[a]The yields refer to the isolated pure products.
[b]Reaction carried under conventional heating.
[c]Reaction carried under microwave irradiation.

microwave irradiation. The microwave mehtod exhibited several advantages over conventional heating by significantly reducing the reaction time and improving the reaction yield, owing to a specific non-thermal microwave effect. The methodology employed for this synthesis shows much scope not only for the synthesis of bipodal and tripodal 1,4-DHPs but also for tetrapodal moieties, which is not possible to do by the methods in the literature.

Experimental section

General

Solvents and reagents were commercially sourced and used without further purification, with the exception of THF, which was freshly distilled over sodium. Melting points were taken with a Elchem microprocessor-based DT apparatus in open capillary tubes and are corrected with benzoic acid. IR spectra were obtained on an Avatar-330 FTIR spectrophotometer (Thermo Nicolet) using KBr pellets, and only noteworthy absorption levels (reciprocal centimetres) are listed. The NMR spectra were recorded on a Bruker 300 and 500 MHz spectrometer, using TMS as internal standard (chemical shifts δ in ppm). Mass spectra were recorded on HRMS and LCMS by an Agilent 1200 series LC and Micromass zQ spectrometer. Microwave oven used is of synthetic microwave, CATA R with the maximum power of 700 W at 100% power level. All reactions were carried at 30% power level, which produces power of 210 W. Thin-layered chromatography (TLC) was performed on preparative plates of silica gel (s.d. fine). Visualization was made with an iodine chamber. Column chromatography was performed by using silica gel (60–120 mesh).

General procedure for synthesis of 1,4-DHPs (4, 5)

A mixture of *p*-hydroxybenzaldehyde (10 mmol, 1.0 equiv.), β-ketoester (20 mmol, 2.0 equiv.) and ammonium acetate (12 mmol, 1.2 equiv.) were heated for 15 min in the presence of ethanol (10 mL). The progress of the reaction was monitored by TLC. After completion of the reaction, the reaction mixture was left aside for the formation of product, filtered to remove the insoluble solids and then the filter cake was washed with diethyl ether. The solid was recrystallized from absolute ethanol to yield respective 1,4-dihydropyridine derivatives as a yellow solid.

Diethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (4)

Yellow solid (recrystallized from ethanol). R_f (pet. ether/EtOAc, 6:4) = 0.83. Mp 228–230 °C (Lit. 230–232 °C).[15] IR (KBr, cm^{-1}): 3345, 2981, 1662, 1486. ^{1}H-NMR (200 MHz, $CDCl_3$) δ: 0.88 (t, J = 7.5 Hz, 6H), 2.77 (s, 6H), 3.66–3.76 (q, J = 6.0 Hz, 4H), 4.49 (s, 1H), 6.30 (d, J = 8.0 Hz, 2H), 6.72 (d, J = 8.0 Hz, 2H), 7.60 (s, -NH, 1H), 8.27 (s, -OH, 1H). HRMS: *m/z* 345.1582 (M^+).

Dimethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (5)

Yellow solid (recrystallized from ethanol). R_f (pet. ether/EtOAc, 6:4) = 0.8. Mp 230–232 °C (Lit. 231–233 °C).[16] IR (KBr, cm^{-1}): 3339, 3003, 2950, 1680, 1647, 1611. ^{1}H-NMR (200 MHz, $CDCl_3$) δ: 2.86 (s, 6H), 3.28 (s, 6H), 4.51 (s, 1H), 6.31 (d, J = 8.0 Hz, 2H), 6.70 (d, J = 8.0 Hz, 2H), 7.73 (s, -NH, 1H), 8.35 (s, -OH, 1H). HRMS: *m/z* 317.1270 (M^+).

Representative procedure for preparation of bipodal, tripodal, and tetrapodal 1,4-DHP derivatives

Method A (Classical method using NaH)

To a slurry of 22 mmol of NaH in 20 mL of dry THF in a three-necked round bottom flask under an N_2 atmosphere, 2 mmol of diethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**4**) dissolved in 30 mL of dry THF was added dropwise and the mixture was refluxed for 1 h. α,α′-Dibromo-*p*-xylene (**6**) (1.1 mmol) was dissolved in 100 mL of THF and added to the above reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/19/12
For personal use only.

with stirring for 12 h and then at reflux for a further 12 h. The reaction mixture quenched with aq NH_4Cl solution to remove excess NaH, and THF was removed under reduced pressure. The residue was extracted with $CHCl_3$ and dried over anhydrous Na_2SO_4. The crude product was purified by column chromatography on silica gel, using pet. ether/EtOAc (8:2) as eluent to give tetraethyl 4,4′-(4,4′-(1,4-phenylenebis (methylene)) bis(oxy)bis(4,1-phenylene))bis(2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate) (**7**) in 32% yield.

Method B (Classical method using powdered K_2CO_3)

To a suspension of 1.05 equiv. of diethyl or dimethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**4** or **5**) in 10 volumes of dry DMF, 3.0 equiv. of powdered K_2CO_3 was added, stirred well for 15 min at just above room temperature (40 °C). To that, alkylating agent (0.5 equiv. in case of **6**, **9a**, **9b**, and **14**; 0.333 equiv. in case of **17a** and **17b;**; 0.25 equiv. in case of **22**) dissolved in minimum amount of DMF was added drop wise for 1 h with stirring at 50 °C. After the complete addition, the reaction mixture heated at 60 °C with stirring for 48 h. The completion of reaction was monitored by TLC. Then the reaction mixture was allowed cool to room temperature, filtered to remove the insoluble solids, and then the filter cake was washed with DMF. Excess solvents were removed under reduced pressure and then quenched with ice-cold water; the obtained crude products were purified by column chromatography (60–120 mesh), which produced the products in good to moderate yields.

Method C (Microwave irradiation)

A mixture of 1.05 equiv. of diethyl or dimethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**4** or **5**), alkylating agent (0.5 equiv. in the case of **6**, **9a**, **9b**, and **14**; 0.333 equiv. in case of **17a** and **17b;**; 0.25 equiv. in case of **22**), 3.0 equiv. of powdered K_2CO_3, and 5 to 6 drops of DMF, which acts as homogenizer were finely ground. Microwave irradiation at 30% power was applied for 12 min (six pulses each of 2 min). The progress of the reaction was followed by TLC. After the completion of reaction, the reaction mixture poured into ice-cold water; the obtained solid was filtered, washed with water, and air dried to afford the desired product. The obtained crude products were purified by column chromatography on silica gel (60–120 mesh), which obtained the products in good to moderate yields.

Tetraethyl 4,4′-(4,4′-(1,4-phenylenebis(methylene))bis(oxy) bis(4,1-phenylene))bis(2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate) (7)

Pale yellow solid (recrystallized from pet. ether/EtOAc, 8:2). Mp 102–104 °C. Silver nanotubes — Biopolymer-assisted hydrothermal synthesis

Jianmao Yang, Shuyan Gao, Xiaoxia Jia, Yanli Chen, Zhigang Chen, and Junqing Hu

Abstract: In this paper, we further the biopolymer-assisted hydrothermal approach to synthesize silver nanotubes with an outer diameter of 200–300 nm, a tube wall around 50 nm, and a length of several micrometers. Here, the biopolymer is a hyaluronic acid potassium salt (HAPS). This result further verified the validity of this green biopolymer-assisted hydrothermal route for the fabrication of nanomaterials. It also gives some proof that HAPS can provide an anisotropic growth environment, which favors the formation of silver nanotubes with a nonlayered structure. The formation mechanism has been tentatively explained based on Ostwald ripening and the capping action of HAPS. In the long run, the obtained silver nanotubes can be used as a chemical template to fabricate alloyed nanotubes through the galvanic replacement reaction.

Key words: green synthesis, silver, nanotubes, hydrothermal, biopolymer.

Résumé : Dans ce travail, on préconise l'approche hydrothermale assistée par des biopolymères pour réaliser la synthèse de nanotubes d'argent avec un diamètre extérieur de 200 à 300 nm, autour d'une surface en forme de tube de 50 nm, et dont la longueur s'étend sur plusieurs micromètres. Dans cette étude, le biopolymère est le sel de potassium de l'acide hyaluronique (SPAH). Ce résultat confirme à nouveau la validité de cette voie hydrothermale assistée par des biopolymères pour la fabrication de nanomatériaux. Il apporte aussi une preuve à l'effet que le SPAH peut fournir un environnement de croissance anisotropique qui favorise la formation de nanotubes d'argent comportant une structure qui n'est pas en couche. On a expliqué provisoirement le mécanisme de formation en faisant appel à un mûrissement d'Ostwald et l'action de recouvrement du SPAH. À long terme, les nanotubes d'argent obtenus pourraient être utilisés comme moules chimiques dans la fabrication de nanotubes qui résulteraient d'alliages obtenus par le biais d'une réaction de remplacement galvanique.

Mots-clés : chimie durable, argent, nanotubes, hydrothermal, biopolymère.

Introduction

Since the discovery of carbon nanotubes in 1991,[1] a lot of attention is currently focused on nanosized tubular materials because of their unique physical properties and potential applications as gas and fluid paths or reservoirs in catalysis, fuel cells, sensors, and separation systems.[2] For example, there have been reports on a variety of inorganic nanotubes based on boron nitride,[3] metal sulfides,[4] metal borates,[5] and metal oxides.[6] Besides harsh high-temperature processes,[1,3–5] other approaches, such as the use of physical templates, have been intensively developed for the synthesis of tubular nanomaterials. Due to the importance of noble metals in catalytic, optical, optoelectronic, magnetic, and other nanotechnological fields, gold,[7] nickel,[8] and palladium[9] nanotubes have been successfully synthesized by using nanoporous polymer and anodic aluminum films as templates. However, the templating synthesis is unfavorable to produce noble metals with tubular nanostructures at a low cost (the problems with scale-up, harsh conditions, and time and energy consumption) and high purity (the problem with impurities in the desired products originate from the templates). So, the preparation of noble metals with tubular nanostructures at low cost and high purity calls for a simpler and more tractable route.

Solution-phase syntheses may represent the most promising route to fabricate nanostructures in terms of cost, throughput, and the potential for high-volume production.[10] However, the growth of noble metals with tubular nanostructures from isotropic solutions has been a more challenging task because almost all noble metals are crystallized in the highly symmetric cubic lattices. For this system, anisotropic confinements have to be applied to induce and maintain one-dimensional (1D) growth. Recently, biomolecule-assisted synthesis of nanomaterials[11] has been developed and attracted great attention. Using this strategy, we successfully fabricated gold and silver sponges by a biopolymer-assisted hydrothermal route,[12] where hyaluronic acid potassium salt (HAPS; consisting of repeating disaccharide units of D-glucuronic acid and *N*-acetyl-D-glucosamine) was selected as the biopolymer and showed its outstanding features, which included benign water solubility, the ability to stabilize nanomaterials. and reducing properties. Fortunately, we obtained silver

nanotubes by modifying our previous one-step green-synthesis procedure.[12] This further verified that the selection of HAPS and the application of hydrothermal treatment are an effective strategy for the fabrication of intriguing metallic nanostructures. More importantly, this gives some evidence that HAPS can provide an anisotropic growth environment, which favors the formation of silver nanotubes. The specific advantages of this system mainly lie in the following aspects: the one-step strategy demonstrates that the process is easy to operate, the hydrothermal treatment determines that the product is well crystalline, the involvement of HAPS demonstrates that the method is environmentally benign, and the absence of a hard template avoids the time- and money-consuming post-treatment and the impurities from a template. To the best of our knowledge, there has been no report on the solution phase-based synthesis of silver nanotubes in the absence of a hard template. The formation mechanism is also tentatively proposed based on Ostwald ripening and the capping action of HAPS. Our goal was to (*i*) perfect and deepen the green biopolymer-assisted strategy for the synthesis of metal nanomaterials and (*ii*) further exploit the characteristic stabilizing, reducing, and capping capacities of HAPS under a hydrothermal condition.

Materials and methods

All chemical reagents were of analytical grade and used without further purification. All water used in this investigation was deionized by a Nanopure filtration system to a resistivity of 18 MΩ cm.

Silver nanotubes were synthesized by modifying our reported method.[12] In a typical procedure, an 8 mL aliquot of a 10 mmol/L aqueous solution of $AgNO_3$ was added to 10 mL of a 2.54 mmol/L aqueous solution of soluble HAPS (calculated by the repeating units). The mixture was then transferred into a stainless steel autoclave with a Teflon liner with a 50 mL capacity, and heated in an oven at 180 °C for 24 h. After the autoclave was air-cooled to room temperature unaided, the resulting gray-black precipitate was filtered and washed with dimethyl sulfoxide (DMSO) and distilled water. The product was redispersed in distilled water for further characterizations with X-ray diffraction (XRD) pattern, transmission electron microscopy (TEM), selected area electron diffraction (SAED), field emission scanning electron microscopy (FESEM), and energy-dispersive X-ray spectroscopy (EDS) to obtain detailed information on its phase purity, crystalline structure, and morphology.

The samples for XRD, TEM, SAED, FESEM, and EDS characterizations were prepared by placing an aliquot of the suspension on an ITO glass slide and carbon-coated copper grids, and allowing the solvent to slowly evaporate at room temperature. All the measurements were carried out at laboratory temperature. The XRD pattern was collected on a D/Max 2500 V/PC X-ray diffractometer using high-intensity Cu Kα1 radiation (λ = 1.54056 Å). TEM and SAED measurements were carried out in a JEM JEOL 2010 instrument operated at an accelerating voltage of 200 kV. The FESEM images and EDS were obtained on an XL30 ESEM FEG scanning electron microscope operated at 20 kV.

Results and discussion

Characterizations of silver nanotubes

The overall quality, phase purity, and composition of the products were assessed by XRD, which is compiled in Fig. 1. All the reflection peaks can be indexed to the face-centered cubic (fcc) unit cell structure of metallic silver with the space group *Fm*3 *m* (Joint Committee on Powder Diffraction Standards (JCPDS)card no. 87-0718). The observation of all the expected diffraction peaks substantiates the formation of crystalline silver. The intense and sharp (111) and (222) peaks in the XRD pattern also reveals that the products are anisotropically grown along the (111) plane of the fcc structure of metallic silver. The lattice constant (*a*) calculated from the XRD pattern was 4.079, which was quite consistent with the standard value of 4.077.

We observed the product through TEM by dropping the product dispersion on a carbon-coated copper grid. Figure 2a, a typical TEM image of the product, shows the 1D structure. Upon closer examination (Fig. 2*b*), the strong contrast between the dark wall and the pale centre can be clearly seen, indicating the formation of the hollow tubes with the diameter of tube wall about 50 nm and the length several micrometers. From other area (not shown), we can observe that there are silver nanoparticles with diameter of around 15 nm attached on the nanotubes' surface or dispersed in the suspension, which may provide a piece of evidence for the growth mechanism. The SAED pattern (Fig. 2*c*) of the tubular nanostructures displays strong, ordered, and linearly arranged electron diffraction spots, which are similar to single-crystal-like diffraction spots. These observations mean that these nanotubes have high crystallinity and preferred growth direction and are organized to form a specially ordered symmetry structure, which is in agreement with the XRD result.

The FESEM image (Fig. 3) reveals that the obtained materials consist of nanotubes, which are approximately 200–300 nm in outer diameter and several micrometers in length. Some nanoparticles not constituting the nanotubes can also be seen from the panorama (Fig. 2*a*), which is consistent with the results of the TEM images. Thus, it should be noted that the present synthesis conditions, such as the reactant concentrations, reactants' molar ratio, reaction time, and the experimental temperature, may not have been well optimized to produce silver nanotubes in a high yield. A much higher morphology purity and yield might be expected. The chemical compositions of the product are determined by EDS (figure not shown), which shows the peak corresponding to silver and indicates that the product is mainly the silver element.

Growth mechanism

Theoretically, the atoms in solid materials featuring a layered structure such as graphite, WS_2, and MoS_2 can be covalently bonded to form 2D layers, which can be stacked together through van der Waals interactions,[13] and rolled up into tubular structures. As a result, production of nanotubes from nonlayered materials often requires the use of templates such as carbon nanotubes (CNTs), nanowires, and porous membranes. The rolling of thin films due to residual stress has also been demonstrated to fabricate inorganic tubes with micrometer-sized openings.[14] Also, the relief from strain in the transformation from bilamellar structures to unilamellar sheets could drive the formation of tubular structures.[15]

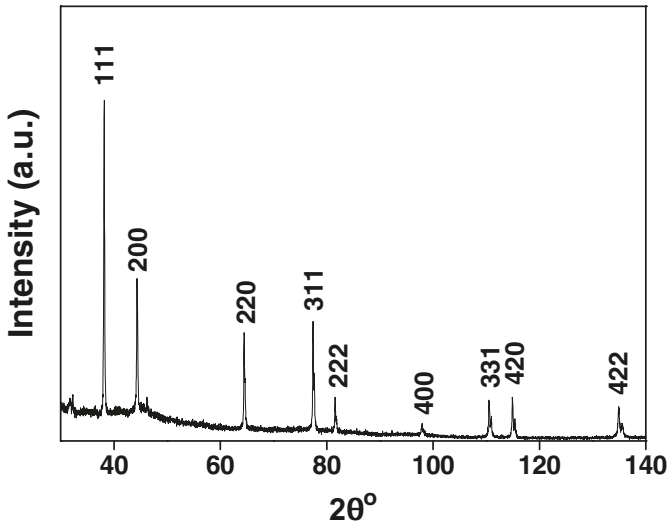

Fig. 2. (*a*) TEM images of a single silver nanotubes, (*b*) a magnified view, (*c*) and its corresponding SAED pattern.

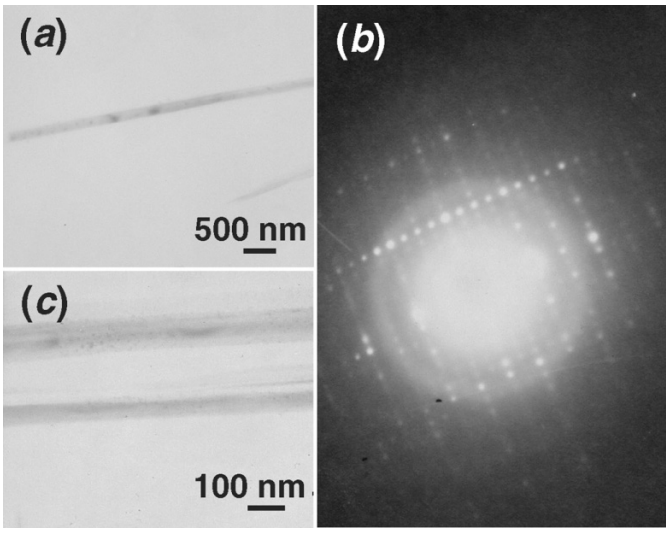

Fig. 3. (*a*) The FESEM image and (*b*) a magnified version of silver nanotubes on an ITO substrate with an initial molar ratio of 1:3 of HAPS to $AgNO_3$ for a reaction time of 24 h at 180 °C.

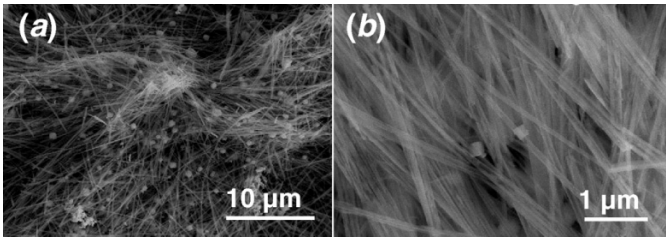

To date, nanotubes have been synthesized from a broad range of nonlayered inorganic materials, with examples including SiO_2,[16] TiO_2,[16] Al_2O_3,[17] In_2O_3,[18] Ga_2O_3,[18] CdS,[19] CdSe,[19] ZnS,[20] and Au.[21] Here, silver also belongs to nonlayered materials. However, the present synthesis conditions cannot meet the requirements of the three established approaches[13b] (i.e., nucleation-induced concentration depletion, hard templating procedures, and electrospinning technique) to fabricate tubular nanostructures from nonlayered materials. In addition, by comparing with the results reported earlier,[12] it can be seen that the participation of HAPS, the molar ratio between $AgNO_3$ and HAPS (Ag^+/HAPS), and the hydrothermal treatment determine the product's final morphology and structure, though without changing the product's crystal phase. An appropriate ratio of Ag^+/HAPS is critical to the construction of a tubular structure. With the increase of the relative concentration of silver ions, the products' structures change from discrete particle structures (not shown) to sponge-like structures[12] and then finally to nanotubes (Figs. 2 and 3). The reason may be that, at a relatively high biopolymer concentration, the biopolymer might have a stronger stabilizing capability, rather than the morphology directing the function.[22] Here, the explanation for the anisotropic formation instead of nanospheres probably involves Ostwald ripening[23] and the capping action of HAPS. Upon the reaction starting, the reduction of the silver ions would start producing small particles of silver metal, which will be stabilized by HAPS. As the reaction continued processing and heating, the small silver particles were no longer stable in solution, and they started to dissolve and contribute to the growth of larger ones. With the assistance of HAPS, some of the large nanoparticles were able to grow into a 1D structure with lateral dimensions. The exact role of HAPS in this process is not clear at the moment. One possible function for HAPS is to behave as a capping agent to kinetically control the growth rates of different crystals, just as Xia and co-workers[23a] report in exploring the poly(vinyl pyrrolidone) (PVP)-mediated silver nanowire growth mechanism, because, at an elevated temperature, the equilibrium constant for HAPS binding to certain crystal faces of silver may begin to differ, leading to selective loss of HAPS on certain crystal faces and allowing for the nanoparticle to grow along only one axis. This agrees with the "poisoning" mechanism. In this case, the "poison" adsorbed on some crystalline surfaces could significantly decrease their growth rates and lead to highly anisotropic growth.[24] In principle, the growth process would continue until all the small silver nanoparticles were completely consumed, and only nanotubes and the larger (more stable) nanoparticles survived (this also verifies that the presence of nanoparticles is reasonable). Certainly, only the above knowledge is far beyond the comprehensive and deep understanding of the growth mechanism of silver nanotubes, instead of nanowires, in our system. The underlying mechanism needs further investigation to make the synthesis of silver nanotubes controllable and their applications in nanotechnology realistic.

Conclusion

In summary, the simple procedure based on a biopolymer-assisted technique has been further developed to spontaneously fabricate silver nanotubes under hydrothermal conditions by controlling the synthesis conditions. This result further verified the validity of this green biopolymer-assisted hydrothermal route for the fabrication of nanomaterials. It also gives some proof that HAPS can provide an anisotropic growth environment, which favors the formation of silver nanotubes with a nonlayered structure. The formation mechanism has also been tentatively explained based on Ostwald ripening and the capping action of HAPS.

From the viewpoint of nanotechnology, the obtained silver nanotubes could act as a chemical template for the fabrication of alloyed nanotubes through the galvanic replacement reaction between Ag nanotubes and an aqueous solution containing the metal ions Mn^{+}, whose redox potential is higher than that of the Ag^{+}/Ag pair. So, intense work aimed at optimizing the reaction conditions for the silver nanotubes synthesis and utilizing the obtained silver nanotubes for alloyed nanotubes is in progress.

Abstract: The thermosensitive and hydrolytic properties and biocompatibility of polyphosphazenes containing lactic acid ester and methoxyethoxyethoxy as co-substitutents were investigated. Depending on the type of lactic acid ester, these polyphosphazenes exhibited lower critical solution temperatures (LCST) (from 33 to 52 °C), which were almost concentration-independent in the range of 1.5 to 15 wt% of the polymers in aqueous solution. The salt effect on the thermosensitivity of the polymers was studied by measuring their LCST in aqueous solutions containing various salts. Bu_4NBr and KI showed salting-in effects among the tested six salts, but NH_4Br, NaBr, NH_4Cl, and NaCl showed salting-out effects. Hydrolysis studies showed the rate of polymer hydrolysis decreased in the order of basic > acidic > neutral solution. The polyphosphazene with bulkier and more hydrophobic ester groups was more stable in hydrolysis. The results of a cytotoxicity study using an MTT assay method with HepG2 cell and K562/VCR cell showed that these polyphosphazenes and their degradation products were biocompatible. The thermoresponsiveness and biocompatibility of these biodegradable polyphosphazenes may favor the polymers as potential stimuli-responsive materials in biomedical applications.

Key words: polyphosphazenes, thermosensitive property, hydrolytic degradation, biocompatibility.

Résumé : On a étudié les propriétés de thermosensibilité et hydrolytiques ainsi que le biocompatibilité des polyphosphazènes contenant un ester de l'acide lactique et un groupement méthoxyéthoxyéthoxy comme cosubstituants. Suivant les types d'esters de l'acide lactique, ces polyphosphazènes présentent des températures critiques inférieures de solubilité (TCIS) qui s'étalent de 33 à 55 °C et qui sont pratiquement indépendantes de la concentration dans la plage de 1,5 à 15 % en poids de polymère, en solution aqueuse. On a étudié l'effet de sel sur la thermosensibilité des polymères en mesurant les TCIS de solutions aqueuses contenant divers sels. Parmi les six sels examinés, le Bu_4NBr et le KI ont pour effet d'augmenter la solubilité alors que le NH_4Br, le NaBr, le NH_4Cl et le NaCl présentent plutôt l'effet inverse de relargage. Les études d'hydrolyse montrent que la vitesse d'hydrolyse diminue dans l'ordre des solutions basique > acide > neutre. Les polyphosphazènes portant des groupes esters plus encombrants ou hydrophobes sont plus stables vis-à-vis de l'hydrolyse. Les résultats de cytotoxicité obtenus à l'aide d'une méthode MTT, aux sels de tétrazolium, avec la cellule HepGe2 et la cellule K562/VCR ont montré que ces polyphosphazènes et leurs produits de dégradation sont biocompatibles. Les propriétés de réponse thermique et de biocompatibilité de ces polyphosphazènes biodégradables pourraient favoriser les polymères comme matériaux potentiels pouvant répondre à des stimulus dans des applications biomédicales.

Mots-clés : polyphosphazènes, propriété de thermosensibilité, dégradation hydrolytique, biocompatibilité.

[Traduit par la Rédaction]

Introduction

Thermosensitive polymers have been investigated for biomedical and pharmaceutical applications.[1,2] Their solutions exhibit a phase transition known as the lower critical solution temperature (LCST), below which the polymers are soluble. When the temperature is raised above the LCST, the polymers precipitate from solution. This phenomenon is reversible and thus when the temperature is lowered, the polymers become soluble again. The most often investigated poly(N-substituted acrylamide)s, including poly(*N*-isopropylacrylamide) (PNIPAM),[3,4] poly(*N*,*N*′-diethylacrylamide),[5] and poly(2-carboxyisopropyl-acrylamide),[6] are representatives of thermosensitive polymers. PNIPAM shows a LCST around body temperature (at 32 °C) and therefore extensive studies have been performed for applications of the homopolymer or copolymers of PNIPAM to drug delivery systems.[7,8] But the

nonbiodegradability of these polymers may be a serious limitation to their widespread use in the biomedical field.

One family of polymers where a large variability in properties is feasible is the polyphosphazenes.[9] Polyphosphazenes are hybrid polymers possessing a backbone of alternating nitrogen and phosphorus atoms with organic side groups attached to the phosphorus atoms. Polymers with a wide range of useful properties can be designed and attained by nucleophilic substitution of poly(dichlorophosphazene) (PDCP) with various organic groups.[10–12] Efforts have been made to develop thermosensitive polyphosphazenes. Allcock and co-workers,[13–15] who extensively explored the field of polyphosphazene synthesis, suggested that polyphosphazenes that bear oligoethylene oxide units exhibit a LCST in aqueous solution. Couffin-Hoarau and Leroux[16] reported that polyphosphazenes with ethylene oxide, alkyl chains, and amino butyric acid substituents presented LCSTs in the range of 32–44 °C and pH-sensitive properties. A series of thermosensitive polyphosphazenes bearing methoxy-poly(ethylene glycol) or α-amino-ω-methoxy-poly(ethylene glycol) and amino acid esters were synthesized by Song and co-workers[17–19] These polyphosphazenes were biodegradable. Thermosensitive amphiphilic graft polyphosphazenes with oligopoly(*N*-isopropylacrylamide) and amino acid esters as side groups were described by Qiu and co-workers[20] Their self-assembly behaviors were also studied in detail.[21] However, to the best of our knowledge, the reports on the biocompatibility of biodegradable thermosensitive polyphosphazenes and their degradation products are very limited.[22]

Our attention has been focused on biodegradable thermosensitive polyphosphazenes containing lactic acid ester side groups.[23] Poly(lactic acid) (PLA) is an important aliphatic polyester with degradable properties and extensive application in the biomedical area.[24] However, PLA degrades slowly and its highly concentrated degradation products have a toxic influence,[25] limiting its use to certain applications. Poly[bis(ethyl lactato) phosphazene] and poly[bis(benzyl lactato) phosphazene] hydrolyze at a faster rate than PLA.[26] In this paper, we present the results of our study on the thermosensitive and hydrolytic properties and the biocompatibility of polyphosphazenes bearing lactic acid esters and methoxyethoxyethoxy (MEE).

Results and discussion

Structural characterization

The existence of only one peak in the ^{31}PNMR spectrum of the mixed-substituent polymer **3** as indicated in the Experimental section is presumably a result of the close resonances of homogeneously substituted bis(MEE)-substituted phosphorus[13] and bis(butyl lactato)-substituted phosphorus and the expected heterogeneously substituted phosphorus. Such a result and the data of elemental analysis implied that the chlorine atoms of poly(dichlorophosphazene) were completely substituted stepwise by butyl lactato and MEE. Polymers **1**–**3** showed almost the same chemical shifts because phosphorous environments were not seriously changed.[23]

The IR spectrum of polymer **3** (Fig. 1) showed absorption bands for a carbonyl of the ester group (1739.1 cm^{-1}), P=N (1240.7 cm^{-1}), and C–O–C (1108.2 cm^{-1}). In the ^{1}H NMR spectrum of polymer **3** (Fig. 2*a*), peaks at 0.93, 1.36, 1.52, 1.61, 4.16, and 4.97 ppm are attributed to the protons of butyl lactate, whereas the protons of one methoxyl and four oxymethylene in MEE appear at 3.37 and 3.71–3.40 ppm, respectively. These results for the ^{1}H NMR spectrum were mirrored in the ^{13}C NMR spectrum (Fig. 2*b*) of polymer **3**, which added further support to the structural assignments. The integration data analyzed between the methyl protons of butyl lactato and the methoxyl protons of the MEE in the ^{1}H NMR spectrum indicated that the relative ratios of two substituents of polymer **3** is about 1:1, the same as designed. Also, the relative ratio of two pendant groups on polymers **1** and **2** is ~1:1.[23]

Fig. 1. IR spectrum of polymer **3**.

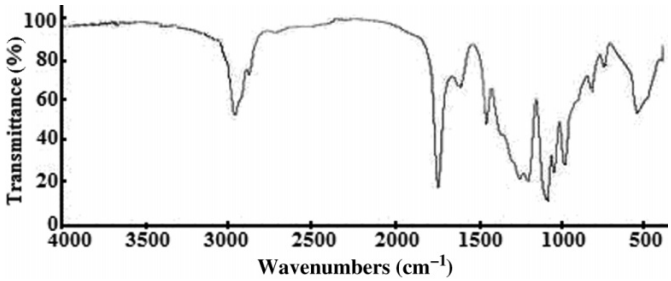

Fig. 2. (*a*) ^{1}H NMR and (*b*) ^{13}C NMR spectra of polymer **3**.

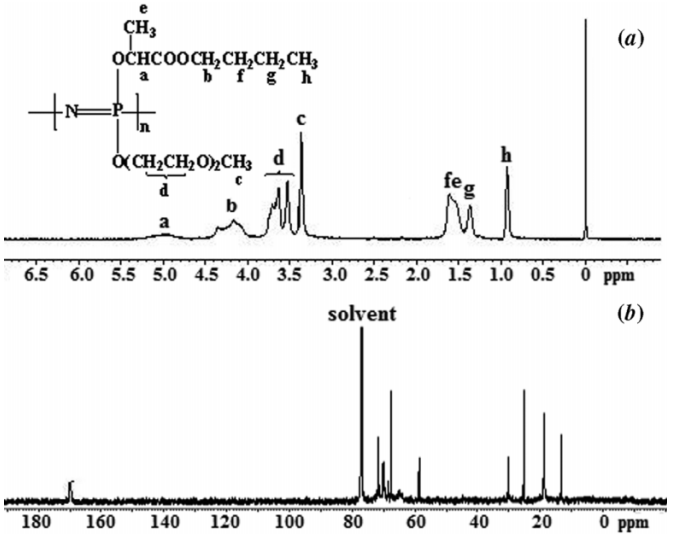

Thermal analyses reveal that the glass transition temperatures (T_g) of polymers **1**–**3** are 49.9, 44.0, and 55.7 °C, respectively.[23] These relatively low T_gs facilitated the fabrication of drug formulations in mild conditions, especially for delicate bioactive substances.[27]

Thermosensitivity

By visual inspection polymers **1**–**3** are readily soluble in water at room temperature, but the clear aqueous solutions turn turbid when heated. The LCSTs of the polymers were measured and the concentration dependence of the LCSTs was investigated in the range of 0.13–15 wt% by turbidity measurements using a UV–vis spectrophotometer. As shown in Fig. 3, the LCSTs of polymers **1**–**3** were 52, 41, and 33 °C, respectively. It has been suggested that the LCST behavior of a polymer is caused by a critical balance between hydrophilic and hydrophobic groups in the polymer and the effect of that

balance on the interaction through hydrogen bonding between the polymer and water molecules. Below the LCST, owing to their three oxygen atoms, the MEE groups develop strong hydrogen-bond interaction with water and thus ensure polymer hydrosolubility. As the temperature is raised, the hydrogen bonds weaken and hydrophobic interactions increase and become predominant above the LCST. Increasing the hydrophobicity of the polymer leads to a decrease in the LCST of the polymer in aqueous solution. Such a tendency was also observed in our polymer system. The LCST decreased in the following order: **1** > **2** > **3**. The more hydrophobic ester afforded the lower LCST. In addition, it was found that the LCSTs of polymers **1**–**3** were independent in the range of 1.5–15wt% of the polymer but increased at lower concentrations as observed for other thermosensitive polymers.[14,18]

The polymers were examined in citric acid / disodium hydrogen phosphate buffer solutions at different pH to determine whether the the LCSTs might be pH dependent, and the results are shown in Fig. 4. Analysis of the LCST values for each polymer showed them to be essentially independent in the buffer solutions at pH > 4. However, a slight increase in the LCST was detected in the acidic media at pH < 3 and was found for all the polymers studied. This result may be explained by the following way: in acidic media, the carbonyl oxygen atoms within lactic acid ester groups are protonated, increasing the solubility of the polymers, resulting in an increase of their LCST.

Thermosensitive polymers may be used as stimuli-responsive materials applicable in the biomedical field. The systems utilized in biological applications are usually not salt-free. It is known that salt component and content can influence the LCST of thermosensitive polymers.[18] To study the salt effect on the LCSTs of polymers **1**–**3**, different concentrations of NaCl, NaBr, KI, NH_4Br, NH_4Cl, or Bu_4NBr were added to the aqueous polymer solutions (1.5%), and their LCSTs were measured; the results are shown in Fig. 5. The LCSTs of polymer solutions in the presence of NaCl, NaBr, NH_4Br, and NH_4Cl decreased with an increase in the salt concentration, within the range used here. The salt effect on the LCSTs of polymers **1**–**3** decreased in the order of NaCl > NH_4Cl > NaBr > NH_4Br. However, the addition of Bu_4NBr caused an increase in the LCSTs of polymers **1**–**3**, and the LCSTs increased with increasing concentration of salt. When KI was added to each aqueous polymer solution, some smaller increases in LCST were observed. Such a phenomenon is known to be a general trend in the salt effect on the LCST of thermosensitive polymers.[28] It is known that the anion is important in the salt effect. The rank of the relative influence of ions on the physical behavior of aqueous systems is well-established.[29] The accepted explanation is based on the ability of a particular ion to alter the hydrogen bond networks of water.[30] Some ions, are believed to be "water structure makers", are strongly hydrated, and have stabilizing and salting-out effects on macromolecules. Others, would-be "water structure breakers", originate salting-in effects and destabilize folded macromolecules. The present results can be explained in a similar context. Cl^- and Br^-, water structure makers, weaken hydrogen bonding between molecules of water and polymers, resulting in a decrease of their LCSTs. However, I^-, a large ion, is a water structure breaker, and thus increases the interaction of water with polymers, resulting in an increase in LCST. The inorganic salts showed nearly the same effect on LCSTs of polymers **1**–**3**. This result seems to be due to lower sensitivity of the hydrophobic lactic acid ester to inorganic salts. Bu_4NBr molecules with a strongly hydrophobic nature make the polymers more soluble because of the binding of Bu_4NBr with the polymers through hydrophobic interactions, resulting in an increase in LCSTs. So it is easy to understand that the LCST of the polymers increased with the addition of Bu_4NBr more sharply because of the increasing hydrophobicity of the lactic acid ester groups.

Hydrolytic degradation

The hydrolytic degradation of polymers **1**–**3** was performed in buffer solutions at pH 3.4, 7.4, and 10.8 at 37 °C. Figure 6 shows the profiles of the time-dependent molecular weight decrease of three polymers in different buffer solutions. The polymers showed a significant decline in molecular weight, the structure of the ester groups of the lactic acids attached to the polymers affected the degradation of

polymers, and polymer **1** showed the fastest degradation, followed by polymer **2**, and then polymer **3** in all the buffer solutions. This trend can be explained on the basis of the differences in the bulkiness and hydrophobicity of the side

groups.[18,31] For polymer **1**, co-substitution of ethyl lactato units and MEE units reduces the steric shield that can protect the polymer backbone against hydrolysis cleavage and leads to a faster loss in molecular weight. For polymer **3**, bulkier butyl lactato groups increase the overall shielding of the polymer backbone and thus result in a slower molecular weight decline. Also, the butyl lactato groups increase the hydrophobicity of the polymer, which reduces the ingress of water to the phosphazene backbone.

As shown in Fig. 6, the hydrolytic behavior of polymers **1**–**3** was dependent on the pH of the buffer solutions. The rate of their hydrolysis in aqueous solution decreased in the order base > acid > neutral solution. For instance, it took only 21 days for polymer **1** to decrease its molecular weight to almost 32% of the original one in the buffer solution of pH 10.8, 24 days at pH 3.4, but 33 days in the buffer solution at pH 7.4. This is consistent with the behavior of poly[bis(glycine ethyl ester)phospazene] where the polymer slabs disappeared faster at basic pH.[32] Thus, a possible explanation for our results is that similar mechanisms by which poly[(lactic acid ester)phospazene] and poly[(amino acid ester)phospazene] might hydrolyze. The hydrolytic mechanisms of polyphosphazenes containing amino acid ester side groups have been discussed previously.[31] Initial steps in the suggested pathways include hydrolytic cleavage of the ester groups from the amino acid or hydrolytic cleavage of the amino acid ester from the backbone. Like poly[(amino acid ester)phospazene],[33] in acidic media, the pendent ester groups of polymers **1**–**3** are hydrolyzed to generate the corresponding free carboxylic acid and then the carboxylic acid group attacks the polymer backbone, resulting in backbone cleavage, while OH^- groups in basic media preferentially displace the lactic acid esters from the phosphorus atoms to form a hydroxyphosphazene intermediate, which then undergoes chain cleavage to phosphate and ammonia. This assumption can be confirmed by the hydrolysis products of the polymers after incubation in different buffer solutions for 42 days (Table 1), which showed that phosphate was formed during hydrolysis of almost all the polymers, and its amount was larger in the buffer solutions at pH 10.8 and 3.4 than in the buffer solution of pH 7.4. A similar trend was observed during ammonia titration. Lactic acid and ethanol, propanol, or butanol derived from the ester group on the lactic acid unit during hydrolysis of all the polymers was also detected.

In vitro cytotoxicity of polymers and degradation products

To evaluate the biocompatibility of polymers **1**–**3**, the in vitro cytotoxicities to two human carcinoma cell lines, epithelial HepG2 and leukemia K562/VCR, were determined by MTT assay. The results are shown in Fig. 7. Polymers **1**–**3** showed very little cytotoxicity toward the two cell lines. The cell viabilities were >90% for HepG2 and >80% for K562/VCR at the concentrations studied. We did not observe a significant difference in the toxicity of different polymers at any of the concentrations used for both cell lines ($p > 0.05$).

Fig. 7. (*a*) Cell viability of HepG2 and K562/VCR cells versus polymers **1**–**3** and the hydrolysis products of polymer **2** after incubation in a buffer solution of pH 7.4 (**D1**) and 10.8 (**D2**).

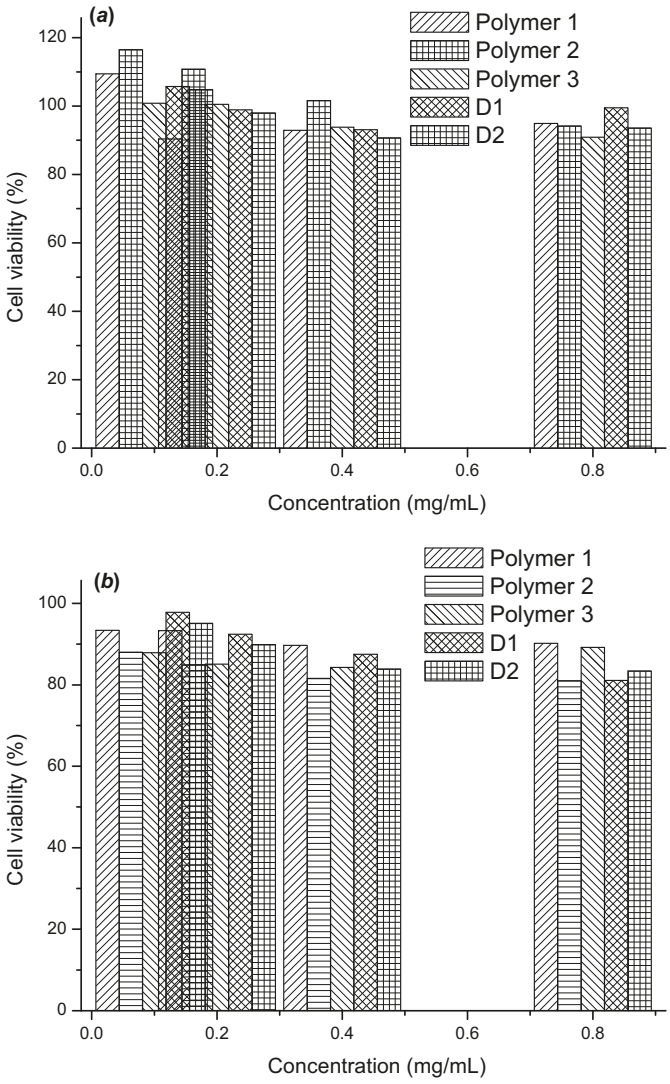

Fig. 8. Microscopic images of HepG2 cells after incubation with untreated cells (Control 1, normal saline; Control 2, buffer at pH 7.4), polymer **2**, and the hydrolysis products of polymer **2** in a buffer solution of pH 7.4 at 37 °C for 48 h.

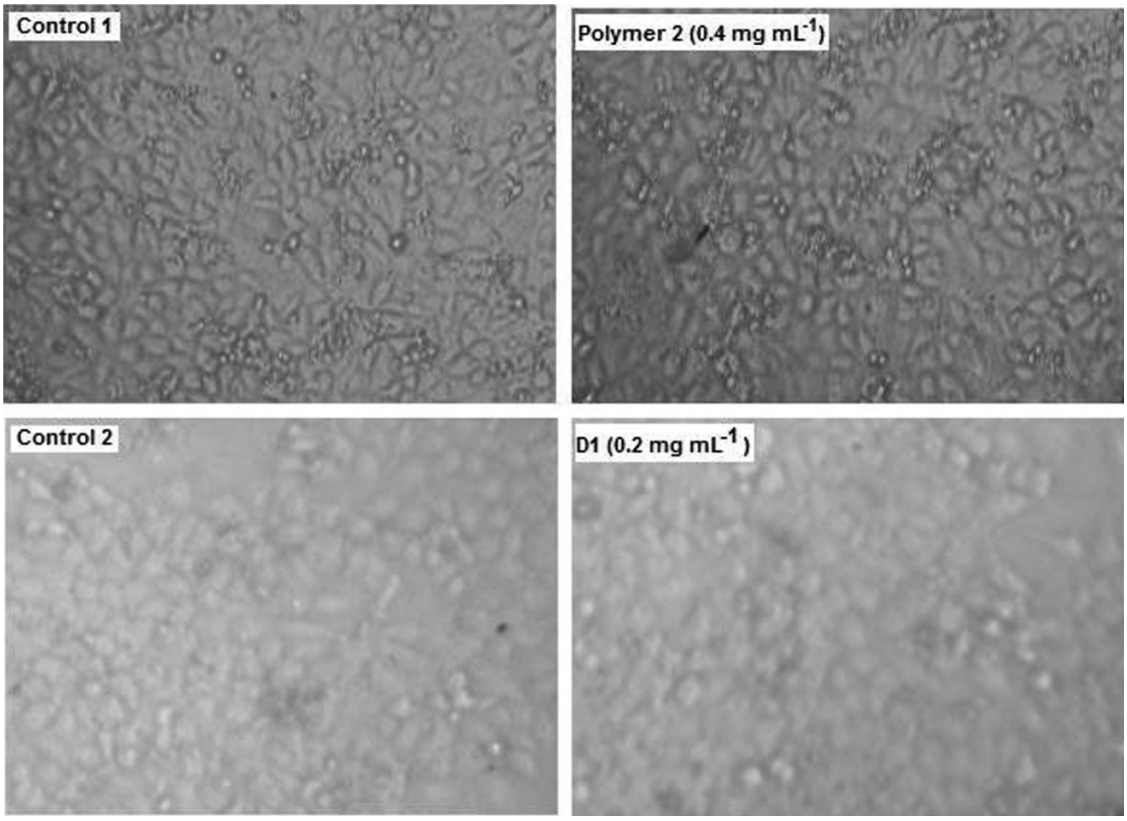


Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Figure 8 reflects the state of cells after they were cultured in a solution of polymer **2** (0.4 mg mL^{-1}) for 48 h. The dimension, shape, and density of the cells in the solution of the polymer were very similar to those in the negative control. Both results suggest that these polymers have good biocompatibility to both cell lines.

One important factor for the evaluation of the biological safety of materials is the cytotoxicity of their degradation products.[34] As mentioned previously, poly(lactide) and poly (lactide-co-glycolide) have satisfactory biocompatibility, but their highly concentrated degradation products have a toxic influence.[25] Here, the cytotoxicity of the hydrolysis products of polymer **2** after incubation in buffer solutions of pH 7.4 and 10.8 for 42 days was also determined by the MTT method against HepG2 and K562/VCR cells. As shown in Fig. 7, cells remained viable even when the concentration of degraded products of polymer **2** was up to 0.8 mg mL^{-1} (degraded products diluted by 10 times). Furthermore, the cell morphologies (Fig. 8) after exposure to the solutions of degraded products remained virtually unchanged as compared with those of the control cells. These results indicate that the degraded products of polymer **2** also have good biocompatibility to both cell lines.

Conclusions

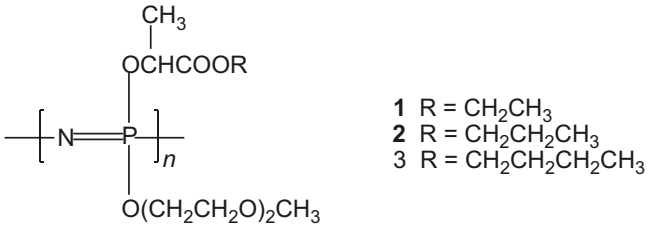
The UV–vis study revealed that the aqueous solution of polyphosphazenes containing lactic acid ester and MEE as co-substituents underwent thermo-induced phase transitions. The LCST of the aqueous solutions of the polymers was affected by the structures of lactic acid ester groups and kinds of salts. The more hydrophobic ester group afforded the lower LCST. NH_4Br, NaBr, NH_4Cl, and NaCl increase the LCST of the polymer solutions, whereas Bu_4NBr and KI decrease the LCST. Hydrolytic degradation of the polyphosphazenes was affected by the structures of the lactic acid ester groups and the pH of the buffer solutions. The polymers in basic solution showed the fastest hydrolysis, followed by acidic and then neutral solution. The structure of the ester groups of the lactic acids attached to the polymers affected the degradation of the polymers, and the order of sensitivity to degradation was ethyl > propyl > butyl esters in all buffer solutions. It seems possible to control the hydrolysis rate of the thermosensitive polyphosphazenes by adjustment of the lactic acid esters. In vitro cytotoxicity studies indicate that these polyphosphazenes and their hydrolysis products are well tolerated at the concentration tested in HepG2 and K562/VCR cell cultures. Therefore, on the basis of their thermoresponsiveness, biodegradability, and biocompatibility, these polyphosphazenes may be promising for biomedical applications.

Experimental

Instruments and materials

NMR spectra were obtained on a Bruker DRX-500 spectrometer. ^1H NMR and ^{13}C NMR spectra were measured in $CDCl_3$ with TMS as an internal standard. ^{31}P NMR chemical shifts were reported in ppm relative to 85% H_3PO_4 at 0 ppm. IR spectra were taken on a PerkinElmer 1640 FTIR spectrometer.

Scheme 1. Structure of polymers **1**–**3**.



1-3

C, H, N, P, and Cl elemental analyses were carried out with a Vario EL-III instrument (Elementar, Germany), IRIS Advantage-ER /S ICP (TJA, USA), and a Metrohm MIC-IC instrument (Metrohm, Switzerland). Thermal analysis of the polymers was carried out using a Netzsch DSC 200PC. The samples were heated at a rate of 10 °C/min in the range of –100 to 200 °C. T_g was determined at half-height. Molecular weights (M_n) were estimated by a Knauer vapour pressure osmometer (VPO) in methanol at 25 °C using sucrose octaacetate (MW = 678.58) as a reference.

NaCl, NH_4Cl, NH_4Br, NaBr, Bu_4NBr, and KI were purchased from Sinopharm Chemical Reagent Co., Ltd. and were used as received. Acetic acid and sodium acetate, boronic acid and borax, and borax and sodium carbonate were dissolved in distilled deionized water to make a 0.1 mol L^{-1} buffer solution of acetic acid / sodium acetate (pH 3.4), boronic acid / borax (pH 7.4), borax / sodium carbonate (pH 10.8), respectively. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma-Aldrich) were used as received.

Poly[(butyl lactato)$_{1.0}$(MEE)$_{1.0}$ phosphazene] (3)

Polymers **1** and **2** were prepared as described in previous work,[23] and polymer **3** (Scheme 1) was synthesized by a similar procedure. The sodium salt of butyl lactate was prepared by reaction of a solution of butyl lactate (4.23 g, 29 mmol) in THF (50 mL) with a suspension of NaH (0.70 g, 29 mmol) in THF (150 mL) overnight at room temperature. The resulting solution was added dropwise to a solution of PDCP (3.36 g, 29 mmol) in THF (200 mL) under dry nitrogen. The reaction mixture was stirred and heated to 50 °C for 36 h. To a suspension of sodium hydride (1.74 g, 72.5 mmol) in THF (150 mL) was added a solution of MEE (8.70 g, 72.5 mmol) in THF (100 mL). The resulting solution was stirred overnight at room temperature and then added dropwise to the mixture containing the partially substituted polymer. The reaction was allowed to proceed at room temperature for 48 h. The completion of the reaction was checked by ^{31}P NMR spectroscopy. The polymer was isolated and purified five times by recipitations from THF into petroleum ether. A viscoelastic, light yellow-colored solid was obtained. Yield: 70%. M_n 4891. T_g 55.7 °C. ^{31}P NMR δ: –8.64 (br s). Anal. calcd (%) for $C_{12}H_{24}NO_6P$: C 46.60, H 7.83, N 4.53, P 10.02, Cl 0.00; found (%): C 46.16, H 7.79, N 4.85, P 10. 26, Cl 0.00.

Determination of phase transitions

The phase transition of each polymer was traced by monitoring the transmittance of a 500 nm light beam on a UV–vis spectrophotometer (Cary 50, Varian). The polymer was dissolved in deionized water at different concentrations. Turbidimetric experiments were performed from 20 to 95 °C with 2 °C increments every 10 min. The light intensity through the solution was measured as a function of temperature. The LCST was defined as the temperature corresponding to the initial break points in the resulting transmittance versus temperature curve.[35] The same method was used to determined the LCSTs of the polymer solutions (1.5 wt%) containing different salts. The pH dependence of LCST was examined in citric acid / disodium hydrogen phosphate buffer solutions at pH 2.3, 3.2, 4.2, 5.0, 6.0, 7.0, and 8.0.

Hydrolytic degradation studies

Polymers were dissolved in buffer solutions at a concentration of 8 mg mL^{-1}. The buffers used were acetic acid / sodium acetate (pH 3.4, 0.1 mol L^{-1}), boronic acid / borax (pH 7.4, 0.1 mol L^{-1}), and borax / sodium carbonate (pH 10.8, 0.1 mol L^{-1}). Degradation testing was carried out at 37 °C. Vials containing polymer solutions were incubated in an incubator–shaker equipped with temperature and speed controls. The molecular weight changes over a period of 3 days were determined by VPO. The hydrolysis products of the polymers were examined using the literature method.[26] Phosphates were detected semiquantitatively by treatment of the hydrolysis media with zirconyl chloride. The ninhydrin test was used to detect ammonia. Lactic acid and alcohols were detected by MS and ^1H NMR spectroscopy, respectively.

Cytotoxicity tests

In vitro cytotoxicity of polymers **1**–**3** and the hydrolysis products of polymer **2** after incubation in buffer solutions of pH 7.4 and 10.8 for 42 days against two human carcinoma cell lines, epithelial HepG2 and leukemia K562/VCR, were determined by MTT assay as described previously.[36,37] Both cell lines were obtained from Yunnan Pharmacological Laboratories of Natural Products, Kunming Medical College, Kunming, P.R. China. Polymers **1**–**3** were dissolved in normal saline at a concentration between 0.1 and 0.8 mg mL^{-1}. The solution of the hydrolysis products was diluted by 10, 20, 40, or 80 times with normal saline. The cells were seeded in 96 well plates at 4×10^4 cells mL^{-1} in 90 μL of RPMI 1640 (Gibco Brl, USA) medium containing 10% fetal bovine serum, and incubated at 37 °C in a 5% CO_2 atmosphere for 24 h. Ten microlitres of the test solutions were added to each well. After 48 h of incubation, 10 μL of MTT solution (5 mg mL^{-1}) was added to each well, followed by further incubation for 4 h. Thereafter, the medium containing unreacted MTT was carefully removed. The dissolving solution (10% sodium dodecyl sulfate (SDS), 5% isobutanol, and 0.012 mol L^{-1} HCl) was added to each well and incubated overnight at 37 °C. Negative (normal saline for polymers **1**–**3** and buffer solutions of pH 7.4 and 10.8, which were diluted similarly as was done with the degradation solution for hydrolysis products) control wells were treated as previously mentioned. Optical density values from the wells were measured at 570 nm with an ELISA Reader (Molecular Devices, USA). Cell viability (as a percentage of the negative control) was calculated from the optical density values.

Abstract: A novel anthracene derivative, disilanyl double-pillared bisanthracene (^{Si}DPBA), has been recently synthesized, which effectively functions as a bipolar carrier transport material in OLEDs. Its charge transport properties have been systemically investigated by band model and hopping model. Band structure calculations of ^{Si}DPBA show that the dispersions of the larger valence band and conduction band are comparable, which demonstrates that both electron and hole are favoured for transport, and that ^{Si}DPBA has the potential to be used as bipolar transport material from the viewpoint of band model. The density of states and transfer integrals in the main pathways show that it is the edge-to-face CH···π interaction that determines the charge transport property, and that the $SiMe_2$ group contibutes little to it. The calculated charge mobilities of holes and electrons are 0.461 and 0.116 $cm^2 \cdot V^{-1} \cdot s^{-1}$, respectively. They are the same order of magnitude, and the electron mobility is on the order of magnitude of perylene-3,4:9,10-tetracarboxylic acid bisimide (PBI) derivatives (0.34 $cm^2 \cdot V^{-1} \cdot s^{-1}$). Both models demonstrate that ^{Si}DPBA has the potential to be used as a bipolar transport material.

Key words: disilanyl double-pillared bisanthracene (^{Si}DPBA), charge transport, band model, hopping model.

Résumé : On a récemment réalisé la synthèse d'un nouveau dérivé de l'anthracène, un disilanyl bisanthracène à double pilier (« ^{Si}DPBA ») qui fonctionne effectivement comme un matériel de transfert de charge bipolaire dans les diodes électroluminescentes organiques (DELO). On a étudié d'une façon systématique ses propriétés de transfert de charge par le modèle de bande et le modèle des sauts. Les calculs de structure de bande pour le « ^{Si}DPBA » montrent que les dispersions de la bande de valence (BV) la plus large et de la bande de conduction (BC) sont comparables, ce qui démontre que, selon le modèle de la bande de conduction, l'électron et le trou favorisent tous les deux le transport et que le « ^{Si}DPBA » a la capacité d'être utilisé comme matériel de transfert de charge. La densité des états et les intégrales de transfert dans les voies principales montrent que la propriété de transfert de charge est déterminée par l'interaction CH···π entre l'arête et la face et que la contribution du groupe $SiMe_2$ est minime. Les mobilités de charge du trou et de l'électron sont respectivement de 0 461 et 0 116 $cm^2 \cdot V^{-1} \cdot s^{-1}$. Elles sont du même ordre de grandeur et la mobilité de l'électron est du même ordre de grandeur que celle des dérivés bisimides de l'acide pérylène-3,4 :9,10-tétracarboxylique (BIP), soit 0,34 $cm^2 \cdot V^{-1} \cdot s^{-1}$. Les deux modèles montrent que le « ^{Si}DPBA » a le potentiel pour être utilisé comme matériel de transfert de charge bipolaire.

Mots-clés : disilanyl bisanthracène à double pilier (« ^{Si}DPBA »), transfert de charge, modèle de bande, modèle des sauts.

[Traduit par la Rédaction]

Introduction

In recent years, organic semiconductors have attracted considerable attention because of their potential applications, such as organic light-emitting diodes (OLED),[1–7] organic field effect transistors (OFETs),[8–10] organic thin-film transistors (OTFTs),[11–16] and photovoltaic cells,[17,18] for which they possess great advantages such as low cost, easy fabrication, and mechanical flexibility.[19–21] A key parameter determining the performance of these devices is the charge-carrier transport mobility. Some typical oligoacene and oligothiophene derivatives have good hole or electron transport abilities. For example, field-effect hole mobilities of 1.1 and 3 $cm^2 \cdot V^{-1} \cdot s^{-1}$ have been reported for thin films of alkyl-substituted oligothiophene[22] and pentacene[23], respectively. The performance of devices using n-type semiconductors is still far from that achieved with p-type materials, because the transport in n-channel conductors is degraded easily by air.[24] An electron mobility of up to 0.6 $cm^2 \cdot V^{-1} \cdot s^{-1}$ has recently been reported for vacuum deposited films of carbonyl-functionalised quarterthiophenes[25].

The fabrication of devices exhibiting ambipolar conduction is crucial to design robust circuits of low-power consumption using organic integrated circuits,[26–32] and the most ideal

ambipolar OFETs are composed of a single semiconductor material, which has high charge mobility for both hole and electron transfer, to simplify the device fabrication processes. However, due to the limitation in the range of metal work functions, most organic semiconductors show one conduction polarity, and only a few organic materials show ambipolar characteristics in a single-component molecular semiconductor. Single crystals prepared from the vapor phase of iron-phthalocyanine gave hole and electron mobilities of 0.3 and 0.03 $cm^2 \cdot V^{-1} \cdot s^{-1}$.[33] Thus, it is still a challenge to design and synthesize bipolar organic transport materials with high performance and good charge transport balance.

Quantum chemistry calculations have been widely applied in the investigation of organic semiconductors, as they provide explanations of experimental phenomenon and help to design more efficient devices.[34–38] For example, Shuai et al. carried out first-principle band-structure calculations for tris (8-hydroxyquinolinato)aluminum (Alq_3) and for the first time concluded that Alq_3 is a good electron transport material from the band structure's view.[39] Recently, Brédas et al. explored the impact of functionalization on the charge transport parameters of 37 perylene tetracarboxylic diimide (PTCDI) crystals, using density functional theory. Their results indicate that large bandwidths along with small effective masses can be obtained with the insertion of appropriate nitorgen substituents, in particular halogenated aromatic groups.[40]

Recently, there has been a report on the synthesis and characterization of a new kind of anthracene derivative, disilanyl double-pillared bisanthracene (^{Si}DPBA), shown in Fig. 1,[41] and they used a straightforward double-pillaring strategy to synthesize a series of derivatives, e.g., ^{Si}DPBAs.[42] Its glass-transition temperature T_g was recorded at 153 °C, which is higher than that found for standard OLED materials, such as α-NPD (T_g = 100 °C). The most important aspect is that the device performance using ^{Si}DPBA as both hole transport layer (HTL) and electron transport layer (ETL) is reasonably high, as the device achieved an external quantum efficiency (EQE) of 8.7%. The authors also discussed the frontier molecular orbitals and the reorganization energy of ^{Si}DPBA theoretically. However, the internal mechanism determining the transporting property is not clear. In this article, we systematically investigate the charge transport properties of ^{Si}DPBA using both band model and hopping model. We calculate the band structure and also the density of states (DOS) using the band model and obtain the charge carrier mobility using the hopping model to give an insight into the internal mechanism. It is hoped that this study can give some guidance to the design of organic transport materials.

Theoretical methodology

At low temperatures, the charge transport in a number of organic crystals can be described by a bandlike regime.[43] As temperature increases, the dynamic structure disorder may invalidate the band transport model, and transport behavior is governed by a thermally activated hopping mechanism,[44] which is usually chosen to describe charge transport at room or high temperature. However, several recent measurements indicate that the mobility decreases with temperature, which points to a bandlike mechanism of carrier transport at room temperature. For example, ultrapure single crystals of pentacene[45] (T = 225–340 K) and rubrene[46] (T = 170–300 K) show a bandlike mobility. To get a full understanding of the relative charge carrier transport properties of our system, both band model and hopping model are selected.

In a standard band-theory model, the group velocity $\boldsymbol{v}(k)$ of the delocalized electron waves or hole waves is given by the gradient of the band energy in k-space,

$$[1] \qquad \boldsymbol{v}(k) = \nabla_k E(k)/\hbar$$

where $E(k)$ is the band structure of the system, k the wave vector, and $\hbar = h/2\pi$, and h is the Planck constant. Under the constant relaxation time approximation at low temperature, the mobility can be given by,

$$[2] \qquad \mu_\alpha = e\tau m_\alpha^{-1}$$

Here, the inverse effective mass m_α^{-1} is a key parameter of the charge transport in the band-like model. The effective mass is related to the curvature of the minimum and maximum of the conductive band (CB) and valence band (VB). It reads,

$$[3] \qquad m_{\alpha\beta}^{-1} = -\frac{1}{\hbar^2}\left(\frac{\partial^2 E(k)}{\partial k_\alpha \partial k_\beta}\right)$$

Here, subscripts α and β denote the Cartesian coordinates in reciprocal space, and $E(k)$ is the band energy. The heavier the effective mass is, the smaller the mobility.

Electronic band structure and density of states calculations were performed with VASP,[47–49] using the PBE exchange-correlation functional[50] and a plane-wave basis set. The lattice parameters used here for ^{Si}DPBA are a = 12.633 Å, b = 14.510 Å, c = 18.083 Å, and α = 81.3°, β = 82.6°, γ = 81.3°. For anthracene, a = 8.562 Å, b = 6.038 Å, c = 11.184 Å, and α=γ=90°, β = 124.7°. Integrations over the Brillouin zone were sampled by 3 × 3 × 3 k points for ^{Si}DPBA, and 4 × 6 2 k points for anthracene, using the Monkhorst–Pack scheme.[51]

The hole or electronic coupling (charge transfer integral) is obtained by a direct dimer Hamiltonian evaluation method[52,53] at PW91PW91[54] /6–31G (d,p),[55–57] using the Gaussian 09 program suite.[58] A detailed computational methodology to predict the mobility is given in the Supplementary data.

Results and discussion

Geometric structure

Isobe et al. designed and synthesized ^{Si}DPBA, a new anthracene derivative.[41] The monomer and packing-mode parallel to the anthracene plane of ^{Si}DPBA are shown in Fig. 1. The $SiMe_2$ group positions two adjacent anthracene planes in an antiparallel manner, and the torsion angles between the Si–Si single bond and the anthracene plane are in the range 61°–73°, which results in a favorable σ_{Si-Si}-π conjugation. The molecules are packed with face-to-edge intermolecular contacts similar to unsubstituted anthracene. The arrangement yields a two-dimensional network of intermolecular contacts in the crystal, although the unique steplike shape of the molecule distorts the packing and hinders the formation of typical herringbone motifs.

Band structure

The crystal of ^{Si}DPBA crystallizes in the triclinic space group P-1, and there are two inequivalent molecules in the unit cell. We calculated the band structures of ^{Si}DPBA using VASP along high-symmetry directions. The high-symmetry coordinates for it are Γ(0, 0, 0), Y(0, 1/2, 0), T(0, 1/2, 1/2), X(1/2, 0, 0), Z(0,0,1/2), and V(1/2,1/2,0). The calculated band structure is shown in Fig. 2, and corresponding dispersions along high-symmetry lines are listed in Table 1. The maximum of the VB (–0.069 eV) is at point Z, and the minimum of CB (1.892 eV) is at point V. The band gap is 1.951 eV and ^{Si}DPBA is an indirect semiconductor. The larger bandwidths are along high symmetry lines T→X and

Fig. 4. Density of states (DOS) of crystals ^{Si}DPBA and anthracene.

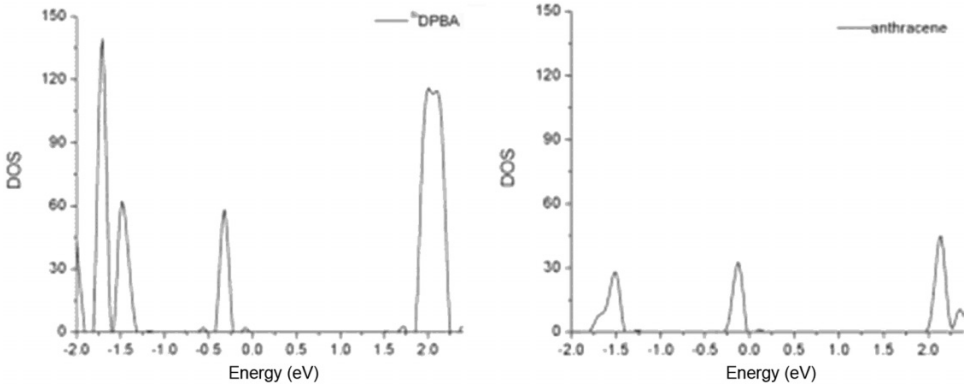

Fig. 5. Partial density of states (PDOS) of $SiMe_2$ group.

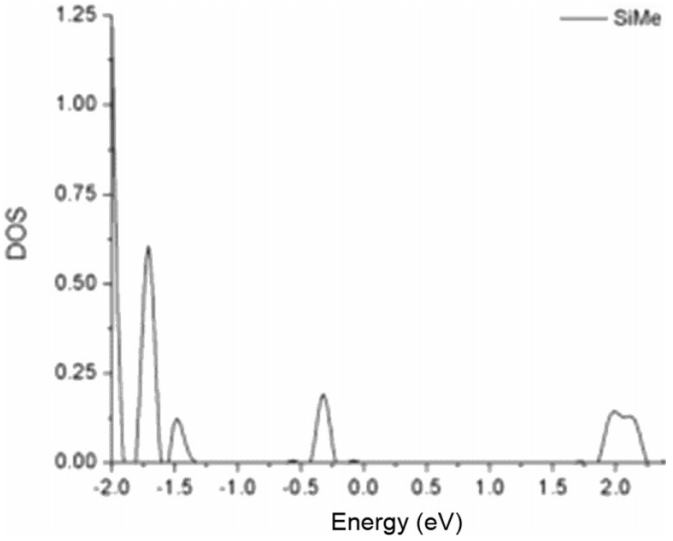

Z→V, compared with other high symmetry directions, which correspond to edge-to-face CH···π interactions between different molecular anthracene groups, and the dispersions of both VB and CB in these directions are comparable. From the viewpoint of the band model, stronger dispersion of the band gives rise to larger carrier mobility. Thus, a ^{Si}DPBA crystal could be a bipolar semiconductor.

A key parameter in the band model is the effective mass of the charge carriers; smaller effective mass gives rise to greater the mobility. We calculated the effective masses of holes in the VB and electrons in the CB along different high-symmetry lines according to the band structure of ^{Si}DPBA, and the results are listed in Table 2. As seen from the values, the results are consistent with band structure. That is, smaller effective mass leads to greater dispersion.

To compare with the band structure in ^{Si}DPBA, we calculated the band structure of anthracene crystal and discuss the differences between them. Crystal anthracene crystallizes in the monoclinic space group $P21/a$. High-symmetry k points in the Brillouin zone are selected as Γ(0, 0, 0), A(1/2, 0, 0), B(0, 1/2, 0), C(0, 1/2, 0), and R(1/2, 1/2, 0). The calculated band structure is depicted in Fig. 3, and the dispersions along different high-symmetry lines are listed in Table 3. The maximum of the VB (–0.064 eV) is at point R, and the minimum of the CB (1.988 eV) is at point C. The band gap is 2.052 eV, and anthracene is also an indirect semiconductor. The minimum of CB is higher than that of ^{Si}DPBA, which is consistent with Ref. 41, in which the LUMO of anthracene is higher than that of ^{Si}DPBA, but their VB maxima are comparable.

Generally, the dispersions of ^{Si}DPBA are smaller than those of anthracene, so the charge transport ability of ^{Si}DPBA should be weaker than in anthracene. This can be explained from the standpoint of molecular packing modes in the crystals. The introduction of Si–Si bridge breaks the coplanarity of the whole molecule, and such a change makes the π-π stacking interaction and also the CH···π hydrogen interaction weaker. As a result, the charge transport properties of ^{Si}DPBA are weaker than that of anthracene.

Density of states (DOS)

The calculated DOS of ^{Si}DPBA and anthracene are shown in Fig. 4. As seen from the plots, the total DOS of the two crystals are similar in the frontier orbital part, i.e., VB and CB. The energy of the VB peak in ^{Si}DPBA is lower than that in anthracene, but the energies of the CB are similar. This is consistent with the band structures that we analyzed above. To clarify the effect of the introduction of Si–Si bridge on the charge transport properties, we also calculated the partial density of states (PDOS) of the $SiMe_2$ group, which is shown in Fig. 5. Comparing with the total DOS of the ^{Si}DPBA crystal in Fig. 4, the DOS of the $SiMe_2$ group in both VB and CB are small, which indicates that the contribution of the $SiMe_2$ group is very small in determining the charge transport properties. On the other hand, the DOS in VB is larger than that in CB, i.e., the $SiMe_2$ group has a stronger influence on the VB than on th CB. This is consistent with the analysis of frontier molecular orbitals (FMOs) carried out by the authors in Ref. 41, in which the $SiMe_2$ group contributes to HOMO, but does not contribute to LUMO.

Transfer integral and charge mobility

Besides the band model, we also calculated the transfer integral and charge mobility using the hopping model, and the results are consistent with those from band model.

Transfer integral

The main charge hopping pathways of ^{Si}DPBA are depicted in Fig. 6, and the calculated transfer integrals in the

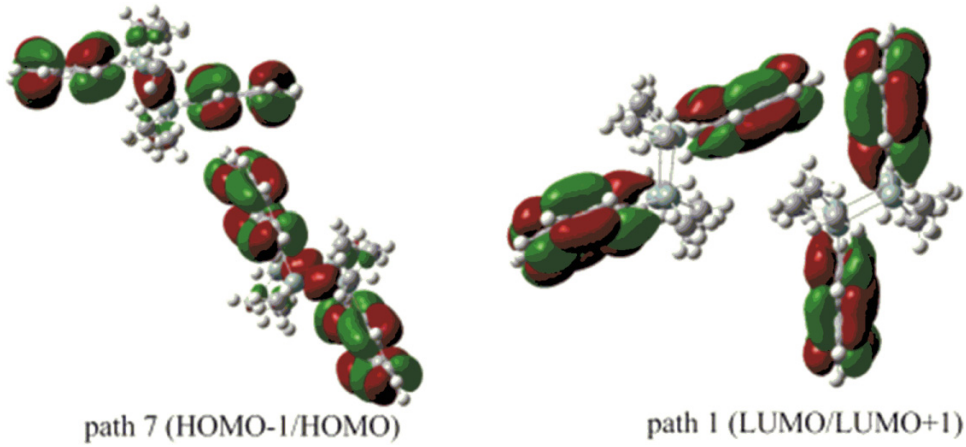
Pathways	t_h (eV)	t_e (eV)
1	3.73×10^{-3}	-1.47×10^{-2}
2	3.45×10^{-3}	-7.98×10^{-3}
3	1.07×10^{-2}	1.16×10^{-2}
4	9.00×10^{-4}	1.24×10^{-3}
5	-1.72×10^{-2}	-1.24×10^{-2}
6	-3.12×10^{-5}	-6.00×10^{-4}
7	2.07×10^{-2}	1.28×10^{-2}
8	3.36×10^{-3}	2.92×10^{-3}
9	-6.15×10^{-4}	-4.82×10^{-4}

Fig. 7. Frontier molecular orbitals of HOMO–1/HOMO in path 7 and LUMO/LUMO+1 in path 1, respectively.



main pathways are listed in Table 4. From the results, we can see that:

1. The directions with the largest electron transfer integral in pathway 1 and largest hole transfer integral in pathway 7 are both along those with edge-to-face CH···π interactions between the anthracene groups in different molecules. This is also reflected in the band structure of ^{Si}DPBA, in which the greater dispersions of the VB and CB are also along the directions involving the CH···π interaction.
2. The pathways with greater transfer integrals are all along the directions with large dispersions in both the VB and CB. The electron transfer integral in pathway 1 is the largest, and this pathway corresponds to the TX direction in reciprocal space, which has larger CB dispersion. Pathway 7 with the largest hole transfer integral is along the ZV direction. That is, the directions with larger transfer integrals are the ones with larger dispersions in the band structure.

From the results listed in Table 4, we find that the largest transfer integral for holes is in pathway 7 and for electrons is in pathway 1. We analyzed the frontier molecular orbitals (FMOs) of HOMO/HOMO–1 for path 7 and LUMO/LUMO +1 for path 1, which are shown in Fig. 7. Clearly, both the HOMO/HOMO–1 and LUMO/LUMO+1 display a significant electronic density on the anthracene parts, and there is some contribution of $SiMe_2$ on HOMO/HOMO–1 compared with LUMO/LUMO+1. This demonstrates that the edge-to-face CH···π interaction determines the charge transport abilities.

Mobility calculation

Combining the transfer integrals and reorganization energies taken from Ref. 41, we estimated the hole (μ_h) and elec-

For personal use only.

tron (μ_e) mobilities. The calculated $\underline{\mu}_h$ is 0.461 $cm^2 \cdot V^{-1} \cdot s^{-1}$, and μ_e is 0.116 $cm^2 \cdot V^{-1} \cdot s^{-1}$. They are the same order of magnitude, and the electron mobility is the same order of magnitude as that of perylene-3,4:9,10-tetracarboxylic acid bisimide (PBIs) derivatives **1a** (0.34 $cm^2 \cdot V^{-1} \cdot s^{-1}$) calculated by Geng et al., which is a typical electron transport material.[59] The results indicate that ^{Si}DPBA has the potential to be used as bipolar organic transport material.

Conclusion

Using first-principle calculations, we investigated the charge transport properties of a new kind of anthracene derivative ^{Si}DPBA using the band and hopping models. The band structure showed that the larger dispersions in VB and CB are comparable. From the viewpoint of the band model, the charge transport abilities are also comparable. The dispersions are generally smaller than those of anthracene crystal, and this can be explained by the crystal packing. That is, introduction of a $SiMe_2$ group breaks the coplanarity of the whole molecule, and such a change weakens the π-π stacking interaction and also the hydrogen interaction. On the other hand, from the DOS analysis, we found that the $SiMe_2$ group has little contribution to the charge transport abilities of crystal ^{Si}DPBA. Larger transfer integrals and frontier molecular orbitals of HOMO–1/HOMO and LUMO/LUMO+1 both show that it is the intermolecular CH···π interaction between the anthracene groups that determine the charge transport properties. Calculated mobilities for holes and electrons are 0.461 and 0.116 $cm^2 \cdot V^{-1} \cdot s^{-1}$, respectively. Such large mobilities demonstrate that the anthracene derivative ^{Si}DPBA has the potential to be used as a new kind of organic bipolar transport material.

Abstract: The use of three shape-persistent, conjugated macrocycles **2a**–**2c** as ligands for self-assembly reactions is described. The macrocycles have been characterized through a combination of spectroscopic analyses and, for compounds **2b** and **2c**, X-ray crystallographic analysis. Whereas the reaction of **2a** with the *cis*-Pt(II) species **3** successfully provides the porous solid **4a**, the analogous reaction of **2b** and **2c** with **3** leads only to mixtures of products. The application of continuous-flow hyperpolarized ^{129}Xe NMR spectroscopy to investigate the solid-state pores of macrocycles **2b** and **2c** and the supramolecular complex **4a** as a function of temperature is described. All three species show permanent porosity upon removal of co-crystallized solvent molecules. Using trends in the ^{129}Xe chemical shifts and temperature-dependent dynamics of Xe atoms in the solids, information is obtained on the nature of the pores in these systems. Using the ^{129}Xe NMR data for complex **4a**, the effective heat of adsorption (ΔH_{ads}) was calculated to be ~29 kJ mol^{-1}.

Key words: macrocycles, solid-state NMR, supramolecular chemistry, xenon NMR, porous solids, metal–organic framework.

Résumé : On décrit l'utilisation des trois macrocycles conjugués à forme persistante, **2a**–**2c**, comme ligands pour des réactions d'auto-assemblage. On a caractérisé les macrocycles par une combinaison d'analyses spectroscopiques et, dans le cas des composés **2b** et **2c**, par analyse de données cristallographiques des rayons-X. Alors que la réaction du composé **2a** avec l'espèce *cis*-Pt(II), **3**, conduit avec succès à la formation du solide poreux **4a**, les réactions analogues des composés **2b** et **2c** avec le composé **3** ne conduisent qu'à des mélanges de produits. On décrit l'application de la spectroscopie RMN du ^{129}Xe en flux continu hyperpolarisé à l'étude des pores à l'état solide des macrocycles **2b** et **2c** et du complexe supramoléculaire **4a** en fonction de la température. Les trois espèces présentent chacune une porosité permanente lors de l'élimination des molécules de solvant cocristallisées. En se basant sur les tendances dans les déplacements chimiques du ^{129}Xe et sur la variation de la dynamique des atomes de xénon en fonction de la température, on a obtenu des informations sur la nature des pores dans ces systèmes. En utilisant les données de la RMN du ^{129}Xe pour le complexe **4a**, on a déterminé que la chaleur effective d'adsorption (ΔH_{ads}) est approximativement égale à 29 kJ mol^{-1}.

Mots-clés : macrocycles, RMN à l'état solide, chimie supramoléculaire, RMN du ^{129}Xe, solides poreux, squelette organométallique.

[Traduit par la Rédaction]

Introduction

The synthesis of organic and organometallic porous materials is a rapidly expanding field of synthetic chemistry.[1–5] Recent efforts to use organic and metal–organic macrocycles to form ordered materials have provided numerous systems that could potentially give rise to porous solids.[6–13] The challenges that face researchers in this field are numerous. Initial synthesis of new macrocycles is often time-consuming with only small amounts of material prepared, often <100 mg. This quantity of material makes conventional analysis techniques such as gas adsorption difficult or impossible to use, and solid-state characterization of the materials often depends almost exclusively on single-crystal X-ray diffraction. Unfortunately, however, single crystals can be difficult to grow, and even when single crystals are obtained, the solids often include guest molecules in the desired pores, typically from the solvent used for crystallization. Obtaining single-crystal

X-ray structures of the material without the guest(s) is difficult and therefore the question must be asked, is the remaining material truly porous?[14]

Inorganic-based porous materials have been studied extensively using a variety of solid-state NMR techniques. In particular, hyperpolarized ^{129}Xe NMR spectroscopy[15,16] has been used to provide information about pore size and shape, as well as the dynamics of guest molecules present within porous structures.[15,17–22] ^{129}Xe NMR spectroscopy is expected to provide important solid-state structural information about macrocyclic organic systems that cannot be obtained using other methods.[23–25]

Xenon has a van der Waals radius of 2.16 Å (approximately the same size as methane), making it an ideal probe for materials that can adsorb small molecular gases. The advantage of using ^{129}Xe NMR to explore porous solids lies in the sensitivity of the xenon atom to the local environment, as reflected in changes in chemical shift values. The chemical shift range of atomic xenon is >300 ppm.[15] The bulk gas is set as the reference (at 0 ppm) and most NMR peaks appear to high frequency of the gas peak. In general, the greater the interaction between ^{129}Xe and the host solid, the larger the observed chemical shift value, i.e., small pores or channels result in a larger chemical shift value than larger pores. For inorganic zeolites, trends between chemical shift and pore size have been established, showing that both the pore structure and Xe dynamics influence the observed ^{129}Xe chemical shift.[26–31] Although a large body of experimental and theoretical data is not yet available for organic materials,[32–45] the principles established for inorganic systems can be qualitatively used to understand the ^{129}Xe NMR spectra for metal–organic systems.[41,42,46,47]

Reported herein is the study of three conjugated macrocycles that have been developed to function as analogues of 4,4′-bipyridine in self-assembly reactions.[6a,48,49] Unlike 4,4′-bipyridine, however, these macrocycles offer the prospect of forming porous metal–organic materials in which the macrocyclic framework can contribute to the porous network. Using these macrocycles, the formation of porous solids was then explored. X-ray crystallographic analysis of some of these materials shows that the solids contain a significant number of the co-crystallized solvent molecules. The porosity of the materials is realized when the guest molecules are removed, creating cavities within the solid where other molecules might adsorb. Finally, using variable temperature ^{129}Xe NMR spectroscopy we have sought to answer two primary questions about these solids. First, from a fundamental perspective, do the solids retain porosity upon desolvation? Second, from a practical standpoint, can ^{129}Xe NMR spectroscopy be a useful tool for determining whether small quantities of a material are porous to atomic and small molecular gases such as methane?[23,24] From these NMR experiments (using as little as 15 mg of sample in the case of **4a**), general conclusions about the Xe adsorption are described and information about the porous nature of these materials in the absence of guest solvent molecules is presented.

Results and discussion

Synthesis and characterization of macrocyclic ligands

Several macrocyclic ligands were employed in this study, and their structures (**2a**–**2c**) are shown in Scheme 1. All macrocycles were prepared through the elaboration of a common starting material, tetrayne **1**. Macrocyclic ligand **2a** was synthesized via an oxidative homocoupling reaction at high dilution, as previously reported.[6a] Platinacycles featuring two pyridine moieties (**2b** and **2c**) were also targeted and their synthesis is outlined in Scheme 1. Reaction of the acyclic oligomer **1** with $PtCl_2(PPh_3)_2$ in the presence of catalytic CuI under high dilution conditions in Et_2NH leads to the formation of platinacycle **2b**, as recently communicated.[50] Macrocycle **2c** was synthesized in an analogous manner through the use of the alternative platinum source, $PtCl_2(PEt_3)_2$. Platinacycles **2b** and **2c** are both stable yellow solids and could be purified by either chromatography or selective precipitation. Compound **2b** is considerably easier to handle than the unfunctionalized derivative **2a**, but it is still only marginally soluble in common organic solvents. This leads to difficulties with respect to its isolation, and the higher isolated yield of derivative **2c** is due to its superior solubility in comparison with **2b**.[51]

Both platinacycles **2b** and **2c** are sufficiently soluble for full spectroscopic characterization. With respect to **2b**, the solution-state ^{31}P NMR spectrum shows a single resonance at δ 18.0 ppm, confirming the presence of the metal–acetylide linkage. This chemical shift value is comparable to that of previously reported macrocycles containing Pt–acetylide units.[50,52] Confirmation of the formation of **2b** comes from mass spectral analysis, in which the ESI mass spectrum shows a large signal at *m*/*z* 2498.7 (100% relative intensity) corresponding to $[M + H]^+$.

All spectroscopic data acquired for the more soluble derivative **2c** are also consistent with the proposed structure. The solution-state ^{1}H NMR spectrum of **2c** confirms the presence of the triethylphosphine ligands, with the methylene and methyl protons observed as multiplets at 1.88–1.83 and 1.10–1.00 ppm, respectively. The ^{31}P NMR spectrum of **2c** shows a single resonance at δ 13.9 ppm ($^1J_{P–Pt}$ = 2344 Hz), at slightly higher frequency relative to **2c** as a result of the ethyl groups. The solution-state ^{13}C NMR spectrum of **2c** shows 18 of the 19 expected nonequivalent carbon resonances, and the ESI mass spectrum shows a base peak at *m*/*z* 1923 ($[M + H]^+$), consistent with the constitution of **2c**.

Single crystals of the pyridine-containing macrocycle **2b**, suitable for X-ray crystallographic analysis, were grown by slow evaporation from CH_2Cl_2/$ClCH_2CH_2Cl$/acetone. The ORTEP drawing of **2b** (shown in Fig. 1) confirms the assigned trans-stereochemistry and square-planar geometry about the platinum centre (see Table 1 for crystallographic details). The macrocyclic core is nearly planar. The mean alkyne and alkylidene bond angles, 174.5° and 114.4°, respectively, show that that macrocycle is not appreciably strained. The triphenylphosphine ligands adopt a conformation in which the platinum–phosphorous bonds Pt–P(1) and Pt–P(2) are tilted by 147.1° and 36.0°, respectively, relative to the plane of the macrocycle (as defined by Pt–Pt′–C(16)–C(26)–C(16′)–C(26′). The cavity circumscribed by the enyne framework, which measures 9.0 × 9.6 (Pt–Pt) Å, is larger than that of macrocycle **2a**, but is partially obscured by the phosphine ligands of a platinum acetylide linkage. While this may initially be seen as a drawback, it is worth noting that ligand exchange at platinum offers the possibility of further opening

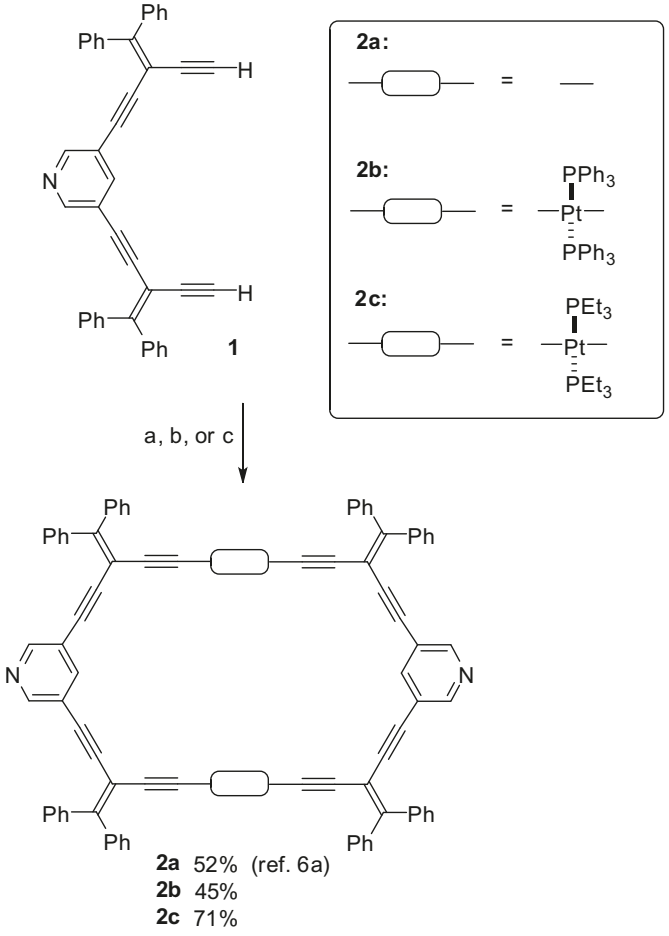
Scheme 1. Synthesis of macrocycles **2a**–**2c**. Reagents and conditions: (a) CuI, TMEDA, CH_2Cl_2, air; (b) $PtCl_2(PPh_3)_2$, CuI, Et_2NH; and (c) $PtCl_2(PEt_3)_2$, CuI, Et_2NH.



these channels and reconstruction of the macrocyclic pore structure,[50] studies of which are underway.

Single crystals of the triethylphosphine-containing platinacycle **2c** have been grown by slow evaporation from a CH_2Cl_2/acetone solution at 4 °C (see Table 1 for crystallographic details). The solid-state structure of **2c** is similar to that of the derivative **2b**, although it adopts a slight chairlike conformation. The ORTEP drawing of **2c** (Fig. 2) shows that the phosphine ligands are again "lying down" into the plane of the macrocycle. The angles between a plane defined by Pt(1)–Pt(2)–C(1)–C(17)–C(18)–C(34) and the Pt(1)–P(1), Pt(1)–P(2), Pt(2)–P(3), and Pt(2)–P(4) bonds are 59.2°, 125.0°, 127.3°, and 46.9°, respectively. Platinacycle **2c**, like **2b**, is relatively unstrained, as reflected in the mean alkyne and alkylidene bond angles, which are 174.7° and 114.2°, respectively.

Self-assembly reactions of macrocycles 2a–2c

The supramolecular assemblies targeted first were those featuring the macrocyclic ligand(s) linked to the corner piece *cis*-$(TfO)_2Pt(PEt_3)_2$ (**3**),[53] which has been well established as a component of supramolecular architectures derived from bipyridine ligands.[54,55] Thus, the reaction of **2a** with **3** gave rise to assembly **4a** (Scheme 2), the synthesis of which has been reported.[49] One equivalent of macrocyclic ligand **2a** was suspended in dry CH_2Cl_2 and then slowly added (over 15 min) to a solution of 2 equiv of *cis*-$(TfO)_2Pt(PEt_3)_2$ (**3**) in dry CH_2Cl_2. The reaction mixture was then stirred at room temperature for 18 h under a positive pressure of N_2. A second portion of the macrocycle was then suspended in dry CH_2Cl_2 and slowly added to the reaction mixture. After stirring at room temperature for a further 18 h, 80% of the solvent was allowed to evaporate in air, yielding assembly **4a** as bright orange crystals in excellent yield.

The synthesis and subsequent isolation of **4a** is only successful if several variables are carefully controlled. Most important is that all starting materials are rigorously dried, in particular, the *cis*-platinum species **3**. This prevents the formation of what is presumably the hydrated platinum species **3·$(H_2O)_2$**, as suggested by X-ray crystallography (Fig. 3; see Table 1 for crystallographic details). The hydration of **3** subsequently inhibits both binding of the pyridine-containing macrocycle to platinum, as well as the isolation of the supramolecular assembly.

Assembly **4a** has been fully characterized in solution using several NMR spectroscopic techniques in combination with IR spectroscopy and ESI mass spectral analysis. The solution-state ^1H NMR spectrum confirms the binding of macrocycles **2a** to the platinum centre(s). The solution-state ^1H NMR spectrum of free macrocyclic ligand **2a** shows resonances for the *ortho*- and *para*-pyridyl protons (H_{ortho} and H_{para}, respectively) as a doublet and a triplet at δ 8.13 and 7.83 ppm, respectively. By contrast, H_{ortho} and H_{para} appear as a second-order multiplet at δ 8.42 ppm and a triplet at δ 7.95 ppm, respectively, in the ^1H NMR spectrum of the complex **4a**. The observed splitting pattern of the ortho protons for **4a** is the result of long-range coupling to the magnetically nonequivalent phosphorous nuclei. This observation was confirmed through analysis of several solution-state NMR decoupling experiments. For example, $^1H\{^{31}P\}$ NMR spectrum of **4a** shows H_{ortho} as a doublet, albeit barely resolved. Likewise, selective decoupling of H_{ortho} from H_{para} results in the collapse of the broad second-order peaks for H_{ortho} into a simple doublet. The $^{13}C\{^1H\}$ NMR spectrum also provides convincing evidence for the formation of **4a** in solution. Signals for all 19 unique carbons for the framework of **4a** are observed (CF_3 of triflate anion not observed). In addition, the $^{31}P\{^1H\}$ and $^{19}F\{^1H\}$ NMR spectra each show only a single signal, at –1.3 and –78.2 ppm, respectively, confirming the presence of a discrete, symmetrical species in solution.

The most convincing evidence for the formation of the *dimeric* assembly **4a** in solution comes from the ESI mass spectral analysis, acquired by slow infusion of a solution of **4a** in $CH_2Cl_2/MeNO_2$. A prominent signal is observed at *m/z* 745 (24%) and assigned to $[\mathbf{4a} - 4(OTf)]^{4+}$. In addition, several peaks consistent with the fragmentation of **4a** are observed at *m/z* 1059 (9%), 492 (78%), and 429 (100%), assigned to $[\mathbf{2a} + H]^+$, $[\mathbf{3} - 2(OTf) + NO_2Me]^+$, and $[\mathbf{3} - 2(OTf)]^+$, respectively. Finally, X-ray crystallographic analysis confirmed the constitution of **4a**, as has been previously communicated.[49]

Larger supramolecular assemblies **4b** and **4c** were then targeted based on the "expanded" macrocycles **2b** and **2c** (Scheme 3). Platinacycles **2b** and **2c** were treated with identical reaction conditions as described above for **2a**, but in neither case was the desired assembly isolated. In both reactions, solution-state ^1H and ^{31}P NMR spectroscopy indicated the

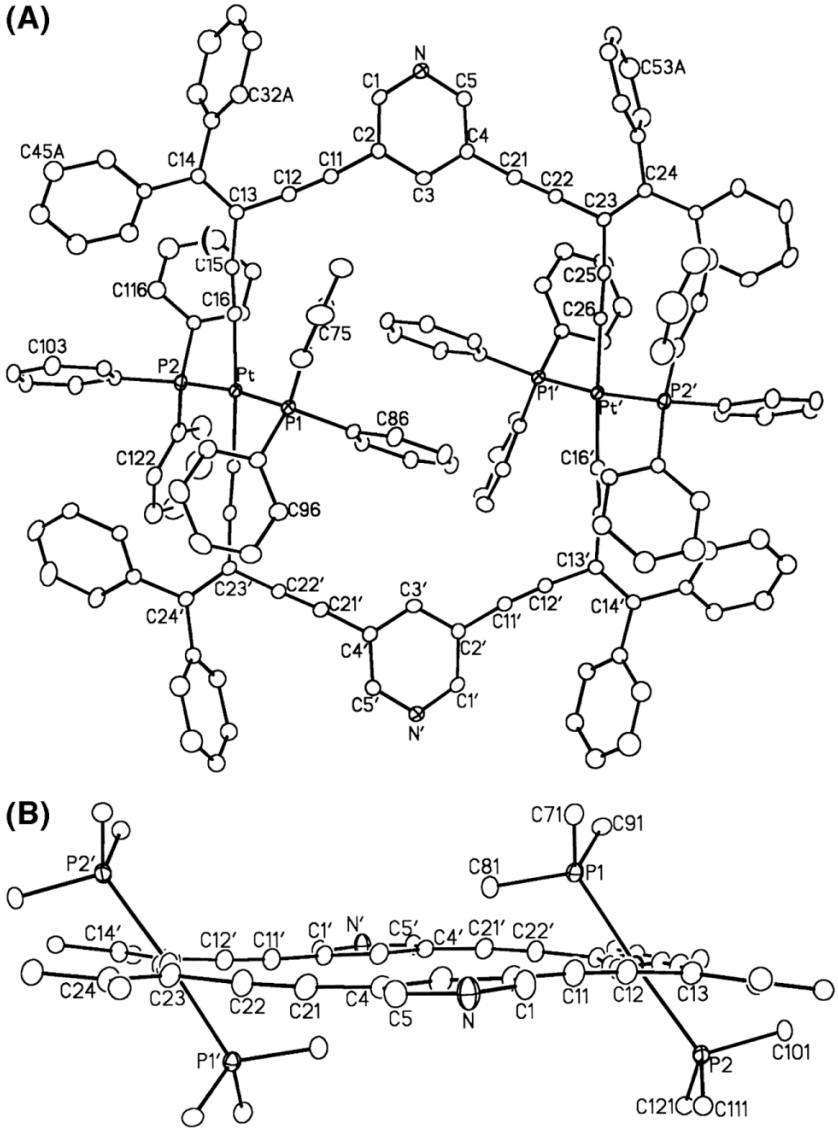
Fig. 1. (A) ORTEP drawing of **2b**. Selected bond lengths (Å) and angles (°): Pt–P(1) 2.3084(15), Pt–P(2) 2.3028(15), Pt–C(16) 2.000(6), Pt–C(26′) 1.985(5), P(1)–Pt–P(2) 173.82(5), C(16)–Pt–C(26′) 177.7(2), C(12)–C(13)–C(15) 114.4(5), C(22)–C(23)–C(25) 114.3(5). (B) Alternate view of **2b** highlighting the planar cyclic core (only the ipso carbons of the triphenylphosphine ligands and pendant phenyl groups are shown for clarity). Thermal ellipsoids are drawn at the 20% probability level. Co-crystallized solvent ($ClCH_2CH_2Cl$) is not shown.



formation of a mixture of products, rather than a single discrete species. To restrict the formation of by-products, numerous NMR titration experiments were performed in which the respective macrocyclic ligand (**2b** or **2c**) was dissolved in CD_2Cl_2 and aliquots of this solution were slowly added to an NMR tube containing 1 equiv of **3** dissolved in CD_2Cl_2. Subsequent monitoring of these reactions by ^1H and ^{31}P NMR spectroscopy revealed the formation of a mixture of products. This was especially frustrating as spectroscopic analysis clearly indicated that all of the starting materials were being consumed upon addition and ESI mass spectral analysis showed signals that were attributable to fragments of the desired assemblies. Thus, these reactions demonstrated that platinacycles **2b** and **2c** were able to coordinate to the platinum species **3**, but no single distinct product could be isolated.

It was hypothesized that steric interactions between the pendant phosphine ligands of platinacycles **2b** and **2c** could be preventing the desired dimerization to form **4b** and **4c**, leading instead to a mixture of oligomeric products. Thus, the synthesis of an assembly was pursued that incorporated the extended bimetallic "spacer" **5**[56] to help mitigate steric interactions between macrocyclic units. While NMR spectroscopy as well as ESI and MALDI MS were suggestive of a supramolecular product from the reaction of **3** and **5**, the structure of this product could not be unequivocally established.

[a]The Cl–C and C–C distances of the solvent dichloroethane molecules were restrained to be 1.80(1) and 1.54(1) Å, respectively.

[b]The C–Cl and the Cl···Cl distances of the dichloromethane solvent molecules were restrained to be 1.80(1) and 2.94(1) Å, respectively. The P–CH_2, CH_2–CH_3, and CH_2···CH_2 distances within the triethylphosphine ligand P2 were restrained to be 1.80(1), 1.54(1), and 2.94(1) Å, respectively. The phenyl rings defined by carbon atoms C41B–C42B–C43B–C44B–C45B–C46B and C91B–C92B–C93B–C94B–C95B–C96B were constrained to be idealized hexagons with C–C distances of 1.39 Å.

[c]An idealized geometry was imposed upon the triflate ions by the following restraints: S–C 1.80(1) Å, S–O 1.45(1) Å, C–F 1.35(1) Å, O···O 2.37(1) Å, F···F 2.20(1) Å, and O···F (gauche interactions) 3.04(1) Å. An idealized geometry was imposed upon the dichloroethane solvent molecules by the following restraints: Cl–C 1.80(1) Å, C–C 1.54(1) Å, and Cl···C 2.73(1) Å. Distance restraints (P–C 1.83(1) Å and C–C 1.54(1) Å) were applied to the triethylphosphine ligands (all bonded distances for the P1 ligand and all but P2–C89 and C89–C90 for the P2 ligand). The phenyl rings defined by atoms C47A to C52A, C47B to C52B, C59A to C64A, C59B to C64B, C77A to C82A, and C77B to C82B were constrained to be hexagons with C–C distances of 1.39 Å.

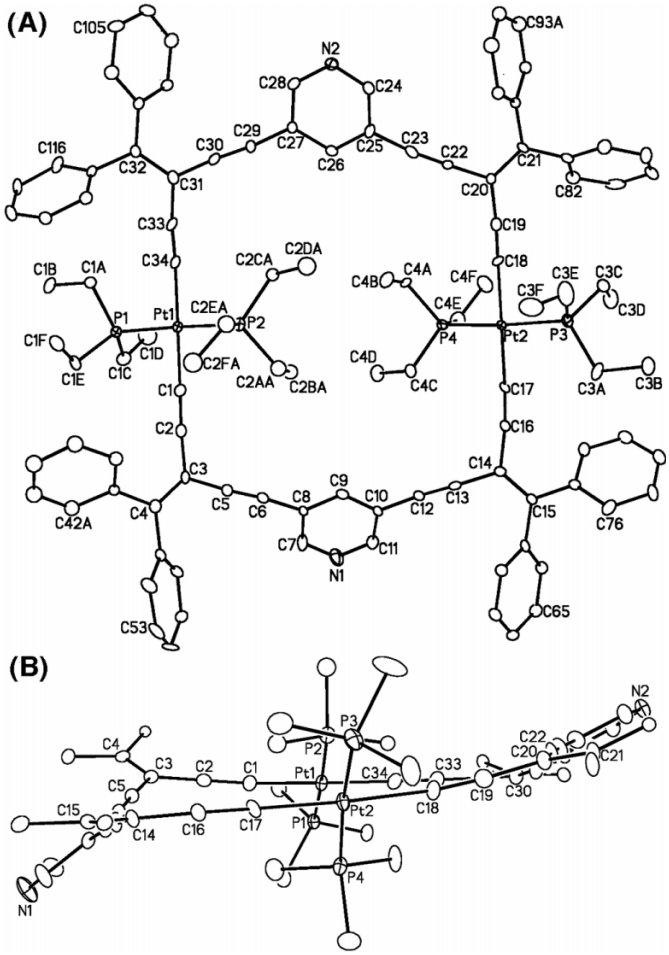
Fig. 2. (A) ORTEP drawing of **2c**. Selected bond lengths (Å) and angles (°): Pt(1)–P(1) 2.282(3), Pt(1)–P(2) 2.311(3), Pt(2)–P(3) 2.300(3), Pt(2)–P(4) 2.286(3), Pt(1)–C(1) 1.967(11), Pt(1)–C(34) 2.009(11), Pt(2)–C(17) 1.975(10), Pt(2)–C(18) 2.030(11), P(1)–Pt(1)–P(2) 175.54(12), C(1)–Pt(1)–C(34) 179.0(5), P(3)–Pt(2)–P(4) 173.32(12), C(17)–Pt(2)–C(18) 177.1(5), C(2)–C(3)–C(5) 111.1(9), C(13)–C(14)–C(16) 113.8(9), C(19)–C(20)–C(22) 115.8(9), and C(30)–C(31)–C(33) 115.9(10). (B) Alternate view of **2c** highlighting the nonplanar, cyclic core (only the methylene carbons of the triethylphosphine ligands and ipso carbons of pendent phenyl groups are shown for clarity). Thermal ellipsoids are drawn at the 20% probability level. Co-crystallized solvent (CH_2Cl_2) is not shown.



macrocycles has previously been investigated using ^{129}Xe NMR spectroscopy, including compound **2a**.[23,24] These studies have shown the solids to be porous to Xe gas after the solvent guest molecules are removed from the solid-state structure. These studies are now extended to explore the permanent porosity of the metal–organic macrocycles **2b** and **2c** using hyperpolarized Xe.

The ^{129}Xe NMR spectra for platinacycle **2b** acquired at various temperatures (Fig. 4A) show that there is little Xe adsorption at temperatures greater than –30 °C. Below this temperature, two distinct signals are observed. A peak at 128 ppm appears at –85 °C and increases in intensity as the temperature is lowered. At –67 °C, a second peak can be resolved from the gas peak; this peak appears at increasing frequencies as the temperature is decreased. The intensity of this signal also increases as the temperature is lowered, and it begins to broaden significantly at –85 °C. The chemical shift values for both signals indicate that Xe is being adsorbed into cavities that are significantly larger than the diameter of Xe.

Scheme 2. Synthesis of porous assembly **4a**.

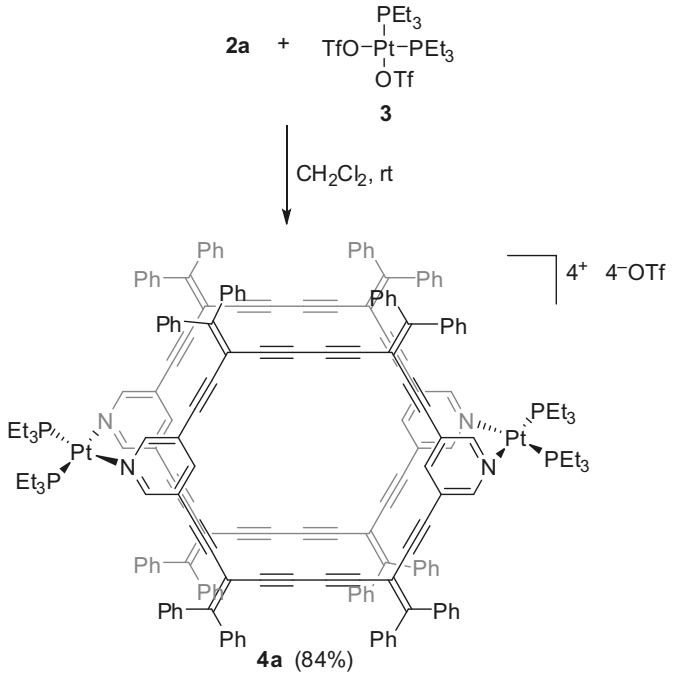


Fig. 3. ORTEP drawing of **3·(H$_2$O)$_2$**. Hydrogen atoms are shown with arbitrarily small thermal parameters for the coordinated water molecules and are not shown for the triethylphosphine groups (primed atoms are related to the unprimed ones by the twofold rotational axis at 1/4, *y*, 0).

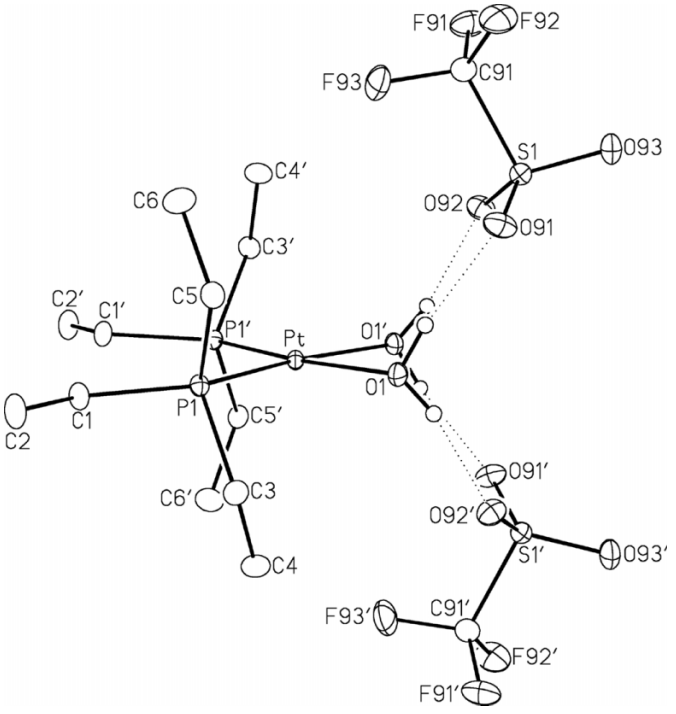
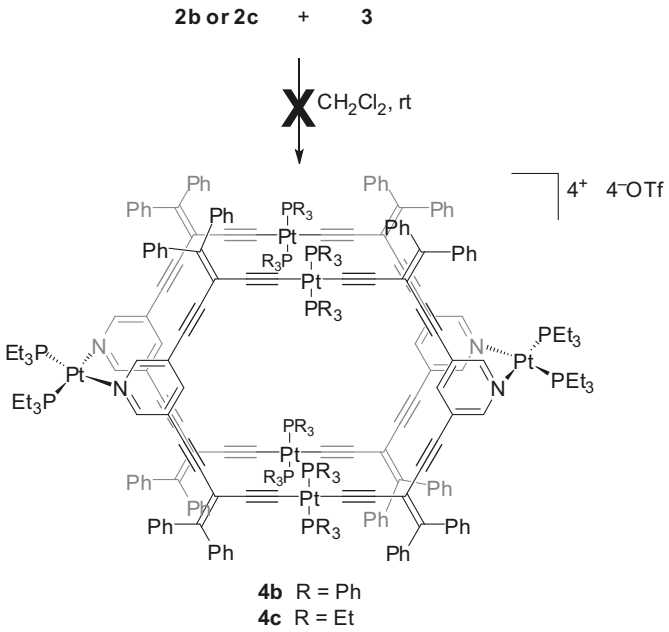


Scheme 3. Attempted synthesis of assemblies **4b** and **4c**.



Shown in Fig. 5 is a portion of the crystal packing diagram of platinacycle **2b**. Overlaid across this structure is a representation of the interstitial void space present within the crystal lattice after the co-crystallized solvent molecules (1,2-dichloroethane) have been removed.[57] There is no obvious channel system present within the crystal lattice, although there is a significant amount of void space (18%) when the solvent molecules are removed from the structure (in the presence of co-crystallized solvent the void space is calculated to be zero). Furthermore, the two chemically nonequivalent solvent cavities are too far apart to be considered "connected". Despite the lack of channels the ^{129}Xe NMR spectra indicate that Xe is able to access these cavities. The ability of solids to adsorb small atomic or molecular gases in the absence of clear channel systems has been demonstrated for other organic materials. Calixarenes, for example, can adsorb small guest molecules such as toluene or nitrobenzene as well as larger organic molecules such as tetradecane.[58–61] Similar behaviour has also been observed for a cyclic organometallic molecule that forms stacks in the solid state.[62] The single-crystal X-ray diffraction analysis of this system revealed that there are solvent cavities in the solid with narrow openings between cages; the free diameter of the openings is 0.89 Å. Despite the lack of clear channels between the solvent cavities, the solvent molecules could readily escape from the structure, even at room temperature and ambient pressure, and other guests could be adsorbed by the solid.[62]

The behaviour of the low frequency peak observed in the ^{129}Xe NMR spectra of **2b** (Fig. 4A) is characteristic of Xe rapidly exchanging between Xe in the free gas and Xe adsorbed in the solid. If Xe atoms exchange between two nonequivalent sites at a rate that is fast with respect to the chemical shift difference (in Hz) that they experience in the two sites (i.e., in the absence of exchange), a single ^{129}Xe NMR peak will be observed with a chemical shift corresponding to the weighted population average chemical shift. The ^{129}Xe NMR spectra therefore indicate that at –30 °C

Fig. 4. Variable temperature hyperpolarized ^{129}Xe NMR spectra (55 MHz) of platinacycles (A) **2b** and (B) **2c**. The three lower spectra in Fig. 4B are scaled by 20% with respect to the upper spectra.

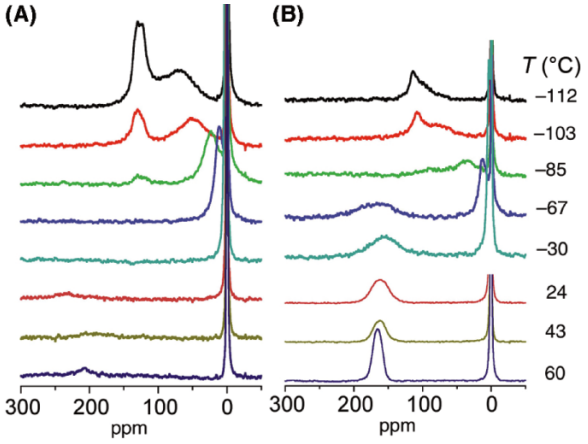


Fig. 5. Schematic representation of the crystal packing diagram of **2b**. Shown is a 2 × 2 × 2 array of unit cells as viewed down the *a* axis. A representation of the void space (when co-crystallized solvent is removed) present within the crystal lattice is shown in light gray.

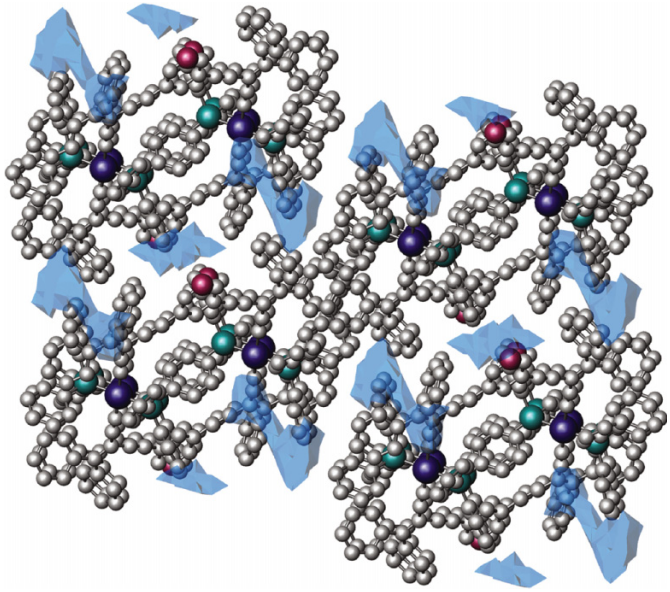

very few Xe atoms sample the cavity for a significant amount of time. As the temperature is lowered further, the Xe population inside the cavity increases, but rapid exchange still results in a narrow peak. Near –85 °C, exchange between the cavities and the free gas slows and two distinct, broad peaks are observed. The large breadth of the two peaks suggests that the adsorbed Xe atoms within the cavities experience different local environments, i.e., there is a distribution of ^{129}Xe chemical shifts. These different environments likely arise from subtle variations in the framework structure such as differences in the phenyl ring orientations or molecular packing. The narrower high frequency peak in Fig. 4A arises from Xe in smaller more uniform cavities while the broader lower frequency peak arises from larger cavities with greater structural heterogeneity; these cavities may correspond to those depicted

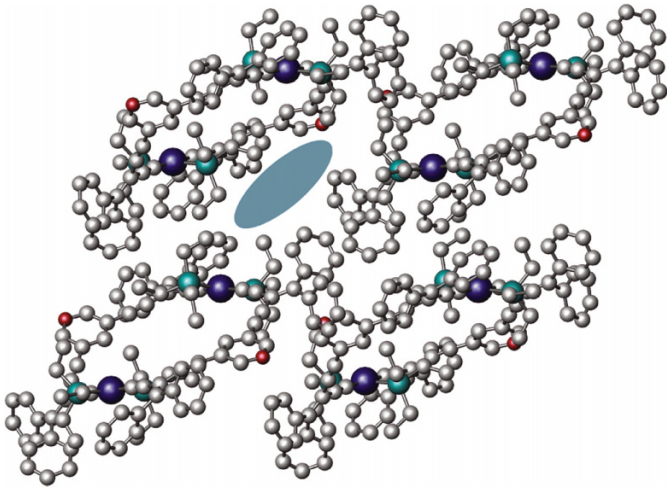
in Fig. 5. It is likely that near –103 °C exchange with the free gas has a minimal effect on the NMR peaks.

Since there is no distinct channel system for **2b** in the solid state, it is unclear why the ^{129}Xe NMR spectra show a trend that is characteristic of Xe in fast exchange with the free gas at –30 °C, with the Xe gas sampling the cavities for longer time periods as the temperature is lowered. One possible explanation is that Xe only samples cavities near the surface and then rapidly exchanges back into the free gas rather than penetrating deeper into the structure. As the temperature is lowered and the Xe atoms spend more time adsorbed in the near-surface cavities, the probability increases that the Xe will penetrate deeper into the cavities, resulting in spectra more characteristic of Xe interaction with the framework.

The ^{129}Xe NMR spectra of platinacycle **2c** acquired at various temperatures (Fig. 4B) show several differences compared with those of **2b**. At higher temperatures, a single peak is found at 166 ppm, and this signal is surprisingly intense considering the small amount of sample used, ~100 mg. The signal intensity decreases as the temperature is lowered, diminishing rapidly between 24 and –30 °C; no signal from this peak, $\delta \approx 166$ ppm, is detected at temperatures below –67 °C. Below –30 °C, a second signal separates from the free Xe gas peak at 0 ppm, and the chemical shift of this signal steadily increases as the temperature is lowered to –112 °C.

Shown in Fig. 6 is a schematic representation of the crystal packing diagram of **2c**, highlighting the channel that results along the crystallographic *b* axis when the co-crystallized CH_2Cl_2 molecules are removed from the structure. This channel has dimensions of approximately 7 Å × 5 Å. The crystal packing of platinacycle **2c** shows that the macrocycles lie nearly parallel to this channel and, in principle, the centre of the macrocycle cores provide for side pockets along the walls of the channel. Given the size of the macrocycle, Xe atoms could potentially adsorb in these pockets as they move along the main solvent channel. The chemical shift of 166 ppm is too large to be attributed to Xe in the relatively large channel and suggests Xe is indeed accessing more confined spaces within the lattice. The pocket created by the macrocycle is surrounded by the ethyl groups of the phosphine ligand and might therefore produce a highly confined alkyl environment for the Xe that would account for the observed high-frequency signal. By way of comparison, the chemical shift of Xe dissolved in ethanol is 161.1 ppm,[63] Xe in diethyl ether is 159.0 ppm,[64] and Xe in *n*-pentane is 154.1 ppm[64] (all at room temperature). Previous studies of Xe adsorbed by porous organic macrocycles shows that the chemical shift of Xe adsorbed in highly confined sites surrounded by phenyl groups is close to that of Xe dissolved in benzene, 193 ppm.[23,24,64] The line width of the peak at 166 ppm can be attributed to small differences in the structure of the pores. The ethyl groups are likely to flex as Xe is adsorbed, and different pores would therefore have slightly different chemical environments. The loss of signal as the temperature is lowered is likely due to a decrease in framework flexibility and subsequent exclusion of Xe from these cavities. The signal loss could also arise from condensation of the Xe atoms. In the hyperpolarized ^{129}Xe NMR experiment, Xe atoms can only be observed once if 90° excitation pulses are used. Therefore, if Xe atoms in the cavities do not exchange for freshly polarized Xe, no NMR signal is observed.[16] However, since there is no increase in the chemical shifts, which is also characteristic of Xe condensation, it is unlikely that condensation is the cause of the signal loss in this case.

Fig. 6. A schematic representation of the location of the channels in the solid-state structure of **2c** (ellipse). Shown is a single unit cell of **2c** as viewed down the *b* axis.



The peak that is observed to separate from the gas peak at –30 °C in the ^{129}Xe NMR spectra of **2c** shows a similar pattern versus temperature as the analogous peak observed for **2b**; the chemical shift steadily increases as the temperature is lowered, which is characteristic of Xe undergoing fast exchange between the cavity and the free gas. The low chemical shift value and, to some extent, the fast Xe exchange dynamics suggest the Xe is sampling a pore environment significantly larger than the Xe atom, i.e., the solvent channels. The broad ^{129}Xe NMR signal obtained at –103 °C suggests that different adsorption regions with different Xe populations exist within the channels, which is not surprising given the structurally varied nature of the channel walls. Above –85 °C this distribution is averaged by fast exchange between the different environments and the gas phase.

In contrast to platinacycles **2b** and **2c**, X-ray crystallography shows that supramolecular assembly **4a** stacks in the solid state such that a clear, bidirectional pore structure is realized (Fig. 7; see Table 1 for crystallographic details). The two sets of perpendicular channels result from the combined attributes of the macrocyclic building block and the supramolecular assembly. The boatlike conformation of the macrocycles bridging the Pt centres define channels that are clearly evident along the *c* axis, with dimensions of ca. 7.5 Å × 16.3 Å (Pt–Pt; Fig. 7, bottom). Stacking of the macrocyclic portion of the assembly provides a perpendicular set of channels along the *a* axis with smaller internal dimensions of 6.6 Å × 9.7 Å circumscribed by the macrocycle (Fig. 7, top). Noteworthy is the selective uptake of $ClCH_2CH_2Cl$ into the crystal lattice from the solvent mixture of $ClCH_2CH_2Cl$ and CH_2Cl_2; the unit cell of **4a** incorporates a total of eight solvent molecules. Overall, there is a significant proportion of void space in the structure, calculated at 13% with the co-crystallized solvent included. The void space in the absence of the co-crystallized solvent is a remarkable 28% of the unit cell volume.

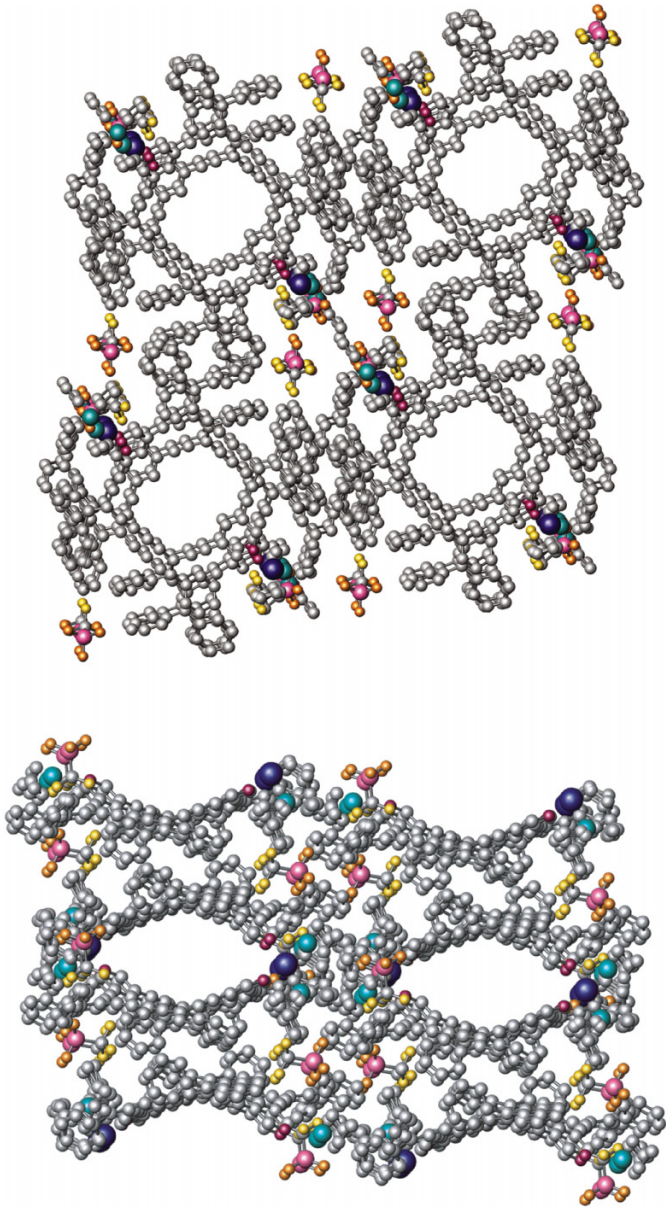
Fig. 7. Crystal packing diagrams of assembly **4a** as viewed down the *a* axis (top) and down the *c* axis (bottom). Solvent molecules have been omitted for clarity.



Whereas the formation of porous assembly **4a** and the inclusion of guest molecules within the structure are important, a porous material can only be useful if the guests can be removed and replaced by other molecules while retaining the host porosity. All attempts to grow crystals of **4a** from other solvents were unsuccessful and provided only noncrystalline precipitates. In the rare case in which crystals were obtained, they desolvated rapidly and shattered before X-ray analysis could be performed. The solvent was removed from crystals grown in CH_2Cl_2/$ClCH_2CH_2Cl$ mixtures by flowing N_2 over the solid at room temperature. Again, these crystals shattered upon removal of the solvent molecules and were no longer suitable for crystallographic analysis. Hyperpolarized ^{129}Xe NMR spectroscopy, therefore, seemed an ideal probe to demonstrate porosity of **4a** in the absence of guest solvent molecules.

Using the pristine crystals of **4a** (i.e., still solvated), ^{129}Xe NMR spectra were acquired at various temperatures and are shown in Fig. 8; it was assumed that the gas flow removed the solvent molecules as mentioned in the previous paragraph. These spectra were, remarkably, acquired using <15 mg of sample. It is immediately apparent that Xe atoms are able to access the channel system of **4a**, and there are two sites or pores present within the solid. First, at high temperatures, a broad resonance is just discernable in the range of 210–180 ppm. Upon cooling to room temperature, a second resonance begins to separate from the gas peak as the resonance at large chemical shift diminishes in intensity. The position of the second resonance stabilizes at 112 ppm at approximately –70 °C.

The broad peak observed near 180 ppm is similar to that observed previously for Xe adsorbed in highly confined regions of organic macrocycles, including **2a** and **2c**.[23,24] This chemical shift is too large to arise from Xe occupying the large channel and must therefore come from Xe in alternate adsorption sites. These smaller sites are likely peripheral to the channels of **4a** and would be bordered by the phenyl groups that decorate the exterior of the macrocycles. This assignment is supported by the fact that the observed chemical shift value is comparable to that of xenon dissolved in organic solvents such as benzene or toluene.[64] Based on the signal intensity, there is relatively little Xe gas accessing these highly confined sites, in contrast to **2c**. As the temperature is decreased below 6 °C the intensity of this peak decreases, possibly the result of Xe condensation into the peripheral sites. It should be re-emphasized that in the hyperpolarized ^{129}Xe NMR experiment, condensed Xe gas atoms would not be spectroscopically detectable owing to the fact that polarization is lost after a single NMR pulse sequence. An alternate explanation is that with lower temperatures, there is no longer sufficient mobility within the solid host to allow the xenon gas to enter the highly confined sites that give rise to the ^{129}Xe NMR signal at 180 ppm. For example, any restriction of slight motion of the pendant alkylidene phenyl groups could restrict access to these more confined sites within the framework.

Starting at about 24 °C, Xe atoms begin to occupy space within the channel structure of **4a** for significant amounts of time, as evidenced by the peak observed near the gas peak at 0 ppm. As with macrocycles **2b** and **2c**, this suggests that Xe is in fast exchange between the gas phase and the channels. Unlike **2b** and **2c**, however, the chemical shift of this signal remains constant at 112 ppm, over a temperature range of ca. 50° (starting at about –67 °C), shifting to 123 ppm only at the lowest temperature measured. This suggests that Xe exchange with the free gas is insignificant below –67 °C. The chemical shift in this region is therefore characteristic of Xe-framework interactions, δ_s. This value of δ_s is surprisingly similar to the values obtained for porous silica materials with pore diameters between 5 and 50 Å.[29] Assuming that the Xe loading is low, i.e., there are minimal Xe–Xe interactions, the chemical shift verses temperature profile above –112 °C can be used to obtain an effective adsorption energy (ΔH_{ads}) for Xe in **4a**. The chemical shift as a function of pore structure, temperature, adsorption energy, and δ_s can be expressed as a linear equation in the form

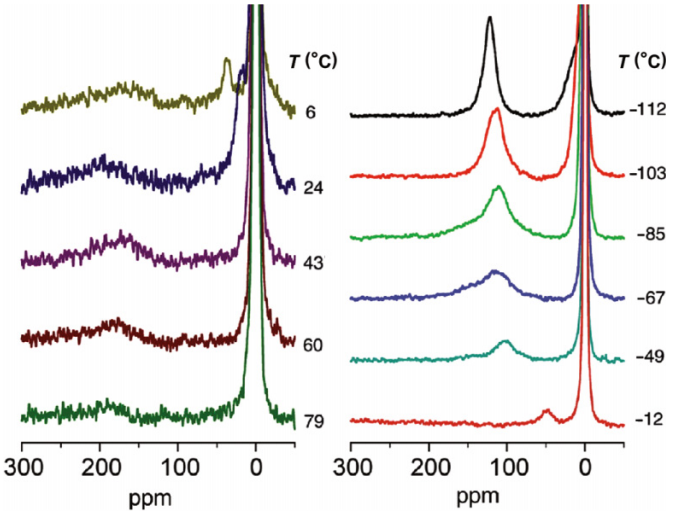
For personal use only.

Fig. 8. Hyperpolarized ^{129}Xe NMR spectra (55 MHz) of porous assembly **4a** acquired at various temperatures.



$$[1] \qquad \ln\left[\left(\frac{\delta_s}{\delta}-1\right)T^{1/2}\right] = C - \frac{\Delta H_{ads}}{RT}$$

where $C = \ln\left(\frac{D}{RK_0\eta}\right)$ and is characteristic of the pore structure, T is temperature, R is the ideal gas constant, D is the mean pore diameter, K_0 is the pre-exponential factor from the Henry's Law equation for adsorption, and η is a pore geometry factor.[65] By plotting $\ln\left[\left(\frac{\delta_s}{\delta}\right)-1\right]T^{1/2}$ vs $1/T$, the value of ΔH_{ads} is obtained from the slope.[66] On this basis, using eq. [1] to analyze the ^{129}Xe NMR spectra of **4a** provides an effective heat of adsorption of ca. 29 kJ mol^{-1}; the error is approximately ±5 kJ mol^{-1}. Clearly, it would be desirable to do the same analysis for samples **2b** and **2c** for which fast exchange is also evident between Xe in the solvent cavities and free Xe gas. Unfortunately, an estimate for δ_s for **2b** and **2c** is difficult, since there is no region where the chemical shift does not change over a significant temperature range.

Molecular dynamics simulation of Xe in **4a** indicates that, while the Xe can move freely throughout the channel system, it spends a majority of its time in the narrowest sections, between the stacked macrocyclic units that form the channel following the *c* axis; Fig. 9 shows the position.[23] The two regions depicted by the contour plots coincide with the position of two of the six 1,2-dichloroethane molecules that occupy the channels before removal of the co-crystallized solvent molecules.

Spectroscopic results have shown that assembly **4a** retains its porosity in the absence of guest solvent molecules.[67] Thus, it has been established that, while solid **4a** may be undergoing some structural changes upon removal of the guest, these changes are not as dramatic as might be expected on the basis of empirical observations of desolvation.

In summary, the appropriately substituted macrocycles **2a**–**2c** can be effectively used for the formation of supramolecular assemblies such as **4a** and **6**. Furthermore, based on the analysis of **2b**, **2c**, and **4a**, hyperpolarized ^{129}Xe NMR spectroscopy is a technique that can be successfully applied to the study of porous organic solids. Trends observed in the ^{129}Xe chemical shift, as well as the dynamic behaviour of the guest xenon gas, have provided substantial insight into the porous nature of these systems. It has also been established that, for the most part, X-ray crystallographic data acquired in the presence of guest solvent molecules can provide a reasonable model for the pore structures of these solids after the removal of the co-crystallized solvent.

Experimental section

General experimental details

Reagents were purchased reagent grade from commercial suppliers and used without further purification. CH_2Cl_2 was distilled from CaH_2 immediately prior to use. All reactions were performed in standard dry glassware under an inert atmosphere of N_2. Deoxygenation of solvents was accomplished by vigorously bubbling N_2 through the solutions for ~45 min. Evaporation and concentration in vacuo was achieved at H_2O-aspirator pressure. Column chromatography: silica gel-60 (230–400 mesh) from Silicycle. Thin layer chromatography (TLC): plastic sheets coated with silica gel G UV_{254} from Macherey-Nagel, visualization by UV light. Melting points: Gallencamp or Fisher-Johns apparatus; uncorrected. IR spectra: Nic-Plan IR microscope (as solids or cast from CH_2Cl_2 as noted). ^{1}H-, ^{13}C-, ^{31}P-, ^{19}F-NMR: Varian Gemini-300, -400, or -500 at room temperature (rt) in CD_2Cl_2; solvent peaks (5.32 ppm for ^{1}H and 53.80 ppm for ^{13}C, respectively) as reference; $CFCl_3$ as ^{19}F reference and 85% H_3PO_4 as ^{31}P reference. ESI MS (*m/z*): Micromass Zabspec oaTOF or PE Biosystems Mariner TOF instruments; solvents as noted.

Continuous-flow hyperpolarized ^{129}Xe NMR spectra were acquired on a Chemagnetics CMX Infinity 200 wide-bore spectrometer operating at a frequency of 55.36 MHz for ^{129}Xe. Hyperpolarized xenon (~7% spin polarization) was generated using a home-built continuous-flow optical pumping system.[23,24] A 60 W dual diode laser from Coherent Inc. was used. The gas mixture consisted of 1% Xe (effective pressure 7 torr (1 torr = 4.184 J)), 1% N_2, and 98% He. The sample temperatures for all spectra were determined using the Chemagnetics temperature controller and calibrated using the ^{207}Pb NMR peak of lead nitrate.[68] The spectra were referenced to the gas peak of ^{129}Xe in the gas mixture (0 ppm) prior to placing samples in the spectrometer. Bloch decay spectra were acquired using π/2 pulse widths of 2.5 μs.

Macrocycle 2a

This compound was synthesized as previously reported (see ref. 6a).

Synthesis of platinacycle 2b[50]

Oligomer **1** (43 mg, 0.082 mmol) was added to a degassed solution of $(PPh_3)_2PtCl_2$ (65 mg, 0.082 mmol) in Et_2NH (150 mL). A catalytic amount of CuI (5 mg, 0.03 mmol) was added and the mixture was sealed under N_2 and then stirred at 50 °C for 14 h. After cooling, ether/CH_2Cl_2 (150 mL, 1:1 *v/v*) was added, and the resulting solution was washed with water (2 × 50 mL) and saturated aqueous NH_4Cl (4 × 50 mL) and then dried ($MgSO_4$). Solvent removal (using *no* heat) followed by precipitation from CH_2Cl_2/acetone afforded platinacycle **2b** (45 mg, 45%) as a bright yellow solid; mp 166 °C (dec.).

Fig. 9. Contour map showing the expected distribution of Xe within the pore structure as predicted by molecular dynamics simulations (ref. 23).

R_f = 0.08 (hexanes/CH_2Cl_2 1:1, alumina). IR (CH_2Cl_2 cast, cm^{-1}): 3050, 2201, 2083, 1581, 1481. ^1H NMR (400 MHz, CD_2Cl_2) δ: 7.77 (d, J = 2.0 Hz, 4H), 7.65–7.59 (m, 24H), 7.42–7.37 (m, 12H), 7.35 (t, J = 2.0 Hz, 2H), 7.31–6.82 (m, 64H). ^{13}C {^1H} NMR (125 MHz, CD_2Cl_2) δ: 150.3, 149.1, 142.3, 140.6, 139.1, 135.4 (pseudo-t, J_{C-P} = 6.2 Hz), 131.2 (pseudo-t, J_{C-P} = 29 Hz), 130.9, 130.8, 130.4, 128.2 (pseudo-t, J_{C-P} = 6.6 Hz), 127.8 (2×), 127.5, 127.2, 120.7, 118.9 (signal too weak to observe P or Pt coupling), 111.2 (signal too weak to observe P or Pt coupling), 105.9, 95.7, 85.5. ^{31}P {^1H} NMR (162 MHz, CD_2Cl_2) δ: 18.0 (coupling to Pt not observed owing to poor signal/noise). ESI MS ($NO_2Me/ClCH_2CH_2Cl$, $C_{154}H_{106}N_2P_4Pt_2$) *m/z* (rel. intensity): 2498.7 ([M + H]$^+$, 100).

Synthesis of platinacycle 2c

Oligomer **1** (35 mg, 0.066 mmol) was added to a degassed solution of $(PEt_3)_2PtCl_2$ (33 mg, 0.066 mmol) in Et_2NH (120 mL). A catalytic amount of CuI (5 mg, 0.03 mmol) was added and the mixture was sealed under N_2 and then stirred at 40 °C for 14 h. After cooling, ether/CH_2Cl_2 (150 mL, 1:1 *v*/*v*) was added, and the resulting solution was washed with water (2 × 50 mL) and saturated aqueous NH_4Cl (4 × 50 mL) and then dried ($MgSO_4$). Solvent removal (using *no* heat) followed by purification using a gradient (CH_2Cl_2 → acetone) silica gel column afforded platinacycle **2c** (45 mg, 71%) as a pale yellow solid; mp 280 °C (dec.). R_f = 0.06 (CH_2Cl_2). IR (CH_2Cl_2 cast, cm^{-1}): 3051, 2927, 2147, 2081, 1580, 1491. ^1H NMR (400 MHz, CD_2Cl_2) δ: 8.00 (d, J = 2.0 Hz, 4H), 7.51–7.26 (m, 42H), 1.88–1.83 (br m, 24H), 1.10–1.00 (pseudo-pentet, J = 8.1 Hz, 36H). ^{13}C {^1H} NMR (100.6 MHz, CD_2Cl_2) δ: 151.1, 150.9, 142.0, 137.8, 130.6, 130.5, 128.0 (3×), 127.7, 120.7, 116.0 (t, $^1J_{C-P}$ = 15 Hz), 107.3, 106.1, 95.4, 85.5, 16.7 (pseudo-t, J_{C-P} = 17 Hz), 8.7 (one signal not observed). ^{31}P {^1H} NMR (162 MHz, CD_2Cl_2) δ: 13.9 ($^1J_{P-Pt}$ = 2344 Hz). ESI MS ($NO_2Me/ClCH_2CH_2Cl$, $C_{106}H_{106}N_2P_4Pt_2$) *m/z* (rel. intensity): 1923 ([M + H]$^+$, 100).

Synthesis of assembly 4a

cis-$(TfO)_2Pt(PEt_3)_2$ **3** (8 mg, 0.01 mmol) and macrocycle **2a** (6 mg, 0.006 mmol) were each dissolved in 10 mL of dry CH_2Cl_2. The solution containing **2a** was slowly added to the solution of **3** and the reaction was stirred at room temperature, under a positive pressure of N_2, for 18 h. A second equivalent of macrocycle **2a** (6 mg, 0.006 mmol) was dissolved in dry CH_2Cl_2 (10 mL) and added to the reaction. The mixture was stirred for a further 18 h and the majority of the solvent was then allowed to evaporate, yielding bright orange crystals, assembly **4a** (17 mg, 84% yield). Note: it is important to control both the dilution of all reactants as well as their order and rate of addition to the reaction mixture. Assembly **4a** can only be isolated in pure form via recrystallization from the reaction mixture, and the presence of excessive numbers and (or) quantities of by-products seriously inhibit the success of this purification step. Melting point 245 °C (dec.). IR (μscope, cm^{-1}): 3503, 3058, 2970, 2932, 2215, 1583, 1520. ^1H NMR (300 MHz, CD_2Cl_2) δ: 8.42 (m, 8H), 7.95 (t, J = 1.7 Hz, 4H), 7.46–7.26 (m, 80H), 1.90–1.72 (m, 24H), 1.22–1.11 (m, 36H). ^{13}C {^1H} NMR (125.3 MHz, CD_2Cl_2) δ: 163.6, 150.2, 145.1, 139.7, 139.1, 131.1, 130.7, 130.3, 130.1, 128.4, 128.3, 125.1, 99.2, 96.2, 84.1, 81.1, 77.5, 15.9 –15.5 (m), 3.3 (*C*F_3 not observed). ^{19}F NMR (400 MHz, CD_2Cl_2, ppm) –78.2. ^{31}P {^1H} NMR (162 MHz, CD_2Cl_2, ppm) –1.3. ESI MS (CH_2Cl_2/NO_2Me, $C_{192}H_{152}F_{12}N_4O_{12}P_4Pt_2S_4$) *m/z* (rel. intensity): 1059 ([**2a** + H]$^+$, 9), 745 ([M – 4(OTf)]$^{+4}$, 24), 492 ([**3** – 2(OTf) + NO_2Me]$^+$, 78), 429 ([**3** – 2(OTf)]$^+$, 100).

Supplementary data

Supplementary data are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v11-077 or as CCDC 666371–666373 and CCDC 205116, which can be obtained, free of charge, via www.ccdc.cam.ac.uk/cgi-bin/catreq.cgi (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk)).

Acknowledgement

The authors wish to thank K. Feindel, Dr. G. Bernard, and Dr. D. Sears for several helpful comments, as well as Dr. C.J. Kuehl for his contributions to the initial formation of **4a**. They acknowledge Drs. S. Lang, I. Moudrakovski, and J. Ripmeester of the Steacie Institute for Molecular Sciences,

National Research Council Canada, for their advice in constructing the continuous flow diode laser system to produce the hyperpolarized xenon, and Professor T. Ueda for his assistance in constructing this apparatus. The Natural Sciences and Engineering Research Council of Canada (NSERC), the Alberta Ingenuity Fund, and the University of Alberta are gratefully thanked for financial support. R.E.W. is a Canada Research Chair in Physical Chemistry at the University of Alberta.

(51) It is worth noting the importance of using no heat when removing the solvent, subsequent to workup, in reactions to form the Pt–acetylide containing macrocycles. Despite the fact that heat is applied during the transmetalation reaction, and that the platinacycles **2b** and **2c** are thermally stable solids, heating during solvent removal leads to a darkening of the solution(s) accompanied by a bad odour. This procedure results in lower overall yields, predominantly because of increased problems with respect to purification.

Abstract: Four new triterpenoid saponins, Catunaroside E (**1**; 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-siaresinolic acid), Catunaroside F (**2**; 3-*O*-{α-L-rhamnopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-28-*O*-(β-D-glucopyranosyl)-oleanolic acid), Catunaroside G (**3**; 3-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl]- 28-*O*-(β-D-glucopyranosyl)-siaresinolic acid), and Catunaroside H (**4**; 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-28-*O*-(β-D-glucopyranosyl)-siaresinolic acid), and the known triterpenoid saponin Mussaendoside J (**5**), were isolated from the stem bark of *Catunaregam* spinosa. Their structures were elucidated on the basis of their spectral data and chemical evidence.

Key words: Catunaregam spinosa, Rubiaceae, triterpenoid saponins, Catunaroside E–H.

Résumé : À partir de l'écorce du tronc de *Catunaregam spinosa,* on a isolé quatre nouvelles saponines triterpénoïdes, le catunaroside E (**1**), l'acide 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}siarésinolique, le catunaroside F (**2**), l'acide 3-*O*-{α-L-rhamnopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-28-*O*-(β-D-glucopyranosyl)oléanolique, le catunaroside G (**3**), l'acide 3-*O*-{α-L-rhamnopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-28-*O*-(β-D-glucopyranosyl)siarésinolique et le catunaroside H (**4**), l'acide 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-28-*O*-(β-D-glucopyranosyl)siarésinolique et une saponine triterpénoïde connue,le mussaendoside J (**5**). Leurs structures ont été élucidées sur la base de leurs propriétés chimiques et de leurs données spectrales.

Mots-clés : Catunaregam spinosa, rubiacée, saponines triterpénoïdes, caturanoside E-H.

[Traduit par la Rédaction]

Introduction

Catunaregam spinosa T. (Rubiaceae), which is mostly distributed in tropical and semitropical areas, was used in the traditional medicinal systems of India and Brazil for its antispasmodic, antidysenteric, anti-inflammatory, immunomodulatory, and antifertility properties.[1–4] Chemical investigation of *C. spinosa* led to the isolation of triterpene and saponins,[4–6] iridoid glucosides,[1] coumarin glucosides,[7] and norneolignans.[8] In continuation of our studies on the chemical diversity of mangrove plants on Hainan Island, this plant was investigated and four new triterpenoid saponins, Catunaroside E–H, together with Mussaendoside J, were obtained from the *n*-BuOH extract of its stem bark (Fig. 1). This paper deals with the isolation and structure elucidation of those triterpenoid saponins. Mussaendoside J was first obtained from this plant.

Results and discussion

Compound **1** was obtained as a colorless amorphous powder. Its molecular formula was assigned as $C_{48}H_{78}O_{19}$ based on the high-resolution electrospray ionization mass spectrometry (HR-ESI-MS; *m/z*: 981.5080 $[M + Na]^+$). The infrared (IR) spectrum exhibited absorption bands at 3418 (OH), 1728 (C=O), and 1644 (C=C) cm^{-1}. The seven tertiary methyl groups (δ 1.26, 1.08, 0.81, 1.06, 1.66, 1.18, and 1.02 ppm) and one olefinic proton (δ 5.55, br s) were observed in the ^1H nuclear magnetic resonance (NMR) spectrum. The ^{13}C and distortionless enhanced polarization transfer (DEPT) NMR data of the aglycon part of **1** confirmed the presence of seven methyl carbons (δ 28.0, 16.7, 15.4, 17.5, 24.9, 28.9, and 24.9 ppm), two olefinic carbons (δ 123.1 and 144.9 ppm), and two oxygenated methine carbons (δ 89.5 and 81.3 ppm) (Table 2). The comparison of ^1H and ^{13}C NMR spectrum data of the aglycon part of **1** with that of Latifolioside H indicated that compound **1** possessed a 3β,19α-dihydroxyolean-12-ene-28-oic acidic aglycon.[9] The chemical shifts of C-3 (δ 89.5) and C-28 (δ 180.9) revealed that **1** was a monodesmosidic glycoside. Eighteen of

Note: Glc, glucose.

48 carbons were assigned to the oligosaccharide moieties. The ^{1}H and ^{13}C NMR spectra of **1** showed three sugar anomeric protons at δ 4.83 (d, J = 7.5 Hz), 5.37 (d, J = 7.6 Hz), and 5.72 (d, J = 7.6 Hz) and carbons at δ 105.1, 104.7, and 103.8 (Tables 1 and 2). The monosaccharides were identified as glucose by comparing the retention factor (R_f) value with that of D-glucose using thin-layer chromatography (TLC) after acid hydrolysis and a combination of DEPT, heteronuclear single quantum coherence (HSQC), and heteronuclear multiple bond correlation (HMBC) experiments, respectively. All glucoses of **1** were in pyranose forms, as determined by their 1D and 2D NMR experiments. The β-anomeric configurations of the glucose units were established by its $^3J_{H1,H2}$ coupling constants (7.5–7.6 Hz). The signal at δ 88.6 in the ^{13}C NMR indicated a substitution at C-3′ of one of the glucoses. The sequence of the glycan part connected to C-3 of the aglycon was deduced from the following HMBC correlations: H-1′ (δ 4.83) of inner glucose with C-3 (δ 89.5) of sapogenin, H-1′′ (δ 5.37) of one terminal glucose with C-3′ (δ 88.6), and H-1′′′ (δ 5.72) of another terminal glucose with C-2′ (δ 79.3) (Fig. 2). The NMR data of the glycan part of **1** was in accordance with that of 3-*O*-[2′,3′-di-*O*-(β-D-glucopyranosyl)-β-D-glucopyranosyl] oleanolic acid.[10] On the basis of the above results, compound **1** was elucidated as 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-siaresinolic acid, named as Catunaroside E.

Compound **2** was determined to have the molecular formula of $C_{54}H_{88}O_{22}$ by its HR-ESI-MS spectrum (*m*/*z*: 1111.5702 [M + Na]$^+$). In the ^{1}H NMR spectrum, seven methyl protons (δ 1.23, 1.15, 0.83, 1.07, 1.23, 0.89, and 0.87 ppm), one olefinic proton (δ 5.41, br s), and four sugar anomeric protons (δ 4.83, d, J = 7.5 Hz; 5.11, d, J = 7.8 Hz; 6.47, br s; and 6.31, d, J = 8.1 Hz) (Table 1) were observed. The signals of seven methyl carbons at δ 28.1, 17.1, 15.7, 17.5, 26.1, 33.1, and 23.7 ppm, two olefinic carbons at δ 122.9 and 144.1 ppm, four sugar carbons at δ 104.9, 103.9, 101.7, and 95.8 ppm, and two carbons at δ 176.4 and 88.7 ppm linked to the glycan part were also shown in the ^{13}C NMR spectrum. The above evidence revealed that **2** was a bisdesmosidic glycoside. The aglycon part of this compound was determined to be oleanolic acid by comparing the ^{1}H, ^{13}C, and DEPT NMR signals of **2** with those of 3-*O*-[β-D-glucopyranosyl-(1→3)-β-D-galactopyranosyl]-olean-12-en-3β-ol-28-oic acid.[5] Acid hydrolysis of **2** suggested that the monosaccharides of this compound were L-rhamnose and D-glucose. In combination with the characteristic proton signal at δ 1.67 (3H, d, J = 6.0 Hz) in the ^{1}H NMR spectrum, **2** could be deduced to contain one rhamnose and three glucose. By comparing with the NMR spectra of Mussaendoside J (**5**), the presence of glucose linked to C-3′ (δ 89.6) in **2** was disclosed. The sequence of the oligosaccharide chain was confirmed by HSQC, HMBC, and ^{1}H-^{1}H double quantum filtered correlation spectroscopy (DQFCOSY) experiments. The key HMBC correlations were observed: H-1′′′′ (δ 6.31) of a glucose and C-28 (δ 176.4) of the aglycon part, H-1′ (δ 4.83) of

Table 2. ^{13}C NMR data of compounds **1–5** in pyridine-d_5.

the inner glucose and C-3 (δ 88.7) of the aglycon part, H-1′′ (δ 5.11) of the terminal glucose and C-3′ (δ 89.6) of the inner glucose, and H-1′′′ (δ 6.47) of the terminal rhamnose and C-2′ (δ 78.7) of the inner glucose (Fig. 2). The β-anomeric configurations of glucose units were determined by the relatively large $^3J_{H1,H2}$ coupling constants (7.5–8.1 Hz). The $^1J_{C1,H1}$ coupling constant (168 Hz) for the rhamnosyl unit confirmed that the anomeric proton was equatorial (α-pyranoid anomeric form).[11] On the basis of this evidence, compound **2**, named as Catunaroside F, was elucidated as 3-*O*-{α-L-rhamnopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-28-*O*-(β-D-glucopyranosyl)-oleanolic acid.

Compound **3**, also an amorphous powder, has the molecular formula of $C_{48}H_{78}O_{17}$ as indicated by its HR-ESI-MS spectrum (*m/z*: 965.5129 $[M + Na]^+$). In the ^1H NMR spectrum, seven methyl protons (δ 1.26, 1.20, 0.88, 1.13, 1.63, 1.14, and 0.98 ppm), one olefinic proton (δ 5.50, br s), and three sugar anomeric protons (δ 4.94, d, J = 7.0 Hz; 6.56, br s; and 6.38, d, J = 8.0 Hz) (Table 1) were observed. The signals of seven methyl carbons at δ 28.1, 17.1, 15.5, 17.6, 24.9, 28.,7 and 24.7 ppm, two olefinic carbons at δ 123.1 and 144.3 ppm, three sugar carbons at δ 105.4, 101.7, and 95.9 ppm, and two carbons at δ 177.2 and 88.9 ppm linked to the glycan part were also shown in the ^{13}C NMR spectrum. The signals in the NMR spectrum of **3** were in agreement with those of Mussaendoside J, except for the signals of the aglycon part at δ 81.1 (d, C-19) ppm, which was oxygenated, and 35.5 (s, C-20) ppm.[12] The aglycon part of **3** was then established as siaresinolic acid by comparing the NMR spectrum data of **3** with that of **1**. From the above evidence, compound **3** was identified as 3-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl]-28-*O*-(β-D-glucopyranosyl)-siaresinolic acid, named as Catunaroside G.

Compound **4**, obtained as an amorphous powder, was deduced to have the molecular formula of $C_{54}H_{88}O_{24}$ as indicated from the HR-ESI-MS data (*m/z*: 1143.5586 $[M + Na]^+$). Acid hydrolysis of **4** showed the existence of D-glucose. The signals at 177.3 and 89.5 ppm in the ^{13}C NMR spectrum suggested that **4** was a bisdesmosidic glycoside. In the ^1H and ^{13}C NMR spectrum, four anomeric carbon signals (δ 4.83, d, J = 7.5 Hz; 5.36, d, J = 8.0 Hz; 5.71, d, J = 7.5 Hz; and 6.36, d, J = 8.0 Hz and δ 105.1, 104.7, 103.9, 95.9 ppm) (Tables 1 and 2) were exhibited. Compound **4** had the same NMR signals as Aralia-saponin V except the signals of C-19 (δ 81.2 ppm) and C-20 (δ 35.6 ppm) of the aglycon part, which is just like the difference between compound **3** and Mussaendoside J.[13] Similarly, the aglycon moiety of **4** was determined to be siaresinolic acid. Thus, compound **4** was elucidated as 3-*O*-{β-D-glucopyranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-β-D-glucopyranosyl}-28-*O*-(β-D-glucopyranosyl)-siaresinolic acid, named as Catunaroside H.

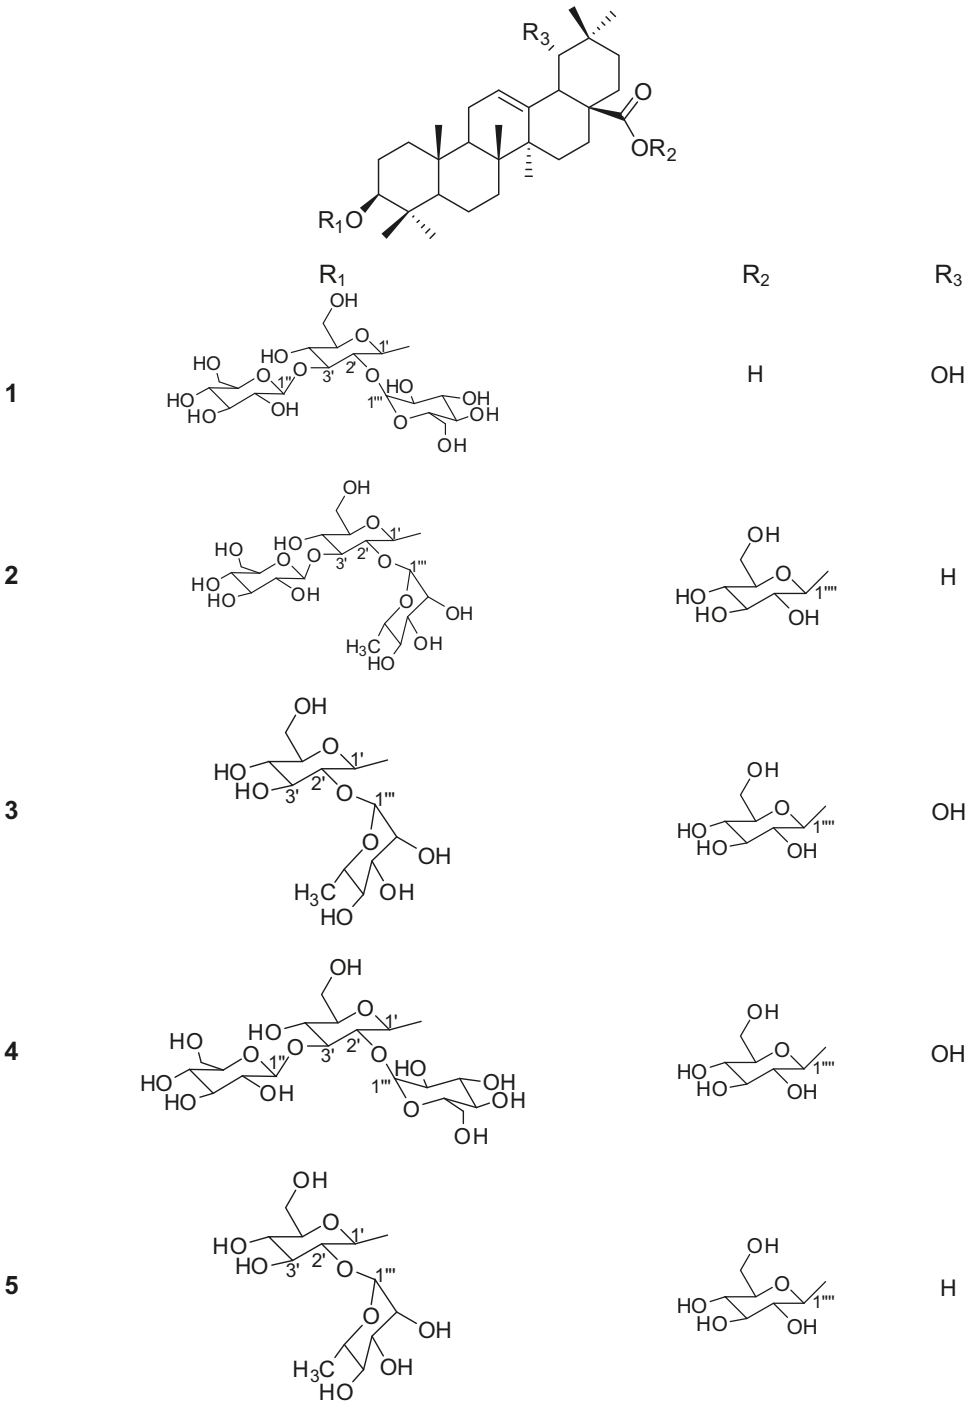
Fig. 1. Structures of compounds **1–5.**



Compound **5** was elucidated as Mussaendoside J by comparing its spectra data with the data reported in the literature (IR, MS, and ^{1}H and ^{13}C NMR).[12]

Experimental

General

MS were recorded on a MDS SCIEX API 2000 LC/MS/MS instrument for ESI and a Bruker BioTOF Q spectrometer for HR-ESI. IR spectra were measured with a Bruker EQUINOX55 infrared spectrometer. ^{1}H and ^{13}C NMR spectra were acquired with a Bruker DRX-500 spectrometer ($SiMe_4$ as the internal standard). Silica gel (Qingdao Haiyang Chemical Co., Ltd., 100–200 mesh and 200–300 mesh) and LiChroprep RP-18 (Merck) were used for the silica gel column chromatography (CC) and medium-pressure liquid chromatography (MPLC). Sephadex LH-20 (Pharmacia) and macroporous resin D101 were also used for column chromatography. TLC was carried on precoated silica gel 60 F_{254} plates (Qingdao Haiyang Chemical Co., Ltd.), and detection was achieved by 10% H_2SO_4–EtOH for saponins. Semipreparative high-pressure liquid chromatography (HPLC) was performed using

an octadecylsilane (ODS) column (YMC-Pack ODS-5-A, 250 mm × 10 mm inside diameter (i.d.), 5 μm; YMC Co., Ltd.) on a Waters-600 HPLC system equipped with a Waters-996 photodiode array detector.

Plant material

The stem bark of *C. spinosa* Tirveng was collected in February 2006 from Sanya, Hainan Province, P. R. China. The specimen was identified by professor Si Zhang, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, P. R. China. A voucher specimen has been deposited in the South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, P. R. China (accession number: GKLMMM020).

Extraction and isolation

The *n*-BuOH extract of air-dried and powdered plant material (9.0 kg) was extracted by the method as previously reported.[8] The *n*-BuOH soluble fraction (170 g) was passed through a macroporous resin (D101) column eluted with H_2O and EtOH–H_2O (3:7, 6:4, and 95:5), whereas the EtOH–H_2O (95:5, 10 g) eluted portion was subjected to silica gel CC eluted with $CHCl_3$–MeOH (98:2–50:50) to give fractions A–G. Fraction E was separated by preparative HPLC using MeOH–H_2O (68:32) to give compound **1** (10 mg). Fraction F was recrystallized to afford compound **2** (50 mg). The EtOH–H_2O (6:4, 35 g) eluted portion was subjected to silica gel CC eluted with $CHCl_3$–MeOH (90:10–50:50) to give fractions a–f. Fraction b was separated by Sephadex LH-20 (MeOH), then fractions 25–28 and 53–54 were purified by preparative HPLC eluting with MeOH–H_2O (55:45) and MeOH–H_2O (70:30) to obtain compounds **3** (22 mg) and **5** (12 mg) separately. Fraction f was rechromatographed to silica gel CC eluted with $CHCl_3$–MeOH–H_2O (80:20:5), then fraction 12 was purified by preparative HPLC using MeOH–H_2O (50:50) to yield compound **4** (70 mg).

Catunaroside E (1)

Colorless amorphous powder. IR (KBr, cm^{-1}) υ_{max}: 3418, 1728, 1644. ^{1}H NMR (500 MHz, pyridine-d_5) δ: 3.25 (1H, dd, J = 4.4, 11.5 Hz, H-3), 5.55 (1H, br s, H-12), 3.62 (1H, br s, H-18), 3.60 (1H, br s, H-19), 1.26 (3H, s, H-23), 1.08 (3H, s, H-24), 0.81 (3H, s, H-25), 1.06 (3H, s, H-26), 1.66 (3H, s, H-27), 1.18 (3H, s, H-29), 1.02 (3H, s, H-30), 4.83 (1H, d, J = 7.5 Hz, H-1′), 5.37 (1H, d, J = 7.6 Hz, H-1″), 5.72 (1H, d, J = 7.6 Hz, H-1‴). ^{13}C NMR (125 MHz, pyridine-d_5) data, see Table 2. Abstract: The stereodynamics of the title reaction on the ab initio ^{1}A′ potential energy surface (PES) (B. Bussery-Honvault, P. Honvault, and J.-M. Launay. 2001. J. Chem. Phys. **115**: 10701) at a collision energy of 16 kJ/mol have been studied using quasi-classical trajectory (QCT) method. Vector properties including angular momentum alignment parameters and four polarization-dependent differential cross sections (PDDCS) of the product CH are presented. Furthermore, the influence of reagent vibrational and rotational excitations on the product vector properties have also been studied in the present work. The calculated results indicate that the angle distributions of the CH product are mainly dominated by backward–forward scattering.

Key words: quasi-classical trajectory, potential energy surface, stereodynamics.

Résumé : Faisant appel à la méthode de la trajectoire quasi-classique (TQC), on a étudié la stéréodynamique de la réaction mentionnée dans le titre sur une surface d'énergie potentielle (SEP) ab initio ^{1}A′ (B. Bussery-Honvault, P. Honvault, and J.-M. Launay. 2001. J. Chem. Phys. **115** : 10701), à une énergie de collision de 16 kJ/mol. On rapporte les propriétés vectorielles, dont les paramètres d'alignement de la quantité de mouvement angulaire et les quatre sections droites différentielles dépendantes de la polarisation (SDDDP) du produit CH. Dans ce travail, on a de plus étudié l'influence de l'excitation rotationnelle et vibrationnelle du réactif sur les propriétés vectorielles du produit. Les résultats calculés indiquent que les angles de distribution du produit CH sont principalement dominés par une diffusion de l'arrière ver l'avant.

Mots-clés : trajectoire quasi-classique, surface d'énergie potentielle, stéréodynamique.

Introduction

The gas-phase reaction C(^{1}D) + H_2 and its reverse reaction play a crucial role in astrophysics and carbon chemistry. In the last few years, the title reaction has attracted considerable attention from experimental and theoretical studies.[1–9] Being a typical atom–diatom indirect insertion reaction, it has the colliding atom in an electronically excited state and is used to test the quality of new theories and experiments. Therefore, extensive studies of the title reaction can help us explore the detailed dynamics of the other insertion-type chemical reactions, such as N(^{2}D) + H_2[10–12] and O(^{1}D) + H_2.[13–16]

Experimentally, Bergeat et al.[1] using the crossed molecular beam (CMB) scattering technique measured the product angular and time-of-flight (TOF) distributions for the C(^{1}D) + H_2 reaction. Balucani et al.[2,3] measured the product angular and velocity distributions in the crossed molecular beam experiments.

Theoretically, in 2001, Bussery-Honvault et al.[4] constructed a potential energy surface (PES) for the title reaction. Motivated by this PES, there were also a number of theoretical studies for the reaction C(^{1}D) + H_2 and its isotopic variants. Bañares et al.[5] calculated integral and differential cross sections at 80 meV collision energy with the initial H_2 rotational quantum numbers $j = 0$ and 1. In addition, they also obtained the total and vibrationally state-resolved reaction probabilities at total angular momentum $J = 0$ in the 0–0.5 eV collision energy range. Using the time-dependent real wave packet method, the state-to-state and state-to-all reactive scattering probabilities for a broad range of energies were calculated on the same PES by Gogtas et al.[17] Recently, Lin and Guo[9,18] performed quantum wave packet calculations of C(^{1}D) + H_2 reactive and inelastic scattering for $J = 0$, integral cross sections, and rate constants.

As mentioned previously, a number of experimental[1–3] and theoretical studies[4–9] on the reaction of C(^{1}D) + H_2 and its isotopic variants have been carried out for the past decades. However, most of these studies only focused on scalar properties not vector properties. The vector properties of chemical reaction can represent an interesting probe into understanding the stereodynamics.[19–21] Since the pioneering work of Fano and Macek,[22] of Case and Herschbach,[23] and of Blais and Truhlar,[24] substantial progress has been made in the field of chemical reaction stereodynamics.[25–32] With the development of new experimental techniques, such as polarized

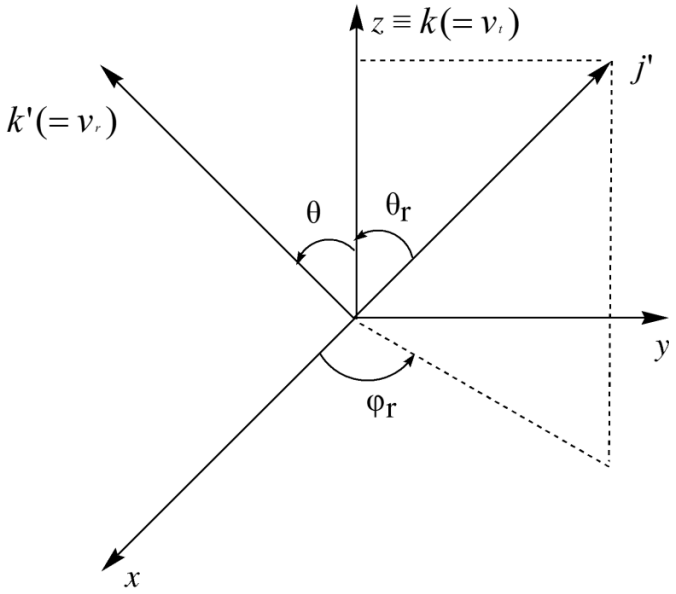
Fig. 1. The center-of-mass coordinate system used to describe the final relative velocity vector (**k**′) and the final rotational angular momentum (**j**′) correlations.



laser-induced fluorescence,[20] laser-induced chemiluminescence,[25] and Doppler-resolved laser-induced fluorescence,[28,29] it is becoming evident that product rotational polarization can provide detailed mechanistic information. One significant step in the theoretical progress is the introduction of the concept of polarization-dependent differential cross sections (PDDCSs) by Shafer-Ray et al.[30] Han and co-workers[25–27] have systematically studied the product rotational polarization of bimolecular reactions with different reagent mass combinations on attractive, mixed, and repulsive potential energy surfaces. In this paper, we focused on the vector properties of the $C(^1D) + H_2$ reaction and the influence of vibrational and rotational excitations on the stereodynamics.

Polarization-dependent differential cross sections (PDDCS)

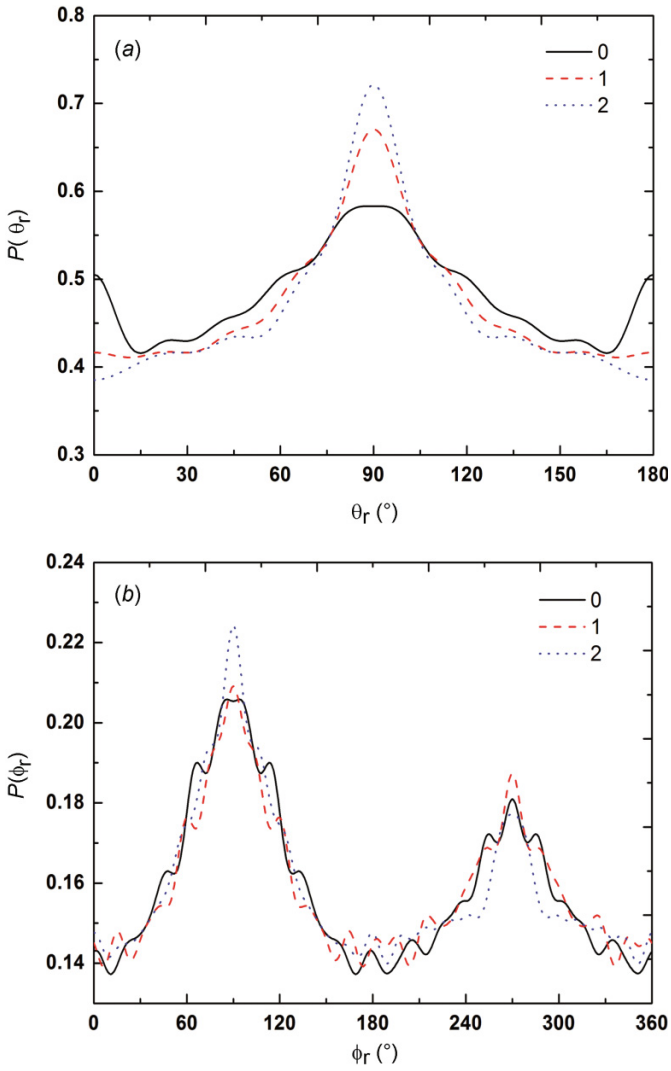
The full three-dimensional angular distribution associated with **k**, **k**′, and **j**′ can be represented by a set of generalized PDDCSs in the center-of-mass (CM) frame,[33,34] which is shown in Fig. 1. The reagent relative velocity vector **k** is parallel to the z axis. The x–z plane is the scattering plane containing the initial and final relative velocity vectors, **k** and **k**′. The angle θ is the so-called scattering angle between the reagent relative velocity and the product relative velocity. The angles θ_r and ϕ_r are the polar and azimuthal angles of the final rotational angular momentum **j**′, respectively.

The distribution function $P(\theta_r)$ corresponding to the **k**–**j**′ correlation is expanded into a series of Legendre polynomials:[16,26]

$$[1] \qquad P(\theta_r) = \frac{1}{2}\sum_k (2k+1)\boldsymbol{a}_0^k P_k(\cos\theta_r)$$

The $\boldsymbol{a}_0^k$ coefficients (polarization parameters) are given by

Fig. 2. The distribution of $P(\theta_r)$ and $P(\phi_r)$ for the CH product from the reaction $C(^1D) + H_2$ ($v, j = 0$) → CH + H at a collision energy of 16 kJ/mol. The $P(\theta_r)$ in (*a*) describes the **k**–**j**′ correlation. The $P(\phi_r)$ in (*b*) shows the dihedral angle distribution of **j**′ with respect to the **k**–**k**′ plane.



$$[2] \qquad \boldsymbol{a}_0^k = \int_0^{\pi} P(\theta_r)P_k(\theta_r)\sin\theta_r d\theta_r = < P_k(\cos\theta_r) >$$

where the angular brackets represent an average over all of the reactive trajectories. In this paper, $P(\theta_r)$ is expanded up to $k = 18$, which shows good convergence.

The dihedral angle distribution function $P(\phi_r)$ described for the **k**–**k**′–**j**′ correction can be expanded as a Fourier series:[24]

$$P(\phi_r) = \frac{1}{2}\left[1 + \sum_{n,\text{even}\geq 2} a_n \cos(\phi_r) + \sum_{n,\text{odd}\geq 2} b_n \sin(\phi_r)\right]$$

where $a_n = 2< \cos\phi_r >$ and $b_n = 2< \sin\phi_r >$. In this work, $P(\phi_r)$ is expanded up to $n = 24$, which shows good convergence.

The full three-dimensional distribution associated with **k**, **k**′, and **j**′ can be represented by a set of generalized PDDCSs. The fully correlated CM angular distribution is given as follows:[24,28]

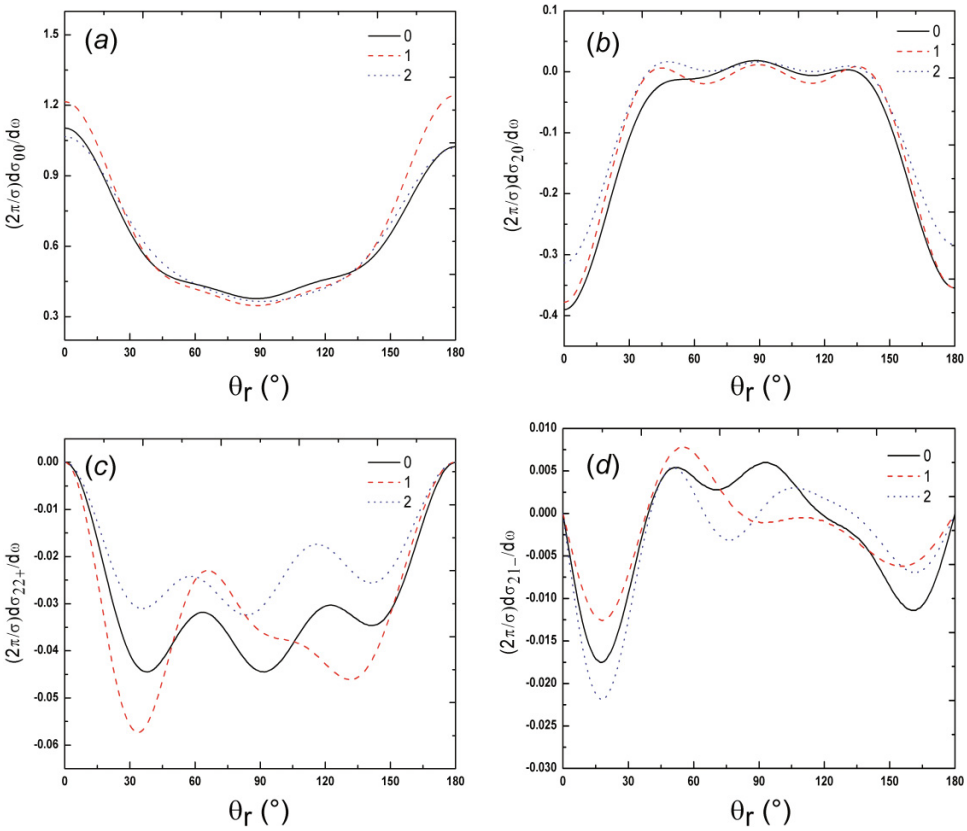
Fig. 3. Four polarization-dependent differential cross sections (PDDCSs) for the CH product from the reaction $C(^1D) + H_2$ (v, $j = 0$) → CH + H at a collision energy of 16 kJ/mol. Panel (*a*) shows the PDDCSs with (k,q) = (0,0). Panels (*b*)–(*d*) depict the PDDCSs with (k,$q\pm$) = (2,0), (2,2+), and (2,1–), respectively.



$$P(\omega_t, \omega_r) = \frac{1}{4\pi}\sum_{kq}(2k+1)\frac{1}{\sigma}\frac{d\sigma_{kq}}{d\omega t}C_{kq}(\theta_r, \phi_r)$$

where $\omega_t = \theta$ and $\omega_r = \theta_r$, and ϕ_r, $C_{kq}(\theta_r,\phi_r)$ are modified spherical harmonics, σ is the integral cross section, $\frac{1}{\sigma}\frac{d\sigma_{kq}}{d\omega t}$ are the generalized PDDCSs, and $\frac{1}{\sigma}\frac{d\sigma_{kq}}{d\omega t}$ yields

$$\frac{1}{\sigma}\frac{d\sigma_{k_0}}{d\omega t} = 0$$

where k is odd,

$$\frac{1}{\sigma}\frac{d\sigma_{kq_+}}{d\omega t} = \frac{1}{\sigma}\frac{d\sigma_{kq}}{d\omega t} + \frac{1}{\sigma}\frac{d\sigma_{k-q}}{d\omega t} = 0$$

where k is even and q is odd or k is odd and q is even,

$$\frac{1}{\sigma}\frac{d\sigma_{kq_-}}{d\omega t} = \frac{1}{\sigma}\frac{d\sigma_{kq}}{d\omega t} - \frac{1}{\sigma}\frac{d\sigma_{k+q}}{d\omega t} = 0$$

where k is even and q is even or k is odd and q is odd.

Quasi-classical trajectory (QCT) calculations

All the QCT calculations have been performed on the 1A′ CH_2 ab initio PES constructed by Bussery-Honvault et al.[4] The QCT method is described in detail elsewhere,[35–37] and the classical Hamiltonian equations are integrated numerically for motion in three dimensions with the sixth-order symplectic integration.[38] The QCT method has already proved successful in describing atom–diatom insertion reactions such as $N(^2D) + H_2 \rightarrow NH + H$[10–12] and $O(^1D) + H_2 \rightarrow OH + H$.[13–16] As pointed out by Ju et al.,[39] the QCT calculated results are in good agreement with the quantum mechanics ones for most chemical reactions. A branching of 100 000 trajectories was run for each of the $C(^1D) + H_2$ (v, j) reactions. The integration step size for the trajectories was chosen to be 10^{-17} s, which guarantees the conservation of the total energy and total angular momentum. The trajectories were started at a distance between the incoming atom and the center-of-mass of the diatom of 10 Å.

Results and discussion

The effect of vibrational excitation on stereodynamics

The $P(\theta_r)$ and $P(\phi_r)$ of the product CH from the reactions $C(^1D) + H_2$ ($v = 0$, 1, or 2, $j = 0$) → CH + H at a collision energy of 16 kJ/mol are shown in Fig. 2. Evidently, the distribution of $P(\theta_r)$ shows significant variations from the vibrational excitation of CH and displays a preference for the product rotational angular momentum vector perpendicular to the relative velocity direction. The peak of $P(\theta_r)$ at the θ_r angle is close to 90° and symmetric with respect to 90° for $v = 0$, 1, or 2, which shows that the product vibrational angular momentum vector is aligned along the direction at right angles to the relative velocity direction. In addition, the peak of $P(\theta_r)$ at 90° becomes narrower and higher with increasing vibrational excitation. $P(\phi_r)$ shown in Fig. 2*b* describes the **k**–**k**′–**j**′ correlation. The peaks of the $P(\phi_r)$ distribution and

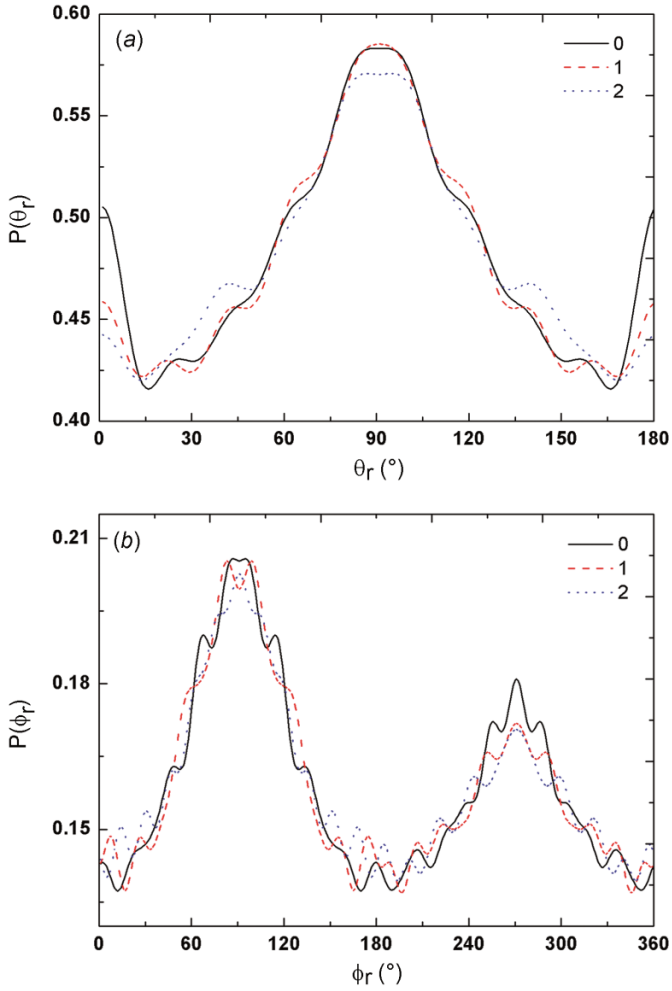
Fig. 4. The distribution of $P(\theta_r)$ and $P(\phi_r)$ for the CH product from the reaction $C(^1D) + H_2$ ($v = 0$, j) → CH + H at a collision energy of 16 kJ/mol. The $P(\theta_r)$ in (*a*) describes the **k**–**j**′ correlation. The $P(\phi_r)$ in (*b*) shows the dihedral angle distribution of **j**′ with respect to the **k**–**k**′ plane.



the peaks also become narrower and higher with increasing vibrational excitation. These indicate that the vibrational angular momentum vectors of the products are mainly aligned along the *y* axis of the CM frame and become stronger as the vibrational excitation increases. In addition, we can also see that the distributions of $P(\phi_r)$ tend to be asymmetric with respect to the **k**–**k**′ scattering plane (or about $\phi_r = 180°$), directly reflecting the handedness of **j**′ with respect to the **k**–**k**′ plane.[24] The peak of $P(\phi_r)$ at 90° is larger than that at 270° for $v = 0$, 1, or 2, which suggests that **j**′ is preferentially oriented along the positive direction of the *y* axis.

The PDDCSs that describe the **k**–**k**′–**j**′ correlation and the scattering direction of the product molecule are presented in Fig. 3 for the reaction $C(^1D) + H_2$ ($v = 0$, 1, or 2, $j = 0$) → CH + H at a collision energy of 16 kJ/mol. Figure 3*a* displays the PDDCSs ($(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$) that describe the **k**–**k**′ correlation and the scattering direction of the product CH. The analysis of the results of $(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$ indicates that the products are forward–backward symmetric scattering and are more affected by the vibrational excitation. Balucani et al.[3] studied the title reaction using a combined crossed molecular beam experimental and theoretical method. Their experimental results show the DCS at E_c (16 kJ/mol) has a pronounced preference for backward–forward symmetric scattering. It can be clearly seen that our calculated results are in good agreement with those calculated by Balucani et al.[3] The distribution of $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$ contains the alignment of **j**′ with respect to **k** as a function of the scattering angle. The behavior of $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$ (see Fig. 3*b*) shows a similar trend with $(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$ and obviously is affected by the vibrational excitation. It is clearly a backward–forward scattering product owing to the negative values of $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$ and suggests that the alignment of **j**′ is preferentially polarized along the direction perpendicular to **k**. Whether the value of $(2\pi/\sigma)(d\sigma_{22+}/d\omega_t)$ is positive or negative indicates the preference of **j**′ alignment along the *x* or *y* axis, respectively. In Fig. 3*c*, we can see that the value of $(2\pi/\sigma)(d\sigma_{22+}/d\omega_t)$ is negative for all scattering angles, indicating a noticeable preference for an alignment of **j**′ along the *y* axis. It is worth mentioning that the CH product displays a stronger polarization when the CH products are scattering at about 30° for $v = 1$. However, for $v = 0$ or 2, the strongest polarization is close to 30° and 90°. The distribution of $(2\pi/\sigma)(d\sigma_{21-}/d\omega_t)$, which is related to $< \sin\theta^2 \cos 2\phi >$, is depicted in Fig. 3*d*. As seen in Fig. 3*d*, the value of $(2\pi/\sigma)(d\sigma_{21-}/d\omega_t)$ is close to zero on the surface, so $(2\pi/\sigma)(d\sigma_{21-}/d\omega_t)$ is obviously isotopic and is weakly influenced by vibrational exciation.

The effect of rotational excitation on sterodynamics

Figures 4 and 5 depict the $P(\theta_r)$, $P(\phi_r)$, and the four PDDCSs of the CH product from the reaction $C(^1D) + H_2$ ($v = 0$, $j = 0$, 1, or 2) → CH + H at a collision energy of 16 kJ/mol. Evidently, the rotational excitation of H_2 has slightly less influence on the distribution of $P(\theta_r)$ than the vibrational excitation of H_2 (see Figs. 2*a* and 4*a*). The peak of $P(\theta_r)$ at the θ_r angle is close to 90° and symmetric with respect to 90° for $j = 0$, 1, or 2, which displays a preference for the product rotational angular momentum vector perpendicular to the relative velocity direction. As can be seen, the rotational excitation also has a weak influence on the distribution of $P(\phi_r)$, which is consistent with the vibrational excitation. However, analysis of the results in Fig. 4*b* shows that the peaks of $P(\phi_r)$ at 90° are slightly larger than those at 270°, i.e., the **j**′ is preferentially oriented along the positive direction of the *y* axis.

From the results of Figs. 5*a* and 5*b*, we can conclude that the rotational excitation has a weak influence on $(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$ and $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$. As we know, the PDDCS of $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$ is related to the product rotational alignment of $< P_2 (\mathbf{j}'\cdot\mathbf{k}) >$, and the expectation values of $< P_2 (\mathbf{j}'\cdot\mathbf{k}) >$ for H_2 ($v = 0$, $j = 0$, 1, or 2) are –0.345, –0.346, and –0.345, respectively, which is in good accordance with the PDDCS $(2\pi/\sigma)(d\sigma_{20}/d\omega_t)$. Whereas the PDDCS $(2\pi/\sigma)(d\sigma_{22+}/d\omega_t)$ exhibits a dependence on the rotational excitation and the scattering angle, it is clearly backward scattering owing to its negative value. Since the value of the PDDCS $(2\pi/\sigma)(d\sigma_{21-}/d\omega_t)$ is close to zero on the surface, it is obviously isotopic and is also weakly influenced by rotational excitation.

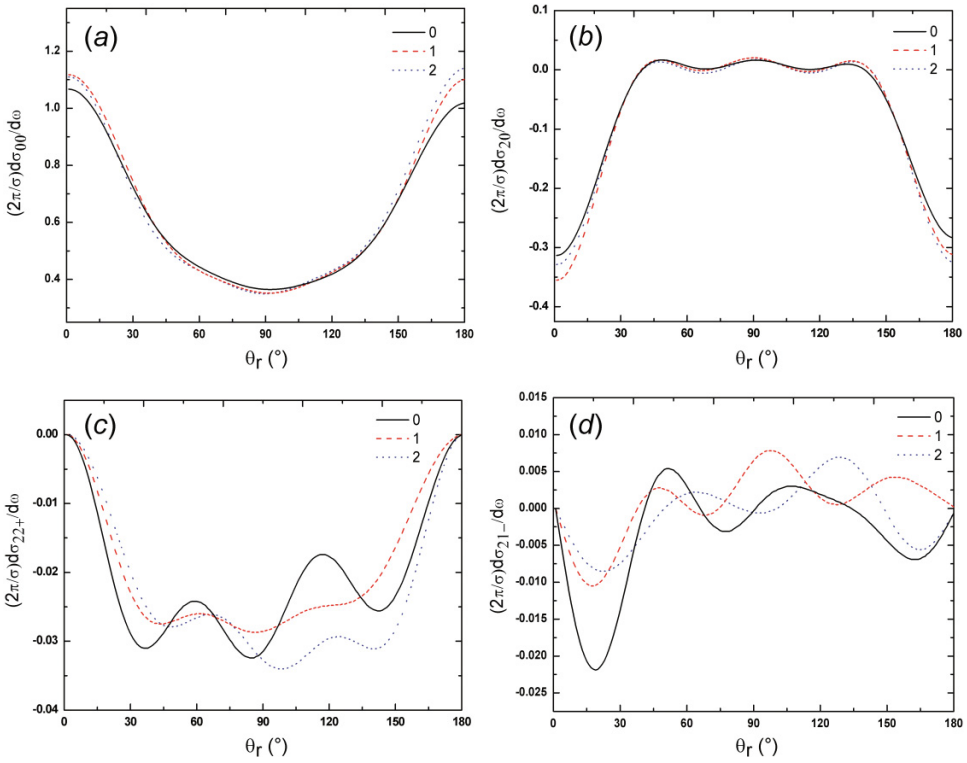
Fig. 5. Four polarization-dependent differential cross sections (PDDCSs) for the CH product from the reaction $C(^1D) + H_2$ ($v = 0, j$) → CH + H at a collision energy of 16 kJ/mol. Panel (*a*) shows the PDDCSs with (k,q) = (0,0). Panels (*b*)–(*d*) depict the PDDCSs with (k,$q\pm$) = (2,0), (2,2+), and (2,1–), respectively.



Conclusion

The major objective of this paper was to study the vector correlation for the chemical reaction $C(^1D) + H_2$ using the QCT method. To this end, the influence of the vibrational and rotational excitation of the reactant molecule (H_2) on the vector correlation was calculated. The calculated results show that the rotational angular momentum vector **j′** of CH is preferentially aligned perpendicular to k and also oriented with respect to the **k**–**k′** plane. The PDDCS of $(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$ predicts that the angle distributions of the CH product are mainly dominated by backward–forward scattering, which is in agreement with the experimental results. Calculations also show that the product polarization is very sensitive to the vibrational excitation. An increase of vibrational excitation can make the peak of $P(\theta_r)$ narrower and higher, whereas the increase of rotational excitation has less effect on the peak of $P(\theta_r)$. We are looking forward to the completion of experimental studies about the stereodynamics for the title reaction system so that a reliable comparision between theory and experiment can be implemented.

Abstract: The peroxymonocarbonate mono- and di-anions (HCO_4^- and CO_4^{2-}) are known to be generated from H_2O_2/HCO_3^-. They are promising oxidants for wood pulp bleaching, but peroxide decomposition catalyzed by ferric complexes can be significant for pulps whose lignin is highly reactive. Dicarboxylates from lignin peroxidation are believed to be the ferric chelators in the pH 8.5 range that is optimum for H_2O_2/HCO_3^-. This investigation aimed to see if HCO_3^- addition caused destabilization of the peroxygen system owing to its partial conversion to HCO_4^-. This anionic peracid is a much stronger oxidant than H_2O_2 and could lead to a higher rate of Fe(II) oxidation to Fe(III) and (or) Fe(IV). For most free radical chain mechanisms, an increase in Fe(II) oxidation results in a higher rate of peroxide decomposition. Based on the kinetic data that were obtained and theoretical analyses, it was concluded that HCO_4^- did not significantly destabilize the peroxygen system when citrate was used as a model chelator for Fe(III). Increasing the [HCO_3^-] fourfold from 0.025 to 0.10 mol/L caused the decomposition rate to increase by only 20%.

Key words: peroxymonocarbonate anions, hydrogen peroxide, ferric complexes, peroxide decomposition, pulp bleaching.

Résumé : Il est bien connu que les mono- et di-anions du peroxymonocarbonate (HCO_4^- et CO_4^{2-}) peut être générés par la réaction du H_2O_2 et du HCO_3^-. Ce sont des oxydants prometteurs pour le blanchiment de la pulpe de bois, mais la décomposition du peroxyde, catalysée par des complexes, peut être importante avec les échantillons de pulpes dont la lignine est très réactive. On croit que les dicarboxylates obtenus par peroxydation de la lignine peuvent donner une réaction de chélation avec les espèces ferriques à un pH de 8,5 optimum pour la réaction du H_2O_2 et du HCO_3^-. Cette étude a été entreprise dans le but de déterminer si l'addition de HCO_3^- provoque une déstabilisation du système de peroxygène en raison de sa conversion partielle en HCO_4^-. Ce peracide anionique est un oxydant beaucoup plus puissant que le H_2O_2 et pourrait conduire à une vitesse plus élevée d'oxydation du Fe(II) en Fe(III) et (ou) Fe(IV). Pour la plupart des mécanismes en chaîne radicalaire, une augmentation dans l'oxydation du Fe(II) conduit à une augmentation de la vitesse de décomposition du peroxyde. Sur la base des données cinétiques obtenues et d'analyses théoriques, on en conclut que le HCO_4^- ne déstabilise pas le système du peroxygène lorsqu'on utilise du citrate comme modèle pour la chélation du Fe(III). Une augmentation de la concentration du HCO_3^- par un facteur de quatre, de 0,025 à 0,10 mol/L, ne provoque qu'une augmentation de 20 % de la vitesse de décomposition.

Mots-clés : anions peroxymonocarbonates, peroxyde d'hydrogène, complexes ferriques, décomposition du peroxyde, blanchiment de la pulpe.

[Traduit par la Rédaction]

Introduction

It has been known for a long time that hydrogen peroxide reacts with the bicarbonate anion to generate the peroxymonocarbonate monoanion (HCO_4^-).[1] The equilibrium reaction and equilibrium constant associated with HCO_4^- formation are presented in eqs. [1] and [2].[1]

$$[1] \quad HCO_3^- + H_2O_2 \rightleftharpoons {}^-OC(=O)OOH + H_2O$$

$$[2] \quad K = 0.32\ (\text{mol/L})^{-1} = \frac{[HCO_4^-]}{[H_2O_2][HCO_3^-]}$$

The peroxymonocarbonate (PMC) monoanions dissociates to the dianion (CO_4^{2-}) with a pK_a ca. 10.0.[1–3] Results were recently reported where the two anions showed great promise as bleaching agents for wood pulps.[2] The results appear to indicate that the monoanion is electrophilic and the dianion is nucleophilic, and both classes of reactions occur in the pH range ca. 8.5.[2] The case of peroxide/bicarbonate (P_B) bleaching in conjunction with a non-sulfur alkaline pulping process such as soda/anthraquinone is particularly attractive. In such a situation, the pulping effluent would be concentrated by evaporation and incinerated to give a Na_2CO_3 or K_2CO_3 stream of high purity. It already has been shown that 1 mol of carbonate in solution reacts quite quickly with 1 mol of

CO_2 at low pressure to generate 2 mol of bicarbonate.[2] Therefore, P_B bleaching would be possible without the purchase of carbonate or bicarbonate if the P_B effluent were to be recycled to the pulping chemical recovery system and Na_2CO_3 or K_2CO_3 recycled back to the P_B stage. Carbon dioxide would be obtained from the flue gas associated with combustion of the concentrated pulping and bleaching effluents.

One problem that has to be solved is the development of stabilization strategies to minimize wasteful decomposition of peroxide catalyzed by Fe and Mn species during a P_B stage. Earlier data clearly showed that these two transition metals catalyze peroxide decomposition in the bleaching slurry and that the process could be retarded by the addition of a hydroxyl radical scavenger.[2] When $Fe_2(SO_4)_3$ or $MnSO_4$ was added to bleaching effluent containing H_2O_2, the inclusion of *N*,*N*′-(5-nitro-1,3-phenylene)bisglutaramide (GAMID) as an ·OH scavenger[4,5] decreased the rate of peroxide decomposition by a factor of at least 10 for both Fe(III) and Mn(II). Because of some of its reactions with both lignin and carbohydrates, ·OH can cause considerable damage to both the optical and physical properties of pulps.[6,7]

A sizeable fraction of the Fe in wood pulps is believed to exist as ferric complexes with the lignin.[8] Some of the Fe(III) is likely to be released when some phenylpropane units in lignin are degraded to carboxylic and dicarboxylic acids by peroxidation. The dicarboxylic acids are likely to form ferric complexes capable of catalyzing peroxide decomposition. A likely redox chain mechanism to explain Fe(III) catalysis is presented in eqs. [3]–[8].[9,10] The initiation step is eq. [3], the propagation steps are eqs. [4]–[6] and eqs. [7] and [8] comprise the termination step.

$$[3]\quad \mathrm{Fe(III)L} + \mathrm{H_2O_2} \xrightarrow{k_1} \mathrm{Fe(II)L} + \cdot\mathrm{O_2^-} + 2\mathrm{H^+}$$

$$[4]\quad \mathrm{Fe(II)L} + \mathrm{H_2O_2} \xrightarrow{k_2} \mathrm{Fe(III)L} + \cdot\mathrm{OH} + \mathrm{OH^-}$$

$$[5]\quad \cdot\mathrm{OH} + \mathrm{H_2O_2} \xrightarrow{k_3} \mathrm{H_2O} + \cdot\mathrm{O_2}^- + \mathrm{H^+}$$

$$[6]\quad \cdot\mathrm{O_2}^- + \mathrm{Fe(III)L} \xrightarrow{k_4} \mathrm{Fe(II)L} + \mathrm{O_2}$$

$$[7]\quad \cdot\mathrm{O_2}^- + \mathrm{Fe(II)L} + \mathrm{H^+} \xrightarrow{k_5} \mathrm{Fe(III)L} + \mathrm{HOO^-}$$

$$[8]\quad \cdot\mathrm{OH} + \mathrm{Fe(II)L} \xrightarrow{k_5} \mathrm{OH^-} + \mathrm{Fe(III)L}$$

The difficulties associated with differentiating between ·OH and a ferryl species (eq. [9]) as the highly reactive intermediate in reaction systems containing Fe(II), Fe(III), $\cdot O_2^-$, and H_2O_2 is widely reported in the literature.[10,11] For the pulp bleaching applications that are of interest, a distinction between ·OH and a ferryl species may not be necessary. Ferryl species are reported to be capable of abstracting electrons from ethanol, *tert*-butanol and from aromatic rings.[12] Therefore, the negative attributes of ·OH towards carbohydrates and lignin are likely to also be associated with ferryl species.

$$[9]\quad \mathrm{Fe(II)L} + \mathrm{H_2O_2} \xrightarrow{k_7} \mathrm{Fe(IV)L{=}O} + \mathrm{H_2O}$$

This report is on an investigation of peroxide decomposition catalyzed by $Fe_2(SO_4)_3$ in $NaHCO_3$ solutions at pH ca. 8.5 and 40 °C and with citrate as a model chelator. Catalysis of H_2O_2 decomposition by ferrous and ferric citrate is reported to increase the rate of ·OH generation.[13,14] A key issue was whether or not HCO_4^-, a much stronger oxidant than H_2O_2,[1] significantly increased the rate of oxidation of Fe(II) to Fe(III) and (or) Fe(IV). That would be expected to accelerate peroxide decomposition because of the higher rate of formation of the highly reactive ·OH and (or) ferryl species. In a companion submission, results are presented for catalysis by Mn species in the pH range of 7.4–8.7.[15]

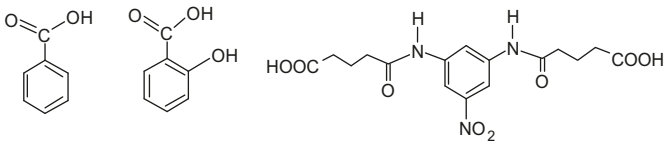
Experimental

The water used was purified by distillation and reverse osmosis and consistently contained <2 ppb Fe and Mn, but 10–15 ppb of Cu. Approximately 40 L of this water was collected on one occasion and used to dissolve the ferric catalysts and $NaHCO_3$ and as diluent in all of the runs where ferric catalysis was investigated. This water typically constituted >95% of the starting liquid for each run. The sodium bicarbonate used in this research was GR ACS grade from EMD Chemicals and contained 0.13 ppm Fe and 2.9 ppm Mn (determined by inductively coupled plasma - mass spectrometry, ICP-MS). The ferric citrate was prepared by dissolving $Fe_2(SO_4)_3{\cdot}H_2O$ in citric acid. The $[Fe^{3+}]$ was 0.018 mol/L (1000 ppm), and citric acid was added at a 5:1 mol ratio to Fe^{3+}. The final solution contained no particles and was nonturbid when its pH was raised from 1.9 to 7.0 with $NaHCO_3$. This solution (1000 ppm Fe) was stored at room temperature and at pH 1.9, and aliquots were taken from it and diluted to 5 or 10 ppm Fe(III). These dilute Fe(III) solutions were used for 3–5 days of research before fresh batches were made. GAMID was the same sample used before[5] and it was synthesized by the method of Singh and Hider.[4] Benzoic acid was USP grade from Fisher Scientific. Its purity was not stated on the bottle, but toluene oxidation as the means of synthesis was stated. The salicylic acid (>99.0% purity) was from ACROS Organics.

High-density polyethylene bottles (250 mL) with screw caps were used as reactors. Two holes were made in each cap, one for a pH electrode and the other for the pipettes used for liquid addition and removal. The reactor was placed in a water bath made of aluminum, maintained at 40 ± 0.5 °C, and stationed on top of two magnetic stirrers. One of the magnetic stirrers was for the reactor and the other was for the water in the bath. A reaction solution containing ferric citrate and $NaHCO_3$ was preheated to 40 °C then a concentrated H_2O_2 solution (<3% of total volume) was added to give a H_2O_2 concentration of 52–55 mmol/L. The reaction solution was given ca. 3 min to be reheated to 40 °C and then aliquots were taken for residual H_2O_2 analysis by iodometric titration at 5 or 10 min intervals.

When radical scavengers were involved, crystals or powder of the scavenger was added at the initial preheat stage, and residual H_2O_2 was determined after 0, 30, 60, and 90 min. The structures of the three scavengers are shown in Fig. 1. When benzoic acid (BA) or salicylic acid (SA) was the scavenger, the residual H_2O_2 in the solution was reduced with

Fig. 1. The three radical scavengers utilized (benzoic acid (BA), salicylic acid (SA), and *N*,*N*′-(5-nitro-1,3-phenylene)bisglutaramide (GAMID); left to right).



$NaHSO_3$ after 90 min. The solution was acidified to pH ca. 2, divided into two equal aliquots, and extracted with ether. Each ether extract was dried over anhydrous $MgSO_4$, decanted, and then evaporated to dryness at reduced pressure. The dry residue along with the internal standard (benzhydrol), were dissolved in 1.0 mL of dichloromethane (DCM). A fraction of the DCM solution (100 μL) was added to another vial along with 100 μL of *N*,*O*-bis(trimethylflouromethyl-silylacetamide) (BSTFA) and a drop of pyridine. The mixture was allowed to sit at room temperature overnight or for ca. 30 min at 40 °C before it was analyzed for residual amounts of the scavenger and hydrolylated products by gas chromatography with flame ionization detection (GC) or gas chromatography – mass spectrometry (GC–MS).

A HP 5890A GC equipped with a flame ionization detector (FID) and a DB-1 (dimethylpolysiloxane) capillary column (30 m × 0.25 mm; film thickness 0.25 μm) was used. Nitrogen was the carrier gas (1 mL/min), and the split ratio was 50:1. The injector temperature was 250 °C and the detector temperature was 270 °C. The following temperature profile was used: initial temperature 120 °C, holding time at initial temperature 5 min, a ramp from 120 to 270 °C at 5 °C/min, and a hold at maximum temperature for 5 min.

GC–MS analyses were performed using a Thermo Scientific Finnigan Trace GC Ultra GC coupled to a Thermo MAT95XP double focus magnetic sector mass spectrometer. The column used was a 30 m × 0.25 mm i.d., Rtx-5MS (5% diphenyl / 95% dimethylpolysiloxane) capillary column (film thickness 0.25 μm). Nitrogen at a flow rate of 1 mL/min was used as the carrier gas. About 1 μL of the sample was injected and analyzed using a split ratio of 50:1. The following temperature profile was used: initial temperature 110 °C, with a hold time of 4 min; a ramp to 260 °C at 5 °C/min followed by a 5 min hold at 260 °C; another ramp from 260 to 300 °C at 5 °C/min; and a final hold for 20 min at 300 °C. The injector and detector temperatures were 250 and 300 °C, respectively. Ionization was carried out at a 70 eV impact voltage in an ion chamber heated to 220 °C. The samples were scanned from *m*/*z* 50 to 400 at a rate of 0.6 scan/s. Peak identification was carried out on the basis of mass fragmentation patterns, comparisons of spectra with those of the authentic compounds obtained from various suppliers, and by comparing the MS data with those in the Pfleger–Mauer–Weber, Wiley, and NIST libraries.

Results and discussion

The first set of experiments was probably the most important, and these trials had to do with the selection of the source of $NaHCO_3$. A supplier was first chosen whose container stated that the crystal contained 2 ppm Fe. However, peroxide decomposition without any added transition metal salt or complex was quite variable and quite high on some occasions (50 to 40 mmol/L in 100 min). The EMD bicarbonate that listed its Fe content as 5 ppm did not cause decomposition, >8% in 100 min (50 to 46 mmol/L) in the absence of a transition metal catalyst. When the two bicarbonates were analyzed by ICP-MS it was found that the EMD sample contained only 0.13 ppm Fe and the other brand contained 0.61 ppm. All of the $NaHCO_3$ used in the investigation of metal-catalyzed peroxide decomposition was GR ACS grade from EMD. The initial concentration of H_2O_2 was ca. 50 mmol/L for all experiments in this investigation. Typically, the initial H_2O_2 concentration would be in the range of 20–40 mmol/L for a P_B stage applied to chemical pulps (0.5%–1.0% H_2O_2 on pulp at 12% consistency) and 50–130 mmol/L for mechanical pulps (1.0% H_2O_2 at 15%–30% consistency).[2] The typical concentrations for $NaHCO_3$ would be 30–50 mmol/L for chemical pulps (2%–3% $NaHCO_3$ on pulp at 12% consistency) and 60–150 mmol/L for mechanical pulps (3% $NaHCO_3$ at 15%–30% consistency).[2] A treatment pH in the range of 8.5 appears to be optimum for most pulp bleaching applications.[2]

The next set of experiments is summarized in Fig. 2 and it shows the decomposition of H_2O_2 (0.1 mol/L $NaHCO_3$, pH 8.5–8.7, 40 °C) in the absence of Fe, 0.1ppm Fe with and without citrate, and ferric citrate at 0.075ppm Fe with and without 10 mmol/L BA. The pH was monitored at 40 °C throughout each run and the readings were typically 0.1 of a unit higher than the standard pH just stated, i.e., pH 8.6–8.8 at 40 °C. In all cases where Fe (III) catalyzed peroxide decomposition to a significant degree (>25%), the disappearance of the peroxide was first-order in H_2O_2 concentration and the R^2 value on k_{OBS} (eq. [10]) was ≥0.99. The values of k_{OBS} for the five runs in Fig. 2 are presented in Table 1. It can be seen that citrate complexation significantly increased the rate of Fe(III)-catalyzed decomposition and that the mechanism responsible for ferric citrate-catalyzed decomposition was significantly retarded by BA, an ·OH scavenger. The rate constants for peroxide decomposition (k_{OBS}) with and without BA were 1.7×10^{-4} s^{-1} and 4.9×10^{-4} s^{-1}. Therefore, BA addition caused a 65% decrease in the peroxide decomposition rate.

$$[10] \qquad \frac{d[H_2O_2]}{dt} = -k_{OBS}[H_2O_2]$$

The decrease in decomposition rate (65%) caused by BA was an ambiguous result. On one hand, it is difficult to envision a mechanism of retardation other than the scavenging of ·OH, but on the other hand, BA at 10 mmol/L should have afforded a higher degree of retardation. The rate constant for benzoate anion reacting with ·OH is 5.9×10^9 $(mol/L)^{-1}$ s^{-1}, a value >200 times greater than for H_2O_2 reacting with ·OH (2.7×10^7 $(mol/L)^{-1}$ s^{-1}).[16] Therefore, 10 mmol/L of benzoate should have almost completely prevented a propagation reaction such as in eq. [5] when the initial $[H_2O_2]$ was 50 mmol/L. Analyses of residual BA and hydroxylated products were then performed. The BA concentration decreased from 10.0 to ca. 9.7 mmol/L after 90 min of reaction and the total yield of *o*-, *m*-, and *p*-hydroxybenzoic acid (HBA) was ca. 0.1 mmol/L. The ratio of *o*-HBA:*m*-HBA:*p*-HBA was approximately 3:1:1. The MS data for the three HBAs are as follows: for *o*-HBA, the major fragments were *m*/*z*:

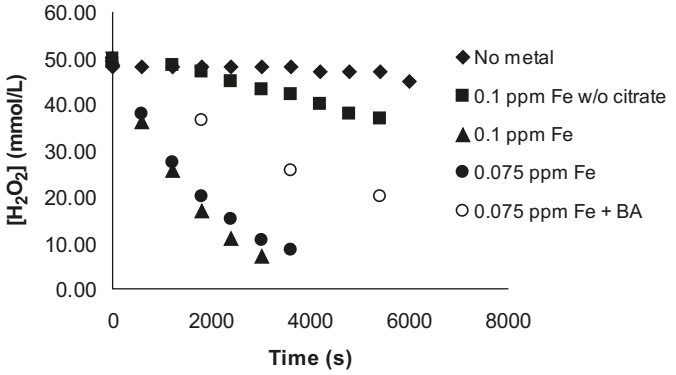
Fig. 2. Effect of ferric sulfate and ferric citrate catalysis on peroxide decomposition.



267 (100), 209 (10), 193 (10), 149 (10), 135 (15), 73 (45); for *m*-HBA, the major fragments were *m/z*: 282 (M^+, 45), 267 (100), 223 (40), 207 (30), 193 (45), 153 (25), 147 (15), 135 (20), 73 (45); and for *p*-HBA, the major fragments were *m/z*: 282 (M^+, 15), 267 (100), 223 (50), 193 (45), 147 (30), 73 (50). It is possible that *m*-HBA and *p*-HBA could act as weak catalysts for peroxide decomposition. Whereas the pK_a of the phenolic group in SA (*o*-HBA) is >13.0,[17,18] the value is ca. 9.3 for *p*-HBA[17,18] and ca. 9.9 for *m*-HBA.[17] The phenolate from *p*-HBA or *m*-HBA could slowly convert to a phenoxy radical (Fig. 3) that could participate in radical coupling and subsequent de-aromatization reactions or abstract an electron from a H_2O_2 molecule to give $\cdot O_2^-$ (Fig. 3). This would aid the propagation step in a redox chain mechanism such as that described in eqs. [3]–[8]. It should be noted that the reduction potential for the phenoxy radical in Fig. 3 has been estimated at 1.04 V at pH 7 and 0.90 V at pH > 11.[19] This species would probably be more reactive in abstracting an electron from H_2O_2 than ferric citrate in eq. [1].

When BA was replaced by 10 mmol/L GAMID the peroxide decomposition rate decreased from 4.9×10^{-4} s^{-1} (without scavenger) to $<0.1 \times 10^{-4}$ s^{-1}. Analysis of residual GAMID by UV spectrometry[4,5] showed that its recovery was close to100% with the generation of hydroxylated products being negligible (<0.1 mmol/L). It should be noted that there are convincing data showing that neither GAMID or its hydroxylated products bind either Fe(II) or Fe(III) at pH 8.[4]

A third radical scavenger, SA or *o*-HBA, was investigated. A SA concentration of 5 mmol/L was used because the rate constant for salicylate reacting with ·OH is more than twice the value for benzoate, i.e., 1.6×10^{10} vs 5.9×10^9 $(mol/L)^{-1}$ s^{-1}.[16] The 5 mmol/L concentration of SA decreased the peroxide decomposition rate from 4.9×10^{-4} to 0.2×10^{-4} s^{-1}. The SA concentration decreased from 5.0 to ca. 4.7 mmol/L after 90 min, and no hydroxylated product(s) was detected. The 0.075 ppm ferric dose was equivalent to a concentration of only 1.34×10^{-6} mol/L, and the citrate concentration was five times as high or 6.72×10^{-6} mol/L. The possibility that SA at 5.0×10^{-3} mol/L was displacing citrate as the ligand from the Fe (III) and producing a noncatalytic complex had to be investigated. If SA was indeed displacing the citrate then that process should not be affected if the SA concentration were to be decreased to 1.0×10^{-3} mol/L or 1.0 mmol/L. The mole ratio of SA to citrate would still be very high at a value of 149. The retardation effect of SA was investigated at 1.0 mmol/L and ultimate care was taken in determining the residual SA. The peroxide decomposition rate was decreased from 4.9×10^{-4} to 1.5×10^{-4} s^{-1} (69%) by 1.0 mmol/L SA. The experiment was repeated on another day and a rate constant of 1.4×10^{-4} s^{-1} was obtained. Analysis of the organic products showed a residual SA of 0.8 mmol/L for both runs and no hydroxylated product(s) was detected. It is likely that a small amount of 2,3-dihydroxybenzoic acid was generated[14], but such an intermediate, with adjacent phenolic hydroxyl groups, would likely be degraded by P_B oxidation. Based on radical scavenging by GAMID and SA at 1.0 and 5.0 mmol/L, it appears that a free radical mechanism is primarily if not totally responsible for the peroxide decomposition.

Table 1. First-order rate constants for ferric-catalyzed peroxide decomposition with various additives (according to eq. [10].

[Fe(III)Cit] (ppm Fe(III))	$[HCO_3^-]$ (mol/L)	Other additives	k_{OBS} ($s^{-1} \times 10^4$)
0	0.1		0.1
0	0.1	10 mmol/L BA	<0.1
0.1[a]	0.1		6.3, 6.5
0.1[b]	0.1		0.5
0.025	0.1		1.6
0.05	0.1		3.5
0.075	0.1		4.8, 5.0
0.075	0.1	25 mmol/L Na_2SO_4	4.9
0.075	0.1	10 mmol/L BA	1.7
0.075	0.1	10 mmol/L GAMID	<0.1
0.075	0.1	5 mmol/L SA	0.2
0.075	0.1	1.0 mmol/L SA	1.5, 1.4
0.075	0.02		3.9
0.075	0.025		4.1
0.075	0.025	25 mmol/L Na_2SO_4	4.2
0.075	0.03		4.4
0.075	0.05		4.9

Note: 50 mmol/L H_2O_2, 40 °C, initial and final pH of 8.4 and 8.6 for $[HCO_3^-] \leq 0.03$ mol/L and 8.5 and 8.7 for $[HCO_3^-] = 0.05$–0.10 mol/L. BA, benzoic acid; SA, salicylic acid; and GAMID, *N,N′*-(5-nitro-1,3-phenylene) bisglutaramide.

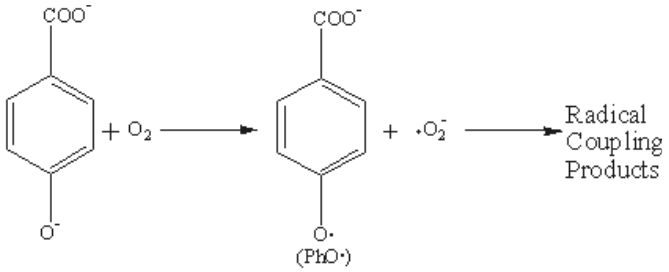
[a]0.1ppm Fe = 1.8×10^{-6} mol/L.

[b]No citrate.

Finally, if the peroxide decomposition mechanism is predominantly free radical in nature then the decomposition rate should not be strongly influenced by ionic strength. When ferric citrate was used at 0.075 ppm Fe the peroxide decomposition rate was unaffected by the addition of 0.025 mol/L Na_2SO_4 (Table 1).

The next step was an investigation of the effect of HCO_4^- on peroxide decomposition. At first glance it would appear that a simple approach of investigating the role of HCO_4^- would be to vary the HCO_3^- concentration and see its effect on the rate of peroxide loss. However, in a complex free radical system it would be helpful to have some idea regarding the expected reaction order for HCO_3^- in advance of initiation of a rigorous experimental protocol. Also, if a complex rate equation is obtained then appropriate concentration ranges can be chosen that would allow for simplifying assumptions to be made regarding the rate equation. Those concentration ranges would then be tested during the experimental phase. It was concluded that theoretical analysis

Fig. 3. A possible scheme to explain catalysis of H_2O_2 decomposition by *m*-hydroxybenzoic acid (HBA) and *p*-HBA.



$$PhO\cdot + H_2O_2 \longrightarrow PHO^- + \cdot O_2^- + 2H^+$$

should precede the experimental research. All of the likely reactions were written in one free radical chain mechanism. The selected reactions are those shown in eqs. [3]–[7] and those in eqs. [11]–[14].

$$[11] \quad HCO_3^- + H_2O_2 \overset{K_1}{\leftrightarrow} HCO_4^- + H_2O$$

$$[12] \quad Fe(II)L + HCO_4^- \overset{k_8}{\rightarrow} Fe(III)L + \cdot OH + CO_3^{2-}$$

$$[13] \quad \cdot OH + HCO_3^- \overset{k_9}{\rightarrow} \cdot CO_3^- + H_2O$$

$$[14] \quad \cdot CO_3^- + H_2O_2 \overset{k_{10}}{\rightarrow} HCO_3^- + \cdot O_2^- + H^+$$

The reactions that were left out included eqs. [8] and [15]–[18].

$$[15] \quad HCO_3^- + Fe(II)L \rightarrow Fe(III)L + \cdot CO_3^- + OH^-$$

$$[16] \quad \cdot CO_3^- + \cdot O_2^- \rightarrow CO_3^{2-} + O_2$$

$$[17] \quad \cdot OH + HOO^- \rightarrow \cdot O_2^- + H_2O$$

$$[18] \quad \cdot CO_3^- + HOO^- \rightarrow \cdot O_2^- + HCO_3^-$$

Barb et al.[9] left out eq. [8] in cases of high H_2O_2:Fe(III) or H_2O_2:Fe(II) mole ratios. In the present case [Fe(II)] will be in the range of 10^{-8} mol/L and [H_2O_2] will be in the range of 10^{-2} mol/L and eq. [5] should dominate over eq. [8]. Equation [15] was left out because if it dominated over ·OH generation by eqs. [4] and [12] then it would be difficult to explain peroxide stabilization with BA. Based on the correlation between Hammett substituent constants and the rate constant for $\cdot CO_3^-$ reacting with aromatics,[20] BA should have a rate constant $<10^5$ (mol/L)$^{-1}$ s^{-1} for its reaction with $\cdot CO_3^-$. The rate constant for $\cdot CO_3^-$ reacting with H_2O_2 is 8.0×10^5 (mol/L)$^{-1}$ s^{-1}.[21,22] Therefore, BA at 10 mmol/L should not be able to scavenge a significant amount of $\cdot CO_3^-$ away from H_2O_2 at 50 mmol/L.

Equation [16] was left out because reaction of $\cdot CO_3^-$ with H_2O_2 (eq. [14]) should dominate over its reaction with $\cdot O_2^-$. The rate constant for eq. [16] is 2.0×10^8 (mol/L)$^{-1}$ s^{-1}.[22] Although this value is 250 times greater than the one for eq. [14], it is likely that the steady-state concentration of $\cdot O_2^-$ will be $<10^{-6}$ mol/L, whereas H_2O_2 concentrations of interest will be $>1.0 \times 10^{-2}$ mol/L (10 mmol/L). Polle[23] reported on an investigation where ascorbate and glutathione were used as scavengers for $\cdot O_2^-$. The rate constants for the two scavengers reacting with the free radical are 2.0×10^5 and 7.0×10^5 (mol/L)$^{-1}$ s^{-1}, respectively.[23] When 10 mmol/L ascorbate, 5 mmol/L of glutathione, and a $\cdot O_2^-$ feed rate of 240 μmol/L s^{-1} were used as inputs in the computer model, the steady-state $\cdot O_2^-$ concentration was estimated at 2.3×10^{-9} mol/L after 0.1 s.[23] A k_{OBS} of 6.5×10^{-4} s^{-1} was the highest observed in the present research (Table 1). Such a rate would correspond to a decrease in [H_2O_2] from 50 to 5 mmol/L over 60 min or 3600 s. A decrease in [H_2O_2] of 45 mmol/L would correspond to the generation of 22.5 mmol/L or 22 500 μmol/L of oxygen. Assuming O_2 is generated only from $\cdot O_2^-$ then the average $\cdot O_2^-$ generation rate would be only 6.25 μmol/L s^{-1} (22 500 μmol/L per 3600 s) for $k_{OBS} = 6.5 \times 10^{-4}$ s^{-1}. It is unlikely the $\cdot O_2^-$ steady-state concentration would exceed 10^{-6} mol/L in the present research because Fe(III) complexes are efficient scavengers for the free radical at pH > 4.8 (eq. [6]). Typical rate constants for eq. [6] are in the range of 1.5×10^8 (mol/L)$^{-1}$ s^{-1}.[24] Equations [17] and [18] were left out because the [HOO^-] concentration will be a thousand times lower than [H_2O_2] at pH 8.5–8.7 (pK_a of H_2O_2 = 11.6). The rate constant for ·OH reacting with HOO^- is only 278 times higher than for its reactions with H_2O_2.[16] Similarly, the rate constant for CO_3^- is only 70 times higher for HOO^- when compared with H_2O_2.[21]

The next step was to try and determine an overall rate equation for the free radical scheme, i.e., eqs. [3]–[7] and eqs. [11]–[14]. The steady-state assumption was used for the concentrations of free radicals.[5,9,10,25] By making two minor assumptions the rate law in eq. [19] was obtained. The full derivation of eq. [19] has been provided as Supplementary data and identified as Scheme 1. The first simplifying assumption was that k_3[H_2O_2] was much greater than k_9[HCO_3^-]. The respective values for k_3 and k_9 are 2.7×10^7 and 8.5×10^6 (mol/L)$^{-1}$ s^{-1}.[16] In the present investigation, the [H_2O_2] after 50% decomposition was 25 mmol/L and k_3[H_2O_2] was 3.18 times greater ($2.7 \times 10^7/8.5 \times 10^6$) than that of k_9[HCO_3^-] at a [HCO_3^-] of 25 mmol/L. This assumption was made with the intent of investigating the [HCO_3^-] of 20, 25, and 30 mmol/L experimentally. The other assumption was that k_4[Fe(III)] was much greater than k_5[Fe(II)]. Typically, k_4 is 15 times greater than k_5 at pH greater than 4.8,[24] and [Fe(III)] would be expected to be much greater than [Fe(II)]. Typical rate constants for Fe(III) oxidation of H_2O_2 (eq. [3]) are <0.01 (mol/L)$^{-1}$ s^{-1} [10,26] and the rate constants for H_2O_2 oxidation of Fe(II) complexes (eq. [4] are typically in the range of 10^3–10^4 (mol/L)$^{-1}$ s^{-1}.[12,27] Fe(II) would be converted to Fe(III) at a much higher rate than for the reverse reaction and [Fe(III)] >> [Fe(II)].

Equation [19] is quite complex with five terms on the right-hand side (RHS). However, a simple, approximate solution can be derived when both the H_2O_2 and HCO_3^-

concentrations are in the range of 0.025 mol/L. To begin, it will be assumed that the first term on the RHS is much less than the second term and can be ignored. The ratio k_9/k_3 in the fourth term is 0.315 ($8.5 \times 10^6/2.7 \times 10^7$) and if the assumption is made that H_2O_2 and HCO_3^- concentrations are approximately equal then the fourth term would be equal to 0.315 times the second term and it can be eliminated by multiplying the second term by 1.315. This is strictly a mathematical manipulation because the H_2O_2 concentration would vary while the HCO_3^- concentrations would be nearly constant. If the fifth term is multiplied by $k_3[H_2O_2]/k_9[HCO_3^-]$ then the third term is obtained. Therefore, the third term is 3.18 times greater than the fifth term (k_3/k_9) or the fifth term is 0.315 as large as the third term. As such, the fifth term can also be eliminated by multiplying the third term by 1.315. The simplified rate expression is eq. [20] when $[H_2O_2] \approx [HCO_3^-]$. The term $K_1[HCO_3^-][H_2O_2]$ is equivalent to $[HCO_4^-]$ by eq. [2], and the rate expression is simply the rate of Fe(II) oxidation by H_2O_2 plus that by HCO_4^-, both multiplied by 1.315.

$$[19] \quad \frac{d[O_2]}{dt} = k_1[Fe(III)L][H_2O_2] + k_2[Fe(II)L][H_2O_2] + K_1k_8[Fe(II)L][HCO_3^-][H_2O_2] + \frac{k_2k_9[Fe(II)L][HCO_3^-]}{k_3} + \frac{K_1k_8k_9[Fe(II)L][HCO_3^-]^2}{k_3}...$$

$$[20] \quad \frac{d[O_2]}{dt} = 1.315k_2[Fe(II)L][H_2O_2] + 1.315K_1k_8[Fe(II)L][HCO_3^-][H_2O_2]$$

If the second term of the RHS of eq. [20] is equal to or greater than the first then the rate of H_2O_2 decomposition (twice that of O_2 evolution) should increase noticeably when $[HCO_3^-]$ is increased from 0.02 to 0.025 to 0.03 mol/L.

The detailed experimental research on the effect of $[HCO_3^-]$ was initiated with the determination of k_{OBS} for 0.025 mol/L HCO_3^- and 0.025 mol/L each of HCO_3^- and Na_2SO_4. The rate constants observed were 4.1×10^{-4} and 4.2×10^{-4} s^{-1}, respectively. Again an increase in ionic strength appeared to have no significant impact. The rate constant for 0.02 mol/L HCO_3^- was 3.9×10^{-4} s^{-1} and the value was $4.4 \times 10^{-4}s^{-1}$ for 0.03 mol/L HCO_3^- (Table 1). If the second term on the RHS of eq. [20] was dominant over the first term then the decomposition rate should have increased by ca. 50% in going from 0.02 to 0.03 mol/L HCO_3^-. The increase observed was only 13%. When $[HCO_3^-]$ was increased to 0.05 mol/L, the decomposition rate increased only to 4.9×10^{-4} s^{-1}, which is also the value previously and reproducibly obtained for 0.1 mol/L HCO_3^-. The effect of $[HCO_3^-]$ was minor; instead of increasing nearly fourfold in going from 0.025 to 0.10 mol/L it increased by only 20%, i.e., 4.9×10^{-4} vs 4.1×10^{-4} s^{-1}. The standard initial and end pH were 8.4 and 8.6 for $[HCO_3^-]$ in the range of 0.02–0.03 mol/L, with corresponding values of 8.5 and 8.7 for the 0.05–0.10 mol/L HCO_3^- range. It did not appear that the 0.2 unit pH increase during the runs caused a significant acceleration in peroxide decomposition. The slope

Fig. 4. First-order rate plots for peroxygen decomposition in the presence of increasing concentrations of Fe(III) citrate complex at 40 °C, pH 8.5–8.7, $[HCO_3^-] = 0.10$ mol/L, and initial $[H_2O_2] = 0.05$ mol/L.

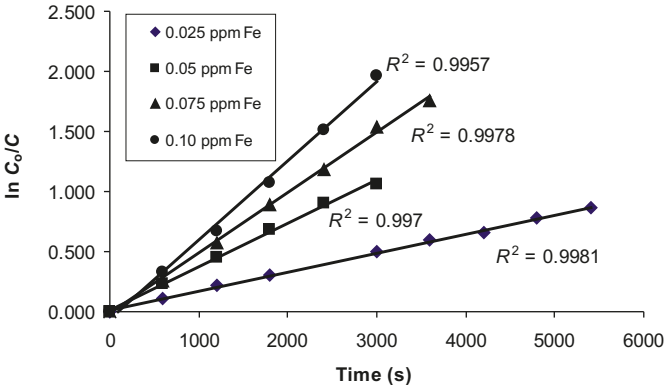

Fig. 5. Plot of $-\ln k_{OBS}$ vs $-\ln[Fe(III)L]$.

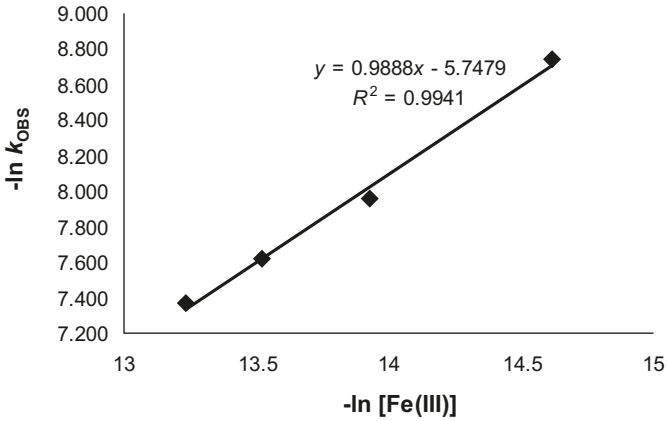

in eq. [10] was always nearly identical for data collected early and late in the runs. The R^2 value for k_{OBS} was always >0.99.

If the second term on the RHS of eq. [20] is ignored then the rate equation becomes $1.315k_2[Fe(II)L][H_2O_2]$ for oxygen generation or $-2.63k_2[Fe(II)L][H_2O_2]$ for peroxide decomposition. The rate law for eqs. [3]–[7] is given in eq. [21] and it differs from the one just stated by a factor of –2.0 instead of –2.63. The relationship between [Fe(II)L] and [Fe(III)L] is given in eq. [22] and the rate expression in terms of Fe(III)L is given in eq. [23]. The full derivations are Scheme 2 in the Supplementary data. Final relationships identical to eqs. [21]–[23] were derived by Barb et al.,[9] although their mathematical approach for the derivation of eq. [22] was different from those used in the present research. If the reactions in eqs. [3]–[7] are indeed primarily responsible for peroxide decomposition then the rate should be first order in both $[H_2O_2]$ and [Fe(III)L] in accordance with eq. [23]. The data in Figs. 4 and 5 show nearly perfect first-order fits for both variables.

$$[21] \quad \frac{d[H_2O_2]}{dt} = -2k_2[Fe(II)L][H_2O_2]$$

$$[22] \quad [Fe(II)L] = \left(\frac{k_1k_4}{k_2k_5}\right)^{\frac{1}{2}}[Fe(III)L]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[23] \qquad \frac{d[H_2O_2]}{dt} = -2\left(\frac{k_1k_2k_4}{k_5}\right)^{\frac{1}{2}}[Fe(III)L][H_2O_2]$$

It appears as if HCO_4^- plays only a minor role in the ferric citrate-catalyzed decomposition of H_2O_2 in the pH 8.5 range. The likely mechanism appears to be consistent with eqs. [3]–[7] proposed by Barb et al.[9] for ferric catalysis under acidic conditions and by Walling et al.[10] for Fe(III)–EDTA in the pH 7–9 range. However, the possibility that a ferryl species is the highly reactive intermediate instead of ·OH cannot be ruled out by the present kinetic data. A ferryl species would be capable of ring hydroxylation via the formation of a radical cation.[10,28] Furthermore, if eqs. [4] and [5] were to be replaced by eqs. [9] and [24] (the ferryl alternative), a rate law similar to that in eq. [23] would be obtained with k_2 being replaced by k_7. The full derivation of this rate law is Scheme 3 in the Supplementary data. If eqs. [4] and [5] are combined the result would be eq. [25], which would also be the product if eqs. [9] and [24] are combined.

$$[9] \qquad Fe(II)L + H_2O_2 \xrightarrow{k_7} Fe(IV)L = O + H_2O$$

$$[24] \qquad Fe(IV)L = O + H_2O_2 \xrightarrow{k_{11}} Fe(III)L + \cdot O_2^- + H_2O$$

$$[25] \qquad Fe(II)L + 2H_2O_2 \rightarrow Fe(III)L + \cdot O_2^- + 2H_2O$$

Conclusion

This research was initiated with some evidence pointing to a free radical mechanism being responsible for peroxide decomposition catalyzed by ferric complexes in H_2O_2/HCO_3^- solutions at pH 8.5–8.7. This was confirmed in the present investigation. A key step in most free radical chain mechanisms is the oxidation of Fe(II) to Fe(III) and (or) Fe(IV), which results in an increase in the peroxide decomposition rate. The anionic peracid (HCO_4^-) is a much stronger oxidant than H_2O_2, and the possibility that the H_2O_2 was inherently less stable in the presence of HCO_4^- was investigated. Based on the kinetic data that were obtained and theoretical analyses, it was concluded that HCO_4^- did not significantly destabilize the peroxygen system when citrate was used as a model chelator for Fe(III).

Abstract: The peroxymonocarbonate mono- and di-anions (HCO_4^- and CO_4^{2-}) are known to be generated from H_2O_2/HCO_3^-. They are promising oxidants for wood pulp bleaching, but peroxide decomposition catalyzed by Mn(II) species may be significant for pulp samples with unusually high Mn contents. This investigation aimed to see if HCO_3^- addition caused destabilization of the peroxygen system owing to its partial conversion to HCO_4^-. This anionic peracid is a much stronger oxidant than H_2O_2 and could lead to a higher rate of Mn(II) oxidation to Mn(III) and (or) Mn(IV). For most free radical chain mechanisms, an increase in Mn(II) oxidation results in a higher rate of peroxide decomposition. Peroxide decomposition catalyzed by Mn(II) was investigated in H_2O_2/HCO_3 in the pH ranges 8.5–8.7 and 7.4–7.9. The rate equation for peroxide decomposition was first order in [H_2O_2] and [Mn(II)] in both pH ranges, but close to second order in [HCO_3^-] in the higher pH range and close to third order in the lower pH range. Free radical chain mechanisms were proposed for both pH ranges and with all the correct reaction orders. Contrary to mechanisms previously proposed, it was concluded that HCO_4^- is the principal oxidizer of Mn(II) in the pH 7.4–7.9 range.

Key words: peroxymonocarbonate anions, hydrogen peroxide, divalent manganese, peroxide decomposition, pulp bleaching.

Résumé : Il est bien connu que les mono- et di-anions du peroxymonocarbonate (HCO_4^- et CO_4^{2-}) peuvent être générés par la réaction du H_2O_2 et du HCO_3^-. Ce sont des oxydants prometteurs pour le blanchiment de la pulpe de bois, mais la décomposition du peroxyde, catalysée par des espèces de Mn(II), peut être importante avec les échantillons de pulpes avec des teneurs exceptionnellement élevées de manganèse. Cette étude a été entreprise dans le but de déterminer si l'addition de HCO_3^- provoque une déstabilisation du système de peroxygène en raison de sa conversion partielle en HCO_4^-. Ce peracide anionique est un oxydant beaucoup plus puissant que le H_2O_2 et pourrait conduire à une vitesse plus élevée d'oxydation du Mn(II) en Mn(III) et (ou) Mn(IV). Pour la plupart des mécanismes en chaîne radicalaire, une augmentation dans l'oxydation du Mn(II) conduit à une augmentation de la vitesse de décomposition du peroxyde. On a étudié la décomposition du peroxyde catalysée par le Mn(II), dans le système H_2O_2/HCO_3^-, dans les plages de pH de 8,5 à 8,7 et de 7,4 à 7,9. L'équation de vitesse pour la décomposition du peroxyde est du premier ordre en [H_2O_2] et en [Mn(II)] dans les deux plages de pH, mais elle s'approche du deuxième ordre en [HCO_3^-] dans la plage élevée de pH et elle est très près du troisième ordre dans la plage de pH plus faible. On propose des mécanismes en chaîne radicalaire pour les deux plages de pH et ils correspondent aux ordres de réaction corrects. Contrairement aux mécanismes proposés antérieurement, on en conclut que l'anion HCO_4^- est l'oxydant principal du Mn(II) dans la plage de pH de 7,4 à 7,9.

Mots-clés : anions peroxymonocarbonates, peroxyde d'hydrogène, manganèse divalent, décomposition du peroxyde, blanchiment de la pulpe.

[Traduit par la Rédaction]

Introduction

It has been known for a long time that hydrogen peroxide reacts with the bicarbonate anion to generate the peroxymonocarbonate monoanion (HCO_4^-).[1] The equilibrium reaction and equilibrium constant associated with HCO_4^- formation are presented in eqs. [1] and [2].[1]

$$[1] \quad HCO_3^- + H_2O_2 \rightleftharpoons {}^-OC(=O)OOH + H_2O$$

$$[2] \quad K = 0.32\ (\text{mol/L})^{-1} = \frac{[HCO_4^-]}{[H_2O_2][HCO_3^-]}$$

The peroxymonocarbonate (PMC) monoanions dissociates to the dianion (CO_4^{2-}) with a pK_a ca. 10.0.[1–3] Results were recently reported where the two anions showed great promise as bleaching agents for wood pulps.[2] However, wasteful decomposition of peroxide catalyzed by transition metal species has to be controlled.[4] Earlier data clearly showed that Fe(III) and Mn(II) species catalyze peroxide decomposition in bleaching slurries and that such decomposition could be

For personal use only.

retarded to a very high degree by the addition of a hydroxyl radical scavenger.[2] When $Fe_2(SO_4)_3$ or $MnSO_4$ was added to bleaching effluent containing H_2O_2, the inclusion of *N*,*N*′-(5-nitro-1,3-phenylene)bisglutaramide (GAMID) as a hydroxyl radical scavenger[5] decreased the rate of peroxide decomposition by a factor of at least 10 for both Fe(III) and Mn(II). In addition to wasteful decomposition of H_2O_2, a second and probably greater concern is that ·OH is generated at a moderate to high rate by Fe (III) and Mn (II) catalysis. This free radical can retard the brightening of mechanical pulps[6] and lower the degree of polymerization of the cellulose in chemical pulps to unacceptable levels.[7]

Data in the literature suggest that carbonates and bicarbonates of Mn are the actual catalysts and rate equations for peroxide decomposition that are second order in $[HCO_3^-]$[8] and third order in $[HCO_3^-]$[9] have been reported. Thermodynamic data have been presented in support of $Mn(HCO_3)_2$ or $[Mn(CO_3)(HCO_3)]^-$ as the actual catalyst.[10–12] The one-electron oxidation potential of those species is reported to be in the range of –0.67 V up from –1.51 V for Mn^{2+} in acid.[11–13] The reduction potential for one-electron abstraction by H_2O_2 at pH 7 is given in eq. [3].[14] It can be seen that the value is only 0.46 V when compared with 0.87 V at pH 0.[14] If eq. [3] were to be combined with eq. [4] then eq. [5] would be obtained and the reaction would only be slightly endoergic.

$$[3] \quad H_2O_2 + e^- \rightarrow \cdot OH + OH^- \qquad (0.46\ V)$$

$$[4] \quad Mn(HCO_3)_2 \rightarrow Mn(HCO_3)_2^+ + e^- \qquad (-0.67\ V)$$

$$[5] \quad H_2O_2 + Mn(HCO_3)_2 \rightarrow Mn(HCO_3)_2^+ + \cdot OH + OH^- \qquad (-0.21\ V)$$

The corresponding reaction in a Mn(III)/Mn(II) cycle would be electron abstraction from H_2O_2 by Mn(III). The half-reactions and the net reactions are given in eqs. [6]–[8]. The voltage of –0.94 V (pH 7) for H_2O_2 losing an electron is from Koppenol and Butler.[14] Once again the net reaction is only slightly endoergic (–0.27 V) and the Mn(III)/Mn(II) redox cycle should be able to catalyze H_2O_2 decomposition in bicarbonate solution in the neutral pH range.

$$[6] \quad H_2O_2 \rightarrow \cdot O_2^- + 2H^+ + e^- \qquad (-0.94\ V)$$

$$[7] \quad [Mn(HCO_3)_2]^+ + e^- \rightarrow Mn(HCO_3)_2 \qquad (0.67\ V)$$

$$[8] \quad [Mn(HCO_3)_2]^+ + H_2O_2 \rightarrow Mn(HCO_3)_2 + \cdot O_2^- + 2H^+ \qquad (-0.27\ V)$$

There are two proposed free radical chain mechanisms to explain Mn(II) catalysis of peroxide decomposition in HCO_3^-, one involving Mn(II), Mn(III), and Mn(IV)[8] and the other involving only Mn(II) and Mn(III).[9] In both cases the rate of peroxide decomposition should increase with an increase in the rate of oxidation of Mn(II) by a peroxygen species. Since HCO_4^- is a much stronger oxidant than H_2O_2,[1] bicarbonate addition could lead to a higher oxidation rate for Mn(II) and an increase in the peroxide decomposition rate.

This report is on an investigation of Mn(II) catalysis of peroxide decomposition in $NaHCO_3$ solutions at pH 7.4–8.7 and 40 °C. Citrate anion was investigated as a model chelator to see if it would form complexes with Mn(II), Mn(III), and (or) Mn(IV) and interfere with the mechanism operative for Mn bicarbonates and (or) carbonates. In a companion submission, results are presented for catalysis by Fe(III) species in a pH range of 8.5–8.7.[4]

Experimental

All of the relevant chemicals are described in the companion paper.[4] Possible Mn–citrate complexes were prepared by dissolving $Mn(SO_4)\cdot H_2O$ in citric acid. The $[Mn^{2+}]$ was 0.018 mol/L (1000 ppm), and citric acid was added at a 5:1 mol ratio to Mn^{2+}. The final solution contained no particles and was nonturbid when its pH was raised from 1.9 to 7.0 with $NaHCO_3$. This solution (1000 ppm Mn) was stored at room temperature and pH 1.9 and aliquots were taken from it and diluted to 10 or 20 ppm Mn(II). These dilute Mn (II) solutions were used for 3–5 days of research before fresh batches were made. The reaction system and chemical and chromatographic analyses were identical to those used in the investigation of ferric catalysis.[4]

Results and discussion

In pulp bleaching, the initial H_2O_2 concentration is in the range of 20–40 mmol/L for a peroxide/bicarbonate (P_B) stage applied to chemical pulps (0.5%–1.0% H_2O_2 on pulp at 12% consistency) and 50–130 mmol/L for mechanical pulps (1.0% H_2O_2 at 15%–30% consistency).[2] The typical concentrations for $NaHCO_3$ are 30–50 mmol/L for chemical pulps (2%–3% $NaHCO_3$ on pulp at 12% consistency) and 60–150 mmol/L for mechanical pulps (3% $NaHCO_3$ at 15%–30% consistency).[2] Mn(II) catalysis was first investigated in the pH 8.5–8.7 range that is optimum for most P_B bleaching applications. The investigation was extended to a pH range of 7.4–7.9 because it is also applicable to P_B bleaching and because of controversies associated with the reaction mechanisms that are believed to be responsible for peroxide decomposition in that pH range. An ionic mechanism was recently proposed to explain the decomposition of hydrogen peroxide in bicarbonate solutions at pH 7.4.[13] However, most of the other proposed mechanisms in the pH range of 7–8 are dominated by free radical reactions.[8,9,15] A first-order dependence on [Mn(II)] was observed by two research groups,[8,9] whereas a second-order dependence was observed by another.[13] However, one of the groups that observed a first-order [Mn(II)] dependence observed a second-order dependence on $[HCO_3^-]$,[8] whereas the other group observed a third-order dependence.[9]

The initial set of experiments for the pH 8.5–8.7 range was aimed at seeing if the rate of peroxide decomposition decreased significantly when a radical scavenger was added. A rate constant (k_{OBS}, eq. [9]) was the basis for all comparison of decomposition rates. The R^2 associated with k_{OBS} was always >0.99 when the extent of peroxide decomposition was >25%. Catalysis of peroxide decomposition by 0.3 ppm Mn(II) (no citrate) in 0.1 mol/L HCO_3^- at 40 °C was investigated in the absence and presence of 1.0 mmol/L salicylic acid (SA). The decomposition rate decreased from 3.9×10^{-4} to 1.0×10^{-4} s^{-1} (74%) when 1.0 mmol/L SA was included

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

(Table 1). Careful analysis for residual SA showed that it decreased to 0.5 mmol/L after 90 min of reaction. When ferric citrate catalysis was investigated under the same conditions of pH, temperature, and time, the SA concentration decreased from 1.0 to 0.8 mmol/L.[4] No hydroxylated product was observed in this case or with ferric citrate. However, the expected product (2,3-dihydroxybenzoic acid)[16] containing adjacent phenolic groups would be expected to be degraded by P_B oxidation. When 5 mmol/L SA and 10 mmol/L GAMID were used as radical scavengers, the peroxide decomposition rate decreased to ca. 0.1×10^{-4} s^{-1} for both additives (Table 1). The peroxide decomposition mechanism appeared to be dominated by a free radical mechanism(s).

$$[9] \qquad \frac{d[H_2O_2]}{dt} = -k_{OBS}[H_2O_2]$$

The concentration of Mn(II) was varied from 0.10 to 0.50 ppm in 0.1 mol/L HCO_3^-. No citrate was added along with the Mn(II). The first-order plots in terms of $[H_2O_2]$ are shown in Fig. 1 for six different [Mn(II)]. When $-\ln k_{OBS}$ was plotted against $-\ln$[Mn(II)] the slope of the regression line was 0.96, indicating a first-order dependence on [Mn(II)] (Fig. 2). The effect of $[HCO_3^-]$ was then investigated. On this occasion both $MnSO_4$ and Mn(II)citrate ($MnSO_4$ plus a 5:1 mol ratio of citrate:Mn(II)) were used as catalysts. The effects of increasing $[HCO_3^-]$ on k_{OBS} are presented in Table 1 and it can be seen that increasing $[HCO_3^-]$ from 0.10 to 0.15 mol/L caused the decomposition rate to increase more than 100%. Also, the decomposition rate was nearly equal with and without citrate. The plots of $-\ln k_{OBS}$ vs $-\ln[HCO_3^-]$ are shown in Fig. 3 for Mn(II) without and with citrate. The slope was 2.13 without citrate and 2.15 with citrate. It appears as if the major reaction mechanism that was operative in this pH range had a second-order dependence on $[HCO_3^-]$.

Research on the peroxide decomposition mechanism for the pH range 7.4–7.9 was initiated with an investigation of SA addition. The radical scavenger at 1.0 mmol/L decreased the peroxide decomposition rate from 6.8×10^{-4} to 1.3×10^{-4} s^{-1} (81%) when a [Mn(II)] of 1.0 ppm was used in 0.1 mol/L HCO_3^-. The decomposition mechanism once again appeared to be free radical in nature.

The reaction order determinations were then repeated at initial pH 7.4. The use of a buffer was avoided and the reaction pH increased from 7.4 to ca. 7.9 when ca. 75% of the H_2O_2 was decomposed. When determining the reaction order for [Mn(II)] a low HCO_3^- concentration (0.05 mol/L) was used and the peroxide residuals were determined after 0, 5, 10, 15, and 20 min. On these occasions, the pH was kept in a range of 7.4–7.7 and peroxide decomposition after 20 min varied from 8% to 35% for [Mn(II)] in the range of 1.0–5.0 ppm. However, the R^2 value on k_{OBS} (eq. [9]) was always >0.985. When $-\ln k_{OBS}$ was plotted against $-\ln$[Mn(II)] the regression line had a slope of 1.01, indicating a first-order dependence on [Mn(II)]. These data will not be shown but similar data will be shown and discussed shortly.

The HCO_3^- concentration effect was then investigated with 1.0 ppm Mn(II), and it was difficult to keep the pH in the range of 7.4–7.7 and collect enough data points when $[HCO_3^-] \geq 0.1$ mol/L. The pH would exceed 7.7 within 10–15 min. However, there did not appear to be a significant pH effect in the range 7.4–7.9. The first-order plots in terms of $[H_2O_2]$ are shown in Fig. 4 for $[HCO_3^-]$ for 0.075, 0.10, and 0.125 mol/L concentrations. If the decomposition rate increased with increasing pH during the run then one would expect the first-order plots to curve concavely upwards. This was not seen (Fig. 4). This lack of a pH dependence in the range 7.4–7.9 is in clear contradiction to Sychev et al.,[8] who observed an increase in peroxide decomposition with increasing pH: $\sim 1/[H^+]^{0.5}$.

At first glance it also appeared that Stadtman and co-workers[9] observed an increase in peroxide decomposition with increasing pH in the range 7.4–7.9. However, their increase in pH was due to an increase in $[HCO_3^-]$. The reaction order for $[HCO_3^-]$ reported by Stadtman and co-workers[9] was almost perfectly third-order. When 12 k_{OBS} (min^{-1}) values from Stadtman and co-workers[9] were plotted against their corresponding $[HCO_3^-]$,[3] a linear relationship with $R^2 > 0.99$ was observed. All 12 $[HCO_3^-]$ resulted in a reaction pH in the range 7.4–7.9. Apparently, an increase in pH does not enhance the rate of peroxide decomposition in the 7.4–7.9 range.

Now that it was known that pH had no significant effect in the range 7.4–7.9, the dependence on [Mn(II)] was repeated in 0.075 mol/L HCO_3^- solutions. The [Mn(II)] was varied from 0.5 to 2.5 ppm and peroxide decomposition after 20 min varied from 15% to 54%. The k_{OBS} values are presented in Table 2 and a plot of $-\ln k_{OBS}$ vs $-\ln$[Mn(II)] is shown in Fig. 5. The slope was 1.00 and there is definitely a first-order dependence on [Mn(II)]. This finding supports the previously reported first-order [Mn(II)] dependence[8,9] and contradicts claims of a second-order [Mn(II)] dependence.[13]

Data from the present investigation on k_{OBS} for 1.0 ppm Mn(II) and $[HCO_3^-]$ varying from 0.075 to 0.15 mol/L are given in Table 2, and a plot of $-\ln k_{OBS}$ vs $-\ln[HCO_3^-]$ is shown in Fig. 6. The reaction order was 2.88. The present results are most consistent with those of Stadtman and co-workers,[9] whose proposed mechanism contained a reaction similar to that in eq. [5].

The salient features associated with results from the literature and the present investigations are

1. Decomposition is via free radical mechanisms.
2. A mechanism that is second order in $[HCO_3^-]$ appears to be operative at pH 8.5–8.7.
3. A mechanism that is third order in $[HCO_3^-]$ appears to be operative at pH 7.4–7.9.
4. The bicarbonate dependence is higher than second order, but less than third order throughout the pH range 7.4–8.7.

A third-order dependence on $[HCO_3^-]$ can be obtained if the assumption of Stadtman and co-workers[9] is accepted that a $Mn(II)(HCO_3^-)_3$ species is involved. However, no evidence can be found in the literature for the existence of such a species at pH < 8.0. The only other approach that could be found to obtain a rate equation for a free radical chain mechanism that was first order in [Mn(II)] and $[H_2O_2]$, but third order in $[HCO_3^-]$ was to include an equilibrium reaction between H_2O_2 and HCO_3^- to produce HCO_4^- and a second equilibrium involving Mn(II) and 2 mol of HCO_3^- to produce $Mn(HCO_3)_2$ (to be discussed later). The only credible explanation that this investigation can provide is based on the

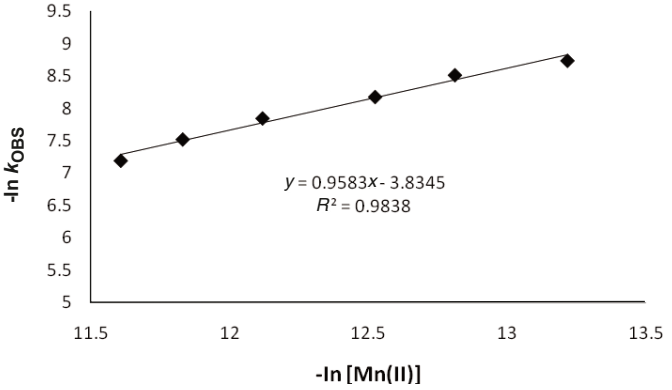

Fig. 3. Plot of $-\ln k_{OBS}$ vs $-\ln[HCO_3^-]$ for peroxide decomposition catalyzed by 0.1 ppm Mn(II) in 0.10–0.30 mol/L HCO_3^- at 40 °C and pH 8.5–8.7. When used, citrate was added at a 5:1 mol ratio to Mn(II).

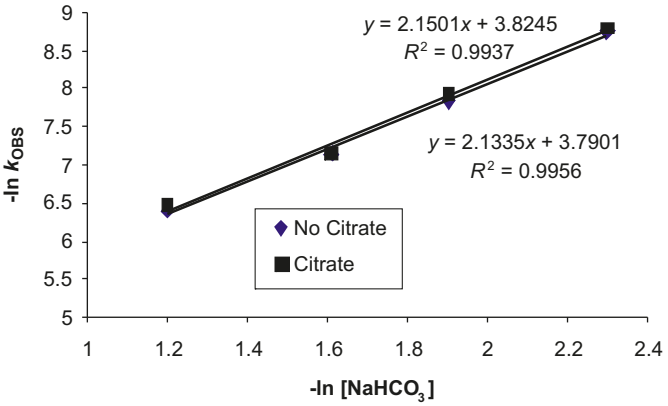

electroreduction and EPR spectroscopic study of Dasgupta et al.[12] where they observed the two species in eq. [10] in HCO_3^- solution at pH 8.3.

$$[10] \qquad Mn(HCO_3)_2 + H_2O \leftrightarrow [Mn(CO_3)(HCO_3)]^- + H_3O^+$$

Dasgupta et al.[12] estimated that the pK_a for $Mn(HCO_3)_2$, in accordance with eq. [10], should be in the range 7.5–8.5. If a pK_a of 8.5 is assumed then the dominant Mn(II) species would be $Mn(HCO_3)_2$ in the pH range 7.4–7.9, whereas the distribution would be ~50:50 between neutral and anionic Mn(II) species at pH 8.5–8.7. If it is assumed that H_2O_2 is capable of abstracting an electron from the anionic Mn(II) species at a much higher rate as compared with the neutral Mn(II) species, then the reaction scheme in eqs. [11]–[16] would give a rate equation that is first order in [H_2O_2] and [Mn(II)], but second order in [HCO_3^-]. In the derivation of

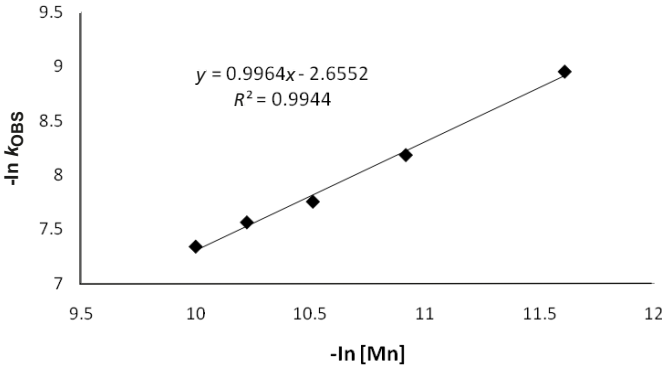
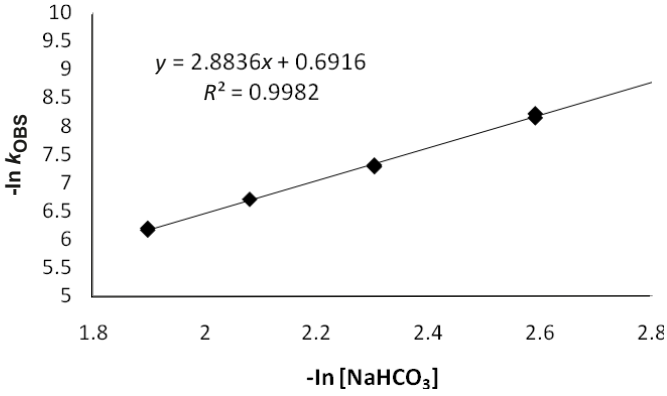
Fig. 5. Plot of $-\ln k_{OBS}$ vs $-\ln[Mn(II)]$ for peroxide decomposition catalyzed by 0.5–2.5 ppm Mn(II) in 0.075 mol/L HCO_3^- at 40 °C and pH 7.4–7.9. No citrate was added.



the rate equation, the reaction in eq. [16] was left out (to be discussed shortly). The redox chain mechanism is identical in form to one that is widely accepted for Fe(II)/Fe(III) catalysis of H_2O_2 decomposition.[17,18] The assumption that H_2O_2 abstracting an electron from the anionic Mn(II) species should occur at a higher rate is reasonable because the anionic Mn(II) species should be more electron-rich than the neutral Mn(II) species.

[11] $$Mn^{2+} + 2HCO_3^- \overset{K_1}{\leftrightarrow} [Mn(CO_3)(HCO_3)]^- + H^+$$

Fig. 6. Plot of $-\ln k_{OBS}$ vs $-\ln[HCO_3^-]$ for peroxide decomposition catalyzed by 1.0 ppm Mn(II) in 0.075–0.15 mol/L HCO_3^- at 40 °C and pH 7.4–7.9. No citrate was added.



[12] $$[Mn(CO_3)(HCO_3)] + H_2O_2 \overset{k_1}{\rightarrow} [Mn(CO_3)(HCO_3)]^- + 2H^+ + \cdot O_2^-$$

[13] $$[Mn(CO_3)(HCO_3)]^- + H_2O_2 \overset{k_2}{\rightarrow} [Mn(CO_3)(HCO_3)_2] + OH^- + \cdot OH$$

[14] $$\cdot OH + H_2O_2 \overset{k_3}{\rightarrow} H_2O + \cdot O_2^- + H^+$$

[15] $$\cdot O_2^- + [Mn(CO_3)(HCO_3)] \overset{k_4}{\rightarrow} [Mn(CO_3)(HCO_3)]^- + O_2$$

[16] $$\cdot O_2^- + [Mn(CO_3)(HCO_3)]^- + H^+ \overset{k_5}{\rightarrow} Mn(CO_3)(HCO_3) + HOO^-$$

On the other hand, if it is assumed that electron abstraction from the anionic Mn(II) by HCO_4^- is retarded by anionic repulsion and that HCO_4^- is a strong enough oxidant to abstract an electron from the neutral Mn(II) species at a relatively high rate, then the reaction scheme in eqs. [17]–[20], [14], and eqs. [21] and [22] would give a rate equation that is first order in $[H_2O_2]$ and [Mn(II)], but third order in $[HCO_3^-]$. Equation [22] was left out in the rate equation derivation.

[17] $$Mn^{2+} + 2HCO_3^- \overset{K_2}{\leftrightarrow} Mn(HCO_3)_2$$

[18] $$HCO_3^- + H_2O_2 \overset{K_3}{\leftrightarrow} HCO_4^- + H_2O$$

[19] $$[Mn(HCO_3)_2]^+ + H_2O_2 \overset{k_6}{\rightarrow} Mn(HCO_3)_2 + 2H^+ + \cdot O_2^-$$

[20] $$Mn(HCO_3)_2 + HCO_4^- \overset{k_7}{\rightarrow} [Mn(HCO_3)_2]^+ + \cdot OH + CO_3^{2-}$$

[14] $$\cdot OH + H_2O_2 \overset{k_3}{\rightarrow} H_2O + \cdot O_2^- + H^+$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

[21] $\cdot O_2^- + [Mn(HCO_3)_2]^+ \xrightarrow{k_8} Mn(HCO_3)_2 + O_2$

[22] $\cdot O_2^- + Mn(HCO_3)_2 + H^+ \xrightarrow{k_9} [Mn(HCO_3)_2]^+ + HOO^-$

In the derivation of the rate equations for both the high pH or anionic Mn(II) case and the low pH or neutral Mn(II) case, the termination reactions (eqs. [16] and [22]) were left out as mentioned earlier. The rate equations so derived are for oxygen generation and not peroxide decomposition. However, the simplification associated with leaving out eqs. [16] and [22] allowed for straightforward derivations of the respective rate equations. The only assumption that has to be made in the high pH case is whether $k_1[H_2O_2]$ is much greater or much less than $k_4[\cdot O_2^-]$. If it is assumed that $k_1[H_2O_2] >> k_4[\cdot O_2^-]$, the final rate equation is given in eq. [23], whereas if the reverse assumption is made the rate equation in eq. [24] is obtained. The two equations are identical in terms of reaction orders. The complete derivations of the rate equations (eqs. [23] and [24]) have been provided as Supplementary data and identified as Schemes 1*a* and 1*b*, respectively.

[23] $$\frac{d[O_2]}{dt} = \frac{2K_1k_2[Mn^{2+}][H_2O_2][HCO_3^-]^2}{[H^+]}$$

[24] $$\frac{d[O_2]}{dt} = \frac{K_1k_2[Mn^{2+}][H_2O_2][HCO_3^-]^2}{[H^+]}$$

The same assumption about relative values of $k_6[H_2O_2]$ and $k_8[\cdot O_2^-]$ is dealt with similarly in the low pH case. If it is assumed that $k_6[H_2O_2] >> k_8[\cdot O_2^-]$ then the rate equation in eq. [25] is obtained, whereas if the reverse assumption is made the rate equation in eq. [26] is obtained. The complete derivations of the rate equations (eqs. [25] and [26]) are presented as Supplementary data as Schemes 2*a* and 2*b*, respectively.

[25] $$\frac{d[O_2]}{dt} = 2K_2K_3k_7[Mn^{2+}][H_2O_2][HCO_3^-]^3$$

[26] $$\frac{d[O_2]}{dt} = K_2K_3k_7[Mn^{2+}][H_2O_2][HCO_3^-]^3$$

The experimental data showed a modest pH effect. When 0.5 ppm Mn(II) was used in 0.1 mol/L HCO_3^- at pH 8.5–8.7 a k_{OBS} of 7.5×10^{-4} s^{-1} was obtained, whereas when 1.0 ppm Mn(II) was used in 0.1 mol/L HCO_3^- at pH 7.4–7.9 a k_{OBS} of 6.8×10^{-4} s^{-1} was obtained. If it is assumed that k_{OBS} would increase to ca. 15×10^{-4} s^{-1} if the Mn(II) concentration were to be increased from 0.5 to 1.0 ppm at pH 8.5–8.7, then the peroxide decomposition rate would be >2.0 times as high at pH 8.5–8.7 as compared with pH 7.4–7.9. However, it would be extremely difficult to incorporate a pH effect into the two reaction schemes presented for high and low pH cases.

In all likelihood, reaction(s) in one scheme would compete with the corresponding reaction(s) in the other scheme. For example, the rate of Mn(III) oxidation of H_2O_2 in the high pH case is probably greater than in the low pH case (eq. [12] vs eq. [19]). It is also possible that the rate of Mn(II) oxidation by H_2O_2 is higher than the corresponding reaction with HCO_4^- (eq. [13] vs eq. [20]). It should be remembered that the ratio of $[HCO_4^-]$:$[H_2O_2]$ is only 0.032 in 0.1 mol/L HCO_3^- (eq. [2]). However, the rate of electron abstraction from $\cdot O_2^-$ in the low pH case eq. [21] may be higher than in the high pH case eq. [15]. Therefore, as pH is increased the concentrations of $[Mn(CO_3)(HCO_3)]^-$ and $Mn(CO_3)(HCO_3)$ would be expected to increase, whereas the concentrations of $Mn(HCO_3)_2$ and $[Mn(HCO_3)_2]^+$ should decrease in accordance with the equilibrium between Mn(II) species in eq. [10]. A possible outcome based on the arguments above is that the rate would increase for two reactions that are instrumental toward oxygen generation but decrease for a third. The net effect of this pH increase would be difficult to assess without having good estimates for the rate constants of the key reactions.

Conclusion

Hydrogen peroxide decomposition catalyzed by Mn(II) was investigated in HCO_3^- solutions in the pH ranges 8.5–8.7 and 7.4–7.9. The first pH range is optimum for pulp bleaching, but there are controversies in the literature regarding the mechanism of peroxide decomposition in the later pH range. It was concluded that free radical mechanisms were dominant in both pH ranges. The rate equation for peroxide decomposition was first order in $[H_2O_2]$ and [Mn(II)] in both pH ranges but close to second order in $[HCO_3^-]$ in the higher pH range and close to third order in the lower pH range. Free radical chain mechanisms were proposed that afforded rate equations that were first order in $[H_2O_2]$ and [Mn(II)]. One of the rate laws had a second-order bicarbonate dependence in the higher pH range and the other had a third-order dependence in the lower pH range.

Theoretical calculation of the low-lying quartet states of the CrF molecule

A. Hamdan and M. Korek

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: The potential energy curves have been investigated for the 11 lowest quartet electronic states in the $^{2s+1}\Lambda^{\pm}$ representation below 28 000 cm^{-1} of the molecule CrF via CASSCF and MRCI (single and double excitations with Davidson correction) calculations. Eight electronic states have been studied theoretically for the first time. The harmonic frequency ω_e, the internuclear distance r_e, the rotational constant B_e, the electronic energy with respect to the ground state T_e, and the permanent dipole moment μ have been calculated. By using the canonical functions approach, the eigenvalues E_v, the rotational constant B_v, and the abscissas of the turning points r_{min} and r_{max} have been calculated for electronic states up to the vibrational level $v = 38$. The comparison of these values to the theoretical results available in the literature shows a very good agreement.

Key words: ab initio calculation, potential energy curves, spectroscopic constants, rovibrational calculation, permanent dipole moment.

Résumé : Faisant appel à des calculs de l'espace actif complet en champ autocohérent (EAC-CAC) et de l'interaction de configuration à référence multiple (IC-RM) (en excitation simple ou double, avec correction de Davidson), on a étudié les courbes d'énergie potentielle des 11 états électroniques quadruplets les plus faibles dans la $^{2s+1}\Lambda^{\pm}$ représentation en dessous de 28 000 cm^{-1} de la molécule de CrF. Huit états électroniques ont été étudiés d'une façon théorique pour la première fois. On a calculé la fréquence harmonique, ω_e, la distance internucléaire, ω_e, la constante de rotation, B_e, l'énergie électronique par rapport à l'état fondamental, T_e, et le moment dipolaire permanent, μ. Utilisant l'approche des fonctions canoniques, on a aussi calculé les valeurs eigen, E_v, la constante de rotation, B_v, et les abscisses des points de changement de sens, r_{min} et r_{max}, des états électroniques jusqu'au niveau vibrationnel $v = 38$. Une comparaison de ces valeurs avec les résultats théoriques disponibles dans la littérature présente un très bon accord.

Mots-clés : calculs ab initio, courbes d'énergie potentielle, constantes spectroscopiques, calcul rovibrationnel, moment dipolaire permanent.

[Traduit par la Rédaction]

Introduction

Diatomic molecules containing a 3d transition-metal atom and a main-group element are of considerable interest in organometalic chemistry, catalysis, high-temperature chemistry,[1,2] constituents of cool stars,[3] sunspots, and as models for the role that d-electrons play in chemical bonds involving a transition element.[4] The large number of low-lying states, often of high multiplicity, in transition-metal-containing diatomic molecules gives rise to a remarkable congestion in their spectra, which presents difficulties for both spectroscopists and theoretical chemists. Since transition-metal compounds are highly refractory, few methods are available to produce gaseous molecules efficiently for spectroscopic study at room temperature; this is the reason why few species containing a transition-metal atom have been studied with high-resolution spectroscopy, and therefore, there is a need for ab initio calculations as guidance for the experiments or analyzing the experimental results for these molecules.

In the literature, there are only few theoretical results for the quartet states $(1)^4\Sigma^+$, $(1)^4\Pi$, and $(1)^4\Delta$ of the molecule CrF. The spectroscopic constants of these states have been calculated by Harrison et al.,[4] Bencheikh et al.,[5] Koukounas et al.[6] and Koivisto et al. [7] by using, respectively, the ligand field and density functional techniques, variety of ab initio method and MRCI, and spin-orbit-configuration interaction calculation. Recently,[8] we investigated the 12 lowest sextet electronic states in the $^{2s+1}\Lambda^{\pm}$ representation below 53 000 cm^{-1} of the molecule CrF via CASSCF and MRCI (single and double excitation with Davidson correction) calculations where we found that the ground state is $X^6\Sigma^+$. In the present work, 11 low-lying quartet electronic states of CrF have been investigated by using the same procedure of ab initio method. The potential energy curves (PECs), along with the transition energy with respect to the minimum energy for the ground state T_e, the equilibrium internuclear distance r_e, the harmonic frequency ω_e, the rotational constant B_e, and the permanent dipole moment μ have been obtained for the lowest-lying quartet electronic states of the CrF molecule. Eight states have been investigated here for the first time. Taking

advantage of the electronic structure of the investigated electronic states of CrF and by using the canonical functions approach, the eigenvalue E_v, the rotational constant B_v, and the abscissas of the turning points r_{min} and r_{max} have been calculated for several vibrational levels of the 11 considered quartet electronic states.

Computational approach

Ab initio calculation

To test the use of ab initio calculation for the study of the transition metal – fluorine, particularly Cr atom – fluorine, we investigate in the present work the lowest-lying quartet electronic states of the CrF molecule via CASSCF method. Multireference CI calculations (single and double excitations with Davidson corrections) were performed. Chromium and fluorine atoms are treated in all electron schemes where the 24 electrons of the chromium and 9 electrons of fluorine are considered using a contracted Gaussian basis set given by Bauschlisher[9] for s, p, d, and f functions to obtain the contracted basis set [7s6p4d3f] for the Cr atom and the contracted [5s4p3d2f] Gaussian basis set aug-cc-PVQZ[10] for the F atom. By recalculating the ground state $X^6\Sigma^+$, the ab initio calculation of this molecule has been done in two ways: (*i*) 28 inner electrons were frozen in subsequence calculations so that five valance electrons were explicitly treated. The active space contains 6σ (Cr: $4s3d^04p^04d^05s$; F: 3s), 3π (Cr: $3d^{\pm1}4p^{\pm1}4d^{\pm1}$), and 2δ (Cr: $3d^{\pm2}4d^{\pm2}$) orbitals in the C_{2v}

symmetry distributed into irreducible representation a_1, b_1, b_2, and a_2 in the following way $8a_1$, $3b_1$, $3b_2$, and $2a_2$ noted.[2,3,8] (*ii*) 20 inner electrons were frozen in subsequent calculations so that 13 valance electrons were explicitly treated. The active space contains 4σ (Cr: $4^s3d^04p^0$), 2π (Cr: $3d^{\pm1}4p^{\pm1}$), and 1δ (Cr: $3d^{\pm2}$) orbitals in the C_{2v} symmetry into irreducible representation a_1, b_1, b_2, and a_2 in the following way 5a1, $2b_1$, $2b_2$, and $1a_2$ noted.[1,2,5] In the range of the internuclear distance r around the equilibrium position of its ground state, the CrF molecule is assumed to be mainly ionic. This calculation has been performed via the computational chemistry program MOLPRO[11] taking advantage of the graphical user interface GABEDIT.[12]

The PECs and the dipole moment for 11 quartet states in the representation $^{2s+1}\Lambda^{\pm}$ have been calculated for 131 internuclear distances in the range 1.2 Å ≤ r ≤ 2.95 Å. These PECs, and the dipole moment in the different symmetries, in case of 13 valance electrons, are given in Figs. 1–4, respectively. In the range of r considered, some crossings between the states occur; the positions of these crossings are given in Table 1. The spectroscopic constants such as the vibrational harmonic constant ω_e, the internuclear distance at equilibrium r_e, the rotation constant B_e, and the electronic transition energy with respect to the ground state T_e have been calculated by fitting the energy values around the equilibrium position to a polynomial in terms of the internuclear distance by using the data obtained from the ab initio calculation with five and 13 valence electron. The comparison of our results with the 12 values for T_e calculated by different techniques in the literature for the states $(1)^4\Pi$, $(1)^4\Delta$, and $(1)^4\Sigma^+$ shows

Table 1. Positions of the crossings and avoided crossing between the different lowest electronic quartet states of the molecule CrF.

			Crossing	Avoid crossing
State 1	State 2	(n_1)state1/(n_2)state2	r_c (Å)	r_{ac} (Å)
$^4\Sigma^+$	$^4\Delta$	3/4	2.13	
	$^4\Pi$	1/1	1.37	
	$^4\Phi$	2/1	2.19	
	$^4\Phi$	2/1	2.37	
	$^4\Sigma^-$	2/1	1.96	
	$^4\Gamma$	2/1	2.10	
$^4\Sigma^-$	$^4\Delta$	1/2	1.38	
	$^4\Delta$	1/2	1.85	
$^4\Delta$	$^4\Phi$	1/1	1.34	
	$^4\Phi$	2/1	2.09	
	$^4\Gamma$	2/1	2.04	
	$^4\Delta$	3/4		1.72
$^4\Gamma$	$^4\Phi$	1/1	1.55	

that 10 values are in good agreement where the relative difference is $0.9\% \leq \delta T_e/T_e \leq 9.3\%$ for the calculation with five valence electron and $0.5\% \leq \delta T_e/T_e \leq 8.4\%$ for the calculation with 13 valence electron. For the states $(1)^4\Delta$ and $(1)^4\Sigma^+$, the comparison of our values of T_e with those calculated by using ligand field theory by Bencheikh et al.[5] and MRCI method by Koivisto et al.[7] shows that two values have larger relative difference equal 11.9% and 12.8% for the calculation with five valence electrons and 11.04% and 11.80% for the calculation with 13 valence electrons, respectively. For ω_e, and for the same states, the comparison of our values with those given in the literature showed a very good agreement for nine values where the relative difference is $0.3\% \leq \delta\omega_e/\omega_e \leq 5.2\%$ for the calculation with five valence electrons and $0.1\% \leq \delta\omega_e/\omega_e \leq 7.5\%$ for the calculation with 13 valence electrons, while the comparison with those given by ligand field theory[5] shows a larger relative difference of $12.0\% \leq \delta\omega_e/\omega_e \leq 19.2\%$ and $10.1\% \leq \delta\omega_e/\omega_e \leq 14.5\%$ for the calculations with five and 13 valence electrons, respectively. This difference in the values of ω_e can be explained by the light difference in the shape of the potential energy curves around the minimum calculated by our method and that used of Bencheikh et al.[5] For the same three states, the 12 values of r_e obtained theoretically in the literature are in very good agreement with our calculated values with a relative difference of $0.3\% \leq \delta r_e/r_e \leq 5.3\%$ and $0.0\% \leq \delta r_e/r_e \leq 3.0\%$ for the calculations with five valence electrons and 13 valence electrons, respectively.

The values of the dipole-moment operator are among the most reliably predicted physical properties; they give useful information about the degree of ionic and covalent character in the bonding, which needs to be correctly represented by the ab initio calculations. The expectation value of the dipole-moment operator is sensitive to the nature of the least energetic and most chemically relevant valence electrons. Since the dipole moment at the Hartree–Fock level is usually large, and to obtain the best accuracy, multireference configuration interaction (MRCI) wave functions were constructed using multiconfiguration self-consistent field (MCSCF) active space. By taking the Cr atom as an origin in our calculation, the permanent dipole moments of the investigated electronic states have been investigated for the 11 lowest quartet electronic states of the molecule CrF. The calculated values of the dipole moments (in Debye (D)) for these electronic states in terms of the internuclear distance r are plotted in Figs. 3 and 4. All these calculations have been performed by using the MOLPRO[11] program. The number of valence electron has a large influence on the calculation of the permanent dipole moments; the comparison of our calculated values, in case of five valence electrons, with the 6 values given in the literature[4,6] shows a relative difference (Table 2) $7.1\% \leq \delta\mu/\mu \leq 69.7\%$, while this relative difference becomes $0.6\% \leq \delta\mu/\mu \leq 15.4\%$ with the 13 valence electrons, which represents a very good agreement. One can notice the agreement between the position of the avoided crossing of the PECs (Fig. 1 and Table 1) of the $(3)^4\Delta$ and $(4)^4\Delta$ and the crossings of dipole-moment curves of these states in Fig. 3, which confirm the accuracy of the present work.

The vibration–rotation calculation

Within the Born–Oppenheimer approximation, the vibration rotation motion of a diatomic molecule in a given electronic state is governed by the radial Schrödinger equation

$$[1] \qquad \left[\frac{d^2}{dr^2} + \frac{2\mu}{\hbar^2}\Big(E_{vJ} - U(r)\Big) - \frac{\lambda}{r^2}\right]\Psi_{vJ}(r) = 0$$

where r is the internuclear distance, v and J are, respectively, the vibrational and rotational quantum numbers, $\lambda = J(J+1)$, and E_{vJ} and ψ_{vJ} are, respectively, the eigenvalue and the eigenfunction of this equation. In the perturbation theory, these functions can be expanded as

$$[2] \qquad E_{vJ} = \sum_{n=0} e_n \lambda^n$$

$$[3] \qquad \Psi_{vJ}(r) = \sum_{n=0} \Phi_n(r)\lambda^n$$

with $e_0 = E_v$, $e_1 = B_v$, $e_2 = -D_v$. ϕ_0 is the pure vibrational wave function and ϕ_n is its rotational correction. By replacing eqs. [2] and [3] into eq. [1], and since this equation is satisfied for any value of λ, one can write[13–15]

Note: (a_1) and (a_2) are for the present work with five valence electrons and 13 valence electrons calculations, respectively; ref. 5: (b); ref. 7: (c); ref. 6: (d_1) MRCI, (d_2) MRACPF, (d_3) MRCI+Q, (d_4) C-MRCI, (d_5) MRCI obtained by the finite field method, and (d_6) C-MRCI+Q obtained by the finite field method; ref. 4 with 21 valence electrons: (e_1) CI(R); ref. 4 with 13 valance electrons: (e_2) CI(NR), (e_3) CI(R), (e_4) CID (NR), and (e_5) MRCI; (f) and (g) represent, respectively, the relative difference between our calculated values (a_1) and (a_2) and those given in the literature.

$$[4] \qquad \phi_0'(r) + [e_0 - U(r)]\phi_0(r) = 0$$

$$[5a] \qquad \phi_1'(r) + [e_0 - U(r)]\,\phi_1(r) = -[e_1 - R(r)]\,\phi_0(r)$$

$$[5b] \qquad \phi_2'(r) + [e_0 - U(r)]\,\phi_2(r) = -[e_1 - R(r)]\,\phi_1(r) - e_2\,\phi_0(r)$$

$$[5c] \qquad \phi_n'(r) + [e_0 - U(r)]\,\phi_n(r) = R(r)\,\phi_{n-1} - \sum_{m=1}^{n} e_m\,\phi_{n-m}(r)$$

where $R(r) = 1/r^2$, the first equation is the pure vibrational Schrödinger equation, and the remaining equations are called the rotational Schrödinger equations. One may project eqs. [5*a*]–[5*c*] onto ϕ_0 and find

$$[6a] \qquad < \phi_0|\phi_0 > e_1 = < \phi_0|\frac{1}{r^2}|\phi_0 >$$

$$[6b] \qquad < \phi_0|\phi_0 > e_2 = < \phi_0|\frac{1}{r^2}|\phi_1 > -e_1 < \phi_0|\phi_1 >$$

$$[6c] \qquad < \phi_0|\phi_0 > e_n = < \phi_0|\frac{1}{r^2}|\phi_{n-1} > - \sum_{m=1}^{n-1} e_m < \phi_{n-m}|\phi_0 >$$

Once e_0 is calculated from eq. [4], e_1, e_2, e_3, …, e_n can be obtained by using alternatively eqs. [5] and [6]. By using these canonical functions and the cubic spline interpolation between each two consecutive points of the potential energy curves obtained from the ab initio calculation of the CrF molecule, the eigenvalue E_v, the rotational constant B_v, the centrifugal distortion constant D_v, and the abscissas of the turning point r_{min} and r_{max} have been calculated for all the considered electronic states up to the vibrational levels v = 38. These values for the states $(1)^4\Sigma^+$ and $(1)^4\Pi$ (as illustrated) are given in Table 3. There is no comparison of these values of with other results, since they are given here for the first time.

Conclusion

In the present work, the ab initio investigation for 11 low-lying quartet electronic states of the CrF molecule has been performed via CAS-SCF/MRCI method. The potential energy curves and the dipole moment curves have been determined along with the spectroscopic constants T_e, r_e, ω_e, and the rotational constant B_e for the considered electronic states. To the best of our knowledge, there is no experimental data for the quartet states of the molecule CrF, while the theoretical results are those of Bencheikh et al.,[5] Harrison and Hutchison,[4] Koivisto et al.,[7] and Koukounas et al.[6] By comparing our calculated values with those obtained theoretically by different techniques, one can confirm the validity and the accuracy of the ab initio MRCI calculation used in the present work with the chosen valence electrons. By using the

Abstract: A series of chiral proline amide – thiourea bifunctional catalysts derived from L-proline and chiral diamine were prepared and successfully applied to highly enantioselective direct aldol reactions of cyclohexanone with various aldehydes in excellent yields (85%–97%), diastereoselectivities (anti/syn > 20:1) and enantioselectivities (up to 91% ee).

Key words: aldol reaction, bifunctional catalyst, proline, amide–thiourea.

Résumé : On a préparé une série de catalyseurs chiraux bifonctionnels amide de la proline – thiourée dérivés de la L-proline et d'une diamine chirale et on l'a appliquée avec succès à la réaction d'aldolisation directe hautement énantiosélective de la cyclohexanone avec divers aldéhydes, avec d'excellents rendements (85 %–97 %), et des diastéréosélectivités (anti/syn > 20 : 1) et énantiosélectivités (allant jusqu'à 91 % ee) élevées.

Mots-clés : réaction aldolique, catalyseur bifonctionnel, proline, amide–thiourée.

[Traduit par la Rédaction]

Introduction

The aldol reaction is considered one of the most important carbon–carbon bond-forming reactions that creates the β-hydroxy ketones frequently found in many biologically active compounds and drugs.[1,2] Since pioneering work discovered that L-proline is a highly efficient catalyst for asymmetric direct aldol reactions,[3] great advances have been made for this reaction.[2–4] The direct aldol reaction involving cyclohexanone principally generates β-hydroxyketone as a mixture of regio-, diastereo-, and enantio-isomers, and it is quite difficult to obtain a single isomer. As a result, many efforts have been made on this conversion. Xiao and co-workers[5a] developed a kind of L-prolinamide derived from L-proline and chiral diamine to catalyze this reaction and provide high entioselectivities, anti-disastereoselectivities, and yields. Since then, a series of L-prolinamides[5] have been prepared and applied to this transformation, and impressive results have been made. As well, L-proline[6] and L-prolinamides,[5] tetrazole,[7] 3-pyrrolidinecarboxylic acid,[8] 4-substituted L-proline,[9] cinchona-derived primary amines,[10] chiral phosphinyl oxide pyrrolidines,[11] prolinethioamides,[12] sulfonamide,[13] 6-APA,[14] *cis*-diamine derivatives,[15] and acyclic amino acids[16] have also been evaluated for this reaction. To the best of our knowledge, L-proline amide – thiourea bifunctional catalysts have not been reported for the catalysis of the aldol reaction of cyclohexanone with aldehydes.

Recently, chiral thiourea organocatalysts have been widely used in asymmetric catalysis because of their effective activation of carbonyl and nitro groups through double-hydrogen-bonding interactions.[17] Among them, secondary amines, especially L-proline and its structural analogues, are powerful tools for the activation of aldehydes and ketones via an enamine or imine transition state.[2,18] However, the chiral proline amide – thiourea catalysts **4a**–**4d** with two catalytic sites of chiral thiourea and L-prolic amide skeleton have not drawn enough attention.[19] Based on this background, we expected to expand the scope of the application for these bifunctional catalysts and wanted to see if these catalysts may catalyze the asymmetric direct aldol reaction of cyclohexanone with aldehydes.

Aldol reactions are typically performed in organic solvents such as DMSO, DMF, or chloroform. In recent years, water has been widely used as a substitute for conventional organic solvents in asymmetric reactions because it is safe, economical, and environment friendly.[20] Therefore, asymmetric aldol reactions using an organocatalyst in water have received considerable attention[21] since Barbas and co-workers[21a] and Hayashi et al.[9] reported the first example of a small molecule catalyzed by direct an asymmetric Aldol reaction in pure water.

As a part of our continuing interest in asymmetric synthesis,[22,23] herein, we wish to report examples of chiral proline

amide – thiourea bifunctional catalyst promoted enantioselective direct aldol reaction of cyclohexanone with various aldehydes in DMSO with water as a co-solvent in excellent yields, as well as high anti-diastereoselectivities (dr > 20:1) and enantioselectivities (up to 91%). These catalysts are illustrated in Fig. 1.

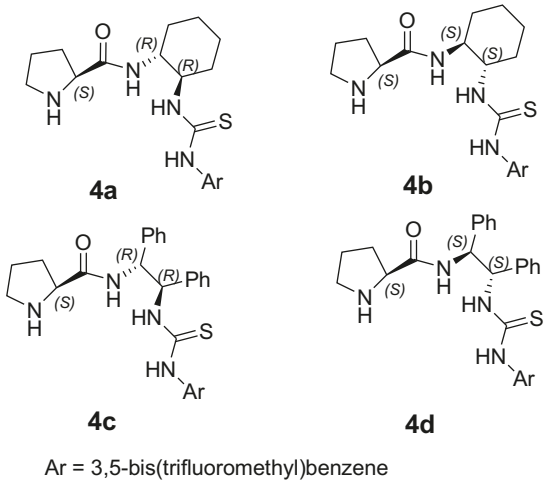
Results and discussion

Chiral catalysts **4a**–**4d** may be similarly prepared as the reported procedures[19] and the catalytic activities of **4a**–**4d** were investigated in the model reaction of cyclohexanone with *p*-nitrobenzaldehyde, and the results are summarized in Table 1, which shows that chiral catalysts with different stereocompatibility and chiral centers have great effects on reactivities and selectivities. Comparatively, catalysts **4a** and **4c** gave better yields and enantioselectivities (Table 1, entries 1 and 3 versus 2 and 4). This is probably due to the compatibility of the two catalytic chiral centers. The less compatible chiral centers in **4b** and **4d** probably exert no synergic or negative effects on enantioselectivity. Catalyst **4a**, bearing a R,R linker, afforded the desired products in excellent yield (97%) and good enantioselectivity (75% ee) and was chosen for further optimization. Next, a range of solvents was screened for the model reaction catalyzed by **4a** at room temperature. As shown in Table 1, the enantioselectivities and yields were highly variable with different solvents. All the solvents delivered good yields (60%–94%), moderate to good enantioselectivities (15%–78% ee), and anti-diastereoselectivities (1:1 to 24:1). Less polar aprotic solvents such as hexane, toluene, and DCM gave good yields and moderate enantioselectivities (Table 1, entries 5–10). Protic solvents such as *i*-PrOH and water separately seemed to have an adverse influence on enantioselectivities (Table 1, entries 14 and 15). Relatively, DMSO gave an excellent yield (92%) and a good enantioselectivity (78%) and was chosen for further investigation (Table 1, entry 12).

To further improve the results, a series of additives were studied and the results are listed in Table 2. Additives have remarkable effects on catalytic activity and enantioselectivity, and the reaction time was reduced to 7 h (entries 1–8). When AcOH was used, the yield increased to 92% and the enantioselectivity was 86% ee (Table 2, entry 8). Interestingly, when water was used as a co-solvent, the reaction rate was dramatically accelerated and the reaction was completed within half an hour with increases in diastereoselectivity (Table 2, entries 9 and 10) and 81% and 87% ee were obtained. Particularly, when the volume ratio of DMSO to water reached 1:2, excellent yield (97%), good enantioselectivity (87% ee), and diastereoselectivity (96:4) were achieved (Table 2, entry 10). Through extensive screening, the optimized reaction conditions were found to be 20 mol% of catalyst **4a** and 10 equiv cyclohexanone in DMSO and water (V_{DMSO}:V_{H_2O} = 1:2) at 25 °C (Table 2, entry 10).

Having established optimized conditions for the model reaction, the scope and the limitations of the reaction with different aldehydes were examined, and the results are summarized in Table 3. All the aldehydes bearing electron-withdrawing groups in the aromatic ring either at ortho (Table 3, entries 6–8), meta (Table 3, entry 5), or para positions (Table 3, entries 1–4) gave excellent yields, diastereoselectivities, and enantioselectivities. Particularly, the strong electron-withdrawing substituents at the ortho position in the benzene ring afforded the best enantioselectivities (up to 91% ee; Table 3, entries 6 and 7). The para position also gave high yields and excellent diastereoselectivities and enantioselectivities (up to 90% ee; Table 3, entries 2 and 3). Cyclopentanone was also investigated under these optimized conditions and gave 94% yield and 71% ee.

Fig. 1. Chiral proline amide – thiourea bifunctional catalysts.



Conclusion

In conclusion, we have successfully applied the chiral proline amide – thiourea bifunctional catalysts **4a**–**4d** for the catalysis of the direct asymmetric aldol reaction of cyclohexanone with various aldehydes in the presence of water in excellent yields (85%–97%) and high anti-diastereoselectivities (dr > 20:1) and enantioselectivities (up to 91% ee). Further studies of the newly developed catalyst model and related catalysts in other organocatalyses are currently underway.

Experimental section

General

All reagents were purchased from a commercial supplier without further purification. Commercial grade solvent was dried and purified by standard procedures as specified in the *Purification of Laboratory Chemicals*;[24] NMR spectra were recorded with tetramethylsilane as the internal standard (δ = 0.0 ppm). ^{1}H NMR spectra were recorded at 300 MHz, and ^{13}C NMR spectra were recorded at 75 MHz (Bruker Avance). Chemical shifts (δ) are reported in ppm downfield from $CDCl_3$ (δ = 7.26 ppm) for ^{1}H NMR and relative to the central $CDCl_3$ resonance (δ = 77.0 ppm) for ^{13}C NMR spectroscopy. Flash column chromatography was carried out using silica gel eluting with ethyl acetate and petroleum ether. Reactions were monitored by TLC and visualized with UV light. Melting points were measured on a Büchi B-545 melting point apparatus. Enantioselectivities (ee) were determined by HPLC using Daicel Chiralpak AD, OD, WHELK, or AS

Colorless solid, mp 176–177 °C. R_f (10% MeOH – EtOAc) 0.23. ^{1}H NMR (300 MHz $CDCl_3$) δ (ppm): 9.89–9.84 (m, 1H), 8.21 (d, J = 10.0 Hz, 1H), 8.15 (d, J = 10.8 Hz, 2H), 7.79 (d, J = 9.5 Hz, 1H), 7.55 (s, 1H), 4.63–4.60 (m, 1H), 3.74–3.67 (m, 2H), 3.01–2.96 (m, 2H), 1.99–1.94 (m, 1H), 1.68–1.22 (m, 12H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 180.9, 176.6, 141.3, 132.1, 128.6, 124.9, 122.1, 121.3, 117.7, 60.3, 56.8, 53.7, 47.1, 32.9, 32.2, 30.9, 25.8, 25.3, 24.7. HRMS (ESI-TOF) calcd for $C_{20}H_{25}F_6N_4OS$ ([M + H]$^+$): 483.1648; found: 483.1660. All physical and spectral data were found to be consistent with those reported.[19,22]

(*S*)-*N*-((1*S*,2*S*)-2-(3-(3,5-Bis(trifluoromethyl)phenyl) thioureido)cyclohexyl)pyrrolidine-2-carboxamide (4b)[19]

Enantiomerically pure **4b** was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:100). Colorless solid, mp 149–151 °C. R_f (10% MeOH – EtOAc) 0.26. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.03–1.35 (m, 2H), 1.47–1.57 (m, 3H), 1.63–1.70 (m, 2H), 1.89–2.01 (m, 7H), 2.97–3.03 (m,2H), 3.69–3.73 (m, 2H), 4.59–4.62 (d, J = 9 Hz, 1H), 7.55 (s, 1H), 7.77–7.80 (d, J = 9 Hz, 1H), 8.13 (s, 2H), 8.19–8.22 (d, J = 9 Hz, 1H), 9.88–9.89 (br, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 180.9, 176.7, 141.4, 132.2, 128.6, 125.0, 122.1, 121.4, 117.0, 60.3, 56.9, 53.7, 47.1, 32.9, 30.9, 25.8, 25.9, 24.7. HRMS (ESI-TOF) calcd for $C_{20}H_{25}F_6N_4OS$ ([M + H]$^+$): 483.1648; found: 483.1658. All physical and spectral data were found to be consistent with those reported.[19,22]

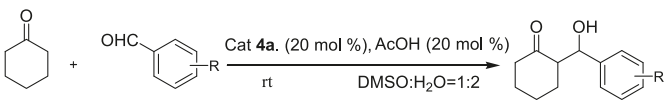
(*S*)-*N*-((1*R*,2*R*)-2-(3-(3,5-Bis(trifluoromethyl)phenyl) thioureido)-1,2-diphenylethyl)pyrrolidine-2-carboxamide (4c)[19]

Enantiomerically pure **4c** was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:80). Colorless solid, mp 166–168 °C. R_f (10% MeOH – EtOAc) 0.28. ^{1}H NMR (300 MHz $CDCl_3$) δ (ppm): 8.92–8.89 (m, 1H), 8.50–8.48 (m, 1H), 8.07 (s, 2H), 7.60 (s, 1H), 7.28–7.12 (m, 10 H), 6.40 (m, 1H), 5.45–5.38 (t, 1H), 3.74–3.69 (m, 1H), 3.14–3.10 (m, 1H), 3.10–2.98 (m, 1H), 2.05–1.64 (m, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 181.5, 176.5, 141.0, 138.0, 131.7, 123.2, 129.0, 128.6, 128.4, 127.9, 127.7, 122.9, 122.1, 117.7, 61.9, 60.5, 58.6, 47.2, 31.1, 26.1. HRMS (ESI-TOF) calcd for $C_{28}H_{27}F_6N_4OS$ ([M + H]$^+$): 581.1804; found: 581.1823. All physical and spectral data were found to be consistent with those reported.[19,22]

(*S*)-*N*-((1*S*,2*S*)-2-(3-(3,5-Bis(trifluoromethyl)phenyl) thioureido)-1,2-diphenylethl)pyrrolidine-2-carboxamide (4d)[19]

Enantiomerically pure **4d** was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:80). Colorless solid, mp 147–148 °C. R_f (10% MeOH – EtOAc) 0.30. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.25–1.63 (m, 2H), 1.83–1.85 (m, 1H), 2.09–2.13 (m, 2H), 2.74–2.78 (m, 1H), 2.98–3.02 (m, 1H), 3.83–3.88 (m, 1H), 5.23–5.29 (t, J = 8.4 Hz, 9.8 Hz, 1H), 6.53–6.55 (d, J = 6 Hz, 1H), 7.08–7.19 (m, 12H), 7.43 (s, 1H), 8.65–8.68 (d, J = 9 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 181.6, 176.4, 140.8, 137.8, 131.8, 129.0, 128.6, 128.2, 127.9, 127.7, 127.5, 123.1, 123.4, 122.1, 118.0, 62.9, 60.6, 59.4, 46.9, 30.4, 25.7. HRMS (ESI-TOF) calcd for $C_{28}H_{27}F_6N_4OS$ ([M + H]$^+$): 581.1804; found: 581.1812. All physical and spectral data were found to be consistent with those reported.[19,22]

Asymmetric direct aldol reactions of cyclohexanone with various aldehydes



1a 2 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

General procedure for direct aldol reaction of cyclohexanone with various aldehydes (Table 3)

A mixture of **2** (0.1 mmol, 1 equiv), **1a** (2 mmol, 20 equiv), **4a** (0.02 mmol, 0.2 equiv), and water–DMSO (0.2 mL, *v*/*v* 2:1) was stirred for 0.5–2 h. Then the crude product was directly purified by silica gel chromatography without workup using a mixture of EtOAc–hexanes (from 1:5 to 1:6) as the eluent and fractions were collected and concentrated in vacuo to provide the desired product.

Spectroscopic data of final products 3

2-[Hydroxy(4-nitrophenyl)methyl]cyclohexanone (3a)

The title compound was prepared according to the general procedure, as described previously, in 97% yield. HPLC (Chiralcel AD-H, *i*-PrOH–hexane = 20:80, flow rate = 1.0 mL/min, λ = 254 nm): t_{minor} = 11.25 min, t_{major} = 14.19 min, ee = 87%, dr > 20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1.5:2). Colorless solid, mp 149–150 °C. (lit.[25] mp 149–151 °C). R_f (50% EtOAc – petroleum ether) 0.40. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.24–1.39 (m, 1H), 1.53–1.65 (m, 3H), 1.81–1.85 (m, 1H), 2.08–2.09 (m, 1H), 2.35–2.39 (m, 1H), 2.47–2.59 (m, 2H), 4.09 (br, 1H), 4.87–4.90 (d, *J* = 9 Hz, 1H), 7.49–7.52 (d, *J* = 9 Hz, 2H), 8.19–8.22 (d, *J* = 9 Hz, 2H). All physical and spectral data were found to be consistent with those reported.[5a,9,21a,25]

2-[(4-Bromophenyl)hydroxy-methyl]cyclohexanone (3b)

The title compound was prepared according to the general procedure, as described previously, in 88% yield. HPLC (Chiralpak AD-H, *i*-PrOH–hexane = 10:90, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 12.98 min, t_{major} = 14.96min, ee = 71%, dr > 85:15. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1.8:2). Yellow solid, mp 126–128 °C. (lit.[25] mp 126–127 °C). R_f (25% EtOAc – petroleum ether) 0.27. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.25–1.31 (m, 1H), 1.51–1.69 (m, 4H), 2.07–2.08 (m, 1H), 2.34–2.38 (m, 3H), 2.45–2.58 (m, 1H), 4.73–4.76 (d, *J* = 9 Hz, 1H), 7.17–7.26 (q, *J* = 15.39 Hz, 8.28 Hz, 5.4 Hz, 2H), 7.44–7.48 (m, 2H). All physical and spectral data were found to be consistent with those reported.[5a,9,21a,25]

2-[Hydroxy(4-oxo-cyclohexyl)methyl]benzonitrile (3c)

The title compound was prepared according to the general procedure, as described previously, in 97% yield. HPLC (Chiralcel AD-H, *i*-PrOH–hexane = 10:90, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 20.48 min, t_{major} = 25.34 min, ee = 90%, dr >20:1. Pure anti-product was obtained by silica gel chromatography (eluent: V_{hexane}/V_{DCM} = 1:1). Furthermore, enantiomerically pure anti-product was obtained after a single recrystallization from petroleum ether – EtOAc (*v*/*v* 1.6:2). Yellow solid, mp 72–74 °C. R_f (50% EtOAc – petroleum ether) 0.33. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.24–1.37 (m, 1H), 1.52–1.64 (m, 3H), 2.08–2.09 (m, 2H), 2.34 (m, 1H), 2.46–2.52 (m, 2H), 2.56–2.58 (br, 1H), 4.81–4.84 (d, *J* = 9 Hz, 1H), 7.40–7.45 (m, 2H), 7.63–7.65 (d, *J* = 6 Hz, 2H). All physical and spectral data were found to be consistent with those reported.[5a,21a]

2-[Hydroxy(4-fluorophenyl)methyl]cyclohexanone (3d)

The title compound was prepared according to the general procedure, as described previously, in 90% yield. HPLC (Chiralpak WHELK, *i*-PrOH–hexane = 20:80, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 9.08 min, t_{major} = 7.48 min, ee = 63%, dr > 20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:2). Colorless solid, mp 84–85 °C. (lit.[25] mp 84–85 °C). R_f (25% EtOAc – petroleum ether) 0.39. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.26–1.30 (m, 1H), 1.52–1.68 (m, 4H), 2.07 (m, 1H), 2.34–2.57 (m, 3H), 3.99 (s, 1H), 4.76–4.78 (d, *J* = 6 Hz, 1H), 6.99–7.06 (m, 2H), 7.26–7.31 (m, 2H). All physical and spectral data were found to be consistent with those reported.[21a,26,25]

2-[Hydroxy(3-nitrophenyl)methyl]cyclohexanone (3e)

The title compound was prepared according to the general procedure, as described previously, in 93% yield. HPLC (Chiralcel OD-H, *i*-PrOH–hexane = 10:90, flow rate = 0.8 mL/min, λ = 220 nm): t_{minor} = 18.77 min, t_{major} = 14.69 min, ee = 90%, dr >20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:3). Yellow solid, mp 102–104 °C (no literature data reported). R_f (50% EtOAc – petroleum ether) 0.50. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.39–1.41 (m, 1H), 1.54–1.65 (m, 3H), 1.81–1.84 (m, 1H), 2.09 (m, 1H), 2.36–2.62 (m, 3H), 4.10–4.11 (s, *J* = 3 Hz, 1H), 4.87–4.91 (m, 1H), 7.49–7.54 (t, *J* = 7.89 Hz, 7.92 Hz, 1H), 7.65–7.68 (m, 1H), 8.13–8.20 (m, 2H). All physical and spectral data were found to be consistent with those reported.[5a,9,21a]

2-[(2-Bromophenyl)hydroxy-methyl]cyclohexanone (3f)

The title compound was prepared according to the general procedure, as described previously, in 91% yield. HPLC (Chiralpak AD-H, *i*-PrOH–hexane = 10:90, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 11.86 min, t_{major} = 10.28 min, ee = 87%, dr > 20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after single recrystallization from petroleum ether – EtOAc (*v*/*v* 1.5:2). Brown solid, mp 105–106 °C (no literature data reported). R_f (50% EtOAc – petroleum ether) 0.39. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.57–1.72 (m, 6H), 2.33–2.45 (m, 2H), 2.70 (m, 1H), 4.03–4.05 (d, *J* = 6 Hz, 1H), 5.28–5.32 (m, 1H), 7.13–7.16 (m, 1H), 7.35–7.37 (m, 1H), 7.51–7.54 (m, 2H). All physical and spectral data were found to be consistent with those reported.[27]

2-[Hydroxy(2-nitrophenyl)methyl]cyclohexanone (3g)

The title compound was prepared according to the general procedure, as described previously, in 94% yield. HPLC (Chiralcel AD-H, *i*-PrOH–hexane = 10:90, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 18.44 min, t_{major} =

17.34 min, ee = 91%, dr >20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after single recrystallization from petroleum ether – EtOAc (*v*/*v* 1.3:2). Gray solid, mp 111–113 °C. (lit.[28] mp 126–127 °C). R_f (50% EtOAc – petroleum ether) 0.21. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.60–1.76 (m, 4H), 2.32–2.44(m, 4H), 2.73–2.76 (m, 1H), 3.68–3.75 (br, 1H), 5.43–5.46 (d, J = 9 Hz, 1H), 7.42–7.45 (m, 1H), 7.629–7.63 (m, 1H), 7.75–7.78 (m, 1H), 7.83–7.86 (m, 1H). All physical and spectral data were found to be consistent with those reported.[5a,21a,28]

2-[Hydroxy(2-oxo-cyclohexyl)methyl]benzonitrile (3h)

The title compound was prepared according to the general procedure, as described previously, in 85% yield. HPLC (Chiralcel AS-H, *i*-PrOH–hexane = 5:95, flow rate = 1.0 mL/min, λ = 220 nm): t_{minor} = 41.79 min, t_{major} = 44.53 min, ee = 87%, dr >20:1. Pure anti-product was obtained by silica gel chromatography (eluent: $V_{hexane}/V_{ethyl\ acetate}$ = 6:1). Furthermore, enantiomerically pure anti-product was obtained after single recrystallization from petroleum ether – EtOAc (*v*/*v* 1:2). Yellow solid, mp: 185–186 °C (no literature data reported). R_f (50% EtOAc – petroleum ether) 0.50. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 1.52–1.58 (m, 4H), 1.83–1.85 (m, 2H), 2.34–2.38 (m, 1H), 2.47–2.53 (m, 1H), 2.67–2.70 (m, 1H), 4.22–4.23 (d, J = 3 Hz, 1H), 5.21–5.23 (d, J = 3.18 Hz, 8.55 Hz, 1H), 7.37–7.43 (m, 1H), 7.59–7.65 (m, 3H). All physical and spectral data were found to be consistent with those reported.[29]

Abstract: A new method for synthesizing chiral 3,3′-bis(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols with high enantiomeric excess is described. The procedure consists of bis-lithiation of diprotected (*S*)- or (*R*)-1,1′-bis(2-naphthol) followed by treatment of the intermediate with methyleneiminium salts. Mild reaction conditions prevent racemization and provide 3,3′-bis(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols or 3-(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols with an enantiomeric excess >99%.

Key words: 3,3′-bis(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols, methyleneiminium salts, chiral, enantiomeric excess.

Résumé : On décrit une nouvelle méthode de synthèse des 3,3′-bis(*N*,*N*-dialkylaminométhyl)-1,1′-bi-2-naphthols chiraux avec des excès énantiomères élevés. Le procédé implique une bis-lithiation du (*S*)- ou (*R*)-1,1′-bis(2-naphthol) diprotégé, suivie d'un traitement de l'intermédiaire avec des sels de méthylèneiminium. Les conditions douces de la réaction permettent d'éviter la racémisation et elles permettent d'obtenir les 3,3′-bis(*N*,*N*-dialkylaminométhyl)-1,1′-bi-2-naphthols ou 3-(*N*,*N*-dialkylaminométhyl)-1,1′-bi-2-naphthols avec des excès énantiomères de plus de 99 %.

Mots-clés : 3,3′-bis(*N*,*N*-dialkylaminométhyl)-1,1′-bi-2-naphthols, sels de méthylèneiminium, chiral, excès énantiomère.

[Traduit par la Rédaction]

Introduction

Axial C_2 chirality of 3,3′-bis(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols (BINOLAMs (**1**), see Fig. 1) and their capability to form adducts with metals and some organic compounds makes them promising chiral auxiliaries in asymmetric synthesis.[1] The first use of BINOLAMs as chiral catalysts was reported[2] in the Michael addition of 2-(trimethylsilyloxy)furans to oxazolidinone enoates. Later they were used in phase-transfer α-alkylation of iminoesters of amino acids,[3] aldol[4] and nitroaldol[5] condensations, and in asymmetric addition of alkynyl-[6a] and diphenylzincs[6a,6b] to aldehydes and ketones. The major application of BINOLAMs so far is the ability of their complexes with metals to catalyze and induce enantioselectivity in various reactions of cyanosilylation,[6a,7] cyanocarbonylation,[8] and cyano-[9a,9b] or hydroxyphospholylation[9c] of aldehydes (other examples in this area are given in the review by Najera et al.[1c])

Recently, it was reported that BINOLAMs are photocytotoxic to DNA, which makes them effective against certain human tumor cell lines.[10] This BINOLAM action is based on their ability to undergo the elimination of dialkylamines under UV irradiation[11] and form highly reactive methylenequinoid structures; the latter are powerful DNA alkylating and cross-linking agents.[10]

Thus, the development of synthetic methods for producing enantiomerically pure BINOLAMs seems to be quite important. These compounds can be obtained from racemic starting material, for example, via photochemical transamination[11b] using L-proline esters as chiral auxiliaries; however, more often they are synthesized from commercial (*S*)- or (*R*)-1,1′-bis(2-naphthol) (BINOL, **2**).

Starting from BINOL, two basic synthetic approaches are described in the literature to prepare BINOLAMs containing tertiary amines in the side chain. The first one is a multistep route that starts with the introduction of the carboxylic[2a] or aldehyde[8c] groups into the 3,3′ positions of BINOL, followed by the formation of amides or imines that are subsequently reduced (a lengthier procedure from BINOL 3,3′-dialdehyde is sometimes used,[4,10] since it provides higher yields[10]). In isolated examples the required enantiomerically pure BINOL 3,3′-dicarboxylic acid was obtained via resolution[3] or enantioselective oxidative biaryl coupling.[12] Once the appropriate 3,3′-disubstituted BINOL intermediates are produced, the following steps are known to proceed without racemization and provide the enantiomerically pure BINOLAMs in 10%–30% chemical yield. The most recent publication based on this traditional approach describes a newly developed synthesis based on bis-anionic Fries rearrangement[7d] of BINOL carbamates, and it provided BINOLAM (*S*)-**1** (R = Et) with 63% yield in three steps. Unfortunately, this method can hardly be called general, because it was reported[13] that for some substrates migration of the second carbamate group is slow, and a significant amount of mono-rearranged by-product is formed.

The second known approach to the enantiomerically pure BINOLAMs utilizes the direct reaction of aminomethylation of BINOL enantiomers with *N*-hydroxymethylmorpholine (**3**, Fig. 2) at 110 °C, followed by enantiomeric enrichment of

3 **4**

the product by recrystallization.[6a,7c] This is the shortest synthesis of BINOLAMs and hence it looks the most convenient. However, it suffers from several shortcomings.

First, the conversion of the starting BINOLs to BINOLAMs in this aminomethylation reaction is not very high, and usually a significant amount of monoaminomethylated product is formed along with the desired BINOLAM. Apparently, the yield in this reaction depends on the purity of the aminomethylating agent **3** and, according to our experience, the reagent **3** (normally prepared by condensation of morpholine with paraformaldehyde) often contains a significant amount of unreactive *N*,*N*-methylene–bismorpholine (**4**). The latter reaction is difficult to control, and the composition of the crude mixture may vary from experiment to experiment. The same is true for preparation of other *N*-hydroxymethyldialkylamines.

Second, since the described direct aminomethylation of BINOL is carried out at elevated temperature (110 °C), noticeable racemization could occur, resulting in the obtained BINOLAM with an ee of about 75%.[6a,7c] These results are understandable and potentially unavoidable because, as it has been demonstrated earlier, the configurational stability of BINOL decreases in the presence of bases.[14] Increasing the ee of (*S*)-**1** by recrystallization as described by other authors[6a,7c] cannot be considered to be a general method applicable to other BINOLAMs, since the recrystallization conditions need to be optimized for each individual compound. This could take significant time and may not be possible in some situations.

Based on these considerations, we thought it would be highly desirable to develop an aminomethylating agent with better reactivity, to make it possible for the aminomethylation reaction to proceed with higher yields and under milder conditions. Since the target aminomethylated BINOLs have useful practical applications and might be required in multigram quantities, we were looking at reagents that could be easily synthesized and purified.

In this study we investigated the possibility of using the methyleneiminium salts **5a**–**5b** (Fig. 3) as such reagents.

Fig. 3. Methyleneiminium salts **5a**–**5d**.

Results and discussion

N,*N*-Dialkylmethyleneiminium salts can be easily generated by a reaction of acyl chlorides or anydrides with methylene–bis(dialkylamines).[15] Thus, chloride **5a** was obtained in 97% yield and triflate **5b** in 99% yield by reacting **4** with acetyl chloride or triflic anhydride accordingly (Scheme 1). Iminium salts **5c** and **5d** are commercially available.

The good reactivity of *N*,*N*-dialkylmethyleneiminium salts in aromatic electrophilic substitution reactions, which was demonstrated for anilines,[16] phenols,[17] furanes,[15c] thiophenes,[18] pyrrols,[19] and various other electron-rich heterocycles,[20] encouraged us to try this approach in the preparation of optically active BINOLAMs.

We started our experiments on BINOL aminomethylation with chloride **5a**, trying to reproduce the conditions that were reported in the literature for 3- and 4-methoxycarbonylphenols.[17] It appeared that the reaction of **2** with iminium salt **5a** in dichloromethane in the presence of K_2CO_3 at room temperature did not occur. Changing the solvent to acetonitrile, increasing the amount of **5a** to 8 equiv, and carrying out the reaction at 60 °C for 19 h did not bring positive results either. No aminomethylation reaction for **2** was observed even when stronger bases were used, such as 1 N NaOH (CH_2Cl_2–H_2O, room temperature, 16 h) or NaH (DMF, room temperature, 19 h).

Based on these results, it was concluded that to make the reaction of methyleneiminium salts with BINOL substrates successful, the increase of nucleophilicity of the latter were required. This can be done, for example, by lithiation of the 3 and 3′ positions of bis-O,O′-diprotected BINOL as described by Snieckus and co-workers.[21]

A series of experiments demonstrated that indeed MOM-protected BINOL **6**, after treatment with *n*-BuLi, reacted smoothly with methyleneiminium salts **5a**–**5d** to produce corresponding BINOLAMs **7a** and **7b** in 54%–88% yields, respectively (Scheme 2 and Table 1). Small amounts of monoaminomethyl derivatives **8a** and **8b** were also formed; however, the yields of these side products were significantly lower then in the case of the reaction of BINOL (**2**) with *N*-hydroxymethylenemorpholine (**3**).[6a,7c]

In a typical aminomethylation procedure, 3.2 equiv of methyleneiminium salt **5** relative to substrate **6** were used.

Table 1. Aminomethylation of (*S*)-**6** with methyleneiminium salts **5a**–**5d** (Scheme 2).

Entry	Methyleneiminium salt	Ratio of **7**:**8** (mol/mol)[a]	Yield (%)[b]
1	**5a**	1:0.2	54
2	**5b**	1:0.2	69
3	**5c**	1:0.2	63
4	**5d**	1:0.02	88
5	**5a**	0.2:1	69

Note: The reaction was carried out in THF at –15 °C to room temperature (1 or 2 h) with 2.6 equiv of *n*-BuLi and 3.2 equiv of **5a**–**5d** for entries 1–4 and with 1.3 equiv of *n*-BuLi and 1.6 equiv of **5a** for entry 5.

[a]In the crude mixture.

[b]Isolated yield of the major product.

Reducing this amount to 1.6 equiv allowed the monomethyleneimine compound **8** to be obtained in 69% yield.

Carrying out the reaction under mild conditions (temperature from –20 to 20 °C) helped to avoid the racemization of substrate **6** and its aminomethylated derivatives **7** and **8**. The high ee (>99%) of isolated products (*S*)-**7a** and (*S*)-**7b** and (*S*)-**8a** as well as BINOLAMs (*S*)-**1a** and (*S*)-**1b**, which were obtained after removing the MOM protective groups (Scheme 3), was confirmed by HPLC analysis using a column with a chiral stationary phase.

Conclusion

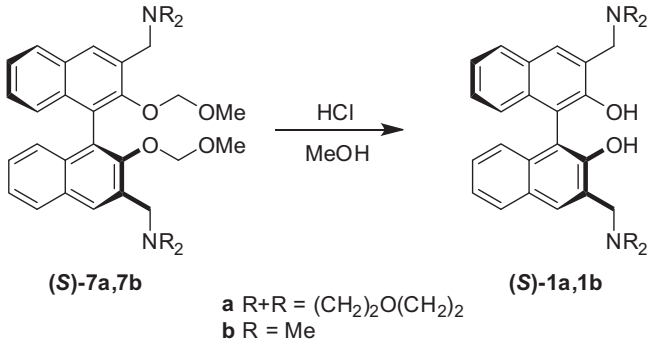
In conclusion, the investigated reaction of lithiated MOM-protected BINOL with methyleneiminium salts can be a convenient and versatile method for the synthesis of BINOLAMs with high enantiomeric excess (>99%).

Experimental

Instrumentation, analysis, and starting materials

All starting materials, solvents, and reagents were used as purchased from commercial suppliers, unless otherwise noted. Anhydrous THF was purchased from Sigma-Aldrich. Reactions were monitored by thin-layer chromatography

Scheme 3. Synthesis of 3,3′-bis(*N*,*N*-dialkylaminomethyl)-1,1′-bi-2-naphthols (BINOLAMs) **1a** and **1b**.



(TLC) carried out on Macherey–Nagel Alugram SIL G/UV254 silica gel 60 plates with a fluorescent indicator using phosphomolybdic acid in ethanol and heat as a developing agent. NMR spectra were recorded on a Varian Mercury 400 NMR instrument (400 MHz frequency for ^{1}H) using residual undeuterated solvent as an internal reference. Low-resolution mass spectra were recorded on a Water Micromass ZQ mass spectrometer with electrospray ionization (ESI). HPLC analyses were performed on a Waters 600 system with a Waters 2996 photodiode array detector using a C-18 reverse-phase column. For the ee determination, a Chiralcel OD-R column was used (MeCN – 0.5 N aq $NaClO_4$, 60:40 as a mobile phase). All dry column chromatography purifications were performed on silica gel 60A with a 5–15 μm particle size.

N-Methylenemorpholinium chloride (5a)

To a stirred solution of acetyl chloride (4.32 g, 55 mmol) in anhydrous Et_2O (100 mL), a solution of methylene–bismorpholine[22] (9.31 g, 50 mmol) in anhydrous Et_2O (50 mL) was added dropwise at 20–24 °C over 1.5 h. The reaction mixture was stirred for an additional 0.5 h at room temperature. The white precipitate was filtered off, washed with anhydrous Et_2O (3 × 40 mL), and dried in vacuum to provide 6.39 g (94%) of *N*-methylenemorpholinium chloride **5a**[15d] as a white powder. ^{1}H NMR (400 MHz) in $(CD_3)_2SO$ δ: 3.90 (4H, t, ^3J = 5.0 Hz, OCH_2), 4.06 (4H, t, ^3J = 5.0 Hz, NCH_2), 8.24 (2H, $^+N=CH_2$).

N-Methylenemorpholinium triflate (5b)

To a stirred solution of trifluoromethanesulfonic anhydride (9.93 g, 35.2 mmol) in anhydrous Et_2O (200 mL), a solution of methylene–bismorpholine[22] (5.96 g, 32 mmol) in anhydrous Et_2O (50 mL) was added dropwise at 20–24 °C over 1 h. The reaction mixture was stirred for an additional 2 h at room temperature. The white precipitate was filtered off, washed with anhydrous Et_2O (3 × 40 mL), and dried in vacuum to provide 7.90 g (99%) of *N*-methylenemorpholinium triflate **5b** as a highly hygroscopic white powder.[23] ^{1}H NMR (400 MHz) in $(CD_3)_2SO$ δ: 3.90 (4H, br. t, OCH_2), 4.08 (4H, br. t, NCH_2), 8.21 (2H, $^+N=CH_2$).

(*S*)-2,2′-Bis(methoxymethoxy)-1,1′-binaphthol (6)

To a stirred cooled (0–5 °C) suspension of NaH (60% in mineral oil, 15.73 g, 0.393 mol) in a mixture of anhydrous THF (660 mL) and anhydrous DMF (330 mL), a solution of **2** (50.41 g, 0.176 mol) in anhydrous THF (200 mL) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

added dropwise at 5–10 °C. The resultant mixture was allowed to warm up to 15 °C and chloromethyl methyl ether (44.73 g, 0.556 mol) was added dropwise at 15–20 °C. The reaction mixture was stirred for 16 h at room temperature, quenched with water (20 mL), concentrated under reduced pressure to a volume of ~400 mL, and diluted with EtOAc (800 mL). The obtained mixture was washed with water (3 × 300 mL), 1 N HCl (300 mL), saturated aqueous $NaHCO_3$ (300 mL), and brine (300 mL) and dried over $MgSO_4$. Filtration through a pad of silica gel and removal of the solvent from the filtrate under reduced pressure provided 72.7 g of a white solid. This solid was suspended in hexanes (300 mL) and the precipitate was filtered off and washed with hexanes (2 × 150 mL). The product **6**[24] (63.2 g, 96%) was obtained as white solid after drying in vacuum. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 3.14 (6H, OMe), 4.98 (2H, d, ^2J = 6.8 Hz, OCH_A), 5.08 (2H, d, ^2J = 6.8 Hz, OCH_B), 7.15 (2H, d, J = 8.2 Hz), 7.22 (2H, t, J = 8.2 Hz), 7.35 (2H, t, J = 8.2 Hz), 7.58 (2H, d, J = 8.8 Hz), 7.87 (2H, d, J = 8.2 Hz), 7.95 (2H, d, J = 8.8 Hz).

(*S*)-3,3′-Bis(*N*-morpholinomethyl)-2,2′-bis(methoxymethoxy)-1,1′-binaphthol (7a)

To a stirred cooled (–5 °C to 0 °C) solution of **6** (1.87 g, 5 mmol) in anhydrous THF (50 mL), a 1.6 mol/L solution of *n*-butyl lithium in hexane (8.13 mL, 13 mmol) was added dropwise at –5 to 0 °C. The reaction mixture was stirred for 2 h at 0–5 °C and cooled to about –15 °C. Avoiding exposure to air, freshly prepared and dried **5b** (3.99 g, 16 mmol) was added portionwise and the reaction mixture was allowed to warm to room temperature. The stirring was continued for an additional 2 h, and the reaction was quenched by addition of water (1 mL). The resultant mixture was concentrated under reduced pressure and the oily residue was dissolved in ethyl acetate (50 mL). The obtained solution was washed with water (2 × 15 mL) and brine (20 mL). After drying over $MgSO_4$, the solution was filtered and concentrated under reduced pressure to provide 3.02 g of a light pink semisolid, which was subjected to dry flash chromatography on silica gel (50% EtOAc–hexanes to 100% EtOAc) to afford 1.98 g (69%) of **7a** as a white solid. Assayed at 98.13% by HPLC. HPLC analysis on a column with a chiral stationary phase showed an enantiomeric excess of >99.5%. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 2.62 (8H, m, NCH_2), 2.70 (6H, OMe), 3.76 (10H, m, OCH_2 + NCH_A), 3.88 (2H, d, ^2J = 13.6 Hz, NCH_B), 4.57 (2H, d, ^2J = 5.6 Hz, OCH_A), 4.74 (2H, d, ^2J = 5.6 Hz, OCH_B), 7.22 (4H, m), 7.41 (2H, t, J = 8.0 Hz), 7.88 (2H, d, J = 8.0 Hz), 8.00 (2H). MS (electrospray), *m*/*z*: 573 (M^+). Anal. calcd for $C_{34}H_{40}N_2O_6$ (%): C 71.31, H 7.04, N 4.89; found: C 71.38, H 7.10, N 4.90.

(*S*)-3,3′-Bis(*N*,*N*-dimethylaminomethyl)-2,2′-bis(methoxymethoxy)-1,1′-binaphthol (7b)

To a stirred cooled (–5 to 0 °C) solution of **6** (1.87 g, 5 mmol) in anhydrous THF (50 mL), a 1.6 mol/L solution of *n*-butyl lithium in hexane (8.13 mL, 13 mmol) was added dropwise at –5 to 0 °C. The reaction mixture was stirred for 2 h at 0–5 °C and cooled to –15 °C. Solid (*N*,*N*-dimethyl) methyleneammonium iodide (**5d**) (2.96 g, 16 mmol) was added portionwise and the reaction mixture was allowed to warm up to room temperature. The stirring was continued for an additional 2 h and the reaction was quenched by addition of water (1 mL). The resultant mixture was concentrated under reduced pressure and the oily residue was dissolved in ethyl acetate (50 mL). The obtained solution was washed with water (2 × 15 mL), a saturated aqueous solution of $Na_2S_2O_7$ (15 mL), and brine (20 mL). After drying over $MgSO_4$, the solution was filtered and concentrated under reduced pressure to provide 2.61 g of a light yellow oil, which was subjected to dry flash chromatography on silica gel (CH_2Cl_2 to 5% MeOH–CH_2Cl_2) to afford 2.15 g (88%) of **7b** as a colourless viscous oil. Assayed at 97.99% by HPLC. HPLC analysis on a column with a chiral stationary phase showed an enantiomeric excess of >99.5%. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 2.38 (12H, NMe), 2.76 (6H, OMe), 3.72 (2H, d, ^2J = 14.2 Hz, NCH_A), 3.80 (2H, d, ^2J = 14.2 Hz, NCH_B), 4.51 (2H, d, ^2J = 5.8 Hz, OCH_A), 4.66 (2H, d, ^2J = 5.8 Hz, OCH_B), 7.20 (2H, t, J = 8.2 Hz), 7.25 (2H, d, J = 8.2 Hz), 7.40 (2H, t, J = 8.2 Hz), 7.88 (2H, d, J = 8.2 Hz), 8.04 (2H). MS (electrospray), *m*/*z*: 489 (M^+ + 1). Anal. calcd for $C_{30}H_{36}N_2O_4$ (%): C 73.74, H 7.43, N 5.73; found: C 73.93, H 7.37, N 5.61.

(*S*)-3-*N*-Morpholinomethyl-2,2′-bis(methoxy-methoxy)-1,1′-binaphthol (8a)

To a stirred cooled (–5 to 0 °C) solution of **6** (13.10 g, 35 mmol) in anhydrous THF (350 mL), a 1.6 mol/L solution of *n*-butyl lithium in hexane (28.4 mL, 45.5 mmol) was added dropwise at –5 to 0 °C. The reaction mixture was stirred for 2 h at 0–5 °C and cooled to –15 °C. Solid **5a** (7.59 g, 56 mmol) was added portionwise and the reaction mixture was allowed to warm up to room temperature. The stirring was continued for additional 2 h and the reaction was quenched by addition of water (7 mL). The resultant mixture was concentrated under reduced pressure and the oily residue was dissolved in ethyl acetate (350 mL). The obtained solution was washed with water (2 × 100 mL) and brine (200 mL). After drying over $MgSO_4$, the solution was filtered and concentrated under reduced pressure to provide 16.8 g of a yellow oil, which was subjected to dry flash chromatography on silica gel (30% EtOAc–hexanes to 60% EtOAc–hexanes) to afford 11.50 g (69%) of **8a** as a white solid. Assayed at 96.81% by HPLC. HPLC analysis on a column with a chiral stationary phase showed an enantiomeric excess of >99.5%. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 2.63 (4H, m, NCH_2), 2.77 (3H, OMe), 3.16 (3H, OMe), 3.57 (4H, m, OCH_2), 3.83 (2H, NCH_2Ar), 4.64 (1H, d, ^2J = 5.6 Hz, OCH_A), 4.71 (1H, d, ^2J = 5.6 Hz, OCH_B), 5.02 (1H, d, ^2J = 7.2 Hz, OCH_A'), 5.11 (1H, d, ^2J = 7.2 Hz, OCH_B'), 7.22 (4H, m), 7.37 (2H, m), 7.58 (1H,d, J = 8.8 Hz), 7.87 (2H, m), 7.96 (2H, d, J = 8.8 Hz), 7.99 (2H). MS (electrospray), *m*/z: 474 (M^+). Anal. calcd for $C_{29}H_{31}NO_5$ (%): C 73.55, H 6.60, N 2.96; found: C 73.81, H 6.72, N 3.07.

(*S*)-3,3′-Bis(*N*-morpholinomethyl)-2,2′-dihydroxy-1,1′-binaphthol (1a)

To a stirred cooled (–5 to 0 °C) solution of **7a** (1.72 g, 3 mmol) in methanol (15 mL), a 4 mol/L solution of HCl in 1,4-dioxane (15 mL, 60 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature and was stirred for an additional 16 h. After removal of solvent under reduced pressure, the solid residue was triturated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

Et_2O (2 × 30 mL) and dried in vacuum to provide 1.69 g of a white solid. The isolated solid was suspended in CH_2Cl_2 (80 mL) and saturated aqueous $NaHCO_3$ (40 mL) was added to the resultant suspension. After 15 min of stirring, the organic phase was separated and dried over $MgSO_4$. Filtration and removal of the solvent from the filtrate under reduced pressure provided 1.51 g of a yellow solid, which was subjected to dry flash chromatography on silica gel (2% EtOAc–CH_2Cl_2 to 20% EtOAc–CH_2Cl_2) to afford 1.31 g (90%) of **1a**[7c] as a white solid. Assayed at 96.53% by HPLC. HPLC analysis on a column with chiral stationary phase showed enantiomeranic excess of >99.5%. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 2.64 (8H, br. m, NCH_2), 3.69 (8H, br. m, OCH_2), 3.89 (2H, d, ^2J = 14.0 Hz, NCH_A), 4.12 (2H, d, ^2J = 14.0 Hz, NCH_B), 7.29–7.12 (6H, m), 7.66 (2H), 7.78 (2H, d, J = 8.4 Hz). MS (electrospray), m/z: 483 ($M^+ - 1$).

(*S*)-3,3′-Bis(*N*,*N*-dimethylaminomethyl)-2,2′-dihydroxy-1,1′-binaphthol (1b)

To a stirred cooled (–5 to 0 °C) solution of **7b** (1.02 g, 2.1 mmol) in methanol (2 mL), a 4 mol/L solution of HCl in methanol (10 mL, 40 mmol) was added dropwise. The reaction mixture was allowed to warm up to room temperature and was stirred for an additional 16 h. After removal of the solvent under reduced pressure, the solid residue was triturated with Et_2O (2 × 20 mL) and dried in vacuum to provide 0.96 g of a white solid. The solid was suspended in CH_2Cl_2 (50 mL) and saturated aqueous $NaHCO_3$ (25 mL) was added to the resultant suspension. After 15 min of stirring, the organic phase was separated and dried over $MgSO_4$. Filtration and removal of the solvent from the filtrate under reduced pressure provided 0.81 g of a yellow solid, which was subjected to dry flash chromatography on silica gel (CH_2Cl_2 to 6% MeOH–CH_2Cl_2) to afford 0.78 g (93%) of **1b**[2a] as a white solid. Assayed at 97.45% by HPLC. HPLC analysis on a column with a chiral stationary phase showed an enantiomeric excess of >99.5%. ^{1}H NMR (400 MHz) in $CDCl_3$ δ: 2.36 (12H, NMe), 3.76 (2H, d, ^2J = 13.6 Hz, NCH_A), 4.10 (2H, d, ^2J = 13.6 Hz, NCH_B), 7.26–7.13 (6H, m), 7.61 (2H), 7.76 (2H, d, J = 7.6 Hz). MS (electrospray), m/z: 400 (M^+).

Abstract: In this paper, we present the first systematic study of correlations between energy levels of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ dimer centers and the crystalline environment by using dielectric theory of chemical bonding for complex crystals. Our model has successfully built links between the $E_{A'}$, $E_{B'}$, and $E_{C'}$ of these centers and the environmental factor h. The h has linear relationships with $E_{A'}$, $E_{B'}$, and $E_{C'}$. The calculated results are in good agreement with the experimental values. This model can serve as a prediction tool and can be applied to assign the absorption band energies of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ centers.

Key words: alkali halides, dimer centers, energy levels, dielectric theory, chemical bond.

Résumé : Dans ce travail, on présente la première étude systématique des corrélations entre les niveaux d'énergie des centres dimères $(Tl^+)_2$, $(In^+)_2$ et $(Ga^+)_2$ et l'environnement cristallin en faisant appel à la théorie diélectrique de la liaison chimique de cristaux complexes. Ce modèle a permis d'établir des liens entre les valeurs $E_{A'}$, $E_{B'}$ et $E_{C'}$ de ces centres et le facteur environnemental h. Ce facteur h est en relation linéaire avec les valeurs $E_{A'}$, $E_{B'}$ et $E_{C'}$. Les résultats calculés sont en bon accord avec les valeurs expérimentales. Ce modèle peut donc servir comme outil de prédiction et il peut être appliqué pour attribuer les énergies des bandes d'absorption des centres $(Tl^+)_2$, $(In^+)_2$ et $(Ga^+)_2$.

Mots-clés : halogénures de métaux alcalins, centre dimères, niveaux d'énergie, théorie diélectrique, liaison chimique.

Introduction

Alkali halide crystals are extremely suitable for experimental and theoretical studies of heavy-metal ions centers. They are fairly well-understood crystals with cubic lattices and outstanding transparency in a wide range from the infrared to vacuum ultraviolet (VUV).[1,2] Ions with the electronic configuration ns^2 for the ground state and $nsnp$ for the first excited state ($n = 4, 5, 6$) are called ns^2-type ions. Table 1 shows 15 ions with the outer electronic configuration s^2. Among these ions, luminescence and related optical properties of Tl^+ in KCl and other similar crystals have been most precisely studied,[3–7] and so s^2 ions are also called Tl^+-like ions.[8] A great deal of effort has been devoted to understand the optical properties of ns^2 ions embedded into alkali halides since the pioneering work of Hilsch in 1927.[9] This subject has been reviewed many times (for example, see Refs. 10–13). In principle, the spectroscopy of alkali halide phosphors doped with ns^2 ions is well understood.[11] The influence of the host lattice on these properties is drastic, a fact that is considerably less well understood.[13]

Usually, the luminescence of ns^2 ions monomer centers [Fig. 1*a*], in which a ns^2 ion is substituted for an alkali ion far from other ns^2 ions, in alkali halides is described by the $^1S_0 \rightarrow {}^3P_{1,2} + {}^1P_1$ transitions, which originate from the $6s^2 \rightarrow 6s6p$ interconfigurational transition. In an absorption spectrum, the transitions from the $^1S_0$ ground state to the $^3P_1$, $^3P_2$, and $^1P_1$ excited states are labeled in order of increasing energy by A, B, and C bands. In addition to the presence of ns^2 ion monomer centers, absorption bands coming from dimer centers (paired Tl^+, In^+, Ga^+, etc., ions) denoted by $(Tl^+)_2$, $(In^+)_2$, $(Ga^+)_2$, and so on, have been widely observed and studied (see Ref. 14 for a review). The first observation of this kind of center was made by Yuster and Delbecq from absorption spectra of KI crystals with different concentrations of Tl^+ doping.[15] They found new absorption and luminescence bands in the spectra of the most heavily doped samples, which did not appear in the spectra of lightly doped samples. Later, the presence of these dimer centers has also been observed on various Tl^+-doped alkali halides, e.g., in KCl,[16–18] KBr,[19,20] KI,[21–25] RbCl,[26,27] RbI,[28,29] NaBr,[30] and NaI.[31,32] Even in the case of small thallium concentration, there are easily formed stable dimer thallium centers, whose spectral bands may overlap with those of the main $T1^+$ centers.[33]

The number of the dimer center in a crystal depends on the geometrical structure of the center.[17] So far, two kinds of structures are possible for the dimer centers: one is a dimer with D_{2h} symmetry, where two Tl^+ ions are at the nearest

cation sites in a ⟨110⟩ direction [Fig. 1*b*], the other is a dimer with D_{4h} symmetry where two Tl^+ ions are at the second-nearest cation sites in a ⟨100⟩ direction [Fig. 1*c*].[16,17,34] In some systems, the D_{2h} dimer and the D_{4h} dimer centers may coexist. It is well established that dimers have absorption bands called A′, B′, and C′ related to A, B, and C monomer absorption bands, respectively.[22,23] The presence of these dimer centers introduces new optical-absorption bands, which may interfere with the lasing properties of the crystals.[18,27] Besides, the dimer centers have a high effective cross-section of charge carrier trapping, so they may essentially influence the character of the recombination processes in the crystal.[35] Absorption spectra of the dimer centers are similar to absorption spectra of the single centers.[36,37] In our recent synthetic studies on the sp energy levels of Pb^{2+}, Sn^{2+}, Tl^+, $Tl^0(1)$, Tl^{2+}, and In^+,[38–41] it was found that major environmental factors influencing the position of the A, B, and C bands are the chemical bond volume polarizability, fractional covalence of the chemical bond, and presented charge of the nearest anion in the chemical bonds. However, to the best of our knowledge, the relationships between the position of the absorption bands for dimer centers and the crystalline environment are still unknown. Therefore, building a theoretical model to understand the correlation between energy levels of the dimer centers for ns^2 ions and the structure of the hosts is very important and deserves further study.

In this paper, according to the experimental data and dielectric chemical bond theory, the major factors of the environment influencing the positions of A′, B′ and C′ bands are the coordination number of the central ion, the bond volume polarizability, and the fractional covalence of the chemical bond between the central ion and the nearest anion. The empirical expressions between band energies of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ dimer centers for these three chemical bond parameters were obtained. The model calculation results are in excellent agreement with experiments. In addition, this theoretical work may also be very important for those who are investigating the optical properties of ns^2-type ion doped phosphors.

Theoretical methods

The dielectric chemical bond theory for complex crystals[42,43] is based on the bond charge model of Levine[44] and the dielectric theory of Phillips[45] and Van Vechten.[46] According to this theory, a complex crystal $E_eF_fG_gH_h$ (crystal molecular formula) can be written as a linear combination of the subformulas of various binary crystals when the crystal structure is known. The subformula of any kind of chemical bond E–F can be written as:

$$[1] \qquad \frac{N(\mathrm{F}-\mathrm{E})\cdot e}{N_{\mathrm{CE}}}\mathrm{E}\frac{N(\mathrm{E}-\mathrm{F})\cdot f}{N_{\mathrm{CF}}}\mathrm{F}$$

where E, F, G, and H represent the different constituents or different sites of the same element in the crystal formula, and e, f, g, and h represent the number of the corresponding elements. N(I–J) is the number of I ions in the coordination group of a J ion. N_{CE} and N_{CF} are the nearest-coordination numbers for each element in the crystal. Therefore in a subformula equation of a complex crystal, the charge Q presented by each coordination anion can be obtained from the valence conservation and electric neutrality of the subformula.

Having listed the subformula equation of a complex crystal and given the charge presented by each ion, we can obtain the number of effective valence electrons of each ion:

$$[2] \qquad (Z_{\mathrm{E}}^{\mu})^* = Z_{\mathrm{E}}^{\mu} q_{\mathrm{E}}^{\mu}$$

where Z_{E}^{μ} is the number of valence electrons of the E ion, and q_{E}^{μ} is the effective charge of each valence electron of each E ion. The effective valence election density associated with the bond μ is,

$$[3] \qquad (N_e^{\mu})^* = \frac{(n_e^{\mu})^*}{v_b^{\mu}}$$

The number of effective valence electrons $(n_e^{\mu})^*$ per μ bond is,

$$[4] \qquad (n_e^{\mu})^* = \frac{(Z_{\mathrm{E}}^{\mu})^*}{N_{\mathrm{CE}}^{\mu}} + \frac{(Z_{\mathrm{F}}^{\mu})^*}{N_{\mathrm{CF}}^{\mu}}$$

The chemical bond volume of the type μ bond, v_b^{μ} (in Å^3) is,

$$[5] \qquad v_b^{\mu} = (d^{\mu})^3 / \sum_{\nu} (d^{\mu})^3 N_b^{\nu}$$

where d^{μ} is the nearest-neighbor distance (in Å), and the denominator is merely the required normalization factor, where the sum over ν runs over all of the different types of bonds. N_b^{ν} is the number of bonds of type ν per cubic centimetres, which can be obtained from the crystal structural data.

According to PV. theory,[45,46] the susceptibility χ^{μ} of any bond is described as,

$$[6] \qquad \chi^{\mu} = \frac{(\hbar\Omega_p^{\mu})^2}{4\pi(E_g^{\mu})^2}$$

CsI	1.789	Cs–I	3.9558	0.0372	1.2032	8	0.598

Note: n is the index of refraction; d^{μ} is the bond distance; f_c^{μ} is the fractional covalence of the chemical bond; α_b^{μ} is the polarizability of the chemical bond volume; Q^{μ} is the presented charge of the nearest anion in the chemical bond; N is the nearest-coordination numbers for each element in the crystal; h is the environmental factor of the crystals.

where Ω_p^{μ} is the plasma frequency,

$$[7] \qquad (\Omega_p^{\mu})^2 = \left[\frac{4\pi(N_e^{\mu})^* e^2}{m}\right] D_{\mu} A_{\mu}$$

where D_{μ} and A_{μ} are the correction factors defined in Refs. 46–47; e and m are the electronic charge and mass, respectively.

In eq. [6], E_g^{μ} (in eV) is the average energy band gap, and can be separated into homopolar energy E_h^{μ} (in eV) and heteropolar energy C^{μ} (in eV) as shown in the equation below,

$$[8] \qquad (E_g^{\mu})^2 = (E_h^{\mu})^2 + (C^{\mu})^2$$

where

$$[9] \qquad E_h^{\mu} = 39.74/(d^{\mu})^{2.48}$$

$$[10] \qquad C^{\mu} = 14.4 b^{\mu} \exp(-k_S^{\mu} r_o^{\mu})[(Z_E^{\mu})^* - w(Z_F^{\mu})^*]/r_o^{\mu}$$

with

$$[11] \qquad r_o^{\mu} = d^{\mu}/2$$

$$[12] \qquad k_s^{\mu} = (4k_F^{\mu}/\pi\alpha_B)^{1/2}$$

$$[13] \qquad k_F^{\mu} = [3\pi^2(N_e^{\mu})^*]^{1/3}$$

Here, b^{μ} is a correction factor that depends on the crystal structure, k_s^{μ} is the Thomas–Fermi screening factor, w is the number ratio of two elements E and F in the subformula, r_o^{μ} is the average radius between E and F atoms, and a_B is the Bohr radius. Once the refractive index n of a crystal is known, the value of b^{μ} and C^{μ} can be obtained by using eqs. [6], [8], [10] and the following equation:

$$[14] \qquad \chi = (\varepsilon - 1)/4\pi = \sum_{\mu} F^{\mu} \chi^{\mu} = \sum_{\mu} N_b^{\mu} \chi_b^{\mu}$$

where χ is the total linear susceptibility of a crystal, ε is the dielectric constant, which can be obtained from the refractive index, n (ε=n^2), F^{μ} is the fraction of bands of type μ composing the crystal, χ_b^{μ} is the susceptibility of a single bond of type μ.

The fractional ionicity f_i^{μ} and covalence f_c^{μ} of the individual bond are given by,

$$[15] \qquad f_i^{\mu} = (C^{\mu})^2/(E_g^{\mu})^2$$
$$f_c^{\mu} = (E_h^{\mu})/(E_g^{\mu})$$

According to the Lorentz formula,

$$[16] \qquad (\varepsilon^{\mu} - 1)/(\varepsilon^{\mu} + 2) = 4\pi\alpha_o^{\mu}/3$$

The polarizability coefficient of the μ bond, α_o^{μ}, can be obtained; this denotes the polarizability of the μ bond per cubic Angström. The polarizability of the type μ bond volume can be written as,

$$[17] \qquad \alpha_b^{\mu} = v_b^{\mu} \alpha_o^{\mu}$$

If the crystal structure and the refractive index n are known, the coordination number of the central ion, the bond volume polarizability α_b^{μ}, the fractional covalence f_c^{μ} of the chemical bond between the central ion and the nearest anion can be calculated by the method given above.

Results and discussion

By using the dielectric theory of chemical bonds for complex crystals, we calculated the chemical bond parameters for 12 alkali halide crystals; the results are displayed in Table 2. The second column shows the refractive index n of the crystals. Other columns in Table 2 give the chemical bond parameters: the bond distance (d^{μ}), the fractional covalence of the chemical bond (f_c^{μ}), the polarizability of the chemical bond volume (α_b^{μ}), the coordination number of the central ion (N).

The peak-positions of the dimer bands observed in absorption spectra of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ in various alkali halides are summarized in Tables 3 and 4. For $(In^+)_2$ and $(Ga^+)_2$ dimer centers, although which of the D_{2h} and D_{4h} dimer centers is responsible for the bands in Table 4 is still uncertain. Polarized luminescence of $(In^+)_2$ and $(Ga^+)_2$ centers in KCl crystals was investigated by Tsuboi and Jacobs[19] and Ermoshkin et al.[35] Ermoshkin et al. suggested that the In^+ dimer consists of two In^+ ions with a Cl^- ion between them along ⟨100⟩ directions (i.e., the D_{4h} dimer model).[35] However,

by comparing experimental results with calculations, Tsuboi and Jacobs suggest that the dimer center of In^+ in KCl has D_{2h} symmetry.[19]

From Tables 3 and 4, it is found that the position of A′, B′, and C′ bands depends not only on the alkali ion but also on the halide ion in alkali halides. For the I series in the sequence NaI→KI→RbI, the positions of the A′ band of the D_{2h} $(Tl^+)_2$ dimer center were 4.072, 4.265, and 4.300 eV, respectively. For the K series in the sequence of KCl→KBr→KI, the positions of A′ band of the D_{2h} $(Tl^+)_2$ dimer center were 4.885, 4.664, and 4.265 eV, respectively. This is because their bond lengths are different and thus the nephelanxetic effects are not the same,[48,49] therefore, the A′, B′, and C′ band energies of different dimer centers shift accordingly. Jörgensen found that the nephelanxetic ratio β can be express as: $\beta = 1 - hk$, where h relates to the ligands and k to the central metal.[48] Duffy and Ingram proposed a quantitative relation between the position of the $^1S_0 \rightarrow {}^3P_1$ transition of ns^2 ions and Jörgensen's h functions.[50] Blasse[49] and Bruce and Duffy[51] investigated the relationships between ns^2 ions $^1S_0 \rightarrow {}^3P_1$ transition, as well as Eu^{3+} charge transfer transition energy and h, and obtained some significant results. However, the detailed factors affecting h were not obtained by them. Gao and Zhang studied the mechanism of the nephelauxetic effect for the electronic structure of 3d elements and identified the main factors responsible for the effect.[43] These are: the covalency of chemical bond, polarizabilities of ligand bond volume for the host, and the valence and spin state of the center ion. Recently, the environmental factor was revised for the lanthanide ions by our group.[52,53] We successfully explained the energy difference between the spin-allowed and spin-forbidden states of Tb^{3+} in crystals,[52] as well as the barycenter of energy of lanthanide $4f^{N-1}5d$ configuration in inorganic crystals.[53]

The environmental factor designated by the symbol h[43] can be expressed as,

$$[18] \qquad h = (N f_c^{\mu} \alpha_b^{\mu})^{1/2}$$

Based on eq. [18] and the corresponding chemical bond parameters (see Table 2), the environmental factors h of the alkali halides have been calculated. The results are presented in column 8 of Table 2.

The relations between the positions of the A′, B′, and C′ bands of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ dimer centers and h are shown in Figs. 2 and 3. It is found that all the $E_{A'}$, $E_{B'}$, and $E_{C'}$ of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ dimer centers decrease with an increase of h.

By fitting the curves in Figs. 2 and 3, we obtained the following empirical formulas:

$$[19] \qquad D_{2h}(Tl^+)_2A' \text{ Band}: \quad E_{A'} = 6.487 - 3.547 \times h$$

$$[20] \qquad D_{2h}(Tl^+)_2B' \text{ Band}: \quad E_{B'} = 7.810 - 4.627 \times h$$

$$[21] \qquad D_{2h}(Tl^+)_2C' \text{ Band}: \quad E_{C'} = 8.419 - 5.453 \times h$$

$$[22] \qquad D_{4h}(Tl^+)_2A' \text{ Band}: \quad E_{A'} = 6.352 - 3.159 \times h$$

$$[23] \qquad (Ga^+)_2C' \text{ Band}: \quad E_{C'} = 7.816 - 5.278 \times h$$

$$[24] \qquad (In^+)_2C' \text{ Band}: \quad E_{C'} = 6.899 - 4.247 \times h$$

We should note that due to the lack of available theoretical mode to predict and assign absorption bands of monomer and dimer centers, the experimental investigation of $(Ga^+)_2$ and $(In^+)_2$ centers in alkali halides is very limited. Only $E_{C'}$ in KX (X = Cl, Br, and I) are available for $(Ga^+)_2$ and $(In^+)_2$ centers. Therefore, we think eqs. [19]–[24] are useful for investigating the absorption bands of $(Ga^+)_2$ and $(In^+)_2$ in alkali halides. $E_{A'}$, $E_{B'}$, and $E_{C'}$ of dimer centers were calculated by using eqs. [19]–[24], and the corresponding results are listed in Tables 3 and 4. The model calculation results excellently agree with the experimental data. Compared with the experimental data, the maximum error is 0.068 eV in the C′ band for D_{2h} $(Tl^+)_2$ center in NaI, the error ratio is only 1.415%. To the best of our knowledge, this is first successful quantitative investigation of the relationships between the absorption band positions of dimer ns^2 ions centers and the crystalline environment. In addition, as shown in Fig. 2, the distance of the C′ and B′ bands for the D_{2h} $(Tl^+)_2$ center decrease with increasing h. For example, $\Delta E_{C'\text{-}A'}$ of the D_{2h} $(Tl^+)_2$ center in KCl (h = 0.453) and NaI (h = 0.675) were 0.19 and 0.092 eV, respectively. This trend indicates that the distance

Fig. 2. The relations between A′, B′, and C′ band energies of D_{2h} and D_{4h} symmetry $(Tl^+)_2$ centers and environmental factors h.

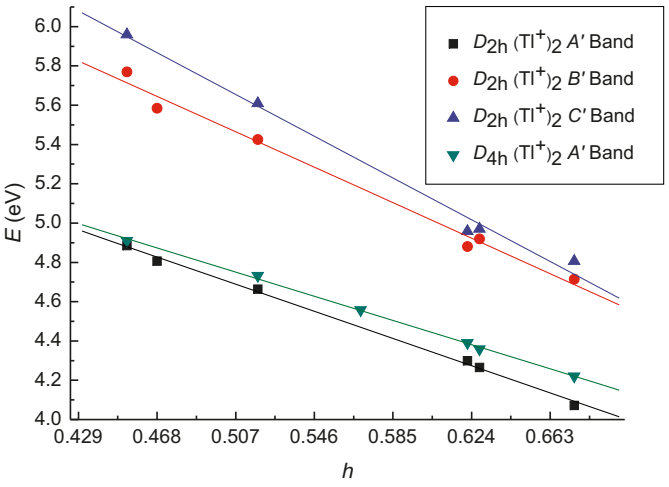

Fig. 3. The relations between C′ band energies of $(Ga^+)_2$ and $(In^+)_2$ centers and environmental factors h.

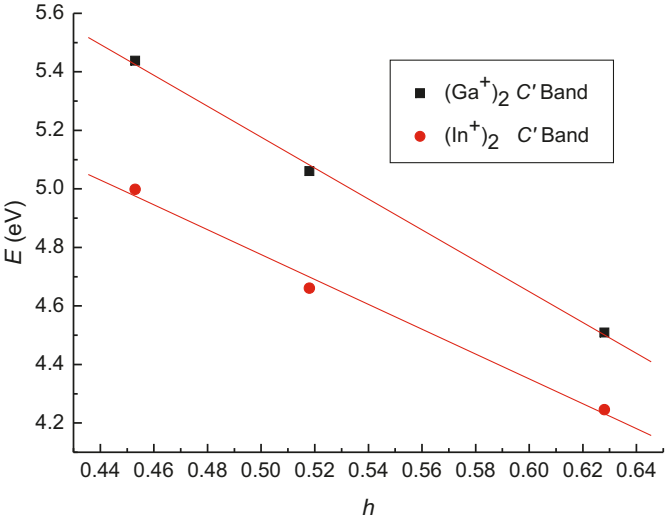

of C′ and B′ bands of Pb^{2+} will become too small to identify each band in the host for which h is very larger. Equations [19]–[21] show that the slopes increase markedly in the sequence of A′→B′→C′; the corresponding values are 3.547, 4.627, and 5.453, respectively. This means that the C′ band is the most sensitive energy level compared with the A′ and B′ bands. Moreover, as shown in Fig. 2, the distance of the A′ band for D_{4h} and D_{2h} $(Tl^+)_2$ centers increase with the increasing h. According to our model, the D_{4h} and D_{2h} symmetry of Tl^+ dimer centers can be assigned easily.

Applications

From the above discussion, it can be concluded that the $E_{A'}$, $E_{B'}$, and $E_{C'}$ of $(Tl^+)_2$, as well as $E_{C'}$ of $(In^+)_2$ and $(Ga^+)_2$ centers have direct relationships with the environmental factor h, and six good empirical formulas are obtained.

Therefore, we consider that the current model can serve as a prediction tool and can be applied to the assignments, reassignments, and predictions of the absorption band of A′, B′, and C′ bands of dimer centers in alkali halides. The applications of our model in these fields are presented in this section.

The environmental factors h of 12 alkali halides are listed in column 8 of Table 2. Using eqs. [19]–[24] we can predict $E_{A'}$, $E_{B'}$, and $E_{C'}$ of $(Tl^+)_2$, as well as $E_{C'}$ of $(In^+)_2$ and $(Ga^+)_2$ centers in these crystals. $E_{A'}$, $E_{B'}$, and $E_{C'}$ of D_{2h} $(Tl^+)_2$ in NaBr as well as $E_{C'}$ of D_{2h} $(Tl^+)_2$ and $E_{A'}$ of D_{4h} $(Tl^+)_2$ in RbCl are predicted and listed in Table 3. For other crystals, if the refractive index n and the crystal structures are known, the chemical bond parameters and environmental factors h can be calculated by using the dielectric theory of chemical bonds for complex crystals, then $E_{A'}$, $E_{B'}$, and $E_{C'}$ of dimer centers can be calculated according to our model.

The assignment of the observed absorption bands due to D_{2h} $(Tl^+)_2$ dimer centers in KCl is ambiguous. For KCl:$T1^+$, where two dimer bands peaking at 5.77 and 5.96 eV are present, an assignment is that both are related to the C′-band of the $^1T_{1u}$ state,[16] another is that the former band is related to the B′ band of the ^3E_u and $^3T_{2u}$ states, whereas the latter to the C′ band of the $(Tl^+)_2$.[17] According to our model, the calculated values of B′ and C′ bands are 5.714 and 5.949 eV, respectively. So it is concluded from our study that 5.77 and 5.96 eV of Tl^+ dimer bands in KCl mentioned above are attributable to the B′ and C′ bands, respectively, in agreement with the suggestion previously given by Tsuboi.[17]

In the case of RbCl:Tl^+, with the rise of thallium content additional absorption bands appear at 258 nm (4.806 eV) and 222 nm (5.585 eV).[26] Sharan et al. suggest that these are attributed to electronic transitions in dimers with D_{4h} symmetry: the 4.806 and 5.585 eV absorption hands have been assigned to A′ and B′ bands, respectively.[26] Unlike the suggestion by Sharan et al., however, Nistor et al.[27] suggested that the Tl^+ dimer in RbCl has D_{2h} symmetry by ESR analysis. From Table 3 it can be seen that the calculated values 4.827 eV (A′ band) and 5.645 eV (B′ band) of the D_{2h} $(Tl^+)_2$ center in RbCl:Tl^+ are in excellent agreement with the experimental data. Thus, we ascribed the 4.806 and 5.585 eV absorption bands to the A′ and B′ bands, respectively, of $(Tl^+)_2$ center with D_{2h} symmetry.

For CsBr:Tl^+, at high thallium concentration, additional absorption bands were obtained at 270 nm (4.592 eV) and

258 nm (4.806 eV).[54] The former was assigned to the A′ band of $(Tl^+)_2$ with D_{4h} symmetry, and the latter were not assigned by any authors.[48] Using eqs. [19] and [22], the calculated values of $(Tl^+)_2$ with D_{2h} and D_{4h} symmetries were 4.660 and 4.725 eV, respectively. Considering the fact that the two dimer centers D_{2h} and D_{4h} may coexist, we re-assign the 4.592 eV that was attributed to $(Tl^+)_2$ with D_{2h} symmetry and the 4.806 eV is assigned to $(Tl^+)_2$ with D_{4h} symmetry.

Conclusions

In this paper, we propose a semi-empirical method for predicting the absorption band positions of $(Tl^+)_2$, $(In^+)_2$ and $(Ga^+)_2$ dimer centers in alkali halides. The environmental factors affecting the absorption band positions of these dimer centers are the coordination number of the central ion, the bond volume polarizability, and the fractional covalence of the chemical bond between the central ion and the nearest anion. It was found that the environmental factors have linear relationships with the $E_{A'}$, $E_{B'}$, and $E_{C'}$ of $(Tl^+)_2$, $(In^+)_2$, and $(Ga^+)_2$ dimer centers. The calculated results are in good agreement with the experimental values. The current semi-empirical model can serve as a prediction tool and can be applied to assign and re-assign the absorption band positions of dimer centers in inorganic crystals. The model predicts that the positions of $E_{A'}$, $E_{B'}$, and $E_{C'}$ of D_{2h} $(Tl^+)_2$ in NaBr are 4.469, 5.177, 5.316 eV, respectively, and $E_{C'}$ of D_{2h} $(Tl^+)_2$ and $E_{A'}$ of D_{4h} $(Tl^+)_2$ in RbCl are 5.867, 4.874 eV, respectively. We re-assign the 5.77 and 5.96 eV bands of D_{2h} $(Tl^+)_2$ center in KCl to the B′ and C′ bands, respectively. In the case of RbCl:Tl^+, we ascribed the 4.806 and 5.585 eV to the A′ and B′ bands, respectively, of $(Tl^+)_2$ center with D_{2h} symmetry. For CsBr:Tl^+, we reassign the 4.592 eV band to $(Tl^+)_2$ with D_{2h} symmetry and the 4.806 eV was re-assigned to $(Tl^+)_2$ with D_{4h} symmetry.

Abstract: Chitosan is a biodegradable natural polymer with great potential for pharmaceutical applications because of its biocompatibility, high charge density, nontoxicity and mucoadhesion. It has been shown that it not only improves the dissolution of poorly soluble drugs but also exerts a significant effect on fat metabolism in the body. Gel formation can be obtained by interactions of chitosans with low molecular counterions such as polyphosphates, sulfates, and cross-linkers. This gelling property of chitosan allows a wide range of applications such as the coating of pharmaceuticals and food products, gel entrapment of biochemicals, plant embryos, whole cells, microorganisms, and algae. This manuscript is an insight into the exploitation of its properties for microencapsulating drugs. Herein, we report a novel method to chemically bind thiazolidine-2,4-dione through cross-linked chitosan nanoparticles using malanodialdehyde as a new cross-linker and well characterized by FT-IR, NMR, TGA, DSC, powder X-ray diffraction, TEM, and cyclic voltametry.

Key words: chitosan, nanoparticles, transmission electron microscopy (TEM), powder-X-ray diffraction (XRD), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC).

Résumé : Le chitosane est un polymère naturel biodégradable qui présente un grand potentiel pour des applications pharmaceutiques en raison de sa biocompatibilité, de sa grande densité de charge, de sa non-toxicité et de sa mucoadhésion. Il a été démontré qu'en plus d'améliorer la dissolution des médicaments peu solubles, il exerce aussi un effet significatif sur le métabolisme des graisses dans le corps. La formation de gel peut être obtenue par les interactions des chitosanes avec des contre-ions de faibles masses moléculaires, tels les polyphosphates, les sulfates et les produits de réticulation. Cette propriété de gélification du chitosane permet réaliser une grande variété d'applications, tel l'enrobage de médicaments et de produits comestibles, l'encapsulation dans un gel de produits biomédicaux, d'embryons de plantes, de cellules entières, de microorganismes et d'algues. Cette présentation présente une revue des domaines dans lesquels ses propriétés pourraient être exploitées pour encapsuler des médicaments. On décrit une nouvelle méthode pour lier chimiquement la thiazolidine-2,4-dione par le biais de nanoparticules de chitosane réticulées à l'aide du dialdéhyde malonique comme nouvel agent de réticulation et bien caractérisées par infrarouge à transformée de Fourier (IR-TF), résonance magnétique nucléaire (RMN), analyse thermogravimétrique (ATG), calorimétrie différentielle à balayage (CDB), diffraction des rayons-X par une poudre, microscopie électronique à transmission (MET) et voltampérométrie cyclique.

Mots-clés : chitosane, nanoparticules, microscopie électronique à transmission (MET), diffraction des rayons X par une poudre, analyse thermogravimétrique (ATG), calorimétrie différentielle à balayage (CDB).

[Traduit par la Rédaction]

Introduction

The potential use of polymeric nanoparticles as drug carriers has led to the development of many different colloidal delivery vehicles.[1–5] The main advantages of this kind of system lie in their capacity to cross biological barriers, to protect macromolecules, such as peptides, proteins, oligonucleotides, and genes from degradation in biological media, and to deliver drugs or macromolecules to a target site followed by controlled release.[6,7] In the last few years several synthetic as

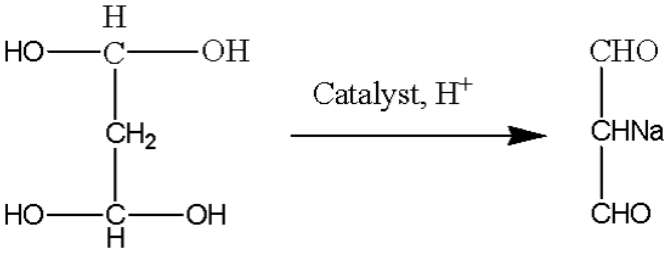
Fig. 1. Structure of chitosan.



well as natural polymers have been examined for pharmaceutical applications.[8–13] The basic prerequisite for a polymer to be used as a delivery agent in an in vivo system is that it has to degrade into molecules with no toxicity for the system where it is used. A very limited number of polymers can be used to prepare biodegradable materials owing to biocompatibility problems.[14–16]

Chitosan is an interesting natural material occurring in abundance in the environment. Chitosan is a polysaccharide comparable to cellulose and it is comprised of copolymers of glucosamine and *N*-acetyl glucosamine linked by β-(1–4) linkages, which can be derived by partial deacetylation of chitin from crustacean shells as shown in Fig. 1.[17] Nanoparticles have a special role in targeted drug delivery in the sense that they have all the advantages of liposomes including the particle size, but unlike liposomes, nanoparticles have a better shelf life and can usually entrap more drugs than liposomes. Although nanoparticles made up of hydrophobic polymers encapsulating hydrophobic drugs have been reported in the literature, very few studies have been made on the preparation of drug-loaded hydrogel nanoparticles.[18–22] Preparation of nanoparticles from chitosan, a hydrogel polymer, for drug delivery can have several advantages over the use of chitosan microspheres and microcapsules.[23] Nanometer range particles have easy accessibility in the body, being transported via the circulation to different body sites. Extremely small nanoparticles of <100 nm diameter with hydrophilic surfaces have been found to have longer circulation in the blood.[24–26]

Particle size, density, viscosity, degree of deacetylation, and molecular weight are important characteristics of chitosan that influence the properties of pharmaceutical formulations based on chitosan. Properties such as biodegradability, low toxicity, and good biocompatibility make it suitable for use in biomedical and pharmaceutical formulations, e.g., it is used for hypobilirubinaemic and hypocholesterolemic effects, antacid and antiulcer activities, wound and burn healing properties, immobilization of enzymes and living cells, and in ophthalmology. Since chitosan has a capacity for forming film, it has been suggested as a biopolymer of choice for the development of contact lenses (soft and hard). Chitosan has been used for the manufacture of ocular bandage lenses used as protective devices for acutely or chronically traumatized eyes. Chitosan membranes have also been found useful as artificial kidney membranes because of their suitable permeability and high tensile strength.[8,12,15,17–19]

Chitosan has been shown to possess mucoadhesive properties owing to molecular attractive forces formed by electrostatic interaction between positively charged chitosan and negatively charged mucosal surfaces. These properties may be attributed to strong hydrogen-bonding groups like –OH, –COOH, strong charges, high molecular weight, sufficient chain flexibility, and surface-energy properties favoring spreading into mucus.

Preparation of nanoparticles with this versatile hydrogel material has been attempted by several workers with the purpose of utilizing its mucoadhesive properties to transport drugs and DNA across mucosal surfaces. The reactive free amino group on the particle surface makes it possible to chemically conjugate various other reactive groups, such as polyethylene glycol (PEG) derivatives, different ligands, antibodies, and other pH- and temperature-sensitive moieties. Considering the advantages of using ultra low sized hydrophilic nanoparticles for drug delivery, we focused on the preparation of chitosan nanoparticles of <100 nm diameter.[22–25]

The thiazolidine-2,4-diones (TZDs), also known as glitazones, are one class of chemotherapeutics that increases sensitivity to insulin and is used for the treatment of type 2 diabetes mellitus.[27,28] These agents enhance insulin action in liver, muscle, and fat tissues. TZDs bind to nuclear receptor peroxisome – proliferator-activated receptor γ (PPARγ) and activates them to trigger the expression of insulin-responsive genes responsible for the regulation of carbohydrate and lipid metabolism.[29–31]

As per Banerjee et al.,[24] the biodistribution of chitosan nanoparticles establishes that chitosan particles are RES evading and circulate in the blood for a considerable amount of time. As per Banerjee et al.,[24] chitosan nanoparticles have gained more attention as drug delivery carriers because of their better stability, low toxicity, simple and mild preparation method, and for providing versatile routes of administration. Their submicron size is not only suitable for parenteral application, but it is also applicable for mucosal routes of administration, i.e., oral, nasal, and ocular, which are noninvasive routes. The application for mucosal delivery is also facilitated by the chitosan absorption enhancing effect. Furthermore, chitosan nanoparticles also have been shown to be a good adjuvant for vaccines.[32]

Banerjee et al.[24] describe the preparation of cross-linked chitosan nanoparticles using reverse micelles as the media, but in this paper, we report a novel method for chemically binding TZD (antidiabetic in nature) for delivery through cross-linked chitosan nanoparticles using malanodialdehyde as a new cross-linker.

Experimental and method

Materials

Chitosan (MW 400 kDa) and a surfactant, i.e., sodium bis(ethylhexyl)sulfosuccinate (AOT), were purchased from Sigma-Aldrich. Sodium salt malanodialdehyde was prepared from tetraethoxypropane. All chemicals were purchased from Sigma-Aldrich and Merck and used without any purification. FT-IR spectrums were recorded on a Spectrum Bx2 IR. Electrochemical properties were determined on a Electrochemical Analyzer CH 201 instrument. Thermogravimetric analyses were done using a PerkinElmer model Pyris 6 computerized thermal analysis system. The rate of heating of the sample was kept at 10 °C/min under nitrogen flow at 20 mL/min. Copper sulfate pentahydrate was used as a calibration standard.

NMR spectra were recorded on a Bruker Spectrospin 300 MHz spectrometer.

Preparation of the sodium salt of malanodialdehyde

Into a 50 mL flask, 4 mL of tetraethoxypropane and 5 mL of concd HCl were added and 20 mg of cation exchange resin, i.e., Amberlyst with the functionality of sulfuric acid (strong acidic), was added to the above reaction mixture. Then the reaction mixture was stirred for 5 min. The reaction mixture was filtered and the pH of the reaction mixture was made 7.2. After this the reaction mixture was precipitated with ice-cold acetone. the solution was filtered and the product was dissolved in a minimum quantity of distilled water and then precipitated out again with ice-cold acetone (Fig. 2) and then characterized by FT-IR, ^{1}H NMR, and ^{13}C NMR.

Preparation of cross-linked chitosan nanoparticles using malanodialdehyde as a cross-linker (Scheme 1*a*)

Cross-linked chitosan nanoparticles were prepared by reverse micelle medium. The surfactant (AOT) was dissolved in *n*-hexane (0.04–0.1 mol/L solution). To 200 mL of the 0.04 mol/L AOT solution, 2 mL of a 0.1% *w*/*v* chitosan solution in 6% *v*/*v* acetic acid, 880 µL of Tris–HCl buffer (0.01%, pH 8.0), 200 µL liquid ammonia, and 20 µL of a 0.01% *v*/*v* malanodialdehyde solution were added, with continuous stirring at room temperature. The solution was homogenous and optically transparent. The system was left, under stirring, overnight at room temperature. The above method produced placebo chitosan nanoparticles with 10% cross-linkage because an increase in percentage cross-linking from 10% to 100% results in an increase of particle size from 30 to ~110 nm diameter at infinite dilution. Thus, at an intermediate dilution, if the particle size is ~75 nm diameter for a 10% cross-linked polymer, then the particle size is 500–600 nm diameter for a 100% cross-linked polymer at the same dilution. The solvent was then evaporated off in a rotary evaporator and the dry mass resuspended in 40 mL of Tris–HCl buffer (pH 8.0) by sonication. Approximately 20 mL of a 30% $CaCl_2$ solution was added dropwise to precipitate the surfactant as the calcium salt of diethylhexylsulfosuccinate

Fig. 2. concluded.

($Ca(DEHSS)_2$). The precipitate was pelleted by centrifugation at 6000 rpm for 15 min at 4 °C. The cake of $Ca(DEHSS)_2$ after centrifugation contained some adsorbed nanoparticles. It was dissolved in 10 mL *n*-hexane and the hexane solution was washed two to three times, each time with 2 mL of Tris–HCl buffer. The phase-separated aqueous layer was drained out and added to the original centrifugate. The total aqueous dispersion of nanoparticles was then dialyzed for ~2–3 h using a dialysis bag. The dialyzed solution was lyophilized to dry powder for subsequent use as shown in Fig. 3*a*.

Preparation of cross-linked thiazolidine-2,4-dione–chitosan nanoparticles using MDA as a cross-linker (Scheme 1*b*)

AOT was dissolved in *n*-hexane (0.04–0.1 mol/L solution). To 200 mL of a 0.04 mol/L AOT solution, 2 mL of a 0.1% *w*/*v* chitosan solution in 6% *v*/*v* acetic acid, 880 µL of Tris–HCl buffer (0.01%; pH 8.0), 200 µL liquid ammonia, 20 µL of a 0.01% *v*/*v* malanodialdehyde solution, and 20 µL of a 0.01% *v*/*v* TZD were added, with continuous stirring at room temperature. The solution was homogenous and optically transparent. The solvent was then evaporated off in a rotary evaporator and the dry mass resuspended in 40 mL of Tris–HCl buffer (pH 8.0) by sonication. Approximately 20 mL of a 30% $CaCl_2$ solution was added dropwise to precipitate the surfactant as the calcium salt of $Ca(DEHSS)_2$. The precipitate was pelleted by centrifugation at 6000 rpm for 15 min at 4 °C. The cake of $Ca(DEHSS)_2$ after centrifugation contained some adsorbed nanoparticles. It was dissolved in 10 mL *n*-hexane and the hexane solution was washed two to three times, each time with 2 mL of Tris–HCl buffer. The phase-separated aqueous layer was drained out and added to the original centrifugate. The total aqueous dispersion of nanoparticles was then dialyzed for approximately 2–3 h using a dialysis bag. The dialyzed solution was lyophilized to dry powder for subsequent use as in Fig. 3*b*.

Size and morphology of the nanoparticles

Quasi-elastic light scattering (QELS) measurements and transmission electron microscopy (TEM) were used to establish the size and morphology of the cross-linked chitosan nanoparticles and TZD cross-linked chitosan nanoparticles.

QELS

QELS was performed using Brookhaven 8000 instrument with a BI200SM goniometer and an air-cooled argon ion laser

nanoparticles was determined from the diffusion of the particles (D) using the Stokes–Einstein equation

$$[1] \qquad d_h = kT/3\pi\eta D$$

where k is the Boltzmann constant, T is the absolute temperature, η is the viscosity of the medium, and d_h is the hydrodynamic diameter of the particles. Lyophilized powder (100 μg) was dispersed in 2 mL water by vortexing and used for QELS measurement. The sample was subsequently diluted to give nanoparticle solutions of known concentration and the particle size distribution was measured. Nanoparticles with different degrees of cross-linking were similarly diluted for the measurement of size distribution (Fig. 4).

TEM

Lyophilized powder (50 μg) cross-linked nanopolymer of chitosan and TZD–chitosan was dispersed in 5 mL of distilled water to have a clear solution. Samples for TEM were prepared using this clear solution. The sample solution was put on a formvar-coated grid. A clean glass slide was dipped in the formvar solution to make a formvar film on the stars, the glass slide was scratched on the edges, and the formvar film was floated on distilled water on a spherical container, and the 2090 mesh copper grids were placed upside down on the floating plastic film. A piece of water filter paper was blotted on the plastic film and lifted out from the distilled

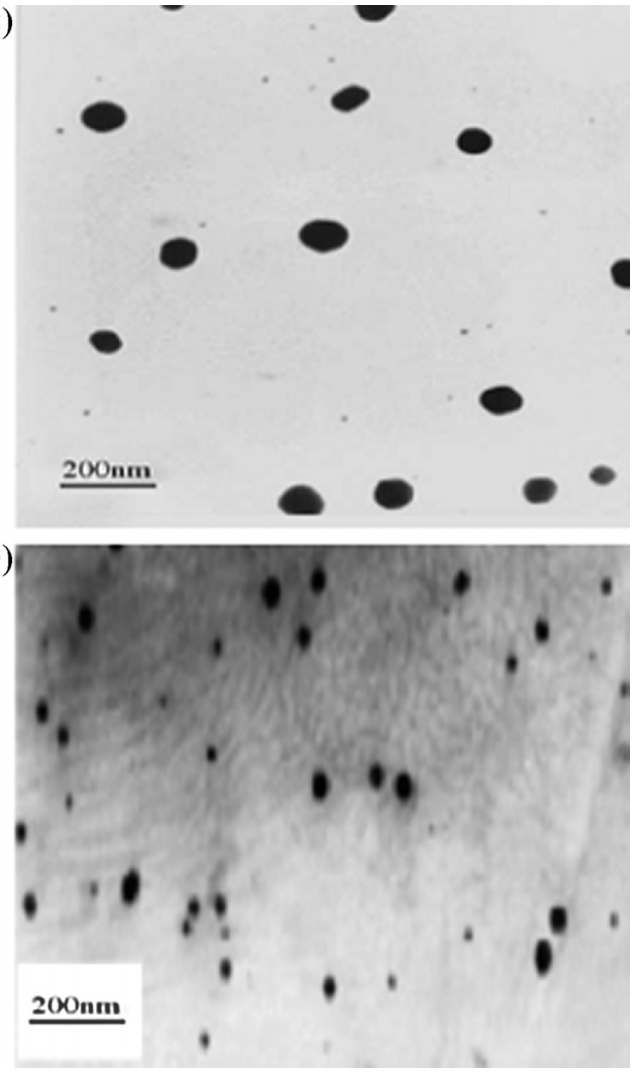
Fig. 4. TEM pictures of cross-linked (*a*) chitosan and (*b*) chitosan–thiazolidine-2,4-dione nanopolymers using the sodium salt of malanodialdehyde as a cross-linker.



water. In this way, the plastic-coated grids were prepared. On this grid, a drop of the sample solution (containing dispersed nanoparticles) was placed and allowed to air dry. A TEM picture was taken using a JOEL JEM 2000 EX200 microscope (Fig. 5).

FT-IR studies

The IR spectra of cross-linked nanopolymer of chitosan and TZD–chitosan were taken in KBr pellets using a PerkinElmer FT-IR instrument.

NMR studies

^{1}H NMR and ^{13}C NMR spectra of cross-linked chitosan and TZD–chitosan nanopolymer in deuterated trifluroacetic acid (TFA) were obtained using a Bruker spectrospin instrument at 300 MHz.

Thermal analysis

Thermogravimetric analyses of cross-linked chitosan and TZD–chitosan nanopolymer were done using a PerkinElmer model Pyris 6 computerized thermal analysis system. The rate of heating of the sample was kept at 10 °C/min under nitrogen flow at 20 mL/min. Copper sulfate pentahydrate was used as a calibration standard.

Powder X-ray diffraction (XRD) analysis

The X-ray diffraction of cross-linked chitosan and TZD–chitosan nanopolymer patterns were recorded using a RIGAKU ROTAFLEX RAD-B (Rigaku Corporation, Japan) diffractometer using Cu target Cu Kα 1 radiation with a tube voltage of 40 kV and at 60 mA in 2θ ranging from 5° to 70°.

Cyclic voltametry analysis

Cyclic voltametry of cross-linked chitosan and TZD–chitosan nanopolymer patterns were recorded using Electrochemical Analyzer CH 201.

Results and discussion

Characterization of cross-linked chitosan and TZD–chitosan nanoparticles.

Size of the nanoparticles

We determined the particle size by QELS measurements. Chitosan is an adhesive hydrogel polymer. Therefore, in aqueous solution, these nanoparticles interact among themselves through their Brownian motion to form clusters. For interacting particles, the average particle size is always found to be higher than the actual size of the particles. The diffusion coefficient (D) of these interacting particles can be studied by QELS. In the low concentration range, D can be written as $D = D_0 (1 + \alpha\phi)$, where D_0 is the intrinsic diffusion coefficient at infinite dilution when the interaction among the particles is zero, α is the virial coefficient of diffusion, and ϕ is the volume fraction of the particles in the medium. The d_h of the dispersed particles is related to D through the Stokes–Einstein equation as mentioned earlier. Observations of TEM revealed a more or less spherical morphology for the nanoparticles having a size of ~50 nm.

FT-IR studies of cross-linked chitosan nanoparticles

The chitosan nanoparticles were prepared by cross-linking the polymer with malanodialdehyde within the reverse micelles. From the IR spectra of cross-linked chitosan and TZD–chitosan nanoparticles, the strong peaks in the range 3400–3200 cm^{-1} correspond to combined peaks of hydroxyl and intramolecular hydrogen bonding and secondary amine. Primary amines also show sharp absorption at 3500 and 3400 cm^{-1} arising from the asymmetric and symmetric stretching of two N–H bonds, but the peaks appear broad here owing to the contributed peaks from O–H stretching and hydrogen bonds. The peak at 1640 cm^{-1} (approximately) corresponds to stretching vibrations of the C=N bond. This strong peak indicates the formation of a Schiff's base as a result of the reaction between the carbonyl group of malanodialdehyde and the amine group of the chitosan chains, as well as between one carbonyl group of malanodialdehyde and one amine group of the chitosan chains and another carbonyl group of malodialdehyde with the active methylene CH_2 of TZD. The C–H stretching vibration of the polymer backbone is manifested through a strong peak at 2900 cm^{-1} (approximately). Acetyl groups absorb in the range 1300–1100 cm^{-1}. The peaks in the fingerprint region of the spectrum

are given by ethereal bonds, where the symmetric stretch of C–O–C is found around 1020–1060 cm^{-1}.

NMR studies of cross-linked chitosan and chitosan–TZD nanopolymer

^{1}H NMR study

As per the spectra, there are peaks for different types of protons. In the spectra, protons are bonded to nitrogen, carbon, and oxygen, i.e., NH, CH, CH_2, and OH. The peak at around an integral value of 9 indicates an N–H, an integral value around 2–3 indicates an aliphatic CH_2 (secondary carbon), an integral value at around 3–4 indicates an O–H, and an integral value around 4–6 also indicates a C–H (primary carbon).

^{13}C NMR study

As seen in the spectra, there are peaks for different types of carbon. The peaks with an integral value in the range of 110–120 indicate carbons that are directly doubly bonded to carbon and nitrogen. The peaks with an integral value in the range of 170–200 indicate carbonyl carbon. The peaks with an integral value in the range of 10–70 indicate aliphatic carbons.

TGA

Decomposition of cross-linked chitosan started at 90 °C and ended at 230 °C. First, the decomposition of the linker that cross-links the chitosan begins during this range of temperature. After this, elimination of small molecules from the cross-linked chitosan polymer begins. These small molecules are H_2O, NH_3, CH_2O, $HCONH_2$, and CH_2O_2, etc., (Fig. 6*a*).

Decomposition of cross-linked TZD–chitosan started at 90 °C and ended at 320 °C. We observed two stops at around 170 and 230 °C. Decomposition of the linker that cross-links the chitosan begins on increasing the temperature above 90 °C, and the decomposition continues until the second stop occurs. At 230 °C, decomposition restarts, which indicates the decomposition of the thiazolidine ring that was cross-linked with chitosan. Then, the elimination of small molecules from the cross-linked chitosan polymer begins. These small molecules are H_2O, NH_3, CH_2O, $HCONH_2$, and CH_2O_2, etc., (Fig. 6*b*).

Differential scaning calorimetry (DSC) analysis

DSC thermograms of amorphous polymers demonstrates the endothermic and exothermic peaks and gives an indication of the solid-state transition, the glass transition, crystallization, and fusion as well as curing the cross-linking temperature.

DSC thermogram of the cross-linked chitosan nanopolymer

The DSC thermogram indicates three peaks at 57, 147, and 327 °C. The endothermic peak starts at 26 °C and ends at 63 °C. The minimum at 57 °C indicates the solid-state transition temperature and the energy liberated was 123 J/g. The peak at 98 °C indicates the glass transition temperature and the minimum at 147 °C indicates the baseline shift temperature, which is endothermic in nature, and the energy liberated was 464 J/g. With a further increase in the temperature, the minimum at 327 °C indicates the fusion temperature and the energy liberated was 115 J/g (Fig. 7*a*).

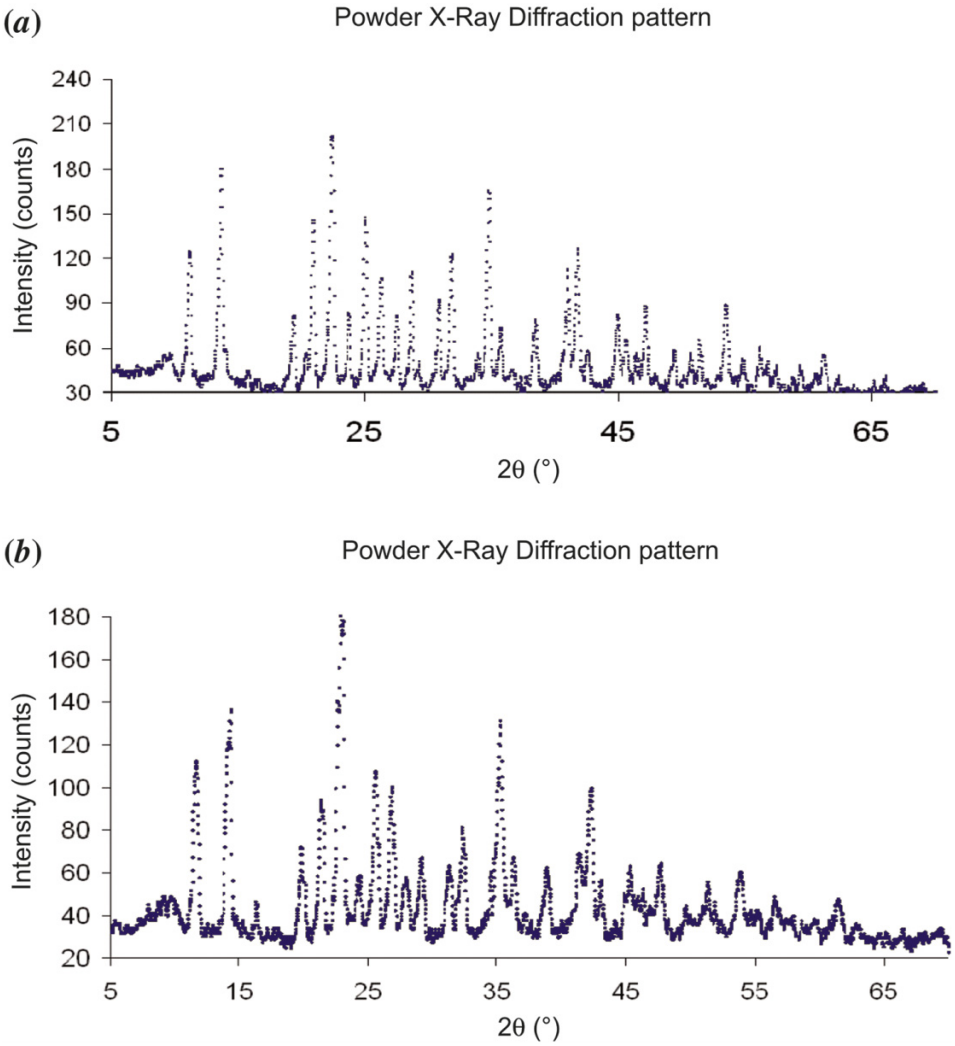
DSC thermogram of the cross-linked chitosan nanopolymer

The DSC thermogram indicates three peaks at 119, 125, 262, and 326 °C. The endothermic peak starts at 30 °C and ends at 120 °C. The minimum at 119 °C indicates the solid-state transition temperature and with a further increase in the temperature, another minimum was observed indicating a baseline shift and the energy liberated was 505 J/g. The peak at 262 °C indicates the crystallization transition temperature, which is exothermic in nature, and the energy liberated was 32 J/g and is in the range of 231 to 300 °C. On further increasing the temperature, the minimum at 326 °C indicates the fusion temperature and the energy liberated was 50 J/g and is in the range of 300 to 330 °C, as well as being endothermic in nature (Fig. 7*b*).

Powder XRD analysis

Powder XRD is the primary technique for the determination of the degree of crystallinity of polymers. The diffraction pattern of polymers is almost a powder pattern (polycrystalline). Crystallite size in polymers is usually on the nanoscale in the thickness direction. The XRD technique is used to report about indexing, degree of crystallinity, and orientation. A synthesized cross-linked polymer is of low symmetry and orthorhombic in nature because of the asymmetry in the bonding of the crystalline lattice, i.e., the *z* axis is contains covalent bonds and the *x* and *y* axes contain van der Waals interactions or hydrogen bonds. As the cross-linking increases, crystallinity decreases, which means the amorphous character in the polymer increases. Along with this, the solubility of the polymer decreases.

Fig. 7. Powder X-ray diffraction plot of cross-linked (*a*) chitosan and (*b*) chitosan–thiazolidine-2,4-dione nanopolymers using malanodialdehyde as a cross-linker.



From the powder XRD curves, cross-linked chitosan nanopolymer is more crystalline in nature than the cross-linked TZD–chitosan because of more peak count intensity. This means that the greater the peak count intensity, the more it will be crystalline in nature (Figs. 8*a* and 8*b*).

Cyclic voltametry analysis

This plot was obtained from an Electrochemical Analyzer CH 201. The scalings of the plot are potential and current on the *x* and *y* axes, respectively.

The potential range is –2 to +2 V and the current range is –7 to + 8 × 10^{-3} A

The scan rate of the sample was 0.1 V/s and the sensitivity was 0.001 A/V. The number of segments were seven to provide the stability on applying voltage on the compound with time. Overlay of the segments indicates the stability of the compound. As per the plot, the overlay means that the compound attained the stability very fast. We checked other ranges of voltage on the compound, but the compound was not stable in those ranges and we found no overlay and a slow decline of the plotsappeared on application of the high voltage range to the compound. On applying this voltage range, the compound gave a current in the range of –7 to +8 × 10^{-3} A (Fig. 8*a*).

The potential range is –2 to +2 V and the current range is –10 to +10 × 10^{-3} A

The scan rate of the sample was 0.1 V/s and the sensitivitywas 0.001 A/V. The number of segments were seven to provide the stability on applying voltage on the compound with time. Overlay of the segments indicates the stability of the compound. As per the plot, the overlay means that the compound attains the stability very fast. We checked other ranges of voltage on the compound, but the compound was not stable in those ranges and we found no overlay and a slow decline of the plotsappeared on application of the high voltage range to the compound. On applying this voltage range, the compound ggave a current in the range of –10 to +10 × 10^{-3} A (Fig. 8*b*).

Conclusion

This study reports the synthesis, characterization, thermal, powder XRD, and cyclic voltametry properties of cross-linked chitosan and TZD–chitosan nanopolymer using

Abstract: Recent experimental reports involving both α-nucleophiles and normal nucleophiles have reported both the presence and absence of an α-effect. In ester systems, such as dimethylmethylphosphonate (DMMP), a small α-effect is reported, but the reference point is a stationary point of the potential energy surface that must rearrange to acquire the near attack conformation (NAC) necessary for the Sn2 pathway to proceed. The second type of study involves use of highly fluorinated alkoxides as normal nucleophiles and reports no α-effect. This paper employs linear free energy plots in an investigation of electronic effects in methyl formate S_N2 reactions, using high-level computations of transition states for determination of energy barriers.

Key words: AIM, valence bond, LFER, overall barrier, central barrier.

Résumé : Des données expérimentales rapportées récemment, impliquant des nucléophiles tant α que normaux, ont mis en évidence la présence ainsi que l'absence d'un effet α. Dans les systèmes impliquant des esters, tel le méthylphosphonate de diméthyle (MPDM), un faible effet α a été noté, mais la valeur de référence est une valeur stationnaire de la surface d'énergie potentielle qui doit être réorganiser pour atteindre la conformation adjacente à l'attaque (CAA) nécessaire pour que la réaction de type S_N2 puisse se produire. Le deuxième type d'étude implique l'utilisation d'alcoolates polyfluorés comme nucléophiles normaux pour lesquels aucun effet α n'a été observé. Dans le présent travail, on utilise des courbes d'énergie libre linéaire pour étudier les effets électroniques dans les réactions S_N2 du formiate de méthyle, en faisant appel à des calculs de haut niveau des états de transition pour la détermination des barrières d'énergie.

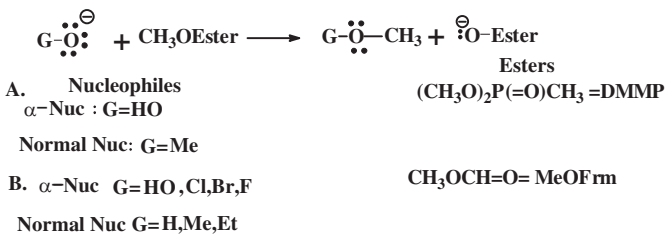
Mots-clés : atomes dans les molécules (ADM), liaison de valence, relation linéaire d'énergie libre (RLEL), barrière globale, barrière centrale.

[Traduit par la Rédaction]

Introduction and purpose

Our purpose is to compare electronic effects in two gas-phase (GP) reaction cases where experimental evidence provides interpretations favoring the existence of α-effects in methyl transfers. The GP experiments under study are the relative product ratios for displacement of methyl methylphosphonate anion (MMP^-) from dimethylmethylphosphonate (DMMP) by hydroperoxide (HOO^-) and methoxide (MeO^-) (rxn. [1A]),[1] and the GP reactions of HOO^- and HO^- displacing methyl groups from formate anion (rxn. [1B]).[2] Recent work by Ren and Yamataka[3–5] has shown the theoretical possibility of an α-effect in methyl transfers. No serious attempts to analyze potential differences in the electronic effects between normal nucleophiles and α-nucleophiles, other than one from this laboratory showing, by indirect means, a potential single electron transfer (SET) component,[6] have appeared. The α-nucleophile (HOO^-) has a lone pair of electrons (LP) adjacent to the nucleophilic atom (O^-). The α-effect is putatively an increase in nucleophilic reactivity when compared with a normal nucleophile of the same basicity (acidity).

rxn. [1]



Gas-phase S_N2 reactions.

It has been generally posited for many years and in many venues that the α-effect is due to a feature or features specific to the transition states. We seek to answer several questions to ascertain which transition-state features might be responsible. Determinations of the α-effect in the gas phase (GP) have been attempted experimentally with mass spectral-SIFT tube methods and theoretically with high-level post-Hartree–Fock, highly correlated methods, as discussed and documented as follows.[1–3] Putatively GP studies simplify matters by excluding solvent effects. This paper will show that GP

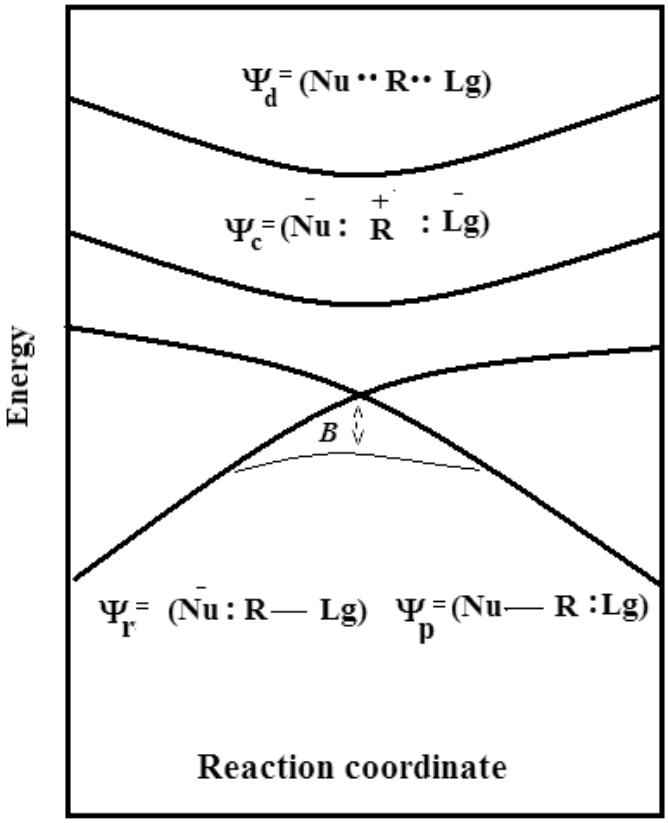
Fig. 1. A state correlation diagram for S_N2 reactions.



experimental results are not without complications themselves, particularly in the hermeneutic employed for interpretations of those results.

Our questions are concerned with the fundamental electronic transactions in S_N2 reactions for methyl group transfers. Such concerted nucleophilic reactions have as a settled issue the exchange of one pair of electrons by another. GP manifestations involve anions and neutrals on both sides of eq. [1]. It is natural to ask the following questions about the S_N2 process: (1) Are there differences in the electronics of normal and α-nucleophiles? (2) Can normal nucleophiles be electronically modified to behave like α-nucleophiles? (3) Can normal nucleophiles ever become more reactive than α-nucleophiles?

The early Ren and Yamataka papers ascribe the α-effect to electrostatic attractions between the α-atom and the partially charged methyl group, but their later paper retreated somewhat from that conclusion, indicating that causes for the α-effect are complex.[3] The authors of the present paper believe it is important to extract as much information as possible to answer the Mulliken question "What are electrons doing in molecules?" To this end we examine the transition-state (TS) structures of two systems where experimental results indicate the presence, or potential presence, of an α-effect, and the pathways toward the TSs in each.

Methods of study

The transition states of all the experimental methyl transfers in rxns. [1A] and [1B] (HOO^-, MeO^-, EtO^- , and HO^-) for the methyl formate case were obtained by several model chemistries. The DMMP reaction TSs were obtained at the B3LYP/6–31+G(d) model chemistry as in the original paper and the CBS-LQ(startmp2)\MP2\6–31+G(d)\HF\6–31+G(d) in the present paper.[1] The formate ester cases were obtained at the CBS-QB3(StartMP2)//mp2/6–31+G(d)/HF\6–31+G(d) model chemistry and CBS-LQ method for direct comparison between the DMMP and MeOFrm systems. This compound model chemistry conveniently gives geometries corresponding to the Ren and Yamataka G2(+) level, with a post-Hartree–Fock extrapolation to complete basis set limits. This type of model chemistry provides very highly accurate GP acidity (GPA) values for the nucleophiles. Additional sets of normal and α-nucleophiles were computed for the methylformate cases to supply information about the presence (absence) of a discernable α-effect in a linear free energy relationship plot (LFER).

Atoms-In-Molecules (AIM) results were obtained by generating wave function files with Gaussian 03W (G03W)[7,8] and performing the AIM analysis with the AIMStudio suite of programs.[9] Natural bond orbital (NBO) results were obtained from the TS geometries from the NBO segment within G03W at a HF\6–311+G(2d,p) model chemistry.

Valence bond (VB) results were obtained by copying the geometry coordinates of each TS into a template file for VB2000.[10] (A template file is available from the corresponding author on request.) The NBO results disclosed that all three of the LP electrons on the nucleophilic O atom must be considered in assessing contributions to the TS stability, therefore, all three LP electrons were included in the CASVB(x,y) computation in VB2000 (x = electron number and y = orbital number).

The results are expressed in Rumer diagrams,[11] which display the Mulliken (Coulson–Chirgin) weighting factors (λ) for each highly localized Lewis-type resonance form. Quantum mechanical resonance energy (QMRE = B) was calculated by eq. [1].[11]

$$[1] \qquad B = \mathrm{QMRE} = 0.5D_0(1 - Q_a)$$

B is the avoided crossing constant in a state correlation diagram (SCD) as in Fig. 1.

Results

The results are presented in the order of categories given in the Methods of study section.

AIM

Table 1 displays the results of the AIM determinations of both ester systems as **ρ** values (electron densities) at bond critical points (BCPs) along the bond pathways. (Details are provided in the Supplemental data).

NBO results are in Table 2 and VB results are in Table 3. An abridged Rumer diagram presentation is included in the Appendix in the Supplementary data.[12]

There are differences in how the nucleophiles store the electrons as anions then donate the electrons to the substrate in the TSs. As an example we consider the HOO^- anion, which has donor–acceptor energy (DAEn) from the donation of LP(3) on O to the BD*H–O orbital of 2.652.65 kcal/mol (1 cal = 4.184 J). In the TS HOO···Me···OFrmt (OFrmt = O–CH=O) donation is of only 1.64 kcal/mol from the LP(2) on O to the BD*HO and augmentation by 0.58 kcal/mol from BDH–O to BD*O–O.

Table 3. Valence bond results and *B* values (quantum mechanical resonance energy, QMRE) for transition states (TS) at mp2/6–31+G(d) geometry.

System TS	QMRE (kcal/mol)	D_o
HOO···MeOMeOP=OMe	39.5	98.2
MeO···MeOMeOP=OMe	38.8	
HO···MeOP(=O)MeOMe	36.8	
HOO···MeOFrmt	40.0	94.2
MeO···MeOFrmt	38.2	
C_2H_5O···MeOFrmt	36.7	
HO···MeOFrmt	38.6	

Note: MeO bond energy in the esters (D_o) values were determined with the Zavitsas formula, which yields nearly quantitative results from vibrational frequencies supplied by NIST.[13]

Table 1 discloses electronic differences between the α-nucleophile (HOO^-) and normal nucleophiles, such as MeO^-, in several electronic features that also show some dependence of the leaving groups. For DMMP, the size of ρ at the BCP of the nuc–OMe bond path indicates slightly larger charge transfer from the nucleophile to this point for HOO^- than for MeO^-. The ρ values at the BCPs of cleavage of the leaving group $^-$O–MMP are slightly larger for the normal nucleophile (MeO^-). The charges (*Q*) of the atoms in the X–O–DMMP TS indicate a net negative charge on HO (α-X), positive on CH_3 (X), negative *Q* (–0.904) on the nucleophile HOO^-, and less negative (–0.883) on MeO^-. On the transfer of CH_3, a slightly more positive charge exists in the HOO^- TS than for the MeO^- TS. A slightly more negative charge is transferred to the leaving O atom in the HOO^-TS than from the MeO^-. Similar values exist for the X–O–MeOFrmt case. Elipticity (*E*) values indicate the amount of π character at a particular point in a bond path display. This indicates the sense of π character in an ethylene double bond path. These differences indicate a difference in quality (i.e., hybridization) of the wave functions in these nucleophiles.

Elipticity values at BCPs for the Me and leaving O–ES groups display more *E* for the normal nucleophiles than for HOO^-. Elipticity for the DMMP case shows much larger *E* between the nucleophilic HOO^- and Me than for the MeO^- case. The BCP between X–O is larger for HOO^- than for Me–O^-. There is a difference in the MeOFrmt case compared with the DMMP case. HO^- has more *E* at the BCP to the Me group than all the other nucleophiles.

The charges on AIM atoms indicate an important electronic difference because the α-nucleophile has negative charge on the α atom, whereas all the normal nucleophiles have positive charges on their α atom. (Supplementary data) This point may be important later in sorting out the putative dependence on electrostatic effects, as shown as follows with the sulfur-containing α-nucleophiles.

The NBO results disclose the point that all three electron LPs on O contribute to the stabilization of the TS in each case. The major contributions, giving 1 kcal/mol or more stabilizations energy upon examination by a deletion routine

Fig. 2. Central barriers in the S_N2 reactions of methyl formate with *B* values (quantum mechanical resonance energy, QMRE).

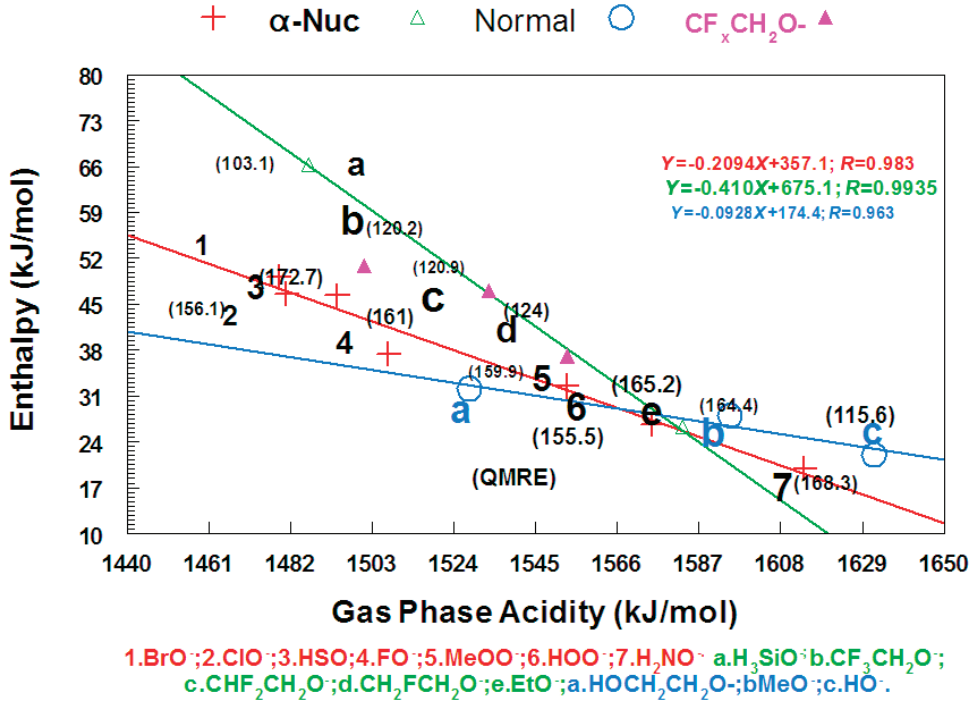

Fig. 3. Potential energy surface (PES) for a gas-phase S_N2 reaction.

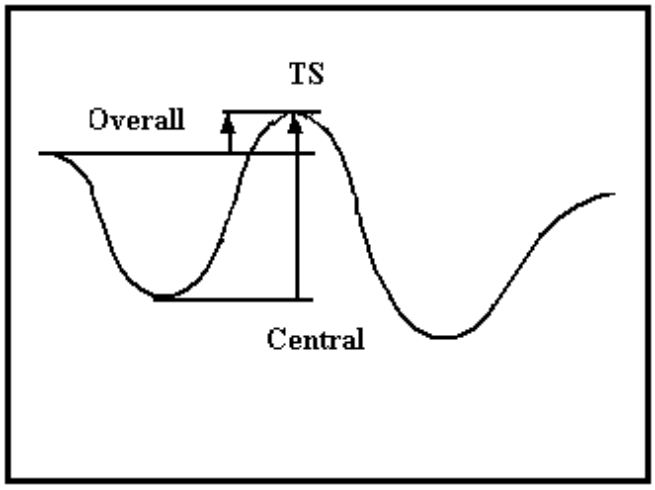

(standard with the G03W software), were retained. The major bond forming LP on O also provides DA stabilization energy by DA interactions with the C–H antibonding orbitals. For the methylformate cases, the second and sometimes the third LP on O for each nucleophile contributes 10.5 kcal/mol in MeO and 10.9 kcal/mol in EtO to the TS, and only 10.84 kcal/mol in HOO^-. The donations to C–H anti-bonding orbitals are greatest in HOO^- and EtO^-. In DMMP systems the values are HOO^-, 8.99; MeO^-, 8.26; and HO^-, 7.38. The way the LPs of the normal nucleophiles are stored in the adjacent regions of the nucleophiles depends on the identity of the atoms in those regions. The nucleophiles (HO^- and HOO^-) store energies in Rydberg orbitals only, except in HOO^-, where small energies are due to donation to the BD*H–O antibonding orbital.

The VB results in Table 3 indicate a clear distinction between HOO^- and all the normal nucleophiles in both the DMMP and MeOFrmt systems. The *B* (kcal/mol) value for the HOOMeOES TS is greater (implying greater resonance stability at the avoided crossing point in the SCD than any of the other nucleophiles) in both systems. These differences (δB, $B_{X-O} - B_{HOO^-}$) between the HOO^- anion TS and the normal nucleophiles are –0.7 kcal/mol (vs MeO^-) for DMMP and –2.7 kcal/mol (vs HO^-), which indicates more stabilizing QMRE energy for the HOO^- cases. For Frm δB is –1.8 kcal/mol(vs MeO^-), –3.3 kcal/mol (vs EtO^-), and –1.4 kcal/mol (vs HO^-). These δ *B* values order the S_N2 reactivity of the nucleophiles as $HOO^- > MeO^- > HO^-$ for DMMP and $HOO^- > HO^- > MeO^- > EtO^-$ for MeOFrmt. These differences are small and by themselves not convincing criteria for determining the α-effect. This fact changes as the LFER is considered over a wider range of GP aciditites as shown in Fig. 2.

A LFER, similar to Ren and Yamataka's[5] foundational theoretical treatment, was constructed from a series of normal and α-nucleophiles for the MeOFrmt system using the CBS-QB3 (startmp2)\mp2\6–31+G(d)\HF\6–31+G(d) model chemistry to determine TS geometries and those of the reactants and their energies.

Determinations of the theoretical α-effects depend on the reference points along the GP acidity scale (*x* axis). In solution-phase reactions, the difference in energies between the reactant complexes and the central barrier determine reactivity.[14] Differences between these barriers for normal and α-nucleophiles determine the α-effect, provided the pK_a values of the two nucleophiles are equal. In the GP reaction diagram two types of barriers are apparent (Fig. 3), an overall difference between uncomplexed reactants and the TS and the difference between the ion–dipole complex and the TS (central barrier).

This point is pertinent in the present paper because the Blanksby α-effect uses the central barrier difference between the nucleophiles, whereas the overall barrier was used by Ren

and Yamataka[5]. A reaction coordinate diagram provided in Blanksby and co-workers[1] shows values of –42 kcal/mol for the overall barrier and a 40 kcal/mol central barrier for HOO$^-$. Table 3 of their paper supplies a barrier value for the MeO–DMMPTS overall barrier of –32 kcal/mol and 47.8 kcal/mol for the central barrier. (Note: these negative values indicate greater stability for the HOO TS case.) The α-effect from the central barriers is similar to that from the overall barrier in this DMMP system (+7.8[47.8 – 40] vs +8[–32 + 40] for the central barriers). Overall barriers are mostly used to compare reactivity owing to the known existence of reactions that have zero or very small central barriers, missing their ion–dipole complexes.[14] Another such example, highly pertinent to the present paper, is a chemical dynamics trajectory study of the atomic-level mechanism of the reaction of HO$^-$ with methyl fluoride (MeF), where even a very low-energy hydrogen-bonded complex did not trap the majority of the trajectories in the channel leading to the dissociated products.[15]

The correlation LFER plot for α-nucleophiles reacting with methyl formate is shown in Fig. 4. This plot indicates that the overall barriers for the methyl formate system indicate

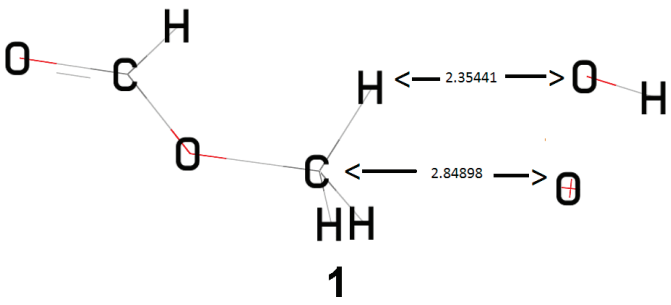
α-effects for all the α-nucleophiles, analogous to those of Ren and Yamataka.[5] A companion plot showing central barriers along with *B* values appears in Fig. 2. The, rather busy, Fig. 4 provides data for a discussion of electronic factors effecting overall barriers. Figure 2 provides the information that a significant difference in *B* values between the normal and the α-nucleophile is important for detection of the presence of an α-effect.

We follow the Ren and Yamataka[5] method of using the overall barriers to express the combined experimental and theoretical α-effects in this paper, but also point to an unpublished study that shows a very good correlation between GP central barriers and the overall barriers, giving a correlation equation, $Y = 1.55X - 97.0$; $R = 0.979$ from this laboratory (available from the corresponding author on request). The role of central barriers is important in this paper because obtaining them requires distinguishing between the complex resulting from a Born–Oppenheimer molecular dynamics (BOMD) procedure or a relaxed scan, which elongates the forming C–O bond. The relaxed scan method proceeds by a systematic elongation of the nucleophile–C bond, which guarantees finding a near attack conformation (NAC). Lau and Bruice discussed such complex reaction systems in terms of correlated motions resulting in NACs for S_N2-type reactions in methyl transfers to COMT.[16] Figure 5 shows the result of the BOMD for HOO···MeO···OFrmt TS. Similar results accrue to the DMMP system. The overall result is a reaction complex that is analogous to **RC1** used by Blanksby and co-workers[1] at point **d**, (a non-NAC (NNAC) complex) with a point like a NAC complex at **a**. Transformation of the complex at point **d** in Fig. 5 to an NAC where an S_N2 reaction can begin requires overcoming a barrier of ~52 kJ/mol. With HOO the transition required was ~18 kJ/mol. From the bottom of the non-NAC curve to the TS for HOMeOFrmt is 81.6 kJ/mol, but for HOOMeOFrmt it is only 43.7 kJ/mol. At point **b**, a modified NAC complex for the HOO–MeOFrm case where the α-OH group forms a complex with H8, and the distance is actually shorter than for the C–O distance (Structure **1**). This finding plus the previous discussion indicates that determination of the α-effect, or even its observation, will depend on exactly how the barriers are designated. The overall barriers give a TS stabilization of HO relative to HOO of –0.86 kJ/mol. This is a nominally incorrect result if the experimental result using the experimental branching ratios, where the ratio HOO:HO is 1.6, favoring the reactivity of HOO over HO, can be taken as representing a rate ratio.



1

From the central barriers the order is $HOO^- < HO^-$, a difference of –1.42 kJ/mol and favoring HOO^-, agreeing with the branching ratios taken as indicative rate ratios.

Something similar is present in the Blanksby results.[1] Figure 6 shows the BOMD scan for the HOO···DMMP TS, elongating the HOO–C bond. The point inside a red circle indicates a NAC complex corresponding to that of the Nuc–MeOFrmt. Figure 6 shows several TSs must be similar to those in Fig. 5 for the methyl formate case to overcome the NNAC complex to form the NAC configuration. The overall appearance of Table 4 discloses the barriers from several points in the DMMP potential energy surface (PES), along with the overall barriers. The HOO and MeO anions are experimental results, with the HO anion given for comparison with the MeOFrmt system.

These results give the order of reactivity for the central barriers from NAC as $HOO^- > HO^- > MeO^-$ and from NNAC as $HOO^- > HO^- > MeO^-$. Overall barriers give (B3LYP\6–31+G(d)) $HO^- > HOO^- > MeO^-$. This difference in ordering of relativities presents a way to establish the most accurate determination of α-effects by determining their GP reactivities experimentally.

Fig. 7. Linear free energy relationships (LFERs) of overall barriers for S_N2 reactions of methyl chloride.

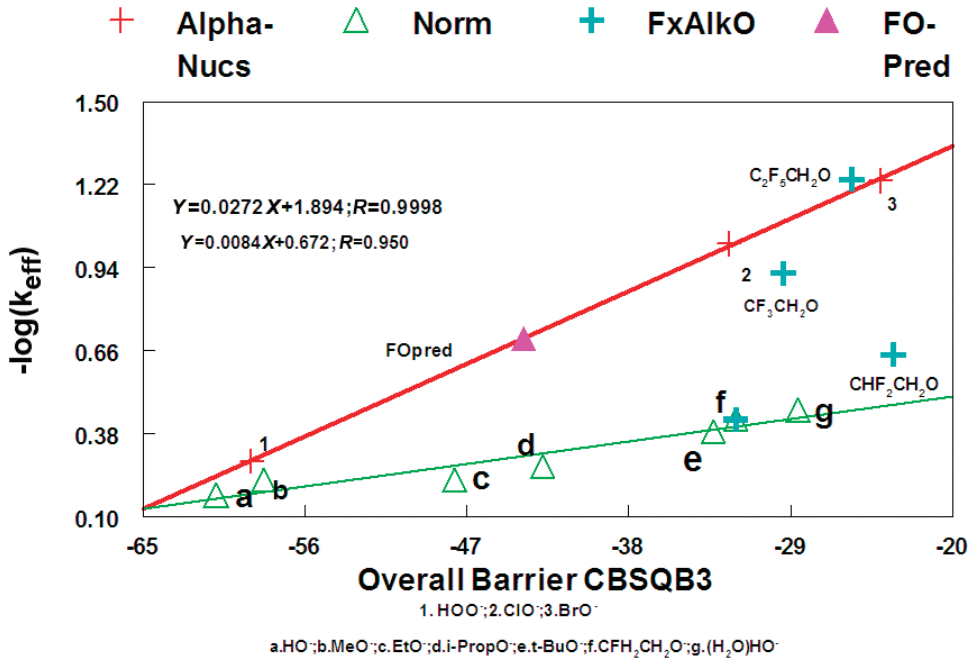

Fig. 8. Linear free energy relationships (LFERs) of central barriers for S_N2 methyl chloride reactions.

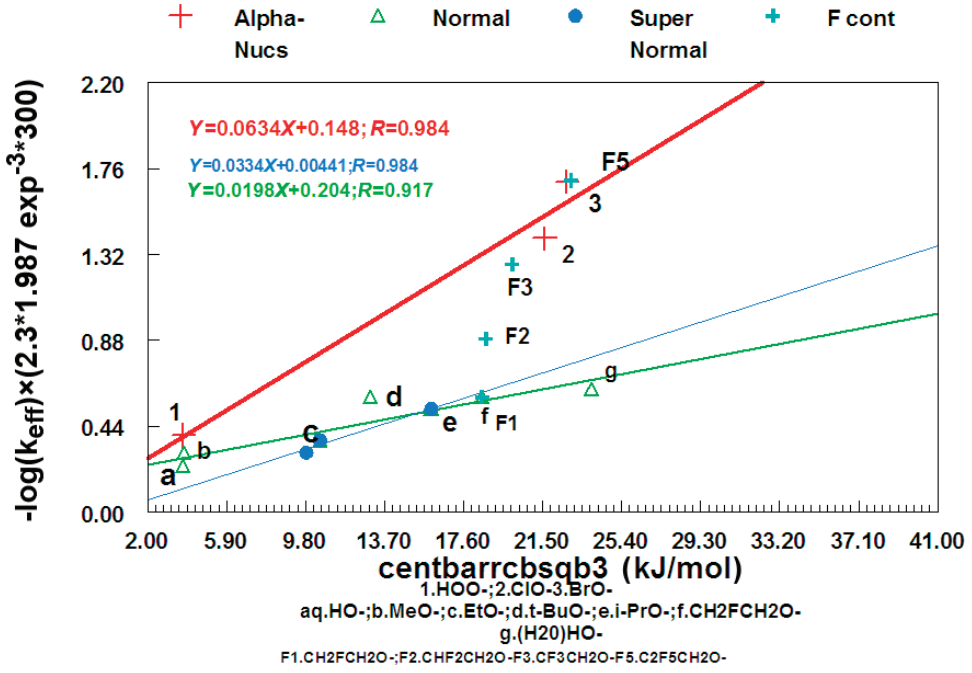

A further point deserves mention. Blanksby and co-workers[1] apparently used only the B3LYP\aug-cc-pVTZ energies at 0 K and added the ZPE energy from B3LYP\6–31+G(d), resulting in an electronic energy that lacked the thermal correction to 298.15 K. The temperature at which the reactions were done is stated as 307 K. Examination of this point to link the theoretical results to experimental ones deserves an attempt.

We examined the DMMP system using the original HOO^- anion, MeO^-, and HO^- anion, for comparison with the MeOFrm system. Likewise, the MeO^- was examined in the formate system. Thus, a direct comparison is possible between the two systems for the alleged α-effects.

A model chemistry similar to G2(+) was used by performing CBS-lq(startmp2) after the normal mp2/6–31+G(d)/HF/6–31+G(d)/ treatment in G2(+), thus, CBS-lq(startmp2)\mp2\6–31+G(d)\hf\6–31+G(d). The results are presented in Table 5. This choice of model chemistry was made because the jobs for the DMMP system at the CBS-QB3(startmp2) level were

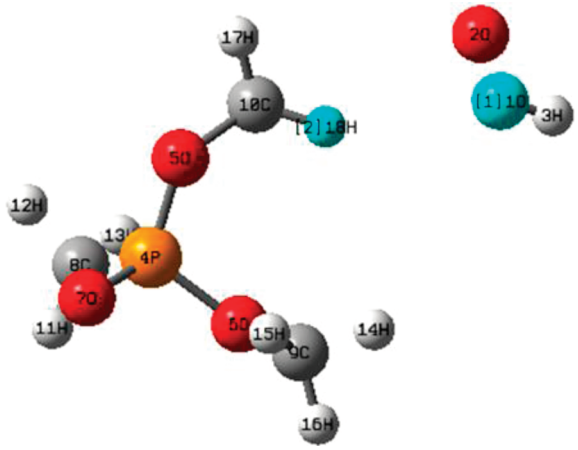
Fig. 9. HOO^- pole vaulting over the C–H bond barrier.



very large and very slow for our available facilities. The CBS-lq model chemistry allows easy treatment of both esters' relativities at the same modeling level and supplies thermodynamic data that is directly comparable in both systems.

The overall barriers are surprisingly the same within both B3LYP\aug-ccpVTZ and CBs-lq models. However, the central barriers are markedly different. The predicted reactivity at 298.15 K gives the order of reactivity as $HOO^- > MeO^- > HO^-$ from the NAC complex for the DMMP system. From the NNAC complex, the order is $HOO^- > HO^- > MeO^-$ at 298.15 K. This result indicates that central barriers with both NAC and NNAC complexes increase with increasing temperature, but the reactivity order is not the same from each set of barriers. Likewise, the overall barriers show $HO^- > HOO^- > MeO^-$.

Table 6 summarizes the issue of overall versus central barrier use to determine the existence or sizes of the α-effects in these two systems. Clearly, selection of the type of barrier will be crucial in the observation of an α-effect or evaluation of its size.

Combining the barrier information with either Fig. 4 or a similar plot of central barrier vs GPA discloses the fact that where one selects the normal α-nucleophile pair along the GPA axis determines both existence and size of the α-effect. An additional point was examined with BOMD trajectories to examine the question, "Is there really a pathway from the NNAC configuration, such as can be used (NAC) for determining the S_N2 α-effect?" The simplest case is for the HO–MeOFrmt system. Following a suggestion of Uggerud,[14] who used Rice–Kramers–Kassel–Marcus (RKKM) theory, we ran the BOMD trajectories backward. From the NNAC configuration for HO^-, shown as structure **2**, the BOMD trajectory was run with an input of temperature at 300 K and 1500 points. At the termination of 1500 points there was no pathway found to obtain the NAC configuration for an S_N2 reaction from the NNAC conformation. By contrast, from the S_N2 TS the NNAC configuration was attained in 326 cycles. Similarly, all the nucleophiles with MeOFrm gave no approach to their corresponding NAC configurations, nor did the nucleophiles used in the DMMP system attain the NAC S_N2 configuration from the NNAC one. Therefore, it is not possible to give credence to the α-effect for the system reported for DMMP. The G03W output files are available for examination from the corresponding author. This conclusion indicates agreement with the doubt expressed in Villano et al.[17] A recent report on S_N2 reactions with halide ions and methyl iodide modeled with trajectory simulation complementing crossbeam experiments indicated that along some trajectories the methyl halide, with sufficient energy (1.9 eV), undergoes reaction by a roundabout mechanism involving rotation of the methyl group, as well as the traditional NAC configuration.[18] When the BOMD routine was run with the anion and neutral oriented to favor S_N2 reaction with methylformate, it was observed that similar rotation of the anion–substrate pair to favor the NNAC configuration occurred in several trajectories and also for the DMMP system.

Table 8. The electrostatic energy in three S-containing α-nucleophiles and the CH_3 in S_N2 transition states.

Discussion

It has been noted that the α-effect probably involves many factors. A review exists for the α-effect in solution.[19] The possibility of simplification to a small number of factors in studying the GP α-effect is at least nominally attractive. However, the present paper shows that such GP studies are not without problems. It is clear that the electronic effects differ within the nucleophiles studied in this paper, and do so in a consistent direction that indicates greater electronic reactivity for the HOO^- ion over both the HO^- and MeO^-. The method of definition, from central barriers computed from NAC, non-NAC (NNAC), or the overall barriers, is important because the energy values differ between the barrier sets. From overall barriers, as in Fig. 4, selection of a particular nucleophile at a particular GPA and a corresponding point on the other regression line denotes a difference in overall barrier for that pair of nucleophiles. This energy difference defines the size of the α-effect for that α-nucleophile – normal nucleophile pair. With no corresponding nucleophile present on the opposite line, the value of the barrier at that point still provides an estimate of the α-effect for the nucleophile selected. Similarly, the two types of central barriers (NAC or NNAC) can be determined in the corresponding two-line plots of barrier height vs GPA. The lines in Fig. 4 are similar to the LFER provided by Ren and Yamataka[3–5] for reactions with methyl halides. An intriguing comparison of the Ren and Yamataka[3–5] data plot (not shown) and the formate data is to note that the ratios of slope of the lines (slope for normal nucs/slope for α-nucs) with three different leaving groups are F = 1.07, Cl = 0.93, and Frm = 1.49. These numbers indicate that the different leaving groups cause differences in the degrees of convergence (or divergence with Cl^- leaving group) of the two lines. The point of convergence is where the size of the α-effect goes to zero, and the implication here is that this zero α-effect point depends on features in the leaving groups. In Fig. 4 the position of the point for HO^- (not included in the regression line) indicates a kind of super reactivity or basicity for this nucleophile, indicating a further complication in GP determination of the α-effect.

Employing the concept of pushing or pulling electron density via substituents along the bonding framework, the points along the blue line in Figs. 2 and 4 were obtained. The existence of these lines and the degree of correlation they exhibit have great powers of explanation about why it has been so difficult to obtain agreement, or even consistent determinations, of the α-effect in the GP. Some GP anions will behave with greater reactivity than a corresponding (GPA-matched) α-nucleophile.

Figure 2, showing central barriers for nucleophiles versus MeOFrmt S_N2 reactions, provides the QMRE (*B*) values as well as energies. The trends in *B* values indicate an electronic affect that provides interpretation of the point that where one selects the pair of normal α-nucleophiles for comparison is reflected in the QMRE energy at the avoided crossing point. When the *B* values are quite close, the detection of an α-effect becomes very difficult. At lower GPA values, the designation of an α-effect is easier, and the differences in *B* values are widely different. The findings that the electronic features of the α-nucleophiles differ markedly from the normal nucleophiles at the TSs indicates that at least one factor in the expression of the size of the α-effect involves such electronic differences. Of course, other factors may be involved, such as solvent effects, in its expression.

The AIM results indicate that electron density between the nucleophilic O atom and the displaced Me group varies only a small amount between the α-nucleophile system and the normal nucleophile system. The α-nucleophile succeeds in transferring electrons to the forming bond best, but the ethoxide case is nearly the same amount. At BCPs connecting atoms in the nucleophile to the nucleophilic atom, the α-nucleophile has the least density, although this number depends on the leaving group system. The large **ρ** numbers for the internal parts of normal nucleophiles indicate that the storage of electrons in this region is larger than for the H–O–O^- and is slightly less available to enter into forming the new bond. The net balance between donation to the forming bond and transfer into the breaking bond indicates that all the nucleophiles are approximately equal in donation to the breaking bond. The charges (*Q*) on the atoms and groups indicate positive charges on the atoms next to the O^- for all normal nucleophiles, but a negative charge on the α-atom in H–O–O^-. For HOO^-, the nucleophilic atom is actually less negative than those of the normal nucleophiles by a large amount.

Charges on the transferring CH_3 group are positive and largest in the HOO case with the $^-$MMP leaving group (LG), but quite similar in the –OFrm cases. Similarly, the charge on the LG O atom is very similar for all the nucleophiles, although a difference occurs between the two systems with the DMMP system having more charge on this atom than the Frm system. The elipticity at the BCP in AIM theory is related to the amount of p character, as in an ethylene double bond. In the DMMP (-lq) case, the size of the elipticity between the nucleophilic O and transferring Me group is nearly threefold that for the normal nucleophile. Similarly, the Frm (-lq) case group is greatly enhanced in elipticity at this BCP for HOO^- over the alkyl-O^- nucleophiles. HO^- as the nucleophile shows more elipticity than HOO^-. Between HO–O bonds the ellipticity ranges six- to seven-fold greater than the O atoms over the analogous BCP in the normal nucleophiles. Summarizing the AIM results we see that the quality of the electron density, as in s, p, sp, etc., seems to be the major difference between HOO^- and the normal nucleophiles.

The NBO study reveals that the LP electrons on the nucleophiles have several roles. In the DMMP system the HOO^- anion distributes electrons of LP(3) on the nucleophilic O atom into both the BD* between O5 and C10, thus, this is the breaking and making bond process, with a value of 50.37 kcal/mol. This same LP distributes to all three BD*C–H orbitals for a total of 8.64 kcal/mol. The contributions are not symmetrically disposed. The total DA energy (DAEn) sums to 59.01 kcal/mol. The MeO^- behaves quite differently, donating from two different LPs on the nucleophilic O^-. LP(2) and LP(3) each contribute for a sum of 50.47 kcal/mol to the bond-making – bond-breaking process. LP(3) also contributes two nearly symmetrical contribution and one larger one to the BD*C–H bonds, for a total of 58.73 kcal/mol. The difference of 0.28 kcal/mol marginally favors a greater TS stability to the HOO^- DMMP TS. This sum is supplemented by a DA contribution 0f 0.88 kcal/mol for LP(2) on O^- to the BD*O–H of the nucleophile. This orbital is of SP3.6-S composition, and the LP(2) orbital is 99% P. The composition of this DA contribution agrees fairly well with the size of the AIM elipticity at the BCP for this bond. The MeO–DMMP TS lacks this donation – back donation DA stabilization, although there does exist back donation into the BD*C–H bonds of the nucleophile. The Nuc–MeOFrm system NBO analysis shows a similar DA contribution from BDO–H to BD*O–O in the HOO^- anion and a back donation of the LP(2) to the BD*OH. This LP(2) is the pair that does the most important segment of the bond making – bond breaking at the CH_3 group. The total DA energy is 74.38 kcal/mol. The HOMeOFrm system lacks the extra HO bond for the DA stabilization apparent in the HOO^- case. The BD*CH_3–OFrm in the TSs for both cases are very rich in p character content, showing substantial agreement with the AIM BCP elipticites. The DA energies are considerably less for the HO^- TS case compared with the HOO^- TS, and donation into the BD*C–H bonds of the transferring CH_3 group is significantly less for HO–MeOFrm than for HOO–MeOFrm. The MeO–MeOfrm system shows a total DA stabilization energy close to the value for HO–MeOFrm, but interestingly less than EtOMeOFrm by ~3.5 kcal/mol. This DA energy for the EtOMeOfrm TS can be traced to the donation from the C–C bond of the Et group. It is helpful to recall that the wave functions used for this NBO perturbation analysis do not have any correction for electron correlation effects.

The VB treatment indicates a pattern of QMRE values consistent with the NBO analysis. The QMRE values differ as the LG changes, with the better phosphonate LG providing the larger QMRE numbers, except in the HO–DMMP TS case where the QMRE is smaller than for the HO–MeOFrmt case by 1 kcal/mol. The numbers apply only to the TSs involved. They show nothing about the pathways to those TSs. The orders of the nucleophilic reactivities are $HOO^- > MeO^- \approx HO^-$ for DMMP and $HOO^- > MeO^- \approx HO^- > EtO^-$ for MeOFrmt. The branching ratios of both systems would indicate agreement with the theoretical results. The question remains, "Do these numbers indicate an α-effect?" The murkiness of the present GP attempts to study the α-effect are illustrated by the following considerations. Mass spectroscopists, who study nucleophilic methyl transfers using SIFT tubes, such as the University of Colorado group, present their results in terms of plots of efficiencies (k_{rxn}/k_{col} = efficiency, where k_{rxn} = absolute rate and k_{col} = collision rate) on semi-log plots vs GPA.[17] Theoreticians plot barrier height vs GPA and predict an α-effect from differences in barrier heights at a particular GPA value, as in Fig. 4. These types of plots (LFERs) differ from the semi-log plots, predicting substantial α-effects or small ones depending on where one selects the GPA point. Consider Figs. 7 and 8 which plot LFERs for the published Bierbaum data for reactions with methyl chloride. In Fig. 7 the Y axis displays the –log(Eff), which is a transform of an energy term via $\Delta G = -RT \log(k_{rate})$ from TS theory. In Fig. 8 the Y axis is transformed into the same energy units as the GPA (kcal/mol). In this case the $T\Delta S$ term was neglected to use ΔH. Thus, these axes represent energy or something related by a simple transform to energy, and ensures that either central barriers or overall barriers provide a faithful correspondence of theoretical and experimental results in this case. One can then assess these plots as indicating that the –log (efficiencies) numbers reflect both overall and central barriers adequately. There are obvious differences between the α-nucleophiles and normal nucleophiles. This fact alone indicates the probable presence of the α-effect in some regions of the dual plot and near absence of one in others. We note that the behavior of the fluorine-containing nucleophiles is erratic compared with the other ones. The greater the F atom content the more nearly the barrier heights and efficiencies look like the ones on the α-effect line. Clearly, these nucleophiles would give very different conclusions for the presence or absence of an α-effect.

The fluorine-containing alkoxides deserve comment, since they seem to determine the conclusion of no α-effect in the published MS results for methyl chloride.[17] The NBO pertubation analysis of these nucleophiles and their TSs with S_N2 reactions with CH_3Cl discloses (at the 6–311+G(2d,p) model chemistry) that the DA energies of the LP electrons involved in DA interaction from the nucleophilic O^- with bond making–breaking and donation to the C–H* bonds is greatly affected by the number of F atoms in the anion. Wiberg[20] examined F-containing alkoxides with AIM theory and concluded from the AIM charges on the O atoms that increasing F content increased negative AIM charge on the O^- atom. The order was MeO^- (–1.478) > FCH_2O^- (–1.454) > F_3CO^- (–1.463), probably indicating larger nucleophilicity for the

CF_3O^- nucleophile.[20] A set of full NBO calculations for all the F-containing alkoxides and their TSs show that storage of electron populations in the C–C* orbitals gives much DA (DAEn) stabilization in the anions and donation from these depots affect attaining the TSs. The most important areas are bond making and bond breaking where the DA changes between the anions and the TS energies are C_2F_5 CH_2O^- = 7.41 kcal/mol and $CF_3CH_2O^-$ = 6.45 kcal/mol, indicating that the additional F-atom content actually increases electrons in the TS as though there is an electron-pair repulsion occurring. A similar phenomenon is discussed by Burton and Wheaton[21] in the productions of difluorocarbene. Hine and Langford,[22] in the early days of halocarbene chemistry, demonstrated the concerted nature of proton abstraction from chloro and bromo halodifluromethanes and indicated that the F atoms cause this owing to repulsion of the LPs involved. A reinforcement for the notion of repulsion of LP electrons on a non-fluorine atom by LPs on F atoms involves a computational study of the conformational analysis of fluorinated dimethyl ethers where the C–O–C bond angle was increased and the C–O bond lengths were reduced in the bond to the fluorinated C atom, and increased in the opposite one, thereby increasing the computed energy with increasing F-atom content and decreasing the rotational barrier height.[23] Such considerations have significant explanatory value in assessing the anomalous behavior displayed by fluoroalkanols in Fig. 7.

Table 7 shows a revealing comparison between the fluorinated alkoxides and other nucleophiles. The DAEn summed over the contributions indicate higher values for the multiple F-substituted alkoxides to bond making by donating into the BD*C–Cl. Similarly, multiple Cl substitution allows greater contribution to bond making. Other groups also provide this additional donation. The putatively best α-nucleophile (HOO^-) is comparatively modest in both DAEn donation and population of the BD*C–Cl and BD*C–H orbitals. This may indicate that some factor related to the quality of electron donation may be working in this case.

A more complete discussion of the MeCl reactivity system is the subject of a future paper (in preparation). These plots indicate that the GPMS efficiencies correlate well with either the overall barriers or central barriers, except for the efficiencies of the fluorinated alkoxides, which may correlate, but will have very different correlation numbers. The question of which type of barrier should be used remains.

The combined results of this electronic study and the BOMD studies indicate the following scenario to explain the findings. In the MS experiments, the generation of the anions and injection of the neutrals occurs at a temperature near 300 K, resulting in a statistical spread of kinetic energies in both the anions and neutral substrates. Random collisions of these entities result in kinetic energies in pairs. The pair anion–neutral, which has a combined kinetic energy at the level of the NAC results in the S_N2 reaction, will undergo an S_N2 reaction. The sum of small attractive forces available to hold the pair close to the NAC must be matched by energies smaller than what it takes to surmount the cage of C–H bonds in the CH_3 group. The number of these complexes is probably statistically determined. The much lower energy NNAC configuration entraps more of the anion–neutral collisions, resulting in the elimination reactions of the formyl H–C from methyl formate or, in the DMMP system, oscillation between MeO groups with no escape to the NAC position for S_N2 reaction. The branching ratios in the methyl formate case indicate much larger elimination or capture by the C=O group than the S_N2 reactions for both nucleophiles. Careful examination of the method of escape of the nucleophile from the NAC approach toward the NNAC position involves many collisions between the nucleophile and the methyl C–H bonds and atoms. This situation provides a kinetic energy trap for the nucleophile at the NAC position, with a small number of substrate–anion pairs possessing less energy than necessary to pass the H atoms. Figure 9 shows the progress in passing the C–H bonds in DMMP by HOO^-. In this case the HO group is close to the H atom (2.565 Å) before the O^- atom passes the H-atom barrier (2.924 Å), as though the HO group pole vaults the rest of the nucleophile over the barrier.

The number of pathways for reaction in these two esters and the percentage of each reaction and HOS^- are shown in Fig. 4. This trio forms the basis of a Popperian risky experiment to confirm the hypothesis that the α-effect is due to electrostatic attraction between a hard electronegative atom in the α-position and a positively charged methyl group being transferred.[24] In such a risky experiment, confirmation of the theory (or hypothesis) can be granted by the result only if the entire theory is placed at risk by performing the experiment. An example of the use of this philosophical tool is provided by Berson[25] in confirming Woodward–Hoffman rules for conservation of orbital symmetry. Table 8 shows the way in which the theory of electrostatic repulsion for the cause of the α–effect is not confirmed with this trio. The lowest overall TS energy from the free reactants is due to the HSO^- nucleophile, but it has a positive (repulsive) electrostatic energy. The HSS^- case plots on the same line as the other α-nucleophiles, but the HOS^- case plots more toward the normal nucleophile line and provides a smaller difference in TS energy, although it should provide a greater (more stabilizing) energy lower than the other two S-containing α-nucleophiles.

Conclusions

Several conclusions can be drawn from this report. First, all the TS calculations showed greater favorable electronic behavior for the reactions of α-nucleophiles than for the GP-matched normal nucleophiles. The AIM results indicate larger π-type character in the forming bonds than the normal nucleophiles and indicate more involvement of electrons from bonds adjacent to the nucleophilic atom. Second, the NBO DA energies for the TSs of the α-nucleophiles indicate greater stabilization for those TSs over those involving normal nucleophiles. The exact amount of stabilizing energies involved will involve more refinement than expressed in this paper. Third, the VB results show that the QMRE found at the avoided crossing point of the wave functions of the product and reactant side of a SCD show a larger stabilization for the α-nucleophile TSs than for the normal ones. Fourth, the BOMD studies indicate that a complication of the GP reactions occurs in the pathway from ions + neutrals to NAC or NNAC complexes and between these pathways. Neither the DMMP or the methyl formate system allows a ready two-way passage between complexes, thus, the reported α-effect for the DMMP system must be re-examined. Finally, the three

questions all have the answer Yes. Sometimes normal nucleophiles are not able to be distinguished from α-nucleophiles. Sometimes normal nucleophiles possess more reactivity than GPA-matched α-nucleophiles. With the answer Yes to question 1 it follows that question 3 shows that sometimes α-nucleophiles possess reactivity less than GPA-matched normal nucleophiles. Finally, the evidence from the S-containing α-nucleophiles indicates that electrostatic attractions cannot play a major role in providing an α-effect.

Abstract: A convenient one-pot method for the synthesis of 4-arylquinolin-2(1*H*)-ones and 4-arylcoumarins has been described. The successive Heck reaction on substituted 2-iodoaniline and 2-iodophenol catalyzed by a Pd/nickel ferrite catalyst followed by in situ cyclization was the key step. The scope of this methodology was extended to the synthesis of bioactive 3-alkenyl derivatives of 4-arylquinolin-2(1*H*)-ones.

Key words: 4-arylquinolin-2(1*H*)-ones, Pd/nickel ferrite, Heck reaction, cross-coupling reactions, heterogeneous catalysis.

Résumé : On décrit une méthode monotope commode de synthèse des 4-arylquinoléin2(1*H*)-ones et 4-arylcoumarines. L'étape clé est une réaction successive de Heck sur une 2-iodoaniline et le 2-iodophénol, catalysée de un catalyseur de Pd/ferrite de nickel, suivie par une cyclisation in situ. On a étendu la portée de cette méthodologie à la synthèse de dérivés 3-alkényles biologiquement actifs des 4-arylquinoléin-2(1*H*)-ones.

Mots-clés : 4-arylquinoléin-2(1*H*)-ones, Pd/ferrite de nickel, réaction de Heck, réactions de couplage croisé, catalyse hétérogène.

[Traduit par la Rédaction]

Introduction

Quinolin-2(1*H*)-ones constitute the basic structural fragments of many natural and synthetic biologically active molecules. They shows antiviral, antineoplastic, anti-ischemic, antiallergic, antihypertensive, and antiulcerative activity.[1] Moreover, quinolin-2(1*H*)-ones also serve as valuable synthetic intermediates because they can be easily transformed into 2-substituted quinolines (e.g., 2-Cl, 2-OTf), which can undergo further functionalization, such as nucleophillic aromatic substitutions and Pd-catalyzed coupling reactions.[2]

In particular, functionalized 4-aryl-quinolin-2(1*H*)-ones (Fig. 1) are excellent inhibitors of acyl co-enzyme A and cholesterol acyltransferase and are potent openers of high-conductance calcium-activated K+ channels.[3,4] They also show potent antibacterial activity and inhibit the replication of human immunodeficiency virus (HIV) induced by tumor necrosis factor (TNF-α) with an IC_{50} of 2.5 μm.[5] The derivatives of 3-(quinolin-3-yl) acrylates **4** and the corresponding reduced allylic alcohols have been identified by a group from Bristol-Myers Squibb (BMS) as novel and potent maxi-K channel openers useful for the treatment of male erectile dysfunction.[3a] In addition, R 115777 (Zarnestra, **5**), an orally active antitumor agent, is currently undergoing human clinical trials.[3c–3d] Although quinolinones exhibit a wide range of biological activities, only a few methods for the synthesis of 4-arylquinolinon-2(1*H*)-ones are reported in the literature.[6] In most instances, an arylquinolin-2(1*H*)-one moiety was achieved by acid–base catalyzed cyclization of *N*-acyl-*o*-amino benzophenone or via closely related procedures.[3c–3d] However, starting materials used for the cyclization approach are mostly amino ketones, which are not readily available; furthermore, these procedures suffer from the disadvantage that the aryl ring attached to the C-4 position of quinolinon-2(1*H*)-ones has to be introduced very early in the overall synthetic scheme, which limits the further laboration of this substituent.

Several research groups have recently demonstrated the successful use of a Pd-catalyzed C–C coupling reaction for the synthesis of quinolin-2(1*H*)-one as a facile, versatile, and practical route.[7,8] Xu et al.[8b] reported a solid-phase protocol (HypoGel Br resin) for the synthesis of 4-substituted quinolinones using Pd-catalyzed Suzuki and Negishi cross-coupling reactions in 63%–90% yield within 14 h. Cacchi and co-workers[8c–8d] developed a methodology for the synthesis of 4-aryl-quinolin-2(1*H*)-ones from 2-bromocinnamides and aryl iodides through Heck reaction followed by an intramolecular Buchwald–Hartwig amination sequence. In addition to this, they also reported Heck reaction and in situ cyclization of methyl β-(*o*-acetamidophenyl)acrylates with aryl iodides for the synthesis of 4-aryl-quinolin-2(1*H*)-ones in the presence of Pd $(OAc)_2$ and KOAc in DMF at 120 °C.[8g] Kappe and co-workers[8e] reported the synthesis of functionalized 4-aryl-quinolin-2(1*H*)-ones by Suzuki coupling from 4-chloroquinoline-2(1*H*)-one and boronic acid using a microwave. Although they reported a good yield in a shorter reaction time, the use of a microwave for industrial large-scale synthesis is not viable and also the

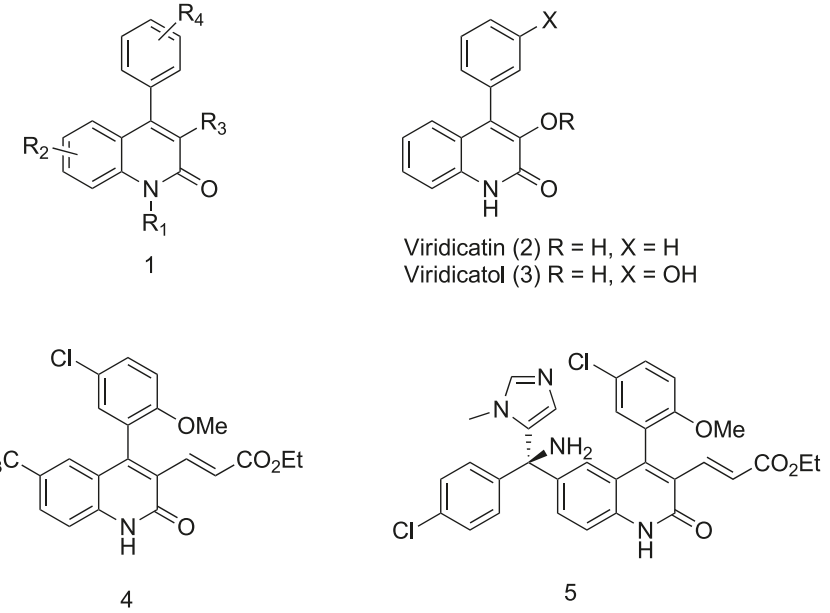
Fig. 1. Biologically active 4-arylquinolin-2(1*H*)-one derivatives.



required boronic acids are costly. More recently, Inamoto et al.[8a] reported a synthetic approach through C–H bond functionalization and intramolecular amidation sequencing in the presence of a catalytic amount of $PdCl_2$ and $Cu(OAc)_2$ under an O_2 atmosphere. Although these authors have reported moderate to good yields of 4-arylquinolin-2(1*H*)-ones, nonrecovery of the precious palladium catalyst and Pd metal contamination of the final products make these processes commercially undesirable. Our ongoing interest is towards the development of new catalyst system; recently, our group[9a,9c,9d] and Manorama and co-workers[9b] reported the filtration-free magnetically separable $Pd/NiFe_2O_4$ as an efficient and inexpensive catalyst for the Heck reaction. In light of this successful methodology, we anticipated that the C–C bond formation using the Heck reaction could lead to an efficient protocol for the synthesis of 4-arylquinolin-2(1*H*)-ones. Herein we report the novel use of Pd supported on nickel ferrite as a heterogeneous and recyclable catalyst for the synthesis of functionalized 4-arylquinolin-2(1*H*)-ones and 4-arylcoumarins in one pot. We have also demonstrated the applicability of this methodology for the synthesis of (2*E*)-ethyl-3-(4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1,2-dihydro-1-methyl-2-oxoquinolin-3-yl)acrylates in four steps.

Results and discussion

Initial studies were performed using 4-(trifluoromethyl)-2-iodoaniline, acrylic acid, and iodobenzene to determine the optimal reaction conditions. We examined various palladium sources, solvents, bases, and temperatures and the results obtained are summarized in Table 1. Amongst the different Pd sources studied, palladium acetate ($Pd(OAc)_2$), tetrakistriphenylphosphine palladium(0) ($Pd(PPh_3)_4$), and tetraamminepalladium(II) chloride ($Pd(NH_3)_4Cl_2·H_2O$) gave good to moderate yields of corresponding 6-(trifluoromethyl)-4-phenyl-2-quinolinone products (Table 1, entries 5 and 6). However, 1,1-bis(diphenylphophino)ferrocene–dichloropalladium ($PdCl_2$(dppf)) and palladium chloride ($PdCl_2$) gave very poor yields (Table 1, entries 3 and 4). The presence of a Pd(IV) oxidation state in the sodiumhexachloropalladate tetrahydrate ($Na_2PdCl_6·4H_2O$) would not allow the catalyzation of the Heck reaction (entry 7).

We conclude that the Pd sources having oxidation states Pd(II) and Pd(0) were catalytically active for the Heck reaction, whereas the Pd(IV) oxidation state was not active at all. In comparison with homogeneous $Pd(OAc)_2$, a slight increase in the yield was observed for the $Pd/NiFe_2O_4$ catalyst (Table 1, entries 2 and 8). Since it was easily separable from the reaction mixture by applying an external magnetic field and no product contamination with Pd metal was observed, from this point forward $Pd/NiFe_2O_4$ catalyst was used unless otherwise stated. Among the different bases studied, triethylamine (TEA) and tributylamine (TBA) were found to be the best (Table 1, entries 8 and 9). These organic bases were superior to inorganic bases such as $NaHCO_3$, NaOAc, and Na_2CO_3 (Table 1, entries 8–12).

The effect of various solvents for consecutive Heck reaction and in situ cyclization was studied and the results showed that DMF and CH_3CN gave 75% and 66% yield, respectively, after 18 h, using TEA as a base. Nonpolar solvents such as toluene and xylene were unproductive (Table 1, entries 15 and 16). Temperature studies revealed that 85 °C was enough to activate the $Pd/NiFe_2O_4$ catalyst for the Heck reaction, whereas at higher temperature (100 °C), a lower yield was observed. Various olefins such as methyl acrylate, ethyl acrylate, butyl acrylate, and acrylic acid were reacted with 4-(trifluoromethyl)-2-iodoaniline and it was found that acrylic acid gave maximum yield.

Using the optimized reaction conditions we explored the general applicability of the $Pd/NiFe_2O_4$ catalyst for the consecutive Heck reaction of different 2-iodoanilines followed by cyclization to yield corresponding 4-arylquinolin-2(1*H*)-ones (Table 2). The transformation of various substituted aryl iodides and bromides to corresponding 4-arylquinolin-2-(1*H*)-one derivatives offered moderate to good yields. Aryl iodides gave superior yields of the desired product as

[a]GC yields.

compared with aryl bromides. The less reactive chlorobenzene and phenylboronic acid did not couple in the second Heck reaction condition (Table 2, entries 11 and 12). The aryl iodides reacted in the second Heck coupling reaction with (*E*)-3-(2-amino-5-(trifluoromethyl)phenyl)acrylic acid containing electron-donating methoxy groups at the ortho, meta, or para positions produced the corresponding 4-arylquinolin-2-(1*H*)-one compounds **10**–**12** in 59%, 61%, and 67% yields, respectively (Table 2, entries 4–6).

We also attempted the synthesis of a biologically active flavonoid (4-aryl-2*H*-chromen-2-one, neoflavone),[10] by a similar route using 2-iodophenol and ethyl acrylates as starting materials (Table 3).

2-Iodophenol successfully reacted with ethyl acrylate and gave 96% yield of the corresponding (*E*)-3-(2-hydroxyphenyl)acrylate, but the second Heck reaction with iodobenzene and in situ cyclization was ineffective. However, after optimization of the reaction conditions we could achieve a maximum yield of up to 31% of the corresponding 4-phenyl-2*H*-chromen-2-one (Table 3, entry 1).

A hot filtration test[11] was performed to investigate Pd leaching into the reaction mixture. The test was done for the 4-(trifluoromethyl)-2-iodoaniline (Table 1, entry 8). After 18 h, the $Pd/NiFe_2O_4$ catalyst was removed from the hot reaction mixture by applying an external magnet and the clear solution was filtered to remove any dispersed particles. The filtrate was concentrated and digested in the presence of concd HNO_3 + H_2O_2. The filtrate was then diluted to 50 mL using a volumetric flask and analyzed by atomic absorption spectroscopy (AAS) analysis. The Pd content detected in the filtrate was only 2.1 ppm.

We believe that the present one-pot synthesis of 4-arylquinolin-2(1*H*)-ones proceed via the pathway shown in Scheme 1. The *trans*-2-aminocinnamic acid formed during the first Heck reaction should not cyclize without first isomerizing.[12] Oxidative addition of Pd to the aryl halide added in the second step attached to an olefinic double bond of *trans*-2-aminocinnamic acid and gave alkyl palladium species **21**. Species **21** then underwent β-hydrogen elimination to produce species **22**, which generated product **7**. Alternatively, **7** also could be formed by the route via intermediate **23** followed by the β-hydrogen elimination.

The usefulness of our methodology was extended to the synthesis of biologically important maxi-K channel opener **4** using the $Pd/NiFe_2O_4$-catalyzed Heck reaction. The synthesis of **4** has been previously described by Hewawasam et al.[3a] in 2003 starting from *N*-Boc-protected 4-(trifluoromethyl)aniline, which involves more than 10 linear steps. The key step in their synthesis was a base-catalyzed cyclization of an appropriate *N*-acyl-*O*-aminobenzophenone precursor. Kappe

and co-workers[8e] reported the synthesis of **4** from *N*,*N*-bis[4-(trifluoromethyl)phenyl]malonide using Pd-catalyzed Suzuki and Heck reactions assisted by microwave, which involves six steps. Recently, Wu and co-workers[8f] also developed a general synthetic methodology for the synthesis of **4** in a combinatorial format starting from 3-bromo-4-trifloxy-quinolin-2(1*H*)-one. Although there are reported methods for the synthesis of **4**, none of the reported methods is practical, concise, or has a short synthetic route.

Our synthesis (Scheme 2) commenced with the consecutive Heck reaction of 4-(trifluoromethyl)-2-iodoaniline (**6**) with acrylic acid and 4-chloro-2-iodophenol was added in a second step in DMF at 85 °C using Pd/$NiFe_2O_4$ as the catalyst in the presence of TEA base. We observed the formation of the

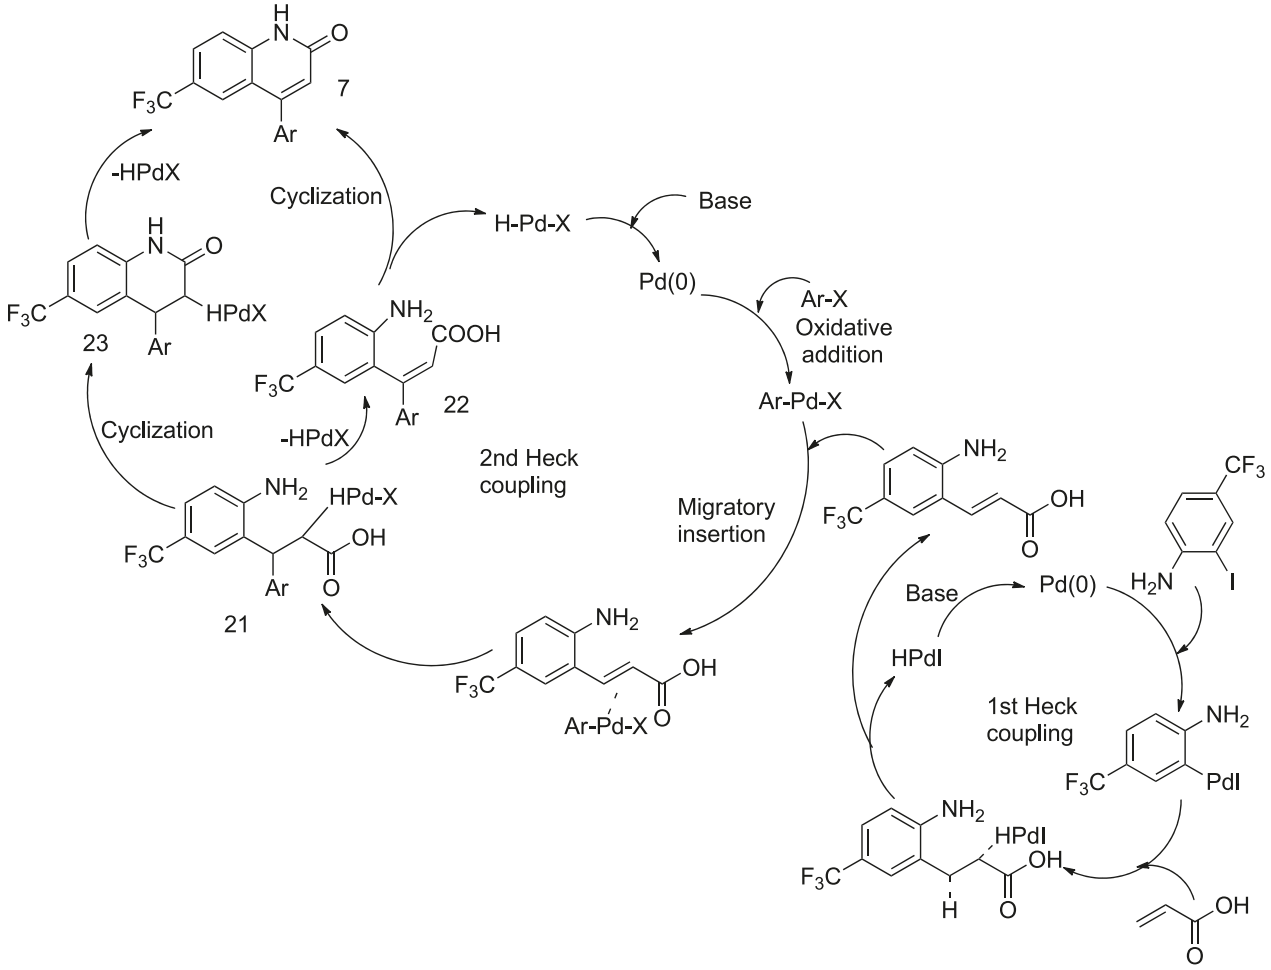
Scheme 1. Catalytic cycle for the consecutive Heck reaction and cyclization step.



desired product (**24**) in 75% yield. The N- and O-methylation of **24** to **25** was carried out using methyl iodide in DMF at room temperature in the presence of K_2CO_3 base. We introduced the bromine moiety at the C-3 position of **25** by using our photochemical reaction approach with *N*-bromosuccinamide (NBS) in acetonitrile under UV irradiation.[13] The required 3-bromo product (**26**) was obtained in 78% yield. Further Heck vinylation of 3-bromoquinolinone (**26**) with ethyl acrylate in the presence of 2.5 mol% $Pd/NiFe_2O_4$ catalyst offered the target molecule **4** in its *N*-methyl-protected form, but in very poor yield (12%). To improve the yield of **4**, we varied the palladium precursor. The reaction carried out with $Pd(OAc)_2$ gave only 26% yield. To further improve the yield, the reaction was performed with $Pd(PPh_3)_4$ in an inert atmosphere, and this transformed into a 79% yield of the product **4**.[14]

Conclusion

In summary, we have presented a practical useful one-pot methodology for the synthesis of various 4-arylquinolin-2(1*H*)-ones from 2-iodoanilines in good yields. The heterogeneous $Pd/NiFe_2O_4$ catalyst efficiently catalyzed the successive Heck reaction in one pot and it could be easily separated from the reaction mixture by applying an external magnetic field. The scope of this methodology was successfully applied for the synthesis of biologically active 3-alkenyl-4-aryl-2-quinolinone from 4-(trifluoromethyl)-2-iodobenzamine in four linear steps in an overall yield of 42.5%.

Experimental section

General methods

Unless otherwise stated, all experiments were performed in an ambient atmosphere. All glasswares were acid and base washed and oven-dried before use. The catalytic reactions were carried out in 25 mL two-neck round-bottomed flasks equipped with a reflux condenser in an air atmosphere. The Pd salts/complexes, reactants, and solvents were obtained from Sigma-Aldrich/Merck or Spectochem and used as received without further purification or drying. The progress of the reaction was monitored by gas chromatography (GC; HP-5890, series II, equipped with a HP-5 capillary column and an FID detector) and TLC. The products were isolated by extractive work-up using ethyl acetate and were purified using silica gel (100–200) column chromatography. The products were characterized by GC–MS (Shimadzu QP-5050, DB-5 column, and FID detector), FTIR (8400 Shimadzu), and NMR (Varian 300 MHz spectrometer in $CDCl_3$ or DMSO-d_6 with TMS as an internal standard) spectroscopies. The Pd content was detected using an atomic absorption spectrophotometer (AAS), model No. Chemito AA-201.

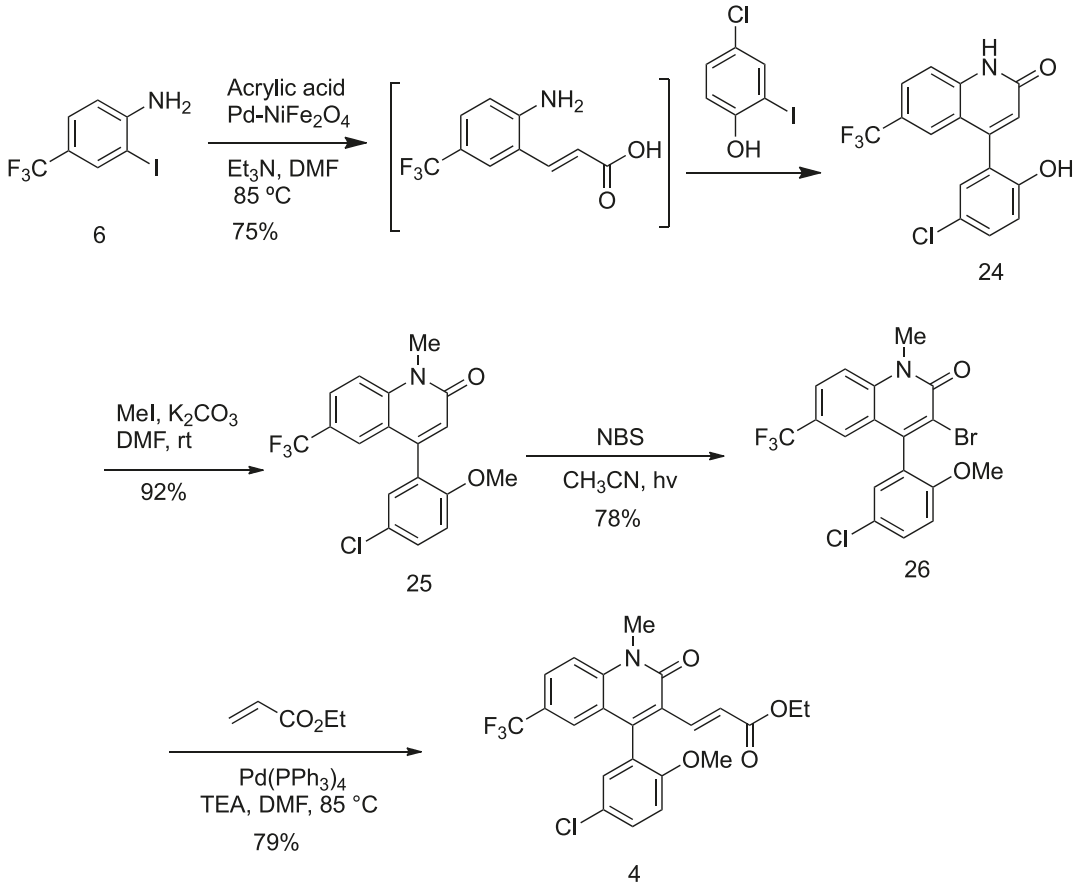
Scheme 2. Synthesis of the 3-alkenyl-4-aryl-2-quinolinone derivative.



*General one-pot procedure for the synthesis of 4-arylquinolin-2(1*H*)-ones (products 7–17)*

To a 25 mL two-neck round-bottomed flask attached with a reflux condenser were added 2-iodo-aniline (1 mmol), acrylic acid (1.5 mmol), triethylamine (3.25 mmol), and Pd/$NiFe_2O_4$ (2.5 mol %) in 4 mL of DMF solvent. The reaction mixture was placed in a preheated oil bath at 85 °C for 30 min. The reactions were analyzed by GC and TLC. The reaction mixture (0.25 mL) was withdrawn by using a syringe, then diluted with water (1.0 mL), and extracted with ethyl acetate (1.0 mL). The ethyl acetate layer was separated, dried over sodium sulfate, and analyzed by GC. After the complete conversion of starting material, the new substrate, aryl halide (1.25 mmol), was added and the reaction continued for a further 16 h.

After the specified time of heating, the reaction mixture was cooled to room temperature and the catalyst was separated from the reaction mixture by applying an external magnet, and the clear solution was extracted with ethyl acetate (3 × 10 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 and solvent was evaporated under reduced pressure. The crude product was then purified by silica gel column chromatography (hexane – ethyl acetate, 7:3). All products were analyzed and characterized by GC, GC–MS, IR, and NMR.

*General one-pot procedure for the synthesis of 4-aryl-2*H*-chromen-2-ones (products 18–20)*

To a 25 mL two-neck round-bottomed flask attached with a reflux condenser were added 2-iodophenol (1 mmol), ethyl acrylate (1.5 mmol), triethylamine (3.25 mmol), and Pd/$NiFe_2O_4$ (2.5 mol %) in 4 mL of DMF solvent. The reaction mixtures were heated at 85 °C for 30 min. The reactions were monitored by GC and TLC. The reaction mixture (0.25 mL) was withdrawn by using a syringe, then diluted with water (1.0 mL), and extracted with ethyl acetate (2 × 1.0 mL). The ethyl acetate layer was separated, dried over sodium sulfate, and analyzed by GC. After the complete conversion of starting material, the new substrate, aryl halide (1.25 mmol), was added and the reaction continued for a further 16 h.

After the specified time of heating, the reaction mixture was cooled to room temperature and the catalyst was separated from the reaction mixture by applying an external magnet, and the clear solution was extracted with ethyl acetate three times. The combined organic extracts were dried over anhydrous Na_2SO_4 and solvent was evaporated under reduced pressure. The crude product was then purified by silica gel column chromatography (hexane – ethyl acetate, 7:3). Purified products were analyzed and characterized by GC, GC–MS, IR, and NMR.

*Synthesis of 4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1-methylquinolin-2(1*H*)-one (25)*

To a solution of **24** (0.34 g, 1.0 mmol) in DMF (4.0 mL) were added methyl iodide (0.35 g, 2.2 mmol) and K_2CO_3 (0.44 g, 3.2 mmol) at ambient temperature. The reaction mixture was stirred for 3 h at room temperature and then diluted with ethyl acetate (3 × 20 mL). The organic layer was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

washed with water (2 × 10 mL) and brine (10 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated under reduced pressure, and the residue was purified by silica gel column chromatography using hexane – ethyl acetate (1:4) as the eluent to give **25** (0.36 g, 96% yield) as a white solid.

*Synthesis of 3-bromo-4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1-methyl quinolin-2(1*H*)-one (26)*

A mixture of **25** (0.37 g, 1.0 mmol) and NBS (0.35 g, 2.0 mmol) was stirred in 4 mL of acetonitrile under an N_2 atmosphere in the presence of a Philips HPL-N lamp (250 W, k_{max} = 200–600 nm) fitted with a water circulation arrangement at room temperature. After completion of the reaction (monitored by TLC and GC), the reaction mixture was quenched with cold water and extracted with ethyl acetate (3 × 25 mL). The organic phase was washed with water and brine, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure to afford the crude product, which was purified by column chromatography over silica gel (60–120 mesh) using ethyl acetate and petroleum ether (1:2) as the eluent to give **26** (0.35 g, 78% yield) as a white solid.

*Synthesis of (2*E*)-ethyl 3-(4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1,2-dihydro-1-methyl-2-oxoquinolin-3-yl) acrylate (4)*

In an oven-dried 25 mL two-neck round-bottomed flask attached with a reflux condenser were added **26** (0.44 g, 1.0 mmol), $Pd(PPh_3)_4$ (0.06 g, 5.0 mol%), ethyl acrylate (0.30 g, 3.0 mmol), triethylamine (0.25 g, 2.5 mmol), and 5.0 mL of dry DMF. The reaction mixture was then heated at 85 °C for 12 h. After the completion of reaction (monitored by TLC), the heating was discontinued and the reaction was quenched by adding ice-water (25 mL). The whitish precipitate was then extracted with ethyl acetate (3 × 25 mL). The combined organic extracts was washed with brine (30 mL), dried over Na_2SO_4, and solvent was evaporated under reduced pressure. The crude product was purified by silica gel (60–120 mesh) column chromatography using ethyl acetate and petroleum ether (1:1) as the eluent to give **4** (0.37 g, 79% yield) as a white solid.

Characterization data for all products

*6-(Trifluoromethyl)-4-phenylquinolin-2(1*H*)-one (7)*

FTIR (KBr, cm^{-1}): 1265, 1475, 1573, 1685, 2918, 3315. ^{1}H NMR (DMSO-d_6) δ: 6.51 (s, 1H), 7.47–7.57 (m, 7H), 7.83 (d, 1H, J = 9.8 Hz), 12.20 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 116.0, 116.9, 118.0, 122.6, 123.1(q), 126.8, 128.5, 128.8, 129.1, 135.7, 139.8, 141.7, 150.9, 161.2. MS (EI): *m*/*z* 289 (M^+). Anal. calcd for $C_{16}H_{10}F_3NO$: C 66.44, H 3.48, N 4.84; found: C 66.47, H 3.95, N 4.83.

*6-(Trifluoromethyl)-4-*p*-tolylquinolin-2(1*H*)-one (8)*

FTIR (KBr, cm^{-1}): 1265, 1508, 1564, 1658, 3007, 3321. ^{1}H NMR (DMSO-d_6) δ: 2.30 (s, 3H), 6.39 (s, 1H), 7.28 (s, 4H), 7.45 (d, 1H, J = 8.8 Hz), 7.52 (s, 1H), 7.76 (d, 1H, J = 8.2 Hz), 12.11 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 20.7, 116.8, 118.0, 122.4, 123.1(q), 125.0, 126.7, 128.4, 129.4, 132.8, 138.7, 141.7, 150.9, 161.2, 168.7. MS (EI): *m*/*z* 303 (M^+). Anal. calcd for $C_{17}H_{12}F_3NO$: C 67.32, H 3.99, N 4.62; found: C 67.33, H 4.10, N 4.63.

*6-(Trifluoromethyl)-4-*m*-tolylquinolin-2(1*H*)-one (9)*

FTIR (KBr, cm^{-1}): 1105, 1577, 1614, 1668, 3005, 3404. ^{1}H NMR (DMSO-d_6) δ: 2.50 (s, 3H) 6.61 (s, 1H), 7.37–7.47 (m, 3H), 7.56 (t, 1H) 7.68 (t, 1H) 7.96 (dd, 1H, J = 8.2 and 1.7 Hz), 12.35 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 20.8, 116.9, 118.0, 121.8, 122.2, 122.5, 123.2(q), 125.6, 126.7, 128.6, 129.0, 129.7, 135.7, 138.3, 141.7, 151.0, 161.3. MS (EI): *m*/*z* 303 (M^+). Anal. calcd for $C_{17}H_{12}F_3NO$: C 67.32, H 3.99, N 4.62; found: C 67.32, H 4.08, N 4.62.

*6-(Trifluoromethyl)-4-(*o*-methoxyphenyl)quinolin-2(1*H*)-one (10)*

FTIR (neat, cm^{-1}): 1070, 1371, 1494, 1579, 1658, 3306. ^{1}H NMR (DMSO-d_6) δ: 3.72 (s, 3H), 6.97 (t, 1H, J = 7.4 Hz), 7.09 (d, 1H, J = 8.2 Hz), 7.27 (d, 1H, J = 7.4 Hz), 7.37 (t, 1H, J = 8.2 and 7.4 Hz), 7.47 (d, 1H, J = 8.5 Hz), 7.80 (d, 1H, J = 8.8 Hz), 7.90 (s, 1H), 8.13 (s, 1H), 12.17 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 55.8, 111.3, 115.6, 118.8, 120.0, 121.9, 122.3 (q), 125.1, 125.3, 126.1, 129.5, 130.7, 132.3, 138.3, 140.8, 156.9, 160.8. MS (EI): *m*/*z* 319 (M^+). Anal. calcd for $C_{17}H_{12}F_3NO_2$: C 63.95, H 3.79, N 4.39; found: C 63.97, H 3.88, N 4.62.

*6-(Trifluoromethyl)-4-(*m*-methoxyphenyl)quinolin-2(1*H*)-one (11)*

FTIR (KBr, cm^{-1}): 1074, 1319, 1473, 1568, 1674, 3007, 3147. ^{1}H NMR (DMSO-d_6) δ: 3.80 (s, 3H), 6.55 (s, 1H), 7.04–7.12 (m, 3H), 7.45–7.63 (m, 3H), 7.85 (d, 1H, J = 8.2 Hz), 12.24 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 55.6, 114.5, 115.2, 117.3, 118.4, 121.2, 123.0(q), 123.7, 127.2, 130.4, 137.5, 142.2, 151.2, 159.9, 161.7. MS (EI): *m*/*z* 319 (M^+). Anal. calcd for $C_{17}H_{12}F_3NO_2$: C 63.95, H 3.79, N 4.39; found: C 63.97, H 4.14, N 4.37.

*6-(Trifluoromethyl)-4-(*p*-methoxyphenyl)quinolin-2(1*H*)-one (12)*

FTIR (KBr, cm^{-1}): 1124, 1317, 1510, 1608, 1668, 2841, 3151. ^{1}H NMR (DMSO-d_6) δ: 3.84 (s, 3H), 6.48 (s, 1H), 7.13 (d, 2H, J = 7.2 Hz), 7.45 (d, 2H, J = 7.2 Hz), 7.56 (d, 1H, J = 8.3 Hz), 7.67 (s, 1H), 7.86 (d, 1H, J = 8.6 Hz), 12.19 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 55.1, 114.2, 116.8, 118.1, 121.7, 122.2, 123.1(q), 125.8, 126.7, 127.8, 130.0, 141.7, 150.6, 159.8, 161.2. MS (EI): *m*/*z* 319 (M^+). Anal. calcd for $C_{17}H_{12}F_3NO_2$: C 63.95, H 3.79, N 4.39; found: C 63.94, H 3.90, N 4.07.

*4-Phenylquinolin-2(1*H*)-one (13, 5855-57-2)[8a]*

FTIR (neat, cm^{-1}): 1072, 1265, 1433, 1496, 1568, 1654, 3306. ^{1}H NMR (DMSO-d_6) δ: 6.30 (s, 1H), 7.03–7.08 (m, 1H), 7.27–7.32 (m, 2H), 7.37–7.44 (m, 6H) 11.79 (s, 1H). MS (EI): *m*/*z* 221 (M^+).

*4-(3-Methoxyphenyl)quinolin-2(1*H*)-one (14, 65848-66-0)[8a]*

FTIR (neat, cm^{-1}): 1045, 1214, 1388, 1432, 1574, 1601, 1653, 2837, 3310. ^{1}H NMR (DMSO-d_6) δ: 3.80 (s, 3H), 6.41 (s, 1H), 7.00–7.15 (m, 4H), 7.39–7.54 (m, 4H), 11.89 (s, 1H). MS (EI): *m*/*z* 251 (M^+).

*4-(4-Methoxyphenyl)quinolin-2(1*H*)-one (15, 37118-72-2)[8a]*

FTIR (neat, cm^{-1}): 1029, 1170, 1251, 1506, 1610, 1674, 2962, 3300.^{1}H NMR (DMSO-d_6): δ 3.81 (s, 3H), 6.33 (s, 1H),

For personal use only.

7.05–7.14 (m, 3H), 7.35–7.52 (m, 5H), 11.79 (s, 1H). MS (EI): *m/z* 251 (M^+).

4*-m-*Tolylquinolin-2(1H)-one (16, 92909-30-4)[8c]

FTIR (neat, cm^{-1}): 1038, 1160, 1271, 1385, 1432, 1547, 1606, 1654, 2836, 3316. ^1H NMR (DMSO-d_6) δ: 2.36 (s, 3H), 6.34 (s, 1H), 7.08–7.13 (m, 1H), 7.20–7.41 (m, 7H), 11.85 (s, 1H). MS (EI): *m/z* 235 (M^+).

4*-p-*Tolylquinolin-2(1H)-one (17, 106015-76-3)[8c]

FTIR (neat, cm^{-1}): 1039, 1383, 1433, 1502, 1608, 1664, 2850, 3319. ^1H NMR (DMSO-d_6) δ: 2.40 (s, 3H), 6.35 (s, 1H), 7.13 (t, 1H, J = 7.7 and 7.9 Hz), 7.35–7.41 (m, 6H), 7.52 (t, 1H, J = 7.9 and 7.2 Hz), 11.82 (s, 1H). MS (EI): *m/z* 235 (M^+).

4-Phenyl-2H-chromen-2-one (18, 15185-05-4)[10]

FTIR (neat, cm^{-1}): 1365, 1444, 1491, 1560, 1606, 1734, 3072. ^1H NMR ($CDCl_3$) δ: 6.36 (s, 1H), 7.22 (t, 1H, J = 7.7 Hz), 7.40–7.57 (m, 8H). MS (EI): *m/z* 222 (M^+).

4*-p-*Tolyl-2H-chromen-2-one (19, 76103-24-7)[10]

FTIR (neat, cm^{-1}): 1365, 1510, 1608, 1726, 3070. ^1H NMR ($CDCl_3$) δ: 2.45 (s, 3H), 6.36 (s, 1H), 7.20 (d, 1H, J = 7.6 Hz), 7.23 (d, 1H, J = 7.6 Hz), 7.34 (m, 4H), 7.54 (m, 2H). MS (EI): *m/z* 236 (M^+).

4*-(4-Methoxyphenyl)-2H-*chromen-2-one (20, 170456-76-5)[10]

FTIR (neat, cm^{-1}): 1294, 1599, 1491, 1670, 1757, 3072.^1H NMR ($CDCl_3$) δ: 3.90 (s, 3H), 6.36 (s, 1H), 7.05 (d, 2H, J = 8.5 Hz), 7.25 (t, 1H), 7.42 (m, 3H), 7.56 (t, 2H, J = 8.5 Hz). MS (EI): *m/z* 252 (M^+).

***4*-(5-Chloro-2-hydroxyphenyl)-6-(trifluoromethyl)quinolin-2(1H)-one (24)**

FTIR (neat, cm^{-1}): 1437, 1558, 1653, 3311. ^1H NMR (DMSO-d_6) δ: 6.49 (s, 1H), 7.02 (d, 1H, J = 8.8 Hz), 7.30–7.35 (m, 3H), 7.52 (d, 1H, J = 8.8 Hz), 7.81 (d, 1H, J = 8.5 Hz), 10.11 (s, 1H), 12.2 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 116.5, 117.3, 117.9, 121.6, 122.0, 122.8, 123.6(q), 124.6, 126.4, 126.5, 129.6, 130.1, 141.1, 147.9, 153.2, 161.4. MS (EI): *m/z* 339 (M^+) 341 (M^++2). Anal. calcd for $C_{16}H_9ClF_3NO_2$: C 56.57, H 2.67, N 4.12; found: C 56.59, H 2.87, N 4.17.

***4*-(5-Chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1-methylquinolin-2(1H)-one (25)**

FTIR (neat, cm^{-1}): 1305, 1494, 1602, 1674, 2845, 3055.^1H NMR (DMSO-d_6) δ: 3.68 (s, 3H), 3.71 (s, 3H), 6.66 (s, 1H), 7.24 (s, 1H), 7.27 (d, 1H, J = 7.0 Hz), 7.40 (d, 1H, J = 2.4 Hz), 7.58 (dd, 1H, J = 8.8 and 2.4 Hz), 7.79 (d, 1H, J = 8.8 Hz), 7.94 (d, 1H, J = 8.8 Hz). ^{13}C NMR (DMSO-d_6) δ: 29.4, 55.8, 113.5, 116.4, 119.0, 122.9, 123.6, 124.7, 125.9, 126.8, 129.7, 130.5, 141.8, 146.1, 155.0, 160.5. MS (EI): *m/z* 367 (M^+), 369 (M^+ + 2). Anal. calcd for $C_{18}H_{13}ClF_3NO_2$: C 58.79, H 3.56, N 3.81; found: C 58.81, H 3.68, N 3.81.

***3*-Bromo-4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1-methylquinolin-2(1H)-one (26)**

FTIR (neat, cm^{-1}): 1120, 1311, 1491, 1654, 2848, 2941. ^1H NMR (DMSO-d_6) δ: 3.36 (s, 3H), 3.81 (s, 3H), 7.19 (s, 1H), 7.29 (d, 1H, J = 8.8 Hz), 7.35 (d, 1H, J = 2.4 Hz), 7.58 (dd, 1H, J = 2.4 and 8.8 Hz), 7.84 (d, 1H, J = 8.8 Hz), 7.97 (d, 1H, J = 8.8 Hz). ^{13}C NMR (DMSO-d_6) δ: 31.2, 56.0, 113.8, 116.7, 119.5, 121.0, 122.6, 123.0, 123.3 (q), 124.5, 126.1, 127.0, 129.1, 130.6, 140.7, 145.8, 154.5, 157.1. MS (EI): *m/z* 445 (M^+), 447 (M^+ + 2), 449 (M^+ + 4). Anal. calcd for $C_{18}H_{12}BrClF_3NO_2$: C 48.40, H 2.71, N 3.14; found: C 48.35, H 3.02, N 3.18.

(2E)-Ethyl-3-(4-(5-chloro-2-methoxyphenyl)-6-(trifluoromethyl)-1,2-dihydro-1-methyl-2-oxoquinolin-3-yl) acrylate (4)

FTIR (neat, cm^{-1}): 1132, 1286, 1371, 1494, 1620, 1662, 1695, 3111.^1H NMR ($CDCl_3$) δ: 1.25 (t, 3H), 3.69 (s, 3H), 3.84 (s, 3H), 4.16 (q, 2H), 7.02 (d, 1H, J = 9.1 Hz), 7.08 (d, 1H, J = 2.4 Hz), 7.27 (s, 1H), 7.35 (d, 2H, J = 2.4 Hz), 7.58 (m, 2H), 7.80 (d, 1H, J = 9.1 Hz). ^{13}C NMR (75 MHz, $CDCl_3$, TMS) δ: 14.1, 30.1, 55.9, 60.3, 112.8, 114.8, 120.0, 124.1, 124.4, 125.1, 125.3, 125.4, 125.5, 126.1, 127.5(q), 130.1, 130.8, 137.4, 141.1, 147.0, 155.0, 160.4, 167.5. MS (EI): *m/z* 465 (M^+), 467 (M^+ + 2). Anal. calcd for $C_{23}H_{19}ClF_3NO_4$: C 59.30, H 4.11, N 3.01; found: C 59.29, H 4.26, N 3.08.

Abstract: A new chemosensor based on the spirolactam form of rhodamine 101 hydrazone (**III**) is found to exhibit a reversible colorimetric response toward Cu^{2+} in aqueous solutions in a selective, sensitive and rapid manner because of a formation of a Cu(II)-**III** complex. The dominating absorption maximum at 584 nm is uniquely red-shifted among rhodamine chemosensors toward Cu^{2+}. The fluorescence of **III** can be detected in a low concentration of Cu^{2+}. The results revealed that **III** is a good colorimetric sensor to Cu^{2+} in the red region.

Key words: chemosensor, rhodamine 101 hydrazone, naked-eye recognition, metal ions.

Résumé : On a observé qu'un nouveau senseur chimique à base de la forme spirolactame de l'hydrazone de la rhodamine 101 (**III**) donne lieu à une réponse colorimétrique réversible vis-à-vis de l'ion Cu^{2+} en solutions aqueuses et que cette réponse est sélective, sensible et rapide en raison de la formation d'un complexe Cu(II)-**III**. Par comparaison avec les senseurs chimiques dérivés de la rhodamine vis-à-vis du Cu^{2+}, le maximum d'absorption dominant à 584 nm est uniquement déplacé vers le rouge. La fluorescence du composé **III** peut être détectée à de faibles concentrations de Cu^{2+}. Les résultats révèlent que le composé **III** est un bon senseur colorimétrique pour le Cu^{2+} dans la région du rouge.

Mots-clés : senseur chimique, hydrazone de la rhodamine I01, reconnaissance à l'oeil nu, ions métalliques.

Introduction

The design and synthesis of new chemosensors for monitoring ionic species, especially heavy and transition metal cations in aqueous solutions, is of great interest because of their significance in chemical, biological, and environmental analyses.[1–3] Much attention has been paid to the design of fluorescent chemosensors, because they allow nondestructive and real-time detection of ionic species with high sensitivity by a fluorescent enhancement or quenching response.[4,5] Although Cu^{2+} plays important roles in biological process,[6] it is an environmental pollutant at high concentrations.[7] Therefore, efforts have been made to design and develop probes for the detection of Cu^{2+} in biological, toxicological, and environmental systems. Current methods for copper screening, including atomic absorption spectrometry (AAS),[8] inductively coupled plasma mass spectrometry (ICP-MS),[9] and inductively coupled plasma atomic emission spectrometry (ICP-AES),[10] often require expensive and sophisticated instrumentation or complex sample-preparation steps. Colorimetric sensing of copper ions would be more desirable, because it is less labor-intensive and highly sensitive.

Rhodamine-based dyes have found applications in complicated biological systems, such as molecular probes[7] and chemosensors,[11,12] because of their excellent spectroscopic properties with large molar extinction coefficient and high fluorescence quantum yield. The spirolactam forms of rhodamine derivatives are nonfluorescent and colorless, whereas their ring-opening forms give rise to strong fluorescence and a pink or red color.[13] Usually, the ring-opening process happens through affecting a carbonyl group in a spirolactone or spirolactam moiety by suitable metal ions or protons (Scheme 1). Consequently, addition of a specific metal ion to an appropriate host, bearing a spirolactam ring, can cause color change as well as fluorescent change of the host. Recently, the spirolactam forms for the derivatives of rhodamine B or rhodamine G have been utilized for the detection of heavy metal ions, such as Hg^{2+},[14–18] Cu^{2+},[19–23] Fe^{3+},[24] Cr^{3+} ,[25–27] and Pb^{2+}, [27] etc., in aqueous solutions via ring-opening processes of spirolactam amides or hydrazides. These cation sensors, based on rhodamine derivatives, can be potentially applied in biological and silica-mesoporous hybrid materials.[28]

However, the fluorescence enhancement or quenching based on rhodamine derivatives in the presence of Cu^{2+} occurring in the longer absorption or emission wavelength region has seldom been reported. In our previous work, rhodamine 101 hydrazide exhibited an irreversible colorimetric and fluorogenic response toward Cu^{2+} in aqueous solution in the red region.[29] The longer emission wavelengths (over 550 nm) are often preferred for the analyte, to avoid the influence of background fluorescence (below 500 nm).[30] As the absorption enhancement of a host in the presence of guests in the red region facilitates naked-eye recognition, spirolactam forms of rhodamine 101 hydrazones **III** and **IV** are

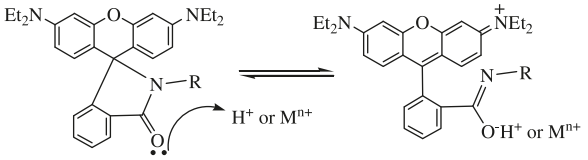
Scheme 1. Ring-opening process for spirolactam form of rhodamine derivatives by proton or metal ions.



synthesized to develop reversible Cu^{2+} chemosensor in the red region in aqueous solutions. The opening of the spirolactam forms may be realized by the interaction of the Cu^{2+} with the corresponding N and O atoms in these compounds. The structural rigidity introduced by multiple *n*-propylene bridges of rhodamine 101 moieties can shift the absorption and emission maxima to longer wavelengths, with higher molar extinguishing coefficients and higher quantum yields compared with rhodamine B.[31]

Experimental

Synthesis of spirolactam rhodamine 101 derivatives III and IV

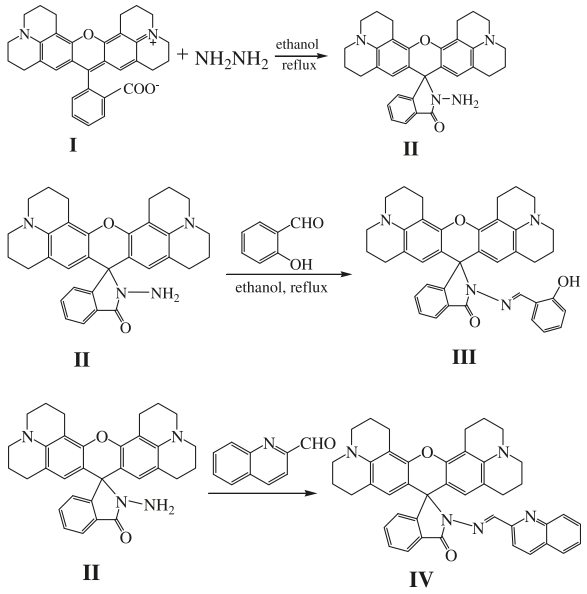
Synthesis of compound III

II was synthesized using a modified procedure from Yang et al.[32] It was recently synthesized in our group.[29] As shown in Scheme 2, 0.0892 g (0.18 mmol) of compound **II** and 0.5 mL (0.19 mmol) of 2-hydroxybenzaldehyde were dissolved in 15 mL of anhydrous ethanol. The mixture was refluxed under N_2 for 10 h. The cooled solution was partially removed upon rotary evaporation and allowed to stand overnight at 0 °C. The resulting precipitate was re-crystallized three times with ethanol to afford a pale-yellow solid (83 mg, 76%). IR (KBr, cm^{-1}, Fig. S4 in Supplementary data): 1687.83 (C=O); 1657.22 (C=N); 3433.98 (OH). ^1H NMR (DMSO-d_6, see Fig. S2 in Supplementary data) δ (ppm): 1.73 (t, 4H); 1.95 (t, 4H); 2.40 (m, 4H); 2.87 (m, 4H); 3.05 (m, 4H); 3.11 (m, 4H); 5.94 (s, 2H); 6.81 (m, 2H); 7.08 (d, 1H); 7.22 (m, 1H); 7.28 (d, 1H); 7.60 (m, 2H); 7.88 (d, 1H), 8.92 (s, 1H); 10.43 (s, 1H). ^{13}C NMR (DMSO-d_6, see Fig. S3 in Supplementary data) δ (ppm): 19.01, 21.16, 21.24, 21.74, 21.92, 27.01, 49.09, 49.52, 66.50, 105.46, 107.60, 116.95, 117.43, 119.37, 119.88, 123.46, 123.59, 129.11, 132.08, 143.97, 148.16, 151.45, 157.67. MS (ESI-MS): *m/z* calcd. for M^+, $C_{39}H_{36}N_4O_3$, 608.73; found: 609 (Fig. S1 in Supplementary data). Anal. calcd. for $C_{39}H_{36}N_4O_3 \cdot 0.6H_2O$: C, 75.61; H, 6.05; N, 9.04; found C, 75.42, H, 6.08, N, 9.00.

Synthesis of compound IV

As shown in Scheme 2, 0.1224 g (0.002 mol) of compound **II** and 0.0489 g (0.0031 mol) of quinoline-2-carbaldehyde were dissolved in 15 mL of anhydrous ethanol. The mixture was refluxed under N_2 for 10 h. The cooled solution was partially removed upon rotary evaporation and allowed to stand overnight at 0 °C. The precipitate was re-crystallized three times with ethanol to afford a pale-gray solid (0.836 g, 65%). IR (KBr, cm^{-1}): 1696.84 (C=O); 1626.30 (C=N). ^1H NMR (DMSO-d_6) δ (ppm): 1.70 (t, 4H); 1.97 (t, 4H); 2.40 (m, 4H); 2.93 (m, 4H); 3.03 (m, 4H); 3.12 (m, 4H); 6.05 (s, 2H); 7.03 (d, 1H); 7.53 (t, 1H); 7.60 (m, 2H); 7.74 (m, 2H); 7.93 (m, 3H); 7.36 (d, 1H), 8.72 (s, 1H). MS (ESI-MS): *m/z* calcd. for M^+, $C_{42}H_{37}N_5O_2$, 643.29; found: 644.4 $[M + H]^+$ (Fig. S5 in Supplementary data). Anal. calcd. for $C_{42}H_{37}N_5O_2 \cdot 0.5H_2O$: C, 77.28; H, 5.87; N, 10.73; found C, 77.03, H, 5.90, N, 10.68.

Scheme 2. Synthesis of compound **III** and **IV**.



General experiments

NMR spectra were recorded with a 400 MHz Varian spectrometer. Electrospray ionization mass spectra (ESI-MS) were measured on a LC-MSD-Trap-SL system. Elemental analyses were carried on a Flash EA 1112 elemental analyzer (Thermo Electron SPA, Italy). IR spectra were recorded on a Thermo IR spectrometer. Absorption spectra were obtained on a TU1901 UV–vis spectrophotometer. The fluorescence spectra were measured with a Cary Eclipse fluorescence spectrometer. The pH values were measured with a pH S-301 pH meter.

Procedures of metal ion sensing

Nitrate salts of metal ions were used to evaluate the metal ion binding property and selectivity of compounds **III** and **IV** in ethanol-Tris-HCl buffer (0.02 mol/L, pH 7.2) (1:1, *v/v*). Stock solutions of the metal ions (5 mmol/L) were prepared in de-ionized water. Stock solutions of **III** and **IV** (1 mmol/L) were prepared in DMSO, respectively. In titration experiments, 3 mL solution of **III** or **IV**, which was diluted to a certain concentration with ethanol-Tris-HCl (0.02 mol/L, pH 7.2) (1:1, *v/v*), was added into a quartz optical cell with an optical path length of 1 cm. The stock solution of each metal ion was added into the quartz optical cell step by step via a syringe. The spectra were recorded at 2 min after the addition and mixing. For fluorescence measurements, excitation wavelength was provided at 540 nm, and emission was collected from 580 to 660 nm.

Results and discussion

Absorption spectroscopic studies

Compound **III** is proposed to chelate with metal ions via its carbonyl O, imino N, and phenol O atoms.[33] Compound

Fig. 1. (*a*) Absorption spectra of **III** (27 μmol/L) upon addition of increasing amount of Cu^{2+} in ethanol-Tris-HCl (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) solution. The inset shows the titration profile evaluated from the absorption at 584 nm. (*b*) Job plot (total concentration is 2×10^{-5} mol/L).

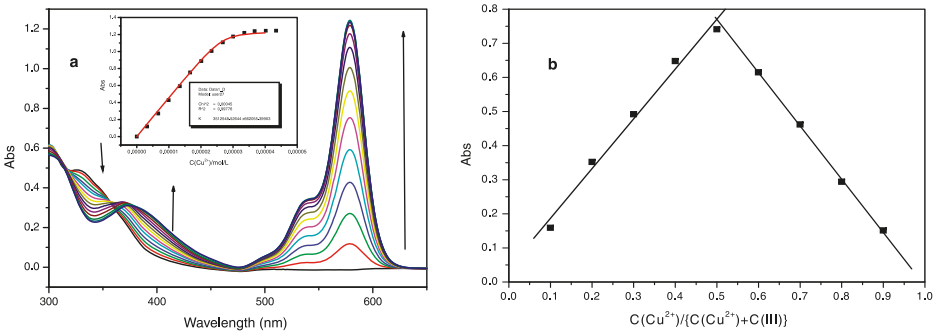

Fig. 2. Absorbance of 10 μmol/L **III** on addition of various metal ions (100 μmol/L of other metal ions) and then addition of 10 μmol/L Cu^{2+} in ethanol-Tris buffer (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) solutions.

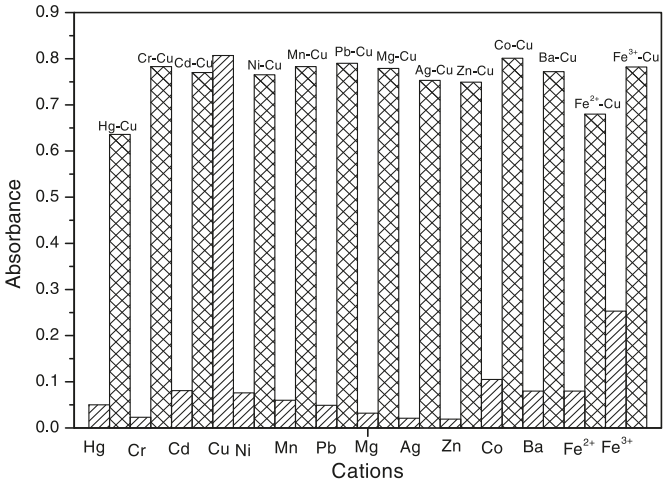

Fig. 3. Photograph of 10 μmol/L **III** as a naked-eye chemosensor for Cu^{2+} in ethanol-Tris-HCl (0.02M, pH 7.2) (1:1, *v*/*v*) solution. From left to right: 0, 2.5, 5.0, 10.0 μmol/L Cu^{2+}.

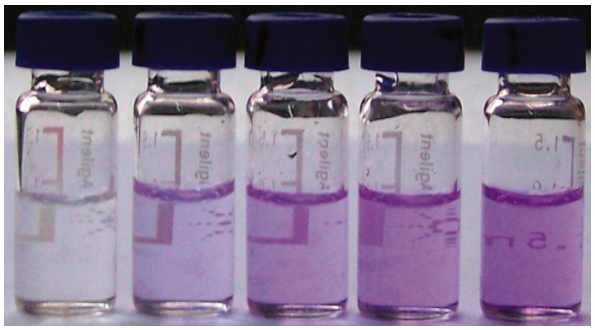

IV may also interact with metal ions via its carbonyl O, imino N, and quino N atoms. The introduction of the rhodamine framework to construct probes of the "off-on" type is a reliable method due to the well-known spirolactam ("off") to ring-opened amide ("on") equilibrium of rhodamine derivatives. The spirolactam moiety of the rhodamine framework served as a signal switcher, which was observed to turn on when the cation was bound.[34,15–27] The absorption spectra of **III**, upon titration with Cu^{2+}, are shown in Fig. 1*a*. The solution of **III** is almost colorless and exhibits almost no absorption in the visible wavelength range (300–650 nm), indicating that **III** is predominantly in the form of spirolactam. The characteristic peak of the spiro-carbon of **III** near 66.5 ppm in the ^{13}C NMR spectrum also supports this conclusion.[35] Upon addition of Cu^{2+}, a new absorption peak at 584 nm appears, and the absorption intensity increases gradually with increasing of Cu^{2+} concentration. The absorbance at 584 nm increases about 70 times upon addition of one equiv. of Cu^{2+}. At the same time, there are three concomitant isosbestic absorption points at 320, 364, and 470 nm, indicating the formation of a 1:1 complex. This stoichiometry is also supported by the Job plot evaluated from the absorption spectra of **III** and Cu (II) with a total concentration of 20 μmol/L (Fig. 1*b*). The changes in the absorption spectra of **III** upon addition of Cu^{2+} indicate the obvious interaction of Cu^{2+} and compound **III**. Nonlinear fitting based on the 1:1 stoichiometry gives a binding constant of $(3.51 \pm 0.66) \times 10^6$ L/mol (insert in Fig. 1*a*),[36] indicating a very strong binding ability of **III** to Cu^{2+}. The absorbance of **III** at 584 nm increases linearly with increasing Cu^{2+} concentration in the range of 2×10^{-7} to 8×10^{-6} mol/L (Fig. S6 in Supplementary data). The relationship between the absorbance at 584 nm and Cu^{2+} concentration was: $A = 0.0844C + 0.0955$, where A is the absorbance at 584 nm and C is the concentration of Cu^{2+} in μmol/L with a correlation coefficient of $R = 0.9999$ ($n = 18$). The detection limit, based on the definition by IUPAC was found to be 2.5×10^{-8} mol/L from 13 blank solutions. The relative standard deviation for ten repeated measurements of 0.5 μmol/L Cu^{2+} was 2.6%.

The absorbance time course of 10 μmol/L **III** to 12 μmol/L Cu^{2+} in ethanol-Tris buffer (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) was investigated. The interaction of **III** with Cu^{2+} was completed in less than 2 min (Fig. S7 in Supplementary data). However, upon addition of 12 μmol/L Cu^{2+} to 10 μmol/L **IV**, no obvious variation in the absorbance at 584 nm was observed over a period of 1 h, indicating a lack of interaction between **IV** and Cu^{2+}. The acidity was chosen to be pH 7.2, because it is close to physiological pH conditions. Both the organic compound and inorganic salts must be dissolved in a suitable solvent. Compound **III** can be dissolved in strong polar solvent, such as DMSO, to prepare the stock solutions. As ethanol is more environmentally friendly and inexpensive than such solvents as acetone, acetonitrile, DMSO, DMF, the effect of ethanol fraction was investigated by using 10%, 30%, 50%, 70%, 90% (*v*/*v*) at pH 7.2 as media for Cu^{2+} determination by 10 μmol/L **III**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12

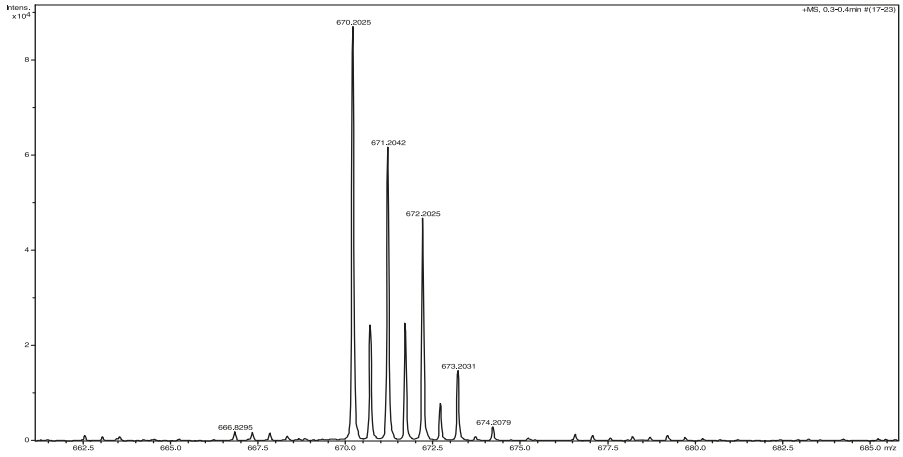
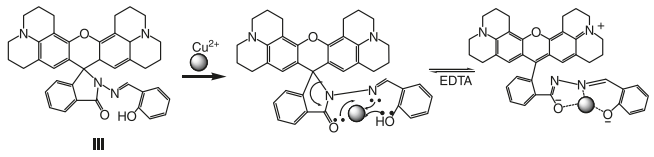
Fig. 4. Observed ESI mass spectra of **III** (10 μmol/L) in presence of 12 μmol/L Cu^{2+}.



Scheme 3. Possible ring-opening process of **III** upon addition of Cu^{2+}.



(Fig. S8 in Supplementary data). A fraction of 50% ethanol was found to efficiently monitor Cu^{2+}. Therefore, ethanol-Tris buffer (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) with a trace amount of DMSO were used for each investigation.

Selectivity studies

The selective sensory studies of **III** were then extended to other metal ions. The changes in color of 10 μmol/L **III** in the presence of different cations are illustrated in Fig. S9 in the Supplementary data. Among the metal ions being investigated, the presence of 10 μmol/L Cu^{2+} brought about an obvious purple color in 10 μmol/L **III**. The presence of 100 μmol/L Co^{2+} caused a very faint pink color in 10 μmol/L **III**. The absorption spectra of 27 μmol/L **III**, upon titration with up to 270 μmol/L Co^{2+}, resulted in very small spectroscopic changes (Fig. S10 in Supplementary data). The presence of 100 μmol/L Fe^{3+} brought a pale purple color in 10 μmol/L **III**. The absorption spectra of 27 μmol/L **III**, upon titration with Fe^{3+}, indicted that Fe^{3+} would be a slight interference with Cu^{2+} detection (Fig. S11 in Supplementary data). Metal ions (100 μmol/L) such as Pb^{2+}, Mg^{2+}, Ba^{2+}, Cd^{2+}, Ag^{+}, Fe^{2+}, Mn^{2+}, Zn^{2+}, Hg^{2+}, and Cr^{3+} did not cause any color or spectral change of 10 μmol/L **III**. It is suggested that compound **III** does not bind these metal ions simply. Spectrophotometric responses of 10 μmol/L **III** in ethanol-Tris buffer (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) solutions to 100 μmol/L of various metal ions before and after addition of 10 μmol/L Cu^{2+} are shown in Fig. 2. The results indicated the presence of other ions, including a 10-fold excess of Co^{2+}, did not interfere with the interaction of **III** with Cu^{2+}.

The solutions of 10 μmol/L **III** exhibited deeper and deeper color in the presence of more and more Cu^{2+} at micromolar levels (Fig. 3). The results indicate that chemosensor **III** can indeed serve as a sensitive naked-eye chemosensor for Cu^{2+} in aqueous solutions in the red region (Fig. 3 and Fig. S9 in Supplementary data). The absorption band in the red wavelength region facilitates the naked-eye recognition of Cu^{2+}. Compound **IV** cannot exert any obvious color change upon the addition of the above cations due to the poorer electron donor effect of quino N compared with phenol O atoms. As the color of **III**-Cu(II) disappears instantly upon the addition of 1-fold EDTA due to competitive binding of Cu^{2+} from **III** by EDTA, further addition of Cu^{2+} can recover the purple colour, so the response of **III** to Cu^{2+} is proposed to be a reversible complexation rather than an irreversible cation-catalyzed reaction.[29,37]

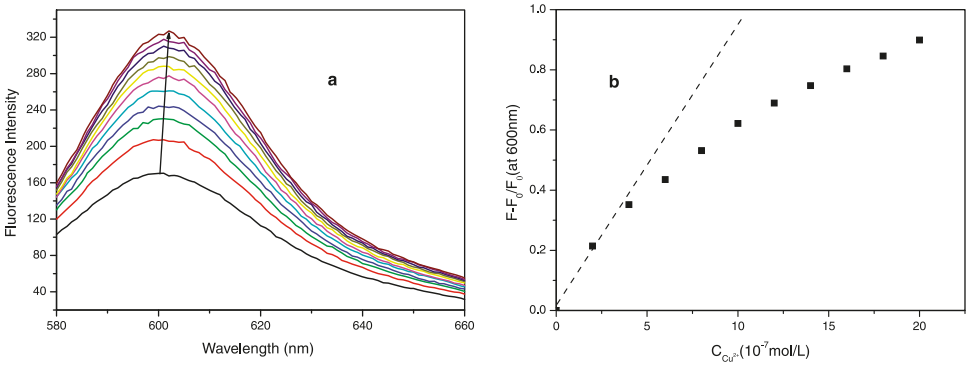
Mass spectroscopic studies

ESI mass spectra provide evidence of the formation of **III**-Cu(II) in ethanol-Tris-HCl (0.02 mol/L, pH 7.2) (1:1, *v*/*v*) solution (Fig. 4). The peak at (*m*/*z* = 670.20) for $C_{39}H_{35}CuN_4O_3$ (calcd. 670.2), corresponding to [**III** + Cu-H]$^+$, is clearly observed when 12 μmol/L Cu^{2+} is added to 10 μmol/L **III**. Whereas **III** without Cu^{2+} exhibits a peak only at *m*/*z* = 609.0 (calcd. 608.3), which corresponds to [**III** + H]$^+$ (Fig. S1 in Supplementary data). To achieve this 1:1 stoichiometry, carbonyl O, imino N, and phenol O atoms of **III** are the most likely binding sites for Cu^{2+}. The proposed mechanism is shown in Scheme 3. The phenol group of **III**, which undergoes deprotonation during the binding, plays an important role in the interaction of **III** with Cu^{2+}, because the comparing compound **IV**, which has no phenol group, displays nearly no colorimetric response to Cu^{2+} in either absorption or ESI mass spectra when treated with excess (100 μmol/L) Cu^{2+}.

Fluorescence spectroscopic studies

Fluorescent probes for copper ions have been extensively explored owing to their biological, toxicological, and environmental significance.[38–46] A solution of **III** with concentration of 2 μmol/L in ethanol or ethanol-Tris-HCl (0.02M, pH 7.2) (1:1, *v*/*v*) is nonfluorescent, indicating that the spirocyclic form is retained in solution (The slight emission band before addition of Cu^{2+} is assigned to the delocalized xanthene tautomer of the rhodamine moiety in small amount of **III**.). Upon titration of Cu^{2+}, the emission band at 600 nm appears and develops (Fig. 5*a*). A slightly amplified (nearly one time) fluorescence intensity is observed in presence of

Fig. 5. (*a*) Fluorescence responses of 2 μmol/L **III** upon addition of 0–2 μmol/L Cu^{2+} in ethanol-Tris-HCl (0.02M, pH 7.2) (1:1, *v*/*v*). The concentrations of Cu^{2+} are 0, 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, and 2 μmol/L, respectively. Spectra were recorded immediately after addition of Cu^{2+}. (*b*) Fluorescence enhancement factor $(F - F_0)/F_0$ at 600 nm as a function of Cu^{2+} concentration (0–2 μmol/L). Excitation was performed at 540 nm.



2×10^{-6} mol/L Cu^{2+}. The titration curve in Fig. 5*b* shows a slight fluorescence intensity increase in concentration range 2×10^{-7} to 2×10^{-6} mol/L of Cu^{2+}. The behaviour of the fluorescence intensity increase is nonlinear and a downward trend is observed. Although the emission spectra undergo a red shift from 600 to 605 nm, the fluorescence intensity at 600 nm has only a 1-fold enhancement, which is much weaker compared with the enhancement of the absorbance. The emission peaked at 600 nm is red-shifted compared with the reported values of 575 nm,[47] 578 nm,[37] 580 nm,[19] and 585 nm.[34] The emissions at longer wavelength may have the advantage of avoiding background signals caused by biological autofluorescence (e.g., from serum, proteins, and other macromolecular compounds) for its application in live cell imaging.

When Cu^{2+} was added to **III**, the enhancement of absorbance is found to be much more significant than that of fluorescence intensity. However, the ring-opening of the spirolactam form of rhodamine derivatives generally results in comparable amplifications of absorption and fluorescence signals.[48] In the case of compound **III**, binding to Cu^{2+} does open the spirolactam ring, but at the same time the fluorescence of the Cu(II) complex is probably quenched by Cu^{2+}. The quenching mechanism may be similar to that of some Cu^{2+} probes, displaying fluorescence quenching for the paramagnetic nature of the copper ion.[49–51] Fluorescence inner filter effects (**FIFTs**) of the **III-Cu** complex itself could reduce the observed fluorescence because of the obvious overlap of the absorption spectra and fluorescence spectra of symmetric rhodamine derivatives. Preliminary experiments found an interfering effect byFe^{3+} on the fluorescence of **III**. So **III** is not as good a fluorescence sensor as a colorimetric sensor for Cu^{2+}.[52]

Conclusions

A new spirolactam form of rhodamine 101 hydrazone (**III**) that has been synthesized as a chemosensor for the recognition of copper ion in aqueous solutions displays a selective and sensitive colorimetric change with rapid response upon addition of Cu^{2+}. The ring-opening process of spirolactam (colorless) to the delocalized hydrazone (purple) and a reversible complexation process are proposed in the spectroscopic response of **III** toward Cu^{2+}. As expected, the fluorescent maximum of this chemosensor to Cu^{2+} can be red-shifted to above 600 nm. But Cu^{2+} in high concentration will quench the fluorescence of the copper (II) complex of delocalized form of **III**. The results revealed that **III** is a sensitive and selective naked-eye chemosensor toward Cu^{2+} in the red region.

Reaction of iodine with metal oxides

Marek Gliński and Urszula Ulkowska

Abstract: The reaction of iodine with various metal oxides has been studied in both vapour phase (373–873 K) and in solution in cyclohexane, under anhydrous conditions. The course of the reaction has been revised in accordance with literature and experimental data. Apart from adsorbed iodine molecules ($[I_2] < 200\ \mu mol \cdot g^{-1}$), the presence of I^- ions ($[I^-] < 50\ \mu mol \cdot g^{-1}$) has been noted. IO_n^- ions have been observed only when both water and strong basic sites, such as those on MgO or La_2O_3, are present. It has been found that the strength of interaction of iodine with metal oxide increases with basicity of the oxide.

Key words: iodine, metal oxides, iodides, basicity.

Résumé : On a étudié les réactions de l'iode avec divers oxydes métalliques, tant en phase vapeur (373–873 K) qu'en solution dans le cyclohexane, dans des conditions anhydres. On a révisé le cours de la réaction afin de le rendre en accord avec les données expérimentales et celles de la littérature. En plus des molécules d'iode absorbées, ($[I_2] < 200\ \mu mol \cdot g^{-1}$), on a aussi noté la présence d'ions I^- ($[I^-] < 50\ \mu mol \cdot g^{-1}$). On n'a observé la présence d'ions IO_n^- que lorsqu'on est en présence à la fois d'eau et de sites fortement basiques, tels ceux présents sur le MgO ou le La_2O_3. On a aussi observé que la force de l'interaction de l'iode avec l'oxyde métallique augmente avec la basicité de cet oxyde.

Mots-clés : iode, oxydes métalliques, iodures, basicité.

Introduction

Although halogens are very potent electron acceptors, little is known about their reactivity with the surface of metal oxides. What is more, there is some controversy in the literature about the products of this reaction.

In 1974, Kibblewhite and Tench reported that halogens react at room temperature (RT) with magnesium oxide, and the effect of the reaction of a given halogen on the oxide surface strongly depends on the halogen type.[1] It has been shown that MgO treated with iodine contains the appropriate I^- ions and exhibits a lack of IO^- and IO_3^- ions. The authors stated that iodine can react with the surface oxide ions of the lowest coordination only, e.g., 3-fold coordination, which are the most reactive.

Also in 1974 a paper on the reduction of iodine in benzene solution by Al_2O_3, Al_2O_3-SiO_2, and SiO_2 surfaces was published by Flockhart et al.[2] The authors stated that hydroxyl groups on the surfaces of metal oxides can act as one-electron donor sites, and that they are responsible for the occurrence of the reaction. The authors have proposed the mechanism of the reduction based on the following equation:

$$[1] \qquad I_2 + 2OH^- \rightarrow IO^- + I^- + H_2O$$

However, they could not explain the absence of IO_3^- ions, derived from the transformations of IO^- ions, which should be formed according to:

$$[2] \qquad 3IO^- \rightarrow IO_3^- + 2I^-$$

The same type of surface reaction has been proposed for the treatment of alumina with gaseous chlorine, although no proof for the formation of ClO^- ions has been given.[3]

In a series of articles Klabunde et al. have reported that MgO-halogen adducts are reactive halogenating agents of organic molecules and exhibit noticeable biocidal character.[4,5] Moreover, magnesium oxide is found to be an active catalyst in the oxidative dehydrogenation of butane to butadiene in the presence of oxygen and iodine.[6] Based on the results of Raman spectroscopy, the authors concluded that upon adsorption of iodine on the surface of MgO, the formation of an Mg–I bond does not take place or it takes place to a negligible extent.[5]

Iodine has been used as a molecular probe of electron donor strength of Lewis base sites of various zeolites.[7,8] As has been stated, I_2 interacts with the basic framework oxygen and not the charge-balancing cation. It has also been shown that a blue shift in the visible spectrum of adsorbed iodine on zeolite increases with increasing basicity of the zeolite.[9] This technique for probing basicity of solids has been extended to classical supports like alumina, silica, and magnesia.[10] The following decreasing order of the strength of interaction has been found: MgO (very high) > Al_2O_3 (significant) > SiO_2 (weak).[10]

Very recently we have demonstrated that MgO treated with a solution of iodine in pentan-2-ol shows a significant increase in the selectivity in the hydrogen transfer reaction to cyclopentanone.[11]

Here, we describe the reaction of iodine with a series of metal oxides. The reactions were carried out in a broad range of conditions: with a solution of I_2 in cyclohexane at RT or with vapours of I_2 in the temperature range 373–873 K. The present study was focused on the strong interaction of iodine with metal oxides, leading to its reduction to I^- ions. We expected that our work would help to resolve the controversy found in the literature about the products of the above mentioned reaction.

Experimental

Metal oxides Al_2O_3, SiO_2, TiO_2, and ZnO

The powders of alumina (type C, Degussa), silica (Aerosil 200, Degussa), titania (P-25, Degussa), and zinc oxide (puriss p.a., Fluka) were mixed with re-distilled water, and the slurries were dried at 333 and 393 K for 24 h at each temperature. The lumps of oxide were crushed, sieved, and the grain fraction 0.4–0.63 mm was collected.

ZrO_2 and La_2O_3

The solutions of $ZrOCl_2 \cdot 8H_2O$ and $La(NO_3)_3 \cdot 6H_2O$ (both puriss p.a., Fluka) in water were treated with an aqueous ammonia solution (25%), and the precipitated hydroxides were successively washed with re-distilled water to remove all soluble salts. After filtration, metal hydroxides were treated according to the procedure described above.

MgO

Magnesium oxide was prepared by thermal decomposition of $Mg(OH)_2$, whose preparation has been described in detail elsewhere.[12] The grains of hydroxide with 0.4–0.63 mm diameter were used.

Before characterization studies and treatment with iodine or its solutions, metal oxides or hydroxides were calcined at 873 K for 1 h in a stream of air and then for 5 h at the same temperature in a stream of dry nitrogen. They were then stored under nitrogen in Schlenk-type containers.

Characterization of metal oxides

The specific surface areas were measured by nitrogen adsorption at 77 K (BET method) using a Gemini 2360 instrument (Micromeritics).

The strength of the surface acid–base sites of selected metal oxides was determined by the Hammett method, using a sequence of indicators in anhydrous toluene as the solvent.[13] The following set of indicators has been used (the values of pK_A or pK_{BH+} are given in parentheses): chalcone (–5.6), dicinnamylideneacetone (–3.0), crystal violet (0.8), methyl red (4.8), bromothymol blue (7.2), phenolphthalein (9.3), 2,4-dinitroaniline (15.0), 4-nitroaniline (18.4), diphenylamine (22.3), 4-chloroaniline (26.5), and triphenylmethane (33.0). The concentrations of acidic and basic sites of metal oxides were determined using solutions (0.01 mol/L) of triethylamine or benzoic acid in anhydrous toluene, according to a procedure described elsewhere.[14] The measurements were performed at ambient temperature under dry nitrogen, after 24 h contact of the oxides with these solutions in grease-less reactors. The results are summarized in Table 1.

Solvents and reagents

Cyclohexane (99+%, Sigma-Aldrich) was dried by filtration through a glass column containing anhydrous molecular sieves, followed by distillation over metallic potassium – benzophenone in nitrogen atmosphere directly to the Schlenk-type container. Chloroform (pure, BDH) was washed three times with distilled water to remove ethanol and dried at 273 K under nitrogen over anhydrous $CaCl_2$. A final purification of $CHCl_3$ was achieved by distillation in a stream of dry nitrogen in an all-glass apparatus. The distillate was kept under nitrogen in a Schlenk-type container, covered with metallic foil.

Potassium iodate (p.a., Merck) was dried in an oven at 423 K for 4 h and kept in a tightly closed container. Iodine (double sublimed, Merck), potassium iodide (p.a., POCh Gliwice, Poland), and sodium thiosulphate pentahydrate (99.5%, Sigma-Aldrich) were used as received. A stock solution of $Na_2S_2O_3$ was prepared (~0.1 mol/L) and stabilized by the addition of $CHCl_3$. Sodium thiosulphate solutions with lower concentrations (0.001–0.005 mol/L) were prepared by dilution of the stock solution immediately before use. Their concentrations were determined using anhydrous potassium iodate as a standard in the presence of iodide ions in an acidic solution. Sulphuric acid (p.a., 98%, Merck) was used to prepare a 1 mol/L solution in water. Starch (AR, soluble, BDH) was used as received. Its solution in water was stabilized by addition of small amounts of salicylic acid.

Reaction of metal oxides with iodine

(*All operations connected with sample preparation and handling were done in a dry nitrogen atmosphere.*) Two different procedures for the introduction of iodine on the surfaces of metal oxides were used.

In the first procedure, a weighed sample of metal oxide (250 mg), placed in an Erlenmeyer flask, was suspended in anhydrous cyclohexane (5 cm^3), and a cyclohexane solution of iodine of known concentration (0.05 mol/L, 5 cm^3) was added. A suspension of the metal oxide in the stoppered flask was stirred at RT for a certain period of time.

In the second procedure, a stream of anhydrous nitrogen (100 $cm^3 \cdot min^{-1}$) was passed through a glass saturator, filled with iodine kept at 293 K. The stream of N_2, saturated with I_2 vapours, was passed through a metal oxide bed (500 mg), placed in a tubular quartz reactor, and heated to the appropriate temperature. After a 3 h long contact with I_2 vapours, the bed of metal oxide was purged with nitrogen at the same temperature for 1 h, and cooled in a stream of N_2. It has been found in a test without a catalyst that the total amount of iodine reaching the reactor during 3 h is equal to 202 ± 6 μmol.

Analytical determinations

These are tests for the presence of I^- and IO_3^- ions. A sample of a metal oxide that had been reacted previously with an iodine solution or gaseous iodine was extracted with chloroform (5 times) to remove the free halogen, and finally the solvent was removed under reduced pressure. The resulting solid was triturated with 1 mol/L H_2SO_4. An acidic solution was treated either with 30% H_2O_2 or with a freshly prepared 0.1 mol/L KI solution in the presence of starch for

the confirmation of the presence of I^- and IO_3^- ions, respectively.

I_2 on metal oxides

(*All operations were performed in a dry nitrogen atmosphere*). A weighed sample of an oxide (250 mg) was placed in an Erlenmeyer flask (100 cm^3) fitted with a ground-glass stopper, and the free iodine was extracted with anhydrous $CHCl_3$ (5 × 5 cm^3). The organic extracts were collected and treated with 10 cm^3 0.05 mol/L KI. The resulting two-phase mixture was titrated with 0.002 mol/L $Na_2S_2O_3$ in the presence of starch.

I^- ions on metal oxides

The solid left from the determination of iodine was stirred with 15 cm^3 1 mol/L H_2SO_4, and 1 cm^3 0.005 mol/L $NaIO_3$ was added. The liberated iodine was extracted with chloroform (5 × 5 cm^3). The extracts were collected, washed with water, and titrated with 0.002 mol/L $Na_2S_2O_3$, according to the procedure described earlier.

The concentrations given in Tables 2–4 are the averages of three measurements.

Results and discussion

We applied the method of Flockhart et al. to introduce iodine onto alumina using cyclohexane instead of benzene as the solvent for iodine.[2] We have found that no IO_n^- ions were formed. Moreover, the consumption of iodine can be described by the following equation:

$$[3] \quad I_2 + 2e^- \rightarrow 2I^-$$

Very small amounts of iodides, around 20 $\mu mol \cdot g^{-1}$, were found on the surface of the oxide apart from the unreacted iodine. Despite the different solvent, the concentration of iodine, the type of alumina, and analytical procedure, a quite good correlation with the results obtained by Flockhart et al. (max. $[I^-] = 76$ $\mu mol \cdot g^{-1}$) has been noted.[2] The source of electrons transferred to iodine is not established. It is said in the literature that they are derived from surface hydroxyls and (or) the lowest coordinated oxygen anions acting as one-electron donor sites.[16,17]

We have also found that stirring the suspension of alumina greatly accelerates reaching an equilibrium, and that daylight has no influence on the rate of the reaction. Stirring of the suspension for more than an hour increases the I^- concentration because of the progressive grinding of the grains of alumina. The results of preliminary measurements are collected in Table 2.

ZnO	21	23	30

[a] The value increases steeply when water is present.

Other metal oxides reacted with iodine in cyclohexane in a similar manner as alumina (Table 3). A partial reduction of iodine also took place with the formation of iodide ions. No formation of IO_n^- ions was noted in the case of all studied metal oxides. Very low concentrations of iodide ions, up to 30 $\mu mol \cdot g^{-1}$, were reached. It has been found that only for strong basic oxides such as MgO or La_2O_3, the presence of water greatly accelerates the reaction of the oxide with I_2 because of the participation of a well-known disproportionation reaction of a halogen in basic media:

$$[4] \quad 6\,Mg(OH)_2 + 6\,I_2 \rightarrow Mg(IO_3)_2 + 5\,MgI_2 + 6\,H_2O$$

However, such a reaction does not occur under the rigorous anhydrous conditions adopted in this work.

Based on the results presented above we decided to further investigate the method of introduction of iodine onto the surface of metal oxides. To simplify the reaction conditions between metal oxide and iodine, we applied a reaction method of heating the oxide to different temperatures with a stream of iodine vapour diluted with anhydrous nitrogen. In this solvent-free method, the absence of any complications connected with the use of a solvent is ensured. The results are summarized in Table 4.

Small concentrations of I^- ions, below 25 $\mu mol \cdot g^{-1}$, accompanied by various concentrations of adsorbed iodine (< 200 $\mu mol \cdot g^{-1}$) were found on the surfaces of all studied oxides. No IO_n^- ions were detected. For MgO, we have observed an excellent agreement of the surface density of I^- determined in this work (0.22 $\mu mol \cdot m^{-2}$) with that determined by Kibblewhite and Tench (0.22 $\mu mol \cdot m^{-2}$).[1] It has been found that the concentration of the adsorbed iodine depends on the temperature and the type of the oxide. After reaction at 473 K, only trace amounts of I^- ions and lack of adsorbed I_2 were found on the surfaces of SiO_2, ZrO_2, and TiO_2. In the case of weakly basic oxides (ZnO, Al_2O_3), besides very minute amounts of I^- ions, the presence of a strongly adsorbed iodine was noted. The halogen could be desorbed at temperatures higher than 473 K. For metal oxides with strong basic properties, such as MgO and La_2O_3, the adsorbed iodine could be removed only at temperatures higher than 673 K. Therefore, it has been concluded that the strength of interaction of iodine with metal oxides increases with their basicity. The results correlate well with those obtained in UV–vis spectroscopy studies.[10]

Conclusion

Iodine, both in vapour phase or in solution in anhydrous cyclohexane, reacts with the surfaces of various metal oxides. Apart from adsorbed iodine molecules ($[I_2] < 200$ $\mu mol \cdot g^{-1}$), the presence of I^- ions ($[I^-] < 50$ $\mu mol \cdot g^{-1}$) has been noted. The formation of IO_n^- ions occurs only when both water and strong basic sites, such as those on MgO or La_2O_3, are present. The strength of interaction of iodine with metal oxide increases with basicity of the oxide.

Abstract: Arrested precipitation technique (APT) has been successfully employed for the deposition of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films. Analytical grade bismuth nitrate complexes with triethanolamine (TEA), sodium tellurosulfite, and sodium selenosulfite were used as precursor materials. The film was obtained at 55 ± 0.5 °C in an aqueous alkaline medium (pH = 10.5 ± 0.2). As-deposited film was characterized by chemical compositional, optical, and electrical analyses. The optical absorption spectrum for the sample was recorded in the wavelength region 400–900 nm. It shows a high coefficient of absorption ($\alpha = 10^5$ cm^{-1}) with an allowed direct type of transition. X-ray diffraction (XRD) study of the film shows a nanocrystalline and rhombohedral structure. From scanning electron microscopy (SEM), atomic force microscopy (AFM), and energy dispersive X-ray analysis (EDAX) studies, the deposited film shows uniform morphology and good stoichiometry. X-ray photoelectron spectroscopy (XPS) was used to study the binding energy and surface oxidation of the material. Electrical conduction study shows that material is an n-type semiconductor and shows good thermoelectric figure of merit.

Key words: chalcogenide thin films by APT, XPS, thermoelectric study.

Résumé : On a utilisé avec succès la technique de la précipitation arrêtée (TPA) pour déposer des films minces de $Bi_2(Te_{0.5}Se_{0.5})_3$. On a utilisé des complexes de nitrate de bismuth de qualité analytique avec de la triéthanolamine (TEA), du tellurosulfite de sodium et du sélénosulfite de sodium comme produits de départ. Le film a été obtenu à 55 ± 0,5 °C, dans un milieu alcalin aqueux (pH = 10,5 ± 0,2). Le film déposé a été caractérisé par des analyses de sa composition chimique et de ses propriétés optiques et électriques. On a enregistré le spectre d'absorption optique de l'échantillon dans la plage de longueur d'onde de 400 à 900 nm. Il présente un coefficient d'absorption ($\alpha = 10^5$ cm^{-1}) correspondant à un type de transition directe permise. L'étude du film par diffraction des rayons-X (DRX) montre que la structure est nanocristalline et rhomboédrique. Les résultats obtenus par microscopie électronique à balayage (MEB), microscopie des forces atomiques (MFA) et d'une analyse par rayons-X de la dispersion d'énergie (AXDE) montrent que le film déposé possède une morphologie uniforme et une bonne stoechiométrie. On a utilisé la spectroscopie photoélectronique des rayons-X (SPX) pour étudier l'énergie de liaison et l'oxydation de la surface du matériel. Une étude de conduction électrique montre que le matériel est un semiconducteur de type n et qu'il possède un bon facteur de mérite thermoélectrique.

Mots-clés : films minces de chalcogénures, technique de la précipitation arrêtée (TPA), étude thermoélectrique, étude par spectroscopie photoélectronique des rayons X (SPX).

[Traduit par la Rédaction]

Introduction

Bi_2Te_3 with Bi_2Se_3 alloys has been an attractive thermoelectric material widely used in cooling devices and proposed for energy conversion applications at room temperature.[1] The performance of thermoelectric materials depends on the thermoelectric figure of merit of the material ZT. Recently progress has been made in improving the figure of merit of thin film. It is approximately 1 for this material at room temperature.[2] Bismuth telluride represents the parent compound of a family of technologically important semiconductor alloys that are used extensively in modern thermoelectric coolers.[3,4]

Many researchers have reported alloying bismuth telluride and bismuth selenide to increase the thermoelectric efficiency.[5–8] In our research, we deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ material by a new simple developed method known as arrested precipitation technique (APT).[9–11] Deposited film was characterized for growth mechanism and optical, morphological structural, and conduction properties of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin

films. The surface morphology and binding energy was also confirmed by X-ray photoelectron spectroscopy (XPS).

Experimental details

For the deposition of the $Bi_2(Te_{0.5}Se_{0.5})_3$ composite, concentrations of bismuth nitrate, sodium selenosulfite, and sodium tellurosulfite were taken to get a 2:3 stoichiometric proportion. All chemicals were A.R. grade. Here, triethanolamine ($N(CH_2–CH_2–OH)_3$, TEA) was used as a complexing agent to arrest the bismuth ions. The $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film was prepared by using APT on a ultrasonically cleaned glass substrate. Bismuth triethanolamine (Bi–TEA, 0.05 mol/L), sodium selenosulfite (Na_2SeSO_3, 0.05 mol/L), and sodium tellurosulfite (Na_2SeSO_3, 0.05 mol/L) were used as a basic source material for bismuth (Bi^{3+}), selenium (Se^{2-}), and tellurium (Te^{2-}) ions, respectively. Cleaned glass slides of dimension 75 mm × 25 mm × 1.35 mm were used as substrates mounted on a specially fabricated Bakelite holder and rotated with constant speed in the reaction mixture.The rotating speed of the glass substrate was 45 ± 2 rpm.The optimized pH temperatures were 10.5 (±0.5) and 55 (±0.5) °C. The film thickness remained constant after 1.5 h. The deposited film was washed with double distilled water, dried at 100 °C in a muffle furnace, and used for further characterization.

Growth mechanism

According to the Ostwald ripening law, if metal ions in solution are arrested using a polydentate complexing agent like TEA, the rate of reaction between metal ions and chalcogenide ions can be well controlled to avoid precipitation and obtain the desired quality of metal chalcogenide thin films. During the deposition process, owing to the Bi–TEA complex, Bi^{3+} ions are slowly released in the solution and react with Te^{2-} and Se^{2-} ions and are deposited on the cleaned glass substrate at basic pH. Deposition of film occurs when the ionic products of Bi^{3+}, Te^{2-}, and Se^{2-} exceeds the solubility product. The overall growth mechanism of the mixed composites of bismuth tellurium selenide is summarized as follows. Therefore, APT is suitable for the deposition of $Bi_2(Te_{0.5}Se_{0.5})_3$ mixed-metal thin films.

$$[1]\quad (NH_4)_3[Bi_2(CH_2-CH_2-O)_3] + 6H_2O \xrightarrow{\text{pH 10.5}} Bi^{3+} + 3NH_4OH + 3OH^- + 2[N(CH_2-CH_2-OH)_3]$$

$$[2]\quad Na_2SeSO_3 + OH^- \rightarrow Na_2SO_4 + HSe^-$$
$$HSe^- + OH^- \rightarrow H_2O + Se^2$$

$$[3]\quad Na_2TeSO_3 + OH^- \rightarrow Na_2SO_4 + HTe^-$$
$$HTe^- + OH^- \rightarrow H_2O + Te^{2-}$$

The reactions given in eqs. [1]–[3] show that the Bi^{3+}, Te^{2-}, and Se^{2-} are condensed on an ion by ion basis on the glass substrate as

$$[4]\quad Bi^{3+} + nNa_2SeO_3 + nNa_2TeO_3 \xrightarrow{\text{pH 10.5, 55(±0.5) °C,}} Bi_2(Te_{1-x}Se_x)_3 + nNa_2SO_4 + n\text{TEA}$$

Finally, the deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ films are found to be uniform and well adherent to the substrate.

Characterization techniques

X-ray diffraction (XRD) analysis was carried out using a Philips PW-1710 X-ray diffractometer for 2θ ranging from 10° to 1000° with the Cu K_α line used as a beam (λ = 1.5405 Å). Optical study of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film was done by using a UV–vis–NIR spectrophotometer (Shimadzu 3600, Japan) in the wavelength range 400 to 900 nm. The film layer thickness was measured by a surface profilometer. We used an XP-1 Ambios Technology surface profilometer (contact mode) having 1.5 Å resolution. Stoichiometry of the films was studied with energy dispersive X-ray analysis (EDAX). Surface morphology was characterized using a JEOL-JSM-6360 scanning electron microscope (SEM) and atomic force microscopy (AFM) (model NSE, serial No. 245). A silicon nitride cantilever was used to probe the surface of the film. XPS was used to study the binding energy and surface oxidation of the material. Electrical conductivity of the film was studied by using the DC two-probe method at 300–500 K. The working temperature was recorded using a Chromel-Alumel thermocouple. Potential drop across the film was measured with the help of a MeCo 801 digital multimeter and current passed through sample was noted using a digital picoammeter (Scientific equipment, Roorkee DPM 111). The thermovoltage was measured using a Testronix microvoltmeter. Thermal conductivity was measured by the ring probe method using a commercial thermal conductivity measurement apparatus (C-T meter, Teleph, France) at room temperature.

Results and discussion

X-ray diffraction pattern of deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films

The XRD pattern of the deposited thin film is shown in Fig. 1*a*. From the XRD pattern it is seen that as-deposited films are nanocrystalline in nature. The comparison of the observed lattice spacing (*d*) values of $Bi_2(Te_{0.5}Se_{0.5})_3$ mixed composites are in good agreement with the standard *d* Joint Committee on Powder Diffraction Standards (JCPDS) data values for the rhombohedral structure JCPD data files (card Nos. 85 and 85-0519).The comparison of the observed *d* values of the deposited samples are given in Table 1. The crystallite size (*D*) of the film was calculated by using the Debye–Scherrer formula[12] and it was found to be 14.75 nm at 0.0149 half peak width β (radians).

$$[5] \qquad D = \frac{k\lambda}{\beta \cos\theta}$$

where *k* is a constant equal to 0.94, λ is the wavelength of the source, β is full-width at half-maximum (FWHM) in radians, and θ is Bragg's angle. The strongest peak for all films occurred at $2\theta = 24.13°$ with d = 5.46 Å corresponding to a (110) reflection. It indicates that the preferred orientation lies along the (110) direction for $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films. The *D* for the deposits was calculated using the Debye–Scherer formula for the (110) peak assuming that microstrain can be neglected.

Optical studies

The resultant APT-deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ film is continuous and adherent to the substrates. The optical absorption spectra of this sample were been studied to evaluate the absorption coefficient, optical band gap, and nature of the transition involved in the wavelength region 400–900 nm. The absorption coefficient depends on the wavelength for $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film and is shown in Fig. 1*b*. It was observed that the optical absorption coefficient was high ($\alpha = 10^5$ cm^{-1}). The α, energy gap (Eg), and photon energy ($h\nu$) are related as

$$[6] \qquad \alpha = \frac{A}{h\nu}(h\nu - \mathrm{Eg})^n$$

where *A* is a constant, *h* is Planck's constant, ν is frequency, Eg is the optical energy gap of investigated sample, and *n* assumes values of 1/2, 2, 3/2, and 3 for allowed direct, allowed indirect, forbidden direct, and forbidden indirect transitions, respectively. For the allowed direct type of transition

$$[7] \qquad (\alpha h\nu)^2 = A(h\nu - \mathrm{Eg})$$

where *A* is a parameter that depends on the transition probability. Figure 1*b* shows the plot of $(\alpha h\nu)^2$ vs $h\nu$ for $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films. The value of Eg was calculated by the best straight line fits in the plot and the corresponding band gap was obtained by extrapolating the straight portion of the graph of $(\alpha h\nu)^2$ vs $h\nu$ on the energy axis at $\alpha = 0$. α was observed to be 10^5 cm^{-1}

Table 2. Energy dispersive X-ray (EDAX) analysis of the as-deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films.

Film composition	Element	Elements (expected at %)	Elements (actual at %)
$Bi_2(Te_{0.5}Se_{0.5})_3$	Bi	40	46.28
	Te	30	25.48
	Se	30	28.24

Fig. 3. X-ray photoelectron spectroscopy (XPS) spectrum of as-deposited $Bi_2(Te_{0.5}Se_{0.5})_3$ film.

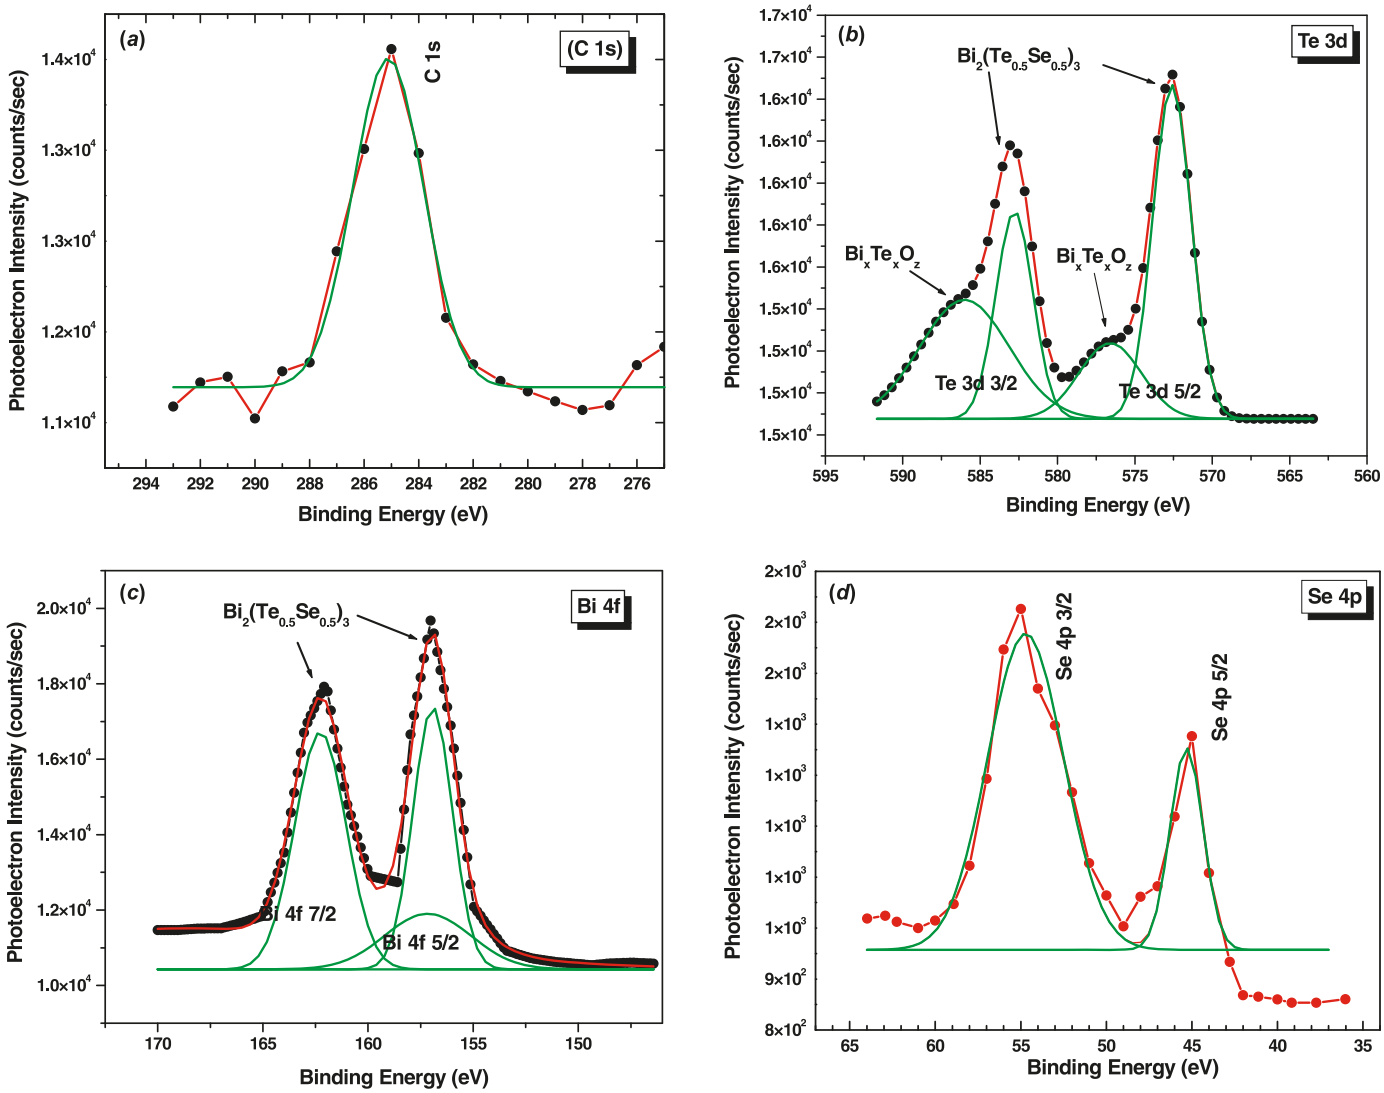
Fig. 4. X-ray photoelectron spectroscopy (XPS) spectra showing (*a*) C 1s, (*b*) Te 3d, (*c*) Bi 4f, and (*d*) Se 4p states.



and supports that the type of transition was direct and allowed and the band gap for $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film was found to be 2.01 eV.

SEM studies

Figure 2*a* shows the surface micrograph of the $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film. The SEM micrograph shows that the film was compact, uniform, and adherent with a pin-hole-free nature and an average of 450 nm. This was due to less agglomeration of ions and the resultant film become nanogain-like.

AFM Studies

The surface morphology of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films was analyzed using the AFM technique. The film surface was well covered with $Bi_2(Te_{0.5}Se_{0.5})_3$ grains. Figure 2*b* shows 2D and 3D AFM images. In the 3D image, an intensity strip is shown that indicates the height of the surface grains along the *z* axis. AFM revels that granular nature of the particles. It was observed that the surface roughness of the film is 8.15 nm × 1 μm × 1 μm. The AFM images are in good agreement with the SEM image.

Table 3. Quantitative analysis of film composition by using XPS.

Film composition	Element	Elements (expected at %)	Elements by XPS (actual at %)
$Bi_2(Te_{0.5}Se_{0.5})_3$	Bi	40	42.07
	Te	30	28.13
	Se	30	27.52

EDAX studies

The elemental analyses of $Bi_2(Te_{0.5}Se_{0.5})_3$ films were done using the EDAX technique. Figure 2*c* shows the EDAX patterns of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films. For the EDAX analysis, BiLa (at 2.50 keV), TeLa (at 3.75 keV), and SeLa (at 1.45 keV) peaks were taken for Bi, Te, and Se elemental analysis, respectively. The atomic percentage ratios of Bi, Te, and Se in deposited thin films of $Bi_2(Te_{1-x}Se_x)_3$ are listed in Table 2. It clearly shows that the theoretical and practical atomic percentages of bismuth, tellurium, and selenium in the $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film is in good agreement. Variation in the percentage analysis of bismuth, tellurium, and selenium might be due to an antisite effect.[13] In the present case,

Table 4. Thermoelectric (TEP) study of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films.

Film composition	S (μVK^{-1})	ρ ($\mu\Omega m^{-1}$)	Thermal conductivity (W m^{-1} K^{-1})	PF (mW K^{-2} m^{-1})	ZT at 300 K
$Bi_2(Te_{0.5}Se_{0.5})_3$	–50.05	9.784	0.409	0.256	0.1878

Note: S, Seebeck coefficient; ρ, resistivity; PF, power factor; ZT, figure of merit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

EDAX analysis shows a value of 46.28 owing to antisite effect. The antisite defect consisted of Bi atoms located on the Te sublattice that carries one negative charge, Mo_{Te}' (As defect).

XPS study

To further confirm the surface composition of the $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films by using XXPS. The XPS data were collected in the constant analyzer energy mode at 20 eV. Mg Kα ($h\gamma$ = 1253.6 eV) radiation was employed as the excitation source with an anode voltage of 15 kV and an emission current of 20 mA. Figure 3 shows a survey spectrum of the $Bi_2(Te_{0.5}Se_{0.5})_3$ thin-film sample. The XPS survey scans from film reveal C, Bi, Te, Se, and O peaks. The presence of the O 1s peak indicates that oxidation of the film takes place after exposure to the atmosphere. The high-resolution spectra of the Bi 4f and Te 3d are obtained using C 1s as the reference at 285 eV. It indicates that the binding energies of different states of the elements present in the films are 596.5, 174.5, and 54.5 eV for Te, Bi, and Se, respectively. The Bi $4f_{5/2}$ and $4f_{7/2}$ peaks have shoulders at higher binding energy, which indicates surface oxidation. The Bi 4f band at 158 eV corresponds to $Bi_2(Te_{0.5}Se_{0.5})_3$, consistent with the phase identified by XRD. These peaks are supported by the presence of Te 3d state at 572.2 eV (Fig. 4). The high binding energy Bi 4f state near 158.7 eV and Te 3d state at 575.8 eV indicate the presence of surface oxide on Bi_2Te_3 nanostructures.[14–16] The Te $3d_{5/2}$ and $3d_{3/2}$ peaks were located at 572.0 and 582.3 eV respecitvely, which indicates the Bi_2Te_3. These results reveal that there is no metallic tellurium impurity, which should appear at lower binding energy. This analysis of sample is consistent with the XRD data.

The quantification in XPS is determined by considering the intensity of the photoelectron. The XPS intensity (I) of a photoelectron peak from a homogeneous solid is given, in a very simplified form, by

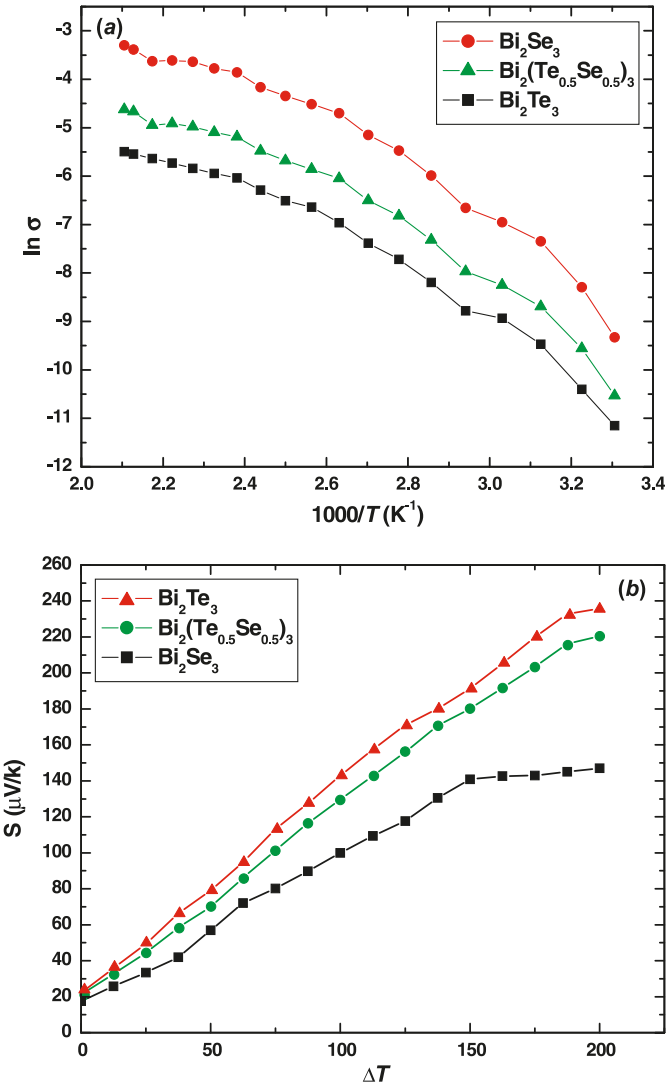
$$[8] \qquad I = J\rho\sigma K\lambda$$

where J is the photon flux, ρ is the concentration of the atom or ion in the solid, σ is the cross-section for photoelectron production (which depends on the element and energy being considered), K is a term which covers all of the instrumental factor (0.7 for MgKα), and λ is the electron attenuation length. The intensity referred to will usually be taken as the integrated area under the peak following the subtraction of a linear or S-shaped background. Equation [8] was used for direct quantification and the analysis is summarized in Table 3.

Conduction studies

Electrical conductivity measurements were made in the temperature range 300 to 500 K at constant voltage (5 V).

Fig. 5. (*a*) The variation of ln σ (Ω^{-1} cm^{-1}) with 1000/T (K) and (*b*) temperature dependence of the Seebeck coefficient of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films.



The temperature dependence of electrical conductivity of the semiconducting thin films is given by

$$[9] \qquad \sigma = \sigma_0 \exp\left(\frac{-E_a}{kT}\right)$$

where k is the Boltzmann constant, σ_0 is the temperature independent part of the conductivity, and E_a is the activation energy. The variation of ln σ with 1000/T in the temperature range 300 to 500 K is shown in Fig. 5*a*. The measurement shows an increase in electrical conductivity of the materials with an increase in temperature, indicating the films are semi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

conducting in nature. For mixed-composite $Bi_2(Te_{0.5}Se_{0.5})_3$ thin films, the electrical conductivities lie between those of Bi_2Te_3 and Bi_2Se_3. From the slopes of the linear plots, activation energies were calculated for a two-temperature region. The activation energies for the low-temperature region and in the high-temperature region were found to be 0.1117 and 0.3161 eV, respectively. The temperature dependence thermo-electromotive force (emf) for all these films is shown in Fig. 5*b* at 300–500 K. Thermoelectric measurements were made using the integral method in which one end of the film was heated and the other kept at a constant low temperature and developed thermal emf was measured with respect to the temperature gradient. In the present work all the samples showed negative polarity of the generated voltage. This confirms n-type conduction of the samples.[17,18] The thermoelectric performance of $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film is quantified by a dimensionless figure of merit (ZT) as

$$[10] \qquad ZT = S^2/\rho K$$

where S^2 is the Seebeck coefficient and K is the thermal conductivity. The room temperature ZT value is 0.1878 as shown in Table 4. Because of a continued increase of the Seebeck coefficient, the power factor ($S^2\sigma$) and thermoelectric performance (ZT) increase substantially at higher temperatures.[7]

Conclusions

It is concluded that $Bi_2(Te_{0.5}Se_{0.5})_3$ thin film was successfully deposited by APT and characterized by opto structural, morphological, and electrical studies. The UV–vis–NIR spectra of the film revealed that the deposited film had a band gap of 2.01 eV. The XRD of the film showed a rhombohedral structure. SEM and AFM micrographs showed that the films are compact, uniform, and adherent with a pin-hole-free nature. From EDAX, the compositions of the films are in good stoichiometric ratios. Electrical and TEP studies showed $Bi_2(Te_{0.5}Se_{0.5})_3$ mixed-metal chalcogenide thin film is semiconducting, having n-type conduction mechanism. A good thermoelectric figure of merit revealed that the $Bi_2(Te_{0.5}Se_{0.5})_3$ thin-film material is suitable for thermocooling devices at room temperature.

Abstract: A simple, efficient, and cost-effective method for the synthesis of a series of sugar–thiazolidinone derivatives by a one-pot reaction of the corresponding thiosemicarbazone of *d*-galactose, *d*-glucose, and *d*-mannose compounds in the presence of dimethyl or diethyl acetylenedicarboxylate is described. Two different methods were used and high yields were obtained in both cases: (A) in EtOAC–H_2O at an ambient temperature and (B) microwave irradiation under solvent-free conditions.

Key words: sugar–thiazolidinone, dimethyl acetylenedicarboxylate, thiosemicarbazone.

Résumé : On a mis au point une méthode simple, efficace et économique de synthèse d'une série de dérivés de type sucre–thiazolidinone impliquant une réaction monotope des dérivés thiosemicarbazone du *d*-galactose, *d*-glucose et *d*-mannose en présence d'acétylènedicarboxylate de diméthyle ou de diéthyle. Deux méthodes différentes ont été utilisées et les deux conduisent à des rendements élevés; l'une implique l'utilisation d'un solvant formé d'eau et d'acétate d'éthyle à la température ambiante et l'autre une irradiation micro-ondes dans des conditions sans solvant.

Mots-clés : sucre–thiazolidinone, acétylènedicarboxylate de diméthyle, thiosemicarbazone.

[Traduit par la Rédaction]

Introduction

Heterocyclic compounds have acquired considerable attention in recent years in organic synthesis because of their potential for use in pharmacological activities.[1] Nitrogen, sulfur, and oxygen containing five- or six-membered heterocyclic compounds have occupied enormous significance in the field of medicinal chemistry. Several substituted thiazolidones have been found to possess hypnotic, anesthetic, sedative, anticonvulsant, and microbiological activities.[2–4] Some of the thiazolines have shown a wide range of pharmaceutical properties.[5] Recently, we reported the synthesis of thiazoline derivatives by the reaction of DMAD and DEADC with thiosemicarbazone derivatives (Scheme 1, structures **1** and **2**).[6] Reaction of thiosemicarbazide with *d*-galactose, *d*-glucose, and *d*-mannose afforded the corresponding thiosemicarbazone derivatives in either acyclic or pyranose structures depending on the solvent and the conditions of the reaction.[7]

The structure–activity relationships (SARs) in a series of thiosemicarbazone and thiosemicarbazide derivatives have been investigated by means of the electron-topological method (ETM).

All derivatives in training sets are potent inhibitors of herpes simplex virus type 1 (HSV-1) replication.[8]

In this work we have considered the reaction of different pyranose – sugar thiosemicarbazone derivatives with dimethylacetylene dicarboxylate and diethylacetylene dicarboxylate to synthesize thiazolidinone derivatives by two different methods: (A) sugar thiosemicarbazone derivatives were mixed with DMAD or DEADC in EtOAC–H_2O as a solvent at ambient temperature and (B) a microwave-assisted synthesis under solvent-free conditions.

Experimental

d-Galactose, *d*-glucose, and *d*-mannose and solvents such as EtOAC, EtOH, and Et_2OH were obtained from the Merck Chemical Co. and were used without further purification. Sugar–thiosemicarbazone derivatives were prepared according to the procedure reported in the literature.[9–12] IR spectra were obtained on a Matson-1000 FT-IR spectrometer. Peaks are reported in wavenumbers (cm^{-1}). All NMR spectra were recorded on a Bruker model DRX-500 AVANCE (^1H, 500 MHz; and ^{13}C, 125 MHz) NMR spectrometer. Chemical shifts are reported in parts per million (ppm) from tetramethylsilane (TMS) as an internal standard with DMSO-d_6 as a solvent. Elemental analyses (C, H, and N) were performed with a Heracus CHN-O-Rapid analyzer. MW irradiation was carried out using a commercial MW oven (SGO 1000 W) with a thermocouple used to monitor the temperature inside the vessel (≈100–115 °C).

A typical procedure

*Synthesis of β-*D*-galactopyranosylthiosemicarbazone (1a–1c)*

Sugar–thiosemicarbazone derivatives were prepared according to the following procedure: to a well-stirred boiling solution of *d*-galactose (10 mmol, 1.80 g) in ethanol

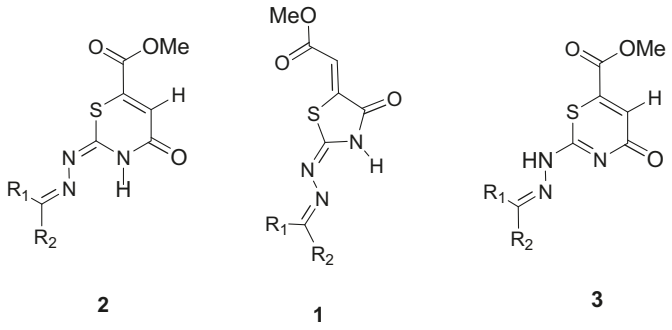
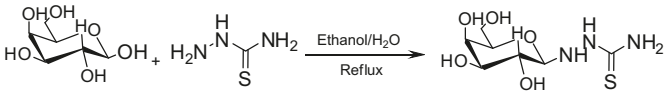
Scheme 1.



2 1 3

Scheme 2. Synthesis of sugar–thiosemicarbazone derivatives.



1b

(30 mL) was added thiosemicarbazide (10 mmol, 0.94 g), and boiling was continued for an additional 8 h, then the reaction mixture was cooled to room temperature and allowed to crystallize, affording a white precipitate as a pyranose (Scheme 2).[9–12]

A typical procedure

*Synthesis of ethyl 2-((***E***)-4-oxo-2-((β-*d*-galactopyranosyl) hydrazono)thiazolidinone-5-ylidene)acetate (3b)*

Method A: To a well-stirred solution of β-*d*-galactopyranosylthiosemicarbazone (4 mmol) in ethyl acetate (10 mL) and water (5 mL) was added a solution of diethyl acetylene dicarboxylate (4 mmol) in small portions. The stirring was continued at ambient temperature for an additional 3 h. The resulting mixture was filtered and recrystallized from EtOH or DMF–H_2O.

Method B: A mixture of β-*d*-galactopyranosylthiosemicarbazone (4 mmol) and DEADC (4 mmol) was subjected to microwave irradiation at a power output of 200 W for 5–7 min and after cooling the reaction mixture to room temperature, the solid residue was recrystallized from EtOH or DMF–H2O. The product was obtained as a yellow powder (Scheme 3). Table 1 shows the reaction conditions and product yields for the Aand B methods.

Yellow powder (recrystallized from EtOH or DMF–H_2O), yield: 88%; mp 189–192 °C. $[\alpha]_D^{25}$ +1.0 (*c* 1.0, DMSO). FT-IR (KBr, cm^{-1}) υ_{max}: 3200–3280 (N–H), 2955–3081 (CH, aliphatic), 1766, 1666 (C=O), 1664, 1630 (C=N) and (C=C). ^{1}H NMR (DMSO-d_6, 500 MHz), ppm) δ: 9.85 (1H, NH), 7.40 (1H, HC=C–), 6.60 (1H, NH), 3.53–5.06 (m, 4H, OH), 4.90 (1H, H-1), 4.39 (1H, H-2) 4.23 (1H, H-3), 3.72 (1H, H-4), 3.68 (m, 1H, H-5), 3.85 (1H, H-6), 3.84 (1H, H-6′) 4.23 (q, 2H, J = 7.14 Hz, –CH_2–), 1.23 (t, 3H, J = 7.14 Hz, –CH_3). ^{13}C NMR (DMSO-d_6, 125.77 MHz), ppm) δ: 168.07, 166.32, 165.74 (C=O, NC=O, C=N), 142.01, 114.53 (C=C), 82.83 (C-1), 76.83 (C-5), 74.20 (C-2), 73.20 (C-3), 70.69 (C-4), 61.66, 60.87 (C-6, –OCH_2–), 14.02 (–CH_3). Results and discussion

In continuing our interest in the synthesis of heterocyclic compounds, such as thiazoline, from thiosemicarbazone derivatives of aldehydes and ketones and also the synthesis of other heterocyclic compounds, we would like now to report the synthesis of a different class of thiazoline compounds from sugar–thiosemicarbazone derivatives. These compounds possess N–H and S=C groups that can react with DMAD and DEADC by attack of the sulfur atom on the triple bond (Scheme 4). The resulting intermediate undergoes aminolysis of the vicinal or distal ester group to the S linkage, with respective formation of the five- or six-membered rings (compounds **3** and **4**) in an 1:1 ratio. Thus, treatment of **2** with DMAD or DEADC afforded two types of cyclic products (**3b** and **4b**, Scheme 3) in moderate to good yields. As the result of conjugate addition of the sulfur center and intermolecular N-acylation, the corresponding thiazolone (**3b**) could be isolated as a major product, which is stabilized by S–O– and S–N close-contact interactions involving the other carbomethoxy group in a quasi five-membered ring and the imino nitrogen of the hydrazone moiety in a quasi four-membered ring, respectively.[10] The reaction of sugar–thiosemicarbazone **1b** also gave one minor product (**4b**). Formation of methyl [1,3]thiazin-4-one-6-carboxylate (**4b**) can be interpreted by the conjugate addition of the sulfur center and alternative N-acylation, presumably furnishing a six-membered ring. As the product ratio **3b**:**4b** increases with longer reaction times, thiazinone **4b** seems to be an unstable kinetic product undergoing ring isomerization to **3b** catalyzed by the methanol that is released in the reaction mixture and can cleave the six-membered lactame at elevated temperature.[13,14]

In this investigation we reported two methods for the synthesis of thiazolinones: (A) β-*d*-galactopyranosyl–thiosemicarbazone was dissolved in ethyl acetate, then DMAD or DEADC is added to this solution. The reaction was carried out with stirring for 2.5–3 h at an ambient temperature and (B) β-*d*-galactopyranosyl–thiosemicarbazone was mixed with DMAD or DEADC, then the reaction was subject to microwave irradiation under solvent-free conditions for a short experimental time. The following results were obtained for the formation of **3c**, after 3 h using method A and after 5 min using method B. A plausible mechanism is shown in Scheme 4.[8]

Compound **3b** has NH groups at 3200–3280 cm^{-1}, a C–H absorption of a thiazine ring at 2955–3081 cm^{-1}, carbonyl groups at 1766 and 1666 cm^{-1}, and C=N and C=C groups at 1664 and 1630 cm^{-1}, respectively, in the FT-IR spectra. The ^1H NMR spectrum of **3b** indicate one singlet quite downfield at δ 9.85 ppm, which are the protons of the NH amide, 7.40 ppm (s, 1H, NH), 6.60 (1H, HC=C, rings), 3.53–5.06 ppm (OH, C4, C5, C6-sugar chain), 3.68–3.85 ppm (3H, C4, C5, C6, sugar), 4.23 and 1.23 ppm ($–CH_2–$ and $–CH_3$ ethoxy groups). The ^{13}C NMR spectra of **3b** indicate carbonyl group carbons (C=O and NC=O) and an imino group (C=N) at 168.07, 166.32, and 165.74 ppm, respectively, alkene groups (C=C) at 142.01 and 114.53 ppm, C-1, C-5, C-2, C-3, and C-4 pyranose cycles at 82.83, 76.83, 74.20, 73.20, and 70.69 ppm, respectively, and a C-6 pyranose cycle and $–OCH_2–$ and $–CH_3$ at 61.66, 60.87, and 14.02 ppm, respectively. Mass spectral data and elemental analyses are also in accordance with the proposed structure. In general, all of the spectral data support the structures for all of the compounds (**3a**–**3f**).

The structures of all the sugar–thiazolidinone derivatives, the reaction conditions, and the product yields are given in Table 1.

Conclusion

In conclusion, sugar–thiazolidinone derivative compounds by two different simple methods were synthesized. Since the use of microwaves is playing an increasingly pivotal role for the synthesis of organic compounds, we used a microwave-assisted method for the preparation of thiazolidinone and obtained excellent yields. No harsh conditions or cumbersome apparatus are required. A simple purification process, a short experimental time for the reaction to be completed, and solvent-free conditions (microwave-assisted) are the main advantages of this method, which make these reactions eco-friendly to the environment.

Abstract: The chemical properties of the triazoline dione have been extensively studied. The relative stability of three tautomers in the gas phase and solution (using PCM model) are evaluated using HF and DFT methods and compared with MP2 level using different basis sets. The results of the calculations indicate that 4*H*-1,2,4-triazole-3,5-dione (**K** form) is more stable in the gas phase than in solution. In addition, the transition states of proton transfer reaction is calculated. The vibrational frequencies and corresponding normal mode assignments of 4*H*-1,2,4-triazole-3,5-dione and 5-hydroxy-3*H*-1,2,4-triazol-3-one (**E1** form) are also theoretically examined. In addition, the variation of dipole moments and charges on atoms with change of solvent is studied. Specific solvent effects with addition of one molecule of water near the electrophilic centers of three tautomers and the transition state of proton transfer assisted by a water molecule was investigated. Aggregation with water molecules does not change the order of stability of isomers, but proton transfer reaction assisted by a water molecule needs less energy than the intramolecular process.

Key words: triazoline dione, tautomerization, solvent effect, specific solvent effect, HOMO–LUMO energies, DFT, MP2, PCM.

Résumé : On a étudié d'une façon extensive les propriétés chimiques de la triazolinedione. On en a évalué les stabilités relatives des trois tautomères en phase gazeuse et en solution en utilisant le modèle de continuum polarisable (MCP) et les méthodes de Hartree-Fock (HF) et de la théorie de la fonctionnelle de la densité (TFD) et on les a comparées avec les valeurs obtenues par la méthode de Møller-Plesset d'ordre 2 (MP2) en utilisant divers ensembles de base. Les résultats de ces calculs indiquent que la 4*H*-1,2,4-triazole-3,5-dione (forme **K**) est la plus stable tant en phase gazeuse qu'en solution. De plus, on a calculé l'état de transition de la réaction de transfert de proton. On a aussi calculé, sur une base théorique, les fréquences vibrationnelles et les attributions des modes normaux correspondants de la 4*H*-1,2,4-triazole-3,5-dione (forme **K**) et de la 5-hydroxy-3*H*-1,2,4-triazole-3-one (forme **E1**). On a aussi étudié la variation des moments dipolaires et des charges sur les atomes avec un changement de solvant. On a aussi étudié l'effet de solvant spécifique pour l'addition d'une molécule d'eau près des centres électrophiles des trois tautomères et l'état de transition du transfert de proton assisté par une molécule d'eau. L'agrégation avec la molécule d'eau ne modifie pas l'ordre de stabilité des isomères, mais la réaction de transfert de proton assistée par une molécule d'eau nécessite moins d'énergie que le processus intramoléculaire.

Mots-clés : triazolinedione, tautomérisation, effet de solvant, effet de solvant spécifique, énergie d'orbitales moléculaires haute-occupée (OM-HO) et basse-vacante (OM-BV), théorie de la fonctionnelle de la densité (TFD), Møller–Plesset d'ordre 2 (MP2), modulation d'impulsion codée (MIC).

[Traduit par la Rédaction]

Introduction

Triazoline diones (TADs) are exceptionally strong electron acceptors and thus are among the most powerful enophiles[1–3] known as well as dienophiles in Diels–Alder reactions.[4–7] TADs are also highly reactive neutral electronphiles that exhibit reactivity smilar to singlet oxygen.[8–13] They react photochemically with compounds having easily abstracted protons and undergo self-reaction to form polymers.[14,15] Reaction with benzene,[16] naphthalene,[17] and phenanthrene[18] gives [4π+2π] adducts. In addition, they act as an aromatization agent of 1,4-dihydropyridines and pyrazolines.[19–21] In the present study, we compare HF, DFT, and MP2 results concerning tautomeric equilibria of triazolinedione molecules in the gas phase and in solution. In addition, we investigate each form when one molecule of water is placed nearby.

Computational method

The vibrational frequencies and optimized structure parameters of triazoline dione and its tautomer have been calculated by using the Hartree–Fock (HF),[22] second-order Møller–Plesset perturbation theory[23,24] and the density functional theory (DFT)[25] level by using the (B3LYP)[26,27] methods at 6–311++G(d, p), 6–311+(d), 6–31++G(d, p), and 6–311G (d) basis set levels. The tautomers were also optimized in polar solvents, and their effects have been considered by using a relatively simple self-consistent reaction field (SCRF)

method[28] based on polarizable continuum model (PCM) of Tomasi.[29,30] The electronic structures of stationary points were analyzed by the natural bond orbital (NBO) method.[31,32] All computations were performed using the Gauss-View molecular visualization program[33] and Gaussian 98 program package on a personal computer.[34]

Results and discussion

Tautomeric equilibria in the gas phase and solution

Triazoline dione can exists as two tautomeric forms (**E** and **K**) in equilibrium (see Fig. 1). Based on PES results and owing to the rotation around the C2–O7 bond, **E** form can be exist as two conformers: in the **E1** form the proton is near the N3 atom, and in the **E2** form the proton is near the N4 atom. The results of calculated total energies and relative stabilities of 5-hydroxy-3*H*-1,2,4-triazol-3-one (**E1** and **E2** forms) and 4*H*-1,2,4-triazole-3,5-dione (**K** form) in the different methods and using many basis sets (presented in Table 1).

The results of our calculations suggest that in the gas phase, **K** form is more stable and the stability order is **K** > **E1** > **E2**. For example, based on the B3LYP/6–311++G (d,p) calculations, the instability of **E1** and **E2** forms over **K** form was found to be 17.32 and 17.76 kcal/mol (1 cal = 4.184 J), respectively. Consideration of the electron correlation effects did not change the stability order, and calculations at the MP2/6–311++G(d,p) level showed **K** form favored by 15.21 and 16.08 kcal/mol over **E1** and **E2** forms, respectively. The addition of a zero-point energy correction (ZPE) does not affect the order of relative stabilities. It is notable that when using large basis sets, the difference between energies of tautomers is slightly reduced. Based on our calculations, it was found that the results of all calculations are not much different from each other, but the differences between **K** form as the most stable isomer and **E1** and **E2** forms decreased.

The results of the calculated equilibrium constants for the **K**→**E1** and **K**→**E2** conversions in the gas phase and with water as the solvent are tabulated in Table 2. As seen in the table, the **K** value for the **K**→**E1** conversion is greater than for the **K**→**E2** one. In addition, going from gas phase to the water solvent phase, the equilibrium constants decreased by a factor near 10^2.

Solvent effects are relevant in tautomer stability phenomena, since polarity differences among tautomers can induce significant changes in their relative energies in solutions. We decided to use polarizable continuum method (PCM) calculations to analyze the solvent effects on tautomerism of triazoline dione. It is important to stress that the PCM model does not consider the presence of explicit solvent molecules, hence, specific solute–solvent interactions are not described, and the calculated solvation effects arise only from mutual solute–solvent electrostatic polarization. The comparison of the results obtained for the gaseous phase and solution presented in Table 3 testify that an energy decrease in tautomers occurrs when changing from gas phase to polar solvents. This means that polar solvents increase the stability of triazoline-3,5-dione compareed with the gas phase. In addition, when going from gas phase to the more polar solvents, a regular decrease in stability of ketone form over enol forms was observed. It is notable that based on HF and DFT calculations, solvation changed the stability order to **K** > **E2** > **E1**. For example, when using HF and DFT calculations using 6–311++G(d,p) basis function, the instability of **E1** and **E2** isomers over **K** form in water was found to be 14.53 and 11.65 kcal/mol (HF), and 10.47 and 11.14 kcal/mol (DFT), respectively. However, the inclusion of electron correlation effects causes the same trends for stability in the gas phase as was observed for solvents.

The intramolecular proton transfer barriers between tautomers **K** and **E1** for title compound by using QST2 method at HF, B3LYP, and MP2 levels using 6–311++G(d,p) basis function were calculated and the results are collected in Table 4. The calculated activation energies were found to be 78.37, 62.82, and 61.47 kcal/mol at the HF, DFT, and MP2 methods, respectively. This reaction in water as solvent was investigated and activation energies were found to be 84.75, 69.63, and 68.27 kcal/mol, respectively. As seen in the table, the process needs more energy in the water solvent case.

In Fig. 2, the optimized structures and selected geometrical parameters of the transition states are presented. As seen in the figure, in the transition state the proton is slightly closer to the nitrogen atom. In addition, when comparing with results obtained from gas phase and water, it was found that the proton in the gas phase is closer to the molecule than in the water case.

Geometrical parameters

The selected geometrical parameters of the possible tautomers of triazoline dione calculated at the MP2/6–311++G (d,p) level in the gas phase and solution are summarized in Table 5.

In the case of triazoline dione (**K** form), a short N4–N5 bond (1.255 Å) is connected to two long bonds N5–C1 (1.503 Å) and C2–N4 (1.501 Å), and this suggests a highly localized N4–N5 bond. These results are with agreement with previously reported data calculated at B3LYP/6–31G* level, for which optimized lengths were found to be N4–N5 1.234 Å, C2–N4 and C2–N5 1.505 Å.[35] However, the calculated N4–N5 bond length in the **E1** and **E2** isomers was found to be 1.250 and 1.246 Å, respectively. The carbonyl bond length C1=O6, calculated for the three isomers in the gas phase, was found to be 1.192, 1.191, and 1.197 Å for **E1**, **E2** and **K** forms, respectively. The selected geometrical parameters of transition state of proton transfer reaction in the gas phase is presented Fig. 2.

The solvent interactions have a pronounced effect on the geometry of the triazoline dion molecule (**K** form). For example, when going from gas phase to polar solution, a regular decrease of the C1–N3 bond length from 1.381 to 1.370 Å was observed. In addition, when going from gas phase to polar solvents, C1–N5, and C2–N4 and N2–N4

bond lengths do not change. Considering the localized nature of the N4–N5 bond, it might also show π-bond reactivity of the N4–N5 bond for cycloaddition, by acting as a dienophile in the gas phase and solution. Similar changes were found for the **E1** and **E2** isomers. For example, when going from gas phase to water, as the most polar solvent, the C1–N3 bond length changed from 1.423 and 1.421 Å to 1.403 and 1.401 Å for **E1** and **E2**, respectively. In addition, when going to polar solvents, the carbonyl bond increased from 1.192 and 1.191 Å to 1.196 and 1.197 Å for **E1** and **E2** isomers, respectively.

Vibrational analysis

To obtain the spectroscopic signature of triazoline dione and its isomers, we performed a frequency calculation analysis. It is notable that based on our literature search only one paper was found in which experimental vibrational modes were reported.[36] The results obtained in this paper are essentially different, and therefore no comparison was made.

Calculations were made for a free molecule in vacuum. The prediction of the vibrational behavior of molecules was based on B3LYP/6–31++G(d,p) results, performed on each stabilized geometry. The data are presented in Table 6.

The frequencies obtained were then scaled by using a scaling factor 0.9679,[37] which should give good agreement between experimental and theoretical results. The highest frequency in the **K** form was found to be 3577.7, 3750.3, and 3524.5 cm^{-1} for the stretching of the N–H group, calculated using the MP2, HF, and DFT methods, respectively. The symmetrical stretching of carbonyl group was found to be 1815.7, 2059.7, and 1848.5 cm^{-1}, calculated with the MP2, HF, and DFT methods, respectively. For the **E1** form, the highest frequency was found for O–H stretching. The

calculated vibrational frequencies were found to be 3642, 3606, and 3951.4 cm^{-1}, calculated using the MP2, DFT, and HF methods, respectively. A comparison of the DFT, HF, and MP2 results shows that these results are strongly dependent on the methods.

Dipole moments, charge distribution, and HOMO–LUMO analysis

Dipole moment is the first derivative of the energy with respect to an applied electric field and is the measure of the asymmetry in the molecular charge distribution. The calculated dipole moments of three tautomeric forms calculated at various methods is presented in Table 7.

A close look at Table 7 indicates that order of dipole moments is **K** < **E1** < **E2** in the gas phase and in solution. The results of calculations show that dipole moments of the **K**, **E1**, and **E2** forms is affected by variation of polarity of the medium, and in all tautomers a regular increase in the dipole moment when using more polar solvents was observed. In addition, calculated dipole moments using large basis sets are slightly lower.

The calculated values of NBO charges using natural population analysis (NPA) of optimized structures of the two forms in the gas phase and solution are given in Table 8.

It can be seen that in the gas phase and in the **K** tautomer, the N3 position carries most negative charge. However in the **E1** isomer, O7 atom takes the most negative charge. The charge distributions of dipolar compounds are often altered significantly in the presence of a solvent reaction field.[38] In the compound **K** when going from gas phase to more polar solvents, the net charge on the N3 atom does not changed. However, the negative charge on the carbonyl oxygens and positive hydrogen atom increases. In addition, the negative charge on the N4 and N5 atoms slightly increases. On the

other hand, the charge on the atoms in the **E1** form is more sensitive to the solvent. For example, the negative charge on the N3 and N5 atoms, when going to polar solvents increases. In addition, when going from gas phase to polar solvents the positive charge on the hydrogen atom increases. HOMOs and LUMOs energies, and energy gaps of two mentioned isomers calculated at HF and DFT method using 6–311++G(d,p) basis set. Three dimensional pictures of HOMO and LUMO of the studied molecules calculated at B3LYP/6–311++G (d,p) level are shown in Fig. 3. The orbital energy level analysis for the title compounds at the B3LYP and HF levels show E_{HOMO} values of –0.2902 and –0.4397 au. in the **K** form. Moreover, the E_{LUMO} values for the triazoline dion isomer were found to be –0.1620 and 0.0021 au, calculated using DFT and HF methods, respectively. These values for the **E1** form were found to be –0.2945 and –0.4478 au for the HOMO and –0.1591 and 0.0011 au for the LUMO, using B3LYP and HF methods, respectively. The HOMO–LUMO energy separation has been used as a simple indicator of kinetic stability.[39,40]

The HOMO–LUMO gaps were found to be 80.44 and 277.2 kcal/mol for **K** and 84.96 and 281.68 kcal/mol for DFT and HF methods, respectively. A large HOMO–LUMO gap implies high kinetic stability and low chemical reactivity, because it is energetically unfavorable to add an electron to a high-lying LUMO or to extract electrons from a low–lying HOMO.[40] The magnitude of the HOMO–LUMO energy separation could indicate the reactivity pattern of the molecule.[41]

The specific solvent effect

Now we investigate the tautomerization of triazoline dion tautomers assisted by a water molecule. In most recent literature studies,[42–46] particular emphasis was laid on the solvation of isolated molecules, because it was proven that explicit water molecules in their first solvation shell have a clear influence on the electronic structure and geometry of the solute and in the tautomerization processes. Selecting the hydrophilic centers on the triazoline dion ring, we searched the most stable monohydrated forms for all tautomers. All geometries were fully optimized using HF, DFT, and MP2 methods with 6–31++G (d, p) basis function. The preferred microsolvated structures optimized with the DFT method are presented in Fig. 4. In addition, the results of calculated total energies and relative stabilities of monohydrated complexes in the gas phase and water solvent case are collected in Table 9. In the **K** form, we find four hydrated complexes in which water can form hydrogen bonding with nitrogen or oxygen atoms (**KW1**, **KW2 KW3**, and **KW4**). The most stable form is the **KW1** form, in which water molecule act as both hydrogen donor and acceptor. In this complex, when oxygen acts as hydrogen acceptor the hydrogen bonding is stronger. However, the difference between the total energies of **KW1** and **KW2** form is small. If one compares the hydrogen bond lengths as a tool to estimate the power of hydrogen bonding, it is clear that in the **KW2** form the hydrogen bonding is stronger.

In addition in the **E** forms (**E1** and **E2**), four aggregations were found (see Fig. 4). The relative stabilities of all complexes were compared, and results are reported in Table 9.

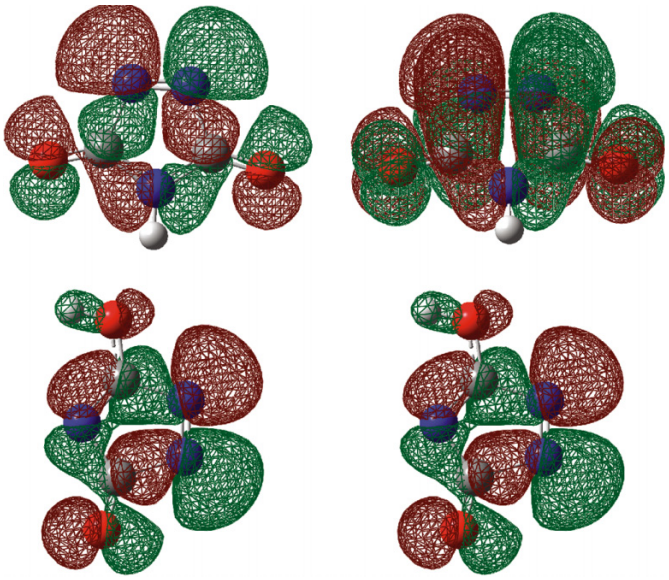

Fig. 4. The optimized geometries of monohydrated triazolinedion tautomers, their total energies (Hartree) and their relative stabilities (kcal/mol) calculated at B3LYP/6–311++G(d,p). Distances in Angstrom.

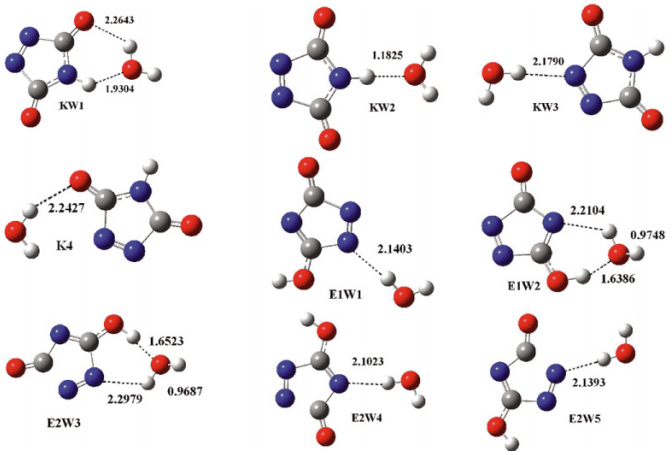

Based on our calculations, the **KW1** complex is most stable. It is clear that **E2** complexes are very unstable. In addition, a close look at Table 9 shows that the difference between stabilities in water decreased.

The optimized structures of the transition state of the proton transfer reaction assisted by a water molecule calculated at HF, DFT, and MP2 levels in the gas phase and water solvent case using 6–311++G(d,p) basis function is presented in Fig. 5. In addition, the results of calculated barriers for proton transfer in the reaction of conversion of **K→E1** assisted by a water molecule in the gas phase and water solvent case is given in Table 10. These results show that all methods predict that activation energies are reduced by the assistance of a water molecule. Interestingly, the activation energy for proton shift greatly decreased to 19.89, 20.83, and 21.93 kcal/mol in the gas phase and to 33.93, 19.46, and 21.79 kcal/mol in the water case, calculated with HF, DFT,

and MP2 methods, respectively. It is clear that the water molecule apparently assists the proton transfer reaction. In addition, it was found that proton transfer assisted by a water molecule in the water solvent case is easier than in gas phase. The selected geometrical parameters in this reaction are presented in Fig. 5. As can be seen, in the gas phase and water case, the water molecule is closer to the oxygen of the carbonyl group in the transition state.

Conclusion

Molecular orbital calculations to study of tautomerism of 4*H*-1,2,4-triazole-3,5-dione and 5-hydroxy-3*H*-1,2,4-triazol-3-one were performed using different calculation levels. In the gas phase, all calculations predict that triazoline dione is more stable. The charge on all eight atoms in the three tautomers were calculated using an NBO method in the gas phase and in solution. The dipole moments of the compounds were calculated in the gas phase and the solvent case and it was observed that they are affected by the solvent. Aggregation with water molecule does not change the stability order of the isomers, but the proton transfer reaction assisted by a water molecule needs less energy than the intramolecular process. The HOMO–LUMO energy separation indicates kinetic stability of the title compound. The values of the NBO charges using the natural population analysis (NPA) are calculated. It was found that in the gas phase and in the **K** form, the N3 position carries most negative charge. However, in the **E1** isomer, O7 atom takes the most negative charge.

Dual-level direct dynamics study on the hydrogen abstraction reaction of fluorine atom with 1,1-difluoro-1-chloroethane

Li Wang, Song Liu, Hongqing He, and Jinglai Zhang

Abstract: The kinetic properties of the reaction of F atoms with $CH_2H'CF_2Cl$ are investigated by a dual-level direct dynamics method. Optimized geometries and frequencies of all the stationary points and extra points along the minimum-energy path (MEP) are obtained at the MPW1K/6–311+G(d,p) level of theory. Two complexes with energy less than that of the reactants are located in the two reactant paths, respectively. The energy profiles of two reactions are refined with the interpolated single-point energies (ISPE) method at the G3(MP2)/MPW1K level. The rate constants are evaluated using the canonical variational transition state theory (CVT) with a small-curvature tunneling correction (SCT) over a wide range of temperature 200–2000 K. Agreement between the calculated CVT/SCT rate constant and the experimental value is good at 295 K. Our calculations show that the reaction path $CH_2H'CF_2Cl + F \rightarrow CH_2CF_2Cl + H'F$ (Ra) is the major reaction path below 400 K. Moreover, the contribution of $CH_2H'CF_2Cl + F \rightarrow CHH'CF_2Cl + HF$ (Rb) to the whole reaction increases with the temperature increasing and exceeds path Ra to be the major reaction path.

Key words: density functional theory, direct dynamics method, rate constants.

Résumé : On a étudié les propriétés cinétiques de la réaction des atomes de fluor avec le $CH_2H'CF_2Cl$ par une méthode dynamique directe à double niveau. On a optimisé les géométries et on a obtenu les fréquences de tous les points stationnaires et les points supplémentaires le long de la voie d'énergie minimale (VEM) au niveau MPW1K/6–311+G(d,p) de la théorie. Les deux complexes comportant moins d'énergie que les réactifs se trouvent respectivement dans les voies de ces deux réactifs. Les profils d'énergie des deux réactions ont été affinés par la méthode des énergies monoponctuelles interpolées (EMPI) au niveau G3(MP2)/MPW1K. Les constantes de vitesse ont été évaluées par la théorie de l'état de transition canonique et variationnelle (TCV) avec une correction pour l'effet tunnel à faible courbature (TFC) sur une grande plage de température allant de 200 à 2000 K. À 295 K, l'accord est bon entre la constante de vitesse calculée par la méthode TCV/TFC. et la valeur expérimentale. Les calculs effectués dans cette étude montre que la voie réactionnelle pour la réaction $CH_2H'CF_2Cl + F \rightarrow CH_2CF_2Cl + H'F$ (Ra) est la voie réactionnelle principale en-dessous de 400 K. De plus, lorsque la température réactionnelle augmente, il y a une augmentation de la contribution de la voie $CH_2H'CF_2Cl + F \rightarrow CHH'CF_2Cl + HF$ (Rb) à la réaction globale au point où elle peut devenir la voie réactionnelle principale.

Mots-clés : théorie de la fonctionnelle de la densité, méthodes dynamiques directes, constantes de vitesse.

[Traduit par la Rédaction]

Introduction

Recognition of the adverse effects of chlorofluorocarbon (CFC) release into the atmosphere has led to an international effort to replace CFCs with environmentally acceptable alternatives.[1,2] Hydrochlorofluorocarbons (HCFCs) are considered to be an important class of CFCs substitutes, since they retain many desirable properties of CFCs and have less ozone depletion potential. Moreover, the inclusion of at least one C–H bond makes them react readily with OH radicals, oxygen atoms, and other atmospheric constituents. A large number of kinetic data are available for the reactions including pure hydrocarbons, however there are limited reports on the reactions including ethane substituted by both fluorine and chlorine, particularly for 1,1-difluoro-1-chloroethane (CH_3CF_2Cl). Only one experimental kinetic study was performed on the reaction of CH_3CF_2Cl with F atoms at 295 ± 2 K.[3] No experimental values are available at other temperatures. Furthermore, only the total rate constant was measured, while the detailed mechanism as well as the branching ratio was not reported. From the mechanistic point of view, two reaction pathways are available,

$$CH_2H'CF_2CL + F \rightarrow CH_2CF_2Cl + H'F\,(Ra)$$

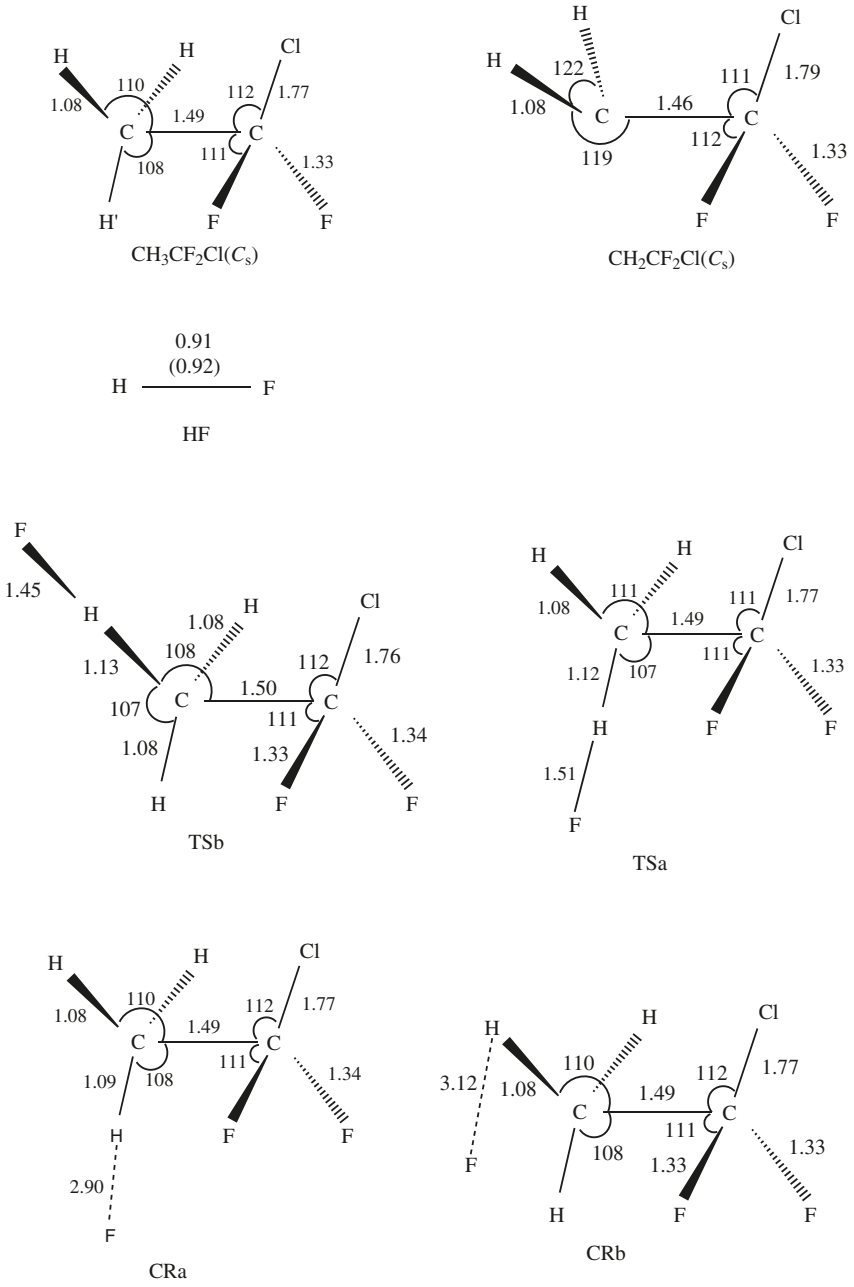
Fig. 1. Optimized geometries of reactants, complexes, products, and two transition states at the MPW1K/6–311+G(d,p) level. The value in the parentheses is the experimental value.[23] Bond lengths are in angstroms and angles are in degrees.



$$CH_2H'CF_2CL + F \rightarrow CH\,H'CF_2Cl + HF\,(Rb)$$

Which reaction path will be the major one? Since this problem is difficult to determine experimentally, a detailed theoretical investigation is very desirable. The aim of the present study is to provide a deep insight into the mechanism of this two-path reaction, as well as to obtain the temperature dependence of the rate constants and branching ratio over a wide temperature range. The dual-level direct dynamics method[4–6] proposed by Truhlar and co-workers are used to investigate the dynamic properties of the title reaction. In this approach, we obtain the potential energy surface (PES) information directly from density functional theory (DFT) calculations and evaluate the rate constants by the variational transition-state theory (VTST).[7–9] The comparison between theoretical and experimental results will be discussed.

Calculation methods

All electronic structure calculations involved in this work were completed using the Gaussian 03 program package.[10] The geometries and frequencies of all the stationary points (including reactants, complexes, products, and transition states) of the title reaction are calculated by modified Perdew–Wang 1-parameter model for kinetics (MPW1K),[11] with the 6–311+G(d,p) basis set (MPW1K/6–311+G(d,p)). It is well-known that hybrid Hartree–Fock density functional theory (hybrid DFT) is a very attractive alternative for many

applications, since its computational cost is low compared with ab initio methods. Although the good performance of hybrid DFT in structural and thermochemical applications is well documented, its usefulness in kinetics calculations has not been established. MPW1K[11] is a method developed over the past decade that shows great promise for improvement in both the calculation of reaction barrier heights and transition state geometries. To obtain more reliable reaction enthalpies and barrier heights, high level single-point calculations for the stationary points are performed by G3(MP2) theory,[12] using the MPW1K-optimized geometries. The minimum-energy path (MEP) is calculated by the intrinsic reaction coordinate (IRC) theory,[13,14] with a gradient step size of 0.05 $(amu)^{1/2}$ bohr at the MPW1K level to confirm that the TS really connects with minima along the reaction path. Also, first and second energy derivatives at geometries along the MEP are obtained to calculate the curvature of the reaction path and to calculate the generalized vibrational frequencies along the reaction path. The dual-level potential profile along the reaction path is further refined with the interpolated single-point energies (ISPE) method.[15] Four nonstationary points, i.e., ±0.05, ±1.0, for the reaction path Ra are used to correct the lower level reaction path. However, only three nonstationary points (–0.05, +0.15, +1.0) are employed for the reaction path Rb, since the points close to –1.0 in the reactant side do not converge at the G3(MP2) level. The information on the potential energy surface is used to evaluate the rate constants by means of the Polyrate 9.7 program.[16] The rate constants are calculated by using the variational transition state theory (VTST)[7–9] proposed by Truhlar and co-workers. The specific level of VTST that we used is the canonical variational transition-state theory (CVT),[17–19] and the tunneling correction is considered by the centrifugal-dominant small-curvature semiclassical adiabatic ground-state (CD-SCSAG)[20,21] method. The CD-SCSAG approximation is a generalization of the Marcus–Coltrin approximation,[22] in which the tunneling path is distorted from the MEP out to a concave-side vibrational turning point in the direction of the internal centrifugal force. In the present study, the small-curvature tunneling correction is computed with equal segments in the Boltzmann and θ integrals, and the number of Gauss–Legendre quadrature points is chosen as 40 for computing the Boltzmann average. Also, the sixth-order Lagrangian interpolation is used to obtain the values of the effective mass for the CD-SCSAG tunneling calculation. The $^2P_{1/2}$ and $^2P_{3/2}$ electronic states of the fluorine atom, with a 404 cm^{-1} splitting due to the spin-orbit coupling, are used in the calculation of the electronic partition functions. The curvature components are calculated by using a quadratic fit to obtain the derivative of the gradient with respect to the reaction coordinate. Finally, the total rate constants are obtained from the sum of the individual rate constants associated with the Ra and Rb reaction paths.

Results and discussion

1. Stationary points

The geometric parameters of all the reactants, complexes, products, and transition states optimized at the MPW1K/6–311+G(d,p) level, along with the available experimental data, are drawn in Fig. 1. The Cartesian coordinates and electronic energies for MPW1K/6–311+G(d,p) optimized geometries of all stationary points are listed in Table 1. It is seen that the theoretical values are in reasonable accord with the experimental ones, with the maximum deviation within 0.01 Å.[23] As shown in Fig. 1, both CH_3CF_2Cl and CH_2CF_2Cl radicals have C_s symmetry. For the CH_2CF_2Cl radical, C_1 symmetry conformation is not obtained. For the three hydrogen atoms in CH_3CF_2Cl, H′ (see Fig. 1) is different from the other two, as a result, two hydrogen abstraction reactions (Ra and Rb) are identified. Reactions Ra and Rb proceed via transition states TSa and TSb, leading to the same product of CH_2CF_2Cl radical with C_s symmetry. The transition states TSa and TSb resemble the reactants more than the products, with a smaller elongation of the C–H bond for 3.7% and 4.6%, compared with the C–H equilibrium bond length in isolated CH_3CF_2Cl, respectively, and a significant elongation of the H–F bond for 65.9% and 59.3% with respect to the equilibrium bond length in HF, respectively, i.e., both reactions proceed via "early" transition states. This rather early character in both transition states is in accordance with the low barrier heights and the exothermicity of both reaction paths, in keeping with Hammond's postulate.[24]

The harmonic vibrational frequencies are calculated at the same level of theory to characterize the nature of each critical point and to make zero-point energy (ZPE) corrections. The number of imaginary frequencies (0 or 1) indicates whether a minimum or a transition state has been located. The harmonic vibrational frequencies of all the reactants, complexes, products, and transition states along with the available experimental data[25] are shown in Table 2. As can be seen, our calculated frequency of HF agrees well with the experimental value with a deviation 3.7%. The transition state is identified with only one negative eigenvalue of the Hessian matrix. The imaginary frequencies are 193*i* cm^{-1} for TSa and 271*i* cm^{-1} for TSb.

The reaction energy at 298 K ($\Delta H_{298}{}^0$), the reaction energy at 0 K (ΔE), and the barrier height (ΔV) calculated at the MPW1K/6–311+G(d,p) and G3(MP2)//MPW1K/6–311+G(d,p) levels, as well as the experimental enthalpy, are summarized in Table 3. Both reaction paths (Ra and Rb) have the same products, for which the reaction energy at 298 K ($\Delta H_{298}{}^0$) of –31.7 kcal mol^{-1} (1 cal = 4.184 J) calculated at the G3(MP2)//MPW1K level agrees well with the experimental value of –32.14 ± 4.3 kcal mol^{-1}, which is derived from the experimental standard heats of formation (CH_3CF_2Cl, –127 ± 2 kcal mol^{-1}; CH_2CF_2Cl, –75 ± 2 kcal mol^{-1}; F, 19.0 ± 0.1 kcal mol^{-1}; HF, –65.14 ± 0.2 kcal mol^{-1}).[26] Since the barrier height of Ra is slightly lower than that of Rb, it is difficult to conclude which one will be the major reaction path. To express this more clearly, a schematic potential energy surface of the title reaction with zero-point energy (ZPE) corrections is plotted in Fig. 2. Note that the energy of the reactants is set to zero as a reference. For each reaction path, the complex with energy below that of the reactants is first formed, then starting from the complex, the reaction proceeds via a transition state to reach the products. The barrier height of TSa (0.8 kcal mol^{-1}) is lower than that of TSb (1.0 kcal mol^{-1}) at the G3(MP2) level. According to the barrier heights, we can tell that these two

Fig. 2. Schematic pathways for the reaction $CH_3CF_2Cl + F \rightarrow$ products. Relative energies with ZPE at the G3(MP2)//MPW1K/6–311+G(d,p) are in kcal mol^{-1}. The values in parentheses are those obtained at the MPW1K/6-311+G(d,p) level.

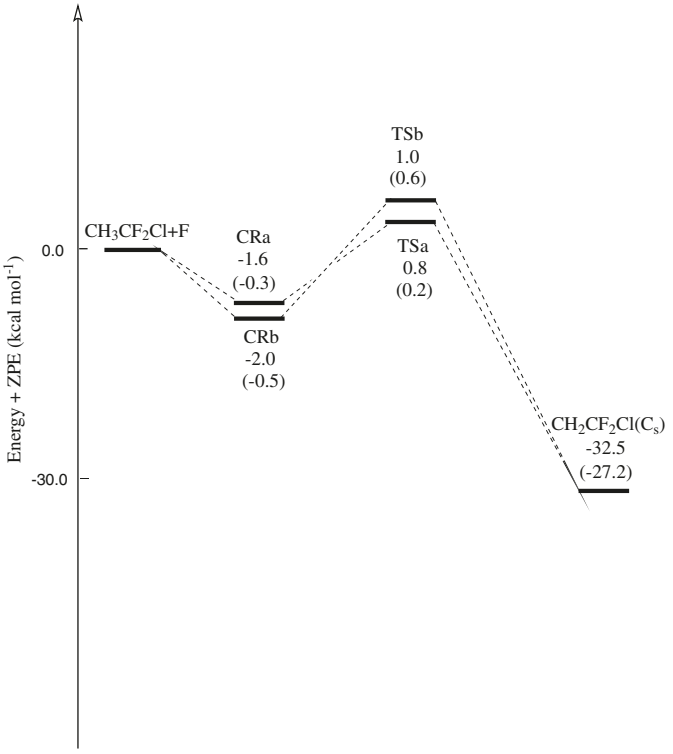

Fig. 3. Classical potential energy curve (V_{MEP}), ground-state vibrationally adiabatic energy curve (V_a^G), and zero-point energy curve (ZPE) as functions of s (amu)$^{1/2}$ bohr at the G3(MP2)//MPW1K/6–311+G(d,p) level for the CH_2H' $CF_2CL + F \rightarrow CH_2CF_2Cl + H'F$ (Ra).

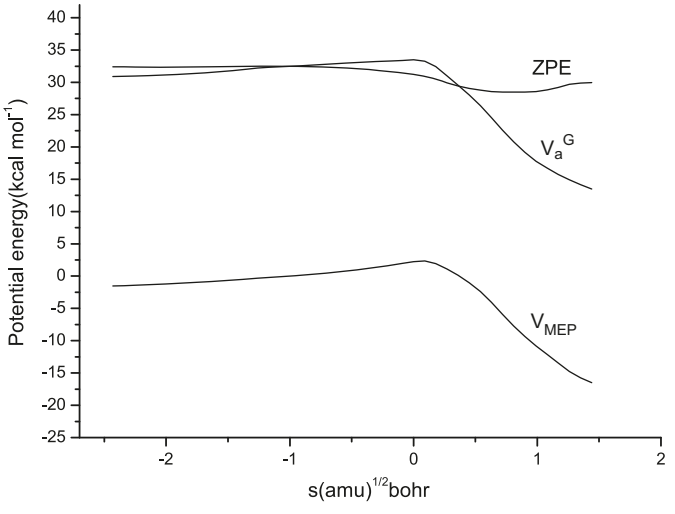

reaction paths should be competitive. Considering that two hydrogen atoms are available for Rb abstraction channel and only one hydrogen atom can be abstracted for Ra path, which reaction path will be the major one is still not clear.

2. Dynamics calculations

The MEP for each reaction path is calculated using the intrinsic reaction coordinate (IRC) theory[13,14] at the MPW1K/6–311+G(d,p) level, and the dynamics calculations of the title reaction are carried out with the VTST-ISPE[15] method at the G3(MP2)//MPW1K level. The classical potential energy ($V_{MEP}(s)$), the ground-state vibrational adiabatic potential energy ($V_a^G(s)$), and the zero-point energy (ZPE) curve of reaction Ra as functions of the intrinsic reaction coordinate (s) are plotted in Fig. 3, where $V_a^G(s) = V_{MEP}(s) + ZPE(s)$. It should be noted that the locations of the maximum on the $V_a^G(s)$ and $V_{MEP}(s)$ energy curves shift in the s-direction toward the products. Similar conclusions can be reached from the other reaction path Rb.

The PES information for each reaction path obtained at the G3(MP2)//MPW1K/6–311+G(d,p) level were put into the Polyrate 9.7 program to calculate the VTST[7–9] rate constants over the temperature range 200–2000 K. The forward rate constants are calculated using CVT[17–19] with the SCT[20,21] correction. The rate constants of k_a, k_b, and the total rate constants $k = k_a + k_b$, along with the available experimental value[3] are plotted against 1000/T (K^{-1}) in Fig. 4*a*, and the temperature dependence of the k_a/k and k_b/k branching ratios

Fig. 4. (*a*) Plot of the calculated individual rate constants k_a, k_b, the total rate constants k, and the available experimental value versus 1000/T for 200–2000 K. (*b*) Calculated branching ratio versus 1000/T for 200–2000 K.

are shown in Fig. 4*b*. Just one experiment was performed for the title reaction at 295 ± 2 K[3], and the total rate constant was obtained. Our calculated rate constant is in reasonable agreement with the experimental one. Based on our calculations, the two reaction paths are competitive, i.e., path Ra to yield product CH_2CF_2Cl + H′F is the major reaction path below 400 K. However, the contribution from Rb leading to $CHH'CF_2Cl$ + HF increases with increasing temperature and exceeds path Ra as the major reaction path. For example, the k_b/k ratio is about 43% at 200 K, 52% at 500 K, and 66% at 2000 K. Furthermore, to achieve a good estimate for the title reaction over a wide temperature range, the CVT/SCT rate constants are fitted by the following four-parameter expression within 200–2000 K (in cm^3 $molecule^{-1}$ s^{-1}),

$$[1] \qquad k = 3.20 \times 10^{-17}\, T^{1.94} \exp\left[80.9 \times \frac{T + 111.7}{T^2 + 111.7^2}\right]$$

Conclusions

In this paper, dual-level direct dynamics method is employed to study the hydrogen abstraction reaction CH_3CF_2Cl with F atom, for which only total rate constants at one temperature is reported, and no detail reaction mechanism is performed. The rate constants calculated by the VTST at the G3(MP2)//MPW1K/6–311+G(d,p) level are observed to agree well with the available experimental value. It is shown that two reaction paths are competitive, i.e., reaction path Ra to yield the products CH_2CF_2Cl and H′F dominates the reaction below 400 K, while the contribution from path Rb increases with increasing temperature and exceeds path Ra to be the major reaction path. The four-parameter expression (in cm^3 $molecule^{-1}$ s^{-1}) for the reaction over the whole temperatures is given by eq. [1]. We hope that the theoretical results may be useful for estimating the kinetics of the reaction over a wide temperature range where no experimental data is available.

Abstract: To investigate the base pair binding probabilities for nucleic acid bases, numerous models were studied for contacts between adenine, thymine, guanine, cytosine, and uracil using density functional theory (DFT) in combination with the 6–311G* basis set. We obtained an assessment for the energy given by our calculations in gas and aqueous phases, which showed that it should be incorporated into hydrogen bonding and propeller rotational energies. The 42 complexes of base pairs (5 regular and 37 irregular base pairs) were proposed and their hydrogen-bonding (H-bonding) properties were verified. The hydrogen bonds in some irregular base pairs, including CC, UU, and TT (series 1), were stronger than in regular GC and AT base pairs. Also, the strength of the hydrogen bonds in the proposed base pairs, including CU, GG, GU, and TU (series 2), were similar to regular base pairs from an energetic point of view. The propeller rotations revealed a higher rotational barrier energy (6–7.5 kcal/mol; 1 cal = 4.184 J) for irregular base pairs (series 1 and 2) than regular GC and AT ones (1–3 kcal/mol). Nevertheless, the trend in these affinities of the complex contact probabilities and their biological properties were confirmed by our calculations.

Key words: nucleic acid bases, base pair binding probability, hydrogen-bonding energy, propeller rotational energy.

Résumé : Dans le but d'évaluer les probabilités de fixation de paires de bases pour des bases d'acide nucléique, plusieurs modèles ont été étudiés pour les contacts entre l'adénine, la thymine, la guanine, la cytosine et l'uracile à l'aide de la théorie de la fonctionnelle de la densité (TFD) en combinaison avec des ensembles de bases 6–311G*. On a pu évaluer les énergies obtenues par nos calculs en phases gazeuses et aqueuses qui montrent qu'elles devraient être incorporées dans les énergies des liaisons hydrogènes et de la rotation de l'hélice. Les 42 complexes de paires de bases (5 régulières et 37 paires de bases irrégulières) ont été proposés et on a vérifié leurs propriétés de liaisons hydrogènes. Les liaisons hydrogènes dans quelques-unes des paires de bases irrégulières, comprenant CC, UU et TT (série 1) sont plus fortes que dans les paires de bases régulières, GC et AT. De plus, d'un point de vue énergétique, les forces des liaisons hydrogènes dans les paires de bases proposées, incluant CU, GG, GU et TU (série 2) sont semblables à celles de paires de bases régulières. Les rotations de l'hélice ont mis en évidence que, pour les paires de bases irrégulières (séries 1 et 2), les barrières à l'énergie de rotation (6 à 7.5 kcal/mol ; 1 cal = 4.184 J) sont plus élevées que celles pour les bases régulières, GC et AT, par environ 1 à 3 kcal/mol. Toutefois, ces calculs confirment la tendance dans ces affinités de probabilités de complexe de contact ainsi que leurs propriétés biologiques.

Mots-clés : bases d'acides nucléiques, probabilité de fixation de paires de bases, énergie de liaison hydrogène, énergie de rotation de l'hélice.

[Traduit par la Rédaction]

Introduction

A DNA molecule is composed of two strands, running in opposite directions, which are bridged by hydrogen bonds between specific pyrimidines in one strand and purines in another (i.e., one strand runs 5′ to 3′and the complementary 3′ to 5′). Also in the RNA molecule, the hydrogen bond interactions between the nucleic acid base heterocycles are of particular importance. In fact, the bases are combined with two different interaction types: hydrogen bonding and aromatic base stacking.[1] The nature of the stabilization of these two types of pairs is different. These are stabilized by electrostatic energy as well as dispersion energy, respectively.[2] Both interactions are of equal importance in nucleic acids. The two strands of a DNA molecule are held together by the hydrogen bonding between the related bases.[3] Adenine can form two hydrogen bonds with thymine and cytosine can form three hydrogen bonds with guanine (Fig. 1).

To study the essential interaction of DNA bases experimentally, gas-phase experiments need to be performed. However, experiments on DNA base pairs are not easy to perform.[4–7] The gas-phase experiments give large amounts of

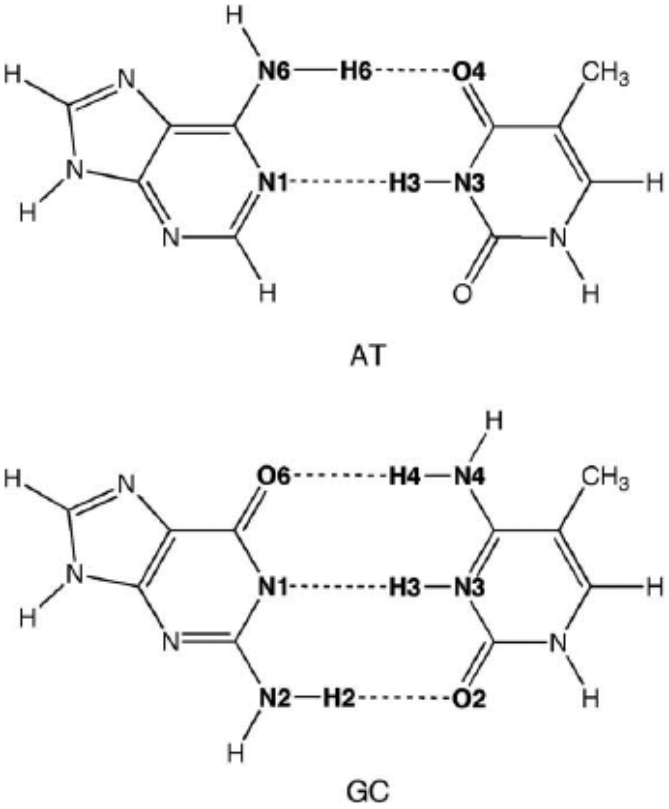
Fig. 1. The Watson–Crick DNA base pairs AT and GC.



data related to the hydrogen-bonding (H-bonding) property. Also, these data are not related to the stacking of bases. For such studies, the stacked configurations might not be considered in the course of the experiment.[8,9] In recent years, theoretical study has developed into a rapid technical method and is comparable to experimental approaches in efficiency.[10] The theoretical methods can be used for simultaneous evaluation of both hydrogen bonding and aromatic base stacking. Following our previous research studies,[11–14] in this paper we investigated all contact probabilities (42 states) that might occur in the base pairs in gas and water phases (Table 1). Interestingly, the unrestricted density functional method satisfactorily confirmed the regular nucleic acid base pairs contacts (e.g., C:G and A:T).

Computational methods

Full geometry optimizations were performed without any symmetry constraints by means of hybrid functional UB3LYP and the 6–311G* basis set, employing the Gaussian 98 code.[15,16] To assess the performance of this approach, all structures were computed at higher theoretical levels, in a way that UHF/STO-3G outputs were used as inputs for the UHF/6–311G*. Also, UHF/6–311G* outputs were used as inputs for the UB3LYP/6–311G*. To improve the accuracy in estimating hydrogen-bond strengths and distances, we have done the calculations in a comparative manner and used the reasonable unrestricted B3LYP (UB3LYP) instead of the B3LYP method. This method was selected because there is significantly less spin contamination found in the DFT calculations, especially when unrestricted Kohn–Sham orbitals are used.

To evaluate the interaction between $base_1$ and $base_2$ in DNA, the basis set superposition error (BSSE) needs to be included in the binding energy calculations in the systems under consideration. For this purpose, the counterpoise method using "ghost" atoms has been used according to the following equation:

$$E_b = E(\mathrm{DNA_{base1}_DNA_{base2}}) - [E(\mathrm{DNA_{base1-ghost}_}E(\mathrm{DNA_{base2}}) + E(\mathrm{DNA_{base1}_}E(\mathrm{DNA_{base2-ghost}})]$$

where E_b is the counterpoise interaction energy and $E(\mathrm{DNA_{base1}_DNA_{base2}})$ is the total energy of $\mathrm{DNA_{base1}}$ interacting with $\mathrm{DNA_{base2}}$. The ghost molecule / $\mathrm{DNA_{base}}$ corresponds to additional basis wave functions centered at the position of the $\mathrm{DNA_{base1}}$ or the $\mathrm{DNA_{base2}}$, but without any atomic potential.

Propeller rotational energy profiles were performed around the hydrogen bonds of 42 proposed base pairs using the UB3LYP calculation and 6–311G* basis sets in the gas phase and in water as a standard biological solvent (Fig. S3 of the Supplementary data; Figs. 2 and 3). The 42 states of the proposed base pairs include 37 states of irregular and 5 states of regular base pairs (e.g., C:G and A:T). The polarizable continuum model (PCM), the polarizable conductor calculation model (PCCM), and the integral equation formalism model (IEFPCM) were applied to perform solvation analysis for structures 1–47 (5 regular, 37 irregular base pairs, and 5 separate bases) in water.

To obtain reliable results, UB3LYP/6–311G* calculations were carried out for 15 states of separated base pairs with no hydrogen bonds (nonbinding base pairs) in the gas and water phases. On the other hand, all H-bonding probabilities for Watson–Crick pairs consisting of 5 regular and 37 irregular base pairs with hydrogen bonds (binding base pairs) were verified at the same level (Tables 1–2; Tables S2 and S3 of the Supplementary data). In these tables, to facilitate the progress of comparison of separated base pairs without any hydrogen bonds (e.g., A + A and A + C) and with hydrogen bonds (e.g., AA and AC), the lowest entry in each box was set to zero and the others were adjusted accordingly. To attain a deeper insight into the nature of H-bonded interactions, Atoms In Molecules (AIM) analysis[17] was also carried out at the UB3LYP/6–311G* level. All the calculations were performed using the Gaussian 98 program package. The bond critical points of the O–H bonds and the H–N interactions were calculated and are reported.

Results and discussion

In this section we begin with listing our results followed by discussions. Therefore, thermodynamic data were calculated at UB3LYP/6–311G* level of theory for: guanine (G), adenine (A), cytosine (C), thymine (T), uracil (U), and the 42 states of the proposed base pairs (Table 1). These data include the sum of the electronic and thermal energies (E) for all complexes in gas and water phases that were obtained by the frequency option of the Gaussian 98 program (Table 2; Tables S2 and S3 of the Supplementary data).

Relative energies (E_r) for the pyrimidine–purine base pairs are presented for the gas phase (Table 2). To facilitate evaluation of the stability of the proposed base pair, the lowest

entry for each binding base pair was set to zero and the related nonbinding base pairs were adjusted accordingly. The mentioned relative energies reflected the stability of the binding base pairs related to those nonbinding base pairs. For the propeller rotational energy, the stabilities of the proposed base pairs, including the regular and irregular ones, are depicted in Figs. 2 and 3. The propeller rotation is described as the turning around of the torsional angle of the aromatic plane in pyrimidines and purines with regard to each strand. The related torsional angles were scanned from 0° to 50° and the relative energies were obtained (Fig. 2). These were separately calculated for pyrimidine–purine, pyrimidine–pyrimidine, and purine–purine contact probabilities. The propeller rotational energy was reflective of aromatic base stacking. Thus, these figures predict the status of aromatic base stacking. The relative energy results in Table 2 indicated that among the studied base pairs AA, AC, AG, AU, CC, CU, GC, GG, GU, UU, CT5, TU4, and GC3 are more stable in

both the gas phase (E_{r1}*) and in water (E_{r2}*) with the PCM method calculated at UB3LYP/6–311G*. On the other hand, in Fig. 2 it could be observed that the stability of the above proposed base pairs were evaluated by torsional angle-scanned aromatic plane (propeller rotation) energy at UB3LYP/6–311G* method. Accordingly, to evaluate the virtual interaction between DNA bases, both hydrogen bonding and aromatic base stacking should be considered simultaneously. On the basis of hydrogen bonding and propeller rotational energies (aromatic base stacking), the most probable nucleic acid base pairs are shown in Fig. 3. Finally, we found a rough estimate of the stability factors including hydrogen bonding and propeller rotational energies of base-pair binding probabilities (Table 3). As shown in Tables 2 and 3, the formation of the complexes were affected by relative energies (E_r*) and propeller rotational energy. Table 3 indicates that the hydrogen bonds in irregular base pairs including CC, UU, and TT4 (series 1) are stronger than those in regular GC and AT base pairs. Moreover, it can be found in Table 3 and Fig. 2 that relative propeller rotational energy parameters showed instability for three of the proposed base pairs mentioned before. Therefore, according to the relevant thermodynamic results, the regular GC and AT base pairs are form easily.

According to the topological analysis of electron density in AIM theory, ρ is used to describe the strength of a bond. In

Note: ρ, bond strength; $\nabla^2\rho$ (describes bond character) = $\lambda_1 + \lambda_2 + \lambda_3$, where λ_i is an eigenvalue of the Hessian matrix of ρ; when $\nabla^2\rho < 0$, a covalent bond is represented; when $\nabla^2\rho > 0$, an ionic bond is represented.

general, the larger the value of ρ is, the stronger the bond. The $\nabla^2\rho$ describes the character of the bond. Where $\nabla^2\rho < 0$, the bond is covalent, whereas $\nabla^2\rho > 0$ shows that the bond is ionic. Here, $\nabla^2\rho = \lambda_1 + \lambda_2 + \lambda_3$, where λ_i is an eigenvalue of the Hessian matrix of ρ. Therefore, when one of the three λ_i was positive and the other two were negative, we represented it by (3, –1) and called it the bond critical point (BCP). When one of the three λ_i was negative and the other two were positive, we represented it by (3, +1) and called it the ring critical point (RCP), indicating that a ring structure exists (Table 4).

All the BCP data for the complexes are shown in Table 4. Analysis of ρ showed two generally H-bond critical points, i.e., the O and H as well as H and N based H-bonding for each most stable base pair, characterized by values of ρ ranging from 0.027 to 0.040. These electron densities at BCPs indicated the presence of C–H···O or C–H···N bonding interactions presented in the pyrimidine and purine base pairs. It can be found that the positive values of $\nabla^2\rho$ in O and H as well as H and N based H-bonding were in the range of 0.077 to 0.119 arb units. Table 4 shows that all the ρ values are in the standard range, showing that these interactions are H-bonding interactions.

Moreover, the electrostatic and nonelectrostatic data values were obtained for binding and nonbinding proposed base pairs using UB3LYP/6–311G* via PCM, CPCM, and IEFPCM methods in the water phase (Table S1 of the Supplementary data). The differences of electrostatic and nonelectrostatic values ($\Delta G_{solvation}$) as well as repulsion, dispersion, cavitations, and polar and nonpolar solutes are shown in Tables S4–S6 of the Supplementary data.

To scrutinize the controversy between theory and experiment regarding hydrogen-bond lengths in Watson–Crick base pairs,[18,19] we have presented the selected Muliken charges along with the bond lengths of the hydrogen bonds in 42 proposed base pairs (Table S7 of the Supplementary data). Moreover, cartesian coordinates for most stable base pairs at UB3LYP/6–311G* can be found in Table S8 of the Supplementary data.

Conclusion

In summary, 42 complexes of base pairs were proposed and consequently their hydrogen-bonding and propeller rotational energies were investigated. According to UB3LYP/6–311G* data, the hydrogen bonding between regular base pairs is established as follows:

1. The hydrogen bonds in irregular base pairs including CC, UU, and TT (series 1) are stronger than those in regular GC and AT base pairs. Also, the strength of the hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

bonds in the proposed base pairs including CU, GG, GU, and TU (series 2) is similar to the strength of those in regular base pairs from an energetic point of view (Table 3).

2. Noticeably, the propeller rotations for the mentioned irregular base pairs in the previous case reveal higher rotational barrier energies (about 6–7.5 kcal/mol) than regular GC and AT base pairs (1–3 kcal/mol) (Figs. 1 and 2).
3. The H-bonded base pairs in AA, AC, AG, AU, CT, and GT are less stable than those in GC and AT base pairs from an energetic point of view (Table 3).
4. In the case of bond length (N-H···X), the strength of the H-bonded base pairs increases with the increasing length of the N–H covalent bond (Fig. S1 of the Supplementary data).
5. All the ρ values are in the standard range, indicating that the studied interactions are H-bonding interactions. However, each of the most stable base pair has at least two H bonds formed and considered in molecular modeling. In the proposed base pairs, the nitrogen atom plays a role as a H-bonding donator or acceptor, whereas the oxygen atom just acts as a H-bonding acceptor. The H-bonding donator and H-bonding acceptor have higher negative and higher positive muliken charges than the related free nucleic acid base, respectively. Consequently, the strength of the hydrogen bonds enhances with increasing muliken charge values (Table S7 and Fig. S3 of the Supplementary data).

Abstract: A density functional theory (DFT) study was performed to examine intra- and inter-molecular hydrogen bond (HB) properties in crystalline salicylic acid (SA). BLYP, B3LYP, and M06 functionals with 6–311++G** basis set were employed to calculate NMR chemical shielding isotropy (σ_{iso}) and anisotropy ($\Delta\sigma$) at the sites of the ^{17}O and ^{1}H nuclei of SA. From this study, it appears that the intra- and inter-molecular O–H···O as well as C–H···O HBs around the SA molecule in the crystal lattice have a major influence on the chemical shielding tensors and more specifically on the carbonyl ^{17}O isotropy value. The quantum theory of atoms in molecules (QTAIM) analysis was also employed to elucidate the interaction characteristics in SA H-bonded network. Based on QTAIM results, a partial covalent character is attributed to the intra- and inter-molecular O–H···O HBs in SA.

Key words: DFT, salicylic acid, chemical shielding, intra-molecular and inter-molecular HBs, QTAIM.

Résumé : On a effectué une étude selon la théorie de la fonctionnelle de la densité (TFD) dans le but d'examiner les propriétés des liaisons hydrogènes (LH) intra- et intermoléculaires dans l'acide salicylique (AS) cristallin. On a utilisé des fonctionnelles BLYP, B3LYP et M06, avec un ensemble de base 6–311++G**, pour calculer l'isotropie (σ_{iso}) et l'anisotropie ($\Delta\sigma$) du blindage chimique en RMN aux sites des noyaux ^{17}O et ^{1}H de l'AS. Sur la base de cette étude, il semble que les liaisons hydrogènes O-H···O intra- et intermoléculaires ainsi que les LH C-H···O autour de la molécule d'AS, dans le réseau cristallin, jouent toutes un rôle important sur les tenseurs de blindage chimique, principalement sur la valeur d'isotropie du ^{17}O du carbonyle. On a aussi utilisé l'analyse par la théorie quantique des atomes dans les molécules (TQADM) pour élucider les caractéristiques de l'interaction dans le réseau de liaisons hydrogènes de l'AS. Sur la base des résultats de l'analyse par la TQADM, on peut attribuer un caractère covalent partiel aux LH intra- et intermoléculaires O-H···O de l'AS.

Mots-clés : théorie de la fonctionnelle de la densité (TFD), acide salicylique, blindage chimique, liaisons hydrogènes intramoléculaires et intermoléculaires, théorie quantique des atomes dans les molécules (TQADM).

[Traduit par la Rédaction]

Introduction

The study of hydrogen-bonding (H-bonding) interactions has long been a topic of intensive scientific research because of its relevance in biochemistry, organic chemistry, inorganic chemistry, solid-state physics, and molecular medicine.[1–4] The double helical structure of DNA, for example, is due largely to hydrogen bonds (HBs) between the base pairs, which link one complementary strand to the other and enable replication. H-bonding interactions also play an important role in determining the three-dimensional structures adopted by proteins and polypeptides. In these macromolecules, bonding between parts of the same macromolecule causes them to fold into a specific shape, which helps determine the molecule's physiological or biochemical role. Thus in recent years, much attention has been focused on HB properties using experimental and theoretical methods.[5–10]

Solid-state nuclear magnetic resonance (NMR) spectroscopy is one of the most valuable tools for studying constitution, state, and structure of compounds.[11] NMR spectra yield a wealth of information, the most commonly reported property being the chemical shielding tensor. This parameter relates an externally applied magnetic field to the resulting change in the local electronic environment of the magnetic nuclei, thereby providing key insights into the underlying atomic structure. The NMR parameters are strongly dependent on molecular structure and on the intra- and inter-molecular HBs that exist within a crystalline framework. On the other hand, the eigenvectors of the proton chemical shielding tensor give proton bond directions with an accuracy rivalled only by neutron diffraction.[12] Hence, this has resulted in numerous studies correlating the ^{17}O, ^{13}C, ^{15}N, and ^{1}H chemical shielding tensors and the structural characteristics in both experimental and theoretical fields.[13–18]

Salicylic acid (SA) and its derivatives are attractive chemicals, since their structures are of significance, particularly in phenolic anti-oxidants, medicine, and enzyme chemistry.[19,20] Like most other carboxylic acids, they exist as a cyclic H-bonded dimer in solid state and in gas phase at moderate

and high concentrations.[21,22] The existence of a relatively strong intra-molecular C=O···H–O HB in SA and its derivatives provides the possibility of intra-molecular proton transfer in the lowest state of these compounds.[23,24] In contrast to other molecules of this group, such as methylsalicylate or salicylaldehyde, the characteristics of the intra-molecular HB in SA can be essentially influenced by inter-molecular interactions, particularly by inter-molecular HBs formed by the carboxylic group. On the other hand, the interdependence of intra- and inter-molecular HBs in similar systems has been provided by experimental NMR and IR studies.[25,26] Hence, it is possible to investigate the NMR chemical shielding tensors at the sites of ^{1}H and ^{17}O nuclei in solid SA, and preferable to correlate the NMR parameters with the molecular structures, in particular, HBs geometries.

In this article, we report the use of quantum chemistry calculations to characterize the properties of intra- and inter-molecular interactions in SA. It is well known that first principles quantum mechanical calculations of shielding parameters have proven useful in assigning experimental NMR spectra.[27–30] Furthermore, correlations of computed parameters with spectroscopic observables can aid in detailed investigations of molecular and crystalline structure. For example, based on their experimental and theoretical data, Tjandra et al. found some linear correlation relationships between HB lengths and the amide proton chemical shielding isotropy value σ_{iso}.[31] They also suggest that "both the isotropic and the anisotropic components of the ^{1}H chemical shielding tensor were found to depend very strongly on the hydrogen bond length. A weaker dependence can also be observed for the hydrogen bond angle."[31]. The present work evaluates chemical shielding tensors by DFT calculations at the sites of ^{17}O and ^{1}H nuclei in the real H–bonded lattice of SA. To this aim, a seven–molecule model system of SA was created using the reported crystalline structure coordinates by earlier neutron diffraction study.[32] Hence, considering the presence of HBs in the calculations, the most probable interacting molecules with the central molecule in the crystalline structure of SA were considered in a heptamer cluster (see Fig. 1 and Table 1 for details). To study systematically the influence of the H-bonding interactions on the various nuclei, chemical shielding tensors were calculated for two molecular models: isolated gas phase (monomer) and H-bonded (heptamer).

It should be noted that NMR chemical shifts in both molecules and solids can now be performed within DFT using methods that employ periodic wave functions. The approach is based on gauge-including projector augmented waves (GIPAWs),[33] themselves derived from Blöchl's PAW electronic structure method that use pseudopotentials to describe the core-valence interactions. The use of pseudopotentials and plane waves in GIPAW provides an excellent balance of speed and accuracy. GIPAW has proved its efficiency in the study of a large range of systems containing elements of the first four rows of the periodic table. Among them, calculations of ^{17}O, ^{23}Na, ^{25}Mg, ^{27}Al, ^{29}Si, ^{31}P, and ^{43}Ca NMR parameters in various silicates,[34–36] phosphates,[37–39] and other inorganic materials[40–42] allowed a precise assignment of the corresponding spectra and exhibited general trends between NMR and structural parameters.

Theory

The chemical shielding tensor $\boldsymbol{\sigma}$ describes the electronic effect on the Zeeman energy levels of magnetic nuclei, due to the response of the electrons to a static external magnetic field B_0.[43] In closed-shell molecules this leads to a second-order change in the molecular energy:

$$[1] \qquad E = E_0 + B_0 \chi B_0 + \sum_{i=1}^{N} \mu_i \sigma_i B_0 + \cdots$$

where the summation is taken over the N nuclei in the system. Here, we are not interested in the magnetic susceptibility χ but only in the bilinear response property σ_i. Hence, the components of the $\boldsymbol{\sigma}$ tensor of nucleus i are defined as:

$$[2] \qquad \sigma_{\alpha\beta_i} = \left(\frac{\partial^2 E}{\partial \mu_{\alpha_i} \partial B_\beta} \right)_{\mu_i = B \to 0} \qquad \alpha, \beta = x, y, z$$

The σ tensor can be considered to arise from a sum of diamagnetic and paramagnetic contributions: $\sigma_i = \sigma_i^{d} + \sigma_i^{p}$. Only the diamagnetic part depends on the ground-state wave function alone; the determination of the paramagnetic term requires knowledge of the first-order wave functions, which have to be calculated using some form of perturbation theory.

In the principal axis system (PAS), the σ_i^{p} tensor is converted to a diagonal matrix with σ_{11}, σ_{22}, and σ_{33} components, where $\sigma_{33} > \sigma_{22} > \sigma_{11}$. The isotropic σ_{iso} and anisotropic $\Delta\sigma$ chemical shielding are related to the principal components by the following equations, respectively:

$$[3] \qquad \sigma_{iso} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$$

$$[4] \qquad \Delta\sigma = \sigma_{33} - (\sigma_{11} + \sigma_{22})/2$$

Computational aspects

All calculations were performed using a modified version of the Gaussian 03 suite of programs.[44] Since the crystalline structure of SA was obtained from a neutron diffraction study,[32] geometry optimization was not needed in this work. We examined the ability of three density functionals [including one GGA (BLYP), one hybrid GGA (B3LYP), and one hybrid meta-GGA (M06)] to evaluate the chemical shielding tensors for ^{17}O and ^{1}H nuclei.[45–47] Zhao and Truhlar have recently developed the M06 family of local (M06-L) and hybrid (M06, M06-2X) meta-GGA functionals that show promising performance for noncovalent interactions.[47] For each BLYP, B3LYP, and M06 functional, 6–311++G** standard basis set was employed. Various combinations of diffuse and polarization functions are incorporated in this basis set that are necessary for computation of chemical shielding tensors of hydrogen and oxygen atoms involved in HBs. Previous studies reveal that 6–311++G** usually lead to satisfactory chemical shielding values.[48–50]

Chemical shielding calculations were performed using the gauge-included atomic orbital (GIAO) method.[51] Since quantum chemical calculations yield absolute chemical shielding values, one must establish the absolute shielding values for a particular nucleus to obtain a direct relation between the

The dashed lines show HB interactions.

calculated results and experimentally reported data. To evaluate the chemical shift isotropy δ_{iso} from the calculated $\sigma_{iso,calcd}$ values, we used

$$[5] \qquad \delta_{iso} = \sigma_{ref} - \sigma_{iso,calcd}$$

where σ_{ref} refers to the absolute ^{17}O and ^{1}H chemical shielding of liquid water and TMS, with σ_{ref} = 307.9,[52] and 30.5 ppm,[12] respectively.

The QTAIM methodology[53] has been used to analyze the electron density of the systems considered at the M06/6–311 ++G** computational level, using AIM2000 program.[54] For atom–atom interactions such as intra- and inter-molecular contacts or valence bonds, the characteristics of the corresponding bond critical point (BCP) of molecular charge density ρ_{BCP} are very important. These are points where the electron density gradient $\nabla\rho_{BCP}$ vanishes, and additional characterization is done using the corresponding Hessian matrix (a 3 × 3 matrix of second derivatives). Diagonalization of this matrix yields the coordinate invariant eigenvalues: $\lambda_1 \leq \lambda_2 \leq \lambda_3$. The quantities Laplacian $\nabla^2\rho_{BCP}$ of charge density at the bond critical point is defined as:

$$[6] \qquad \nabla^2\rho_{BCP} = \sum_{i=1}^{3} \lambda_i$$

There are well-known relationships between energetic topological parameters and the Laplacian of electron density at BCP:

$$[7] \qquad \frac{1}{4}\nabla^2\rho_{BCP} = 2G_{BCP} + V_{BCP}$$

$$[8] \qquad H_{BCP} = G_{BCP} + V_{BCP}$$

where G_{BCP}, V_{BCP}, and H_{BCP} are the kinetic, potential, and total electron energy densities at the critical point, respectively. G_{BCP} is a positive value, whereas V_{BCP} is a negative one.

Results and discussion

The ^{17}O and ^{1}H NMR parameters, as well as electron density analysis in the H-bonded lattice of SA, are evaluated in the present computational study. To this aim, a seven-molecule

Table 1. Selected H-bond distances and angles of the SA crystalline lattice.

Bond distances (Å)	
$r_{H1(1)\cdots O1(2)}$	1.626
$r_{O1(1)\cdots H1(2)}$	1.626
$r_{H2(1)\cdots O1(1)}$	1.785
$r_{H6(3)\cdots O2(1)}$	2.490
$r_{H3(1)\cdots O3(4)}$	2.640
$r_{H4(1)\cdots O3(4)}$	3.007
$r_{H5(1)\cdots O3(5)}$	2.546
$r_{H6(1)\cdots O2(6)}$	2.489
$r_{H3(7)\cdots O3(1)}$	2.639
Bond angles (°)	
O2–H1(2)···O1(1)	174.81
O2-H1(1)···O1(2)	174.81
O3-H2(1)···O1(1)	142.88
C-H6(3)···O2(1)	131.17
C-H3(1)···O3(4)	124.81
C-H4(1)···O3(4)	113.30
C-H5(1)···O3(5)	177.56
C-H6(1)···O2(6)	131.18
C-H3(7)···O3(1)	124.82

Note: The value within the parenthesis refers to the molecule number in Fig. 1*b*. The H-bond distances and angles of crystalline SA are from Ref. 32.

model system of SA was created by neutron diffraction coordinates. As seen in Table 1, the inter-molecular O–H···O HBs in SA are almost linear (the O–H···O angle equals 174.81°), and their lengths are 1.626 Å. The intra-molecular HB between the hydroxyl and the oxygen atom of the carbonyl group is strongly bent (the O–H···O angle equals 142.88°) and the O–H···O distance is 1.785 Å.

This section is divided into three subsections. First, we present the results for the ^{17}O chemical shielding tensors of SA, both in the gas phase and in solid lattice. Here we evaluate the role of intra- and inter-molecular interactions in the solid lattice, and we seek to find the main factors that differentiate calculated ^{17}O NMR parameters in SA. Second, we discuss the results for ^{1}H shielding tensors and compare them with the available experimental results for other related compounds. Finally, we present a QTAIM topological analysis of different HB interactions and evaluate their strength in crystalline SA. Unless otherwise noted, following results refer to the M06/6–311++G** level of theory.

^{17}O NMR parameters

Table 2 presents the evaluated NMR parameters from the calculated chemical shielding tensors at the sites of ^{17}O nuclei in SA. Considering the evaluated $\delta_{iso}(^{17}O)$ values, it is evident that the results obtained by different DFT methods agree with each other to within 1.14–12.70 ppm. As shown in Fig. 1, there are three crystallographically distinct oxygen sites in SA[32]: C=O, carboxylic, and phenolic O–H. From Table 2, it can be seen that all of the $\delta_{iso}(^{17}O)$ values of the monomer SA lie within the 125.92–370.62 ppm and that of phenolic O–H oxygen is relatively more shielded. Clearly, a different δ_{iso} value observed for the oxygen sites in monomer SA must arise from differences in the surrounding environment. Besides the covalent bonds (C=O or O–H) to carbon that contribute to the different ^{17}O chemical shielding regions, the phenolic oxygen also experiences an intra-molecular HB with carbonyl C=O moiety, $r_{H2(1)\cdots O1(1)}$ = 1.785 Å and angle for O3–H2(1)···O1(1) = 142.88°. It is also interesting to note that O2 and O3 exhibit somewhat similar $\Delta\sigma$ values, 145.04 and 152.42 ppm, respectively, despite the fact that the two oxygen atoms belong to quite different functional groups.

In crystal lattice, SA molecules are mainly held together in dimers by the familiar carboxylic acid dimeric linkage, involving two symmetry-equivalent HBs (Fig. 1*b*). These are of medium strength, with O···O separation of around 2.6 Å.[32] A quick look at the results reveals that inter-molecular HB interactions affect the calculated ^{17}O NMR parameters at the O1, O2, and O3 sites; however, this influence is not equivalent for the three oxygen nuclei. As seen in Table 2, M06 calculations reveal that the δ_{iso}(O1) parameter decreases by 61.30 ppm depending on whether the SA molecule is in the gas phase or in the crystal lattice. On the other hand, the corresponding anisotropy decreases about 84.49 ppm on going from the single monomer to the target molecule in the cluster. The calculated δ_{iso} parameter for O1 in crystalline SA is 309.32 ppm, which is slightly larger than that of aspirin (ca. 302.2 ppm) but quite smaller than phthalic acid (ca. 347.3 ppm) and maleic acid (ca. 343.7 ppm).[55] In contrast, the ^{17}O NMR parameters for O2 show less sensitivity to the H-bonding interactions. Figure 1 shows that O2 contributes to two HBs in crystalline SA, O–H···O (1.626 Å), and C–H···O (2.490 Å). Because of the proper HB distances, δ_{iso} increases by 12.59 ppm from the monomer to the target molecule in the cluster. The $\Delta\sigma$ also decreases by 4.71 ppm from the monomer to the cluster. These significant changes reveal the importance of the carboxylic group in contributing to the strong HBs in the crystalline SA.

It was previously reported[8] that the ^{17}O δ_{iso} values tend to decrease when the oxygen atoms are involved in stronger H-bonding environments. Recently, Smith et al[55] reported solid state ^{17}O NMR parameters for a series of carboxylic acid compounds with their C=O···H–O distance ranging from 1.2 to 2.0 Å. For C=O oxygens, δ_{iso} increases (downfield shifts) as the HB distance increases and the bond strength decreases. In contrast, δ_{iso} of O–H oxygen decreases (upfield shifts) as the HB strength decreases. Table 2 also shows correlation between the theoretical and available experimental ^{17}O NMR parameters. Compared with the ^{17}O chemical shift isotropy values for carboxylic acids in ref. 55, the calculated $\delta_{iso}(^{17}O)$ values of SA at the carboxyl site correlate well with those experimental reported of maleic acid, phthalic acid and oxalic acid.$2H_2O$ suggesting that the local environments of the oxygen sites are approximately similar from those in carboxylic acids (Table 2). The discrepancy of δ_{iso}(O–H) can be mainly attributed to the existence of C–H···O interactions, especially between O2 and molecule No.3, in crystalline SA.

As mentioned above, the phenolic O3 atom contributes to an intra-molecular interaction in monomer SA. For the NMR parameters at this site, the comparison of the isolated model and the heptamer cluster shows some discrepancies, although not as dramatic as the one seen for O1 and O2. By a quick look at Fig. 1*b*, it is found that the O3 atom of the target molecule can form an C–H···O inter-molecular HB with molecule **7**, which is located at an adjacent perpendicular sheet. From having two possibilities to formation of HBs, $r_{H2(1)\cdots O1(1)}$ = 1.785 Å

and $r_{H3(7)\cdots O3(1)}$ = 2.639 Å, the M06 calculations reveal that δ_{iso} and $\Delta\sigma$ decrease by only 3.43 and 4.75 ppm from the monomer to the target molecule in the cluster, respectively. Besides, the evaluated δ_{iso} value at the O3 site deviates significantly from that of maleic acid (Table 2)

^{1}H NMR parameters

As shown in the previous part, H–bonding interactions affect remarkably the ^{17}O shielding parameters. In this part, we discuss the influence of H–bonding interactions on the calculated ^{1}H NMR parameters, see Table 3. Considering the evaluated $\delta_{iso}(^1H)$ values, it is found that different DFT methods agree reasonably well with each other to within 0.02–0.98 ppm.

^{1}H NMR spectroscopy is probably the most direct spectroscopic technique for investigating H-bonding. Since it is not possible to obtain absolute values of the HB strengths from experimental solid-state studies, correlations between ^{1}H NMR and HB strength have been frequently used to infer information about the HBs formed.[57] Table 3 shows the calculated δ_{iso} and $\Delta\sigma$ values of SA at the sites of six ^{1}H nuclei, both in the gas phase and solid lattice. As illustrated in Fig. 1*b*, the target molecule in the cluster is capable of participating in a variety of inter-molecular O–H···O=C, and C–H···O=C HBs with the molecules **2**–**7**; however, their strengths are not equivalent in the seven-molecule cluster. Table 3 shows that the NMR parameters of the carboxylic hydrogen atom (H1) vary considerably between the monomer and heptamer cluster, $\Delta\delta_{iso}$ = 6.80 and $\Delta(\Delta\sigma)$ = 12.55 ppm. The calculated δ_{iso} and $\Delta\sigma$ values for H1 of the target molecule have been obtained as 13.66 and 23.77 ppm at the M06 level, respectively. These values, which are obtained by taking the whole cluster into consideration, are expected to be close to the other carboxylic compounds.[57] Compared with experimental values of carboxylic acids given in Ref. 57, the smallest difference occurs for maleic acid, sqauric acid, and trichloroacetic acid (Table 3).

The correlation of the isotropic shielding and the shielding anisotropy of carboxylic hydrogen with HB distance ($r_{O\cdots O}$) has been empirically established for strong and medium strength HBs.[58] Berglund et al.[57] reported that the δ_{iso} of the H-bonded proton in an OH···O=C HB is primarily dependent on the distance between the proton and the donor atom and showed how a combined experimental and theoretical approach can be used to refine the hydrogen position. Using such a correlation equation, the δ_{iso} value of the carboxylic proton in SA falls into the category of a moderately strong HB, i.e., associated with a generic HB geometry of: O–H···O=C of ~1.6 Å. These values closely resemble those of the reported neutron diffraction structure.[32]

As seen in Table 3, the δ_{iso} value of H2 in monomer SA downshifts by 1.6 ppm from that of carboxylic H1 site. This discrepancy can be explained in terms of formation of an intra-molecular between phenolic O–H and carboxylic C=O groups. However, due to the weak nonlinear C–H3(7)···O3 interaction, 0.32 and 4.17 ppm increases in δ_{iso} and $\Delta\sigma$ parameters are observed from the monomer to the target molecule in the cluster, respectively. Table 3 also indicates that there is a reasonable agreement between the calculated shielding anisotropy of H2 in SA and the experimental value of maleic acid.[57]

The carbon-bound hydrogen atoms (H3 to H6) have almost identical positions in the monomer SA and therefore it is expected to have a quite similar ^{1}H isotropic shielding. However, the H3 atom contributes to a weak intra-molecular C–H···O=C interaction with O2, hence its δ_{iso} is slightly larger than those of others (Table 3). These hydrogen atoms also occupy a different position in the H-bonding network of the crystalline SA, so have slightly different isotropy and anisotropy values. According to the SA crystalline structure, each of the H3 to H6 atoms are involved in a single inter-molecular HB. Therefore, the variation in the calculated ^{1}H shielding tensors for these sites can be fully explained in terms of the changes in the corresponding C–H···O bond length and angle between the SA monomers. For example, both $\Delta\delta_{iso}$ = 1.43 ppm and $\Delta(\Delta\sigma)$ = 1.93 ppm for the H5 site in the heptamer structure relative to those of others arise because of the corresponding proper $r_{H5\cdots O3(5)}$ = 2.546 Å and angle for C–H5(1)···O3(5)= 177.56°. Hence, it may be deduced that such differences in hydrogen chemical shielding are attributed to the H-bonding environments mentioned above. In this context, it is to be noted that Brown et al. have observed isolated gas phase to solid-state changes of up to 1.90 ppm in the ^{1}H chemical shifts of CH and CH_2 protons in two anomeric forms of maltose, with the authors assigning these changes to weak inter-molecular C–H···O H-bonding.[59]

QTAIM analyses

A great deal of information about the nature of intra- and inter-molecular HB interactions in SA can be obtained from a

topological analysis of its electron density. Based on QTAIM theory,[53] properties of BCPs serve to summarize the nature of the interaction between two atoms as shared (covalent) or closed-shell (ionic) interaction. For a set of H-bonded complexes, Koch and Popelier[60] found the correlation between the HB energy and ρ_{BCP} to be linear as long as the acceptor atom remained unchanged. In characterizing the HBs of our cluster structures, we have adopted the classification used by Rozas et al.:[61] a HB is defined as weak if $\nabla^2\rho_{BCP} > 0$ and $H_{BCP} > 0$, medium-strength if $\nabla^2\rho_{BCP} > 0$ but $H_{BCP} < 0$, and strong if $\nabla^2\rho_{BCP} < 0$ and $H_{BCP} < 0$.

A molecular graph of crystalline dimer SA is depicted in Fig. 2. For the both intra- and inter-molecular O–H···O interactions, there are corresponding bond paths and critical points (CPs) within the equilibrium structures. As indicated in previous studies, characteristics of proton···acceptor BCPs are very useful to study the nature of H-bonded systems. Parameters such as electron density at the proton···acceptor BCP, ρ_{BCP} and its Laplacian $\nabla^2\rho_{BCP}$, often correlate with the HB energy or other parameters, like proton···acceptor distance, the proton donating bond length, etc.[62] As presented in Fig. 2, there are specific bond paths and BCPs for intra- and inter-molecular OH···O connections. Therefore, the first topological criterion of the existence of H-bonding interaction is fulfilled.

Table 4 shows the ρ_{BCP}, $\nabla^2\rho_{BCP}$, the H_{BCP} and its components G_{BCP} and V_{BCP} values for the all HBs interactions examined in this work. From Table 4, it is evident that the ρ_{BCP} values are calculated to be in the range of 0.005–0.051 au, whereas the values of $\nabla^2\rho_{BCP}$ are all positive, ranging from 0.021 to 0.152 au. These values are within the common accepted values for H-bonding interactions, thus indicating closed-shell interactions in this system. As pointed out above, the electron energy density H_{BCP} is a more appropriate index to gain a deeper understanding of noncovalent interactions.[63] The sign of H_{BCP} at BCP determines whether the interaction is electrostatic dominant ($H_b > 0$) or covalent dominant ($H_{BCP} < 0$). From Table 4, it is revealed that for the all inter-molecular C–H···O interactions, the H_{BCP} values are all greater than zero, suggesting that the interactions are basically electrostatic in nature. However, negative values of H_{BCP} are predicted for both intra- and inter-molecular O–H···O, suggesting that the interactions in these HBs have some degree of covalent character. On the other hand, different contributions of various nuclei to HB interactions and observed trends of calculated NMR parameters are well justified by QTAIM analyses at the BCPs of these interactions. For example, the low values of charge density at the BCPs of C–H···O interactions suggest that δ_{iso} and $\Delta\sigma$ (H3 to H6) should not reduce considerably from the monomer to heptamer cluster. According to these results, we can conclude that strong HBs are more covalent in nature and weak HBs are mainly electrostatic interactions, which follows the electrostatic-covalent model observed for HBs (ECHBM).[64] As shown in Fig. 3, a plot of the electron densities Laplacian versus the ^{1}H isotropies are approximately linear (R^2 = 0.952). This means that, the Laplacian of electron densities is a good indication of the amount of ^{1}H shielding in SA, which reproduces the well-documented properties of HBs.

Conclusion

In this paper, we performed a systematic computational investigation on the intra- and inter-molecular HB interactions in crystalline SA by means of DFT calculations of the chemical shielding tensors at the sites of ^{17}O and ^{1}H nuclei, as well as a QTAIM analysis of charge density in two gas phase (monomer) and seven-molecule (cluster) models. Some results are listed below.

1. Our calculations indicate that NMR parameters of ^{17}O and ^{1}H nuclei are influenced by H-bonding interactions and as such are appropriate parameters to characterize the properties of these interactions.
2. Considering the calculated $\delta_{iso}(^{17}O)$ and $\delta_{iso}(^1H)$ values, it is evident that the results obtained by different DFT methods are agree with each other to within 1.14–12.70 and 0.02–0.98 ppm for the ^{17}O and ^{1}H nuclei, respectively.
3. The chemical shielding calculations reveal that inter-molecular HB interactions affect the calculated ^{17}O NMR parameters at O1, O2, and O3 sites; however, these influences are not equivalent for the three oxygen nuclei. Comparing SA monomer and heptamer clusters, it is evident that in the carboxylic group, O1 has the major role in contributing to the both intra- and inter-molecular interactionsn whereas the role of hydroxyl O–H is rather less. Moreover, the calculated ^{17}O δ_{iso} values of SA at the carboxyl site correlate well with those reported experimental data.

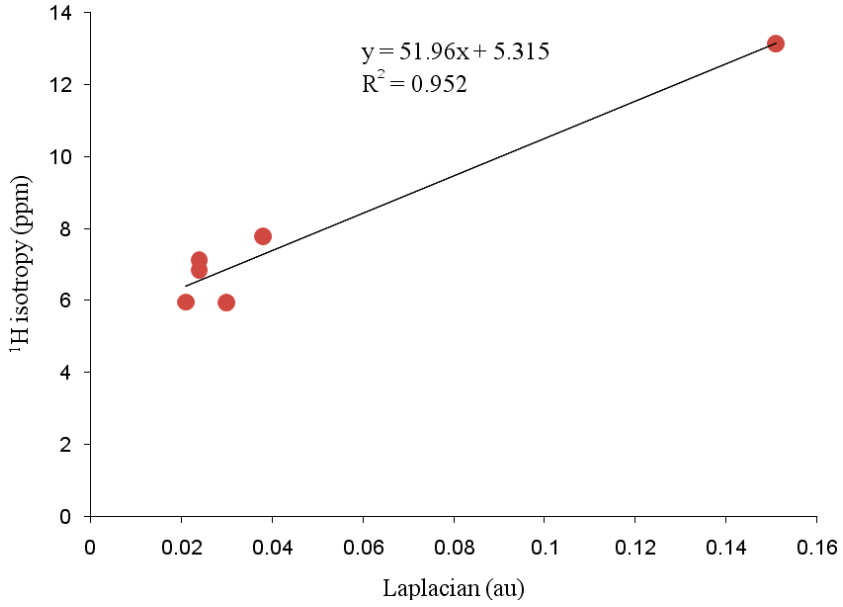
H6(1)···O3(6)	0.008	0.030	0.006	–0.005	0.832	0.001
H3(7)···O3(1)	0.007	0.024	0.005	–0.005	0.866	0.001

Note: All ρ_{BCP}, ∇^2_{BCP}, G_{BCP}, V_{BCP}, and H_{BCP} in au.

Fig. 3. Correlation between ^{1}H shielding isotropy values and the Laplacian of electron densities at O–H···O and C–H···O BCPs of crystalline SA.



4. The NMR parameters of the carboxylic hydrogen atom (H1) vary considerably between the monomer and heptamer clusters, $\Delta\delta_{iso}$ = 6.80 and $\Delta(\Delta\sigma)$ = 12.55 ppm. The calculated δ_{iso} and $\Delta\sigma$ values for H1 of the target molecule have been obtained to be 13.66 and 23.77 ppm at the M06 level, respectively. These values, which are obtained by taking the whole cluster into consideration, are expected to be close to the other carboxylic compounds.
5. Different contributions of various nuclei to HB interactions and observed trends of calculated NMR parameters are well rationalized by QTAIM analyses at the BCPs of the interactions.

Abstract: Diethyl phthalate (1,2-benzenedicarboxylic acid diethyl ester, DEP) is one of a group of widely used plasticizers, which can lead to serious environmental problems. Because of manufacturing and application, DEP can be released into the atmosphere where it can undergo transport and chemical transformation. To assess the atmospheric behavior of pollutants, it is critical to know their atmospheric reactions. In this paper, the reaction mechanism and possible oxidation products for the OH-initiated atmospheric reaction of DEP were theoretically investigated by using the density functional theory (DFT) method. The geometries and frequencies of the reactants, intermediates, transition states, and products were calculated at the MPWB1K/6–31+G(d,p) level, and the energetic parameters were further refined by the MPWB1K/6–311+G(3df,2p) method. The present study shows that H abstractions from the CH_3 and CH_2 groups, as well as OH addition to the benzene ring, are energetically favorable reaction pathways for the reaction of DEP with OH radicals. Detailed degradation products are provided.

Key words: diethyl phthalate, OH radicals, atmospheric oxidation, reaction mechanism, quantum calculation, oxidation degradation.

Résumé : Le phtalate de diéthyle (ester diéthylique de l'acide benzène-1,2-dicarboxylique, PDE) est un des plastifiés les plus utilisés et il peut provoquer de sérieux problèmes environnementaux. Lors de sa fabrication et son application de PDE peut se répandre dans l'atmosphère où il peut transporter et subir des transformations chimiques. Afin de pouvoir évaluer le comportement des polluants dans l'atmosphère, il est important de connaître leurs réactions dans l'atmosphère. Dans ce travail, faisant appel à la méthode de la théorie de la fonctionnelle de la densité (TFD), on a étudié d'un point de vue théorique le mécanisme de la réaction et les produits potentiels d'oxydation résultant d'une réaction atmosphérique du PDE, initiée par des radicaux OH. Les géométries et les fréquences des réactifs, des intermédiaires, des états de transition et des produits ont été calculées au niveau MPWB1K/6–31+G(d,p) et les paramètres énergétiques ont ensuite été affinés par la méthode MPWB1K/6–311+G(3df,2p). La présente étude montre que l'enlèvement d'hydrogène à partir des groupes CH_3 et CH_2, ainsi que l'addition du radical OH sur le noyau benzénique sont des voies réactionnelles énergétiquement favorables pour la réaction du PDE avec les radicaux OH. Des produits de dégradation détaillés sont fournis.

Mots-clés : phtalate de diéthyle, radicaux OH, oxydation atmosphérique, mécanisme réactionnel, calculs quantiques, dégradation par oxydation.

[Traduit par la Rédaction]

Introduction

Diethyl phthalate (1,2-benzenedicarboxylic acid diethyl ester, DEP) is a commercially important phthalate ester. It is used extensively as an additive in the manufacture of polyvinyl chloride, polyvinyl acetates, plastics, cellulosics, and polyurethanes. It is also used in many other products such as automobile parts, paints, lubricating oils, glues, insect repellents, perfumes, and food-packaging material.[1–3] The global production volume of DEP is ~5.2 million tons per year.[4] The increasing use of DEP is causing worldwide pollution.[5–9] It has been detected in the air, water, soil, and vegetation,[10–13] as well as the issues and fluids of wildlife and people.[14] DEP may act as endocrine disruption compounds, which interfere with the normal hormone-regulated physiological processes of people and wildlife.[15,16] A response experiment in fiddler crabs showed that 7-day exposure to DEP at 50 mg/L significantly inhibited the activity of chitobiase in the epidermis and hepatopancreas.[17] DEP is known not only for its endocrine disruption and toxicity but also for its adverse reproductive effects on people and wildlife,[18–20] and its estrogenic activity has recently been documented as well.[21,22] Therefore, DEP has been categorized as a priority pollutant by the US Environmental Protection Agency.[23]

DEP can enter the atmosphere and travel many kilometres.[24] The vapor pressure of DEP is 6.48×10^{-2} Pa at 25 °C and it can vaporize quickly.[25] It is frequently detected in indoor and outdoor air.[24] In a North Sea (German Bright) field test, the atmospheric concentration of DEP was 1.6 ng/m^{-3} in the gas phase and 0.06 ng/m^{-3} in the particle phase. The

fraction of DEP in the gas phase reached up to 96%.[25] This has greatly increased the potential for human exposure to this highly toxic material. Particle-phase DEP may be removed from the atmosphere through dry or wet deposition. The tropospheric removal of gas-phase DEP involves wet and dry deposition and photolysis, oxidation reactions with OH, NO_3, or O_3. The wet and dry deposition of gaseous DEP is of relatively minor importance as a removal pathway. Among the various oxidants, OH radicals play the most essential role in determining the oxidation power of the atmosphere. The DEP reaction with OH radicals is considered to be a dominant removal process for gaseous DEP.

To assess the atmospheric behavior of pollutants, it is critical to know their atmospheric reactions. The OH-initiated degradation of phthalate esters (PAEs) in water can be found.[26,27] Blanco et al.[28] investigated the reaction mechanism of methacrylates with OH radicals in the atmosphere. Frankcombe and Smith[29] studied the mechanism of OH-initiated oxidation of toluene in the atmosphere. However, the current knowledge of the reactions of DEP in the atmosphere is very limited, and its oxidation mechanism has received little attention in experimental or computational chemistry. Quantum calculation is especially suitable for establishing whether a reaction pathway is feasible or not.[30–33] In this paper, we carried out a theoretical study of the application of quantum calculations for the OH-initiated atmospheric oxidation reaction of DEP to find favorable reaction pathways and sites. To find the formation mechanism of secondary pollutants from the OH-initiated atmospheric reactions of DEP, some possible secondary reaction pathways were also investigated. To our knowledge, this is the first study of the OH-initiated atmospheric oxidation of DEP using quantum chemistry.

Computational method

High-accuracy molecular orbital calculations for the OH-initiated atmospheric oxidation reaction of DEP were carried out in the presence of O_2 and NO. All the calculations were performed on an SGI Origin 2000 supercomputer with the Gaussian 03 package.[34] The choice of computational levels and basis sets requires a compromise between accuracy and computational time. The geometries of reactants, intermediates, transition states, and products were fully optimized at the MPWB1K[35,36] level with the 6–31+G(d,p) basis set. Zhao and Truhlar[37] compared the MPWB1K method with other DFT methods and found that the MPWB1K method gave better results for thermochemistry and gave more excellent saddle-point geometries. The MPWB1K/6–31+G(d,p) structures were employed in single-point energy calculations. The corresponding harmonic vibrational frequencies were also calculated at the MPWB1K/6–31+G(d,p) level to determine the nature of the stationary points, the zero-point energies (ZEP), and the thermal contributions to the free energy of activation. To verify that each transition state actually connected the designated reactants with products, intrinsic reaction coordinate (IRC)[38] calculations were performed. A more flexible basis set (6–311+G(3df,2p)) was used to evaluate the energetic parameters of the various species more accurately. The profile of the potential energy surface was constructed at the MPWB1K/6–311+G(3df,2p)//MPWB1K/6–31+G(d,p) level. All the relative energies quoted and discussed in this paper include ZPE corrections with unscaled frequencies obtained at the MPWB1K/6–31+G(d,p) level.

Results and discussion

The reaction of DEP with OH radicals

Since OH is strongly nucleophilic, H abstraction from DEP by OH radicals should be a possible reaction pathway. In addition, there is a benzene ring in the DEP molecule and, therefore, OH addition to the benzene ring is another possible reaction pathway. Altogether, seven possible reaction pathways (R1–R7) are presented in Fig. 1.

H-abstraction pathways

Four kinds of hydrogen atoms are found in the DEP molecule: H atoms in the CH_3 group, H atoms in the CH_2 group, H atoms bonded with the C_6 atom in the benzene ring, and H atoms bonded with the C_7 atom in the benzene ring. Thus, four primary reaction pathways (R1–R4) were identified. R1 and R2 are H abstractions from the CH_3 and CH_2 groups. R3 and R4 represent H abstractions from the benzene ring in the DEP molecule.

H abstractions from the CH_3 and CH_2 groups occur via the transition states, TS1 and TS2. The optimized structures of TS1 and TS2 are shown in Fig. 2. The transition vector of TS1 clearly shows the motion of H_1 between C_1 and O, with an imaginary frequency of 1273i cm^{-1}. The transition vector of TS2 shows the motion of H_4 between C_2 and O, with an imaginary frequency of 1269i cm^{-1}. H abstraction from the CH_3 group has a low potential barrier of 3.05 kcal/mol (1 cal = 4.184 J) and is exothermic by 14.34 kcal/mol at the MPWB1K/6–311+G(3df,2p) level. H abstraction from the CH_2 group also has a low potential barrier of 0.83 kcal/mol and is strongly exothermic by 18.14 kcal/mol. In the TS1 and TS2 structures, the breaking C_1–H_1 and C_2–H_4 bonds are elongated by 0.125 and 0.119 Å, respectively, whereas the forming O–H_1 and O–H_4 bonds are 0.328 and 0.338 Å, respectively, longer than the equilibrium value of 0.967 Å in H_2O.

H abstractions from the benzene ring in the DEP molecule require crossing potential barriers of 3.64 and 5.32 kcal/mol, respectively, via the transition states TS3 and TS4. The transition vector of TS3 shows the motion of H_6 between O and C_6, and the transition vector of TS4 shows the motion of H_7 between O and C_7. Comparison of the four H-abstraction pathways shows that H abstractions from the alkyl group have a lower barrier than H abstractions from the benzene ring. Also, H abstractions from the alkyl group are more exothermic than H abstractions from the benzene ring. The H atoms in the alkyl group are more activated than the H atoms in the benzene ring. Therefore, H abstractions from the alkyl group are expected to play an important role for the OH-initiated degradation of DEP in the atmosphere. The intermediates, denoted IM1 and IM2, produced from H abstractions from the alkyl group are open-shell activated radicals and will be further oxidized by O_2/NO and removed from the atmosphere.

OH addition to the benzene ring

Here, we analyze the reaction pathways of OH addition to the C=C bond in the benzene ring. As to the symmetry, the

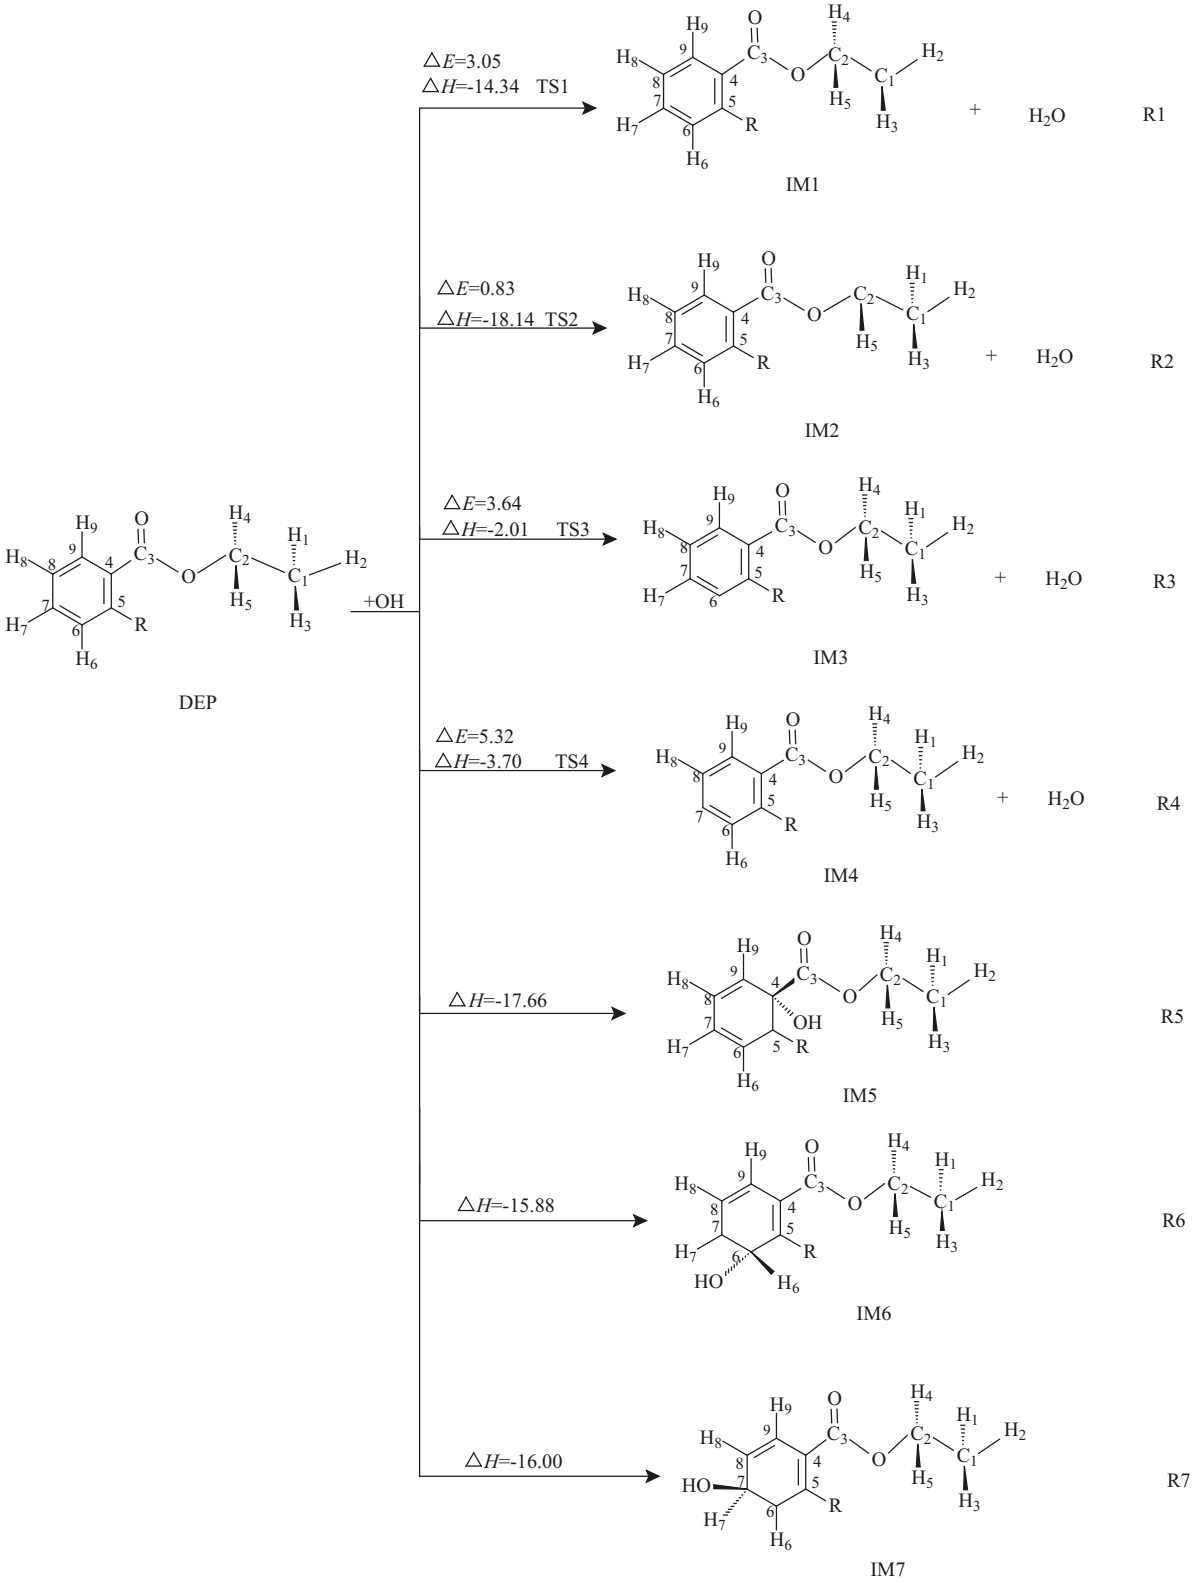
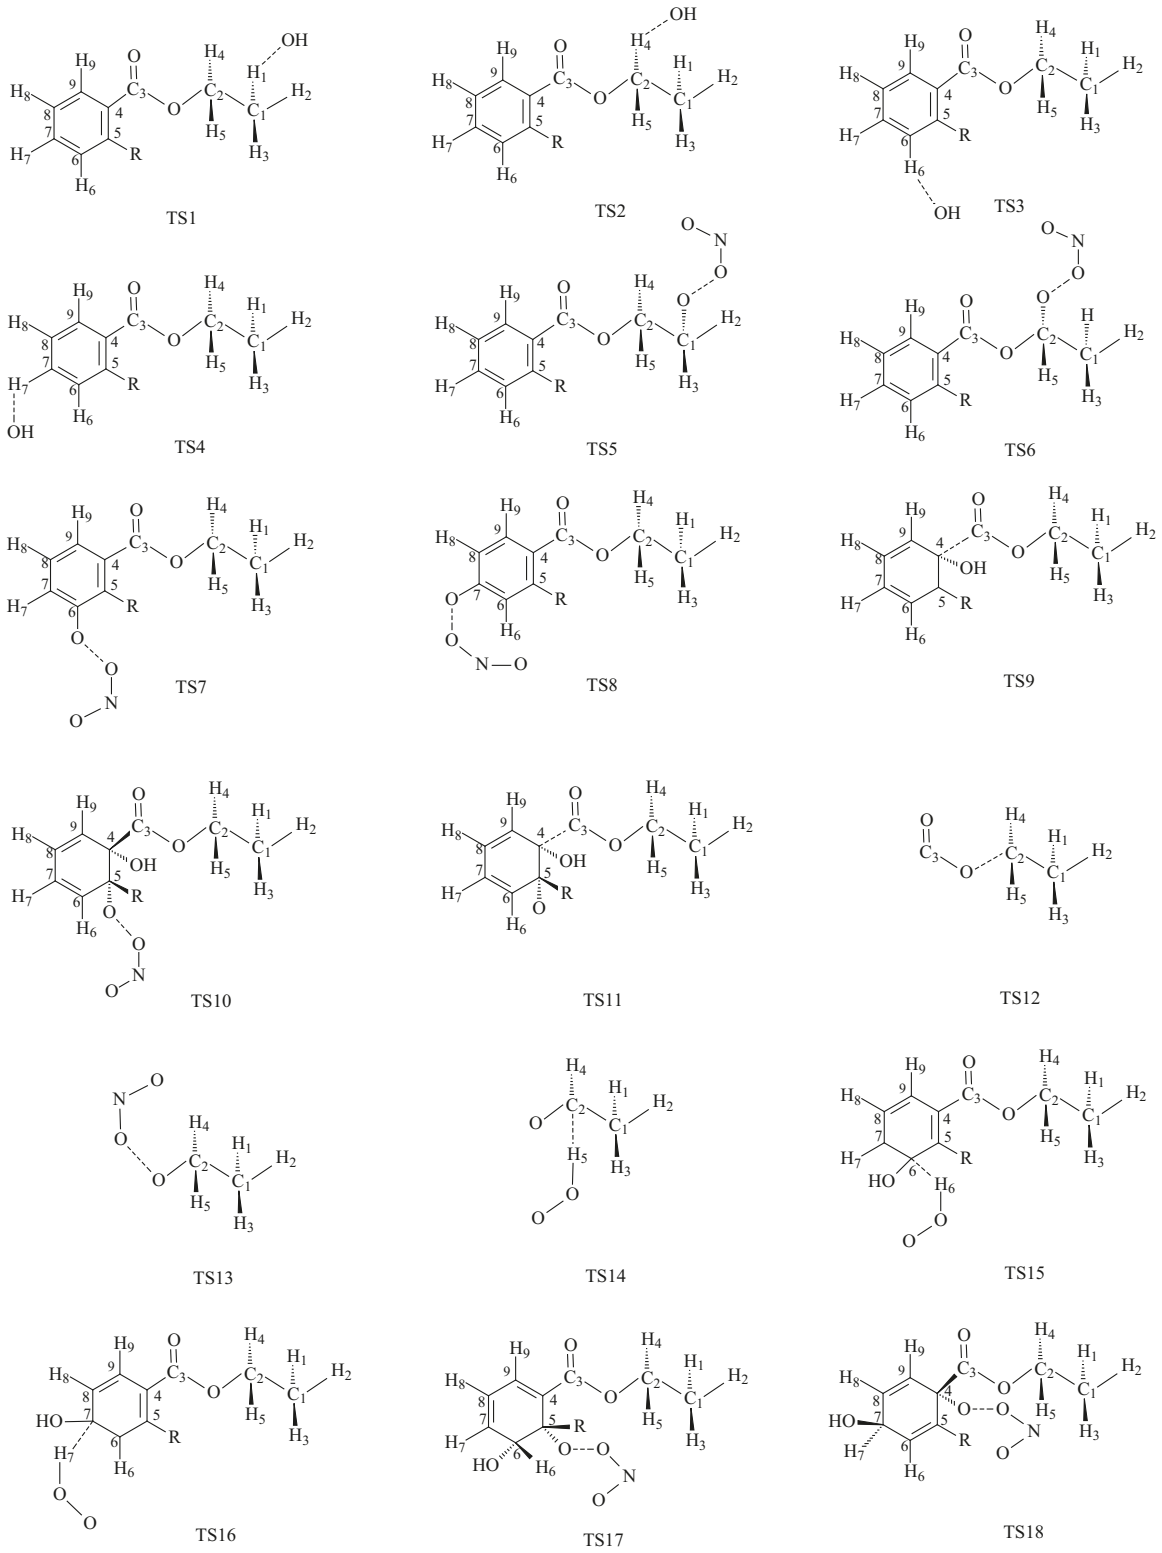
Fig. 1. Reaction pathways for the reaction of 1,2-benzenedicarboxylic acid diethyl ester (DEP) with OH radicals. Units: kcal/mol (1 cal = 4.184 J). ΔE, the reaction potential barrier; ΔH, the reaction enthalpy (0 K).



C atoms in the benzene ring fall into three groups: the C_4 and C_5 atoms are equivalent, the C_6 and C_9 atoms are equivalent, and the C_7 and C_8 are equivalent. Therefore, three different OH–DEP adduct isomers can be formed through the addition of the OH radical to the C_4, C_6, and C_7 atoms in the DEP molecule. The calculations show that OH additions to the C_4, C_6, and C_7 atoms are strongly exothermic and energetically favorable. It can be seen from Fig. 1 that addition of

Fig. 2. MPWB1K/6–31+G(d,p) optimized geometries for the transition states.



OH to the C_4, C_6, and C_7 atoms is barrierless and is a strongly exothermic processes. The high reaction energies are retained as the internal energy of the adducts. The energy-rich OH–DEP adducts (IM5, IM6, and IM7) can further react in the atmosphere.

Secondary reactions

The previous discussion shows that H abstractions from the alkyl group and OH additions to the benzene ring are energetically favorable pathways for the reactions of DEP with OH radicals. IM1–IM7 are important intermediates produced

from the degradation of DEP initiated by OH radicals. IM1–IM7 are open-shell activated radicals and will further react via unimolecular decomposition and (or) with O_2 or O_2/NO in the atmosphere.

Atmospheric reaction pathways of IM1 and IM2

IM1 can react with O_2 readily to form an intermediate, IM8. The calculated profile of the potential energy surface shows that the reaction of IM1 with O_2 is barrierless and strongly exothermic by 71.05 kcal/mol. In the atmosphere, IM8 will further immediately react with NO to form intermediate IM9. IM9 subsequently reacts via a direct decomposition to form P1 and NO_2 through the transition state TS5, and this reaction requires a potential barrier of 29.01 kcal/mol and is endothermic by 0.07 kcal/mol.

Similarly, IM2 can also be oxidized by O_2/NO in the atmosphere. The reaction pathways are depicted in Fig. 3.

Atmospheric reaction pathways of IM3 and IM4

The intermediates IM3 and IM4, from the H abstraction of the benzene ring, have similar atmospheric reactions. The intermediate IM3 reacts with O_2 to yield IM12 in the atmosphere and it is exothermic by 42.11 kcal/mol. Then IM12 reacts with NO to form IM13. The intermediate IM13 immediately decomposes to form product P3 and NO_2 via the transition state TS7 and it requires to cross a potential barrier of 15.17 kcal/mol.

Similar to IM3, IM4 can also be oxidized by O_2/NO in the atmosphere. The reaction pathways are depicted in Fig. 4.

Atmospheric reaction pathway of IM5

The unimolecular decomposition of IM5 results in the formation of P5 and IM16 via the transition state TS9. This process has a high potential barrier of 19.52 kcal/mol and is strongly endothermic by 9.30 kcal/mol, indicating that the decomposition is energetically unfavorable. In the troposphere, IM5 will mainly be removed by reaction with O_2.

IM5 has three possible sites to react with O_2 and three possible products (IM17, IM18, and IM19) can be formed throughthe addition of O_2 to C_5, C_7, or C_9 atoms in the IM5 molecule. The calculated profile of the potential energy surface shows that these addition reactions are barrierless and strongly exothermic by 42.07, 43.76, and 36.50 kcal/mol, respectively, indicating that these addition reactions are energetically favorable and can occur easily in the atmosphere. IM17, IM18, and IM19 have similar structures and will be removed from the atmosphere by a similar reaction mechanism. Therefore, we will just discuss the atmospheric reactions of IM17 here. IM17 could further react with NO to form IM20. IM20 will directly decompose via the transition state TS10 to form IM21 and NO_2 with a potential barrier of 15.15 kcal/mol. IM21 further decomposes to form P6 and IM16 via the transition state TS11. The O_1–C_2 bond in IM16 will rupture through the transition state TS12 with an imaginary frequency of 891i cm^{-1} to form IM22 and CO_2. This process is exothermic by 19.28 kcal/mol and a potential barrier of 15.62 kcal/mol. In the TS12 structure, the O_1–C_2 bond is elongated to 1.879 Å from 1.446 Å in IM16. IM22 subsequently readily reacts with O_2 to form an intermediate, IM23. The calculations show that the reaction of IM22 with O_2 is barrierless and strongly exothermic by 72.12 kcal/mol.

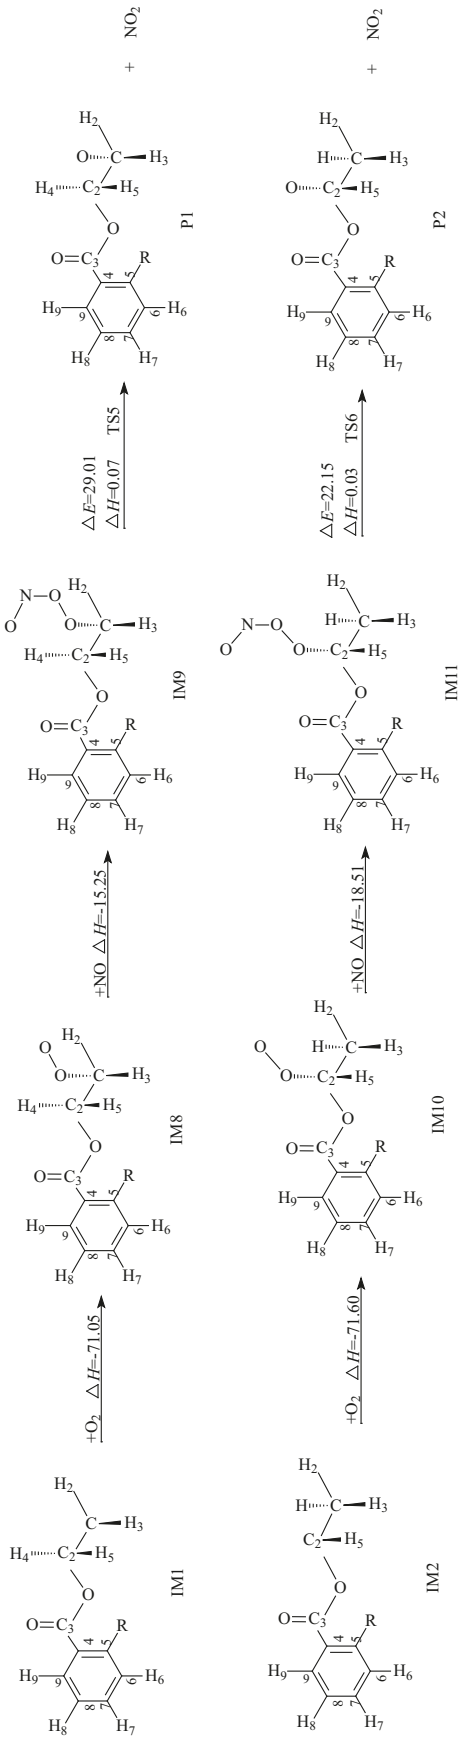

Fig. 3. Secondary reaction routes from intermediates IM1 and IM2. Units: kcal/mol (1 cal = 4.184 J). ΔE, the reaction potential barrier; ΔH, the reaction enthalpy (0 K).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

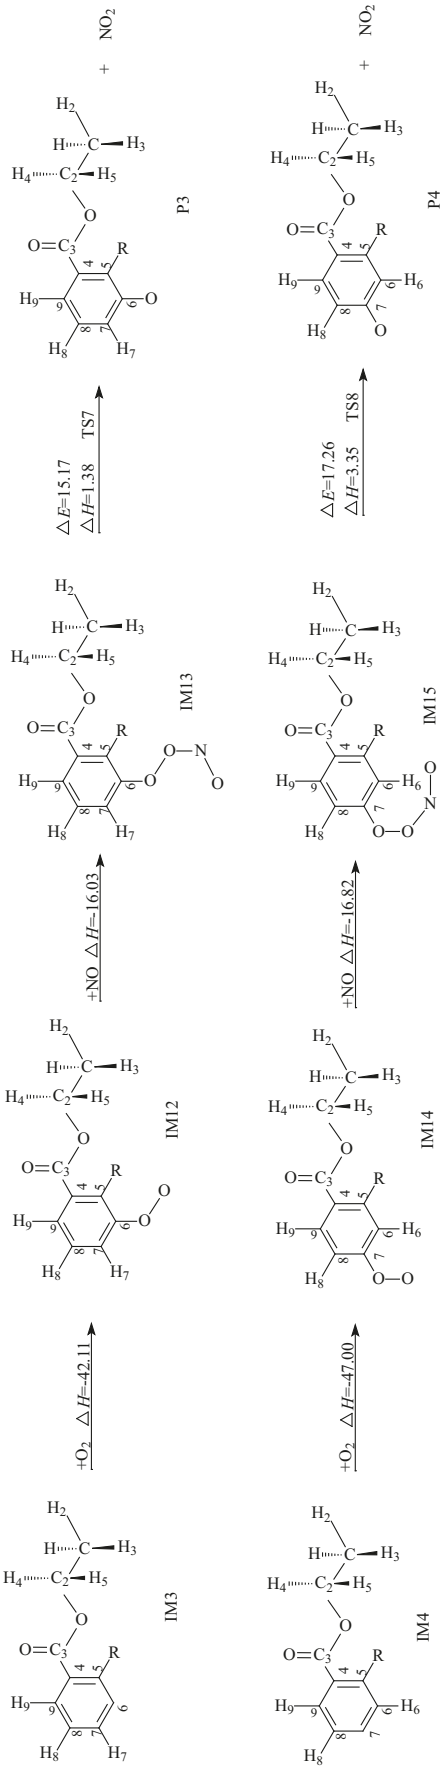

Fig. 4. Secondary reaction routes from intermediates IM3 and IM4. Units: kcal/mol (1 cal = 4.184 J). ΔE, the reaction potential barrier; ΔH, the reaction enthalpy (0 K).

In the atmosphere, IM23 will react with NO immediately to form an intermediate, IM24. IM24 subsequently reacts via a direct decomposition to form oxyl radical IM25 and NO_2 with a potential barrier of 18.83 kcal/mol, and the process is endothermic by 1.57 kcal/mol. IM25 can react with O_2 to yield P7 and HO_2 via transition state TS14. The reaction pathways are shown in Fig. 5.

Atmospheric reaction pathways of IM6 and IM7

The H atom in IM6 can be abstracted by O_2 via the transition state TS15. The process has a low potential barrier of 0.26 kcal/mol and is strongly exothermic by 71.14 kcal/mol. TS15 has an imaginary frequency of 1415i cm^{-1}. Similarly, the H atom in IM7 can be abstracted by O_2 as well. The two abstraction reactions are energetically favorable and will readily occur in the atmosphere.

Similar to IM5, IM6 can react with O_2 via an addition mechanism. There are three possible sites in IM6 to react with O_2. Three products IM26, IM27 and IM28 can be formed through addition of O_2 to C_5, C_7 and C_9 atoms in IM6. The three addition reactions are strongly exothermic by 44.45, 45.12 and 43.43 kcal/mol. IM26, IM27 and IM28 have similar structure and will be removed from the atmosphere by similar reaction mechanism. Therefore, we just discuss the atmospheric reactions of IM26 here. In the atmosphere, IM26 will further react with NO immediately to form an intermediate IM29. IM29 subsequently reacts via a direct decomposition to form oxyl radical P10 and NO_2, and this reaction requires crossing a potential barrier of 14.96 kcal/mol and is endothermic by 2.84 kcal/mol.

Similarly, IM7 can react with O_2 through the addition mechanism. The possible products are IM30, IM31, and IM32. The reaction pathways are described in Fig. 6.

Conclusion

The OH-initiated atmospheric oxidation reaction of DEP has been theoretically investigated in this paper. This study shows that the reaction of DEP with OH radicals can proceed through three energetically favorable channels: H abstraction from the CH_3 group, H abstraction from the CH_2 group, and OH addition to C_4, C_5, and C_6 atoms in the benzene ring.

On the one hand, our quantum calculations can provide a detailed degradation mechanism, which is helpful for understanding the atmospheric-chemistry transformation of the DEP. On the other hand, the quantum chemistry calculations can provide the basic information for direct kinetic studies, such as the energy, force constants, and Hessian matrices of the stationary points. The kinetic studies are planned for future work.

Abstract: For the formation of a complex of Cu^{2+} with the amyloid-β (Aβ) proxy *N*-α-dihydrourocanylhistamine (**L**) in unbuffered aqueous solution (pH ~ 5.7, 25.0 °C), UV spectrophotometric measurements give a stability constant of 3.8×10^5 L mol^{-1}. This stability constant is within the lower limit of the range of stability constants reported in the literature for complexes of Aβ with Cu^{2+} — as expected, in view of the smaller number of coordination sites in **L**. Computer modeling indicates that the Cu^{2+}–**L** complex is $Cu\mathbf{L}(H_2O)_2^{2+}$, with terdentate **L** bound to Cu^{2+} via two N_π atoms and the O atom of the peptide link. Attempts to make stability constant measurements for Cu^{2+} with **L** in aqueous solution buffered with Tris/$TrisH^+/ClO_4^-$ to pH near 7.2 were unsuccessful because the Tris base when in large excess over $Cu\mathbf{L}^{2+}$ promoted its dissociation to Cu^{2+} + **L** by scavenging free Cu^{2+} as $Cu(Tris)(TrisH_{-1})^+$, or when in roughly equimolar concentrations formed a ternary adduct, $Cu\mathbf{L}(Tris)^{2+}$. The interactions of Cu^{2+} with Tris buffer were re-examined spectrophotometrically and with the aid of computations that show that the most stable Cu^{2+}–Tris complexes are the syn- and anti-isomers of $Cu(Tris)_2^{2+}$, but in the experimental pH ranges these are present as $Cu(Tris)(TrisH_{-1})^+$. Since $Cu^{2+}(aq)$ is strongly complexed by almost any base capable of forming a buffer system with near-physiological pH, stability constants reported for Cu^{2+}–Aβ complexes in any buffer solution should be regarded with skepticism unless interactions of the buffer with Cu^{2+} and with $CuA\beta^{2+}$ are taken quantitatively into account. Moreover, in vivo, biological buffers will reduce the physiological importance of Aβ–Cu^{2+} complexes by competing with Aβ for Cu^{2+}.

Key words: N-α-dihydrourocanylhistamine complexes with copper(II), amyloid-β complexes with copper(II), Tris buffer complexes with copper(II), buffer interferences in biochemical measurements.

Résumé : Sur la base de mesures spectrophotométriques UV, il a pu être établi que pour la formation, en solution aqueuse non tamponnée (pH ~ 5,7, 25,0 °C) d'un complexe du Cu^{2+} avec la *N*-α-dihydrourocanylhistamine (**L**), un produit de remplacement de l'amyloïde-β (Aβ), la constante de stabilité est égale à $3{,}8 \times 10^5$ L mol^{-1}. Tel qu'on pouvait s'y attendre compte tenu du nombre plus faible de sites de coordination dans le produit **L**, cette constante de stabilité se situe à la limite inférieure de la plage des constantes de stabilité rapportées dans la littérature pour les complexes entre l'Aβ et le Cu^{2+}. La modélisation par ordinateur indique que le complexe Cu^{2+}–**L** est $Cu\mathbf{L}(H_2O)_2^{2+}$, avec un groupe **L** tridentate lié au Cu^{2+} par le biais de deux atomes N_π et un atome O de la liaison peptidique. Les essais effectués pour faire des mesures de constante de stabilité du Cu^{2+} avec le groupe **L**, en solution aqueuse tamponnée par du Tris/$TrisH^+/ClO_4^-$ à un pH d'environ 72, n'ont pas été fructueux parce que, lorsque la base tris est en grand excès par rapport au complexe $Cu\mathbf{L}^{2+}$, elle provoque sa dissociation en Cu^{2+} + **L** par épuisement du Cu^{2+} sous la forme de $Cu(Tris)(TrisH_{-1})^+$ ou, lorsque les entités sont en concentrations pratiquement équimolaires, elles forment un adduit ternaire, $Cu\mathbf{L}(Tris)^{2+}$. Les interactions du Cu^{2+} avec le tampon Tris ont été réexaminées par des études spectrophotométriques et à l'aide de calculs théoriques qui ont montré que les complexes Cu^{2+}–Tris les plus stables sont les isomères syn et anti du $Cu(Tris)_2^{2+}$; toutefois, dans les plages de pH expérimentaux, ces isomères sont présents sous la forme de $Cu(Tris)(TrisH_{-1})^+$. Considérant que le Cu^{2+} est fortement complexé par pratiquement toutes les bases capables de former un système de tampon près du pH physiologique, les constantes de stabilité rapportées pour les complexes Cu^{2+}–Aβ et mesurées dans n'importe quelle solution tampon doivent être considérées avec scepticisme à moins que les interactions du tampon avec le Cu^{2+} et le $CuA\beta^{2+}$ aient été prises en compte d'une façon quantitative. De plus, in vivo, les tampons biologiques réduisent l'importance physiologique des complexes Aβ–Cu^{2+} en étant en compétition avec Aβ pour le Cu^{2+}.

Mots-clés : complexes de la *N*-α-dihydrourocanylhistamine avec le cuivre(II), complexes de l'amyloïde β avec le cuivre(II), complexes tamponnés tris avec le cuivre(II), interférences des tampons dans les mesures biochimiques.

Introduction

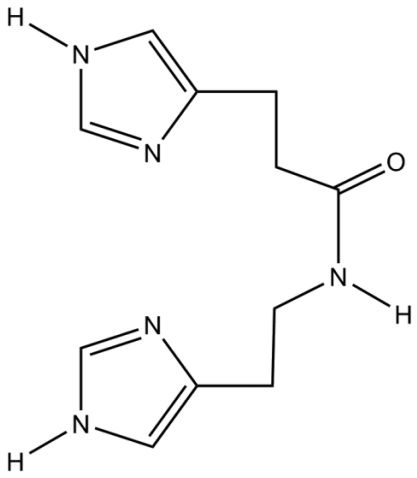
The water-soluble 4.3 kDa amyloid-β peptide (Aβ), associated with Alzheimer's disease (AD), forms complexes with aqueous metal ions such as Fe^{3+}, Al^{3+}, Zn^{2+}, and Cu^{2+}, and it is likely that such complexes of Aβ in its Aβ1–42 form are involved in the formation of the senile plaque deposits that are characteristic of AD.[1–8] The aqueous Cu^{2+} ion, which typically has the highest stability constants for complex formation among divalent transition-metal ions in the Irving–Williams series,[9] has a particular affinity for nitrogen bases, notably histidine. Indeed, Cu^{2+}(aq) evidently interacts with Aβ of various chain lengths primarily through the N_π atoms of the His13 and His14 residues.[2,4,5,10] Copper(II) has been shown to initiate the nucleated precipitation of Aβ1–40 and Aβ1–42[11] and is found in elevated concentrations in amyloid plaques.[5] Moreover, copper(II)–Aβ complexes may be responsible for the generation of reactive oxygen species that are believed to play a key role in AD.[1,3]

There is, however, no consensus on the mode of coordination of Cu^{2+} to Aβ, although it is recognized that differences in the coordination of Cu^{2+} by human and rodent Aβ may account for the absence of formation of senile Aβ plaques in rodents.[12] Because copper(II) complexes are typically highly labile in ligand substitution,[13] there may be no unique structure of a Cu^{2+}–Aβ complex; rather, the Cu^{2+} ion may be bound in dynamic equilibrium to N_π in His6, His13, His14, and a terminal $–NH_2$ site, as well as to an O atom (e.g., an O of Asp1 or Ala2) in distorted square-planar CuN_3O arrangements.[4–6,12] The populations of the alternative structures are pH dependent; at pH 7.4, there are two main coexisting forms, forms **I** and **II**, whereas at lower pH form **I** is dominant. Not surprisingly, then, the experimental stability constants $K_{A\beta}$ reported for Cu^{2+}–Aβ complexes vary widely; values ranging from 5.0×10^4 to 1.5×10^9 L mol^{-1} were tabulated by Hatcher et al.,[14] whereas Faller and Hureau[5] derived conditional $K_{A\beta}$ values of 10^7–10^{11} L mol^{-1} by reanalyzing data from the literature and expressed a preference for 10^9–10^{10} L mol^{-1}. These inconsistencies are due in part to differences in the Aβ chain length chosen (1–16 through 1–42) and to differences in the mode of calculation of the stability constants, but at least some of the discrepancies may be due to the presence of competing ligands such as buffer components, and this issue is pursued in the present article.

Elucidation of the Cu^{2+}–Aβ interaction by computational modeling is therefore very desirable, but is hindered by the size and complexity of Aβ molecules. Raffa et al.[2] therefore carried out ab initio computations on the interactions of aqueous Cu^{2+} with the model Aβ fragment 3-(1*H*-imidazol-5-yl)-*N*-[2-(1*H*-imidazol-5-ylethyl]propanamide (*N*-α-dihydrourocanylhistamine, **L**; Fig. 1), which affords two N_π bases corresponding to His13 and His14 of Aβ connected by the appropriate peptide link.

Raffa et al.[2] calculated that the most energetically favoured species were the four-coordinate 1:1 complexes $Cu\mathbf{L}(OH_2)^{2+}$ (designated species **20** by Raffa et al.[2]), in which the metal binds to terdentate **L** through the two N_π histidine atoms and the amide oxygen, and $Cu(\mathbf{L}H_{-1})(OH_2)^{+}$ (species **35**) in which Cu^{2+} again bonds through the two N_π atoms but displaces the NH proton in the peptide link to form a coordinate bond to the amido group rather than the peptide O. The amido coordination mode is feasible because the pK_a of the peptide NH was calculated to be 15.7 in free aqueous **L** but only 5.5 in species **20**.[2] The computed stability constant $K_{\mathbf{L}}$ for $Cu^{2+} + \mathbf{L} \rightarrow \mathbf{20}$ was 1.3×10^{19} L mol^{-1}, and $K_{\mathbf{L}}'$ for $Cu^{2+} + \mathbf{L} \rightarrow \mathbf{35} + H^+$ was 4.3×10^{17}. The computed value of $K_{\mathbf{L}}$ was markedly higher than the range of measured $K_{A\beta}$ noted above (although Atwood et al.[11] found $K_{A\beta} = 1.6 \times 10^{17}$ L mol^{-1} for Cu^{2+}–Aβ1–42), which is surprising because there are fewer potential donor sites in **L** relative to Aβ. In any event, an experimental value of $K_{\mathbf{L}}$ is needed. A further question to be resolved experimentally is which of the species **20** and **35** of Raffa et al. is more relevant to Cu^{2+}–**L** solution chemistry.

Fig. 1. Model amyloid-β fragment **L** (*N*-α-dihydrourocanylhistamine).



The interactions of Aβ with metal ions are known to be pH-dependent,[5] and so the use of a buffer system to maintain physiological pH is customary. However, by virtue of the position of Cu^{2+} in the Irving–Williams series,[9] it will form complexes of high stability with any ligand having a greater basicity and (or) ligand field strength than solvent water, and we recognized at the outset that this would include the base component of any practical buffer system giving pH near 7, including "Tris" (2-amino-2-(hydroxymethyl)-1,3-propanediol), which is very widely used to control pH in biochemical experiments. After we began the experimental work described here, several authors reported buffer interference in measurements on Cu^{2+}–Aβ complexation,[14–17] and in 2010 Rózga et al.[17] were particularly critical of the use of Tris, although their choice of a Hepes buffer was not necessarily better.[5]

It is surprising that the use of Tris buffers has been widespread in studies of biochemical reactions involving metal ions, particularly Cu^{2+}, as the formation of Cu^{2+}–Tris complexes has long been recognized,[18–24] although Rózga et al.[17] noted that a definitive set of stability constants for Cu^{2+}–Tris complexes is still lacking. Bai and Martell,[20] in a potentiometric study over a pH range 4–12, reported stability constants K_n for $Cu(Tris)_n^{2+}$ at 25 °C and ionic strength at 0.10 mol L^{-1}; for the assumed n = 1, 2, 3, and 4, they reported log K_n = 3.95, 3.68, 3.47, and 3.0, respectively. They also reported, however, that $Cu(Tris)^{2+}$ and $Cu(Tris)_2^{2+}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

underwent deprotonation to $Cu(TrisH_{-1})^+$ and $Cu(Tris)(TrisH_{-1})^+$ with pK_a values of 6.0 and 6.32, respectively, and $Cu(Tris)(TrisH_{-1})^+$ to $Cu(TrisH_{-1})_2$ with $pK_a = 7.90$; on this basis, at our target pH of 7.20, 94% of the mono(Tris) complex would be present as $Cu(TrisH_{-1})^+$ and, if the double deprotonation is ignored, 88% of the bis(Tris) complex would exist as $Cu(Tris)(TrisH_{-1})^+$. Of the groups other than Bai and Martell that have published stability constants for the Cu^{2+}–Tris system, only Kemula et al.[19] reported potentiometric data for all of $n = 1$, 2, 3, and 4; Hall et al.[18] used visible-NIR spectrophotometry to obtain K_1, K_2, and K_3 values, whereas Takahashi et al.[21] reported only the cases $n = 1$ and 2. In general, the K_1 and K_2 data are in reasonable agreement with those of Bai and Martell.[20] Bologni et al.,[22] however, supplied further potentiometric data and analyzed all existing data statistically according to various models, finding the best fit for one which included $Cu(Tris)^{2+}$, $Cu(TrisH_{-1})^+$, and $Cu(Tris)(TrisH_{-1})^+$, plus other deprotonated species relevant only to high pH, but not $Cu(Tris)_2{}^{2+}$ or $Cu(Tris)_4{}^{2+}$; the apparent absence of $Cu(Tris)_2{}^{2+}$ may be interpreted as confirming that it is converted largely to $Cu(Tris)(TrisH_{-1})^+$ at near-physiological pH, as the pK_a reported by Bai and Martell[20] for $Cu(Tris)_2{}^{2+}$ implies. Colombo et al.[23] demonstrated the presence of Cu^{2+}–Tris complexes in solution at pH 10 by optical and ESR methods, and obtained crystal structures for solid $[Cu(TrisH_{-1})_2(OH_2)]$. Kotila[24] reported X-ray structures of solid $[Cu(Tris)(TrisH_1)OH_2]X$ (X = Cl, Br, etc.), obtained by evaporation of solutions containing CuX_2 (0.01 mol) and Tris (0.04 mol), and of other complexes containing deprotonated Tris such as $[Cu(TrisH_{-1})_2]KF{\cdot}3H_2O$.[25–28]

Thus, there is ample evidence for the existence of Cu^{2+} complexes with Tris and $TrisH_{-1}{}^-$ in solution and in the solid state. In their recent review of measurements of the Cu^{2+}–Aβ interaction in buffer systems, Faller and Hureau[5] applied corrections to Cu^{2+}–Aβ stability constants from the literature for interactions of the various buffers with Cu^{2+}, and concluded that measurements in Tris buffer systems were the most reliable relative to those with other buffers once the buffer–Cu^{2+} interactions were taken into account. One question we address here is how, and to what extent, the use of Tris or other buffers affects attempts to determine a meaningful stability constant for Cu^{2+} with the Aβ proxy **L**, either by competition between Tris and **L** for $Cu^{2+}(aq)$ or by direct complex formation between Tris and $Cu\mathbf{L}^{2+}$ or both. These complications are such, however, that we resorted to measurement of the stability constant K_{CuL} for $Cu\mathbf{L}^{2+}$ in the absence of buffers; with this information, it became possible to interpret the behavior of $Cu\mathbf{L}^{2+}$ in buffered solutions.

Experimental

Materials and methods

Synthesis of L

As the preparative method for **L** differed somewhat from that of Baures et al.,[29] it is given here in detail. Histamine dihydrochloride, urocanic acid (3-(4-imidazolyl)acrylic acid), ethyldisopropylamine(benzotriazo-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP), and anhydrous DMF (Sigma-Aldrich) were used without further purification. Methanol and dichloromethane were from EMD, with the latter dried over 4 Å molecular sieves. Celite 545 was obtained from Fisher Scientific Canada. Column chromatography was performed on silica gel 60 (230–400 mesh Merck cat. No. 9385, Sigma-Aldrich). ^1H and ^{13}C NMR spectra were measured at 400 and 100 MHz, respectively, with a Bruker Instruments Co. DRX-400 spectrometer of solutions in MeOH-d_4 (CDN Isotopes Inc.) using the solvent signals at δ_H 3.30 and δ_C 49.0 ppm as references; the HMBC spectra were measured with a program that was optimized for a long-range coupling of 5 Hz.

N-α-Urocanylhistamine

To a solution of histamine dihydrochloride (184 mg, 1.00 mmol) dissolved in MeOH (10 mL) was added diisopropylethylamine (500 mg, 3.88 mmol) and the solvent was then removed under reduced pressure (Rotovap, bath 50 °C). The residue was dissolved in dry DMF (5 mL) and the magnetically stirred solution was cooled to 0 °C. To this, with exclusion of moisture, was added a slurry of urocanic acid (138 mg, 1 mmol), diisopropylethylamine (270 mg, 2.1 mmol), and (benzotriazo-1-yloxyphosphonium) hexafluorophosphate (520 mg, 1 mmol) in CH_2Cl_2 (10 mL). The ice bath was allowed to melt, and the mixture was stirred for a further 18 h. The suspension of finely divided solid was then concentrated (Rotovap, bath 50 °C), first at 15 and then 0.1 torr (1 torr = 133.3224 Pa) to remove the solvents. The residual pale brown oil was applied to a column of silica gel 60 (18 cm × 1.8 cm). Flash chromatography with CH_2Cl_2–MeOH (9:1 *v*/*v*; 20 mL fractions) eluted by-products in f 1–5 but little else and the eluant was then changed (f 25) to CH_2Cl_2–MeOH–NH_4OH (180:30:5 *v*/*v*), which eluted material (159 mg) in f 31–33 that crystallized upon removal of the solvents as a white solid mp 243–244 °C (uncorr.; lit.[29] mp 240–241 °C). ^1H NMR δ_H: 7.73 (1H, s), 7.60 (1H, s), 7.42 (1H, d, $J = 15.6$ Hz), 7.32 (1H, s), 6.87 (1H, s), 6.46 (1H, d, $J = 15.6$ Hz), 3.54 (2H, t, $J = 7.2$ Hz), 2.83 (2H, t, $J = 7.2$ Hz, as lit.;[29] and ^{13}C NMR δ_C: 169.2 s, 138.5 s. 136, 8 v br s, 136.2 s, 136.0 s, 132.3 s, 122.5 v br s, 119.5 s, 118.2 s, 40.7 t, 27.8 t, as lit.[29], but all signals were displaced by 2 ppm to lower field (presumably because of a difference in references). EIMS *m*/*z*: 231 (M^+, 12), 150 (27), 138 (30), 121 (100), 93 (40), 82 (40) Da. HREIMS *m*/*z*: 231.1122; req. for $C_{11}H_{13}N_5O$: 231.1120 Da.

N-α-Dihydrourocanylhistamine (L)

Urocanylhistamine (81 mg, 0.35 mmol) in MeOH (10 mL) was added to a suspension of Pd(10%)-on-C (25 mg) in MeOH (5 mL) and hydrogenated at atmospheric pressure. Hydrogen uptake was complete within 20 min. The suspension was filtered through a pad of Celite and the filter cake washed with a little MeOH. Evaporation (Rotovap, bath 50 °C) of the combined filtrate and washings gave a white solid (75 mg), which was recrystallized from MeOH, mp 176–178 °C (uncorr.; lit.[29] mp 163–164 °C). ^1H NMR δ_H: 7.59 (1H, s), 7.57 (1H, s), 6.80 (1H, s), 6.78 (1H, s), 3.40 (2H, t, $J = 7.1$ Hz), 2.85 (2H, t, $J = 7.4$ Hz), 2.73 (2H, t, $J = 7.2$ Hz), 2.47 (2H, t, $J = 7.4$ Hz) (cf. Baures et al.[29]). ^{13}C NMR δ_C: 175.0 s, 137.3 s, 136.0 d, 135.9 d, 135.7 s, 118.1 d, 117. 6 d, 40.3 t, 36.8 t, 27.7 t, 23.9 t (as Baures et al.[29]), but with those signals displaced by 1.0–1.8 ppm to lower field (presumably because of a difference in references).

The connectivities of the two units within the structure was confirmed by HMBC spectra, which revealed the expected ^2J and ^3J couplings of H-2 (δ_H 2.47) to C-1, -3, and -4 (δ_C 175.1, 23.9, and 137.3, respectively); H-3 (δ_H 2.85) to C-1, -2, -4, and 5 (δ_C 175.1, 36.8, 137.3, and 117.6, respectively); H-1′ (δ_H 3.40) to C-1, -2′, and 3′ (δ_C 175.1, 27.7, and 135.7, respectively); and H-2′ (δ_H 2.73) to C-1′, 3′, and 4′ (δ_C 40.4, 135.7, and 118.1, respectively). EIMS *m/z*: 233 (M^+, 20), 140 (46), 123 (70), 95 (100), 94 (35), 82 (47), 81 (100) Da. HREIMS *m/z*: 233.1280; req. for $C_{11}H_{15}N_5O$: 233.1277.

Copper(II) interactions with L and Tris

Copper(II) perchlorate hexahydrate (Alfa; formula weight determined by cation-exchange acidimetry to be 371.7 ± 1.1), Tris (Omnipur), and standardized HCl (0.1003 mol L^{-1}, J.T. Baker) were used as received. $HClO_4$ (Baker analyzed, 69.1%) was standardized against Baker standard NaOH solution (0.250 mol L^{-1}) with accuracy better than ±0.3%. House reverse-osmosis water was further purified to >18.0 MΩ cm using a Barnstead E-Pure train.

Measurements of pH were made at room temperature (21 ± 1 °C) using an Orion Model 420 pH meter calibrated at pH 4.00, 7.20, and 10.04 with buffer solutions traceable to NIST standards. Stock Tris/$TrisH^+$ buffer solutions (50.0 mmol L^{-1} in total [Tris]) were made up for pH 7.20 from Tris and standard HCl or $HClO_4$ (0.1 mol L^{-1}) following the quantities of Bates and Bower[30]; 89.4% of the total [Tris] was then present as $TrisH^+$.

Spectrophotometric measurements were made using a 10.0 mm silica cuvette on a Cary 5E UV–vis–NIR spectrophotometer with a cell block thermostated at 25.0 ± 0.1 °C with circulating water. Spectra were automatically corrected for baselines run on each solution without the solute of interest (i.e., any absorption owing to the buffer, etc., was subtracted).

Computational methods

Geometry optimization and harmonic frequency analysis were carried out by Gaussian 03 and 09[31] calculations using the hybrid density functional method, B3LYP[32], and the 6–31+G(d) basis set, which we will refer to as the small basis set (SB). The frequency calculation confirmed that the optimized structure was at a local minimum on the potential energy hypersurface and yielded zero point energies and thermochemical parameters. The zero point energies were scaled by 0.9806.[33] However, this was not done for the thermal correction of enthalpy or entropies. Calculated entropies were adjusted in several ways. (*i*) Since we are adding the influence of solvation (see below), we interpret ΔG_{solv} values as being the free energy change that occurs when 1 mol of substrate is added to a 1 L box of water. Thus, the reference state of the entropy is modified from 24.46 L, the volume of 1 mol of ideal gas at 298 K and 1 atm pressure (1 atm = 101.325 kPa), to 1 L: S_{298} (1 mol L^{-1}) = S_{298} (1 atm) + R ln(1/24.46) = S_{298} (1 atm) – 26.585 in J mol^{-1} K^{-1}. (*ii*) Two of the species (**L** and **Tris**) exist in numerous rotameric forms of similar energy in aqueous solution. The entropy of a substance consisting of n conformers in equilibrium is given by $S = \Sigma_i\ \chi_i[S_i + R\ \ln(\chi_i)]$, where χ_i is the mol fraction of conformer i and S_i is its entropy. It is not practical to carry out a comprehensive conformer search in solution. It has been shown[34] that the entropy of a substance is well approximated as $S \approx S_i + R\ \ln(n)$, where S_i is the entropy calculated by Gaussian for the lowest energy conformer obtained by a limited conformer search in the gaseous phase and n is the number of conformers estimated by simple count of stereoisomers including rotamers. It is important to take this entropy of mixing into consideration if the number of degrees of conformational freedom changes significantly because of complex formation, as in the present case. A precise value is not important, since an error of a factor of 2 only affects the free energy change by <2 kJ mol^{-1}. Neglecting it altogether may incur a much larger error (RT ln(63) = 10 kJ mol^{-1} for the complexation of **L** with Cu^{2+}). Values used for n in this work for individual substances are listed in Supplementary data Table S2.

For more accurate enthalpies, single point energies were calculated using B3LYP with a larger basis, 6–311+(2df,2p) (= LB). To compensate for the lack of long-range dispersion at the B3LYP level,[35] single point MP2/SB calculations at the B3LYP/SB geometry were carried out to estimate MP2/LB values using the additive approximation E(MP2/LB) ≈ E('MP2/LB') = E(MP2/SB//B3LYP/SB) + E(B3LYP/LB//B3LYP/SB) – E(B3LYP/SB), where // represents "at the geometry optimized at". Computational results derived from the 'MP2/LB' level, referred to henceforth simply as MP2/LB, are tabulated and discussed in the Results section.

Details of all computed quantities and structural information are provided in Supplementary data Tables S1 and S2, respectively. Molden 4.0 was used as a visualization tool.[36]

Free energies of solvation (ΔG_{solv}) and empirical corrections

To calculate the free energy change in water ($\Delta G_{(aq)}$) the change in the free energy of solvation ($\Delta\Delta G_{solv}$) was added to the free energy change in the gaseous phase ($\Delta G_{(g)}$), corrected for a standard state of 1 mol L^{-1}. ΔG_{solv} was determined using the integral equation following polarizable continuum model (IEFPCM)[37–39] and the B3LYP/6–31+G(d) density. In our experience, charged species are undersolvated by the IEFPCM with standard scaling of the united atom Hartree–Fock (UAHF) radii, so selective scaling was applied as follows: the radii of the metal ion and atoms directly attached to it were scaled by a factor of 1.1; all other atoms were scaled by the default value, 1.2. Experimental rather than calculated relative free energies of solvation were applied where available to reduce errors further. For the proton, $\Delta G_{solv}(H^+)$ = –1107 kJ mol^{-1} was adopted.[40] In addition, for processes that liberate a proton in the buffer medium, it is important to be able to calculate the pK_a of $TrisH^+$ accurately (pK_a = 8.07).[41] As the calculated values (pK_a = 8.7 (MP2) and pK_a = 7.6 (B3LYP)) are close to the experimental value, no adjustment in the free energy of solvation of $TrisH^+$ was necessary. In summary, experimental values of ΔG_{solv} were adopted as follows (in kJ mol^{-1}): H^+, –1107; and H_2O, –16.2. For all other species, free energies of solvation were taken as calculated by the procedure described above. The largest uncertainties in the calculated numbers will be with the gaseous-phase enthalpies approximated at the MP2/LB level. However, we expect that *changes* in aqueous free energies ($\Delta G_{(aq)}$) will be accurate to ±15 kJ mol^{-1} for all of the reactions considered.

Calculations of UV–vis spectra

For selected species, optical spectra in the range 200–800 nm were calculated using the time-dependent version of B3LYP[37–39] with the more flexible basis set 6–311+G(d,p) in water represented by the IEFPCM solvent reaction field. Spectra are displayed as superimposed bands with half-widths at half-height = 0.2 eV and area derived from the calculated oscillator strengths by procedures internal to Gaussview 4.07.[42]

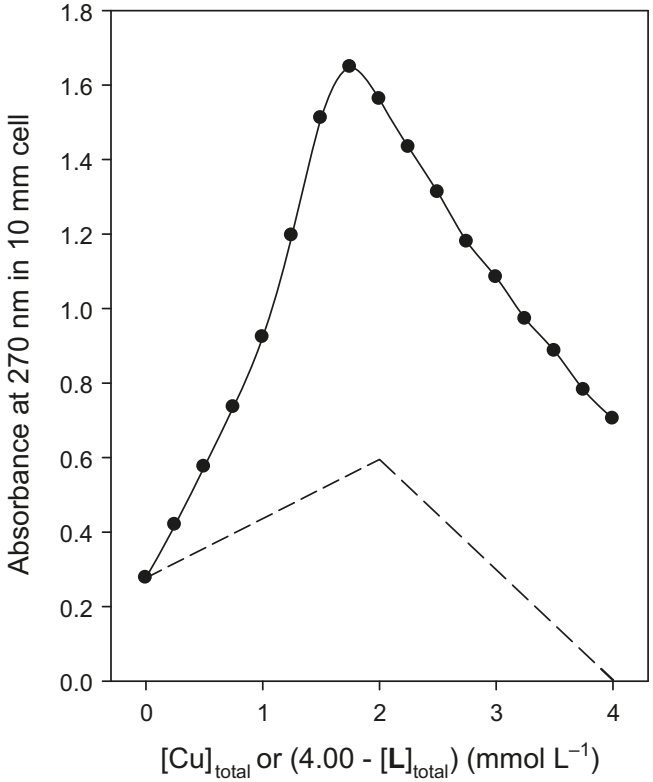
Results

Preliminary measurements

An exploratory attempt was made to characterize the Cu^{2+}–**L** interaction using the continuous variations method of Job,[43] with pH control by a minimal amount (10.0 mmol L^{-1}) of Tris/$TrisH^+$/Cl^- buffer; attempts at such measurements with a $H_2PO_4^-$/HPO_4^{2-} buffer (9.1/20.5 mol L^{-1}, pH 7.2) failed because of precipitation. The UV absorbances of a series of solutions containing x mmol L^{-1} Cu^{2+} and $(4 - x)$ mmol L^{-1} **L** ($0 \leq x \leq 4$) were measured in the region 250–320 nm (e.g., Fig. 2 for 270 nm). All spectra were time-independent, meaning that any interactions of Cu^{2+} with **L** or Tris were complete within the time of sample preparation, as is typical of copper(II).[13,44,45] It was quickly found, however, that Job's method is not appropriate for this system because free **L** absorbs substantially in this spectral region, and moreover the apparent molar absorbance of Cu^{2+} (negligible for Cu^{2+}(aq) itself) increased markedly with [Tris], indicating the formation of Cu^{2+}–Tris species. In Fig. 2, the broken line plot shows the expected dependence of absorbance on x for formation of a 1:1 Cu^{2+}–**L** complex in absence of buffer (see below), whereas the continuous curve shows that the Tris buffer base reacts with Cu**L**$^{2+}$ and (at far right) Cu^{2+} to form Cu^{2+}–Tris and probably Cu**L**$^{2+}$–Tris complexes with higher molar absorbances in the UV than Cu**L**$^{2+}$. Detailed interpretation of Fig. 2 is not warranted because the supply of unprotonated Tris base, initially only 1.07 mmol L^{-1} at zero [Cu^{2+}], must soon have been exhausted by complex formation as [Cu^{2+}] was increased; the shape of the continuous curve implies Cu**L**$^{2+}$–Tris complex formation, but there is no obvious feature at $[Cu]_{total} \approx 1.3$ mmol L^{-1}, expected if Cu$\mathbf{L}_2^{2+}$ were important. The key point that emerges is that Tris interferes strongly with Cu^{2+}–**L** complex formation by scavenging Cu^{2+} and also by Cu**L**$^{2+}$–Tris complex formation.

The shape of Fig. 2 does, however, imply that there is a strong 1:1 interaction of **L** with Cu^{2+} when these are present in equimolar concentrations. Spectra of 1:1 mixtures of $Cu(ClO_4)_2$ + **L** (hereinafter referred to as {Cu^{2+},**L**}, to accommodate any dissociation of Cu**L**$^{2+}$) were therefore obtained in plain water and in Tris/$TrisH^+$ buffers (Figs. 3 and 4). The visible spectra of Fig. 3 quantify the obvious colour change that occurred on exposing aqueous {Cu^{2+},**L**} to Tris buffer; the absorption maximum shifted to shorter wavelengths with significant intensification. In Fig. 4, the UV spectrum of {Cu^{2+},**L**} is compared with those of Cu^{2+}(aq) and **L**; close examination of the {Cu^{2+},**L**} curve shows slight discontinuities between the segments representing 10-fold changes in concentration owing to small degrees of dissociation of Cu**L**$^{2+}$ to Cu^{2+} and **L** that increase on dilution. This effect was used as follows to estimate the stability constant of Cu**L**$^{2+}$ in the absence of a buffer.

Fig. 2. Optical absorbance at 270 nm of solutions made up with x mL $Cu(ClO_4)_2$ (4.98 mmol L^{-1}), $(4.00 - x)$ mL **L** (5.00 mmol L^{-1}), and 1.00 mL Tris/$TrisH^+$/Cl^- buffer (50.0 mmol L^{-1}), at 25.0 °C. Broken line, without buffer.



Interaction of Cu^{2+} with L in the absence of a buffer

Addition of 25.0 mL of pale sky blue $Cu(ClO_4)_2$ solution (10.01 mmol L^{-1}) to incompletely dissolved **L** (0.501 mmol) in ~20 mL water gave a clear royal blue solution; addition of a further 25.0 mL of the $Cu(ClO_4)_2$ solution caused the hue to change to a moderately intense sky blue. These respective colour changes are consistent with the formation of at least some Cu$\mathbf{L}_2^{2+}$ with excess **L** and then Cu**L**$^{2+}$ when [Cu^{2+}] = [**L**]; however, Fig. 2 and computational results (see below) indicated that Cu$\mathbf{L}_2^{2+}$ is of low stability relative to Cu**L**$^{2+}$ and was not considered further. The mixture was made to 100.0 mL with water to give a 5.0 mmol L^{-1} solution of the 1:1 complex {Cu,**L**$^{2+}$}. The measured pH of this {Cu,**L**}$(ClO_4)_2$ solution at 21 °C increased slowly from an initial 5.45 to settle at 5.69, cf. 5.23 for $Cu(ClO_4)_2$ (10 mmol L^{-1}) and 8.48 for aqueous **L** (5.0 mmol L^{-1}). From computer modeling described below, the aqueous complex is expected to be Cu$\mathbf{L}(OH_2)_2^{2+}$ with terdentate **L** (with the procedures in use in the previous study,[2] the most stable species was predicted to be Cu$\mathbf{L}(OH_2)^{2+}$). If we attribute the measured pH to acid dissociation of an aqua ligand,

$$[1] \qquad Cu\mathbf{L}(OH_2)_2{}^{2+} = Cu\mathbf{L}(OH)^+ + H_3O^+; \qquad K_{a(Cu\mathbf{L})}$$

we have $pK_{a(CuL)} \geq 9.08$ for this complex (a minimum value because of the possible presence of adventitious CO_2), cf.

Fig. 3. Visible spectra of equimolar (2.5 mmol L^{-1}) solutions of $Cu(ClO_4)_2$ + **L** without buffer (black line), in 25.0 mmol L^{-1} Tris/TrisH^+/ClO_4^- buffer (dark green line), and in 50.0 mmol L^{-1} Tris/TrisH^+/Cl^- (red line).

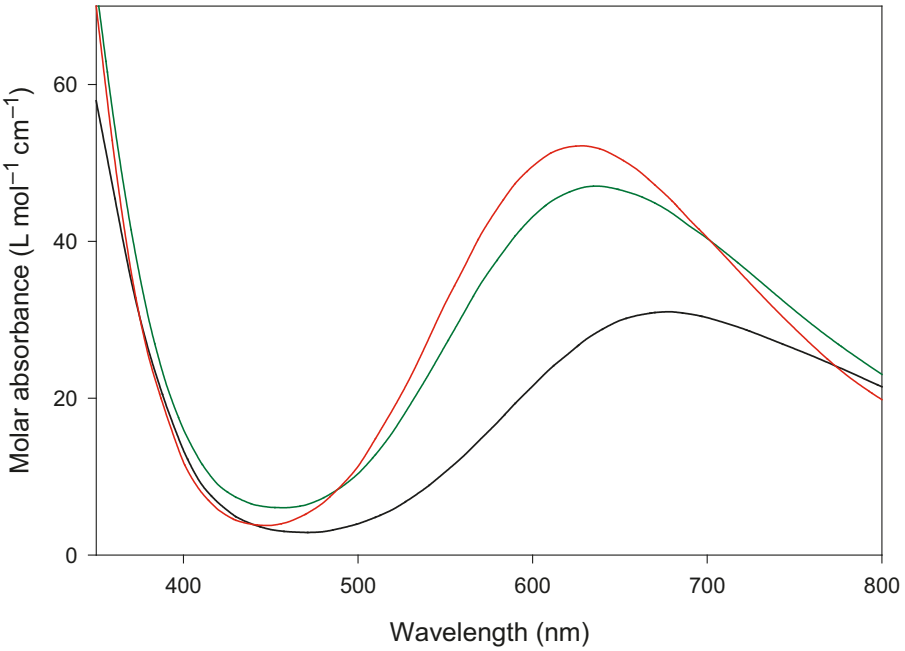


Fig. 4. Ultraviolet spectra of 1:1 $Cu(ClO_4)_2$ + **L** in water (upper curve: black segment, 0.050 mmol L^{-1}; red segment, 0.50 mmol L^{-1}; green segment, 5.0 mmol L^{-1}), and $Cu(ClO_4)_2$ in 1.0 mmol L^{-1} aqueous $HClO_4$ (blue line). The grey line is the spectrum of **L** (1.0 mmol L^{-1}) in 10.0 mmol L^{-1} Tris/TrisH^+/ClO_4^-.

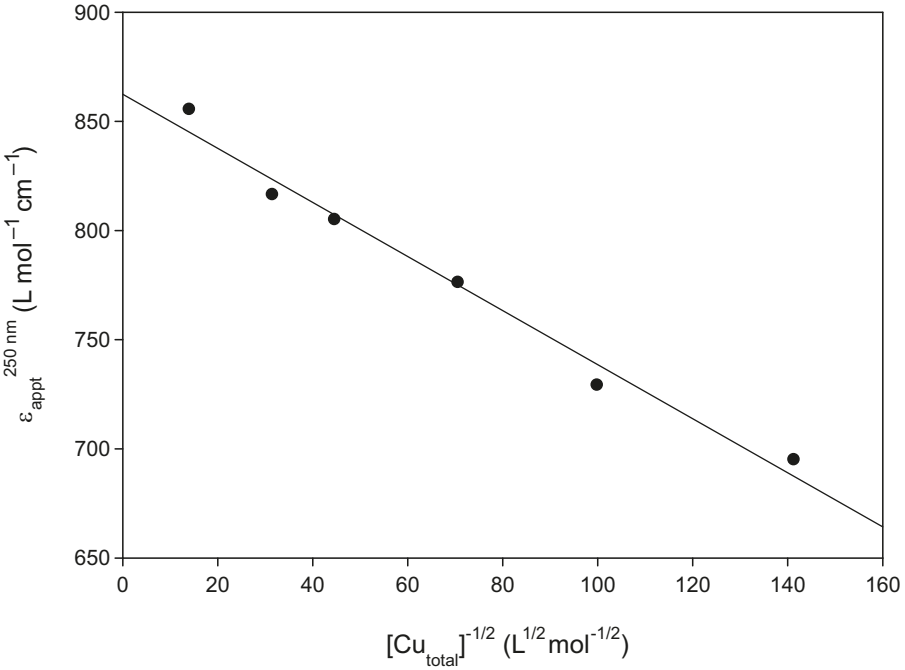
Fig. 5. Extrapolation of apparent molar absorbance of $\{Cu^{2+},\mathbf{L}\}$ at 250 nm in pure water to "infinite concentration".



8.16 for $Cu^{2+}(aq)$ and 5.26 for aqueous $\mathbf{L}H^+$ from the pH measurements. These data indicate that the three donor atoms of **L** in $Cu\mathbf{L}(OH_2)_2^{2+}$ include the peptide O along with the two N_π bases; the alternative species **35** of Raffa et al.[2] can be ruled out as requiring release of one H^+ from the amido N per $\{Cu,\mathbf{L}H_{-1}^+\}$ formed, which on going to completion would have given pH 2.3.

The apparent UV molar absorbance ε_{appt} of $\{Cu,\mathbf{L}^{2+}\}(ClO_4)_2$ in pure water was found to decrease by about 17% with progressive dilution from 5.0 to 0.050 mmol L^{-1}. This can be confidently attributed to dissociation of $Cu\mathbf{L}^{2+}$:

$$[2]\qquad \underset{c-x}{Cu\mathbf{L}^{2+}} = \underset{x}{Cu^{2+}}(aq) + \underset{x}{\mathbf{L}};\qquad K_{Cu\mathbf{L}}{}^{-1}$$

where c is the total concentration of $\{Cu^{2+},\mathbf{L}\}$ and affords a means of determining the stability constant $K_{Cu\mathbf{L}}$ of the complex. (An alternative possibility, that the change in absorbance might be due to acid dissociation as in eq. [1], can be discounted because the minimum value found for $pK_{a(Cu\mathbf{L})}$ indicates that no more than about 0.4% of $Cu\mathbf{L}(OH_2)_2^{2+}$ would undergo acid dissociation at 0.05 mmol L^{-1}.) Fig. 4 shows that the wavelength range best suited to estimation of $K_{Cu\mathbf{L}}$ (i.e., where the absorbances of **L** and $Cu^{2+}(aq)$ are smallest relative to $Cu\mathbf{L}^{2+}$) is 235–260 nm. The molar absorbances $\varepsilon_{\mathbf{L}}$ of **L** and ε_{Cu} of $Cu^{2+}(aq)$ were measured directly at 5 nm intervals in this range, and corresponding $\varepsilon_{Cu\mathbf{L}}$ values for undissociated $Cu\mathbf{L}^{2+}$ at each wavelength were obtained with adequate precision for $x << c$ by extrapolating linear plots of ε_{appt} vs $c^{-1/2}$ (e.g., Fig. 5) to zero. Then, the concentrations x of Cu^{2+} and **L** and thence $K_{Cu\mathbf{L}}$ were obtained from eqs. [3] and [4]. The relevant data are collected in Tables 1 and 2.

$$[3]\qquad x = (\varepsilon_{Cu\mathbf{L}} - \varepsilon_{appt})c/(\varepsilon_{Cu\mathbf{L}} - \varepsilon_{\mathbf{L}} - \varepsilon_{Cu})$$

$$[4]\qquad K_{Cu\mathbf{L}} = (c - x)/x^2$$

Table 1. Apparent molar absorbances (ε_{appt}) of 1:1 Cu^{2+}–**L** solutions at 25.0 °C

	ε_{appt} (L mol^{-1} cm^{-1})				
	λ (nm)				
Total [Cu] c (mmol L^{-1})	235	240	245	250	255
1.00	1686	1195	978	816	680
0.50	1668	1176	961	804	665
0.20	1635	1136	929	776	654
0.10	1563	1075	872	729	635
0.05	1498	1015	825	695	598

Note: c, concentration; λ, wavelength.

The average value of $K_{Cu\mathbf{L}}$ (10^5 L mol^{-1}) was 3.76 ± 0.11 (standard error; ±0.31 at the 99% confidence limit). A working value of $K_{Cu\mathbf{L}} = 3.8 \times 10^5$ L mol^{-1} at 25 °C may be adopted.

Interaction of $Cu^{2+}(aq)$ with Tris

Figure 6 shows the UV spectrum of 0.10 mmol L^{-1} aqueous Cu^{2+} in the presence and absence of Tris/TrisH$^+$/ClO_4^- buffer ($[Tris]_{base} = 0.107[Tris]_{total}$) over a fourfold range of $[Tris]_{total}$; the effect of the presence of the buffer is evident (cf. spectra reported by Bai and Martell[20] for the visible region). It can be seen that the spectral shapes — in particular, the wavelengths of the absorbance maxima at 238 nm and shoulders at ~265 nm — are independent of concentration and that a limiting molar absorbance is rapidly being approached as the concentration of buffer increases, suggesting the dominance of a single Cu^{2+}–Tris species. When the maximum apparent molar absorbances ($\varepsilon_{appt}^{238} = 3054$, 3246, and 3316 L mol^{-1} cm^{-1} for [buffer] = 10, 20, and 40 mmol L^{-1}, respectively) are plotted against the concentration of uncomplexed Tris base (i.e., $\{[Tris]_{base} - n[Cu^{2+}]_{total}\}$, for $Cu(Tris)_n^{2+}$), equally good linear correlations ($r^2 = 0.9998$ and 0.9999)

Table 2. Molar absorbances (ε, L mol^{-1} cm^{-1}) of Cu^{2+}(aq) and **L** obtained by direct measurement, Cu**L**$^{2+}$(aq) by extrapolation of apparent molar absorbances (ε_{appt}) as in Fig. 5, and stability constant K_{CuL} (L mol^{-1}) for Cu**L**$^{2+}$(aq) from eqs. [2]–[4].

λ (nm)	ε_{Cu}	ε_{L}	ε_{CuL}	K_{CuL} (10^5 L mol^{-1}) [a]
235	139.6	146.4	1747±7	4.03±0.30
240	66.4	101.1	1250±4	3.64±0.17
245	29.6	57.9	1025±5	3.74±0.20
250	12.8	54.8	862±7	3.32±0.19
255	5.4	56.9	695±4	4.08±0.26

Note: λ, wavelength.
[a]Average of five measurements at each wavelength; 25.0 °C.

are obtained for assumed $n = 3$ and 4, giving a limiting ε of 3376 ± 7 L mol^{-1} cm^{-1} at the 238 nm maximum. However, the pH of the 10 mmol L^{-1} Tris medium, with and without the added 0.10 mmol L^{-1} Cu^{2+}, was 7.01 and 7.15, respectively (the decrease in the pH of the buffer itself on dilution, initially 7.20 as prepared at 50 mmol L^{-1}, confirms the effect noted by Bates and Bower[30]). If this perturbation of the buffer pH by Cu^{2+} were due solely to consumption of unprotonated Tris base to form $Cu(Tris)_n^{2+}$, then eqs. [5] and [6] give the average n in that solution as 3.0 ± 0.3.

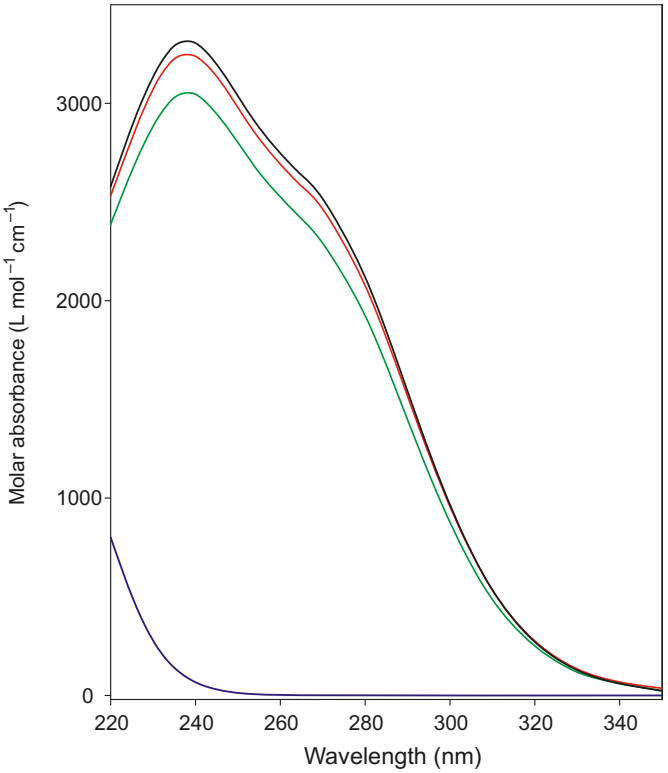
$$[5] \quad [Tris]_{free} = K_{a(TrisH)}[TrisH^+]/10^{-pH}$$

$$[6] \quad n_{average} = ([Tris]_{total} - [Tris]_{free})/[Cu^{2+}]_{total}$$

Similarly, for the solution with 20 mmol L^{-1} buffer, Cu complex formation caused a pH shift of 7.10 from 7.16, corresponding to $n_{average} = 2.8 \pm 0.6$, but in 40 mmol^{-1} buffer the pH shift was too small (7.17 from 7.19) to allow a meaningful estimate of $n_{average}$. Thus, within the error limits, the perturbation of the buffer pH corresponds to the removal of three free Tris molecules per added Cu^{2+} in both 10 and 20 mmol L^{-1} buffer.

The simplest explanation for these results is the formation of $Cu(Tris)_3^{2+}$. An alternative interpretation, however, is that the perturbation of the buffer pH was due to formation of $Cu(Tris)(TrisH_{-1})^+$ as the dominant Cu species in 10 and 20 mmol L^{-1} Tris buffer at least, each added Cu^{2+} complexing two unprotonated Tris and releasing one H^+ from the complex to protonate a third Tris. Bai and Martell[20] gave the pK_a of $Cu(Tris)^{2+}$ and $Cu(Tris)_2^{2+}$ as 6.0 and 6.32, respectively, implying that the major bis(Tris)–Cu^{2+} species at the pH values spanned by Fig. 6 would indeed be $Cu(Tris)(TrisH_{-1})^+$, which is consistent with the data analyses of Bologni et al.[22] as well as theoretical computations described as follows, and is also the complex most readily isolable as a solid salt from Cu^{2+}–Tris solutions.[24–28] Moreover, Kotila[24] showed crystallographically that Tris and $TrisH_{-1}$ in solid salts of $Cu(Tris)(TrisH_{-1})^+$ are, respectively, terdentate (O, O′, N) and bidentate (O, N), the sixth site in the distorted octahedral coordination sphere around Cu^{2+} being taken up by an aqua ligand; any additional Tris ligand would therefore be expected to replace the aqua ligand and so be only unidentate with consequent low stability. No structural information is available for the putative $Cu(Tris)_3^{2+}$ or $Cu(Tris)_4^{2+}$, but our computations (see the following) indicate that $Cu(Tris)_3^{2+}$ has limited stability in water and that $Cu(Tris)_4^{2+}$ is sterically improbable. Thus, the simplest and most probable interpretation of Fig. 6 and the pH data is that they represent nearly complete formation of $Cu(Tris)(TrisH_{-1})^+$ and that the limiting maximum ε of 3376 ± 7 L mol^{-1} cm^{-1} at 238 nm refers to this species.

Fig. 6. Ultraviolet spectra of $Cu(ClO_4)_2$ (0.10 mmol L^{-1}) in Tris/$TrisH^+/ClO_4^-$: $[Tris]_{total}$ = 40.0 (black line), 20.0 (red line), and 10.0 mmol L^{-1} (green line). Blue line: $Cu(ClO_4)_2$ (0.10 mmol L^{-1}) in $HClO_4$ (1.0 mmol L^{-1}).



Bai and Martell[20] gave visible-region spectra (their Fig. 3) of solutions with $[Cu^{2+}]$:[Tris] ratios of 1:1 to 1:4, with various amounts of added NaOH. Interestingly, the close similarities between their spectra 4 and 7 and between their spectra 5 and 6, in which the $[Cu^{2+}]$:[Tris] ratio ranges from 2 to 4, imply that the number of Tris or $TrisH_{-1}^-$ ligands per Cu^{2+} never exceeds two at pH ~ 8 (cf. Fig. 4 of Bai and Martell). Again, this points to the dominance of $Cu(Tris)(TrisH_{-1})^+$ in the pH range 6–8.

Interaction of {Cu^{2+},L} with Tris

When aliquots of a $\{Cu,\mathbf{L}\}(ClO_4)_2$ solution were added to an excess of Tris/$TrisH^+$ buffer, the colour intensified and the hue shifted toward royal blue. This is shown in Fig. 3; the hypsochromic shift (678 to 636 nm for 25 mmol L^{-1} Tris/$TrisH^+/ClO_4^-$, to 627 nm for 50 mmol L^{-1} Tris/$TrisH^+/Cl^-$) is as expected for the replacement of aqua ligands in Cu**L**$(OH_2)_2^{2+}$ by nitrogen donor ligands (unprotonated Tris) giving Cu**L**$(Tris)^{2+}$, but could also be due to displacement of coordinated **L** by tris to form Cu^{2+}–$TrisH_{-1}^-$ complexes (cf. spectra 4–7 in Fig. 3 of Bai and Martell,[20] for which added NaOH forced deprotonation of coordinated Tris).

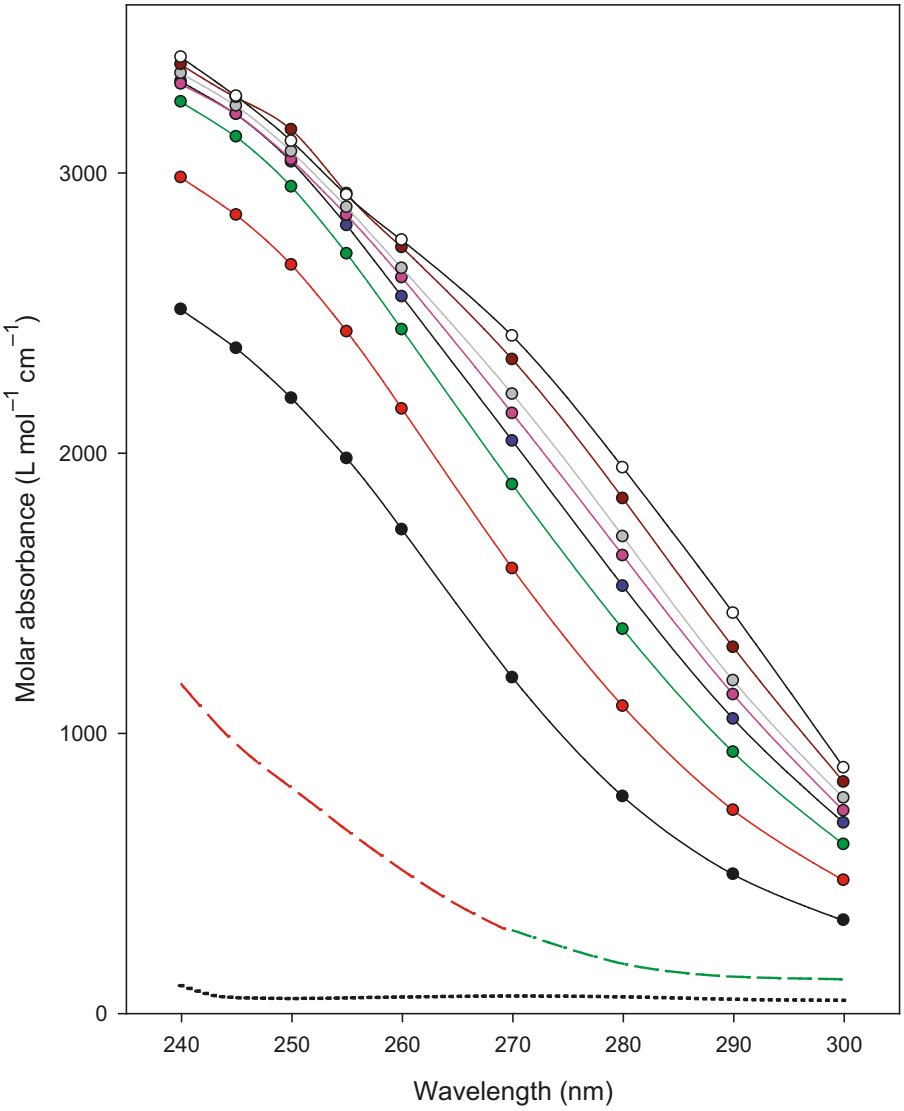
Fig. 7. Solid lines: UV spectra of $\{Cu^{2+},\mathbf{L}\}$ perchlorate in 10.0 mmol L^{-1} Tris/$TrisH^+/ClO_4^-$; $[Cu^{2+},\mathbf{L}]$ = 1.00 mmol L^{-1} (black symbols), 0.50 mmol L^{-1} (red symbols), 0.20 mmol L^{-1} (green symbols), 0.10 mmol L^{-1} (blue symbols), 0.05 mmol L^{-1} (pink symbols), 0.04 mmol L^{-1} (grey symbols), 0.02 mmol L^{-1} (brown symbols), and 0.01 mmol L^{-1} (white symbols). Broken line: $\{Cu^{2+},\mathbf{L}\}$ in water, no buffer; red segment, $[Cu^{2+},\mathbf{L}]$ = 0.5 mmol L^{-1}; green segment, $[Cu^{2+},\mathbf{L}]$ = 5.0 mmol L^{-1}. Dotted line: **L** in buffer, pH 7.2.



The latter interpretation is supported by computational results (see the following) that show that $Cu\mathbf{L}(Tris)^{2+}$ would be of relatively low stability in water. Detailed interpretation of the present Fig. 3 is impractical because the concentrations of free Tris base were only 1.07 and 2.14 times that of the total [Cu] for the chloride and perchlorate buffers, respectively, but the similarity of the spectrum in the 50 mmol L^{-1} chloride buffer to spectra 4 and 7 of Bai and Martell's Fig. 3[20] suggests that $Cu\mathbf{L}^{2+}$ is largely destroyed by the Tris base under these conditions to give $Cu(Tris)(TrisH_{-1})^+$. Spectra 1 and 2 of Bai and Martell's Fig. 3 rule out $Cu(Tris)^{2+}$ and $Cu(TrisH_{-1})^+$ as significant contributors to the spectra of the present Fig. 3. In any event, spectra in the visible region were unsuitable for the measurement of the dissociation of **L** from $Cu\mathbf{L}^{2+}$ on dilution because of the high concentrations of the Cu species required and were not pursued in detail.

Figure 7 shows that the apparent molar UV absorbance of the 1:1 complex $\{Cu^{2+},\mathbf{L}\}$ in 10.0 mmol L^{-1} Tris/$TrisH^+/ClO_4^-$ buffer increased as its concentration was decreased 100-fold from 1.00 mmol L^{-1}. This is attributable to an interaction between $Cu\mathbf{L}^{2+}$ and free Tris base, the concentration of which was only 1.07 mmol L^{-1} in the absence of $\{Cu^{2+},\mathbf{L}\}$ (i.e., barely in excess of $[\{Cu^{2+},\mathbf{L}\}]$ at its highest); thus, the excess of $[Tris_{free}]$ over $[\{Cu^{2+},\mathbf{L}\}]$ increased as the latter decreased. Indeed, $\{Cu^{2+},\mathbf{L}\}$ caused marked perturbations of the buffer pH through consumption of unprotonated Tris base. For the solutions represented in Fig. 7 with $[\{Cu^{2+},\mathbf{L}\}]$ = 1.00, 0.50, 0.20, and 0.10 mmol L^{-1}, the measured pH was 6.48, 6.81, 7.07, and 7.14, respectively, as compared with 7.24 for this particular buffer preparation alone, corresponding to removal of 0.9 ± 0.1, 1.3 ± 0.1, 1.7 ± 0.2, and 2.2 ± 0.4 free Tris molecules per $\{Cu^{2+},\mathbf{L}\}$ — the pH measurements were insufficiently precise to continue the calculations to lower $[\{Cu^{2+},\mathbf{L}\}]$. It could be argued that these pH data are consistent with the formation of $Cu\mathbf{L}(Tris)^{2+}$ when the free Tris supply barely exceeds $[\{Cu^{2+},\mathbf{L}\}]$, and

[a] pK_a of $Cu(Tris)_2^{2+}$.

Cu**L**$(Tris)_2^{2+}$ or Cu**L**$(TrisH_{-1})^{+}$[20,22] for low concentrations of {Cu^{2+},**L**} when Tris is in large excess. Figures 4 and 7, however, show that the apparent ε of {Cu^{2+},**L**} in pure water continues to rise on scanning to wavelengths shorter than 250 nm, whereas the absorbance of {Cu^{2+},**L**} in Tris buffer solution, though initially higher, levels off around 240 nm as dilution progresses and shows an incipient shoulder at ~265 nm. These features correspond to the displacement of **L** from Cu$\mathbf{L}^{2+}$ or Cu**L**$(Tris)^{2+}$ by Tris base to form the Cu^{2+}–Tris complex (deduced to be $Cu(Tris)(TrisH_{-1})^+$) of Fig. 6, which has an ε maximum at 238 nm and a pronounced shoulder at 265 nm; we have seen that the Cu^{2+} ion can cause the removal of up to three Tris per Cu, most likely by forming $Cu(Tris)(TrisH_{-1})^+$ + $TrisH^+$. Although the $K_1 \times K_2$ and pK_a values for $Cu(Tris)_2^{2+}$ given by Bai and Martell[20] may be inaccurate (see the following), they may be taken together with $K_{CuL} = 3.8 \times 10^5$ L mol^{-1}, obtained in this study, to estimate the fractions of {Cu^{2+},**L**} destroyed by the free Tris base in 10.0 mmol L^{-1} Tris/$TrisH^+$/ClO_4^- buffer to be 68%, 87%, and 94% for c = 0.2, 0.1, and 0.05 mmol L^{-1}, respectively, in qualitative agreement with the progression seen in Fig. 7 (insufficient Tris base for eq. [7] was present with c = 1.0 and 0.5 mmol L^{-1}).

$$[7] \qquad Cu\mathbf{L}^{2+} + 3Tris = Cu(Tris)(TrisH_{-1})^{+} + TrisH^{+} + \mathbf{L}$$

The limiting molar absorbances of Fig. 7 approach those expected for an equimolar mixture of $Cu(Tris)(TrisH_{-1})^+$ and **L**, although difficulty in accounting quantitatively for the progression of molar absorbances on dilution suggests that a ternary Cu^{2+}–**L**–Tris complex that absorbs more strongly than Cu$\mathbf{L}^{2+}$ is formed as precursor to rxn. [7]. Indeed, computer modeling (see the following) indicates that Cu**L**$(Tris)^{2+}$ would have significant stability in aqueous solution. Rózga et al.[17] reported that there was no evidence for the formation of a ternary complex between $Cu(A\beta)^{2+}$ and the base of Hepes buffer. Whether or not ternary complexes form, the scavenging of Cu^{2+}, either from $Cu(A\beta)^{2+}$ by Hepes base or from Cu$\mathbf{L}^{2+}$ by Tris, must seriously interfere with attempts to measure the stability constants of the Cu^{2+} complexes.

The key features of Fig. 7 are seen more clearly in Fig. 8, which shows the spectrum of progressively diluted {Cu^{2+},**L**} in a fivefold more concentrated Tris/$TrisH^+$/Cl^- buffer (use of Cl^- rather than ClO_4^- made no significant difference). The ε at ~250 nm actually begins to decrease on diluting {Cu^{2+},**L**} beyond 0.10 mmol L^{-1}, even as the ε near 265 nm characteristic of $Cu(Tris)(TrisH_{-1})^+$ continues to rise, which implies that the form of Cu$\mathbf{L}^{2+}$ being destroyed must be at least in part a Cu^{2+}–**L**–Tris complex such as Cu**L**$(Tris)^{2+}$ that absorbs more strongly than Cu$\mathbf{L}^{2+}$ itself or $Cu(Tris)(TrisH_{-1})^+$. When interpreting Figs. 7 and 8, however, it should be borne in mind that the measured absorbances at the highest dilutions were small, and that the corresponding molar absorbances were therefore subject to relatively large uncertainties.

Computational results

Ab initio computational methods were applied to determine plausible structural and thermodynamic properties of the species involved in mixtures of **L**, Cu^{2+}, and Tris buffer. The calculated results are given in Table 3. The geometries and primary computed properties of all structures are listed

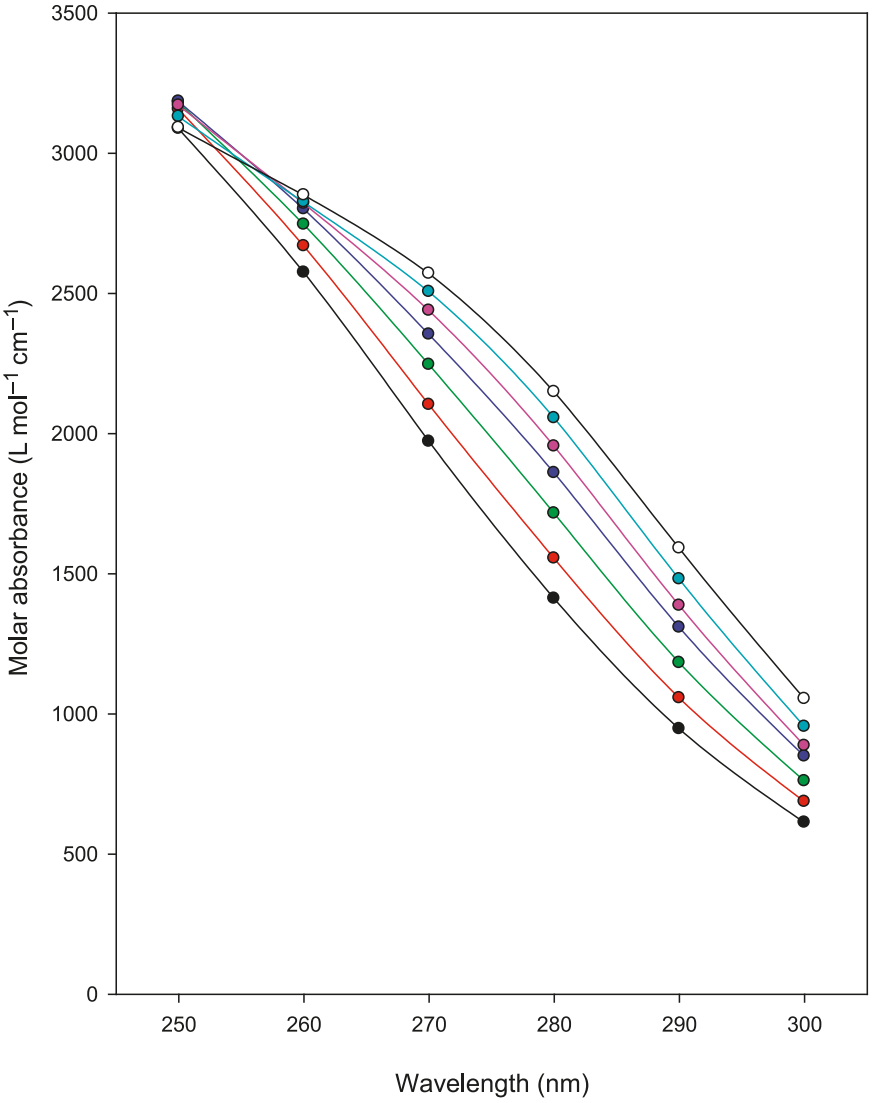
Fig. 8. Ultraviolet spectra of {Cu^{2+},**L**} perchlorate in 50.0 mmol L^{-1} Tris/TrisH^+/Cl^-. From the bottom, [Cu^{2+},**L**] = 1.00 mmol L^{-1} (black symbols), 0.50 mmol L^{-1} (red symbols), 0.20 mmol L^{-1} (green symbols), 0.10 mmol L^{-1} (dark blue symbols), 0.05 mmol L^{-1} (pink symbols), 0.02 mmol L^{-1} (light blue symbols), and 0.01 mmol L^{-1} (white symbols).



in Supplementary data Tables S1 and S2, respectively. The Cu^{2+}(aq) ion was taken to be $Cu(H_2O)_5^{2+}$, as predicted by the computational method; the burden of experimental evidence, however, indicates a tetragonally distorted octahedral Cu $(H_2O)_6^{2+}$ in aqueous solution, although some authors have argued for five-coordination.[13]

The Cu**L**$^{2+}$ coordination pattern (Fig. 9) has been previously characterized.[2] Re-evaluation of the free energy of binding of **L** to Cu^{2+} by eq. [8*a*] yielded a stability constant substantially lower than that previously determined ($\log K_{8a}$ = 19).[2] The origin of the difference lies in the improved theoretical level (MP2/LB//B3LYP/6–31+G(d) vs B3LYP/LB//B3LYP/6–31G(d)) and a renewed search of the conformational space of **L**, which yielded a structure that is 21 kJ mol^{-1} more stable than that previously found. Calculation of the pK_a value for **L**H$^+$ yielded pK_a = 5.7, in excellent agreement with the experimental value determined above, pK_a = 5.26. The value obtained at the MP2/LB level for the reaction of Cu^{2+} and **L** ($\log K_{8a}$ = 6.3) is also in good agreement with the experimental value derived above, $\log K_{CuL}$ = 5.58. At the B3LYP/LB level (Supplementary data Table S3), the calculated value is similar, $\log K_{8a}$ = 6.1.

[8*a*] $$Cu(H_2O)_5^{2+} + \mathbf{L} = Cu\mathbf{L}(H_2O)_2^{2+} + 3H_2O;$$
$$\Delta G_{(8a,aq)} = -36 \text{ kJ mol}^{-1};\ \log K_{8a} = 6.3$$

Coordination of a second **L** to Cu**L**$(H_2O)_2^{2+}$ yielding Cu$\mathbf{L}_2^{2+}$ is weakly exergonic (eq. [8*b*], $\Delta G_{(8b,aq)}$ = –10 kJ mol^{-1}). Steric crowding prevents coordination of all four imidazole groups to the copper. The second **L** in Cu$\mathbf{L}_2^{2+}$ (Fig. 9) is attached via one imidazole and the carbonyl oxygen. At the B3LYP/LB level (Supplementary data Table S3), attachment of the second **L** is strongly disfavoured, $\Delta G_{(8b,aq)}$ = 46 kJ mol^{-1}.

[8*b*] $$Cu(H_2O)_2^{2+} + \mathbf{L} = Cu\mathbf{L}_2^{2+} + 2H_2O;$$
$$\Delta G_{(8b,aq)} = -10 \text{ kJ mol}^{-1};\ \log K_{8b} = 1.7$$

The computations predict that Cu^{2+} will form 1:1, 1:2, and 1:3 complexes with Tris. The structures of the studied Cu–Tris

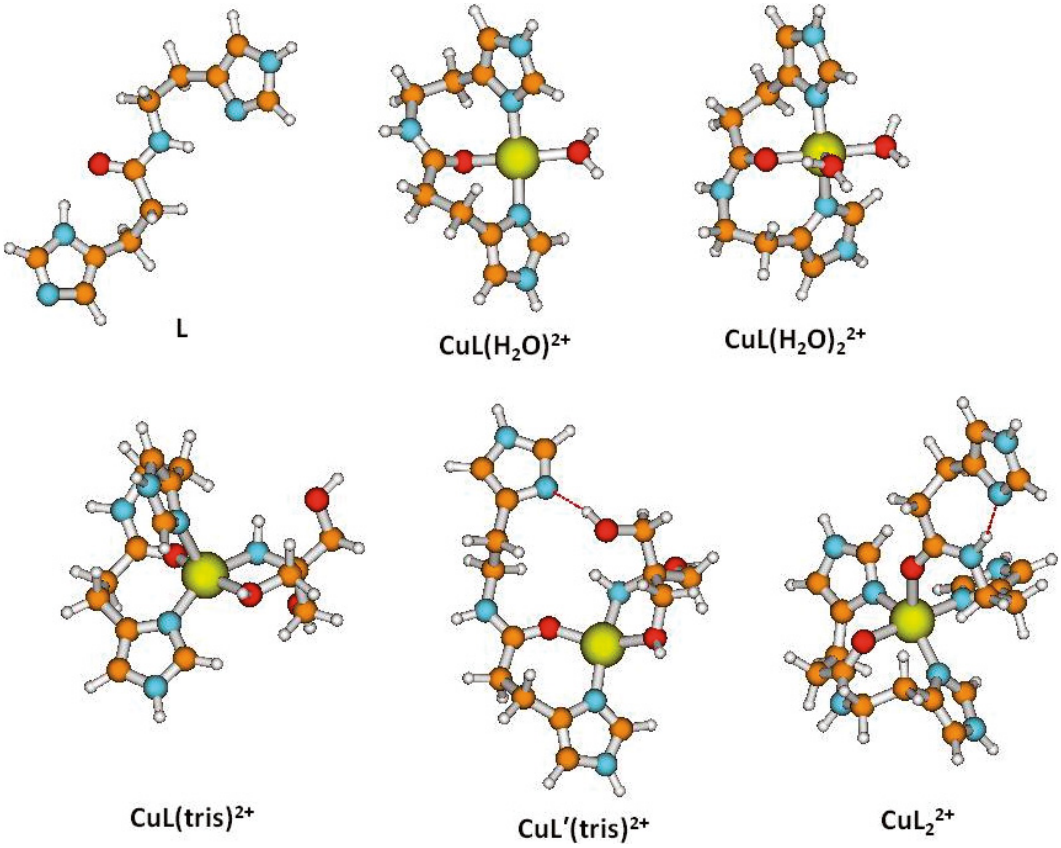
Fig. 9. The most stable computed structures for the aqueous Cu**L**$^{2+}$ and Cu**L**$_2{}^{2+}$ complexes. Orange atoms, C; blue atoms, N; red atoms, O; yellow atoms, Cu^{II}; and white atoms, H.



complexes, Cu(Tris)$(H_2O)_2{}^{2+}$, Cu(TrisH$_{-1}$)$(H_2O)_2{}^{+}$, *s*-Cu(Tris)$_2{}^{2+}$, *a*-Cu(Tris)$_2{}^{2+}$, Cu(Tris)$_3{}^{2+}$, Cu(Tris)$_4{}^{2+}$, *s*-Cu(Tris)(TrisH$_{-1}$)$^{+}$, and *a*-Cu(Tris)(TrisH$_{-1}$)$^{+}$, are shown in Fig. 10. The prefixes *s*- and *a*- specify the syn and anti orientation, respectively, of the two ligated NH_2 groups. Of the two bis(Tris) complexes, the anti isomer is calculated to be 4 kJ mol^{-1} more stable than the syn isomer. The opposite is true for the two singly deprotonated complexes, where the *s*-isomer is 5 kJ mol^{-1} more stable than the *a*-isomer. As these small differences are well within the anticipated uncertainties, they cannot be taken as significant. However, we note that crystal structures of Cu(Tris)(TrisH$_{-1}$)$^{+}$ are exclusively of the *s*-stereoisomer.[24,26,28] Calculated formation and acid dissociation results for all species are shown in Table 3.

The association constant (logK_9) of Cu^{2+} and Tris to form the 1:1 complex may be derived from eq. [9]:

$$[9] \quad Cu(H_2O)_5{}^{2+} + \text{Tris} = Cu(\text{Tris})(H_2O)_2{}^{2+} + 3H_2O; \quad \Delta G_{(9,aq)} = -8 \text{ kJ mol}^{-1}; \ \log K_9 = 1.4$$

The calculated association constant for the formation of Cu(Tris)$(H_2O)_2{}^{2+}$ is predicted to be considerably lower than the accepted experimental value, logK_{as} = 3.97.[20] At the B3LYP/LB level, the value is much closer, 4.8. At both the MP2/LB and B3LYP/LB theoretical levels, the computed K_{as} for both *s*-Cu(Tris)$_2{}^{2+}$ and *a*-Cu(Tris)$_2{}^{2+}$ unexpectedly exceeds that for Cu(Tris)$(H_2O)_2{}^{2+}$ (eq. [10]) by a large margin:

$$[10] \quad Cu(\text{Tris})(H_2O)_2{}^{2+} + \text{Tris} \rightarrow s\text{- or } a\text{-Cu(Tris)}_2{}^{2+} + 2H_2O; \quad \Delta G_{(10,aq)} \approx -60 \text{ kJ mol}^{-1}; \ \log K_{10} \approx 11$$

The value log K_{10} = 11 is more than seven orders of magnitude larger than the experimental value (log $K_{as2} \approx 3.7$).[18–24] At the B3LYP/LB level (Supplementary data Table S3), it is four orders of magnitude larger. These results suggest that the mono(Tris) adduct will disproportionate to Cu^{2+}(aq) and a bis(Tris) adduct, e.g., eq. [11]:

$$[11] \quad 2Cu(\text{Tris})(H_2O)_2{}^{2+} + H_2O \rightarrow s\text{- or } a\text{-Cu(Tris)}_2{}^{2+} + Cu(H_2O)_5{}^{2+}; \quad \Delta G_{(11,aq)} \approx -55 \text{ kJ mol}^{-1}$$

At the B3LYP/LB level, the exergonicity is less, –17 kJ mol^{-1}. The anomalously high computed stability of the Cu(Tris)$_2{}^{2+}$ isomers relative to other Cu(Tris)$_n{}^{2+}$ species can be attributed to the attainment of full terdentate binding by both Tris ligands in Cu(Tris)$_2{}^{2+}$ and the high symmetry of these complexes (Fig. 10).

The two isomeric conjugate bases of Cu(Tris)$_2{}^{2+}$ are *s*-Cu(Tris)(TrisH$_{-1}$)$^{+}$ and *a*-Cu(Tris)(TrisH$_{-1}$)$^{+}$ (Fig. 10). The calculated acidity constants, pK_a = 15 and pK_a = 16 (12 and 13 at the B3LYP level), respectively, are high because of the exceptional stabilities of *s*- and *a*-Cu(Tris)$_2{}^{2+}$. The influence of the positively charged metal would normally lower

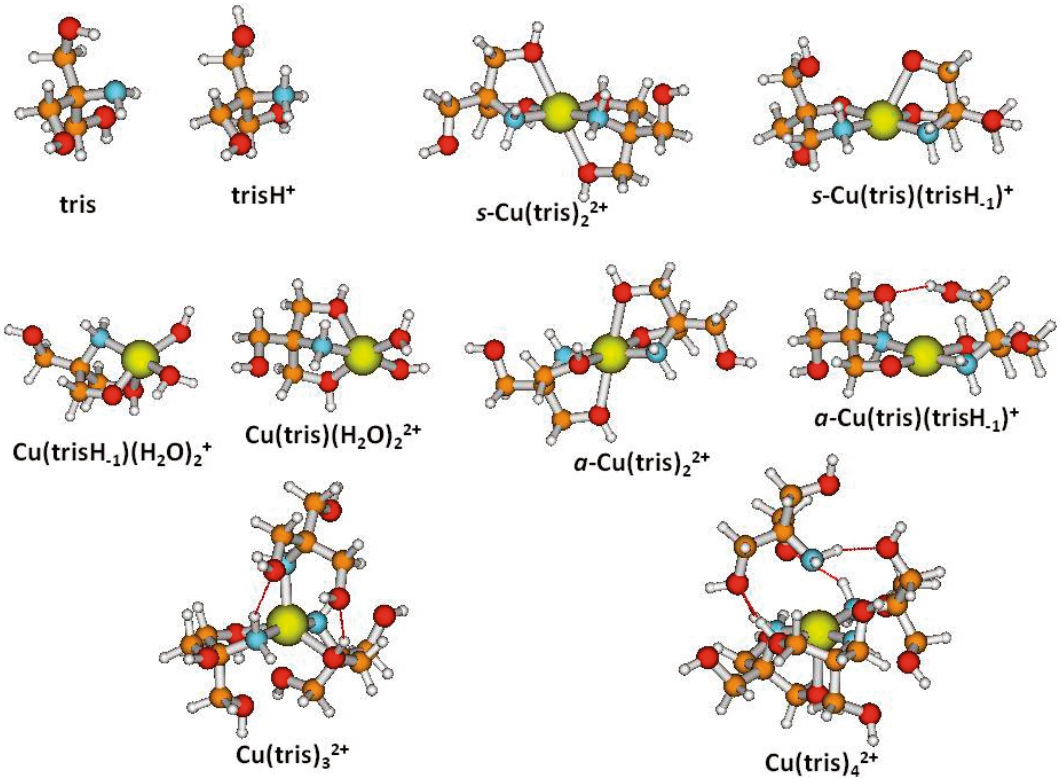
Fig. 10. The most stable computed structures for aqueous Cu^{2+}–Tris complexes.



the pK_a of one of the attached OH groups to below that of an alcohol (p$K_a \approx 16$). The equation for the direct formation of either *s*-Cu(Tris)(TrisH$_{-1}$)$^+$ or *a*-Cu(Tris)(TrisH$_{-1}$)$^+$ from aqueous Cu^{2+} and Tris (Table 3) bypasses the anomalously stabilized parents and predicts that spontaneous ionization should take place with an effective p$K_a \approx 4$. In a similar vein, reaction of aqueous Cu^{2+} with three Tris to yield *s*- or *a*-Cu(Tris)(TrisH$_{-1}$)$^+$ and TrisH$^+$ is exergonic by 32 kJ mol^{-1} (by 48 kJ mol^{-1} at the B3LYP level of theory). The attachment of all three Tris to the copper, yielding $Cu(Tris)_3^{2+}$, is only weakly exergonic ($\Delta G_{(aq)} = -7$ kJ mol^{-1}) at the MP2/LB level (Table 3), but endergonic at the B3LYP/LB level, $\Delta G_{(aq)} = 41$ kJ mol^{-1} (Supplementary data Table S3). These results suggest that Cu^{2+}(aq) can consume 3 equiv of Tris to form the singly deprotonated complexes (*s*-Cu(Tris)(TrisH$_{-1}$)$^+$ and *a*-Cu(Tris)(TrisH$_{-1}$)$^+$) and a protonated Tris, in accordance with the experimental observations as interpreted above.

The most stable $Cu(Tris)_4^{2+}$ complex, optimized in the gaseous phase, is shown in Fig. 10. The fourth Tris is is only weakly bound to the Cu^{2+} and is held in place by a network of hydrogen bonds which would not persist in aqueous solution. The $Cu(Tris)_4^{2+}$ complex was found to be 33 kJ mol^{-1} higher in energy than $Cu(H_2O)_5^{2+}$ + 4 Tris. At the B3LYP level, the endergonicity is much greater, 163 kJ mol^{-1}. One must conclude that the formation of either $Cu(Tris)_3^{2+}$ or $Cu(Tris)_4^{2+}$ in water is very unlikely.

As for the interactions of $Cu\mathbf{L}^{2+}$ with Tris, we considered more than a dozen plausible structures and found one complex of the form $Cu\mathbf{L}(Tris)^{2+}$ (Fig. 9) that is weakly bound at the MP2/LB level ($\Delta G_{12} = -7$ kJ mol^{-1}), but unbound at the B3LYP/LB level ($\Delta G_{12} = 22$ kJ mol^{-1}). A second complex, $Cu\mathbf{L}'(Tris)^{2+}$, from which **L** is partially dissociated (Fig. 9), is predicted not to be bound ($\Delta G_{12} = 39$ kJ mol^{-1}). Thus, the calculations suggest that, in a 1:1:1 mixture of $Cu_{(aq)}^{2+}$, **L**, and Tris, the ternary complex, $Cu\mathbf{L}(Tris)^{2+}$ (Fig. 9) should be dominant.

[12] $$Cu\mathbf{L}(H_2O)_2^{2+} + Tris \rightarrow Cu\mathbf{L}(Tris)^{2+} + 2H_2O; \quad \Delta G_{12} = -7 \text{ kJ mol}^{-1}$$

Equations [13]–[16] examine the possible reactions of **L** with copper–Tris complexes:

[13] $$Cu(Tris)(H_2O)_2^{2+} + \mathbf{L} \rightarrow Cu\mathbf{L}(Tris)^{2+} + 2H_2O; \quad \Delta G_{13} = -36 \text{ kJ mol}^{-1}$$

[14] $$a\text{Cu(Tris)}_2^{2+} + \mathbf{L} \rightarrow Cu\mathbf{L}(Tris)^{2+} + Tris; \quad \Delta G_{14} = 27 \text{ kJ mol}^{-1}$$

[15] $$a\text{Cu(Tris)(TrisH}_{-1})^+ + \mathbf{L} + H^+ \rightarrow Cu\mathbf{L}(Tris)^{2+} + Tris; \quad \Delta G_{15} = -57 \text{ kJ mol}^{-1} \text{ (pH = 7)}$$

[16] $$Cu(Tris)_3^{2+} + \mathbf{L} \rightarrow Cu\mathbf{L}(Tris)^{2+} + 2Tris; \quad \Delta G_{16} = -37 \text{ kJ mol}^{-1}$$

These results indicate that **L** will form a ternary complex with any of the preformed Cu^{2+}–Tris complexes. The possible exception is with *a*- (or *s*-) $CuTris)_2^{2+}$ (eq. [14]).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

Alternatively, eqs. [17]–[20] examine the probability of reaction of a preformed Cu**L** complex with Tris:

[17] $$Cu\mathbf{L}(H_2O)_2^{2+} + Tris + H_2O \rightarrow Cu(Tris)(H_2O)_2^{2+} + \mathbf{L}; \quad \Delta G_{17} = 29 \text{ kJ mol}^{-1}$$

[18] $$Cu\mathbf{L}(H_2O)_2^{2+} + 2Tris \rightarrow a\text{-}Cu(Tris)_2^{2+} + \mathbf{L} + H_2O; \quad \Delta G_{18} = -34 \text{ kJ mol}^{-1}$$

Alternatively, one may apply eq. [19] to bypass $Cu(Tris)_2^{2+}$:

[19] $$Cu\mathbf{L}(H_2O)_2^{2+} + 3Tris \rightarrow a\text{-}Cu(Tris)(TrisH_{-1})^{+} + \mathbf{L} + H_2O + TrisH^{+}; \quad \Delta G_{19} = 0 \text{ kJ mol}^{-1}$$

[20] $$Cu\mathbf{L}(H_2O)_2^{2+} + 3Tris \rightarrow Cu(Tris)_3^{2+} + \mathbf{L} + H_2O; \quad \Delta G_{20} = 30 \text{ kJ mol}^{-1}$$

Equations [12] and [17] indicate that stoichiometric or substoichiometric amounts of Tris relative to $Cu\mathbf{L}^{2+}$ will result in the addition of Tris to $Cu\mathbf{L}^{2+}$ to form a 1:1:1 complex, rather than a displacement of **L** from the copper ion. Reaction 18 shows that **L** can be displaced by excess Tris to yield the bis(Tris) adduct of copper. Formation of the singly deprotonated form may also be possible, since reaction 19 is isoergonic. The formation of the tris(Tris) adduct, $Cu(Tris)_3^{2+}$, under these conditions is not likely by eq. [20].

The simulated TD–B3LYP/6–311+G(d,p) spectra in the visible region (350–800 nm) of the dominant species are collected in Fig. 11. The spectra are displayed as a superposition of Gaussian line shapes with half-width-at-half-height = 0.2 eV. In general, up to six low oscillatory strength transitions are predicted to fall in this region. The spectrum of $Cu\mathbf{L}(H_2O)_2^{2+}$ is relatively intense in the range 500–800 nm because of a grouping of four low-intensity transitions near 600 nm. It is of interest that none of the other doubly charged complexes is predicted to have appreciable intensity in this range. The 1:1:1 complex $Cu\mathbf{L}(Tris)^{2+}$ has a relatively strong transition at 870 nm. The highly symmetrical bis(Tris) complex (a-$Cu(Tris)_2^{2+}$) has no allowed transitions in this spectral range, and the isomeric s-$Cu(Tris)_2^{2+}$ has only weak absorbances near 600 nm and at wavelengths longer than 800 nm. The most intense spectrum, that of a-$Cu(Tris)(TrisH_{-1})^{+}$, is a superposition of two stronger transitions near 550 nm and 600 nm. The stereoisomeric deprotonated form, s-$Cu(Tris)(TrisH_{-1})^{+}$, has lower intensity in this spectral region.

Discussion

Consideration of Figs. 2–4 and 6–8, together with perturbation of the pH of Tris buffer solutions, shows that Cu^{2+} and **L** form a stable 1:1 complex in solution, but that addition of a Tris buffer to give a nominal pH of 7.2 results in displacement of **L** from $Cu\mathbf{L}^{2+}$ with formation of Cu^{2+}–Tris complexes, predominantly $Cu(Tris)(TrisH_{-1})^{+}$ when Tris base is in large excess over Cu, with about twice the molar absorbance of $\{Cu^{2+},\mathbf{L}\}$(aq) in the 235–260 nm region. When the molar concentration of Tris base is comparable to or less than that of $\{Cu^{2+},\mathbf{L}\}$, the formation of a ternary Cu^{2+}–**L**–Tris complex is indicated on the basis of computer modeling and consideration of Figs. 7 and 8, but the important result is that the presence of excess Tris seriously affects the measurement of the stability constant $K_{Cu\mathbf{L}}$ of aqueous $Cu\mathbf{L}^{2+}$ by scavenging free Cu^{2+}(aq), therefore forcing eq. [7] to the right.

In the discussion that follows, the species adopted to model $Cu\mathbf{L}^{2+}$(aq) is the five-coordinate structure with terdentate **L**, $Cu\mathbf{L}(H_2O)_2^{2+}$ (Fig. 9). A ternary complex, $Cu\mathbf{L}(Tris)^{2+}$ (Fig. 9), is predicted to be weakly stable. Attempts to model $Cu\mathbf{L}^{2+}$ complexes containing more than one Tris ligand, or involving deprotonation of the coordinated Tris to give $Cu\mathbf{L}(TrisH_{-1})^{+}$, failed to yield structures that were stable in water at pH 7.

The formation of complexes between Cu^{2+}(aq) itself and Tris has been widely studied,[18–24] but the existence of $Cu(Tris)_n^{2+}$ with $n > 2$ is not universally recognized and there is no definitive set of stability constants for Cu^{2+}–Tris species.[17] Our computer modeling accommodates two exceptionally stable species with $n = 2$ (Fig. 10) differing by the orientation of the two coordinated amino groups, with slight preference for the anti form over the syn form. A structure for $n = 3$, $Cu(Tris)_3^{2+}$, is marginally stable with respect to complete dissociation into Cu^{2+}(aq) and 3 Tris, but is unstable relative to the two bis(Tris) species. Modeling of a gaseous-phase complex with four Tris, $Cu(Tris)_4^{2+}$ (Fig. 10), revealed that there is not enough room to coordinate all four Tris to the copper. There is the additional complication that one or more Tris ligands bound to Cu^{2+} may be deprotonated in the pH range of our experiments (6.4–7.2).[20]

Although the potentiometric measurements of Bai and Martell[20] were clearly made with expertise and care over a wide range of pH, it is possible that too many species (seven) were invoked to reduce the data to a set of stability constants, especially since these constants could not have been independent of each other. Bologni et al.,[22] in a reanalysis of all the available data including their own, found the data best fit models in which neither $Cu(Tris)_2^{2+}$ nor $Cu(Tris)_4^{2+}$ were present but $Cu(Tris)(TrisH_{-1})^{+}$ was important — in other words, $Cu(Tris)_2^{2+}$ was not present in significant amounts in solutions of the pH range studied, despite the prediction of our calculations that its two isomers should be the most stable of all Cu^{2+}–Tris complexes, because it is converted to $Cu(Tris)(TrisH_{-1})^{+}$. Indeed, solid Cu^{2+}–Tris complexes isolated from solution invariably contain bidentate $TrisH_{-1}^{-}$,[23–28] with Tris, if present, in terdentate coordination. In fact, our calculations indicate that the 1:1 Cu–Tris complex is only weakly stable and will disproportionate to the 1:2 complexes. There is no definitive evidence for the independent existence of the 1:1 complex. As the spectra of Fig. 6 appear to be of a single species, with apparent ε rapidly approaching a limit as the Tris concentration increases, and whereas buffer pH data perturbations indicate complexation or protonation of up to three Tris per Cu^{2+}, that species may be taken to be $Cu(Tris)(TrisH_{-1})^{+}$, presumably with terdentate Tris and bidentate $TrisH_{-1}$ as in the solid-state structure reported by Kotila.[24] We note, however, that the Cu^{2+} complexes of neutral Tris, s- and a-$Cu(Tris)_2^{2+}$, are predicted to have very low absorbances in the visible region and therefore may have gone undetected spectroscopically at

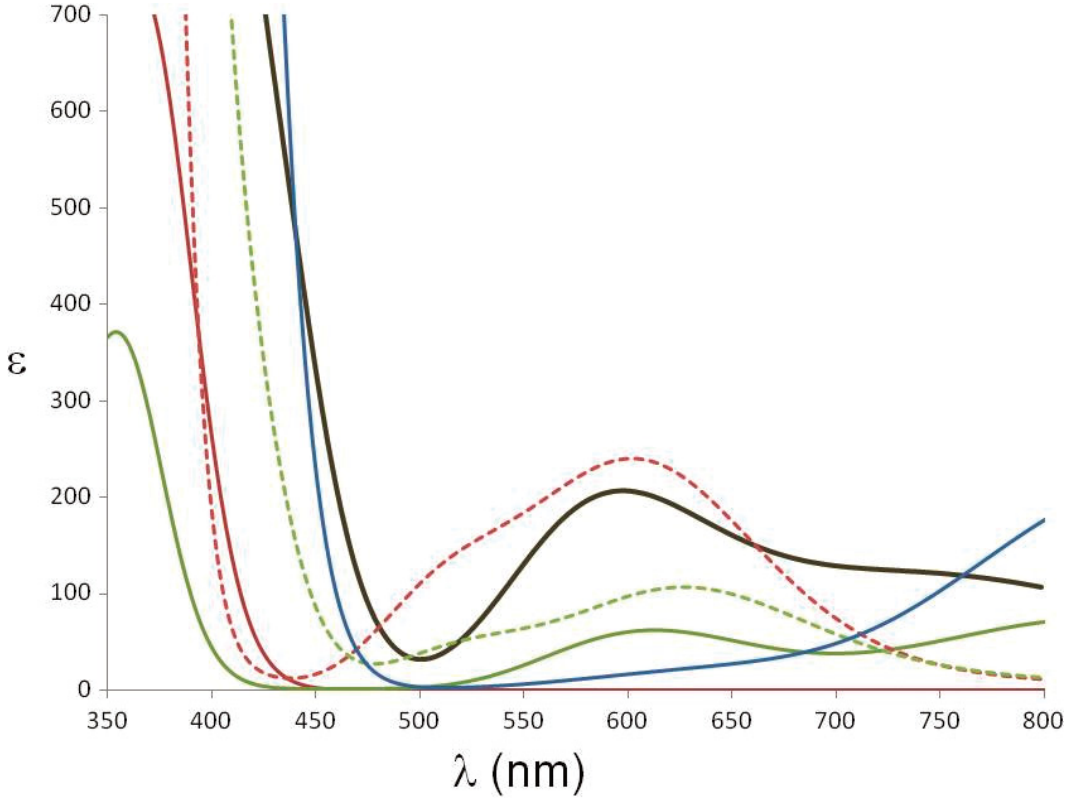
Fig. 11. Simulated spectra in the visible region of complexes of Cu^{2+}, **L**, and Tris. The vertical axis is the extinction coefficient (ε) and the horizontal axis is the wavelength in nm. Cu**L**$(H_2O)_2^{2+}$ (black line), *a*-Cu$(Tris)_2^{2+}$ (red line), *s*-Cu$(Tris)_2^{2+}$ (green line), Cu(Tris)$(TrisH_{-1})^+$ (broken red line), *s*-Cu(Tris)$(TrisH_{-1})^+$ (broken green line), and Cu**L**$(Tris)^{2+}$ (blue line).



low pH, hence the assertion by Bai and Martell that "Before addition of base, little complex formation takes place".[20] The principal absorbing species is predicted to be *a*-Cu(Tris)$(TrisH_{-1})^+$ (Figs. 10 and 11).

In view of the interference of Tris in the determination of the stability constant K_{CuL} for Cu$\mathbf{L}^{2+}$, this quantity was measured in plain water, giving 3.8×10^5 L mol^{-1} at 25 °C. The pH of the unbuffered solution was 5.7, governed by the slight acid dissociation of an aqua ligand in Cu**L**$(H_2O)_2^{2+}$ or adventitious CO_2 or both, and is in the range in which form **I** Aβ–Cu^{2+} complexation is dominant — thus, in our measurements Cu$\mathbf{L}^{2+}$ is a proxy for form **I** Aβ–Cu^{2+} interactions. The measured value of K_{CuL} is close to the lower limit of the range of stability constants tabulated by Hatcher et al.[14] for Aβ–Cu^{2+}, which is as expected, since **L** represents only a fragment of the Aβ molecule and has fewer potential coordination sites.

Faller[4] makes the interesting observation that, if $K_{CuAβ}$ values are indeed around 10^9–10^{10} L mol^{-1} and the rate constant k_{on} for attachment of Cu^{2+} to Aβ is diffusion-controlled ($k_{on} \approx k_{diff} = 8000RT/3\eta = 7.4 \times 10^9$ L mol^{-1} s^{-1} at 25 °C, where η is the viscosity of water), then the rate constant k_{off} for the dissociation of Cu^{2+} from $CuAβ^{2+}$ would be on the order of $k_{on}/K_{CuAβ} \approx 1$ s^{-1}, which is 2–4 orders of magnitude smaller than those obtained from ^{1}H NMR for Cu^{2+} exchange on histidine-containing proteins by Gaggelli et al.[45] By the same reasoning, however, k_{off} for dissociation of Cu^{2+} from Cu$\mathbf{L}^{2+}$ would be $k_{diff}/K_{CuL} = 2.0 \times 10^4$ s^{-1}, which fits well with the results of Gaggelli et al.[45] for Cu^{2+} complexes with other histidine proteins.

L models only the His13–His14 dyad of Aβ. Since Aβ has additional possible Cu^{2+} binding sites at His6, terminal $–NH_2$, and aspartate and carbonyl oxygens,[6,12] it can be expected to compete with buffer bases for Cu^{2+} more effectively than does **L**. Nevertheless, since Cu^{2+}(aq) is quite strongly complexed by almost any base capable of forming a buffer system for near-physiological pH,[46,47] stability constants obtained for Cu^{2+}–Aβ complexes in any buffer solution should be regarded with skepticism. This applies regardless of whether the buffer base forms complexes directly with Cu^{2+}(Aβ) species and indeed to any measurements on chemical or biochemical systems involving reactions of copper(II) in presence of a buffer. In a living organism, it means that even a reliable value of $K_{CuAβ}$ may have limited significance, as potential ligands for Cu^{2+} include proteins and other nitrogen bases, which will be present in abundance.

Abstract: The adsorption of CO molecules onto small metal clusters was studied using density functional theory (DFT) calculations, and experimental electrochemical and attenuated total reflection-Fourier transform infrared spectroscopic (ATR-FTIR) techniques were used to examine CO adsorbed onto nanostructures of similar composition. The adsorption strengths and CO vibrational stretching frequencies were calculated and analyzed for clusters of the form M–CO for all of the period 4, 5, and 6 d-block transition metals. A direct link between the ν_{CO} and the population of d orbitals of the metal was observed. All possible binding sites for CO on clusters of the form Pd_4–CO, Pd_2Pt_2–CO, and Pd_2Au_2–CO were determined and the corresponding adsorption energies and CO stretching frequencies were examined. Pure Pd and bimetallic PdPt and PdAu nanostructures were fabricated and used as catalysts for the adsorption and electrochemical oxidation of CO. The relative quantities of CO molecules adsorbed to surface of the catalysts decrease in the order of PdPt > Pd > PdAu, consistent with our DFT results. The location of ν_{CO} bands of CO adsorbed onto the nanostructured catalysts were determined by means of ATR-FTIR spectroscopy and were found to have values close to that predicted by DFT. This paper shows that DFT calculations on very small metal clusters M_n–CO ($n \leq 4$) can be a simple but effective way of screening catalysts for their adsorbing properties.

Key words: carbon monoxide, nanoparticles, metal clusters, DFT calculations, CO adsorption.

Résumé : On a étudié l'adsorption de molécules de CO sur de petits agrégats métalliques en utilisant des calculs théoriques sur la base de la théorie de la fonctionnelle de la densité. D'un point de vue expérimental, on a utilisé des techniques électrochimiques et de la spectroscopie infrarouge à transformée de Fourier avec réflexion totale atténuée pour étudier l'adsorption du CO sur des nanostructures de compositions semblables. On a calculé et analysé les forces d'adsorption et les fréquences d'élongation vibrationnelles du CO pour des agrégats de la forme M–CO pour tous les éléments de transition des blocs 4, 5 et 6 d. On a observé une relation directe entre la valeur de ν_{CO} et la population des orbitales d du métal. On a déterminé tous les sites de liaison possibles pour le CO sur des agrégats de la forme Pd_4–CO, Pd_2Pt_2–CO et Pd_2Au_2–CO et on a examiné les énergies d'adsorption correspondantes et les fréquences d'élongation du CO. On a préparé les nanostructures de palladium pur ainsi que les structures bimétalliques PdPd et PdAu et elles ont été utilisées pour la réaction d'adsorption et d'oxydation électrochimique du CO. Les quantités relatives de molécules de CO adsorbées sur la surface des catalyseurs diminue dans l'ordre PdPt > Pd > PdAu, en accord avec les résultats des calculs à base de la théorie de la fonctionnelle de la densité (TFD). On a déterminé la position des bandes, ν_{CO}, du CO adsorbé sur les catalyseurs à nanostructures en faisant appel à la spectroscopie infrarouge à transformée de Fourier avec réflexion totale atténuée et on a trouvé que ces valeurs sont proches de celles prédites par les calculs de la TFD. Dans ce travail, on montre que des calculs selon la TFD sur de très petits agrégats métalliques M_n–CO ($n \leq 4$) peuvent s'avérer être une méthode simple et efficace d'évaluer les propriétés absorbantes de catalyseurs.

Mots-clés : monoxyde de carbone, nanoparticules, agrégats métalliques, calcules d'après la théorie de la fonctionnelle de la densité (TFD), adsorption du CO.

[Traduit par la Rédaction]

Introduction

Carbon monoxide adsorption on metallic nanoparticles has been extensively investigated because of its importance in the water–gas shift reaction, in emission control, and in fuel cell reactions.[1] In the case of fuel cells, CO is generated in the process of electrocatalytic oxidation of formic acid and other small organic compounds (often via dissociative chemisorption) and it causes substantial poisoning of the active sites on precious metal catalysts.[2] Likewise, if hydrogen gas is used as a fuel, the presence of CO at trace levels (>10 ppm) as an impurity resulting from the production of H_2 by steam reforming of methane also gives rise to catalyst poisoning and performance degradation.[3]

[a]Renner–Teller splitting gave two π-type frequencies.

When metals are combined in an appropriate manner, the chemisorption of CO can be tuned and controlled. As catalyst design becomes more involved, alloying of various compounds becomes an attractive method to control the reaction pathway. To properly design catalysts, it is important to have an understanding of the interaction between the catalyst and the chemisorbed reactant or intermediate species. CO poisoning of alloyed PtRu and PtPb catalysts is diminished compared with pure Pt.[4,5] PtRu is possibly the most widely studied anode catalyst material for direct methanol fuel cells.[6,7] It has been proposed that the enhanced activity of PtRu towards methanol oxidation compared with Pt arises from ruthenium's ability to generate oxygen-containing species on the catalyst surface to easily oxidize the poison CO species.[8,9] In the case of PtPb, CO adsorption is avoided or very weak owing to modification of the catalyst crystal structure. This alters the reaction mechanism for formic acid oxidation, greatly enhancing its performance.[4,10]

In the past few decades, Pd-based materials have been studied rigorously to improve and extend their environmental applications for the elimination of contaminants related to automobile exhaust pipe gases like CO, NO_x, and SO_x[11] and, at one-fifth of the cost, are viewed as the most promising alternative to Pt-based catalysts.[12,13] Pd has been shown to possess superior performance as anodes for the oxidation of formic acid compared with Pt-based catalysts,[14,15] but, despite these promising properties, not nearly as much research has gone into studying them compared with Pt-based materials.

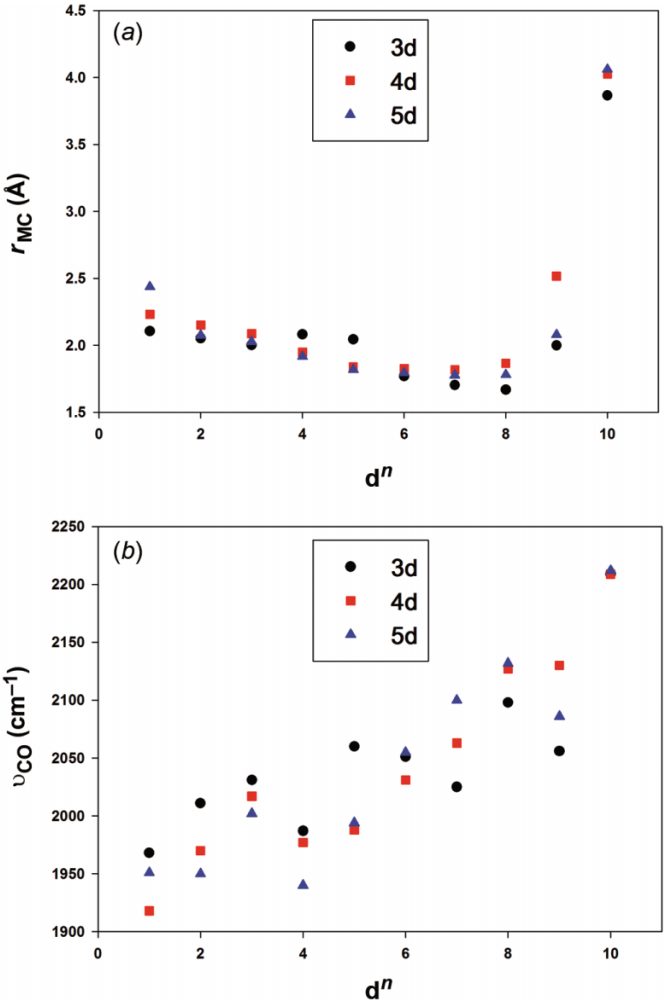
Fig. 2. The calculated metal–carbon bond distance (*a*) and vibrational CO-stretching frequencies (*b*) versus the number of d electrons of the metal (M) for all of the transition metal–carbonyl clusters of the form M–CO. The 3d, 4d, and 5d metals are represented by circles, squares, and triangles, respectively.



The aim of this paper is to use standard computational techniques to examine the adsorption of CO on small Pd-based metal clusters, with attempts to expand the research involving Pd-based catalytic materials.

In many studies, the adsorption energy of CO on certain transition metals is compared.[11,16–27] Zeinalipour-Yazdi et al.[16] examined several transition-metal M_2–CO and M_4–CO cluster complexes, but, to the best of our knowledge, never before has an extensive comparison been made of the CO adsorption on the entire series of transition metals. This could provide insight to new combinations of metals for catalysts involving CO as a reactant or intermediate. In this study, the CO adsorption energy is first determined for all single-atom transition-metal elements using density functional theory (DFT). Next, CO adsorption energies for Pd_4, Pd_2Au_2, and Pd_2Pt_2 clusters are calculated and compared with results from two experimental techniques: electrochemical oxidation of adsorbed CO on Pd, PdAu, and PdPt nanostructures and C–O stretch frequency analysis of CO-adsorbed nanostructures by in situ attenuated total reflection - Fourier transform infrared spectroscopy (ATR-FTIR).[10,28]

Experimental methods

Computational methods

There is an ongoing debate regarding the type of model to use for simulations of adsorption on catalytic surfaces. Periodic boundary conditions can be used to reproduce extended surfaces.[29–31] In this method one defines a unit cell that is then used to expand the cell in *x*, *y*, and (or) *z* directions, thus providing the electronic structure for linear, slab (surface), and bulk materials, respectively.[32] Alternatively, a cluster approach, where a discrete number of atoms are used to represent the active site region, has shown considerable promise.[20,21,23,24] The basic premise is that chemisorption and reactivity are local phenomena, primarily affected only by the nearby surface structure.[32–34] Several studies have shown that models based on clusters containing a very small number of atoms can obtain results for local phenomena such as CO stretches and bond distances closer to experiment than slab models for nanosized particles.[11,20,35,36]

In this work, DFT calculations were carried out using the Gaussian 03 software package[37] with the use of the Becke's three-parameter hybrid exchange functional[38] combined with the Lee–Yang–Parr nonlocal correlation functional[39] (B3LYP) and the default integration grid. The LANL2DZ effective core potential basis set[40] was employed for all transition metals and the 6–31G(d) basis set was used for C and O atoms. As shown in the literature,[16,28–30] the use of the LANL2DZ basis set significantly reduces the computational demands with minimal effect on the binding energy of CO. All considered systems were fully optimized and characterized through harmonic frequency analysis.

It is well known that CO can bond to a metal surface in three possible sites (on top, bridging, and hollow) as displayed in Fig. 1. By using a four-atom metal cluster, all of these sites can be examined with minimal computational demands.[16] Various spin multiplicities were examined for the individual metal atoms and the metal–CO (M–CO) clusters. The lowest energy spins were used in calculating the adsorption energies (E_{ads}) according to the following equation:

$$[1] \qquad E_{ads} = E_{cluster-CO} - E_{cluster} - E_{CO}$$

where $E_{cluster-CO}$, $E_{cluster}$, and E_{CO} are the total energies of the metal–carbonyl cluster, the metal cluster, and molecular CO, respectively. From this equation, as the E_{ads} becomes more negative, the adsorption of CO to the metal cluster is favoured because of the stabilization of the M–CO cluster.

Fabrication of Pd, PdAu, and PdPt catalysts

The nanostructured catalysts were fabricated using a hydrothermal-assisted reduction of Pd, Au, and Pt precursors.[41,42] For electrochemical tests, Ti plates were coated with the catalysts. The Ti substrate plates (1.25 cm × 0.80 cm × 0.5 mm) were first degreased in an ultrasonic bath of acetone for 10 min followed by 10 min in pure water (18.2 MΩ cm^{-1}) obtained from a NANOpure Diamond UV ultrapure water purification system. The substrates were then etched in 18% HCl at approximately 85 °C for 30 min. The etched Ti substrates were transferred into Teflon-lined autoclaves and 10 mL of an aqueous mixture of inorganic metal precursors and an excess amount of the reducing agent

were added. Ammonium formate (Sigma-Aldrich, 99.995%) was used as the reducing agent, and the metal precursors were $PdCl_2$ (Alfa Aesar, 99.9%), $HAuCl_4{\cdot}xH_2O$ (Alfa Aesar, 99.9%), and $H_2PtCl_6{\cdot}6H_2O$ (Alfa Aesar, 99.9%). In all cases, the total amount of inorganic precursor and reducing agent added were kept constant at 5 mmol/L and 1 mol/L, respectively. Pure water was used as the solvent in all cases, with a dilute HCl solution used to aid in the solubility of $PdCl_2$. For the Pd catalyst, only $PdCl_2$ was added to the vessel, whereas for the PdAu and PdPt catalysts, stoichiometric amounts of the $PdCl_2$, $HAuCl_4{\cdot}xH_2O$, and $H_2PtCl_6{\cdot}6H_2O$ precursors were added to obtain the desired composition of Pd–Au and Pd–Pt of 50:50. The autoclaves were sealed and heated at 180 °C for 8 h. After cooling to room temperature, the Ti

plates coated with the Pd, PdAu, and PdPt films were dried under argon and then rinsed with pure water.

Electrochemical and spectroscopic examination of the Pd, PdAu, and PdPt catalysts

The electrochemical performance of the electrodes towards the oxidation of surface-adsorbed CO was characterized using cyclic voltammetry (CV). For this, a three-electrode cell system and a VoltaLab 80 PGZ402 potentiostat were used. The counter electrode was a Pt wire coil (10 cm^2) that was cleaned before each experiment by flame annealing and quenching with pure water. The reference electrode was a saturated calomel electrode connected to the cell through a salt bridge. The working electrodes used were the prepared Ti/Pd, Ti/PdAu, and Ti/PdPt plates (1 cm^2). The coated Ti plates were annealed at 250 °C for 2 h in a tube furnace under argon to ensure a good surface adhesion of the particles. These plates were then soldered to Ti wire leads for use as working electrodes. The electrolyte for these CV studies was 0.5 mol/L H_2SO_4, and the solution was deaerated with ultrapure argon gas prior to measurements to remove any dissolved oxygen. Argon gas was continually passed over the solution throughout the experimentation. Data acquisition and analysis were performed using VoltMaster 4 software. Carbon monoxide (PRAXAIR, 99.9%) was used for the CO-stripping study. Before scanning the applied potential, the working electrode was held at –0.1 V for 360 s while a stream of pure CO was bubbled into the solution during the first 180 s. Then the solution was purged with pure Ar for the remaining 3 min holding period. Immediately following the electrode pretreatment, two cycles of CV were recorded for each electrode. All measurements were conducted at room temperature (22 ± 2 °C).

All in situ ATR-FTIR experiments were performed using a Nicolet FTIR spectrometer with a liquid N_2-cooled MCT detector. The spectro-electrochemical cell consisted of a Teflon

chamber with a ZnSe hemisphere window sealed on the bottom. The synthesized nanoparticles were suspended in pure water with the aid of ultrasonic treatment and then coated onto the ZnSe window. The incidence angle of the IR beam was controlled with a variable angle home-made accessory and was set to 60° for all experiments. All interferograms were acquired at 4 cm^{-1} resolution, and 400 scans were added and averaged. The interferograms were shown in terms of relative change of the electrode reflectivity, which is defined as $\Delta R/R = (R(E_2) - R(E_1))/R(E_1)$, where $R(E_1)$ and $R(E_2)$ are the thin films' reflectivity at potentials E_1 and E_2, respectively. The spectra recorded at E_1 = –0.20 V was used as reference.

Results and discussion

CO adsorption onto single metal atoms

Calculations were run first on the metal atoms and CO in various spin states to determine the lowest energy spin. As expected, CO is most stable in the singlet state and the ground-state spin multiplicity for the metal atoms varies depending on the electron configuration. The energies for all

metal atoms in the different spin states can be found in the Supplementary data. For the M–CO molecules, an initial linear structure ($C_{\infty v}$) was considered and fully optimized, again assessing various spin states. The E_{ads} for the most stable species were calculated as described in the Experimental methods section and are reported in Table 1 along with the corresponding structural parameters and harmonic frequencies. It can be seen that all of the metal carbonyl molecules are linear, except those involving group 11 and 12 metals and Cr–CO and Mn–CO. In general, the smallest E_{ads} are for those that do not possess a linear geometry. As expected, the platinum group metals have the largest CO E_{ads} and, consistent with a previous DFT study that examined several transition metals,[16] iridium exhibits the largest E_{ads} followed closely by platinum. With the respect to the whole series of transition metals, CO-stretching frequencies range from 1918 (Y–CO) to 2212 cm^{-1} (Hg–CO).

There does not seem to be a good linear relationship between the E_{ads} and either the bond lengths or the vibrational frequencies over the complete set of transition metals.[16,43] On the other hand, a link between the accepted number of d electrons (d^n) on the metal and the M–C bond distances as well as the CO-stretching frequencies can be seen in Figs. 2*a* and 2*b*. The principal quantum number has little effect on either the CO-stretching frequencies or the M–C bond distances. The classical model for CO chemisorbed onto metals is the Blyholder model,[44] where there is a combination of σ donation from the carbon atom's highest occupied molecular orbital (HOMO) to the metal's lowest unoccupied molecular orbital (LUMO) along with π back-donation from the metal HOMO to the antibonding 2π* LUMO orbital of CO. This simple model does not fit well with our calculations. Instead, we suggest that the bonding of CO to metal atoms is more complex and arises primarily from metal π to CO 2π* with some repulsive σ interaction, as proposed by Bagus et al.[45] and observed by others.[46,47] As the d orbitals become more filled at a given quantum number, the M–C bond distance decreases slightly for d^1 to d^7 metals and then increases from d^7 to d^{10} (Fig. 2*a*). From d^1 to d^8, the metals can accept donation from the 5σ orbital (HOMO) of CO and there is an increasing amount of donation from the metal's HOMO to the CO's LUMO. This binding combination strengthens the M–C bond and obeys the Blyholder model. However, when the d orbitals of the metals become full, from d^7 to d^{10}, σ repulsion occurs and in turn less π back-donation, causing a very sharp increase in the M–C bond distance. Similarly, ν_{CO} increases with an increasing number of d electrons of the metals (Fig. 2*b*) owing to the effect of progressively less σ donation (and π back-donation) from the CO HOMO to the metal LUMO. This causes a weaker M–C bond, and subsequently, a stronger C–O bond, as evidenced by the ν_{CO} increase with filling of the d orbitals. There is little, if any, bonding interaction between CO and metals with filled d orbitals (d^{10} metals). The calculated ν_{CO} of free CO is 2209 cm^{-1}, which is the same as that of Zn–CO and Cd–CO, and is even slightly lower than that of Hg–CO (2212 cm^{-1}).

Shown in Fig. 3 is a comparison of our calculated M_1–CO E_{ads} with the experimental values.[17] For comparisons sake, this figure also includes the results for larger M_2–CO and M_4–CO clusters as reported by Zeinalipour-Yazdi et al.[16] It can be seen that while our work varies slightly from the experimental values, the same general trend is observed for the larger cluster models. Although CO bonded to single metal atoms does not give accurate E_{ads}, this approach can be used to compare M–CO bond strength for different elements to screen their viability as catalyst components.

[c]Actual composition of the nanostructures determined by subtracting the final solution concentrations from the initial concentrations.

To examine the effect of CO adsorption on combined metals ("alloys"), Pd was chosen as a base because it is a commonly used catalyst for CO oxidation and fuel cell applications. We then chose two metals to combine with Pd to assess the preferential binding sites of CO: one with a stronger affinity for CO (Pt; E_{ads} = –67.76 kcal/mol; 1 cal = 4.184 J)) and one with a weaker affinity for CO (Au; E_{ads} = –7.96 kcal/mol). These two metals were chosen because they are possibly the most widely studied catalysts on the nanoscale.[4,18,20,48–50]

CO adsorption onto a Pd_4 cluster

It is well known that CO can bind to a Pd surface via the carbon in three ways: on top of a single Pd atom, bridged between two Pd atoms, or in a hollow threefold position (see Fig. 1). Each of these binding sites, along with a Pd_4 metal cluster, were examined in the singlet and triplet spin states with the results given in Fig. 4. The known ground-state triplet spin for the metal cluster was reproduced (Fig. 4*a*).[11,51] With CO on top of a Pd atom, minima were obtained in both singlet (Fig. 4*b*) and triplet (Fig. 4*c*) states. With CO bridging two Pd atoms, only the triplet-state minimum was obtained, whereas the hollow site binding motif was located only on the singlet surface (Fig. 4*e*). The hollow site attachment has the strongest CO adsorption strength, followed by the triplet state on-top minimum, bridged site attachment, and lastly, the singlet state on-top minimum.

The E_{ads} for the two on-top minima are quite different (–14.99 kcal/mol for the singlet state vs –29.34 kcal/mol for the triplet state), yet the CO-stretching frequencies are the same (2121 and 2118 cm^{-1}, respectively). Additionally, the CO adsorption strength for the on-top sites differs from that for CO bound to a single Pd (Table 1), but the CO-stretching frequencies compare favourably. The CO stretch is a local phenomenon[35] and highly dependent on the binding motif. For example, the CO-stretching frequency for all on-top sites is ~2100 cm^{-1}, whereas for a bridging motif it is around 1900 cm^{-1}, and when bound to a hollow site the CO-stretching frequency is just under 1800 cm^{-1}. This general finding has been used extensively to identify experimental binding motifs. The reason for the variation in CO-stretching frequencies is the change in CO distance. The value of r_{CO} is 1.149–1.151 Å when CO is coordinated to one metal atom, it increases to 1.170 Å when coordinated to two metal atoms, and it elongates further (1.196 Å) when coordinated to three metal atoms. As will be evident in the following, this is an observation common to all metal clusters investigated in this study.

CO adsorption onto a Pd_2Au_2 cluster

As seen in Table 1, Au (E_{ads} = –7.96 kcal/mol) has a much lower affinity for CO than Pd (E_{ads} = –42.97 kcal/mol). To examine the effect of a metal with weaker adsorption strength for CO than Pd, a Pd_2Au_2 cluster was modeled. Our results for the binary metal complex (Fig. 5*a*) indicate that the ground state is a singlet with C_{2v} symmetry, consistent with the results of Zanti and Peeters.[52] As far as we know, this is the first study on the adsorption of CO on a Pd_2Au_2 cluster.

A total of seven adsorption sites were considered on each the singlet and triplet surfaces: CO on-top Pd, CO on-top Au, CO bridging Pd_2, CO bridging Au_2, CO bridging PdAu, CO in a Pd_2Au hollow site, and CO in a $PdAu_2$ hollow site. Of the 14 possible structures, only 7 were located (Figs. 5*b*–5*h*). The addition of Au to Pd completely hindered CO adsorption to any hollow sites and no bridging structures involving Au were located.

Unlike Pd_4–CO, the highest binding affinity in Pd_2Au_2–CO is for the singlet surface on-top Pd site (Fig. 5*b*), followed by the singlet surface Pd_2-bridged species (Fig. 5*g*), and then the triplet surface on-top Pd structure (Fig. 5*d*). All other minima have E_{ads} under 24 kcal/mol. Thus, alloying Pd with Au changes the order of site preference and reduces the overall binding affinity. However, the CO-stretching frequency (2118–2148 cm^{-1}; 1967–1990 cm^{-1}) again depends on the CO distance (1.144–1.149 Å; 1.165–1.168 Å), which is dictated by the degree of metal coordination. This can be verified by FTIR spectroscopic studies.

CO adsorption onto a Pd_2Pt_2 cluster

To examine the effect of a metal with a greater adsorption strength for CO than Pd, a Pd_2Pt_2 cluster was modeled. The optimized molecular structure of the Pd_2Pt_2 cluster is displayed in Fig. 6*a*. It has a triplet ground state and like Pd_2Au_2 is of C_{2v} symmetry. Again, all seven binding motifs were explored on each singlet and triplet surface. This time only the triplet surface Pd_2Pt hollow site was not obtained (Figs. 6*b*–6*n*). Interestingly, for CO bridging two Pd atoms, the singlet state possesses a more energetically favourable planar structure (Fig. 6*f*) that is unique compared with all other tetrahedral-like cluster geometries. The strongest adsorption site for CO is on top of a Pt atom, with an E_{ads} of

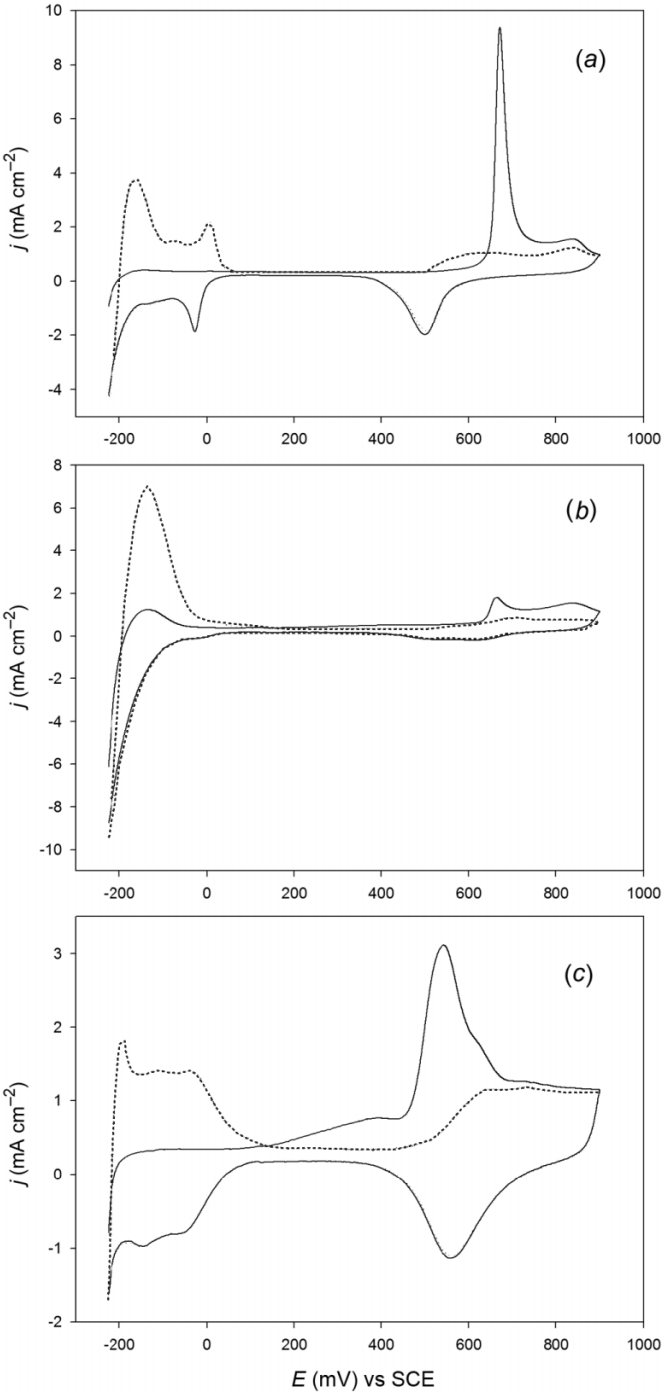
Fig. 8. Cyclic voltammograms (CV) of CO stripping on the prepared electrodes: (*a*) Pd, (*b*) Pd–Au, and (*c*) Pd–Pt. Two cycles of the CV were recorded for each electrode in 0.5 mol/L H_2SO_4 at a potential scan rate of 20 mV/s. The first sweep cycle is shown with a solid line and the second with a dotted line.



–36.91 kcal/mol in the singlet state and –44.83 kcal/mol in the triplet state. The next favoured site is CO bridging two Pt atoms in the singlet state (E_{ads}= –33.85 kcal/mol). The same binding motif in the triplet state has a much weaker CO interaction (E_{ads} = –19.35 kcal/mol). The large differences in E_{ads} between spin states emphasizes the importance of considering various spin multiplicities when performing DFT calculations on these small metal clusters to find the lowest energy configurations. Other sites, such as on top a Pd atom and a $PdPt_2$ hollow still have large E_{ads}, indicating strong interaction between CO and these sites as well.

With such a large array of structures, the previous observation that the CO-stretching frequency depends on the CO distance, which is dictated by the degree of metal coordination, is confirmed. All on-top binding minima have a ν_{CO} range between 2097 and 2126 cm^{-1} and a r_{CO} range between 1.148 and 1.155 Å, whereas bridging structures have a ν_{CO} range of 1826–1981 cm^{-1} corresponding to a r_{CO} range of 1.163–1.194 Å and hollow sites have a ν_{CO} range between 1735 and 1754 cm^{-1} and a r_{CO} range between 1.202 and 1.206 Å. Again, this demonstrates that IR spectroscopy is a valuable tool for ascertaining binding motifs.

Electrochemical oxidation of surface-adsorbed CO on Pd, PdAu, and PdPt

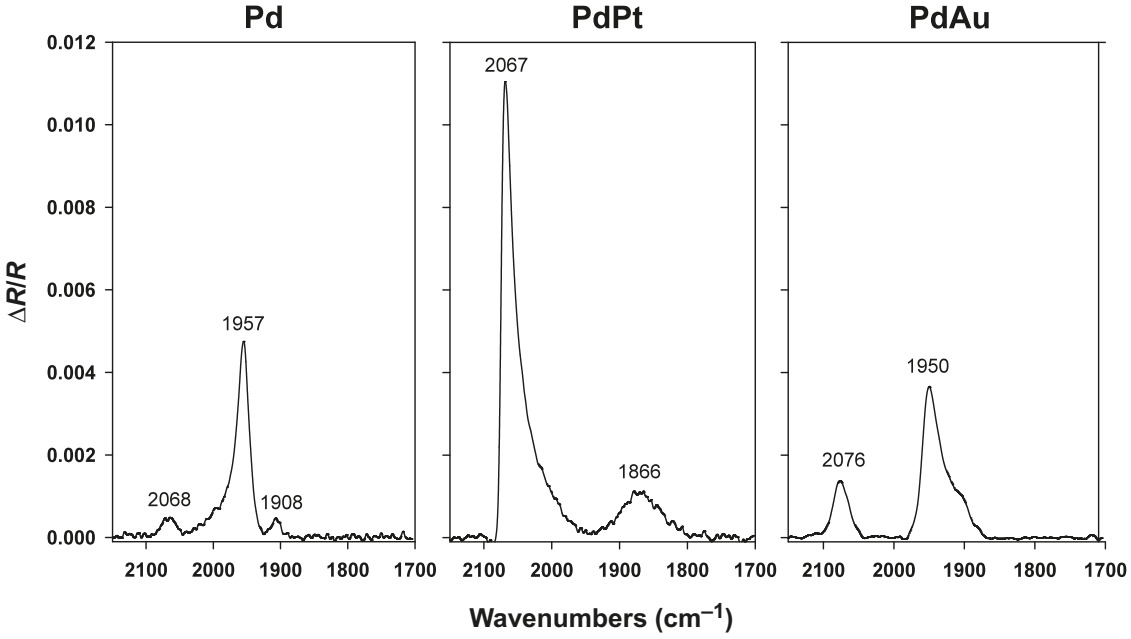
Scanning electron microscopic (SEM) images of the prepared nanostructures of Pd, PdPt, and PdAu are displayed in Fig. 7. It can be seen that the pure Pd exhibits nanoporous morphology with randomized small particles, which vary in size from approximately 50 to 200 nm. The PdAu and PdPt both possess a nanodendritic morphology. This is consistent with our previous work on nanodendrites and is attributed to a "foreign-particle induced mechanism" for intermetallics fabricated with the hydrothermal method used here.[10,41,42] The PdAu nanodendrites are much smaller in size, with thin trunks of approximately 1 μm in length and side branches of about 200 nm long and 50 nm wide. The PdPt nanodendrites are broader in nature and appear to be built up of particles approximately 60 nm in diameter. Although it is not realistic to compare nanostructures of these sizes with the four-atom clusters examined using DFT, it allows us to verify the general acceptance that calculations using small metal clusters compare well with experimental results for CO adsorption.[11,29,36]

The compositions of the Pd, PdPt, and PdAu nanostructures were confirmed using inductively coupled plasma atomic emission spectroscopy (ICP-AES) (Table 2). The results indicated that <0.2 ppm of metal remained in solution in all cases. Through subtraction of the final metal concentrations from the initial metal concentrations, it was found that the bulk composition of the nanostructures were exactly equal to the input compositions. This shows that the metal precursors were completely reduced by ammonium formate under the hydrothermal conditions.

Because CO is strongly adsorbed to platinum group metals, it is a major poisoning species for many catalysts in the process of the oxidation of small organic molecules. Therefore, one of the most important merits of an effective catalyst is its efficient removal of surface-adsorbed CO.[28] To compare the performance of the as-synthesized Pd, PdAu, and PdPt electrodes with CO poisoning, CO-stripping experiments were carried out in a 0.5 mol/L H_2SO_4 solution. The results are presented in Fig. 8.

There are two common characteristics in Figs. 8*a*–8*c*. First, the hydrogen desorption peaks of these electrodes are suppressed in the first positive-going scan owing to preadsorbed CO blocking the active surface sites. Second, a current peak resulting from CO oxidation appears in the potential range from 0.0 to 0.8 V. The Pd catalyst (Fig. 8*a*) displays a very sharp CO oxidation peak centred at

Fig. 9. In situ electrochemical attenuated total reflection-Fourier transform infrared spectroscopic (ATR-FTIR) spectra for the oxidation of CO adsorbed to the surfaces of Pd, PdPt, and PdAu at a potential of –0.1 V. The spectra recorded at –0.2 V were used as references.



~675 mV, indicating that all of the adsorbed CO is rapidly oxidized at this potential. In the first forward scan of the PdAu CV (Fig. 8*b*), the entire hydrogen desorption peak is not suppressed. This proves that CO did not adsorb to all of the surface sites of the PdAu catalyst. Also, the CO oxidation peak is significantly smaller than the one on the pure Pd catalyst. The hydrogen adsorption–desorption peaks of PdAu are notably larger than those of Pd, indicating that Au may have the opposite adsorption energy effect on Pd for hydrogen compared with carbon monoxide. The CV for PdPt (Fig. 8*c*) shows some catalytic improvement towards the oxidation of CO compared with pure Pd. There is a shoulder beginning at around 75 mV on the broad CO oxidation peak centred at 550 mV.

The CO oxidation charge (Q_{CO}) can be determined by integrating the area under the CO oxidation peaks in the CVs along with the geometric surface area, and it is proportional to the amount of CO that has been adsorbed to the catalyst surface. Q_{CO} decreases in the order PdPt (23.18 mC/cm^2) > Pd (19.67 mC/cm^2) > PdAu (7.93 mC/cm^2), consistent with the ordering of the most stable CO bound four-atom clusters: PdPt (E_{ads} = –44.83 kcal/mol) > Pd (E_{ads} = –41.39 kcal/mol) > PdAu (E_{ads} = –33.87 kcal/mol). Additionally, the order also correlates with the number of types of possible binding sites in each cluster: PdPt (on top, bridging, and hollow), Pd (on top, bridging, and hollow), PdAu (on top, bridging) (Figs. 4–6). The preferential hollow binding site for pure Pd requires three Pd atoms per CO ligand, limiting the CO coverage on the surface as compared with the preferential on-top and bridging sites for PdPt, which require one and two atoms, respectively, per CO ligand.

In situ electrochemical ATR-FTIR study of surface-adsorbed CO

As noted earlier, the C–O stretching frequency in the four-atom clusters is sensitive to the nature of the binding site, but almost independent of the type of metal. Infrared spectroscopy, using CO as a probe, is an effective technique for investigating alloying effects of metal catalysts.[53] The presence or absence of characteristic CO stretches can be used to monitor adsorption sites on the surface, providing insight into the ensemble (geometric) effect. The CO vibrational frequency shift can be used to identify changes in the interaction between the substrate and CO molecules, which reflect the electronic modifications of the substrate surface induced by the second metal (the ligand effect).[53] By comparing the results obtained from theoretical simulations in this study with those obtained from experimental ATR-FTIR, we are able to see what sites are preferential for CO to bind to the Pd alloys.

Shown in Fig. 9 are the electrochemical ATR-FTIR spectra for CO adsorbed to Pd, PdPt, and PdAu. Because the CO frequencies are a local phenomena, we can assign the experimental peaks using the predicted values from our DFT calculations. On the pure Pd nanostructure, the largest peak at 1957 cm^{-1} is for CO in a bridge position with the smaller peaks at 2068 and 1908 cm^{-1} corresponding to CO in the on-top and hollow sites, respectively. On the PdPt surface, the most intense peak, at 2067 cm^{-1}, is for CO in the on-top position with a less intense peak at 866 cm^{-1} for CO bound in a hollow site. No peak is observed for CO bound to a bridge site. On the PdAu surface, CO adsorption occurs only at on-top sites (2076 cm^{-1}) and bridging sites (1950 cm^{-1}).

Conclusions

In conclusion, DFT calculations were carried out for CO bonded to individual atoms of the transition metals. It was found that this method is very efficient for comparing the strength of CO adsorption with different metals. To obtain accurate adsorption energies, however, other factors need to be considered. The various binding sites and the corresponding stretching frequencies for CO attachment to three metal

clusters (Pd_4, Pd_2Pt_2, and Pd_2Au_2) were assessed. Because of the strong CO affinity of Pt, CO was most strongly adsorbed on top Pt in the Pd_2Pt_2 cluster, but minima for nearly all possible binding sites were obtained. On the other hand, in the Pd_2Au_2 cluster, the hollow sites were completely avoided as a result of the weak interaction between Au and CO. Thus, by combining metals in an appropriate manner, the adsorption sites of CO may be controlled. Experimental electrochemical results confirmed the weaker interaction of CO with PdAu than with Pd and showed that PdPt has a greater catalytic activity for the electrochemical oxidation of CO. ATR-FTIR was used as a tool to determine CO-binding sites in the nanostructured material. Interestingly, the CO-stretching frequencies in the clusters depend almost exclusively on the CO distance, which is dictated by the degree of metal coordination and not the metal upon which it is adsorbed. The relatively simplistic approach described within may be adapted to many other catalytic adsorbate reactants or intermediates, as well as countless adsorbent catalysts, allowing for easy screening of catalyst properties.

Supplementary data

Supplementary data (energies and Cartesian coordinates of all of the optimized molecules studied here) are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v11-120.

Abstract: Homochiral AB segments for (+)- and (–)-pillaromycinone were prepared in 11 steps from 2-acetylfuran. The synthesis featured an intramolecular Diels–Alder reaction of a 2,5-disubstituted furan and a hydroxyl-directed homogeneous hydrogenation of the tetrasubstituted alkene double bond of two enones. The CD segment was attached by a modified Staunton–Weinreb annulation to produce the desired homochiral tetracycle **21c** related to (+)-pillaromycinone. An unusual acetonide migration enabled the synthesis of a tetracyclic model for premithramycinone.

Key words: naphthacenone antibiotics, diastereoselective hydrogenation, Stauton–Weinreb annulation, furan Diels–Alder, regioselective dehydrogenation.

Résumé : On a préparé les segments AB homochiraux des (+)- et (–)-pillromycinone en onze étapes à partir du 2-acétylfurane. La synthèse implique une réaction de Diels–Alder intramoléculaire d'un furane 2,5-disubstitué et une hydrogénation homogène orientée par le groupe hydroxyle de la double liaison de l'alcène tétrasubstitué de deux énones. Le segment CD a été fixé par une réaction d'annelation de Staunton–Weinreb modifiée pour conduire au dérivé tétracyclique **21c** désiré, apparenté à la (+)-pillromycinone. Une réaction inusitée de migration d'un acétonide a permis de réaliser la synthèse d'un modèle tétracyclique de la prémithramycinone.

Mots-clés : antibiotiques de la naphtacénone, hydrogénation diastéréosélective, annelation de Stauton–Weinreb, réaction de Diels–Alder avec le furane, déshydrogénation régiosélective.

[Traduit par la Rédaction]

Introduction

Pillaromycin A (**1**) was isolated from a culture of *Streptomyces flavovirens* 40 years ago. Its aglycone, (+)-pillaromycinone **2**, is a linear tetracycle[1] with structural similarities to both the tetracyclines and anthracyclinones. Although it has attracted sporadic attention from the synthetic community,[2–4] no enantioselective route to (+)- or (–)-pillaromycinone has been disclosed as yet. Premithramycinone (**3**), isolated in 1998 from a blocked mutant of *Streptomyces argillaceus* ATCC 12956 is a key intermediate in the biosynthesis of the anticancer aureolic acids.[5] No synthetic work towards this compound has been recorded in the literature.

Some years ago[4a] we tested the viability of a convergent AB + CD plan, designed to provide rapid access to the tetracyclic system of **2**. Accordingly, the structurally appropriate AB intermediates, bicyclic enones (±)-**4a** and (±)-**4b**, were prepared in only 10 steps from furfural and incorporated into tetracycles (±)-**5a** and (±)-**5b** by a Staunton–Weinreb annulation. Two serious problems remained to be solved if the work was to be successfully adapted to a synthesis of any tetracycle related to (+)-pillaromycinone. The configuration at C-4a, established by heterogeneous hydrogenation of a tetrasubstituted double bond, was incorrect and no simple method existed for its correction in (±)-**4a** or (±)-**4b**. The Staunton–Weinreb annulation, although successful, needed four separate steps[4a] to form a tetracycle in an unacceptable yield of only 18% (Fig. 1).

We now report that the stereochemical deficiency has been remedied, the annulation has been profitably modified, overall yields have been improved substantially, and our basic plan[4a] has been adapted into a 14 step route to a homochiral tetracycle closely related to (+)-pillaromycinone from 2-acetylfuran. In addition, a serendipitous migration of an acetonide in one tetracyclic intermediate was discovered. Its possible application to the synthesis of premithramycinone **3** was briefly explored.

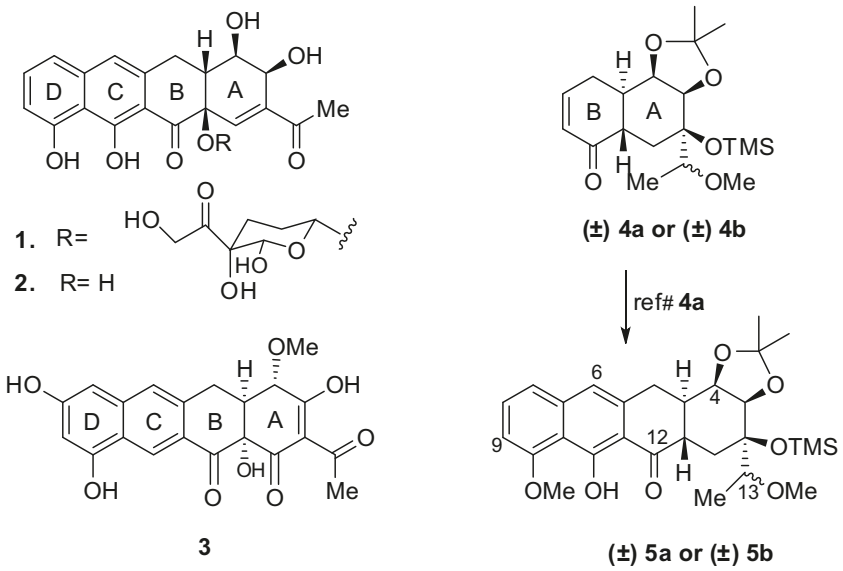
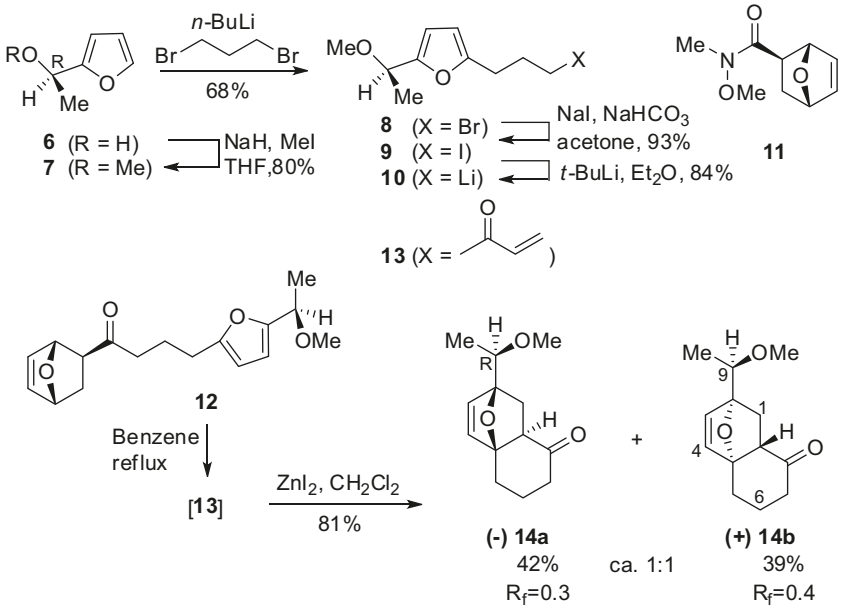


Scheme 1. Preparation of diastereomeric Diels–Alder adducts.



Results and discussion

The synthesis of homochiral AB units 18a–18d

The prochiral ketone 2-acetylfuran was reduced with borane in the presence of 5 mol % of the chiral ligand, diphenyl prolinol.[6] The resulting *R*(+) alcohol **6** (96% yield, >99% enantioselectivity) was methylated (NaH/MeI) to provide methyl ether (+)-**7** (80% yield). Both reactions were routinely conducted on 20 g scales and the product from each step isolated by distillation. The iodopropyl side chain was attached at the remaining furanoid α-carbon atom of **7** as before[4a] in two steps, through the bromide **8** (68%) and the iodide **9** (93%). Lithium–iodine exchange (*t*-BuLi, –78°) produced intermediate **10**, which was quenched in situ with *exo*-amide **11** to form the desired ketone **12** in 84% yield. This circuitous protocol "masks" the double bond of *N*,*O*-dimethyl acrylamide; a necessity because the conjugated amide did not react cleanly with **10**, and the 2,5-disubstituted furanoid core of these compounds was very sensitive to oxidizing agents. The enone **13** was unmasked by a retro-Diels–Alder reaction, effected by refluxing **12** in benzene overnight and removing the solvent under reduced pressure. The residue (**13**) was dissolved in dry methylene chloride and stirred at ambient temperature with 50 mol % zinc iodide for 48 h. The diastereomeric exo adducts[7] **14a** and **14b** resulting thereby were formed in an ~1:1 ratio and a combined yield of 81%. They were separated by flash column chromatography as before[4a] (Scheme 1). The three new chiral centres must have absolute configurations 2*S*,4a*S*,8a*R* and 2*R*,4a*R*,8a*S* with the already established 9*R* centre common to both. In our earlier work with racemates, X-ray crystallography of acetonide (±)-**15b** prepared from the chromatographically

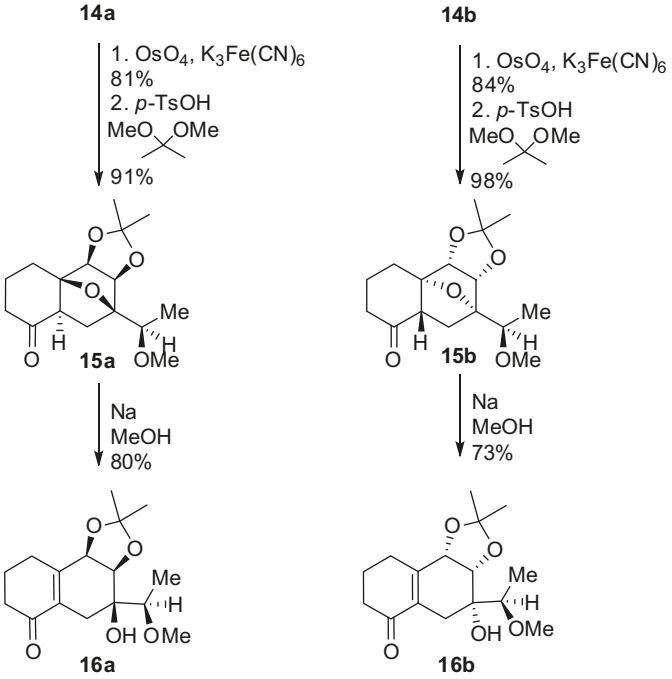
Scheme 2. Synthesis of hydroxy enones **16a** and **16b**.



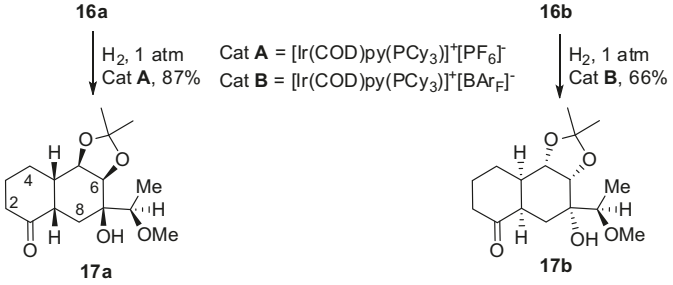
faster adduct (Scheme 2), indicated that its relative configuration was 2*S**,4a*S**,8a*R**,9*S**. It therefore follows that the absolute configuration of the faster adduct (**14b**) is 2*R*,4a*R*,8a*S*,9*R* (R_f = 0.4, $[\alpha]_D$ = +32.2) and the slower (**14a**) is 2*S*,4a*S*,8a*R*,9*R* (R_f = 0.3, $[\alpha]_D$ = –37.5). These assignments are also recorded in Scheme 1.

The 9*R* centre must be destroyed at a subsequent stage to generate the C-2 acetyl group of pillaromycinone, thereby converting the two diastereomers into enantiomers each of which can relate to (+)- or (–)-pillaromycinone. The chiral 9*R* substituent thus serves as a traditional resolving agent, but one that is also an integral part of the target molecule.

Proceeding as before,[4a] the C-3, C-4 double bond of each adduct was dihydroxylated and converted to the respective acetonides **15a** and **15b**. Each acetonide was then subjected to cleavage of the oxygen bridge by brief treatment with sodium in refluxing methanol. The resulting hydroxy enones **16a** and **16b** (higher R_f) were obtained in 10% and 9.3% overall yields, respectively, from 2-acetylfuran after nine steps (Scheme 2). We were able to separate (±)-**16a** on a chiralcell-OD column and show that our sample of **16a** was >99% enantiomerically pure (Fig. 1 of the Supplementary data).

It was now necessary to face the difficult problem of hydrogenation of the tetrasubstituted C-4a, C-8a double bond of each enone with delivery of hydrogen syn to the C-7 hydroxyl group and C_5–C_6 acetonide. Indeed, this was the step that had failed to produce the desired AB ring fusion in our earlier work.[4a] Some promising precedents[8] employing homogeneous hydrogenation techniques are available in the literature. A cationic rhodium catalyst had efficiently hydrogenated a tetrasubstituted double bond syn to a homoallylic hydroxyl group,[9] but our substrates **16a** and **16b** were unaffected by 5 or 10 mol % of $[Rh(nbd)(diphos\text{-}4)]^+BF_4^-$ at pressures of 1–50 atm (1 atm = 101.325 kPa) of hydrogen, at room temperature, after 24 or 36 h. Diimide, used earlier[10]

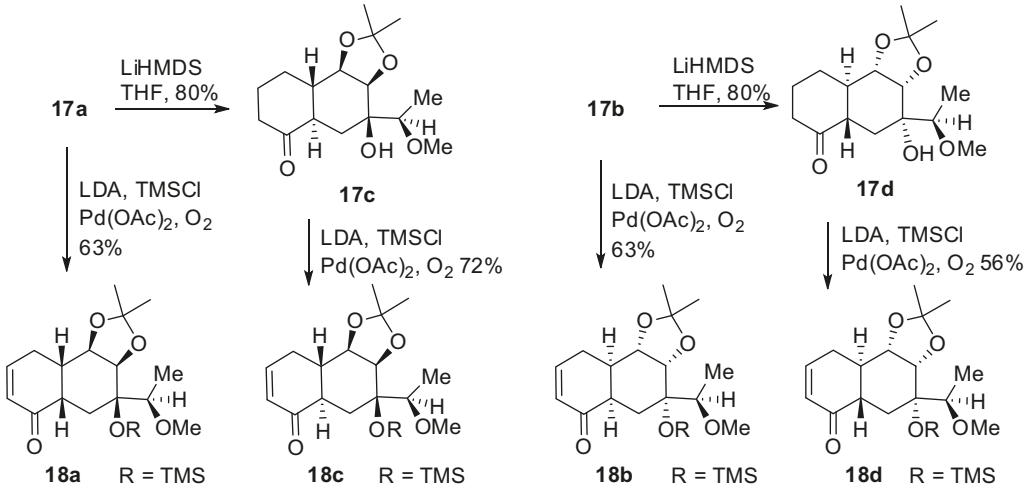
Scheme 3. Synthesis of *cis*-decalones **17a**–**17b**.



for a similar hydrogenation, also left these enones intact. The cationic iridium catalysts were evaluated next. A structural requirement for the successful hydrogenation of 3-cyclohexenols was that the hydroxyl group of the substrate be axially disposed. This ensures that both the hydroxyl group and the double bond are within reach of the metal in the putative octahedral Ir^{3+} complex resulting from oxidative addition of hydrogen[8] to the precatalyst. Our substrates did meet this criterion admirably, but they were seriously crowded around the reaction site. The homogenous hydrogenation with the Crabtree catalyst[11] was initially conducted in methylene chloride with the "slower" enone **16a** at various pressures of hydrogen, catalyst loadings, and reaction times. In general, the reaction was slow and incomplete. This was not surprising: tetrasubstituted double bonds are not easily hydrogenated. However, the desired product (the *cis*-decalone **17a**) was obtained in 87% yield after 48 h at a pressure of 1 atm of hydrogen (Scheme 3).

Surprisingly, and for reasons unknown, no conditions could be found that would hydrogenate the double bond of **16b** with the Crabtree catalyst. It has been reported that this catalyst can suffer deactivation over time by the formation of trimeric hydrogen-bridged iridium species, and this would be especially likely in slow reactions such as this. However, it is also known[12] that exchanging the PF_6^- counterion for the more lipophilic tetrakis[3,5-bis(trifluoromethyl)phenyl] borate $(BAr_F)^-$ improved catalyst performance and resistance to deactivation. We decided to prepare this catalyst by reaction of the Crabtree catalyst with $Na^+(BAr_F)^-$ in a two-phase methylene chloride – water system.[13,14] Column chromatography of the product (methylene chloride / silica) followed by crystallization from ethanol/ether gave the desired catalyst $[Ir(cod)py(PCy_3)]^+[BAr_F]^-$, whose structure was confirmed by X-ray crystallography (Supplementary data). Hydrogenation of the other diastereomeric enone (**16b**) with 10 mol % of this catalyst overnight, at a pressure of 1 atm of hydrogen produced the decalone **17b** in 66% yield. These reactions were also performed with the racemates (±)-**16a** and (±)-**16b** and the products (±)-**17a** and (±)-**17b** analysed by X-ray crystallography to establish their structures and relative stereochemistry (Supplementary data). It was gratifying indeed to observe that the difficulty with the configuration at C-4a had finally been resolved and the desired hydroxyl-directed hydrogenation had been achieved. At this stage we decided to also investigate the possibility of epimerising **17a** and **17b** at C-8a to obtain the *trans*-decalones **17c** and **17d** (Scheme 4). This was achieved in 80% yield by treatment with LiHMDS in THF (–78° → 0°), but the reactions could not be taken to completion and the products contained

Scheme 4. Synthesis of *cis*- and *trans*-enones **17a**–**17d**.



~20% of the starting *cis*-decalones **17a** and **17b**, which were separated by column chromatography. In Fig. 2 of the Supplementary data, the ^{1}H NMR spectra (500 MHz) of **17a**–**17d** are displayed. Particularly noteworthy is the small, but measureable W-coupling (found only in **17a**) between H-8α and the C-7 hydroxyl proton. This coupling is greatly reduced upon D_2O exchange. The other diagnostic feature in the figure is the lack of any signals between 2.5 and 3.2 ppm in the spectra of **17c** and **17d**. This region contains the cis-ring junction protons H-4a and H-8a in **17a** and **17b** and their absence reflects the trans-ring fusion in the former compounds.

Unlike the previous reports[2,3] that employed the Diels–Alder reaction to create the AB cis-ring fusion, our hydrogenation/epimerization sequence produces two pairs of AB intermediates cis and trans fused at will, each with a rigorously predetermined absolute configuration. The first pair (**17a** and **17c**) had stereochemistry at C-4a, C-5, and C-6 identical with that of (+)-pillaromycinone, whereas the second (**17b** and **17d**) related to the (–)-enantiomer in a similar manner. With each pair, a choice of configuration at the enolisable C-8a centre was available. We soon found that this versatility was a valuable asset in a subsequent step of the synthesis. Dehydrogenation of each decalone (**17a**–**17d**) at C-2, C-3 was achieved by the two-step Saegusa method.[15] The kinetic enolates were quenched with excess TMSCl and the resulting enol silanes were each oxidized with $Pd(OAc)_2$ in DMSO under an atmosphere of oxygen.[16] The enones (**18a**–**18d**) were isolated in 56%–72% yields. At this stage a final check on structure and stereochemistry of these AB segments was secured by a X-ray crystal structure of one of them, (±)-**18b**. We decided to continue the synthesis with the **18a**, **18c** pair only, because their configurations related to the natural antibiotic and they were produced in the highest overall yields from 2-acetylfuran (5.5% and 4.3%, respectively).

Synthesis of homochiral tetracycles

The next obstacle, the unacceptable yield of the Staunton–Weinreb annulation, was overcome by our "stannane modification" of the process.[4b] No less than seven cyclic enones, with and without[17] enolisable hydrogen atoms, were found to undergo the Michael addition – Dieckmann condensation sequence to afford polycyclic ketones in satisfactory yields. Both diastereomers **18a** and **18c** reacted with the stannane **19** after tin–lithium exchange to form ABCD tetracycles **20a** (62%) and **20c** (71%), respectively.

These homochiral tetracycles were then dehydrogenated with dicyanodichloroquinone (DDQ) in benzene. The AB cis fused heterocycle **20a** was unexpectedly resistant to the aromatisation of ring C and the reactions were difficult to complete, with product (**21a**) yields around 30%. Using other dehydrogenating agents (e.g., Pd/C or chloranil) did not improve matters.

This unfortunate setback was alleviated somewhat by testing the *trans*-enone **18c** instead, in the two-step annulation. As it happened, the AB trans tetracycle **20c** produced (71% yield) in the first step was quantitatively dehydrogenated by DDQ to (+)-**21c** ($[\alpha]_D$ = +32.4). This florescent yellow-green compound bearing the requisite substitution and absolute stereochemistry at C-3, C-4, and C-4a suitable for progressing to (+)-pillaromycinone was obtained in 14 steps and 3.95% overall yield from 2-acetylfuran (Scheme 5).

However, the configuration at the enolisable C-12a centre will have to be inverted in a subsequent hydroxylation step.

We began our effort to approach (+)-pillaromycinone by examining the possibility of O-desilylation and subsequent elimination of the tertiary hydroxyl group at C-2. Initially, treatment with TBAF in wet THF resulted in a complex mixture of products (see later), but PPTS in methanol at 0° did accomplish the desired desilylation in excellent yield. Many attempts were made to dehydrate the resulting C-2 tertiary hydroxyl group of **22**. With milder reagents like DCC, thiocarbonyl diimidazole, and mesyl chloride / DMAP, the starting material was recovered. Other reagents like thionyl chloride or triphenyl phosphine / iodine caused extensive decomposition. Acid-catalyzed dehydration with *p*-TsOH in moist THF was examined at temperatures between 0° and 25° with regular monitoring by TLC. After reaction under such conditions overnight at room temperature, the starting material **22** was consumed and two products were detected. One was the deprotected acetonide, a tetrahydroxy compound that could be eluted from a column only with neat ethyl acetate. The other, slightly slower on TLC than the starting

Scheme 5. Synthesis of homochiral tetracycles.

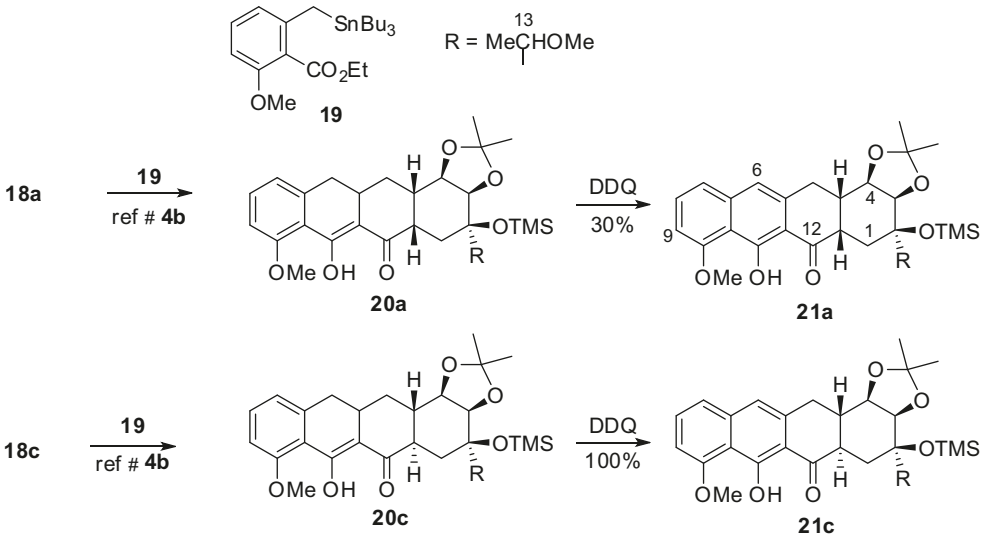

Fig. 2. Progress made towards pillaromycinone and premithramycinone.

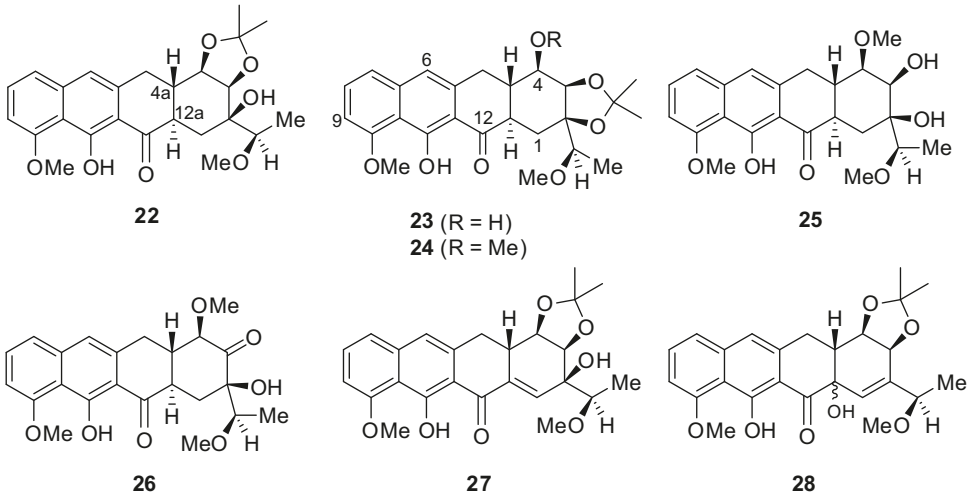

material **22**, had the same molecular formula (HRMS), but a different ^{1}H NMR spectrum, particularly in the signals of the protons on ring A (H-1, H-3, H-4, and H-4a, Table 1).[18] We were able to crystallize this product and establish its structure as **23** by X-ray crystallography. This isomeric acetonide was also formed from the silyl ether **21c** under identical conditions. Although these results were frustrating, we did not lose sight of the fact that the formation of **23** from **21c** or **22** represents the selective deprotection of the C-3, C-4 acetonide at C-4. This finding could be of much significance for a future attempt to synthesize premithramycinone **3**. To illustrate, methylation (NaH/MeI) of the now unprotected C-4 hydroxyl group afforded methyl ether **24** quantitatively. Hydrolysis of the acetonide (THF / aq HCl) left the C-2, C-3 diol **25**, which was oxidized (IBX, acetonitrile, 80°)[19] to provide the C-3 ketone **26**. These simple transformations produced a tetracycle with structure and stereochemistry not far removed from the A ring of **3** (Fig. 2).

Even though these were interesting and potentially useful reactions, they represented no advance towards pillaromycinone. In particular, we had no success in dehydrating the C-2 alcohol to generate the C-1, C-2 double bond as we had intended to do in our synthetic planning. Therefore, we decided to examine the complex mixture produced by the TBAF treatment of **21c** more carefully. Purification by chromatography provided a crystalline reddish yellow compound in an optimized yield of 60%. It had a molecular formula of $C_{25}H_{28}O_7$ (HRMS) in contrast to the starting material **21c** ($C_{28}H_{38}O_7Si$). Therefore, it must have been desilylated ($-C_3H_8Si$), but in addition had a deficiency of two hydrogen atoms. These features were confirmed by comparison of its ^{1}H and ^{13}C NMR spectra with those of **21c**.

In particular, the ^{1}H NMR signals assigned to the C-1 protons (δ 1.68, 2.67) and the C-12a proton (δ 2.95) of the starting material were absent in the spectrum of the product, but a new signal was evident as a singlet at 7.13 ppm. The ^{13}C spectrum confirmed the presence of a trisubstituted alkene with the appearance of two new signals at 135.3 and 136.5 ppm (protonated and nonprotonated, respectively). Based on these and other NMR comparisons (Table 1) we assigned the structure **27** to this compound and confirmed it by single-crystal X-ray analysis. We found that **27** was also

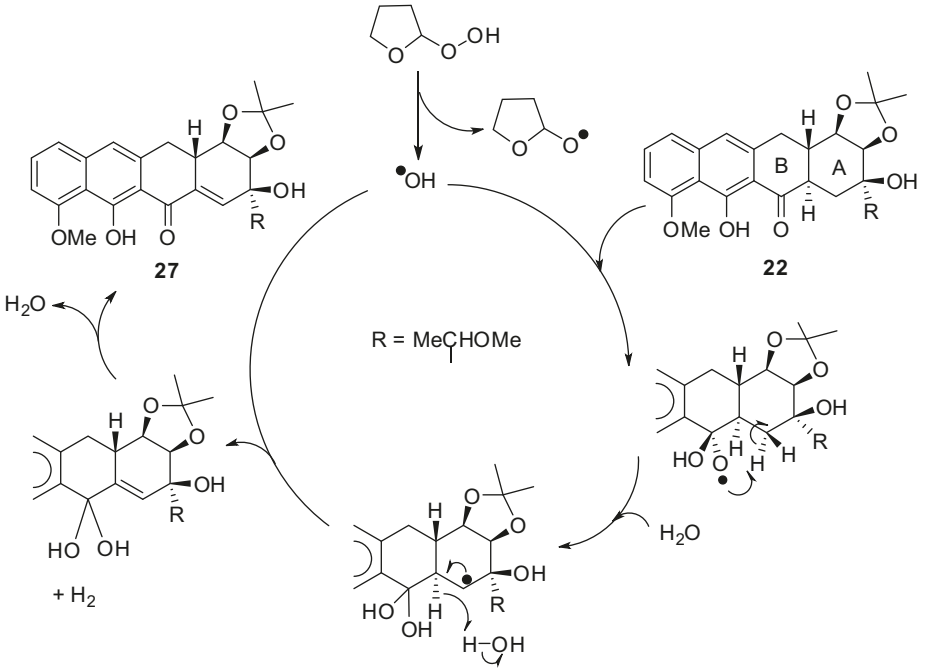
Scheme 6. Proposed mechanism for the formation of **27** from **21c** or **22**.



produced from the desilylated tetracycle **22** in similar yield under identical conditions. This remarkably selective dehydrogenation probably occurs by means of a radical chain process initiated by THF peroxide[20] and propagated by hydroxyl radicals. We propose a mechanism (Scheme 6) that accounts for the regioselectivity by assigning a crucial role to the carbonyl group at C-12 and avoids the intermediacy of an enolate radical at C-12a. The collapse of such a radical would result in the aromatization of ring B. The absolute configurations at every other chiral centre besides C-12a were unaffected in the transformation, and we had recognized earlier that the existing configuration at that centre would have to be corrected eventually. Consequently, we saw this γ-hydroxy enone **27** as an opportune substrate either for introducing the required hydroxyl group at C-12a in the correct orientation or for generating the desired C-2 acetyl group by dehydration at C-2, C-13.

We attempted the dehydration first by applying a simple procedure recommended specifically[21] for tertiary alcohols and illustrated with many examples of success with sensitive substrates. Under the conditions cited (mesyl chloride, triethylamine, DMAP in dry dichloromethane 0° → rt, 30 min) we obtained a green fluorescent compound that was separated from the reaction mixture by column chromatography on silica gel, first in ethyl acetate / hexane and then in dichloromethane/ether (85:15). However, even after careful chromatography, this material (a single spot on the TLC analysis) could not be obtained pure. The base peak at *m*/*z* 440 in its mass spectrum corresponded to a molecular formula $C_{25}H_{28}O_7$ (by HRMS) making it isomeric with the starting enone. In addition, the spectrum did not display an ion of significant intensity at *m*/*z* 422, thereby implying that the projected dehydration had not occurred. The ^{1}H and ^{13}C NMR spectra indicated the presence of about 10% of an impurity that appeared to be structurally similar to the major component. The ^{1}H spectrum of the green fluorescent product, when compared with the starting enone, showed many changes in the chemical shifts of protons associated with ring A. The alkene proton remained as a singlet, now at 6.9 ppm, and the signals assigned to H-3, H-4, and H-13 showed significant downfield shifts, whereas H-4a, no longer allylic, was shifted upfield considerably (Table 1). These changes taken together suggested that an allylic rearrangement[22] had occurred in ring A. The structure **28** is proposed for the fluorescent product with the double bond now at C-1, C-2 and the hydroxyl group at C-12a. The evident lack of a C-12a proton and the presence of a broad OH signal at 2.21 ppm supported the structural assignment. The configuration of the hydroxyl substituent at C-12a is still uncertain, however, and the difficulties experienced with purification of the product implies that it is an epimeric mixture of two C-12a alcohols. We have tried very hard to obtain suitable crystals of **28** for X-ray analysis without success so far, but these attempts are continuing.

Conclusion

If the configuration of **28** can be conclusively settled it would mean that we have succeeded in developing a synthesis of a very advanced intermediate for (+)-pillaromycinone requiring only minor structural adjustments for completion. It incorporates the correct absolute configuration at C-3, C-4, and C-4a and the double bond at C-1, C-2. Its synthesis required only 16 steps from 2-acetylfuran and features novel protocols for (*i*) stereochemical control at C-4a, C-4, and C-3; (*ii*) the Staunton–Weinreb annulation; (*iii*) regioselective dehydrogenation of a tetracyclic ketone at C-1, C-12a; and (*iv*) introduction of the hydroxyl group at C-12a. In addition, an interesting possibility of modifying ring A for the synthesis of premithramycinone has been created.

Experimental

Experimental procedures and spectroscopic data for racemic compounds **6**–**15**, stannane **19**, and chiral tetracycles **20a** and **20c** have been published previously.[4] Experimental protocols have been modified in some instances and yields improved. In such cases, the new conditions and yields are provided. See the Supplementary data for notes on general experimental methods.

R-(+)-1-Furylethanol (6)

To a stirred solution of *S*-diphenylprolinol (2.3 g, 9.08 mmol) in THF (650 mL) was added 2.0 mol/L BH_3–SMe_2 (64 mL, 128 mmol). The mixture was stirred overnight at room temperature (rt). A solution of 2-acetylfuran (20 g, 181.6 mmol) in THF (30 mL) was added slowly via a syringe pump and the mixture was stirred overnight at rt. The reaction was quenched with methanol and the solvents removed in vacuo at rt. Distillation (water aspirator) gave **6** (19.5 g, 96%) as a clear colourless liquid, bp 64°–70°. $[\alpha]_D = +21.1$ (*c* 1.06, $CHCl_3$). Optical rotation suggests >99% enantioselectivity for the reduction.[23]

R(+)-2-(1′-Methoxy)ethylfuran (7)[4a]

$[\alpha]_D = +109.9$ (*c* 1.006, $CHCl_3$), 80% yield.

R(+)-2-(3-Bromopropyl)-5-(1′-methoxy)ethylfuran (8)[4a]

$[\alpha]_D = +67.0$ (*c* 1.216, $CHCl_3$), 68% yield.

R(+)-2-(3-Iodopropyl)-5-(1′-methoxy)ethylfuran (9)[4a]

$[\alpha]_D = +59.1$ (*c* 1.482, $CHCl_3$), 93% yield.

2β-(*N*-Methyl-*N*-methoxyamido)-7-oxabicyclo[2.2.1]hept-5-ene (11)[4a] and *R*(+)4-[5-(1-methoxyethyl)furan-2-yl]-1-(7-oxabicyclo[2.2.1]hept-5-ene-2-yl)butan-1-one (12)[4a]

$[\alpha]_D = +61.0$ (*c* 1.184, $CHCl_3$), 84% yield.

2*H*-2-(1′-Methoxyethyl)-2,4a-epoxy-1,8a,5,6,7,8-hexahydronaphthalen-8-one (14a and 14b)

A solution of ketone **12** (10.98 g, 37.8 mmol) in benzene (100 mL) was heated at reflux for 48 h. The liquids were evaporated and the residue dissolved in dichloromethane (100 mL) and zinc iodide (4.82 g, 15.1 mmol) was added. The suspension was stirred for 48 h at rt and quenched with aqueous sodium bicarbonate. The mixture was extracted with dichloromethane (3 × 50 mL), the organic extracts combined and washed with brine, then dried ($MgSO_4$) and concentrated. Flash chromatography (30% ethyl acetate – hexanes) gave 6.7 g (81%) of a mixture of **14a** and **14b** and 0.23 g of unchanged starting material. The diastereomeric adducts **14a** and **14b** were separated as before[4a] by chromatography. **14b** $R_f \approx 0.4$; $[\alpha]_D = +32.2$ (*c* 1.006, $CHCl_3$); 39% yield. **14a**: $R_f \approx 0.3$; $[\alpha]_D = -37.5$ (*c* 1.004, $CHCl_3$); 42% yield.

Dihydroxylation of 14a and 14b: 2*H*-2-(1′-methoxyethyl)-3β,4β-dihydroxy-2,4a-epoxy-octahydronaphthalen-8-one[4a]

Modified procedure

A mixture of **14a** or **14b** (1 equiv), OsO_4 (0.2 equiv), $K_3Fe(CN)_6$ (3.0 equiv), K_2CO_3 (3.0 equiv), H_2O, and *tert*-butyl alcohol were stirred at rt for 48 h. The reaction was quenched with solid $NaHSO_3$ and stirred for a further 0.5 h. It was extracted with ethyl acetate (3×) and the remaining aqueous layer continuously extracted with ethyl acetate for a further 48 h. The ethyl acetate extracts were combined, dried ($MgSO_4$), and then evaporated. The residue was purified by chromatography to obtain a white solid in each case.

Dihydroxylation of 14a

13a (2.87 g, 12.9 mmol), OsO_4 (0.0714 mol/L) in water (36 mL), $K_3Fe(CN)_6$ (12.73 g, 38.7 mmol), K_2CO_3 (5.35 g, 38.7 mmol), *t*-BuOH (50 mL), and water (14 mL). Yield: 2.63 g (81%). $[\alpha]_D = -4.73$ (*c* 0.676, $CHCl_3$).

Dihydroxylation of 14b

13b (2.0 g, 9.0 mmol), OsO_4 (0.098 mol/L) in water (18 mL), $K_3Fe(CN)_6$ (8.89 g, 27 mmol), K_2CO_3 (3.73 g, 27 mmol), *t*-BuOH (35 mL), and water (17 mL). Yield: 1.934 g (84%). $[\alpha]_D = +4.44$ (*c* 0.608, $CHCl_3$).

2*H*-2-(1′-Methoxyethyl)-3β,4β-di-*O*-isopropylidene-2,4a-epoxy-octahydronaphthalen-8-one (15a and 15b)[4a]

To a refluxing solution of the diol (1.0 equiv) in 2,2-dimethoxypropane and dichloromethane was added a few crystals of TsOH. Refluxing was continued for a further 0.5 h, the mixture cooled, neutralized with solid K_2CO_3, and the solvents removed in vacuo. Flash column chromatography (3:1, hexanes / ethyl acetate) gave the pure acetonides. **15a**: Diol (5.817 g, 22.7 mmol), 2,2-dimethoxy propane (66.2 g, 636 mmol), CH_2Cl_2 (360 mL), TsOH (a few crystals). Yield: 6.09 g (91%). $[\alpha]_D = -26.8$ (*c* 0.954, $CHCl_3$). **15b**: Diol (1.774 g, 6.92 mmol), 2,2-dimethoxypropane (20 g, 194 mmol), CH_2Cl_2 (150 mL), TsOH (a few crystals). Yield: 2.0 g (98%). $[\alpha]_D = +33.2$ (*c* 1.05, $CHCl_3$).

7-(1′-Methoxyethyl)-7β-hydroxy-5β,6β-di-*O*-isopropylidene-4a,8a-dehydro-1-decalone (16a and 16b)

To a solution of sodium (5 equiv) in methanol was added the ketone **15a** or **15b** (1 equiv) in methanol. After 20–30 min the solution was cooled and poured onto dry ice. It was diluted with ether and filtered. The filtrate was evaporated to dryness and purified by flash chromatography (hexanes / ethyl acetate, 2:1). **16a**: ketone **15a** (2.0 g, 6.75 mmol), MeOH (55 mL), sodium (0.775 g, 33.7 mmol) in MeOH (55 mL), refluxed for 20 min. Yield: 1.595 g (79.8%). $[\alpha]_D = -102.7$ ($c = 0.736$, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.17 (3H, d, $J = 6.3$ Hz), 1.42, 1.46 (3H each, s), 1.99 (2H, m), 2.2, 2.42 (4H, m), 2.68 (2H, m), 3.25 (1H, qt), 3.31 (3H, s), 4.42 (1H, d, $J = 7.2$ Hz), 4.53 (1H, d, $J = 7.2$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.2, 22.1, 24.7, 24.8, 26.6, 26.9, 37.7, 57.1, 71.3, 74.6, 75.2, 78.6, 109.0, 130.1, 150.6, 198.6. EI HRMS $(M - CH_3)^+$ found: 281.1387; $C_{15}H_{21}O_5$ calcd: 281.1367. **16b**: ketone **15b** (0.485 g, 1.63 mmol) in MeOH (11 mL), sodium (0.188 g, 8.18 mmol) in MeOH (11 mL) refluxed for 30 min. Yield: 0.353 g (73%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.13 (3H, d, $J = 6.3$ Hz), 1.35, 1.36 (3H each, s), 1.99 (2H, m), 2.2, 2.42, 2.64 (6H, m), 3.09 (1H, qt), 3.29 (3H, s), 4.42 (1H, d, $J = 7.2$ Hz), 4.48 (1H, d, $J = 7.2$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.7, 22.2, 25.3, 26.6, 27.1, 27.4, 37.6, 57.1, 72.8, 75.4, 76.1, 79.9,

109.3, 129.8, 151.4, 198.6. EI HRMS $(M - Me)^+$ found: 281.1386; $C_{15}H_{21}O_5$ calcd: 281.1356.

7-(1′-Methoxyethyl)-7-hydroxy-5,6-di-*O*-isopropylidene-decal-1-ones (**17a** and **17b**)

A solution of the enone **16a** or **16b** (1 equiv) with iridium catalyst (0.1 equiv) in dichloromethane was flushed with hydrogen (3×) and stirred under an atmosphere of hydrogen for 24–48 h at rt. Brine was added and the layers separated. The aqueous layer was extracted with dichloromethane (3×) and the organic layers were combined, dried ($MgSO_4$), and concentrated. Flash column chromatography (hexanes / ethyl acetate, 2:1) yielded pure products as white solids. **17a**: enone **16a** (0.332 g, 1.12 mmol), $[Ir(COD)py(PCy_3)]^+[PF_6]^-$ (0.09 g, 0.112 mmol) in CH_2Cl_2 (80 mL), stirred under H_2 for 48 h. Yield: 0.291 g (87%). $[\alpha]_D$ = +9.63 (*c* 0.114, $CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.10 (3H, d, *J* = 6.3 Hz), 1.28 (3H, s), 1.62 (1H, dd, *J* = 15.0, 8.0 Hz), 1.8–1.9 (4H, m), 2.08 (1H, ddd, *J* = 15.0, 6.5, 2.1 Hz), 2.31 (2H, m), 2.45 (1H, d, *J* = 2.1 Hz), 2.81 (2H, m), 3.08 (1H, q, *J* = 6.3 Hz), 3.28 (3H, s), 3.89 (1H, dd, *J* = 8.0, 7.6 Hz), 4.16 (1H, d, *J* = 7.6 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.1, 22.5, 23.0, 24.6, 25.6, 26.7, 39.0, 40.7, 44.4, 57.3, 73.1, 73.3, 74.4, 80.4, 108.0, 212.7. Anal calcd for $C_{16}H_{26}O_5$: C 64.41, H 8.78; found: C 64.60, H 8.87. **17b**: enone **16b** (0.125 g, 0.421 mmol), $[Ir(COD)py(PCy_3)]^+[BAr_F]^-$ (0.064 g, 0.042 mmol) in CH_2Cl_2 (30 mL) under H_2 for 24 h. Yield: 0.0835 g (66%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.20 (3H, d, *J* = 6.3 Hz), 1.36 (3H, s), 1.51 (3H, s), 1.63 (1H, dd, *J* = 15.0, 8.0 Hz), 1.89 (4H, m), 2.27 (1H, ddd, *J* = 15.0, 9.4, 1.5 Hz), 2.40 (2H, m), 2.84 (1H, m), 2.91–2.93 (2H, m), 3.09 (1H, q, *J* = 6.3 Hz), 3.34 (3H, s), 3.86 (1H, dd, *J* = 9.2, 7.5 Hz), 4.11 (1H, d, *J* = 7.5 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 13.0, 22.5, 25.0, 25.3, 26.3, 27.0, 38.5, 40.7, 44.2, 57.5, 73.2, 73.5, 75.1, 83.0, 108.4, 213.0. EI HRMS $(M - Me)^+$ found: 283.1548; $C_{15}H_{23}O_5$ calcd: 283.1546.

4aβ,8aα-Decal-1-one (**17c**)

cis-Decalone **17a** prepared above was dissolved in dry THF (0.25 mol/L solution) and cooled to –78°. LiHMDS (1.5 equiv) was added and the mixture stirred at –78° for 10 min. It was allowed to warm to 0° and stirred at that temperature for a further 30 min. The reaction was quenched at 0° with methanol and allowed to reach rt. The solvents were removed and the crude product purified by chromatography to leave a thick oil. Yield: 80%. $[\alpha]_D$ = –10.6 (*c* 0.46, $CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.17 (3H, d, *J* = 6.3 Hz), 1.29–1.34 (1H, m), 1.36 (3H, s), 1.45 (3H, s), 1.63 (1H, qt, *J* = 13.6, 4.0 Hz), 1.77 (1H, dd, *J* = 15.0, 7.1 Hz), 1.96–2.06 (3H, m), 2.38–2.41 (1H, m), 3.21 (1H, m), 3.21 (1H, q, *J* = 6.3 Hz), 3.29 (3H, s), 3.99 (1H, dd, *J* = 9.0, 7.1 Hz), 4.18 (1H, d, *J* = 7.1 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 12.1, 24.2, 24.9, 25.8, 27.2, 30.3, 41.6, 43.5, 46.3, 57.0, 73.4, 76.2, 80.3, 80.7, 108.3, 210.1. EI HRMS M^+ found: 298.1780; $C_{16}H_{26}O_5$ calcd: 298.1779.

4aβ,8aα-Decal-1-one (**17d**)

Prepared from **17b** as above. The product was obtained in a similar yield as a 7:1 mixture of **17d**:**17b** and purified by column chromatography as before. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.15 (3H, d, *J* = 6.3 Hz), 1.23–1.30 (1H, m), 1.35 (3H, s), 1.46 (3H, s), 1.66 (1H, br.q, *J* = 14.0 Hz), 1.81 (1H, q, *J* = 9.1 Hz), 1.98 (1H, br.q, *J* = 11.0 Hz), 2.06–2.12 (3H, m), 2.21–2.31 (2H, m), 2.42 (1H, br.d, *J* = 14.0 Hz), 2.5–2.7 (1H, br), 3.14 (1H, q, *J* = 6.0 Hz), 3.33 (3H, s), 3.90 (1H, dd, *J* = 8.4, 6.5 Hz), 4.24 (1H, d, *J* = 6.5 Hz). ^{13}C NMR (125 MHz) δ: 12.5, 25.2, 25.9, 27.5, 27.9, 29.8, 41.5, 43.6, 47.0, 57.3, 73.4, 74.8, 80.2, 81.8, 108.7, 209.7. EI HRMS (M^+) found: 298.1788; $C_{16}H_{26}O_5$ calcd: 298.1780

The ^{1}H NMR (500 MHz) spectra of **17a**–**17d** are displayed in Fig. 2 of the Supplementary data.

7-(1′-Methoxyethyl)-7-trimethylsilyloxy-5,6-di-*O*-isopropylidene-2,3-dehydrodecal-1-ones (**18a**–**18d**)

Diisopropylamine (12 equiv) in THF at 0° was stirred with *n*-BuLi (12 equiv) for 15 min. The solution was cooled to –78° and the ketone **17** (1 equiv) in THF was added slowly by a syringe. After stirring for a further 1 h at –78°, TMSCl (20 equiv) was added and the stirring was continued for a further 1.25 h. The solution was allowed to warm to 0° and was stirred for a further 15 min and then quenched with aq NH_4Cl, extracted with ether (3×), washed with brine, dried ($MgSO_4$), and concentrated. The crude bis-silylether was taken up in DMSO and $Pd(OAc)_2$ (0.5 equiv) was added and flushed with O_2 (3×). It was then stirred under an atmosphere of oxygen for 48 h at rt. The reaction was quenched with brine and extracted with EtOAc (5×) and the extracts washed with water and then brine, and then dried ($MgSO_4$). The solvents were removed and the residue purified by flash chromatography (hexanes / ethyl acetate, 8:1). **18a**: **17a** (0.336 g, 1.13 mmol in THF 12 mL), 2.0 mol/L *n*-BuLi (6.75 mL, 13.5 mmol), *i*-Pr_2NH (2.0 mL, 14.0 mmol), THF (12 mL); TMSCl (2.9 mL, 22.5 mmol), $Pd(OAc)_2$ (0.126 g, 0.563 mmol), DMSO (12 mL) yielded **18a** as an oil. Yield: 0.264 g, (63%). $[\alpha]_D$ = +13.4 (*c* 0.298, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.13 (9H, s) 1.16 (3H, d, *J* = 6.3 Hz), 1.30 (3H, s), 1.48 (3H, s), 1.89 (1H, dd, *J* = 14.7, 7.1 Hz), 2.08 (1H, dd, *J* = 14.7, 6.0 Hz), 2.42–2.48 (2H, m), 2.59–2.69 (2H, m), 3.12 (1H, q, *J* = 6.3 Hz), 3.16 (3H, s), 3.87 (1H, d, *J* = 6.0 Hz), 4.01 (1H, dd, *J* = 7.5, 6.2 Hz), 5.99 (1H, dt, *J* = 10.0, 1.9 Hz), 6.76 (1H, dd, *J* = 10.0, 4.3 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 2.8 (3C), 12.0, 25.6, 26.5, 27.2, 27.5, 35.3, 41.9, 55.7, 76.1, 76.9, 77.5, 82.5, 107.6, 130.1, 146.3, 199.0. EI HRMS $[M - Me]^+$ found: 353.1785; $C_{18}H_{29}O_5Si$ calcd: 353.1785. **18b**: **17b** (0.171 g, 0.572 mmol in THF (6 mL)), 2.0 mol/L BuLi (3.43 mL, 6.86 mmol), *i*-Pr_2NH (1.0 mL, 7.16 mmol) in THF (6 mL), TMSCl (1.5 mL, 11.44 mmol); $Pd(OAc)_2$ (64 mg, 0.286 mmol) in DMSO (6 mL). Yield: 0.133 g (63%) of **18b** as a pale yellow oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.12 (9H, s), 1.16 (3H, d, *J* = 6.3 Hz), 1.25 (3H, s), 1.45 (3H, s), 1.65 (1H, dd, *J* = 14.9, 6.8 Hz), 2.22 (1H, dd, *J* = 14.9, 7.0 Hz), 2.41–2.46, (2H, m), 2.76–2.85 (2H, m), 3.19 (3H, s), 3.15–3.21 (1H, m), 3.91 (1H, d, *J* = 6.6 Hz), 4.0 (1H, t, *J* = 6.3 Hz), 5.99 (1H, d, *J* = 10.0 Hz), 6.80 (1H, dt, *J* = 10.0, 4.0, 4.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 2.6 (3C), 13.6, 25.8, 26.7, 27.2, 28.2, 35.1, 40.8, 56.0, 74.3, 75.7, 77.1, 81.7, 108.3, 129.7, 147.3, 199.8. **18c**: ketone **17c** (0.463 g, 1.56 mmol)

11-Hydroxy-10-methoxy-2-trimethylsilyloxy-2-(1′-methoxyethyl)-3,4-di-*O*-isopropylidene-1,2,3,4,4a,5,12,12a-octahydronaphthacen-12-one (21a)

A solution of tetracycle **20a**[4b] (120 mg, 0.232 mmol) and DDQ (79 mg, 0.348 mmol) in benzene (18 mL) was refluxed for 4 h. The solution was cooled, diluted with ether and water, and extracted with ether (3 × 20 mL). The organic extracts were combined, washed with water and then with brine, and dried over $MgSO_4$. The solvents were removed and the residue chromatographed (hexanes / ethyl acetate, 8:1) and the bright fluorescent band (R_f = 0.38) was separated from the starting material (R_f = 0.26), which did not fluoresce. Yield: 25.1 mg (21%); starting material recovered: 48.8 mg (41%). ^1H NMR (500 MHz, $CDCl_3$) δ: 1.20 (3H, d, *J* = 6.3 Hz), 1.31 (3H, s), 1.54 (3H, s), 1.98 (dd, *J* = 14.7, 7.4 Hz), 2.45 (1H, dd, *J* = 14.5, 4 Hz), 2.49–2.54 (1H, m), 2.80 (3H, s), 2.94 (1H, m), 3.02 (1H, dd, *J* = 15.8, 3.8 Hz), 3.05 (1H, q, *J* = 6.3 Hz), 3.08 (1H, dd, *J* =15.8, 3.8 Hz), 3.83 (1H, d, *J* = 5.3 Hz), 3.92 (1H, dd, *J* = 9, 5.3 Hz), 3.99 (3H, s), 6.76 (1H, d, *J* = 7.9 Hz), 6.97 (1H, s), 7.17 (1H, d, *J* = 7.9 Hz), 7.42 (1H, t, *J* = 8 Hz). EI HRMS M^+ found: 514.2380; $C_{28}H_{38}O_7Si$ calcd: 514.2374.

11-Hydroxy-10-methoxy-2-trimethylsilyloxy-2-(1′-methoxyethyl)-3,4-di-*O*-isopropylidene-1,2,3,4,4a,5,12,12a-octahydronaphthacen-12-one (21c)

Silyl ether **20c**[4b] (286 mg, 0.55 mmol) was dissolved in benzene (55 mL) under argon. The solution was then treated with 2,3-dichloro-5,6-dicyanobenzoquinone (197 mg, 0.87 mmol) in one portion at 25 °C. The reaction was stirred for 5 h at 25 °C and then quenched with water. The product was extracted into Et_2O and washed sequentially with saturated $NaHCO_3$ and brine. The organic layer was dried (Na_2SO_4), filtered, and concentrated to dryness under reduced pressure. The crude product was purified by silica gel chromatography (EtOAc/hexanes, 1.9) to afford the desired product **21c** (282 mg, 0.515 mmol, 100%) as a bright green amorphous solid. $[\alpha]_D$ = +32.4 ($CHCl_3$). R_f 0.36 (EtOAc/hexanes, 1:4). ^1H NMR ($CDCl_3$, 500 MHz): data are shown in Table 1. ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 2.7 (3C), 12.5, 26.4, 28.6 (2C), 33.9, 41.4, 44.7, 56.1, 57.2, 77.5, 80.4, 81.3, 85.1, 105.4, 107.8, 111.1, 115.1, 116.6, 119.7, 130.8, 137.8, 140.1, 159.8, 165.7, 204.9. EI HRMS calcd for $C_{28}H_{38}O_7Si$ *m*/*z*: 514.2387; found: 514.2380.

2,11-Dihydroxy-10-methoxy-2-(1′-methoxyethyl)-3,4-di-*O*-isopropylidene-1,2,3,4,4a,5,12,12a-octahydronaphthacen-12-one (22)

To ensure complete dissolution, THF (0.60 mL) was added to a solution containing silyl ether **20c** (95.7 mg, 0.186 mmol) partially dissolved in HPLC grade MeOH (6.0 mL). The solution was cooled to 0 °C prior to adding pyridinium *p*-toluenesulfonate (52.8 mg, 0.210 mmol) as a solid in one portion. The reaction mixture was stirred in the dark under an Ar atmosphere at 0 °C for 4 h. The reaction mixture was quenched with saturated $NaHCO_3$ (0.5 mL) at 0 °C and the organic solvent removed in vacuo. The crude mixture was redissolved in CH_2Cl_2 and washed with saturated $NaHCO_3$ and saturated NaCl. The organic layer was dried over $MgSO_4$, filtered, and evaporated to dryness. The crude product was purified by flash column chromatography (EtOAc/hexanes, 2:3) to give the tetracyclic diol **22** (82.5 mg, 0.186 mmol, 100%) as a fluorescent green, amorphous solid. R_f 0.29 (EtOAc/hexanes, 3:7). ^1H NMR ($CDCl_3$, 500 MHz): data are shown in Table 1. ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 12.2, 25.1, 25.6, 27.3, 34.9, 39.2, 43.9, 56.1, 57.0, 73.7, 76.2, 79.9, 80.9, 105.5, 108.6, 111.2, 115.1, 116.6, 119.7, 130.9, 137.4, 140.1, 159.8, 165.7, 204.6. EI HRMS calcd for $C_{25}H_{30}O_7$ *m*/*z*: 442.1992; found: 442.1990.

4,11-Dihydroxy-10-methoxy-2-[1′-methoxyethyl]-2β,3β,-di-*O*-isopropylidene-1,2,3,4,5,12,12a-octahydronaphthacen-12-one (23)

To a vial containing a solution of **21c** (16.6 mg, 0.032 mmol) in THF (0.40 mL) was added H_2O (0.10 mL) as a co-solvent. To the vial was then added a catalytic amount of *p*-toluenesulfonic acid monohydrate (2.0 mg, 0.011 mmol) and the reaction stirred at 25 °C for 48 h. The reaction was terminated by removal of the solvent in vacuo. The crude reaction was applied directly to silica gel and purified by flash column chromatography (EtOAc/hexanes, 2:3) to afford **23** (6.0 mg, 0.014 mmol, 42%) as a fluorescent yellow-green amorphous solid, recrystallized from CH_2Cl_2/hexane. $[\alpha]_D$ = –26.3 ($CHCl_3$). R_f 0.51 (EtOAc/hexanes, 1:1). ^1H NMR ($CDCl_3$, 500 MHz): data are shown in Table 1. ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 13.6, 26.9, 28.4, 28.9, 33.0, 40.3, 46.3, 56.1, 56.7, 74.2, 81.5, 82.4, 83.3, 105.4, 108.8, 111.2, 115.1, 116.6, 119.8, 130.9, 137.6, 140.2, 159.8, 165.8, 204.5. EI HRMS calcd for $C_{25}H_{30}O_7$ *m*/*z*: 442.1992; found: 442.1988.

11-Hydroxy-4,10-dimethoxy-2β,3β-di-*O*-isopropylidene-2α-(1′-methoxyethyl)-1,2,3,4,4a,5,12,12a-octahydronaphthacen-12-one (24)

Tetracyclic ketone **23** (6.0 mg, 0.014 mmol) dissolved in dry THF (1 mL) was treated with excess sodium hydride that had been previously rinsed with dry THF. Iodomethane (0.2 mL) was added and the mixture stirred at rt with occasional monitoring by TLC. After 1.5 h the starting material was completely consumed. The THF solution was poured into saturated aqueous ammonium chloride and extracted with dichloromethane (3 × 10 mL). The combined organic extracts were dried (Na_2SO_4) and evaporated. The residue was purified by chromatography (ethyl acetate / hexanes, 5:7). Yield: 6 mg (94%) ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.31 (3H, d, J = 6.2 Hz), 1.35 (3H, s), 1.43 (1H, t, $J \approx$ 1.34 Hz), 1.45 (3H, s), 2.33 (1H, qd, $J \approx$ 12.4, 12.4, 3.5 Hz), 2.59–2.69 (2H, m), 2.80 (1H, dd, $J \approx$ 14, 3.6 Hz), 3.31 (3H, s), 3.39–3.47 (3H, m), 3.56 (3H, s), 4.0 (3H, s), 4.27 (1H, d, J = 3.25 Hz), 6.77 (1H, d, J = 7.9 Hz), 6.97 (1H, s), 7.19 (1H, d, J = 8 Hz), 7.44 (1H, t, $J \approx$ 8 Hz), 15.17 (1H, s). EI HRMS M$^+$ found: 456.2155; $C_{26}H_{32}O_7$ calcd: 456.2148.

2β,3β,11-Trihydroxy-4β,10-dimethoxy-2α-[1′-methoxyethyl]-1,2,3,4,4a,5,12,12a-octahydronaphthacen-12-one (25)

Tetracycle **24** (6.0 mg, 0.013 mmol) dissolved in THF (1 mL) was treated with 1 N aq HCl (0.4 mL) and stirred at rt with monitoring by TLC. After 36 h, the solution was poured into saturated aq $NaHCO_3$ and extracted with dichloromethane (4 × 10 mL). The extracts were combined, dried (Na_2SO_4), and the solvents removed. The residue was chromatographed (ethyl acetate / hexanes, 3:1) to obtain the triol **25**. Yield: 5 mg (91%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.26 (3H, d, J = 6.2 Hz), 1.54 (1H, s), 1.60 (1H, t, $J \approx$ 13 Hz), 2.25 (1H, qd, $J \approx$ 12.6, 12.6, 3.4 Hz), 2.57–2.65 (2H, m), 2.69 (1H, dd, $J \approx$ 13.6, 3.55 Hz), 2.79 (1H, s), 3.31 (1H, dd, J = 10.3, 2.7 Hz), 3.34 (3H, s), 3.37 (1H, q, J = 6.3 Hz), 3.49 (3H, s), 3.97 (1H, d, J = 2 Hz), 4.0 (3H, s), 6.78 (1H, d, $J \approx$ 7.9 Hz), 6.96 (1H, s), 7.18 (1H, d, J = 8 Hz), 7.45 (1H, t, J = 8 Hz), 15.07 (1H, s). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 12.5, 28.3, 33.4, 37.3, 45.7, 56.2, 57.0, 57.3, 69.7, 75.2, 79.7, 83.3, 105.5, 111.3, 115.1, 116.8, 119.8, 130.9, 137.7, 140.2, 159.8, 165.7, 204.3. EI HRMS M$^+$ found: 416.1832; $C_{23}H_{28}O_7$ calcd: 416.1835.

2β,11-Dihydroxy-4β,10-dimethoxy-2α-[1′-methoxyethyl]-1,2,3,4,4a,5,12,12-octahydronaphthacene-3,12-dione (26)

Triol **25** (5 mg, 0.012 mmol) in acetonitrile (1 mL) was heated to 70° with *o*-iodobenzoic acid and the progress of the reaction monitored by TLC. After 18 h, almost all the starting material had been consumed. The solvents were removed and the residue was chromatographed (ethyl acetate / hexanes, 4:1). The product **26** was isolated, but a small amount of starting material **25** also remained. Yield: 3.5 mg (70%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.27 (3H, d, J = 6.2 Hz), 2.27–2.35 (2H, m), 2.86 (1H, td, J = 13, 13, 1 Hz), 3.17 (1H, td, J = 12.5, 12.5, 3.7 Hz), 3.35 (3H, s), 3.41 (1H, q, J = 6.2 Hz), 3.44 (1H, dd, J = 15.8, 3.5 Hz), 3.56 (3H, s), 3.88 (1H, s), 4.0 (3H, s), 4.11 (1H, d, J = 11.1 Hz), 6.80 (1H, d, J = 8 Hz), 6.97 (1H, s), 7.19 (1H, d, J = 8.3 Hz), 7.47 (1H, t, J = 8 Hz), 14.99 (1H, s). EI HRMS M$^+$ found: 414.1687; $C_{23}H_{26}O_7$ calcd: 414.1679.

2,11-Dihydroxy-10-methoxy-2-hydroxy-2-(1′-methoxyethyl)-3,4-di-*O*-isopropylidene-2,3,4,5,12-hexahydronaphthacene-12-one (27)

To an oven-dried vial containing **21c** (10.4 mg, 0.020 mmol) dissolved in anhydrous THF (0.40 mL) was added a THF solution of TBAF (1 mol/L, 0.40 mL, 0.040 mmol) at 0 °C. The reaction mixture was stirred in darkness for 4.5 h at 0 °C and then at 25 °C for 18 h. The reaction was quenched by the addition of H_2O (0.30 mL) and purified directly by flash column chromatography using silica gel. The desired product was eluted using EtOAc/hexanes (2:3) to afford intermediate **27** (6.0 mg, 0.014 mmol, 70%) as a yellow-orange solid and crystallized from methylene chloride / hexane. $[\alpha]_D$ = –345 ($CHCl_3$). R_f 0.49 (EtOAc/hexanes, 2:3). ^{1}H NMR ($CDCl_3$, 500 MHz): data are shown in Table 1. ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 12.7, 25.4, 27.4, 34.5, 39.0, 56.2, 56.8, 72.6, 76.8, 79.8, 80.6, 105.8, 109.3, 111.7, 115.2, 116.5, 119.9, 131.4, 135.3, 136.5, 138.1, 140.4, 159.9, 167.2, 189.7. EI HRMS calcd for $C_{25}H_{28}O_7$ *m/z*: 440.1835; found: 440.1837.

11,12a-Dihydroxy-10-methoxy-3,4-di-*O*-isopropylidene-2-(1′-methoxyethyl)-3,4,4a,5,11,12a-hexahydronaphthacen-12-one (28)

The enone **27** (16 mg, 0.036 mmol) dissolved in dry dichloromethane (5 mL) was treated with methylamine (0.2 mL) and DMAP (4 mg). The solution was cooled to 0 °C and methanesulfoxyl chloride (0.5 mL) was added. The mixture was stirred at 0 °C for 0.5 h and monitored by TLC for the disappearance of the starting material. It was poured into cold aqueous sodium bicarbonate and the solution was extracted with dichloromethane (3 × 10 mL). The combined organic extracts were dried (Na_2SO_4) and the residue chromatographed on silica (ethyl acetate / hexanes, 1:2). The greenish yellow fluorescent fraction, slightly slower on the TLC than **22** or **27**, was collected and evaporated. Further purification by column chromatography (dichloromethane/hexane, 85:15) resulted in the collection of a product that showed a single spot on the TLC, but still appeared to be contaminated by ~10% of an impurity (^{1}H and ^{13}C NMR). ^{1}H NMR ($CDCl_3$, 500 MHz): data are shown in Table 1. ^{13}C NMR (125 MHz, $CDCl_3$) δ: 12.2, 19.2, 25.7, 27.1, 28.1, 41.8, 56.2, 56.5, 70.8, 71.7, 75.5, 77.4, 105.7, 105.9, 109.6, 109.7, 115.0, 117.2, 119.8, 124.9, 131.5, 137.3, 159.8, 163.7, 199. EI HRMS M$^+$ found: 440.1832; $C_{25}H_{28}O_7$ calcd: 440.1835.

First-principles computational studies of the torsional potential energy surface of the *sec*-butyl radical

Ya Kun Chen and Yan Alexander Wang

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

Abstract: First-principles calculations were carried out to investigate the torsional potential energy surface (PES) of the *sec*-butyl radical. All the wave function methods employed predict a cis-like stable conformation with a dihedral angle of about 47° in addition to the trans-like global minimum conformation and a gauche conformation. However, most of the popular density functional approaches predict only the latter two local minima and lack the cis conformation that was experimentally observed. On the other hand, some density functional methods that incorporate the exact exchange and asymptotically corrected correlation functionals can locate the cis conformation successfully. The basis-set effect was also measured using popular B3LYP and MP2 Hamiltonians: only moderate shape changes were found for PES profiles upon basis-set variations. The stationary structures and their Hessians were obtained at both MP2 and B3LYP levels, with or without incorporating the zero-point energies. Opposite to the relative stability within the Born–Oppenheimer approximation, the cis conformation is more stable than the gauche conformation upon the zero-point correction, consistent with the experiment observations.

Key words: sec-butyl, torsional potential energy surface, density functional theory, wave function theory.

Résumé : On a effectué des calculs théoriques à partir des principes premiers pour étudier la surface d'énergie potentielle (SEP) de torsion du radical *sec*-butyle. Toutes les méthodes de fonction d'onde utilisées prédisent qu'il existe sous une conformation de type cis stable avec un angle dièdre de 47° à côté d'une conformation de type trans avec minimum global et d'une conformation gauche. Toutefois, la plupart des approches populaires par la fonctionnelle de la densité ne prédisent l'existence que des deux derniers minima locaux sans prédire celle de la conformation cis observée expérimentalement. Par ailleurs, certaines méthodes de la fonctionnelle de la densité qui incorporent l'échange exact et des fonctionnelles de corrélation corrigées d'une façon asymptotique permettent de localiser avec succès la conformation cis. On a aussi mesuré l'effet de l'ensemble de base en faisant appel aux hamiltoniens populaires B3LYP et MP2 : toutefois, avec ces changements d'ensembles de base, on n'a pu observer que des changements modérés de la forme des profils de la surface d'énergie potentielle (SEP). On a obtenu les structures stationnaires et leurs matrices hessiennes aux niveaux MP2 ainsi que B3LYP, avec et sans incorporation des énergies du point zéro. Contrairement à la stabilité relative observée dans l'approximation de Born–Oppenheimer, la conformation cis est plus stable que la conformation gauche lorsqu'on introduit une correction pour l'énergie au point zéro et ceci est en accord avec les observations expérimentales.

Mots-clés : sec-butyle, surface d'énergie potentielle de torsion, théorie de la fonctionnelle de la densité, théorie de la fonction d'onde.

Introduction

Torsional potential energy surfaces (PESs) of many chemical species have been studied numerous times because they provide the key information for molecular thermodynamic state functions. At the same time, it is also of great interest to compare the theoretically predicted PES and available experimental data to develop and improve computational methods and to provide deep insight into the nature of torsional barriers.

Even molecules as simple as ethane have attracted much theoretical attention for the investigation of the physical nature of its torsional barrier. The rotational barriers of ethane and its congeners were mainly attributed to hyperconjugation interactions by some researchers, challenging the popular belief in many textbooks of the importance of steric repulsive interactions.[1] However, using generalized valence bond theory, a recent theoretical study, in which the torsional barrier of ethane was decomposed adiabatically into steric repulsion and hyperconjugation as well as several other insignificant contributions, manifested that the steric repulsion is the main factor to the stabilization of staggered conformation and hyperconjugation is only of a secondary effect.[2]

Without the ambiguity in the physical origin of torsional barriers, it is widely accepted that conjugation effect dominates the torsional barrier of the conjugated systems. However, this well-adopted understanding does not promise good agreement between experimental results and theoretical predictions in many conformational studies. The torsional energy profile of 2,2′-bifuran was studied using various forms of Hamiltonians, in which density functional theory (DFT) methods were found inappropriate for the conformation study of this system.[3] Not only does the form of the Hamiltonian matter, but the basis set employed also plays a significant role. When biphenyl PES was studied using several wave function theory (WFT) methods, the quality of basis sets was found to be more important than that of the Hamiltonians.[4,5] Besides the individual Hamiltonian or the basis-set effect, delicate selection of certain combinations of Hamiltonians and basis sets can be critical for an accurate calculation of these (semi)rigid molecules. Theoretical study of the torsional barriers of biisothianaphthene showed that an accurate and balanced description of both conjugation and steric repulsion between nonvicinal hydrogens could be only achieved using high-level Hamiltonians and large basis sets.[6] Therefore, one must be aware of the limitations of popular theoretical tools; extensive studies are required to avoid false predictions even for small molecules based on calculations using a single Hamiltonian with a single basis set.

Other than these well-documented molecules, it might become even more challenging to study the conformations of some open-shell and complex species, including radicals whose PESs are usually so flat that an accurate description of the electronic energies involved goes beyond the reach of popular computational methods. For example, in the case of haloethyl radicals, a theoretical study showed that the DFT methods with the generalized gradient approximation (GGA) outperformed the local Møller-Plesset (MP2) method in predicting the dissociation energy of haloethyl radicals.[7] On the other hand, large spin contamination was found from DFT calculations of OOBr and OOCl, contradicting the popular view that DFT methods suffer less spin contamination than WFT methods. Sometimes, poor results can come from many different methods in a single case. In a conformational study of annulene molecules, both MP2 and DFT methods were found to fail one way or another.[8] All the uncertainties and controversies mentioned above suggest that some popular theoretical methods are still unable to work equally well for conformation studies of various molecular systems. Therefore, a convincing conclusion for the conformation studies often requires systematical benchmarking comparisons.

In this study, the torsional PES of *sec*-butyl was theoretically investigated. The available experimental data were mainly from hyperfine coupling constant (HFCC) study of its muoniated *sec*-butyl formed from muonium addition to 2-butene isomers.[9,10] As a short-lived, light isotope of hydrogen, the muonium, which is composed of a positive muon (antimuon) and an electron, is a good probing atom for the study of various systems.[11]

Before any comparison is made, it is important to point out that all *sec*-butyl isotopomers share the same PES within the Born–Oppenheimer (BO) framework, since the electronic Hamiltonian only parametrically depends on nuclear positions and has nothing to do with nuclear masses. Thus, a conformational study within the BO approximation is equally applicable for both regular (unmuoniated) and muoniated *sec*-butyl radicals (from muonium addition to 2-butene).

Based on the analysis of muon spin resonance (μSR) data, the muoniated *sec*-butyl radical formed from *cis*-2-butene has a large 0 K HFCC value on muon and this value is different from the muon HFCC from muonium addition to *trans*-2-butene. Further temperature-dependent HFCC study also supported the existence of two distinct muoniated *sec*-butyl radicals, both with large values of HFCCs on muon. However, calculations using the popular hybrid B3LYP-DFT Hamiltonian, normally believed to be well suited to predict HFCCs of small organic molecules,[12] only located two equilibrium structures on the ground-state torsional PES:[9,10] one corresponding to the radical formed from muonium addition to *trans*-2-butene and the other, a gauche conformation with HFCC on muon only about one-third of the experimental value. The absence of the experimentally observed muoniated *sec*-butyl formed from *cis*-2-butene from B3LYP calculations prompted us to carry out extensive theoretical studies of the torsional PES of the *sec*-butyl radical.

Besides providing static conformations, the PES also offers valuable information for temperature-dependent HFCC studies. The dynamic (vibrational) and thermodynamic corrections obtained based on the PES can be used to calculate the temperature-dependent behaviour of HFCCs by solving torsional Schrödinger equations. Something worrisome is that the non-BO effect may in turn be significant in a molecule containing muon, which may weaken the validity of our study based on the BO approximation. However, a study of the reaction rate of $Mu + H_2$ indicates that the non-BO effect only changes the reaction barrier height by 3.8%.[13] Therefore, we can expect much less non-BO effect in the muoniated *sec*-butyl radicals in the current study.

To our knowledge, some other experimental results from the homolysis of butyl radicals are also available. Thermodynamic and kinetic studies of the decomposition of the *sec*-butyl radical into propene and the methyl radical were performed,[14] but detailed conformational information of the *sec*-butyl radical could not be inferred from the homolysis study, since the experiment carried out at high temperature averaged out the behaviours of all distinct conformations. Therefore, theoretical calculations have to be done to illuminate possible conformations of the *sec*-butyl radical. Thus far, the first ab initio study on *sec*-butyl conformations can be traced back to the Hartree–Fock (HF) calculations in the 1980s,[15] in which the dynamic correlation effect was not taken into account. Therefore, a systematical study of the *sec*-butyl radical with various correlated Hamiltonians and different basis sets is much needed.

Computational details

All calculations in this study were carried out using the Gaussian 03 package within the BO framework.[16] Different first-principles electronic Hamiltonians, including spin-unrestricted HF, MP2, CCSD, CISD, QCISD, CCSD(T), and a variety of Kohn–Sham DFT methods were utilized. Wave functions were expanded in terms of atomic-centred one-electron basis functions including Pople-type basis sets (6–31g(d),

6–311++g(d,p), and 6–311++g(3df,2pd)),[17,18] and Dunning's correlation-consistent basis sets (cc-pVDZ, cc-pVTZ, AUG-cc-pVDZ, and AUG-cc-pVTZ).[19] For the DFT calculations, two-electron integrals were numerically integrated with the default grid quality in Gaussian 03 (75 radical shells and 302 angular points per shell) unless otherwise specified.

Geometry optimization was performed using the z-matrix coordinate system. Completely relaxed torsional PESs of the *sec*-butyl radical as a function of the dihedral angle (θ) of the four backbone carbon atoms were plotted using selected combinations of electronic Hamiltonians and basis sets (Fig. 1). The dihedral angle was scanned from 0° to 180° with a step size of 5°, while all the degrees of freedom other than the backbone dihedral angle were allowed to be fully optimized. The PES profile of θ in the range from 180° to 360° is essentially the mirror image of the profile from 0° to 180°, if

certain symmetry constraints are applied at proper points. However, for the simplicity and uniformity of the calculations, the symmetry of the molecule was subject to no constraint throughout unless otherwise noted.

In addition, the optimized conformations were calculated at both the MP2 and B3LYP levels to obtain the diagonalized Hessian matrices to identify the nature of the stationary structures and to include the zero-point vibrational corrections. Because the harmonic approximation is usually inappropriate for the shallow minimum of the cis-structure, anharmonic vibrational calculations were also carried out at the MP2 level of theory to obtain the anharmonic zero-point corrections.

In this study, single-reference spin-unrestricted Hamiltonians were used. Spin contamination, believed to be responsible for the failure of UMP2 in determining the reaction barrier of radical formation reactions,[20,21] was found to be very small for all the spin-unrestricted Hamiltonians in the current study. This is not surprising because it is well established that the simple alkyl radical has a localized unpaired electron at the radical centre. As a result, a single-reference method should be adequate to treat alkyl radicals well. Thus, spin-unrestricted single-reference methods were utilized in this study.

Results and discussion

The torsional PES profiles calculated using different Hamiltonians and basis sets are shown in Fig. 1, with their lowest points as the common reference zero point to simplify the comparison. The cc-pVDZ basis set was utilized in Figs. 1*a*–1*d* because geometry optimization is usually carried out with a relatively small basis set and cc-pVDZ was found to be adequate for this purpose.[3]

In Fig. 1*a*, the torsional energy curve obtained from the HF calculation lies above all other potential energy profiles. The PES profiles from the CCSD, B3LYP, and MP2 calculations lie at the bottom across each other, whereas the potential energy curve obtained from the CISD calculation is situated in the middle. The PES calculated at the B3LYP level drops at a slower rate with respect to the dihedral angle increment when compared with all the WFT methods. The B3LYP calculation predicts two stable conformations when the dihedral angle θ is less than 180°, whereas all the WFT methods predict three stable conformations. The most stable conformation is uniformly predicted to be a trans-like structure at $\theta \approx 170°$ (conformation I in Fig. 2*f*). A stable gauche conformation (structure II in Fig. 2*d*) is also universally predicted at $\theta \approx 80°$. This gauche local minimum is ~0.3–0.6 kcal/mol (1 cal = 4.184 J) energetically higher than the global minimum, depending on the Hamiltonian used.

The existence of a third cis-like conformation (structure III in Fig. 2*b*) is worth some elaboration. All the WFT methods predict the existence of a stable structure on a relatively flat segment of the PES curves around $\theta \approx 50°$, whereas selected B3LYP methods predict an accelerated energy drop with increased dihedral angle in the same range. This cis-like conformation was earlier recognized as one of the three stable conformations in the very first theoretical conformation study of the *sec*-butyl radical by Chen et al.[15] The correlation effects, which are important to describe dispersion interactions for a correct prediction of stable conformations, was not included by the HF calculations performed by Chen et al.[15] though. Thus, methods taking account of correlation effects must be employed here for a reliable conformation study. Both DFT (B3LYP) and high-level post-HF WFT methods can incorporate correlation effects, but predict different torsional profiles for the *sec*-butyl radical in this study. As verified by a μSR experiment, the cis-like conformation does exist and carries a large value of HFCC on the β-muon.[9,10] In this regard, WFT methods outperform B3LYP-DFT methods decisively.

When $\theta = 0°$, the HF calculation predicts that the barrier TS0 (Fig. 2*a*), the global maximum and the transition state connecting the cis-conformation with its mirror image, is 2.3 kcal/mol higher (less stable) than the global mininum, the trans-like conformation. This indicates that the HF calculation predicts stronger bulky repulsion (by about 0.4 kcal/mol) between the two terminal methyl groups of the *sec*-butyl radical than any other correlated methods owing to the neglect of the correlation effects. The barrier separating conformations II and III, TS1 (Fig. 2*c*), is located around $\theta \approx 55°$ using correlated WFT methods and is at $\theta \approx 60°$ using the HF Hamiltonian. This TS1 barrier is very low energetically with respect to conformation III and can be easily overcome. The height of the energy barrier between conformations I and II, TS2 (Fig. 2*e*), in comparison to conformation II is about 0.5 kcal/mol from WFT calculations, whereas it drops to as low as ~0.1 kcal/mol using the B3LYP method. At $\theta \approx 180°$, the actual torsional barrier between conformation I and its mirror image was not obtained directly from the PES curve because the symmetry was not constrained during the relaxed potential energy scan. Instead, the C_s symmetry was used to help acquire the torsional barrier at $\theta \approx 180°$. Based on separate calculations, this TS180 torsional barrier is 0.13 kcal/mol at the B3LYP/cc-pVDZ level and 0.29 kcal/mol at MP2/cc-pVDZ. For the sake of simplicity, no further effort was devoted to obtain this barrier height using other methods.

Besides the comparison between WFT methods and the representative B3LYP Hamiltonian, DFT methods with various functionals were also examined using the cc-pVDZ basis set. Based on the shape of the calculated potential energy profiles between $\theta = 40°$ and 60°, where the presence of conformation III is of interest, the functionals are classified into three different categories (Figs. 1*b*–1*d*).

Figure 1*b* shows the functionals that predict no minimum within the range of interest. This group comprises some popular hybrid or pure GGA functionals. The PES profile obtained from the VSXC calculation (inset of Fig. 1*b*) is erratically different from other functionals. The VSXC functional fails to describe the potential energy needed to approach the energy maximum at $\theta = 0°$ with the big overall steric repulsion between the terminal methyl groups. The other functionals in this group yield very similar potential energy profiles with only two stable conformations (I and II). At any particular value of the dihedral angle, the energy difference between any two functionals in this group (VSXC excluded) is within 0.2 kcal/mol.

In Fig. 1*c*, the second group of functionals predict relative flat features around $\theta = 60°$ before the accelerated energy drop to conformation II. Usually, geometry optimization has a hard time to converge to a stationary point if the potential

(*e*) TS2 (*f*) trans-like (I) (*g*) TS180 (θ=180°)

gradient is very small in a case like this. Thus, further calculations to verify the existence of a minimum might not be successful. Note that some of these functionals contain components like PW_X91 or B_C95 that were designed for systems characterized by weak interactions,[22–24] which may partly compensate for the weakness of the DFT models in Fig. 1*b* so that a flat segment around $\theta = 55°$ is predicted.

In Fig. 1*d*, calculations using the third group of functionals predict a shallow potential well lying on the torsional PES around $\theta = 50°$, similar to the PES profiles obtained from MP2 and other WFT calculations. However, it is well-known that the SVWN functional, as with any other LDA-type functionals, should not be trusted unless the electron density undergoes only a small variation in space. The isolated molecular systems usually exhibit big density gradients especially around the nuclei and their electronic structure cannot be well predicted by LDA calculations. Just as in this case, the SVWN calculation predicts a distinct PES curve, quite different from its peers. This indicates that SVWN fails to capture the nonlocal exchange and correlation effects. Different from what it is usually referred to, BHandH, comprising 50% exact exchange and 50% LDA-level exchange and LYP correlation functionals as implemented in Gaussian 03,[16] is also inappropriate for the conformation study of the *sec*-butyl radical because it produces a much deeper potential well about conformation III.[25] The calculation using the PBE0 (or PBE1PBE) exchange-correlation functional, a hybrid functional with about 25% exact exchange, predicts a potential energy curve with a shallow potential well around $\theta = 50°$, in contrast to the flat surface predicted by the pure PBEPBE calculation. The other three functionals in this group combine mPW (modified PW_X91) exchange with exact exchange and PW_C91 or meta-B_C95 correlation functionals that were designed for a better long-range behaviour. PBE0 and MPW1K calculations produce similar potential energy curves to those from correlated WFT calculations. MPW1B95 and mPWB1K, on the other hand, predict low-lying curves in the range of $\theta = 0°–60°$, a clear indication of the underestimated repulsion of the terminal methyl groups compared with other Hamiltonians.

Based on the PES curves of each exchange-correlation functional combination, it is evident that incorporating the exact exchange is crucial for locating the cis-like conformation III. This implies that the nonlocal exchange-correlation effects may play an important role in this conformation study. At the same time, correlation functionals should also be carefully chosen, since mPW3LYP in group one, using a similar exchange-correlation functional as for mPW1B95, predicts a PES profile without any sign of the cis conformation III.

The basis-set effect was examined using both B3LYP and MP2 Hamiltonians. Based on some early studies,[4,5] the quality of basis functions can be more important than the form of the Hamiltonians in conformational analysis. The cc-pVDZ and 6–31g(d) basis sets were believed to be too small to include correct dispersion interaction, which lead to overstabilization of the coplanar conformer of biphenyl.[4,5] In a theoretical study of radicals, calculations using the Pople-type basis sets with various Hamiltonians approach converged results only after the size of the basis set went beyond 6–311g(d).[26] To visualize the basis-set effect, the torsional PES profiles of the *sec*-butyl radical at the B3LYP and MP2 levels with different basis sets are plotted in Figs. 1*e* and 1*f*, respectively.

Because of its single determinant nature, the Kohn–Sham DFT method is usually less sensitive to the variation of the basis set than multideterminant post-HF methods. In Fig. 1*e*, the PES profiles appear to be insensitive to the selection of the basis sets when their sizes grow bigger than cc-pVDZ or 6–31g(d,p), both of which predict the appearance of a small cusp at $\theta \approx 55°$. Calculations with larger basis sets predict smooth and high-lying potential energy curves compared with those with cc-pVDZ or 6–31g(d,p). The energy difference between calculations using any two basis sets is no more than 0.2 kcal/mol at any given dihedral angle. The convergence of basis sets is quickly achieved beyond the 6–311++g(d,p) basis set. With the size of the basis sets increased within

Note: Bond lengths are in Å. Bond angles and dihedral angles (θ) are in degrees. The relative energies are measured from the global minimal conformation III. The harmonic vibrational zero-point-corrected energy values are shown in the last two columns for hydrogen and muoniated isotopomers, respectively. For the MP2 calculation results, the anharmonic vibrational zero-point-corrected energies are shown in parentheses. NA, not available; E_{ele}, relative energy.

the Pople basis-set family, the PES curve moves upwards without exception. However, the basis-set effect within the Dunning family of basis sets is complicated. Adding diffuse functions to the cc-pVDZ or cc-pVTZ basis sets greatly raises the relative energies of the gauche conformation (II) and the TS2 barrier separating conformations I and II. On the other hand, incrementing splitting valence functions or polarization functions to the basis set results in a moderate relative energy rise (to more unstable) of conformation II and TS2, but a dramatic energy increase of TS0. This implies that, when θ is between 70° and 130°, long-range interactions may dominate the PES where diffuse basis functions play an important role. Meanwhile, adding splitting valence and polarization functions noticeably influences the PES curves at small torsion angles.

Other than the basis-set effects, the quality of numeric integration also affects the accuracy of a DFT calculation. A recent theoretical study of the *sec*-butyl cation showed that the quality of numerical integration of a DFT study that uses grid summation can be important for an accurate prediction of the equilibrium geometries.[27] Thus, an ultra-fine grid of higher quality consisting of 99 radical shells and 590 angular points per shell was also tested, but no significant difference to the default grid quality was found for the system we studied here.

Unlike the Kohn–Sham DFT and HF methods, the MP2 method, as with many other correlated WFT methods using excited configurations, is normally sensitive to the size of the basis set employed because correlated WFT methods utilize virtual orbitals that are less optimized during the SCF procedure. Thus, in most cases, MP2 calculations require a large basis set to achieve a certain level of accuracy. A study of biphenyl torsional PES indicated that the unbalanced treatment of repulsive and attractive dispersion interactions occurred if only a small Dunning correlation consisted basis set was used.[4,5] In the present study, except for those using small basis sets like cc-pVDZ and 6–31g(d,p) with which the repulsion between the terminal methyl groups is overestimated, the PES profiles obtained from other Pople basis sets lie below the potential energy profiles obtained from the Dunning correlation-consisted basis sets. The congregations of the PES profiles within each basis-set family suggest a fast convergence within each basis-set family. On the other hand, some significant difference persists between the two sets of PES curves from the two basis-set families, indicating that either or both of these basis-set families are still far away from the complete basis-set limit.

To draw a convincing conclusion, calculations using more accurate Hamiltonians with larger basis sets are always desired. Limited by our computer resources and the complexity of the open-shell systems involved, only single-point CCSD(T)/6–311++g(d,p) calculations using MP2/cc-pVTZ-optimized geometries were carried out for benchmarking purposes. In the end, the resulting "true" torsional PES profile calculated from CCSD(T) very closely resembles the MP2 one, which lends confidence to the results from the MP2 calculations.

As occurs here, disagreement between the DFT and WFT methods also took place in earlier studies. Some good agreements to the experimental data from DFT calculations were attributed to the parameterization with which the functionals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

were developed. DFT methods were reported to be unsuitable for the conformation study of 2,2′-bifuran for missing a shallow gauche conformation on the torsional PES curve.[8] It was also noted that MP2 and DFT gave very similar geometries, whereas DFT failed to describe the energetics of the torsional potential of biisothianaphthene.[6] In addition, many popular density functionals are believed inappropriate to describe noncovalent interactions and are difficult to improve systematically. In contrast to DFT methods, correlated WFT methods are in principle controllably adequate and, although with much higher computational cost, can be progressively improved. High-level correlated post-HF methods can then be used as a benchmark to justify low-level calculations. Alternatively, comparison between theoretical predictions and experimental data provides another way to validate the theories. Up to today, one of the most convincing ways to tell whether a theoretical method can be trusted on a specific system is to make a comparison with available experimental data. In our current study, all WFT methods predict the existance of the cis-like conformation III irrespective of the selection of the basis sets. A comparison with available experiments has confirmed the existence of the cis-like conformation III by low-temperature HFCC measurements.[9,10] Thus, the WFT methods and several DFT methods in group III (Fig. 1*d*) outperform other theoretical methods by being more in line with experimental results.

The stable geometries of the *sec*-butyl radical were optimized at both B3LYP and MP2 levels with the cc-pVDZ basis set. The optimized geometric parameters of those stable conformations are listed in Table 1. These two employed methods predict very similar bond lengths and bond angles for the same stationary structure except that the dihedral angle of the gauche conformation calculated at the B3LYP level differs by about 10° from the MP2 calculation. The C2–C3 bond length descends almost monotonically as the torsion angle increases from 0° to 180°. This indicates that the C2–C3 bond grows stronger from the cis-conformation to the trans-conformation because of decreased repulsion between the two terminal methyl groups. The hydrogen–hydrogen repulsion and hyperconjugation involving C2 and C3 exert only minor corrections to the PES profiles because the energy barrier from conformation III to conformation II is very small. Based on the optimized structures, the C1–C2 bond distance reaches maximum in TS1. This implies that the internal rotation about the C1–C2 bond plays an important role in forming the rotational barrier between conformations II and III.

In an early theoretical study by Chen et al.,[15] the shallow potential well embracing conformation III was merely regarded as a shoulder extension to the electronically more stable conformation II. If only the static electronic potential energy is considered, muoniated *sec*-butyl formed from mounium addition to *cis*-2-butene will not exist or can be easily turned into the gauche conformation II by an extremely small fluctuation (e.g., through vibration) to overcome the tiny barrier TS1, contradicting the experimental observation that the muon HFCC of this structure remained visibly strong over a wide temperature range.[9,10] There is no doubt that other effects stabilizing this molecular species must be taken into consideration.

In addition to the electronic energy, the zero-point vibrational correction also affects the relative energy difference between two structures in reality. More complete thermodynamic correction must be considered if the experiment is conducted at a higher temperature. To make a sound comparison to the experimental data at low temperatures, both harmonic and anharmonic vibrational corrections of the stable structures and the corresponding thermal corrections were calculated and are summarized in Table 1. It turns out that the zero-point corrected energy of the muoniated isotopomer of conformation III becomes lower than that of the muoniated conformation II, opposite to the prediction based on electronic energies alone. Thus, the large value of the muon HFCC of the muoniated radical formed from *cis*-2-butene can be definitely assigned after including zero-point correction. Another change in relative stability owing to the inclusion of the vibrational correction is the transition state TS180 connecting conformation I and its mirror image: the transition-state structure becomes the lowest point after the vibrational correction. Similar effects of the zero-point correction were also reported in other studies but without detailed discussion.[7]

Conclusion

First-principles calculations using spin-unrestricted HF, MP2, CCSD, and a variety of DFT Hamiltonians with different basis sets were employed to investigate the stable conformations of *sec*-butyl. Several DFT methods only predict two equilibrium structures with backbone dihedral angles of about 85° and 170°, whereas all WFT methods and some DFT methods yield an extra cis-like stable conformation with a dihedral angle of about 55°, followed by a low torsional barrier towards the gauche conformation, in agreement with existing experimental results. Inclusion of exact exchange and long-range behaviour-corrected correlation functionals is crucial to locate this elusive cis-like conformation for DFT methods. The selection of the basis sets using the B3LYP or the MP2 Hamiltonian does not affect the number of stable conformations found but only modifies the shape of the PES profiles. Noting the stable conformation of any molecular species in reality is not simply solely determined by electronic energies, calculations including the zero-point vibrational effect were further carried out. The zero-point corrected energy shows that the cis-like muoniated conformer is more stable than the gauche one, in line with the available experiment data.

Abstract: The procedure abbreviated as ΔPBE0(SAOP)/et-pVQZ, based on density functional theory, was developed recently for the calculation of vertical ionization energies of the valence electrons of organic and other small molecules and succeeded in giving results with an average absolute deviation of 0.21 eV from experiment for a collection of 115 reliable test cases of nonperhalo molecules. The objective of this work is to add a number of test cases to the benchmark database. We chose the set of molecules cyclo-C_4H_4X, with X = CH_2, NH, O, and S, previously studied by many workers both experimentally and theoretically. The results show that the ΔPBE0(SAOP)/et-pVQZ procedure is not only as good as ab initio methods such as SAC-CI, OVGF, and ADC(3) in performance, but also handles inner valence ionized cations more efficiently. Although the core-electron binding energies of the titled molecules have not been as well investigated theoretically, we apply the methods we developed in recent years to calculate the binding energies of C1s, N1s, O1s, S1s, and S2p, which compare well with available experimental data.

Key words: vertical ionization energies, photoelectron spectra, PES, density functional theory, cyclopentadiene, pyrrole, furan, thiophene, ESCA, XPS.

Résumé : On a développé récemment une méthode à base de la théorie de la fonctionnelle de la densité, désignée par l'acronyme ΔPBE0(SAOP)/et-pVQZ, qui permet de calculer les énergies d'ionisation verticale des électrons de valence de petites molécules organiques et autres et qui fournit des résultats avec une déviation moyenne absolue de 0,21 eV par rapport aux valeurs expérimentales pour un ensemble de 115 cas typiques de molécules qui ne sont pas perhalogénées. L'objectif de ce travail était d'ajouter un certain nombre de cas typiques à la banque de données de référence. On a choisi l'ensemble de molécules cyclo-C_4H_4X, dans lesquels CH_2, NH, O et S qui avait été étudié antérieurement par plusieurs autres auteurs, tant d'un point de vue expérimental que théorique. Les résultats montrent que la performance de la méthode ΔPBE0(SAOP)/et-pVQZ n'est pas uniquement aussi bonne que celle des méthodes ab initio SAC-CI, OVGF et ADC(3), mais qu'elle permet de manipuler d'une façon plus efficace les cations ionisés de valence interne. Même si les énergies de liaison des électrons de coeur des molécules mentionnées dans le titre n'ont pas aussi bien été étudiées d'un point de vue théorique, on leur a appliqué dans les années récentes les méthodes qu'on a développé pour calculer les énergies de liaison de C1s, N1s, O1s, S1s et S2p qui se comparent bien avec les données expérimentales disponibles.

Mots-clés : énergies d'ionisation verticale, spectres photoélectroniques (SPE), théorie de la densité fonctionnelle, cyclopentadiène, pyrrole, furane, thiophène, spectroscopie électronique pour l'analyse chimique (SEAC), spectroscopie photoélectronique des rayons X (SPX).

Introduction

During the last few decades, the interpretation of photoelectron spectra has evolved with the development of computer hardware and software. The early predictions of vertical ionization energies (VIEs) by semiempirical molecular orbital (MO) methods, such as CNDO, MINDO, MNDO, and AM1, based on Koopmans' theorem (KT), were surpassed by a highly parametrized semiempirical MO method known as HAM/3,[1] based on an approximate transition-state model, a concept often used in density functional theory (DFT). Although the average absolute deviation (AAD) of results from HAM/3 from observed VIEs is usually about 0.3 eV, the method is not generally applicable because it is limited to molecules containing C, N, O, F, and H only.

On the other hand, use of KT in ab initio calculations leads to larger errors. When the ordering of MOs is predicted incorrectly, the term Koopmans' breakdown is used. In any case, the AAD from KT is often around 1 eV and the procedure

is sometimes known as Koopmans' approximation. When we used a similar method of approximating VIEs with the negative of orbital energies, but within DFT, using the exchange-correlation potential V_{xc} known as statistical average of orbital potential (SAOP),[2–4] the AAD was found to reduce to 0.4 eV.[5] This approach was named meta-Koopmans' theorem (mKT).[6] Recently, the AAD of similar mKT has been further improved by a better choice of hybrid density functional[7] based on the Baer–Neuhauser–Livshitz range separation.[8,9]

To go beyond KT, we applied the method of perturbation corrections to Koopmans' theorem from 1974[10] to 1985[11] and obtained AADs of 0.3–0.4 eV. A similar but more efficient approach using Green's function (GF) was developed by Cederbaumet al.[12] This method was later known as the outer-valence Green's function (OVGF).[13] The basis sets used were typically medium size and the AAD was usually around 0.3 eV. We tried a simplified second-order GF approach with one empirical parameter, called pGF2, to improve the efficiency and obtained AAD = 0.3 eV for a limited number of cases.[14] A method similar to OVGF called partial third order (P3) was developed by Ortiz[15] and gave slightly better results than OVGF. The OVGF method has been popular since it has been available in the Gaussian program package[16]. However, OVGF may not be as accurate as one wishes in two situations: (*i*) when the basis set, usually limited by computational facilities, is not large enough and (*ii*) when the pole strength is small owing to significant shake-up effects, in which case the method known as two-particle-hole Tamm–Dancoff approximation (2ph-TDA)[17] may be more reliable, provided a sufficiently large basis set is used. The 2ph-TDA method was used briefly but was superseded by a better approach known as third-order algebraic diagrammatic construction (ADC(3)).[18] The AADs of OVGF and ADC(3) results can be as low as 0.2 eV or better in some cases. Finally, there is the method of symmetry-adapted configuration interaction (SAC-CI)[19], also available in the Gaussian package, which can give very accurate VIEs, but the computational demand of SAC-CI calculations usually limits the size of the basis set used in practice.

We continued to look for an efficient method of predicting reliable VIEs and turned to DFT. After testing various forms of the transition-state model, with the best choice giving AAD = 0.3 eV,[20,21] we finally discovered a reliable and efficient procedure.[22] It is abbreviated as ΔPBE0(SAOP), which means the energy difference calculated with the parameter-free Perdew–Burke–Ernzerhof (PBE0) exchange-correlation functional,[23–25] using the electron density obtained with the exchange-correlation potential V_{xc} = SAOP.[2–4] It should be mentioned that, when there is a choice between maintaining symmetry and insisting on integer occupations in a cationic calculation, the latter has been found to lead to better prediction of VIEs (except for perhalo systems). This procedure of ΔPBE0(SAOP) succeeded in giving AAD = 0.21 eV for over 100 cases of nonperhalo molecules.[22] More recent studies showed that the AADs of the ΔPBE0(SAOP) method are

On the other hand, the five-membered heterocyclic aromatic molecules of pyrrole, furan, and thiophene are of considerable scientific interest to chemists. The importance of these molecules in pharmaceutical production, in coal conversion technology, and in the synthesis of pesticides and inorganic polymers, has been mentioned by Rennie et al.[31,32] Perhaps because of the industrial relevance, many studies, both theoretical and experimental, of the electron spectra have been undertaken. The UV absorption spectra of these molecules were thoroughly studied by Palmer et al.[33–35] However, the experimental data on the excited states are not as well understood as the photoelectron spectra of the valence electrons. Therefore, we concentrate on the photoelectron spectra in this study. The objective of this work is to apply the ΔPBE0(SAOP) procedure to the valence ionization of cyclopentadiene, pyrrole, furan, and thiophene, and to compare the accuracy with other theoretical methods. For core-electron ionization, we can only compare our results with available experimental data.

Method

The computational details for vertical ionization energies of valence electrons have been given previously.[22] We used the Amsterdam Density Functional (ADF) program[36] with the large basis set known as even-tempered valence quadruple-zeta (et-pVQZ) set of Slater-type orbitals.[37] The approach can be abbreviated as ΔPBE0(SAOP)/et-pVQZ. There remains only the geometry to specify. When no experimental geometry was available, we generally used the Gaussian03 program package[16] to optimize the geometry of each parent neutral molecule with the popular exchange-correlation functional known as B3LYP and the internal basis set 6–311+G(d,p). Thus, the procedure can be labelled as ΔPBE0(SAOP)/et-pVQZ//B3LYP/6–311G+(d,p). For the four molecules included in this paper, cyclo-C_4H_4X (with X = CH_2, NH, O, and S) experimental geometries are available[38–41] and were therefore employed. Thus, the procedure can be abbreviated as ΔPBE0(SAOP)/et-pVQZ//expt.

For core-electron binding energies (CEBEs) of C1s, N1s, and O1s, the method of ΔPW86-PW91+C_{rel} was developed in 1999[42] for contracted Gaussian-type orbitals. In 2003,[43] we found a more convenient alternative using the ADF program[36] with Slater-type orbitals. The procedure used in this work is ΔPW86-PW91/et-pVQZ+C_{rel}. For C1s, N1s, and O1s, we used the empirical allometric correction of

$$C_{rel} = kI_{nr}{}^n$$

where I_{nr} is the nonrelativistic value, with $k = 0.2198 \times 10^{-6}$ and $n = 2.178$ when both C_{rel} and I_{nr} are in units of eV.[44] Finally, the methods used for S2p and S1s, developed more recently, are ΔBmTau1(SAOP)/et-pVQZ+C_{re}[45] and scalar zeroth-order regular approximation (ZORA)+ΔPBE-PW91/et-pVQZ.[46] For C_{rel} for S1s, we used $k = 0.625 \times 10^{-6}$ and $n = 2.0616$, based on uncorrelated relativistic atoms.[47] Thus, the relativistic effects are approximated in different ways for the three cases. There were not enough experimental data on CEBEs of S2s to enable us to develop a reliable DFT procedure and therefore the S2s ionization energy for thiophene was not calculated.

Results and discussion

The results of this work are summarized in Tables 1–7 and compared with experimental and other theoretical studies.[48–75] The probable error of some of the observed VIEs is likely to be about 0.05 eV and the numbers written as subscripts in the tables are uncertain. Different workers report different numbers for the VIEs, and the AAD is presented in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

tables as AAD(N) for N VIEs. It is from such comprehensive comparisons that one sees the quality of the recommended approach of ΔPBE0(SAOP)/et-pVQZ. To simplify the comparison of this work with previous ab initio studies of cyclopentadiene, pyrrole, furan, and thiophene, we select the performance of each method on the first 10 VIEs of each of the four molecules and present the results in Table 8. The difficulty of computational demands of the SAC-CI method can be seen in the AADs of over 0.3 eV in some cases. Our conclusion is that the procedure of ΔPBE0(SAOP)/et-pVQZ is as good as (if not better than) the ab initio methods of OVGF and ADC(3). Because both OVGF and ADC(3) are truncated approximations in perturbation expansions, there is a possibility of residual errors even when the basis sets approach the complete basis set limit. Moreover, the efficiency of our method enables us to use sufficiently large basis sets. Another advantage of our approach is that we can converge on cations of inner-valence ionizations. From the outstanding performance of our ΔPBE0(SAOP)/et-pVQZ procedure, we draw the tentative conclusions that (*i*) the exchange-correlation potential V_{xc} = SAOP provides excellent electron densities; (*ii*) the exchange-correlation functional PBE0 gives excellent energies from a given density; and (*iii*) the basis set of et-pVQZ is large enough for most purposes.

On the other hand, the procedure we recommend is not perfect for every molecule. When the effect of shake-up satellites is significant, the single configuration used in our DFT calculation may not be able to give an accurate enough description of the cation; and we do not have intensities like the pole strengths in OVGF and ADC(3). Another caution note must be taken into account by other users of the present method: for some unknown reason, the same procedure did not perform as well for the limited database of 13 VIEs of perhalo molecules. Instead, choosing to maintain symmetry rather than integer occupations gave a reasonable AAD of 0.25 eV.

The starting point of OVGF and ADC(3) corrections to the one-body model is the set of Hartree–Fock MOs and therefore the language used, such as terms like breakdown of one-particle picture and pole strength, refer to the Hartree–Fock model. DFT is also a one-particle model; whereas the so-called meta-Koopmans' theorem[5] models the cations by frozen Kohn–Sham holes, the present method of ΔPBE0(SAOP) models them by relaxed Kohn–Sham holes.

For the calculation of VIEs presented above, no attempt was made to include relativistic effects. Even for selenophene, the AAD of the first 10 VIEs from experiment[76,77] is only 0.2_1 eV,[78] compared with 0.3_4 eV from ADC(3).[77] However, for CEBEs, relativistic effect is unavoidable. The results of our CEBE calculations are presented in Table 9. The agreement of the calculated CEBEs with the experimental data of Gelius et al.[56] is remarkable. On the other hand, the observed values reported by Chambers and Thomas[80] appear to be 0.3 eV too high on the average. Everything considered, there are not enough experimental data to provide a reliable assessment of our computed results.

Finally, the large basis set of et-pVQZ may prohibit the study of large molecules such as nonsteroid anti-inflammation drugs. Table 10 summarizes the effect of using smaller basis sets on the performance of ΔPBE0(SAOP) for the VIEs of formamide, at the experimental slightly nonplanar geometry reported by Costain and Dowling.[83] Since many previous studies on formamide use a planar geometry, the symmetry labels in both C_1 and C_s point groups are given in Table 10. It can be seen that a small basis set such as polarized double-zeta DZP leads to serious errors and that a good compromise is the polarized triple-zeta TZP basis (which includes double-zeta core).

Summary

To further support our recommendation of ΔPBE0(SAOP)/et-pVQZ for the calculation of vertical valence ionization energies of organic and other small molecules, we show, in this study on cyclopentadiene. pyrrole, furan, and thiophene, that the recommended procedure can perform as well as, if not better than, the ab initio methods of OVGF and ADC(3). The results on core-electron binding energies also support the various procedures developed in recent years. The effect of basis set on the VIEs of formamide suggests that the large basis set of et-pVQZ may be reduced to a much smaller set of polarized triple-zeta quality without great loss of accuracy. It is therefore our hope that other workers will be encouraged to adopt our recommendation for their work.

Theoretical study on chemical bond parameters and properties of $LnAl_3(BO_3)_4$

Zhiping Li and Faming Gao

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

Abstract: The detailed chemical bond parameters of $LnAl_3(BO_3)_4$ crystals were calculated using the chemical bond theory of complex crystals. Results indicated that Ln–O bonds are ionic and B–O bonds possess higher covalency. The environment factor defined by electron polarizabilities and covalency was employed to predict Racah parameters. The hardness of $YAl_3(BO_3)_4$ was predicted using Gao's model, which is also in agreement with the experimental value.

Key words: dielectric properties, hardness.

Résumé : On a calculé les paramètres détaillés des liaisons chimiques dans les cristaux de $LnAl_3(BO_3)_4$ en faisant appel à la théorie de la liaison chimique dans les cristaux. Les résultats indiquent que les liaisons Ln–O sont ioniques alors que les liaisons B–O possèdent un degré important de covalence. On a fait appel au facteur d'environnement défini par les polarisabilités et la covalence pour prédire les paramètres de Racah. La valeur de la dureté du $YAl_3(BO_3)_4$ qui a été prédite sur la base du modèle de Gao est aussi en accord avec la valeur expérimentale.

Mots-clés : propriétés diélectriques, dureté.

[Traduit par la Rédaction]

Introduction

The huntite-type borate $LnAl_3(BO_3)_4$ was synthesizd by Ballman in 1962 and the structures of $YAl_3(BO_3)_4$, $NdAl_3(BO_3)_4$, and $GdAl_3(BO_3)_4$ were reported.[1] $YAl_3(BO_3)_4$ was found to have excellent nonlinear optical properties and is widely used as a host material for solid laser crystal. The microchip laser emissions from Nd^{3+}-doped $YAl_3(BO_3)_4$ was revealed.[2] Because of their important practical applications as host materials for fluorescence and piezoelectricity materials, they have attracted considerable attention in the past few decades. For optical applications, $LnAl_3(BO_3)_4$ crystals should also possess excellent mechanical properties. The hardness of $YAl_3(BO_3)_4$ crystals is thus measured.[2] However, the effects of bond parameters on their hardness have been not studied. In addition, Racah parameters play an important role in predicting optical properties. In this paper we will employ the dielectric theory of complex structure crystals to calculate their bonding properties, and apply the obtained chemical bond parameters to predict their hardness and Racah parameters.

Theoretical method

A chemical bond theory of complex structure crystals was proposed by Zhang.[3,4] Its crucial step is decomposing the complex crystal into pseudobinary crystals, each containing only one type of chemical bond. For the multibond crystal $A_aB_b\ldots$, the subformula for any kind of chemical bond A–B can be expressed as

$$[1] \qquad \left[\frac{N(\mathrm{B}-\mathrm{A})a}{N_{\mathrm{CA}}}\right]\mathrm{A}\left[\frac{N(\mathrm{A}-\mathrm{B})b}{N_{\mathrm{CB}}}\right]\mathrm{B}$$

where A, B,… represent different elements or different sites of the same element in the crystal formula, a, b,… represent numbers of the corresponding element, N(B – A) represents the number of B ions in the coordination group of the A ion, and N_{CA} represents the nearest coordination number of the A ion. These binary crystals are related to each other, and every binary crystal includes only one type of chemical bond. However, the properties of these pseudobinary crystals are different from those of real binary crystals, although their chemical bond parameters can be calculated in a similar way. According to eq. [1], each type of bond has its corresponding subformula, and the sum of all subformulas equals the crystal formula, which is called the bond-valence equation.

On the analogy of the work of Phillips[5] and Zhang and coworkers,[3,4] the average energy gap E_g^{μ} for every μ bond in the pseudobinary crystals can be separated into homopolar $E_h^{\mu}$and heteropolar C^{μ} parts. The homopolar gap E_h^{μ} can be interpreted as being produced by the symmetric part of the total potential, whereas the ionic or charge-transfer gap C^{μ} results from the effect of the antisymmetric part. The average valence-conduction band gap is give by

$$[2] \qquad (E_g^{\mu})^2 = (E_h^{\mu})^2 + (C^{\mu})^2$$

The ionicity and covalency of any type of chemical bond is defined as follows:

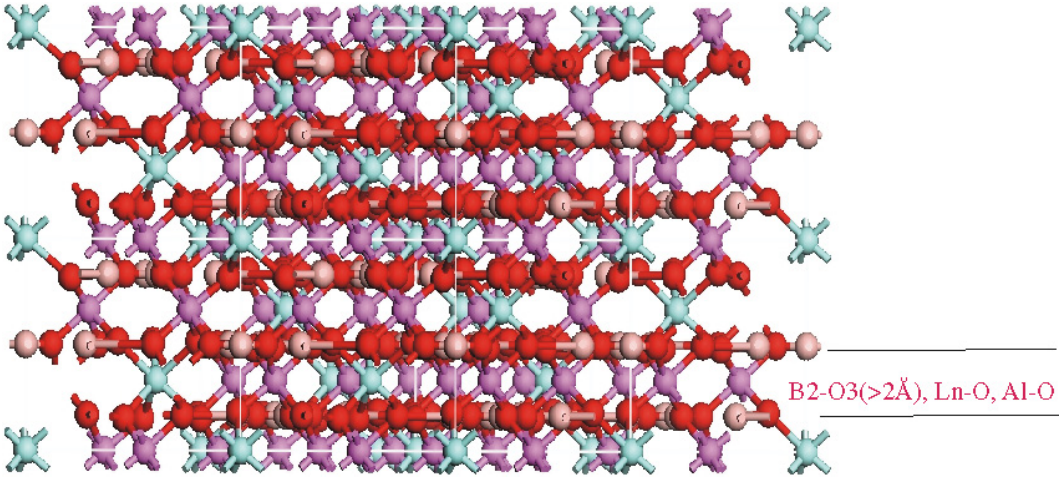
Fig. 1. Crystal structure of $LnAl_3(BO_3)_4$.



[3] $$f_i^{\mu} = (C^{\mu})^2/(E_g^{\mu})^2$$

[4] $$f_c^{\mu}(E_h^{\mu})^2/(E_g^{\mu})^2$$

and

[5] $$E_h^{\mu} = 39.74/(d^{\mu})^{2.48} \quad \text{eV}$$

where d^{μ} is the bond length. For any binary crystal, i.e., AB_n-type compounds, the heteropolar C^{μ} part is defined as

[6] $$C^{\mu} = 14.4b^{\mu}[(Z_A^{\mu})^* + \Delta Z_A^{\mu} - n(Z_B^{\mu})^*]e^{-k_s^{\mu}r_0^{\mu}}/r_0^{\mu} \quad \text{eV}$$

where $r_0^{\mu} = d^{\mu}/2$.

[7] $$k_s^{\mu} = (4k_F^{\mu}/\pi a_B)^{1/2} = 1.551(k_F^{\mu})^{1/2}$$

[8] $$(k_F^{\mu})^3 = 3\pi^2 N_e^{\mu}$$

[9] $$N_e^{\mu} = (n_e^{\mu})^*/v_b^{\mu}$$

[10] $$(n_e^{\mu})^* = [(Z_A^{\mu})^*/N_{CA}^{\mu} + (Z_B^{\mu})^*/N_{CB}^{\mu}]$$

[11] $$v_b^{\mu} = (d^{\mu})^3/\sum_{\nu}[(d^{\nu})^3 N_b^{\nu}]$$

where v_b^{μ} is the bond volume; $(n_e^{\mu})^*$ is the number of effective valence electrons per μ bond; N_e^{μ} is the number of valence electrons of the μ bond per cm^3, k_F^{μ} and k_s^{μ} are the Fermi wave number and the Thomas–Fermi screening wave number of a valence electron in a binary crystal composed of only one type of bond (μ), respectively; a_B is the Bohr radius; n is the ratio of element B to element A in the subformula; $(Z_A^{\mu})^*$ and $(Z_B^{\mu})^*$ are the number of effective valence electrons of the A and B ions, respectively; $(Z_A^{\mu})^* = Q_{AB}^{\mu} \cdot N_{CA}^{\mu}$, $(Z_B^{\mu})^* = [(Q_{AB}^{\mu} \cdot N_{CB}^{\mu})/(8 - Z_B^{\mu})] \cdot Z_B^{\mu}$; Q_{AB}^{μ} is the Pauling bond valence of the A–B bonds, Z_B^{μ} is the number of valence electrons of the B atoms; ΔZ_A^{μ} is a correction factor for the d electrons and the Jahn–Teller effect;[6,7] and b^{μ} is proportional to the square of the average coordination number N_c^{μ}.

[12] $$b^{\mu} = \beta(N_c^{\mu})^2$$

[13] $$N_c^{\mu} = N_{CA}^{\mu}/(1+n) + nN_{CB}^{\mu}/(1+n)$$

where β is a coefficient. The dielectric constant at the long wave limit (ε) can be calculated from the Kramers–Kronig relation for the dielectric function as follows:[8]

[14] $$\varepsilon = \sum_{\mu} F^{\mu}\varepsilon^{\mu}$$

[15] $$\varepsilon^{\mu} = 1 + [(4\pi N_e^{\mu} e^2/m)D^{\mu}/(E_g^{\mu})^2] \times [1 - E_g^{\mu}/4E_F^{\mu} + (E_g^{\mu})^2/48(E_F^{\mu})^2]$$

where ε^{μ} is the low-frequency dielectric constant of a binary crystal composed of only one type of μ bond, D^{μ} is the periodic dependent constant, E_F^{μ} is the Fermi energy, and F^{μ} is the fraction of the binary crystal composing the actual complex crystal.

Results and discussions

The structure of $LnAl_3(BO_3)_4$ is shown in Fig. 1. According to theory,[3,4] the crystal formula of $LnAl_3(BO_3)_4$ can be converted into a subformula equation as follows:

[16] $$LnAl_3(BO_3)_4 = LnO(3)_{3/2} + AlO(1)_2 + AlO(2)_2 + AlO(3)_{3/2} + B(1)O(1)_2 + 3/5B(2)O(2)_{5/3} + 6/5B(2)O(3)_{5/4} + 6/5B(2)O(3)_{3/2}$$

Using the theory mentioned above we can calculate the detailed bond parameters and linear optical susceptibilities of individual bonds of $LnAl_3(BO_3)_4$. The results of these calculations are listed in Table 1. The refractive indices (n_o and n_e) of $YAl_3(BO_3)_4$ are 1.773 and 1.722, respectively.[9] The average dielectric constant of $YAl_3(BO_3)_4$ is $\varepsilon = (1/3\ n_o n + 2/3 n_e)^2 = 3.024$. The calculated dielectric constants of $LnAl_3(BO_3)_4$ agree with their experimental values determined by the refractive index.[9]

Using the calculated chemical bond parameters we can estimate the hardness of these materials. The average hardness $H_{v\ av}$ of complex crystals may be calculated by a geometric

Note: $H_{v\ av}$ is the calculated average Vickers hardness on prisms; B_{calcd} and B_{exp} are the calculated and experimental Racah parameters of Cr^{3+} at the Al site, respectively; ε_{av} and $\varepsilon_{av\ exp.}$ are the calculated and experimental dielectric constants, respectively; $d^{\mu}$is the bond length; v_b^{μ} is the bond volume; N_e^{μ} is the number of valence electrons of the μ bond per cm^3; E_h^{μ} is the homopolar gap; E_g^{μ} is the average energy gap; f_i^{μ} is the ionicity of the bond; $\chi^{\mu} = \varepsilon^{\mu} - 1$, where ε^{μ} is the low-frequency dielectric constant of a binary crystal composed of only one type of μ bond; and h_e is the chemical environmental factor.

average of hardness of the pseudobinary compound composed of a μ-type bond as follows:[10]

$$[17] \qquad H_{v\ av} = [\prod^{\mu}(H_v^{\mu})^{n^{\mu}}]^{1/\Sigma n^{\mu}}$$

$$[18] \qquad H_v^{\mu} = 350(N_e^{\mu})^{2/3}e^{-1.191 f_i^{\mu}}/(d^{\mu})^{2.5}$$

where n^{μ} is the number of bonds of type μ composing the actual complex crystal. From Fig. 1, we may observe the layer structure along the *c* axis in the $LnAl_3(BO_3)_4$ crystal. In these layers, B–O3 (>2Å), Ln–O, and Al–O bonds are contained. Thus, the hardness on prisms should be equal to a geometric average of hardness of the pseudobinary compound $LnO(3)_{3/2}$, $AlO(1)_2$, $AlO(2)_2$, $AlO(3)_{3/2}$, and B(2)O(3) (>2Å). Using eq. [17], the calculated hardness on prisms are listed in Table 1. For $YAl_3(BO_3)_4$, the calculated hardness on prisms is 10.564 GPa, which is in good agreement with the experimental value, 10. 5 GPa.[2]

The room-temperature excitation spectrum of the luminescence of Cr^{3+} in the $YAl_3(BO_3)_4$ single crystal has been used to estimate the crystal-field strength D_q and the Racah parameters *B* and *C*. The crystal-field strength was obtained as $10D_q = 16\,620$ cm^{-1}and $B = 684$ cm^{-1} and $C = 3194$ cm^{-1}.[11] The chemical bond parameters can also be applied to the study on nephelauxetic effect. It is known that the nephelauxetic effect depends on covalency and the polarizabilities of ligands. Jørgensen[12] found that the nephelauxetic effect can be factored into a function of just a ligand and the centre metal:

$$[19] \qquad B/B_0 = 1 - k(\text{centre ion})h_e(\text{ligand})$$

where *B* and B_0 are the Racah parameters of free ions and the ions in crystals, respectively. We introduce the chemical environmental factor(h_e) written as[13]

$$[20] \qquad h_e = \left(\sum_{\mu} \alpha_L{}^{\mu} f_c{}^{\mu}\right)^{1/2}$$

where $\alpha_L{}^{\mu}$ is the polarizability of the ligand in the μ bond.

$$[21] \qquad \alpha_L{}^{\mu} = \{(r_B{}^{\mu})^3/[(r_A{}^{\mu})^3 + (r_B{}^{\mu})^3]\}\alpha_b{}^{\mu}$$

$$[22] \qquad \alpha_b{}^{\mu} = v_b{}^{\mu}(3/4\pi)(\varepsilon^{\mu} - 1)/(\varepsilon^{\mu} + 2)$$

where $r_A{}^{\mu}$ and $r_B{}^{\mu}$ are the effective radii of the A and B ions,[14] respectively; $\alpha_b{}^{\mu}$ is the polarizability of the bond volume in the μth bond. The effect of the centre ion is expressed as[13]

$$[23] \qquad k = [(Z + 2 - S)/5]^2$$

where *Z* is the valence of the ion and *S* is the spin of the electron configuration of the ion. The *k* value of the Cr^{3+} ions is calculated as 0.49. The Racah parameter of the free Cr^{3+} ion (B_0) is 918 cm^{-1}.[15] The h_e for Fe sites in the $YAl_3(BO_3)_4$ crystals iwas obtained using eq. [22]. According to eq. [21], the calculated Racah parameter $B(Cr^{3+}$ at Al site) is 692 cm^{-1}. It is in good agreement with the experimental value, $B = 684$ cm^{-1}.[11]

Conclusion

In conclusion, the detailed chemical bond parameters of $LnAl_3(BO_3)_4$ crystals were calculated using the chemical bond theory of complex crystals. Results indicated that Ln–O bonds are ionic and B–O bonds possess higher covalency. The environment factor defined by electron polarizabilities and covalency was employed to predict Racah parameters. The hardness of $YAl_3(BO_3)_4$ was predicted using the hardness model, which is also in agreement with the experimental value.

Abstract: Ruthenium-catalyzed [2+2] cycloaddition reactions of a 2-oxa-3-azabicyclo[2.2.1]hept-5-ene with unsymmetrical alkynes were investigated. Yields of up to 90% were obtained though regioselectivity was modest. Select cycloadducts could be separated and used to access a highly functionalized [3.2.0] bicyclic structure through reductive cleavage of the N–O bond. These ring-opened products displayed a chemical exchange phenomenon in 1D carbon NMR and required characterization by 2D NMR techniques.

Key words: ruthenium, [2+2] cycloadditions, bicyclic alkene, ring opening, 2-oxa-3-azabicyclo[2.2.1]hept-5-enes.

Résumé : On a étudié des réactions de cycloaddition [2+2] catalysées par le ruthénium du 2-oxa-3-azabicyclo[2,2,1]hept-5-ène avec des alcynes non symétriques. On a obtenu des rendements allant jusqu'à 90 %, même si la régiosélectivité est modeste. Il a été possible de séparer des cycloadduits choisis et de les utiliser pour accéder à une structure bicyclique [3,2,0] hautement fonctionnalisée, en procédant à un clivage réducteur de la liaison N–O. Ces produits d'ouverture de cycles présentent un phénomène d'échange chimique dans la RMN du carbone 1D et leur caractérisation a nécessité l'utilisation de techniques de RMN 2D.

Mots-clés : ruthénium, cycloadditions [2+2], alcène bicyclique, ouverture de cycle, 2-oxa-3-azabicyclo[2.2.1]hept-5-ènes.

[Traduit par la Rédaction]

Introduction

The 2-oxa-3-azabicyclo[2.2.1]heptenes **1** are a group of heterobicyclic alkenes that have been extensively investigated because of their utility as synthetic intermediates. Synthesized through a nitroso hetero-Diels–Alder reaction, these relatively simple cycloadducts provide access to more complex molecular structures.[1] Though rearrangements and other chemical reactions can also occur, heterobicyclic alkene **1** is generally modified in one of four ways (Scheme 1).[2] These four categories consist of cleavage of the N–O bond, cleavage of the C–O bond, cleavage of the N–acyl bond, and modification of the alkene component.

Heterobicyclic alkene **1** is most commonly derivatized through reductive cleavage of the N–O bond to provide amino alcohol **2**. Widely used reagents include molybdenum-hexacarbonyl ($[Mo(CO)_6]$),[3,4] catalytic hydrogenation, zinc in acetic acid, samarium diiodide,[5] and titanocene(III) chloride.[6] Examples that employ enzymatic,[7] photochemical,[8] and other chemical processes to reductively cleave this bond are also present in the literature.[9]

The second area of structural modification of **1** is cleavage of the C–O bond to form compounds **3** and **4**, where the stereochemistry depends on the method used. These methods include acid-catalyzed ring-opening rearrangements,[10] palladium- and Lewis acid-catalyzed ring openings,[11] copper-catalyzed Grignard or organozinc nucleophilic ring-opening reactions;[12] ruthenium-catalyzed ring-opening reactions with alcohols,[13] and rhodium-catalyzed ring-opening reactions with arylboronic acids.[14]

The third category represents hydrolysis of the carbonyl group under mild conditions to yield compound **5**.[15] This allows removal of any chiral auxiliaries used to induce chirality during the acylnitroso hetero-Diels–Alder reaction.

In the final category, it is the alkene component of **1** that is modified to yield structures such as **6** or **7**. A number of transformations have been carried out on the alkene moiety of the related 2-oxa-3-azabicyclo[2.2.1]hept-5-ene system **8** (Scheme 2). Examples include oxidative cleavage to give diacid compound **9**, ring opening cross-metathesis providing compounds **10a** and **10b**,[16] dihydroxylation to yield diol **11**,[17] and alkylidenecyclopropanation resulting in compound **12**.[18] In addition, the dipolar cycloaddition of alkene **8** with organic azides and nitrile oxides provides regioisomeric mixtures **13a**, **13b**, and **14a** and **14b**, respectively.[19]

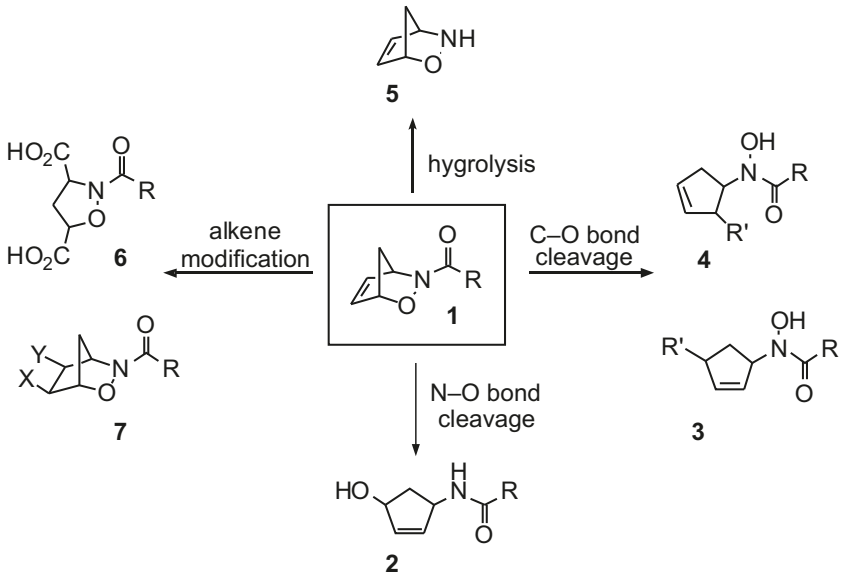
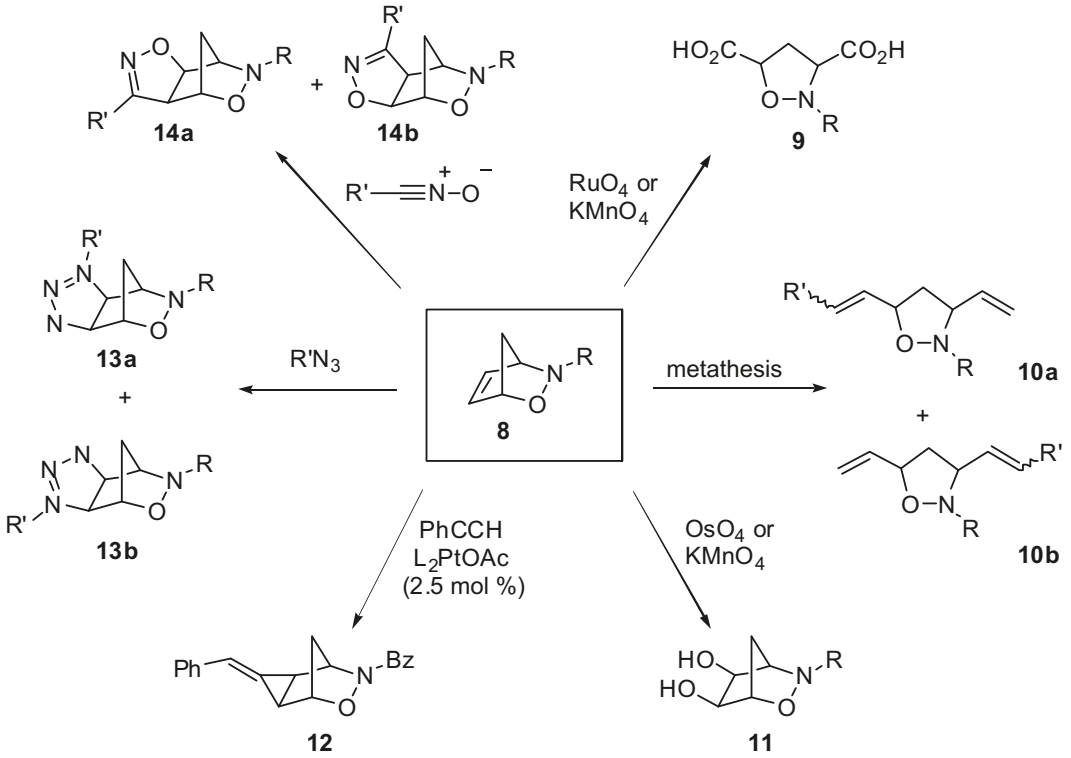
Scheme 1. Modification of 3-aza-2-oxabicyclo[2.2.1]heptanes.



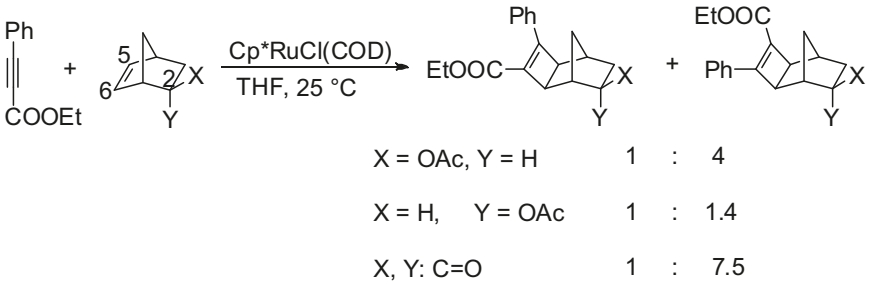
Scheme 2. Chemical transformations involving the alkene component of 3-aza-2-oxabicyclo[2.2.1]hept-5-enes.



Like their heterobicyclic analogues, derivatives of norbornene are involved in a number of chemical transformations. One such example is the ruthenium-catalyzed [2+2] cycloaddition reaction between a bicyclic alkene and an alkyne. The Mitsudo group previously discovered that Cp*Ru(COD)Cl was a successful catalyst for the [2+2] cycloaddition reaction between norbornene derivatives and both aliphatic and aromatic alkynes.[20] Since then several groups have contributed to the knowledge of ruthenium-catalyzed [2+2] cycloadditions. An investigation by the Tam group focused on 2-substituted norbornenes and unsymmetrical alkynes (Scheme 3).[21] The unsymmetrical nature of both reaction partners allowed the regioselectivity of the [2+2] reaction to be studied. A variety of substituents at the C2 position of the norbornenes resulted in regioselectivities ranging from 1.2:1 to 7.5:1. Overall, the exo-2-substituted norbornenes provided higher regioselectivities than the corresponding endo-2-substituted norbornenes. The highest regioselectivites were observed when the substituent at the C2 position possessed an exocyclic double bond such as a ketone.

This and other studies on 2-substituted norbornenes demonstrate that the remote substituents at C2 are exerting an

Scheme 3. An investigation of the remote substituent effects of 2-substituted norbornenes on ruthenium-catalyzed [2+2] cycloadditions.



electronic effect on carbons five and six. It is the bent geometry of norbornene that causes this effect by orienting the orbitals of the alkene and the C2 substituent in such a way that through-space interactions are possible (Scheme 4). When a 2-substituted norbornene possesses a substituent Y, electron delocalization can take place between the filled π (C5–C6) orbital and the empty π* (C2–Y) or σ* (C2–Y). This causes polarization of the C5–C6 bond, which affects the stability of the transition states leading to the two possible regioisomers. If one transition state is more stable than another, one regioisomer may be formed preferentially, resulting in regioselectivity. Computational studies have revealed that an exocyclic double bond at C2 allows for more homoconjugation to occur compared with norbornenes with exo-2-substituents. Furthermore, norbornenes with endo-2-substituents do not provide any significant homoconjugation. The stronger the homoconjugation and electron delocalization, the greater the polarization of the C5–C6 double bond and the greater the effect of the remote substituent. This accounts for the trends previously observed by Tam and co-workers.[21]

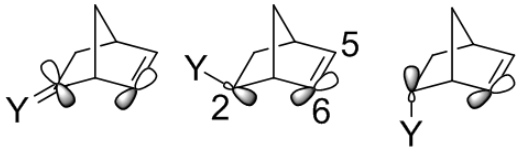
In summary, a multitude of transformations involving 2-oxa-3-azabicyclo[2.2.1]hept-5-enes have been explored. In addition, many examples of ruthenium-catalyzed cycloadditions are present in the literature and investigations into the ruthenium-catalyzed [2+2] cycloadditions of 2-substituted norbornenes have demonstrated trends in regioselectivity. Like these 2-substituted norbornenes, the 2-oxa-3-azabicyclo [2.2.1]hept-5-enes possess an unsymmetrical structure yet no studies into ruthenium-catalyzed cycloaddition reactions have been carried out. The purpose of this paper is to investigate the regioselectivity of ruthenium-catalyzed [2+2] cycloaddition reactions involving 2-oxa-3-azabicyclo[2.2.1]hept-5-enes and various unsymmetrical alkynes.

Results and discussion

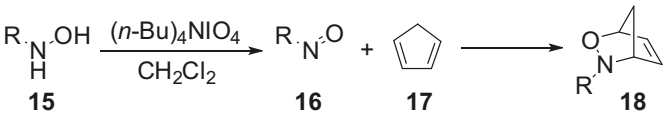
To evaluate the regioselectivity of the [2+2] cycloaddition reaction it was first necessary to synthesize the heterobicyclic alkene as well as the unsymmetrical alkynes. Construction of the 2-oxa-3-azabicyclo[2.2.1]hept-5-enes can be achieved in high yields under oxidizing conditions (Scheme 5).[1] Hydroxyl amine **15** is used to generate nitroso dienophile **16**, which can then undergo a hetero-Diels–Alder reaction with cyclopentadiene **17** to produce the heterobicyclic cycloadduct **18**.

A wide variety of unsymmetrical alkynes were also synthesized to explore the various electronic and steric effects of

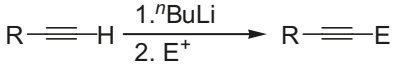
Scheme 4. Orbital interactions of 2-substituted norbornenes.



Scheme 5. Synthesis of 3-aza-2-oxabicyclo[2.2.1]hept-5-enes through a hetero-Diels–Alder reaction.



Scheme 6. General synthesis of the unsymmetrical alkynes.



this component. In general, the alkynes were synthesized by deprotonating the appropriate terminal acetylene and subsequently trapping the resulting anion with the desired electrophile (Scheme 6). For example, 4-methoxyphenyl acetylene can be deprotonated with *n*-BuLi, followed by trapping with ethyl chloroformate to provide ethyl 4-methoxyphenylpropynoate **20c**. This strategy was altered for certain alkynes that could not be synthesized by the previous method. For instance, the construction of the haloacetylene ethyl bromopropiolate **20n** required treatment of ethyl propiolate with *N*-bromosuccinimide and silver nitrate in acetone to yield the desired acetylene.

Once prepared, heterobicyclic alkene **19** was subjected to the different unsymmetrical alkynes in the presence of ruthenium catalyst Cp*Ru(COD)Cl in THF (Table 1). Though all examples displayed modest regioselectivity (ranges from 52:48 to 76:24) of the two exo-cycloadducts, yields ranged from low to high. For the first set of alkynes, one group was fixed as an ethyl ester (R^2 = COOEt) and the other substituent was varied as different aromatic groups (R^1 = Ar) (Table 1, entries 1–9). When this substituent was a methoxyphenyl group (**20a**–**20c**), the highest yield had the methoxy moiety in the meta position (Table 1, entry 2). A similar result was observed when the aromatic substituent possessed a chlorine group (**20d**–**20e**), with *m*-chlorophenyl displaying a higher yield than the corresponding para-substituted group (Table 1, entries 4 and 5). this trend are the tolyl substituents (**20f**–**20g**), with the *m*-tolyl group demonstrating a higher yield than the *p*-tolyl group (Table 1, entries 6 and 7). The trifluoromethylbenzene substituents **20h**–**20i** showed higher yields with the trifluoromethyl group in the meta position (Table 1, entry 8) similar to previous aryl substituents. Although at this stage we do not have a good explanation on why meta-substituted groups always gave the highest yield with the same substituents, several points can be noted. The yields of the cycloadditions of *ortho*-methoxyphenyl-substituted alkyne (**20a**) and *para*-methoxyphenyl-substituted alkyne (**20c**) are similar, however, the *ortho*-methoxyphenyl substituted alkyne (**20a**) took almost four times longer for the reaction to go to completion (456 vs 120 h). The *ortho*-methoxyphenyl-substituted alkyne (**20a**) probably hindered the coordination of the Ru catalyst with the alkyne because of steric effect. Since both the meta and para substituents are farther away from the alkyne, steric factor should not be the one that affected the yields most. Thus, it is likely that meta substituents somehow showed a stronger electronic effect on the alkyne than the para substituents and affected the relative stability of the Ru–metallocycles intermediates, giving higher yields in the cycloadditions of the meta substituents.

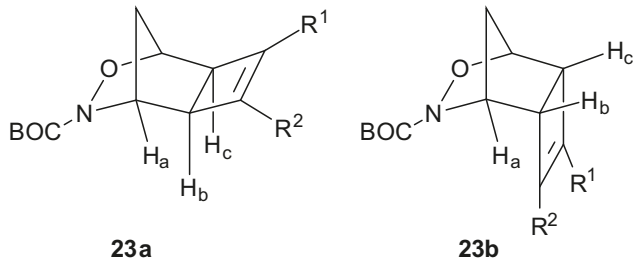
When the R^1 substituent is changed to an alkyl group, higher yields are observed with primary alkyl group **20j** compared with secondary alkyl group **20k** (Table 1, entries 10 and 11). Modest yields are observed when R^1 is a propagylic alcohol (**20l**) or a TBS-protected alcohol (**20m**; Table 1, entries 12 and 13). Haloalkynes and alkynyl sulphides **20n**–**20r** result in yields that are moderate to low (Table 1, entries 14–18).

Fig. 1. exo versus endo cycloadducts.



These ruthenium-catalyzed [2+2] cycloaddition could theoretically produce both exo- and endo-cycloadducts; however, because of the results of previous Tam group studies, only exo products were expected.[21] Using the coupling constant of H_b in the ^{1}H NMR it was possible to verify the exo-isomerism of the cycloadducts (Fig. 1). Computational studies show that the dihedral angle between protons H_a and H_b in an exo-addition product such as **23a** is in the range of 70°–75°.[21] The Karplus curve indicates that this corresponds to a very small coupling constant ($J \sim 0$–2 Hz). Alternatively, an endo-cycloadduct like **23b** would have a dihedral angle on the scale of 35°–40°, resulting in a coupling constant of 6–9 Hz. The cycloadducts synthesized over the course of this investigation did not display any noticeable coupling between H_a and H_b, confirming the presence of exo-cycloadducts.

Though each [2+2] reaction carried out during this study produced two exo-regioisomers, only a few examples had cycloadducts that were separable by column chromatography. Once these regioisomers were physically separated, NMR techniques, including HSQC and HCOSY, were used to

Scheme 7. Ring opening of the [2+2] cycloadducts through reductive cleavage of the N–O bond.

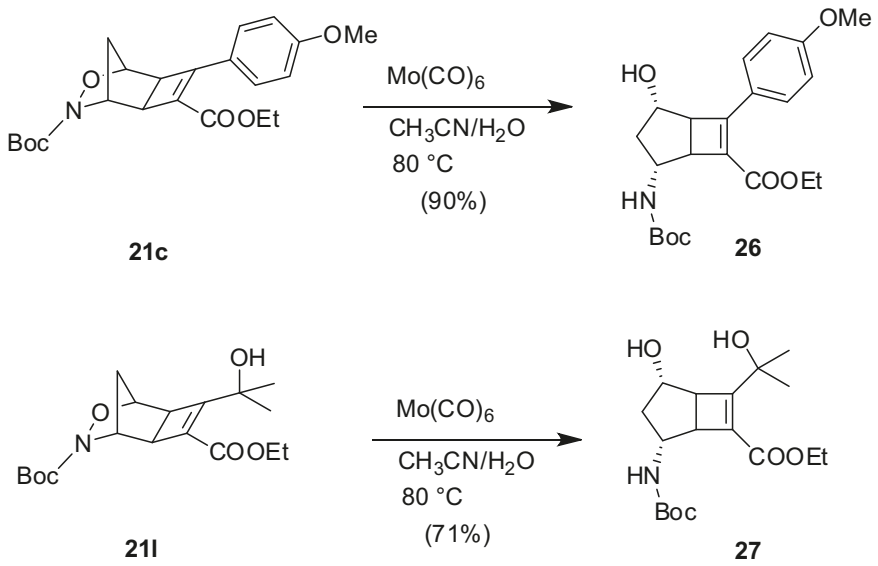

Fig. 2. Using gradient NOESY experiments to distinguish the regioisomers.

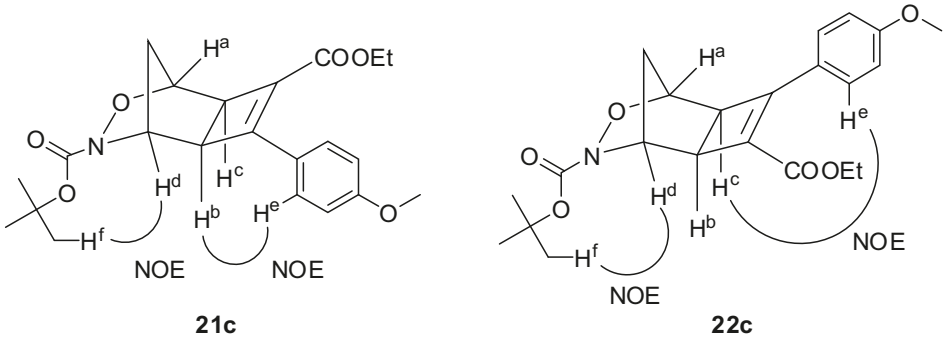
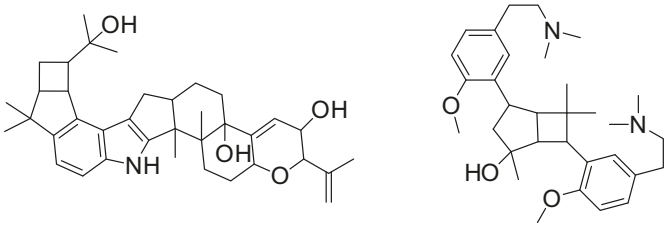


unambiguously identify each proton and carbon. The regioisomers were then distinguished using a gradient NOESY experiment (Fig. 2). In regioisomer **21c**, H_e displays an NOE with H_b, but not with H_c, whereas H_f shows an NOE with H_d, but not with H_a. Compound **22c** proves to be the opposite regioisomer with H_e showing an NOE with H_c, but not with H_b, and H_f displaying an NOE with H_d, and but not with H_a. Although the regioselectivities of the cycloadditions were low, in all cases, cycloadducts **22a**–**22r** were found to be the major regioisomers. This observation matched with our previous studies with 2-substituted norbornenes (Scheme 3).[21] With 2-substituted norbornenes, the major regioisomers formed are the ones with the aromatic group (Ph) syn to the electron-withdrawing group X (or Y) (Scheme 3). Similarly, with 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19**, the major regioisomers **22a**–**22r** formed have the aromatic groups (R^1) syn to the more electronegative atom (oxygen).

Once a [2+2] cycloadduct has been constructed and distinguished from its regioisomer, the product can then be used to synthesize more complex molecules. Ring opening of [2+2] cycloadducts to a [3.2.0] bicyclic structure is one way that these products can be used to access more complex molecular structures. Several natural products have been identified that contain a [3.2.0] heptane skeleton (Fig. 3). PC-M4 (**24**) was isolated from the fungus *Penicillium crustosum* and may

Fig. 3. Natural products containing a [3.2.0] heptane skeleton.



PC-M4 **24** Avicennamine **25**

be a biosynthetic precursor to the penitrems.[22] Also, avicennamine **25**, isolated from the shrub *Zanthoxylum avicennae*, acts as a platelet aggregation inhibitor and a DNA isomerize inhibitor and has antibacterial and cyctotoxic properties.[23]

One of the many transformations previously carried out on the 3-aza-2-oxa-bicyclo[2.2.1]hept-5-ene precursor was a reductive cleavage of the relatively weak N–O bond to form a cyclopentene ring-opened product. A similar reductive cleavage reaction has been applied to select [2+2] cycloadducts, resulting in the formation of highly functionalized [3.2.0] bicyclic ring systems (Scheme 7). Addition products **21c** and **21l** were subjected to molybdenumhexacarbonyl in the presence of an acetonitrile/water mixture providing ring-opened products **26** and **27**, respectively. Cycloadduct **21c** provided

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12

the corresponding [3.2.0] bicycloheptene in a higher yield of 90% compared with cycloadduct **21l** with a yield of 75%. Difficulties were encountered when attempting to characterize these ring-opened products through standard 1D NMR techniques. Several of the expected peaks appeared to be missing from the ^{13}C NMR despite a promising ^{1}H NMR spectrum. This was found to be due to intermediate chemical exchange.[24] The nitrogen atom moves from one rotamer to another, which leads to near coalescence of several ^{13}C lines in the spectrum. Although these peaks are nearly invisible in a 1D experiment, they show up clearly in a 2D correlation spectrum. These 2D experiments involve detection of the protons, whose coupling remains largely unaffected. As result, the 2D NMR techniques HSQC and HMBC were necessary to fully characterize and clearly identify the ring-opened products.

Conclusion

In summary, we have demonstrated the first examples of ruthenium-catalyzed [2+2] cycloaddition reactions of a 2-oxa-3-azabicyclo[2.2.1]hept-5-ene with unsymmetrical alkynes. Reactions in the presence of Cp*Ru(COD)Cl in THF were found to give two regioisomers of the exo-addition product. Low to appreciable yields of the cycloadducts were observed with modest regioselectivies. Ring opening of the addition products to a functionalized [3.2.0] heptene provides the opportunity to access more complex structures from relatively simple precursors.

Experimental

General information

All reactions were carried out in an atmosphere of dry nitrogen at ambient temperature unless otherwise stated. Standard column chromatography was performed on 230–400 mesh silica gel (obtained from Silicycle) using flash column chromatography techniques.[25] Analytical thin-layer chromatography (TLC) was performed on Silicycle-precoated silica gel F_{254} plates. All glassware was oven-dried. Infrared spectra were taken on a Thermo Scientific Nicolet 380 FTIR spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded on Bruker Avance-400 and -600 spectrometers. Chemical shifts for ^{1}H NMR spectra are reported in parts per million (ppm) from tetramethylsilane with the solvent resonance as the internal standard (chloroform: δ 7.26 ppm). Chemical shifts for ^{13}C NMR spectra are reported in parts per million (ppm) from tetramethylsilane with the solvent as the internal standard (deuterochloroform: δ 77.0 ppm). High-resolution mass spectra were done by Mass Spectrometry at Queen's University, Kingston, Ontario.

Reagents

Unless stated otherwise, commercial reagents were used without purification. Solvents were purified by distillation under dry nitrogen from CaH_2 (1,2-dichloroethane, hexanes) and from potassium/benzophenone (THF). Cp*Ru(COD)Cl was bought from Strem Chemicals. Alkynes **20a**–**20r** were prepared according to literature procedures and the NMR spectra obtained matched those found in the literature.[26–31] Alkene **19** was prepared according to previously described procedures.[1]

General procedure for ruthenium-catalyzed [2+2] cycloaddition reactions of 2-oxa-3-azabicyclo[2.2.1]hept-5-enes with unsymmetrical alkynes

2-Oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (0.2–1.7 mmol, 1 equiv) and an unsymmetrical alkyne (1 equiv) were added to separate oven-dried vials. These vials were purged with nitrogen and transferred into a dry box. In the dry box, to a third oven-dried vial, was added Cp*Ru(COD)Cl (3 mol %). THF was added to the vial containing the bicyclic alkene and this was transferred slowly to the vial containing the ruthenium catalyst. Likewise, THF was added to the vial containing the alkyne and this was transferred to the vial containing the Ru–catalyst and bicyclic alkene. The vial was then sealed with a screw cap and removed from the dry box and heated to 65 °C. The crude products were purified by column chromatography (EtOAc–hexanes mixture) and concentrated in vacuo to give the corresponding [2+2] cycloadduct.

Cycloadducts 21a and 22a

Following the above procedure with ethyl 2-methoxyphenylpropynoate **20a** (201.1 mg, 1.02 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (209.0 mg, 1.02 mmol), the reaction was allowed to stir at 65 °C for 456 h. The crude product was purified by column chromatography (gradient of 0%–30% EtOAc in hexanes) to provide cycloadducts **21a** as a colourless viscous oil (94.7 mg, 0.236 mmol, 23%) and **22a** as a pale yellow viscous oil (201.2 mg, 0.501 mmol, 49%).

Cycoadducts 21c and 22c

Following the general procedure with ethyl 4-methoxyphenylpropynoate **20c** (335.4 mg, 1.63 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (326.6 mg, 1.66 mmol), the reaction was allowed to stir at 65 °C for 120 h. The crude product was purified by column chromatography (30% EtOAc in hexanes) to provide cycloadducts **21c** as a pale yellow viscous oil (170.2 mg, 0.424 mmol, 26%) and **22c** as a yellow viscous oil (325.7 mg, 0.811 mmol, 50%). Relative regio- and stereo-chemistry of each isomer was confirmed by various 2D NMR (COSY, HSQC, or HMBC) experiments and a gradient NOESY experiment preformed on a 400 MHZ NMR spectrometer.

Cycloadduct 21c

R_f 0.38 (EtOAc–hexanes, 30:70). IR (neat, NaCl, cm^{-1}): 2977 (m), 1736 (m), 1701 (s), 1603 (s), 1509 (s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 7.99–7.95 (m, 2H), 6.90–6.87 (m, 2H), 4.76–4.75 (m, 1H), 4.23–4.15 (m, 2H), 3.81 (s, 3H), 3.34 (m, 1H), 3.23 (m, 1H), 2.13 (d, 1H, J = 11.4 Hz), 1.69 (d, 1H, J = 11.4 Hz), 1.50 (s, 9H), 1.29 (t, 3H, J = 7.1 Hz). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 162.2, 161.6, 157.2, 155.3, 130.7, 125.9, 124.7, 113.9, 82.2, 77.5, 60.2, 57.3, 55.3, 43.8, 42.9, 30.8, 28.1, 14.2. HREI calcd for $C_{22}H_{27}NO_6$ (M^+): *m/z* 401.1838; found: *m/z* 401.1823.

Cycloadduct 22c

R_f 0.29 (EtOAc–hexanes, 30:70). IR (neat, NaCl, cm^{-1}): 2978 (m), 1737 (m), 1703 (s), 1603 (s), 1509 (s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 7.91 (d, 2H, J = 8.8 Hz), 6.86 (d, 2H, J = 8.9 Hz), 4.73 (m, 1H), 4.59 (s, 1H) 4.22–4.17 (m, 2H), 3.78 (s, 3H), 3.29 (m, 1H), 3.22 (m, 1H), 2.11 (d, 1H, J = 11.4 Hz), 1.65 (d, 1H, J = 11.8 Hz), 1.47 (s, 9H), 1.29 (t, 1H, J = 7.2 Hz). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 162.3, 161.6, 157.3, 155.8, 130.7, 125.5, 124.7, 113.9, 82.0, 76.8, 60.1, 57.9, 55.2, 44.6, 42.5, 30.8, 28.1, 14.2. HREI calcd for $C_{22}H_{27}NO_6$ (M^+): *m/z* 401.1838; found: *m/z* 401.1847.

Cycloadducts 21d and 22d

Following the general procedure with ethyl 3-chlorophenylpropiolate **20d** (42.0 mg, 0.206 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (41.1 mg, 0.209 mmol), the reaction was allowed to stir at 65 °C for 168 h. The crude product was purified by column chromatography (gradient of 15%–40% EtOAc in hexanes) to provide an inseparable mixture (68:32) of cycloadducts as a yellow viscous oil (60.1 mg, 0.148 mmol, 74%). R_f 0.32 (EtOAc–hexanes, 30:70). IR (neat, NaCl, cm^{-1}): 2979 (m), 1736 (m), 1705(s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.04 (m, 1H), 7.81 (d, 0.3H, J = 7.2 Hz), 7.74 (d, 0.7H, J = 7.2 Hz), 7.37–7.30 (m, 2H), 4.78 (m, 1H), 4.63 (s, 0.68H), 4.59 (s, 0.32H), 4.28–4.21 (m, 2H), 3.36 (m, 1H), 3.28 (m, 1H), 2.10 (m, 1H), 1.72 (m, 1H), 1.51–1.50 (m, 9H), 1.36–1.30 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 161.9, 161.8, 157.4, 157.3, 154.3, 153.7, 134.7, 133.2, 130.8, 130.7, 130.4, 129.9, 129.8, 128.8, 128.7, 126.7, 82.5, 82.4, 77.2, 76.6, 60.7, 57.6, 57.2, 44.9, 44.3, 43.2, 43.0, 30.8, 28.2, 14.2. HRESI calcd for $C_{21}H_{24}ClNO_5$ (M + H): *m/z* 406.1421; found: *m/z* 406.1420.

Cycloadducts 21e and 22e

Following the general procedure with ethyl 4-chlorophenylpropynoate **21e** (40.3 mg, 0.19 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (40.5 mg, 0.21 mmol), the reaction was allowed to stir at 65 °C for 120 h. The crude product was purified by column chromatography (20% EtOAc in hexanes) to provide an inseparable mixture (67:33) of cycloadducts as a yellow viscous oil (38.0 mg, 0.0936 mmol, 45%). R_f 0.30 (EtOAc–hexanes, 20:80). IR (neat, NaCl, cm^{-1}): 2979 (s), 2934 (w), 1736 (m), 1706 (s), 1488 (m). ^1H NMR ($CDCl_3$, 400 MHz) δ: 7.94 (d, 0.7H, J = 8.5 Hz), 7.90–7.89 (m, 1.3H), 7.37–7.35 (m, 2H), 4.78 (s, 0.33H), 4.76 (s, 0.67H), 4.63 (s, 0.67H), 4.57 (s, 0.33H), 4.28–4.18 (m, 2H), 3.36 (m, 1H), 3.27 (m, 1H), 2.11 (m, 1H), 1.72 (m, 1H), 1.51–1.50 (m, 9H), 1.34–1.29 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 162.1, 162.0, 157.4, 157.3, 154.8, 154.3, 137.0, 136.9, 130.2, 130.1, 130.0, 129.6, 129.3, 129.0, 82.5, 82.4, 77.3, 76.7, 60.7, 57.7, 57.2, 44.8, 44.3, 43.2, 43.0, 30.9, 28.2, 14.3. HRESI calcd for $C_{21}H_{24}{}^{35}ClNO_5$ $(M + H)^+$: *m/z* 406.1421; found: *m/z* 406.1432.

Cycloadducts 21f and 22f

Following the general procedure with ethyl 3-tolylpropiolate **20f** (191.0 mg, 1.01 mmol) and 2-oxa-3-azabicyclo [2.2.1]hept-5-ene **19** (202.0 mg, 1.03 mmol), the reaction was allowed to stir at 65 °C for 120 h. The crude product was purified by column chromatography (20% EtOAc in hexanes) to provide an inseparable mixture (66:34) of cycloadducts as a pale yellow viscous oil (336.2 mg, 0.873 mmol, 85%). R_f 0.28 (EtOAc–hexanes, 20:80). IR (neat, NaCl, cm^{-1}): 2979 (m), 1739 (m), 1705 (s); ^1H NMR ($CDCl_3$, 400 MHz) δ: 7.76–7.74 (m, 1.34H), 7.67 (d, 0.66H, J = 7.6 Hz), 7.22 (m, 1H), 7.15 (m, 1H), 4.73 (m, 1H), 4.58 (s, 0.66H), 4.55 (0.34H), 4.23–4.13 (m, 2H), 3.32 (m, 1H), 3.21 (m, 1H), 2.31 (s, 3H), 2.08 (m, 1H), 1.65 (m, 1H), 1.46–1.45 (m, 9H), 1.30–1.24 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 162.1, 162.0, 157.3, 157.2, 156.1, 155.6, 138.2, 131.7, 131.6, 129.2, 128.7, 128.5, 128.4, 125.9, 82.2, 82.1, 77.4, 76.8, 60.4, 57.7, 57.3, 44.8, 44.0, 43.1, 42.7, 30.8, 28.1, 21.3, 14.2. HRESI calcd for $C_{22}H_{27}NO_5$ (M^+): *m/z* 385.1889; found: *m/z* 385.1898.

Cycloadducts 21g and 22g

Following the general procedure with ethyl 4-tolylpropiolate **20g** (191.3 mg, 1.02 mmol) and 2-oxa-3-azabicyclo [2.2.1]hept-5-ene **19** (201.9 mg, 1.02 mmol), the reaction was allowed to stir at 65 °C for 96 h. The crude product was purified by column chromatography (gradient of 0%–30% EtOAc in hexanes) to provide an inseparable mixture (65:35) of cycloadducts as a yellow viscous oil (283.2 mg, 0.735 mmol, 74%). R_f 0.29 (EtOAc–hexanes, 20:80). IR (neat, NaCl, cm^{-1}): 2979 (s), 1740 (s), 1704 (s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 7.89–7.83 (m, 2H), 7.20–7.17 (m, 2H), 7.46 (m, 1H), 4.61 (s, 0.65H), 4.57 (s, 0.35H), 4.25–4.19 (m, 2H), 3.35 (m, 1H), 3.24 (m, 1H), 2.35–2.34 (m, 3H), 2.12 (m, 1H), 1.68 (m, 1H), 1.50–1.49 (m, 9H), 1.33–1.28 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 162.2, 162.1, 157.3, 157.2, 156.1, 155.5, 141.4, 129.3, 129.0, 128.8, 128.7, 127.7, 127.4, 82.2, 82.1, 77.4, 76.8, 60.3, 57.8, 57.3, 44.7, 43.9, 43.0, 42.7, 30.8, 28.1, 21.5, 14.2. HRESI calcd for $C_{22}H_{27}NO_5Na$ $(M + Na)^+$: *m/z* 408.1787; found: *m/z* 408.1776.

Cycloadducts 21h and 22h

Following the general procedure with ethyl 3-trifluoromethylphenylpropiolate **20h** (64.2 mg, 0.265 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (52.0 mg, 0.264 mmol), the reaction was allowed to stir at 65 °C for 165 h. The crude product was purified by column chromatography (30% EtOAc in hexanes) to provide an inseparable mixture (69:31) of cycloadducts as a yellow viscous oil (29.4 mg, 0.841 mmol, 32%). R_f 0.44 (EtOAc–hexanes, 30:70). IR (neat, NaCl, cm^{-1}): 2980 (m), 2933 (w), 1736 (m), 1708 (s), 1621 (w), 1335 (s), 1306 (s), 1166 (s), 1129 (s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.33 (m, 1H), 8.10 (d, 0.31H, J = 7.6 Hz), 8.03 (d, 0.69H, J = 7.8 Hz), 7.64 (m, 1H), 7.53 (m, 1H), 4.81 (m, 1H), 4.66 (s, 0.69H), 4.61 (s, 0.31H), 4.30–4.23 (m, 2H), 3.42 (m, 1H), 3.32 (m, 1H), 2.13 (m, 1H), 1.52–1.51 (m, 9H), 1.36–1.31 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 161.9, 161.8, 157.4, 157.2, 154.0, 153.4, 132.2, 131.7, 131.6, 131.4, 131.2, 131.1, 130.9, 129.3, 127.2, 125.6, 82.6, 82.4, 77.1, 76.5, 60.9, 57.5, 57.2, 44.8, 44.4, 43.2, 43.1, 30.9, 28.2, 14.2, 14.1. HREI calcd for $C_{22}H_{24}F_3NO_5$ (M^+): *m/z* 439.1607; found: *m/z* 439.1619.

Cycloadducts 21i and 22i

Following the general procedure with ethyl 4-trifluoromethylphenylpropiolate **20i** (134.8 mg, 0.682 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (152.3 mg, 0.629 mmol), the reaction was allowed to stir at 65 °C for 120 h. The crude product was purified by column chromatography (20% EtOAc in hexanes) to provide an inseparable mixture (68:32) of cycloadducts as a pale yellow viscous oil (74.5 mg, 0.170 mmol, 27%). R_f 0.28 (EtOAc–hexanes, 20:80). IR (neat, NaCl, cm^{-1}): 2981 (m), 1741 (s), 1710 (s), 1614 (m). ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.11–8.04 (m, 2H), 7.65–7.63 (m, 2H), 4.79 (m, 1H), 4.65 (m, 0.68H), 4.60 (br s, 0.32H), 4.29–4.20 (m, 2H), 3.41 (m, 1H), 3.31 (m, 1H), 2.11 (m, 1H), 1.73 (m, 1H), 1.51–1.50 (m, 9H), 1.35–1.30 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 161.8, 161.7, 157.4, 157.2, 154.2, 153.7, 134.6, 132.3, 131.9, 131.6, 129.0, 125.6, 82.5, 82.4, 77.1, 76.5, 60.8, 57.5, 57.1, 44.9, 44.5, 43.3, 43.2, 30.8, 28.2, 14.2. HRESI calcd for $C_{22}H_{24}F_3NO_5Na$ $(M + Na)^+$: *m/z* 462.1504; found: *m/z* 462.1523.

Cycloadducts 21j and 22j

Following the general procedure with ethyl 2-heptynoate **20j** (30.6 mg, 0.198 mmol) and 2-oxa-3-azabicyclo[2.2.1] hept-5-ene **19** (39.7 mg, 0.202 mmol), the reaction was allowed to stir at 65 °C for 144 h. The crude product was purified by column chromatography (30% EtOAc in hexanes) to provide an inseparable mixture (63:37) of cycloadducts as a yellow viscous oil (48.5 mg, 0.1304 mmol, 65%). R_f 0.43 (EtOAc–hexanes, 30:70). IR (neat, NaCl, cm^{-1}): 2962 (m), 1712 (s), 1455(w), 1161 (s). ^1H NMR ($CDCl_3$, 400 MHz) δ: 4.70 (m, 0.37H), 4.59 (m, 0.63H), 4.54 (m, 0.63H), 4.41 (m, 0.37H), 4.17–4.10 (m, 2H), 3.11 (m, 1H), 2.96 (m, 1H), 2.47–2.28 (m, 2H), 2.08 (m, 1H), 1.65 (m, 1H), 1.47 (m, 9H), 1.45–1.22 (m, 7H), 0.91–0.86 (m, 3H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 164.3, 163.7, 162.1, 157.4, 157.3, 131.8, 131.3, 82.2, 82.1, 77.2, 76.4, 76.3, 60.0, 57.6, 57.5, 56.8, 46.6, 44.9, 44.2, 42.9, 30.8, 30.7, 29.1, 28.8, 28.2, 22.7. HRESI calcd for $C_{19}H_{29}NO_5$ (M + H): *m/z* 352.2124; found: *m/z* 352.2140.

Cycloadducts 21k and 22k

Following the general procedure with ethyl cyclohexanepropynoate **20k** (181.3 mg, 1.01 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (203.7 mg, 1.03 mmol), the reaction was allowed to stir at 65 °C for 144 h. The crude product was purified by column chromatography (20% EtOAc in hexanes) to provide an inseparable mixture (67:33) of cycloadducts as a yellow viscous oil (104.6 mg, 0.277 mmol, 27%). R_f 0.31 (EtOAc–hexanes, 20:80). IR (neat, NaCl, cm^{-1}): 2978 (m), 2929 (s), 2853 (m), 1740 (m), 1712(s), 1646 (w), 1449 (m), 1335 (m), 1162 (m). ^1H NMR ($CDCl_3$, 400 MHz) δ: 4.65 (s, 0.33H), 4.56 (s, 0.67H), 4.49 (s, 0.67H), 4.40 (s, 0.33H), 4.14–4.07 (m, 2H), 3.04 (m, 1H), 2.96 (m, 1H), 2.74–2.69 (m, 1H), 2.10–2.07 (m, 1H), 1.68–1.58 (m, 6H), 1.45–1.44 (m, 9H), 1.28–1.01 (m, 8H). ^{13}C NMR (APT, $CDCl_3$, 100 MHz) δ: 168.2, 167.6, 162,0, 157.3, 157.2, 129.9, 129.4, 82.1, 82.0, 77.0, 76.6, 59.9, 57.4, 57.1, 45.3, 43.8, 43.6, 42.5, 38.6, 38.4, 30.6, 30.5, 30.3, 30.2, 30.1, 28.1, 25.6, 25.5, 25.4, 14.2. HRESI calcd for $C_{21}H_{31}NO_5$ (M^+): *m/z* 377.2202; found: *m/z* 377.2210.

Cycloadducts 21l and 22l

Following the general procedure with 4-hydroxy-4-methyl-2-pentynoic acid ethyl ester **20l** (62.3 mg, 0.399 mmol) and 2-oxa-3-azabicyclo[2.2.1]hept-5-ene **19** (80.3 mg, 0.408 mmol), the reaction was allowed to stir at 65 °C for 144 h. The crude product was purified by column chromatography (gradient of 5%–50% EtOAc in hexanes) to provide cycloadducts **21l** as a pale yellow viscous oil (27.5 mg, 0.0778 mmol, 19%) and **22l** as a pale yellow viscous oil (39.7 mg, 0.1123 mmol, 28%). Relative regio- and stereo-chemistry of each isomer was confirmed by various 2D NMR (COSY, HSQC, HMBC) experiments and a gradient NOESY experiment preformed on a 400 MHZ NMR spectrometer.

General procedure for oxidative ring-opening reactions of the [2+2] cycloadducts

A [2+2] cycloadduct (0.1–0.3 mmol, 1 equiv) was added to an oven-dried vial and dissolved in an acetonitrile/water mixture (94:6). $Mo(CO)_6$ (0.2–0.4 mmol, 1.1 equiv) was then added to the reaction vial. The mixture was heated to 80 °C. The crude products were purified by column chromatography (EtOAc–hexanes mixture) and concentrated in vacuo to give the corresponding [3.2.0] bicyclic product.

Ring-opened product 26

Following the above procedure with cycloadduct **21c** (131.9 mg, 0.328 mmol) and $Mo(CO)_6$ (96.2 mg, 0.364 mmol), the reaction was refluxed at 80 °C for 5 h. The crude product was purified by column chromatography (50% EtOAc in hexanes) to provide a [3.2.0] bicyclic product **26** as a pale yellow viscous oil (118.8 mg, 0.294 mmol, 90%). R_f 0.23 (EtOAc–hexanes, 50:50). IR (neat, NaCl, cm^{-1}): 3409 (br, s), 2977 (s), 1693 (s), 1603 (m), 1510 (s), 1257 (m), 1211 (m), 1176 (m). ^1H NMR ($CDCl_3$, 600 MHz) δ: 8.00 (d, 2H, J = 8.6 Hz), 6.86 (d, 2H, J = 8.6 Hz), 5.56 (br s, 1H), 4.37 (s, 1H), 4.25–4.20 (m, 3H), 3.79 (s, 3H), 3.47 (m, 1H), 3.36 (m, 1H), 2.77 (br s, 0.5H), 2.14 (br s, 1H), 1.82 (d, 1H, J = 14.7 Hz), 1.44 (s, 9H), 1.32 (t, 3H, J = 7.0 Hz). ^{13}C NMR (APT, $CDCl_3$, 150 MHz) δ: 162.9, 161.2, 158.8, 155.6, 130.9, 126.4, 124.9, 113.8, 79.5, 71.7, 60.1, 55.3, 52.3, 51.0, 50.1, 38.5, 28.5, 14.4. Synthesis of an iridium porphyrin amido complex

Jenkins Yin Ki Tsang and Kin Shing Chan

Abstract: A synthetic route for iridium porphyrin amido complexes has been established. Treatment of a THF solution of Ir(ttp)(CO)Cl (**1**) (ttp = 5,10,15,20-tetrakis(*p*-tolyl)porphyrinato dianion) with an aqueous mixture of NaOH and $NaBH_4$, followed by 2-iodoethanol leads to the clean formation of the β-hydroxyethyl complex Ir(ttp)(C_2H_4OH) (**2**) in 92% yield. Heating a pyridine solution of complex **2** in the presence of ca. 5–10 equiv. of phthalimide ($HNC_8H_4O_2$; HPhth) leads to the formation of Ir(ttp)(C_5H_5N)(CH_2CH_2Phth) (**3**). The replacement of pyridine by THF as the reaction solvent leads to the formation of the THF adduct Ir(ttp)(THF)(Phth) (**4**), which has been characterized spectroscopically. Heating a solution of **4** in pyridine leads to the formation of Ir(ttp)(C_5H_5N)(Phth) (**5**), which has been isolated in 72% yield. Complexes **3** and **5** have been characterized by X-ray crystallographic studies. Complexes **4** and **5** are rare examples of monomeric late transition metal-amido complexes and are the first examples of iridium-amido complexes featuring a porphyrin as a supporting ligand.

Key words: porphyrin, iridium amido, phthalimide.

Résumé : On a développé une méthode de synthèse pour les complexes iridium/porphyrine amido. Le traitement d'une solution de Ir(ttp)(CO)Cl (**1**) (ttp = dianion 5,10,15,20-tétrakis(*p*-tolyl)porphyrinato) dans du THF par un mélange aqueux de NaOH et de $NaBH_4$, suivi d'une réaction avec le 2-iodoéthanol conduit à une formation propre du complexe β-hydroxyéthyle Ir(ttp)(CH_2CH_2OH) (**2**) avec un rendement de 92 %. Le chauffage du composé **2**, en solution dans la pyridine, en présence d'environ 5 à 10 équivalents de phtalimide [[$C_6H_4(C{=}O)_2NH$], PhthH] conduit à la formation du Ir(ttp)(C_5H_5N) CH_2CH_2Phth (**3**). Le remplacement de la pyridine par du THF comme solvant conduit à la formation de l'adduit Ir(ttp)(THF)Phth (**4**) qui a été caractérisé par des méthodes spectroscopiques. Le chauffage d'une solution du composé **4** dans de la pyridine conduit à la formation du complexe Ir(ttp)(C_5H_5N)Phth (**4**) qui a été isolé avec un rendement de 72 %. Les complexes **3** et **5** ont été caractérisés par des études de diffraction des rayons-X. Les complexes **4** et **5** correspondent à de rares exemples de complexes monomères amido d'un métal de la fin de la période de transition et ce sont les premiers exemples de complexes iridium-amido comportant une porphyrine comme ligand support.

Mots-clés : porphyrine, iridium-amido, phtalimide.

Introduction

Transition metal-nitrogen covalently-bonded species are an interesting and important class of complexes.[1] They have been observed as key precursors and intermediates during important catalytic processes, such as amination of organic substrates,[2] hydroamination of olefins,[3] transfer hydrogenation,[4] amine dehydrogenation,[5] and ammoxidation.[6] In addition, metal-amidos can also effect nontrivial stoichiometric transformations such as C–H activation.[7] Late transition metal-amidos are by far less common than their early transition metal counterparts.[8] This is often rationalized by the hard-soft-acid-base theory, that hard amido or alkoxo ligands do not form strong bonds with late transition metals, which are generally considered soft. More specifically, there exists considerable electron repulsion between the filled dπ orbitals of the late transition metal and the pπ electrons of the amido ligand.[9] As a result, late transition metal-amidos are often reactive species that feature highly nucleophilic nitrogen atoms,[10] and the metal-nitrogen bonds often participate in amido exchange[11] or insertion chemistry.[10c,12] In addition, just like alkyl ligands, amido ligands are prone to undergo β-elimination.[13] Finally, amido ligands can also reductively eliminate in the presence of other suitable ligands.[14]

Our group has been researching carbon-hydrogen bond activation chemistry with iridium-porphyrin complexes to yield iridium porphyrin alkyls and acyls.[15] We have only once reported an Ir-phenoxide complex[16] but have never identified or isolated any Ir-N covalently-bonded species. This phenomenon is best explained by thermodynamics that late transition metal-carbon (alkyl or aryl) bonds are often stronger (by at least 20 kcal/mol) than the isoelectronic amido M–N bonds (1 cal = 4.184 J).[17]

Results and discussion

Our research group has attempted to construct iridium-nitrogen covalent bonds using the conventional metathesis reactions by treatment of the iridium-chloro species Ir(ttp)(CO)Cl[15] (**1**; ttp = 5,10,15,20-tetrakis(*p*-tolylporphyrinato

dianion; Fig. 1) with freshly-prepared lithium anilide, lithium diethylamide, or potassium phthalimide ($KC_8H_4NO_2$; KPhth). Disappointingly, these reactions only yielded mixtures of unidentifiable porphyrin-containing products without the incorporation of the amide onto the metal.

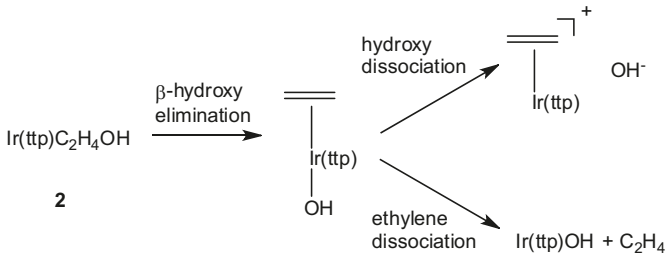
With complex **1** failing to serve as a viable source of a cationic iridium precursor for the synthesis of Ir-amidos, we decided to seek alternatives. Treatment of a THF solution of complex **1** with an aqueous solution of excess $NaBH_4$ in the presence of NaOH at 70 °C, followed by a slight excess of 2-iodoethanol, led to the formation of the β-hydroxyethyl complex Ir(ttp)(C_2H_4OH) (**2**) as a maroon solid in 92% yield (eq. [1]). The ^{1}H NMR spectrum of **2** closely resembles those of our recently reported rhodium complex Rh(ttp)(C_2H_4OH),[18] which has been demonstrated to be a precursor for the masked Rh(ttp)$^+$ cation after undergoing β-hydroxy elimination (Scheme 1).[18,19] Complex **2** is also closely related to a series of complexes with the general formula Rh(tpp)(CH_2CHROH) (tpp = 5,10,15,20-tetraphenylporphyrinato dianion), reported by Sanford et. al.,[20] as these complexes were synthesized via the reaction between the rhodium-porphyrin anion Rh(tpp)$^-$ and various epoxides.

[1] *IND, r, lf*) = ″ : 1 :: .v11 − 126eq1.gif″

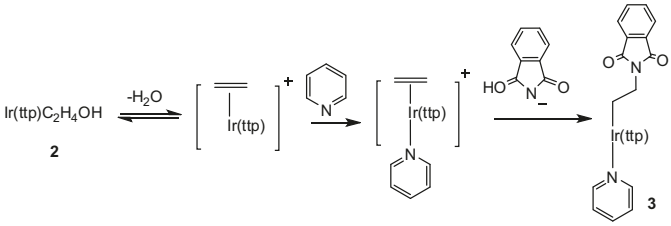
Phthalimide ($HNC_8H_4O_2$; HPhth; Fig. 1) is deemed a good initial candidate as an amido precursor, because (*i*) it is quite acidic, with the pK_a of the N–H of ca. 8, a desirable feature, as the successful incorporation of the amido ligand would require the loss of this proton and (*ii*) the nitrogen lone pair is delocalized in the bicyclic aromatic system, thereby greatly reducing possible dπ–pπ electron repulsion in the target Ir-phthalimido complex.

Heating a pyridine solution of **2** in an excess (10 equiv.) of phthalimide led to formation of a new porphyrin-containing species Ir(ttp)(C_5H_5N)(CH_2CH_2Phth) (**3**) in good yields (80%, eq. [2], as evidenced by a single new β-pyrrole proton signal at 8.50 ppm). Phthalimide has been deprotonated and symmetrically incorporated onto the final product, as indicated by a pair of 2-proton doublet of doublets at 7.07 and 7.16 ppm, respectively, attributable to the two different types of aryl protons. These signals have been shifted upfield from 7.77 and 7.87 ppm of free phthalimide. The presence of coordinated pyridine is indicated also by characteristic upfield-shifted signals. Intriguingly, in addition to these expected phthalimido and pyridine signals, two sets of 2-proton multiplets appear at –6.06 and –2.19 ppm, respectively. These signals suggest that the ethylene moiety is still present in

Scheme 1. Possible reaction pathways initiated by **2**.



Scheme 2. Proposed mechanism for the formation of **3**.



this product. Purification of this new product was achieved by chromatography on Alumina, resulting in the isolation of a red-purple powder after solvent removal. Dark-red needle-shaped single crystals were obtained by slow diffusion of layered hexanes into a concentrated CH_2Cl_2 solution. An X-ray crystallographic analysis confirms the atom connectivity in **3**, as deduced from NMR spectroscopic data (Fig. 2). Table 1 lists the crystal data and collection parameters. Regrettably, the quality of the X-ray data precludes any meaningful discussion of metrical parameters of **3**. Nevertheless, the X-ray data indicate that the ethylene moiety has been retained. A possible explanation for the formation of **3** is the nucleophilic attack by phthalimido anion on the bound ethylene (Scheme 2).[12,18,19b,21] Consistent with previous related findings, compound **3** is thermally stable and does not undergo β-elimination,[22] with the crude reaction mixture remaining unchanged upon heating for a further 3 days at 150 °C.

[2] *IND, r, lf*) = ″ : 1 :: .v11 − 126eq2.gif″

We next employed THF, a polar aprotic but less coordinating solvent than pyridine. We reasoned that a weaker σ-donor opposite to the Ir-ethylene bond would weaken the synergic interaction between the metal and the π-acceptor,[23] thereby rendering the ethylene more prone to dissociation to allow preferred nucleophilic attack on the iridium centre rather than the carbon atom. Heating a THF solution of **2** in phthalimide at 150 °C cleanly yielded a single porphyrin-containing product. Pleasingly, the ^{1}H NMR spectrum of the crude product strongly suggests the exclusive formation of Ir(ttp)(THF)(Phth) (**4**) (eq. [3]). Specifically, phthalimide has been deprotonated and symmetrically incorporated, likely directly onto the metal center, as the aryl proton resonances now appear at 6.14 and 6.51 ppm, respectively, and are further upfield-shifted compared with the corresponding signals in complex **3**. The presence of coordinated THF is indicated by distinctive upfield signals at –2.33 and –0.70 ppm, respectively. Furthermore, no ethylene signals are present in the ^{1}H

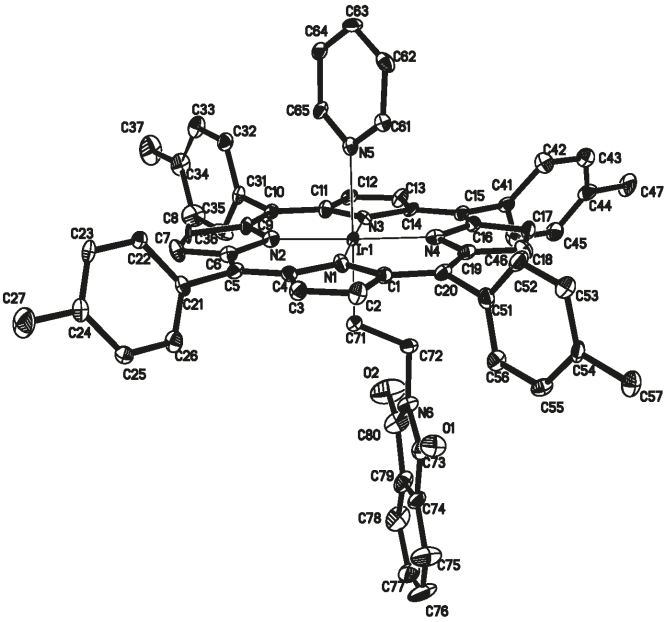
Fig. 2. Solid-state molecular structure of 3 with 50% thermal ellipsoids shown. Hydrogen atoms are omitted for clarity.



NMR spectrum of **3**. Unfortunately, the physical separation between **4** and the excess phthalimide proved to be problematic. Extraction with CH_2Cl_2–hexanes was unsatisfactory, washing with warm water led to the partial decomposition of **4** with the concomitant formation of new porphyrin-containing species, and chromatography on Alumina or silica yielded decomposition products.

[3] *IND, r, lf*) = ″ : 1 :: .v11 − 126eq3.gif″

Fortunately, under thermal conditions the THF ligand can be displaced by other ligands that yield more robust complexes. Thus, heating the crude mixture of **4** and phthalimide in neat pyridine at 100 °C for 15 h led to quantitative formation of Ir(ttp)(C_5H_5N)(Phth) (**5**), which was isolated in 78% yield as a red microcrystalline solid after chromatography on Alumina (eq. [4]). Single rod-shaped crystals were obtained from a CH_2Cl_2–hexanes bilayer, and an X-ray diffraction study confirmed the proposed structure for **5** (Fig. 3, Table 1). The distance between iridium and the phthalimido-N (Ir(1)–N(5)) is 2.083(2) Å, comparable to the iridium-pyridine distance (Ir(1)–N(6)) of 2.084(2) Å. The similarity between Ir–N covalent versus coordination bond distances has also been observed in a few other reported systems[11c,24] and could suggest low multiple-bond character between iridium and phthalimido. To our knowledge, complex **5** is the first example of an iridium porphyrin amido complex, whose structure has been studied by X-ray crystallography.

[4] *IND, r, lf*) = ″ : 1 :: .v11 − 126eq4.gif″

In conclusion, we have shown that the β-hydroxyethyl complex Ir(ttp)(C_2H_4OH) (**2**) can serve as a precursor towards novel iridium-nitrogen covalently bound species. We are currently exploring the scope of this reaction and examining the reactivity of **4** and **5**.

Experimental

General

Unless otherwise noted, all reagents were purchased from commercial suppliers and directly used without further purification. Hexanes were distilled from anhydrous $CaCl_2$. THF was distilled from sodium benzophenone ketyl. $CDCl_3$, used in the preparation of NMR samples, was distilled from CaH_2. Ir(ttp)Cl(CO) (**1**) was prepared according to the literature procedures.[15] Neutral Alumina (Merck, 70–230 mesh) / H_2O (10:1 *v*/*v*) was used for column chromatography.

NMR spectra were recorded at room temperature (RT) on Bruker DPX-300 or AV-400 spectrometers. ^{1}H NMR spectra are referenced to the residual protio isotopomer present in $CDCl_3$ (δ = 7.26 ppm) and ^{13}C NMR spectra are referenced to the natural-abundance carbon signal of the same solvent (δ = 77.23 ppm). Chemical shifts (δ) are reported as part per million (ppm) in (δ) scale downfield from TMS. Coupling constants (*J*) were reported in Hertz (Hz). High-resolution mass spectra (HRMS) were performed on a ThermoFinnigan MAT 95 XL mass spectrometer in fast atom bombardment (FAB) mode using 3-nitrobenzyl alcohol (NBA) matrix and CH_2Cl_2 as solvent or electrospray ionization (ESI) mode using MeOH:CH_2Cl_2 (1:1) as solvent.

Single X-ray crystal data were collected at 293 K using a Bruker AXS Kappa ApexII Duo diffractomter with Mo Kα radiation (λ = 0.71073 Å). Data collection and reduction were performed using ApexII software. Empirical multiscan absorption correction was applied. Structures were solved by direct method and refined by full-matrix least-squares on F^2, using the SHELXTL program package. The presence of solvent accessible void was corrected by Platon/Squeeze program. Riding refinement was used for hydrogen treatment.

Preparation of Ir(ttp)C_2H_4OH (2)

A 250-mL sealable round-bottomed flask, equipped with a Rotaflo valve, was charged with Ir(ttp)(CO)Cl (46.2 mg, 50.0 mmol) and THF (50 mL). A 10 mL Schlenk tube was charged with aqueous NaOH (1 mol/L, 3 mL) and $NaBH_4$ (20.0 mg, 529 mmol). The two solutions were degassed separately for 15 min. The $NaBH_4$/NaOH solution was added to the solution of **1** using a cannula. The resulting mixture was sealed and heated to 70 °C for 2 h, after which a color change from red to dark orange-brown was observed. The reaction mixture was cooled to RT, and 2-iodoethanol (100 mg, 581 mmol) was added via a micropipette. The mixture was stirred for 15 h at RT, after which the color of the mixture did not change significantly. Solvents were removed in vacuo and the residue was washed with water, leaving behind Ir(ttp)(C_2H_4OH) (**2**) as a maroon solid. Compound **2** was further purified by chromatography on Alumina, eluting with CH_2Cl_2/hexanes (1:1). Yield 41.7 mg (92%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: –5.32 (t, $^3J_{HH}$ = 7.2, 2H, IrCH_2CH$_2$OH), –2.49 (t, $^3J_{HH}$ = 6.0, 1H, OH), –2.20 (m, 2H, IrCH$_2$CH_2OH), 2.69 (s, 12H, CH_3), 7.53 (m, 8H, Ar H), 7.97 (d, $^3J_{HH}$ = 7.2, 4H, Ar H), 8.02 (d, $^3J_{HH}$ = 8.4, 4H, Ar H), 8.54 (s, 8H, β-pyrrole H).

Table 1. Crystal data and summary of data collection and refinement for **3** and **5**.

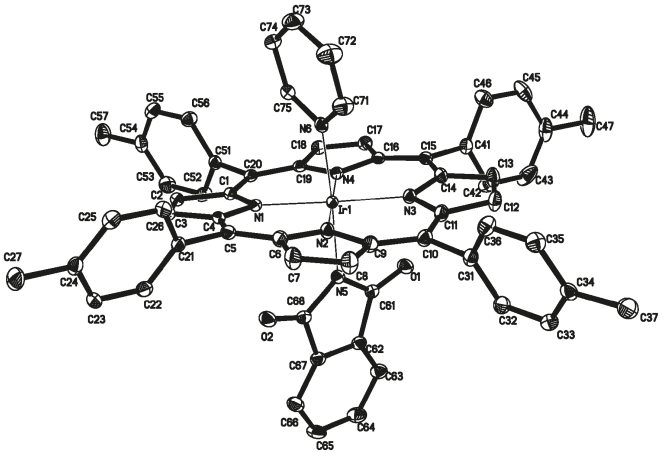
Param	**3**	**5**
Color, shape	Red needles	Red rods
Formula	$C_{63}H_{49}N_6O_2Ir$	$C_{61}H_{45}N_6O_2Ir$
Crystal size (mm)	0.40 × 0.30 × 0.20	0.40 × 0.30 × 0.20
Formula weight	1114.28	1086.23
Crystal system	triclinic	monoclinic
Space group	*P*-1	*P*2(1)/*c*
A (Å)	11.260 (2)	11.1705 (9)
B (Å)	13.461 (3)	17.3969 (14)
C (Å)	18.521 (4)	24.3961 (11)
A (°)	89.035 (4)	90
B (°)	73.592 (4)	100.4430 (10)
Y (°)	81.450 (4)	90
V (Å^3)	2662.0 (10)	4662.4 (6)
Z	2	4
D_{calcd} (Mg/m^3)	1.390	1.547
Radiation (λ) (Å)	0.71073	0.71073
θ range (°)	1.53–25.00	1.85–25.00
F(000)	1124	2184
Reflections collected	29460	32806
Independent reflections	8540	8217
Data, restraints, parameters	8540, 0, 649	8217, 0, 631
Goodness of fit	1.186	1.088
Final R_1[a] , wR_2[b] [$I > 2\sigma(I)$]	0.0735, 0.1778	0.0208, 0.0511
Final R_1[a] , wR_2[b] (all data)	0.0829, 0.1809	0.0273, 0.0565
w_1, w_2[c]	0.0000, 78.186	0.0259, 5.1729

[a] $R_1 = \sum(||F_0| - |F_c||)/\sum|F_0|$.

[b] $wR_2 = \{\sum[w(F_0^2 - F_c^2)^2]/\sum[w(F_0^2)^2]\}^{1/2}$.

[c] Weighting scheme $w^{-1} = \sigma^2(F_0^2) + (w_1P)^2 + w_2P$ where $P = (F_0^2 + 2F_c^2)/3$.

Fig. 3. Solid-state molecular structure of **5** with 50% thermal ellipsoids shown. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (º): Ir(1)–N(5) 2.083(2), Ir(1)–N(6) 2.084 (2), N(5)–C(61) 1.394(4), N(5)–C(68) 1.398(4), N(5)–Ir(1)–N(6) 176.51(9), C(61)–N(5)–C(68) 109.2(2), C(61)–N(5)–Ir(1) 125.75 (18), C(68)–N(5)–Ir(1) 124.69(18).



HRMS (FABMS) calcd. for $[C_{50}H_{41}N_4OIr]^+$: *m*/*z* 906.2904; found: *m*/*z* 906.2912.

Preparation of Ir(ttp)(C_5H_5N)($CH_2CH_2NC_4H_8O_2$) (3)

A glass tube equipped with a Rotaflo valve was charged with **2** (10.0 mg, 11.0 mmol), phthalimide (18.0 mg, 122 mmol), and pyridine (2 mL). The mixture was subjected to three freeze-pump-thaw cycles before being heated to 150 °C for 15 h, as the color changed from red-brown to red. Pyridine was removed in vacuo, and the mixture was analyzed by NMR spectroscopy. Hexanes were added to the $CDCl_3$ sample, and the solution was loaded onto an Alumina column, after which the column was eluted with CH_2Cl_2/hexanes (1:1). The major fraction was collected. Solvents were removed in vacuo, resulting in the deposition of **3** as a red microcrystalline powder. Yield 9.8 mg (80%). Single needle-shaped crystals suitable for X-ray crystallography were obtained from a CH_2Cl_2–hexanes bilayer. ^{1}H NMR (400 MHz, $CDCl_3$) δ: –6.06 (m, 2H, Ir$CH_2$$CH_2$), –2.19 (m, 2H, Ir$CH_2$$CH_2$), 2.18 (br d, 2H, py ortho H), 2.66 (s, 12H, CH_3), 5.31 (t, 7.53 (m, $^3J_{HH}$ = 7.2, 2H, py meta H), 6.17 (t, $^3J_{HH}$ = 7.6, 2H, py para H), 7.07 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H), 7.16 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H) 7.48 (m, 8H, Ar H), 7.97 (d, $^3J_{HH}$ = 7.2, 4H, Ar H), 8.05 (d, $^3J_{HH}$ = 7.6, 4H, Ar H), 8.50 (s, 8H, β-pyrrole H). ^{13}C NMR (100 MHz, $CDCl_3$) δ. HRMS (FABMS) calcd. for $[C_{63}H_{49}N_6O_2Ir - C_5H_5N]^+$: *m*/*z* 1035.3119; found: *m*/*z* 1035.3130.

Preparation of Ir(ttp)(C_4H_8O)($NC_4H_8O_2$) (4)

A glass tube equipped with a Rotaflo valve was charged with **2** (10.0 mg, 11.0 mmol), phthalimide (18.0 mg, 122 mmol), and THF (2 mL). The mixture was subjected to three freeze-pump-thaw cycles before heated to 150 °C for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

15 h, as the color changed from red-brown to red. THF was removed in vacuo, and the mixture was analyzed by NMR spectroscopy, which showed clean formation of **4**. Attempts to remove the excess phthalimide were not successful. ^{1}H NMR (400 MHz, $CDCl_3$) δ: –2.33 (m, 4H, THF), –0.71 (m, 4H, THF), 2.67 (s, 12H, CH_3), 6.14 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H), 6.51 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H), 7.49 (d, $^3J_{HH}$ = 8.0, 8H, Ar H), 7.95 (d, $^3J_{HH}$ = 7.6, 4H, Ar H), 8.11 (d, $^3J_{HH}$ = 8.0, 4H, Ar H), 8.66 (s, 8H, β-pyrrole H).

Preparation of Ir(ttp)(C_5H_5N)($NC_4H_8O_2$) (5)

To a crude mixture of Ir(ttp)(C_4H_8O)($NC_4H_8O_2$) (**4**) and phthalimide was added pyridine (2 mL). The resulting solution was subjected to three freeze-pump-thaw cycles and then heated for 15 h at 100 °C, during which little color change was observed. The resulting mixture was dried in vacuo. Compound **5** was obtained in 78% yield as a red solid after chromatography on Alumina, eluting with CH_2Cl_2/hexanes (1:1). Single rod-shaped crystals suitable for X-ray crystallography were grown from a CH_2Cl_2–hexanes bilayer. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.13 (br d, 2H, py ortho H), 2.65 (s, 12H, CH_3), 5.05 (t, 7.53 (m, $^3J_{HH}$ = 7.2, 2H, py meta H), 6.06 (t, $^3J_{HH}$ = 7.6, 2H, py para H), 6.19 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H), 6.54 (dd, $^3J_{HH}$ = 5.4, $^4J_{HH}$ = 3.0, 2H, phthalimido Ar H), 7.46 (m, 8H, Ar H), 7.86 (d, $^3J_{HH}$ = 7.2, 4H, Ar H), 8.10 (d, $^3J_{HH}$ = 7.6, 4H, Ar H), 8.64 (s, 8H, β-pyrrole H). HRMS (FABMS) calcd. for $[C_{61}H_{45}N_6O_2Ir]^+$: *m/z* 1086.3228; found: *m/z* 1086.3244.

Supplementary data

Text, tables, figures of crystallographic data for complexes **3** and **5** (CIF files), and ^{1}H and ^{13}C NMR spectra for complexes are available on the journal Web site (www.nrcresearchpress.com/doi/suppl/10.1139/v11-126). CCDC 831991 has also been deposited with the Cambridge Crystallographic Data Centre. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/cgi-bin/catreq.cgi (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1Ez, UK; fax +44 1223 336033; or e-mail deposit@ccdc.cam.ac.uk).

Abstract: In molecular optoelectronics, high-quality contacts at electrode|organics interfaces are crucial for charge carriers to efficiently flow through and therefore play a critical role on device performance. Electrode surface morphology, adhesibility, wettability, and work function are thus many parameters that must be accurately controlled, which is achievable using self-assembling monolayer (SAM) surface chemistry. Herein, we employ this technique to alter the electronic and surface energy-related properties of indium–tin oxide (ITO). In comparison to unmodified ITO, the newly introduced SAM-derivatized surface exhibits limited wettability and considerably higher work function ($\Delta\Phi$ = ~1.2 eV). Several applications are proposed for this organic coating, notably at the anode of organic light-emitting diode (OLED) devices for decreasing the hole injection barrier or as an atmospherically stable protective layer in the coatings industry.

Key words: work function, indium–tin oxide, self-assembled monolayer, scanning Kelvin nanoprobe.

Résumé : En optoélectronique moléculaire, des contacts de haute qualité sont cruciaux pour s'assurer d'un transfert efficace des porteurs de charge aux interfaces électrode|composé organique et jouent ainsi un rôle critique sur la performance des appareils optoélectroniques. La morphologie de surface, l'adhérence, la mouillabilité et travail de sortie des électrodes sont ainsi autant de paramètres qui doivent être précisément controllés, ce que permet la chimie de surface des monocouches auto-assemblées (MAA). Ici, nous utilisons cette technique afin de modifier les propriétés électroniques et celles associées à l'énergie de surface de l'oxyde d'indium–étain (OIE). En comparaison avec la surface non-modifiée d'OIE, la surface d'OIE derivatisée avec la MAA nouvellement introduite montre une mouillabilité restreinte ainsi qu'une augmentation considérable du travail de sortie ($\Delta\Phi$ = ~1,2 eV). Plusieurs applications sont proposées pour ce film organique, notamment pour diminuer la barrière de potentiel à l'anode de diodes électroluminescentes organiques (DELO) ou en tant que couche protectrice stable dans les conditions atmosphériques pour l'industrie du revêtement.

Mots-clés : travail de sortie, oxyde d'indium–étain, monocouche auto-assemblée, nanosonde de Kelvin à balayage.

Introduction

Work function is an intrinsic property of matter that is defined as the minimum amount of energy required to extract one electron from a material. With respect to energy levels, work function thus corresponds to the difference in energy between the highest populated electronic state of a material (the Fermi level, E_F) and the vacuum level. In practice, work function is extremely sensitive to very subtle surface changes of any physical or chemical nature, which makes its measurement an invaluable analysis/detection tool in many surface science fields when information about the alteration of a surface is sought.[1,2] Conversely, the ability to control work function through surface engineering has also attracted much interest, notably in molecular optoelectronics where electrodes having finely tuned energy levels are of particular importance for interfacial charge carrier flow to occur more efficiently.[3,4]

In the field of surface science, self-assembling monolayer (SAM) chemistry constitutes a powerful and versatile tool for the rapid and economical preparation of thin organic films on various solid inorganic materials such as gold, quartz, or indium–tin oxide (ITO).[5] In SAM chemistry, customizable molecules are engineered for surface modification purposes to spontaneously form ordered molecular assemblies with tailored properties usually pertaining to wettability and adhesibility. However, recent studies carried out in the field of molecular optoelectronics on organic light-emitting diodes (OLED) and organic solar cells (OSC) have shown that SAM chemistry could also be used to modulate work function.[6–16] The resulting SAM-based devices exhibited markedly improved performance, which is attributed to an enhanced charge carrier transport across the SAM-derivatized electrode | adjacent active layer junction due to higher quality contact and better frontier energy level positioning.[16–26]

At the anode of OLED devices, SAMs with appropriate dipole moment direction (pointing towards the anode) are thus used to increase the electrode work function (Φ) by imposing an interfacial dipole that permanently alters the surface

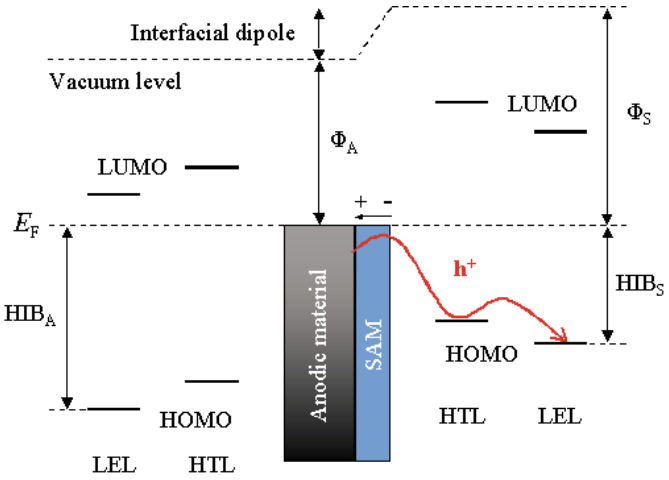
Fig. 1. Schematic energy level diagram depicting the position of the pinned Fermi level (E_F) and the local vacuum levels relative to the hole transporting layer's (HTL) and the light-emitting layer's (LEL) highest occupied molecular orbital (HOMO) levels before (left) and after (right) derivatization of an anodic material with a self-assembling monolayer (SAM) having a dipole moment pointing towards the surface. Φ_A and Φ_S are the associated work functions, HIB_A and HIB_S are the respective energy barriers to hole injection. For simplicity, Fermi level pinning and other vacuum level shifts occurring at the (SAM-derivatized) anodic material / HTL and HTL/LEL interfaces are not represented.[27–29]



electrostatic potential and shifts the local vacuum level upwards, as illustrated in Fig. 1.[6,18,25] This in turn may allow for the hole injection barrier (HIB) to be lowered thereby enhancing hole injection (h^+) from the anode to the light-emitting layer (LEL) through the conventionally intercalated hole transporting layer (HTL).

For OLED applications where LELs having particularly low-lying HOMO levels[30] are aimed to be integrated within substrate|SAM|LEL HTL-free structures,[31,32] SAM-derivatized anodes with correspondingly high(er) work function may be required to minimize the HIB and lower the operating/driving voltages.[17,18,27] In the case of ITO, which is a commonly employed anodic material,[33] only a limited number of publications have appeared in the literature to describe SAM-derivatized ITO surfaces that display substantially higher work function than bare ITO ($\Delta\Phi > 1$ eV) and are actually operational[23,25,34,35] in an OLED device or have the potential[7,13,36,37] to be. In this context, we wish to introduce herein a new SAM-derivatized ITO surface that presents considerably higher work function than unmodified ITO ($\Delta\Phi = \sim 1.2$ eV), as determined using the scanning Kelvin nanoprobe (SKN).[1,2]

Experimental section

Materials

The following includes detailed protocols for ITO cleaning, OEG–TTTA SAM formation, and contact potential difference (CPD) measurements. SAM characterization using angle-resolved X-ray photoelectron spectroscopy (XPS) and contact angle goniometry is reported in the accompanying Supplementary data. OEG–TTTA synthesis is reported elsewhere.[5] ITO-coated glass slides (R_S = 4–8 Ω, ITO thickness of 1500–2000 Å) were purchased from Delta-Technologies Ltd. (Stillwater, Minnesota). ITO silanization was prepared in a glovebox maintained under an inert (N_2) and anhydrous (P_2O_5) atmosphere using glassware (20 mL glass scintillation vials) that had been pretreated overnight with a 1:20 (*v*/*v*) solution of octadecyltrichlorosilane (Sigma-Aldrich) in anhydrous toluene. The slides were systematically handled with thoroughly precleaned stainless steel tweezers to minimize any external contamination.

ITO cleaning procedure

ITO slides (13 mm × 13 mm × 1.1 mm) were first sonicated in concentrated dishwashing soap for 30 min, after which they were thoroughly rinsed with hot tap water followed by distilled water and then finally dried under a gentle stream of forced air. The slides were next sonicated in spectrograde methanol for 20 min, after which they were copiously rinsed with methanol, gently dried with forced air, and then N_2-plasma cleaned for 10 min. Contact angle measurements (CAM) were then performed using ultrapure water as the test liquid. The slides presenting complete wetting (CAM = 0°) were then selected and immediately transferred into a humidity chamber, maintained at 70% relative humidity (using $MgNO_3 \cdot 6H_2O$), and set aside overnight. The same procedure, with the exception of sonication, was followed for the cleaning of the Au/Pt-plated ITO slide used for measuring CPDs.

Silanization procedure (SAM formation)

Neat OEG–TTTA (10 µL) was first diluted with anhydrous toluene (10 mL). The resulting solution was portioned in six vials (1000 µL/vial) into which cleaned ITO slides were then individually soaked in a horizontal position. The vials were then tightly capped, removed from the glovebox, and placed on a spinning plate for 30 min. Next, the slides were thoroughly rinsed with toluene (3×) and then sonicated in another portion of toluene for 5 min. After a final rinse with toluene, the previous procedure was repeated with chloroform, after which the slides were dried under a gentle stream of forced air. They were then transferred into a dessicator (filled with indicating Drierite) that was subsequently high-vacuumed for 2 h. After backfilling the chamber with N_2, the surfaces were then characterized by angle-resolved XPS and contact angle goniometry. Identical preparation procedure, with the exception of the slide being vertically immersed at the desired level into the OEG–TTTA solution, was followed for the Au/Pt-plated ITO slide dedicated to CPD measurements. No protective coating mask was applied to the unsoaked part of the slide prior to immersion.

CPD measurements

CPD measurements were performed on a specially designed Au/Pt-plated ITO slide (25 mm × 25 mm × 1.1 mm) using the SKN apparatus.[1,2] CPD measurements were rapidly recorded under ambient atmospheric conditions on a freshly prepared surface immediately after its removal from the N_2-backfilled dessicator (vide supra). Data were acquired with a LabView 6 platform and then analyzed using the Origin 7 program (OriginLab Corp., Northampton, Massachusetts). Shifts in work function ($\Delta\Phi$) were calculated using the relationship $\Delta\Phi = e\Delta CPD$, where e is the elementary charge.

Results and discussion

SAM preparation and XPS characterization

Surface engineering using SAM chemistry for the development of antifouling biosensing platforms is currently the object of intense research in our laboratory.[5] Recently, we also became interested in the possibility offered by SAM chemistry to modulate electrode work function in molecular optoelectronics for the fabrication of better performing devices. Our aim was notably to develop new SAM-derivatized ITO surfaces having both tailored work function and wettability for application as anodes in photonic devices. For that purpose, we initially investigated OEG–TTTA, a molecule that had recently proven to be effective at coating hydroxylated substrates.[5]

OEG–TTTA (Scheme 1) is a bifunctional molecule that possesses a highly reactive trichlorosilyl tail function (Cl_3Si–) for strong and durable siloxane anchorage onto the underlying hydroxylated ITO surface. Another important feature of oOEG–TTTA resides in its long oligoethylene glycol (OEG) backbone that not only serves to drive self-assembly but also provides ordering and rigidity to the resulting SAM through intermolecular interactions. Lastly, OEG–TTTA possesses an electron-withdrawing trifluoroethyl ester (TFEE) head function that also participates in endowing the molecule with a dipole moment. Upon chemisorption of OEG–TTTA onto ITO, robust and polar SAMs are thus expected to form and permanently alter the surface electrostatic potential, hence work function.[6–18]

SAM-derivatized ITO surfaces (a batch of six samples) were readily prepared upon immersion of cleaned ITO slides into a 1:1000 (*v*/*v*) solution of OEG–TTTA in anhydrous toluene, for 30 min at room temperature (Scheme 1). The successful and reproducible deposition of OEG–TTTA onto ITO was determined using angle-resolved XPS. As expected for the formation of OEG–TTTA films onto bare ITO, signals for fluorine, silicon, and carbon (elements exclusively found in OEG–TTTA) appeared in the XPS profiles, as shown in Fig. 2. With respect to carbon, the peaks expected for the OEG backbone of OEG–TTTA (C–O) and TFEE head function (C=O, C–O, and CF_3) are also clearly discernible on the C1s narrow scan at ~288–294 eV.[38,39] Moreover, the signals for the characteristic elements of ITO (indium, tin, and oxygen) conversely decreased as expected for a now buried underlying ITO layer (Fig. 2). The shift to higher binding energy observed for oxygen (as well as for indium and tin) and the accompanying change in signal shape (appearance of an Si–O shoulder at ~533 eV) are also indicators that OEG–TTTA molecules are tightly bound to ITO.[34,36,40] Finally, it is important to note that XPS data showed high consistency from one sample to another (with relative standard deviations (RSDs) ranging from 2% to 13%), demonstrating that these OEG–TTTA films were prepared in a reproducible manner with respect to molecular coverage.

Contact angle measurements

Surface wettability was next determined by contact angle goniometry using ultrapure water as the test liquid (Table 1). The measurements revealed that these OEG–TTTA surfaces exhibit a quite pronounced hydrophobic character, with an average static CAM of 76°, as opposed to the complete wetting (CAM = 0°) observed for freshly cleaned hydrophilic ITO. CAM reproducibility from one sample to another was excellent (3% RSD) indicating that these OEG–TTTA surfaces were also prepared in a reproducible manner with respect to surface wettability.

Contact potential differences/work function shift

We turn now to the measurement of the shift in work function caused by the OEG–TTTA SAM using the SKN.[1,2] In practice, this instrument operates by vibrating a sharp guarded tungsten tip at close proximity over a sample placed

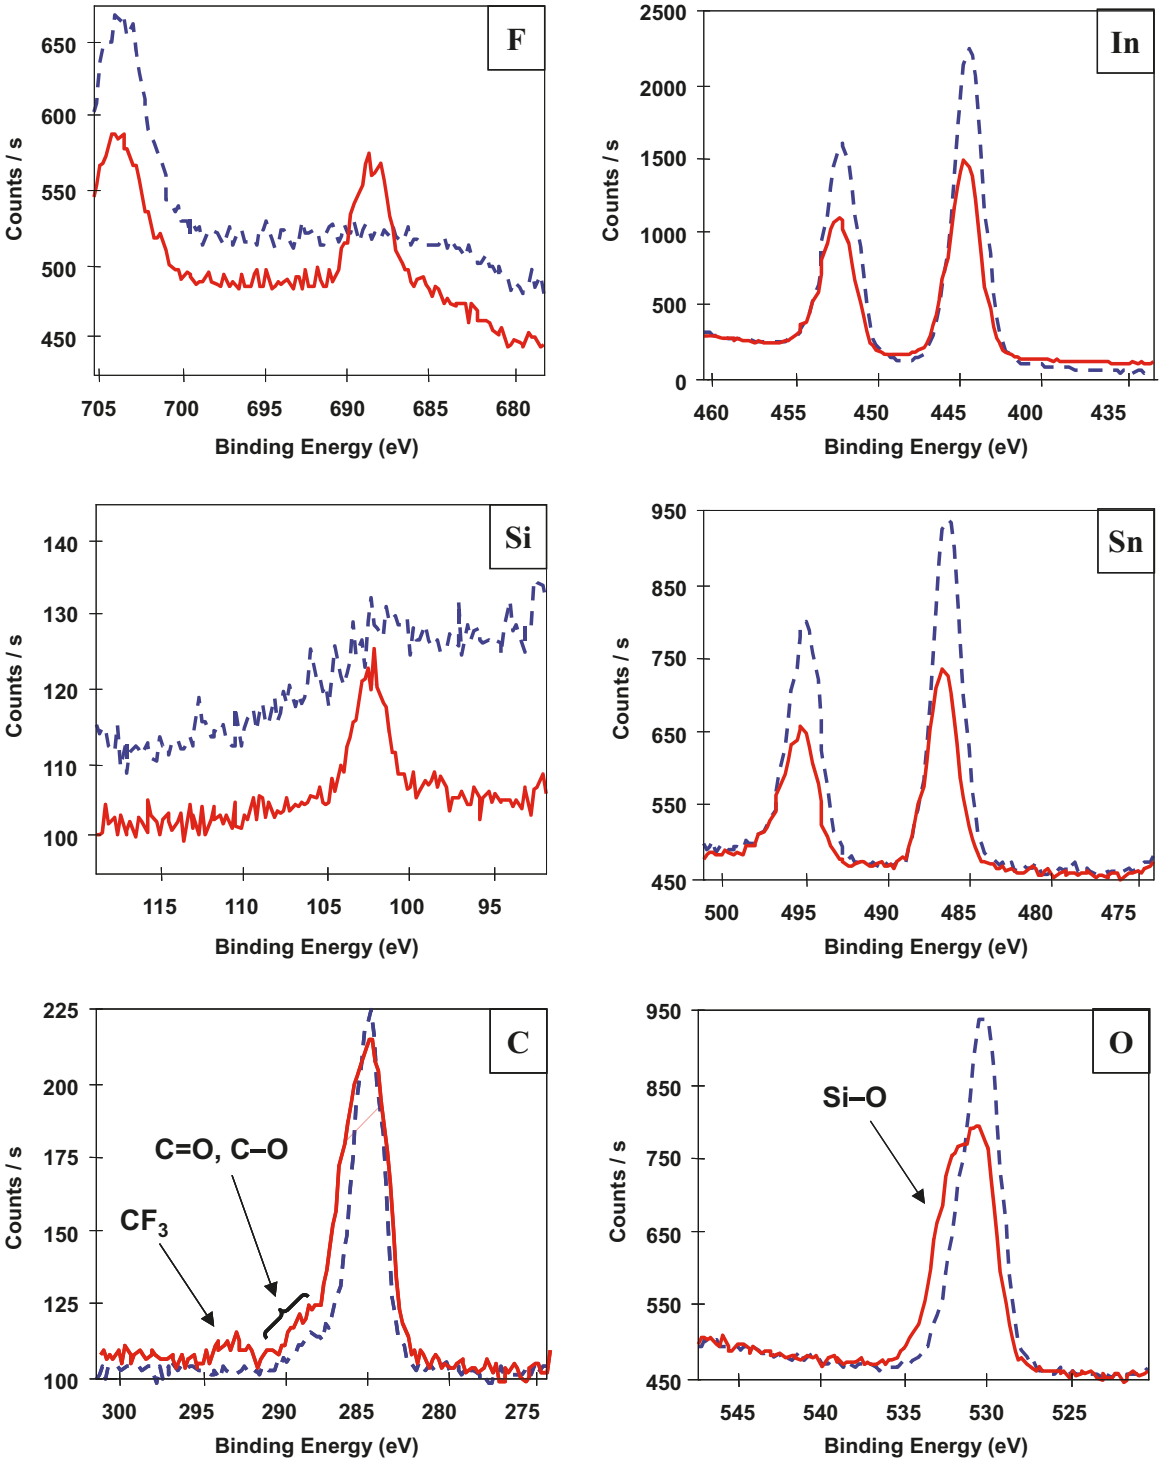
Fig. 2. Typical XPS narrow scans for bare ITO (broken line) and OEG–TTTA-coated ITO (solid line) recorded for each characteristic element of OEG–TTTA (left column) and ITO (right column). The presence of carbon in the XPS profile of bare ITO is due to contamination by adventitious carbon. The binding energy scale is calibrated to the main C1s signal at 285 eV. The take-off angle shown here is 20° relative to the surface. Complete angle-resolved XPS analysis is available in the Supplementary data.



on top of a conducting table. This triggers a flow of charge between the tip and the sample (i.e., their Fermi levels), which are electrically connected via an external circuit. This movement of charge induces a difference of potential between the tip and the sample, whose amplitude depends on the nature of the sample area being scanned. In other words, SKN essentially behaves as a one-plate-varying capacitor that merely measures CPDs between the tip and the sample, with $CPD = (\Phi_{sample} - \Phi_{tip})/e$. Shifts in work function ($\Delta\Phi$) between two materials can later be calculated using the relationship $\Delta\Phi = e\Delta CPD$. However, direct access to work function requires the use of a reference material with a known and stable

Fig. 3. Schematic representation of the Au/Pt-plated SAM-derivatized ITO slide used to measure CPDs. Partial SAM covering was achieved upon vertical immersion of the slide at the desired level into solution. No protective coating mask was applied to the unsoaked part beforehand, which resulted in a capillary fringe at the air/solution interface.

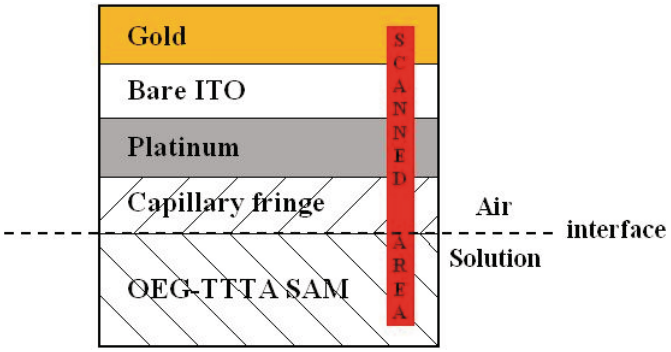

Fig. 4. CPD profile of OEG–TTTA-coated ITO vs bare ITO relative to the Au and Pt internal references. The measurement was performed under ambient atmospheric conditions on a freshly prepared surface.

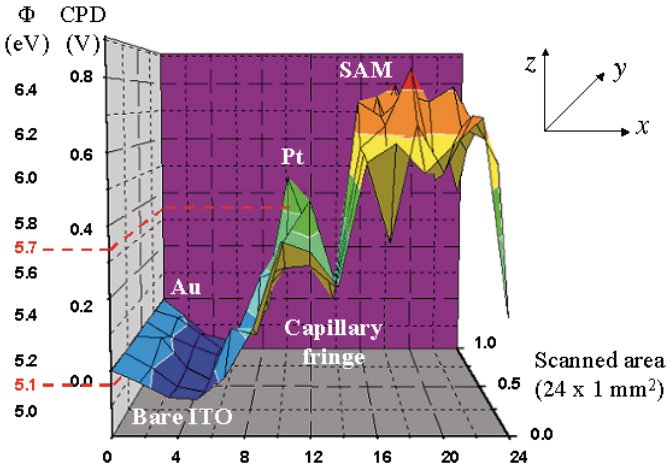

work function, such as highly ordered pyrolytic graphite (HOPG).[37] For our study, we designed an ITO-coated glass slide onto which two narrow strips of gold and platinum were plated, as illustrated in Fig. 3. These noble metals, which have respective work functions of 5.1 and 5.7 eV as measured under ultra-high vacuum (UHV) conditions,[41] can serve as internal references and offer the possibility of converting the measured CPD values into calibrated work functions. The SAM-derivatized ITO surface for CPD measurement (CAM = 76°) was prepared following the aforementioned conditions, the cleaned ITO slide being, however, only partially coated with the SAM, as shown in Fig. 3, upon vertical immersion into solution.

Upon preparation, this slide was then immediately and rapidly scanned across with the SKN under ambient atmospheric conditions, in a raster pattern of 100 μm × 200 μm step size and a total area of 24 × 1 mm^2 (Fig. 3). On the resulting CPD 3D map (Fig. 4), one can clearly recognize the successive zones depicted in Fig. 3 from (left to right) gold (lighter blue), bare ITO (darker blue), platinum (green), to the OEG–TTTA film (yellow-orange; for a colour view, please see the Web version of this paper). Capillary action at the unmasked air/solution interface during SAM formation resulted in the intermediate CPD response observed at $x \sim 14$ mm (capillary fringe).[17]

As can be seen in Fig. 4, the difference in CPD between SAM-derivatized and bare ITO is ~0.75 V under our experimental conditions, which represents a tremendous increase in work function of ~1.2 eV. Indicatively, when the scale is expressed in eV and calibrated with the Au (5.1 eV) and Pt (5.7 eV) references, the work function of bare ITO is ~4.9 eV, which is within the range reported.[13] On the other hand, the work function of the SAM-derivatized area becomes ~6.1 eV. However, we must point out that this conversion is only valid provided that the values $\Phi_{Au} = 5.1$ eV and $\Phi_{Pt} = 5.7$ eV measured under UHV still stand under our scanning conditions (ambient atmosphere), which would appear to be a reasonable assumption here. Regardless, such an increase in work function makes this hybrid material a potential anode candidate for decreasing the HIB in hole-limited OLED devices. As discussed earlier, this may also be interesting for OLED applications that aim to integrate LELs with very low-lying HOMO levels,[35] such as in the key class of blue OLEDs.[42] Another benefit anticipated is higher resistance to oxidation[35,43] that, combined with its hydrophobic character, could also make this robust molecular adlayer an atmospherically stable coating of nanometric size to prevent underlying materials or fabrics from corroding, deteriorating, or wetting.[44]

Conclusions

In this article, we have introduced new SAM chemistry for the surface modification of ITO with respect to its electronic and surface energy-related properties. It was shown that, in comparison to unmodified ITO, the novel SAM-derivatized surface exhibits limited wettability and considerably higher work function ($\Delta\Phi$ = ~1.2 eV). It was also argued that an organic coating with such attributes can be expected to draw much attention in many surface science fields, notably in molecular optoelectronics for decreasing the HIB at the anode of hole-limited OLED devices or in the coatings industry as a multipurpose, environmentally stable protective layer. Research attention is currently focused on generating a collection of surface modifiers capable of self-assembling onto various substrates and form versatile molecular coatings with customized properties.

Supplementary data

Supplementary data (including complete contact angle goniometry and angle-resolved X-ray photoelectron spectroscopy

data for SAM characterization) are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v11-140.

Abstract: The inclusion process involving β-cyclodextrin (β-CD) with dopamine (DA) was investigated by using PM6, HF, and ONIOM methods. The most stable structure was obtained at the optimum position and angle. The complex orientation in which the catechol ring of dopamine penetrates into the β-CD cavity near primary hydroxyls is preferred in energy. The structures show the presence of several intermolecular hydrogen bond interactions that were studied on the basis of natural bonding orbital analysis, employed to quantify the donor–acceptor interactions between dopamine and β-CD. A study of these complexes in solution was carried out using the CPCM model to examine the influence of solvation on the stability of the dopamine β-CD complex.

Key words: dopamine, β-cyclodextrin, inclusion complexes, quantum mechanics.

Résumé : Faisant appel à des calculs théoriques suivant la méthode paramétrisée-6 (MP-6), celle de Hartree–Fock (HF) ou la méthode personnalisée « ONIOM », on a étudié le processus d'inclusion impliquant la β-cyclodextrine (CD) et la dopamine (DA). La structure la plus stable a été obtenue à la position et l'angle optimal. L'orientation du complexe dans laquelle le noyau catéchol de la dopamine pénètre dans la cavité de la β-CD près des hydroxyles primaires correspond à un minimum d'énergie. Les structures montrent la présence de plusieurs interactions de liaisons hydrogènes intermoléculaires qui ont été étudiées sur la base d'une analyse d'orbitales de liaison naturelle (OLN) pour quantifier les interactions donneur-accepteur entre la dopamine et la β-CD. Dans le but d'examiner l'influence de la solvatation sur la stabilité du complexe dopamine-β-CD, on a effectué une étude de ces complexes en solution en faisant appel au modèle du milieu continu conducteur polarisé (MCCP).

Mots-clés : dopamine, β-cyclodextrine, complexes d'inclusion, mécanique quantique.

Introduction

Dopamine (3,4-dihydroxyphenethylamine, DA) is an important neurotransmitter molecule of catecholamines. It plays a very important role in the functioning of central nervous, renal, hormonal, and cardiovascular systems. Its deficiency will lead to brain disorders such as Parkinson's disease and schizophrenia.[1]

Quantitative determination of DA is therefore important and has attracted much interest from neuroscientists and chemists. Dopamine can be detected by electrochemical methods, which constitute a great advantage because of their simplicity, speed, and sensitivity.[2] However, in assay of DA, these methods suffer from less selectivity owing to the presence of other species that have higher concentrations than DA in physiological fluids and for which their oxidation potential is always close to that of DA, 0.2–0.4 V. Therefore, it is important to separate the peak potential oxidation of DA from the peaks of other species present in medium. Many electrochemical approaches have been developed using pretreated electrodes, polymer-modified electrodes, and monolayer-modified electrodes to solve these problems.[3,4]

Among these methods, the electrode modifiers belonging to the cyclodextrin (CD) family[5,6] are very interesting. Naturally occurring cyclodextrins have been widely studied because of their ability to form inclusion complexes with a large variety of organic molecules. The α-, β-, and γ-cyclodextrin rings contain six, seven, and eight glucose units, respectively, and exhibit a hydrophobic conical internal cavity and a hydrophilic exterior due to the presence of hydroxyl groups. They are α-1, 4-linked cyclic oligomers of D-glucopyranose. Their well-known ability to form supramolecular complexes with suitable organic and inorganic, neutral, and ionic substances has resulted in the design of selective electrodes.[7]

CD-modified electrodes, used to determine DA, displayed excellent selectivity and sensitivity, which could separate DA and the oxidation peak potentials of other species and could detect DA at low concentration.[4–6] Therefore, it is important to clarify the structures of the inclusion complexes from a

viewpoint of molecular recognition within the hydrophobic cavities of CDs. The main driving forces for the complex formation have been attributed to hydrophobic interactions, van der Waals interactions, hydrogen bonding, and release of ring strain in the CD cavity.[8]

Computer modeling studies of CD complexes are an important method to understand the mechanism of complex formation, to interpret experimental data, and to elucidate structures. Thus, in spite of its experimental detection, the geometry of the β-CD–DA complex was not elucidated due to technical difficulties related to its low solubility, not making it possible to carry out observations in NMR.[9]

In this article we propose a theoretical approach to describe the geometry of the DA–β-CD complex and to evaluate the principal intermolecular interactions between DA and β-CD.

In this paper, we first describe the formation of the host–guest complexes between β-CD and dopamine, using Parametric Model 6 (PM6)[10] semi-empirical method implemented in the MOPAC 2009 program[11] to localize the minimum energy structures, which are used as starting structures for subsequent optimizations. After that, the structures are subjected to higher level calculations, such Hartree–Fock with 3–21G*

level and ONIOM (our own N-layered integrated molecular orbital mechanics) method to approach the ideal geometry and provide further insight of the complexation process of DA with β-CD. Within the ONIOM procedure, two levels are defined: (*i*) density functional theory with B3LYP functional where the 6–31G* basis set was performed on the guest molecule and (*ii*) Hartree–Fock method with 3–21G* basis set was used for the β-CD. The natural bonding orbital (NBO) population analysis procedure is employed to quantify the donor-acceptor interactions between host and guest.

Computational method

All the calculations were performed using GAUSSIAN 03 and MOPAC 2009 software packages.[12] The starting structures of β-CD and DA were constructed with the help of the Cambridge ChemBio 3D Ultra (version 11.0, Cambridge software). Dopamine was optimized with B3LYP method at the 6–31G* level, and the β-CD was used without optimization.

The method used by Liu and Guo was employed.[13] The glycosidic oxygen atoms of the β-CD were placed onto the *XY*-plane, and their center was defined as the center of the coordinate system. Then the guest was placed along the *Z*-axis of the coordinate system. The guest molecule is allowed to enter and then pass through the β-CD molecule by steps, with the ring to chain bond coincident with the *Z*-axis. The relative positions between the host and the guest was measured by the *Z*-coordinate of the common carbon atom between the cyclic part (catechol ring) and the DA chain.

For the complexation process, the β-CD molecule stays at a fixed position, while the dopamine structure approaches along the *Z*-axis toward the wide edge of the β-CD torus.[14]

To find an even more stable structure of the complex, we rotate the DA molecule to find the optimal angle at each step by scanning θ, circling around the *Z*-axis at 20° intervals from 0° to 360° and scanning the *Z*-coordinate at 1 Å intervals, where θ is the angle circling around the *Z*-axis of the system, and the bond of DA is coincident with the *Z*-axis.

Several energy expressions were used to characterize the inclusion complexes. In addition to the absolute energy of the complex (the HF value as reported by Gaussian), the binding energy ($\Delta E_{binding}$) is defined as the difference between the energy of the complex and the energy of the individual components in their optimized geometry ($E_{opt,DA}$ or $E_{opt,\ CD}$) from the complex,

$$[1] \qquad E_{binding} = E_{complex} - (E_{opt,\ \beta-CD} + E_{opt,DA})$$

The stabilization (complexation) energy upon complexation between DA and β-CD was calculated for the minimum energy structure as follows:

$$[2] \qquad E_{complexation} = E_{complex} - (E_{\beta-CD} + E_{DA})$$

where: $E_{complex}$, $E_{\beta\text{-}CD}$, and E_{DA} represent the energies of the complex, the free DA, and the free β-CD, respectively.

The gas phase full optimizations were carried out at PM6 and HF/3–21G*. To improve the precision of the theoretical results, ONIOM[15] calculations were used to optimize the CD molecule with HF at the 3–21G* level, while we treated the guest molecule using the functional of Lee et al. (B3LYP) with the split-valence 6–31G (d) basis set. The ONIOM energy is described as[16]:

$$[3] \qquad E^{ONIOM} = E(\text{high; model}) + E(\text{low; real}) - E(\text{low; model})$$

where *E*(high, model) is the energy of DA at the B3LYP/6–31g(d) level, *E*(low, real) is the energy of the complex at the HF/3–21G* level, and *E*(low, model) is the energy of β-CD at the HF/3–21G* level.

The interaction between dopamine and β-CD structures is quantified on the basis of an NBO population analysis. The NBO calculations were performed using NBO 3.1 program, as implemented in the Gaussian 03 package, to understand various second-order interactions between the filled orbitals of one subsystem and vacant orbitals of another subsystem, which is a measure of the intermolecular delocalization on hyperconjugation.[17]

The optimized structures for complexes were used for further calculations, including calculation of energies in the presence of solvent. To calculate the solvation effect, the framework of a continuum solvation model using a conductor, such as a screening model (COSMO), was used. This method, developed by Barone and Cossi, is an implementation of the COSMO model from Klamt et al. in the Gaussian software. The solvation calculations were carried out using B3LYP/3–21G*. In the CPCM (COSMO) model, the solvatation energy is partitioned into four components, including electrostatic interaction ΔG_{elec}, a cavity term ΔG_{cav}, dispersion ΔG_{dis}, and repulsion energy ΔG_{rep}, the last three terms

being related to the non-electrostatic interactions between solute and solvent.[18]

Results and discussion

The inclusion complex DA–β-CD has two orientations (Fig. 1), which will be denoted head and tail orientations, respectively: aromatic ring oriented to the center of mass of β-CD, namely the head orientation and aliphatic ring oriented to the center of mass of β-CD, namely the tail orientation.

The inclusion complex β-CD–DA was determined using the PM6 method to obtain the minimum energy structures. Considering the negative values of all complexation energies, we can say that the complexation process is energetically favorable. The most stable structure of DA–β-CD is reached at $Z = 6$ Å for the head orientation, and at this point the binding energy is –20.79 kcal/ mol (1 cal = 4.184 J). For the tail orientation, the optimum position was found at –5 Å, with binding energy –21.38 kcal/ mol (Fig. 2).

The energies of DA, β-CD, and the complexation energies of their inclusion complexes obtained with PM6, HF/3–21G*, and B3LYP/6–31G(d) methods are shown in Table 1. The most stable structure can be obtained by comparing energies of the two orientations of the complexes, as shown in Table 1. Thus, the complexation energies from HF/3–21G* for the head and tail orientations are –39.49 and –28.48 kcal/mol, respectively. These values show that the inclusion complex head orientation is more stable than the tail orientation. ONIOM (B3LYP/6–31G(d):HF/3–21G*) results follow the same trend as the HF data. The complexation energies from the ONIOM calculations for head and tail orientations are –38.71 and –29.68 kcal/mol, respectively. The complexation energy differences for the two complexes from HF/3–21G* and ONIOM (B3LYP/6–31 G(d):HF/3–21G*) are –11 and –9.04 kcal/mol, respectively.

The results in Table 1 indicate that for HF/3–21G(d), the zero-point energy gives energy deviation of 1.1 kcal/mol from that without corrections; for ONIOM, the zero-point energy gives an absolute deviation of 0.87 kcal/mol.

NBO analysis

To obtain additional insight into the nature of interaction between DA and β-CD, we undertook a population analysis using the NBO method. The advantages of this approach are that it concentrates almost all the molecular energy and molecular change within structures that mimic the traditional Lewis molecular model of strictly localized bonds. The very small residual energetic and charge contributions in saturated systems are largely due to the delocalization of noncovalent interactions between bonding and anti-bonding orbitals of the NBO approach. This noncovalent bonding–anti-bonding interaction gives a quantitative description of hyperconjugation. In terms of the NBO approach, this is expressed by means of a second-order perturbation interaction energy $E^{(2)}$ involving neighboring orbitals. The selected electron donor orbitals, electron acceptor orbitals, and their corresponding second-order interaction energies $E^{(2)}$ indicate the intensity of the interaction between the electron donor and electron acceptor orbitals. Thus, the greater value of $E^{(2)}$, the more tendency of a higher donor orbital.[19]

The electron donor orbitals, electron acceptor orbitals, and their corresponding $E^{(2)}$ energies, bond distances, and angles between the hydrogen bonding are also shown in Tables 2 and Table 3.

The structures of the energy minimum obtained with ONIOM calculations show the presence of several intermolecular hydrogen bond interactions, as shown in Fig. 3. In the present study the hydrogen bond analysis is carried out using an NBO approach. In the head orientation, the catechol ring of DA is included deeply in the β-CD cavity from the wide secondary hydroxyl group, so that the hydroxyl groups of DA are close to 6-OH of β-CD. This disposition allows the formation of two hydrogen bonds between the hydroxyls catechol and one hydroxyl (O47–H129) of the narrow edge

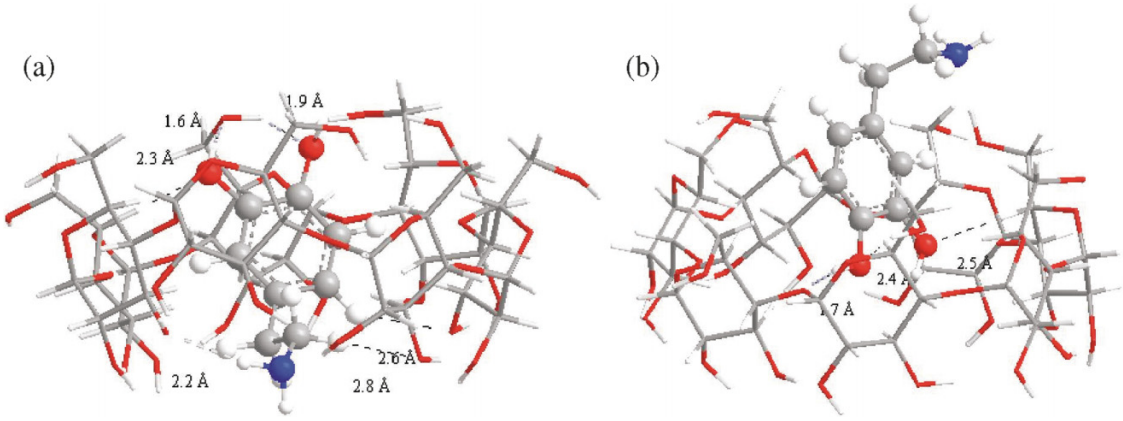
Fig. 3. Geometrical structures optimized at ONIOM for DA–β-CD complexes: (*a*) tail orientation and (*b*) head orientation.



of the β-CD: the first as proton acceptor (O47···H162–O154) located at 1.646 Å with an angle equal to 167.4° and the second as proton donor (O47–H129···O155) positioned at 1.907 Å with an angle of 135.4°. The interaction energy for the second hydrogen bond (0.44 kcal/mol) was lower than the first (1.65 kcal/mol).

At the wide secondary face, one hydrogen bond is established between an oxygen atom (O69) of β-CD and a hydrogen atom (H169) of the H169–N158 bond, and that allows the chain group to remain inside the cavity; the O···H distance is about 2.16 Å, with an angle of 166.7 ° and interaction energy equal to 3.33 kcal/mol.

At the same time, several C–H···O hydrogen bonds were established between DA and β-CD. DA plays the role of donor from the carbon atoms (C157) and (C150) to the oxygen atoms (O59) and (O54) of the wide face of β-CD (C157–H167···O59 and C150–H160···O54). The DA molecule accepts a C–H···O weak hydrogen bond from hydrogen atom (H124) of the C41–H124 bond of the wide hydrophilic face (C41–H124···O154). The interaction energies of these C–H···O hydrogen bond are 0.44, 0.70, and 1.42 kcal/mol, respectively. These values are typical of weak hydrogen bonds according to the values of conventional hydrogen bonding (the C–H···O bond energies were around 0.5–2 kcal/ mol).

While in the tail orientation, we can see the guest molecule is partially incorporated in the cavity, and the chain is left out from the narrow primary face. In this structure, one strong O···H–O hydrogen bond (5.43 kcal/ mol) is established between the glycosidic oxygen atom (O75) and the hydrogen atom (H163) of the O155–H163 bond located at 1.669 Å with an angle equal to 169.7°. The oxygen atoms of the two hydroxyls of DA (O155) and (O154) accept C–H···O hydrogen bonds with (H5) C23 and C35 of the narrow face of the β-CD positioned, respectively, at 2.54 and 2.36 Å with angles equal to 173.2° and 147.1°.

The solvation energies consisting of electrostatic and non-electrostatic terms were computed using the CPCM (COSMO) model, and indicate that the head orientation is favored over the tail by 16.24 kcal/mol. This result is in agreement with those obtained in the gas phase. This is due to the difference between the mode of penetration of the guest molecule in the β-CD cavity, the full and the partial inclusions in head and tail orientations, respectively.

Conclusion

The inclusion process of DA with β-CD was studied according two orientations using quantum mechanics PM6, HF level theory with 3–21G* basis set and ONIOM (B3LYP/6–31G(d): HF/3–21G*) hybrid calculations. The minimum energy structure for each orientation was localized with the PM6 method. The affinity of these minimum energies structures was carried out with HF and ONIOM methods. The HF and ONIOM results show that the head orientation is preferred, according to complexation energy. In this configuration, the catechol ring is deeply included into the hydrophobic cavity of β-CD. However, the ONIOM method allowed better understanding the type of DA–β-CD interactions. The NBO population analysis used to quantify these interactions shows that the driving forces of DA–β-CD complexes was due to the intermolecular hydrogen bonds in addition to the hydrophobic interactions. The study in solution by using CPCM model follows the same trend as that in gas phase, thus favoring the head orientation.

Abstract: The interaction of lithium (Li^+) cation and hexafluorophosphate (PF_6^-) anion with nonaqueous electrolytes is studied by using density functional theory at the B3LYP/6–311++G(d,p) level in the gas phase in terms of the coordination of Li^+ and PF_6^- with these solvents. Ethylene carbonate (EC) coordinates with Li^+ and PF_6^- most strongly and reaches the anode and cathode most easily because of its highest dielectric constant among all the solvent molecules, resulting in its preferential reduction on the anode and oxidation on the cathode. For cyclic carbonates EC and propylene carbonate (PC), the structure $Li^+(S)_4$ is found to be the most stable. However, for linear carbonates dimethyl carbonate (DMC), diethyl carbonate (DEC), and ethyl methyl carbonate (EMC), the formation of $PF_6^-(S)_{n=1–3}$ is not favorable. Such analysis may be useful in applications for lithium ion batteries.

Key words: density functional theory, solvents, stability, exothermic, oxidation, heat of formation.

Résumé : Faisant appel à la théorie de la fonctionnelle de la densité au niveau B3LYP/6–311++G(d,p), on a étudié d'un point de vue théorique l'interaction du cation lithium (Li^+) et de l'anion hexafluorophosphate (PF_6^-) avec des électrolytes non aqueux, en phase gazeuse, en termes de la coordination du (Li^+) et du (PF_6^-) avec ces solvants. Le carbonate d'éthylène (CE) est celui qui donne la coordination la plus forte avec le (Li^+) et le (PF_6^-) et il atteint l'anode et la cathode le plus facilement en raison de sa constante diélectrique qui est la plus élevée de toutes les molécules de solvant; il en résulte que sa réduction à l'anode et son oxydation à la cathode sont les réactions privilégiées. Pour les carbonates cycliques, tel le CE et le carbonate de phénylène (CP), on a trouvé que la structure $Li^+(S)_4$ est la plus stable. Toutefois, pour les carbonates linéaires, tel le carbonate de diméthyle (CDM), le carbonate de diéthyle (CDE) et le carbonate d'éthyle et de méthyle (CEM), la formation de la structure $Li^+(S)_{n=1–3}$ n'est pas favorisée. Une telle analyse peut être utile dans les applications de batteries au lithium.

Mots-clés : théorie de la fonctionnelle de la densité, solvants, stabilité, exothermique, oxydation, chaleur de formation.

[Traduit par la Rédaction]

Introduction

The lithium ion battery has found wider and wider applications in electronic devices, tools, and vehicles because it provides a good combination of high-energy density and reversibility.[1] Electrolytes are of special interest because of their applications in high-energy density battery systems. The electrolytes are comprised of a lithium salt ($LiClO_4$, $LiPF_6$, $LiBF_4$, $LiAsF_6$, etc.) dissolved in an aprotic solvent with high dielectric permittivity. Progress has been made in enhancing the conductivity of solid electrolytes; however, liquid electrolytes are still the most commonly used in electrochemical systems. The common electrolytes used in electrochemical systems are ethylene carbonate (EC), propylene carbonate (PC), dimethyl carbonate (DMC), diethyl carbonate (DEC), and ethyl methyl carbonate (EMC), etc., because of their high ionic conductivity and low melting and high boiling points that can provide a suitable temperature range for the liquid state, low viscosity, as well as chemical and electrochemical stability. It is well known that some organic electrolytes decompose during the first lithium intercalation into graphite to form a solid electrolyte interphase (SEI) film on the graphite anode surface, and SEI film largely determines the performance of the graphite anode in rechargeable batteries.[2] Unlike PC, which can be cointercalated into the graphite anode with Li^+, EC is not intercalated but helps to build the SEI layer that can inhibit the decomposition of solvent molecules on the anode.[3,4] Because of the high melting point of EC (37 °C), it has resulted in products that build up a stable SEI.[5] Therefore, the mixture of linear carbonates, for

example DMC with a high-content of EC, are widely used in lithium ion batteries[6,7] because of the fact that the high dielectric permittivity of linear carbonates (DMC, DEC, or EMC) combined with the low viscosity of the cyclic carbonates (EC or PC) provides the electrolyte with a high ionic conductivity.

Much experimental work has been focused on the oxidative decomposition of solvents on the cathodes of lithium ion batteries.[8–14] Recently, a detailed mechanism on the oxidative decomposition of PC was given with theoretical calculations.[15] Similarly, a wide variety of experimental techniques have been used[5,16] to determine the reduction mechanism of EC. In addition, whereas a lithium ion battery can be cycled in an electrolyte using DMC or EMC as a solvent, this does not seem to be the case when DEC is used as an electrolyte.[17] The decomposition of the behaviors of various electrolytes apparently differs in the first cycling, and the reason for the difference remains unclear. Recently, several models have been proposed to explain the differences among the solvents.[18–20] The aim of this investigation is to understand the reductive and oxidative stability of solvents for Li^+ on the anode and PF_6^- on the cathode, respectively, by investigating the interaction between the organic solvent molecules and these ions.

In this work, the interaction of the lithium (Li^+) cation and the hexafluorophosphate (PF_6^-) anion with the nonaqueous electrolytes EC, PC, DMC, DEC, and EMC is investigated using density functional theory (DFT) at the B3LYP/6–311++G(d,p)

Computational details

All calculations were performed using the Gaussian 09 package[21] and PCGAMESS/Firefly package.[22] The equilibrium and transition-state structures were optimized by the B3LYP[23] method in conjunction with the 6–311++G(d,p) basis set[24] for simple solvent molecules, and one solvent molecule coordinating with Li^+ and PF_6^- and the 6–31G(d) basis set[24] for $Li^+(S)_{n=2-5}$ for S = EC or PC and $Li^+(S)_{n=2-3}$ for S = DMC, DEC, or EMC, and $PF_6^-(S)_{n=2-3}$ for S = EC, PC, DMC, DEC, or EMC. To confirm each optimized and stationary point and to make zero-point-energy (ZPE) corrections, frequency analyses were done with the same basis set. Enthalpies and Gibbs free energies were obtained at 298.15 K. The charge distribution was analyzed by the natural bond orbital (NBO) theory. The optimized structures of Li^+–S and PF_6^-–S (S = EC, PC, DMC, DEC, or EMC) complexes are shown in Figs. 2 and 3, respectively.

Results and discussion

The interaction between Li^+ and a solvent molecule was analyzed by the IR spectra, as illustrated in Fig. 4. In all cases, the asymmetric stretching frequency of C=O ($\nu_{C=O}$) is significantly decreased (1908 vs 1790 cm^{-1} for EC, 1914 vs 1772 cm^{-1} for PC, 1813 vs 1689 cm^{-1} for DMC, 1806 vs 1665 cm^{-1} for DEC, and 1801 vs 1677 cm^{-1} for EMC), indicating that C=O is weakened by the interaction of Li^+–O=C,

Fig. 4. Simulated IR spectra of EC, Li^+–EC, PC, Li^+–PC, DMC, Li^+–DMC, DEC, Li^+–DEC, EMC, and Li^+–EMC systems on the basis of B3LYP/6–311++G(d,p) calculations. EC, ethylene carbonate; PC, propylene carbonate; DMC, dimethyl carbonate; DEC, diethyl carbonate; and EMC, ethyl methyl carbonate.

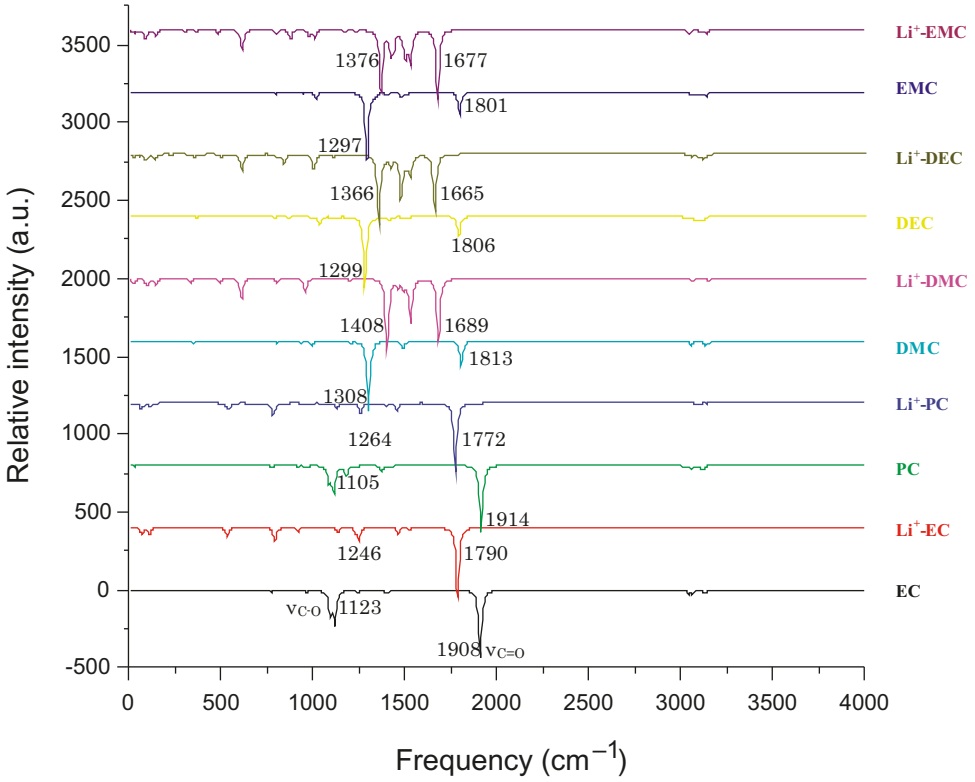

Table 1. Bond lengths R_1 and R_2 (in Å) and vibrational frequencies ν_1 and ν_2 (in cm^{-1}) of C=O before and after interaction with Li^+ calculated at the B3LYP/6–311++G(d,p) level.

Solvent	R_1	R_2	ΔR	ν_1	ν_2	$\Delta\nu$
EC	1.186	1.223	0.037	1908	1790	–118
PC	1.186	1.225	0.039	1914	1772	–142
DMC	1.205	1.243	0.038	1813	1689	–124
DEC	1.206	1.246	0.040	1806	1665	–141
EMC	1.206	1.246	0.040	1801	1677	–124

Note: EC, ethylene carbonate; PC, propylene carbonate; DMC, dimethyl carbonate; DEC, diethyl carbonate; and EMC, ethyl methyl carbonate.

whereas that of O–C (ν_{C-O}, O: linked with CH_2; C: carbonyl group) is increased (1123 vs 1246 cm^{-1} for EC, 1105 vs 1264 cm^{-1} for PC, 1308 vs 1408 cm^{-1} for DMC, 1299 vs 1366 cm^{-1} for DEC, and 1297 vs 1376 cm^{-1} for EMC). Such variations are in line with the corresponding bond changes, i.e., C=O is stretched (1.186 vs 1.223 Å for EC, 1.186 vs 1.225 Å for PC, 1.205 vs 1.243 Å for DMC, and 1.206 vs 1.246 Å for DEC and EMC), and O–C (1.362 vs 1.316 Å for EC, 1.360 vs 1.317 Å for PC, 1.338 vs 1.303 Å for DMC, and 1.339 vs 1.303 Å for DEC and EMC) is contracted. Table 1 shows that the C=O stretching is in the range of 0.037 to 0.040 Å. The interaction between PF_6^- and a solvent molecule can also be analyzed by the IR spectra, as illustrated in Fig. 5. The optimized C=O and C–O bond lengths and corresponding vibrational frequencies for EC, PF_6^-–EC, PC, PF_6^-–PC, DMC, PF_6^-–DMC, DEC, PF_6^-–EC, EMC, and PF_6^-–EMC systems are summarized in Table 2. The asymmetric stretching frequency of C=O ($\nu_{C=O}$) is significantly decreased (1908 vs 1791 cm^{-1} for EC and 1914 vs 1778 cm^{-1} for PC), indicating that C=O is weakened by the interaction of PF_6^-–O=C, whereas that of O–C (ν_{C-O}, O: linked with CH_2; C: carbonyl group) is increased (1123 vs 1256 cm^{-1} for EC and 1105 vs 1263 cm^{-1} for PC). Such variations are in line with the corresponding bond changes, i.e., C=O is stretched (1.186 vs 1.195 Å for EC and 1.186 vs 1.191 Å for PC), and O–C (1.352 vs 1.316 Å for EC and 1.355 vs 1.317 Å for PC) is contracted. However, for linear carbonates, the asymmetric stretching frequency of C=O ($\nu_{C=O}$) is slightly decreased (1813 vs 1812 cm^{-1} for DMC, 1806 vs 1804 cm^{-1} for DEC, and 1801 vs 1798 cm^{-1} for EMC), indicating very weak interaction for PF_6^-–O=C, whereas that of O–C (ν_{C-O}, O: linked with CH_2; C: carbonyl group) is also slightly increased (1308 vs 1309 cm^{-1} for DMC, 1299 vs 1301 cm^{-1} for DEC, and 1297 vs 1300 cm^{-1} for EMC). Such small variations are in line with the corresponding small bond changes, i.e., C=O is stretched (1.205 vs 1.206 Å for DMC and 1.206 vs 1.207 Å for DEC and EMC), and O–C (1.338 vs 1.336 Å for DMC and 1.339 vs 1.334 Å for DEC and EMC) is contracted. It does not favor the interaction of the PF_6^- ion with linear carbonates DMC, DEC, and EMC.

The interaction strength between Li^+ and a solvent can be quantified by calculating the binding energy of the formation of the Li^+(S) complexes (S = EC, PC, DMC, DEC, or EMC), which was defined as the difference between the product and reactant energy and can be calculated by

$$\Delta E = E[\mathrm{Li}^+(\mathrm{S})_n] - E[\mathrm{Li}^+] - nE[\mathrm{S}]$$

where $E[\mathrm{Li}^+(\mathrm{S})_n]$, $E[\mathrm{Li}^+]$, and $E[\mathrm{S}]$ represent the total energies of the $\mathrm{Li}^+(\mathrm{S})_n$ complexes, Li^+, and the solvent molecule, respectively. The binding energies of $\mathrm{Li}^+(\mathrm{S})$ complexes are listed in Table 3. It should be noted from Table 3 that the interactions between Li^+ cation and cyclic carbonates are stronger, especially the interaction with EC, than between Li^+ and linear carbonates because of the fact that the binding energy between EC and Li^+ is higher than that of the three linear carbonates (DMC, DEC, and EMC) as well as than that of PC by a few kcal/mol (1 cal = 4.184 J). The positive charge on lithium tends to transfer to the anode when the battery is charged. Thus, Li^+–EC reaches the anode more easily than other solvent molecules, resulting in its preferential reduction on the anode when a lithium ion battery is charged. Similarly, the binding energies of the PF_6^-–S complexes (S = EC, PC, DMC, DEC, or EMC) were calculated and are listed in Table 4. This table clearly shows that the interactions between PF_6^- and cyclic carbonates are stronger, especially between PF_6^- and EC, than between PF_6^- and linear carbonates. The negative charge on hexafluorophosphate tends to transfer to the cathode when the battery is charged. Thus, PF_6^-–EC reaches the cathode more easily than other solvent molecules, resulting in its preferential oxidation on the cathode when a lithium ion battery is charged. For example, Wang and Balbeuna[25] showed that EC was more reactive than other alkyl carbonates in electrochemical reduction reactions and Moshkovich et al.[26] reported EC to be more reactive as compared with other alkyl carbonates in electrochemical oxidative reactions.

Moreover, the enthalpy of reaction for coordination is given by

$$[1] \qquad \Delta H = H[\mathrm{Li}^+(\mathrm{S})_n] - H[\mathrm{Li}^+(\mathrm{S})_{n-1}] - H(\mathrm{S})$$

where H represents the ground-state calculated enthalpies, n is the number of solvent molecules, and ΔH is the enthalpy of the coordination reaction. The coordination reaction that

corresponds to the enthalpy of reaction can be written as $Li^+(S)_{n-1} + S = Li^+(S)_n$.

Results for the calculated heats of formation for complexes of solvents with Li^+ are presented in Table 5. The heats of formation of the first four complexes ($Li^+(EC)_{1-4}$) result in exothermic reactions, suggesting that the formation of $Li^+(EC)_4$ is favorable. These results are in full agreement with the conclusions drived from Raman intensity data.[27] The optimized structures of the $Li^+(EC)_{2-5}$ complexes are shown in Fig. 6. This is also true for the $Li^+(PC)_4$ complex. The stability of the $Li^+(S)_4$ complex (S = EC or PC) is also supported by the saturated charge on Li^+. It is evident from Table 5 that the Gibbs free energies of formation and heats of formation for $Li^+(EC)_{3-5}$ complexes are larger than those for $Li^+(PC)_{3-5}$ and $Li^+(S)_3$ (S = DMC, DEC, and EMC) complexes, indicating EC as a better electrolyte in comparison of PC, DMC, DEC, and EMC in applications of lithium ion batteries.

$PF_6^-(EMC)_1 + EMC = PF6^-(EMC)_2$	–10.5	–9.8	4.0	–8.2
$PF_6^-(EMC)_2 + EMC = PF6^-(EMC)_3$	–14.7	–14.0	5.9	–11.3

Note: EC, ethylene carbonate; PC, propylene carbonate; DMC, dimethyl carbonate; DEC, diethyl carbonate; and EMC, ethyl methyl carbonate.

Finally, the binding energies of the $PF_6^-(S)_{n=1-3}$ complexes in the gas phase are listed in Table 6. It can be found from Table 6 that $PF_6^-(EC)_3$ and $PF_6^-(PC)_3$ are the most stable solvation structures in EC and PC electrolytes. The positive Gibbs free energies of the linear alkyl carbonates indicate that the formation of $PF_6^-(S)_n$ is not favorable. The calculated result is consistent with the reference result.[28]

Conclusions

In summary, the interaction of the lithium (Li^+) cation and the hexafluorophosphate (PF_6^-) anion with nonaqueous electrolytes EC, PC, DMC, DEC, and EMC is studied by using density functional theory at the B3LYP/6–311++G(d,p) level in the gas phase in terms of the coordination of Li^+ and PF_6^-

with these solvents. EC coordinates with Li^+ and PF_6^- most strongly and reaches the anode and the cathode most easily because of its highest dielectric constant among all the solvent molecules, resulting in its preferential reduction on the anode and oxidation on the cathode. For cyclic carbonates EC and PC, the structure $Li^+(S)_4$ is found to be the most stable. However, for linear carbonates DMC, DEC, and EMC, the formation of $PF_6^-(S)_{n=1-3}$ is not favorable. Such analysis may be useful in applications for lithium ion batteries.

Abstract: Various 1,3-dicarbonyl compounds reacted readily with benzylic alcohols in the presence of $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ salt to produce 2-benzylic-1,3-dicarbonyl compounds in high yields. It was found that this catalyst could be completely recovered and reused without loss of its catalytic activities and is thus environmentally conscious especially in solvent-free conditions. The use of this method provides improved modification of the direct benzylation of 1,3-carbonyl compounds in terms of low reaction times, solvent-free conditions, usage of a small amount of the catalyst, and a clean reaction profile. Furthermore, the use of this catalyst is feasible because of its easy preparation, its easy handling, its stability, its easy recovery, its reusability, being environmentally green, its excellent activity, and its selectivity.

Key words: heteropoly salt, benzylation, 1,3-dicarbonyl compounds, nucleophilic substitution, solvent-free conditions.

Résumé : Divers composés 1,3-dicarbonylés réagissent facilement avec des alcools benzyliques, en présence du sel $Cs_{2,5}H_{0,5}PW_{12}O_{40}$, pour conduire à la formation de dérivés 2-benzylique-1,3-dicarbonylés, avec des rendements élevés. On a trouvé que ce catalyseur peut être complètement récupéré et réutilisé sans perte de ses activités catalytiques et qu'il est donc écologique, particulièrement dans des conditions expérimentales sans solvant. L'utilisation de cette méthode apporte une modification améliorée à la benzylation directe des composés 1,3-dicarbonylés en termes de temps de réaction plus courts, de conditions sans solvant, d'utilisation de quantités faibles de catalyseur et de profil réactionnel propre. De plus, l'utilisation de ce catalyseur est possible en raison de sa facilité de préparation et de manipulation, de sa stabilité, de sa facilité de récupération et de réutilisation, de son caractère écologique, de son excellente activité et de sa sélectivité.

Mots-clés : sel hétéropolaire, benzylation, composés 1,3-dicarbonylés, substitution nucléophile, conditions sans solvant.

[Traduit par la Rédaction]

Introduction

The construction of carbon–carbon bonds is a fundamental task in organic synthesis.[1,2] An important type of such reactions involves the alkylation of 1,3-dicarbonyl compounds.[3–7] The direct nucleophilic substitution of the hydroxyl group in alcohols with nucleophiles generally requires preactivation of the alcohol because of its poor leaving ability. Therefore, a promoter would be required for in situ activation of C–OH from the alcohol and C–H from the diketone for direct C–C bond formation. Recently, Lewis and Brönsted acids such as $BF_3{\cdot}OEt_2$,[8] $InCl_3$,[9] $FeCl_3$,[10,11] LnOTf (Ln = La, Yb, Sc, or Hf),[12,13] $Bi(OTf)_3$,[14] *p*-toluene sulfonic acid,[15] and *H*-montmorillonite[16] have also been reported to catalyze these reactions efficiently. Also, phosphomolibdic acid supported on silica gel has been used for the propargylation of aromatic compounds[17] and the alkylation of 1,3-dicarbonyl compounds with benzylic and propargylic alcohols.[18,19] Moreover, nucleophilic substitution reactions of different alcohols with sulfonamides, benzamides, and 4-nitroaniline have been reported in the presence of phosphotungstic acid.[20]

However, most of these methods have problems including drastic reaction conditions, long reaction times, and the use of expensive, toxic, and moisture-sensitive reagents. Therefore, the direct catalytic substitution of alcohols with 1,3-dicarbonyls using an efficient, cost-effective, and recyclable catalyst is highly desirable. Recently, the use of heteropoly acids (HPAs) as environmentally friendly and economically viable solid acids has gained increasing attention owing to their ease of handling and high catalytic activities and reactivities.[21] These compounds possess unique properties, such as well-defined structure, Brönsted acidity, the possibility of modification of their acid–base and redox properties by changing their chemical composition ability to accept and release electrons, high proton mobility, etc.[22] In view of green chemistry, the substitution of harmful liquid acids by reusable solid HPAs as catalysts in organic syntheses is a promising application of these acids.[23,24] Among HPAs,

$H_3PW_{12}O_{40}$ (PW), which belongs to the Keggin-type of HPAs, is the most widely used catalyst owing to their high acid strength, high thermal stability, and low reducibility. For acidic heterogeneous reactions, the bulk HPAs generally exhibit low catalytic performance because of their low surface area. Alkali-exchanged HPAs exhibit dramatic increases in surface area and profound changes in solubility over the parent HPAs; for example, salts with large monovalent ions, such as Cs^+, NH_4^+, and Ag^+, are insoluble in water. It has been demonstrated that $Cs_xH_{3-x}PW_{12}O_{40}$ possesses super acidity.[25] Cesium salts have high surface areas and thus much more acidic sites are available for catalytic reactivity.[26] This high surface area makes Cs salt a more active catalyst than the parent acid and also other known solid acids such as zeolites. Solvent-free reactions have been getting more and more attention recently, often providing clean, efficient, and high-yielding organic processes in modern synthetic chemistry. Thus, using this condition makes a clean reaction profile for organic synthesis.

We report herein the alkylation of a wide variety of 1,3-dicarbonyl compounds with benzylic alcohols catalyzed by cesium salts of PW under solventfree conditions.

Results and discussion

Reaction of benzhydrol and acetyl acetone was carried out as a model system with different solvents and temperatures and different kinds and quantities of catalysts (Scheme 1). It is obvious that the reaction does not proceed in the absence of catalysts (Table 1, entry 1). The model reaction was examined in the presence of PW and its cesium salts. The reaction was more efficient in the presence of $Cs_xH_{3-x}PW_{12}O_{40}$ compared with PW, and $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (Cs2.5) showed the best reactivity in a shorter reaction time. The efficiencies of several organic solvents for comparison with solvent-free systems were investigated (Fig. 1). Obviously, the coordinating solvents, such as acetonitrile, were unfavorable for this reaction. 1,2-Dichloroethane was found to be an effective solvent in terms of time and yield. However, a significant improvement was observed in which the product yield increased to 95% after only 1.0 h in solvent-free conditions.

The quantity of the catalyst used in this reaction was also optimized (Table 1, entries 5–7). No improvement in yield or time of the reaction was observed when catalyst loading was increased from 10 to 20 mol %. The effect of temperature was also studied. It was observed that by increasing the reaction temperature from 25 to 80 °C, the product yield was increased from 11% to 95% after 1.0 h.

Encouraged by these results, we turned our attention to various 1,3-diketones and benzylic alcohols (Table 2). It should be noted that with acetyl acetone and ketoesters, approximately the same results were obtained. Methyl acetoacetate and ethyl acetoacetate reacted smoothly with benzylic alcohols give the corresponding 2-benzylic-1,3-dicarbonyl compounds in excellent yields and with short reaction times. Other types of benzylic alcohols (Table 2, entries 3–10) underwent smooth conversion to the desired products with excellent yields.

Measurement of acidity can provide us with a better understanding of the catalytic reactivity. The acidity measurement of PW and its cesium salts by means of potentiometric titration with *n*-butylamine let us estimate the strength and the number of acid sites and their distribution. This method, based on the measured potential difference, is mainly determined by the acidic environment around the electrode membrane. The measured electrode potential is an indicator of the acidic properties of the dispersed solid particles. An aliphatic amine, such as *n*-butylamine with a basic dissociation constant of ~10^{-6}, allows a potentiometric titration of strong acids. The titration curves obtained for $Cs_xH_{3-x}PW_{12}O_{40}$ (x = 0, 1, 2, or 2.5) are presented in Fig. 2. The initial electrode potential (Ei) indicates the maximum strength of the acid sites and the value from which the plateau is reached (mequiv amine / g catalyst) indicates the total number of acid sites that are present in the titrated solid. The acidic strength of the acid sites can be classified according to the following ranges: Ei > 100 mV (very strong sites), 0 < Ei < 100 mV (strong sites), –100 < Ei < 0 mV (weak sites), and Ei < –100 mV (very weak sites).[27] According to the mentioned scale, all the catalysts present very strong acid sites. It was observed that PW is more acidic than these salts. This is

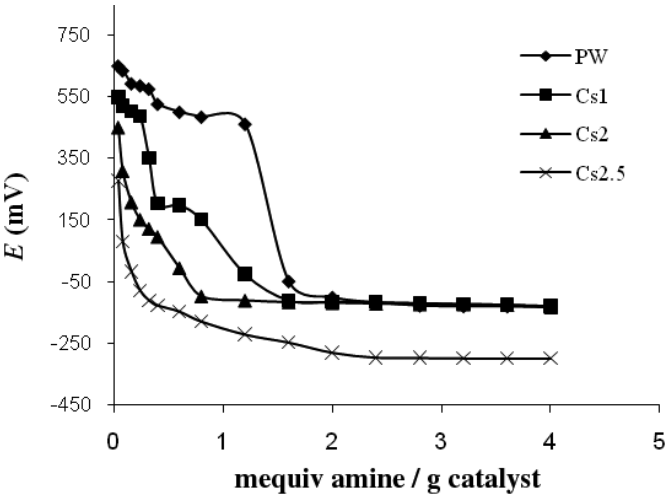
Fig. 2. Potentiometric titration curves of PW and its cesium salts.



indicated by the initial electrode potential that is lower for cesium salts than for PW. As expected, the acidity decreases with increasing cesium content, but the number of acidic sites in Cs2.5 is higher than in other cesium salts and PW. So it seems that the higher reactivity of Cs2.5 is related to the higher functional acid sites that are dispersed on the surface of the solid catalyst.

The applicability of this method for large-scale operations was investigated in the reactions of **1a**–**1c** (20.0 mmol) with **2a** (20.0 mmol) under optimized conditions (Table 2, entries 1–4). Corresponding products were obtained with approximately similar yields but at higher reaction times. As can be seen, Cs2.5 is a good candidate for large-scale operations in the direct benzylation of 1,3-dicarbonyl compounds.

A suggested mechanism for this alkylation reaction is shown as Scheme 2. By the action of Cs2.5, the alcohol was protonated to generate a stable benzyl cation after dehydration. This carbocation could quickly combine with the employed 1,3-dicarbonyl compound to produce, after the release of H^+, the final alkylated product (Scheme 2). It should be noted that the GC–MS control before the complete conversion of the starting material of the reaction showed that the corresponding symmetrical ether was not detected as an intermediate or at the end of the reaction.

In addition, Cs2.5 was found to be reusable several times without loss of activity. After completion of the model reaction, the catalyst was filtered, washed with acetonitrile dried, and reused. After reusing the catalyst four times, the yield of the reaction was 90% (Fig. 3).

Conclusion

In conclusion, we have demonstrated an efficient methodology for solvent-free direct benzylation reactions of 1,3-dicarbonyl compounds catalyzed by Cs2.5. The reactions proceeded in excellent yields and avoided the usage of toxic organic solvents. No toxic reagent(s) or by-product(s) were involved. Low reactions times, an environmentally friendly procedure, low cost, and excellent selectivity are some of the salient features of this green method. Low loading of catalyst, ease of workup, ease of handling, stability, and recyclability

Scheme 2. Proposed mechanism for catalytic addition of diketones to alcohols.

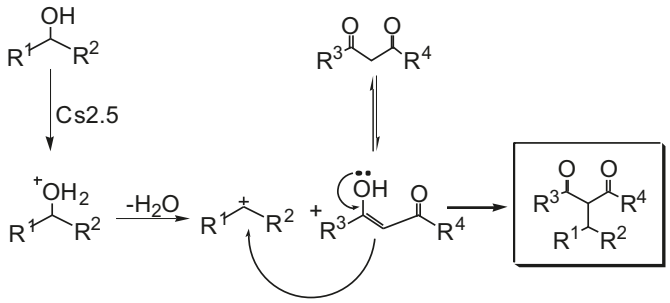


Fig. 3. Reaction profile of the five successive runs of the model reaction.

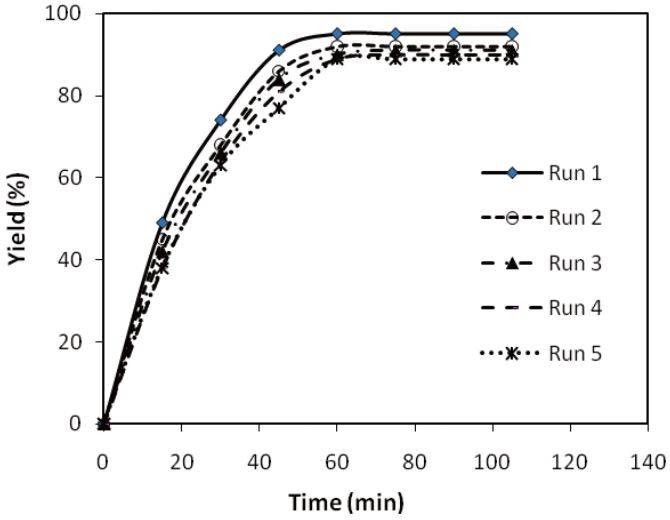

of the catalyst are other advantages of this catalyst. Large-scale synthesis is also beneficial in this method. Further applications of this catalyst to other transformations are currently under investigation.

Experimental

General remarks

All organic materials were purchased commercially from Fluka Chemical Corp. and Merck & Co., Inc. and were used without further purification. PW from Sigma-Aldrich was used. IR spectra were recorded with KBr pellets or nujol in the case of oily compounds, using a Shimadzu 470 spectrophotometer. NMR spectra were recorded on a Bruker Avance 200 MHz NMR spectrometer with $CDCl_3$ as the solvent and TMS as the internal standard. CHN compositions were measured by Hekatech elemental analysis model Euro EA 3000. Mass spectra were determined on an Agilent 6890 N GC–MS. Melting points were determined using a digital Gallenkamp apparatus.

Preparation of the catalysts ($Cs_xH_{3-x}PW_{12}O_{40}$)

The acidic salts of $Cs_xH_{3-x}PW_{12}O_{40}$ were prepared by adding the required amount of aqueous cesium carbonate to an aqueous solution of PW with stirring. An appropriate amount of the aqueous solution of Cs_2CO_3 (0.10 mol/L) was added dropwise to the aqueous solution of PW (0.08 mol/L) at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

room temperature with vigorous stirring. The Cs content was adjusted by the amount of Cs_2CO_3 solution added. As an example, for the synthesis of Cs2.5, the appropriate amounts of solution for Cs_2CO_3 and PW were 8.3 and 8.4 mL, respectively. From the beginning of the addition of Cs_2CO_3, very fine particles (precipitates) were formed to make the solution milky. After that the solution was aged at room temperature overnight. The precipitate obtained was dried at 40 °C in a rotary evaporator.

Acidity measurement

For the potentiometric titration, 0.05 g of solid catalyst was suspended in acetonitrile (90 mL) and stirred for 3 h. The suspension was titrated with a 0.05 N solution of *n*-butylamine in acetonitrile. The potential variation was measured with a Hanna 302 pH meter using a double junction electrode.

General procedure for benzylation of the 1,3-dicarbonyl compound

The solid acid catalyst (10 mol %) was added to a mixture of alcohol (1 mmol) and 1,3-dicarbonyl compound (1 mmol) at 80 °C. The reaction mixture was stirred for a short period of time (listed in the Table 2). The progress of the reaction was monitored by thin-layer chromatography (TLC). After completion of the reaction, the catalyst was removed by filtration and was washed with acetonitrile for reuse. The filtrate was concentrated and the product was purified by column chromatography on silica gel using EtOAc/hexane as eluent.

Recycling of the catalyst

The catalyst was separated from the reaction mixture, washed with acetonitrile, and dried at 120 °C for 2 h to give recycled Cs2.5. Isolated catalyst was reused in a subsequent reaction. The model reaction was repeated with recycled catalyst and the yields were found to remain in the range of 95%–90% for five successive runs.

Large-scale synthesis

Three entries of Table 2 (entries 1, 3, and 4) were selected for large-scale synthesis. The reactions of **1a**–**1c** (20.0 mmol) with **2a** (20.0 mmol) in the presence of Cs2.5 (10 mol %) were done at 80 °C under solvent-free conditions. As can be seen, Cs2.5 is a good candidate for large-scale synthesis and yields of the reactions were in the range of 90%–92% with longer reaction times compared with smallscale synthesis.

All products were identified by comparing their spectral data with those of the authentic samples, except for new compounds (**3ab**, **3bb**, **3cb**, **3bc**, **3bd**, and **3ce**). Analytical data for these compounds are presented in the following sections.

3-Benzylpentane-2,4-dione (compound 3ab)

Colorless oil. IR (KBr, cm^{-1}): 1695, 1715. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.08–7.21 (m, 5H), 3.32–3.79 (m, 3H), 2.01 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.2, 141.3, 128.1, 127.2, 125.8, 70.5, 28.7, 27.6. Anal. calcd for $C_{12}H_{14}O_2$: C 75.76, H 7.42; found: C 75.79, H 7.39. HRMS calcd for $C_{12}H_{14}O_2$: M, 190.2384; found: 190.2382.

Methyl 2-benzyl-3-oxobutanoate (compound 3bb)

Colorless oil. IR (KBr, cm^{-1}): 1715, 1735. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.08–7.30 (m, 5H), 3.91 (s, 3H), 3.30–3.81 (m, 3H), 2.05 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.2, 171.5, 141.2, 128.5, 127.6, 125.9, 51.2, 50.8, 29.8, 27.6. Anal. calcd for $C_{12}H_{14}O_3$: C 69.88, H 6.84; found: C 69.84, H 6.88. HRMS calcd for $C_{12}H_{14}O_3$: M, 206.2377; found: 206.2378.

Ethyl 2-benzyl-3-oxobutanoate (compound 3cb)

Colorless oil. IR (KBr, cm^{-1}): 1714, 1737. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.10–7.31 (m, 5H), 4.00 (q, 2H, J = 7.0 Hz), 3.31–3.80(m, 3H), 2.06 (s, 3H), 1.10 (t, 3H, J = 7.0 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.2, 171.5, 141.5, 128.5, 127.7, 126.1, 61.1, 54.4, 29.9, 27.5, 13.9. Anal. calcd for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.93, H 7.28. HRMS calcd for $C_{13}H_{16}O_3$: M, 220.2643; found: 220.2644.

Methyl 2-(2-hydroxybenzyl)-3-oxobutanoate (compound 3bc)

Pale yellow solid, mp 110–112 °C. IR (KBr, cm^{-1}): 1716, 1737. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.7–7.02 (m, 4H), 5.09 (s, 1H), 3.90 (s, 3H), 3.31–3.80 (m, 3H), 2.03 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.1, 171.5, 155.6, 128.8, 127.2, 126.7, 121.0, 115.6, 51.1, 50.7, 27.6, 20.1. Anal. calcd for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.80, H 6.39. HRMS calcd for $C_{12}H_{14}O_4$: M, 222.2371; found: 222.2372.

Methyl 2-(3-methoxybenzyl)-3-oxobutanoate (compound 3bd)

Pale yellow solid, mp 67–68 °C. IR (KBr, cm^{-1}): 1715, 1736. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.61–7.10 (m, 5H), 3.92 (s, 3H), 3.81 (s, 3H), 3.29–3.78 (m, 3H), 2.04 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.3, 171.4, 161.4, 142.5, 129.1, 119.2, 112.4, 111.1, 57.8, 51.2, 50.8, 30.7, 27.5. Anal. calcd for $C_{13}H_{16}O_4$: C 66.09, H 6.83; found: C 66.12, H 6.81. HRMS calcd for $C_{13}H_{16}O_4$: M, 236.2637; found: 236.2636.

Ethyl 2-(4-chlorobenzyl)-3-oxobutanoate (compound 3ce)

Pale yellow solid, mp 70–71 °C. IR (KBr, cm^{-1}): 1717, 1738. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.01–7.31 (m, 4H), 4.01 (q, 2H, J = 7.0 Hz), 3.31–3.81 (m, 3H), 2.03 (s, 3H), 0.98 (t, 3H, J = 7.0 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 205.3, 171.5, 137.0, 130.2, 129.0, 128.7, 61.1, 51.2, 29.8, 27.6, 13.9. Volatile organic compounds analyzed by direct insertion probe mass spectrometry

Jian Jun Li

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12

Abstract: A modified approach for analyzing volatile organic compounds through standard direct insertion probe mass spectrometry is presented. With aluminum oxide or silica powder packed in a capillary tube, the sample's evaporative loss in a high vacuum instrument chamber is significantly reduced and the retention time is increased accordingly. With this technique, organic compounds with lower boiling points (e.g., 2-butanol at 99 °C) can be readily detected and analyzed.

Key words: direct insertion probe, mass spectrometry, volatile compounds, packed capillary tube.

Résumé : On présente une approche modifiée pour l'analyse des composés organiques volatiles par spectrométrie de masse avec sonde à insertion directe standard. L'utilisation de tubes capillaires remplis d'oxyde d'aluminium ou de silice permet de réduire considérablement la perte d'échantillon par évaporation dans la chambre de l'instrument et il en résulte que le temps de rétention en est accru d'autant. Cette technique permet de détecter et d'analyser les composés organiques de points d'ébullition faibles, tel le 2-butanol, à 99 °C.

Mots-clés : sonde à insertion directe, spectrométrie de masse, composés volatiles, tubes capillaires remplis.

[Traduit par la Rédaction]

Introduction

Direct insertion probe mass spectrometry is a useful technique that has been routinely used for decades for the study of moderately volatile compounds in a variety of chemical laboratories.[1–5] The advantages of this technique include short analysis times (usually within 20 min) and simplicity (no need for sample preparation). However, volatile compounds are difficult to analyze directly with this method because they readily evaporate and are often lost in the high vacuum system before being detected. This results in weak signal intensity and poor quality mass spectra. To reduce the evaporation rate of the volatile sample, modifications to this probe have been made.[6–10] For example, glass wool packed into the sample crucible was found to slow down the evaporation rate.[6] However, very few applications of this technique have been reported. Another approach, subambient operation of a direct insertion probe, has been addressed more frequently.[8] In this approach, with the assistance of a cooling device, the direct insertion probe has been applied for the analysis of some volatile compounds, e.g., methyl laureate and dimethylnaphthalene. However, the cooling system is expensive and inconvenient to operate routinely. Furthermore, the samples used in these studies have relatively high boiling points (>250 °C). Generally, volatile compounds remain a class of compounds that are seldom analyzed by direct insertion probe mass spectrometry. In addition to the direct insertion probe, other early-developed types of probes for volatile compound introduction (e.g., heated reservoir inlet) have also been used to analyze volatile compounds.[11–12] However, there are disadvantages in using them. For example, some compounds may linger in the probe system long after experiment completion, causing a "memory" effect. In addition, this probe is a relatively expensive accessory and therefore not frequently used to analyze volatile compounds. As a separation instrument, GC–MS can be used to analyze volatile compounds. However, there are disadvantages in using it as well. For example, the instrument is more expensive and its operation cost is relatively higher (sample preparation, solvent consumption, and longer running times). Furthermore, some volatile compounds may overlap with the solvent peak, causing interference.

Here, an approach for the use of a standard direct insertion probe mass spectrometry to analyze volatile organic compounds without any hardware modification is described. Instead, a small amount of several inert powdered materials were packed in a capillary tube along with the sample of interest. The packing material acts as a flow restrictor that considerably reduces the sample's evaporation rate. This enables the mass spectrometric data to be recorded under normal operating conditions and a good quality sample evaporation profile to be obtained. In this paper the practical details of this method are described.

Experimental

A Finnigan SSQ7000 quadrupole mass spectrometer equipped with a standard direct insertion probe system was

used. The mass spectrometer was operated in electron impact (EI) mode with electron energy at 70 eV, filament current at 400 μA, multiplier voltage at 1400 V, vacuum at 4.5×10^{-7} Torr (1 Torr = 133.3224 Pa), and filament-on delay at 1 min. The probe was inserted into the instrument's ion source 0.3 min before the filament was turned on. After insertion, the probe tip was heated from ambient temperature (holding for 2 min) to 300 °C at a rate of 15 °C/min. Disposable capillary tubes with an o.d. of 1.5–1.8 mm and a length of 8–10 mm were used for sample loading. For regular experiments, approximately 1 μg of sample (solid or liquid) was transferred to the bottom of the capillary tube with a stainless steel needle and then the capillary tube was positioned in the probe tip and inserted into the ion source of the mass spectrometer. For packing experiments, the sample was placed at the bottom of the capillary tube and inert packing materials were added to fill the tube. After packing, the capillary tube was tapped gently to ensure that the packing material was tightly packed.

Both aluminum oxide powder (Al_2O_3) and silica powder were used as packing materials in this study. Aluminum oxide powder (analytical reagent, particle size 60–70 μm) was provided by The British Drug Houses Ltd. (Poole, UK). Ultrapure silica gel (5 μm, regular) was provided by Silicycle Inc. (Quebec, Quebec). Quartz (silica) wool was provided by Elemental Microanalysis Ltd. (Okehampton, UK). All other chemicals used had purities >95%. The packing materials and quartz wool were treated in an oven overnight before being used (800 °C for aluminum oxide and 650 °C for both silica and quartz wool). The retention time is defined as the peak time of the sample evaporation profile.

For the Al_2O_3 experiments, the capillary tube containing the sample was packed solely with Al_2O_3 powder onto the sample 5–6 mm high. For the silica experiments, silica was packed first 3–4 mm high, followed by Al_2O_3 powder 2–3 mm high. This approach was taken to prevent the silica powder from being pumped out by the high vacuum, since Al_2O_3 powder is heavier than silica. Finally, the quartz wool was placed on the top of the layers in the capillary tube to hold the content in place. The details of sample loading are shown in Fig. 1.

Results and discussion

Camphor is a solid substance (molecular weight 152 Da, boiling point 204 °C) that readily sublimes. When the sample was introduced into the mass spectrometer through the vacuum interlock, most of the substance was pumped out instantly. As a result, the spectrum signal was not completely recorded. As seen in Fig. 2A, camphor shows only a small fraction of the evaporation profile in an experiment performed using a standard direct insertion probe, without any modification to the sample holder. Next, Al_2O_3 powder was packed in the capillary tube, causing the evaporation rate of camphor to be significantly reduced, thereby allowing most of the sample to remain in the source during ionization. Consequently, a complete evaporation profile of camphor was obtained, as seen in Fig. 2B.

In addition to camphor, a number of volatile organic compounds also showed promising results, yielding truncated evaporation profiles in regular experiments, but complete

Fig. 1. Sample loading and packing for different experiments. (A) Regular experiment without packing, (B) packing experiment with Al_2O_3, and (C) packing experiment with silica (primarily) plus Al_2O_3.

evaporation profiles in Al_2O_3-packing experiments. The compounds tested are listed in Table 1. In general, these compounds all have moderately low boiling points (~200 °C). One exception is quinoline, having the lowest boiling point (109 °C), but its retention time on Al_2O_3 packing material was not significantly different from other compounds. It is likely that there existed a stronger absorptive interaction between quinoline and Al_2O_3.

When Al_2O_3 was used as the packing material for the examination of organic compounds with even higher volatility, such as 1-butanol, the results were poor. One reason is that aluminum oxide powder has a larger particle size (more than 10 times as large as the silica) that is inefficient at preventing rapid evaporative loss. To improve this, a substance with a smaller particle size, silica powder, was chosen to partially replace Al_2O_3 in the capillary tube. In comparison experiments, silica showed a stronger ability to restrict the evaporative loss of the sample and the retention time was increased by more than 40%. Using a combination of silica and Al_2O_3 as packing material allowed complete evaporation profiles to be observed for the compounds with higher volatility. Table 2 lists several compounds of higher volatility that were successfully analyzed using combined silica and Al_2O_3 as the packing material. It is interesting to note that chlorobenzene

Table 1. Volatile compounds showing complete evaporation profiles on Al_2O_3.

Chemical name	Molecular weight (Da)	Boiling point (°C)	Retention time (min)	Peak width at 1/2 peak height (min)
1-Bromo-4-nitrobenzene	201	261	5.6	0.9
Naphthalene	128	218	4.1	1.0
2,4-Dimethyl phenol	122	211	2.8	0.5
1-Octanol	130	195	8.0	1.1
2-Octanol	130	175	4.9	1.6
Quinoline	129	109	4.1	0.9

Note: Quinoline shows no signal in regular experiment. Ion source temperature, 150 °C.

Table 2. More volatile chemicals showing complete evaporation profiles on silica/Al_2O_3.

Chemical name	Molecular weight (Da)	Boiling point (°C)	Retention time (min)	Peak width at 1/2 peak height (min)
Chlorobenzene	112	131	1.5	1.0
Methyl isobutyl ketone	100	117	7.3	3.4
1-Butanol	74	117	3.6	1.4
2-Butanol	74	99	1.7	0.3

Note: All of these compounds show no signals in regular experiments. Ion source temperature, 120 °C.

had the highest boiling point in this table, but its retention time was the shortest. This may be attributed to its lower polarity.

Silica/Al_2O_3 was also used to study highly volatile and nonpolar compounds, such as toluene (boiling point 110 °C, molecular weight 92 Da) and hexane (boiling point 69 °C, molecular weight 86 Da). Although the complete evaporation profiles were not obtained in the study, the profile was sufficient to produce an adequate mass spectrum.

Conclusion

With the aid of inert packing materials, volatile organic compounds can be readily analyzed by standard direct insertion probe mass spectrometry. The evaporative loss of volatile compounds can be reduced significantly when packing material is used in the sample capillary tube. The retention time depends on the particle size of the packing material, as well as the boiling point and polarity of the compound. Our results show that this is a simple, inexpensive and convenient means of achieving direct insertion probe mass spectrometry of volatile compounds that can be implemented in any laboratory.

TRIBUTE

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

The name Juan Cesar Scaiano, of course, better known to most as Tito Scaiano, is synonymous with photochemistry and indeed chemistry in Canada. Since settling in Canada in 1979, Tito has made the Ottawa area his home and the place where he established and built his reputation as one of the world's foremost experts in photochemistry and reactive intermediates. It is a fitting tribute for the *Canadian Journal of Chemistry* to provide his friends and colleagues with the venue to present their own scientific contributions in honour of one of our country's preeminent chemists, on the occasion of his 65th birthday.

Tito was born in Buenos Aires, Argentina, in 1945. He obtained his undergraduate degree from the University of Buenos Aires in 1967 and then his Ph.D. from the University of Chile in 1970 working with Eduardo Lissi (who is a coauthor of a paper in this issue). Following a post-doc with Alwynn Davies at University College London, he returned to Chile briefly and then took a position at the University of Rio Quarto in Argentina. The stories of this part of Tito's personal and scientific life in Argentina during the years of the Peronist revolution would fill a volume on their own, and we will leave them to Tito to relate. Suffice it to say that it was this terrifying time in South American history that brought Tito to Canada in 1975, when he joined Keith Ingold (also a contributor to this issue) as a visiting scientist at the National Research Council (NRC) in Ottawa. He left Canada briefly to take up his first faculty position at the Radiation Laboratory at the University of Notre Dame, but the lure of Canada and the NRC brought him and his family back to stay in 1979. He remained at the NRC until 1991, when he gave up his position as Principal Research Officer to move to the University of Ottawa as a Professor. He is now a Distinguished University Professor and the Canada Research Chair in Applied Photochemistry, a position he has held since 2003. There is a very nice biography of Tito that appeared in the journal *Photochemistry and Photobiology* (**2006**, *82*: 1–4) that covers most aspects of his biography and his career up to 2005. This article accompanied a special issue of that journal that was dedicated to Tito after a symposium entitled *Reactive Intermediates in Photochemistry*, which celebrated his contributions on the occasion of his 60th birthday. We will not repeat much of what was so elegantly written then; instead, we summarize some of the more recent achievements that continue to highlight his remarkable career.

Tito's research interests have always been built from the foundation for which he is best known, namely, the application of laser techniques for the study of short-lived reactive intermediates and reaction mechanisms in solution, supramolecular systems, and heterogeneous media. This underlying theme led to the pioneering use of two-photon photochemistry for the study of reactive intermediates and the discovery of new photochemical pathways, and the development of novel lithographic imaging techniques. In the 1990s some of his group's focus was shifted to studying photochemical applications of biologically relevant molecules, where they examined the photostability and photodegradation mechanisms of pharmaceuticals, most notably ketoprofens. This led to the development of new photocages for the rapid and selective release of small molecules in biological systems. His extensive contributions to our knowledge of the reactivity of reaction intermediates such as radicals and biradicals has also been instrumental in the discovery of new antioxidants. In the last 6 years or so he has been a key contributor to the application of photochemical methods for the preparation and application of nanomaterials, in particular Au, Ag, and Cu nanoparticles. As one looks over his 606 (and counting) research papers, 75 in the last 5 years alone, it is evident that there is not an area of photochemistry to which Tito has not made seminal contributions. His H-index has been in the 60s over the last decade or so, making him one of Canada's most highly cited chemists. His excellence in research led to the most highly prized research awards for both Ontario and Canada, namely, the Premier's Platinum Excellence Award and the Gerhard Herzberg Canada Gold Medal in Science and Engineering. These awards cap a long list of other accolades he has earned throughout his career that are reserved for the very best in the field, including the Rutherford Memorial Medal, the Steacie Prize in Natural Sciences, the E.W.R. Steacie Award, the Inter-American Photochemical Society Award in Photochemistry, a Killam Research Fellowship, the Henry Marshall Tory Medal of the Royal Society of Canada, The Porter Medal for Photochemistry awarded jointly by the European, Japanese, and Inter-American Photochemical Societies, the Photon Award from the American Society for Photobiology, and the Sir Christopher Ingold Fellowship and Medal of the Royal Society of Chemistry. He is a Fellow of the Royal Society of Canada and the Chemical Institute of Canada, and is the University of Ottawa's first named Distinguished University Professor.

In addition to giving a number of named lectureships, in the last 5 years he has also received a number of other distinctions including Honorary Doctorates from Dalhousie University (2006) and from the Universidad de Cordoba in Argentina (2010). He was also appointed "Académico" of the National Academy of Sciences of Argentina and an Officer of the Order of Canada in 2006. The citation for the latter describes him as "*an inspiring teacher to students, nurturing their creative spirit and conveying to them a sense of community responsibility*." Tito ranks his role as a mentor to the long list of undergraduate and graduate students and post-doctoral researchers who have passed through his lab as the biggest contribution of his career. Since 2005 he has mentored 9 M.Sc. and 15 Ph.D. students, 18 post-doctoral fellows, and 19 undergraduate students, who join the more than 485 of his past collaborators and coauthors who are listed at the end of this tribute. Most of his former students and post-doctoral researchers have gone on to establish impressive careers of their own, and many have made remarkable contributions as academics or leaders in major companies and government laboratories. No less than a dozen of his former group members are faculty members at Canadian Universities. Tito's name will live on for the next generations of young chemists who may not have the good fortune to work with him directly, on the front covers of the two "bibles" of the trade — *Principles of Molecular Photochemistry: An Introduction* and *Modern Molecular Photochemistry of Organic Molecules*, published by University Science Publishers — which he coauthored with two of his longtime collaborators, Nick Turro and V. Ramamurthy.

Not surprisingly for someone of his stature, Tito has also held a number of leadership roles in national and international organizations. He served as President of both the Inter-American Photochemical Society and the American Society for Photobiology. He was the first Editor-in-Chief of *Photo-*

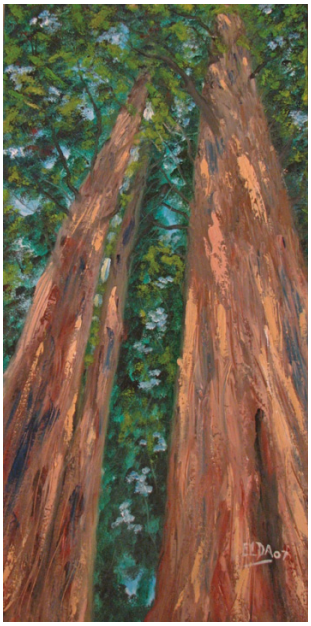
Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

chemistry and Photobiology from outside of the United States, and has also served on the Editorial Board of many journals, including *Accounts of Chemical Research* and the *International Journal of Chemical Kinetics*.

Tito is also an entrepreneur. Anyone who has heard him give a lecture will know from his subtle "plugs" of Luzchem Research Inc., the Ottawa-based company that he started in the late 1990s with his wife, Elda. Luzchem (www.luzchem.com) specializes in the design and manufacture of instruments and equipment used in photochemistry. From its humble beginnings building photoreactors, Luzchem now offers a wide range of photochemical equipment including a miniaturized laser flash photolysis system, systems for film metrology, xenon illumination products, solar simulators, and spectroradiometers. Luzchem is a successful, family-run business (all five shareholders are Scaianos) with 13 employees, and was honored by the Ottawa Chamber of Commerce in 2007 with the award for Small Business of the Year.

Interestingly, a part of Tito's motivation for starting Luzchem was to plan for a second career once he turned 65 years of age and had to retire from academia. Tito is rarely guilty of poor planning, but as we write this in late 2010, the year Tito turned 65, there is no longer mandatory retirement in Ontario, he has recently been renewed as the CRC Chair in Applied Photochemistry at Ottawa until 2017, and he now serves as Chair of the Department of Chemistry there. It is clear that his 65th birthday is but just another milestone, and there will be much more in his career to be celebrated in the coming years.

When not "working", Tito spends time with his family — the love of his life Elda, their four grown children and their spouses, and his and Elda's grandchildren. Tito and Elda continue their adventurous spirit from the early days and now that their children are grown they can often be found traveling the world together. Recently, they have taken to adventures that involve cruising the oceans, seas, and fiords of the world. The photograph of Tito and Elda shown in this issue was taken in 2010 during a cruise of the fiords of Norway. We are honored that Elda, an accomplished artist, has agreed to allow one of her paintings to be used as the cover artwork for this Special Issue. Another painting of hers, suitably entitled "Growing in Canada" appears below. We believe that Tito has always been grateful for the opportunities that have been provided to him in his adopted country, and the cover artwork, with its distinctly Canadian theme, and "Growing in Canada" captures the essence of his career and family life.



Tito is indeed a remarkable colleague and mentor. As you read the two issues dedicated to Tito, the first in February and the second in March, you will be struck by the high quality and diversity of the chemistry presented by his friends, colleagues, past students, and post-docs from across the country and around the world. They are a fitting testament to the wide-ranging impact he has had on our field, and there is something here for everyone. Tito wouldn't have it any other way.

HOMMAGE

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

Juan Cesar Scaiano, que la plupart connaissent mieux sous le nom de Tito Scaiano, est synonyme de photochimie et bien entendu de chimie au Canada. Depuis qu'il s'est établi au Canada en 1979, Tito a choisi de vivre dans la région d'Ottawa où il a établi et bâti sa réputation comme l'un des plus grands experts au monde dans le domaine de la photochimie et des intermédiaires réactifs. La *Revue canadienne de chimie* est l'endroit tout indiqué pour donner l'occasion à ses amis et à ses collègues de présenter leurs propres contributions scientifiques en l'honneur de l'un de nos éminents chimistes au pays, à l'occasion de son 65e anniversaire.

Tito est né à Buenos Aires (Argentine) en 1945. Il a obtenu son diplôme de premier cycle de l'Université de Buenos Aires en 1967, puis son doctorat de l'Université du Chili en 1970, sous la direction d'Eduardo Lissi (coauteur d'un article dans le présent numéro). Après avoir effectué un postdoctorat au sein du groupe d'Alwynn Davies au University College de Londres, il est retourné brièvement au Chili et a accepté par la suite un poste à l'Université de Rio Quarto en Argentine. Les récits de cet épisode de sa vie personnelle et scientifique en Argentine pendant les années de la révolution péroniste rempliraient, à eux seuls, un volume tout entier. Nous laisserons donc le soin à Tito de nous les raconter. Qu'il suffise de dire que ce sont ces moments terrifiants de l'histoire sud-américaine qui ont amené Tito au Canada en 1975, lorsqu'il a rejoint Keith Ingold (également collaborateur au présent numéro) à titre de chercheur invité au Conseil national de recherches du Canada (CNRC), à Ottawa. Il a quitté brièvement le Canada pour occuper son premier poste de professeur au laboratoire de rayonnement de l'Université Notre Dame (É.-U.), mais l'attrait du Canada et du CNRC l'a ramené s'installer au pays avec sa famille en 1979. Il a travaillé au CNRC jusqu'en 1991, année où il a renoncé à son poste d'agent principal de recherche pour occuper celui de professeur à l'Université d'Ottawa. Il est maintenant professeur distingué et titulaire de la Chaire de recherche du Canada en photochimie appliquée, poste qu'il occupe depuis 2003. Il existe une très belle biographie de Tito, parue dans la revue scientifique *Photochemistry and Photobiology* (**2006**, *82*: 1–4), qui porte sur la plupart des aspects de sa vie et de sa carrière jusqu'en 2005. Cet article accompagnait un numéro spécial de la revue consacré à Tito, à la suite d'un colloque intitulé *Reactive Intermediates in Photochemistry*, qui soulignait ses contributions à l'occasion de son 60e anniversaire. Nous ne répéterons pas ce qui a été écrit de manière si élégante à ce moment-là; nous résumerons plutôt certaines de ses plus récentes réalisations qui continuent de mettre en évidence sa carrière remarquable.

Les travaux de recherche de Tito ont toujours eu comme fondement le thème pour lequel il est le mieux connu, à savoir l'application des techniques laser pour l'étude des intermédiaires réactifs de courte durée de vie et des mécanismes de réaction en solution, dans les systèmes supramoléculaires et dans les milieux hétérogènes. Ce thème de fond a mené à l'utilisation novatrice de la photochimie à deux photons pour l'étude des intermédiaires réactifs et la découverte de nouvelles voies photochimiques, de même qu'à la création de nouvelles techniques lithographiques. Dans les années 1990, une partie des efforts de son groupe s'est tournée vers l'étude d'applications photochimiques de molécules d'intérêt biologique, où l'on a examiné la photostabilité et les mécanismes de photodégradation de médicaments, en particulier des kétoprofènes. Cette étude a mené à la création de nouvelles molécules photolabiles (« photocages ») pour la libération rapide et sélective de petites molécules dans des biosystèmes. Ses contributions considérables à l'avancement de nos connaissances sur la réactivité d'intermédiaires réactionnels comme les radicaux et les biradicaux ont également joué un rôle important dans la découverte de nouveaux antioxydants. Au cours des six dernières années, il a participé activement à l'application de méthodes photochimiques pour la préparation et l'utilisation de nanomatériaux, en particulier des nanoparticules d'or, d'argent et de cuivre. Si l'on se penche sur ses 606 articles scientifiques publiés jusqu'à maintenant, dont 75 dans les cinq dernières années seulement, il est évident qu'il n'y a aucune sphère de la photochimie à laquelle Tito n'a pas contribué de manière exceptionnelle. Son indice h a oscillé dans la soixantaine au cours de la dernière décennie, ce qui en fait l'un des chimistes canadiens les plus souvent cités. Son excellence dans la recherche l'a mené à l'obtention des prix les plus convoités en recherche en Ontario et au Canada, à savoir la Bourse du premier ministre de l'Ontario pour l'excellence en recherche et la médaille d'or Gerhard-Herzberg en sciences et en génie. Ces prix viennent couronner une longue liste d'autres récompenses remportées tout au long de sa carrière et que l'on réserve aux meilleurs du domaine, dont la médaille commémorative Rutherford, le prix Steacie en sciences naturelles, le prix E.W.R. Steacie, le prix de l'Inter-American Photochemical Society en photochimie, la bourse de recherche Killam, la médaille Henry Marshall Tory de la Société royale du Canada, la médaille Porter en photochimie décernée conjointement par l'Association européenne de photochimie, l'Inter-American Photochemical Society et la Japanese Photochemical Society, le prix Photon de l'American Society for Photobiology et le Sir Christopher Ingold and Medal de la Royal Society of Chemistry. Il est membre de la Société royale du Canada et de l'Institut de chimie du Canada et le premier à recevoir le titre de Professeur distingué de l'Université d'Ottawa.

En plus d'avoir donné un certain nombre de conférences commémoratives, il a également reçu plusieurs autres distinctions au cours des cinq dernières années, dont un doctorat honorifique de l'Université Dalhousie (2006) et un autre de l'Université de Córdoba en Argentine (2010). Il a également été nommé « Académico » de l'Académie nationale des sciences de l'Argentine et Officier de l'Ordre du Canada en 2006. La note biographique de cette dernière nomination le décrit comme « un pédagogue qui a su inspirer et guider ses étudiants en cultivant leur créativité et en leur inculquant un sens des responsabilités communautaires ». Tito classe son rôle de mentor de la longue liste d'étudiants de premier cycle, de diplômés et de chercheurs postdoctoraux qui sont passés par son laboratoire comme étant la plus grande contribution de sa carrière. Depuis 2005, il a mentoré 9 étudiants à la maîtrise et 15 autres au doctorat, 18 boursiers postdoctoraux et 19 étudiants de premier cycle, qui rejoignent les rangs de plus de 485 de ses anciens collaborateurs et coauteurs dont la liste apparaît à la fin de cet hommage. La plupart de ses anciens étudiants et chercheurs postdoctoraux ont entrepris de brillantes carrières, et beaucoup d'entre eux contribuent de façon remarquable en tant que professeurs d'université ou chefs de file dans des entreprises importantes et des labora-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/18/12
For personal use only.

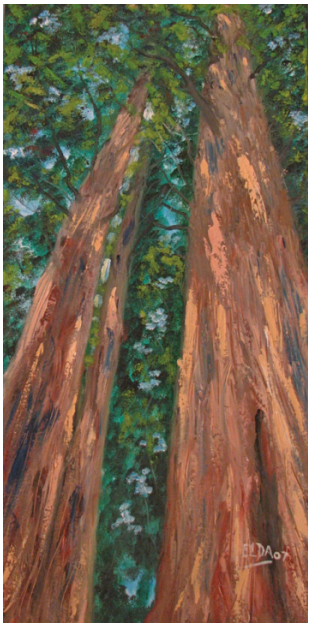
toires gouvernementaux. Pas moins d'une douzaine d'anciens membres de son groupe font partie du corps professoral d'universités canadiennes. Le nom de Tito continuera de se perpétuer au sein des prochaines générations de jeunes chimistes qui n'auraient pas la chance de collaborer avec lui directement grâce aux deux « bibles » du domaine intitulées *Principles of Molecular Photochemistry: An Introduction* et *Modern Molecular Photochemistry of Organic Molecules*, publiées par les University Science Publishers, et qu'il a corédigées avec deux de ses collaborateurs de longue date, soit Nick Turro et V. Ramamurthy.

Comme on peut s'y attendre de la part de quelqu'un de sa stature, Tito a également assumé des rôles de leadership au sein d'organismes nationaux et internationaux. Il a été président de l'Inter-American Photochemical Society et de l'American Society for Photobiology. Il a été le premier directeur de la publication non états-unien de la revue *Photochemistry and Photobiology* et a également été membre du comité de rédaction de nombreuses revues, notamment de l'*Accounts of Chemical Research* et de l'*International Journal of Chemical Kinetics*.

Tito est également entrepreneur. Toute personne qui a déjà assisté à l'une de ses conférences aura entendu parler, en raison de ses allusions intéressées subtiles, de Luzchem Research inc., une entreprise d'Ottawa qu'il a créée avec sa femme, Elda, à la fin des années 1990. Luzchem (www.luzchem.com) se spécialise dans la conception et la fabrication d'instruments et de matériel utilisés en photochimie. De ses débuts modestes, où elle ne fabriquait que des photoréacteurs, Luzchem a prospéré et offre maintenant une vaste gamme d'appareils dont un système de photolyse éclair au laser miniaturisé, des systèmes pour l'analyse de films, des lampes au xénon, des simulateurs solaires et des spectroradiomètres. Luzchem est une entreprise familiale florissante (les cinq actionnaires sont des Scaiano) qui compte 13 employés et en 2007, elle a reçu le prix de la petite entreprise de l'année de la Chambre de commerce d'Ottawa.

Fait intéressant, l'une des raisons pour lesquelles Tito voulait fonder son entreprise était de planifier une seconde carrière en vue de sa retraite du milieu universitaire qu'il devrait prendre une fois qu'il aurait atteint 65 ans. Tito est rarement coupable d'une mauvaise planification, mais au moment où nous écrivons ces lignes, à la fin de 2010 et l'année même où il a atteint l'âge de 65 ans, il n'existe plus de retraite obligatoire en Ontario, le poste de titulaire de la Chaire de recherche du Canada en photochimie appliquée à Ottawa lui a été confié de nouveau jusqu'en 2017 et il est maintenant directeur du Département de chimie à cet endroit. Il est clair que son 65^{e} anniversaire n'est qu'une autre étape importante et que l'on soulignera encore de nombreuses réalisations professionnelles au cours des prochaines années.

Lorsqu'il ne « travaille » pas, Tito passe du temps en famille avec l'amour de sa vie, Elda, leurs quatre enfants maintenant adultes et leur conjoint ou conjointe, et les petits-enfants. Tito et Elda ont gardé leur esprit d'aventure des premiers jours, et maintenant que les enfants sont grands, on les trouve souvent parcourant le monde ensemble. Récemment, ils ont pris goût aux aventures qui touchent les croisières dans les océans, les mers et les fjords du monde. La photo de Tito et d'Elda présentée dans le présent numéro a été prise en 2010 lors d'une croisière dans les fjords de Norvège. Nous sommes très honorés qu'Elda, une artiste accomplie, ait consenti à ce que nous utilisions l'une de ses toiles comme illustration de la page couverture du présent numéro spécial. Une autre de ses œuvres, intitulée à juste titre *Growing in Canada*, apparaît ci-dessous. Nous croyons que Tito a toujours été reconnaissant des possibilités qui lui ont été offertes dans son pays d'adoption, et cette illustration de la page couverture, dont le thème est typiquement canadien, ainsi que *Growing in Canada* capturent l'essence de sa carrière et de sa vie familiale.



Tito est en effet un collègue et un mentor exceptionnels. En parcourant les pages des deux numéros consacrés à Tito, le premier en février et le second en avril, vous serez frappé par la grande qualité et diversité de la chimie présentée par ses amis, collègues, anciens étudiants et boursiers postdoctoraux de partout au pays et d'ailleurs dans le monde. Ils témoignent avec justesse des vastes répercussions qu'il a eues sur notre domaine, et chacun y trouve son compte ici. Tito ne voudrait pas qu'il en soit autrement.

For personal use only.

Rod was born on July 6th, 1944 in rural Alberta, approximately 250 km east of Edmonton, where his grandparents on both sides of his family homesteaded near the turn of the last century. Rod's father operated a bulk oil and gas agency together with a welding and general farming machinery repair shop in the farming community known as Landonville. When Rod was in grade one, he attended Telegraph, a one-room school, where his aunt Eunice was the teacher. Everyday he walked the 3.5 miles to school. When the winter weather was too miserable for walking, which was frequent in central Alberta, he stayed with his aunt in a small teacher's "shack" adjacent to the school. The school had only nine students, but Rod feels that he profited immensely from having his aunt as one of his first teachers in this unique environment. In 1957, Rod's family moved to Vermilion, a bustling town of approximately 2500 situated on the river of the same name, which serves the surrounding rural communities. Rod spent much of his summer "vacations" working on his grandparents' farm — repairing fences, painting, gardening, picking rocks, harvesting hay, etc. Rod's interest in chemistry was sparked by a grade 10 science teacher, Mr. Matheson, who performed a number of in-class chemistry demonstrations. To acquire a deeper understanding of chemistry, Rod constructed a laboratory in the basement of his home, much to the annoyance of his family, particularly when loud bangs from exploding hydrogen or smells of hydrogen sulfide or other noxious gases emanated from the basement.

After finishing high school, Rod spent 2 years at the Southern Alberta Institute of Technology (SAIT) in Calgary where he completed the Chemical Research Laboratory Technology program. After graduation, he took up a full-time position at Atomic Energy of Canada Limited in Pinawa, Manitoba. He quickly decided that he wanted to further his education, so he continued his move eastward to Waterloo where he obtained a B.Sc. Honours in chemistry in 1968. Forty years later, he received one of the 50 Alumni of Honour Awards to mark the 50th anniversary of the Faculty of Science at the University of Waterloo. It was here that Rod was first introduced to NMR spectroscopy while working as a summer student in the laboratory of Terry Gough. One other important discovery that Rod made in Waterloo was his future wife, Valerie, who was at the time a graduate student in Learning Psychology. Valerie hailed from the east (Kingston, Ontario, and Arvida, Quebec) so they decided to get married in the middle of the country, Winnipeg, in the fall of 1968. Rod completed his M.Sc. (1970) and Ph.D. (1972) under the supervision of Ted Schaefer at the University of Manitoba. The title of Rod's M.Sc. thesis was "A study of benzene solvent-induced shifts in the proton magnetic resonance spectra of some substituted benzenes"; the Ph.D. thesis was about "Some applications of experimental and theoretical nuclear spin-spin coupling constants to study molecular structure". Approximately 15 papers, all published in the *Canadian Journal of Chemistry*, resulted from Rod's graduate research in Schaefer's laboratory. His graduate research demonstrated the importance of performing high-precision NMR measurements (i.e., the measurement of NMR frequencies to ±0.01 Hz and line widths at half-maximum height of less than 0.10 Hz) in obtaining information on the conformations and dynamics of small molecules in solution. Another significant aspect of Rod's early research was his use of the very best theoretical methodology available at the time to interpret experimental data. For example, he used semiempirical molecular orbital theory to aid the interpretation of long-range spin-spin coupling constants; see Fig. 1. The model, while crude by today's standards, has withstood the test of time. The synergy of experiment and theory has become a hallmark of Rod's groundbreaking research in advancing our understanding of the fundamental NMR tensors.

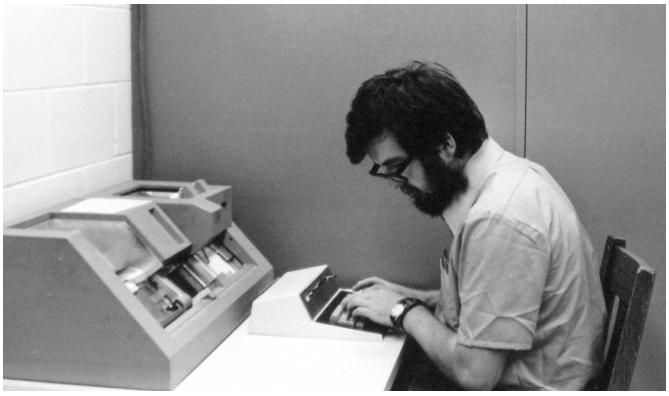

Fig. 1. Rod Wasylishen as a graduate student, ca. 1971–1972, in the old Engineering Building of the University of Manitoba. He is shown preparing punched-card computer input for John A. Pople's semi-empirical INDO program that Rod had modified to calculate spin-spin coupling constants. The FORTRAN code consisted of approximately 2000 lines (i.e., a big box of computer cards).

Between 1972 and 1974, Rod was a National Research Council postdoctoral fellow with Ted Becker at the Laboratory of Chemical Physics of the National Institutes of Health (Bethesda, Maryland). Here Rod was introduced to pulsed Fourier transform (FT) NMR spectroscopy. In 1974, Rod took up an assistant professorship at the University of Winnipeg, working on chemical applications of solution NMR spectroscopy. At Winnipeg, he also recognized the power of multinuclear NMR in studying the dynamics of orientationally disordered solids. During a one-year sabbatical (1980–1981) in Colin Fyfe's laboratory at the University of Guelph, Rod had his first opportunity to investigate rigid solids using magic-angle spinning and cross-polarization techniques.

In 1982, Rod moved to Dalhousie University, Halifax, Nova Scotia, where he established a vigorous solid-state NMR research program aimed at better understanding the relationship between NMR tensors and molecular structure. During this period, he and his research group made seminal contributions to the understanding of fundamental NMR tensors. These tensor properties and their relationships to molecular structure and chemical bonding are the foundation on which the power of NMR spectroscopy lies. He carried out extensive measurements of chemical shift tensors for a wide range of important chemical compounds. In many cases, his reports have represented the first ever measurement for a particular functional group. In the late 1980s, Rod recognized that magnetic shielding tensors and electric field gradient tensors are not necessarily coincident for quadrupolar nuclei. He developed and implemented a theoretical treatment for understanding NMR spectra of quadrupolar nuclei. This work is of paramount importance for researchers all around the world who are studying

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/16/12
For personal use only.

quadrupolar nuclei by solid-state NMR. Rod reported unambiguous experimental measurements of indirect spin-spin coupling tensors, which provide important information on bonding and intramolecular conformation. Although thousands of isotropic values of indirect spin-spin coupling constants have been reported in the NMR literature, very little reliable information is available about indirect spin-spin coupling tensors. Rod's laboratory is one of very few in the world that has produced reliable experimental data to prove the existence of sizable anisotropies in ***J*** tensors. For example, Rod's group performed some beautiful single-crystal NMR measurements of ^{199}Hg–^{31}P spin-spin coupling tensors and conclusively demonstrated that *J* anisotropies are comparable to the isotropic values. Rod's group was also the first to establish absolute magnetic shielding scales for oxygen, sulfur, chlorine, and tin, making it possible for other scientists to properly understand and interpret chemical shifts observed for these nuclei. In collaboration with Jan Kwak, Rod also developed an NMR paramagnetic relaxation method to determine distribution coefficients of solubilizates in micellar systems.

In 2000, Rod returned to Alberta after 36 years, taking up a Tier 1 Canada Research Chair in Physical Chemistry at the University of Alberta. Here he established a state of the art laboratory for investigating solid materials by NMR spectroscopy and magnetic resonance imaging (MRI). His group also built a 60 W diode laser system for producing hyperpolarized Xe-129 to investigate porous materials. His group was the first to report successful MR imaging of a functional hydrogen–oxygen fuel cell. Rod's laboratory also demonstrated the advantages of using hyperbolic secant inversion pulses for the sensitivity enhancement of NMR signals from quadrupolar nuclei in solid materials. This method has become widely used by other researchers in the field. Rod has had a long-standing interest in high-resolution molecular beam and microwave spectroscopy. Most chemists are unaware of the relationship between the nuclear spin-spin coupling tensor (***J***) and the molecular beam parameters (c3 and c4). Rod's laboratory demonstrated that using high-quality molecular-beam data one could obtain the anisotropy in the indirect spin-spin coupling tensor (Δ***J***). Furthermore, he showed that first-principles multiconfigurational SCF calculations using large correlation-consistent basis sets are capable of reproducing the experimental data for first- and second-row diatomics and that, for heavier diatomics and polyatomics, Ziegler's ZORA-DFT method provides encouraging results. In recent years, Rod also demonstrated the feasibility of carrying out solid-state NMR studies on many exotic nuclei that had been seldom explored in the literature (e.g., ^{53}Cr and ^{99}Ru).

To date, Rod's prolific research program has produced more than 324 peer-reviewed publications in scientific journals and 21 invited book chapters and reviews. Since 1984, he has given over 140 invited talks and plenary lectures. He is also a co-editor of two NMR books. Rod has been recognized with many awards and honours including the Fellow of the Chemical Institute of Canada (1987), Gerhard Herzberg Award from the Spectroscopy Society of Canada (1994), Canada Council Killam Research Fellowship (1995–1997), Fellow of the Royal Society of Canada (1998), Betts Lectureship (2004), John C. Polanyi Lecture Award (2004), Fellow of the American Association for the Advancement of Science (2006), Killam Annual Professorship Award (2007), Fellow of the International Society of Magnetic Resonance (2005), and EAS Award for Outstanding Achievements in Magnetic Resonance (2011).

Rod is not only a world-class scientist, but also a great educator and mentor. Because of the nature of his research discipline, he has generally maintained a research group of moderate size, graduating a total of 30 graduate students and trained 15 PDFs, 6 visiting scientists, and numerous undergraduates. Fourteen of Rod's former group members are now faculty members in universities in Canada and worldwide. Others hold NMR-related positions across Canada and worldwide, including managers of NMR laboratories and researchers in government laboratories and in universities. Rod has the undeniable ability to inspire his students to continue in scientific research and to train them to become independent researchers. His Ph.D. students received the Canadian Association for Graduate Studies (CAGS/UMI) Distinguished Dissertation Award in natural sciences and engineering in 2003 and the Natural Sciences and Engineering Research Council of Canada (NSERC) Doctoral Prize in 1995 and 2003. Most of his Ph.D. students have held NSERC Postdoctoral Fellowships. This reflects Rod's incomparable mentoring skills. It is perhaps not an overstatement to say that Rod has educated a new generation of solid-state NMR spectroscopists in Canada.

Over the course of his career, Rod has made distinguished contributions to the Canadian and international magnetic resonance communities. He has been an associate editor of the *Canadian Journal of Chemistry* since 1998 and serves on the editorial boards of *Solid State Nuclear Magnetic Resonance, Magnetic Resonance Review*, and *Canadian Journal of Analytical Sciences and Spectroscopy*. In 2008, he joined Robin Harris as one of the two editors-in-chief for a new edition of *Encyclopedia of Magnetic Resonance* (approximately 10 000 printed pages in length, to be published by John Wiley & Sons, Inc. in 2012). He was elected to the Council of the International Society of Magnetic Resonance in 2001. Since 2004 he has been a member of the AMPERE Society. Rod has served on many NSERC committees: member of the Grant Selection Committee (1987–1990), chair of the NSERC/NMR Site Visit Committee (1991, 1992, 1995, and 2000), member of the NRC/NSERC Research Project Review Committee (1996), chair of the NSERC Accelerator Grant Program (2003–2004), and member of the Major Resources Support Committee (2007–2010). In 2003–2005, he served as secretary of the Mathematical and Physical Sciences Division of the Royal Society of Canada. It is particularly worth pointing out his continued support of this Journal. Over the years Rod has published more than 75 papers in the *Canadian Journal of Chemistry*.

Rod has demonstrated tremendous leadership and worked tirelessly on improving the NMR infrastructure in Canada. He is one of the leading founders of the National Ultrahigh-Field NMR Facility for Solids. This national facility, located in Ottawa, Ontario, features the only NMR spectrometer in Canada operating at a magnetic field of 21 T (900 MHz). This is also the first 900 MHz NMR spectrometer worldwide entirely dedicated to solid-state NMR research. Since 2005, Canadian NMR researchers from 20 universities from 7 provinces and 4 National Research Council of Canada (NRC) institutes have benefited from having access to this world-leading NMR facility. Rod was instrumental in making this unique facility a reality. This facility has provided a huge boost to the level of challenging problems that can be tackled by Canadian researchers.

In his spare time, Rod enjoys photography, astronomy, hiking, cross-country skiing, and jogging. Each summer he also tries to find time to participate in occasional 10 km running races. Although he is teased about a direct correspondence between his 10 km time in minutes and his age in the past 20 years, Rod should get credit for motivating many of his students to take up jogging. For the past 2 years, he participated in the 31 km cross-country ski race held at the Canadian Birkebeiner Ski Festival just outside of Edmonton, Alberta.

On many occasions, Rod mentioned that without Valerie's support, he would have accomplished much less in his career. Indeed, over the years, she has enjoyed getting to know

the students as well as proofreading their manuscripts. Many fond memories are associated with the group gatherings at the Wasylishens' residence, together with their children Stephen and Eric. Of course, all these group gatherings typically finished with Bob Dylan records being played on the turntable. Rod's enthusiastic fondness of Dylan's music is legendary.

Throughout his career, Rod's research contributions have always reflected his remarkably deep chemical insight. His emphasis on combining the most careful experimental measurements with the best theoretical interpretation makes his contributions of the highest quality in the literature. Rod is one of the most respected and influential scientists in Canadian chemistry. In August 2009, his former students organized an NMR Symposium in his honour at the 55th International Conference on Analytical Sciences and Spectroscopy (ICASS) in Kingston, Ontario. Now we are privileged to have this special issue of the *Canadian Journal of Chemistry* dedicated to him, to celebrate his outstanding contributions to scientific research, to science education, and his service to a broad scientific community in Canada and worldwide.
