindered double bond led to diol **18**, whose protection as its isopropylidene ketal gave **19**. Substitution of the bromine by $MeNH_2$ provided the methyl amine **20**. This was followed by the removal of the isopropylidene group and protection of the secondary amine as its Boc carbamate to afford diol **21**, whose regioselective silylation provided the key ring C fragment **22** in 31% overall yield from **3**. This optimized route to fragment **22** is more robust than the one we reported in the context of an earlier total synthesis of codeine.[22]

Following the preparation of the two fragments **17** and **22**, their union was accomplished by the Mitsunobu reaction, as shown in Scheme 2, to provide the aryl ether **23** in yields in the range of 76%–85% and on a maximum scale of 10 g. By-products from the large-scale Mitsunobu coupling isolated by chromatography included phenol **17** (8%) and its silylated derivative (4%). The latter compound likely resulted from the trans-silylation of the free phenol by the TBS ether **22** and (or) the product **23**.

To set the C-13 quarternary center, the aryl ether **23** was subjected to an intramolecular Heck coupling using $Pd_2(dba)_3$ with tri-*tert*-butylphosphine and K_2CO_3 in toluene[31–33] to provide an inseparable mixture of homoallylic and allylic TBS ethers **24** and **25** in an approximate 5:1 ratio and in 86% combined yield.[34] The minor allylic alcohol **25** is likely the product of palladium-mediated isomerization of the double bond (**24** → **25**). The mixture of **24** and **25** was treated with TBAF in THF to furnish alcohols **26** and **27**, respectively, which were separated by chromatography.

The two regioisomeric alcohols **26** and **27** obtained on desilylation were oxidized with IBX to the key intermediates ketone **28** and its conjugated isomer **29**, respectively (Scheme 3), which under either acidic or basic conditions should provide the same dienolate or dienolate anion to be tested in various cyclization schemes.

Treatment of the crude ketone **28** or enone **29** with trifluoroacetic acid resulted in a clean conversion to the [3.3.1] bicyclic adduct **30**, formed in 45%–55% yield over the two steps, and without the expected condensation of the secondary amine with the masked aldehyde as shown in Scheme 3. This was a disappointing turn of events, as it appeared that the conjugate addition of the free secondary amine occurred much faster than the formation of the required iminium species.

The precursors to the aza-Prins and Mannich cyclizations were generated from the protected aldehyde derivative **26** or, in the earlier approach, also from the enol ether equivalent **33**,[35] synthesized from aldehyde **5** by a Wittig reaction. Thus the enamine **32** was generated by treatment of **31** with trifluoroacetic acid, as shown in Scheme 4. Treatment of alcohol **26** with trifluoroacetic acid in CH_2Cl_2 resulted in a mixture of secondary amine **31** (49%–65%) and enamine **32** (10%–21%) in an approximate 3:1 ratio. Secondary amine **31** was smoothly converted to enamine **32** with treatment of oxalic acid in water, with a yield of 88%.

The cyclic enamine **32** was a minor product in the TFA-mediated deprotection of **26,** but was the exclusive product in the corresponding deprotection of **33** with TFA. The cyclic enamine proved reasonably stable to storage and manipulation. Reduction of **32** with cyanoborohydride provided amine **34**, and served to confirm the structure of the enamine.

With these results we turned to the investigations of the cyclizations proposed in Fig. 2. The summary of our attempts, most of which proved unsuccessful, is shown in Scheme 5.

Enamine **32** was subjected to Lewis-acid-catalyzed cyclizations to attempt the C-9/C-14 closure via the aza-Prins reaction of the iminium ion **7** (Scheme 5). All attempts resulted only in the recovery of the starting material and traces of

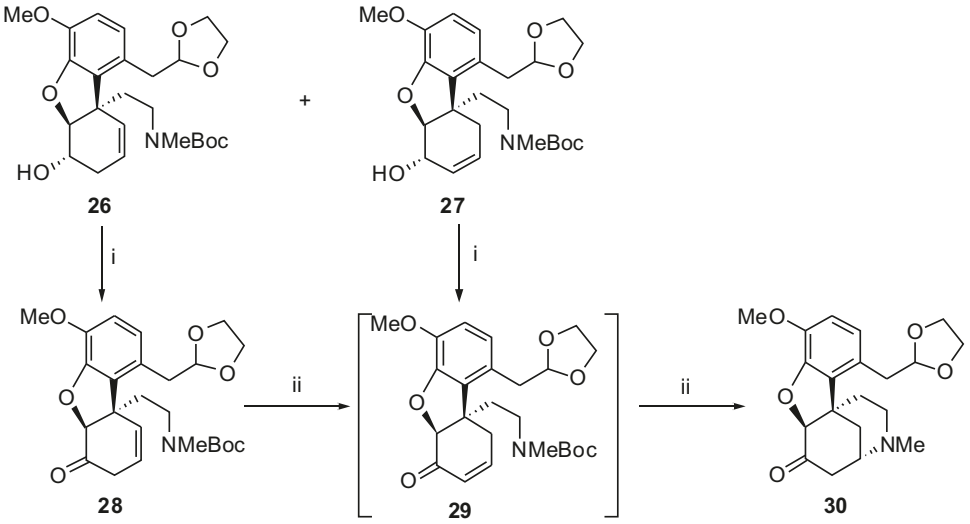
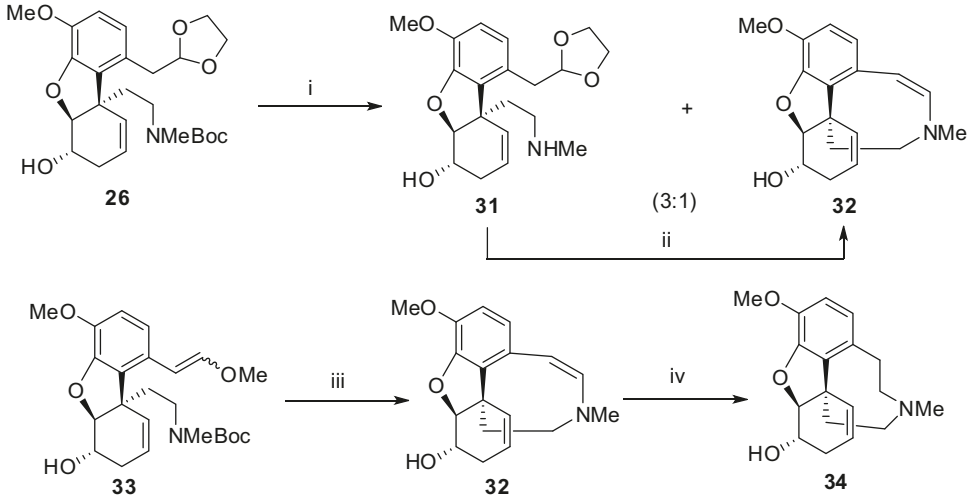
Scheme 3. Reagents and conditions: (*i*) IBX, AcOEt, reflux; (*ii*) TFA, CH_2Cl_2, 45%–55% (2 steps).



Scheme 4. Reagents and conditions: (*i*) TFA, CH_2Cl_2, 49%–65% of **31**, 10%–21% of **32**; (*ii*) oxalic acid, H_2O, 45 °C, 88%; (*iii*) TFA, CH_2Cl_2, 0 °C to 25 °C; (*iv*) $NaBH_3CN$, AcOH, MeOH, 0 °C to 25 °C, 41% (from **33**).



minor products that were not further identified. The presence of *ent*-isocodeine **35** (or its neopine isomer, with the olefin at C-8/C-14) was not detected by either TLC or HPLC analysis.

As mentioned above, the attempted generation of **8**, the precursor for the Mannich cyclization, failed and only the [3.3.1]bicyclic adduct **30** was formed, presumably via the α,β-conjugated isomer generated under the reaction conditions.

We were not able to produce intermediates, such as **36** or **38,** required for the enolized enone-iminium species **8** (Scheme 5) essential for the Mannich reaction. In addition, any attempts to establish an equilibrium between **39** and **38** also failed.

The free aldehyde **39** was obtained by treating **30** with aqueous oxalic acid at 40 °C (88%–92% yield), Fig. 4. Interestingly, when the hydrolysis was conducted with HCl in aqueous acetonitrile at pH 1 and 40 °C, a mixture of **39** and **40** was obtained in various ratios depending on the reaction time. When we subjected aldehyde **39** to HCl in aqueous acetonitrile, it was cleanly converted to **40** over 20 h. Benzaldehyde **40** exhibits a typical downfield shift of the CHO and aromatic CH signals in the ^{1}H-NMR spectrum, found at 9.91 ppm (CHO) and at 7.43 and 6.91 ppm (Ar CH), while the same signals of **39** resonate upfield, at 9.70 ppm (CHO) and at 6.79 and 6.66 ppm (Ar CH). We were interested in whether this "demethylenation" could be applied to other substrates, and therefore subjected the structurally related phenol **17** (Fig. 4) to the same conditions. Treatment of phenol **17** with aqueous oxalic acid at 40 °C afforded a mixture of homobenzaldehyde **41** and benzaldehyde **14** in a 3:1 ratio, while the reaction in aqueous acetonitrile in the presence of HCl afforded benzaldehyde **14** as the major product (**41/14,** 1:3.5). These results suggested that in addition to apparent solvent effects, there must be another factor affecting the outcome of this reaction. Indeed, degassing the HCl–H_2O–MeCN mixture, prior to the addition of phenol **17**, and stirring at 40 °C led to homobenzaldehyde **41** as the major product, accompanied by traces of **14**. When these reaction conditions (degassed HCl–H_2O–MeCN) were applied to the acetal cleavage in **30**, we isolated homobenzaldehyde **39** as the major product, with only traces of **40**. The proposed

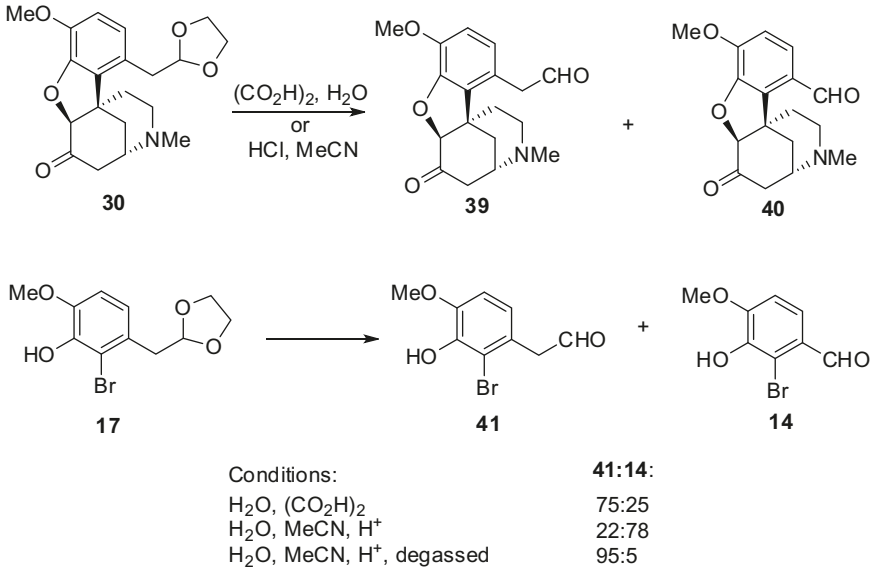
Fig. 4. Generation of byproducts during the hydrolysis of acetals **30** and **17**.



mechanism for the formation of benzaldehyde **40** is shown in Fig. 5. We speculate that in the presence of oxygen (Option A) the transformation likely involves an oxidation at the benzylic position leading to intermediate **42**, which is then converted, via **43**, to hydroperoxide **44**. Fragmentation of **44** then leads to benzaldehyde **40** and formic acid. The fact that trace amounts of benzaldehydes **40** and **14** were present even in the degassed oxygen-free reaction mixtures led us to propose an alternative mechanism shown in option B. This pathway would assume the formation of the acetonitrile adduct **47** from the readily enolisable **39** via the enol form **46**, followed by the formation of epoxide **48**. Opening of the oxirane ring with water generates **49** and the retro aldol reaction then leads to **40**. This option is indeed highly speculative as we did not isolate **51**, an expected by-product of this pathway, during the initial experiments. However, further studies of this transformation are warranted to assess both the mechanism as well as potential general utility.

Returning to the synthesis of *ent*-codeinone, we expected that base-catalyzed treatment of **39** would generate the desired dienone **9**, while acid catalysis would ultimately lead to the dienolate-iminium species **8**, as indicated in Scheme 5; however, neither of these attempts led to appreciable concentrations of the enone or dienone species. The presence of *ent*-codeinone or *ent*-neopinone **37** was not detected in the reaction mixtures. We were unable to solve the functional incompatibility issues between the hydrolysis of the acetal and the deprotection of the Boc group.

To test the feasibility of formation of dienone **9** (Scheme 5) we exchanged the Boc group in **26** for a more robust acetyl group in **52** (Scheme 6). Deprotection of **26** with TFA provided the secondary amine **31** whose acetylation gave **52**. Oxidation of **52** with IBX provided the deconjugated enone **53**, whose treatment under acidic conditions led to the formation of the inseparable mixture of diastereomeric alcohols **54** in 22% in a 1:1 ratio. The IR spectrum exhibited two bands corresponding to the OH groups. Presence of a sharp band at 3606 cm^{-1} and a broad band at 3386 cm^{-1} suggested that one diastereoisomer possessed free OH while the OH group of the other diastereoisomer participated in hydrogen bonding. This was supported also by the ^1H NMR spectrum in which only one diastereoisomer displayed two rotameric sets of signals, typical for amides. We assumed that the α-hydroxy diastereoisomer of **54**, the isomer having the OH and NMeAc groups on the same face, forms an intramolecular hydrogen bond favoring one of the rotamers. Isolation of **54** validated the aldol approach as the alcohols **54** would be convertible to the required dienone of type **9**.

As our work was nearing completion, Fukuyama[36] reported a conceptually identical approach to the natural enantiomer of morphine, using a derivative of type **54** bearing a DNS protecting group on the nitrogen atom, so we have decided to formalize our synthesis. Thus the problem of aldol cyclization and the ultimate 1,6-addition of the ethylamino side chain was solved in a similar way as was done in Fukuyama's synthesis. *ent*-Neopinone was prepared as shown in Scheme 7.

After generating the DNS protected amine **55**, we subjected it to the sequence used in the Fukuyama's synthesis, namely hydrolysis of the acetal with aqueous trifluoroacetic acid, intramolecular aldol reaction, and mesylation of the resulting hydroxy group. The repetition of the aforementioned sequence with the ethylene glycol acetal **55** provided lower yields than those reported for the route utilizing the dimethoxy acetal. The robust nature of the acetal in **56** required longer reaction times to generate the free aldehyde that would undergo the aldol reaction whose product was isolated as the mesylate **57**. The use of 1.2 equiv of MsCl and 1.5 equiv of Hünig's base (Fukuyama's conditions) in the reaction following the aldol closure led to isolation of **57** in only 6% yield from **55**. We speculated that traces of ethylene glycol present in the reaction mixture contributed to the low yield. Performing the mesylation with large excess of both MsCl (4.5 equiv) and Hünig's base (5 equiv) led directly to in situ elimination and a mixture of **58** and **59** was obtained in 42% and 13% yield, respectively, over the two steps from

55. Enantiomers of both **57** and **58** have been converted via neopinone and codeinone to (–)-codeine by Fukuyama,[36] thus their attainment completed the formal synthesis.

The desired dienone **58** was separated and treated with thioglycolic acid in the presence of triethylamine. NMR and TLC analysis of the reaction mixture confirmed the formation of *ent*-neopinone (**61**) accompanied by a small amount of *ent*-codeinone (**60**). For the purpose of direct comparison, a sample of neopinone was prepared from thebaine according to Rapoport's procedure,[37] and matched with the product of this reaction. Fukuyama[36] reported isomerization of neopinone obtained from the cyclization to codeinone followed by reduction of the latter to codeine. Thus the attainment of *ent*-neopinone also formalizes the synthesis of *ent*-codeinone and *ent*-codeine.

To ensure that the low yields obtained from acetal **55** were indeed the function of the robust protecting group, we decided to repeat the chemistry with Fukuyama's acetal, generated by treatment of **55** with *p*TsOH in MeOH at reflux (Scheme 8). Oxidation of **62** with IBX in AcOEt at 80 °C afforded ketone **63** having optical rotation of +25.5°, opposite to that of *ent*-**63** (–24.2°).[36] Treatment of **63** with aqueous trifluoroacetic acid, followed by mesylation afforded mesylate **57** in 28% and dienone **58** in 24% yield from **62**. The cyclization of **63** indeed provided higher yields of **57** and **58** than the corresponding reaction of the acetal **56**.

Fig. 5. Proposed mechanism for the formation of benzaldehyde **40**.

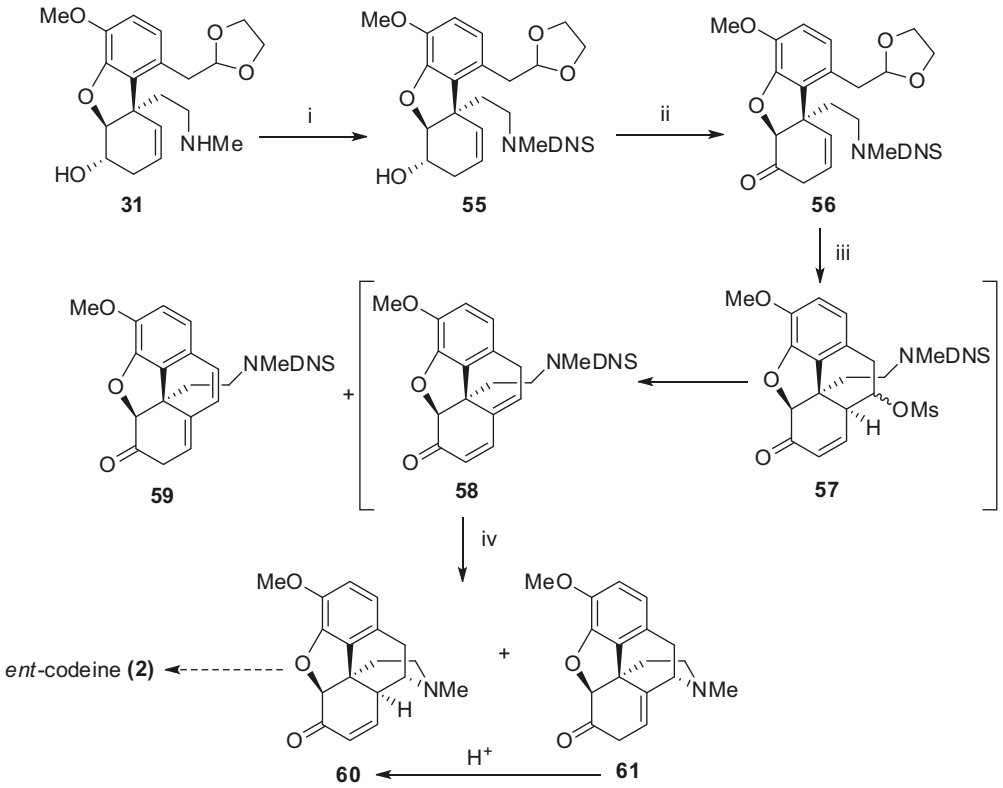
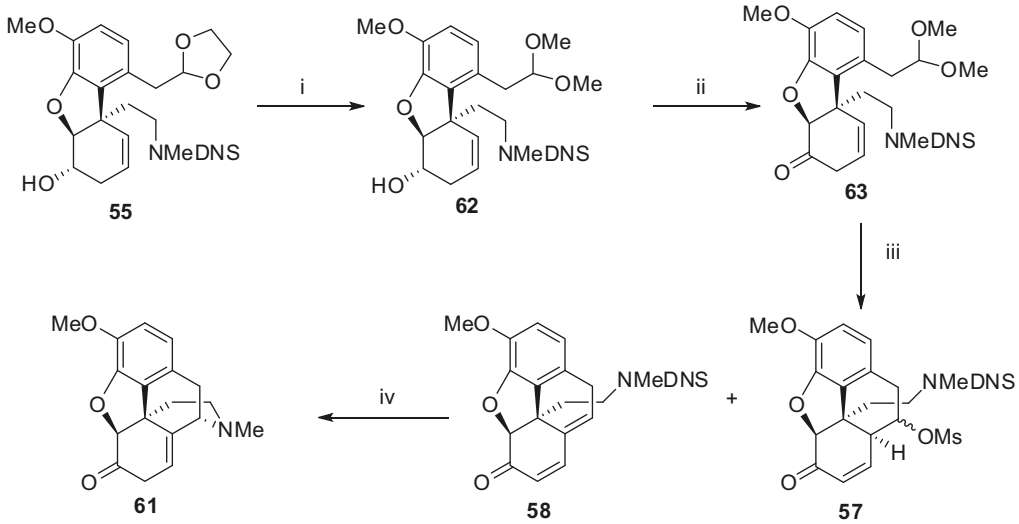
Scheme 7. Reagents and conditions: (*i*) 2,4-dinitrobenzenesulfonyl chloride, *i*Pr$_2$NEt, CH_2Cl_2 (51%); (*ii*) IBX, AcOEt, 80 °C; (*iii*) (*a*) 50% aqueous TFA, toluene, 50 °C, (*b*) MsCl (4.5 equiv), *i*Pr$_2$NEt (5 equiv), CH_2Cl_2, 0 °C (42% of **58** from **55**, 13% of **59** from **55**); (*iv*) thioglycolic acid, *i*Pr$_2$NEt, CH_2Cl_2, 0 °C .



Scheme 8. Reagents and conditions: (*i*) MeOH, *p*TsOH, reflux (86%); (*ii*) IBX, AcOEt, 80 °C; (*iii*) 50% aqueous TFA, toluene, 50 °C; MsCl *i*Pr$_2$NEt, CH_2Cl_2, 0 °C (24% of **58** from **62**, 28% of **57** from **62**); (*iv*) thioglycolic acid, *i*Pr$_2$NEt, CH_2Cl_2, 0 °C.



Treatment of the mixture of **57** and **58** with thioglycolic acid and Hünig's base, as reported by Fukuyama,[36] afforded a full conversion to *ent*-neopinone (**61**), matched with authentic samples.

Conclusions

ent-Neopinone was synthesized from β-bromoethyl benzene in 14 steps via enzymatic dihydroxylation, Heck closure to establish the C-13 stereogenic center, and 1,6-conjugate addition of the ethylamono side chain to C-9 of the dienone **9**, obtained by aldol cyclization. Attempts at intramolecular Mannich cyclizations or aza-Prins cyclizations to iminium species derived from enamines of type **32** or **36** proved unsuccessful. The synthesis of *ent*-neopinone by the route described also constitutes a formal synthesis of *ent*-codeinone and *ent*-codeine.

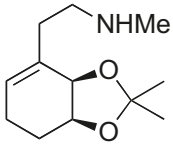
Experimental section

General

Reactions were carried out under inert atmosphere in oven-dried glassware unless stated otherwise. Solvents were distilled: CH_2Cl_2, DMF, iPr$_2$NEt, and pyridine from CaH_2; MeOH from magnesium methoxide; THF from Na/benzophenone; toluene from Na. Qualitative TLC was done with precoated silica gel aluminium sheets (EMD silica gel 60 F_{254}); detection by UV or by spraying with "CAM" solution (5 g of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, 1 g of $Ce(SO_4)_2$, 100 mL of 10% H_2SO_4) or 0.5% aqueous $KMnO_4$ solution followed by heating. Column chromatography was performed using silica gel SiliaFlash P60 from Silicycle (40–66 μm). Optical rotation was measured in a 1 dm cell at 20–25 °C and 589 nm; concentration c in g 100 mL^{-1}. IR spectra were recorded as ca. 2% solutions in $CHCl_3$ or as a thin film. ^{1}H NMR and ^{13}C NMR spectra were recorded at 300 or 600 MHz and 75 or 150 MHz, respectively, and were calibrated to the solvent signal or tetramethylsilane; the chemical shifts are reported in ppm. Mass spectra were recorded on Kratos/MsI Concept 1S mass spectrometer at Brock University. Combustion analyses were performed by Atlantic Microlabs, Norcross, Georgia, USA.

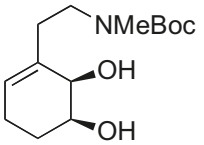
*2-(2,2-Dimethyl-3a,6,7,7a-tetrahydrobenzo[d][1,3]dioxol-4-yl)-*N*-methylethanamine (20)*



20

A solution of diol **18**[22] (45.2 g, 204.5 mmol) in acetone (400 mL) was treated with 2,2,-dimethoxypropane (37.6 mL, 306.8 mmol) and *p*TsOH. The reaction was stirred for 4 h at room temperature, whereupon the solvent was evaporated. The residue was diluted with H_2O (50 mL) and extracted with CH_2Cl_2 (3 × 200 mL). The combined organic layers were washed with saturated aqueous Na_2CO_3 solution (2 × 20 mL), and brine, then dried (Na_2SO_4), filtered, and evaporated to yield bromide **19** (46.1 g) as a clear colorless oil, which was used without further purification. Bromide **19** (10.05 g, 38.3 mmol) was dissolved in THF (35 mL) and transferred to a 200 mL thick-walled reaction vessel containing K_2CO_3 (2.64 g, 19.1 mmol) and a magnetic stirring bar. The reaction vessel was cooled to –40 °C, and the solution was saturated with methylamine by passing gaseous methylamine from a lecture bottle through the solution for 15 min. The reaction vessel was sealed, and the mixture was stirred at 25 °C for 18 h. The mixture was cooled to –40 °C before the vessel was opened. Potassium salts were removed by filtration and rinsed with CH_2Cl_2. The solvent was evaporated to obtain amine **20** (7.56 g, 94%), which was used without further purification. R_f (AcOEt/MeOH/aqueous NH_3, 7:3:1) 0.3; Mp 143–147 °C (oxalate salt); $[\alpha]_D^{24}$ = 25.8 (c 1, MeOH); IR (film): ν 3324 (w), 2983 (s), 2932 (s), 2844 (s), 2790 (m), 1674 (m), 1563 (w), 1443 (m), 1367 (s), 1242 (s), 1221 (s), 1156 (m), 1077 (s), 1030 (s), 869 (m) cm^{-1}; ^{1}H NMR ($CDCl_3$, 300 MHz): δ 5.63 (s, 1H); 4.34 (d, J = 5.5 Hz, 1H), 4.27 (td, J = 5.8, 3.2 Hz, 1H), 2.78–2.72 (m, 2H), 2.41 (s, 3H), 2.38–2.31 (m, 1H), 2.25 (q, J = 7.4 Hz, 1H), 2.14 (dddd, J = 9.0, 7.3, 3.9, 1.7 Hz, 1H), 1.91 (t, J = 5.3 Hz, 1H), 1.86–1.79 (m, 1H), 1.75–1.69 (m, 1H), 1.48 (s, 1H), 1.36 (s, 6H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 133.97, 126.58, 108.24, 73.64, 73.47, 49.81, 36.32, 34.28, 27.91, 26.46, 25.56, 20.80; LRMS-EI (*m*/*z*): M$^+$ 196 (3), 153 (14), 136 (5), 44 (100); anal. calcd. for $C_{12}H_{21}NO_2\cdot(COOH)_2$: C, 55.80; H, 7.69; found C, 55.75; H, 7.66.

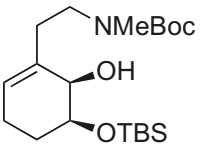
tert-*Butyl 2-((5*S*,6*R*)-5,6-dihydroxycyclohex-1-enyl)ethyl (methyl)carbamate (21)*



21

A solution of acetonide **20** (7.02 g, 33.2 mmol) in EtOH (40 mL) and H_2O (4 mL) was treated with 3 mol L^{-1} HCl (16.6 mL, 49.8 mmol). The reaction mixture was stirred for 4 h, treated with $NaHCO_3$ (42 g, 498 mmol), and stirred vigorously for 1 h. Then Boc anhydride (10.9 g, 49.8 mmol) was added, reaction mixture was stirred for additional 4 h, filtered, and evaporated. The residue was diluted with H_2O (25 mL) and extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layers were washed with saturated aqueous NH_4Cl solution (2 × 10 mL), brine, dried (Na_2SO_4), filtered, and evaporated. Flash column chromatography (hexanes/AcOEt, 6:1 → 1:2) afforded **21** (6.48 g, 72%) as a colorless oil. R_f (hexanes/AcOEt, 1:1) 0.20; $[\alpha]_D^{23}$ = –95.5° (c 0.75, $CHCl_3$); IR (film): ν 3394 (s), 2975 (s), 2931 (s), 1674 (s), 1483 (s), 1353 (s), 1397 (s), 1366 (s), 1308 (m), 1247 (m), 1220 (m), 1160 (s), 1075 (m), 1053 (m), 989 (m), 945 (w), 919 (w) cm^{-1}; ^{1}H NMR ($CDCl_3$, 300 MHz): 5.43 (s, 1H), 4.87 (s, 1H), 3.96 (s, 2H), 3.56 (s, 1H), 2.99 (d, J = 8.8 Hz, 1H), 2.91 (s, 1H), 2.86 (s, 3H), 2.42–2.30 (m, 1H), 2.18 (d, J = 13.4 Hz, 1H), 2.03 (s, 2H), 1.74–1.63 (m, 1H), 1.60–1.45 (m, 1H), 1.43 (s, 9H); ^{13}C NMR ($CDCl_3$, 150 MHz): 157.0, 133.9, 128.8, 79.9, 70.0, 69.8, 48.3, 34.8, 34.0, 28.3, 25.4, 24.8; LRMS-EI (*m*/*z*): M$^+$ 271 (1), 197 (3), 171 (1), 153 (9), 144 (29), 110 (23), 88 (16), 57 (88), 44 (100); HRMS-EI (*m*/*z*): M$^+$ calcd. for $C_{14}H_{25}NO_4$: 271.1784, found 271.1796.

tert-*Butyl 2-((5*S*,6*R*)-5-(*tert*-butyldimethylsilyloxy)-6-hydroxycyclohex-1-enyl)ethyl(methyl)carbamate (22)*



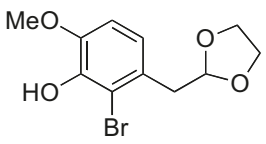
22

A solution of carbamate **21** (7.76 g, 28.6 mmol) and imidazole (3.89 g, 57.2 mmol) in CH_2Cl_2 (50 mL) was treated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

with TBSCl (4.75 g, 31.5 mmol) at –78 °C, the reaction mixture was left to warm slowly to 25 °C overnight and treated with saturated aqueous NH_4Cl solution (15 mL). After extraction with CH_2Cl_2 (3 × 100 mL), the combined organic layers were washed with saturated aqueous $NaHCO_3$ solution (20 mL), brine (20 mL), dried ($MgSO_4$), filtered, and evaporated. Flash column chromatography (hexanes/AcOEt, 3:1) afforded **22** (8.54 g, 77%) as a clear colorless oil. R_f (CH_2Cl_2/AcOEt, 96:4) 0.47; $[\alpha]_D^{24}$ = –22.6 (*c* 0.5, $CHCl_3$); IR (film): ν 3556 (w), 3475 (w), 2953 (s), 2857 (s), 1692 (s), 1472 (s), 1392 (s), 1253 (s), 1085 (s) cm^{-1}; ^1H NMR ($CDCl_3$, 600 MHz, mixture of rotamers): δ 5.54 (s, 1H), 5.52 (s, 1H), 3.98 (s, 1H), 3.90 (s, 1H), 3.79 (s, 1H), 3.77 (s, 1H), 3.26–3.20 (m, 2H), 2.85 (s, 3H), 2.82 (s, 3H), 2.39–2.32 (m, 2H), 2.30–2.23 (m, 2H), 2.13 (br s, 2H),1.98 (br s, 2H) 1.80–1.72 (m, 2H),1.54 (s, 2H),1.44 (s,18H), 0.9 (s,18H), 0.11 (s, 6H), 0.10 (s, 6H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 155.7, 134.8, 126.6, 79.0, 71.0, 68.8, 48.4, 47.2, 34.1, 33.3, 32.8, 28.4, 25.8, 25.4, 25.3, 24.3, 24.1, 18.1, –4.4, –4.8; LRMS-EI (*m*/*z*): M^+ 228 (21), 197 (21), 136 (12), 74 (22), 73 (15), 57 (63), 44 (100); HRMS-EI (*m*/*z*): [M-57]$^+$ calcd. for $C_{12}H_{30}NO_4Si$: 328.1944, found 328.1946; anal. calcd for $C_{20}H_{39}NO_4Si$: C, 62.10, H,10.22; found C, 62.29, H,10.19.

2-Bromo-3-(1,3-dioxolan-2-ylmethyl)-6-methoxyphenol (17)



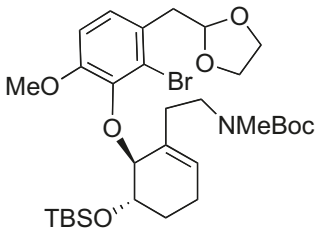
17

A solution of bromoisovanillin **14** (10.0g, 43.4 mmol) in CH_2Cl_2 (300 mL) was cooled to 0 °C and treated with *i*Pr_2-NEt (15.1 mL, 86.7 mmol) and MOM-Cl (4.94 mL, 65.1 mmol). Reaction mixture was stirred for 3 h while the light yellow solution turned clear. The reaction mixture was diluted with H_2O (100 mL), the layers were separated and the aqueous layer was extracted with AcOEt (3 × 40 mL). The combined organic layers were washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield crude **15** as a light yellow/brown solid (12.2 g) which was used without further purification. R_f (hexanes/AcOEt, 1:1) 0.69.

A solution of $Ph_3P^+CH_2OCH_3Cl^-$ (23.1 g, 67.2 mmol) in THF (125 mL) was cooled to –78 °C, treated with *t*BuLi (35.9 mL, 61.1 mmol) dropwise over 10 min, and stirred for 15 min. The solution was warmed to 0 °C and treated with crude **15** (16.3 g, 61.1 mmol) in THF (17 mL) dropwise over 5 min while the deep orange solution turned to a deep yellow suspension. The suspension was refluxed for 3.5 h, cooled to 25 °C, diluted with AcOEt (100 mL), and washed with H_2O (100 mL). The aqueous layer was extracted with AcOEt (3 × 50 mL) and the combined organic layers were washed with brine, dried ($MgSO_4$), filtered, and evaporated to yield crude **16** as a yellow solid (30.8 g) which was used without further purification.

A solution of crude **16** (32.2 g, 106 mmol) in THF (300 mL) was treated with *p*TsOH (10.1 g, 53.0 mmol), ethylene glycol (29.6 mL, 530.3 mmol), and refluxed for 2 h. Reaction mixture was cooled to 25 °C, concentrated, diluted with AcOEt (150 mL), and washed with H_2O (2 × 20 mL). Organic layer was washed with brine, dried ($MgSO_4$), filtered, and evaporated. The residue was dissolved in CH_2Cl_2 (100 mL) and extracted with 0.5 mol L^{-1} NaOH (3 × 10 mL). The combined aqueous layers were neutralized with 1 mol L^{-1} HCl to pH 7 and extracted with AcOEt (3 × 15 mL). Combined organic layers were washed saturated aqueous $NaHSO_3$ solution (5 × 15 mL), and brine, then dried ($MgSO_4$), filtered, and evaporated to yield **17** (16.2 g, 76% from **14**) as a light yellow solid. Sample for analysis was recrystallized from AcOEt/hexanes. R_f (hexanes/AcOEt, 1:1) 0.59; Mp 118–120 °C (AcOEt/hexanes); IR ($CHCl_3$): ν 3370 (w), 2959 (w), 2892 (w), 1607 (w), 1577 (w), 1490 (s), 1465 (w), 1441 (m), 1404 (w), 1362 (w), 1336 (w), 1283 (s), 1232 (m), 1199 (w), 1169 (w), 1130 (m), 1034 (s), 986 (w), 942 (w), 820 (w), 802 (w) cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz): 6.88 (d, *J* = 8.3 Hz, Ar H), 6.79 (d, *J* = 8.3 Hz, 1H), 5.95 (s, exchange with D_2O, 1H), 5.12 (t, *J* = 4.9 Hz, 1H), 4.03–3.80 (m, 4H), 3.89 (s, 3H), 3.09 (d, *J* = 4.9 Hz, 1H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 145.97, 143.20, 128.86, 111.36, 122.13, 109.66, 103.51, 65.05, 56.41, 40.17; LRMS-EI (*m*/*z*): M^+ 289 (1), 73 (100), 45 (14); HRMS-EI (*m*/*z*): M^+ calcd. for $C_{11}H_{13}BrO_4$: 287.9997, found 287.9994; anal. calcd. for $C_{11}H_{13}BrO_4$: C, 45.70, H, 4.53; found: C, 45.99, H, 4.47.

tert-*Butyl 2-((5′S,6′S)-6′-(3″-((1,3-dioxolan-2-yl)methyl)-2″-bromo-6″-methoxyphenoxy)-5′-*(tert-*butyldimethylsilyloxy) cyclohex-1′-enyl)ethyl(methyl)carbamate (23)*



23

An orange solution of DIAD (7 mL, 35.6 mmol) in degassed THF (45 mL) was cooled to –10 °C and treated with PBu_3 (9.5 mL, 38.5 mmol) at one portion. The resulting pale yellow solution was stirred for 25 min at –10 °C and cannulated during 35 min into a chilled (4 °C) solution of alcohol **22** (10.6 g, 27.4 mmol) and phenol **17** (8.7 g, 30.2 mmol) in degassed THF (90 mL). The mixture was allowed to reach 25 °C, stirred for 12 h, and evaporated. The residue was adsorbed on silica gel and subjected to chromatography (hexanes/AcOEt, 8:1) obtaining **23** (13.8 g, 76%) and recovered phenol **17** (664 mg, 8%). Data for **23**: Yellow oil; R_f (hexanes/AcOEt, 2:1) 0.75; $[\alpha]_D^{20}$ = + 43.7 (*c* 0.125, $CHCl_3$); IR ($CHCl_3$): ν 3294 (w), 2930 (s), 2857 (m), 1736 (w), 1697 (s), 1594 (w), 1482 (s), 1441 (m), 1393 (m), 1365 (m), 1293 (m), 1252 (s), 1171 (s), 1137 (s), 1105 (m), 1085 (m), 1035 (s),

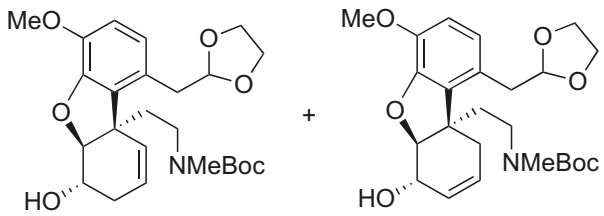
24 **25**

A solution of **23** (6.38 g, 9.7 mmol) in degassed toluene (60 mL) was treated with K_2CO_3 (2.01 g, 14.6 mmol), $Pd_2(dba)_3$ (888 mg, 0.97 mmol), and t-Bu_3P (393 mg, 1.94 mmol), immersed in a preheated oil bath (110 °C), and stirred for 16 h. The reaction mixture was filtered through a plug of Celite (washing with CH_2Cl_2) and evaporated. Flash column chromatography (hexanes/AcOEt, 4:1) afforded an inseparable mixture of **24** and **25** (**24/25** ≈ 5:1, 4.82 g, 86%) as a brown oil. R_f (hexanes/AcOEt, 2:1) 0.59; $[\alpha]_D^{20}$ = +34.8 (*c* 1.00, $CHCl_3$); IR ($CHCl_3$): ν 3010 (w), 2956 (m), 2931 (m), 2895 (w), 2857 (w), 1730 (w), 1683 (m), 1626 (w), 1584 (w), 1506 (m), 1482 (w), 1472 (w), 1438 (w), 1401 (w), 1394 (w), 1367 (w), 1321 (w), 1282 (w), 1258 (m), 1221 (s), 1216 (s), 1213 (s), 1210 (s), 1155 (m), 1127 (m), 1048 (w), 1009 (w) cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz): δ 6.78 (d, J = 8.3 Hz, 1H), 6.72 (d, J = 8.3 Hz, 1H), 6.01–5.97 (m, 1H), 5.73–5.68 (m, 1H), 5.05 (m, 1H), 4.45 (m, 1H), 4.01 (m, 2H), 3.90–3.86 (m, 3H), 3.82 (s, 3H), 3.07 (m, 1H), 3.00–2.88 (m, 2H), 2.77 (s, 3H), 2.28–2.18 (m, 1H), 2.13–1.95 (m, 1H), 1.92–1.83 (m, 2H), 1.57 (m, 2H), 1.43 (s, 9H), 0.89 (s, 9H), 0.13 (s, 3H), 0.01 (s, 3H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 155.5, 146.1, 143.9, 132.3, 129.4, 124.8, 123.1, 111.7, 104.7, 104.5, 89.8, 79.4, 68.4, 65.0, 64.9, 55.8, 51.4, 45.2, 37.5, 36.3, 35.4, 34.2, 30.8, 29.7, 28.4, 25.8, 25.7, 18.1; LRMS-EI (*m*/*z*): 310 (7), 237 (1), 184 (10), 139 (4), 91 (22), 73 (66), 57 (80), 43 (100); HRMS-EI (*m*/*z*): M^+ calcd. for $C_{31}H_{49}NO_7Si$: 575.3278, found 575.3276.

tert-*Butyl 2-((5aS,6S,9aR)-1-((1,3-dioxolan-2-yl)methyl)-6-hydroxy-4-methoxy-5a,6,7,9a tetrahydrodibenzo[*b,d*]furan-9a-yl)ethyl(methyl)carbamate (26) and* tert-*butyl 2-((5aS,6S,9aR)-1-((1,3-dioxolan-2-yl)methyl)-6-hydroxy-4-methoxy-5a,6,9,9a-tetrahydrodibenzo[*b,d*]furan-9a-yl)ethyl (methyl)carbamate (27)



26 **27**

A solution of **24** and **25** (**24/25** ≈ 5:1, 4.818 g, 8.34 mmol) in THF (50 mL) was cooled to 0 °C and treated with a 1.0 mol L^{-1} solution of TBAF in THF (12.6 mL, 12.6 mmol). The mixture was stirred for 16 h at 25 °C, diluted with AcOEt (40 mL), and washed with H_2O (25 mL). The aqueous layer was extracted with AcOEt (3 × 45 mL) and the combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated. Flash column chromatography (hexanes/AcOEt, 4:1 → 1:1) afforded **27** (593 mg, 15%) as a light yellow foam and **26** (3.14 g, 82%) as a light yellow foam.

33

TBS-protected derivative of the enol ether **33** was prepared from aldehyde **5** by a Wittig reaction with (methoxymethyl) triphenyl-phosphonium chloride as previously described.[35] The TBS ether (384 mg, 0.704 mmol) was dissolved in THF (6 mL) at 0 °C, and then TBAF (1.0 mol L^{-1} in THF, 775 μL, 0.775 mmol) was added. The reaction mixture was stirred at 25 °C for 3 h. A second portion of TBAF (352 μL, 0.352 mmol) was added at 25 °C and the reaction was stirred for 2 h, diluted with H_2O (10 mL) and extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were washed with brine and dried (Na_2SO_4). Flash column chromatography (AcOEt/hexanes, 1:9 → 1:4 → 1:1) afforded **33** (mixture of *E* and *Z* isomers, 225 mg, 74%) as an oil. R_f (hexanes/AcOEt, 1:1) 0.2; IR (film): ν 3426 (m), 2933 (s), 1682 (s),

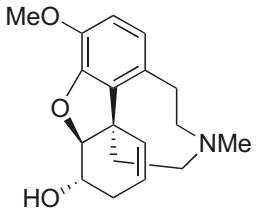
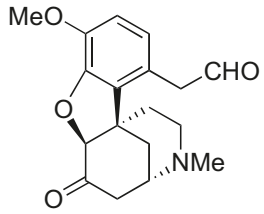
(4aS,5S,8aR)-3-Methoxy-11-methyl-4a,5,6,9,10,11,12,13-octahydrobenzo[2,3]benzofuro[3,4-de]azocin-5-ol (34)



34

Enol ether **33** (146 mg, 0.34 mmol) was dissolved in a 4/1 mixture of CH_2Cl_2 and TFA (0.5 mL) at 0 °C. The reaction mixture was warmed to 25 °C and stirred overnight before being treated with cold saturated aqueous $NaHCO_3$ solution (2 mL) and extracted with $CHCl_3$ (3 × 4 mL). The combined organic layers were dried (Na_2SO_4) and evaporated. The resulting enamine **32** was dissolved in dry MeOH (0.3 mL) and treated with $NaBH_3CN$ (7 mg, 0.11 mmol) and AcOH (19 μL, 0.34 mmol) at 0 °C. The reaction mixture was warmed to 25 °C, stirred overnight and treated with cold saturated aqueous $NaHCO_3$ solution (2 mL). Methanol was evaporated and the aqueous residue was extracted with $CHCl_3$ (3 × 3 mL) and dried ($NaSO_4$). Flash column chromatography (CH_2Cl_2/AcOEt, 4:1) afforded amine **34** (42 mg, 41%) as a colorless oil. R_f (CH_2Cl_2/AcOEt, 96:4) 0.49; ^1H NMR ($CDCl_3$, 600 MHz): δ 6.71 (d, J = 8.1 Hz, 1H), 6.59 (d, J = 8.1 Hz, 1H), 5.74–5.68 (m, 1H), 4.32 (m, 1H), 4.00–4.93 (m, 1H), 3.87 (s, 3H), 3.13–3.05 (m, 1H), 2.85–2.76 (m, 1H), 2.74–2.65 (m, 1H), 2.59–2.52 (m, 2H), 2.46–2.38 (m, 2H), 2.31 (s, 3H), 2.17–2.11 (m, 1H), 2.01–1.96 (m, 1H), 1.83–1.75 (m, 1H), 1.32–1.25 (m, 2H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 145.54, 143.79, 132.20, 129.65, 122.74, 122.09, 111.18, 96.13, 67.48, 60.51, 55.79, 52.60, 47.51, 42.29, 33.06, 29.22; LRMS-EI (*m/z*): M^+ 42 (27), 43 (50), 44 (27), 57 (38), 58 (56), 70 (100), 71 (27), 83 (22), 149 (49), 179 (62), 301 (41); HRMS-EI (*m/z*): M^+ calcd. for $C_{18}H_{23}NO_3$: 301.1678, found 301.1678.

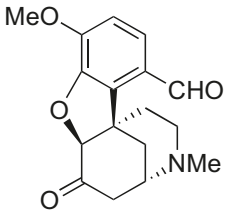
[(4S,6aS,11bR)-8-Methoxy-3-methyl-6-oxo-2,3,4,5,6,6a-hexahydro-1H-4,11b-methano[1]benzofuro[3,2-d]azocin-11-yl]acetaldehyde (39)



39

A mixture of **30** (231 mg, 0.643) and oxalic acid (159 mg, 1.766 mmol) in H_2O (6 mL) was stirred at 40 °C for 13 h, cooled to 25 °C, poured into saturated aqueous $NaHCO_3$ solution (15 mL), and extracted with $CHCl_3$ (3 × 15 mL). The combined organic layers were washed with brine (15 mL), dried ($MgSO_4$), and evaporated to get crude aldehyde **39** (227 mg) that was used without further purification. A sample was purified by flash column chromatography ($CHCl_3$/MeOH/aqueous NH_3, 92:8:1). Colorless oil; R_f ($CHCl_3$/MeOH/aqueous NH_3, 92:8:1) 0.52; ^1H NMR ($CDCl_3$, 600 MHz, crude): δ 9.70 (br t, J = 1.9 Hz, 1H), 6.79 (d, J = 8.3 Hz, 1H), 6.66 (d, J = 8.3 Hz, 1H), 4.76 (s, 1H), 3.86 (s, 3H), 3.78 (dd, J = 17.0, 1.9 Hz, 1H), 3.72 (dd, J = 17.0, 1.9 Hz, 1H), 3.53–3.48 (m, 1H), 2.96–2.91 (m, 1H); 2.68 (d, J = 17.4 Hz, 1H), 2.50–2.30 (m, 3H), 2.35 (s, 3H), 2.19 (br d, J = 12.8 Hz, 1H), 1.89–1.84 (m, 1H), 1.71 (dt, $J \approx$ 12.8, 2.3 Hz, 1H); LRMS-EI *(m/z)*: M+ 315 (3), $[M\text{-}OH]^+$ 298 (21), $[M\text{-}H_2O]^+$ 297 (100), 282 (11), 229 (18), 214 (20), 188 (10), 43 (11), 42 (14); HRMS-EI *(m/z)*: M^+ calcd. for $C_{18}H_{21}NO_4$: 315.1471, found 315.1469.

(4S,6aS,11bR)-8-Methoxy-3-methyl-6-oxo-2,3,4,5,6,6a-hexahydro-1H-4,11b-methano[1]benzofuro[3,2-d]azocine-11-carbaldehyde (40)



40

A solution of crude aldehyde **39** (4 mg) in MeCN (0.2 mL) and H_2O (0.2 mL) was treated with concentrated HCl until the pH reached 1, the mixture was stirred at 40 °C for 22 h, cooled to 25 °C, poured into saturated aqueous $NaHCO_3$ solution (5 mL), and extracted with $CHCl_3$ (4 × 5 mL). The combined organic layers were washed with brine (5 mL), dried ($MgSO_4$), and evaporated to furnish crude **40** (4 mg). A pure sample was obtained by flash column chromatography (AcOEt/MeOH, 7:1 → 5:1). R_f (AcOEt/MeOH, 5:1) 0.33; IR ($CHCl_3$): ν 3027 (w), 3012 (w), 2963 (m), 2964 (m), 2845 (w), 2789 (w), 2745 (w), 1726 (s), 1691 (s), 1615 (s), 1574 (m), 1507 (m), 1447 (m), 1438 (m), 1410 (w), 1377 (w), 1340 (w), 1293 (s), 1270 (m), 1260 (m), 1169 (m), 1144 (m), 1117 (m), 1102 (m), 1066 (w), 1054 (w), 1017 (m), 981 (w), 953 (w), 927 (w) cm^{-1}; ^1H NMR ($CDCl_3$,

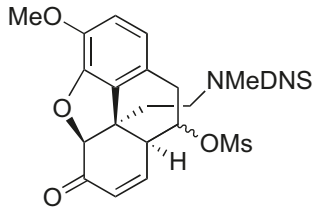
56

A suspension of alcohol **55** (64 mg, 0.11 mmol) and IBX (45 mg, 0.16 mmol) in AcOEt (3 mL) was stirred at 80 °C for 4 h, cooled to 25 °C, and filtered through Celite (washing with AcOEt) affording crude **56** (60 mg), which was used without further purification. R_f (hexanes/AcOEt, 1:1) 0.23; IR ($CHCl_3$): ν 3101 (w), 3032 (w), 2981 (w), 2893 (w), 1738 (m), 1556 (s), 1541 (s), 1508 (m), 1366 (s), 1351 (s), 1283 (m), 1164 (s), 1131 (m), 1044 (m), 908 (s) cm^{-1}; ^1H NMR ($CDCl_3$, 600 MHz): δ 8.49 (dd, *J* = 8.6, 1.9 Hz, 1H); 8.44 (d, *J* = 1.9 Hz, 1H), 8.15 (d, *J* = 8.6 Hz, 1H), 6.85 (d, *J* = 8.4 Hz, 1H), 6.77 (d, *J* = 8.4 Hz, 1H), 6.03 (d, *J* = 9.9 Hz, 1H), 5.87 (ddd, *J* = 10.0, 3.9, 3.9 Hz, 1H), 5.02 (dd, *J* = 5.6, 4.1, 1H), 4.81 (s, 1H); 4.00–3.96 (m, 2H), 3.92–3.84 (m, 2H), 3.87 (s, 3H), 3.40–3.35 (m, 1H), 3.09 (ddd, *J* = 19.31, 3.86, 1.99, 1H), 3.07–3.02 (m, 2H), 2.96–2.93 (m, 1H), 2.94 (s, 3H), 2.30–2.22 (m, 2H); ^{13}C NMR ($CDCl_3$, 150 MHz): δ 203.68, 149.70, 148.09, 146.74, 143.84, 137.65, 132.65, 129.82, 128.73, 126.17, 124.71, 124.53, 124.12, 119.77, 112.67, 104.37, 87.68, 64.99, 64.97, 57.38, 56.17, 46.37, 37.30, 36.86, 36.14, 35.05; LRMS-EI (*m/z*): M^+ 591 (12), 147 (16), 136 (24), 91 (14), 89 (14), 77 (13), 73 (100); HRMS-EI (*m/z*): M^+ calcd. for $C_{26}H_{29}N_3O_{11}S$: 591.1507, found 591.1522.

(2a²R,6aS,9aS)-5-Methoxy-2a²-(2-(N-methyl-2,4-dinitrophenylsulfonamido)ethyl)-7-oxo-1,2,2a²,6a,7,9a-hexahydrophenanthro[4,5-bcd]furan-1-yl methanesulfonate (57)



57

A solution of crude **56** (15 mg, 0.025 mmol) in toluene (1 mL) was treated with 50% aqueous TFA (0.14 mL) and the biphasic mixture was stirred at 50 °C for 2 h. The volatiles were removed in vacuo, the residue was dissolved in CH_2Cl_2 (1 mL) and treated with *i*Pr_2NEt (5 μL, 0.038 mmol) and MsCl (2.4 μL, 0.031 mmol) at 0 °C. The mixture was stirred for 30 min at 0 °C, treated with saturated aqueous NH_4Cl solution (1 mL) and extracted with CH_2Cl (3 × 5 mL). The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated. Flash column chromatography ($CHCl_3$/EtOAc, 3:1) afforded **57** (1 mg, 6% from **55**). The ^1H NMR spectrum was identical to one reported in the literature.[36]

R_f (hexanes/AcOEt, 1:3) 0.51; ^1H NMR ($CDCl_3$, 600 MHz): δ 8.49–8.44 (m, 2H); 8.08 (d, *J* = 8.4 Hz, 1H), 6.90 (dd, *J* = 10.3, 4.0 Hz, 1H), 6.77 (d, *J* = 8.6 Hz, 1H), 6.73 (d, *J* = 8.6 Hz, 1H), 6.20 (dd, *J* = 10.6, 2.3 Hz, 1H), 4.86 (s, 1H), 3.88 (s, 3H), 3.51–3.43 (m, 1H), 3.23–3.18 (m, 1H), 3.16 (s, 3H), 3.16 (s, 1H), 3.12–3.09 (m, 1H), 2.94 (s, 3H), 2.89–2.87 (m, 1H), 2.26–2.18 (m, 2H).

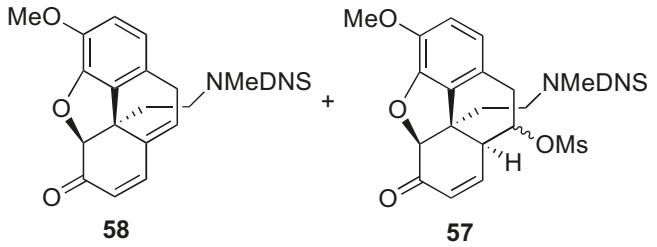
124.47, 119.90, 112.77, 105.60, 87.72, 57.59, 56.29, 54.43, 53.70, 46.50, 37.43, 36.77, 35.99, 35.14; LRMS-EI (*m*/*z*): M^+ 591 (1), 327 (3), 270 (9), 248 (100), 231 (55), 227 (10), 203 (19), 187 (5), 167 (25), 163 (7) 149 (72), 128 (69), 127 (51), 122 (38.9), 105 (57); HRMS-EI (*m*/*z*): M^+ calcd. for $C_{26}H_{29}N_3O_{11}S$: 591.1523, found 591.1531.

N-*(2-((2a[1]*R*,5a*S*)-7-Methoxy-5-oxo-1,2a1,5,5a-tetrahydrophenanthro[4,5-*bcd*]furan-2a1-yl)ethyl)*-N-*methyl-2,4-dinitrobenzenesulfonamide (58) and (2a[2]*R*,6a*S*,9a*S*)-5-methoxy-2a[2]-(2-(*N*-methyl-2,4-dinitrophenylsulfonamido)ethyl)-7-oxo-1,2,2a[2],6a,7,9a-hexahydrophenanthro[4,5-*bcd*]furan-1-yl methanesulfonate (57)



A solution of **63** (13 mg, 0.022 mmol), 50% aqueous trifluoroacetic acid (0.12 mL) in toluene was heated to 50 °C for 2 h, cooled to 25 °C and concentrated. The volatiles were removed in vacuo, the residue was dissolved in CH_2Cl_2 (1 mL) and treated with *i*Pr_2NEt (6 μL, 0.034 mmol) and MsCl (2 μL, 0.031 mmol) at 0 °C. The mixture was stirred for 30 min at 0 °C, treated with saturated aqueous NH_4Cl solution (1 mL) and extracted with CH_2Cl (3 × 7 mL). The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated. Flash column chromatography (hexanes/AcOEt, 1:1) afforded **57** (3.6 mg, 28% from **62**) and **58** (3.6 mg, 24% from **62**). The ^{1}H NMR spectrum of **57** was identical to that reported in the literature for its enantiomer.[36]

ent-*Neopinone (61)*

A solution of **57** and **58** (6 mg, 0.01 mmol), *i*Pr_2NEt (5.25 μL, 0.03 mmol) and thioglycolic acid (1 μL, 0.014 mmol) in CH_2Cl_2 was stirred at 0 °C for 30 min, treated with saturated aqueous Na_2CO_3 and stirred for 30 min at 25 °C. The solution was extracted with CH_2Cl_2 (3 × 7 mL) and the combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated. The product was matched with a sample of neopinone standard.[37] R_f (CH_2Cl_2/EtOH, 85:15) 0.4.

(34) In our earlier synthesis of codeine (ref. 22), intermediate **5**, Fig. 2, was prepared in 82% yield by an intramolecular Heck coupling using $Pd(OAc)_2$, 1,1′-bis(diphenylphosphino)ferrocene (dppf) and Ag_2CO_3 in boiling toluene. In that reaction the isomerization of the double bond was not observed. These conditions, however, when used for the cyclization of **23** to **24**, led to low yields and formation of side-products. Optimization of this reaction (**23** → **24**) revealed that Fu's conditions (see refs. 31 and 32) using $Pd_2(dba)_3$, $(t\text{Bu})_3\text{P}$, and K_2CO_3 in boiling toluene were superior to other methods and led reproducibly to high yields. The reaction proceeds faster in boiling *m*-xylene; $Pd(OAc)_2$ and $Cs_2(CO)_3$ can be used instead of $Pd_2(dba)_3$ and K_2CO_3, respectively, while use of Ag_2CO_3 leads to a formation of side products. Starting aldehydes used in the formation of **5** and **24** are both electronically and sterically very different. The reaction leading to **5** and promoted by Ag_2CO_3 likely follows a cationic Heck mechanism, which appears to be unfavorable for the cyclization of **23**. The cyclization of **23** to **24** with $(t\text{Bu})_3\text{P}$ likely involves the formation of the monophosphine complex $[Pd(Pt\text{Bu})_3]$. For the detailed discussion of the reactivity of such monoligated palladium complexes see ref. 33 and refs. quoted there.

Abstract: Magnetic resonance imaging (MRI) is known to provide a useful approach for the exploration of the chemistry and dynamics of a wide range of soft condensed materials. However, its application to solids has been limited to those materials with relatively narrow resonances. The time needed to obtain an image of a solid with a given resolution and signal-to-noise ratio (SNR) is directly proportional to the line width of the resonance. For MRI to become practical for the imaging of solids it will have to rely on the development and use of MR sequences that avoid the issues raised by line broadening of the resonance. In this paper we review the latest contributions towards MR imaging of solids from our laboratory, in particular, applications using optimized gradient waveforms. Acoustic noise reduction and SNR improvement obtained with modifications of the standard single-point imaging sequence are presented and discussed using examples.

Key words: MRI, solids, gradient shape, gradient ramp, sound pressure, signal-to-noise ratio.

Résumé : L'imagerie par résonance magnétique (IRM) est connue comme une approche utile pour explorer la chimie et la dynamique d'un grand nombre de matériaux condensés et mous. Toutefois, son application aux solides a été limitée aux matériaux avec des résonances relativement étroites. Le temps requis pour obtenir une image d'un solide avec une résolution et un rapport de signal à bruit (RSB) donnés est directement proportionnel à la largeur de la raie de résonance. Pour que l'IRM devienne pratique dans la production d'images de solides, il faudra développer et utilise des séquences de résonance magnétique qui éviteront les problèmes liés à l'élargissement des raies de résonance. Dans ce travail, on présente une revue des plus récentes contributions de notre laboratoire à l'IRM des solides, en particulier aux applications utilisées pour optimiser le gradient des formes des ondes. On présente la réduction acoustique du bruit et l'amélioration du rapport signal à bruit obtenues par modifications de la séquence d'imagerie habituelle avec point localisé et on en discute à l'aide d'exemples.

Mots-clés : imagerie par résonance magnétique (IRM), solides, gradient de forme, gradient de forme, pression du son, rapport signal à bruit.

[Traduit par la Rédaction]

Introduction

Over the last decades magnetic resonance imaging (MRI) has become a major diagnostic tool in medicine and biomedical research. Nearly all applications involve the study of ^{1}H magnetization in soft water-containing tissues. Within these soft tissues, water mobility is more or less unrestricted, resulting in a typically narrow ^{1}H resonance and a corresponding long transverse relaxation time (T_2). Thus, the Hamiltonian best describing these spin systems consists of one major contribution, the Zeeman interaction.[1] Perturbations to the Hamiltonian usually do not have to be considered unless measurements are performed near interfaces, where susceptibility effects from metal parts or air can be large.[2] Because of this high degree of water mobility, spatial information can be obtained using frequency encoding techniques.[3] However, in solid materials the line width of the resonance is perturbed by large anisotropic interactions (approximately in the order of a few kHz), therefore, frequency encoding techniques result in images with poor resolution and sensitivity.

Although many different experimental approaches have been used to reduce unwanted line broadening, standard NMR line-narrowing techniques such as CPMAS, multipulse sequences, etc.,[4,5] require additional attention to spatially dependent gradient interactions modulating image

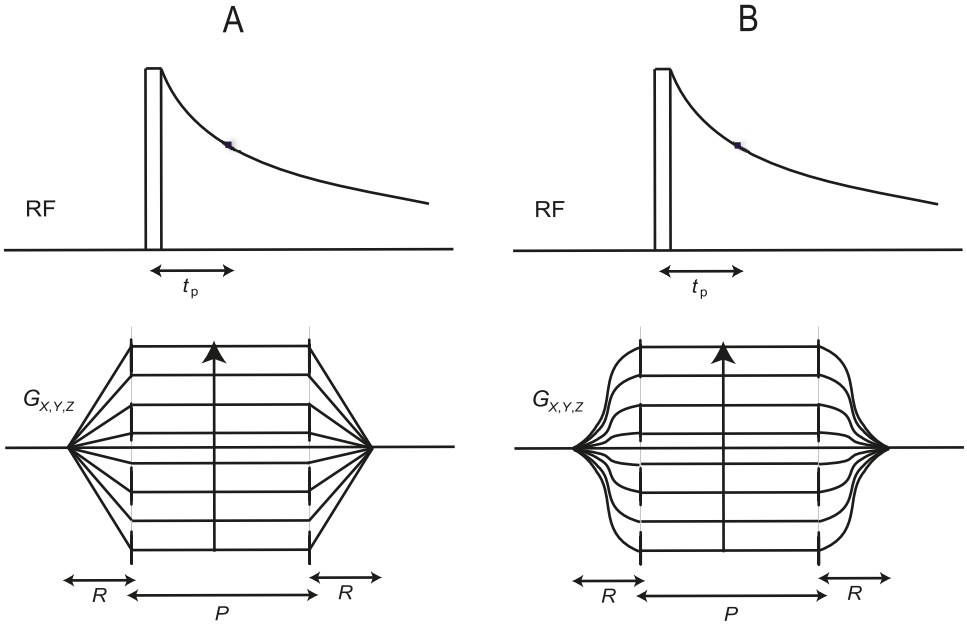
Fig. 1. (A) Single point imaging (SPI) sequence showing RF and gradient sections. During RF excitation the gradient is kept stable (interval *P*) while a single datum point is collected at an encoding time t_p. One set of encoding gradients is shown and up to three gradients can be used to perform 3D spatial encoding. The time intervals *R* and *P* represent the gradient ramp and plateau time, respectively. (B) As in (A), except sinusoidal gradient ramps were used.



resolution. Also, these techniques are not suitable for larger objects and in vivo MR imaging of, for example, human bones or teeth. Emid and Creyghton[6] proposed a spatial encoding technique based on pure phase encoding in combination with the collection of one point of the free induction decay after RF excitation, the so-called single point imaging (SPI) technique. As only one point of the NMR signal is collected, any convoluting effects from time-dependent perturbations such as the chemical shift, quadrupolar effect, etc., will not be observed in the acquired data. Resolution and sensitivity of the image will thus only be determined by the strength of the applied gradient.[7] In general, when the gradient switching time becomes longer than the longitudinal relaxation (T_2*) of the sample, SPI will provide a superior signal-to-noise ratio (SNR) compared with frequency-encoding techniques. The only drawback of the SPI pure phase-encoding technique is the replacement of a single line of frequency-encoded data with individual phase-encode steps, each requiring a relaxation delay. However, for many solids spin-lattice relaxation times (T_1) are relatively short, allowing fast repetition of the phase-encode steps without the risk of signal saturation. As an example we will show images of human teeth in which the water T_1 is relatively short vide infra.

A typical SPI experiment consists of three gradients, one for each spatial dimension, as shown in Fig. 1A. As soon as the ramped gradient has reached its plateau value, a RF pulse is applied and after an encoding time interval t_p (~50–400 μs) a single datum point is collected. After the gradients are ramped down and sufficient time for T_1 relaxation is given, the experiment can be repeated. Typically repetition times range from 1 to 20 ms. The signal intensity *S* from the spin density ρ of a voxel in an SPI image acquired with a repetition time TR is given by[8]

$$[1] \qquad S_{SPI}(t_p) = \rho \exp\left(-\frac{t_p}{T_2^*}\right)\left[\frac{1-\exp\left(-\frac{TR}{T_1}\right)}{1-\cos\alpha\,\exp\left(-\frac{TR}{T_1}\right)}\sin\alpha\right]$$

where α is the RF flip angle. Thus, $S_{SPI}(t_p)$ has an optimum for $\cos\alpha = \exp\left(-\frac{TR}{T_1}\right)$. Transverse and longitudinal weighting of the image can be introduced through careful selection of t_p and TR. For comparison, the signal intensity in a standard frequency-encoded spin-echo experiment can be described by

$$[2] \qquad S_{SE}(TE) = \rho \exp\left(-\frac{TE}{T_2}\right)\left[1-\exp\left(\frac{TR}{T_1}\right)\right]$$

with TE defining the echo time, and assuming that diffusion can be ignored. Thus, in the case where TR is long and (or) the RF flip angle α is small:

$$[3] \qquad S_{SPI}(t_p) = \rho \exp\left(-\frac{t_p}{T_2^*}\right)$$

resulting in a T_2* weighted spin-density image in SPI. Frequency-encoding experiments use typical echo times of ~10 ms, whereas SPI-encoding times typically are ~100 μs. Gravina and Cory[7] discuss these differences in more detail.

In general, MRI experiments generate acoustic noise owing to the rapid switching of the magnetic field ($\frac{dB}{dt}$) in the gradient coils, inducing strong Lorentz's forces causing mechanical vibrations in the gradient coils and cryostat. SPI, with its high gradient duty cycle and relatively long experiment time, can cause dangerous levels of mechanical vibrations. This, of course, sets a limit on the speed of the data acquisition and could severely hamper SPI applications on medical MRI systems because of acoustic noise exposure limits set by

regulatory bodies. To improve the efficiency of the SPI sequence and significantly reduce the mechanical vibrations, the single point ramped imaging with the T_1 enhancement (SPRITE) technique was introduced[9] followed by later modifications.[10–12] SPRITE uses gradual gradient switching (step-function-like), avoiding large gradient ramps between successive phase-encoding steps. However, because of the large currents flowing through the gradient coils, overheating can become an issue for long experiments. Additional cooling delays will need to be introduced into the experiment to avoid equipment damage.[13]

Recently, we introduced an SPI modification different from SPRITE, using a sinusoidal gradient ramp that efficiently attenuates acoustic noise and at the same time has a lower power deposition into the gradient set.[14] In a second modification we introduced SPI/VTI, an SPI modification using a variable phase-encoding time,[15] introducing a substantial gain in SNR. Combining SPI/VTI with the use of soft shaped gradients resulted in an efficient pulse sequence for high-resolution solid-state MRI. These methods are described in detail in the following.

Theory

Acoustic noise reduction

Gradient coils in MR scanners have been observed to show a linear response to applied gradient pulses.[16] Each gradient coil in each MR scanner can thus be characterized by its corresponding frequency response function (FRF).[14,16] The product of the FRF and the frequency spectrum of the gradient pulse determines the frequency output of the gradient set. The FRF of a gradient coil can be determined as the Fourier transform of its response to a frequency-limited sinc-shaped gradient pulse. This type of excitation can be achieved using a 10 ms long 40-lobed sinc pulse that has a flat frequency spectrum in the human audible, most sensitive frequency range of 0–4000 Hz. Figure 2 shows the typical FRFs for a transverse gradient coil (Fig. 2A) and the longitudinal coil (Fig. 2B).

The gradient pulse program for SPI is straightforward and can be described as a train of trapezoids with amplitude A, ramp time R, a plateau duration P, and a repetition time TR (see Fig. 1A). Assuming these phase encode gradients are an even periodical function, the gradient train $G(t)$ can be written as a Fourier series:[17]

$$[4] \qquad G(t) = \frac{a_0}{2} + \sum_{n=1}^{\infty} a_n \cos\left(nt\frac{2\pi}{\mathrm{TR}}\right)$$

$$[5] \qquad a_n = \frac{2}{\mathrm{TR}}\int_0^{\mathrm{TR}} G(t)\,\cos\left(nt\frac{2\pi}{\mathrm{TR}}\right)\mathrm{d}t, \quad \text{with } n = 0, 1, 2, \ldots$$

where a_n (n = 0, 1, 2, ...) are the expansion coefficients of the Fourier series. Expressions for the coefficients a_n for the specific case of linear and sinusoidally ramped gradients was presented by Latta et al.[14] Each coefficient a_n corresponds to a frequency $f_n = \frac{n}{\mathrm{TR}}$. The spectral power (sound pressure level, SPL) for a specific gradient pulse can now be calculated for various combinations of $\frac{R}{\mathrm{TR}}$ and $\frac{P}{\mathrm{TR}}$. It has been shown that the power of the fundamental frequency, corresponding to $f_1 = (\mathrm{TR})^{-1}$, is relatively insensitive to changes in $\frac{R}{\mathrm{TR}}$ and $\frac{P}{\mathrm{TR}}$. However, for the remaining frequencies a minimum value in the total power can be obtained.[14] Moving the fundamental frequency to the low-frequency range of the FRF of the gradient set by fixing $\mathrm{TR} > f_{\mathrm{R}}^{-1}$, with f_{R} the cut-off frequency in the FRF, audible acoustic noise is significantly reduced. In addition, choosing sufficiently long P and R values adds to the total accomplished acoustic noise reduction.

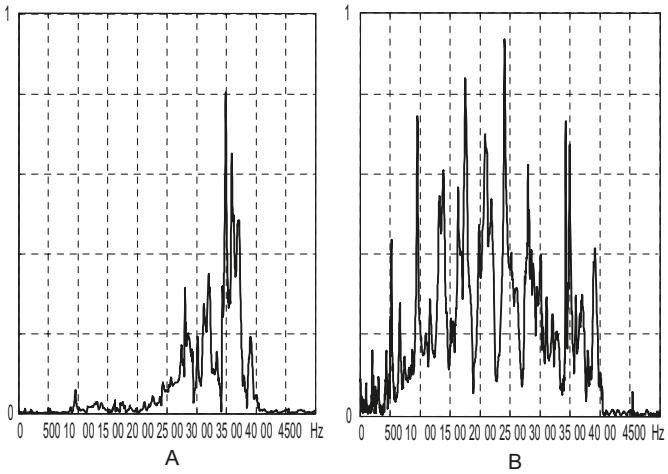

Fig. 2. (A) Frequency response function (FRF) of a transverse gradient coil. (B) FRF of the longitudinal gradient coil. Both spectra were obtained on the 11.7 T wide bore vertical bore system. The FRF magnitudes were scaled to 1 a.u. The transverse gradients show a typical reduced response for the low-frequency region up to ~800 Hz, whereas this is absent for the longitudinal coil. However, the sound pressure level for the longitudinal coil is ~18 dB (in C mode), below that of the transverse coils.

SNR optimization

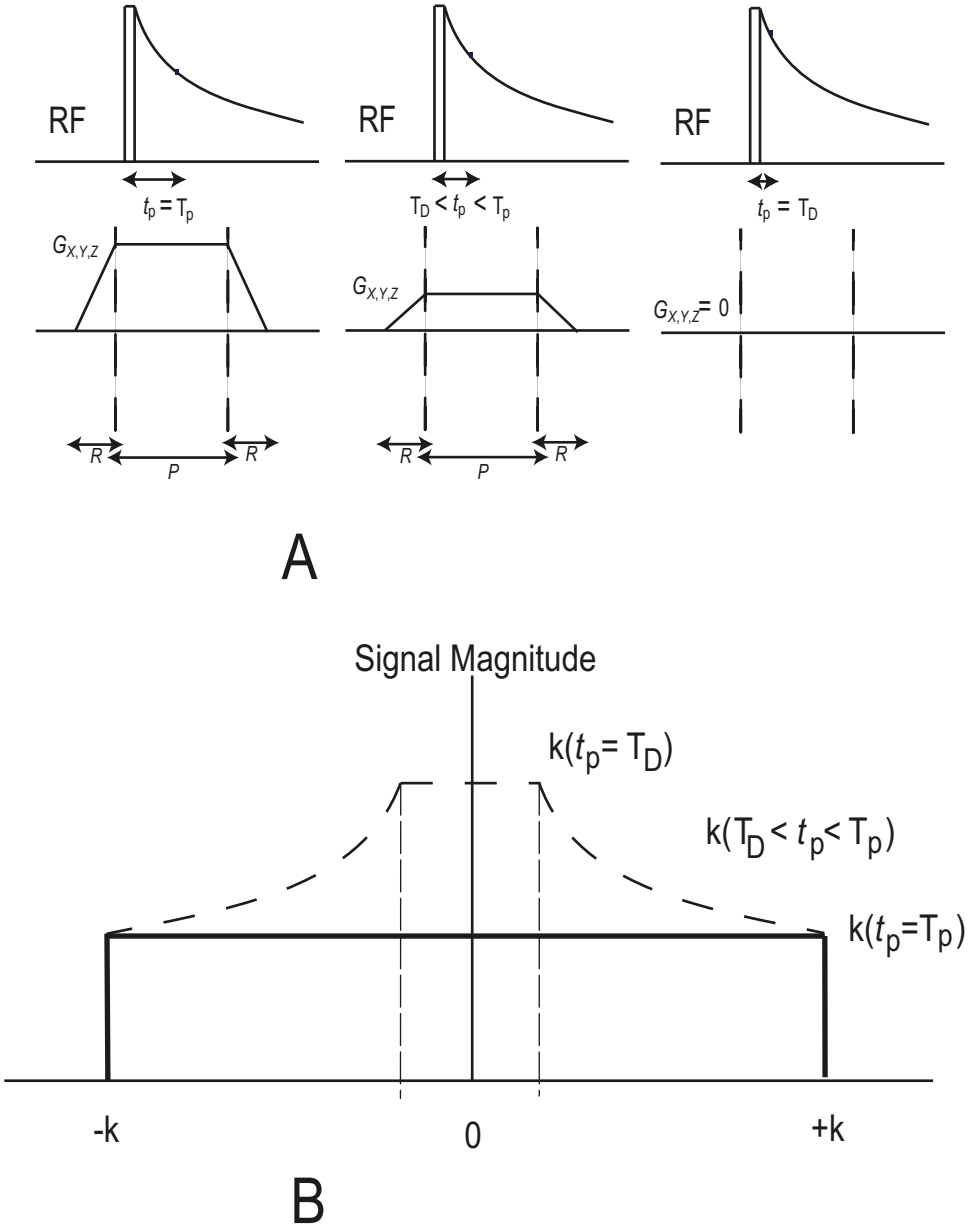
When imaging an object with MR, data is collected in k-space (the spatial frequency domain). After acquisition the data is Fourier-transformed to obtain a map of the spin-density distribution. The spatial frequency vector in the raw-data map is given by the product of the gradient vector ($\boldsymbol{G}$) and the encoding time t_{p}:

$$[6] \qquad \boldsymbol{k} = \frac{\gamma_H \boldsymbol{G} t_{\mathrm{p}}}{2\pi}$$

Here, $\boldsymbol{G}$, is kept constant during t_{p} and the position in k-space is thus determined by the product of the gradient vector and the encoding time. During the standard SPI experiment, k-space is traversed by changing the gradient vector while leaving the encoding time constant. The SPI/VTI method traverses k-space differently than an SPI experiment, introducing a variable encoding time[15] (Fig. 3). To obtain the same spatial frequency mapping we introduced a scaling constant that ensures encoding with the same spatial frequencies, however, with additional enhancement in the spin-density mapping, resulting in an increase in SNR. In short, the rescaled parameters are

$$[7] \qquad t_{\mathrm{p}} = cT_{\mathrm{p}}$$

Fig. 3. (A) Single point imaging (SPI) / VTI pulse diagram, showing the variable encoding delay t_p. Close to the centre of k-space (t_p) varies as follows: $T_D < t_p < T_p$ (where T_D is the minimal encoding time possible and T_p is the maximum phase encoding time. (B) The SPI experiment, with a constant t_p, displays a constant signal amplitude (solid line); the SPI/VTI experiment shows a larger signal amplitude for $T_D < t_p < T_p$, close to the centre of k-space, while reducing at the extremities of k-space to the value obtained in the SPI experiment (broken line).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[8] \qquad G_i' = \frac{1}{c} G_i, \quad \text{with } i = x, y, z$$

where c is the scaling constant, T_p is the phase encode interval, G_i' is the rescaled gradient magnitude, and G_i is the original gradient magnitude.

This allows for the variation of t_p; $T_D < t_p < T_p$, where T_D represents the minimal encoding time possible set by hardware limitations. The sensitivity, defined as SNR per unit time, of SPI and SPI/VTI can be compared as both sequences use the same bandwidth and thus have an identical noise level per measurement.[7] Comparing the total signal amplitude for the two sequences in one phase-encode cycle we obtained:[15]

$$[9] \qquad \frac{S_{SPI}}{S_{SPI/VTI}} = \frac{1}{T_p}\left[(T_D + {T_2}^*)e^{\frac{(T_D - T_p)}{{T_2}^*}} - {T_2}^*\right]$$

A phase-encode interval $T_p = \frac{{T_2}^*}{2}$ provides the optimal sensitivity for SPI.[7] However, for this ratio, the maximal gain in sensitivity using SPI/VTI would be 1.28 for $\frac{T_D}{T_p} = 0.2$. However, with increasing $\frac{T_p}{{T_2}^*}$ sensitivity enhancements by a factor of 3–4 can easily be achieved.[15] Thus, using SPI/VTI becomes beneficial when experimental limitations prevent the selection of a sufficiently short T_p. The ratio $\frac{T_D}{T_p}$ can be used to control image resolution, which in turn can be affected be-

Fig. 4. Top and bottom rows represent two different orientations of a human tooth. Data was collected with the silent 3D single point imaging (SPI) sequence (see text) and reconstructed according to Šrámek et al.[18] (A) Surface reconstruction, (B) volume reconstruction, and (C) object reconstruction, with particular attention to the area with high water content (caries), indicated in the crown area.

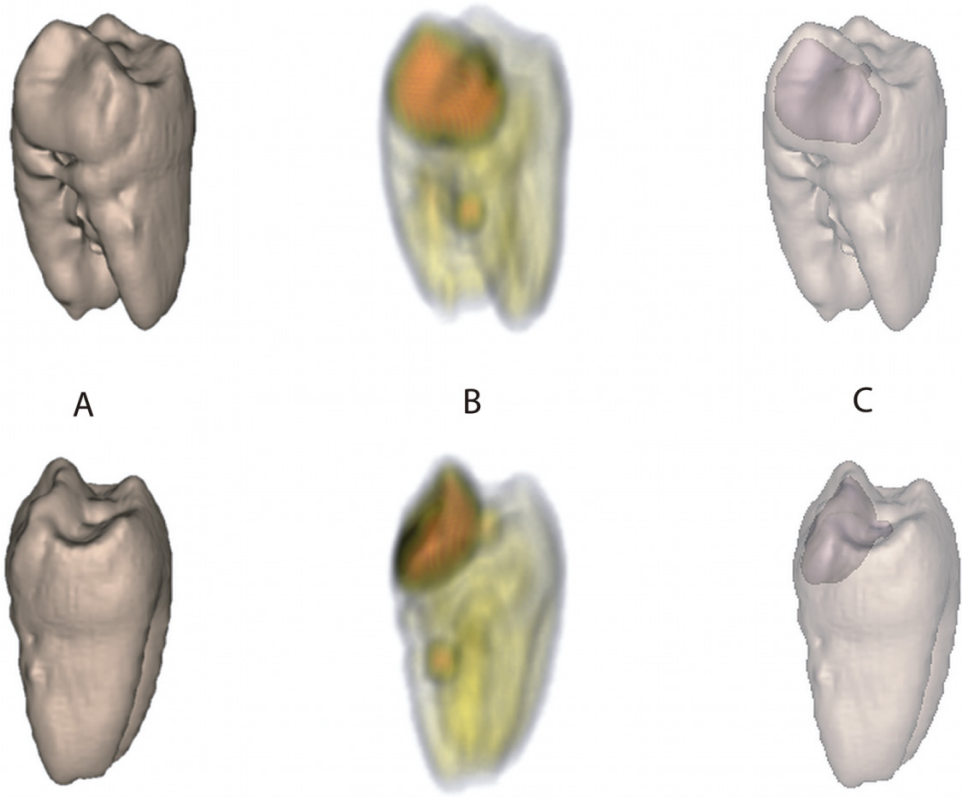


Fig. 5. Maximum intensity projections[17] of the same tooth shown in Fig. 4. The two orientations shown in the top and bottom row of Fig. 4 correspond to (A) and (B), respectively.

cause of the influence of T_2* related line broadening as SPI/VTI uses a variable encoding delay.

Experimental

The new methods were tested on human teeth and rubber stoppers. All MRI experiments were performed on an Avance DRX Bruker console (Bruker, Karlsruhe, Germany) using a 72 mm self-shielded gradient system SGRAD 123/72/S (o.d./i.d.) (Magnex, UK) installed in a vertical bore, 11.7 T magnet (Magnex, UK). Acoustic noise was measured using a Bruel and Kjær (Nærum, Denmark) 2238 Mediator sound level meter equipped with a prepolarized free-field condenser microphone type 4188. For all measurements the microphone was centred 20 cm deep into the magnet and connected to

Fig. 6. Images of a phantom using different pulse sequences. Each image represents a slice in the phantom acquired at exactly the same position, using the following parameters: (A) 3D single point imaging (SPI), encoding time (t_p) = 270 μs, repetition time (TR) = 10 ms. (B) 3D-SPI/VTI, 30 μs ≤ t_p ≤ 120 μs, TR = 10 ms. (C) 3D gradient echo, echo time (TE) = 4 ms, TR = 40 ms. (D) 3D spin-echo, TE = 15 ms, TR = 1000 ms. All data were acquired with a matrix size of 64 × 64 × 8 and a field of view (FOV) of 11 × 11 × 25 mm^3. These images show that SPI/VTI is not sensitive for susceptibility artifacts despite the variable encoding time used in the phase encoding. The phantom consists of a cylinder of water containing an air bubble (visible at top in the images) and two smaller cylinders with different diameters and thicknesses placed at the bottom.

the sound meter by a double-shielded cable. In all acoustic measurements the mean equivalent SPL was recorded (as defined by IEC 1672) and the results were obtained in both C and A modes. The latter takes into account the physiological characteristics of human hearing.

Experiments were performed using a home-built probe containing a Helmholtz RF coil tuned to 500 MHz for ^{1}H imaging and an orthogonally positioned three-turn RF solenoid tuned to 202 MHz for ^{31}P experiments. The sample chamber had a diameter of 12 mm (i.d.) and a length of 12 mm.

^{1}H images were obtained using a data matrix of 96 × 96 × 32 with a field of view (FOV) of 3 × 3 × 4 cm^3. Unless mentioned otherwise, SPI experiments used a detection time of t_p = 125 μs in combination with a 10 μs excitation pulse and a repetition time of 15 ms. The gradients were sinusoidally shaped with a ramp time of 1.0 ms for optimal acoustic noise reduction (Fig. 1B). The resulting total experiment time was 80 min.

Teeth were obtained with consent from University of Manitoba Faculty of Dentistry, Winnipeg, Manitoba, patients. After sterilization, samples were stored in distilled water while refrigerated. Prior to an MRI experiment a tooth was removed from the container, blotted dry with tissue paper, and acclimatized to room temperature. Teeth used in this study did not contain living dental pulp.

Results and discussion

Using the simple modification of gradient shape adjustment as shown in Fig. 1B, SPI experiments can be made effectively silent for the 3D measurement of teeth. Restricting the TR of the experiment to values set by the flat part in the

Fig. 7. Single point imaging (SPI) images with a resolution of 64 × 64 × 16 points, encoding time (t_p) = 120 μs and a total acquisition time of 11 min; signal-to-noise ratio (SNR) = 8.25. (B) SPI/VTI with a resolution of 64 × 64 × 16 points, 40 μs ≤ t_p ≤ 120 μs and a total acquisition time of 11 min; SNR = 32.6. All other parameters were kept identical using the same maximal gradient amplitude. (A) and (B) Central slice of the 3D experiment. (C) and (D) A zoomed detail of the object, indicated by the square in (A). The SPI/VTI (B) sequence exhibits an ~4× higher SNR compared with SPI (A).

FRF in Fig. 2A, containing frequencies up to ~800 Hz; TR > 800^{-1} s, will result in significant modulation of the fundamental acoustic frequency. Excellent acoustic noise suppression was achieved for the 11.7 T gradient system when the R = 175 μs linear gradient ramps were replaced by a 1 ms sinusoidal slope while keeping the duration of the gradient at P = 0.4 ms and TR = 15 ms. These parameters resulted in an approximate sound pressure level of ~68 dB, close to the background value (measured in A scale) in the laboratory.

SPI with shaped gradients also significantly reduced the power deposition into the gradient system compared with SPRITE.[9] The ratio of power deposition for the two sequences can be calculated as[14]

$$[10] \qquad \frac{\mathbf{P}_{\text{ShapedSPI}}}{\mathbf{P}_{\text{SPRITE}}} = \frac{0.625R + P}{\text{TR}}$$

where $\mathbf{P}_{\text{ShapedSPI}}$ and $\mathbf{P}_{\text{SPRITE}}$ represent the power deposited by the shaped SPI and the SPRITE sequences, respectively. For a gradient ramp time R = 1 ms, a plateau time P = 0.4 ms, and a repetition time TR = 15 ms, a reduction by a factor of 15 can be obtained. Of course, SPRITE was designed for samples with smaller T_1 values, allowing for a shorter TR.

SPI was used to obtain 3D maps of the mobile proton distribution in teeth, shown in Figs. 4 and 5. Most of the observed signal will arise from water; however, a small negligible fraction of the signal arises from proteins. Intact teeth (no caries) show T_1 relaxation with a relaxation constant of ~500 ms.[19–21] T_2 relaxation is bi-exponential, arising from water in dentin tubules and in enamel. Water in the latter compartment is more restricted in mobility and thus has a shorter relaxation time. In Fig. 4B, which shows a volume reconstruction of the SPI data, the root canals can clearly be observed. Roots are mainly composed of dentin and show a higher water content. Also visible in Figs. 4B and 4C are the areas with tooth decay. Caries makes enamel porous, allowing the absorption of water, hence providing a larger proton density on the SPI images. SPI can be used as an analytical tool to study both tooth surface as well as volume. Images can be used to provide detailed 3D information on roots that can be used to construct accurate inner root canal fixations for tooth restoration purposes. Figure 5 shows a gray scale

image of the tooth, reconstructing the proton spin density in a maximum intensity projection.

Figure 6 shows the effect of susceptibility changes at the air–water interface. Images of a water phantom filled with an air bubble were obtained with SPI, SPI/VTI, gradient echo, and spin echo sequences (see Fig. 6 for details). The reconstructed images reveal that despite severe inhomogeneity artifacts observed in the gradient and, to a lesser extend, spin echo acquisition, no artifacts were detected for the SPI/VTI acquisition when compared with the SPI image, which is known to be artifact free. The influence of the variable time encoding in the SPI/VTI sequence did not significantly affect image resolution.[15] In vivo applications of SPI are being developed, especially with an increasing number of people having bones replaced (hip, knee, etc.).[22] These applications would benefit from the use of SPI/VTI and (or) silent SPI.

The use of the SPI/VTI sequence was demonstrated by imaging a small object made of soft rubber with $T_2^* = 73 \pm 4$ μs. Figure 7 shows the results comparing the central slice of 3D SPI (Figs. 7A and 7C) experiment with that of the SPT/VTI (Figs. 7B and 7D) experiment. Both experiments were performed with the same data matrix ($64 \times 64 \times 16$), gradient strengths, 1 average, FOV = $20 \times 20 \times 20$ mm^3 and a 32° RF pulse. The SPI/VTI experiment, with 40 μs ≤ 120 μs, resulted in an SNR of 32.6, whereas the SPI experiment, with $t_p = 120$ μs, only resulted in an SNR of 8.25. The finer details of the images (see Figs. 7C and 7D)) show that the SPI/VTI acquisition, despite the partial filtration effect owing to the variable encoding time, is capable of reproducing the geometric details of the object while providing substantial SNR enhancement compared with SPI.

Conclusions

In summary, two modifications of the SPI sequence were discussed and tested experimentally. The first modification was based on a general reduction of the SPL of SPI, associated with the fast switching of encoding gradients. Shaped gradients were shown to significantly reduce acoustic noise while offering an attractive alternative to the SPRITE sequence, reducing the overall power deposition into the gradient set of the magnet. The second modification was based on a reduction of signal attenuation during the phase-encoding period (SPI/VTI sequence), using a variable reduction of the encoding time. Used on materials with short T_2^* values, the SPI/VTI sequence showed a significant increase in SNR with minimal distortions owing to susceptibility effects.

Abstract: The ^{13}C chemical shift tensors of two crystalline forms of glucose (α-glucose and α-glucose·H_2O) were determined from one-dimensional (1D) and two-dimensional (2D) solid-state nuclear magnetic resonance (NMR) spectroscopy experiments. The experimental values determined from 1D and 2D methods are in very good agreement. Quantum chemical calculations were also carried out using the gauge-including projector augmented wave (GIPAW) method for plane-wave density functional theory (DFT) as implemented in the CAmbridge Serial Total Energy Package (CASTEP). The calculated ^{13}C chemical shifts were found to be in excellent agreement with experimental values for crystal structures that had their hydrogen atoms optimized and after an appropriate calibration was applied to convert calculated chemical shieldings into chemical shifts. The work presented here lays an important foundation for future solid-state NMR and quantum chemical calculation investigations of the various crystalline forms of cellulose.

Key words: NMR crystallography, carbohydrates, cellulose, quantum chemical calculations, crystal structure.

Résumé : On a déterminé les tenseurs des déplacements chimiques du ^{13}C de deux formes cristallines du glucose (α-glucose et α-glucose·H_2O) à partir des valeurs obtenues par résonance magnétique nucléaire (RMN) monodimensionnelle (1D) et bidimensionnelle (2D), à l'état solide. Les valeurs expérimentales obtenues par les méthodes 1D et 2D sont en très bon accord. On a aussi effectué des calculs de chimie quantique en faisant appel à une onde améliorée par un opérateur de projection comportant une jauge de la théorie de la fonctionnelle de la densité (« GIPAW-DFT ») avec une onde plane telle, qu'appliquée dans le « CAmbridge Serial Total Energy Package (CASTEP) ». On a trouvé que les valeurs calculées pour les déplacements chimiques du ^{13}C sont en excellent accord avec les valeurs expérimentales pour des structures cristallines pour lesquelles les atomes d'hydrogène avaient été optimisés et après qu'une calibration appropriée a été appliquée pour convertir les déplacements chimiques calculés en déplacements chimiques. Le présent travail pose une fondation importante pour des études futures de RMN à l'état solide et pour des calculs de chimie quantique de diverses formes cristallines de la cellulose.

Mots-clés : cristallographie par RMN, hydrates de carbone, cellulose, calculs de chimie quantique, structure cristalline.

Introduction

The detailed characterization of the structure of cellulose, the most abundant biopolymer on earth, has presented numerous challenges due mainly to its fibrous nature and multiplicity of crystalline forms. Two of the most important contributions to the understanding of the structure of cellulose have come from solid-state NMR spectroscopy and neutron and X-ray fibre diffraction experiments. The solid-state ^{13}C NMR work of Atalla and Vanderhart revealed that native celluloses consist of two crystalline forms, referred to as cellulose I_α and cellulose I_β, and that these two forms can coexist in the same sample of cellulose.[1] Langan, Nishiyama, and Chanzy have reported structures of various crystalline forms of cellulose derived from X-ray and neutron diffraction data collected on carefully aligned fibres of cellulose.[2–4] While these structures are considered to be the best structural models for the various forms of cellulose, there may still be a place for further study of the structures. The fact that diffraction data were collected on fibre samples places a limitation on the accuracy of the derived structures.

Solid-state NMR spectroscopy may provide an opportunity to probe the structures of cellulose in greater detail. Recent advances in solid-state NMR techniques and quantum chemical calculation methods for solids have expanded the opportunities for solid-state NMR spectroscopy to provide structural information for materials whose structures are difficult to characterize. Broadly referred to as "NMR crystallography",[5] innovative and creative ways of integrating solid-state NMR data with quantum chemical calculations and diffraction experiments have led to significant achievements in the structural characterization of inorganic[6–12] and organic solids.[13–22]

However, before jumping right in to applying NMR crys-

tallography approaches to the structures of cellulose, it is important to do some foundational work on model compounds to gain confidence that such an approach will be successful. In this paper, we present solid-state NMR experiments and quantum chemical calculations for two crystalline forms of glucose: α-glucose and α-glucose·H_2O. Since glucose is the monomer from which cellulose is built, these structures are appropriate model systems to test and develop an NMR crystallography approach.

Chemical shielding tensors are particularly sensitive probes of the local structure around a nucleus. The ability to reliably measure and calculate these tensors provides a powerful combination for testing structural models and even refining structures. We have previously shown how measurements and quantum chemical calculations of ^{29}Si tensors in zeolites can be integrated into an NMR crystallography structure determination process for zeolite crystal structures.[10–12,23] We hope to extend these successes to other materials such as cellulose. The work presented here on measuring and calculating ^{13}C tensors for α-glucose and α-glucose·H_2O is a first step in that direction.

Intermolecular O–H···O hydrogen bonds play a key role in the organization of all of the glucose and cellulose structures. Therefore, it is very important to consider the full three-dimensional periodicity of the crystal structures in any quantum chemical calculations of NMR properties, rather than simply treating the glucose molecules or monomers as isolated units. Recent developments in quantum chemical calculations for solids, most notably the gauge-including projector augmented wave (GIPAW) approach[24–26] for density functional theory (DFT) implemented in the CAmbridge Serial Total Energy Package (CASTEP) program,[27] now allow for accurate calculations of NMR properties on actual crystal structures, rather than molecular fragments or clusters extracted from a crystal structure. The successes and limitations of this method for performing calculations on organic molecular crystals have recently been reviewed.[18,28]

In this paper we present one-dimensional (1D) and two-dimensional (2D) solid-state NMR experiments for measuring ^{13}C chemical shift tensors in α-glucose and α-glucose·H_2O and demonstrate that GIPAW DFT quantum chemical calculations can accurately reproduce these experimental NMR measurements, providing us with the confidence needed for future NMR crystallography studies on the more complicated crystal structures of cellulose.

Experimental

Samples

The α-glucose·H_2O sample in this work was ^{13}C-enriched at every carbon site to a level of 6%. A sample of [6% $^{13}C_6$] D-(+)-glucose was purchased from Sigma-Aldrich and dissolved in a minimum amount of hot water, after which the water was slowly evaporated at room temperature over several days. Anhydrous α-glucose was prepared at ^{13}C natural abundance by heating a sample of α-glucose·H_2O (with ^{13}C natural abundance) at approximately 70 °C overnight under vacuum. The cellulose sample was bio-synthesized by growing *Acetobacter xylinum* (ATCC 23769) bacterial cultures at 30 °C in sterile Hestrin and Schramm medium[29] with glucose as the carbon source. After 20 days, the cellulose pellicle was extracted, washed, and blended with 1 mol/L NaOH. The resulting slurry was centrifuged and the supernatant was decanted. This was followed by two additional cycles of resuspension in water and centrifugation.

Solid-state NMR

Experiments were carried out on a Bruker Avance 200 MHz spectrometer operating at a magnetic field strength of 4.7 T (50.42 MHz ^{13}C Larmour frequency) using a wide-bore double-resonance 7 mm MAS NMR probe. Samples filled the entire 7 mm rotors. The ^{13}C chemical shifts were referenced by setting the low-field ^{13}C resonance for a sample of adamantane to 38.84 ppm. ^{13}C cross-polarization/magic-angle spinning (CP MAS) spectra were collected with moderate MAS frequencies (4 kHz) for spectra with only isotropic resonances and slow MAS frequencies (285 Hz and 275 Hz for α-glucose·H_2O and α-glucose, respectively) for spectra with spinning sideband manifolds. All 1D spectra were acquired with a recycle delay of 20 s, 4 ms of cross-polarization from protons, and SPINAL-64 decoupling[30] during acquisition with a radio frequency (rf) field strength of 83 kHz. A modified version[23] of the 2D 4π-pulse chemical shift anisotropy (CSA) recoupling sequence[31] was used in this work, which correlates quasi-static powder line shapes to the isotropic chemical shifts. These quasi-static powder line shapes have the same shape as static powder line shapes but are narrowed by a scaling factor of 0.393 and have their centers of gravity at zero frequency in the indirect dimension. Composite 90_x–180_y–90_x recoupling pulses were employed, since the sensitivity of the CSA-recoupled line shapes to errors in the rf amplitude of the recoupling pulses has been shown to be dramatically reduced compared with using regular 180° pulses.[23] The pulse sequence was implemented with ^{13}C 90° and 180° pulses of 6 and 12 μs, respectively. The experiments were carried out at a spinning frequency of 2000 Hz and employed 4 ms of cross-polarization from protons, a recycle delay of 5 s, a continuous-wave ^{1}H decoupling rf field strength of approximately 100 kHz during the CSA recoupling period, and 83 kHz SPINAL-64 ^{1}H decoupling during the acquisition period. Twelve t_1 increments, each with two spectra, were acquired with 64 scans for α-glucose·H_2O and 320 scans for α-glucose. The displayed experimental and simulated quasi-static CSA-recoupled line shapes have the frequency axis scaled using a pulse sequence scaling factor of 0.393.

Spectrum fitting

To estimate ^{13}C chemical shift tensors from experimental data, spectrum fitting of the slow MAS spectra and CSA-recoupled line shapes was carried out according to the protocols described previously.[23] The Herzfeld–Berger convention[32] for quantifying the chemical tensor was employed in which the three principal components of the CS tensor, $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, are expressed in terms of the isotropic chemical shift $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$, which is observed in MAS experiments, the span $\Omega = \delta_{11} - \delta_{33}$, which describes the breadth of the tensor, and the skew $\kappa = (3\delta_{22} - \delta_{iso})/\Omega$, which describes the asymmetry of the tensor. To find the values of Ω and κ giving the best fit to the experimental data, a series of simulations were carried out using SIMPSON[33] over a range of values for Ω and κ. Contour plots of χ^2 (sum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

the squares of the differences between experimental and simulated data) as a function of Ω and κ were constructed to locate the values of Ω and κ giving the χ^2 minimum, χ^2_{min}. The uncertainties in Ω and κ were estimated from the values of Ω and κ with $\chi^2 = 2\chi^2_{min}$. The uncertainties of δ_{11}, δ_{22}, and δ_{33} were determined from the widest possible ranges of their values given the uncertainties in δ_{iso}, Ω, and κ.

Quantum chemical calculations

Plane-wave DFT calculations of nuclear magnetic shielding tensors were performed using the NMR module of the CASTEP code[27] that employs the GIPAW algorithm[24–26] and is a part of the Accelrys Materials Studio simulation and modeling package.[34] The Perdew–Burke–Ernzerhof (PBE) functional was used with the generalized gradient approximation for all calculations.[35] On-the-fly pseudopotentials were used as supplied in Materials Studio. All calculations were performed on primitive cells using the cell parameters and atomic coordinates from the X-ray diffraction structure of α-glucose·H_2O,[36] the neutron diffraction structure of α-glucose,[37] and structures of both in which the hydrogen positions were optimized with the CASTEP program (with the unit cell parameters fixed to those measured by diffraction). The NMR calculations and geometry optimizations of hydrogen positions were carried out at the "fine" level with basis set cutoff energies of 550 eV and *k*-point spacing of 0.05 $Å^{-1}$. The geometry optimization was performed using the PBE functional and the same Monkhorst–Pack *k*-point grid spacings and cutoff energies as in corresponding single point energy calculations. Convergence tolerance parameters in geometry optimization were set as follows: energy, 10^{-5} eV/atom; maximum force, 0.03 eV/A; maximum stress, 0.05 GPa; maximum displacement, 10^{-3} Å.

Results and discussion

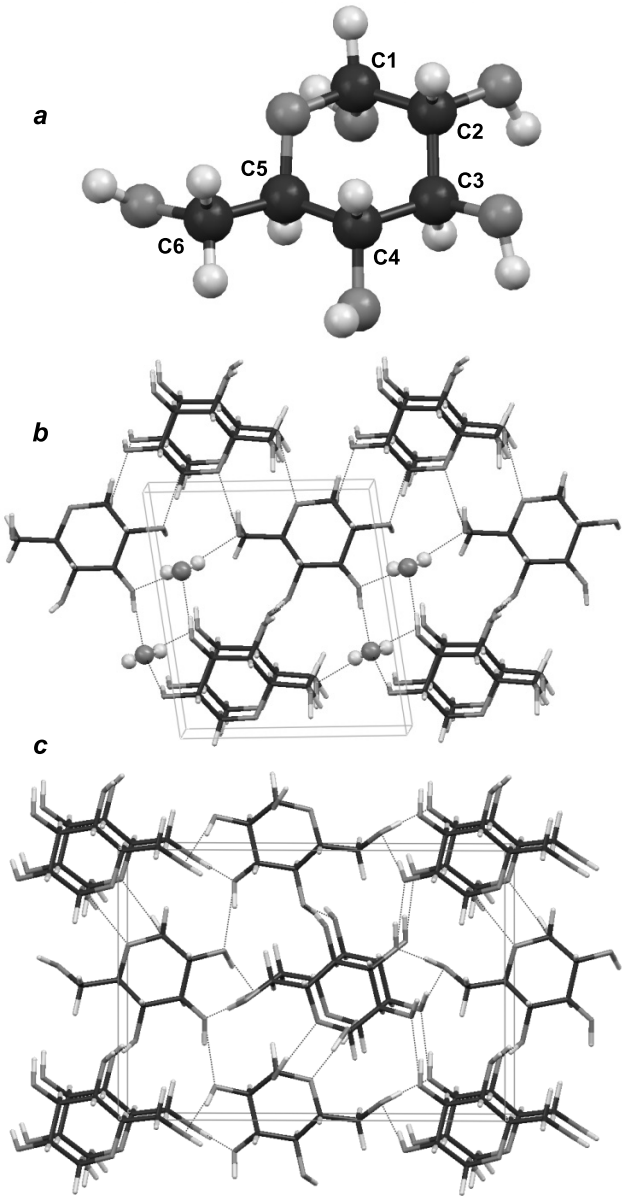
Crystal structures

The crystal structures for α-glucose·H_2O[36] and α-glucose[37] have been determined previously from single-crystal X-ray and neutron diffraction data, respectively. The structure of a single glucose molecule and the packing of the two-crystal structures are shown in Fig. 1. α-Glucose·H_2O crystallizes in the $P2_1$ space group with a unit cell volume of 430.674 $Å^3$, which contains two symmetry-related glucose and two symmetry-related water molecules, while α-glucose crystallizes in the $P2_12_12_1$ space group with a large unit cell of 765.919 $Å^3$ containing four symmetry-related glucose molecules. The molecules pack together with a large degree of intermolecular O–H···O hydrogen bonding involving the -OH groups of the glucose molecules and also involving the water molecules in the case of α-glucose·H_2O.

Solid-state NMR spectroscopy

The asymmetric unit of each material contains a single glucose molecule and this fact is confirmed in the ^{13}C CP MAS spectra of α-glucose·H_2O (Fig. 2*a*) and α-glucose (Fig. 2*b*), which each consist of six peaks corresponding to the six carbon sites. The spectra are clearly different, yet the isotropic chemical shifts are for the most part quite similar between the two materials. The main exception is C6, which has a greater orientational degree of freedom than the other

Fig. 1. (*a*) Glucose molecule with carbon numbering scheme indicated. (*b*) Crystal structure of α-glucose·H_2O. (*c*) Crystal structure of α-glucose. Carbon, oxygen, and hydrogen atoms are represented by dark, medium, and light grey shading, respectively, while intermolecular hydrogen bonds are indicated by dotted lines.



carbons in the glucopyranose ring. The peaks are very narrow, indicating very crystalline and well-ordered materials. The peaks are labeled according to the peak assignments worked out previously in selective ^{13}C labeling experiments.[38]

Figure 2*c* presents a ^{13}C CP MAS spectrum of bacterial cellulose for comparison. C1 and C4 are at significantly different shifts owing to the 1,4-glycosidic linkage that exists between joined neighbouring glucose moieties in the cellulose polymer chains. The chemical shifts of the other carbons remain in the same general regions. The peaks in the cellulose spectrum are not nearly as sharp and simple as those in the glucose spectra. The complexity of the spectrum is due mainly to the existence of two crystalline forms of cellulose[1]

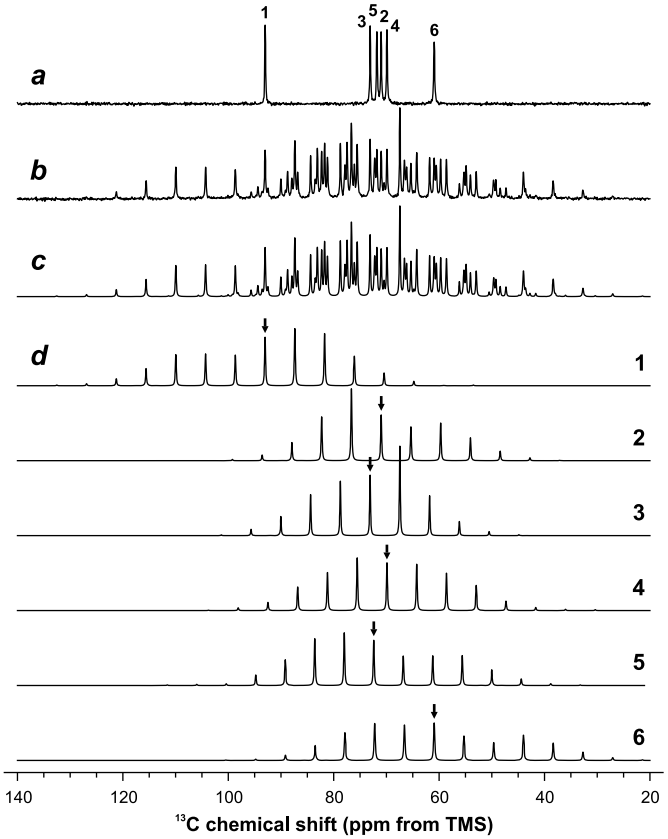
(I_α and I_β), which each consist of two glucose units in their asymmetric units,[3,4] and the presence of non-crystalline cellulose. Each labeled peak is actually a superposition of at least four peaks, which leads to the complex line shapes. The cellulose spectrum is presented here as a comparison with the much simpler glucose spectra to demonstrate that the measurement of ^{13}C chemical shift tensors of cellulose requires more sophisticated NMR experiments than just simply collecting a spectrum at a slow MAS frequency and analyzing the spinning sideband profile.

A straightforward approach to measuring the six ^{13}C chemical tensors in the two glucose samples is to analyze the spinning sideband manifolds in ^{13}C CP MAS spectra collected at slow MAS frequencies. Figures 3 and S1 (see Supplementary data) show the slow MAS spectra for α-glucose·H_2O and α-glucose, respectively, along with the individual spinning sideband manifolds for each carbon site. The spinning frequencies were carefully chosen to ensure that there was no overlap of the peaks and that the spinning was sufficiently slow so that enough spinning sidebands would be present. The relative simplicity of the glucose spectra allows for such an approach, whereas the complexity of the cellulose spectrum means that a sufficiently slow MAS frequency does not exist such that peak overlap is avoided.

A more sophisticated approach is to perform a 2D experiment in which the chemical shift tensor is recoupled by a series of carefully timed pulses synchronized with the rotation of the sample about the magic angle. While there are a variety of approaches to measuring chemical shift tensors in complex spectra using 2D methods,[39–47] we have chosen to employ a composite-pulse version of the 4π CSA recoupling experiment introduced by Tycko et al.[31] This modified pulse sequence was highly successful for measuring small ^{29}Si chemical shift tensors in zeolites at ultrahigh magnetic fields.[23] The resulting spectra give quasi-static powder patterns in the indirect dimension that are each correlated to the isotropic chemical shift in the direct dimension. The 2D spectra for α-glucose·H_2O and α-glucose are presented in Figs. 4 and S2 (see Supplementary data), respectively. In each case, six distinct scaled powder patterns are obtained

Fig. 3. (*a*, *b*) Experimental ^{13}C CP MAS NMR spectra of α-glucose·H_2O obtained using MAS spinning frequencies of (*a*) 4000 Hz (8 scans) and (*b*) 285 Hz (200 scans) with recycle delays of 20 s. (*c*) Simulated 285 Hz MAS spectrum composed of (*d*) individual simulated spinning sideband patterns for each carbon site. The arrows indicate the isotropic peaks. Corresponding data for α-glucose are presented in Fig. S1 in the Supplementary data.



from which the principal components of the ^{13}C chemical shifts tensors can be estimated.

The intention here is to examine the reliability of this 2D method in comparison with analyzing spinning sideband manifolds for the two simple glucose samples, so that further studies involving the ^{13}C chemical shift tensors of the more complicated cellulose sample can be done with confidence. To that end, the spinning sideband manifolds obtained in the slow MAS spectra and the quasi-static powder patterns obtained in the 2D experiments were analyzed and compared. In each case, a series of simulations were performed as a function of the span Ω and skew κ of the chemical shift tensors and compared with the experimental data to map out a contour plot not only to identify the values of Ω and κ that give the best fit in each case, but also to estimate their uncertainties. Figure 5 presents these contour plots for each carbon site, for each experimental method, and for each glucose sample. These plots show that the two methods are in agreement within their estimated uncertainties. The plots also reveal that the uncertainties estimated from the spinning sideband manifolds are considerably less than those estimated from the 2D recoupling spectra. Not unexpectedly, the uncertainties for the ^{13}C-enriched sample (α-glucose·H_2O) are noticeably less for both methods.

Fig. 4. (*a*) 2D ^{13}C CSA recoupling spectrum for α-glucose·H_2O. (*b*) Experimental (solid lines) and best-fit simulated (dashed lines) pseudo-static CSA-recoupled line shapes for the indicated carbon sites extracted from the 2D spectrum. Corresponding data for α-glucose are presented in Fig. S2 in the Supplementary data.

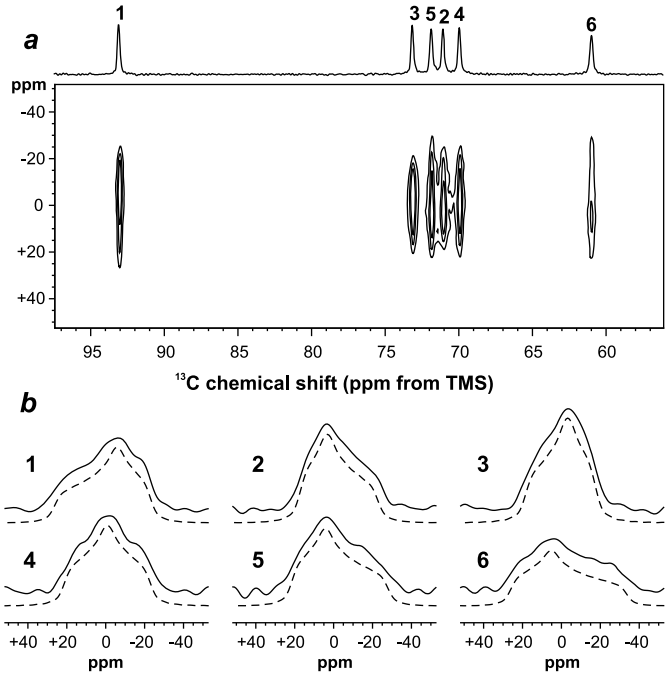

Fig. 5. Contour plots of χ^2 from which the best-fit values of Ω and κ and their uncertainties were estimated for each carbon site in (*a*) α-glucose·H_2O and (*b*) α-glucose. The solid contours indicate the χ^2 surfaces near the minima obtained from the analysis of the spinning sideband manifolds in Figs. 3 and S1, while the dashed contours indicate those obtained from the analysis of the recoupled pseudo-static powder patterns in Figs. 4 and S2. The contours are at multiples of $\sqrt{2}$ and 2 of the minimum χ^2 value for each carbon site and method. The plus symbols indicate the quantum chemical calculated Ω and κ values for each carbon site. The experimental and calculated values are listed in Tables S1 and S2 in the Supplementary data.

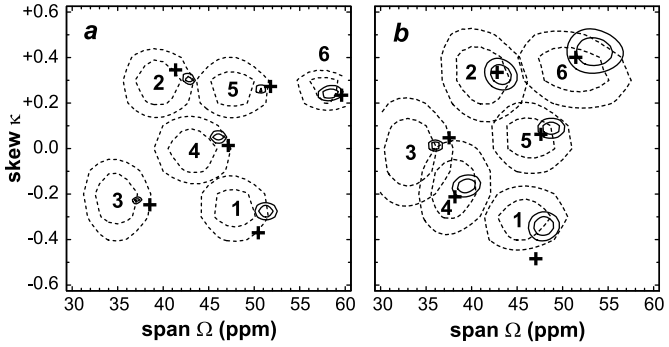

Figure 6 also provides a comparison of the two methods in which the span and skew obtained from each method are compared. The span values seem to be systematically slightly underestimated in the 2D experiment (Fig. 6*a*), while the skew values agree very well between the two methods (Fig. 6*b*). The difference in span values likely results from the fact that, based on simulations of the pulse sequence,[23]

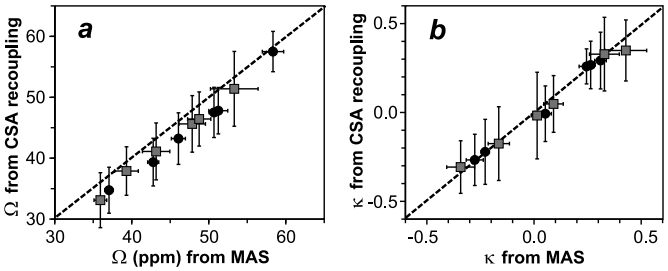
Fig. 6. Comparison of (*a*) the span Ω and (*b*) the skew κ values determined from the CSA recoupling experiment with those determined by analysis of the spinning sideband manifolds in the slow MAS experiments. The black circles and grey squares represent the values obtained for α-glucose·H_2O and α-glucose, respectively.



any error in the recoupling pulses tends to decrease the observed span in the 2D recoupling experiment. Overall, however, these results do indicate that the 2D recoupling approach can be employed with confidence for situations that are considerably more complex than the glucose spectra presented here, such as cellulose.

Quantum chemical calculations

Quantum chemical calculations of ^{13}C chemical shielding tensors were carried out on the as-published α-glucose·H_2O crystal structure determined from X-ray diffraction data. In Fig. 7*a* the principal components (σ_{11}, σ_{22}, σ_{33}) of the six calculated ^{13}C chemical shielding tensors are plotted against the corresponding principal components (δ_{11}, δ_{22}, δ_{33}) of the ^{13}C chemical shift tensors determined experimentally from the spinning sideband profiles in the slow MAS spectrum. While there is a clear linear correlation between the calculated and experimental values, there remains a significant degree of scatter (the root-mean-square deviation, RMSD, is 2.8 ppm) and, most noticeably, the slope of the line of best fit (–1.358) is quite a bit steeper than the expected slope of –1.

The hydrogen atom positions in α-glucose·H_2O were then optimized and the ^{13}C chemical shielding tensors were recalculated. Figure 7*b* shows the substantial improvement in the agreement between calculated shieldings and experimental shifts, with the RMSD improving to 1.0 ppm. This improvement is a reflection of the fact that X-ray diffraction data do not provide H atom positions to a sufficiently high accuracy owing to the low X-ray scattering ability of hydrogens.

Similarly, quantum chemical calculations of ^{13}C chemical shielding tensors were carried out on the α-glucose structure before (Fig. 7*c*) and after (Fig. 7*d*) optimization of H atom positions. However, in this case the published crystal structure for α-glucose was determined from neutron diffraction data and the H atom positions have a high degree of accuracy. Consequently, optimization of the H atom positions does not improve agreement between calculated and experimental NMR parameters, with the RMSD being 0.9 ppm before and after optimization.

Notice that for both α-glucose·H_2O (Fig. 7*b*) and α-glucose (Fig. 7*d*), the slopes of the lines still deviate noticeably from the expected slope of –1. For the H-optimized structures, the lines of best fit are $\sigma = -1.149\delta + 179.6$ ppm for α-glucose·H_2O and $\sigma = -1.123\delta + 178.0$ ppm for α-glucose (see Table 1). If the data for both structures are pooled, the

Fig. 7. Comparison of the principal components (σ_{11}, σ_{22}, σ_{33}) of the chemical shielding tensors for each carbon site calculated using CASTEP with the principal components (δ_{11}, δ_{22}, δ_{33}) of the chemical shift tensors measured experimentally from the spinning sideband manifolds in slow MAS spectra. The chemical shielding tensors in *a* and *b* were calculated from the published X-ray diffraction structure of α-glucose·H_2O[36] (*a*) before and (*b*) after geometry optimization of the H positions, while those in *c* and *d* were calculated from the neutron diffraction structure of α-glucose[37] (*c*) before and (*d*) after geometry optimization of the H positions. The dashed lines indicate the best fits with the slope fixed to –1. In *a* and *c* the solid lines indicate the line of best fit, while in *b* and *d* each solid line corresponds to the equation $\sigma = -1.139\delta + 177.9$ ppm[48] (see text).

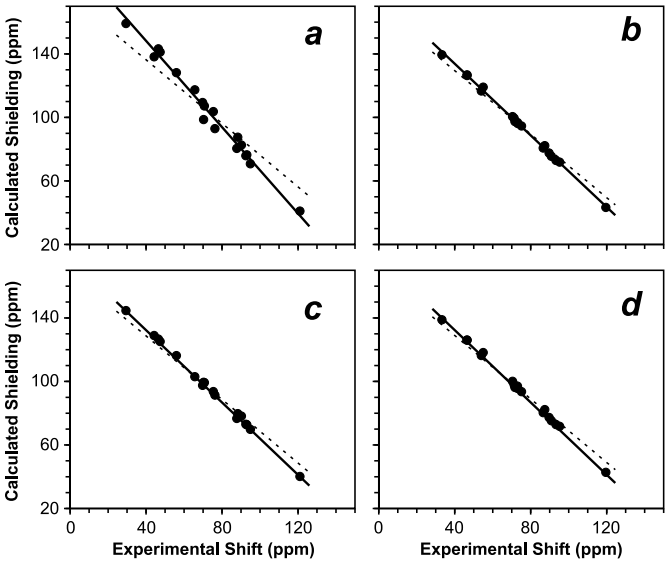

Table 1. Results of linear least-squares fitting of the relationship between calculated chemical shielding and experimental chemical shifts in Fig. 7.

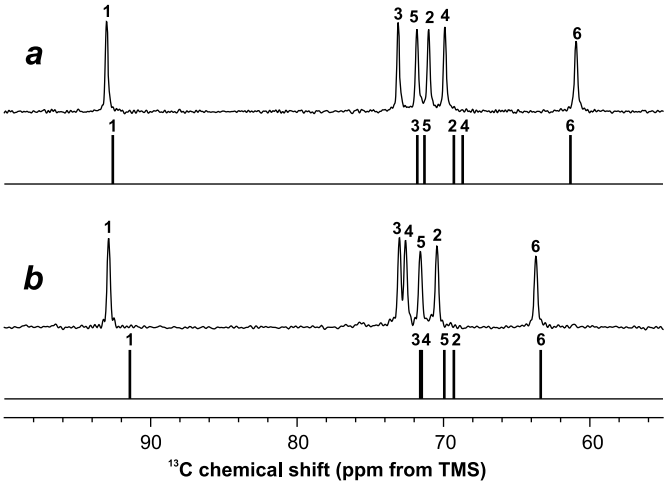
Structure	Slope	Intercept	RMSD
α-Glucose·H_2O			
XRD structure	–1.358	202.6	2.8
H-optimized	–1.149	179.6	1.0
α-Glucose			
Neutron structure	–1.128	178.9	0.9
H-optimized	–1.123	178.0	0.9

line of best fit for all the data is $\sigma = -1.137\delta + 178.9$ ppm with an overall RMSD of 1.0 ppm.

Johnston and co-workers recently reported the exact same phenomenon in a very detailed study of GIPAW DFT calculations of ^{13}C shielding tensors in carbohydrate crystal structures.[48] A set of 10 carbohydrates with the highest quality crystal structures and solid-state NMR data were examined; each of the structures examined was determined from single-crystal neutron diffraction and the ^{13}C chemical shift tensors were all determined from single-crystal NMR experiments. Calculations of the ^{13}C chemical shielding tensors were performed under the same conditions as those reported in this work (using CASTEP at the "fine" level of calculation after optimizing the hydrogen atom positions). For the entire set of ^{13}C tensors from all of the structures, the relationship between calculated shieldings and experimental shifts was found to be $\sigma = -1.139\delta + 177.9$ ppm with an overall RMSD of 1.88 ppm.

Fig. 8. Comparison of experimental and calculated ^{13}C isotropic chemical shifts for (*a*) α-glucose·H_2O and (*b*) α-glucose. The relationship $\sigma = -1.139\delta + 177.9$ ppm[48] was used to convert calculated chemical shieldings to chemical shifts.



The results presented here for α-glucose·H_2O and α-glucose are entirely consistent with this larger data set. As shown in Figs. 7*b* and 7*d*, both sets of data are very well fit by the relationship derived from this larger high-quality data set. The RMSDs of the data points from this line are 1.3 and 1.5 ppm for α-glucose·H_2O and α-glucose, respectively.

Therefore, the relationship $\sigma = -1.139\delta + 177.9$ ppm found by Johnston and co-workers can reliably be used as a "calibration curve" for carbohydrates to convert calculated chemical shieldings into chemical shifts to make comparisons with experimental measurements of chemical shifts. These calculated principal components of the chemical shift tensors are listed in Tables S1 and S2 (see Supplementary data). In Fig. 8 the experimental and calculated isotropic chemical shifts are compared visually. In Fig. 5 the calculated Ω and κ for each ^{13}C tensor have been added for comparison purposes to the contour plots for the two experimental determinations of the chemical shift tensors. Additionally, the calculated principal components of the ^{13}C chemical shift tensors are compared in Fig. 9 with those determined experimentally by the two methods (along with estimates of their experimental uncertainties). In each of these representations, the agreement between calculated and experimental chemical shifts is shown to be quite remarkable. Therefore, we have confidence that measurements and calculations of ^{13}C chemical shift tensors hold promise to be valuable tools for future work in probing the crystal structures of cellulose in greater detail.

Johnston and co-workers[48] suggested two main reasons for the deviation of the slope from –1. The first is that the calculations assume a static molecule where temperature effects and zero-point energy corrections are neglected. Dumez and Pickard recently reported calculations that attempt to account for motional effects.[49] Although there is improved agreement when this is done, there is still a deviation from a slope of –1. The second suggested reason is that there are systematic

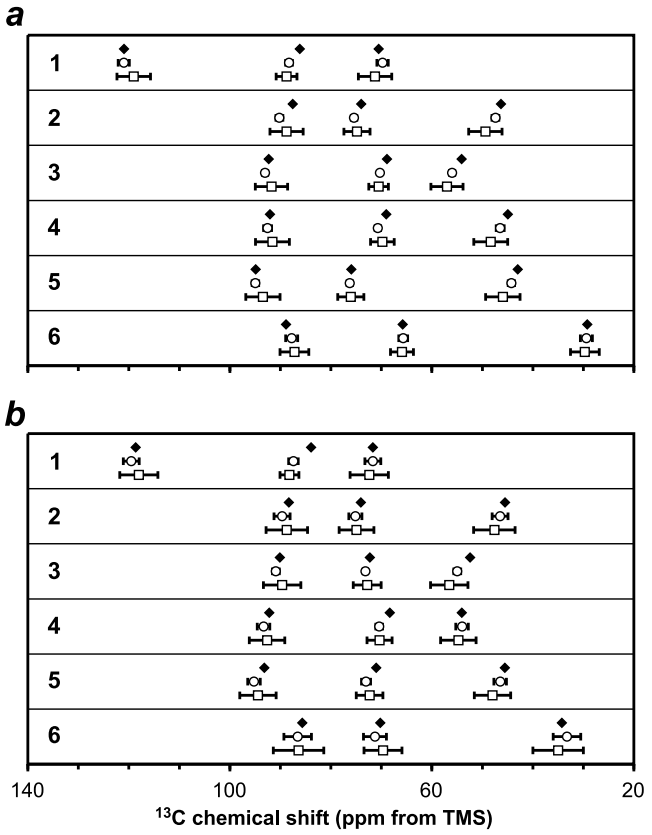
Fig. 9. Comparison of principal components (δ_{11}, δ_{22}, δ_{33}) of the ^{13}C chemical shift tensors for (*a*) α-glucose·H_2O and (*b*) α-glucose calculated using CASTEP (filled diamonds) with those obtained from spinning sideband manifolds in slow MAS experiments (open circles) and those obtained from 2D CSA recoupling experiments (open squares). The relationship $\sigma = -1.139\delta + 177.9$ ppm[48] was used to convert calculated chemical shieldings to chemical shifts.



errors in the quantum chemical calculation method itself, related to the calculation of the paramagnetic contribution to the chemical shielding, which stem from the fact that it is difficult for existing exchange-correlation functionals to reproduce dynamic polarization in low electron density regions.[48] Nonetheless, with an appropriate calibration curve that relates chemical shieldings and chemical shifts, highly accurate calculations of chemical shift tensors can be still be performed.

Conclusions

The work presented here lays an important foundation for future solid-state NMR and quantum chemical calculation investigations of the various crystalline forms of cellulose. Using two crystalline forms of glucose, the monomer from which cellulose is constructed, we have established two important points. First, it has been demonstrated that the principal components of the ^{13}C chemical shift tensors in systems with complicated spectra (such as cellulose) can be reliably measured with the 2D recoupling experiment used here. The ^{13}C chemical shift tensors determined from spinning sideband manifolds and 2D recoupling spectra for α-glucose·H_2O and α-glucose are in good agreement, although higher uncertainties are to be expected for tensors determined from 2D recoupling experiments. Second, this work on glucose crystal structures demonstrates that quantum chemical calculations of ^{13}C chemical shift tensors are very accurate if two important precautions are taken. The crystal structure must have highly accurate atomic positions, especially hydrogen atom positions, which can be achieved by using a neutron diffraction structure or by performing a geometry optimization of hydrogen atom positions. The second precaution is that an appropriate conversion between calculated chemical shielding and chemical shifts must be applied. This work confirms the "calibration" for this conversion, as the results are very consistent with previous work on other carbohydrate crystal structures.[48]

With the confidence to accurately measure and calculate ^{13}C chemical shift tensors, it will be possible to evaluate the existing structural models for the various forms of crystalline cellulose[2–4] by comparing experimentally measured and quantum chemical calculated chemical shift tensors. For example, these experiments could potentially adjudicate between two reported structures of cellulose I_α.[4,50] Should neither of these structural models show consistency between calculated and experimental chemical shifts, CASTEP calculations also provide the ability to perform geometry optimizations of the structures which may, in the end, lead to more accurate structural models of cellulose. This would be a significant achievement in the field of NMR crystallography.

Supplementary data

Supplementary data (Figs. S1 and S2, Tables S1 and S2) are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Acknowledgements

Access to the 200 MHz solid-state NMR spectrometer was provided by the National Research Council Canada. Access to CASTEP software was provided by the National Ultra-high-field NMR Facility for Solids (http://nmr900.ca). We thank Victor Terskikh for assistance with NMR experiments and quantum chemical calculations. We thank the Natural Sciences and Engineering Research Council of Canada for research support in the form of a Discovery Grant (D.H.B.) and an undergraduate student research award (Q.F.).

Abstract: A parallel-plate radio frequency resonator has been designed for high-resolution thin film magnetic resonance imaging. The $\mathbf{B}_1$ field produced by the resonator was evaluated through experiment and numerical simulation. The resonator, composed of two conductive plates sandwiching the sample, generates a uniform $\mathbf{B}_1$ field parallel to the plates. This feature renders the resonator largely immune to radio frequency screening from conductive layers parallel to the sample. The resonator is custom fabricated according to the dimensions of the sample, yielding a high filling factor. The radio frequency probe is shown to facilitate high-sensitivity depth profiling of thin films. Three variations on the basic design are examined. Since the intention is to employ these resonators for functional studies of membranes, we introduce perforations in the parallel plates to permit mass transfer in and out of the thin films under study. One-dimensional depth profiles of Nafion 117 are presented with and without the addition of additional plates of conductive material. One-dimensional depth profiles of Nafion 1110 and a two-dimensional image of Nafion 117 in an operating fuel cell, which was integrated into the radio frequency circuit, are also illustrated.

Key words: RF coil, parallel plate, zero-mode transverse electric and magnetic (TEM), Nafion, fuel cell.

Résumé : On a développé un résonateur de radiofréquence à plaques parallèles pour l'imagerie de résonance magnétique à haute résolution de films minces. On a évalué le champ $\mathbf{B}_1$ produit par le résonateur par le biais d'une expérience et d'une simulation numérique. Le résonateur, qui est composé de deux plaques conductrices maintenant l'échantillon en sandwich, génère un champ $\mathbf{B}_1$ uniforme, parallèle aux plaques. Cette caractéristique fait que le résonateur est grandement protégé de l'effet d'écran de radiofréquence des couches conductrices parallèles à l'échantillon. Le résonateur a été fabriqué sur mesure, d'après les dimensions de l'échantillon, ce qui lui assure un facteur de remplissage élevé. On a démontré que la sonde de radiofréquence facilite une grande sensibilité dans la détermination du profil en profondeur des films minces. On a examiné trois variations sur le modèle de base. Puisque l'intention est d'utiliser ces résonateurs pour des études fonctionnelles de membranes, on a introduit des perforations dans les plaques parallèles afin de permettre des transferts de masse à partir de et vers les films minces étudiés. On présente les profils de profondeur unidimensionnelle du Nafion 117, avec et sans addition de plaques additionnelles de matériel conducteur. On illustre aussi les profils de profondeur unidimensionnelle du Nafion 1110 et une image bidimensionnelle du Nafion 117 dans une pile à combustible opérationnelle intégrée dans un circuit de radiofréquence.

Mots-clés : bobine RF, plaque parallèle, mode électrotransversal (MET) zéro, Nafion, pile à combustible.

Introduction

In high-resolution magnetic resonance imaging (MRI), selecting a suitable resonator is of great significance in determining the final signal-to-noise ratio (SNR).[1] The surface coil, due to its strong $\mathbf{B}_1$ field strength, is often a natural selection for this purpose.[2,3] However, the sensitivity of the surface coil decreases rapidly with distance.

In previous high-resolution imaging of thin films, we positioned a surface coil directly below the thin film sample.[4] The $\mathbf{B}_1$ field is thus perpendicular to the plane of the film. However, in many practical thin film devices, for example,

fuel cells and batteries, the thin layer of interest is sandwiched between conductive electrodes. In these cases the radio frequency (RF) excitation of a surface coil will be shielded from the thin film. Moving to lower RF will increase the skin depth and potentially permit better excitation, but this is not an appealing strategy. A better choice, which we explore in this paper, is to introduce a $\mathbf{B}_1$ field oriented parallel to the plane of the thin film while still orthogonal to $\mathbf{B}_0$. A surface coil is clearly not appropriate for this application, while the use of a standard volume coil will incur a substantial filling factor penalty.

Parallel-plate resonators have been employed in many scientific areas,[5,6] but their use is relatively new for thin film MRI. Zhang et al. have employed a type of parallel-plate resonator to study liquid crystal properties in both bulk and constrained thin film capillaries[7] and have undertaken chemical shift resolved velocity mapping in microfluidic systems.[8] A similar RF coil has been developed for MRI histology by Meadowcroft et al.[9] The Meadowcroft design was not intended to be part of a functioning electrochemical device and does not permit mass transport through the resonator plates, contrary to the current design.

For thin film MRI, in this study we present a zero-mode transverse electric and magnetic (TEM)[10] parallel-plate resonator, which uses two parallel conductive plates to sandwich the sample. This approach avoids the RF shielding problem, as the plates are in the same orientation as the conductors in the sample, and the resultant $\mathbf{B}_1$ field is parallel to the plane of the membrane being imaged. A homogeneous current distribution on the plates will lead to a homogeneous $\mathbf{B}_1$ field distribution. In addition, such a resonator will structurally confine the sample and maintain its geometrical shape with controlled pressure if the sample is morphologically sensitive to its environment. The parallel-plate resonator features high sensitivity, because the excitation volume will structurally match the sample size, yielding a high filling factor.

We compare the experimental $\mathbf{B}_1$ field distribution with the results of numerical simulations for different plate assemblies. We also present the results of high-resolution depth imaging of Nafion 117 membranes with graphite plates of different thicknesses inserted inside the parallel-plate resonator. Testing with graphite plates adjacent to the resonator is critical in regards to use of the parallel-plate resonator for studies of electrochemical cells, for example a fuel cell. The graphite plates provide mechanical support and an electrical connection to the remainder of the electrochemical cell.

As the resonator is immediately adjacent to the sample, it will distort the $\mathbf{B}_0$ field and introduce artifacts into a frequency-encoded image if the plate material's magnetic susceptibility differs substantially from that of the sample. Pure phase-encoding methods were implemented in all measurements because they are free from distortions due to $\mathbf{B}_0$ inhomogeneity, susceptibility variations, and chemical shift.[11,12] Two-dimensional centric-scan SPRITE imaging was employed to visualize the $\mathbf{B}_1$ field distribution generated by the parallel-plate resonator. Double half *k*-space (DHK) spin echo (SE) single point imaging (SPI)[4,13] was employed to acquire high-resolution water content profiles of Nafion samples. Both techniques are centric-scan MRI methods, with an extended recovery time preceding each $k = 0$ RF pulse to permit full recovery of longitudinal magnetization, M_z, and are thus immune to T_1-contrast.[14–16]

The application of MRI methods to study water content and water transport in Nafion proton electrolyte membrane fuel cells was pioneered by Tsushima[17,18] and Wasylishen.[19,20] This new parallel-plate resonator aims to improve the limited MRI sensitivity of conventional RF probes that hinders sensitivity and limits resolution. To demonstrate its capabilities, an image was acquired of water in the membrane layer of an operating fuel cell. The fuel cell design requires that the layer be sandwiched between conductive plates during operation. The new resonator design, combined with the DHK SE SPI method, allows high-resolution (less than 10 μm) 1D images with SNR > 40 to be acquired in 90 s. Information about the structure and function of an operating fuel cell may be inferred from such high-quality results.

The current paper is intended as background justification and explanation of the RF probe employed in our recent MRI study of an operational fuel cell.[21]

Theory

RF circuit with an integrated parallel-plate transmission line

A schematic diagram of the parallel-plate resonator is presented in Fig. 1. The parallel plates sandwich the thin film sample and are bolted together as illustrated. The $\mathbf{B}_1$ field from a plate curls around the flowing current. Therefore, the fields from both plates add along *x* in the gap between them and cancel outside. If the thin film sample is layered with conductive material, the cross section seen by $\mathbf{B}_1$ is small and there is therefore minimal interference from the conductor.

The parallel plates chiefly represent a distributed inductance, but there will be a substantial capacitive component for closely spaced plates. The inductance is tuned to resonance with a fixed capacitor, C_m, and a standard matching circuit, as shown in the figure.

Numerical simulation

A design with perforated plates, allowing mass transport through the resonator to the sample, was required. Changes in the field due to the plate geometry were first studied through simulation. The longest dimension of the resonator was ~9 cm and as a result only the TEM00 mode will be excited at the 100 MHz operating frequency. This mode will have the same field pattern as for a static current flowing in the plates, allowing static methods to be used in modeling the probe.

The current distribution in the plates was simulated by modeling each plate as a grid of vanishingly small, equal resistors. Assuming the current enters the plate at a single point and leaves it at a second point, the current distribution in the resistor grid is obtained by numerically solving Kirchoff's voltage and current laws. The corresponding magnetic field was calculated from the current distribution using the Biot–Savart law.

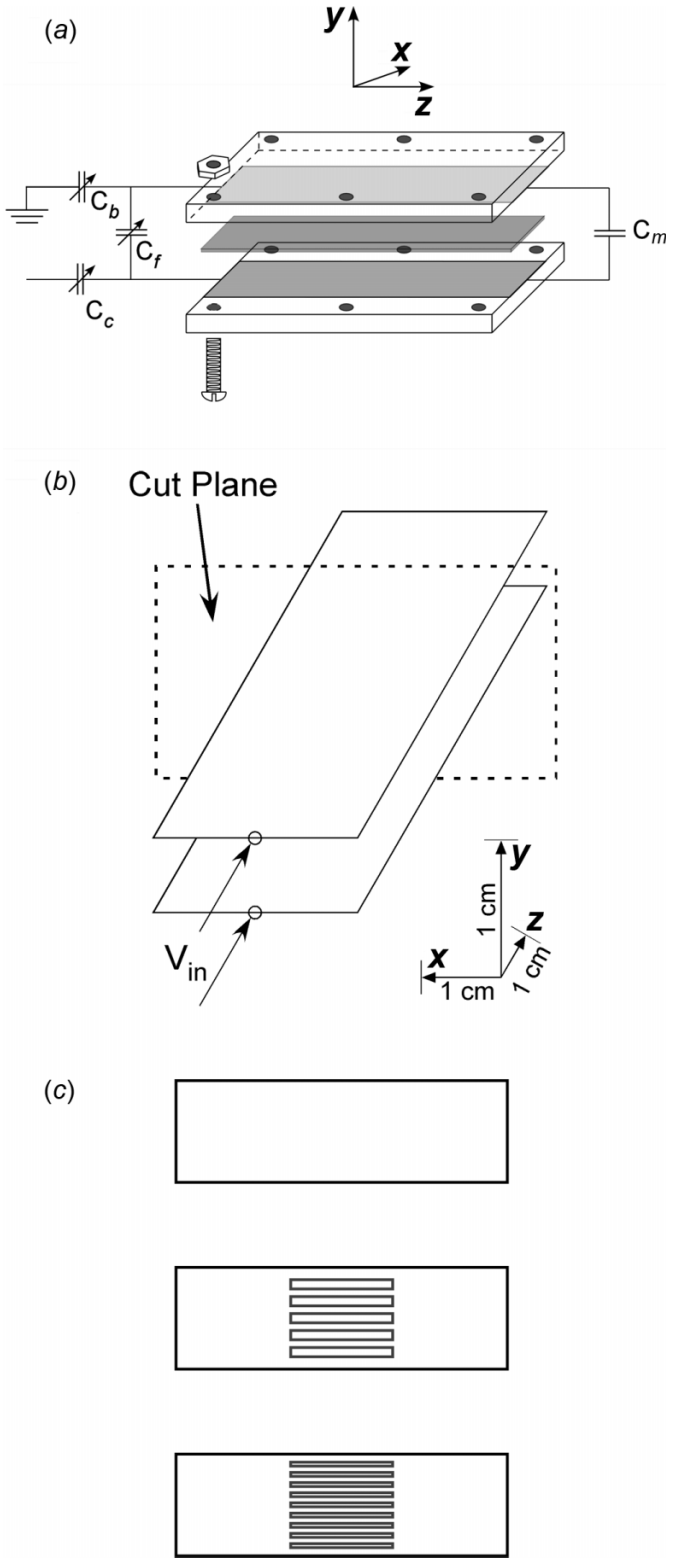
Fig. 1. (*a*) Schematic of a zero-mode parallel-plate resonator. The sample membrane was sandwiched between the plates. (*b*) Simplified diagram of the parallel-plate resonator for numerical simulation. (*c*) Three different designs for the top plate of the resonator, which were separately employed for numerical simulation and experimental visualization of the $\mathbf{B}_1$ field distribution. The bottom plate of the resonator was solid in all three cases.



Results and discussion

Numerical simulation with experimental examination in three cases

Three cases, illustrated in Figs. 2–4, were investigated through simulations and imaging experiments. The figures show current and magnetic field distributions and imaging results for the cases of a solid top plate, a top plate with several large longitudinal slits, and a top plate with a large number of smaller slits cut to permit mass transport. The plate geometry for the three cases is illustrated in Fig. 1*c*. The bottom plate was solid in each case. Plot (*a*) of each figure shows the simulated current distribution in the top plate. Plot (*b*) is a 2D magnetic resonance image of a silicone rubber film sample acquired with the chosen parallel-plate resonator. The local image intensity reflects the $\mathbf{B}_1$ field strength, which is expected to be proportional to the local current intensity in the plates. Plot (*c*) is the simulated magnetic field in a cut-plane, as illustrated in Fig. 1*b*, along *x* through the center of the resonator. The position of the plates is indicated by the horizontal lines. Plot (*d*) is a 1D MRI profile from a 2D image along *x* of the rubber phantom, arbitrarily selected from plot (*b*) around the middle region of the parallel-plate resonator. The length scale of the simulations is arbitrary but has been selected to show the features of the field–current distribution.

Figure 2*a* illustrates that for the solid plate, there is a small region close to the current feed point where the current is not uniform. The current quickly becomes uniform in the central region of the plate. This is reflected experimentally in Fig. 2*b*. The image acquisition parameters are such that the signal intensity is proportional to the magnetic field $\mathbf{B}_1$. With the exception of the feed points, which have a higher current density, the signal intensity is uniform throughout the image. The uniformity of the field between the plates is clear from Fig. 2*c* and is confirmed by the uniform profile in Fig. 2*d*.

Figure 3*a* depicts the current distribution for a plate with several large slits. The current in each remaining "rung" is equal and reasonably uniform. The current distribution away from the slits is not substantially changed from that of the solid plate. In Fig. 3*b*, gaps in the signal appear in the position of the slots and the signal over the rungs is higher than that over the surrounding plate, owing to the higher current density. In Fig. 3*c*, the effect of the slits in the top plate is pronounced: the field between the plates varies by ~50%, depending on the position. The variation decreases closer to the bottom plate. This manifests as a series of peaks and troughs in the profile (Fig. 3*d*).

The results for the case of many smaller slits, Fig. 4, are comparable to those in Fig. 3. However, the effect of the smaller slits is less pronounced than for the previous case. This is expected, as it is well known that the extent of a disturbance in a magnetic field will occur on the length scale of the feature creating the perturbation.[22] Thus, many smaller slits is a better choice.

High-resolution depth imaging with and without integrated graphite plates

A primary goal of the parallel-plate resonator design was robust behavior in the presence of conductive layers adjacent to the sample. With this in mind, depth profiles through thin

films were obtained with and without the presence of conductive graphite plates.

High-resolution 1D depth profile of Nafion 117

A high-resolution depth profile of a fully hydrated Nafion 117 film, approximately 200 μm thick, was obtained with the parallel-plate resonator. The DHK SE SPI technique developed by Ouriadov et al.[4] was employed, with the result shown in Fig. 5*a*. The image was acquired in ~90 s with an SNR better than 40. The blurred edges of the profile indicate a degradation of the true image resolution compared with the nominal resolution, 4.5 μm. This occurs because of a mismatch between the encoding gradient direction and the axis normal to the sample plane.[4]

Depth profiles of Nafion 117 with graphite plates inserted

In a functional fuel cell, a thin membrane is sandwiched between conductive electrodes. Imaging water in this layer in situ requires the ability to tolerate the presence of conductive plates on either side of the membrane.

The previous depth-imaging experiments were repeated with a graphite plate inserted on either side of the sample to explore the effect of the conductive materials on the probe system. Two pieces of 0.254 cm thick graphite sheet were used to sandwich the Nafion 117 layer, and the resultant 1D depth profile is shown in Fig. 5*b*. Thicker (0.635 cm) graphite plates were then inserted, yielding the resulting profile shown in Fig. 5*c*. The nominal spatial resolution of both profiles, with the graphite plates, was approximately 5.5 μm.

The graphite plates degrade the performance of the parallel-plate resonator, as indicated by the decreased SNR and the increased blurring observed. Decreased SNR is due to higher resistive losses as the $\mathbf{B}_1$ field induces currents in the conductive graphite. In addition, the distance between the plates is increased substantially in the presence of the graphite, which decreases the filling factor.[23,24] The additional graphite plates will increase the probe resistance without substantially changing its inductance, therefore decreasing the quality (Q) factor, according to $Q = \omega_0 L/R$. If there is electrical contact between the probe plates and the conductive insert, some current will flow through the graphite and may contribute to the probe sensitivity. However, because the conductivity of graphite is approximately 100 times less than that of copper, according to Ohm's law, the amount of the current in the graphite plates will be quite small.

The corresponding Q value, SNR, and 90° pulse length of these three cases (no graphite, thin graphite layer, and thick graphite layer) are reported in Table 1. Notice that while the Q and SNR decrease as graphite is added, the pulse width changes minimally, indicating that the $\mathbf{B}_1$ strength is little affected by the presence of the conductors.

1D depth imaging and 2D lateral imaging of Nafion in an operating fuel cell

This parallel-plate resonator concept was developed specifically for the study of operating proton electrolyte membrane (PEM) fuel cells.[21] The water distribution within the PEM is a critical parameter in fuel cell operation, and an ongoing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

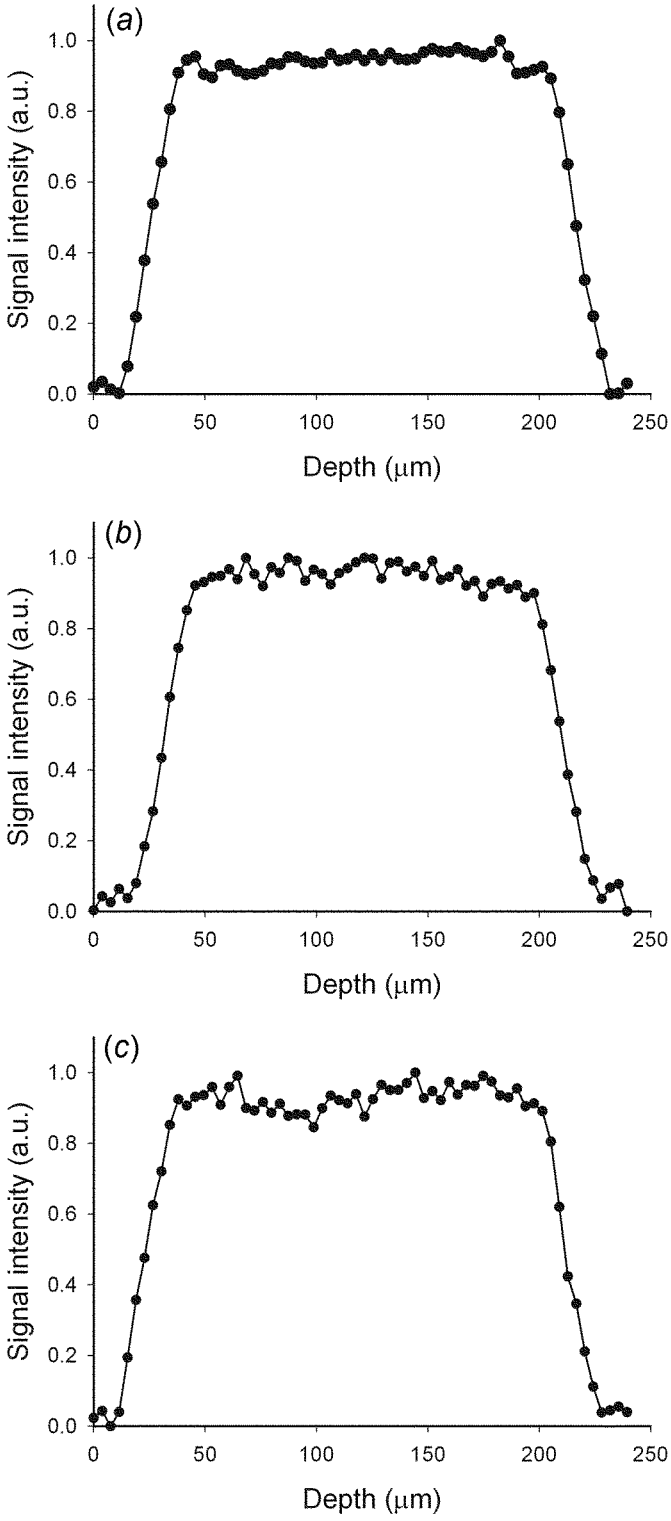
Fig. 5. (*a*) Depth profile of a static, fully hydrated Nafion 117 film. The image was derived from the first echo. (*b* and *c*) Similar depth profiles of water content across Nafion 117 film, with 2.54 mm and 6.35 mm graphite plates sandwiching the membrane, respectively. The SNR and the resolution were degraded compared with (*a*).



challenge is to obtain quantitative water maps within an operating cell. At the heart of a typical fuel cell is the membrane electrode assembly (MEA), which is a PEM (in this case, Nafion 1110) sandwiched between two conductive gas diffusion electrodes, which represent the catalyst-sprayed gas diffusion layers. The MEA is held by two conductive plates, perforated to allow the ingress of water, hydrogen, and oxygen.[25,26] The presence of the metal electrodes has previously hindered attempts to image operating fuel cells using MRI.[27]

Table 1. Quality (*Q*) factor, signal-to-noise ratio (SNR), and 90° pulse length for a Nafion 117 sample in the parallel-plate resonator.

	SNR	*Q* factor	90° pulse length (μs)
No graphite	41	115	10.5
Thin graphite (2.54 mm thick)	26	70	12.5
Thick graphite (6.35 mm thick)	15	52	13.5

A homemade operating fuel cell was designed following the schematic shown in Fig. 6*a*. The electrodes of the homemade fuel cell were made of gold-plated printed circuit (PC) boards, with slots cut in the surface to allow gas flow. The Nafion layer, sandwiched by two catalyst-sprayed gas diffusion layers, is held between the electrodes. This assembly was tightened by brass bolts to a desired pressure and sealed with homemade Teflon O-rings. As shown in Fig. 6*a*, this assembly was then connected with capacitors to complete the RF circuit and achieve probe tuning and matching. The capacitors block DC currents and thus do not affect the operation of the fuel cell. A 3 Ω carbon resistor was directly connected with the electrodes of the cell as the electrical load of the fuel cell. This resistor was located inside the magnet bore to reduce the external RF noise introduced to the experiment. In this design, the parallel plates of the RF resonator also function as electrodes of the fuel cell. The cell operated for 7 h, at which point several 1D depth profiles of the water content in Nafion during quasi-steady-state operation and a 2D lateral image of water in Nafion were acquired.

Four 1D 128-pixel profiles are illustrated in Fig. 6*b*, with the anode on the left side of the profiles and the cathode on the right side. During operation, the chemical reaction at the cathode generates water as a byproduct. Condensed water adjacent to the Nafion layer in the flow channels could introduce undesired signal into the water content profiles.[28] However, as illustrated in Fig. 4*c*, with small slots applied as flow channels, the $\mathbf{B}_1$ field beside the slots is approximately 10 times less than that beside the intact plate. In addition, the $\mathbf{B}_1$ fields inside the gas channels are very small and will not efficiently excite the water or vapor in the channels.[21] As a result, water content serves as a marker for chemical activity in the cell. We estimate the edges of the Nafion layer to be at 230 μm and 520 μm. The poor edge definition is due to sample misalignment with the imaging axis and potentially due to nonlinearity of the Nafion surface. An apparent peak is observed close to the cathode side, as predicted. The signal then decreases and levels out near the center of the profile. Near the anode, the signal intensity decreases once again. Less water is anticipated near the anode. All the above observations agree with our common understanding of an operational fuel cell.[25,26] MRI results of this type, however, offer the prospect of quantifiable studies.

In the 2D image shown in Fig. 6*c*, a generally uniform water signal intensity was observed. The slightly higher signal inten-

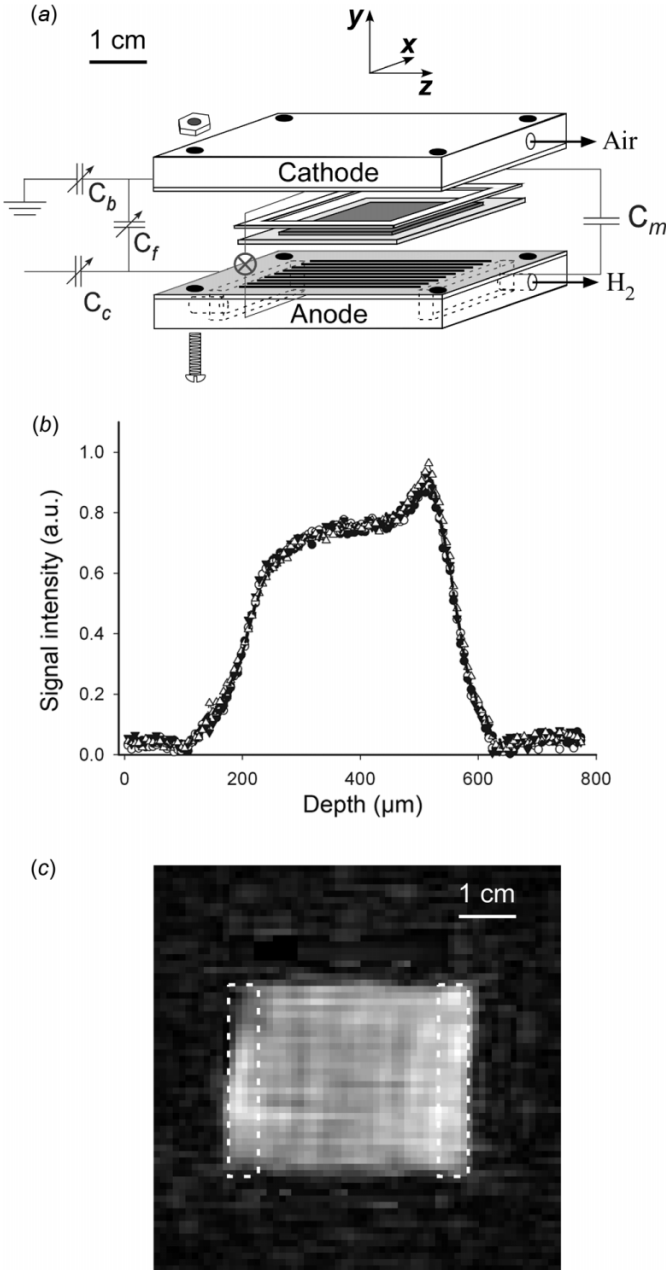
Fig. 6. (*a*) Schematic of a homemade operating fuel cell combined into the RF probe circuit (figure from Zhang et al.,[21] reproduced with permission of *Journal of Magnetic Resonance*, © 2008 Elsevier). Outer load (⊗) and tuning capacitors are connected to complete the DC circuit for fuel cell operation and the high-frequency AC circuit for RF resonance. The outlets of the reactant gases, H_2 and air, are marked, while the inlet connections are on the left side but not shown. Grooves, as shown by discrete lines, are machined on two G10 fiberglass substrates, which support the PC boards, to generate paths for gas flow. (*b*) Four 1D depth profiles of water, acquired during quasi-steady-state operation of the cell. Each profile is from the first echo. Experiments (●), (○), (▼), and (▽) correspond to experimental times of 3.4, 3.6, 3.8, and 4.0 h, respectively. (*c*) Lateral 2D image, acquired with 2D SE SPI, of the operating fuel cell. The dashed lines indicate the position of the flow inlets/outlets on the left and right sides of the image. The flow inlets are illustrated in (*a*).



sity to the left and right suggests that water vapor in the humidified reactant gases may have condensed at the flow inlets.

The 2D image also confirms the essentially uniform excitation of this parallel-plate resonator. No pattern due to the perforated electrodes is observed in the image. The signal in this case is averaged over the depth of the Nafion. One-dimensional depth profiles of course do not reveal information about lateral variation in water content.

The parallel-plate resonator employed for this experiment used 30 slits, each 0.5 mm wide, to allow gas to flow to the membrane. The size of the slots was empirically determined through balancing the $\mathbf{B}_1$ uniformity in the lateral plane with the efficiency of feeding the reactant gases. As discussed above, because of the large number of small slits the spatial variation of signal intensity is minimal. In the 1D images, averaging over the lateral extent of the Nafion yields a smooth image with no manifestation of the slots employed for mass transport through the plates.

Conclusion

A novel parallel-plate RF resonator was investigated through experiment and simulation. The RF probe has an inherently high filling factor, which permits high-SNR imaging.

The parallel-plate resonator allows high-resolution depth imaging of thin films and can be employed in a fully functioning fuel cell. The presence of auxiliary conductive materials does not significantly degrade the performance of the probe.

Experimental

Design of the parallel-plate resonators and homemade operating fuel cell

Figure 1*a* shows the geometry of a typical parallel-plate resonator. Two pieces of 2.54 cm wide, 7.62 cm long copper tape were affixed to two pieces of G10 fiberglass substrate, 5.08 cm wide and 7.62 cm long, purchased from McMaster (Cleveland, Ohio). The phantom employed in the $\mathbf{B}_1$ field visualization measurements, a 381 μm thick silicone rubber sheet purchased from AAA-ACME (Tempe, Arizona), was cut to the same size as the copper tape.

The top plates with slots employed in the imaging measurements were made of PC board and were of the same size as the bottom copper tape. The slots were all cut 2.54 cm long, with a width of 2.38 mm for the larger ones and 0.79 mm for the smaller ones.

Each plate of the homemade operating fuel cell, 5 cm long and 4 cm wide, consists of a gold-plated PC board and the substrate to which it is affixed. Thirty slots, 3 cm long, 0.5 mm wide, and 0.5 mm deep, were cut and homogeneously distributed in a 3 cm × 3 cm area on the PC board, 1.59 mm in thickness. The substrate, 9.53 mm thick G10 fiberglass, was fabricated following the discrete line shown in Fig. 6*a* to construct a path for flow. Each gas-diffusion electrode was cut into a 3.2 cm × 3.2 cm square, and the Nafion was cut into a 3.5 cm × 3.5 cm square.

Nafion and its preparation

The sample films, Nafion 117, 178 μm thick, and Nafion

For personal use only.

1110, 250 μm thick, were purchased from Ion Power (New Castle, Delaware). The Nafion films were cut to desired sizes (2.03 cm × 6.10 cm for Nafion 117 and 2.54 cm × 2.54 cm for Nafion 1110) and pretreated by heating in ~3–5 wt % H_2O_2 solution at 80 °C for 1 h. The sample was then rinsed in deionized water at 80 °C for 1 h and then heated in 0.5 mol/L H_2SO_4 at 80 °C for 1 h. The sample was finally cleaned by prolonged heating in deionized water at 80 °C for 1 h to remove any possible chemical residues. The basic procedure was based on the work of Jalani et al.[29] and Moore and Martin.[30]

MRI details

The 2D DHK SPRITE and DHK SE SPI experiments were implemented on a Nalorac (Martinex, California) 2.4 T 32 cm i.d. horizontal-bore superconducting magnet. A water-cooled 7.5 cm i.d. gradient set driven by a Techron (Elkhart, Indiana) 8710 amplifier, which provided maximum gradients of 100 Gauss/cm, was employed for all experiments. The imaging console was a Tecmag (Houston, Texas) Apollo in all cases.

The homemade RF probes, driven by a 2 kW AMT (Brea, California) 3445 RF amplifier, were respectively custom-built single-channel parallel plate probes and an operating fuel cell style resonator. They were tuned to 100 MHz with three tuning capacitors, C_f, C_c, and C_b, in a standard series-parallel tank circuit. The fixed capacitor, C_m, illustrated in Fig. 1*a* and Fig. 6*a*, was 1000 pF.

In the 2D DHK SPRITE measurement, the encoding time, t_p, was 150 μs. The flip angle was 4.3° with a pulse duration of 0.5 μs. The dwell time was 4 μs with a repetition time of 2 ms. The 90° pulse length was 10.5 μs in all three cases.

Nafion 117, a form of perfluorosulfonic acid, is a hydrophilic ionic polymer with measured ^{1}H relaxation times that are reasonably long (T_1, 100 ms; T_2, 13 ms[31,32]) and ideally suited to these measurements.

In DHK SE SPI and 2D SE SPI measurements, the repetition time was maintained at 500 ms, a period approximately equal to $5T_1$. The encoding time, t_p, was 2.2 ms and the echo time was 5.5 ms. Dwell times were set to 200 μs to narrow the filter width in all measurements.

In high-resolution depth imaging measurements, the Nafion film cannot be exactly positioned at the origin of the gradient G_y. Experimental profiles therefore wrap around the field of view (FOV) and are translated into the center of the FOV for display and subsequent data processing.

Matrices of 64 points by 64 points were collected for most of the 2D lateral images, with one exception, a 64 by 128 *k*-space matrix employed in measurement of the $\mathbf{B}_1$ distribution with the presence of small slits in the top plate. For 1D depth images, 64 *k*-space points were collected. In the 2D DHK SPRITE measurements, 4 signal averages were accumulated for each profile, with an acquisition time of 30 min. In the DHK SE SPI measurements, the acquisition time was 90 s with 4 signal averages. Four averages, with a 2 h acquisition time, were acquired for 2D SE SPI measurement.

In the operational fuel cell measurement, the nominal resolution for the 1D depth image (Fig. 6*b*) is approximately 6 μm with an 800 μm FOV. The 2D lateral image (Fig. 6*c*) had a resolution of approximately 1.2 mm × 1.2 mm, with a FOV of 7.5 cm × 7.5 cm. No filtering or zero-filling was applied prior to Fourier transform for all the measurements. The SNR of the two experiments was, respectively, 40 and 15.

Abstract: The group 2 metal halides and corresponding metal halide hydrates serve as useful model systems for understanding the relationship between the electric field gradient (EFG) and chemical shift (CS) tensors at the halogen nuclei and the local molecular and electronic structure. Here, we present a $^{35/37}$Cl and ^{43}Ca solid-state nuclear magnetic resonance (SSNMR) study of $CaCl_2$. The ^{35}Cl nuclear quadrupole coupling constant, 8.82(8) MHz, and the isotropic chlorine CS, 105(8) ppm (with respect to dilute NaCl(aq)), are different from the values reported previously for this compound, as well as those reported for $CaCl_2{\cdot}2H_2O$. Chlorine-35 SSNMR spectra are also presented for $CaCl_2{\cdot}6H_2O$, and when taken in concert, the SSNMR observations for $CaCl_2$, $CaCl_2{\cdot}2H_2O$, and $CaCl_2{\cdot}6H_2O$ clearly demonstrate the sensitivity of the chlorine EFG and CS tensors to the local symmetry and to changes in the hydration state. For example, the value of δ_{iso} decreases with increasing hydration. Gauge-including projector-augmented wave (GIPAW) density functional theory (DFT) calculations are used to substantiate the experimental SSNMR findings, to rule out the presence of other hydrates in our samples, to refine the hydrogen positions in $CaCl_2{\cdot}2H_2O$, and to explore the isostructural relationship between $CaCl_2$ and $CaBr_2$. Finally, the ^{43}Ca CS tensor span is measured to be 31(5) ppm for anhydrous $CaCl_2$, which represents only the fifth CS tensor span measurement for calcium.

Key words: solid-state NMR, chlorine, ^{35}Cl, ^{37}Cl, ^{43}Ca, $CaCl_2$, polymorphism, hydrates, C_Q, chemical shift anisotropy (CSA), electric field gradient.

Résumé : Les halogénures des métaux du groupe 2 et les hydrates d'halogénures métalliques sont des systèmes modèles qui permettent comprendre la relation entre le gradient du champ électrique (GCE) et les tenseurs du déplacement chimique (DC) au niveau du noyau d'halogène et la structure électronique et moléculaire locale. Dans ce travail, on présente les résultats d'une étude de résonance magnétique nucléaire à l'état solide (RMN-ES) du $^{35/37}$Cl et ^{43}Ca du $CaCl_2$. Les valeurs de la constante de couplage quadripolaire nucléaire du ^{35}Cl, 8,82(8) MHz, et le DC isotrope du chlore, 105(8) ppm [par rapport au NaCl(aq) dilué], sont différentes de celles rapportées pour ce composé ainsi que les valeurs rapportés pour le $CaCl_2{\cdot}2H_2O$. Les spectres RMN-ES du ^{35}Cl sont aussi presentés pour le $CaCl_2{\cdot}6H_2O$ et, lorsqu'on les compare, les observations relatives aux spectres RMN-ES du $CaCl_2$, du $CaCl_2{\cdot}2H_2O$ et du $CaCl_2{\cdot}6H_2O$ démontrent clairement la sensibilité du GCE du chlore et des tenseurs du DC sur la symétrie locale et aux changements dans l'état d'hydratation. Par exemple, les valeurs de δ_{iso} diminuent avec une augmentation de l'hydratation. On a fait appel à des calculs selon la théorie de la fonctionnelle de la densité en utilisant une onde améliorée par un opérateur de projection comportant une jauge (« GIPAW-DFT ») pour corroborer les observations faites par RMN-ES, pour éliminer la présence d'autres hydrates dans nos échantillons, pour affiner les positions des atomes d'hydrogène dans le $CaCl_2{\cdot}2H_2O$ et pour explorer la relation isostructurale entre le $CaCl_2$ et $CaBr_2$. Enfin, on a établi que la portée du tenseur de DC du ^{43}Ca est de 31(5) ppm pour le $CaCl_2$ anhydre, ce qui représente seulement la cinquième valeur mesurée pour l'anisotropie du tenseur du DC du calcium.

Mots-clés : RMN à l'état solide, chlore, ^{35}Cl, ^{37}Cl, ^{43}Ca, $CaCl_2$, polymorphie, hydrates, C_Q, anisotropie du déplacement chimique (ADC), gradient du champ électrique.

[Traduit par la Rédaction]

Introduction

Solid-state nuclear magnetic resonance (SSNMR) spectroscopy is an important tool that is used to characterize structure and dynamics within a range of chemical systems. Recent developments in SSNMR[1,2] have extended its applicability to a number of "exotic" nuclei. To obtain a more complete picture of a given solid-state system, however, it is

often desirable to complement SSNMR data with information acquired using other methods. Recently, density functional theory (DFT) methods have been paired with ultrasoft pseudopotentials[3] and the gauge-including projector-augmented wave (GIPAW) formalism[4] to calculate magnetic shielding and electric field gradient (EFG) tensors at the nuclei in solid materials.[4–6] These tensors are important SSNMR observables, and a number of recent studies have illustrated that magnetic shielding and EFG tensor calculations using GIPAW DFT can provide additional insights in the study of a variety of chemical systems.[7–17]

There is an increasing interest in "NMR crystallography", which pertains to obtaining molecular-level and crystal structure information for solid materials using SSNMR data.[18] Although there have been a number of exciting recent advances in this area of research,[6,19–25] one cannot currently convert SSNMR data into a unique solid-state structure in a completely generalized manner. With a small amount of a priori knowledge, however, NMR crystallography methods have been applied to solve and refine the structures related to certain classes of materials, such as zeolites,[26–28] which are sometimes subject to crystal twinning and typically do not possess enough long-range order to produce crystals that would be considered suitable for X-ray diffraction (XRD) studies. With the aid of computational modeling, SSNMR data acquired for spin-1/2 nuclei have been used to solve or refine structures of organic molecules such as β-L-aspartyl-L-alanine[6] and thymol.[22] We have recently contributed to this area by exploiting quadrupolar nuclei (i.e., nuclear spin quantum number, $I > 1/2$); for example, $^{79/81}$Br SSNMR data have been complemented with GIPAW DFT computations to refine the structure of the simple salt $MgBr_2$.[29] This work showed the pronounced sensitivity of the $^{79/81}$Br EFG tensor to minute structural changes. Quadrupolar nuclei possess a quadrupole moment (Q) which couples with the EFG at the nucleus to produce characteristic SSNMR spectral line shapes. These line shapes can usually be modeled using analytical simulation software, such as that developed by Wasylishen and co-workers, which treats this "quadrupolar interaction" (QI) as a second-order perturbation to the Zeeman states (the magnitude of which depends on the nuclear quadrupole coupling constant, C_Q, and the quadrupole asymmetry parameter, η_Q).[30] Owing to the presence of the QI, SSNMR experiments using these probe nuclei should be able to offer additional structural restraints, relative to spin-1/2 nuclei.

A recent focus of our research group has been SSNMR spectroscopy of the quadrupolar halogen nuclides ($^{35/37}$Cl, $^{79/81}$Br, and ^{127}I).[12,14,29,31–37] We have observed that the NMR spectra of these nuclei are very sensitive to the EFG produced by the ions and molecules of the surrounding environment. There exist two NMR-active chlorine nuclides (^{35}Cl and ^{37}Cl), both of which are quadrupolar ($I(^{35/37}\text{Cl}) = 3/2$) and of moderately high abundance (75.779(46)% for ^{35}Cl, 24.221(46)% for ^{37}Cl).[38] The Q associated with these nuclei are moderate ($Q(^{35}\text{Cl}) = -81.65(80)$ mb; $Q(^{37}\text{Cl}) = -64.35(64)$ mb);[39] however, their magnetogyric ratios (γ) are rather low (below that of ^{15}N). Probe ringing and second-order QI line shape broadening are both reduced by performing the SSNMR experiments in as high an applied magnetic field ($\mathbf{B}_0$) as available. A variety of chlorine environments have been probed using $^{35/37}$Cl SSNMR spectroscopy at "ultrahigh" $\mathbf{B}_0$, including (*i*) group 4 organometallic[40,41] and group 13 inorganic materials,[31] (*ii*) amino acid hydrochlorides,[34,36] (*iii*) ionic liquids,[42,43] (*iv*) group 2 metal chlorides,[44] and (*v*) pharmaceutical hydrochlorides.[45] As a result of these recent studies, a number of trends in the halogen SSNMR parameters have been observed and rationalized. For example, for the group 2 metal halides studied to date, it has been observed that sample hydration will (*i*) generally result in a decrease in the halogen isotropic chemical shift (CS) and (*ii*) nearly always lead to a decrease in the halogen C_Q value.[12,14,44] It was also noted, however, that the currently available ^{35}Cl SSNMR data collected for $CaCl_2$ indicate that this system does not follow the latter trend;[46] rather, the data suggest that upon hydration the C_Q value increases substantially. We therefore sought to carry out additional NMR studies on $CaCl_2$, which included multiple $\mathbf{B}_0$ data acquisition and modern quantum chemical calculations, to confirm or refute the prior ^{35}Cl SSNMR data.

We present here the results of ^{35}Cl SSNMR measurements for $CaCl_2$ and $CaCl_2{\cdot}6H_2O$. The ^{37}Cl and ^{43}Ca SSNMR spectra of anhydrous $CaCl_2$ are also discussed. The results of GIPAW DFT computations on $CaCl_2$ and its known crystalline hydrates (i.e., $CaCl_2{\cdot}2H_2O$, ($\alpha/\beta/\gamma$)–$CaCl_2{\cdot}4H_2O$, and $CaCl_2{\cdot}6H_2O$) are discussed in an attempt to understand the prior ^{35}Cl SSNMR measurements for $CaCl_2$, to refine the hydrogen positions for $CaCl_2{\cdot}2H_2O$, and to complement our experimental SSNMR data.

Experimental

Sample preparation

$CaCl_2$ (99.99%) and $CaCl_2{\cdot}6H_2O$ (98%) were purchased from Sigma-Aldrich and received as powders. Sample purity for both compounds was confirmed by the manufacturer (see the Supplementary data, Additional Experimental). As $CaCl_2$ is hygroscopic, it was stored and prepared for use under either dry N_2 or Ar. $CaCl_2{\cdot}6H_2O$ was handled for short periods of time in a low humidity atmosphere to avoid further hydration. Prior to SSNMR experiments, the samples were powdered and then tightly packed into either 4 mm or 7 mm o.d. Bruker magic-angle spinning (MAS) ZrO_2 rotors.

Solid-state $^{35/37}$Cl and ^{43}Ca NMR

Data were acquired at the National Ultrahigh-field NMR Facility for Solids in Ottawa and at the University of Ottawa. Experiments at the Ultrahigh-field Facility used a standard-bore Bruker AVANCE II spectrometer, which operates at $\mathbf{B}_0 = 21.1$ T ($\nu_0(^1\text{H}) \approx 900.08$ MHz). For $^{35/37}$Cl SSNMR experiments at 21.1 T ($\nu_0(^{35}\text{Cl}) = 88.189$ MHz; $\nu_0(^{37}\text{Cl}) = 73.408$ MHz), home-built static probes (single-channel 7 mm or 4 mm HX) were used. Calcium-43 SSNMR experiments at the same field ($\nu_0(^{43}\text{Ca}) = 60.575$ MHz) employed a single-channel 7 mm Bruker MAS probe. Experiments performed at the University of Ottawa used a wide-bore Bruker AVANCE spectrometer, which operates at $\mathbf{B}_0 = 11.75$ T ($\nu_0(^1\text{H}) \approx 500.13$ MHz). All ^{35}Cl SSNMR experiments at 11.75 T ($\nu_0(^{35}\text{Cl}) = 49.002$ MHz) used a 4 mm Bruker HX MAS probe. The $^{35/37}$Cl SSNMR spectra were referenced to 0.1 mol/dm^3 NaCl in D_2O at 0 ppm[47] using solid KCl as a secondary reference ($\delta_{iso}(\text{KCl(s)}) = 8.54$ ppm).[32] Calcium-

For personal use only.

43 SSNMR spectra were referenced to a 2 mol/dm^3 aqueous solution of $CaCl_2$ (δ_{iso} = 0 ppm).[48] Chlorine and calcium pulse widths were established using the $^{35/37}$Cl and ^{43}Ca SSNMR signals of solid KCl and saturated $CaCl_2$ (aq), respectively. Central transition (CT) selective (i.e., "solid $\pi/2$") pulse widths were determined by scaling the $\pi/2$ pulse widths measured for the above standards by $1/(I + 1/2)$ (i.e., 1/2 for $^{35/37}$Cl and 1/4 for ^{43}Ca). All $^{35/37}$Cl SSNMR signals were acquired using the Solomon (i.e., "solid") echo (i.e., $\pi/2$–τ_1–$\pi/2$–τ_2–*acq*)[49–51] pulse sequence. Typical $^{35/37}$Cl SSNMR experimental parameters were as follows: CT-selective $\pi/2$ pulse width = 2.4–3.2 μs; spectral window = 200–1000 kHz; τ_1 = 27.5–50 μs; and 512–2048 complex time-domain data points. All ^{43}Ca SSNMR signals were acquired using a single-pulse experiment (typical parameters: CT-selective $\pi/2$ ~1.0 μs; spectral window = 20 kHz; 512–1024 complex time-domain data points). The pulse delays used, as well as the number of scans required for the collection of the spectra, may be found in the figure captions and the Supplementary data (Table S1). For ^{35}Cl SSNMR experiments on $CaCl_2$ at 11.75 T, variable offset cumulative spectrum (VOCS)[52,53] data acquisition was used (offset = 110 kHz). After VOCS data acquisition, each component spectrum was processed as usual and combined in the frequency domain by co-addition. For $CaCl_2 \cdot 6H_2O$, continuous-wave ^{1}H decoupling was tested at both applied fields ($\nu_1(^1H)$ ~50 kHz at 11.75 T and ~85 kHz at 21.1 T). For additional experimental details, see the Supplementary data, Table S1. Observed spectra were modeled using WSolids1, an analytical simulation software package developed by Eichele and Wasylishen.[54]

Quantum chemical calculations

GIPAW DFT calculations employed CASTEP-NMR (v. 4.1) software,[4,5,55,56] while the input files were generated using Materials Studio (v. 3.2.0.0) (Accelrys). Computations used either ultrasoft[3] or "on-the-fly" pseudopotentials and the generalized gradient approximation. Further details pertaining to the relevant on-the-fly pseudopotentials may be found in the Supplementary data, Table S2. All geometry optimizations were carried out using the exchange-correlation (XC) functional of Perdew, Burke, and Ernzerhof (PBE),[57,58] while the EFG and magnetic shielding tensor parameters were calculated using either the PBE XC functional or the XC functional of Perdew and Wang (PW91).[59–63] Computed chlorine magnetic shielding tensor elements (σ_{ij}) were transformed into CS tensor elements (δ_{ij}) using the following procedure: the chlorine isotropic magnetic shielding value (σ_{iso}) for NaCl was determined using a plane-wave cutoff energy (E_{cut}) of 1200 eV, a 4 × 4 × 4 Monkhorst–Pack *k*-point grid,[64] and the same XC functional as the sample of interest. Using the above calculated σ_{iso} value and the known chlorine chemical shift of solid NaCl relative to 0.1 mol/dm^3 NaCl in D_2O (i.e., δ_{iso}(NaCl(s)) = –41.11 ppm),[32] the σ_{iso} value for 0.1 mol/dm^3 NaCl in D_2O could be calculated; hence, all computed σ_{ij} values could be placed on an experimental δ scale. The E_{cut} and *k*-point grid used for the GIPAW DFT calculations on each system are in the footnotes to Tables 1 and 2. For computed structure energies, structure references, optimized structure parameters, the pseudopotentials used, and additional computational details, see the Supplementary data, Tables S2 and S3.

Results and discussion

Experimental $^{35/37}$Cl and ^{43}Ca SSNMR observations and analysis for $CaCl_2$

The ^{35}Cl EFG tensor parameters reported previously[46] for $CaCl_2$ appeared to be inconsistent with the trends observed for other group 2 metal halides,[12,44] prompting us to reinvestigate this system using SSNMR spectroscopy. Chlorine-35 SSNMR spectra were obtained for $CaCl_2$ at two applied fields ($\mathbf{B}_0$ = 11.75 and 21.1 T), and analytical modeling of all observed line shapes resulted in identical EFG and CS tensor parameters (Fig. 1). Additional ^{37}Cl SSNMR experiments were performed at 21.1 T, and the spectra were modeled using the same parameters as those for the ^{35}Cl SSNMR line shapes, after appropriate scaling of C_Q by the $Q(^{37}Cl)/Q(^{35}Cl)$ ratio of 0.788 (Fig. 2). Extracted parameters are summarized in Table 1. It is immediately clear that the observed $^{35/37}$Cl SSNMR line shapes and EFG tensor parameters are inconsistent with the prior literature account for $CaCl_2$.[46]

The presently measured $C_Q(^{35}Cl)$ value of 8.82(8) MHz is more than twice as large as the values observed for other anhydrous and hydrated group 2 metal chlorides.[44,46,69] This is primarily attributed to the arrangement of the Ca^{2+} ions within the first coordination sphere of each chloride, which forms a distorted trigonal plane.[65] Our measured $\eta_Q(^{35/37}Cl)$ value of 0.383(15) confirms the absence of high-symmetry rotational axes (i.e., C_n where $n > 2$), in support of the local symmetry for this site determined using XRD data, which is *m*.[65] The observed chlorine chemical shift value (δ_{iso} = 105 ± 8 ppm, or 146 ppm with respect to solid NaCl) is deshielded by 36 ppm relative to $CaCl_2 \cdot 2H_2O$, which is consistent with the general trend observed for halogen chemical shift values upon hydration in group 2 metal halides.[12]

Experiments at 21.1 T were essential to characterize chlorine chemical shift anisotropy (CSA) and non-coincident EFG and CS tensor principal axis systems (PASs) in this sample. The prior ^{35}Cl SSNMR study on $CaCl_2$ was carried out under MAS conditions only and CSA information was not reported.[46] Our measured chemical shift tensor span of 135 ± 15 ppm is by far the largest measured for a group 2 metal chloride system (72 ppm for $CaCl_2 \cdot 2H_2O$ being the second largest reported to date).[44] The span value measured by modeling the ^{35}Cl SSNMR spectrum is identical to the one extracted from the ^{37}Cl SSNMR signal at 21.1 T (Fig. 2). As expected, the ^{35}Cl SSNMR line shape of $CaCl_2$ acquired at 11.75 T was not particularly sensitive to CSA effects, as nearly all the broadening could be attributed to the QI.[70] The measured Euler angle values (these angles describe the relative orientation of the EFG and CS tensor PASs) for $CaCl_2$ (i.e., $\alpha = 90° \pm 20°$, $\beta = 90° \pm 5°$, $\gamma = 0° \pm 5°$) are consistent with the presence of mirror plane symmetry at the chloride anion, in agreement with prior X-ray data.[65]

Natural abundance ^{43}Ca SSNMR experiments were also performed at $\mathbf{B}_0$ = 21.1 T to more completely characterize the sample. The resonance observed in the ^{43}Ca MAS SSNMR spectrum (Fig. 3*e*) of $CaCl_2$ (i.e., δ_{peak} = 54.1 ± 0.2 ppm relative to 2 mol/dm^3 $CaCl_2$(aq)) cannot, unfortunately, be rigorously compared with that reported previously

Note: Measurement errors are within parentheses and parameters are defined as follows: $C_Q = eQV_{33}/h$; $\eta_Q = (V_{11} - V_{22})/V_{33}$, where $|V_{11}| \leq |V_{22}| \leq |V_{33}|$; $\Omega \approx \delta_{11} - \delta_{33}$; $\kappa \approx 3(\delta_{22} - \delta_{iso})/\Omega$; $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$, where $\delta_{33} \leq \delta_{22} \leq \delta_{11}$; and α, β, and γ describe the relative orientation between the EFG and CS tensor principal axis systems, which are disclosed here using the "ZYZ" convention[67] and generated using EFGShield.[68] All calculated results in this table used the PBE XC functional. Additional computational results and details can be found in the Supplementary data, Tables S2–S4. N/A, not applicable.

[a]While C_Q may take any real value, $|C_Q|$ is measured experimentally. Experimental signs are attributed based upon the GIPAW DFT results.

[b]Experimental chlorine chemical shifts are relative to 0.1 mol/dm^3 NaCl in D_2O ($\delta_{iso}(^{35/37}Cl) = 0$ ppm) and were established using solid KCl as a secondary reference ($\delta_{iso}(^{35/37}Cl) = 8.54$ ppm). For the computational reference, NaCl(s), $\sigma_{iso}(^{35/37}Cl)$ was calculated to be 975.06 ppm (4 × 4 × 4 *k*-point grid and E_{cut} = 1200 eV). Additional details can be found in the Experimental section.

[c]Calculations for this compound used a 4 × 4 × 6 *k*-point grid and E_{cut} = 800 eV.

[d]For the current study, calculations for this compound used a 4 × 3 × 2 *k*-point grid. Optimization of the hydrogen atomic positions used E_{cut} = 500 eV, and EFG and CS tensor parameter calculations used E_{cut} = 600 eV.

[e]Calculations for this compound used a 4 × 4 × 3 *k*-point grid and E_{cut} = 650 eV.

[f]Calculations for this compound used a 3 × 2 × 2 *k*-point grid and E_{cut} = 500 eV.

[g]Calculations for this compound used a 4 × 3 × 3 *k*-point grid and E_{cut} = 650 eV.

Table 2. Experimental and GIPAW DFT-computed ^{43}Ca EFG and chemical shift tensor parameters for $CaCl_2$.

Experimental or computed	$C_Q(^{43}Ca)$ (MHz)[a]	η_Q	Ω (ppm)	κ	δ_{iso} (ppm)[b]	α (°)	β (°)	γ (°)	Notes

Fig. 1. Analytical simulations (*a*, *b*, *c*, *e*), experimental static Solomon echo (*d*), and experimental static VOCS Solomon echo (*f*) ^{35}Cl SSNMR spectra of powdered $CaCl_2$, acquired at (*d*) $\mathbf{B}_0$ = 21.1 T (ν_0 = 88.189 MHz) and (*f*) $\mathbf{B}_0$ = 11.75 T (ν_0 = 49.002 MHz). In (*a*), the principal axis system orientations of the EFG and CS tensor frames are assumed to be equivalent (i.e., $\alpha = \beta = \gamma = 0°$), while in (*b*), CSA effects are ignored (i.e., Ω = 0 ppm). The best-fit spectra presented in (*c*) and (*e*) are simulated with the parameters given in Table 1. For (*d*), an optimized pulse delay of 10.0 s was used and 400 transients were collected, while for (*f*), a pulse delay of 1.0 s was used and 40 000 transients were collected for each of 6 transmitter frequencies (offset value used: 110 kHz).

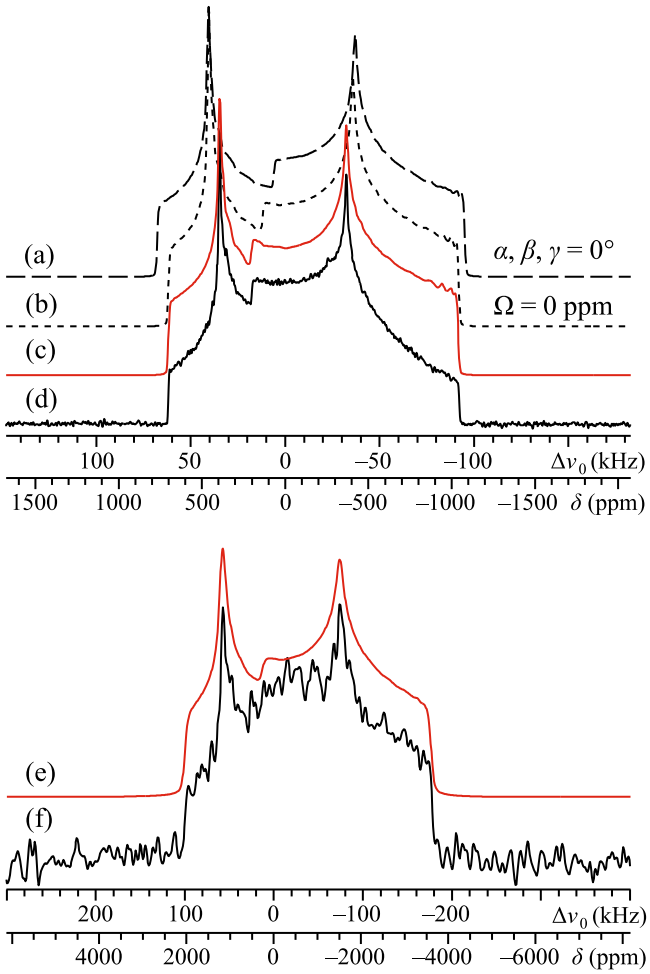

Fig. 2. Analytical simulation (*a*) and experimental static Solomon echo ^{37}Cl SSNMR spectrum (*b*) of powdered $CaCl_2$, acquired at $\mathbf{B}_0$ = 21.1 T (ν_0 = 73.408 MHz). A pulse delay of 10.0 s was used and 960 transients were collected.

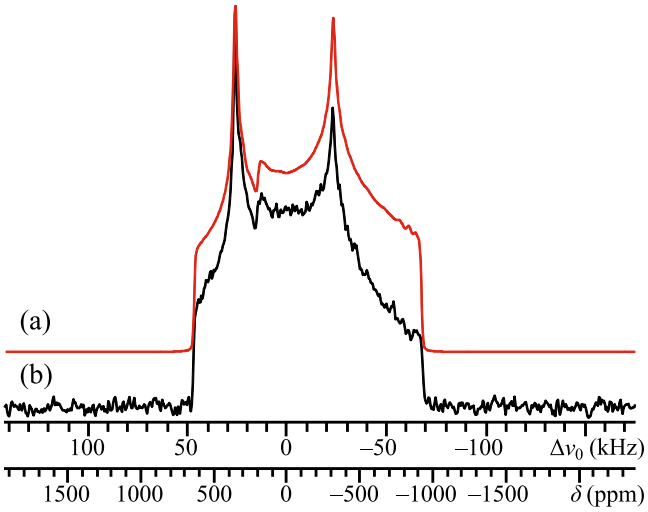

by Lin et al. (δ_{peak} = 53.1 ± 2.0 ppm relative to saturated $CaCl_2$(aq)).[71] This is because the reference standard used in the earlier account (i.e., "saturated" $CaCl_2$(aq)) shows a highly variable resonance position that depends on the preparation method (approx. ±10 ppm).[48,72] Analytical modeling of the ^{43}Ca MAS SSNMR line shape was used to establish approximate ^{43}Ca EFG tensor parameters as well as the isotropic calcium CS for $CaCl_2$: $C_Q(^{43}Ca)$ = –0.95 ± 0.20 MHz, η_Q = 0.7 ± 0.2, and δ_{iso} = 54.8 ± 0.5 ppm, where the sign of C_Q is based upon the results of GIPAW DFT computations (*vide infra*). Calcium-43 SSNMR experiments were also carried out under stationary conditions (Fig. 3*b*) and the parameters measured from the ^{43}Ca MAS NMR spectrum were used to estimate the static line shape broadening that could be attributed to the ^{43}Ca QI (Fig. 3*c*). It is clear that the QI does not dominate the line shape for this sample under static conditions at 21.1 T and that additional line broadening due to calcium CSA is present. Analytical line shape modeling of the static ^{43}Ca SSNMR spectrum allows us to report a calcium CS tensor span of 31 ± 5 ppm (Fig. 3*a*), which represents the fifth measurement of calcium CSA in the literature[73] and the first where oxygen atoms are not coordinated to the calcium. The calcium CS tensor span for $CaCl_2$ is moderate, as calcium CS tensor spans range

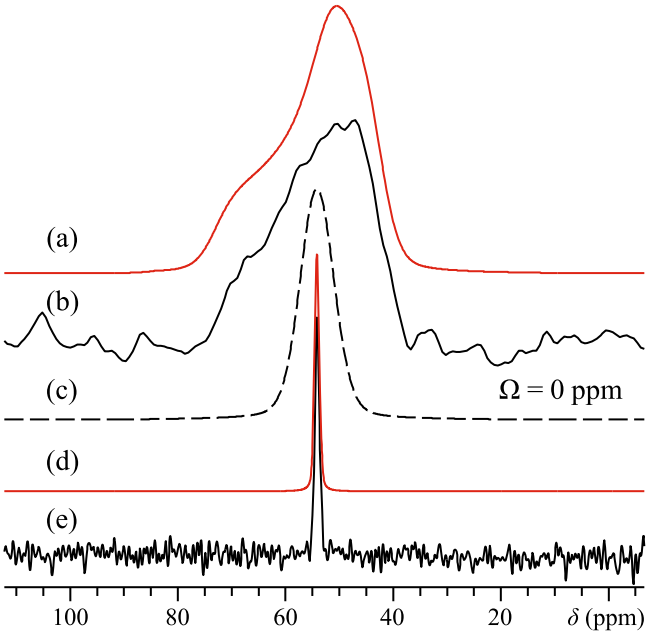
Fig. 3. Analytical simulations (*a*, *c*, *d*) and experimental single-pulse (*b*, *e*) ^{43}Ca SSNMR spectra of powdered $CaCl_2$, acquired at $\mathbf{B}_0$ = 21.1 T (ν_0 = 60.575 MHz) under (*a*, *b*, *c*) static and (*d*, *e*) MAS conditions. In (*c*), the effects due to calcium CSA are ignored (i.e., Ω = 0 ppm), while the simulation in (*a*) includes calcium CSA. The spectrum in (*e*) was acquired using a MAS frequency of 4 kHz. The experimental pulse delay for both (*b*) and (*e*) was 5.0 s. The spectrum in (*b*) is the result of the collection of 25 648 transients, while the spectrum in (*e*) is the result of the collection of 4313 transients.



from 8 ± 2 ppm in the calcite polymorph of $CaCO_3$ to 70 ± 20 ppm in the vaterite polymorph of $CaCO_3$.[72] The remaining calcium SSNMR parameters for $CaCl_2$ are summarized in Table 2.

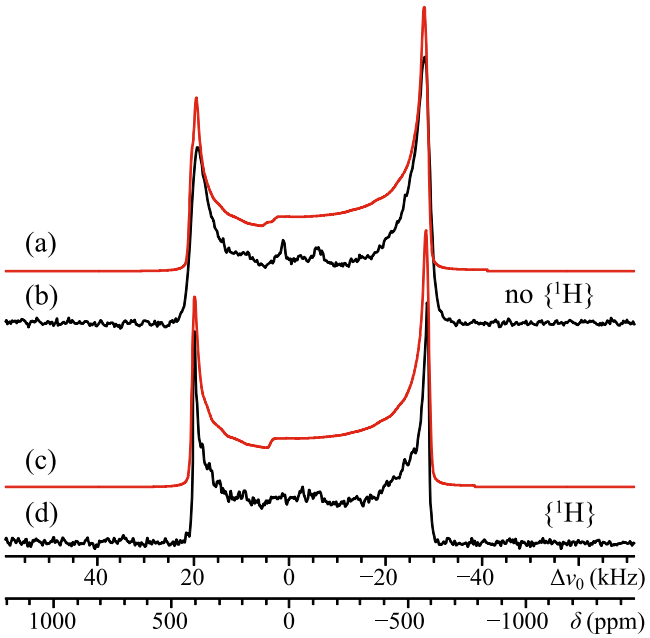
$CaCl_2$·6H_2O and other hydrates

It is well known that $CaCl_2$ is a strongly hygroscopic material, and as such it is widely used as a desiccant. In this section, we discuss the known experimental data for $CaCl_2$ and selected hydrates to ensure that the spectral data above have been correctly interpreted. We have characterized $CaCl_2$·6H_2O using ^{35}Cl SSNMR experiments at 11.75 and 21.1 T (Figs. 4 and 5), and analytical line shape modeling of both spectra yields identical parameters, which are summarized in Table 1.

Our discussion of the $^{35/37}$Cl SSNMR data for the $CaCl_2$ hydrates begins by noting that $^{35/37}$Cl SSNMR data were recently reported for $CaCl_2$·2H_2O[44] and that this dihydrate possesses distinctly different EFG and CS tensor parameters compared with anhydrous $CaCl_2$ (Table 1). To the best of our knowledge, two other hydrated forms of $CaCl_2$ are stable under typical laboratory conditions: α–$CaCl_2$·4H_2O[74] and $CaCl_2$·6H_2O.[66] Additional polymorphic forms of the tetrahydrate (β–$CaCl_2$·4H_2O[75] and γ–$CaCl_2$·4H_2O[76]) may be prepared under normal conditions but appear to slowly convert to the α-form.[77] As the hexahydrate is commercially available in a highly pure form, ^{35}Cl SSNMR experiments were carried out on this material.

By observing the ^{35}Cl SSNMR line shapes associated with

Fig. 4. Analytical simulations (*a*, *c*) and experimental static Solomon echo (*b*, *d*) ^{35}Cl SSNMR spectra of powdered $CaCl_2$·6H_2O, acquired at $\mathbf{B}_0$ = 11.75 T. The spectrum in (*b*) did not employ proton decoupling during signal acquisition, while the spectrum in (*d*) was acquired using proton decoupling. The simulation parameters used in (*a*) and (*c*) are identical, except for the addition of 1000 Hz of dipolar broadening in (*a*) ($\alpha^d = \beta^d = 0°$, inferred from the neutron crystal structure), due to the expected ^{1}H–^{35}Cl distances of ~2.27 Å. The experimental pulse delay for both (*b*) and (*d*) was 3.0 s. The spectrum in (*b*) is the result of the collection of 16 000 transients, while the spectrum in (*d*) is the result of the collection of 5616 transients.



$CaCl_2$·6H_2O (Figs. 4 and 5), it is clear that $CaCl_2$·6H_2O possesses a distinct line shape with respect to both anhydrous $CaCl_2$ and $CaCl_2$·2H_2O. The measured ^{35}Cl EFG tensor parameters (C_Q(^{35}Cl) = 4.33 ± 0.03 MHz, η_Q < 0.01) strongly suggest that each chloride anion in $CaCl_2$·6H_2O is located on a C_3 (or higher) rotational axis. The smaller value of C_Q (^{35}Cl) for this sample is consistent with earlier observations for group 2 metal halides, which nearly always exhibit smaller halogen C_Q values upon hydration.[12] It is also important to note that $CaCl_2$·2H_2O and all the polymorphs of $CaCl_2$·4H_2O place the chloride anions at positions lacking any local symmetry elements and hence the axial ^{35}Cl EFG observed is unique to the hexahydrate. We also see a clear broadening of the discontinuities in Fig. 4*b* when ^{1}H decoupling is not applied, which indicates that the sample is hydrated.

The observed chlorine chemical shift for $CaCl_2$·6H_2O (δ_{iso} = 57 ± 3 ppm) is smaller than that of both $CaCl_2$ and $CaCl_2$·2H_2O, which is in agreement with earlier observations that the halogen shift value decreases (i.e., shielding increases) upon increasing hydration.[12] The observed ^{35}Cl SSNMR line shape of $CaCl_2$·6H_2O was best modeled when CSA effects were included (Ω = 40 ± 8 ppm, κ = –1; also see Fig. 5). The observed chlorine Ω value is quite similar to that measured for other group 2 metal chloride hydrates.[44] Based on the above discussion, it is clear that our anhydrous

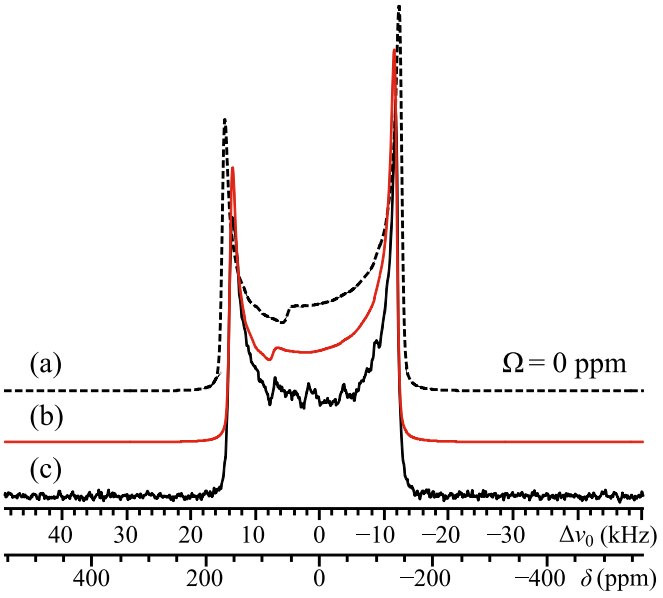
Fig. 5. Analytical simulations (*a*, *b*) and experimental static Solomon echo (*c*) ^{35}Cl{^{1}H} SSNMR spectra of powdered $CaCl_2·6H_2O$, acquired at $\mathbf{B}_0$ = 21.1 T. The spectrum in (*b*) is the best fit to the experimental spectrum, while the spectrum in (*a*) does not include chlorine CSA (i.e., Ω = 0 ppm). A pulse delay of 5.0 s was used and 272 transients were collected.



$CaCl_2$ sample cannot be $CaCl_2·2H_2O$ or $CaCl_2·6H_2O$, and it is very unlikely to be a $CaCl_2·4H_2O$ polymorph, owing to the observed large positive chlorine chemical shift value, the large C_Q(^{35}Cl) value, and the mirror site symmetry implied by the EFG and CS tensor interplay observed in the $^{35/37}$Cl SSNMR spectra of $CaCl_2$.

Quantum chemical computations

GIPAW DFT quantum chemical calculations were carried out using the accepted crystal structures of $CaCl_2$,[65] $CaCl_2·2H_2O$,[78] α–$CaCl_2·4H_2O$,[74] β–$CaCl_2·4H_2O$,[75] γ–$CaCl_2·4H_2O$,[76] and $CaCl_2·6H_2O$,[66] although for the hydrates (except $CaCl_2·6H_2O$, whose structure was solved using neutron diffraction data) the H positions were optimized computationally (*vide infra*). The computed ^{35}Cl EFG and chlorine CS tensor parameters are presented in Table 1, while more detailed computational results can be found in the Supplementary data, Table S4.

Agreement between experimental and GIPAW DFT-computed chlorine CS and EFG tensor parameters

For nearly all of the relevant $^{35/37}$Cl NMR tensor parameters, excellent agreement between experimental observations and GIPAW DFT computations is seen for $CaCl_2$ and $CaCl_2·6H_2O$. The calculated C_Q(^{35}Cl) values for these compounds are slightly overestimated relative to the experiment (~1 MHz), which appears to be a general feature for chloride anions when using this computational method and pseudopotential.[79] In addition, while there is a lack of quantitative agreement between the quantum chemical and experimental δ_{iso} values, the pertinent experimental trend is reproduced computationally (i.e., as hydration increases, δ_{iso} decreases). The quantitative disagreement in δ_{iso} extends to the computational reference standard used in this study (i.e., NaCl(s)). According to the absolute shielding scale established by Gee et al.,[80] the experimental absolute shielding at the chlorine nuclei in solid NaCl is 1015 ± 4 ppm, while the present GIPAW DFT calculations provide a value of 975.06 ppm. Our data therefore suggest the presence of a systematic error in the calculation of σ_{iso} values using the GIPAW DFT method and the current pseudopotential. We note that all calculated shift values reported in Table 1 used the computational shielding standard (i.e., σ_{iso}(NaCl) = 975.06 ppm).

There is also clear disagreement between the chlorine quantum chemical results for $CaCl_2$ and the earlier ^{35}Cl MAS NMR experimental observation:[46] for example, the computed C_Q(^{35}Cl) is too large by roughly a factor of 4. Therefore, the quantum chemical result for $CaCl_2$ provides independent evidence that the earlier ^{35}Cl MAS NMR experimental measurements were either not correctly interpreted or were inadvertently carried out on a material other than $CaCl_2$. The GIPAW DFT result for $CaCl_2·6H_2O$ confirms the local symmetry (i.e., C_3) for the chloride anions, as η_Q = 0.0 and κ = –1.0. It is also rather interesting to note the quantitative agreement between the calculated and experimental Euler angle values for $CaCl_2$ and $CaCl_2·6H_2O$.

While there typically exists very good agreement between experimental and computational values for the $^{35/37}$Cl EFG and magnetic shielding tensors in $CaCl_2$ and $CaCl_2·6H_2O$, relatively poor agreement was observed for $CaCl_2·2H_2O$ in a previous study.[44] Inspection of the source data for the accepted crystal structure of $CaCl_2·2H_2O$ reveals that the structure was generated using X-ray diffraction data, rather than neutron diffraction data, and hence the hydrogen positions are not precisely known. Out of all the group 2 metal chloride hydrates where ^{35}Cl or ^{37}Cl SSNMR data are available, $CaCl_2·2H_2O$ represents the only structure for which neutron diffraction data are unavailable. The H positions in $CaCl_2·2H_2O$ were therefore optimized using the GIPAW DFT method. Subsequent GIPAW DFT calculation of the EFG and magnetic shielding tensor parameters using this optimized structure yields markedly different tensor parameters as compared with the prior study (Table 1). Relative to the earlier computational results, there is a decrease in the computed C_Q(^{35}Cl) by about 34% (6.69 MHz to 4.43 MHz) and a substantial increase in η_Q (0.04 to 0.520). Both of these significant changes result in better agreement between the experimental and computed EFG tensor parameter values.

GIPAW DFT-computed chlorine EFG and CS tensor parameters for $CaCl_2·4H_2O$ polymorphs

Good agreement between the observed and computed $^{35/37}$Cl NMR tensor data was seen for the compounds above; hence, we explored whether GIPAW DFT computations would predict that chlorine SSNMR experiments could be used to differentiate between the α, β, and γ polymorphs of $CaCl_2·4H_2O$. The differentiation of polymorphs using chlorine SSNMR has been demonstrated previously for chlorine-containing pharmaceuticals,[45] and as seen in Table 1, these experiments should also be able to distinguish the polymorphs of $CaCl_2·4H_2O$. Each polymorph should present a different number of magnetically unique chloride sites (ranging from 1 to 3). In addition, there exists significant disparity in the other relevant NMR parameters (notably η_Q, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

ranges from 0.149 in γ–$CaCl_2{\cdot}4H_2O$ to above 0.776 for all three sites in β–$CaCl_2{\cdot}4H_2O$).

Are $CaCl_2$ and $CaBr_2$ isostructural?

Based on prior XRD data, the ambient-condition structures of both $CaCl_2$ and $CaBr_2$ belong to the same space group and place the halogen anions at the same Wyckoff positions.[65,81] The absolute $C_Q(^{81}Br)$ value for $CaBr_2$ is the largest amongst the group 2 metal bromides ($C_Q(^{81}Br) = 62.8 \pm 0.4$ MHz).[14] At the same time, the previously measured $C_Q(^{35}Cl)$ value for $CaCl_2$ was among the smallest measured relative to other group 2 metal chlorides ($C_Q(^{35}Cl) = 2.1$ MHz).[46] The above sections have provided ample evidence that the earlier report was in error, likely because of the formation of a $CaCl_2$ hydrate or the neglect to acquire spectral data using VOCS (or equivalent) methods. In addition, we now have reliable $C_Q(^{35/37}Cl)$ measurements for $CaCl_2$.

It was recently shown by Wu and Terskikh[82] that for a series of isostructural compounds, a linear relationship exists between the measured C_Q values and the quantity $Q(1 - \gamma_\infty)/V$, where γ_∞ is the Sternheimer antishielding factor[83–86] and V is the unit cell volume. This finding has been extended by observations made for the $^{35/37}Cl$,[44,46,69] $^{79/81}Br$,[14,29] and ^{127}I[12] nuclides within several isostructural series of group 2 metal halides and selected hydrates thereof. This linear relationship between C_Q and $Q(1 - \gamma_\infty)/V$ is therefore useful for both confirming and predicting isostructural series within classes of analogous compounds. Although enough data do not exist in this case to construct a meaningful plot of $C_Q(X)$ vs. $Q(1 - \gamma_\infty)/V$, we can compare the respective $C_Q(^{81}Br)/C_Q(^{35}Cl)$ and $[Q_{81Br}(1 - \gamma_{\infty(Br)})/V]/[Q_{35Cl}(1 - \gamma_{\infty\ (Cl)})/V]$ ratios, which should be equivalent according to the above model if these two compounds are isostructural. Using the experimental SSNMR data for $CaCl_2$ and $CaBr_2$, the $C_Q(^{81}Br)/C_Q(^{35}Cl)$ ratio is ~7.12. Using additional known information, with the volume of the unit cells established using X-ray diffraction,[65,81] the $[Q_{81Br}(1 - \gamma_{\infty(Br)})/V]/[Q_{35Cl}(1 - \gamma_{\infty(Cl)})/V]$ ratio is calculated to be 5.19 (a 31.4% difference). This percent difference is comparable to what has been calculated previously for pairs of group 2 metal halide compounds that are understood to be isostructural; in fact, for the isostructural group 2 metal chlorides and bromides studied to date, it is observed that $C_Q(^{81}Br)/C_Q(^{35}Cl)$ ratios range between 6.30 and 7.08, while the calculated $[Q_{81Br}(1 - \gamma_{\infty(Br)})/V]/[Q_{35Cl}(1 - \gamma_{\infty(Cl)})/V]$ ratios for the same systems vary between 5.48 and 5.64.[12] A likely contributor to the disagreement between the calculated $[Q_{81Br}(1 - \gamma_{\infty(Br)})/V]/[Q_{35Cl}(1 - \gamma_{\infty(Cl)})/V]$ ratios and the experimental $C_Q(^{81}Br)/C_Q(^{35}Cl)$ ratios is the uncertainty associated with the γ_∞ values: these values for the quadrupolar halogens are not known to high precision, unlike the group 1 metal atom γ_∞ values used in the study by Wu and Terskikh.[82] At this time it is noted that, using the accepted structures for $CaCl_2$ and $CaBr_2$, the GIPAW DFT-calculated $C_Q(^{81}Br)/C_Q(^{35}Cl)$ ratio is ~7.16, which is in excellent agreement with our experimental observations (a difference of 0.56%).

Likewise, upon consideration of the fine details associated with the $CaCl_2$ and $CaBr_2$ crystal structures, two points are clear: (*i*) the structure of $CaCl_2$ is rather old (1935), and (*ii*) the placement of the halogen anions is, in fact, not equivalent for the two structures (in $CaBr_2$ the bromide is at $x/a = 0.2636 \pm 0.0029$, $y/b = 0.3417 \pm 0.0026$, $z/c = 0$, whereas in $CaCl_2$ the chloride is at $x/a = 0.275 \pm 0.08$, $y/b = 0.325 \pm 0.08$, $z/c = 0$). It is therefore probable that this discrepancy in the halide positions within their respective crystalline lattices would contribute to the difference between the $[Q_{81Br}(1 - \gamma_{\infty(Br)})/V]/[Q_{35Cl}(1 - \gamma_{\infty(Cl)})/V]$ ratio and the $C_Q(^{81}Br)/C_Q(^{35}Cl)$ ratio. Indeed, it has been demonstrated recently that very small displacements of the halide anion (typically < 0.05 Å) can dramatically alter the calculated halogen C_Q value for several similar systems.[12,29] Therefore, while it is clear that the $C_Q/[Q(1 - \gamma_\infty)/V]$ relationship appears to be of general use for group 2 metal halides, the precision of the halogen γ_∞ values is a limiting factor and the compounds must be rigorously isostructural to obtain exactly equal ratios.

Conclusions

Solid-state $^{35/37}Cl$ NMR experiments are sensitive probes of the local structure of inorganic materials and have allowed for differentiation between the hydrates of $CaCl_2$. By performing chlorine SSNMR experiments in two applied magnetic fields, both the EFG and CS tensor parameters could be accurately measured in $CaCl_2$ and $CaCl_2{\cdot}6H_2O$. The measurement of these tensor parameters allowed us to correct the ^{35}Cl SSNMR literature data for $CaCl_2$ and illustrate that this species conforms to the established quadrupolar halogen NMR trends for group 2 metal halide systems (i.e., that both the halogen C_Q value and the halogen chemical shift will decrease upon hydration). GIPAW DFT quantum chemical calculations have provided complementary data for the $CaCl_2$ hydrates where experimental SSNMR data exist and predict that $^{35/37}Cl$ SSNMR experiments should be able to distinguish the three known polymorphs of $CaCl_2{\cdot}4H_2O$. It is seen that optimization of the H positions for $CaCl_2{\cdot}2H_2O$, whose structure has been determined using X-ray diffraction data, is necessary to obtain good agreement between the quantum chemical and experimental EFG tensor parameter values. By carrying out ^{43}Ca SSNMR experiments at ultrahigh $\mathbf{B}_0$ (i.e., 21.1 T), we have been able to measure the fifth calcium CS tensor anisotropy, which is expected to prove useful in future SSNMR studies that correlate calcium CS tensor information to local structure and symmetry in other calcium-containing materials. Lastly, although it has been demonstrated that comparing $C_Q/[Q(1 - \gamma_\infty)/V]$ ratios can provide evidence that a series of compounds are isostructural when using group 1 metal nuclei as probes, additional problems (i.e., uncertainty in halogen γ_∞ values and a requirement that the compounds be rigorously isostructural) present themselves when the quadrupolar halogen nuclei are used.

Supplementary data

Supplementary data, including detailed $^{35/37}Cl$ and ^{43}Ca SSNMR experimental data acquisition parameters, GIPAW DFT quantum chemical calculations (pseudopotential files used, structure energies, structure references, crystal structure parameters used, and additional information), and GIPAW DFT-computed $^{35/37}Cl$ and ^{43}Ca EFG and magnetic shielding

tensor parameters, are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: The effect of a pulse in NMR is usually considered as a rotation of the frame of reference of the spin system. For spins-1/2, this concept is an important and very useful tool. The assumption behind this concept is that while the radio frequency irradiation is on, this term dominates all other interactions. Although this is usually true for spins-1/2, typical interactions for a quadrupolar nucleus can be very large and the assumption is no longer valid. The full solution is complex, but two extreme cases are already solved. If the quadrupole interaction is very small, then the assumption is valid and the pulse does act like a rotation of the frame of reference. At the other extreme, if the interaction is large and the spin, I, is half-integral, then the central transition remains relatively narrow and can be treated as a fictitious spin-1/2. The pulse then acts as a rotation, but with a scaling factor of $I + 1/2$. This paper treats the general case, where no approximations are made. The effects can be observed in a nutation experiment, in which the observed signal is plotted as a function of pulse width, in a simple one-pulse experiment. If the pulse acts as a rotation, then the nutation plot will be a sine wave, but otherwise it will be a sum of sinusoids. This is true even for a single-crystal sample with a single quadrupolar coupling. If the sample is a powder, then the nutation plot will be a sum of many sinusoids, since the quadrupole coupling will vary with the powder average. This paper sketches out the theory of these effects based on a full and exact description of a quadrupolar system and illustrates it with some nutation spectra of ^{23}Na in a powdered sample of sodium nitrate.

Key words: NMR, quadrupolar nuclei, nutation spectra, radio frequency interactions, spin-3/2, spin operators.

Résumé : L'effet d'une pulsation en RMN et généralement considéré comme une rotation du système de référence du système de spin. Pour les spins 1/2, ce concept est un outil important et très utile. L'hypothèse derrière ce concept est que lorsque l'irradiation par une radiofréquence est appliquée, ce terme domine toutes les autres interactions. Même s'il est généralement vrai que pour les spins 1/2, les interactions typiques pour un noyau quadripolaire peuvent être assez importantes et l'hypothèse n'est plus valide. La solution totale est complexe, mais deux cas extrêmes ont déjà été résolus. Si l'interaction quadripolaire est très faible, l'hypothèse est alors valide et la pulsation agit comme une rotation du système de référence. À l'autre extrême, si l'interaction est grande et que le spin, I, n'est pas un nombre entier, la transition centrale demeure alors étroite et elle peut être traitée comme un spin 1/2 fictif. La pulsation agit alors comme une rotation, mais elle comporte un facteur d'étalement de $I + 1/2$. Dans ce travail, on traite du cas général pour lequel aucune approximation n'est faite. Les effets peuvent être observés dans une expérience de nutation au cours de laquelle on trace un graphique du signal observé en fonction de la largeur de la pulsation exercée dans une expérience simple à une pulsation. Si la pulsation agit comme une rotation, le graphique de la nutation sera une onde sinusoïdale simple, autrement il sera la somme de sinusoïdes. Ceci est vrai pour un échantillon de cristal unique avec un couplage quadripolaire simple. Si l'échantillon est une poudre, le graphique de la nutation sera la somme de plusieurs sinusoïdes puisque le couplage quadripolaire variera avec la moyenne de la poudre. Le présent travail esquisse la théorie de ces effets en se basant sur une description complète et exacte d'un système quadripolaire et il les illustre à l'aide de spectres de nutation du ^{23}Na dans un échantillon en poudre de nitrate de sodium.

Mots-clés : RMN, noyau quadripolaire, spectres de nutation, interactions avec des radiofréquences, spin 3/2, opérateurs de spin.

[Traduit par la Rédaction]

Introduction

In most fields of NMR, a common assumption is that the pulses are "hard" and that they act like a rotation of the frame of reference. This arises from the assumption that the radio frequency (rf) magnetic field dominates all the other interactions.[1–4] This is equivalent to assuming that there is no other evolution during the pulse — it effectively has zero length, yet has a finite flip angle; hence, the common parlance of 90° pulses, etc. This is usually a valid assumption for spins-1/2, but for quadrupolar nuclei it fails because

quadrupole couplings can be several megahertz. Solutions of this problem are available for very large and very small (with respect to the rf) quadrupole couplings, but a general solution is more complicated. In this paper, we give some preliminary discussion of the theory, based on an exact solution (no perturbation theory) of the quadrupole system without rf irradiation. The specific results may well be familiar to the reader, but the approach is very general[5] and more systematic than standard methods. This paper represents a test and a validation of these methods.

Nutation plots

One manifestation of the rotation character is that a plot of signal against pulse width gives a sine wave. This plot, called a nutation plot, usually forms the basis for pulse power calibrations and rf homogeneity tests. Even when this hard pulse approximation is not fully justified, the rotation picture is remarkably successful, and it pervades almost all NMR. Since rf fields are typically 40 kHz or so, the approximation is often acceptable for spins-1/2 in solution. Few spin interactions in this case are of that size. Offsets from resonance can approach that magnitude, so that both precession and rf interactions occur during the pulse but the pulse is still well approximated by a rotation around a tilted effective rf field.[2,3,6–8]

Quadrupolar nuclei, on the other hand, have much larger interactions, so the hard pulse approximation is much more difficult to justify. For example, one consequence of this failure is that a single pulse can create substantial multiple-quantum coherence, as in the original multiple-quantum magic-angle spinning experiment.[9] Similarly, the selection rules break down and multiple-quantum and overtone spectra can be observed.[10–13] Even though this breakdown complicates the spin dynamics, it also gives us an easily manipulated experimental parameter (the pulse width) with which to probe the system. To study the effects of pulses on quadrupolar systems, we must look at the simultaneous interaction of rf and quadrupole coupling in more detail.

A good way of probing the effects of a general quadrupole interaction is to study the nutation plots.[14–18] Quadrupolar systems with large interactions can give very broad spectra, but nuclei with half-integral spins have a central transition (from m_z of –1/2 to +1/2) which remains sharp even in the presence of large quadrupole couplings (>1 MHz).[19,20] This central transition is perturbed only to second order in the quadrupole coupling,[21] so it is much narrower than the satellites, whose width is directly proportional to the quadrupole coupling. The nutation experiment in this case usually involves the intensity of the central transition as a function of pulse width.

There are two easily treated extremes: the quadrupole coupling is very much bigger or very much smaller than the rf field. In both these cases, the nutation plot still has a sinusoidal form, but the nutation frequencies differ. For small quadrupolar coupling, the hard pulse approximation applies and all the transitions are affected equally: the spin acts like a spin-1/2. For large couplings, the central transition is essentially isolated and can be treated as a fictitious spin-1/2 system. The nutation plot is again sinusoidal, but the period is reduced (the nutation frequency is increased) by a factor of $I + 1/2$, where I is the nuclear spin.

Theory

The intermediate case is more complicated and forms the subject of this paper. A number of solutions have already been published for spin-3/2.[22–29] Since spin-3/2 is a small finite system, the calculations are not particularly difficult. Straightforward numerical density matrix manipulations[30,31] can be peformed, either with the density matrix as a matrix in Hilbert space,[1] as in eq. [1],

$$[1] \qquad \hat{\rho}(t) = \exp(-i\hat{H}t)\hat{\rho}(0)\exp(i\hat{H}t)$$

or with the density matrix as a vector in Liouville space under the influence of $\boldsymbol{L}$, the Liouvillian,[32,33] as in eq. [2].

$$[2] \qquad \rho(t) = \exp(-iLt)\rho(0)$$

Solutions that are clear and meet our intuitions are more elusive — we are very attached to the rotation and vector picture of a pulse, even though it does not apply here. If the hard pulse approximation applies to a weakly coupled system of spins-1/2, the product operator formalism[34] gives an excellent description of the time evolution. This has become the standard way of describing pulse sequences, but for strongly coupled or quadrupolar nuclei, the calculations are less clear. On the other hand, if a transition is relatively isolated because the interactions are large, then the evolution can be treated as a fictitious spin-1/2 and described by single transition operators.[35,36] However, this creates an overcomplete basis — more operators than the dimensionality of the system — so a full treatment is clumsy. In the present case, neither is appropriate. All transitions are potentially involved simultaneously, even though it is only the central transition that is measured. We must expect that the result could be complicated.

The various solutions must agree, since they are all exact, but there is virtue in solving a problem in a number of different ways. Simple numerical integration will simulate the experiments, but it tends not to provide much insight into mechanisms. Provided approximations are made, then explicit formulae can often be derived for the evolution of the system. This gives us a functional form which we can manipulate analytically. In this paper, we present a new solution based on a recently published exact description of a quadrupolar system.[13,37] The present approach is exact, but the full solution is too complicated to present algebraically. However, its structure is quite simple and it is clear where approximations can be made to give explicit formulae.

Analogy to NQR

As with all NMR experiments, the system is described by the density matrix, which evolves in time according to the Liouville–von Neumann equation. The solution to this equation is given in eqs. [1] and [2]. For a single quadrupolar spin, the total Liouvillian includes terms from the Zeeman interaction, the quadrupole coupling, and the effect of the rf irradiation. The rf is treated in the laboratory frame of reference rotating at the transmitter frequency, so the Zeeman term is zero, or reduced to a small offset from resonance.

This means that we only deal with the quadrupole and rf terms.

In the pure quadrupole interaction, the energy of a spin state is proportional to the *square* of the z component of the spin angular momentum, so the levels with z component $\pm 1/2$ are degenerate, as are the other pairs of corresponding levels. This is shown schematically in Fig. 1 for the spin-3/2 with just a quadrupole interaction. There are two energies, which are separated by $e^2qQ/2$, the frequency at which nuclear quadrupole resonance (NQR) absorption appears.[38]

Note that we are not using the usual frame of reference for NQR. There, the convention is that the principal axes of the electric field gradient tensor define the frame. For a powder sample, then, the rf field will have a powder distribution, with respect to the field gradient. In our calculation, we use the laboratory frame, in which the z axis is defined by the Zeeman interaction and the rf is in the xy plane. In either case, the relative orientation of the rf and the quadrupole interaction will define the ratio of the sizes of these two, and it will be different for each crystallite in the powder.

A magnetic field will lift this degeneracy of the levels. If a small static field is applied in the laboratory frame, this mixes the $\pm 1/2$ states strongly, since they differ by only one unit of angular momentum and there is a direct matrix element between them. The $\pm 3/2$ states are less affected.[38]

Since there are four spin states, there are six possible coherences with nonzero resonance frequency. In the NQR spectrum, there are four transitions close to the NQR frequency.[38] Two are allowed transitions, $-1/2 \rightarrow -3/2$ and $+1/2 \rightarrow +3/2$ (transitions *1* and *2* in Fig. 1), where the z component changes by one unit. Since the $\pm 1/2$ states are strongly mixed, the formally forbidden transitions $-1/2 \rightarrow +3/2$ and $+1/2 \rightarrow -3/2$ (transitions *3* and *4* in Fig. 1) also have substantial transition probabilities. There are clearly analogies with the AB system of two spins-1/2. The other two coherences are the low-frequency (zero, if the magnetic field is zero) coherences $-1/2 \rightarrow +1/2$ and $-3/2 \rightarrow +3/2$ (transitions *5* and *6* in Fig. 1).

This is the pattern of frequencies when the Zeeman interaction is much smaller than the quadrupole and we are doing NQR. As the Zeeman interaction increases and comes to dominate, we change to the regime of quadrupole-perturbed NMR, and the correlation of the coherences is given in Fig. 2. While the rf is on, even in a large magnetic field, the interaction of rf with a quadrupole system still belongs in the NQR regime, since the rotating frame reduces the Zeeman interaction. It is still useful to keep the NMR situation in mind, however.

For the calculation we are doing, the Liouvillian has three terms: $\boldsymbol{L}_z$, the Zeeman term, $\boldsymbol{L}_q$, the quadrupole term, and $\boldsymbol{L}_{rf}$, the term describing the rf. We have formulae for the matrix elements of all these terms,[5,37] so eq. [2] gives an exact solution for any set of parameters. In practical terms, valid approximations such as neglecting the Zeeman term (because of the transformation to the rotating frame of reference) can be easily imposed. If we assume that the electric field gradient tensor is cylindrical, then the Liouvillian is further simplified and we can extract explicit formulae. For the purposes here, we will use the numerical solution to the exact equation. Future work will explore approximations and algebraic solutions.

Fig. 1. Schematic energy-level diagram of a spin-3/2 in a small magnetic field. Six transitions are possible amongst the four energy levels: there are two formally allowed transitions, *1* and *2*, and two formally forbidden transitions, *3* and *4*. These are the transitions that would be observed in a Zeeman-perturbed NQR spectrum. The final two transitions, *5* and *6*, are low-frequency ones.

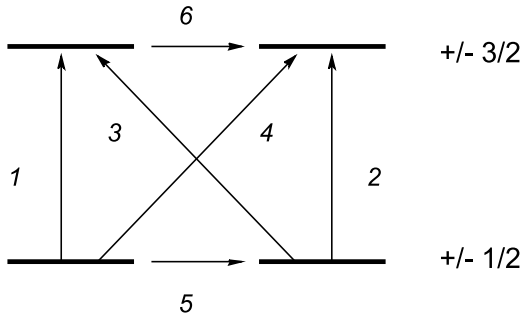

Fig. 2. Schematic energy levels of a spin-3/2 in zero applied magnetic field (left) and high field (right). The splittings are nominal and not to scale.

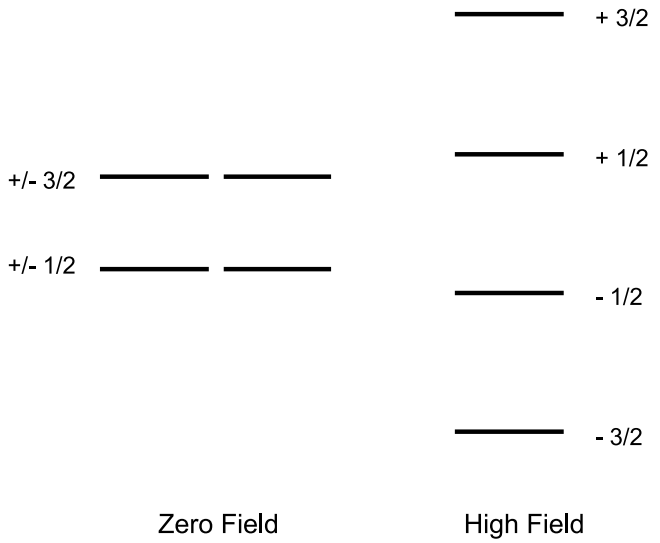

Experimental

NMR spectra were acquired on a Bruker Avance I 500 MHz spectrometer using a standard 2.5 mm MAS probe. The samples were not spinning, and all spectra were acquired at ambient temperature. Sodium nitrate was purchased from Sigma-Aldrich and used without further purification. The sample was ground in a mortar and pestle and put into a standard 2.5 mm rotor.

The magnetic field associated with the rf was determined from measurements of a 90° pulse on a solution of sodium nitrate in water. For each spectrum of the solid sample, 64 acquisitions were made with a delay time of 40 s between pulses. The full spectral width was 500 kHz, and 4K points were acquired in the time domain.

The simulations for a given quadrupole coupling were done with a specifically written program in the C language. No attempt was made to make the code numerically efficient, since the goal was to implement the theory clearly. Source code is available from A. D. Bain on request. The signal for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

a powder sample was then simulated by doing a powder average over the orientation and the quadrupole coupling using the Zaremba–Conroy–Wolfsberg method.[39,40] For a system with approximately 1000 powder average points and 256 points along the nutation plot, the calculations took approximately 30 s on an Intel-based personal computer running at 1.5 GHz with 512 MB of RAM.

Results and discussion

Figure 3 shows the plot of signal intensity of the central transition of the ^{23}Na spectrum of sodium nitrate as a function of pulse width. The data points are the solid circles and the smooth curve shows the simulation. No adjustable parameters were used in the simulation other than a slight adjustment of the rf field strength to improve the fit. This discrepancy may have been caused by small differences in the probe tuning between the liquid solution (used to calibrate the rf field) and the solid sample. The quadrupole parameters for sodium in sodium nitrate were fixed at values from the literature (e^2qQ = 335 kHz, η = 0).[23,41–43] The quadrupole coupling could be verified, since the signal/noise ratio was good enough to see the edges of the powder pattern of the satellite transitions.

Since there are six possible coherences for a spin-3/2, any time evolution can be written as a sum of six oscillations, although a selection rule reduces this to four. Even for a crystal with a single quadrupole coupling, the nutation plot will not be a simple sinusoid (Fig. 4), but rather a sum of them. The frequencies of these oscillations are given by the eigenvalues of the Liouvillian. This is always true, but the question is how much does each oscillation contribute to the observed signal?

In the extreme limits, a single term dominates. For $\gamma B_1 >> e^2qQ$ (hard pulse), the dependence on pulse width is sinusoidal with a nutation frequency of γB_1. At the other extreme (large quadrupole coupling), a spin-3/2 shows a sinusoidal dependence, but now with a nutation frequency of $2\gamma B_1$, obeying the $I + 1/2$ rule. In the intermediate range, even though there is a single quadrupole coupling, the signal is a sum of sinusoidal terms, each with substantial contributions.

A powder sample will have a range of quadrupole couplings, depending on the orientation of the crystallite in the magnetic field. If the rf field is comparable to the quadrupole coupling, then there will be signals at the edges of the powder pattern where the quadrupole coupling dominates, but there will also be crystallites close to the magic angle for which the rf is the major term. This means that not only does a single crystallite have a time evolution made up of a sum of sine waves, but the powder average will contribute many more frequencies to the total evolution. Figure 5 shows a number of simulated nutation plots for a number of orientations of the crystal.

This means that for a powder sample, the central transition will not show a sinusoidal nutation plot, except in extreme cases. All of the sinusoids will start out together, so the signal will initially increase in an apparent sine wave with increasing pulse width. As the nominal flip angle (for a sample with no quadrupole interaction) approaches 90°, the oscillations will grow out of phase with each other and start to cancel. This leads to the occasional phenomenon of never

Fig. 3. Experimental nutation plot for the central transition in the ^{23}Na spectrum of a powder sample of sodium nitrate. The solid circles represent measured data, and the line represents the simulation. No adjustable parameters were used in the simulation.

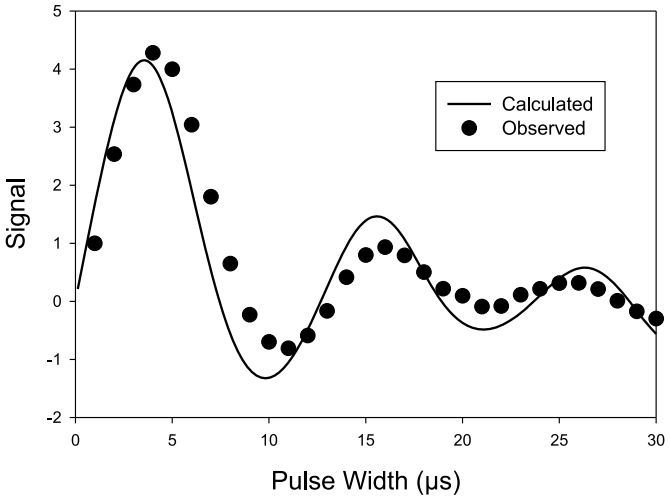

Fig. 4. Simulation of a ^{23}Na nutation plot for a single crystal of sodium nitrate oriented at an angle of 140° with the z axis in the laboratory frame — the frame in which the rf magnetic field is in the xy plane. The parameters used were γB_1 = 200 kHz, e^2qQ = 337 kHz, and η = 0. The curve is a sum of up to six sinusoids with different frequencies and scale factors.

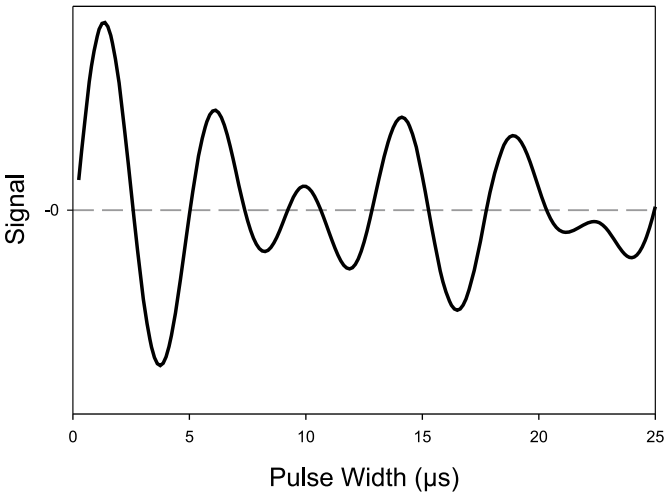
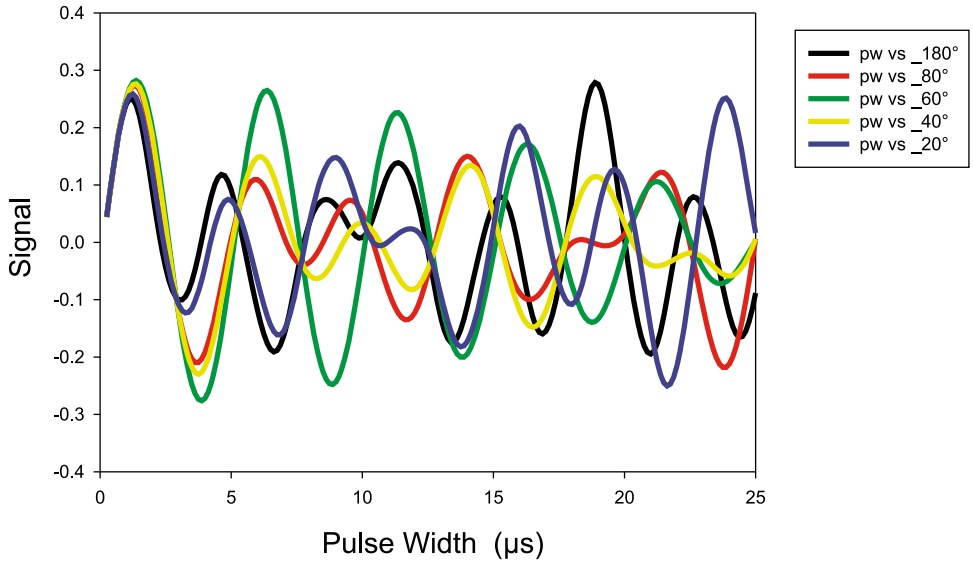


getting an inversion in a nutation plot of a powder sample — the parameters are such that the signal stays positive and just dies away.

Figure 3 shows the correspondence between theory and experiment for the ^{23}Na spectrum of powdered sodium nitrate. No adjustable parameters were used in the theoretical calculation. The match between the experimental data and the simulations is good, but not perfect. We think that the discrepancies are long pulse widths that may be due to poor rf homogeneity in the probe, and experiments to provide a more rigorous test of the theory are under way.

This discussion is in the time domain — the width of the pulse is the independent variable. Many nutation experiments take the Fourier transform of these data to create a nutation

Fig. 5. Simulations of single-crystal ^{23}Na nutation plots for a number of different orientations of a sodium nitrate crystal. The orientation with respect to the laboratory frame is given in the legend. The parameters used were $\gamma B_1 = 200$ kHz, $e^2qQ = 337$ kHz, and $\eta = 0$. The full powder pattern will be an average over all such plots, representing all orientations with appropriate weightings.



spectrum. The time domain and the frequency domain are equivalent, of course. The arguments above show that for a spin-3/2, a single crystal will have a nutation spectrum with four frequencies (of various intensities) in it. When averaged over a powder, there will be a complete range of frequencies, leading to a broad nutation spectrum with some maxima and other features. These frequencies are important in setting up matching curves for cross-polarization with quadrupolar nuclei.[44] Both the time domain and the frequency domain will give poorly resolved data, so it is up to the user to choose which presentation provides more insight.

Finally, Fig. 1 suggests why multiple-quantum coherence can be created by a single pulse. The transition from –3/2 → +3/2 is a low-frequency transition for a quadrupolar nucleus in a very small magnetic field, even though it is triple-quantum coherence at high field. It is therefore well within the range of the relatively weak rf pulse. After the rf is switched off, the system reverts to the NMR regime (Fig. 2) and the coherence created in the NQR situation will evolve as triple-quantum coherence with the attendant advantages. We aim to follow this qualitative explanation more quantitatively in future work.

Conclusions

We have presented a clear and rigorous picture of nutation behaviour for a quadrupolar spin. The calculation makes no approximations and is applicable to any spin. Its major application will be to half-integral rather than integral spins, but both can be treated. The nutation plot will be a sum of sinusoids, even for a single crystal with one quadrupole coupling. A powder sample will show an almost continuous range of nutation frequencies. The results of the calculation agree well with experimental nutation plots of the ^{23}Na spectrum of a powder sample of sodium nitrate.

Abstract: The NMR spectra of polymorphs I, II, and III of the pharmaceutical drug compound phenobarbital are discussed in relation to the crystal structures. Whilst some features can be explained by inspection of the structures, others require more detailed work. In this paper, shielding computations for the ^{13}C, ^{15}N, and ^{1}H nuclei using crystallographic repetition (with optimization of the positions of all atoms) are presented. These have enabled the majority of the signals to be assigned with some confidence and several features of NMR crystallography are illuminated. In particular, resonances have been attributed separately for the three independent molecules of form I (and also for form II). Moreover, the chemically equivalent but crystallographically distinct nuclei forming the two halves of the phenyl ring (and likewise of the heteronuclear ring) have been distinguished and a structural conformational motif attached to the ^{15}N chemical shifts revealed. The small differences between the spectra of forms I and II (which have very closely related crystal structures) are well-reproduced. The value of computations for establishing precise assignments of signals to crystallographic sites of atoms is emphasised. Conversely, the work provides a good test of the accuracy of computations for crystalline materials.

Key words: NMR crystallography, phenobarbital, polymorphism, shielding computation, assignment of signals.

Résumé : On discute des spectres RMN des polymorphes I, II et III du phénobarbital, un composé médicamenteux, en relation avec leurs structures cristallines. Alors que certaines caractéristiques peuvent être expliquées par l'examen des structures, d'autres demandent un travail plus détaillé. Dans ce travail, on rapporte des calculs de blindage des noyaux ^{13}C, ^{15}N et ^{1}H à l'aide de répétitions cristallographiques (avec optimisation des positions de tous les atomes). Ces résultats ont permis d'attribué pratiquement tous les signaux avec un certain degré de confiance et plusieurs caractéristiques de la cristallographie par RMN sont mis en lumière. En particulier, les résonances ont pu être attribuées séparément pour les molécules indépendantes de la forme I (ainsi que de la forme II). De plus, on a pu établir une distinction entre les noyaux chimiquement équivalents, mais distincts d'un point de vue cristallographique, des deux moitiés du noyau phényle (de même que pour le noyau hétéronucléaire) et mettre en évidence un motif conformationnel attaché aux déplacements chimiques du ^{15}N. Les petites différences entre les spectres des formes I et II (dont les structures cristallines sont très semblables) sont bien reproduites. On met en relief la valeur des calculs dans l'établissement d'attributions précises de signaux à des sites cristallographiques d'atomes. Et en conséquence, ce travail fournit un bon test de la précision des calculs pour des matériaux cristallins.

Mots-clés : cristallographie par RMN, phénobarbital, polymorphisme, calcul de blindage, attribution de signaux.

Introduction

Phenobarbital (5-ethyl-5-phenyl-2,4,6(1*H*,3*H*,5*H*)-pyrimidinetrione), $C_{12}H_{12}N_2O_3$, is a well-known barbiturate drug, which is still in clinical use nearly a century after first being put on the market. It has the molecular structure given on the right, together with the atomic numbering used for the NMR spectra and for the reported crystal structure of polymorph III (although it needs to be noted that the numbering for the other two crystal forms is not entirely consistent).

The characteristics of eleven polymorphs of phenobarbital, including six metastable forms that crystallize only in the presence of other barbiturates, have been reviewed recently.[1,2] New crystal-structure determinations of the most stable forms (I, II, and III) were presented (see the Cambridge Structural Database[3] CCDC codes PHBARB07–09), as were the high-resolution ^{13}C and ^{15}N solid-state NMR spectra. However, the chemical shifts were not discussed in detail and, since no shielding computations were carried out, it was not possible to assign the chemical shifts to the different independent molecules in the asymmetric unit of forms I and II or to link the chemical shifts to crystallographic sites for any of the forms. The aim of the present paper is to investigate these aspects, so as to provide a complete relationship between chemical shifts and atomic positions, and to include, for the first time, solid-state proton MAS spectra.

The computations have been carried out with the CASTEP program, which uses the gauge-including projector augmented wave (GIPAW) method,[4–6] the successes and limitations of which have been recently reviewed for organic systems.[7]

The salient features of the crystal structures are as follows. Forms I (space group $P2_1/n$) and II ($P\bar{1}$) both contain three crystallographically independent molecules (denoted A, B, and C). The structures are built up from the same 2D packing fragments but differ in the symmetry operation, either a glide plane (I) or an inversion (II), between adjacent 2D building blocks.[1] Each of the two polymorphs exhibits two separate hydrogen-bonded patterns, a 1D chain formed by molecules of type C and a 2D network that is composed of molecules A and B (see Fig. 1). A-type molecules as well as C-type molecules are linked together in a similar fashion by strong N–H···O hydrogen bonds so that two independent 1D chains are generated. Additionally, B molecules act as bridges between adjacent A-type chains via two weaker N–H···O interactions, so that a 2D hydrogen-bonded network A + B is generated. Molecules of type B are hydrogen-bonded only through the nitrogen atoms, so none of the carbonyl groups are hydrogen-bonded. The crystal structure of form III (space group $P2_1/c$) contains a single type of molecule, which forms the same sort of 1D chain motif as those for the A-type and C-type molecules of polymorphs I and II (see Fig. 2). In each case the hydrogen bonds involve carbonyl groups at C4 and C6, but not C2. It is noteworthy that molecules forming the 1D motif can be related either by inversion symmetry (form I, C-type molecule; and form II, A- and C-type molecules) or glide symmetry (form I, A-type molecule) or by a 2_1 screw axis (form III). Thus, the two N–H···O bonds linking two adjacent molecules of the chain are either crystallographically equivalent (inversion) or are crystallographically independent (glide or 2_1).

All independent molecules adopt the same fundamental conformation in which the mean plane of the phenyl ring and one C5–C bond in the pyrimidinetrione ring deviate somewhat from being coplanar, and the corresponding C–C5–C9–C torsion angle lies between 7.8° and 27.6°. The molecules themselves are not symmetrical because the plane of the phenyl group is not perpendicular to the pyrimidinetrione plane in any of the systems, so the two sides of the pyrimidinetrione ring are nonequivalent in an NMR sense (see Fig. 3). We will refer to the carbonyl group and the

Fig. 1. The structure of phenobarbital form II, showing the three independent molecules and their hydrogen bonding. Top: the 2D hydrogen-bonded network composed of molecules A and B; bottom: the 1D chain of a C-type molecule. Hydrogen and oxygen atoms linked by N–H···O bonds are drawn as balls, and selected intermolecular distances are given in Å. Symmetry operations: (*i*) $x + 1, -y + 1, -z + 2$; (*ii*) $-x, -y + 1, -z + 1$; (*iii*) $x + 1, y, z$; (*iv*) $-x, -y + 2, -z$; (*v*) $-x + 1, -y + 2, -z + 1$.

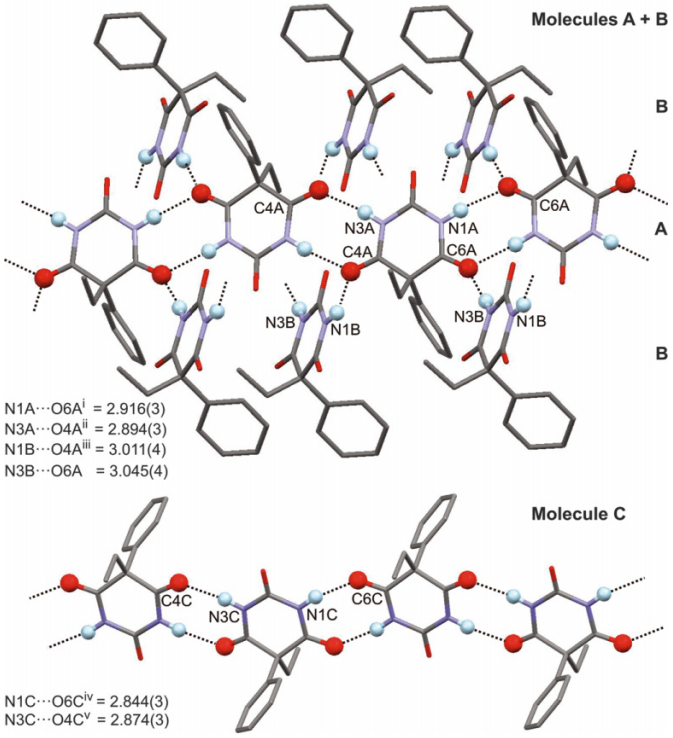

Fig. 2. The 1D hydrogen-bonded chain of phenobarbital form III. Hydrogen and oxygen atoms linked by N–H···O bonds are drawn as balls, and selected intermolecular distances are given in Å. Symmetry operations: (*i*) $-x + 2, y + 1/2, -z + 1/2$; (*ii*) $-x + 2, y - 1/2, -z + 1/2$.

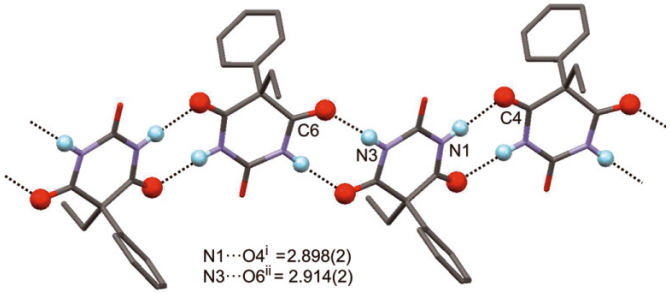

nitrogen atom on the right of Fig. 3, together with the corresponding ortho and meta phenyl carbons, as the "edge" atoms because of their proximity in the molecular projection shown. As a consequence of this situation, form III is expected to give two ^{15}N resonances and carbons C4 and C6 should give two ^{13}C signals. The spectra of forms I and II are predicted to be more complicated, with every nucleus giving three signals, so there should be six ^{15}N resonances. These predictions have been borne out in practice.[1] As mentioned above, the 1D NMR spectra leave a number of assignment

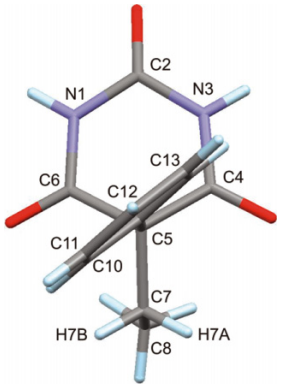
Fig. 3. View of a molecule of phenobarbital showing the conformation of the phenyl ring in the crystal structures. The right-hand side is designated in the text as the "edge" side. Some atoms are labelled with crystal structure notation (as for form III).



questions unanswered; for instance, it was not possible to assign the signals to the nuclei of the two sides of the phenyl ring or to the two sides of the pyrimidinetrione ring. It is also not feasible to assign the signals for forms II and III to the three independent molecules separately. Whilst more sophisticated NMR experiments might allow some of these questions to be addressed, only computational work is able to completely evaluate the relationship between chemical shifts and atomic positions, thus forming an essential link in NMR crystallography.

Experimental

Phenobarbital was available as a mixture of forms I and II (Mallinckrodt Chemical Works, USP XIII powder, USA). Phase-pure form I was prepared by annealing the commercial product at 160 °C for 2 h, and forms II and III by crystallization from hot ethanol and acetonitrile solutions, respectively.

The experimental details for the ^{13}C and ^{15}N spectra appear in ref. 1. The proton spectra were obtained at 400 MHz and ambient temperature using a Varian VNMRS spectrometer and a 4.0 mm o.d. pencil rotor, with magic-angle spinning at modest rate (12 kHz). A windowed phase-modulated Lee–Goldburg (PMLG) pulse sequence[8] was employed to obtain homonuclear dipolar-decoupled spectra, with 10.0 ms acquisition time, a recycle time of 10.0 s, 90° pulse angles (2.5 μs), and 32 FIDs. The experimental ^{13}C spectra[1] were referenced using the high-frequency signal for a replacement sample of adamantane (δ_C = 38.5 ppm). The experimental ^{15}N spectra[1] were referenced to the resonance of neat nitromethane via the nitrate signal of ammonium nitrate (δ_N = –5.1 ppm). The proton spectra were referenced indirectly[8] to the signal for tetramethylsilane via a spectrum of glycine obtained under exactly the same conditions. The scaling factor was obtained by adjusting the shift difference for glycine to its known value.

The GIPAW computations were carried out on the Hamilton supercomputer cluster at the University of Durham, Durham City, UK. For structures determined by X-ray diffraction (as in the present case), rather than by neutron diffraction, it is always necessary to optimize the positions of hydrogen atoms before the magnetic shieldings are computed, since otherwise all X–H distances are underestimated (diffraction of X-rays being caused by electron density, not atomic nuclei). However, we chose to optimize all atomic positions to still further improve the agreement between computed and experimental chemical shifts. The Perdew–Burke–Ernzerhof (PBE) functional was used, with 3 k-points and a cutoff energy of 600 eV for the geometry optimization stage, but 800 eV for the shielding calculations. Forms I, II, and III contain 12, 6, and 4 molecules per unit cell (348, 174, and 116 atoms per unit cell, respectively). The computation of form I was challenging for the Durham Hamilton facility. The full sets of computed isotropic shieldings are given in the Supplementary data. The ^{13}C shieldings (σ) were converted to chemical shifts[7] (δ) by equating the average shielding (σ_{ave}) with the average observed chemical shift (δ_{ave}) for forms II and III together and using the equation

$$[1] \qquad \delta = \sigma_{ave} + \delta_{ave} - \sigma$$

For form II, only the lines that were clearly assignable were used to obtain σ_{ave}. The nitrogen shieldings were similarly converted for forms II and III, treated together. However, because the low resolution in the proton spectrum prevented assignments of individual lines, the computed ^{1}H spectra (with a line width of 100 Hz) were simply adjusted in scale to give the best comparison to the experimental spectra. The computed ^{13}C and ^{15}N spectra were plotted with a line width of 30 Hz.

Results and discussion

Figures 4, 5, and 6 compare the experimental ^{13}C, ^{15}N, and ^{1}H MAS NMR spectra of forms II and III of phenobarbital. The signals assigned to C2 are substantially broadened by second-order effects arising from dipolar coupling to the two neighbouring ^{14}N nuclei, the C4/C6 signals being less affected because of the orientation of the electric field gradient at the single neighbouring ^{14}N nucleus. The spectra of forms I and II are remarkably similar[1] (though there are subtle differences in detail), so much of the discussion herein will focus on comparisons involving forms II and III. The ^{13}C and ^{15}N chemical shifts of all three forms are listed in full in ref. 1. Tables 1 and 2 of the present paper contain selected experimental ^{13}C data for forms II and III. Table 3 gives the ^{15}N shifts for forms II and III and Table 4 lists the ^{1}H shifts for all three forms (not reported previously), although resolution of the separate signals is not very high. Several features of the experimental results are of particular interest and require explanation in terms of the crystal structure:

- The number of ^{13}C and ^{15}N peaks observed clearly shows that there are three molecules in the asymmetric unit for forms I and II, but only one for form III.
- The most obvious difference in the ^{13}C spectra of forms I and II is that, for the methylene group, form I shows overlap of two of the resonances, to high frequency of the third, whereas form II has three clearly resolved peaks.
- The range of ^{15}N resonance frequencies is slightly smaller for form II (8.85 ppm) than for form I (9.51 ppm), and the second and third lines (from high frequency) are closer together for form I (separation 0.66 ppm) than for form II (1.28 ppm).

Fig. 4. The $^{1}H \rightarrow {}^{13}C$ CPMAS spectra of forms II and III of phenobarbital. Top: high-frequency region; bottom: low-frequency region. In each case the simpler spectrum is that of form III. The signals in the 45–60 ppm region (marked with an asterisk) are spinning sidebands.

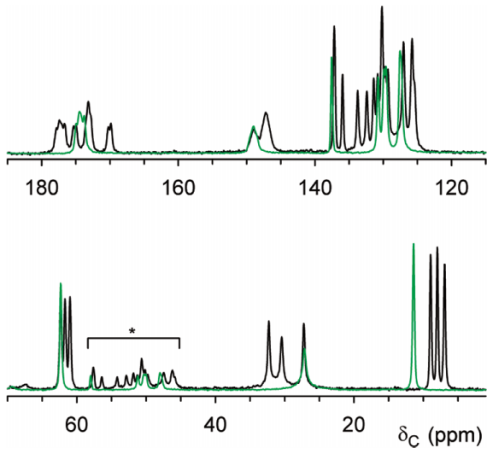

Fig. 5. The ^{15}N CPMAS spectra of forms II and III of phenobarbital. Top: form II; bottom: form III. In each case the experimental spectrum can be recognised by the noise level.

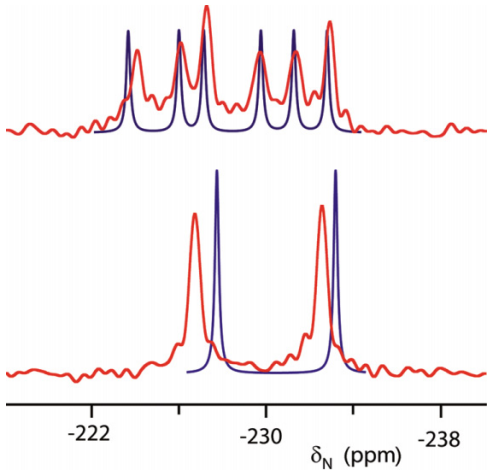
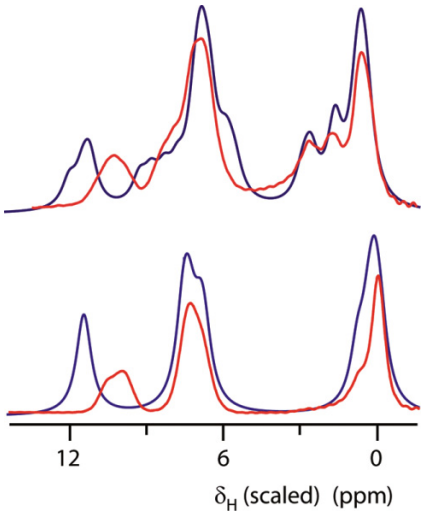


- The chemical shifts for some carbons of form III are almost identical to those of forms I and II.
- On the other hand, the methyl signal of form III is distinctly shifted from those of the other two forms.
- The range of CH carbon peaks is rather narrow for form III, in contrast with the situation for forms I and II.
- The six ^{15}N peaks for forms I and II appear to be created by a doubling of three peaks at an interval of ca. 5 ppm.
- Two of these six peaks are more intense than the other four, presumably because of more efficient cross polarization.
- The two ^{15}N peaks of form III lie close to the more intense resonances of forms I and II.
- The proton spectra all contain peaks at ca. 10 ppm, indicating hydrogen bonding.
- The proton spectra of forms I and II contain two signals in the range 1.5 to 3.0 ppm, typical of methylene protons, but such resonances are absent (presumably shifted to lower frequency) from the proton spectrum of form III.

Some of these facts are readily explained by the crystal structures. Thus, the nearly identical appearance of the spectra for forms I and II arises from the unusual similarity of the two structures. In all three cases the number of molecules in the asymmetric units derived from NMR is in agreement with the crystal structures. All the structures contain moderately strong N–H···O hydrogen bonding, which explains the high-frequency proton signals.

Fig. 6. The MAS proton spectra of forms II and III of phenobarbital. Top: form II; bottom,: form III. In each case the experimental spectrum can be recognised by the noise level. A Gaussian broadening of 0.010 s was used to plot the experimental spectra and a line width of 100 Hz was imposed for the computed spectra.



Other features cannot be readily explained merely by examination of the structures. Some speculations are, of course, possible. Thus, it can be noted that molecules A, B, and C in I and II differ somewhat in their conformation (in the rotation of the Ph ring about C5–C9); the single torsion angle for III is closer to 0° (where the Ph ring and C5–C4 would be coplanar) than in the other cases.

C–C5–C9–C torsion angles (°):

I: A = 27.6; B = 13.4; C = 15.8;
II: A = 22.3; B = 16.2; C = 12.8;
III: 7.8.

Such variations are sufficiently large to cause the magnitudes of the changes in ^{13}C chemical shifts observed experimentally. The spread of ^{15}N frequencies could arise from hydrogen-bonding differences, or from long-range effects of "ring currents" in the phenyl groups or of electric fields of the carbonyl groups.

However, other features do not have any obvious structural explanation and assignment of signals to atomic sites in the crystal structures is not straightforward. Thus, there is no simple experimental method to separately distinguish the signals arising from the three independent molecules for forms I and II. Whilst an INADEQUATE pulse sequence can, in principle, link signals arising from the same independent molecule, such an experiment would leave uncertain which molecule gives which signals. In any case, an INADEQUATE experiment is not feasible in practice for the present samples (especially for ^{15}N) without isotopic enrichment because of the inherently very low sensitivity. Other

experiments, such as DQ-CRAMPS are more sensitive but still do not give a direct relationship of signals to crystallographic sites. A further limitation of experiment is an inability to assign signals for chemically equivalent atoms (such as C4 and C6) to the structural positions. On the other hand, suitable computation, if accurate enough, should allow such assignments. Moreover, spectral simulation, if successful, should reproduce the observed special features indicated above. In some situations the assignments may then reveal simple structural explanations of those features that could be used, for example, to make assignments for related chemical systems.

First, one must establish that the computations are sufficiently accurate and robust to give confidence in the use of the data produced. The results of GIPAW computations (which involve use of crystallographic repetition of the unit cell) for ^{15}N for forms II and III are presented in Table 3. They match the experimental chemical shifts very well (see Fig. 5). The computed chemical shifts are plotted against the experimental values in Fig. 7 *assuming the orders of computed and experimental shifts for form II are the same*. It can be seen that a very satisfactory linear correlation is obtained. The two peaks for form III fall slightly below the line established for form II, which may be the result of globally equating average computed and experimental shifts rather than separately doing this for the two forms. Figures 5 and 7 show that the computed results are essentially valid and, thus, the linking of chemical shifts to crystallographic sites is robust. The computations allow the assignments of form II signals to the three independent molecules A, B, and C. Somewhat surprisingly, the signals for form III (which has a C-type chain) are close to those for molecule A of form II, not molecule C. The chemically equivalent nitrogens of each molecular type can now be assigned to the relevant structural positions. Overall, there is no correlation of the ^{15}N chemical shifts with the strength of the hydrogen bonds. However, the doubling, at an interval of ca. 5 ppm, of three signals for form II can now be seen to arise from the two nitrogens of each independent molecule N1 and N3 (Figs. 1 and 2). A close look at the crystal structure with this in mind reveals that the distinction can be traced to the conformation of the phenyl group (see Fig. 3). The high-frequency trio of signals arises for the nitrogens closer to one edge of the phenyl plane. An analogous assignment can be made for the signals of form III. This situation suggests that a major influence may be the ring current, since the nitrogens with the high-

frequency shifts are in the deshielding region of space, whereas the other nitrogens are in the shielding region. Whilst such a qualitative explanation may not be quantitatively satisfactory, there is no doubt about the structural assignments of the signals.

The computations also correctly reproduce the observed small differences between the ^{15}N spectra of forms I and II. Thus, the range of computed shifts is slightly smaller for form II (10.27 ppm) than for form I (11.25 ppm), and the separation of the second and third peaks is smaller for form I than for form II (0.66 vs 1.28 ppm)

The results of computation for the ^{13}C chemical shifts of forms II and III are also generally in excellent agreement with the observed spectra, although there are a few divergences in detail (see Figs. 8 and 9, which show the aliphatic region and the 120–150 ppm range, respectively). Thus, the following experimental features are reproduced by the computations (with special mention of comparisons between data for forms II and III, those for form I being generally very similar to those for form II):

- The C4/C6 signals for form III are near the middle of the range covered by form II peaks. However, in contrast to the ^{15}N results, there is no correlation of chemical shifts with the orientation of the phenyl ring.
- Hydrogen bonding has some influence; the C4/C6 signals for molecule A (which has both a strong and a weak hydrogen bond to C4 and to C6) are at the highest frequencies, whereas those for molecule B (which has no hydrogen bonds to C4 or C6) are at the lowest frequencies.

CH_2	2.4[f]	2.7[f]	ca. 0.8 sh
CH_2	1.5[f]	1.7[f]	—
CH_3	0.3	0.6	0.0

[a]The peaks are broad and tend to have unsymmetrical shapes arising from overlapping resonances.

[b]sh = shoulder.

[c]For molecules A and C.

[d]With a shoulder to high frequency.

[e]For molecules B.

[f]The computing shows that each of the three CH_2 groups for each form has one resonance at the higher shift and one at the lower.

Fig. 7. Plot of computed versus experimental ^{15}N chemical shifts for phenobarbital forms II and III. The two points falling below the straight line are for form III.

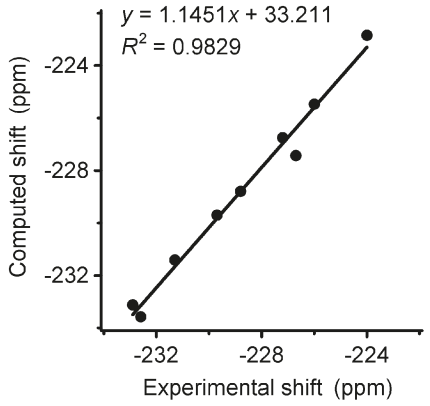

Fig. 8. Carbon-13 CPMAS spectra of forms II and III for the aliphatic region of phenobarbital. Top: form II; bottom: form III. In each case the experimental spectrum can be recognised by the noise level. The signals in the 45–60 ppm region for the experimental spectra (marked with an asterisk) are spinning sidebands.

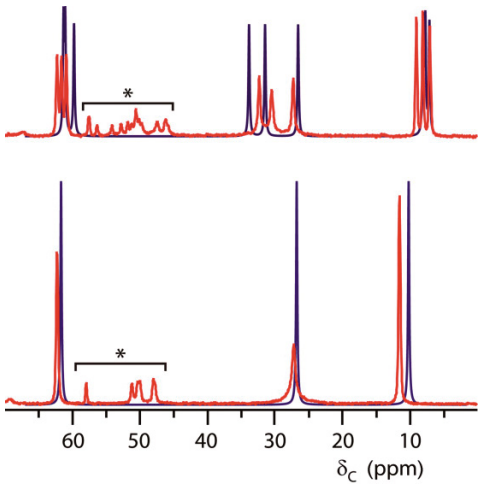

Fig. 9. Carbon-13 CPMAS spectra of forms II and III for the high-frequency region of phenobarbital. Top: form II; bottom: form III. In each case the experimental spectrum can be recognised by the noise level.

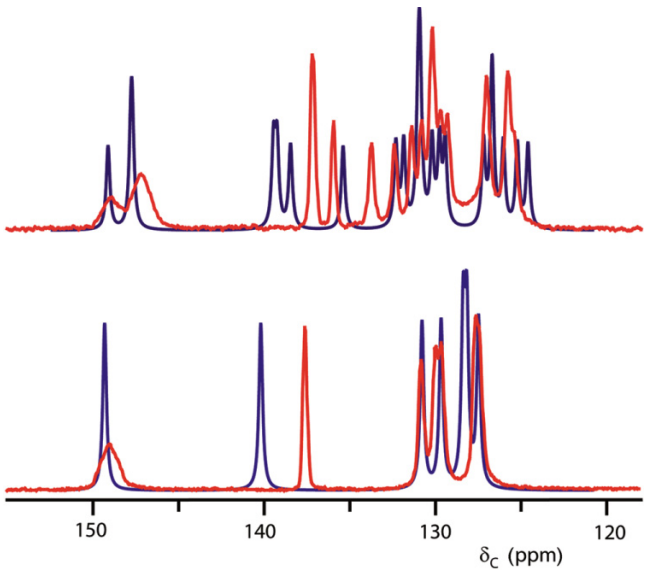

Fig. 10. Plot of computed versus experimental ^{13}C chemical shifts for phenobarbital forms II and III. Only resonances with reasonably certain assignments (15 for form II and 13 for form III) are used for the plot.

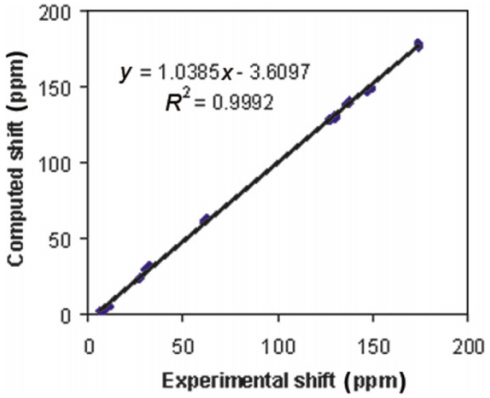

- The C2 signal for form III is very close to the high-frequency C2 peak for form II (which is for molecule B).
- The range of aromatic signals (excluding the ipso carbon) for form III is significantly narrower than that for form II.
- The CH_2 peak for form III is very close to the lowest frequency form II CH_2 signal (which is for molecule C).
- The CH_3 resonance of form III is substantially to high frequency of those for form II.

The computed ^{13}C chemical shifts for form III and some of those for form II (where assignments are reasonably certain, assuming the order of the computed resonances for the three independent molecules of form II is correct) are given in Table 1 and are plotted against the experimental values in Fig. 10. The correlation is excellent, but the slope deviates from the ideal value of unity (and thus the intercept is non-zero). To compare the data sensibly, the computed values given in Table 1 have been adjusted to give unit slope and zero intercept. The maximum deviation is 2.6 ppm. However,

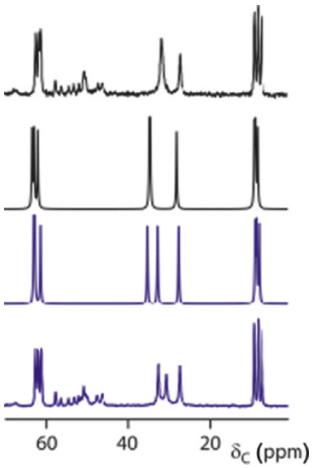
Fig. 11. The low-frequency regions of the observed and computer-simulated ^{13}C spectra for forms I and II of phenobarbital. Top to bottom: form I experimental; form I computed; form II computed; and form II experimental. The low-intensity signals in the 45–60 ppm region in the experimental spectra are spinning sidebands.



this understates the value of the computation, since if like is compared to like, i.e., if comparisons are made for particular types of carbon, the agreement is much better. In other words, there are consistent deviations for related carbons; for example, the four C2 carbons all have deviations between 1.3 and 1.9 ppm. This points out the particular value of applying GIPAW computations to restricted crystallographic aspects, especially comparison between polymorphs and between different molecules in asymmetric units, as has been emphasised before.[7]

Having established the ^{13}C correlation using the set of results in Table 1, it is of interest to compare computed and experimental data for the rest of the aromatic signals, which are in a much more crowded region of the spectra. This is done in Table 2, assuming the order of signals is the same for computed and experimental cases. This provides a tentative assignment of the resonances. The agreement is good, though not perfect, as is shown in Fig. 9. Most importantly, assignments can be made separately for the three independent molecules of forms I and II. Similarly, the two sides of the ring are distinguished (Tables 1 and 2), as they were for the ^{15}N resonances.

The computed ^{13}C spectrum for form I is, as expected, close to that of form II. Remarkably, the computing reproduces the only major experimental difference, namely, the closeness of the CH_2 signals for molecules A and B for form I (A to high frequency of B by 0.26 ppm), in contrast with the case for form II (A to low frequency of B by 2.69 ppm) — see Fig. 11. For the aromatic ^{13}C signals the largest computed differences (still small on an absolute scale, but significant) between forms I and II are for molecule A. This can be traced to the fact that this molecular chain has glide symmetry for form I (resulting in the phenyl groups being on the same side as viewed down the chain) in contrast to form II, which has inversion symmetry for chain A, so that the phenyl groups are on opposite sides of the chain from the same viewpoint (as is the case for all the remaining chains in all three forms) — see Fig. 10 of ref. 1.

The computed proton shifts also show very good correlation with the observed spectra (see Fig. 6). Thus, the lack of signals in the usual methylene region for form III is reproduced. The two CH_2 signals for forms I and II are shown to arise from the individual protons, all three independent molecules giving two resonances, 1.0–1.5 ppm apart, to high frequency of the methyl signal. In each case the lower frequency signal is from the proton on the "edge" side. For form III, the separation of the two methylene proton signals is also computed to be ca. 1.0 ppm (with the proton on the "edge" side at the lower frequency), but in this case the resonances straddle those for the methyl protons, thus, explaining why they are not clearly visible. The greater experimental separation between the methyl and aromatic protons for form III is also found for the computed spectra. The signals for the NH protons for form III and for molecules A and C of forms I and II are at similar high-frequency positions, but those for molecule B of forms I and II are ~3 ppm to lower frequency (and can be observed experimentally as a shoulder on the aromatic signals). This corresponds to the significantly weaker N–H···O hydrogen-bond strengths for molecule B.

Conclusions

Computations using the GIPAW approach have successfully simulated the ^{1}H, ^{13}C, and ^{15}N spectra of three polymorphs of phenobarbital, with the results closely matching the observed spectra. Therefore, full assignments of ^{13}C and ^{15}N signals have been made to atomic sites in the crystal structures and various features of the spectra can now be understood. The experimental proton spectra have been presented and these too are adequately explained by the computations.

Quadrupolar central transition (QCT) and ^{13}C NMR competition studies of metal ion binding to ovotransferrin

Jillian A. Saponja and Hans J. Vogel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: The transferrins are a family of relatively large bilobal proteins that play a major role in the transport of Fe^{3+}, as well as several other physiological and nonphysiological metal ions. Transferrins can also act as antimicrobial agents, by tightly sequestering iron and making it unavailable for bacterial growth. Using a combination of quadrupolar central transition (QCT) metal ion NMR (^{27}Al, ^{45}Sc, ^{51}V, and ^{71}Ga) and ^{13}C NMR, the binding and displacement of a variety of metal ions to ovotransferrin was studied through direct metal ion competition experiments. The metal ions investigated (Al^{3+}, Co^{3+}, Fe^{3+}, Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+}, and VO_2^+) were of differing ionic radius and charge, thus allowing for an assessment of how these factors contribute to metal ion affinity. The competition for the N- and C-terminal metal ion binding sites on ovotransferrin was directly followed by metal ion QCT NMR. Moreover, ^{13}C NMR was used to study the two protein-bound synergistic anions (^{13}C-labeled carbonate), whose chemical shifts are distinct and dependent on the bound metal ion that is present in the binding sites. The observed order of decreasing affinity for the metal ions studied was $Fe^{3+} \approx In^{3+} \geq Sc^{3+} \geq Ga^{3+} > Al^{3+} > VO_2^+ > Y^{3+} \geq Co^{3+}$. These results illustrate how a combination of multinuclear solution NMR methods can provide unique insights into the ligand binding properties of larger metalloproteins.

Key words: quadrupolar central transition NMR, ^{13}C NMR, ovotransferrin, quadrupolar nuclei, metal ions, competition experiments.

Résumé : Les transferrines correspondent à une famille relativement grande de protéines bilobales qui jouent un rôle majeur dans le transport du Fe^{3+} ainsi que ceux de plusieurs autres ions métalliques physiologiques et non physiologiques. Les transferrines peuvent aussi agir comme agents antimicrobiens en séquestrant fortement le fer et en le rendant indisponible pour la croissance des bactéries. Faisant appel à une combinaison de RMN du ^{13}C et d'ions métalliques (^{27}Al, ^{45}Sc, ^{51}V et ^{71}Ga) de transition centrale quadripolaire (TCQ), on a étudié la fixation et le déplacement d'une variété d'ions métalliques vers l'ovotransferrine par le biais d'expériences de compétition directe entre les ions métalliques. Les ions métalliques étudiés (Al^{3+}, Co^{3+}, Fe^{3+}, Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+} et VO_2^+) possédaient des rayons ioniques et des charges différentes qui ont permis d'évaluer l'influence de ces facteurs sur l'affinité des ions métalliques. Les compétitions pour les sites de fixation en positions N- et C-terminales de l'ovotransferrine ont été suivies directement par RMN-TCQ des ions métalliques. De plus, on a utilisé la RMN du ^{13}C pour étudier les deux anions de synergie liés à la protéine (carbonate marqué au ^{13}C) dont les déplacements chimiques sont distincts et qui dépendent de l'ion métallique qui est présent sur les sites de fixation. L'ordre observé d'affinité décroissante pour les ions métalliques étudiés est $Fe^{3+} \approx In^{3+} \geq Sc^{3+} \geq Ga^{3+} > Al^{3+} > VO_2^+ > Y^{3+} \geq Co^{3+}$. Ces résultats illustrent comment une combinaison de méthodes de RMN multinucléaires en solution peut jeter une lumière unique sur les propriétés de fixation de ligands par des métalloprotéines plus volumineuses.

Mots-clés : RMN de transition centrale quadripolaire, RMN du ^{13}C, ovotransferrine, noyau quadripolaire, ions métalliques, expériences de compétition.

[Traduit par la Rédaction]

Introduction

The transferrins are a family of iron-binding proteins found in serum, milk, and other bodily fluid secretions. These large (~80 kDa) bilobal glycoproteins function in iron metabolism, where they primarily sequester and transport iron. It has also been reported that the high affinity binding of iron(III) to ovotransferrin, serum transferrin, and lactoferrin can give rise to an antimicrobial activity by withholding iron required for bacterial growth or biofilm formation.[1,2] All transferrin proteins are comprised of two lobes that each possess a high-affinity ferric iron-binding site that contains a unique binding motif where an additional anion (usually called the synergistic anion) is required for metal ion binding (for a

review see ref. 3). The three-dimensional structure of the protein and the organization of the two metal ion and synergistic anion binding sites are illustrated in Fig. 1. To satisfy the preference of Fe^{3+} for an octahedral coordination sphere, all the transferrins provide four ligands from the protein (1 Asp, 2 Tyr, and 1 His) and in vivo the synergistic anion carbonate provides two additional oxygen ligands.[4] However, several other anions, such as oxalate, can substitute for carbonate, and act as the synergistic anion in vitro.[5–7] Numerous high-resolution crystal structures for the various proteins of the transferrin family have been reported, and some common structural motifs for proteins involved in ferric iron and heme binding have emerged from these studies.[8]

In addition to binding iron(III) with very high affinity, the transferrins can bind a wide variety of metal ions, varying both in ionic radius and charge. Serum transferrin, the principal iron carrier in the mammalian circulatory system, is found to be only 30% saturated with iron in blood, leading to speculation that this protein can also play a significant role in the metabolic fate of other nonphysiological trivalent and divalent metal ions.[9] A complete understanding of how such a wide range of metal ions can be accommodated in the binding sites of the transferrins is still missing. It is clearly more complicated than simply being related to the ionic radius of the metal ion alone.[10–12] In fact, Sadler and co-workers[13] reported that the strength of metal binding to the transferrins correlates with the metal ion acidity. Several of the metal ions that have been found to bind to transferrin are of toxicological interest (e.g., aluminum), but some also have therapeutic and diagnostic uses. For example, the ^{111}In and ^{67}Ga isotopes are used as radiopharmaceuticals for the labeling of leukocytes and tumors.[14,15] Interestingly, unlike iron, some nonphysiological serum transferrin-bound metal ions are not deposited in bone marrow,[16] suggesting that the binding of these metal ions to the protein must affect its recognition by the transferrin receptor, probably through a conformational change.[17] Plutonium, for example, is known to bind to serum transferrin in blood, but it is not found in bone marrow reticulocytes.[18]

Competitive metal ion binding experiments provide a direct method for determining the relative metal ion affinity. Tan and Woodworth[19] previously compared the affinity of ovotransferrin (oTf) for a variety of transition metal ions using UV-difference spectroscopy to detect the preferential binding of certain metal ions over others. This study was the first to describe the binding and displacement of one metal ion by another. Cochran et al.[20] also observed Al^{3+}/Fe^{3+} competition for the two serum transferrin (sTf) binding sites, and their results enabled them to calculate the binding affinity for Al^{3+}. Displacement of oTf-bound Cd^{2+} by Fe^{3+} has been observed by ^{13}C NMR by studying the bound ^{13}C-labeled synergistic carbonate. The latter results indicate the potential of ^{13}C NMR spectroscopy to monitor metal ion substitution in the transferrins in aqueous solution.[6,21,22]

In addition to studying transferrin-bound isotopically labeled synergistic anions, such as carbonate and oxalate, by ^{13}C NMR, it is also possible to study the binding of several half-integer quadrupolar metal ions to the transferrins directly by quadrupolar central transition (QCT) NMR.[23–28] QCT NMR spectroscopy involves the specific detection of the 1/2 to –1/2 transition of quadrupolar metal ions that are bound to

Fig. 1. Overall fold of the hen ovotransferrin protein (A, PDB 1OVT) and the structures of the two metal ion binding sites of the two ferric binding sites (B, N lobe; and C, C lobe). The direct interactions to the metal ion are identical for the N lobe and the C lobe of the protein, suggesting that other features of the protein must govern their distinct preferences for larger and smaller trivalent metal ions. Fe^{3+} is drawn as an orange sphere, carbonate is coloured in green, and the ovotransferrin (oTf) residues that directly coordinate Fe^{3+} are shown as stick models. (B) and (C) illustrate the role of carbonate acting as the synergistic anion for metal ion binding in both sites.

Table 1. ^{13}C and quadrupolar central transition (QCT) NMR chemical shifts at 9.4 T of metal-bound ovotransferrin (oTf) with ^{13}C-labeled carbonate at 25 °C.

Metal ionic ion	Radius (Å)[a]	Binding site	^{13}C chemical shift (ppm)	QCT NMR nucleus	Chemical shift (ppm)
Al^{3+}	0.51	N	165.7	^{27}Al	–4.6
		C	165.5		–6.8
Ga^{3+}	0.62	N	166.1	^{71}Ga	–151
		C	165.9		–192
Co^{3+}	0.63	N	169.3	—	—
		C	168.8		
Fe^{3+}[b]	0.64				
Sc^{3+}	0.73	N	166.7	^{45}Sc	78.1
		C	166.6		66.0
In^{3+}	0.81		166.4	—	—
Y^{3+}	0.89	N	168.6	—	—
		C	168.2		
VO_2^{+}[c]		—	—	^{51}V	–534.5

Note: Data for Al^{3+}, Sc^{3+}, Ga^{3+} were obtained from Aramini and Vogel[25,38] and Aramini et al. 1994.[24] Data for VO_2^{+} were obtained from Saponja and Vogel.[28] Data for In^{3+}, Y^{3+}, and Co^{3+} were determined in this study.

[b] Fe^{3+} is paramagnetic, resulting in no NMR data.

[a] Ionic radii were taken from the *CRC Handbook of Chemistry and Physics*.[39]

[c] VO_2^{+} binds without a synergistic anion.

large proteins in aqueous solution. Under conditions of slow overall protein tumbling, as is the case for proteins with a similar size as oTF, this so-called central transition gives relatively narrow spectral lines that can be detected by NMR, whereas all the other transitions of half integer spin nuclei are too broad to be detected (for a brief summary of the relevant quadrupolar relaxation theory see ref. 29). QCT NMR can provide detailed information on the binding site symmetry and protein motions through the measurement of frequency-dependent chemical shifts and line widths (for reviews see refs. 29 and 30).

In this work, the relative affinities of oTf for Al^{3+}, Co^{3+}, Fe^{3+}, Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+}, and VO_2^{+} are evaluated through metal ion competition experiments that were followed by multinuclear NMR spectroscopy. Because of the extremely tight binding of Fe^{3+} to transferrin ($K_D = 10^{-21}$),[31] NMR spectroscopy cannot be used for direct binding experiments, necessitating the use of competition experiments. Moreover, transferrin-bound Fe^{3+} is paramagnetic and hence it cannot be observed directly by iron-57 NMR. Scandium(III) and yttrium(III) were included in this work because of their larger ionic radii, whereas aluminum(III) is much smaller than ferric iron (see Table 1). Despite its smaller ionic radius the coordination of Al^{3+} bound to oTf closely resembles that of iron (III).[32] The medically relevant metal ions, indium(III) and gallium(III), were included in this study to assess their affinities with respect to iron; gallium(III) has a similar ionic radius as ferric iron,[33] whereas indium(III) is somewhat larger. Also, the micronutrient cobalt(III) has been shown to bind to the transferrins,[34] and its binding was analyzed in this study as well because its ionic radius is very similar to that of ferric iron. Finally, serum transferrin is believed to be the major transporter of vanadate in physiological fluids,[35–37] and hence competition with VO_2^{+} binding was also examined. The metal ion competition for the two binding sites of ovotransferrin was monitored directly by ^{27}Al, ^{45}Sc, ^{71}Ga, and ^{51}V QCT NMR, and indirectly by ^{13}C NMR of the bound synergistic anion, using isotopically enriched $^{13}CO_3^{2-}$.

Methods and materials

Metal ion stock solutions of $ScCl_3$, $GaCl_3$, and $InCl_3$ were prepared by dissolving Sc_2O_3 (Sigma-Aldrich), Ga_2O_3 (Sigma-Aldrich), or In metal (Alfa Inorganics) in 12 mol/L HCl and evaporating to dryness. The residue was then carefully taken up in double distilled water to form the appropriate stock solution. Aluminum nitrate and yttrium chloride stock solutions were prepared by directly dissolving the metal salt (Sigma-Aldrich) in water. The vanadium stock solution was prepared as described by Butler and Eckert.[26] Nitrilotriacetic acid (NTA) solutions of Fe^{3+} or Sc^{3+} were prepared with a metal–chelate ratio of 1:2. All metal ion stock solutions were kept at an acidic pH to prevent hydrolysis.

Iron-free chicken oTf (also known as conalbumin) was purchased from Sigma-Aldrich. It was shown to be >95% pure by gel electrophoresis and was used without further purification. The protein concentration was determined on a Hitachi U-2000 spectrophotometer at 280 nm, using a molar extinction coefficient of 91 200 for the apo-protein.

The preparation of Co_2–oTf essentially followed the procedure of Zweier et al.,[22] except that the Co_2–oTf complex was put through a Biorad Econo-Pac 10DG desalting column equilibrated with 10 mmol/L NH_4HCO_3 to remove the excess carbonate and peroxide prior to freeze drying.

Samples for NMR spectroscopy were prepared by dissolving the lyophilized protein in 1.30 mL double distilled water and 0.50 mL D_2O. ^{13}C-labeled Na_2CO_3 (99%, MSD Isotopes, Montreal, Quebec) was added to a final concentration of 10 mmol/L. The pH was adjusted with small amounts of 1.0 mol/L KOD or 1.0 mol/L DCl and measured with a Fisher Accumet 805MP pH meter fitted with an Ingold Electronics 3.5 mm glass electrode.

The metal ion competition experiments were performed by the addition of a known amount of the competing metal ion

For personal use only.

to an oTf metal ion NMR sample, followed by pH adjustment and incubation at 20 °C for at least 12 h prior to acquisition of the NMR spectra.

NMR spectroscopy

NMR spectroscopy was performed on a Bruker widebore AM400 spectrometer equipped with a 10 mm broadband probe. All spectra were acquired at 25 °C. ^{13}C (100.6 MHz), ^{27}Al (104.3 MHz), ^{45}Sc (97.2 MHz), ^{51}V (105.2 MHz), and ^{71}Ga (122.0 MHz) NMR data were acquired and processed using parameters given elsewhere.[24,25,28,38] Chemical shifts were referenced to 0 ppm as follows: ^{13}C, TMS; ^{27}Al, 1.0 mol/L $Al(NO_3)_3$; ^{45}Sc, 1.0 mol/L $ScCl_3$; ^{51}V, $VOCl_3$; and ^{71}Ga, 1.0 mol/L $Ga(NO_3)_3$. ^{13}C NMR experiments with diamagnetic metal ions were acquired as described earlier.[28] ^{13}C NMR experiments on solutions containing iron(III) were performed as follows. Because of the paramagnetic relaxation caused by ferric iron, conditions were set up to allow complete relaxation of the signals of interest prior to the addition of iron to ensure that the spectra could be analyzed quantitatively. The T_1 of 100 mmol/L $Na_2{}^{13}CO_3$ (~15 s) was obtained using the method of inversion recovery. Acquisition parameters for ^{13}C NMR (100.63 MHz) of the iron-containing competitions were as follows: a pulse length (45°) of 7.5 ms, a sweep width of 25 kHz, an acquisition time of 0.3 s, and a relaxation delay of 37.7 s. The spectra for the iron(III)-containing samples were otherwise processed in the same manner as the other ^{13}C NMR experiments (e.g., Aramini and Vogel[38]).

Results

^{13}C NMR chemical shifts of bound $^{13}CO_3^{2-}$

The chemical shifts for ^{13}C-labeled CO_3^{2-} bound to oTf in the presence of various trivalent metal ions were determined by NMR spectroscopy (Table 1). Many of the peaks for the bound carbonate ions are well-resolved for the two binding sites of oTf. They are also distinct from the peak for free carbonate, and hence ^{13}C NMR can be used to follow the metal ion competition indirectly by observing the bound anion. The signals could be assigned to the N and C sites, respectively, by studying the individual isolated lobes of oTf, which can be obtained through limited proteolysis (data not shown; see, for example, Aramini and Vogel[40]). For most metal ions, the chemical shifts show small differences for the two sites, and hence the two binding sites of the protein can be distinguished for most of the metal ions.

Metal ion competitions with binding site preferences

^{13}C NMR spectra for a titration of Sc^{3+} into a solution of Ga_2–oTf containing ^{13}C-labeled carbonate are shown in Fig. 2. The spectra of the carbonyl region show that bound Sc^{3+}–anion signals ($Sc_2(^{13}CO_3)_2$oTf; δ_{Nlobe} = 166.74 ppm and δ_{Clobe} = 166.61 ppm) displace the bound gallium–anion signals (δ_N = 166.09 ppm and δ_C = 165.91 ppm) during the titration. The displacement of the gallium is not totally complete at two molar equivalents of scandium as shown by the small remaining peaks for bound gallium–carbonate (δ_N = 166.09 ppm). ^{45}Sc QCT NMR (Fig. 2) also provides similar results in which two overlapping signals corresponding to oTf-bound scandium appear during the titration; they also indicate a stepwise binding mechanism wherein the C-lobe site of oTf is filled first by the scandium ions. The broad peak that appears upfield from the protein-bound scandium signals is free scandium, which is not bound to the metal ion binding sites of the protein. A separate titration experiment showed that gallium is unable to displace oTf-bound scandium (data not shown).

The displacement of aluminum by scandium follows a distinctive site order as well. Figure 3 shows this titration as detected through three different NMR-active nuclei. The ^{13}C NMR spectra show a drastic decrease in intensity for the bound aluminum–anion signal corresponding to the C-lobe binding site after the addition of 1 equiv of scandium; at the same time a new signal corresponding to $Sc_2(^{13}CO_3)_2$oTf appears. No $Al_2(^{13}CO_3)_2$oTf signal is seen after the addition of 2 equiv of scandium, indicating that scandium has a much higher affinity for oTf than aluminum. Complete displacement of Al^{3+} by Sc^{3+} was also observed via ^{27}Al and ^{45}Sc QCT NMR. Also, the QCT NMR spectra show that aluminum is preferentially displaced by scandium in the C lobe of the protein. At 1 equiv of scandium, it is apparent from both the ^{27}Al and ^{45}Sc QCT NMR spectra that the C lobe has significantly more scandium bound than the N lobe. At 2 equiv of Sc^{3+}, no bound Al^{3+} is seen by ^{27}Al NMR; thus, aluminum has been completely displaced from the protein. The small sharp signal seen at –7 ppm arises from a transmitter spike lying near the centre of the spectrum.

In a previous ^{51}V NMR study,[28] the displacement of VO_2^+ from oTf by aluminum was already noted. As expected, ^{27}Al QCT NMR demonstrated that aluminum(III) is capable of displacing the bound vanadate from the protein (Fig. 4). However, the displacement of vanadate is not complete after the addition of 2 equiv of Al^{3+}, with some VO_2^+ remaining bound in the C-lobe site. Unexpectedly, VO_2^+ showed a higher binding affinity than yttrium under our experimental conditions, as evidenced by the disappearance of the bound carbonate signals in the ^{13}C NMR spectra and the appearance of oTf-bound vanadate by ^{51}V QCT NMR (data not shown). The yttrium(III) was preferentially displaced from the N-lobe site, and only a small amount of yttrium(III) remained bound in the C-lobe site at the end of the titration.

Displacement of oTf-bound yttrium(III) by aluminum(III) also showed a similar pattern to what was observed for vanadate. Figure 5 depicts the displacement of Y^{3+} by Al^{3+}. In the ^{13}C NMR spectra, the signal for the N-lobe $Y_2(^{13}CO_3)_2$oTf dramatically decreases in intensity and is absent when 2 equiv of Al^{3+} were added. In contrast, the ^{13}C signal corresponding to the C lobe only begins to decrease in intensity when 2 equiv were added, indicating that the N lobe is completely exchanged before aluminum is able to dislodge yttrium from the C site. This slow displacement at the C site was also observed by ^{27}Al QCT NMR; only when 2 equiv of Al^{3+} were added is a small signal seen for the C lobe of oTf (δ = –6.5 ppm). Even at an excess of aluminum, the intensity of the C-lobe signal is only slightly increased.

Displacement of bound yttrium by gallium also exhibited a slight site preference. Inspection of the ^{13}C NMR spectra of the competition showed the two bound carbonate signals for $Y_2(^{13}CO_3)_2$oTf decrease at different rates (Fig. 6), with the signal corresponding to the N-lobe site decreasing slightly

Fig. 2. Ga_2–ovotransferrin (oTf, 0.98 mmol/L) and $^{13}CO_3^{2-}$ (10 mmol/L, pH 7.5) back-titration with Sc^{3+}. ^{13}C NMR spectrum of the expanded carbonyl region, 20 000 scans; ^{45}Sc quadrupolar central transition (QCT) NMR, 1 000 000 scans.

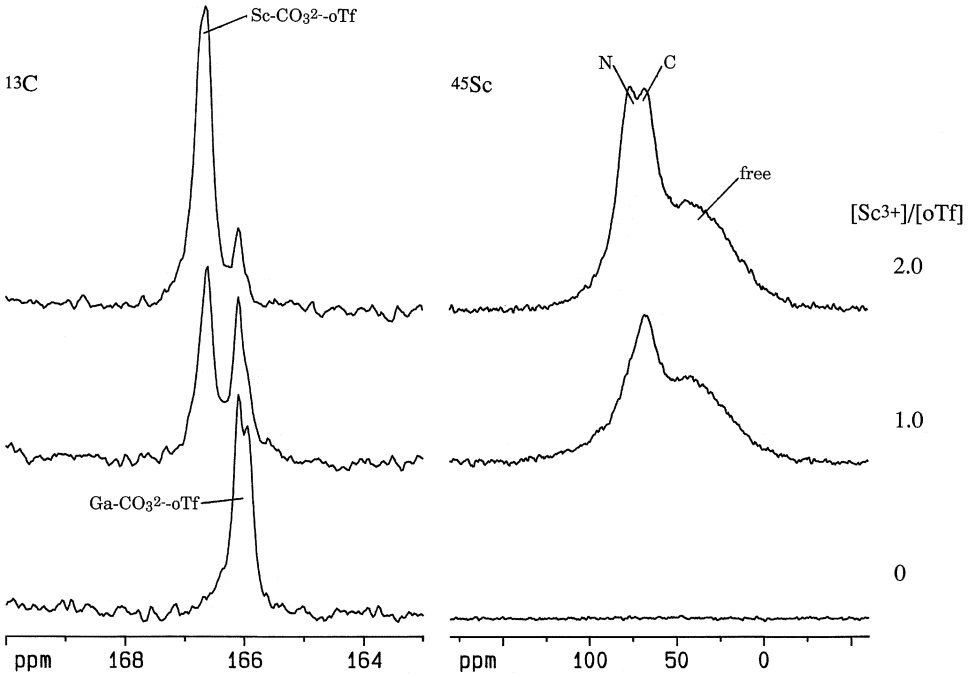

Fig. 3. Al_2–ovotransferrin (oTf, 0.98 mmol/L, pH 7.6) with 10 mmol/L $^{13}CO_3^{2-}$ back-titrated with Sc^{3+}. ^{13}C NMR spectrum, 20 000 scans; ^{45}Sc quadrupolar central transition (QCT) NMR spectrum, 1 000 000 scans; and ^{27}Al QCT NMR spectrum, 150 000 scans.

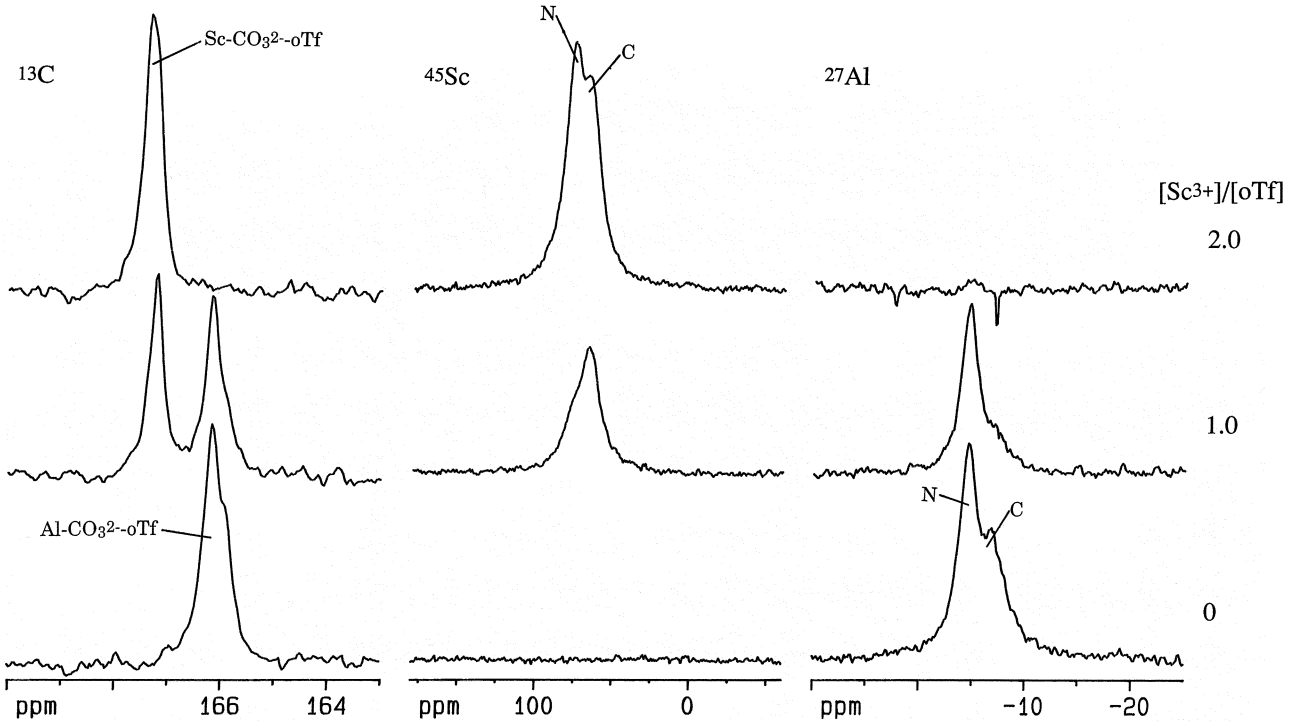

faster. Unfortunately, the two gallium–carbonate signals are overlapped at this magnetic field strength, so the occupancy of individual sites with gallium by ^{13}C NMR could not be followed. In the ^{71}Ga NMR spectra, a single broad signal corresponding to the N-lobe binding site is observed and increases in intensity during the titration. At 2 equiv of Ga^{3+} a slightly upfield broader signal (C-lobe site) can be resolved. The titration was almost complete at 2 equiv.

Metal ion competitions with no site preference

Titration of gallium into a solution of $Al_2(^{13}CO_3)_2$oTf induces the displacement of Al^{3+} from the protein. The ^{13}C chemical

shifts of the bound anion in the presence of Ga^{3+} and Al^{3+} have quite similar chemical shifts (see Table 1), and hence ^{13}C NMR did not provide information on their competition. ^{27}Al QCT NMR showed a decrease in the bound aluminum signals as gallium(III) was added to the protein (data not shown). The displacement of Al^{3+} is only nearly complete

when 3 equiv of gallium are added, with aluminum being displaced at an equal rate from both binding sites.

The relative affinities of oTf for Al^{3+} and Co^{3+} were also tested. Displacement of Co^{3+} was observed via both ^{13}C and ^{27}Al NMR (data not shown). The intensities of the ^{13}C NMR signals of $Co_2(^{13}CO_3)_2$oTf decreased and a new signal corresponding to $Al_2(^{13}CO_3)_2$oTf appeared with increasing intensity after the addition of 0.5 equiv of aluminum. Signal intensities, in both the ^{13}C and ^{27}Al spectra did not appear to change after 1 equiv of Al^{3+} was added. Furthermore, at equimolar concentrations of cobalt and aluminum, a significant amount of cobalt still remained bound to the protein. Thus, nonspecific displacement of Co^{3+} and binding of Al^{3+} was observed.

Competition experiments between cobalt(III) and yttrium (III) provided ambiguous results. Titration of Y^{3+} into Co_2–oTf yielded little information by ^{13}C NMR because of overlapping signals. Addition of YCl_3 to the solution of Co_2–oTf also resulted in the precipitation of the $^{13}CO_3^{2-}$ present, causing the free carbonate signal to broaden and decrease severely in intensity, thus likely affecting the availability of yttrium to bind to the protein. A small, partly obscured, signal around 168 ppm appeared during the titration, which corresponds to the known chemical shift of $(Y^{3+})_2$oTf$(^{13}CO_3)_2$, suggesting that some yttrium was able to bind to the protein.

Metal in competitions involving higher affinity metal ions

Previous studies have indicated that a chelator, such as NTA, is required for the binding of higher affinity metal ions to occur at a reasonable rate.[14,31] Therefore, NTA was added to the competition experiments involving Fe^{3+}, Sc^{3+}, and In^{3+} in an attempt to achieve equilibrium within the 12 h incubation period used.

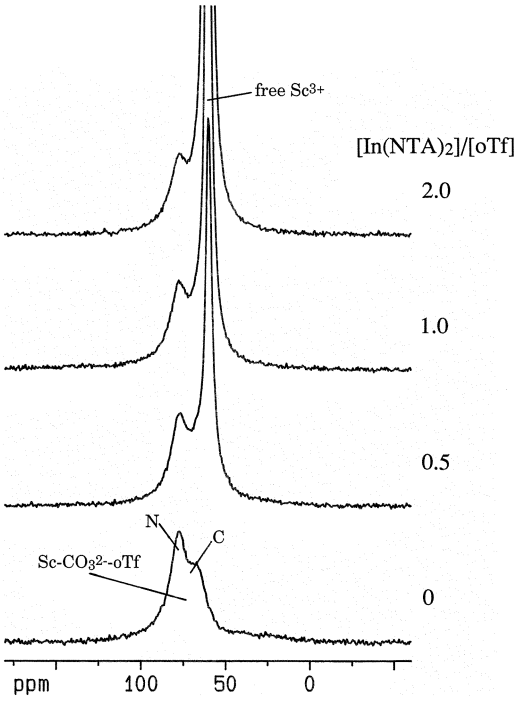
Indium(III) was competed with scandium(III) to assess the affinity of scandium, whose binding constants have not been reported for any of the transferrins. $In(NTA)_2$ was added to a solution of $Sc_2(^{13}CO_3)_2$oTf and this titration was followed by ^{45}Sc NMR (Fig. 7) and revealed the gradual displacement of scandium from the protein. Because of the signal overlap of free $ScCl_3$ (δ = 60.2 ppm) and Sc_2–oTf, it was impossible to determine if any site-specific displacement had occurred. Integration of the N-lobe signal (δ = 78.1 ppm) during the titration showed that ~40% of the scandium is displaced from the N lobe of the protein when an equal amount of indium is added.

Competition experiments involving iron(III) are more difficult to study by NMR because of the paramagnetic properties of this metal ion. The ^{13}C NMR signals for $Fe_2(^{13}CO_3)_2$oTf cannot be observed because they are broadened beyond detection. The competition experiments involving iron(III) with scandium or indium had surprising results. When $Fe(NTA)_2$ was back-titrated into a sample containing Sc_2oTf, an immediate dark red colour appeared, characteristic of iron binding to the protein. Furthermore, release of bound scandium was observed via ^{45}Sc QCT NMR and by ^{13}C NMR, where a reduction in signal area of the bound $^{13}CO_3^{2-}$ was seen. Notably, after the addition of 2 equiv of Fe^{3+}, some scandium remained bound (data not shown).

Displacement of indium by iron was also examined in the presence and absence of NTA. Titration of $Fe(NTA)_2$ into $In_2(^{13}CO_3)_2$oTf in the presence of NTA caused the formation of a red colour, characteristic of the formation of Fe_2oTf,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 7. Sc_2–ovotransferrin (oTf, 1.1 mmol/L, pH 7.5) back-titrated with $In(NTA)_2$ in the presence of 10 mmol/L $^{13}CO_3^{2-}$. ^{45}Sc quadrupolar central transition (QCT) NMR spectrum, 900 000 scans.



whereas addition of $Fe(NO_3)_3$ resulted in the protein solution having an orange colour similar to the ferric nitrate. Surprisingly, no decrease in the $In_2(^{13}CO_3)_2$oTf ^{13}C NMR signal was observed during the addition of either $Fe(NTA)_2$ or $Fe(NO_3)_3$ (not shown). Similarly, ^{13}C NMR of the reverse titration failed to show the appearance of a $In_2(^{13}CO_3)_2$oTf signal.

Discussion

A combined NMR spectroscopy approach allowed us to observe the competition between Al^{3+}, Co^{3+}, Fe^{3+}, Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+}, and VO_2^+ for the two ferric iron binding sites of oTf in a straightforward and qualitative manner. Metal ion QCT NMR and ^{13}C NMR of the bound synergistic anion allowed for the observation of the binding and displacement of metal ions either directly or indirectly by observing the bound carbonate. This combined approach offers several advantages: the ratios of the competing metal ions that are bound to the protein can be observed, and differences between the two binding sites can often be detected. The observed order of decreasing affinity for the metal ions studied was $Fe^{3+} \approx In^{3+} \geq Sc^{3+} \geq Ga^{3+} > Al^{3+} > VO_2^+ > Y^{3+} \geq Co^{3+}$.

Ichimura et al.[41] noted that aluminum has a higher affinity for the N-lobe site of oTf, and this behaviour is also observed in our NMR experiments. When aluminum displaced a lower affinity metal ion, such as yttrium or vanadate, binding of aluminum occurred preferentially at the N-lobe site. Displacement of aluminum by scandium occurred more rapidly at the C-lobe site, suggesting that aluminum is bound more tightly at the N site. Unexpectedly, this site preference was not observed when gallium displaced aluminum. This can be explained by the observation that gallium also has a preference for the N-lobe site.[24] From the competition experiments, gallium was shown to displace the lower affinity yttrium from this site; as well, gallium itself was displaced more slowly from this site by scandium. Scandium clearly exhibited a preference for the C lobe of the protein. Ichimura et al.[41] reported that Al^{3+}, Co^{2+}, Cu^{2+}, and Fe^{3+} all bind with higher preference to the N site, whereas the lanthanides with a larger ionic radius all bind to the C site with higher affinity, suggesting that the two binding sites have different size preferences. Additionally, Yamamura et al.[42] also reported that the lanthanides exhibited a higher affinity for the C site. Taken together with our results, this supports the notion that the ferric binding site in the N lobe of oTf is more suited for smaller ions, whereas the C-lobe site is better able to accommodate larger ions. Consistent with this, the relatively large Bi^{3+} ion (1.03 Å) also has been shown to bind preferentially to the C lobe of transferrin.[43] However, protein structure analysis of the iron-saturated oTf does not show any major differences between the sites located in the N and C lobes (see Fig. 1). The first coordination sphere is essentially the same in both lobes, and hence these differences must be caused by more distal parts of the protein. We also note that in biological experiments gallium(III) is often used as a direct substitute for iron(III), because it is not redox active and has the same ionic radius. Our data clearly show that Ga^{3+} binds much weaker than Fe^{3+} to oTf and probably to other transferrins as well. Similar results have been reported for the bacterial ferric binding protein FBP.[44]

The metal ions that were found to be at the weak end of the affinity series were VO_2^+, yttrium(III), and cobalt(III). The weak affinity for Co^{3+} when compared with Fe^{3+} was somewhat surprising, considering that both have similar ionic radii and both have a preference for the octahedral geometry found in the oTf binding sites. The weak affinity for cobalt (III) observed here is possibly due to its solution chemistry. $Co(III)_2$oTf is prepared by the oxidation of Co(II) by peroxide.[22] The standard reduction potential for cobalt is such that any Co(III) released from the protein is reduced to Co(II), which in turn has a rather low affinity for oTf.[19] In addition, the formation of insoluble cobalt–carbonate can occur. The appearance of paramagnetic Co(II) was actually observed in our cobalt–yttrium and cobalt–aluminum competition experiments; the free carbonate signal in these ^{13}C spectra was observed to broaden and decrease severely in intensity, indicating the presence of a paramagnetic moiety.

The displacement of yttrium by all metal ions, except possibly cobalt, is attributed to two factors. Yttrium is the largest metal ion that was studied in this series (Table 1) and therefore its large ionic radius may put it at a steric disadvantage. Secondly, yttrium forms highly insoluble carbonate complexes and therefore the amount of available free yttrium is likely to be low, thus giving other more soluble metal ions a competitive advantage.

Vanadate exhibited a higher binding affinity than yttrium and cobalt, but not aluminum. The oxo ligands of VO_2^+ have been found to be ideally suited for coordinating the ligands in the anion binding site of serum transferrin, thus overcoming the need for the simultaneous binding of the synergistic anion.[28,45,46] Therefore, the ability of vanadate to displace yttrium and cobalt is believed to be due to the fact that VO_2^+ does not require an anion and thus it is not dependent

For personal use only.

on the available carbonate in solution, which poses a significant problem with yttrium (see above). Harris and Carrano[47] found that gallium was able to displace vanadate from serum transferrin to some extent, suggesting that the affinities were similar. Since gallium was found in the competition experiments to displace aluminum from oTf, it is likely that the high rate of hydrolysis of gallium caused the incomplete displacement of vanadate by this metal ion in our experiments.

The ability of scandium to displace gallium was at first surprising to us, since gallium has an ionic radius more similar to that of ferric iron. This higher binding affinity of scandium correlates with earlier findings in which oTf-bound scandium was found to have a lower electric field gradient (eq_{ionic}) than bound gallium.[24,25] These results directly showed that the symmetry of the ligand environment in the binding site is higher in the presence of scandium, and this could possibly contribute to the higher binding affinity for this metal ion over gallium.

Competition experiments involving higher affinity metal ions (Fe^{3+}, In^{3+}, and Sc^{3+}) were not as straightforward as those involving the lower affinity metal ions. In this work, the dividing point between the low-affinity and the high-affinity metal ions appeared to be gallium. Competitions between any two of the metals higher in the series than gallium resulted in the inability of one metal to displace a significant amount of the other at an equal concentration. This was probably due to the slow off-rates of these metal ions under our experimental conditions preventing equilibrium from being reached during the 12 h incubation period. In an attempt to accelerate this process, the iron–indium competitions were performed with and without NTA for comparison. Direct observation of the colour of the oTf solutions indicated that some ferric oTf complex was formed, but no displacement of indium was observed by ^{13}C NMR. Evans and Ogwang,[48] using UV spectroscopy, also found that ferric-NTA was unable to displace indium from oTf. Although the observed colour change of the solution suggests the binding of some iron, it may be that the protein was not fully saturated. Aside from this, indium was found to displace some scandium from the protein, indicating that the observed binding affinity of scandium falls between that of indium and gallium.

It should be noted that NTA was not added to competition experiments involving metal ions that had a lower affinity than that of scandium to exclude the possibility that the presence of NTA would bias the outcome. For example, NTA has previously been shown to interfere with the binding of gallium and zinc to serum transferrin.[15,49] Indeed, NTA has also been shown to bind as a ligand to the protein-bound metal ion in partial protein fragments of duck ovotransferrin.[50] Thus, the presence of NTA could give rise to potentially confounding results when studying the lower affinity metal ions.

Overall, our results demonstrate that the combination of QCT NMR and ^{13}C NMR spectroscopy offers a valuable alternative approach to observe the binding of metal ions to the transferrins. The approach used here has the advantage of directly detecting metal ions that are otherwise spectroscopically silent; moreover, in many cases it was possible to observe site-specific effects that are not easily detectable by optical spectroscopy methods. This work could be further extended by studying the binding of spin 1/2 metal nuclei, such as Cd^{2+} and Tl^{3+} to oTf, which have been studied by cadmium-113 and thallium-205 NMR, respectively.[6,51] Understanding the affinities of proteins for metal ions is a complex issue because of their different solution chemistries, and thus many factors must be taken into account when observing the displacement of one metal ion over another. The order of the binding affinities found here is not unlike the observations of others using different methods,[13–15,19,41,52] indicating that our approach provides a viable and reliable method for assessing metal ion affinity. It should be noted that Li et al.[13] reported a different order for gallium and scandium than we observed; however, these authors studied human serum transferrin rather than ovotransferrin and this likely could have influenced the outcome. In future studies the same multinuclear NMR approach could be used to study other metalloproteins. However, the simultaneous binding of the synergistic anion is a unique property of the transferrins and hence ^{13}C NMR may not be as conveniently done for other proteins. On the other hand, the high concentrations of free carbonate in solution caused precipitations in some of our experiments and such complications would be avoided with soluble proteins. Whereas direct solution-state QCT NMR of protein-bound diamagnetic metal ions in other large metalloproteins would be possible, analogous indirect ^{13}C NMR work would require biosynthetic stable isotope labeling of the metal-liganding amino acid residues in these proteins.

Abstract: Zeroth-order regular approximation (ZORA) density functional theory (DFT) calculations of one-bond X–^{19}F indirect nuclear spin-spin coupling (**J**) tensors were performed on a series of fluorine-containing compounds covering several valence shell electron pair repulsion (VSEPR) theory geometries for which **J**, by symmetry, is not required to be axially symmetric. The calculations show that the antisymmetric components of **J** are only of the same order of magnitude as the principal components of the symmetric **J**-coupling tensor for a few geometries, and that in cases of approximate axial symmetry along the bond, **J** remains nearly axially symmetric with its unique component along the bond. In general, different species having the same nominal geometry tend to have similar tensor orientations, magnitudes of anisotropy of **J** relative to the isotropic coupling constant, as well as the same dominant contributions from the different coupling mechanisms. Structures are also systematically modified to determine how the tensor components depend on geometrical parameters. The isotropic coupling constants are subsequently interpreted using a natural localized molecular orbital (NLMO) approach. Our results could prove to be useful for future experimental characterizations of **J** tensors in systems having symmetry properties that do not force **J** to be axially symmetric or coincident with the dipolar coupling tensor.

Key words: nuclear magnetic resonance, *J* coupling, ZORA-DFT calculations, natural localized molecular orbitals.

Résumé : Des calculs de théorie de la fonctionnelle de la densité (DFT) de couplage spin-spin nucléaire indirect (**J**) X–^{19}F d'une liaison employant l'approximation régulière d'ordre zéro (ZORA) ont été effectués sur une série de composés du fluore couvrant plusieurs géométries de la théorie de la répulsion des paires électroniques de la couche de valence (RPECV) ayant une symétrie pour laquelle **J** n'est pas forcément axialement symétrique. Les calculs démontrent que les composants antisymétriques de **J** sont seulement du même ordre de magnitude que les composants du tenseur de couplage **J** symétrique pour très peu de géométries et que dans les situations de symétrie approximativement axiale le long de la liaison, **J** est axialement symétrique. En général, différentes espèces ayant la même géométrie ont des orientations de tenseur similaires, des anisotropies de **J** du même ordre de grandeur, par rapport à la constante de couplage isotropique, ainsi que les mêmes mécanismes de couplage dominants. Les structures ont par la suite été modifiées afin de déterminer la dépendance des composants principaux de **J** par rapport à la géométrie. Ces données sont ensuite reliées aux orbitales moléculaires en employant une approche d'orbitales moléculaires localisées naturelles (NLMO) pour investiguer les constantes de couplage isotropiques. Nos résultats pourraient être utiles dans la caractérisation complète de tenseurs **J** pour des systèmes ayant des symétries qui ne nécessite pas que **J** soit axialement symétrique ou coïncident avec le tenseur de couplage dipolaire.

Mots-clés : résonance magnétique nucléaire, calculs ZORA-DFT, couplage *J*, orbitales moléculaires localisées naturelles.

[Traduit par la Rédaction]

Introduction

Solid-state nuclear magnetic resonance (SSNMR) spectroscopy has become one of the prime methods for the characterization of solid materials. A wealth of information can be extracted from NMR spectra that can be used to refine or solve the solid-state structures of compounds that are difficult to crystallize or that lack long-range order.[1] The dipolar coupling interaction is commonly used in structure determinations, since its magnitude (R_{DD}) depends on the motionally averaged inverse cube of the internuclear distance ($\langle r_{1,2}^{-3} \rangle$):

$$[1] \qquad R_{DD} = \left(\frac{\mu_0}{4\pi}\right)\left(\frac{\gamma_1\gamma_2\hbar}{2\pi}\right)\langle r_{1,2}^{-3}\rangle$$

where μ_0 is the magnetic constant, γ_1 and γ_2 are the magnetogyric ratios of the two nuclei, and $\hbar$ is the reduced Planck's constant.

Several experiments have been designed for the measure-

ment of dipolar coupling constants for homonuclear spin systems[2–5] as well as heteronuclear spin systems.[6–8] In all these cases an effective dipolar coupling constant is measured that has a contribution from the anisotropy of the indirect nuclear spin-spin coupling tensor, ΔJ. The effective dipolar coupling constant, R_{eff}, is often represented as follows when one assumes that **J** is axially symmetric and coincident with the dipolar coupling tensor, **D**:[9,10]

$$[2] \qquad R_{\text{eff}} = R_{\text{DD}} - \Delta J/3$$

where the anisotropy of **J** is

$$[3] \qquad \Delta J = J_{33} - (J_{11} + J_{22})/2$$

and the principal components of the **J** tensor are ordered as $|J_{33} - J_{iso}| \geq |J_{11} - J_{iso}| \geq |J_{22} - J_{iso}|$. Often, the strategy for determining ΔJ from SSNMR spectra is to compare the measured value of R_{eff} with the direct dipolar coupling constant calculated on the basis of the atomic coordinates extracted using diffraction data. This can lead to an overestimation of the anisotropy of **J**, since the dipolar coupling constant reflects the average bond distance resulting from molecular vibrations and librations.[10,11] Programs have been developed that take vibrations into account when calculating dipolar coupling constants using the harmonic oscillator[12] or anharmonic oscillator[13] models. Even so, there is still the general issue that **J** is neither required to be axially symmetric nor coincident with **D**, unless symmetry dictates this to be the case.[14–17] It has been shown theoretically that if ΔJ is significant relative to R_{DD} in cases where **J** is noncoincident with **D** or where **J** is non-axially symmetric, there can be pronounced changes in the line shapes associated with stationary powder samples.[18] In these cases, simulations must take into account the asymmetry of **J**, which is

$$[4] \qquad \eta_J = (J_{22} - J_{11})/(J_{33} - J_{\text{iso}})$$

where η_J is the asymmetry parameter, and can take values ranging from 0 to 1. An asymmetry parameter of 0 means the tensor is axially symmetric. **J** also has an antisymmetric component that has never been observed experimentally. Nonetheless, guidelines on how it could be measured have been published.[19–21] The antisymmetric **J** tensor is defined as follows:

$$[5] \qquad \mathbf{J}^{\text{antisym}} = (\mathbf{J} - \mathbf{J}^{\text{t}})/2$$

where $\mathbf{J}^t$ denotes the transpose of **J**.

The original theory for indirect nuclear spin-spin coupling was developed by Ramsey.[22] Generally, one nucleus polarizes the electronic network, which can be detected by neighbouring nuclei. There are two general classes of coupling mechanisms: electron-spin mechanisms and orbital-current mechanisms labelled spin-orbit (SO). The first electron-spin mechanism, known as Fermi-contact (FC), results from the magnetic interaction between the nucleus and an electron that has a finite probability of being located at the nucleus. This mechanism is purely isotropic and is the dominating mechanism in cases where s orbitals dominate bonding as is typically the case for hydrogen. The magnetic interaction between the nuclear spin and the dipole moment of an electron located elsewhere around the nucleus is labelled spin-dipolar (SD). The effects of FC can also be detected through the SD mechanism and vice versa. This leads to a nonzero cross-term between the two that is symmetric, anisotropic, and traceless. Analogously to magnetic shielding, the SO term can be partitioned into two submechanisms. There is a diamagnetic spin-orbital term (DSO), which is often negligible, and a paramagnetic spin-orbital term (PSO), which is often the dominant term in couplings between atoms where the s orbitals contribute little to bonding (e.g., fluorine).[23,24] When relativistic spin-orbit coupling is included, there is also the introduction of cross-terms between the PSO and the electron-spin coupling mechanisms.[25,26]

Autschbach[27–29] introduced a method for the analysis of isotropic *J*-coupling constants with respect to natural localized molecular orbitals (NLMOs) and other types of localized orbitals in general (relativistic and nonrelativistic) density functional computations. This approach is of great use to better understand isotropic coupling constants and their variation as a function of geometry. NLMOs, as opposed to the more common canonical orbitals,[30] are intuitive as they can be partitioned into contributions that represent bonds, lone pairs, and core orbitals. In this study, the complete one-bond **J**-coupling tensors are computed using the zeroth-order regular approximation (ZORA) DFT method for a series of neutral fluorine-containing compounds covering several valence shell electron pair repulsion (VSEPR) geometries that could yield significant **J** tensor asymmetries. Previous studies of some of these fluorine–X indirect nuclear spin-spin coupling tensors, from Wasylishen and co-workers,[31,32] mostly focused on the performance of the calculations relative to experimental data. In this paper, we focus on determining when large asymmetries and antisymmetric components are to be expected as well as when the assumptions that **J** is axially symmetric and coincident with **D** are well-founded, as the use of these assumptions could lead to a false interpretation of experimental data.[18,19] Additionally, the structures are systematically modified from their gas-phase geometries to see how **J** correlates with these changes, and this information is related to the NLMOs that contribute the most to the coupling.

Computational details

The structural models used for the calculations were built in Gaussview using previously published gas-phase structures. The structures of OF_2,[33] PF_3,[34] PF_5,[35] ClF_3,[36] and BrF_3[37] were determined using microwave spectroscopy. The structure for SF_2 was taken from a previous ab initio study by Irikura[38] in which calculated heats of formation were compared with thermochemical data. The structure of NF_3 was taken from a high level ab initio optimized geometry.[39] The structures of AsF_5,[40] BF_3,[41] AlF_3,[42] and SF_4[43] were determined using electron diffraction, and the structure of BrF_5 was determined by a joint electron diffraction and microwave spectroscopy study.[44] The structure of ClF_5 was determined using a joint Raman and IR spectroscopic analysis,[45] whereas the structures of SeF_4[46] and XeF_4 were determined by IR spectroscopy.[47]

The indirect nuclear spin-spin coupling tensors were calculated using the CPL program,[25,26,48,49] which is part of the Amsterdam density functional (ADF) software package.[50–52] Scalar and SO relativistic effects[53] were included using

For personal use only.

ZORA.[54] In the ZORA formalism, only the sum of the coupling tensors arising from FC, SD, and their cross-term is given. This tensor is reported as FC + SD. All calculations used the same all-electron ZORA triple zeta doubly polarized basis sets (ZORA/TZ2P). The local density approximation (LDA) of Vosko–Wilk–Nusair[55] (VWN) was used along with the generalized gradient approximation (GGA) of Becke88[56] and Perdew86.[57,58] It was shown that the quality of the results improve significantly in pure DFT calculations of **J** when LDA and GGA are implemented in succession.[59,60] The integration keyword was set to 6.0 and an SCF convergence of 10^{-7} was used for the spin-spin coupling calculations. Previous fluorine–X indirect nuclear spin-spin coupling calculations using the same computational methodology produced results in near-quantitative agreement with experiment.[31,32] Recent studies on the calculation of indirect nuclear spin-spin coupling tensors using the ZORA formalism have shown that these approach quantitative agreement with experiment even for heavy atoms.[61]

The calculated data were then analyzed using a modified version of the program EFGShield[62] that was altered to analyze the indirect nuclear spin-spin coupling information from the ADF output files. For the gas-phase geometries, the output files were critically analyzed to select the NLMOs with large contributions to the isotropic J coupling. Only the sum of the Lewis and non-Lewis terms is reported. The natural bonding orbitals (NBOs) and NLMOs[27–29,63] were calculated using NBO 5.0[64] and were visualized using the program adfview from the ADF package.

Results and discussion

The following results are organized in terms of geometry. In general, two compounds of each geometry were selected. The complete **J**-coupling tensor information, including symmetric and antisymmetric tensor components, is organized by coupling mechanism in Tables 1–8. The tensor orientations are reported in terms of two Euler angles (α and β) that describe the relative orientation of the principal axis systems (PAS) of **J** and **D**. The angle β is that between J_{33} and D_{33} (i.e., the bond axis) and α is the angle between J_{11} and the projection of D_{33} onto the plane formed by J_{11} and J_{22}.[65] If β is close to zero, then the assumption that **J** is coincident with **D** is valid. The results from the NLMO analysis are then discussed and are related to the geometry modifications and main coupling mechanisms for each geometry. Only the NLMOs having a contribution to the isotropic coupling constant of at least an order of magnitude larger than the remaining NLMOs were considered. Depictions of these NLMOs, as well as figures plotting the change in ΔJ and η_J as a function of bond angles are included in the Supplementary data. When possible, the calculated isotropic coupling constants are compared with experimental data. In these cases, the sign of the experimental coupling constants is taken from the calculations.

Bent geometry

To study the **J** tensors of bent molecules, the one-bond **J** (^{19}F, ^{17}O) coupling tensor of OF_2 was calculated along with the one-bond **J**(^{33}S, ^{19}F) coupling tensor of SF_2. The results are given in Table 1. Although these molecules are of C_{2v} point symmetry, the symmetry along the bond is C_s, and **J** therefore has five independent components. Even though the isotropic coupling constants are moderate, the anisotropy of **J** is approximately 5 (OF_2) to 12 (SF_2) times larger than J_{iso}. The asymmetry parameters of **J**(X, ^{19}F) in these compounds are fairly large (0.49 and 0.32), which is to be expected as they have low symmetry along the bond. It is also interesting to note that J_{33} is nearly perpendicular to the bond and it is J_{11} that lies nearly along the bond for both OF_2 and SF_2. The one-bond **J**(^{19}F, ^{17}O) coupling tensor for OF_2 was previously calculated using multiconfigurational self-consistent field (MCSCF) methods[66] and similar results were obtained, although the ZORA method yields a larger value for ΔJ. The PSO mechanism is the main contributor to the J coupling for OF_2, but the analogous one-bond coupling in SF_2 is dominated by the FC + SD mechanism. In both cases, the asymmetry of **J** originates almost entirely from the FC + SD cross-term.

Calculations were also carried out using structures in which the bond angle was incremented to determine how **J** responds to these geometry modifications. Figure 1 presents the change in the principal components of **J**(^{19}F, ^{17}O) for OF_2, and it can be seen that the magnitude of the anisotropy and the asymmetry of **J** increase as the bond angle is increased relative to the experimental geometry (Figs. S19 and S20 of the Supplementary data). The fact that the asymmetry of **J** increases with the bond angle in the range of realistic bond angles is consistent with the data for SF_2 (having a bond angle of 99.2° compared with 103.07° for OF_2) in which the **J**-coupling tensor has a smaller asymmetry parameter. The dominance of the PSO mechanism for OF_2 can be rationalized by looking at the NLMOs responsible for the coupling (Fig. 2). The coupling is dominated by p-type lone pairs on the oxygen and fluorines; in the context of Ramsey's equations, these orbitals are expected to largely contribute via the PSO and SD mechanisms. The orbitals responsible for the J coupling in SF_2 have significant s character (Fig. 2), which is consistent with the increased importance of the FC + SD mechanism for the isotropic coupling constant. Even though the anisotropy of **J** for SF_2 is dominated by the PSO mechanism, this cannot be currently explained using the NLMOs, since only their contribution to J_{iso} is given from the calculations. The value of $J(^{17}O, ^{19}F)_{iso}$ in OF_2 is known from solution studies to be (–)300 ± 30 Hz.[67] However, the computational value from this study (–265.6 Hz) is farther away from the experimental value than the previous MCSCF value of –309 Hz.[66]

Trigonal pyramidal geometry

In the case of trigonal pyramidal geometry, the one-bond **J**(^{19}F, ^{14}N) coupling tensor of NF_3 as well as the one-bond **J**(^{31}P, ^{19}F) coupling tensor of PF_3 were calculated. Even though these molecules belong to the C_{3v} point group, the symmetry along the individual bonds is C_s and **J** should have five independent components. The isotropic coupling constants are slightly larger than the anisotropy of **J** in both cases and the FC + SD mechanism dominates the total **J**-coupling tensor in NF_3 (Table 2). In the case of PF_3, the PSO mechanism dominates the anisotropy of **J** with a ΔJ of 547.1 Hz, whereas the FC + SD tensor has a ΔJ of only 196.1 Hz. The experimental isotropic ^{31}P–^{19}F coupling con-

[a]The antisymmetric tensor components are given in the principal axis system (PAS) of the total **J**-coupling tensor with J_{22} being perpendicular to the plane of the molecule in all cases. For the axial fluorines the only nonzero component of the antisymmetric tensor is J_{xz}, whereas they are all zero for the equatorial fluorine.

stant of –1439 Hz,[68] which was measured in the nematic solvent *N*(*p*-ethoxybenzylidene)-*p*-butylaniline (EBBA), is close to the calculated value of –1468.5 Hz; solvent effects may be partly responsible for the small difference. For both NF_3 and PF_3, J_{33} is oriented at <20° from the bond axis, with the orientation of the other two components changing from one compound to the other. In Fig. 3, the dependence of the principal components of **J**(^{19}F, ^{14}N) on geometry are shown as all three F–N–F bond angles are changed simultaneously while maintaining the C_{3v} point symmetry of the molecule. The anisotropy and asymmetry parameters both depend strongly on geometry, increasing by 12.8% and 48.9%, respectively, following a decrease of the bond angle by only 1.6° from the experimental value (Figs. S21 and S22 of the Supplementary data). Interestingly, if the various contributions are examined, the asymmetry parameters for the PSO and FC + SD tensors are fairly constant with respect to geometrical changes, characterized by standard deviations of 0.03 and 0.05, respectively, but the orientation of the two contributing tensors relative to one another causes a large variation in the total **J**-coupling tensor. A previous computation of **J**(^{31}P, ^{19}F) for PF_3 using the ZORA-DFT method also gave a large asymmetry parameter of 0.876.[32]

For both NF_3 and PF_3, the contributing NLMOs are largely s and σ-type orbitals, which is consistent with a FC-dominated coupling (Figs. S2 and S3 of the Supplementary data). It is interesting to note that there are no symmetry requirements forcing the antisymmetric component J_{yz} to be zero but it remains very small at <2% of the value of the isotropic coupling constants. It is therefore unlikely that one could observe the antisymmetric components of **J** in a trigonal pyramidal compound as one of the requirements given in ref. 19 for the observation of $\mathbf{J}^{antisym}$ is that it must be of the same order of magnitude as that of the symmetric components of **J**.

Trigonal bipyramidal geometry

The one-bond **J**(^{31}P, ^{19}F) coupling tensors of PF_5 as well as the one-bond **J**(^{75}As, ^{19}F) coupling tensors of AsF_5 were studied. The calculated parameters are given in Table 3. These molecules are of D_{3h} symmetry, but the symmetry along the axial bond is C_{3v}. The **J**-coupling tensor between

[a]The antisymmetric tensor components are given in the principal axis system (PAS) of the total **J**-coupling tensor. For the equatorial sites in both molecules J_{11} is oriented perpendicular to the symmetry plane, and in the case of the axial sites J_{22} is the component perpendicular to the relevant symmetry plane. In all these cases, J_{xy} was forcibly zero.

each of the axial fluorines and the central atom should therefore have two independent **J**-coupling tensor components, whereas coupling to the equatorial fluorines would have three, as there is C_{2v} symmetry along these bonds. $\mathbf{J}^{antisym}$ must be null for all fluorine sites and J_{33} must be oriented along the bond. The asymmetry parameter of the **J**-coupling tensor between the central atom and the axial fluorine must also be null because of the C_{3v} symmetry.[20] In both cases it can be seen that the FC + SD mechanism dominates the isotropic J coupling, although the asymmetry in **J** for the equatorial sites originates almost entirely from the PSO mechanism. Only the average experimental one-bond isotropic coupling constant of PF_5 is known at (–)929 ± 1 Hz, which was measured in a gas-phase study.[69] This value is smaller than the calculated average isotropic coupling constant of –1442.4 Hz, which was noted previously by Feindel and Wasylishen[32] using the same computational method. The use of large basis sets with a high exponent in the core region could perhaps improve the calculations.[70] The F_{eq}–P–F_{ax} bond angles in PF_5 were varied to move the equatorial fluorines towards the axial sites while maintaining C_{3v} point symmetry for the molecule (Fig. 4). Figure 4 shows that the

Table 8. One-bond ^{129}Xe–^{19}F **J**-coupling tensor parameters of XeF_4.

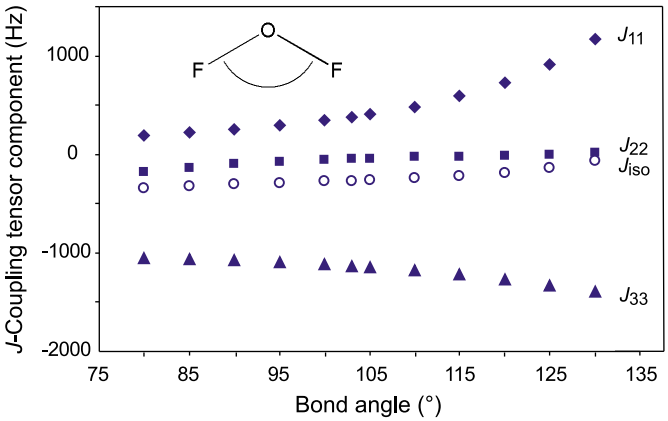
Tensor	J_{iso} (Hz)	ΔJ (Hz)	η_J	β (°)[a]	α (°)[b]
Total	–3279.2	–5295.5	0.11	90	0
DSO	–0.4	–81.9	0.01	0	N/A
PSO	–229.3	–5615.2	0.05	90	90
FC + SD	–3049.4	–643.1	0.13	90	0

Note: $\Delta J = J_{33} - (J_{11} + J_{22})/2$; $\eta_J = (J_{22} - J_{11})/(J_{33} - J_{iso})$; DSO, diamagnetic spin orbital; PSO, paramagnetic spin orbital; FC + SD, Fermi contact and spin dipolar; and α and β, Euler angles.

[a]When J_{33} is along the bond axis, the angle α is not defined.

[b]The symmetry along the Xe–F bond forces all of the antisymmetric components to be zero.

Fig. 1. Tensor components of the one-bond **J**(^{19}F, ^{17}O) coupling tensor of OF_2 as a function of the bond angle. The experimental bond angle is 103.07°.[33]



J(^{31}P, $^{19}F_{eq}$) coupling tensor parameters did not change substantially (Figs. S24 and S25 of the Supplementary data), but both the isotropic coupling constant and the anisotropy of **J**(^{31}P, $^{19}F_{ax}$) dramatically increased as the F_{ax}–P–F_{eq} bond angles were increased (Fig. S23 of the Supplementary data). The important NLMOs for the isotropic coupling constant seem to be a σ-bonding orbital, a lone pair on the fluorine atom, and a core orbital on the fluorine atom (Fig. S4 of the Supplementary data). The large change in J_{iso} as the F_{ax}–P–F_{eq} bond angles increase can be attributed to both the bonding orbital between phosphorus and the axial fluorine and the lone pair on the coupled fluorine, since the contributions to J_{iso} from these become more negative as the bond angle is increased. In the case of AsF_5, the bonding orbital between the two coupled nuclei is less important when compared with PF_5, and the bonding orbitals between the arsenic and fluorine atoms *not* directly implicated in the coupling become important (Figs. S6 and S7 of the Supplementary data). These orbitals extend farther out in space than those in PF_5 and give significant contributions to J_{iso}.

Trigonal planar geometry

In the case of trigonal planar geometry, the one-bond **J**(^{19}F, ^{11}B) tensor of BF_3 was calculated along with the one-bond **J**(^{27}Al, ^{19}F) tensor of AlF_3. Whereas these molecules have D_{3h} point symmetry, the symmetry along each bond is C_{2v}, forcing **J** to only have three independent tensor components. In both cases, the computed isotropic coupling constants of –143.5 and –380.4 Hz for BF_3 and AlF_3, respectively, are relatively small, and the anisotropy and asymmetry parameters are moderate: 420.4 Hz and 0.28, respectively, for BF_3. The antisymmetric components of **J** are all zero in this case because of the two mirror planes going through the bond axis.[20] Several geometry modifications were performed such as varying a single bond angle or

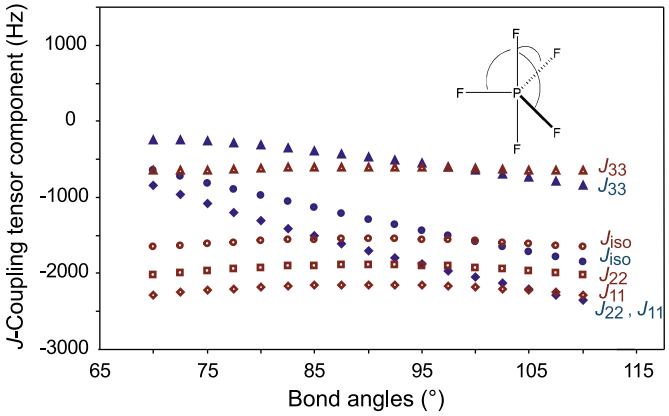
Fig. 2. Fig. 4. Tensor components of the one-bond **J**(^{31}P, ^{19}F) coupling tensors of PF_5 as a function bond angle. All three bond angles are changed simultaneously to maintain a C_{3v} point symmetry for this molecule. The solid symbol data points correspond to the **J**-coupling tensor components for the coupling to the axial fluorines, whereas the open symbol data points correspond to the tensor components for the coupling to the equatorial fluorines. The bond angles in the experimental geometry are 90°.[35]



bending the fluorine atoms downwards while maintaining C_{3v} symmetry. The **J** tensor parameters remained relatively constant: the isotropic coupling constant changed by only 2.7 Hz after a bond angle was modified by 15°, which is consistent with the observation made in the case of the equatorial fluorines in PF_5. Again, the PSO mechanism dominates the asymmetry of **J**, but the magnitude of the total **J**-coupling tensor originates largely from the FC + SD mechanism, which is consistent with the picture provided by the most significant NLMOs that are of s type (Figs. S8 and S9 of the Supplementary data). In this case, as well, the PSO contribution is stronger for the heavier analogue, but the asymmetry parameter of the PSO tensor is smaller. These findings suggest that **J**-coupling tensor parameters for trigonal planar molecules could be more likely to agree with experimental data than other geometries, since they would be less sensitive to small deficiencies in the molecular structure and to molecular vibrations. However, Jackowski et al.[71] studied the ^{19}F–^{11}B indirect nuclear spin-spin coupling constant of BF_3 in the gas phase at various temperatures and pressures, from which an isotropic coupling constant of 16.4 Hz at zero pressure and 300 K could be extracted. This experimental value differs greatly from our calculated value of –143.5 Hz. Since FC is often the dominating coupling mechanism for the elements located in the first groups of the periodic table,[72] the use of basis sets optimized for *J* coupling would likely improve the computed value. Using the ZORA/QZ4P basis set, the anisotropy and asymmetry parameter values remained essentially constant (within 2.5%), although the magnitude of the isotropic coupling constant decreased by 35%, solely because of a change in the FC + SD tensor. Jackowski et al.[71] calculated an isotropic coupling constant of 19.277 Hz at the CCSD/TZsu3+2p1d level of theory. Still, a non-negligible discrepancy of 15% remains between the experimental value and their computed value, particularly given that the experimental value has been extrapolated to zero pressure. They emphasized the importance of the choice of basis set for the calculation of the FC contribution, although the PSO and DSO contributions were not sensitive to the choice of basis set and those values previously calculated are very similar to the values reported here. As ΔJ, η_J, and $\mathbf{J}^{antisym}$ do not depend on the pure Fermi-contact mechanism, these ZORA values are likely much more accurate than our computed value of J_{iso}.

T-shaped molecules

The one-bond **J**(^{35}Cl, ^{19}F) and **J**(^{81}Br, ^{19}F) coupling tensors were calculated for ClF_3 and BrF_3, respectively, and the data are summarized in Table 5. The symmetry along the equatorial bond is C_{2v} and therefore the **J**-coupling tensor between the equatorial fluorine and the central atom can have up to three independent components, whereas the axial fluorines may have five independent components, since the bond symmetry is C_s. In these compounds, for both the equatorial and axial sites, the anisotropy is three to six times larger than the isotropic coupling constant. The asymmetry parameter is also fairly large, ranging from 0.30 to 0.64. For the axial fluorines, the isotropic coupling constant is dominated by the FC + SD mechanism, whereas the PSO mechanism is the source of the sizeable anisotropy. In the case of the equatorial sites, PSO dominates both the isotropic coupling constant and the anisotropy, although FC + SD remains important and is the principal source of the asymmetry of **J**. The average isotropic *J*-coupling constant is known to be (+)260 Hz for liquid ClF_3.[73] The calculated isotropic *J*-coupling constant for ClF_3 from this study is in better agreement with the experimental data than the previous MCSCF study,[66] and is very similar to previous ZORA-DFT results.[31] The NLMO analysis reveals that the orbitals primarily responsible for the coupling, in all cases, are lone pairs on both the chlorine and the fluorine. In the case of the equatorial site, these orbitals resemble p orbitals, which explains the importance of the PSO mechanism, although the important NLMOs for BrF_3 are mostly s-type orbitals (Fig. 5; Figs. S11 and S12 of the Supplementary data). It is also important to note that J_{33} lies perpendicular to the bond, which is in agreement with previous computational studies of **J** for ClF_3 and BrF_3.[31,66] It is again noted that the non-Lewis terms from the NLMOs become more important with the larger atomic number as the lone-pair orbitals responsible for the coupling extend farther out in space. Interestingly, large antisymmetric tensor components of 152.3 and 818.3 Hz were calculated for the axial fluorines in ClF_3 and BrF_3, respectively (i.e., of the same order of magnitude as the isotropic *J*-coupling constant).

The F_{ax}–Cl–F_{eq} bond angles were incremented (Fig. S26 of the Supplementary data), but the tensor parameters for the axial site remained fairly constant: the isotropic coupling constant changed by only 4% after an increase of 10° in the bond angles (also see Figs. S27 and S28 of the Supplementary data). In the case of the equatorial F, both ΔJ and η_J increased as the bond angles were increased (Figs. S29 and S30 of the Supplementary data). It was also noticed that as the bonds were lengthened, both the anisotropy and the isotropic coupling constant increased.

Square pyramidal geometry

The one-bond **J**(^{35}Cl, ^{19}F) tensors of ClF_5 and the one-bond **J**(^{81}Br, ^{19}F) tensors of BrF_5 were calculated and are

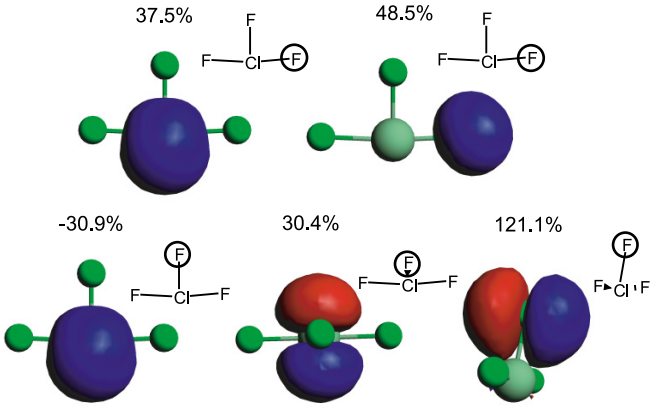
Fig. 5. Natural localized molecular orbitals (NLMOs) having the largest contributions to the isotropic chlorine–fluorine nuclear spin-spin coupling constant of ClF_3 for the axial fluorine (top) and the equatorial fluorine (bottom). The percentages above the orbitals represent their contributions to the isotropic *J*-coupling constant.



given in Table 6. Both these molecules, as well as the axial bonds, have C_{4v} symmetry; hence, the **J**-coupling tensor to the axial fluorine has two independent components, the asymmetry parameter is forcibly zero, and J_{33} orients along the bond. The **J**-coupling tensor between the central atom and each of the equatorial fluorines has five independent tensor components, as the symmetry along this bond is C_s. The ratio $\Delta J/J_{iso}$ for the axial fluorines is small when compared with the T-shaped molecules. In the case of the equatorial sites, the isotropic *J* couplings to the central atom (120.1 and 375.6 Hz for ClF_5 and BrF_5, respectively) are small when compared with the axial site and the T-shaped compounds discussed earlier. The anisotropy of **J** for the equatorial sites is, however, large when compared with the isotropic coupling constants, and J_{xz} remains small (5.4 and 42.1 Hz for ClF_5 and BrF_5, respectively).

The experimental isotropic $^{35}Cl–^{19}F_{ax}$ *J*-coupling constant was measured to be (–)192 Hz in liquid ClF_5, whereas the isotropic $^{35}Cl–^{19}F_{eq}$ *J*-coupling constant was estimated to be smaller than 20 Hz.[73] The calculated value of –193.8 Hz for the isotropic $^{35}Cl–^{19}F_{ax}$ *J*-coupling constant is in excellent agreement with the experimental value, whereas the calculated isotropic coupling constant to the equatorial fluorines (120.1 Hz) is much larger than experiment. A previous ZORA-DFT study of the **J**-coupling tensor of ClF_5 using the triple-polarized ADF ZORA V basis set predicted a much larger value for $J(^{35}Cl–^{19}F_{ax})_{iso}$ of –276 Hz, and a smaller value for $J(^{35}Cl–^{19}F_{eq})_{iso}$ of 69 Hz.[31] The FC + SD tensor does dominate **J**, although the PSO contribution is not negligible and the addition of the two tensors contributes to the nonzero asymmetry parameter of the total **J**-coupling tensor. From the plots in Fig. 6, which show the progression of the tensor components as the $F_{ax}–Cl–F_{eq}$ bond angles are changed (while maintaining the C_{4v} point symmetry of the molecule), it can be seen that the tensor components for both sites are extremely sensitive to those bond angles. J_{33} remains close to the bond (within 20°) as the angles are varied until it exchanges orientation with J_{11} when the bond angles are >95°. These large variations can be qualitatively understood by considering the contributions from the NLMOs. In the case of the coupling between chlorine and the axial fluorine, the bonding orbitals between the equatorial fluorines and the chlorine as well as the lone pairs on the equatorial fluorines contribute significantly to the coupling. The important NLMOs for the coupling between the axial fluorine and the chlorine are shown in Fig. 7. The change of J_{iso} owing to the contributions from all six important NLMOs can also be calculated and is outlined presently.

In Fig. 8, the one-bond $^{35}Cl–^{19}F_{ax}$ isotropic coupling constants owing to each NLMO are plotted as the bond angle is changed. The contributions to J_{iso} from most orbitals change in a similar fashion as the bond angle is increased. This change reflects the way J_{33} changes as the bond angle is increased, although the sign of the coupling varies. Overall, many of the contributions from the different NLMOs nearly cancel one another, and the behaviour of the isotropic *J*-coupling constant for the $^{35}Cl–^{19}F_{ax}$ spin pair is dominated by the s-type lone pair orbital on the chlorine.

For square pyramidal molecules, it is then expected that the calculation of **J**-coupling tensors would be particularly sensitive to geometry and to vibrational effects, as, for example, even a decrease of the bond angles by 5° relative to the experimental geometry causes a change in the asymmetry parameter of 0.33 and a decrease in ΔJ of 24.5% in the case of the $^{35}Cl–^{19}F_{eq}$ spin pair (Figs. S31–S33 of the Supplementary data).

Seesaw geometry

When considering the seesaw geometry, the one-bond $\mathbf{J}(^{33}S, ^{19}F)$ tensors of SF_4, as well as the one-bond $\mathbf{J}(^{77}Se, ^{19}F)$ coupling tensors of SeF_4, were calculated, and the data are given in Table 7. These molecules have C_{2v} symmetry, two nonequivalent fluorine sites, and the one-bond **J**-coupling tensors are restricted to five independent components for both sites as there is C_s symmetry along both bonds. In these cases, both sites are very different: the axial sites have small isotropic *J*-coupling constants (–97.7 Hz for SF_4 and –210.7 Hz for SeF_4), slightly larger ΔJ (–185.8 for SF_4 and 616.6 Hz for SeF_4), and antisymmetric **J** tensor components of the same order of magnitude as J_{iso}. The equatorial sites, on the other hand, have relatively large isotropic *J*-coupling constants (–339.3 Hz for SF_4 and –1027.3 Hz for SeF_4), but small values for ΔJ (83.1 Hz for SF_4 and 365.6 Hz for SeF_4) and $\mathbf{J}^{antisym}$ (4.5 Hz for SF_4 and 17.4 Hz for SeF_4). In all cases, contributions from the FC + SD and PSO mechanisms to the total **J**-coupling tensor are of the same order of magnitude, which is consistent with the fact that the important NLMOs have both s and p character (Figs. S15–S18 of the Supplementary data). It is important to note that the orientation of J_{33} does not appear to be reflective of any particular geometric feature (but its orientation remains constant from one compound to the other with β at 59.7° and 59.5° for the equatorial sites and 15.1° and 27.3° for the axial sites in SF_4 and SeF_4, respectively), whereas J_{11} has a predictable orientation perpendicular to the mirror plane. The small isotropic *J*-coupling constants in the case of the axial fluorines can be explained as follows: although many NLMOs contribute to the coupling, their contributions are of opposite signs and hence largely cancel one another. In the case of SeF_4, as the orbitals extend farther out in space, there are then more orbitals to contribute to the coupling, making the reduced coupling

Fig. 6. Tensor components of the one-bond **J**(^{35}Cl, ^{19}F) coupling tensors of ClF_5 as a function of bond angle. These bond angles are changed simultaneously while maintaining a C_{4v} point symmetry for the molecule. The solid symbol data points correspond to the **J**-coupling tensor components for the coupling to the axial fluorine, whereas the open symbol data points correspond to the **J** tensor components for the coupling to the equatorial fluorines. The experimental bond angles are 90°.[45]

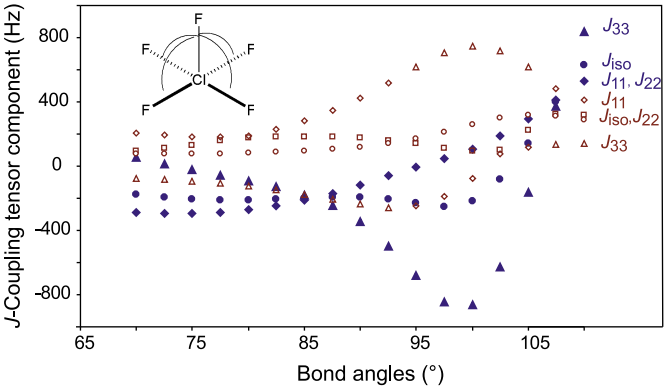

Fig. 7. Natural localized molecular orbitals (NLMOs) having the largest contributions to the isotropic chlorine–fluorine nuclear spin-spin coupling constant of ClF_5 (axial fluorine). The percentage above the orbitals represents their contributions to the isotropic *J*-coupling constant.

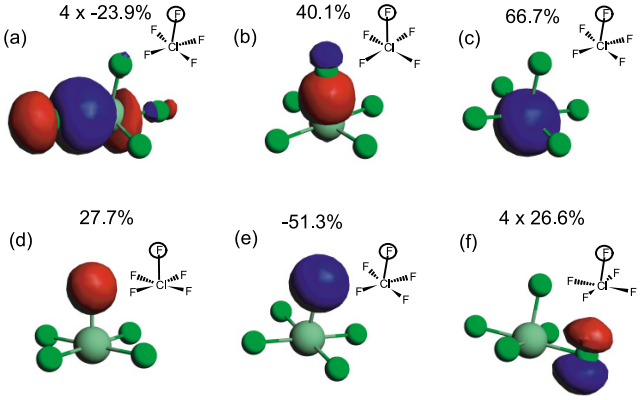

constant of -47.5×10^{20} N A^{-2} m^{-3} in SeF_4 larger in comparison with the reduced coupling constant of -39.1×10^{20} N A^{-2} m^{-3} in SF_4. This effect is consistent with the periodic trend that the reduced coupling constants become larger as the atomic number increases.[23,74] In Fig. 9, the principal components of **J**(^{33}S, ^{19}F) are shown as the axial bond angle is increased. The magnitude of the anisotropy for the axial site increases as the bond angle is increased (Fig. S35 of the Supplementary data), whereas it remains constant within 2.5 Hz in the case of the equatorial site (Fig. S37 of the Supplementary data). The asymmetry parameters for the axial and equatorial sites increase and decrease, respectively (Figs. S36 and S38 of the Supplementary data) with increasing bond angle. If we look at the separate contributions from the PSO and FC + SD mechanisms, we can see that the asymmetry parameters are fairly constant as the bond angle is changed, having standard deviations of 0.02 and 0.01, respectively (Fig. S36 of the Supplementary data), but the relative

The experimental bond angle is 176.8°.[43]

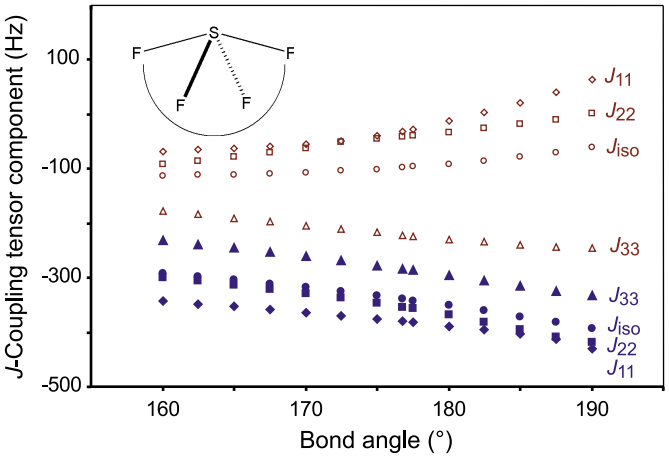

Fig. 10. Tensor components of the one-bond **J**(^{33}S, ^{19}F) coupling tensors of SF_4 as a function of the equatorial bond angle shown in the bottom left corner. The solid symbol data points correspond to the **J**-coupling tensor components for the coupling to the equatorial fluorine, whereas the open symbol data points correspond to the tensor components for the coupling to the axial fluorines. The experimental bond angle is 103.8°.[43]

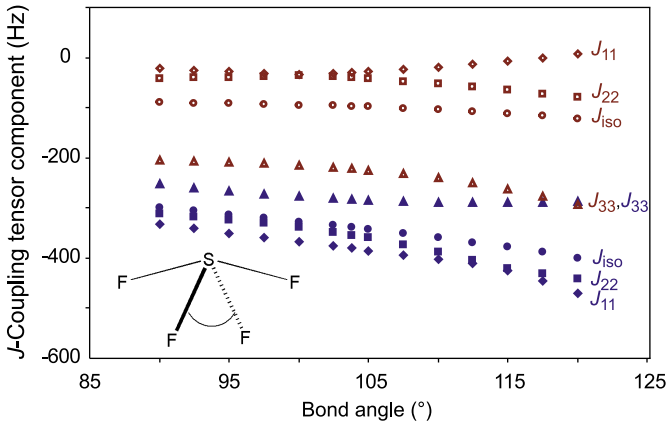

orientation of the two tensors varies, which in turn causes large variations in the asymmetry parameter of the total **J**-coupling tensor. The magnitude of the anisotropy becomes larger as the equatorial bond angle is increased for both sites (Fig. 10 and Figs. S39 and S41 of the Supplementary data). The asymmetry parameters of the PSO and FC + SD tensors for the equatorial fluorine atoms vary by only 0.3 as the equatorial bond angle is changed from 90° to 120° (Fig. S42 of the Supplementary data), although the total **J**-coupling tensor's asymmetry parameter varies significantly from 0.6 to 0 because the relative orientation of the two tensors changes. In the case of the axial sites, the asymmetry originates from the PSO term, whereas the FC + SD tensor has a relatively constant asymmetry parameter as the bond angle is varied, having a standard deviation of 0.006 over the range shown in Fig. S40 of the Supplementary data.

From solution NMR studies, the experimental ^{77}Se–^{19}F isotropic *J*-coupling constants are known to be (–)284 Hz for the axial fluorine and (–)1206 Hz for the equatorial fluorine.[75] These values are close to the values calculated here, which are –210.7 and –1027.3 Hz, respectively, but both coupling constants are underestimated.

Square planar geometry

For square planar geometry, the one-bond **J**(^{129}Xe, ^{19}F) coupling tensor of XeF_4 was studied. The symmetry along the Xe–F bond is C_{2v}, which restricts the number of allowed **J**-coupling tensor components to three.[20] The calculated **J** tensor parameters are given in Table 8. Interestingly, the computed isotropic *J*-coupling constant of –3279.2 Hz is mostly dominated by the FC + SD mechanism, although the anisotropy is dominated by the PSO mechanism. Multiple experimental values, ranging from (–)3801 to (–)3913 Hz have been published for the isotropic ^{129}Xe–^{19}F *J*-coupling constant of XeF_4,[76–80] which is solvent dependent. A previous ZORA-DFT study using the triple-polarized ADF ZORA V basis sets reported an isotropic coupling constant of –3925 Hz.[31] The responsible NLMOs in this case are shown in Fig. 11, and it is noticed that the largest contributions to the isotropic *J*-coupling constant are from s-type orbitals, which is consistent with a FC dominated coupling. Xenon is the heaviest element in this study, and a larger number of NLMOs have important contributions to the coupling: the six largest contributions noted here account for 87.8% of the total isotropic *J*-coupling constant. In the case of heavier elements, the orbitals extend farther out in space and therefore more orbitals have important contributions to the coupling.

To probe how sensitive the indirect nuclear spin-spin coupling tensor in XeF_4 is to geometrical changes, two opposite bond angles were changed simultaneously so as to maintain D_{2h} symmetry for the molecule. The variation in the tensor components as those angles are changed is shown in Fig. 12. The anisotropy remains fairly constant as the bond angles are changed, decreasing in magnitude by only 8% after a change of 20° in the bond angles, and the asymmetry parameter remains fairly small and ranges from 0.1 to 0.3. This is in agreement with the good fits obtained in the measurement of $\Delta J(^{31}P–^{195}Pt)$ in platinum–phosphine complexes using the approximations that **J** is axially symmetric and coincident with **D**.[81] This comparison is relevant because the platinum–phosphine complexes in that study have an approximate square planar geometry at the platinum site and a tetrahedral geometry at the phosphorus site.

Conclusions

The complete one-bond fluorine–X **J**-coupling tensors for a series of neutral fluorinated compounds belonging to several VSEPR geometry classes were calculated. It was noted that the tensor orientations for various molecules of the same geometry remain nearly identical, although in many cases J_{33} was not the tensor component closest to the internuclear bond vector. J_{33} remained nearly perpendicular to the bond vector in bent and T-shaped molecules, and was 59.7° and 59.5° from the bond vector for the equatorial sites and 15.1°

Fig. 11. Natural localized molecular orbitals (NLMOs) having the largest contributions to the isotropic xenon–fluorine nuclear spin-spin coupling constant of XeF_4. The percentage above the orbitals represents their contributions to the isotropic *J*-coupling constant.

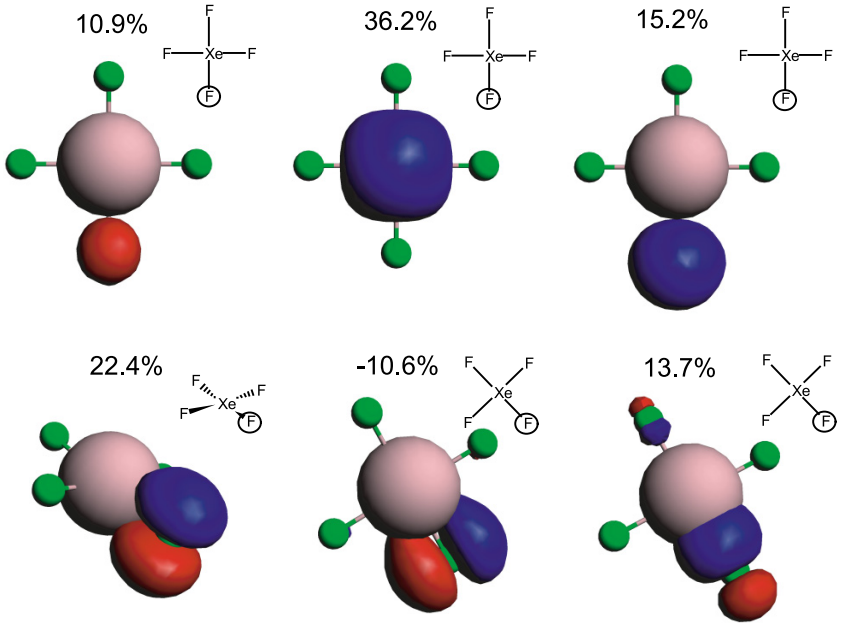

Fig. 12. Components of the one-bond $\mathbf{J}(^{129}Xe, ^{19}F)$ coupling tensors of XeF_4 as a function of the opposite bond angles. The two angles are changed simultaneously so as to maintain a D_{2h} point symmetry for the molecule. The experimental bond angle is 90°.[47]

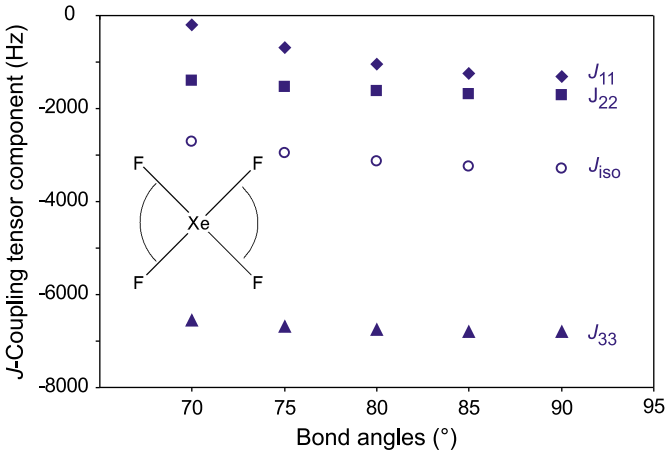

and 27.3° from the bond vector for the axial sites in SF_4 and SeF_4, respectively. In all other systems, **J** was nearly coincident with **D**. The use of NLMOs to filter the isotropic *J*-coupling constants in terms of their contributions from bonds and lone pairs proved to be useful in understanding the dominance of the PSO mechanism for bent, T-shaped, and seesaw molecules in which lone pairs in the form of p-like orbitals contributed significantly to the isotropic *J*-coupling constants.

It was also noted that when *J* coupling involved heavier atoms, a greater number of NLMOs contribute to J_{iso}. This is a result of these orbitals extending farther out in space and having larger non-Lewis contributions to J_{iso}. It could be pinpointed that the variations of $\mathbf{J}(^{35}Cl, ^{19}F_{ax})$ as the F_{ax}–Cl–F_{eq} bond angles were augmented were largely because of the s-type lone pair orbital on the chlorine, instead of the orbitals involving fluorine.

Assumptions that **J** is both coincident with **D** and axially symmetric are only truly valid in cases of near axial symmetry along the bond, as seen in mercury– and platinum–phosphine complexes.[18,81–86] Sizeable asymmetries were calculated for bent, trigonal pyramidal, T-shaped, and square pyramidal molecules. In other systems, the asymmetry parameter of **J** was fairly small and would therefore not greatly affect the NMR spectrum. It was determined that for bent molecules, the equatorial sites of T-shaped molecules, and square planar molecules the asymmetry originated from the FC + SD tensor, even though the anisotropy of **J** was dominated by the PSO mechanism. Conversely, in the case of trigonal planar and trigonal bipyramidal molecules, the anisotropy originated from the FC + SD mechanism, but the asymmetry of **J** largely depended on the PSO mechanism. In all other cases, both the FC + SD and the PSO mechanisms contributed to the anisotropy, but the asymmetry arose from the addition of the various tensors. Thus, in cases where many mechanisms contribute significantly to **J**, there can be an increase in the asymmetry because of the different orientations of multiple contributing tensor PASs.

Finally, large antisymmetric components were predicted only for particular *J*-coupling tensors in bent, T-shaped, and seesaw molecules. A successful experimental observation of $\mathbf{J}^{antisym}$ would then likely benefit from a spin pair in one of these geometries. The consistency of the calculated **J**-coupling tensor parameters and orientations when going from one system to another of the same geometry (e.g., ClF_3 to BrF_3) suggests that computational methods serve as valuable tools to assist in the experimental characterization of **J** for systems without approximate C_n (with $n > 2$) symmetry along the bond.

Abstract: Natural abundance ^{25}Mg solid-state magic-angle spinning and static NMR spectra of several representative layered magnesium phosphates were acquired at 21.1 and 9.4 T by using quadrupolar echo and double-frequency sweep quadrupolar Carr–Purcell–Meiboom–Gill pulse sequences. The spectra were dominated by the second-order quadrupolar interaction. The electric field gradient tensor parameters were extracted from the spectra via spectral simulations. These parameters, such as the quadrupolar coupling constant (C_Q), appear to be sensitive to some parameters describing the distortion of the MgO_6 octahedron in the layer. The empirical relationships between C_Q and several structural parameters were established and used to obtain partial information on the Mg environment in a layered material ($MgHPO_4{\cdot}1.2H_2O$) with unknown structure. Theoretical calculations suggest that the C_Q values of the Mg sites are affected not only by the oxygen atoms in the first coordination sphere, but also by the spatial arrangements of the atoms in the second and third coordination spheres and beyond.

Key words: layered magnesium phosphates, ^{25}Mg NMR, quadrupolar echo, QCPMG.

Résumé : Opérant à 21,1 et 9,4 T, et faisant appel à l'écho quadripolaire et aux séquences pulsées quadripolaires à balayage à double fréquence de Carr-Purcell-Beiboom-Gill, on a mesuré les spectres RMN, statiques et en rotation à l'angle magique, en abondance naturelle du ^{25}Mg et à l'état solide de plusieurs phosphates de magnésium en couches représentatives. Les spectres sont dominés par l'interaction quadripolaire du deuxième ordre. On a extrait les paramètres du tenseur du gradient du champ électrique à partir des spectres en faisant appel à des simulations spectrales. Il semble que ces paramètres, telle la constante de couplage quadripolaire (C_Q), sont sensibles à certains paramètres qui décrivent la distorsion de l'octaèdre MgO_6 dans la couche. On a établis des relations empiriques entre la valeur de C_Q et plusieurs paramètres structuraux et on les a utilisés pour obtenir de l'information partielle sur l'environnement du Mg dans un matériau de ($MgHPO_4{\cdot}1,2H_2O$) de structure inconnue. Les calculs théoriques suggèrent que les valeurs de C_Q des sites de Mg ne sont pas uniquement affectées par les atomes d'oxygène de la première sphère de coordination, mais qu'ils le sont aussi par l'arrangement spatial des atomes, au moins dans les seconde et troisième sphères.

Mots-clés : phosphates de magnésium en couches, RMN du ^{25}Mg, écho quadripolaire, QCPMG.

[Traduit par la Rédaction]

Introduction

Layered metal phosphates (MPs) have potential applications as ion exchangers, ionic conductors, and catalysts because of their structural topologies and the properties of intercalation of various guest species. The structures of MPs are, in general, not very well-characterized owing to the fact that it is difficult to grow good single crystals suitable for X-ray diffraction. Recently, we applied solid-state NMR techniques to directly characterize the metal centre environments of several important MPs, including layered titanium phosphates,[1] niobium phosphates,[2] vanadium phosphates,[3] and zirconium phosphates.[4] The focus of this work is on the layered magnesium phosphates. Layered magnesium phosphates (MgPs) have proved useful in various processes of interest including removal of heavy metal ions from aqueous solutions,[5,6] removal of aqueous ammonium,[7] and catalysis of a variety of reactions.[8–11] These studies showed that the ion-exchange selectivity and catalytic activity of MgPs depend largely on their composition and structure. Therefore, detailed structure information regarding these layered materials is desired.

As mentioned earlier, because of the difficulty in the preparation of large single crystals for X-ray diffraction, most structures of this type of material have been determined from powder X-ray diffraction (XRD) data. Solid-state NMR is a complementary technique to X-ray diffraction. However, only a few ^{31}P MAS NMR studies[12,13] have been performed and ^{25}Mg solid-state NMR has never been used to directly probe the MgP-based materials. This is because ^{25}Mg ($I = 5/2$) has a low gyromagnetic ratio ($\gamma = -1.63890 \times 10^7$ rad T^{-1} s^{-1}) and a relatively low natural abundance (10.13%).[14] In addition, ^{25}Mg has a moderate quadrupole moment ($Q = -2.01 \times 10^{-29}$ m^2),[15] resulting in significant line broadening in the presence of an electric field gradient (EFG). The combination

of these properties renders the observation of solid-state ^{25}Mg NMR spectra difficult. Despite the challenge, the feasibility of solid-state ^{25}Mg NMR was demonstrated by Dupree and Smith[16] who observed the MAS signals in several inorganic salts at 8.45 T. Since then, solid-state ^{25}Mg NMR has been performed on a variety of Mg-containing materials.[17–35] In recent years, a combination of ever higher magnetic fields and the development of sensitivity enhancement pulse sequences for low-γ quadrupolar nuclei such as quadrupolar Carr–Purcell–Meiboom–Gill (QCPMG) and related sequences[36–38] has made the observation of these low-γ quadrupolar nuclei much more practical.

In the present study, the local environments of the magnesium centres in several representative MgPs such as $NH_4MgPO_4{\cdot}H_2O$ (dittmarite), $[NH_3(CH_2)_2NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-EN, UiO stands for University of Oslo), $[NH_3(CH_2)_4NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-DAB), and $MgHPO_4{\cdot}1.2H_2O$ were directly probed using solid-state ^{25}Mg NMR. Magic-angle spinning (MAS) spectra were acquired first. Spinning the sample at the magic angle eliminates the effect of chemical shift anisotropy (CSA). The isotropic chemical shift (δ_{iso}) and the EFG parameters including the nuclear quadrupolar coupling constant (C_Q) and the asymmetry parameter (η_Q) can be extracted by simulating the MAS spectra. To examine the possible effect of the CSA, ^{25}Mg static echo or QCPMG spectra were then obtained. The experiments were carried out at two field strengths (9.4 and 21.1 T) to ensure the reliability of the extracted NMR parameters. Relationships between the NMR parameters and the structural properties were discussed. Correlations between C_Q and the distortion of the MgO_6 octahedron were established and used to obtain partial information on the Mg local structure in $MgHPO_4{\cdot}1.2H_2O$, a representative MgP with unknown structure. Theoretical calculations were also performed to assist in understanding the observed spectra.

Experimental

Synthesis

Dittmarite and UiO-24 compounds were synthesized using the method described by Fjellvåg and co-workers.[13] The procedure was as follows: $Mg_3(PO_4)_2{\cdot}8H_2O$, H_3PO_4 (85%), diamine, and water were mixed to form a homogeneous gel. The gel was then transferred into Teflon-lined steel autoclaves and heated at a specific temperature for 24 h; after the reaction, the autoclaves were quenched in cold water and the white precipitate was retrieved by filtration and air-dried. The use of ethylenediamine (EN) as a template yielded UiO-24-EN, while employing 1,4-diaminobutane (DAB) as the template produced dittmarite and UiO-24-DAB. The specific masses of each reactant and reaction temperatures are given in Table S1 of the Supplementary data.

$MgHPO_4{\cdot}1.2H_2O$ was synthesized hydrothermally in the presence of diethylamine (DEA).[39] The reaction mixture containing 5.0 g $MgAc_2{\cdot}4H_2O$, 2.69 g H_3PO_4, 0.908 g DEA, and 10.50 g H_2O was stirred until homogeneous and then transferred into a Teflon-lined steel autoclave and heated at 180 °C for 3 days under autogeneous pressure. The crystalline product was recovered by filtration and washing with water and then dried at room temperature.

The identity of the synthesized materials was confirmed by comparing the powder XRD patterns with those reported in the literature.[13,39] Powder XRD measurements were performed on a Rigaku rotating anode diffractometer (45 kV/160 mA) using graphite-monochromated Co Kα radiation with a wavelength of 1.7902 Å. The powder XRD patterns were recorded within the range $5° \leq 2\theta \leq 65°$ with a 10°/min step width and a 6 min count time.

NMR measurements

^{25}Mg NMR experiments were performed at two fields, 21.1 and 9.4 T, corresponding to the operating frequencies at 55.11 and 24.46 MHz, respectively. The experiments at 21.1 T were performed on a 900 MHz Bruker Avance II spectrometer at the National Ultrahigh-field NMR Facility for Solids in Ottawa, Ontario. The MAS spectra at a spinning rate of 5 kHz were obtained using the one-pulse sequence. The static spectra were acquired using the spin-echo pulse sequence with a $\pi/2$ refocusing pulse, i.e., ($\pi/2 - \tau - \pi/2 - \tau -$ acq), and the phase cycling developed by Oldfield and coworkers.[40] An interpulse delay time of 100 μs was used.

The experiments at 9.4 T were performed on a Varian Chemagnetics Infinityplus 400 WB spectrometer. A low-γ tuning box was used to tune the probe to the frequency range of ^{25}Mg. The MAS spectra at 9.4 T were obtained using the spin-echo pulse sequence to remove probe ring-down and acoustic ringing at the beginning of the free induction decays (FIDs). A $\pi/2$ pulse of 8.0 μs was calibrated on a 1.0 mol/L $MgCl_2$ aqueous solution, corresponding to a selective $\pi/2$ pulse width of 2.67 μs for central transition. A recycle delay of 5.0 s was used. Since the samples were spun at a rate of 10 kHz, the interpulse delay time was set to be 100 μs, synchronized with the spinning rate. The echo was collected prior to the echo maximum and shifted to ensure that the FIDs used in Fourier transformation began exactly at the echo maximum.

Because of the low sensitivity of ^{25}Mg at the low field of 9.4 T, the double-frequency-sweep (DFS) QCPMG pulse sequence,[41] was employed. The inter-pulse and inter-acquisition delays were $\tau_1 = \tau_2 = \tau_3 = \tau_4 = 30$ μs. The acquisition time (τ_a) for each echo was adjusted to obtain a spikelet separation ($1/\tau_a$) between 1000 and 2000 Hz in the frequency spectra for different samples. The number of Meiboom–Gill (MG) loops was set to 14. DFS was implemented using a converging amplitude-modulated pulse[42] with a starting frequency of 3.0 MHz and a final frequency of 400 kHz at a sweep-rate of 4333 MHz/s.

MAS probes of 5 and 7.5 mm were used for 9.4 and 21.1 T, respectively. ^{25}Mg chemical shifts were referenced to a 1.0 mol/L $MgCl_2$ aqueous solution ($\delta_{iso} = 0$ ppm). The spectral simulations were carried out using the WSOLIDS1 software package provided by Professor R.E. Wasylishen (University of Alberta, Edmonton, Alberta).

Calculations of the EFG tensors

The calculations of the ^{25}Mg EFG tensors in dittmarite and UiO-24 compounds were performed using the Gaussian 03 program[43] on a computer cluster.[44] To make the calculation practical, simplified molecular clusters containing the structural units of interest were examined. Two different model complexes, MgO_6H_{10} and $Mg_5P_4O_{32}H_{34}$, were examined for all three compounds. The model complexes were constructed according to the crystal structures of the MgPs determined by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

powder XRD[13] and no further optimization was performed. It should be noted that the limited accuracy of the powder XRD structures may affect the calculated NMR parameters. The clusters were terminated with OH groups to reduce the total charge to zero. This is an approach widely used in ab initio calculations of ^{27}Al EFG tensors in zeolites.[45–49] Terminal H atoms take the positions of P or Mg atoms, which are connected to the terminal O atoms. We also performed the calculations of the EFG parameters by placing the hydrogens at a shorter distance of 1 Å along the O–Mg vector. However, the agreement between calculated and observed values is poorer and, therefore, the data are not presented. Calculations were carried out using the restricted Hartree–Fock (RHF) method. Several researchers[50,51] have shown that this method yields EFG predictions superior to that of the hybrid density functional theory (DFT) with the B3LYP functional. To examine basis set dependence, various basis sets including 3–21G, 6–31G**, 6–31++G**, 6–311G**, and 6–311++G(2d,2p) were used.

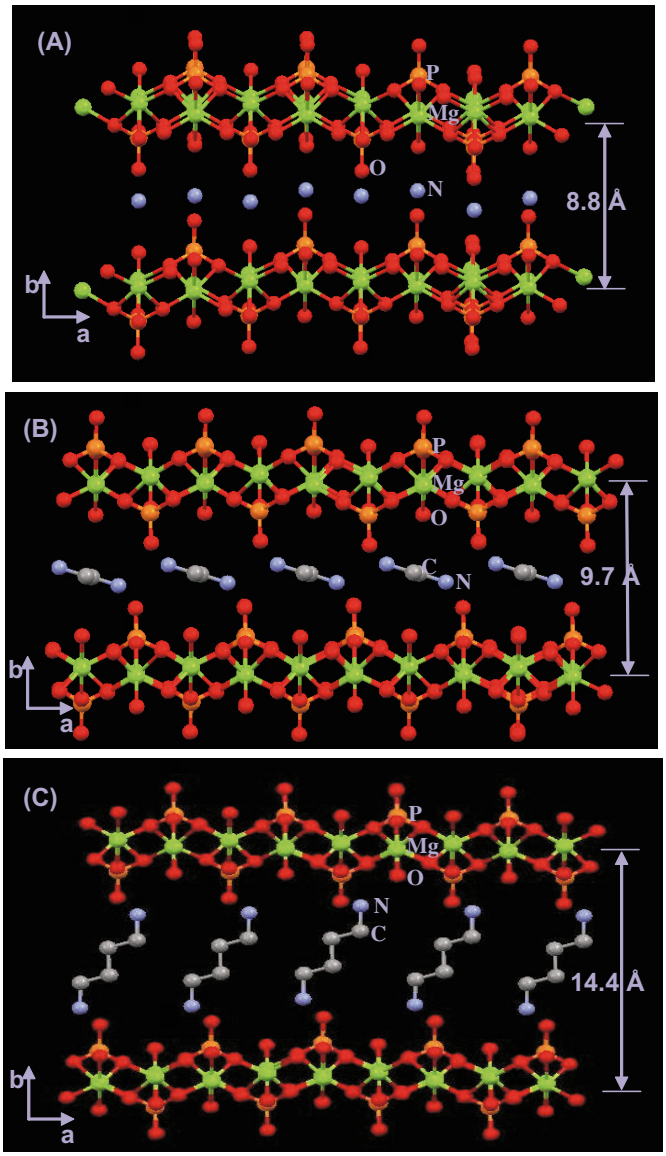
The calculated EFGs (V_{XX}, V_{YY}, V_{ZZ}) were transferred to the quadrupolar coupling constant and asymmetry parameter according to the following definition: $|V_{XX}| \leq |V_{YY}| \leq |V_{ZZ}|$; $C_Q = (eV_{ZZ}Q/h)9.71736 \times 10^{21}$; and $\eta_Q = (V_{XX} - V_{YY})/V_{ZZ}$, where e is the electronic charge, Q is the nuclear quadrupolar moment ($Q(^{25}\text{Mg}) = -2.01 \times 10^{-29}$ m^2),[15] and h is Planck's constant. The constant 9.71736×10^{21} is used in the equation because V_{ZZ} is calculated in atomic units.

The EFG tensors were also calculated using the CASTEP code,[52] which has shown to be successful in calculating NMR parameters in a variety of systems,[53–61] including ^{25}Mg parameters in several inorganic salts.[20–22] This method employs the DFT approach to calculate the electronic structure of periodic solids by using a plane wave basis and pseudopotentials to describe the core electrons. The present calculations were performed by Dr. V. Terskikh (at the National Ultrahigh-field NMR Facility for Solids) using ultrasoft pseudopotentials generated from the "on-the-fly" method implemented within CASTEP. The generalized gradient approximations (GGA) PBE exchange-correlation functional was used. Plane wave cutoff energies of 550, 500, and 450 eV were applied for dittmarite, UiO-24-EN, and UiO-24-DAB, respectively. For integrations in reciprocal space, 4 × 3 × 5, 4 × 1 × 4, and 3 × 1 × 3 Monkhorst–Pack grids, corresponding to 12, 8, and 5 k-points, were used for dittmarite, UiO-24-EN, and UiO-24-DAB, respectively. Geometry optimization was performed on dittmarite prior to the calculation of the EFG tensors, but not for UiO-24-EN and UiO-24-DAB because of the large number of atoms in their unit cells. Note that small plane wave cutoff energies and k-points were used for UiO-24-EN and UiO-24-DAB also because of the large number of atoms in the unit cell, which may introduce errors to the calculated NMR parameters.

Results and discussion

Layered magnesium phosphate, $NH_4MgPO_4{\cdot}H_2O$, occurs naturally as mineral dittmarite. Its structure was solved from powder XRD data.[13] The structure is composed of magnesium layers separated by ammonium ions (Fig. 1A). Each MgO_6 octahedron is connected to four other MgO_6 octahedra and a PO_4 tetrahedron via corner-sharing oxygens and a

Fig. 1. Structures of (A) dittmarite, (B) UiO-24-EN, and (C) UiO-24-DAB. H atoms are omitted for clarity.



water molecule. The PO_4 tetrahedron is joined together with four MgO_6 octahedra by three corner- and edge-sharing oxygens. The fourth oxygen in the PO_4 tetrahedron points towards the interlayer space and is hydrogen bonded with four hydrogen atoms in four ammonium ions. The structures of $[NH_3(CH_2)_2NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-EN) and $[NH_3(CH_2)_4NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-DAB) are very similar to that of dittmarite except that the ammonium ions are replaced by organic templates; namely, EN and 1,4-diaminobutane (DAB) (Figs. 1B and 1C).[13] The introduction of organic templates causes the increase in the interlayer distances from 8.8 Å for dittmarite to 9.7 and 14.4 Å for UiO-24-EN and UiO-24-DAB, respectively. The significant difference in the interlayer distance between UiO-24-EN and UiO-24-DAB is because the EN molecules are oriented almost parallel to the inorganic magnesium phosphate layers (Fig. 1B), whereas the DAB molecules are tilted with respect to the layers (Fig. 1C). The insertion of organic templates also results in more distorted MgO_6 octahedra. The

powder XRD patterns of synthesized dittmarite, UiO-24-EN, and UiO-24-DAB are shown in Fig. S1 of the Supplementary data. The interlayer spaces estimated from the low angle diffractions are 8.71, 9.60, and 13.92 Å for dittmarite, UiO-24-EN, and UiO-24-DAB, respectively, consistent with those reported in the literature.[13] It is noted that there are several small peaks in the XRD pattern of dittmarite owing to an impurity. The identities of MgPs were also confirmed by ^{31}P MAS NMR spectra (not shown). ^{31}P signals at 6.8, 5.2, and 7.3 ppm were observed for dittmarite, UiO-24-EN, and UiO-24-DAB, respectively, in good agreement with the corresponding reported values of 6.2, 4.3, and 6.5 ppm.[13] The ^{31}P MAS spectrum of dittmarite also shows another signal at –1.0 ppm, which is probably due to the P in the impurity.

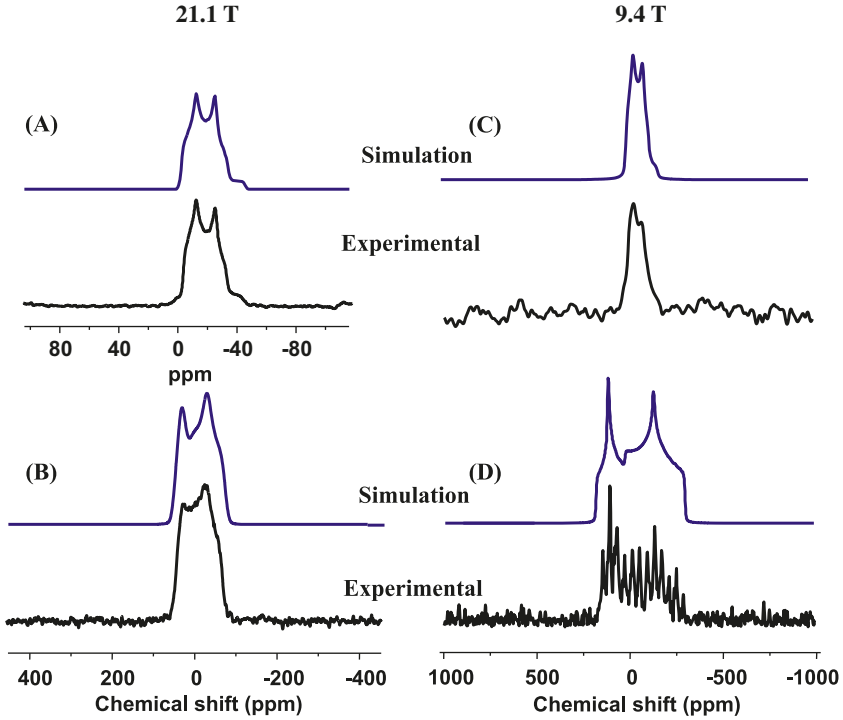
As mentioned previously, the insertion of organic templates results in a more distorted MgO_6 octahedron in UiO-24-EN and UiO-24-DAB compared with dittmarite, leading to a larger EFG at the Mg. The increase in EFG results in a larger quadrupolar interaction, which should be detected by solid-state ^{25}Mg NMR. ^{25}Mg MAS and static spectra of these three layered MgPs were recoded at 21.1 and 9.4 T. In all cases, the quadrupolar parameters were obtained and no CSA effects were observed.

Dittmarite

According to the crystal structure, there is only one Mg lattice site,[13] suggesting that there should be only one signal in the ^{25}Mg NMR spectrum. The ^{25}Mg MAS spectrum of dittmarite acquired at 21.1 T (Fig. 2A) shows two signals: a strong narrow peak and a weak pattern with a typical line shape owing to second-order quadrupolar interaction, indicating two different Mg environments. Based on the intensities of the signals and the proposed structure, the strong narrow peak is assigned to the Mg centre in the MgO_6 octahedra of dittmarite. The broad weak component is presumably due to the impurity noted in the XRD pattern. The spectrum can be well fitted (Fig. 2A) using the following parameters: δ_{iso} = 2 ppm, C_Q = 1.7 MHz, and η_Q = 0.5 for Mg in dittmarite; and δ_{iso} = 4 ppm, C_Q = 3.8 MHz, and η_Q = 0.6 for Mg in the impurity.

Similar to the MAS spectrum, two ^{25}Mg resonances were seen in the static-echo spectrum at 21.1 T (Fig. 2B), with a narrow peak superimposed on a weak broader pattern. The spectrum can be well-simulated using the same sets of quadrupolar parameters without CSA. To verify the parameters, ^{25}Mg spectra at a second field (9.4 T) were also acquired. The ^{25}Mg MAS spectrum at 9.4 T (Fig. 2C) also shows two Mg components. The strong signal can be fitted using the same set of parameters obtained from the simulation of the MAS spectrum at 21.1 T. It is difficult to accurately simulate the signal of the impurity because of its low intensity. The static DFS-QCPMG spectrum at 9.4 T is shown in Fig. 2D. The overall line shape is not well-defined owing to the fact that only a few spikelets were obtained after 3 days of data

Fig. 3. ^{25}Mg MAS (A) and (C) and static (B) and (D) NMR spectra of $[NH_3(CH_2)_4NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-DAB) at 21.1 and 9.4 T. A recycle delay of 5 s was used at both fields. Scans (8192 and 2660), corresponding to 11.4 and 3.7 h, were collected for the static and MAS spectra at 21.1 T, respectively. Scans (49 728 and 21 248), corresponding to 69.1 and 29.5 h, were collected for the static and MAS spectra at 9.4 T, respectively.



acquisition. To illustrate what is expected at 9.4 T, the spectra calculated by using the EFG parameters obtained from the 21.1 T spectra are shown in Figs. 2C and 2D.

Observing a small C_Q of 1.7 MHz is somewhat surprising because, although the variation in Mg–O bond length (2.024–2.211 Å) is not extremely large, the dispersion of the O–Mg–O bond angle in the MgO_6 octahedron is rather substantial, ranging from 67.33° to 101.93°. A possible explanation is that the spatial arrangement of the atoms beyond the oxygens in the first coordination sphere results in a charge distribution that partially cancels out the effect of the angle distortion in MgO_6, leading to an overall small C_Q value. The C_Q values of various inorganic magnesium salts[20–25] and magnesium silicates[18,19] reported in the literature also have similar magnitudes (<5 MHz). The value of η_Q is 0.5, implying that the EFG tensor is not axially symmetric, which is consist with the low site symmetry of the Mg site (C_s).

UiO-24-DAB

The crystal structure of UiO-24-DAB suggests that there exists only a single Mg site.[13] Indeed, the ^{25}Mg MAS spectrum at 21.1 T (Fig. 3A) shows only one signal with a typical line shape resulting from the second-order quadrupolar interaction. Fitting the MAS spectrum gives a single set of parameters: δ_{iso} = 2 ppm, C_Q = 2.7 MHz, and η_Q = 0.4, which can also be used to simulate the static-echo spectrum at 21.1 T (Fig. 3B) without CSA. ^{25}Mg MAS and static DFS-QCPMG spectra at a lower field of 9.4 T were also obtained. The same set of EFG parameters extracted from the spectra of 21.1 T can be used to well simulate the spectra of 9.4 T, confirming that these parameters are reliable. The spectra (Fig. 3) are broader than the corresponding ones of dittmarite (Fig. 2) because of a larger Mg C_Q in UiO-24-DAB.

Compared with dittmarite, the larger C_Q value of 2.7 MHz in UiO-24-DAB is probably due to a more distorted MgO_6 octahedron. The crystal structure of UiO-24-DAB, indeed, shows that the Mg–O bond lengths are more dispersed and that the O–Mg–O angles are more distorted[13]: the Mg–O bond lengths are in the range of 2.039–2.300 Å with a maximum difference of 0.261 Å, larger than that in dittmarite (0.187 Å); the O–Mg–O bond angles are in the range of 66.54°–101.37° with a maximum difference of 34.83°, also slightly larger than that in dittmarite (34.60°).

UiO-24-EN

There is also one Mg lattice site in UiO-24-EN.[13] Similarly, ^{25}Mg MAS and static spectra of this material were acquired at both 21.1 and 9.4 T (Fig. 4). The spectra are again dominated by the EFG as indicated by the observation that the signals, especially the static ones, exhibit typical line shapes owing to the second-order quadrupolar interactions. Furthermore, the resonance becomes much narrower at 21.1 T. The spectra of UiO-24-EN are broader than those of UiO-24-DAB, indicating a larger C_Q. Simulating the MAS spectra yields the following parameters: δ_{iso} = 4 ppm, C_Q = 3.3 MHz, and η_Q = 0.5. The static spectra can also be well fitted without the CSA. The larger EFG at the Mg can be attributed again to the more distorted MgO_6 octahedron. This is consistent with the crystal structure data[13] showing a large Mg–O bond length distribution from 2.006 to 2.360 Å and a large O–Mg–O bond angle range from 66.39° to 103.76°.

Correlations between the C_Q and the distortion of MgO_6 octahedra

With insertion of the organic templates into the interlayer space of dittmarite, the MgO_6 octahedra become more distorted, resulting in larger C_Q values. In the literature, linear correlations between the C_Q values and the parameters describing the distortion of the metal–oxygen octahedron in MgO_6,[16,19] ZnO_6,[62] AlO_6,[63,64] TiO_6,[1,65,66] and ZrO_6[4] have been reported. Several parameters have been suggested for estimating the relative degree of distortion around an octahedral site. The simplest parameter characterizing the distortion of the octahedral bond angle is the angular distortion index (DI) of Baur[67] defined as

$$[1] \qquad \mathrm{DI} = (\sum |\Theta_i - \Theta_m|)/12\Theta_m \qquad (i = 1 - 12)$$

where Θ_i and Θ_m are the observed and undistorted bond angles, respectively. The other parameters are the shear strain (ψ) and the longitudinal strain (α) suggested by Ghose and Tsang,[68] defined as

$$[2] \qquad \psi = \sum |\tan(\Theta_i - \Theta_m)| \qquad (i = 1 - 12)$$

$$[3] \qquad \alpha = \sum |\ln(l_i/l_0)| \qquad (i = 1 - 6)$$

where l_0 is the "ideal" Mg–O bond length, a perfect octahedron with bond length l_0 having the same volume as the "real" octahedron.

The DI, ψ, and α values of the Mg sites in dittmarite, UiO-24-DAB, and UiO-24-EN were calculated from their crystal structures. The distortion parameters are compared with their NMR parameters in Table 1. The C_Q values follow the trend mentioned above, i.e., the more distorted site has a larger quadrupolar coupling constant. The isotropic shifts of different compounds differ only by several ppm, suggesting that δ_{iso} is not sensitive to the distortion of the MgO_6 octahedra.

To examine the relationship between C_Q and the degree of distortion in the MgO_6 octahedra, the four C_Q values (from the three compounds under investigation and the origin assuming C_Q is zero for a perfect MgO_6 octahedron) were plotted against the three distortion parameters. As shown in Figs. 5A and 5B, the data points in the plots of C_Q against the angular parameters (DI and ψ) are rather scattered. On the other hand, an approximate linear correlation between C_Q and α appears to exist (Fig. 5C).

$$[4] \qquad C_Q\,(\mathrm{MHz}) = 10.5 * \alpha - 0.08$$

Similar phenomena were reported by Smith and co-workers[21] for some Mg oxyanion compounds. Since both the angular and the bond length distortions contribute to the EFG and, consequently, the C_Q, a parameter reflecting the contributions from the distortion of both bond angle and bond length may give a better correlation with the C_Q. Here we simply use the product of the angular and bond length distortion parameters such as DI*α and ψ*α. Indeed, slightly better linear correlations were established when these new parameters were used (Figs. 5D and 5E).

Table 1. Fitting parameters of the ^{25}Mg spectra of magnesium phosphates (MgPs) and calculated [MgO_6] octahedra distortion parameters of MgPs from their structure data.

Compound	δ_{iso} (ppm)	C_Q (MHz)	η_Q	DI	Shear strain (ψ)	Longitudinal strain (α)
Dittmarite	2±1	1.7±0.1	0.5±0.1	0.0591	1.139	0.226
UiO-24-DAB	2±2	2.7±0.1	0.4±0.1	0.0620	1.197	0.232
UiO-24-EN	4±2	3.3±0.2	0.5±0.1	0.0651	1.259	0.301
$MgHPO_4{\cdot}1.2H_2O$	−1±2	3.5±0.2	0.6±0.1	0.0625	1.202	0.341

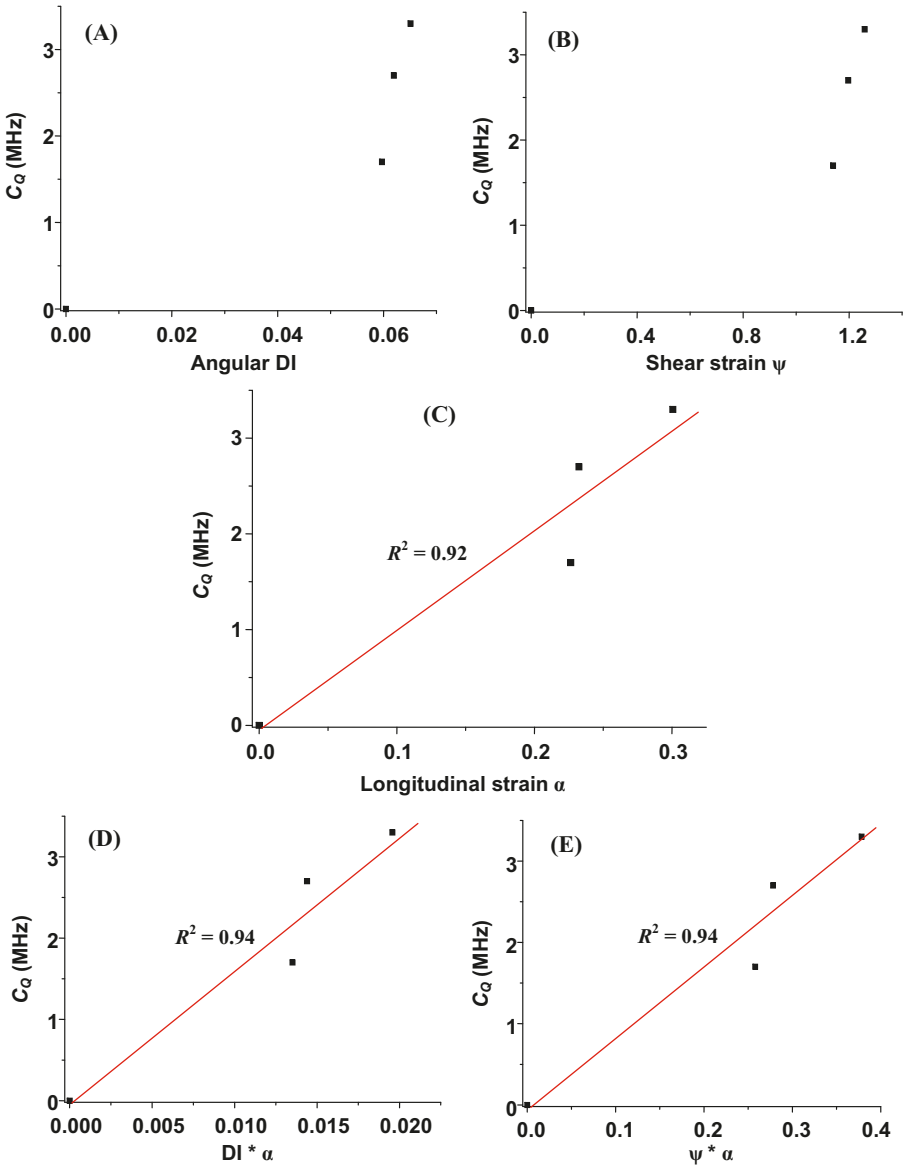
Fig. 5. Correlation between (A) the quadrupolar coupling constant (C_Q) and angular DI, (B) C_Q and the shear strain (ψ), (C) C_Q and the longitudinal strain (α), and C_Q and a combination of angular and bond length distortion parameters (D) DI*α and (E) ψ*α.

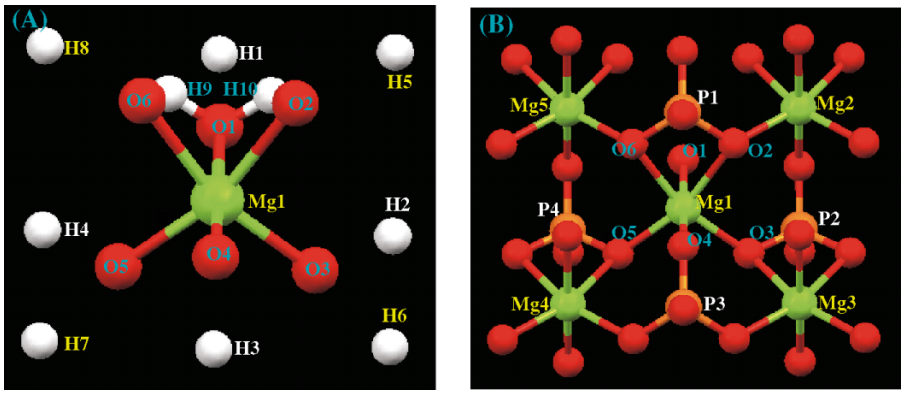


$$[5] \quad C_Q\,(\mathrm{MHz}) = 167.4{*}\mathrm{DI}{*}\alpha - 0.06$$

$$[6] \quad C_Q\,(\mathrm{MHz}) = 8.69{*}\psi{*}\alpha - 0.06$$

We wish to point out that these correlations should only be used as a guideline for estimating the parameters that describe the local environment around Mg in a material with unknown structure. This is because the structural parameters used to establish the correlations were derived from powder

Fig. 6. Clusters used in the ab initio calculations. (A) MgO_6H_{10} and (B) $Mg_5P_4O_{32}H_{34}$. H atoms in (B) are omitted for clarity.



XRD data, which are much less reliable than those from single crystal work.

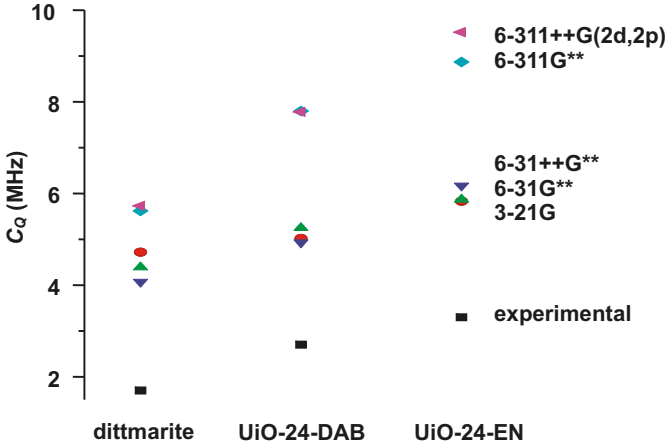
Theoretical calculations

To verify these empirical correlations, which are only based on four points, theoretical calculations were performed. The ab initio calculations were first carried out on a simple model compound, MgO_6H_{10} (Fig. 6A). The model consists of a MgO_6 octahedron and 10 H atoms connected to the 6 O atoms. The 10 H atoms are H1–H4 replacing P1–P4 (Fig. 6B), H5–H8 replacing Mg2–Mg5, and H9–H10 from the water molecule coordinated to Mg1. The calculation results (Fig. 7 and Table 2) are basis set dependent. However, the calculations do give the same trend as the experimental ones i.e., C_Q increases from dittmarite to UiO-24-DAB to UiO-24-EN with increasing distortion of the MgO_6 octahedra (Fig. 7), regardless of the basis sets used. The calculated trends are consistent with the empirical correlations between the C_Q and MgO_6 distortion parameters. However, all of the calculations overestimate the magnitude of the C_Q value for each compound. This is not completely unexpected, since the distortions of the MgO_6 octahedra are quite large and, therefore, should lead to large C_Q values. The reason why experimentally measured C_Q values are smaller might be due to the fact that the nature and the location of the atoms beyond the first coordination sphere also contribute to the C_Q, since the EFG is a long-range effect. It is possible that the spatial arrangements of the atoms in the second and third coordination spheres and even beyond affect the EFG in such a way that their contributions partially offset that from the distortion of the MgO_6 octahedron.

To verify this argument, the larger clusters with a composition of $Mg_5P_4O_{32}H_{34}$ (Fig. 6B) were truncated from the crystal structures. Indeed, smaller C_Q values (Table 2) that are in better agreement with the experimental ones were obtained. Among the basis sets used, the 6–31++G** basis set seemed to give overall the best predictions.

The Gaussian calculation results suggest that even larger clusters should be employed. This would, however, require much more expensive calculations. Alternatively, CASTEP,[52] a program able to calculate electronic properties of periodic structures, was applied. The results are also listed in Table 2. The calculations give the right trend, i.e., the C_Q values decrease in the order dittmarite < UiO-24-DAB < UiO-24-EN. However, the C_Q values calculated using the CASTEP are still overestimated. This is probably because the large number of atoms in unit cells limits the accuracy level of the calculation that can be performed. The fact that the model clusters used for calculation were built upon the structure derived from powder XRD data, which are not accurate enough, may also have led to the discrepancies between experimental and calculated C_Q values.

Fig. 7. Comparison of experimental and calculated quadrupolar coupling constant (C_Q) values of ^{25}Mg in dittmarite, $[NH_3(CH_2)_4NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-DAB), and $[NH_3(CH_2)_2NH_3]_{0.5}[MgPO_4{\cdot}H_2O]$ (UiO-24-EN). The calculations were performed using the MgO_6H_{10} cluster with different basis sets.



$MgHPO_4{\cdot}1.2H_2O$

The empirical relationships between C_Q and the structural parameters are useful. It allows one to extract, at least, partial information on the Mg local structure for the MgPs with unknown crystal structures, which is often the case for the MP derivatives. To illustrate this point, a layered acidic magnesium phosphate, $MgHPO_4{\cdot}1.2H_2O$,[39] was examined.

$MgHPO_4{\cdot}1.2H_2O$ was first synthesized in 1993 by Thomas and co-workers.[39] The special feature of this compound is that, unlike most layered magnesium phosphates, it undergoes reversible hydration up to 200 °C. The powder XRD pattern of the material synthesized in this study is shown in Fig. 8A. The number of reflections and their d spacing are exactly the same as those reported in the literature.[39,69] The pattern suggests that this material has an interlayer distance

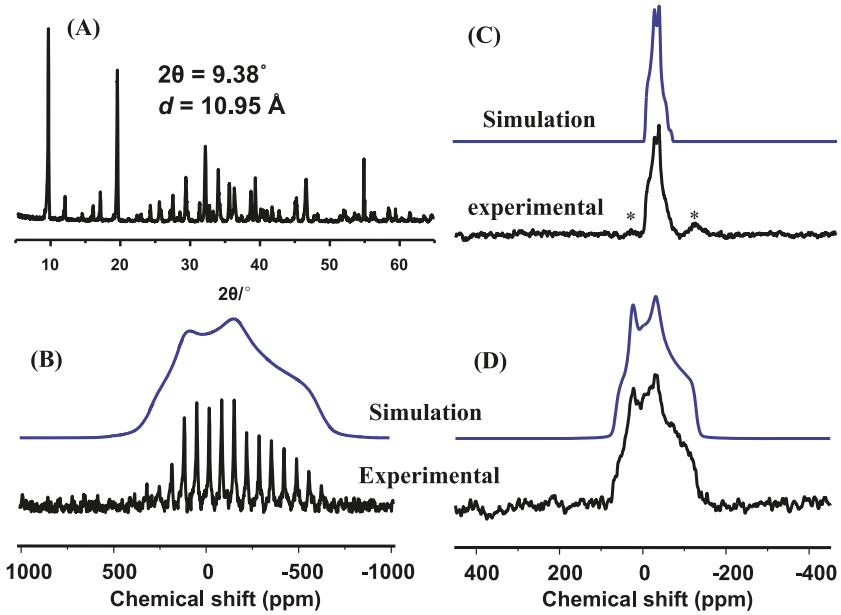
(A) Powder X-ray diffraction (XRD) pattern of $MgHPO_4{\cdot}1.2H_2O$ and (B) and (D)^{25}Mg static NMR spectra and (C) MAS NMR spectra of Mg in $MgHPO_4{\cdot}1.2H_2O$ at (B) 9.4 and (C) and (D) 21.1 T. Recycle delays of 5 and 0.5 s were used for 21.1 and 9.4 T, respectively. Scans (8192 and 1400), corresponding to 11.4 and 1.9 h, were collected for the static and MAS spectra at 21.1 T, respectively. Scans (129 760), corresponding to 18.0 h, were collected for the static spectrum at 9.4 T. (* denotes spinning side bands.)



of 10.95 Å. Although the powder XRD data can be indexed on an orthorhombic cell, the crystal structure of this compound has yet to be solved. ^{31}P MAS NMR spectrum (Fig. S2 in the Supplementary data) shows that there are two crystallographically nonequivalent P sites with equal occupancy.

To characterize the local Mg environment in this material, the ^{25}Mg MAS spectrum at 21.1 T was first acquired (Fig. 8C). The spectrum shows a typical line shape owing to the second-order quadrupolar coupling and can be well fitted using a single set of parameters: $\delta_{iso} = -1$ ppm, $C_Q = 3.5$ MHz, and $\eta_Q = 0.6$, suggesting that there is only one Mg site. The static spectrum at 21.1 T also exhibits a typical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

quadrupolar line shape and can be well simulated using the above parameters without the CSA. The ^{25}Mg static DFS-QCPMG spectrum of $MgHPO_4 \cdot 1.2H_2O$ at 9.4 T was obtained and it can be well simulated by using the parameters extracted from the spectra at 21.1 T, confirming the reliability of these parameters. Using the C_Q value and eqs. [4]–[6], α, DI*α, and ψ*α are calculated to be 0.341, 0.0213, and 0.410, respectively. Further, using the α value derived from eq. [4], the angular DI and ψ were further calculated to be 0.0625 and 1.202. Comparing these distortion parameters with other MgPs discussed earlier (Table 1), the MgO_6 octahedron in $MgHPO_4 \cdot 1.2H_2O$ should have a larger bond length dispersion than all other three MgPs, whereas the angular distortion is similar to that of UiO-24-DAB.

Conclusions

In this work, ^{25}Mg MAS and static NMR spectra of several representative MgPs at two field strengths were acquired. The spectra are dominated by the second-order quadrupolar interaction. From the observed spectra, the quadrupolar parameters were extracted via spectral simulations. In this series of related layered MgPs, the C_Qs are sensitive to the distortion in the MgO_6 octahedron. Correlations between C_Q and the structural parameters reflecting the distortion such as α and its products with angular DI and ψ (DI*α, and ψ*α) were observed. Theoretical calculation results showed that the EFG and, therefore, the C_Q of the Mg site are not only determined by the distortion of the MgO_6 octahedron but also affected by the spatial arrangement of the atoms in the second and third coordination spheres. Solid-state ^{25}Mg NMR was used to obtain partial structural information on $MgHPO_4 \cdot 1.2H_2O$, which belongs to the same class of layered MgP, but the structure is unknown. The results show that this material only has a single Mg site and the MgO_6 octahedron has a large Mg–O bond length dispersion.

Supplementary data

Supplementary data are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Acknowledgements

Y.H. acknowledges the financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) for a research grant and the Canadian Foundation for Innovation (CFI) for the equipment grants. Funding from the Canada Research Chair program is also gratefully acknowledged. Access to the 900 MHz NMR spectrometer was provided by the National Ultrahigh Field NMR Facility for Solids (Ottawa, Ontario), a national research facility funded by the CFI, the Ontario Innovation Trust, Recherche Québec, the National Research Council of Canada, and Bruker BioSpin, and managed by the University of Ottawa (http://nmr900.ca). The authors wish to thank Professor R.W. Schurko (University of Windsor, Windsor, Ontario) for providing the DFS-QCPMG pulse sequence and Professor R.E. Wasylishen (University of Alberta) for the WSOLIDS1 software. They also thank Drs. Terskikh, Pawsey, and Kirby for technical assistance in the NMR experiments.

$[Pt@Pb_{12}]^{2-}$ — A challenging system for relativistic density functional theory calculations of ^{195}Pt and ^{207}Pb NMR parameters

Boris Le Guennic and Jochen Autschbach

Abstract: We report computations of NMR chemical shifts and indirect spin-spin coupling constants (*J* couplings) for the $[Pt@Pb_{12}]^{2-}$ "superatom". The system is strongly influenced by relativistic effects. The Pt–Pb coupling constant is predicted to be negative, with its magnitude being in reasonable agreement with experiment. Pt and Pb chemical shifts also agree reasonably well with experiment. The Pb shielding tensor is strongly anisotropic, with a large deshielding principal component dominated by magnetic coupling between frontier orbitals of the cluster that resemble atomic g orbitals. The NMR parameters are sensitive to approximations made in the computations and require the inclusion of spin-orbit coupling in the theoretical model to achieve reliable results. Computing the NMR parameters of the compact $[Pt@Pb_{12}]^{2-}$ system with its many electrons proves to be a challenging test case for relativistic density functional methods.

Key words: NMR shielding, NMR indirect spin-spin coupling, relativistic quantum chemistry, density functional theory, superatoms.

Résumé : Les déplacements chimiques RMN ainsi que les constantes de couplage spin-spin indirectes (couplages *J*) ont été calculés pour le « super-atome » $[Pt@Pb_{12}]^{2-}$ pour lequel les effets relativistes jouent un rôle primordial. Il est ainsi proposé que la constante de couplage Pt–Pb est probablement négative, son amplitude étant en bon accord avec les résultats expérimentaux. De même, les déplacements chimiques tant du Pt que du Pd reproduisent raisonnablement les données expérimentales. Le tenseur de blindage du Pb est fortement anisotrope, avec une importante composante principal de déblindage dominée par le couplage magnétique entre les orbitales frontières du cluster ressemblant à des orbitales atomiques de type g. Les paramètres RMN sont fortement sensibles aux approximations faites dans les calculs. En particulier, la prise en compte du couplage spin-orbite dans le modèle théorique est indispensable pour obtenir des résultats fiables. Le calcul des paramètres RMN du système compact $[Pt@Pb_{12}]^{2-}$, avec ses nombreux électrons, s'est avéré représenter un défi pour les approches DFT relativistes.

Mots-clés : blindage RMN, couplage spin-spin indirect en RMN, chimie quantique relativiste, théorie de la fonctionnelle de la densité, super-atome.

Introduction

The past decade has seen intense research efforts directed at stable metal clusters that can be classified as artificial atoms or *superatoms* that are potential building blocks for nanoscale structures. This is particularly true for gold clusters because of the recent discovery of their fascinating optical, magnetic, and catalytic properties.[1–9] Among the various highly symmetrical geometries adopted by these systems, metal-encapsulated icosahedral gold clusters have been intensively studied both theoretically and experimentally.[10–19]

The closed-shell neutral WAu_{12} cluster may be singled out as a system where theoretical methods have been proven to be particularly useful to guide experimental efforts. Pyykkö and Runeberg[20] first predicted its existence and explained its stability by a synergy of aurophilic attraction and relativistic effects. This species was experimentally synthesized and characterized in the gas phase by Li et al.[10] a few months later. Pyykkö et al.[21] theoretically predicted a large selection of properties for this system, such as vibrational spectra, NMR chemical shifts, spin-spin and quadrupole coupling constants, and optical spectra. WAu_{12} was also used by Qiu et al.[12] as a benchmark molecule in the comparison of several computational approaches for the calculation of interatomic distances, atomization energies, energy gaps, and electron affinities. More recently, photoabsorption and catalytic properties were investigated on the basis of density functional theory (DFT),[16,22] and a DFT molecular dynamics study revealed surface melting of this cluster between ~100 and 200 °C.[23] Finally, Wang and co-workers[19,24] studied the binding energies of a single ligand on WAu_{12} and an isoelectronic series, whereas it was predicted that the metal-

surface-protected $W@Au_{12}(CO)_{12}$ molecule could exist also in the bulk.[25]

However, gold does not have a monopoly of forming ion-encapsulated icosahedral clusters. For instance, several ion-centered plumbaspharene clusters $[MPb_{12}]^x$ (M = Mg, Al, Co, Ni, Pd, Pt; $x = +1$, 0, –1, or –2) have been studied experimentally,[26–30] or predicted theoretically (M = Mg, Al, Sc, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Ga, In, Sr, Ba, Tl, Pb, Pu; $x = +1$ or 0).[31–36] Among these, one may focus on the inclusion compound $[Pt@Pb_{12}]^{2-}$ synthesized by oxidation of the $[Pb_9]^{4-}$ Zintl ion, since $[Pt@Pb_{12}]^{2-}$ is the only hitherto known Pt-centered bare-metal cluster.[28,29] This lead cluster was mainly characterized by energy-dispersive X-ray analysis and single crystal XRD. However, the present work is motivated by the reported experimental ^{207}Pb and ^{195}Pt NMR spectroscopy data. In particular, the measurement of a Pt–Pb coupling constant allows us to study this fascinating property theoretically, while being able to make a comparison with experimental data. Though there is a significant amount of literature related to ^{207}Pb and ^{195}Pt chemical shifts (see refs. 37–44 for pertinent reviews), measurements of Pb–Pt spin-spin coupling constants are rare. Indeed, since the first reported value of ^1J(Pt–Pb) in platinum–lead bonded compounds by Carr et al.,[45] and the observation of a small Pt–Pb coupling (^1J(Pt–Pb) = 274 Hz) in the ^{195}Pt NMR spectrum of a Pb(II)–Pt(II) complex by Balch et al.,[46] no further data has been published until the work of Esenturk et al.[28,29]

To our knowledge, among the quickly growing amount of works on first-principles relativistic calculations of transition-metal NMR properties (see refs. 44 and 47–53 for recent reviews), relatively few of them were devoted to the computation of ^{207}Pb NMR chemical shifts.[54–57] For early semiempirical calculations of Pb NMR chemical shifts see ref. 58. Calculations of spin-spin couplings of Pb to light nuclei have been addressed in several studies of "benchmark" type character,[59–66] but there are still no computational data on Pb – heavy metal couplings. Following pioneering work by Gilbert and Ziegler,[67] recent years have seen an increasing number of computational studies of Pt NMR parameters.[68–79] However, it remains very challenging to accurately predict Pt NMR parameters because of their strong sensitivity to geometry, solvent effects, relativistic effects, and related approximations in the computational model.[76–78]

The NMR parameters in $[Pt@Pb_{12}]^{2-}$ are particularly fascinating from a theoretical point of view because this system is composed entirely of two of the heaviest NMR active atoms. In the present work, the ^{207}Pb and ^{195}Pt chemical shifts as well as the Pt–Pb and Pb–Pb spin-spin coupling constants of $[Pt@Pb_{12}]^{2-}$ are computed and investigated using relativistic DFT. The results are discussed in comparison with experimental data.[28,29] The tensorial properties[80] of the nuclear magnetic shielding, in particular of Pb in $[Pt@Pb_{12}]^{2-}$, are also considered. We report a rather pronounced sensitivity of the computed data to the level of theory used. Our best theoretical estimates are in reasonable agreement with experimental data, indicating that $J(^{195}Pt–^{207}Pb)$, or J(Pt–Pb) in shorthand notation, is negative. The Pt nucleus inside the Pb cage has an isotropic shielding tensor with a comparatively small paramagnetic component. The Pb shielding tensors are strongly anisotropic. The calculations confirm the large deshielding (downfield shift) of the Pb nuclei relative to the $PbMe_4$ reference noted by the experimentalists that was tentatively attributed to s aromaticity in the Pb_{12} cage.[29]

Computational details

Relativistic DFT computations, based on the zeroth-order regular approximation (ZORA) Hamiltonian,[81] were carried out with 2004 and 2010 versions of the Amsterdam Density Functional (ADF) package.[82,83] The computations employed a modified version[84,85] of the code for the two-component relativistic computation of indirect nuclear spin-spin coupling constants originally developed by Autschbach and Ziegler[61,86] and a modified version[74,87] of the code developed by Wolff et al.[88] for the two-component relativistic computation of nuclear shielding constants. See refs. 68–70 for a more detailed description of the computational protocol. Time-dependent DFT (TDDFT) computations of singlet excitation energies employed the linear scaling code developed by van Gisbergen et al.[89] In all calculations, a distance cut-off parameter of 7.5 was employed to speed up the computations. Numerical integration accuracy parameters of 6.0 and 4.5 were assigned for the atomic cores and the remainder of the molecule, respectively, roughly indicating the number of significant figures for the electron density integration.

The Vosko–Wilk–Nusair (VWN)[90] local density approximation (LDA) functional was used in the geometry optimization and some computations of the NMR parameters. For comparison, the revised Perdew–Burke–Ernzerhof (PBE)[91–94] nonhybrid functional and the PBE0 hybrid density functional[95] (25% Hartree–Fock exchange) were applied in calculations of NMR chemical shifts and J-coupling constants. The geometry optimization was carried out in D_{5d} symmetry employing valence triple-ζ Slater-type atomic orbital (AO) basis sets with polarization functions (TZP). Inner shells up to, but not including 5spd and 6sp for Pt and Pb, were kept as frozen core. All electron Slater-type multiple-z basis sets with one (TZP), two (TZ2P), and for Pt four (QZ4P) sets of polarization functions, respectively, were used for the computations of NMR chemical shifts and spin-spin coupling constants as discussed in the Results section. In addition, for some of the J-coupling computations, the Pt and Pb TZ2P basis were augmented with an even-tempered set of 1s and 2p Slater functions with exponents α up to 10^4 as detailed in ref. 84. We denote this basis set as JCPL. Overall, the computations employed between 1580 and 2182 Cartesian Slater-type basis functions. Unless noted otherwise, the J-coupling computations employed a spherical Gaussian nuclear charge model to model effects from a finite nuclear volume.[85] The magnetogyric ratios used to convert calculated reduced spin-spin coupling constants K to J-coupling constants in units of Hz were 5.8385 and 5.5805 for Pt and Pb, respectively,[96] in units of 10^7 rad (T s)$^{-1}$. Solvent effects have been taken into account in a subset of the computations by using COSMO (conductor-like screening model)[97] as implemented in ADF.[98] The radii of the atomic spheres used in the COSMO calculations were 2.1 and 2.4 Å for Pt and Pb, respectively. The solvent used in the NMR experiments was DMF. Therefore, we used a value of 37 for the dielectric constant in the COSMO calculations.

Results and discussion

Experimentally, $[Pt@Pb_{12}]^{2-}$ was found to have near-perfect I_h point symmetry. Because of the lack of support of this point symmetry group in the software version used for the geometry optimizations, the geometry optimization was carried out in D_{5d} symmetry, which is a subgroup of I_h. The optimized structure is shown in Fig. 1. Excellent agreement between the optimized and experimental geometries is obtained with average optimized distances of 3.051 Å (expt. 3.058 Å) and 3.209 Å (expt. 3.216 Å) for the Pt–Pb and Pb–Pb bonds, respectively. A comparatively large HOMO–LUMO gap of 1.97 eV is computed with COSMO/PBE/TZP, with a fivefold degenerate HOMO at –3.47 eV and a fourfold degenerate LUMO at –1.51 eV. Gas-phase calculations yielded a positive HOMO but the same frontier orbital degeneracy as the COSMO computations and a comparable value of 1.96 eV for the HOMO–LUMO gap. TDDFT computations with the PBE functional located a set of lowest energy allowed singlet transitions in the range of 2.7 to 3.2 eV both for gas-phase and COSMO computations (scalar ZORA, TZP). The absorption energy range is consistent with the intense reddish brown color reported in refs. 28 and 29.

Some of the scalar relativistic frontier orbitals are shown in Fig. 2. The triply degenerate HOMO-1 level exhibits distinct p-like superatom orbitals with inner nodes in the Pb_{12} cage. The HOMO and LUMO orbitals exhibit the shape and nodal structure of atomic g orbitals that, in a perfectly spherical atom and with equal populations, would be ninefold degenerate. In $[Pt@Pb_{12}]^{2-}$ these g-like orbitals are split into the fivefold degenerate HOMO (of H_g symmetry in the I_h point group[27]) and the fourfold degenerate LUMO (G_g). The orbital diagram in Fig. 1 indicates that these are linear combinations of Pb 6p AOs in the Pb_{12} cage. The frontier orbitals are seen to be comparable to those in the $AlPb^{+}_{12}$ superatom[27] albeit with a much smaller HOMO–LUMO gap in $[Pt@Pb_{12}]^{2-}$.

The calculated NMR chemical shifts for $[Pt@Pb_{12}]^{2-}$ are collected in Table 1. When assessing the Pt and Pb chemical shifts with respect to experiment, one should keep in mind that the calculation of the chemical shift involves the nuclear magnetic shielding σ of the probe and a reference nucleus:

$$[1] \qquad \delta = \frac{\sigma^{ref} - \sigma}{1 - \sigma^{ref}} \approx \sigma^{ref} - \sigma$$

The approximation is valid for small σ^{ref}. For convenience, we use the approximate form in this work. For heavy nuclei such as ^{195}Pt and ^{207}Pb neglecting the reference shielding in the denominator may lead to chemical shift changes on the order of 1%, which is much less than the variations of the chemical shifts with respect to approximations in the computational model.

Calculations with a hybrid functional (PBE0) turned out to be extremely demanding of computational resources and, in particular in conjunction with COSMO and spin-orbit (SO) coupling, suffered from very slow convergence. Therefore, a set of calculations was realized that allowed some extrapolations, with the PBE0 computations performed at an affordable level of theory. Given the definition of the chemical shift, eq. [1] systematic errors in the computations may cancel between probe and reference, or affect only one of the compounds in which case errors do not cancel. We refer the reader to a detailed discussion of the Pt shielding in the reference compound $[PtCl_6]^{2-}$ in solution;[73,76] the uncertainties in the Pt chemical shift from the reference may easily amount to several hundred ppm. The variations among the different calculations listed in Table 1 can be used to assess the overall accuracy limits of the computations.

Both the Pt and Pb chemical shift of $[Pt@Pb_{12}]^{2-}$ are sensitive to approximations in the computational model. The calculated values bracket the experimental data. The comparison of scalar relativistic computations with those that include SO coupling reveals large positive SO shielding contributions for the Pt nucleus both in the reference and in $[Pt@Pb_{12}]^{2-}$. The SO mechanism is much more pronounced in the $[PtCl_6]^{2-}$ reference, yielding a large net positive SO effect on the Pt chemical shift. For Pb, the SO effect on the shielding is also positive both in the reference and in $[Pt@Pb_{12}]^{2-}$, but here the magnitude for $[Pt@Pb_{12}]^{2-}$ dominates, leading to a net negative SO effect on the Pb shift. Switching the functional from PBE to the simpler VWN local density approximation has a comparatively small impact at the COSMO/SO level of theory. The net solvent effects on the chemical shifts do not exceed 300 ppm. This allows further comparisons based on gas-phase computations, which afforded faster SCF convergence. The comparison of the B1 with the B2 = TZP data shows that basis set effects are sizable for the Pb shift in the SO computations. Finally, there is a significant change in the chemical shifts when going from the "pure" PBE to the hybrid PBE0 functional at the scalar ZORA level. Unfortunately, full COSMO SO PBE0 computations with the large basis set B1 were not feasible for $[Pt@Pb_{12}]^{2-}$. Extrapolating the trends among the different computations, the Pb chemical shift expected for this level of theory likely exceeds the 3578 ppm obtained with the PBE nonhybrid functional. For Pt, the functional effect is also likely to increase the magnitude of the negative chemical shift. The chemical shifts obtained here at the highest level of theory that we were able to apply (PBE/SO/COSMO with the larger basis set) are smaller in magnitude than the experimental shifts, and therefore using a hybrid functional might offer some improvement both for Pt and Pb. However, SO effects must not be neglected.

The Pt shielding tensor in $[Pt@Pb_{12}]^{2-}$ is isotropic, as dictated by the highly symmetric icosahedral environment of the Pt atom. The data in Table 1 show that the Pt nucleus in the reference compound $[PtCl_6]^{2-}$ is particularly strongly deshielded while at the same time Pt in $[Pt@Pb_{12}]^{2-}$ is strongly shielded. Per eq. [1], this causes the Pt shift in $[Pt@Pb_{12}]^{2-}$ to be large and negative. The strong deshielding of Pt in $[PtCl_6]^{2-}$ was investigated in ref. 75; it is a result of a paramagnetic current density induced in the Pt 5d shell by the external magnetic field. Pyykkö et al.[21] reported large SO contributions to the ^{183}W chemical shifts in $W@Au_{12}$ and found an exceptionally strong shielding of the magnetic field inside the gold cage. By comparison, for the central Pt atom in $[Pt@Pb_{12}]^{2-}$ no particularly strong shielding from the Pb_{12} cage is noted. The atom-like (isotropic) diamagnetic shielding of Pt is on the order of 9300 ppm and partially compensated by paramagnetic shielding tensor contributions that are, however, much smaller than those in $[PtCl_6]^{2-}$. Therefore, the Pt shielding tensor in $[Pt@Pb_{12}]^{2-}$ is more similar to that of a free spherical non spin-polarized atom than the shielding tensor in

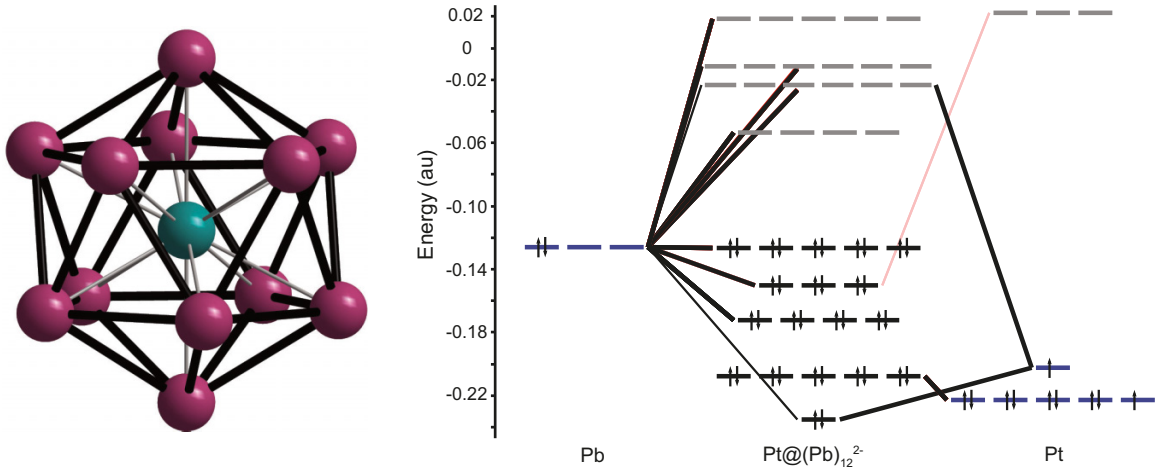

Fig. 2. Selected molecular orbitals (MOs) of $[Pt@Pb_{12}]^{2-}$ (scalar zeroth-order regular approximation (ZORA) conductor-like screening model (COSMO) / Perdew–Burke–Ernzerhof (PBE) / triple-ζ Slater-type atomic orbital (AO) basis set with polarization (TZP)). One of three degenerate HOMO-1 (p like), one of five degenerate HOMOs (g like), and one of four degenerate LUMOs (g like). Isosurfaces at ±0.003 au enclosing more than 95% of the electron density for the HOMO.

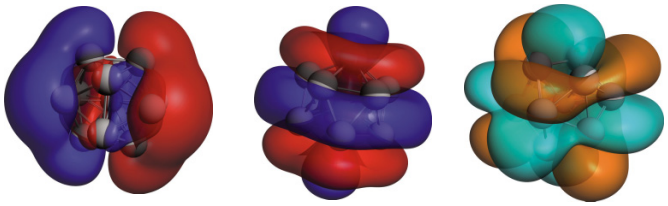

the reference compound. Paramagnetic contributions to the shielding tensor would be suppressed by symmetry for a spherical closed shell atom in the absence of SO coupling. The presence of sizable paramagnetic shielding terms demonstrate the impact of the deviation of the $[Pt@Pb_{12}]^{2-}$ superatom from spherical symmetry on the NMR shielding.

All computations confirm the atypical large positive chemical shift of the Pb nuclei in $[Pt@Pb_{12}]^{2-}$, which was already noted by the experimental group[28,29] who reported the synthesis and NMR spectra of $[Pt@Pb_{12}]^{2-}$. This large downfield shift of the NMR signal of Pb in $[Pt@Pb_{12}]^{2-}$ calls for a more detailed analysis. Owing to the tetrahedral Pb environment, the Pb shielding tensor in the reference compound $PbMe_4$ is isotropic, with a calculated diamagnetic shielding of 9941 ppm and a paramagnetic shielding of –5462 ppm, which is to a large extent compensated by a 3007 ppm SO shielding (COSMO/PBE/B1/SO). The shielding tensor of Pb in $[Pt@Pb_{12}]^{2-}$ has axial symmetry as depicted in Fig. 3, with a negative radial principal component σ_R and two positive degenerate orthoradial components σ_O. The anisotropy of the tensor is caused by the paramagnetic and SO mechanisms. The orthoradial components are on the order of $+10^4$ ppm, close to the diamagnetic shielding. The radial component is almost of the same magnitude but negative, with negative paramagnetic and SO "linear response" mechanisms reinforcing each other. An analysis[74,75] of the radial shielding tensor component in terms of contributions from individual MOs carried out within a SO computation indicated very large contributions from the HOMO level, with the bulk of the paramagnetic mechanism caused by matrix elements involving magnetic coupling between the HOMOs and LUMOs. The strong negative radial shielding tensor component calculated for Pb in $[Pt@Pb_{12}]^{2-}$ therefore supports the notion of σ aromaticity in the cluster[27,29] by which the magnetic field may induce particularly strong paramagnetic ring-current densities in the surface of the Pb_{12} cage. Per eq. [1] the large negative contributions in the shielding tensor of the Pb nuclei in $[Pt@Pb_{12}]^{2-}$ lead to a particularly large positive Pb chemical shift.

The Pt–Pb spin-spin coupling constants J(Pt–Pb) calculated at various levels of theory are collected in Table 2. The relative importance of different J-coupling mechanisms is similar for all calculations and therefore a detailed breakdown is not provided. The spin mechanism (Fermi-contact and, to a minor degree, spin-dipole) is negative and amounts to about 1.1 times the total coupling constant. This mechanism therefore dominates the coupling constant. It is to a small degree balanced by contributions from the orbital-current density mechanism. The diamagnetic contributions are smaller than 0.5 Hz and therefore they can safely be ignored. In Table 2 the basis set "LD" is a locally dense basis set of TZ2P quality where the high-exponent augmentation of the JCPL basis, required to calculate accurate spin-mechanism contributions, has only been used for selected atoms for which coupling constants were determined. The comparison with the full JCPL basis set for all atoms shows that, whereas the results are in good agreement across different theoretical levels, the differences cannot be completely ignored. The LD basis set is somewhat imbalanced, since the high-exponent augmentation not only affects the quality of the calculated coupling constants but also the extent to which relativistic effects in the ground-state electronic structure are described variationally both for core and valence orbitals. Thus, for a system like $[Pt@Pb_{12}]^{2-}$ the use of a locally dense basis set is not entirely satisfactory. We note in passing that larger differences between the LD and the full JCPL basis set results were obtained for

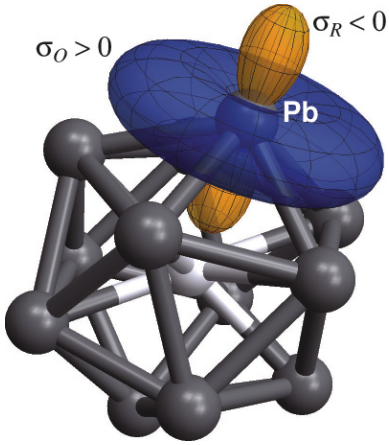
PBE0/TZP/SC	–5937	–3247

Note: Experimentally, $J(^{195}Pt–^{207}Pb)$ = 3440 Hz. PBE, Perdew–Burke–Ernzerhof; COSMO, conductor-like screening model; TZP, triple-ζ Slater-type atomic orbital (AO) basis set with polarization; VWN, Vosko–Wilk–Nusair.

[a]See the Computational details section for an explanation of the applied methods. LD = locally dense basis set where JCPL was used only for four atoms for which coupling constants were calculated, and TZ2P for the remaining atoms. JCPL = TZ2P augmented with high-exponent s and p basis functions. SC = scalar ZORA, SO = spin-orbit ZORA. Gaussian nuclear model applied except for "point nuc". The estimated uncertainty of K for PBE0 is ±10 because of slow convergence of the PSO mechanism. Gas-phase calculations unless the COSMO model is indicated.

Fig. 3. Graphical representation of the ^{207}Pb shielding tensor in $[Pt@Pb_{12}]^{2-}$ (conductor-like screening model (COSMO) / Perdew–Burke–Ernzerhof (PBE) / spin orbit (SO) with QZ4P(Pt)/TZ2P(Pb) basis). The plot indicates the tensor orientation as well as the relative magnitudes and signs of the principal components (dark gray / light gray = positive/negative). The diamagnetic contribution to the tensor is almost perfectly isotropic, but the paramagnetic +SO contributions are strongly anisotropic and overall negative, with a particularly large negative radial σ_R component in the direction of the Pb–Pt axis. Shielding tensor plot is as described in ref. 99.



the two- and three-bond Pb–Pb coupling constants (vide infra).

Since J(Pt–Pb) is dominated by the spin mechanism, finite nucleus effects are pronounced; they reduce the magnitude of J(Pt–Pb) by as much as 16%. SO coupling increases the magnitude of J(Pt–Pb) by ~11%–12% (PBE). The simultaneous neglect of finite nucleus corrections and SO coupling therefore offers some error compensation for this system. The importance of augmenting the basis set with high-exponent basis functions in addition to those already present in the ZORA-optimized ADF basis sets is seen in the comparison of the TZP with the JCPL data, with JCPL yielding an over 30% increase in the coupling constant magnitude at the scalar ZORA PBE level of theory. The effects from the functional are also pronounced, with an increase of $|J|$ from VWN to PBE to PBE0 by ~40%. Solvent effects are seen to slightly reduce the coupling constant magnitude.

Since the magnetogyric ratios for ^{195}Pt and ^{207}Pb are both positive the reduced coupling and the J coupling have the same sign. The calculations consistently predict J(Pt–Pb) to be negative. It is well-recognized that it is difficult to experimentally determine the sign of coupling constants ^1J(Pb–M) where M is a metal nucleus because of the often strong

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

polarizability and relative weakness of Pb–M bonds.[41] This situation is also partially explained by the lack of available experimental data. A comparison with similar platinum–tin compounds may be used to work around this problem. For instance, Wrackmeyer[41] proposed a positive sign for ^1J(Pt–Pb) in platinum–lead bonded compounds,[45] by considering data for comparable Pt–Sn complexes.[100] In the present case, because reasonable agreement with experiment is obtained for the heavy-metal chemical shifts as well as for the coupling constant magnitude, it is unlikely that the computations of the coupling constants predict the wrong sign. We therefore propose that $J(^{195}Pt–^{207}Pb)$ in $[Pt@Pb_{12}]^{2-}$ has a negative sign.

We have also calculated the Pb–Pb coupling constants, but owing to the lack of experimental data we forgo a detailed discussion. At the PBE/JCPL/SO/COSMO level of theory, using a Gaussian nuclear model, we have determined the reduced one-bond Pb–Pb coupling as 13 736, the two-bond coupling as –2235, and the three-bond coupling as 1639, in SI units of 10^{19} T^2/J.

Summary

Spin-orbit coupling causes important contributions to NMR parameters in $[Pt@Pb_{12}]^{2-}$ that may be considered as a "strongly relativistic" system because it is entirely composed of heavy atoms. The calculated NMR parameters proved to be somewhat sensitive to the computational model, but overall the agreement with experimental data for the highest affordable levels of theory is acceptable. Ideally, the computations should combine the gains in accuracy from including SO coupling, from using a hybrid functional, and from using a very flexible basis set with high-exponent augmentation for all atoms. The more affordable COSMO/PBE/B1/SO computational model appears to offer a good compromise. All calculations of $J(^{195}Pt–^{207}Pb)$ predicted this coupling constant to be negative. The Pb shielding tensor in $[Pt@Pb_{12}]^{2-}$ is strongly anisotropic. The large negative radial principal component calculated for the Pb shielding tensor is consistent with the proposed σ aromaticity in the Pb_{12} cage. The paramagnetic mechanism for the radial Pb shielding tensor component can, to a large extent, be attributed to magnetic coupling between g-orbital-like superatom HOMOs and LUMOs, resulting in a particularly strongly downfield shifted (deshielded) NMR resonance for the Pb nuclei in $[Pt@Pb_{12}]^{2-}$.

Abstract: The results of a $^{35/37}$Cl solid-state nuclear magnetic resonance (SSNMR) study of the 1-butyl-3-methylimidazolium chloride complex of *meso*-octamethylcalix[4]pyrrole (**1**) are reported. Line shapes obtained from magic-angle-spinning and stationary powder samples collected at 9.4 and 21.1 T are analyzed to provide the $^{35/37}$Cl quadrupolar tensor and chemical shift (CS) tensor and their relative orientation. The relatively high symmetry of the chloride ion coordination environment is manifested in the small value of the quadrupole coupling constant, $C_Q(^{35}Cl) = 1.0$ MHz. The isotropic chemical shift of 120 ppm (with respect to NaCl(s)) is at the upper edge of the typical range seen for organic hydrochlorides. Consideration of chemical shift anisotropy (span, $\Omega = 50$ ppm) and non-coincidence of the quadrupolar and CS tensors were essential to properly simulate the experimental spectra. The utility of gauge-including projector-augmented wave density functional theory (GIPAW-DFT) calculations of chlorine quadrupolar and CS tensors in organic chlorides was explored by validation against available benchmark experimental data for solid amino acid hydrochlorides. The calculations are shown to systematically overestimate the value of the ^{35}Cl quadrupole coupling constant. Additional calculations on various hydrated and solvated models of **1** are consistent with a structure in which solvent and water of hydration are absent.

Key words: solid-state NMR, octamethylcalix[4]pyrrole, quadrupolar coupling, chemical shift tensor, halogen NMR, solvates, ion binding, receptors.

Résumé : On rapporte les résultats d'une étude RMN à l'état solide (RMN-ES) du $^{35/37}$Cl du complexe du chlorure de 1-butyl-3-méthylimidazolium avec le *méso*-octaméthylcalix[4]pyrrole (**1**). On a analysé les formes des raies obtenues pour des échantillons de poudre à l'état stationnaire et à l'angle de rotation magique, à 9,4 et 21,1 T, pour en extraire le tenseur quadripolaire et le tenseur du déplacement chimique (DC) du $^{35/37}$Cl ainsi que leur orientation relative. La symétrie relativement élevée de l'environnement de coordination de l'ion chlorure se manifeste par la faible valeur de la constante de couplage quadripolaire, $C_Q(^{35}Cl) = 1{,}0$ MHz. Le déplacement chimique isotrope de 120 ppm (par rapport au NaCl) se trouve à la limite supérieure de la plage typique observée pour les chlorhydrates organiques. Une considération de l'anisotropie du déplacement chimique (portée, $\Omega = 50$ ppm) et de la non coïncidence des tenseurs quadripolaires et du déplacement chimique sont essentiels pour simuler correctement les spectres expérimentaux. L'utilité des calculs des tenseurs quadripolaires et du déplacement chimique du chlore, par la théorie de la fonctionnelle de la densité en utilisant une onde améliorée par un opérateur de projection et comportant une jauge (« GIPAW-DFT »), est vérifié en comparant avec les données expérimentales disponibles pour des chlorhydrates solides d'acides aminés. Il est démontré que les calculs surévaluent systématiquement la valeur de la constante de couplage quadripolaire du ^{35}Cl. Des calculs supplémentaires sur divers modèles hydratés et solvatés du composé **1** sont en accord avec une structure dans laquelle le solvant et l'eau d'hydratation sont absents.

Mots-clés : RMN à l'état solide, octaméthylcalix[4]pyrrole, couplage quadripolaire, tenseur du déplacement chimique, RMN des halogènes, produits solvatés, fixation d'ion, récepteurs.

Introduction

Calix[*n*]arene rings are metacyclophanes made up of aromatic units bridged with methylene links. These units have a hydrophobic wide rim and a hydrophilic narrow rim that encompass a cavity, making them ideal for encapsulating smaller guest molecules.[1,2] The rings can be functionalized to tune a variety of physical properties, such as their hydrophobicity, solubility, reactivity, etc. For example, conversion of calixarenes to esters greatly increases their solubility in organic solvents whereas sulfonation increases water solubility.[2]

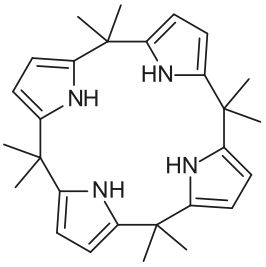
This article is part of a Special Issue dedicated to Professor Roderick E. Wasylishen in honour of his outstanding contributions to NMR spectroscopy, to chemistry in Canada, and to the training of NMR spectroscopists.

Scheme 1. Structure of *meso*-octamethylcalix[4]pyrrole.



Calix[*n*]arene rings are known for their high melting points, generally around or over 250 °C, which was one of the initial features that drew interest to this family of compounds.[2] Given their tunability and thermal stability, calix[*n*]arene rings have been used for a wide range of applications including field effect transistors, biomimetic catalysts, nonlinear optic materials, potential drug carriers, and ion separators.[1–3] Calix[4]arenes are the most prevalent member of the calixarene family, with a great number of different functionalized rings having been produced. In the anion complexation arena, compounds containing pyrrole have been shown to be effective anion receptors.[4,5] Simple and easy-to-make macrocyclic polypyrroles such as *meso*-octamethylcalix[4]pyrrole, a known anion receptor and shown in Scheme 1, have been known since 1886,[6] but their anion complexation properties, only reported in 1996, together with salt binding properties, continue to be explored.[7–14] This compound can be regarded as a pyrrolic analogue of the calixarenes and has been found to adopt a cone conformation when complexed with a halide ion (including Cl^-) in the solid state.[8–11,14]

Solid-state nuclear magnetic resonance (SSNMR) spectroscopy has proven to be an effective method for the characterization of calixarene structure and complexation properties in the past.[15–18] Spectra of several different nuclei have been collected and analyzed in these studies, including both spin 1/2 (e.g., ^{1}H or ^{13}C) and quadrupolar nuclei (e.g., ^{2}H, ^{133}Cs, or ^{139}La).[15–19] Over the past decade, chlorine-35/37 SSNMR spectroscopy has become an increasingly popular method for studying the environments of chloride ions in a variety of organic and inorganic materials.[20,21] For example, Wasylishen and co-workers[22] studied a series of organic hydrochlorides in 2001 and found the magnitude of the nuclear quadrupole coupling constant to be related to the hydrogen bonding environment. The appeal of the technique stems from the sensitivity of chlorine NMR parameters to the local structural and electronic environment about the chlorine nucleus. Whereas some of the NMR properties of chlorine, primarily the moderately large quadrupole moments (Q) for both nuclides (–81.65 and –64.35 mb for ^{35}Cl and ^{37}Cl, respectively),[23] make collection of spectra difficult, the increasing availability of high magnetic field instruments and signal enhancement techniques have allowed chlorine SSNMR to become more routine.[21,24–29] Despite its slightly higher quadrupole moment, the higher natural abundance and higher resonance frequency of ^{35}Cl vs ^{37}Cl (75.53% and 39.2 MHz vs 24.47% and 32.6 MHz at 9.4 T) makes the former the more popular nucleus for study.

Often, computational studies can serve as a useful complement to SSNMR experiments, providing additional information and aiding analysis. While several commercial programs exist for the calculation of both electric field gradient (EFG) and magnetic shielding (MS) tensor properties, many are not ideal for solids as calculations are effectively carried out in the gas phase. The gauge-including projector-augmented wave density functional theory (GIPAW-DFT) method as implemented in the CASTEP program, however, is ideal for solids as it utilizes plane wave pseudopotentials and periodic boundary conditions, thus describing the system as an infinite crystal lattice.[30–32] The GIPAW-DFT method has proven useful in SSNMR studies of a wide variety of nuclei, including chlorine SSNMR studies.[21,27,33–41] However, the majority of materials included in the few studies for which GIPAW-DFT has been shown to be effective in the calculation of chlorine NMR parameters were inorganic systems.[27,40] Thus, a systematic study involving a large data set is beneficial to establish the reliability of the method for calculating chlorine NMR tensor parameters in organic chloride systems. The series of amino acid hydrochlorides is ideal for this type of study, as there exists high quality SSNMR data along with X-ray (or neutron) diffraction structures for 15 of these salts.[22,24–26]

Here, we present a $^{35/37}$Cl SSNMR study of the chloride ion receptor, 1-butyl-3-methylimidazolium chloride complex of *meso*-octamethylcalix[4]pyrrole (**1**), and establish the reliability of GIPAW-DFT calculations of chlorine NMR parameters for organic chloride compounds.

NMR tensor conventions

Presented here is a brief summary of the NMR tensor conventions used in the current study. A more complete description of the relevant theory of SSNMR spectroscopy of half-integer quadrupolar nuclei under the high-field approximation may be found in the literature.[42,43] In this study, only the spectrum owing to the $^{35/37}$Cl central transition (CT, $m_I = +1/2 \leftrightarrow -1/2$) was observed and all experiments are assumed to have been carried out under "high field" conditions as the Larmor frequency (ν_0) was much greater than the quadrupolar frequency, $\nu_Q = 3C_Q\sqrt{1 + (\eta_Q^2/3)}/[2I(2I-1)]$, where C_Q is the quadrupolar coupling constant and I is the nuclear spin quantum number. The spectral line shapes observed in this study are primarily due to anisotropic magnetic shielding and the quadrupolar interaction.

Nuclear magnetic shielding can be described by a second rank tensor ($\boldsymbol{\sigma}$) that, when expressed in its principal axis system (PAS), can be characterized by three eigenvalues, $\sigma_{33} \geq \sigma_{22} \geq \sigma_{11}$, and three corresponding eigenvectors. Experimentally, it is the chemical shift (CS) tensor ($\boldsymbol{\delta}$) that is measured and, similar to the MS tensor, its magnitude may also be represented by three eigenvalues, $\delta_{11} \geq \delta_{22} \geq \delta_{33}$. In the case of chlorine, it is possible to convert between the MS and CS tensors as an absolute shielding scale is available. For an infinitely dilute solution of aqueous NaCl, Wasylishen and co-workers[22] showed that σ_{iso}(ref) is 974 ppm.[44] Therefore,

$$[1] \qquad \delta_{iso} = \frac{974 \text{ ppm} - \sigma_{iso}}{1 - 974 \text{ ppm}}$$

In this study, the Maryland convention is used. Under this convention the CS tensor components are described using the span (Ω) and skew (κ), with the isotropic part simply equal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

to one-third the trace of the tensor ($\sigma_{iso} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$; $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$).

$$[2] \qquad \Omega = \sigma_{33} - \sigma_{11} \approx \delta_{11} - \delta_{33}$$

$$[3] \qquad \kappa = \frac{3(\sigma_{iso} - \sigma_{22})}{\Omega} \approx \frac{3(\delta_{22} - \delta_{iso})}{\Omega}$$

Both ^{35}Cl and ^{37}Cl have nuclear spin quantum numbers of 3/2 and are therefore also affected by the nuclear quadrupole interaction (QI) between Q and the EFG at the nucleus. In its PAS, the EFG tensor may be diagonalized to yield three eigenvalues, which are ordered $|V_{33}| \geq |V_{22}| \geq |V_{11}|$. In this work, these eigenvalues are presented in terms of C_Q, which is related to the principal component of largest magnitude, and the asymmetry parameter (η_Q).

$$[4] \qquad C_Q = \frac{eV_{33}Q}{h}$$

$$[5] \qquad \eta_Q = \frac{V_{11} - V_{22}}{V_{33}}$$

where h is Planck's constant.

Because of the moderate quadrupole moment of both isotopes of chlorine it is often the case that observed line shapes are dominated by the QI. The breadth of the CT line shape of a stationary powdered sample owing to the QI depends on four parameters (C_Q, ν_0, I, and η_Q), as shown below.[45]

$$[6] \qquad \Delta\nu_{CT} = \left[\frac{3C_Q}{2I(2I-1)}\right]^2 \frac{(\eta_Q{}^2 + 22\eta_Q + 25)[I(I+1) - 3/4]}{144\nu_0}$$

The inverse proportionality between the CT line width and the Larmor frequency demonstrates why higher magnetic fields are advantageous for chlorine SSNMR studies: increasing B_0 increases ν_0, which results in an overall decrease in the second-order quadrupolar broadening of the CT. In addition, the effects of chemical shift anisotropy (CSA) increase at higher fields, allowing for them to be more easily observed. Generally, for both isotopes of chlorine, even in cases where the CSA can be easily observed, the spectrum obtained is usually still dominated by the QI and displays a typical second-order quadrupolar line shape.

The orientation of the EFG and CS tensors relative to one another can also be determined experimentally under favourable conditions. The relative orientation is described by three Euler angles.[42] The Arfken convention is used in this work, with the EFG PAS acting as the reference coordinate system.[46]

Experimental and computational details

Sample preparation

The 1-butyl-3-methylimidazolium chloride complex of *meso*-octamethylcalix[4]pyrrole (**1**) was prepared as described in ref. 7. The structure consists of a chloride ion bound to a *meso*-octamethylcalix[4]pyrrole ring and a 1-butyl-3-methylimidazolium group. The crystal structure described in ref. 7 also includes one dichloromethane and two water solvent molecules. Phase purity of the sample was confirmed by a ^{13}C CP/MAS NMR experiment collected with a spinning frequency of 8 kHz at 9.4 T. ^{13}C CP/MAS NMR of *meso*-octamethylcalix[4]pyrrole was also collected under the same conditions to ensure no free ligand was present in the sample. These spectra are included in the Supplementary data (Figs. S1 and S2).

The sample was also analyzed using thermogravimetric analysis (TGA) using a TA instruments 2960 SDT V3.0F unit in the temperature range of 25–593 °C, the outcome of which will be addressed in the Results and discussion section.

NMR spectroscopy

9.4 T

Chlorine-35/37 SSNMR experiments were carried out on a 400 MHz (B_0 = 9.4 T) Bruker Avance III spectrometer at the University of Ottawa, Ottawa, Ontario. A 4 mm Bruker HX MAS probe, tuned to 39.2 MHz (^{35}Cl) or 32.6 MHz (^{37}Cl), was used. Samples were ground into fine powders and packed into 4 mm o.d. zirconia rotors. Experimental setup and pulse calibrations were performed using solid NaCl or NH_4Cl, and all $^{35/37}$Cl NMR spectra were referenced to the $^{35/37}$Cl MAS centreband of solid NaCl at 0 ppm. The "solid" $\pi/2$ chlorine pulse was found by halving the nonselective $\pi/2$ pulse measured using solid NaCl or NH_4Cl, and was typically 2.3 and 2.4 μs for ^{35}Cl and ^{37}Cl, respectively. Recycle delays were 2 s. All spectra collected under stationary conditions used the $\pi/2 - \tau - \pi/2 - \tau -$ acquire echo sequence,[47–49] whereas MAS experiments used only a single pulse. Proton decoupling was applied during all experiments. To offset the effects of sample heating owing to fast spinning during MAS experiments, the environment of the sample was cooled to ~283 K (spectrometer VT setting) using liquid nitrogen boil-off.

21.1 T

Chlorine-35/37 SSNMR experiments were also performed on a 900 MHz (B_0 = 21.1 T) Bruker Avance II spectrometer at the National Ultrahigh-Field NMR Facility for Solids in Ottawa, Ontario. A 4 mm Bruker DVT MAS HX probe tuned to 88.2 MHz (^{35}Cl) or 73.4 (^{37}Cl) MHz was used for all experiments. Experimental setup, pulse calibration, and referencing were done using solid NaCl, as above. The pulse sequences used were identical to those used at 9.4 T, again with proton decoupling. The solid $\pi/2$ ^{35}Cl pulse was found to be 3.4 μs and a recycle delay of 2 s was used for all acquisitions. The same parameters were used for ^{37}Cl. All experiments, both static and MAS, were conducted with cooling to ~283 K (spectrometer VT setting).

Data processing and simulations

All NMR spectra were processed using Bruker's TopSpin 1.3. NMR spectra were simulated using the WSolids1 software package from the laboratory of R. Wasylishen,[50] which incorporates the space-tiling algorithm of Alderman et al.[51] Interpretations of the spectra were done within the high-field approximation and assumed a single magnetically unique site, in accord with the X-ray diffraction structure.[7] All stack plots presented were created using DMFit.[52]

GIPAW-DFT calculations

All quantum chemical calculations were carried out with

$C_Q(^{35}Cl)$ (MHz)*	η_Q	δ_{iso} (ppm)†	Ω (ppm)	κ	α (°)	β (°)	γ (°)
1.0±0.1	0.7±0.1	120±10	50±5	0.4±0.4	15±30	27±20	60±15

Note: C_Q, quadrupolar coupling constant; η_Q, asymmetry parameter; δ_{iso}, isotropic chemical shift; Ω, chemical shift tensor span; κ, skew; α, β, γ, Euler angles.

*The ^{37}Cl quadrupolar coupling constant was identical to $C_Q(^{35}Cl) \times Q(^{37}Cl)/Q(^{35}Cl) = C_Q(^{35}Cl) \times 0.788$, where Q is the nuclear electric quadrupole moment.

†The ^{35}Cl chemical shift is with respect to solid sodium chloride at 0 ppm.

the CASTEP program using Materials Studio (version 3.2.0.0) and the PBE functional.[30,32] The planewave energy cutoffs and number of k-points used are included in the Supplementary Data, along with information about the chlorine on-the-fly pseudopotential. In the case of the models based on the available crystal structure of **1**, the highest energy cutoff that allowed for the calculations to complete was used. Calculations of the chlorine MS and EFG tensors used the atomic coordinates and unit cell parameters from the X-ray structure found in ref. 7 for **1** and the published structures for the amino acid hydrochlorides, listed below. Neutron diffraction structures were used for phenylalanine hydrochloride, valine hydrochloride, tyrosine hydrochloride, glutamic acid hydrochloride, lysine hydrochloride dihydrate, and glycine hydrochloride.[53–58] X-ray diffraction structures were used for arginine hydrochloride monohydrate, alanine hydrochloride, aspartic acid hydrochloride, cysteine hydrochloride monohydrate, methionine hydrochloride, proline hydrochloride, threonine hydrochloride, and tryptophan hydrochloride.[24,59–63] For histidine hydrochloride monohydrate, the neutron diffraction structure of Fuess et al.[64] was used; however, because of obvious typographical errors the *z* coordinate for C5 and the estimated position for H9 were taken from the X-ray structure of Donohue and Caron.[65] In cases where an X-ray structure was used, optimization of the proton positions was attempted, and in cases where this was computationally possible, the optimized structures were used for NMR calculations.

The EFG and MS tensors contained in the CASTEP output files were analyzed using a modified version of the EFG-Shield program (version 2.2).[46]

Results and discussion

Experimental results

The three MAS NMR spectra collected, and their corresponding spectral simulations, are presented in Fig. 1. The EFG tensor parameters and isotropic chemical shift were first extracted from the MAS NMR spectra, as CSA is averaged by the fast rotation of the sample. The quadrupolar and chemical shift tensor parameters for **1** are shown in Table 1. It is evident from the spectra that the QI at the chlorine nucleus in **1** is very small, as the MAS NMR line shapes are relatively featureless. The line width at half height is ~500 Hz for the ^{35}Cl NMR spectra collected at 21.1 T. The collection of the spectra at two fields and for two isotopes (^{35}Cl at 9.4 and 21.1 T and ^{37}Cl at 21.1 T) was useful to ensure the accuracy of the fits, as the same parameters were used to fit all three spectra (with the value of $C_Q(^{35}Cl)$ scaled by $Q(^{37}Cl)/Q(^{35}Cl) = 0.788$ to give the value of $C_Q(^{37}Cl)$). In addition, nutation spectroscopy was helpful to verify the accuracy of the obtained parameters (vide infra).

The ^{35}Cl quadrupolar coupling constant of 1.0 MHz is small in magnitude compared with most other organic chloride systems that have been studied to date with chlorine SSNMR.[20,21] This small $|C_Q(^{35}Cl)|$ is consistent with the low

For personal use only.

end of those observed in the study by Honda[66] on a series of *n*-alkylammonium chlorides, *n*-$C_xH_{(2x+1)}NH_3Cl$ (both deuterated and non-deuterated samples), in which the coupling constants observed were all between 1.0 and 1.5 MHz. In the *n*-$C_xH_{(2x+1)}NH_3Cl$ series, the chlorine lies on a high symmetry (C_4) axis, in contrast with **1**. In the case of the amino acid hydrochlorides, another comparable series of organic chlorides, the magnitude of $C_Q(^{35}Cl)$ ranges from 2.035 MHz in arginine hydrochloride monohydrate to 7.1 MHz in aspartic acid hydrochloride, demonstrating that the chloride ion in **1** sits at a site with a significantly smaller EFG compared with those systems.[21,24–26] This observation is consistent with the structure of the *meso*-octamethylcalix[4]pyrrole ring and the placement of the chloride ion within it. According to ref. 7, the chloride rests slightly above and close to the centre of the *meso*-octamethylcalix[4]pyrrole ring (in a cone conformation), nearly equidistant from the four amine groups of the arene ring that lie below. In addition, if we consider that the calix ring is lying directly "below" the chloride ion, then the 1-butyl-3-methyl imidazolium moiety lies directly above the chloride ion. Thus, the chloride ion interacts with six hydrogen atoms, which is more than most of the amino acid hydrochlorides.[24–26] The EFG η_Q determined from the fits has a value of 0.7, and hence the EFG tensor is non-axial. The accuracy of the parameters extracted from the fits was also confirmed with a nutation analysis,[67,68] which gave results that were consistent with the reported parameters (see Supplementary data, Fig. S3).

Shown in Figs. 2*a*–2*f* and 2*g*–2*l* are experimental and simulated ^{35}Cl NMR spectra of **1** collected at 9.4 and 21.1 T under stationary conditions. Figures 2*m*–2*n* present the ^{37}Cl experimental and simulated spectra at 21.1 T. As the EFG tensor parameters were known from the MAS experiments and nutation analysis, the static spectra were fit to extract the CS tensor parameters (Table 1). The collection of spectra of both isotopes at two fields was essential to ensure the accuracy of the extracted parameters. In addition, the small magnitude of $C_Q(^{35}Cl)$ resulted in the simulations being highly sensitive to slight changes in the magnitudes of the CS tensor parameters, giving further confidence in the values listed. Although small, the measured CS tensor span (50 ppm) is within the range observed for the amino acid hydrochlorides (26–129 ppm).[24–26] In addition, the chlorine chemical shift (120 ppm) is at the high end of those observed for the amino acid hydrochlorides (37–120 ppm).[24–26] The shift is within the range observed for the alkaline earth chloride hydrates, but lower than the range observed for other noncubic metal chlorides (e.g., $AlCl_3$).[20,21] The results clearly demonstrate that the EFG and CS tensors reflect different aspects of the chloride ion environment: whereas the EFG about the chlorine in **1** is relatively small compared with other organic hydrochloride systems, the isotropic chlorine CS and CS tensor span are not.

The experimental spectrum collected at 9.4 T under static conditions (Fig. 2*a*), has a line shape that approximately resembles that solely owing to a second-order quadrupolar interaction demonstrating, at this field, that the QI does dominate the spectrum despite the small magnitude of this interaction (shown by simulations in Figs. 2*d* and 2*f*). However, the effects of CSA are clearly observable as shown by the simulated spectrum in Fig. 2*d*, which assumes no CSA and is clearly not an ideal fit to the experimental spectrum. The QI is not the dominant interaction at 21.1 T (Figs. 2*g*–2*l*), as both the experimental and best-fit simulation spectra have line shapes that resemble the line shape observed for static spin-1/2 nuclei in powdered samples, for which CSA dictates the line shape. This is demonstrated in Figs. 2*j* and 2*l*, in which the simulation assuming no QI (*l*) is quite similar to the experimental line shape, whereas the experimental line shape that assumes no CSA (*j*) is a very poor fit. This type of CSA-dominated NMR spectrum is not typical for chlorine because of its moderately high Q value, and is a clear demonstration of the power of high field instruments to enhance the effects of CSA while reducing the effects of the QI.

Computational results

Meso-*octamethylcalix[4]pyrrole 1-butyl-3-methyl imidazolium chloride*

As an X-ray crystal structure is available for **1**·CH_2Cl_2·$2H_2O$,[7] complementary GIPAW-DFT calculations of the chlorine SSNMR parameters of that material were carried out. In addition, to assess the effects of slight changes to the chlorine environment on the NMR interaction tensors, five different models were used for calculations in which parts of the structure were removed to observe the effect that this would have. These models are shown in Fig. 3. All models employ the full X-ray crystal structure as a starting point: model (*a*) consists of the full X-ray crystal structure, including CH_2Cl_2 and water molecules; in model (*b*) the CH_2Cl_2 is removed; model (*c*) has only CH_2Cl_2 and no water molecules; model (*d*) has no CH_2Cl_2 or water molecules; and model (*e*) has only the *meso*-octamethylcalix[4]pyrrole ring and the chloride ion. It should be emphasized that the models used are only approximate, since no further optimization of the geometries were done. The results of the GIPAW-DFT calculations are shown in Table 2.

Inspection of the results in Table 2 reveals some interesting differences among the calculated NMR parameters for the five models. For example, the presence of the dichloromethane solvent molecule (models *a* and *c*) results in lower values of $|C_Q(^{35}Cl)|$, whereas the presence of water solvent molecules (models *a* and *b*) results in a much lower chlorine chemical shift, relative to models without it. Similarly, the CS tensor span only changes notably when water molecules are removed from the model structure. The results of the calculations on model *e* are quite interesting and further demonstrate an observation made on the basis of the experimental spectrum regarding the CS tensor span. Removal of the 1-butyl-3-methyl imidazolium group from model *d* (in addition to the solvent molecules) results in a structure with only the chloride ion lying slightly above and roughly in the centre of the *meso*-octamethylcalix[4]pyrrole ring. This results in an absence of chlorine–hydrogen bonds above the chloride ion, opposite to the calix ring. One may expect this structure to result in both a large value for $|C_Q(^{35}Cl)|$ and the CS tensor span; however, this is not what the calculations predict. Whereas both the CS tensor span and chlorine chemical shift jump significantly to 346 and 336 ppm, respectively, (much greater than those values in typical organic chloride systems) the value of $|C_Q(^{35}Cl)|$ does not rise signifi-

*Models are shown in Fig. 3.

†To convert from calculated shielding constants to chemical shifts, a shift of 45.37 ppm was used (for the conversion from solid to aqueous NaCl chemical shift scales) in addition to the absolute shielding conversion of 974 ppm.[44]

‡NMR calculation performed after the optimization of hydrogen positions.

cantly. In fact, the calculated value of 1.21 MHz is still lower than *all* the ^{35}Cl quadrupolar coupling constants observed for the amino acid hydrochloride salts and the calculated values for both models *b* and *d*. The large CS tensor span and chemical shift value calculated for model *e* demonstrate that the calix ring environment alone results in a significant amount of CSA. This result suggests that other chloride-containing calix[*n*]arene systems may also display measureable CSA and relatively high chlorine chemical shift values, even if the QI is small.

Comparison of the experimental NMR parameters from Table 1 with those from model *a* reveals a significant discrepancy. Specifically, the GIPAW-DFT calculations predict a β value close to 90°, which indicates non-coincidence of the largest components of the EFG and CS tensors. This result was *not* observed experimentally, as non-coincidence results in a very different line shape, as shown by Figs. 2*o*–2*r*. Only model *d* has a calculated β value that is consistent with the experimental value and the line shape observed. This observation suggests that the CH_2Cl_2 and water molecules were not part of the structure, and were likely lost as a result of the sample grinding prior to the NMR experiments. This is perhaps not surprising for CH_2Cl_2, as these molecules are simply solvates that were included in the structure during crystallization. Further confirmation was provided by a TGA analysis that showed, definitively, that there were no water or dichloromethane solvent molecules in the sample of **1** that was analyzed with SSNMR, as only one mass loss event occurred, at a temperature of ~265 °C (see Supplementary data, Fig. S4). This value is consistent with the melting point of a calix[4]arene system,[2] indicating that the calix ring is intact at temperatures lower than 265 °C. If water or dichlorome-
