†To convert from calculated shielding constants to chemical shifts, a shift of 45.37 ppm was used (for the conversion from solid to aqueous NaCl chemical shift scales) in addition to the absolute shielding conversion of 974 ppm.[44]

‡Experimental values are all with respect to solid NaCl at 0 ppm.

§NMR calculation performed after hydrogen atom positions were optimized using the method described in the Experimental section.

‖NMR calculation performed without hydrogen atom positions optimization.

thane were part of the structure, they would evaporate near their respective boiling points of 100 and 40 °C, resulting in multiple mass loss events in the TGA curve. To help verify that the sample maintained similar packing (and therefore unit cell parameters) upon loss of solvent molecules, a powder X-ray diffraction pattern was collected. The resulting pattern was consistent with the cell parameters of the parent compound (**1**·CH_2Cl_2·$2H_2O$), suggesting that the structure does not change significantly (Supplementary data Fig. S5). Furthermore, comparison of the ^{13}C CPMAS NMR spectrum of the free *meso*-octamethylcalix[4]pyrrole ligand with that of **1** (Supplementary data Figs. S1 and S2) shows that compound **1** has not decomposed into a mixture of free ligand and 1-butyl-3-methylimidazolium chloride. Comparison of the SSNMR tensor parameters calculated for model *d* with the experimental values listed in Table 1 shows relatively good agreement but overestimates $\lvert C_Q(^{35}Cl)\rvert$, Ω, and the chlorine chemical shift. The good agreement with model *d* further suggests that the cell parameters of the sample are likely similar to those of **1**·CH_2Cl_2·$2H_2O$. We next looked to determine if the overestimation computed for $\lvert C_Q(^{35}Cl)\rvert$, Ω, and δ_{iso} would be consistent with the results of GIPAW-DFT calculations for other organic chlorides.

Amino acid hydrochlorides

To determine whether these overestimations were inherent to GIPAW-DFT calculations of chlorine NMR parameters in organic hydrochlorides, a systematic computational study of the amino acid hydrochlorides was carried out. This also provided an opportunity to compare the results of GIPAW-DFT calculations with those carried out previously using a B3LYP or RHF level of theory and a cluster model,[24–26] as implemented in the Gaussian program.[69] The optimal method for determining chlorine SSNMR parameters using a cluster model has been determined previously to be B3LYP for CS tensor parameters and RHF for EFG tensor parameters (ideal basis sets were also determined).[25] This set of compounds is ideal as there is a large body of precise experimental chlorine SSNMR data,[24–26] in addition to published crystal structures.

Whereas the majority of the amino acid hydrochlorides have had their structures determined through X-ray diffraction, the availability of neutron diffraction structures for

*Lysine hydrochloride salt is a dihydrate.

†To convert from calculated shielding constants to chemical shifts, a shift of 45.37 ppm was used (for the conversion from solid to aqueous NaCl chemical shift scales) in addition to the absolute shielding conversion of 974 ppm.[44]

‡Experimental values are all with respect to solid NaCl.

some of these salts (those of glutamic acid, glycine, lysine, phenylalanine, tyrosine, and valine)[53–58] allowed for more complete testing of the accuracy of the calculations carried out using the GIPAW-DFT level of theory. From the neutron structures, the positions of all atoms (including hydrogens) in those amino acid hydrochlorides are known experimentally, meaning that any inaccuracy in the calculated NMR parameters compared with experiment may largely be attributed to deficiencies in the computational method. This is not true in the case where only X-ray structures are available, as incorrect placement of the hydrogen atoms may be the primary cause of inaccuracies relative to experiment.[25]

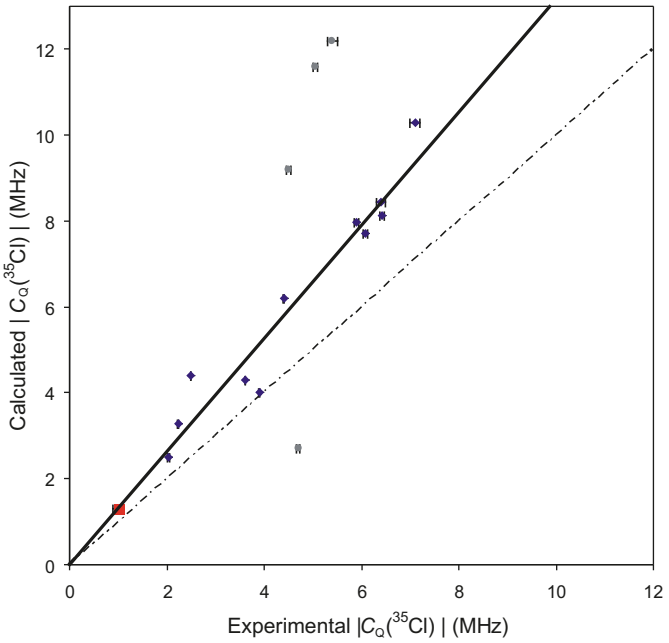
As the exact hydrogen atom positions are not known from X-ray structures, it is often standard to computationally optimize the proton positions prior to the NMR calculation, as was attempted above for all five models based on **1**. Therefore, we also chose to use the amino acid hydrochlorides to test the effect of optimizing the proton positions in GIPAW-DFT calculations, i.e., to determine if this would have a significant impact on the accuracy of the calculated NMR parameters. The calculated chlorine NMR parameters for the amino acid hydrochlorides for which there is an X-ray structure appear in Table 3, whereas those with a neutron structure appear in Table 4. In both these tables, the experimental data from the literature are included for comparison. As expected, hydrogen atom position optimization improved the accuracy of the calculations in most cases and confirm that, as with B3LYP and RHF calculations,[24–26] it is recommended to optimize proton positions in all cases for which they are not known exactly, provided it is computationally feasible.

A comparison of the experimental and calculated values of $C_Q(^{35}Cl)$ listed in Tables 3 and 4 clearly demonstrates that, even in cases where the full structure of the salt is known accurately, the quadrupolar coupling constant is significantly overestimated by GIPAW-DFT calculations. Shown in Fig. 4 is a graph of the experimental and calculated magnitudes of $C_Q(^{35}Cl)$ for 15 of the amino acid hydrochlorides. Eleven of the amino acids are represented by filled diamond symbols and four outliers appear as filled circle symbols. The data represented by the diamond symbols demonstrate that the experimental versus calculated values of $|C_Q(^{35}Cl)|$ can be fit by a linear equation, but also reveal a systematic overestimation by calculation. This overestimation is quantified by the line of best fit shown on Fig. 4: the slope of the line is 1.3203, the y intercept is 0.045 MHz, and the value of the correlation coefficient (R^2) is 0.9356. For three of the four outlier salts (those of proline, threonine, and tryptophan), the computed values of $|C_Q(^{35}Cl)|$ are more significantly overestimated compared with experiment. It is not known why these three amino acid hydrochlorides lie off the line of best fit, but it is clear that GIPAW-DFT calculations consistently overestimate the magnitude of the chlorine EFG in the vast majority of the amino acid hydrochlorides. The overestimation of this parameter is consistent with the results obtained from RHF calculations.[24–26]

The GIPAW-DFT results are consistent with those observed for **1**, where the calculated value of $|C_Q(^{35}Cl)|$ for model *d* was 1.35 MHz, a 35% overestimation of the experimental value (1.0 MHz). In fact, inclusion of the data point for **1** (1.0 MHz, 1.35 MHz) in Fig. 4 shows that the agreement between experiment and theory for **1** is completely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

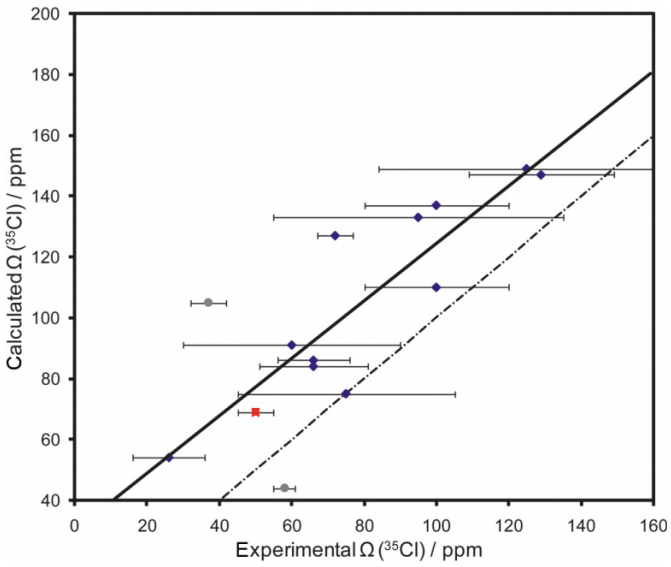
Fig. 4. Comparison between the experimentally determined ^{35}Cl quadrupolar coupling constant (*x* axis) and the gauge-including projector-augmented wave density functional theory (GIPAW-DFT) calculated values (*y* axis) for the amino acid hydrochlorides. Data for 11 of the amino acid salts are presented as filled diamond symbols (♦) and that of the four outliers (not included in the fit) are shown as filled circle symbols (●). The equation for the line of best fit for the data represented by ♦ is y (MHz) = 1.3203x (MHz) + 0.045 MHz, with a R^2 value of 0.9356. The broken line represents the line $y = x$. Experimental data are from refs. 22 and 24–26. Also shown but not included in the line of best fit is the data point for *meso*-octamethylcalix[4]pyrrole 1-butyl-3-methyl imidazolium chloride (**1**), i.e., model (*d*) of Fig. 3 (■).



analogous to the agreement obtained for many of the amino acid hydrochlorides. These results further suggest that model *d* is representative of the compound analyzed experimentally, as the predicted |C_Q(^{35}Cl)| for the hydrated and solvated model *a* is actually *underestimated*, and therefore inconsistent with the correlations established between experimental and computed |C_Q(^{35}Cl)| values.

The trend observed for the CS tensor spans is similar to that observed for the chlorine quadrupolar coupling constants. Comparison of the calculated and experimental spans in Tables 3 and 4 again reveal consistent overestimation by calculation. Figure 5 displays these data graphically, with 11 of the amino acids shown as filled diamond symbols and two outliers shown as filled circle symbols. The data represented by the filled diamonds show a linear relationship and an overestimation by calculation, with the line of best fit having a slope of 0.9459, and a *y* intercept of 29.856 ppm. More telling, however, are the data presented in Fig. 6, where only the data points for those amino acid salts for which there is a crystal structure obtained from neutron diffraction are shown. The line of best fit has a slope of 0.9352, a *y* intercept of 25.299 ppm, and a correlation coefficient of 0.9771. These results differ from earlier B3LYP calculations, in which the trends in CS tensor span were not reproduced.[24–26] The present GIPAW-DFT results clearly reproduce the experimental trend, but indicate that even with accurate structures for the calculations, the value of Ω is overestimated. This overestimation is usually outside the error bounds of the experimental value. These results are perfectly consistent with the results for **1** (model *d*), as in that case the experimental value of 50 ppm was overestimated by 38% and predicted to be 69 ppm. As with the chlorine quadrupolar coupling constant, the data point for **1** using the calculation for model *d* (50 ppm, 69 ppm) is close to the line of best fit shown in Figs. 5 and 6.

Fig. 5. Comparison between the experimentally determined chlorine chemical shift (CS) tensor span (*x* axis) and the gauge-including projector-augmented wave density functional theory (GIPAW-DFT) calculated values (*y* axis) for all of the amino acid hydrochlorides for which experimental data are available. Data for 11 of the amino acid salts are presented as filled diamond symbols (♦) and that of the two outliers (not included in the fit) are shown as filled circle symbols (●). The equation for the line of best fit for the data represented by ♦ is y (ppm) = 0.9459x (ppm) + 29.856 ppm, with a R^2 value of 0.7878. The broken line represents the line $y = x$. Experimental data are from refs. 24–26. Also shown but not included in the line of best fit is the data point for *meso*-octamethylcalix[4]pyrrole 1-butyl-3-methyl imidazolium chloride (**1**), i.e., model (*d*) of Fig. 3 (■).



Similar to the CS tensor span, the calculated chlorine δ_{iso} values were significantly overestimated, usually by 30–50 ppm, in almost all cases. This demonstrates that all three components of the CS tensor are generally overestimated by calculation. Unfortunately, the same qualitative agreement between the experimental and calculated values that was observed for Ω was not observed for the chlorine δ_{iso}. These results differ significantly from those obtained with B3LYP calculations, where it was found that the chlorine chemical shifts are always underestimated by a significant margin. With B3LYP, the underestimation can be very significant, with some computed shifts for the amino acid salts being off by more than 70 ppm from experiment.[24–26] Although the calculated value of δ_{iso}(^{35}Cl) for **1** (188 ppm) was slightly more overestimated compared with the amino acid hydrochloride results, its calculated value is also consistent with the results for model *d* as the computation using model *a* results

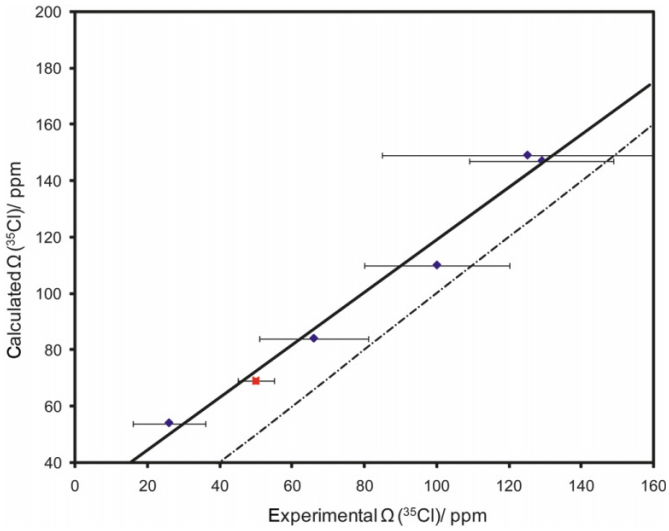
Fig. 6. Comparison between the experimentally determined chlorine chemical shift (CS) tensor span (*x* axis) and the gauge-including projector-augmented wave density functional theory (GIPAW-DFT) calculated values (*y* axis) for the amino acid hydrochlorides for which there are neutron diffraction structures (◆). The equation for the line of best fit is *y* (ppm) = 0.9352*x* (ppm) + 25.299 ppm, with a R^2 value of 0.9771. The broken line represents the line $y = x$. Experimental data are from refs. 24–26. Also shown but not included in the line of best fit is the data point for *meso*-octamethylcalix[4]pyrrole 1-butyl-3-methyl imidazolium chloride (**1**), i.e., model (*d*) of Fig. 3 (■).



in an underestimation of the experimental chlorine chemical shift.

The series of GIPAW-DFT calculations of the chlorine SSNMR parameters of the amino acid hydrochlorides thus are consistent with those of compound **1**. The results demonstrate that with GIPAW-DFT calculations there is a consistent overestimation of the chlorine quadrupolar coupling constant, CS tensor span, and chlorine chemical shift compared with experiment for organic hydrochlorides.

Conclusions

Chlorine SSNMR was used to characterize the chloride ion receptor **1** at two magnetic field strengths. The EFG and CS tensor parameters, along with the relative orientation of the tensors, were extracted from simulations of the spectra collected. Interestingly, low-field spectra were clearly QI-dominated, whereas high-field spectra were CSA-dominated. The small $|C_Q(^{35}Cl)|$ observed (1.0 MHz) demonstrated that the EFG about the chloride was small because of a relatively symmetric environment. The chemical shift of 120 ppm (with respect to solid sodium chloride) is higher than typically observed for other organic chlorides. Inclusion of CSA and nonzero Euler angles were required to achieve quality fits to the experimental spectra. The CS tensor span is 50 ppm, which is within the range observed for other organic chlorides.

In addition, GIPAW-DFT calculations were carried out on a series of models based on the structure of **1** and those amino acid hydrochlorides for which there is both a known structure and chlorine SSNMR experimental data. These calculations systematically overestimate both $|C_Q(^{35}Cl)|$ and the CS tensor span and significantly overestimate the chlorine isotropic chemical shift in nearly all cases. Despite these problems, the GIPAW-DFT method is found to have more advantages than B3LYP or RHF calculations (e.g., the trend in CS tensor span is reproduced). The computational results for **1** were consistent with the loss of dichloromethane and water solvent molecules. The calculations also suggest that the NMR parameters of chloride ion receptors will be highly sensitive to slight changes in structure, such as the loss of solvent or water molecules. Overall, the computational benchmarks of this study will be useful in future chlorine NMR studies by aiding in the interpretation of the results of GIPAW-DFT calculations on similar systems.

Supplementary data

Supplementary data (information about the chlorine on-the-fly pseudopotential, carbon-13 CP/MAS NMR spectra, computational details, TGA curve, powder X-ray diffraction data, and nutation NMR data) are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: We report structural determination of cation-templated self-assembly of a guanosine derivative, 2′,3′,5′-*O*-triacetylguanosine (TAG), in the presence of three alkaline earth metal ions (Ca^{2+}, Sr^{2+}, and Ba^{2+}) in $CDCl_3$. Using a combination of nuclear magnetic resonance (NMR) and electrospray ionization mass spectrometry (ESI-MS) methods, we have found that TAG molecules form discrete octamers in the form of $[TAG]_8M^{2+}$ (M^{2+} = Ca^{2+}, Sr^{2+}, and Ba^{2+}), which is composed of two G-quartets and a sandwiched metal ion. We have determined the ability of the three alkaline earth metal ions to promote TAG self-assembly (relative binding affinity) to be $Sr^{2+} \gg Ba^{2+} > Ca^{2+}$. More importantly, we have used two-dimensional (2D) NMR methods to determine the structural details of $[TAG]_8Sr^{2+}$. In particular, we found that each octamer consists of an all-anti G-quartet stacking on top of an all-syn G-quartet in a tail-to-head fashion with a twist angle of 45° between the two G-quartets. This TAG octamer structure represents a unique case quite different from other lipophilic guanosine octamers reported in the literature.

Key words: nuclear magnetic resonance, mass spectrometry, self-assembly, guanosine (G), alkaline earth metal, G-quartet, structural elucidation.

Résumé : On a déterminer la structure d'un autoassemblage sur gabarit de cation d'un dérivé de la guanosine, 2′,3′,5′-*O*-triacétylguanosine (TAG), en présente de trois ions de métaux de terres alcalins (Ca^{2+}, Sr^{2+} et Ba^{2+}), dans du $CDCl_3$. Faisant appel à une combinaison des méthodes de résonance magnétique nucléaire (RMN) et de spectrométrie de masse avec ionisation par électronébulisation (SM-IEN), on a trouvé que les molécules de TAG forment des octamères individuels de la forme $[TAG]_8M^{2+}$ (M^{2+} = Ca^{2+}, Sr^{2+} et Ba^{2+}) qui se composent de deux quartets-G et d'un ion métallique en sandwich. On a déterminé que l'habilité relative des trois ions de métaux de terres alcalins à faire la promotion de l'autoassemblage du TAG (par rapport à l'affinité de fixation) est $Sr^{2+} \gg Ba^{2+} > Ca^{2+}$. En plus, on a fait appel à des méthodes de RMN bidimensionnelles (2D) pour déterminer les détails de la structure du $[TAG]_8Sr^{2+}$. On a trouvé, en particulier, que chaque octamère est formé d'un quartet-G complètement anti empilé sur un autre quartet-G complètement syn, d'une façon tête à queue, avec un angle de torsion de 45° entre les deux quartets-G. Cette structure de TAG octamère correspond à un cas unique différent des autres octamères de guanosine lipophiles rapportés dans la littérature.

Mots-clés : résonance magnétique nucléaire, spectrométrie de masse, autoassemblage, guanosine (G), métal de terre alcalin, quartet-G, élucidation de structure.

[Traduit par la Rédaction]

Introduction

Guanosine (G) is a biological molecule composed of a guanine nucleobase and a ribose ring (Scheme 1). Guanine is unique among nucleobases as its hydrogen-bond donors and acceptors are almost 90° to each other, making it possible to form a square-shaped, planar tetramer known as the G-quartet. It has been known for many years that G derivatives can self-assemble into G-quartets in the presence of certain cations,[1–4] except for just a few cases where cations are not required.[5–7] Within a G-quartet, Hoogsteen-type hydrogen bonds (O6···H–N1 and N7···H–N2; Scheme 2) are formed between the four guanine bases.[1] With assistance from certain cations, the disk-shaped G-quartets can stack on top of one another by ion–dipole and π–π interactions forming a rodlike structure in which the two adjacent G-quartets are separated by ~3.3 Å with a twist rotation ranging from 30° to 45°.[2–4] The most common mode of cation binding within the rodlike structure is the sandwich type where a cation is located at the centre between two G-quartets coordinating to eight carbonyl oxygen atoms (O6) in a square antiprism fasion.[8,9] Both ionic radius and charge of the cation are important for the formation and stability of the rodlike structure. In aqueous solution,

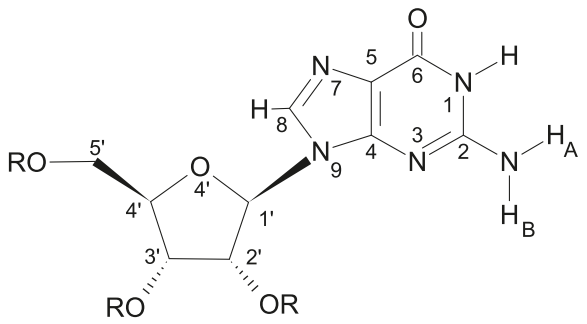
Scheme 1. Guanosine (R = H) and 2′,3′,5′-*O*-triacetylguanosine (R = acetyl).



dehydration energy of the cation also plays a crucial role during the process.[2–4,9] Pinnavaia et al.[10] discovered that cations such as Li^+ and Cs^+ (ionic radius 0.92 and 1.69 Å, respectively) are not effective in promoting self-assembly of guanosine 5′-monophosphate (5′-GMP), whereas Na^+, K^+, and Rb^+ (ionic radius 1.18, 1.51, and 1.61 Å, respectively) are optimal for stable formation of the rodlike structure. The averaged $O_6 \cdots M^+$ distance in G self-assembled structures is 2.2–2.3 Å. Among monovalent alkali metal ions, K^+ has the strongest ability to promote 5′-GMP self-assembly followed by Na^+ and Rb^+. Using combined diffusion nuclear magnetic resonance (NMR) and dynamic light scattering methods, Wong et al.[11] showed that the length of the rodlike structure formed by 5′-GMP self-assembly can be on the order of several nanometers. For 5′-GMP, it is also known that cations are responsible for structural polymorphism. For example, in the presence of Na^+, Wu and Kwan[12] found that 5′-GMP self-assembles into a unique helix containing alternating C2′- and C3′-*endo* sugar puckering. In the presence of K^+ or Rb^+, on the other hand, the self-assembled structures of 5′-GMP in aqueous solution were quite complex as demonstrated by Walmsley and co-workers.[13,14] Studies on divalent cations (Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}) are less common. In general, a higher binding affinity is observed for these divalent cations compared with monovalent cations.[2,9,15] Moreover, as illustrated in Scheme 2, divalent cations are usually found at every other site to reduce electrostatic repulsion between positive charges.[9] Recently, we discovered that trivalent lanthanide metal ions can promote G-quartet formation in a new triple-decker mode of ion binding; see Scheme 2.[16]

Most previous studies were concerned with G self-assembly in aqueous solution because of potential therapeutic applications.[17–20] Folded G-rich DNA oligomers can prevent telomerase binding to the telomere, which in turn could prevent cancer formation as a result of natural cell death.[21] In comparison, G-quartet formation in organic solvents is less common.[2–4,9,22] In recent years, specially designed G-quartet motifs have been widely studied and used in applications of artificial ion channels and nanomaterials.[2–4,9,22–28] It remains a challenge to be able to synthesize homogenous and stable G self-assembled structures as many factors such as solvent, temperature, and concentration are at work. Because of its relevance to molecular biology and supramolecular chemistry, detailed information about G self-assembled structures can not only help us in the development of anticancer drugs and artificial ion channels, but also in molecular recognition in DNA that may enhance drug design.[27,29,30]

Although formation of G-quadruplexes with alkaline earth metal ions (Ca^{2+}, Sr^{2+}, and Ba^{2+}) has been previously documented in the literature,[15,26,31–40] there are very few cases where structural details are determined for the G-quadruplexes containing these metal ions in solution. In a previous study, we have used the Ca^{2+}-directed self-assembly of a simple lipophilic guanosine derivative, 2′,3′,5′-triacetylguanosine (TAG) as shown in Scheme 1, to obtain ^{43}Ca NMR signature.[41] In this work, we report a comprehensive NMR and electrospray ionization mass spectrometry (ESI-MS) study of TAG self-assembly in the presence of Ca^{2+}, Sr^{2+}, and Ba^{2+}. Our primary objective is to elucidate the structural details of TAG self-assemblies.

Experimental

Picrate salts

Picrate salts of Ca^{2+}, Sr^{2+}, and Ba^{2+} were synthesized by neutralizing picric acid (Sigma-Aldrich, 99+%) with $Ca(OH)_2$, $Sr(OH)_2$, and $Ba(OH)_2$, respectively. Crystalline picrate salts were obtained from aqueous solution. *WARNING:* Caution should be exercised when handling picric acid.

[TAG]M^{2+} complexes

2′,3′,5′-*O*-Triacetylguanosine (98%) was purchased from Sigma-Aldrich without further purification. [TAG]M^{2+} complexes were prepared using the following solvent–solvent extraction method described by Andrisano et al.[42] To 0.2 mmol of TAG (81 mg) suspended in $CHCl_3$ (cloudy solution) was added dropwise 1.6 mmol of picrate salt (i.e., $CaPic_2$, $SrPic_2$, $BaPic_2$) dissolved in H_2O (clear, yellow solution) with stirring. The two-phase solution was stirred until the organic phase became visually clear and yellow. The aqueous phase was then removed, and solid [TAG]M^{2+} complexes were obtained after the organic phase was dried in air.

NMR spectroscopy

All solution-state NMR spectra were recorded on a Bruker Avance 600 MHz spectrometer in $CDCl_3$. For ^1H NMR experiments, a π-pulse of 20 μs at a power level of 0 dB was used. Spectra were obtained at various temperatures achieved carefully by a Bruker BT-3000 unit.

Correlation spectroscopy (COSY)

Two-dimensional homonuclear shift correlation (^1H–^1H COSY) spectra were recorded at 15 °C using the pulse program COSYGPQF (XWinNMR, version 3.5, Bruker) on a Bruker Avance 600 MHz spectrometer. The data were collected using a 90° pulse of 10.0 μs and a relaxation delay of 1 s. The spectral width was 13 227 Hz on either dimension. One scan was collected. Final data matrix was 2048 ($F2$) × 256 ($F1$).

Diffusion-ordered spectroscopy (DOSY)

^1H diffusion experiments were carried out using the pulse sequence of longitudinal eddy current delay with bipolar-gradient pulses: LEDBPGP2s (XWinNMR, version 3.5, Bruker) on 1.0 mmol/L samples in $CDCl_3$. The pulse field gradient duration (δ) ranged from 1.0 to 2.0 ms, and the variable gradient strength (G) was changed from 5.75 to 5.8 mT/m. The diffusion period (Δ) was 50 ms. A total of 16 scans

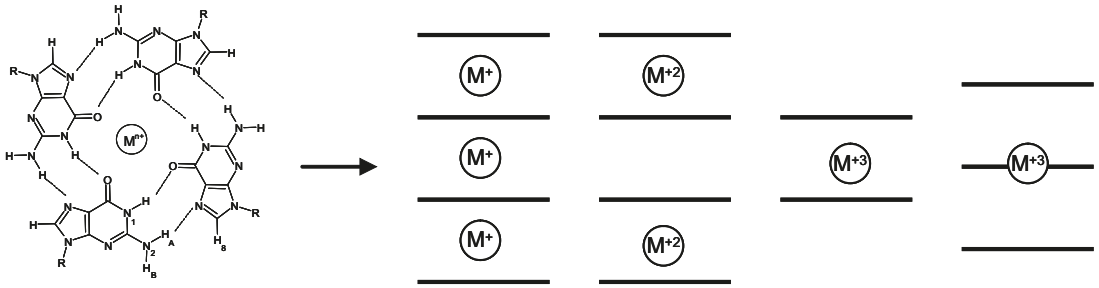
Scheme 2. A guanine (G)-quartet (left) and common modes of metal ion binding (right). Each bar represents a G-quartet.



were collected for each of the 16 increment steps with a recycle delay of 5 s. The eddy current delay (t_e) was 5 ms, and the gradient recovery delay was 0.2 ms. All diffusion experiments were performed at 298.2 K. Calibration of the field gradient strength was performed by measuring the value of the translational diffusion coefficient (D_t) for the residual ^1H signal in D_2O (99.99% ^2H atom), where $D_t = 1.90 \times 10^{-9}$ m^2/s.[43] All diffusion coefficients were acquired using integration of the proton peaks to a single exponential decay, using the Simfit software (XWinNMR, version 3.5, Bruker).

Heteronuclear multiple bond correlation (HMBC)

Two-dimensional (2D) spectra of ^1H–^{13}C correlation through heteronuclear zero and double quantum coherence transfer were performed using the pulse program INV4GPLPLRND (XWinNMR, version 2.6, Bruker) at 11.7 T at room temperature. A low-pass J-filter was employed to suppress one-bond correlations. No ^{13}C decoupling was applied during acquisition. The long-range coupling delay was 100 ms. The 90° pulses were 10.0 μs and 13.4 μs for ^1H and ^{13}C nuclei, respectively, with a relaxation relay of 1 s. The spectral width was 10 965 Hz in the *F*2 dimension (^1H) and 27 667 Hz in the *F*1 dimension (^{13}C). A total of 48 scans were collected for each 946 increments of the *F*1 dimension. The final data matrix was 2048 (*F*2) × 1024 (*F*1).

Nuclear Overhauser enhancement spectroscopy (NOESY)

The 2D NOESY spectra were performed using the pulse program NOESYGPPH (XWinNMR, version 3.5, Bruker) with a mixing time (τ_{mix}) of 400 ms and the phase-sensitive TPPI mode. The data were collected using a 90° pulse of 10.0 μs and a relaxation delay of 3.0 s. A total of 8 scans were collected for each time increment. The final data matrix was 2048 (*F*2) × 1024 (*F*1).

Electrospray ionization (ESI) MS

ESI-MS spectra were recorded with an Applied Biosystems QSTAR XL quadrupole time-of-flight (QqTOF) mass spectrometer at positive ionization mode, and data were acquired using the Analyst QS 1.1 software (Applied Biosystems). Samples were dissolved in anhydrous nitromethane (CH_3NO_2) and injected with a syringe pump at a flow rate of 3.0 μL/min. The mass range of single MS measurements was set at *m*/*z* 300–5000. The declustering potential (DP) was 20 V. Subsequent tandem mass spectrometry (ESI-MS/MS) measurements were performed using nitrogen as the collision gas, and collision induced dissociation (CID) energy of 35–40 eV was applied to break down the octamers. The mass range of MS/MS measurements was set at *m*/*z* 0–4000. For spectral assignment, theoretical MS peaks were generated using Data Explorer version 4.0.0.0 (1997–2000) by Applied Biosystems.

Results and discussion

The ^1H NMR spectra of TAG–M^{2+} complexes in $CDCl_3$ are shown in Fig. 1, together with the ^1H spectrum of TAG in DMSO for comparison. In each of the ^1H NMR spectra for TAG–M^{2+} complexes, two sets of signals (in a 1:1 ratio) are observed for each proton compared with the corresponding signal in the spectrum of TAG in DMSO where TAG exists as monomers.[44] Of particular interest are the ^1H NMR signals from the imino (N^1H) and amino (N^2H_A and N^2H_B) groups. As indicated in Fig. 1, the single ^1H NMR signal of N^2H_2 observed for TAG in DMSO (at 6.3 ppm) splits into two well-separated signals, N^2H_A (at ~9–10 ppm) and N^2H_B (at ~5.2 ppm), upon extraction of Ca^{2+}, Sr^{2+}, and Ba^{2+} ions into $CDCl_3$. This suggests that N^2H_A is now involved in strong hydrogen bonding, thus considerably increasing the energy barrier for rotation about the C–N bond. At the same time, the observation of very sharp signals for N^1Hs in the range of 11.2–11.6 ppm suggests that this proton is also involved in strong hydrogen bonding. Using the integrated area of the picrate signal (indicated in Fig. 1) as a measure of the M^{2+} content (one M^{2+} per two Pic^-), we were able to determine that the ratio of TAG–M^{2+} is 8:1 for this hydrogen bonded structure. Of course, this stoichiometric ratio can be the result of many different structures, e.g., TAG_4–M^{2+}–TAG_4 octamers or TAG_4–M^{2+}–TAG_4–TAG_4–M^{2+}–TAG_4 hexadecamers or some kind of linear polymers known as G-ribbons; see Scheme 3.[2] To verify that the self-assembled structure is related to G-quartet formation, we obtained ^1H NOESY spectra for $[TAG]_8Ca^{2+}$, $[TAG]_8Sr^{2+}$, and $[TAG]_8Ba^{2+}$ species in $CDCl_3$ at 268 K. If TAG molecules form G-ribbons, the NOE cross peak formed between H8 and N^2H_A resonances in the NOESY spectrum would be less intense than that between H8 and N^1H resonances (see Scheme 3). As seen from Fig. 2, the NOE cross peaks between H8 and N^2H_A resonances are, in fact, stronger than those between H8 and N^1H resonances, providing definite proofs of G-quartet formation.

To further determine the size of the TAG self-assembly, we performed two types of experiments: diffusion-ordered spectroscopy (DOSY) NMR and electrospray ionization mass spectrometry (ESI-MS). DOSY allows the determination of the translational diffusion coefficient (D_t) of any molecular aggregate in solution, from which the size of the molecular aggregate can be inferred. According to the

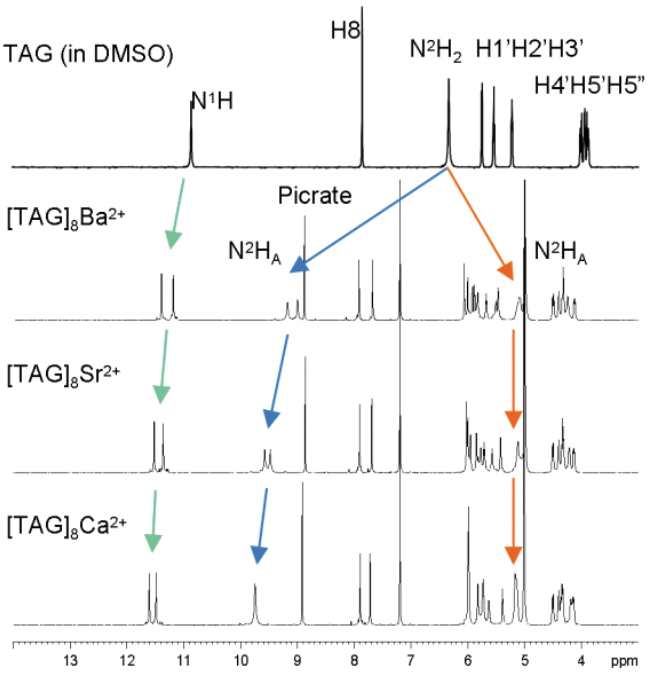

Scheme 3. (*a*) G-quartet, (*b*) G-ribbon A, and (*c*) G-ribbon B.

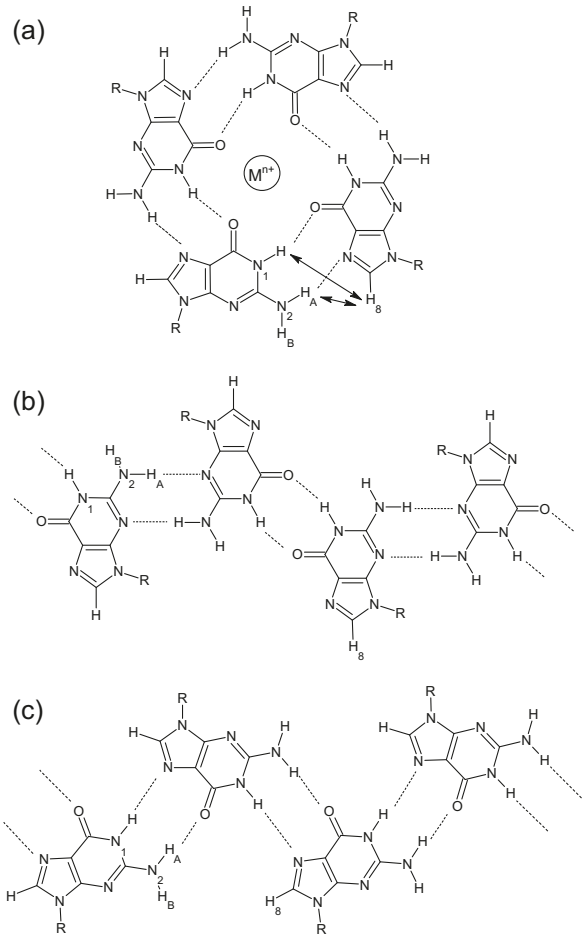

Fig. 2. A portion of the 2D NOESY spectrum of $[TAG]_8Sr^{2+}$ in $CDCl_3$ at 268.2 K. Cross peaks between N^2H_A and H8 resonances are highlighted in the broken box while those between N^1H and H8 resonances are enclosed in the unbroken box.

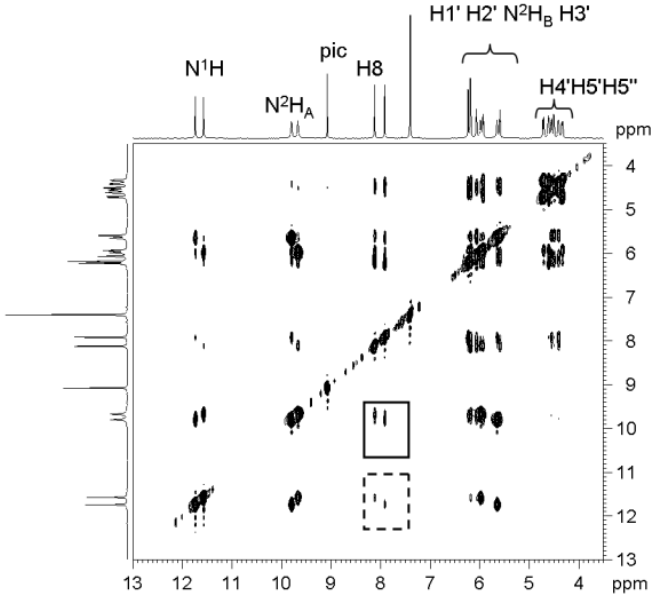

Stokes–Einstein equation, a sphere's diffusion coefficient is inversely related to the hydrodynamic radius and solvent viscosity: $D_t = kT/6\pi\eta R$, where k = Boltzmann constant, T = temperature, R = hydrodynamic radius, and η = solvent viscosity. In the DOSY experiments, dilute samples were prepared at 15 mmol/L and the sample temperature was carefully maintained at 298.2 K (±0.1 K) for solvent viscosity consistency. We have found two important pieces of information from the ^{1}H DOSY NMR experiments. First, the two sets of ^{1}H NMR signals mentioned earlier exhibit the same value of D_t, suggesting that they belong to the same self-assembled structure. Second, the D_t values measured for $[TAG]_8Ca^{2+}$, $[TAG]_8Sr^{2+}$, and $[TAG]_8Ba^{2+}$ are all very similar, ~3.9 ± 0.5 × 10^{-10} m^2/s, which is in agreement with a previously reported value for a G-octamer (D_t = 4.19 × 10^{-10} m^2/s).[45] In comparison, the value of D_t for TAG monomers measured under a similar condition in $CDCl_3$ is 7.0 × 10^{-10} m^2/s, and the D_t value for hexadecamers in the same solvent is 3.30 ± 0.07 × 10^{-10} m^2/s.[45] Therefore, we can conclude that TAG molecules exclusively form octamers in the presence of Ca^{2+}, Sr^{2+}, and Ba^{2+} in $CDCl_3$. We also note that, in the TAG systems, the value of D_t for the picrate anion is 5.4 ± 0.5 × 10^{-10} m^2/s, which is much larger than that of $[TAG]_8M^{2+}$. This suggests that the picrate anion is not involved in G-octamer formation.

To gain further evidence about the size of TAG self-assembly, we obtained ESI-MS and tandem MS (MS/MS) spectra for $[TAG]_8Ca^{2+}$, $[TAG]_8Sr^{2+}$, and $[TAG]_8Ba^{2+}$. ESI-MS allows molecular aggregates under study to be transferred from solution to the gas phase in a soft and smooth manner that is suitable for obtaining the sizes of both stable and short-lived molecules.[46] As seen in Fig. 3, positive mode (+)ESI-MS spectra allowed us to conclude that the self-assembled structures are exclusively octamers. Detailed isotopic pattern analyses of the MS spectra are given in the Supplementary data (Table

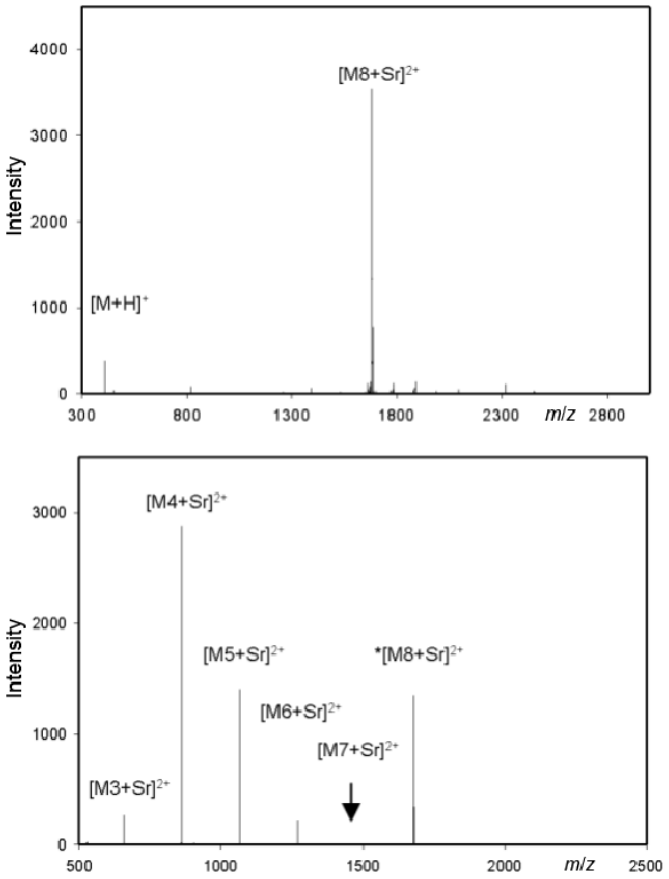
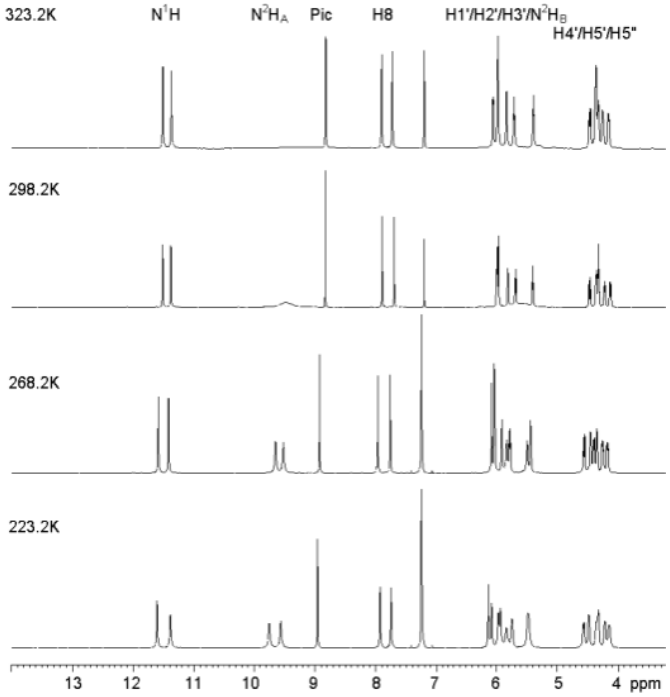
Fig. 3. (+)ESI-MS spectrum of $[TAG]Sr^{2+}$ in nitromethane (top) and tandem (+)ESI-MS/MS spectrum of $[TAG]_8Sr^{2+}$ (bottom) at 1680.403 *m/z*. The asterisk (*) denotes the parent ion. M = monomeric TAG with 409.35 amu.



S1). Another important piece of information obtained from the ESI results is that the counter-ion picrate does not associate with any $[TAG]_8M^{2+}$ complexes under the current experimental conditions. Davis and co-workers[34] have previously reported that four picrate anions can "clamp" two G-octamers together to form a hexadecamer. In that case, a picrate anion utilizes the central phenoxide group and the two nitro groups in the ortho potions to link exocyclic amino N^2H_B protons from two G-quartets through hydrogen bonding. In the case of TAG, we did not observe any hexadecamer formation (vide infra). Discrete G-octamer formation has been previously seen in several other cases. For example, Marlow et al.[47] reported the first G-octamer formation in organic solvent from 3′,5′-didecanoyl-2′-deoxyguanosine promoted by K^+ ions. Shi et al.[48] observed that 5′-*tert*-butyl-dimethylsilyl-2′,3′-isopropylidene-guanosine can form G-octamers in the presence of Ba^{2+} and Sr^{2+}. Liu et al.[49] and Martić et al.[50] reported the G-octamer formation from N^2-modified guanosines.

Figure 4 shows a series of various-temperature (VT) ^1H NMR spectra for $[TAG]_8Sr^{2+}$ octamers to demonstrate its thermal stability. The fact that the ^1H NMR signals of the imino N^1H protons remain sharp at $\sim\delta = 11.6$ ppm suggests that integrity of the $[TAG]_8Sr^{2+}$ octamers do not break apart even at 323 K. It is also interesting to note that the amino protons N^2H_A and N^2H_B were not observed above room temperature because of severe line broadening from fast chemical exchange.

Fig. 4. ^1H NMR of $[TAG]_8Sr^{2+}$ complex at different temperatures in $CDCl_3$.



Although all three alkaline earth metal ions, Ca^{2+}, Sr^{2+}, and Ba^{2+}, are shown to be able to promote TAG self-assembly, the relative stabilities of $[TAG]_8Ca^{2+}$, $[TAG]_8Sr^{2+}$, and $[TAG]_8Ba^{2+}$ may be different. For example, their ionic radii are different (octa-coordinate ionic radius: Ca^{2+} 1.12 Å, Sr^{2+} 1.26 Å, and Ba^{2+} 1.42 Å).[51] To determine the relative binding affinity between the three metal ions, we performed a series of competitive extraction experiments. In each experiment, an equal molar mixture of two ions was used for the aqueous phase. The amount of each ion being extracted into the organic phase containing TAG can be monitored by ^1H NMR spectra. The results are shown in Fig. 5. For example, when Ca^{2+} or Ba^{2+} picrate salts (1:1) were used during extraction, the amount of $[TAG]_8Ba^{2+}$ formed in $CDCl_3$ is approximately eight times greater than that of $[TAG]_8Ca^{2+}$, suggesting that Ba^{2+} has a higher affinity than does Ca^{2+}. Similarly, when Ba^{2+} and Sr^{2+} were used, only $[TAG]_8Sr^{2+}$ can be found in $CDCl_3$. This indicates that Sr^{2+} has an even higher affinity than does Ba^{2+}. Using these simple experimental results, we can reach a qualitative conclusion that the relative binding affinity of TAG towards these three divalent cations is $Sr^{2+} \gg Ba^{2+} > Ca^{2+}$. We believe that this trend represents the true thermodynamic properties rather than kinetic effects, because extraction experiments performed over several days did not show any variation. This trend is indeed very common in G-quartet formation and has been documented in the literature for monovalent and divalent cations in biological G-quadruplexes systems.[2,9] Figure 5 also shows the result from an experiment where three kinds of $[TAG]_8M^{2+}$ octamers were first prepared separately in $CDCl_3$ and then mixed. We did not observe any change in the ^1H NMR spectrum of such a mixture for several months. This observation

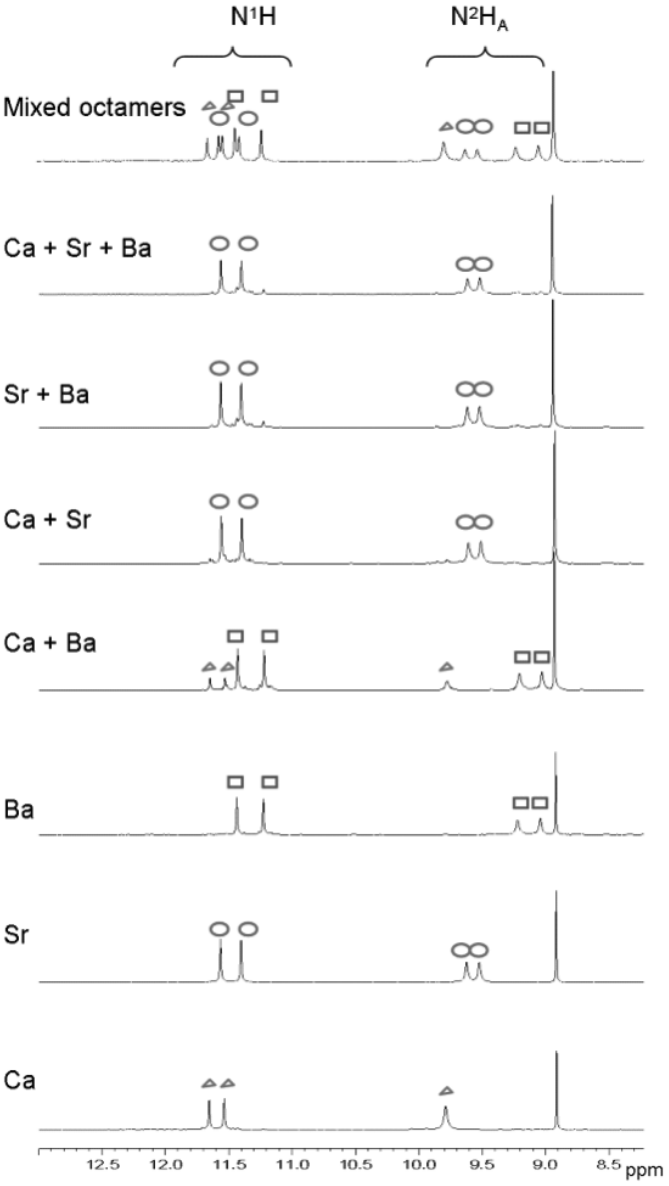
Fig. 5. ^{1}H NMR spectra of TAG–M^{2+} complexes obtained at 268.2 K from the "mixed" ion experiments. See the text for discussion.



suggests that individual $[TAG]_8M^{2+}$ octamers do not stack on top of one another to form hexadecamers with mixed ions (e.g., $[TAG]_4$–Sr^{2+}–$[TAG]_4$–$[TAG]_4$–Ba^{2+}–$[TAG]_4$, etc.). This is in sharp contrast to the situations seen by Shi et al.[35] where hexadecamers with mixed ions are formed for 5′-*tert*-butyldimethylsilyl-2′,3′-isopropylidene-guanosine when the clamping anions are picrate and 2,5-dinitrophenolate.

Now we have established that, in $CDCl_3$, eight TAG molecules and one M^{2+} ion self-assemble into an octamer and that each octamer is composed of two structurally distinct TAG molecules in a 1:1 ratio. However, the structural details remain unknown with respect to the following aspects: (*i*) orientation of the guanine base with respect to the ribose ring (anti or syn conformers), (*ii*) intraquartet arrangement, and (*iii*) relative interquartet orientations within the octamer. Here, we decided to further investigate these structural features. To this end, we must first carry out complete spectral

Fig. 6. A region of the 2D COSY spectrum obtained for $[TAG]_8Sr^{2+}$ in $CDCl_3$ at 288.2 K revealing $^{3}J_{HH}$ relationships.

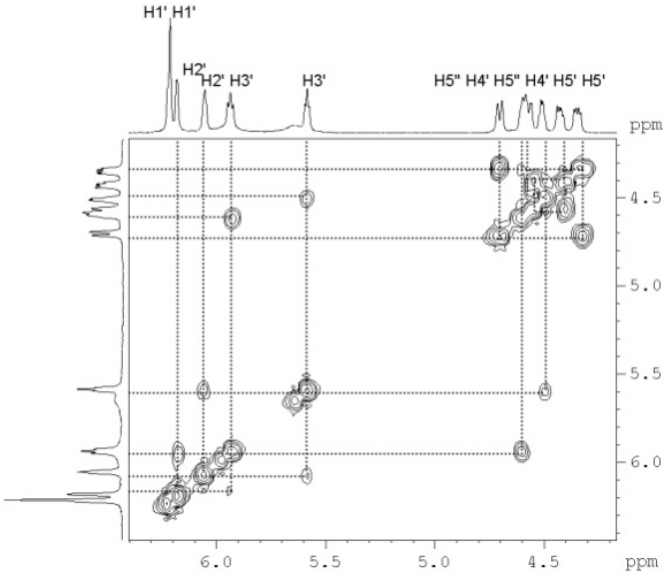


Fig. 7. Regions of the 2D NOESY spectrum for $[TAG]_8Sr^{2+}$ in $CDCl_3$ at 268.2 K showing the intra- and inter-quartet cross peaks (marked by green boxes) between H8 and sugar proton resonances. assignment. In the discussion that follows, we selected only $[TAG]_8Sr^{2+}$ for structural elucidation. In general, non-exchangeable protons (H1′/H2′/H3′/H4′/H5′/H5″) of the ribose ring were assigned using COSY, where $^{3}J_{HH}$ relationships were used (Fig. 6) along with NOESY (Fig. 7).

Scheme 4. NOE and $^3J_{CH}$ interactions in TAG used for spectral assignment.

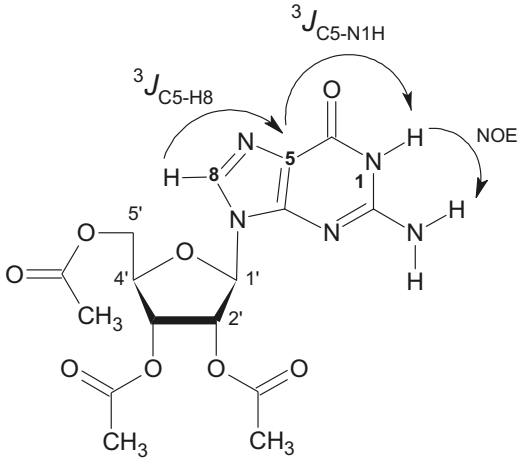

Fig. 8. A region of the ^{13}C–^1H HMBC spectrum obtained for $[TAG]_8Sr^{2+}$ in $CDCl_3$ at 298.2 K revealing correlation peaks due to $^3J_{C5–N1H}$ and $^3J_{C5–H8}$.

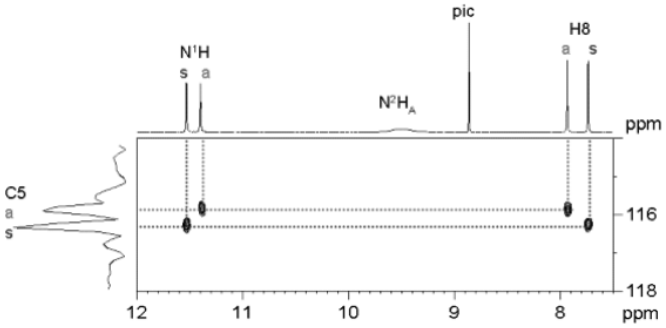

Fig. 9. A region of the 2D NOESY spectrum obtained for $[TAG]_8Sr^{2+}$ in $CDCl_3$ at 268.2 K showing the cross peaks of N^1H, N^2H_A, and N^2H_B resonances from either anti or syn molecules.

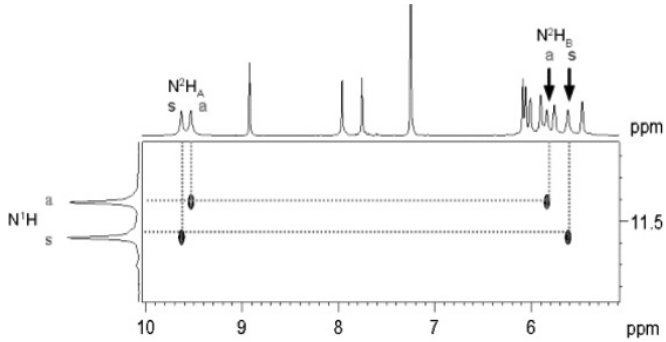

The exchangeable protons in the guanine base, N^1H, N^2H_A, and N^1H_B were located at δ = 11.6, 9.5, and 4.5 ppm, respectively.

The results from both COSY and NOESY experiments immediately reveal that the two sets of signals from TAG molecules are due to the presence of both anti and syn conformers. By definition, the anti conformation has an O4–C1′–N9–C4 torsion angle (χ) of 180° ± 90° while it is 0° ± 90° for the syn conformer.[52] As seen from Fig. 7, one of the H8 signals (δ = 7.75 ppm) exhibits a medium H8–H2′ NOE and no H8–H3′ cross peak (Fig. 7, boxes a and c). Thus, this H8 signal is from the syn conformer. In addition, NOE cross peaks between H8 and H4′, H5′, and H5″ were not observed for the syn conformer. On the other hand, the other H8 signal (δ = 7.96 ppm) has strong H8–H2′ and H8–H3′ NOEs (Fig. 7, boxes b and d), plus weak NOEs between H8 and H4′/H5″ and H5′ from the same molecule (Fig. 7, box e). These features are consistent with an anti conformation. The NOE cross peaks have almost the same intensity between H8 and H1′ protons from both conformers, suggesting that the distances between H8 and H1′ are very similar in both anti and syn conformers. This provides an approximate range for possible χ angles in both syn and anti monomers. In our case, the χ angle for the anti TAG conformer was determined to be in the "high-anti" region between –170° and –180°, while the syn conformation has a χ value between 60° and 70°. Observations of nucleosides in the syn conformer are rare because the C1′–N9 glycosidic bond is flexible and anti is preferred due to steric effect.[53] The syn conformers have been observed mostly in purines with C8 substituents that form intramolecular hydrogen bonding. In this case, the observation of equal population between syn and anti conformation further suggests that a divalent metal ion both templates and stabilizes the TAG octamer structure. As also shown in Fig. 7, several cross peaks (highlighted by arrows) were observed between anti and syn TAG molecules, which arise from either intra- or inter-quartet NOEs and will be further examined in a later section.

Next, while the assignment of the exchangeable imino N^1H and amino $N^2H_{A/B}$ protons is straightforward from NOESY, the connectivity between N^1H and H8 cannot reply on NOESY. Here, the standard technique is, as demonstrated by Phan,[54] a 2D HMBC experiment utilizing the two $^3J_{C–H}$ coupling constants between H8 and C5 and between N^1H and C5 (Scheme 4). As seen from Fig. 8, the HMBC experiment clearly shows the identity of the N^1H resonances. Having identified the N^1H resonances, $N^2H_{A/B}$ resonances were readily assigned using strong intraresidue NOE cross peaks due to their close proximity in space (~1.76 Å), as shown in Fig. 9. For amino N^2H protons, the anti conformer has chemical shifts at δ = 9.53 and 5.84 ppm, and the syn conformer has δ = 9.63 and 5.61 ppm. The large chemical shift difference ($\Delta\delta_{anti}$ = 3.69 ppm, $\Delta\delta_{syn}$ = 4.02 ppm) suggests that one of these amino protons is involved in strong hydrogen bonding as previously mentioned. A summary of the ^1H resonance assignment was given in Table 1.

Now, having anti and syn TAG molecules in a 1:1 ratio, there are still quite a few possible combinations to make two G-quartets within an octamer. As explained in detail by Davis and co-workers,[47] there are four possible combinations of conformer arrangement within the G-quartet. They are (*i*) all-syn, (*ii*) all-anti, (*iii*) alternating syn and anti, and (*iv*) adjacent syn and anti.[47] Because the bond distance of N^2H_A and H8 are within the NOE detection range (~3 Å), the cross peaks between these two protons can be used to determine the pattern of the G-quartets. All-anti or all-syn G-quartets would give strong NOEs between anti–anti and syn–syn signals, while alternating G-quartets would yield signals only between anti and syn conformers. Moreover, adjacent G-quartet arrangement would give four equal intensity cross peaks between all-anti and -syn signals.[43] The targeted spectral area for $[TAG]_8Sr^{2+}$ is shown in Fig. 10. The observed

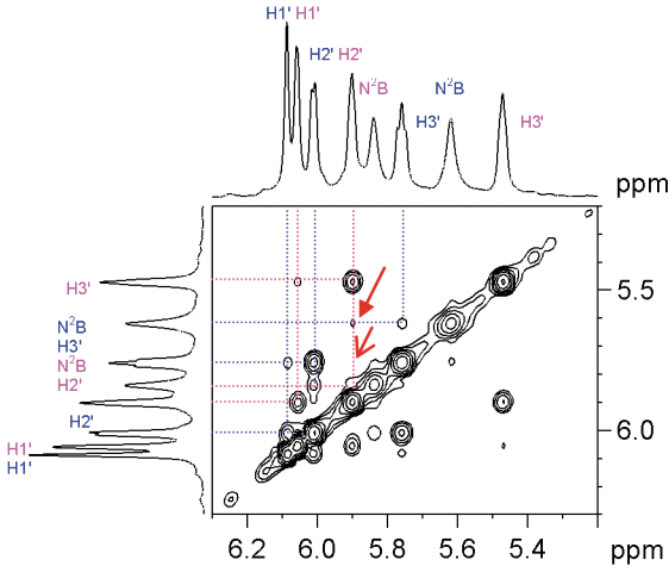
Red lines indicate the anti structure and blue lines indicate the syn structure. Red arrows indicate the presence or the lack of crucial intra- or inter-quartet interactions.



pattern within the NOE cross peaks suggests that the two G-quartets forming the $[TAG]_8Sr^{2+}$ octamer adopt an all-anti and all-syn conformation. On the other hand, the weak NOEs between anti and syn signals can be attributed to inter-quartet interactions within the octamer, which provides us with further information about the relative orientation between the two G-quartets as discussed later. We can now conclude that the $[TAG]_8Sr^{2+}$ octamer is composed of an all-anti G-quartet stacking on top of an all-syn G-quartet.

The next step of structure determination is to find the exact stacking orientation between the two G-quartets within $[TAG]_8Sr^{2+}$. In this regard, if the side of a G-quartet has a N^1–H···O–C6 hydrogen bond that has a clockwise rotation (from donor to acceptor), this side is defined as the "head" face; if the rotation was counterclockwise, the side is the "tail" face.[55] We used the NOE cross peaks from interquartet interactions, as shown in Figs. 7 and 11, to determine the interface between the two G-quartets in the $[TAG]_8Sr^{2+}$ octamer. Detailed NOESY assignment is given in the Supplementary data (Tables S2 and S3).

We have also built molecular models using basic units from the crystal structures of previously reported guanosine derivatives (see Table S3 in the Supplementary data).[56–58] These models include head–head, head–tail, tail–head, and tail–tail interface arrangements. In all these octamer models, the G-quartets were rotated 45° with respect to each other. This arrangement provides the least repulsion between the carbonyl oxygen atoms at the centre of the G-quartets and maximizes the π-stacking interaction between guanine bases. Using these models, theoretical interquartet NOE interactions were extracted and compared with the experimental NOEs. As reported in Table S2 in the Supplementary data, several important NOEs provided key information about the relative orientation of the two G-quartets in $[TAG]_8Sr^{2+}$. The signature NOE cross peaks included interactions between anti H8 and syn H2′/H3′. These interactions eliminated the head–tail and tail–tail structures because anti H8 and syn H2′ and H3′ are too far away in these models to be registered by NOESY (Table S3 in the Supplementary data). The other two models (head–head and tail–head) had orientations that allowed anti H8 to interact with syn H2′ and H3′. Furthermore, in order for H2′ from the anti conformer to be close enough to interact with the all-syn quartet underneath, the tail–head model is determined to be the most plausible solution (Table S3 in the Supplementary data). This model also explained the N^{2}H$_A$–H8 interquartet NOE interaction (Fig. 7) instead of the Hoogsteen-type hydrogen bond within a G-quartet. The interquartet NOEs arising from interactions of protons between the all-anti and the all-syn G-quartets also support the proposed twist angle of 45° about the octamer's central C_4 axis. As mentioned earlier, no NMR evidence was detected for further formation of a hexadecamer from two octamers. A plausible reason that hinders the hexadecamer formation from two $[TAG]_8Sr^{2+}$ octamers is related to how the two G-quartets are oriented within each octamer. We were quite confident that the stacking within each $[TAG]_8Sr^{2+}$ octamer is head(all-anti)-to-tail(all-syn), and the interoctamer interface is always a head(all-syn)-to-head(all-syn) symmetrical arrangement

Scheme 5. (*a*) A literature hexadecamer formed with two octamers and four clamping picrates. The head-to-head interoctamer interface is formed between all-syn G-quartets. Only one picrate is shown for clarity. (*b*) $[TAG]_8Sr^{2+}$ cannot form hexadecamers with a different interoctamer interface.

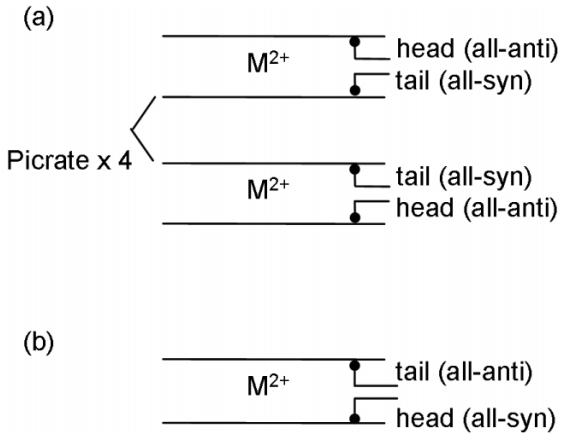

Fig. 12. An illustration of the $[TAG]_8Sr^{2+}$ octamer structure with an all-anti G-quartet stacking on top of an all-syn G-quartet in a tail–head fashion. The arrows indicate the N1–H···O=C6 hydrogen-bond rotation of each quartet's inner face (clockwise = head face).

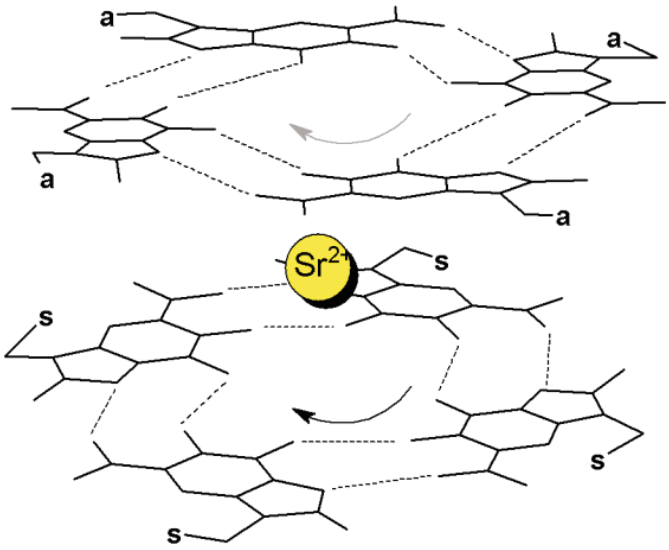

when hexadecamers are formed from two octamers.[2] In fact, the two octamers are related by a C_2 symmetry. In the case of $[TAG]_8Sr^{2+}$, the head-to-tail stacking is slightly different: two G-quartets in $[TAG]_8Sr^{2+}$ have a head(all-syn) stacking on top of a tail(all-anti). This may have prevented hexadecamer formation because of the steric repulsion from the remaining tail(all-syn) and head(all-anti) faces (Scheme 5). Besides, previously formed hexadecamers are comprised of octamers that are twisted 30° instead of 45° to each other.[48] The larger twist angle results in a larger separation between the exocyclic N^2H protons from the adjacent G-quartets, which may make them difficult to be clamped by a picrate anion. Our final structure for the $[TAG]_8Sr^{2+}$ octamer where the tail face of an all-anti G-quartet is stacked on the head face of an all-syn G-quartet is illustrated in Fig. 12. The similarity in the ^1H NMR spectra of $[TAG]_8Ba^{2+}$, $[TAG]_8Ca^{2+}$, and $[TAG]_8Sr^{2+}$ strongly suggests that all three octamers have the same structure.

Conclusion

In this study, we have used NMR and ESI-MS techniques to characterize the nature of $[TAG]M^{2+}$ complexes (M^{2+} = Ca^{2+}, Sr^{2+}, and Ba^{2+}). In all three cases, we observed formation of discrete TAG octamers composed of two G-quartets and a central M^{2+} ion. We also observed the following sequence for relative binding affinity towards $[TAG]_8$: $Sr^{2+} \gg Ba^{2+} > Ca^{2+}$. Using 2D NMR methods, we determined key structural details of the $[TAG]_8M^{2+}$ octamer. The octamer formation between TAG and alkaline earth metal ions represents a rather rare class of G-octamer structures and, hopefully, this new addition to the diverse family of G-quadruplex structures may bring some insights into the driving forces behind lipophilic G nucleoside self-assembly. It is possible that a controlled balance of monovalent and divalent cations can provide additional flexibility for making new G self-assembled structures. We are also currently investigating the possibility of using these simple G-octamer systems to obtain NMR spectral signatures for such exotic nuclei as ^{87}Sr and ^{137}Ba. It would also be of interest to investigate the impact of the chain length of the protecting groups and the nature of counteranions on the self-assembly.

Supplementary data

Supplementary data for this article are available on the journal Web sit (nrcresearchpress.com/cjc).

Abstract: The clay mineral kaolinite was used as support of gold nanoparticles for heterogeneous catalysis of oxidation reactions, particularly of carbon monoxide oxidation. The application of clay minerals in the preparation of new functional materials provides an alternative approach for the use of these abundant raw materials. To improve the physicochemical properties of kaolinite, as well as to ensure a strong immobilization of the adsorbed species, kaolinite was functionalized by grafting 2-amino-2-methyl-1,3-propanediol on the internal and external surfaces of the octahedral sheets by reaction with the aluminol groups. Gold nanoparticles were then deposited on the external surfaces of the fine particles of the functionalized kaolinite. The resulting gold kaolinite nanohybrid material was characterized by various physicochemical techniques. X-ray diffraction, X-ray photoelectron spectroscopy, transmission electron microscopy, and energy-dispersive X-ray spectrometry confirmed that gold was effectively reduced to the metallic state during adsorption onto the external surfaces of the modified kaolinite. The gold nanoparticles have a narrow size distribution: more than 88% are less than 4 nm in diameter. Gold nanoparticles deposited on kaolinite catalyze the electro-oxidation of carbon monoxide in alkaline solution at room temperature.

Key words: kaolinite, grafting, organoclay, nanohybrid materials, gold nanoparticles, carbon monoxide, oxidation.

Résumé : On a utilisé la kaolinite, une argile minérale, comme support pour des nanoparticules d'or pour la catalyse hétérogène de réactions d'oxydation, particulièrement l'oxydation du monoxyde de carbone. L'application des argiles minérales dans la préparation de nouveaux matériaux fonctionnels fournit une approche alternative à l'utilisation de ces matières premières abondantes. Afin d'améliorer les propriétés physico-chimiques de la kaolinite ainsi que pour s'assurer d'une immobilisation forte des substances adsorbées, on a procédé à une fonctionnalisation de la kaolinite en lui greffant du 2-amino-2-méthylpropane-1,3-diol sur ses surfaces internes et externes par réaction avec les groupes aluminol des couches octaédriques. Les nanoparticules d'or sont ensuite déposés sur les surfaces externes de fines particules de kaolinite fonctionnalisée. On a caractérisé le matériel nanohybride de kaolinite d'or qui en résulte par diverses techniques physico-chimiques. La diffraction des rayons-X, la spectroscopie photoélectronique des rayons-X, la microscopie électronique de transmission et la spectrométrie des rayons-X à dispersion d'énergie confirment que l'or est effectivement réduit à l'état métallique lors de son adsorption sur les surfaces extérieures de la kaolinite modifiée. La distribution des tailles des nanoparticules d'or est étroite : plus de 88 % ont un diamètre inférieur à 4 nm. Les nanoparticules d'or déposées sur la kaolinite catalysent l'électro-oxydation du monoxyde de carbone en solution alcaline, à la température ambiante.

Mots-clés : kaolinite, greffage, argile organique, matériaux nanohybrides, nanoparticules d'or, monoxyde de carbone, oxydation.

[Traduit par la Rédaction]

Introduction

The fascinating physicochemical properties of metallic nanoparticles, and particularly of gold nanoparticles (AuNP), lead to a large variety of applications, including the field of catalysis.[1,2] Gold nanoparticles were immobilized successfully on a variety of metal oxides, such as TiO_2, Fe_2O_3, CeO_2, and Al_2O_3,[3–5] as well as on other layered supports.[6] Their preparation is usually based on the method of deposition–precipitation, employing the most common gold precursor $HAuCl_4$. Although clay minerals are known to be useful catalytic supports, owing to their strong thermal and chemical stabilities, their use in the preparation of supported gold catalysts is scarce compared with metal oxides. Large gold nanoparticles with an average diameter ranging between 20 and 50 nm were deposited on laponite,[7] sepiolite,[8,9] and montmorillonite modified by polyethylenimine using $HAuCl_4 \cdot 3H_2O$ as precursor.[10] In 2009, Zhu et al.[11] prepared

small gold nanoparticles on the external surfaces of sepiolite and montmorillonite using $Au(en)_2Cl_3$ as precursor. They showed the usefulness of functionalizing sepiolite by a silane reagent such as aminopropyltriethoxysilane (APTES).[11] The mean diameters of the gold nanoparticles, supported both on sepiolite and on montmorillonite, were below 5 nm. More recently, Zhang et al.[12] deposited AuNP on commercial clay particles functionalized by APTES.

Kaolinite is one of the most abundant clay minerals found in nature. It is a 1:1 layered dioctahedral aluminosilicate[13–15] with a theoretical formula $Al_2Si_2O_5(OH)_4$ and a molecular weight of 258.10 g/mol, corresponding to an ideal composition of 46.55% SiO_2, 39.49% Al_2O_3, and 13.96% H_2O.[16] The kaolinite structure consists of a Si_2O_5 sheet bound on one side to a dioctahedral gibbsite-type layer through van der Waals interactions and hydrogen bonds. Although kaolinite is widely abundant in nature and is characterized by a much higher density of hydroxyl groups than clay minerals of the smectite group, its interlayer chemistry is much less developed in comparison with smectites. To access the aluminol groups, which are the prominent candidates for grafting reactions, kaolinite must be previously intercalated by small polar molecules like dimethylsulfoxide (DMSO) or urea.

The number of gold catalyzed reactions is extensive and varied including O_2 reduction,[17,18] the water gas shift reaction,[19] and selective oxidation of hydrocarbons,[20,21] as well as low temperature CO oxidation.[22,23] What makes gold an especially interesting catalyst is that its performance can be varied and tuned by varying the support material and (or) the catalyst loading. In the presence of O_2, H_2, and a gold catalyst supported on TiO_2, propylene was oxidized to propane, propylene oxide, and ultimately to CO_2, depending on the catalyst loading.[23,24] The optimization of the catalytic effectiveness has been linked to the role of the support material, to the Au oxidation state, to particle size and morphology, and to the operating conditions. An understanding of the catalytic process is important, as values in the literature for the rate of low temperature CO oxidation on similar catalysts vary by orders of magnitude.[23] In the study of CO oxidation, catalyst supports have been identified as active (generally reducible transition metal oxides) or inactive (typically Al_2O_3, SiO_2, and MgO).[25] It is not clear, however, if the activity of the Au catalyst is a direct reflection of the reducibility of the support, as catalysts prepared on Al_2O_3 have been found to show similar activities to those on TiO_2 supports. Furthermore, the catalytic activity can be significantly affected by operating conditions; it has been observed that the rate of CO oxidation at Au/TiO_2 was four times that at Au/Al_2O_3 surfaces at 298 K, but only twice as active at 273 K.[26]

In this work, carbon monoxide catalytic oxidation was obtained by gold nanoparticles (AuNP) supported on a modified kaolinite clay mineral. The preparation of the gold–clay nanoparticles was carried out by a wet chemical process using $Au(en)_2Cl_3$ salt as precursor.[11] Characterization results by X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) confirmed the presence of metallic gold. High-resolution transmission electron microscopy (HRTEM) showed a homogeneous distribution of the gold nanoparticules with an average diameter of less than 5 nm.

Experimental

Materials

Well-crystallized Georgia kaolinite (KGa-1) was obtained from the Source Clay Minerals Repository, University of Missouri. 2-Amino-2-methyl-1,3-propanediol (AMPD), hydrogen tetrachloroaurate hydrate ($HAuCl_4 \cdot 3H_2O$), and ethylenediamine (en) pure grade were obtained from Sigma-Aldrich and were used without further purification.

Sample preparation

Kaolinite (K)

Kaolinite was purified using standard sedimentation techniques and the <2 μm fraction was used in the experiments.

Dimethyl sulfoxide (DMSO)–kaolinite intercalate (DMSO–K)

Kaolinite (10 g) was added to a mixture of 60 mL of DMSO and 5 mL of H_2O. The suspension was stirred continuously for 10 days with the temperature maintained at 80 °C, then it was allowed to cool to room temperature and stirred for a further 5 days. The resulting material was recuperated after two series of washing centrifugation using first dioxane (2 × 50 mL), then isopropanol (2 × 50 mL). The product was finally dried at 50 °C.

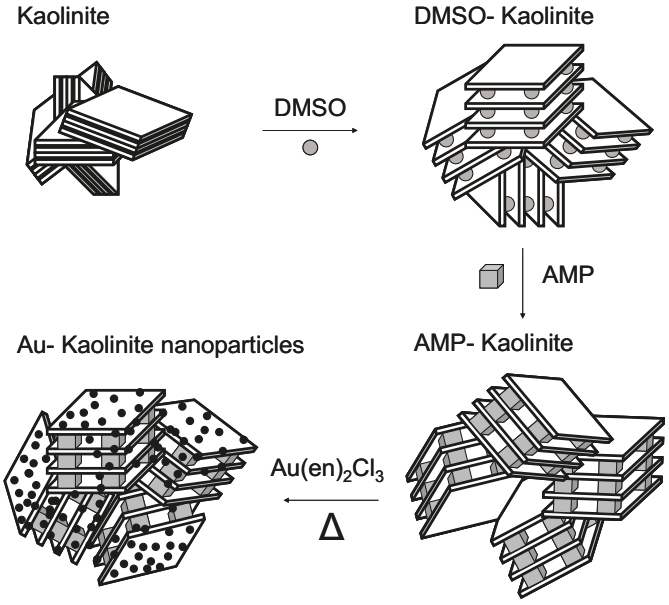
2-Amino-2-methyl-1,3-propanediol (AMPD)–kaolinite intercalate (AMPD–K)

The grafting of 2-amino-2-methyl-1,3-propanediol on kaolinite was performed under nitrogen at 180 °C over a 2 h period. In a typical set of experiments, 1 g of DMSO–K was mixed with 4 g of AMPD. The temperature of the mixture was then increased slowly from room temperature to 180 °C and maintained stable during 2 h. The resulting materials were recuperated after three series of centrifugation following washing with isopropanol (3 × 50 mL). The recovered solid sample was dried at 60 °C overnight, ground and suspended again in water and stirred for 72 h to remove the residual DMSO and intercalated, nongrafted, organic units from the sample.

Clay-supported gold nanoparticles (AuNP–AMPD–K)

The clay suspension was prepared by adding 0.5 g of modified kaolinite to 100 mL of distilled water. It was then dispersed by ultrasonic treatment for 10 min. To achieve 10 wt % of nominal gold loading, 0.050 g of $Au(en)_2Cl_3$ was dissolved in 50 mL of distilled water. The $Au(en)_2Cl_3$ solution was then added to the clay suspension. The mixture was maintained under stirring for 24 h at 60 °C. The colour of the suspension consisting of the gold precursor and of the modified kaolinite turned to dark violet. This colour change indicated that the gold precursor was autoreduced in situ to metallic gold in the presence of the modified kaolinite. The suspension was then filtered and the resulting solid was washed three times with water. The gold–clay nanohybrid materials were dried at 60 °C and stored for further characterization and application (Scheme 1). The reddish colouration of the resulting nanocomposites is a good indication that the gold nanoparticles exhibit a small diameter, in general between 5 and 20 nm.[27] The same procedure was applied using the nonmodified kaolinite and the kaolinite modified

Scheme 1. A schematic illustration of the preparation of gold nanoparticles deposited on the external surfaces of kaolinite.



by intercalation of DMSO. In these cases, the gold precursor was reduced by adding a 0.1 mol/L $NaBH_4$ solution.

Catalytic test

Electrode preparation

Thin films of both the gold nanohybrid material and the AMPD–K support material were prepared by spin-coating on the surface of a glassy carbon electrode (GCE). The modified clay (10 mg; with and without inclusion of Au nanoparticles) was added quickly to 5 mL of 10 wt % dispersion of polystyrene in water and agitated for 10 min. The obtained suspension (1 mL) was spin-coated at 500 rpm for 10 min on the active surface of the GCE. The resulting organoclay-modified electrodes were dried at room temperature and used for electrochemical measurements without further treatment.

Cyclic voltammetry measurement

Electrochemical measurements were performed using a Princton Applied Research (PAR) VersaSTAT 3 potentiostat/galvanostat/frequency response analyzer and V3-Studio electrochemical software version 1.0.281 (2008) (PAR) employing a three compartment glass cell, a working-GCE spin-coated with gold nanohybrid material, a platinum gauze counter electrode, and a relative hydrogen electrode (RHE). The electrolyte was degassed with nitrogen prior to experiments, and subsequently saturated with carbon monoxide by bubbling with CO 99.3%. Nitrogen gas was bubbled through the cell during the measurements. Cyclic voltammograms were recorded over various potential ranges at 50 mV/s. Potential ranges were optimized to show the best response for each of the samples.

Characterization

X-ray diffraction (XRD) patterns were obtained with a Philips PW 3710 instrument equipped with a Ni filter and Cu Kα radiation (λ = 0.15418 nm) operating at 45 kV and 40 mA.

Differential thermal analyses (DTA) and thermal gravimetric analyses (TGA) were recorded on a SDT 2960 Simultaneous DSC-TGA instrument under N_2 flow (100 mL/min) with a heating rate of 10 °C/min.

The ^1H and ^{13}C NMR spectra in solution were recorded on a Bruker 400 MHz spectrometer. Solid-state ^{13}C NMR CP/MAS spectra were collected on a Bruker Avance 500 NMR spectrometer operating at 125.77 MHz. The ^{13}C chemical shifts were referenced to TMS at 0 ppm using the high frequency signal of adamantane at 38.4 ppm as a secondary standard.

Transmission and high-resolution transmission electron microscopic images were obtained on a JEOL JEM-2100F electron microscope. The powders were suspended in ethanol for about 10 min under ultrasonic treatment before depositing them on the carbon support.

XPS spectra of the gold nanoparticles deposited at the external surface of modified kaolinite were collected using a Kratos Axis Ultra DLD spectrometer, equipped with a standard Al Kα excitation source (1486.6 eV). The binding energy (BE) scale was calibrated by measuring C 1s peak from the surface contamination at 285.1 eV.

Results and discussion

X-ray diffraction

XRD diffractograms of pure kaolinite, of the precursor DMSO–kaolinite (DMSO–K), and of the organo-modified kaolinite (AMPD–K) before and after deposition of gold nanoparticles are presented in Fig. 1. The d_{001} spacing of kaolinite is 0.71 nm, and that of the DMSO–K intercalate is 1.10 nm (Figs. 1*a* and 1*b*).[28] The intercalation of DMSO into the interlamellar spaces of kaolinite is clearly observed by a shift of the 001 reflection to lower angles, owing to the keying of one of the DMSO methyl groups in the siloxane rings of the tetrahedral sheets.[29] After reaction with AMPD, the XRD pattern exhibits a well-developed 001 peak with a d_{001} spacing of 1.08 nm. There is, at this point, no evidence if the AMPD is intercalated, co-intercalated with DMSO, or grafted to the octahedral sheet, since no displacement of the 001 reflection to higher or lower angles upon displacement of DMSO was observed. To verify that AMPD is grafted to the octahedral sheet, the material was suspended in water and stirred for 72 h at room temperature. Intercalates of kaolinite are usually displaced by washing with water to recover the original kaolinite or to form a kaolinite hydrate.[30,31] However, in strong contrast, the grafted derivatives of kaolinite, resulting from esterification of the aluminol surfaces, are stable towards extensive washing.[31] The 001 reflection of the material obtained after treatment with water for 72 h is observed at 1.08 nm (Fig. 1*c*), and the intercalation ratio is still higher, which confirms that AMPD is grafted to the internal surfaces. An XRD diffractogram of the gold nanoparticles deposited on the grafted kaolinite (Au–AMPD–K) is given in Fig. 1*d*. The position of the 001 reflection (1.06 nm), as well as the characteristic peaks of kaolinite 001 (0.71 nm) and 060 (0.149 nm), remain at the same position. This indicates that the organic entities grafted into the interlayer space remain unaffected, and that the structure of kaolinite is not

Fig. 1. Powder X-ray diffractograms (2θ = 2°–70°) of (*a*) pristine kaolinite (K), (*b*) kaolinite intercalated by DMSO (DMSO–K), (*c*) kaolinite grafted by 2-amino-2-methyl-1,3-propanediol, and (*d*) kaolinite supported gold nanoparticles (AuNP–AMPD–K).

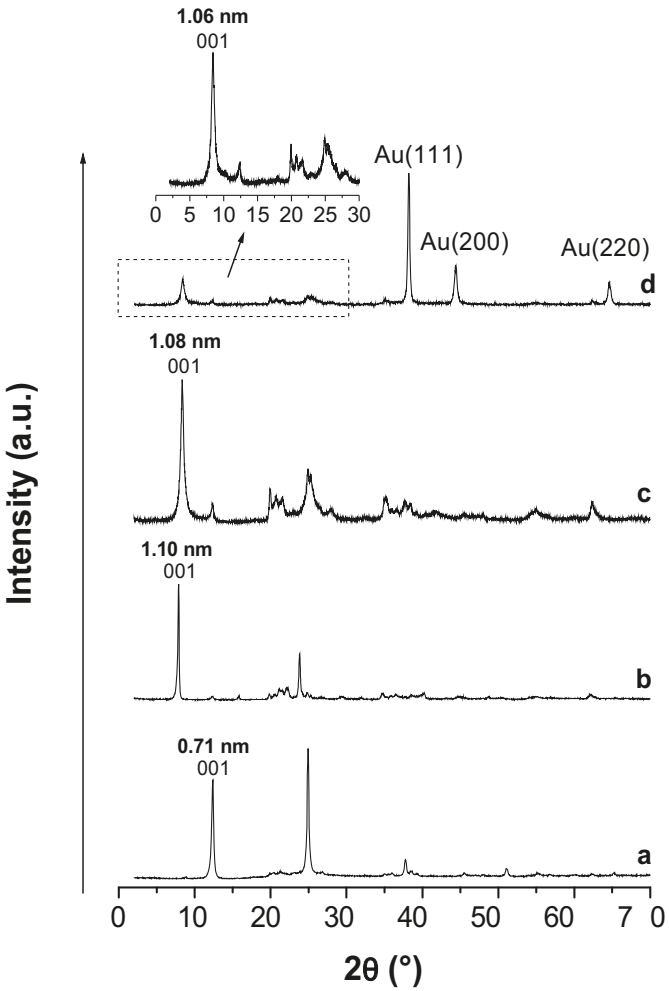

Fig. 2. ^{13}C CP/MAS NMR spectra of (*a*) kaolinite intercalated by DMSO (DMSO–K) and (*b*) kaolinite supported gold nanoparticles (AuNP–AMPD–K).

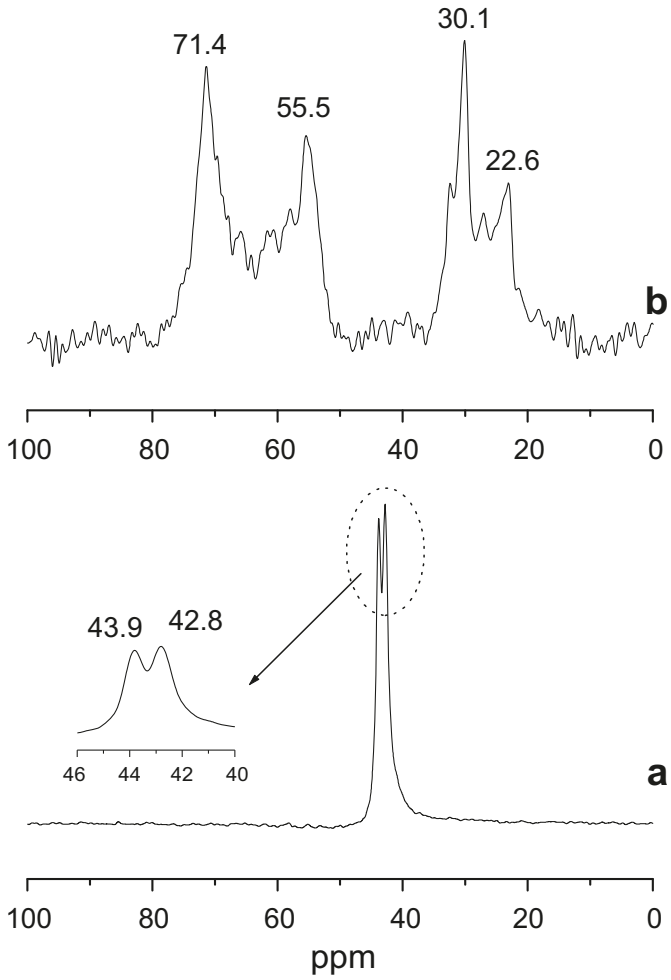

altered during the deposition process. In addition to the typical kaolinite diffraction peaks, three intense reflections at 38.2°, 44.5°, and 64.6° could be observed in the region of 2θ = 2°–70°. They correspond, respectively, to the (111), (200), and (220) reflection peaks of metallic gold. The presence of these peaks indicates that metallic gold particles have been successfully deposited on the modified kaolinite, using $Au(en)_2Cl_3$ as a precursor.

Nuclear magnetic resonance

The ^{13}C CP/MAS NMR spectra of the nanohybrid materials obtained by grafting AMPD onto kaolinite, then adsorbing gold nanoparticles onto the resulting surface, are shown in Fig. 2, along with a spectrum for the precursor DMSO–K. In DMSO–K, the two peaks characteristic of the asymmetric location of DMSO within the interlayer spaces of kaolinite are clearly observed at 43.9 and 42.8 ppm.[29] These peaks are absent in the spectrum of AMPD–K, confirming the complete removal of DMSO upon grafting of AMPD. For AMPD–K, the expected signals characterizing AMPD are observed with chemical shifts close to those observed in solution. To further test the chemical stability of the organo-modified kaolinite during the reaction of deposition of gold nanoparticles, the ^{13}C CP/MAS NMR spectra were recorded after deposition of gold. They are essentially identical to the one before decoration with gold, which confirms that the organo-kaolinite is not decomposed.

X-ray photoelectron spectroscopy

XPS was used to check the oxidation state of the gold nanoparticles deposited at the external surface of kaolinite. The XPS spectrum of the Au 4f region of the gold nanohybrid material is shown in Fig. 3. This region shows two peaks, owing to the Au $4f_{7/2}$ and Au $4f_{5/2}$ transitions. The Au $4f_{7/2}$ peak appears at a binding energy of 82.6 eV and the Au $4f_{5/2}$ peak appears at a binding energy of 86.0 eV. They correspond to the formation of gold in a metallic state.[32–34]

Transmission electron microscopy

Figure 4 displays TEM micrographs of unmodified kaolinite. Well-defined pseudohexagonal crystals could be observed. The average equivalent diameter of these crystals is about 100–500 nm. Figure 5 shows the micrograph of gold nanoparticles deposited on unmodified kaolinite. The existence of gold nanoparticles on the external surface of kaolin-

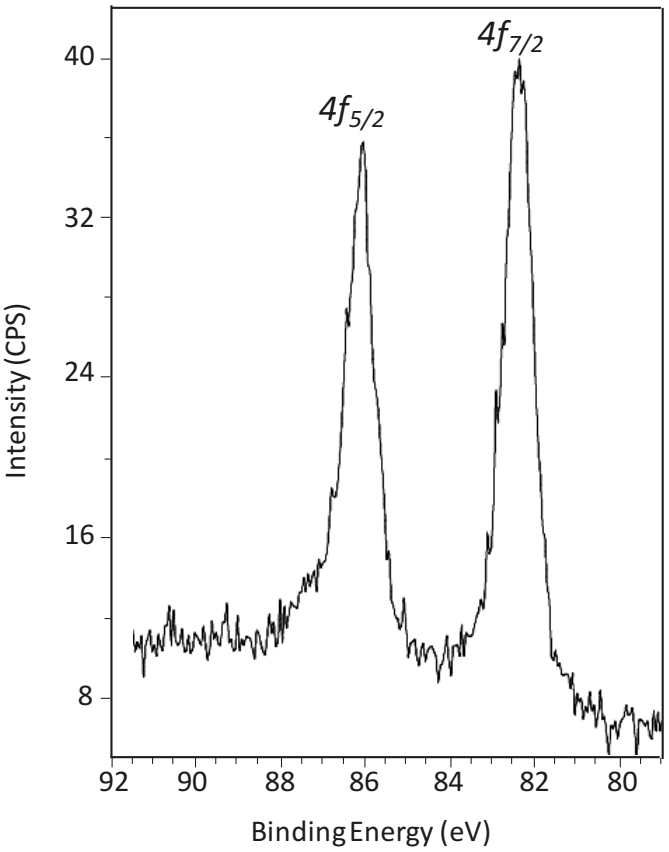
Fig. 3. X-ray photoelectron spectra of gold nanoparticles deposited at the external surface of modified kaolinite, with amplification of the region Au 4f.



ite is supported by detection of dark spots and confirmed by in situ energy-dispersive X-ray spectrometry (EDXS) measurement. The gold loading is low and the gold particles are not homogenously dispersed throughout the kaolinite. This is evident in Fig. 5 in which large gold agglomerates having an average particle size on the order of 90 nm are clearly visible. TEM of gold nanoparticles prepared using DMSO–K as starting material are presented in Fig. 6. Regions of this micrograph are identical to pure kaolinite, which indicates that no gold was retained on the external surfaces. In other regions, the presence of gold nanoparticles with a broad size distribution could be observed (15–60 nm). TEM images as well as the particle size distribution of the gold nanoparticles prepared using AMPD–K as starting material are presented in Fig. 7. In this case, the Au nanoparticles cover all the surfaces of kaolinite. They are homogeneously scattered, not agglomerated, and characterized by a narrow size distribution (diameter $\leq$ 6 nm), with more than 88% of the resulting gold nanoparticles having diameters less than 4 nm. Several different regions within the sample were analyzed and no evidence of agglomeration of the gold nanoparticles was observed. Grafting of AMPD on the interlayer aluminol surfaces of kaolinite has a dramatic effect on the size of the gold nanoparticles. The same behaviour was observed in the preparation of Pd nanoparticles from reduction of $Pd(OAc)_2$ by ethanolamine ($HOCH_2CH_2NH_2$) at room temperature.[34] Similarly, it is expected that the two functions of AMPD are necessary for the formation of the nanoparticles. On one

hand, the hydroxyl groups, which are not grafted to the aluminol surfaces, can serve as reducing agents. On the other hand, the amine groups protect gold nanoparticles from undesirable growth and aggregation via chemical interaction between Au and NH_2,[11,35–39] similarly to what has been reported in the case of Pd[35–38] and NH_2 interactions.[39–43]

Thermal gravimetric analyses

The thermal decomposition of the pristine kaolinite and of the resulting materials was studied by conventional thermal methods: TGA and DTA. In the case of kaolinite, two weight losses are observed (Fig. 8). The first weight loss observed below 60 °C corresponds to the loss of water adsorbed on the external surfaces. The second one observed around 518 °C is due to the dehydroxylation of kaolinite during the transformation of kaolinite to metakaolinite. In the case of AMPD–K, the TGA traces are mainly characterized by different weight losses. The first one at low temperature (below 100 °C) is due to the removal of water adsorbed on the external surfaces. The second one between 200 and 400 °C corresponds to the decomposition of the organic material. The third one observed at 427 °C is due to the dehydroxylation of kaolinite. Finally, the last one, observed around 560 °C, is due to the removal of remaining organic moieties. A significant decrease of the dehydroxylation temperature of AMPD–K (427 °C) compared with 518 °C for kaolinite was observed. This decrease of temperature is an indication that AMPD is grafted to the aluminol groups.[44] On the basis of the percentage of weight loss of water and organics leading to the formation of metakaolinite, the TGA data allow the calculation of the formula unit of AMPD–K as $Al_2Si_2O_5(OH)_4(AMPD)_{0.90}$. After deposition of AuNP, the evolution of the TGA curve of the Au–AMPD–K kaolinite is identical to the AMPD–K, indicating that the clay lattice was not modified during the reaction of deposition of the gold nanoparticles. Taking into account the total weight loss of AMPD–K and of Au–AMPD–K, one can calculate the amount of gold loaded on the nanohybrid material. It is close to 8.7%. The actual loading

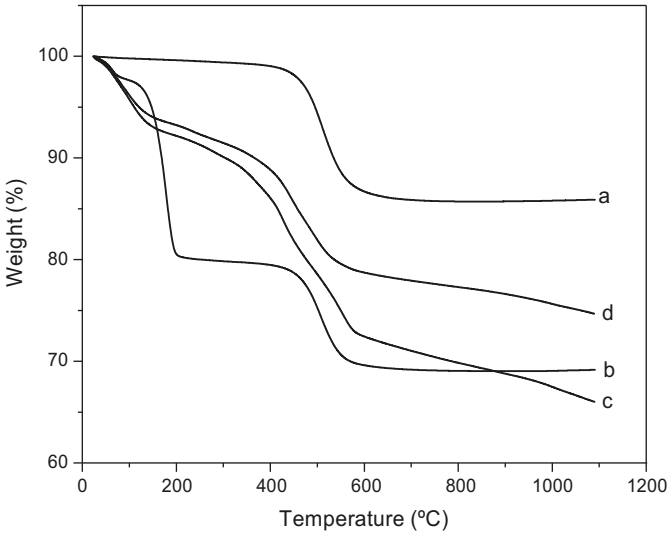
Fig. 8. Thermal gravimetric analysis patterns of (*a*) pure kaolinite (K), (*b*) kaolinite intercalated with DMSO (DMSO–K), (*c*) kaolinite grafted with 2-amino-2-methyl-1,3-propanediol (AMPD–K), and (*d*) kaolinite supported gold nanoparticles (AuNP–AMPD–K).



is marginally lower than that of the precursor materials (10%) indicating that a nominal portion of the gold precursor was displaced during washing.

Oxidation of carbon monoxide

Supported Au nanoparticles have been identified as suitable catalysts for carbon monoxide oxidation.[45,46] The use of kaolinite as a structural support of the gold nanocatalyst for CO oxidation was studied in a series of cyclic voltammetry experiments. Results are presented in Fig. 9 for (*a*) bare GCE, (*b*) kaolinite coated GCE without Au nanoparticles, and (*c*) Au–AMPD–K in the absence of carbon monoxide. No evidence of a faradic reaction is observed over the potential range of 0.8–1.4 V. In this potential region, only double layer charging at the electrode surface was observed. Above 1.4 V, oxygen evolution occurs at all electrodes. Similarly, in Fig. 10 the cyclic voltammograms are presented for the same electrodes in the presence of carbon monoxide. The CV response at the glassy carbon and kaolinite electrodes in the presence of carbon monoxide are identical to those in the absence of CO (compare with Fig. 9*b* and Fig. 10*a*). The Au–AMPD–K electrode shows markedly different response in the presence of CO. The potential was initially scanned from 0.9 V (RHE) in the positive direction to 1.7 V (RHE). Again, oxygen evolution was observed at potentials positive of 1.4 V; on the reversal of potential, a well-defined oxidation peak was observed in the potential range of 1.0–1.15 V (associated with oxidation of CO). This peak was found to increase upon repeated cycling into the oxygen evolution regime. Similar "activation" of supported Au catalysts has been reported in the literature.[32,47,48]

Conclusion

This work shows the potential of an abundant naturally occurring clay mineral, kaolinite, for the use in the development of novel advanced materials for heterogeneous catalysis of oxidation reactions. Kaolinite was intercalated by a bifunctional organic molecule, 2-amino-2-methyl-1,3-propanediol (AMPD), which was grafted on the internal and external surfaces of kaolinite fine particles. The hydroxyl functions have a dual function: (*i*) reacting with aluminol groups resulting in the grafting of the organic units and (*ii*) serving as reducing agent. The amino functions protect gold nanoparticles from undesirable growth and aggregation via chemical interaction between Au and NH_2. While the deposition of gold on unmodified kaolinite and on DMSO intercalated kaolinite lead to relatively large gold particles inhomogeneously dispersed on the solid, the situation was dramatically different in the case of the AMPD grafted kaolinite nanohybrid material, in which case gold nanoparticles were obtained with a narrow size distribution (diameter $\leq$ 6 nm) and with more than 88% of the resulting gold nanoparticles having diameters less than 4 nm. This material was coated on GCEs and studied in a

series of cyclic voltammetry experiments, which showed a well-defined oxidation peak in the potential range of 1.0–1.15 V (associated with oxidation of CO).

Acknowledgements

This paper is in honour of the outstanding career contributions of Professor Rod Wasylishen to the chemical sciences in general and particularly to the field of nuclear magnetic resonance. This work was financially supported by a Discovery Grant of the Natural Sciences and Engineering Research Council of Canada (NSERC). The Canada Foundation for Innovation and the Ontario Research Fund are gratefully acknowledged for infrastructure grants to the Center for Catalysis Research and Innovation. Dr. Glenn A. Facey is thanked for recording the NMR spectra, Dr. Yun Liu for help in TEM microscopy measurements, and Dr. A. Mommers for the XPS measurements.

Investigation of the disorder of dibromo- and dichloromethane in their tri-*ortho*-thymotide clathrates using X-ray diffraction and solid-state ^{2}H NMR spectroscopy

Abstract: The tri-*ortho*-thymotide (TOT) clathrates of dibromo- and dichloromethane were characterized by single crystal X-ray diffraction at 200 K and solid-state ^{2}H NMR spectroscopy as a function of temperature. The host structure was found to be typical of other cage-type TOT clathrates. The X-ray results showed a substantial amount of disorder among the guest molecules. In both clathrates, multiple guest molecule positions could be modeled. The heavy atoms of all the guest molecule positions lie approximately in the same plane, with some out-of-plane distortion. The guest molecules were of two different types in positions symmetric about the crystallographic twofold rotation axis: type A guests, with carbon atoms well removed from the crystallographic twofold axis, and type B guests, with carbon atoms very close to the twofold axis. The ^{2}H NMR spectra for the guests confirmed that the disorder was dynamic. The experimental results could be accounted for by the presence of three simultaneous types of molecular motion, all fast with respect to the ^{2}H quadrupolar interaction: (*i*) twofold molecular flips about the molecular C_2 symmetry axis, (*ii*) exchange between the type A and type B sites in a single plane, and (*iii*) a two-site libration of the plane containing the heavy atoms of the A and B guest sites with a temperature-dependent amplitude.

Key words: tri-*ortho*-thymotide, ^{2}H NMR, dibromomethane, dichloromethane, clathrate.

Résumé : On a caractérisé les clathrates de tri-*ortho*-thymotide (TOT) avec du dibromo- et du dichlorométhane en faisant appel à la diffraction des rayons-X sur un cristal unique à 200 K et par spectroscopie RMN du ^{2}H à l'état solide en fonction de la température. On a trouvé que la structure hôte est typique des autres clathrates TOT de type cage. Les résultats de la diffraction des rayons-X permettent d'observer une quantité importante de désordre parmi les molécules invitées. Dans les deux clathrates, il a été possible de faire des modèles de nombreuses positions des molécules invitées. Les atomes lourds de toutes les positions de la molécule sont approximativement dans le même plan, avec un peu de distorsion en dehors de ce plan. On a observé deux types différents de molécules invitées dans des positions symétriques autour de l'axe de rotation cristallographique binaire : les invitées de type A pour lesquelles les atomes de carbone sont éloignés de l'axe cristallographique binaire et les invitées de type B pour lesquelles les atomes de carbone sont très près de l'axe cristallographique binaire. Les spectres RMN du ^{2}H des molécules invitées confirment que le désordre est dynamique. Les résultats expérimentaux peuvent être expliqués par la présence de trois types simultanés de mouvements moléculaires, tous rapides par rapport à l'interaction ^{2}H quadripolaire : (*i*) des inversions moléculaires binaires autour de l'axe de symétrie moléculaire C_2, (*ii*) un échange entre les sites de type A et de type B dans un seul plan et (*iii*) une libration sur deux sites du plan contenant les atomes lourds des sites invités A et B avec une amplitude qui varie avec la température.

Mots-clés : tri-*ortho*-thymotide, RMN du ^{2}H, dibromométhane, dichlorométhane, clathrate.

Introduction

Inclusion compounds have generated a great deal of interest over the years for their applications in the pharmaceutical, agricultural, environmental, and food industries. Solid inclusion compounds consist of a host material and a guest material. There are several types, including those with ionic and neutral guest molecules. The hosts can be comprised of tunnels, cages, or both. Tri-*ortho*-thymotide (TOT, **1**) is the trimeric lactone of *ortho*-thymotic acid and is a versatile organic host material forming inclusion compounds with many guest molecules.[1–12] It is able to form both channel- and cage-type inclusion compounds.[13] In the solid state, the TOT molecules can adopt a helical conformation where two of the three carbonyl bonds in the macrocyclic ring point in

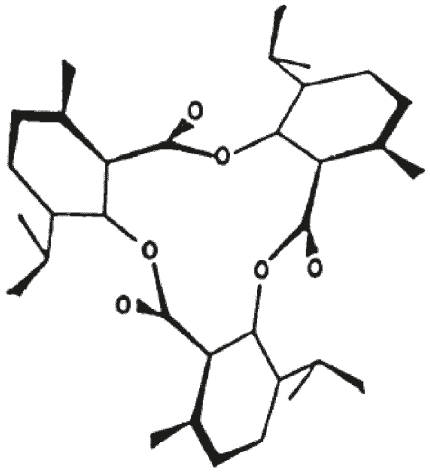
one direction and the third points in the opposite direction. This conformation is present in the channel-type inclusion compounds. TOT molecules can also adopt propeller conformations where all three carbonyl groups point in the same direction. It is the propeller conformations of the host molecules that are present in the cage type inclusion compounds. It is primarily the guest molecule that determines the type of inclusion compound formed. Guests with an overall length exceeding ~9.5 Å will form channel type inclusion compounds, whereas those guests whose overall lengths are less than ~9.5 Å form cage type inclusion compounds, although there are a few exceptional cases where channel TOT inclusion compounds of small molecules are known.[10,11] The cages are comprised of eight TOT molecules and have been described as distorted ellipsoids with C_2 crystallographic symmetry.[12] The dimensions of the cages are ~7.0 Å × ~6.1 Å × ~5.2 Å and they are lined primarily with the methyl and isopropyl groups of the host with two carbonyl oxygens at one end. The propeller conformation of the TOT molecules forming the cage-type inclusion compounds can have either a left-hand or a right-hand pitch and therefore possess chirality. Furthermore, optical resolution of each of the two types of propellers is accomplished simply by recrystallization. Each TOT–guest crystal contains either all left-handed or all right-handed propellers. The presence of chiral host molecules leads to the void spaces also having chirality, making TOT cage-type inclusion compounds chirally selective towards racemic guests. This has generated a great deal of interest.[1–4,7,8,11,14–19] Also, the chiral TOT cages containing prochiral guest molecules render the prochiral groups of the guest diastereotopic and therefore nonequivalent.[20]

Guests trapped in confined spaces have the properties of neither their bulk material nor the bulk host material. It has been shown that for many inclusion compounds the guest molecules exhibit a great deal of dynamic behaviour, complicating the determination of the structure by single crystal X-ray diffraction methods. Sometimes the guest molecules cannot be located at all.[7] Dynamic disorder of the guest leads to smeared out electron density distributions, as the time scale of the diffraction experiment is hours compared with the wide range of much shorter motional correlation times for guest molecules. In such cases the refinement of the X-ray structure depends on modelling the disorder of the guest. There are cases where a guest molecule can undergo symmetric reorientations and this motion (by way of its symmetry) can go undetected by diffraction methods.[21] An example of this is the twofold reorientation of acetone in its TOT clathrate about its carbonyl bond.[22] Guest molecules can also exhibit static disorder, where the immobile rigid guest molecule can occupy a number of possible sites. As in the case of dynamic disorder, modelling is required in refining the X-ray structure. X-ray diffraction methods are unable to distinguish between dynamic and static disorder. Solid-state NMR spectroscopy, on the other hand, is very sensitive to dynamics on time scales of the same order as or shorter than the reciprocal of the span of the NMR interaction being observed. One of the proven methods for characterizing molecular motion is solid-state ^{2}H NMR spectroscopy. Using both X-ray diffraction and solid-state NMR techniques is essential for developing models to explain the observed disorder. In this work we employ both X-ray diffraction and wide line ^{2}H NMR spectroscopy to study the cage-type TOT–dibromomethane and TOT–dichloromethane inclusion compounds with the goal of characterizing the dynamic disorder of the guest molecules.



1

Background

Solid-state ^{2}H nuclear magnetic resonance spectroscopy (NMR) is an extremely sensitive technique for characterizing the molecular motion of molecules. ^{2}H is a spin $I = 1$ nucleus having three Zeeman energy levels perturbed by the electric quadrupolar interaction resulting in each crystallographically unique deuteron having two resonance frequencies. The separation between the resonances depends on the quadrupolar coupling constant ($\chi = e^2Qq/h$), where eQ is the electric quadrupole moment, eq is the electric field gradient at the nuclear site, and h is Planck's constant, and the orientation of the electric field gradient tensor ($\mathbf{V_{ij}}$) at the nuclear site with respect to the externally applied magnetic field. $\mathbf{V_{ij}}$ is traceless and symmetric. In its principal axis system, it is diagonal and characterized by its three principal components V_{xx}, V_{yy}, and V_{zz} ($|V_{zz}| > |V_{yy}| \geq |V_{xx}|$). For deuterons in C–D bonds the largest component, V_{zz}, lies along the C–D bond. In powdered samples, where all orientations of the electric field gradient tensor with respect to the magnetic field are represented, each unique deuteron will give rise to a powder pattern similar to the ones shown in Fig. 1. The spectra have a characteristic shape consisting of three pairs of features $\Delta\upsilon_{xx}$, $\Delta\upsilon_{yy}$, and $\Delta\upsilon_{zz}$, which are proportional to V_{xx}, V_{yy}, and V_{zz}, respectively. The asymmetry parameter (η) is defined by $(\Delta\upsilon_{yy} - \Delta\upsilon_{xx})/\Delta\upsilon_{zz}$ and can take on values between 0 and 1. When a molecular motion occurs on a time scale of the same order as $1/\chi$, the line shapes are distorted compared with those in Fig. 1 and contain a great deal of information about the mechanism and rate of the motion.[23] When a molecular motion is fast with respect to $1/\chi$, an averaged electric field gradient tensor ($\mathbf{a_{ij}}$) is produced. To calculate $\mathbf{a_{ij}}$, one must first define the components of each of the $\mathbf{V_{ij}}$ visited over the course of the motion in a common axis system defined by the axis of the molecular motion. The components of each $\mathbf{V_{ij}}$ are then expressed in terms of the Euler angles[24] α, β, and γ, relating them to the common axis system. The components of $\mathbf{a_{ij}}$ are calculated by taking

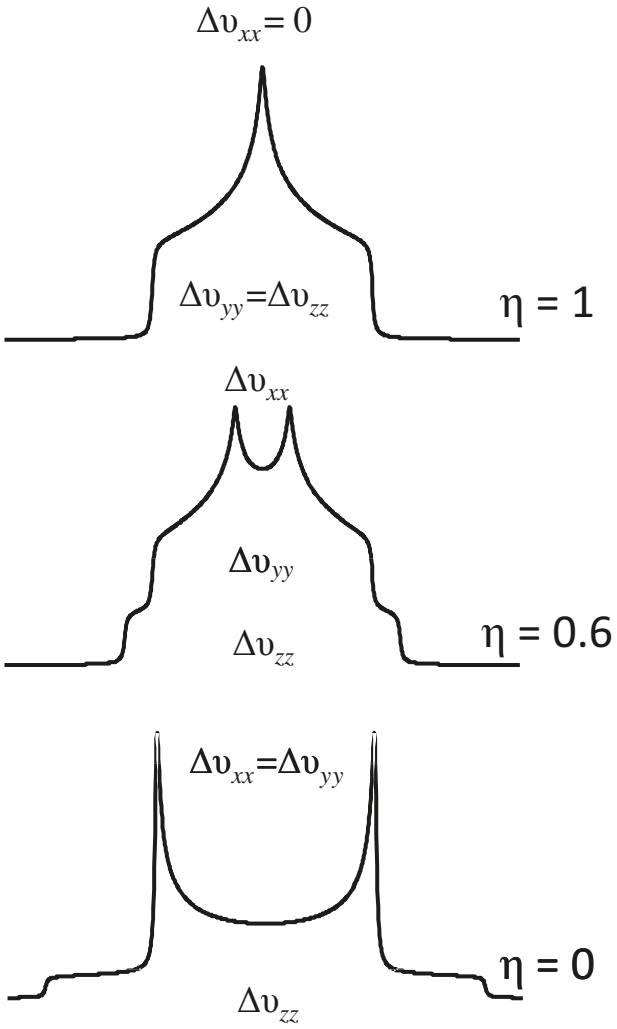
Fig. 1. Examples of line shapes for ^{2}H NMR spectra for either rigid molecules or molecules undergoing motions fast with respect to the reciprocal quadrupolar coupling constant $1/\chi$. The separations between the features in the spectra ($\Delta\upsilon_{xx}$, $\Delta\upsilon_{yy}$, and $\Delta\upsilon_{zz}$) are proportional to the principal components of the electric field gradient tensor.



the population weighted average of each of the components of $\mathbf{V_{ij}}(\alpha, \beta, \gamma)$ visited over the course of the motion. The averaged tensor is then diagonalized, if necessary, yielding the three principal components a_{11}, a_{22}, and a_{33}. If the motion is symmetric $\mathbf{a_{ij}}$ will have one of its principal components along the axis of molecular rotation. The time-averaged ^{2}H NMR spectrum will be defined by $\mathbf{a_{ij}}$ rather than $\mathbf{V_{ij}}$; hence, the frequency separation between features in the averaged spectrum, $\Delta\upsilon'_{xx}$, $\Delta\upsilon'_{yy}$, and $\Delta\upsilon'_{zz}$, will be proportional to the principal components of $\mathbf{a_{ij}}$. The spectra will still retain the same general shapes as those depicted in Fig. 1. If more than one mode of fast molecular motion occurs, this averaging technique is applied in series. One first calculates $\mathbf{a_{ij}}$ as an average of $\mathbf{V_{ij}}(\alpha_1, \beta_1, \gamma_1)$ for the first motion and then $\mathbf{a_{ij}}'$ as an average of $\mathbf{a_{ij}}(\alpha_2, \beta_2, \gamma_2)$ for the second motion, etc.

Experimental section

TOT was purchased from Sigma-Aldrich and used without further purification. Dibromomethane-d_2 and dichloromethane-d_2 were purchased from CDN Isotopes (Pointe-Claire, Quebec) and used as received. The isotopic purities were reported to be 99.4% and 99.9%, respectively. The clathrates used for the ^{2}H NMR studies were prepared by dissolving TOT in CD_2Br_2 or CD_2Cl_2 and allowing for slow evaporation over the course of several days. The crystals of TOT–CH_2Br_2 and TOT–CH_2Cl_2 were grown by dissolving TOT in the respective solvent and allowing for slow evaporation.

The X-ray diffraction results for TOT–CH_2Cl_2 and TOT–CH_2Br_2 represent the best data sets obtained from several trials for each sample. The crystals were mounted on thin glass fibers using paraffin oil and cooled to 200.15 K. Data were collected on a Bruker AXS SMART single crystal diffractometer equipped with a sealed Mo tube source (wavelength 0.710 73 Å) APEX II CCD detector. Data for both samples were collected with a sequence of 0.5° ω scans at 0°, 120°, and 240° in φ. Initial unit cell parameters were determined from 60 data frames collected at the different sections of the Ewald sphere. Semiempirical absorption corrections based on equivalent reflections were applied.[25] Systematic absences in the diffraction data set and unit cell parameters were consistent with trigonal space group $P3_221$ for both TOT–CH_2Cl_2 and TOT–CH_2Br_2. Solutions in the centrosymmetric space groups yielded chemically reasonable and computationally stable results on refinement. The structures were solved by direct methods, completed with difference Fourier synthesis, and refined with full-matrix least-squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement coefficients. All hydrogen atoms were treated as idealized contributions. All scattering factors are contained in several versions of the SHELXTL program library, with the latest version used being v.6.12.[26] Crystallographic data and selected data collection parameters are reported in Table 1.

The ^{2}H NMR data for the TOT–CD_2Br_2 clathrate were collected on a Bruker AVANCE III 200 operating at 30.7 MHz for ^{2}H using a 5 mm solenoid probe. The quadrupolar echo technique[27] was used with 90° pulses of 4.3 μs and an interpulse delay of 20 μs. The delay following the second pulse was set to 8 μs and the data were left-shifted to the top of the echo. A 1 MHz spectral width was employed and 1024 data points were collected. The recycle time was set to 2 s. Typically, 1024 scans were collected. The ^{2}H NMR data for the TOT–CD_2Cl_2 clathrate were collected on a Bruker AVANCE III 400 NMR spectrometer operating at 61.4 MHz for ^{2}H using a 10 mm solenoid probe. The quadrupolar echo technique was used with 90° pulses of 3.25 μs and an interpulse delay of 35 μs. The delay following the second pulse was set to 12 μs and the data were left-shifted to the top of the echo. A 1 MHz spectral width was employed and 1024 data points were collected. The recycle time was set to 2 s. Typically, between 3000 and 10 000 scans were collected and signal averaged. On both instruments, dry boil-off nitrogen gas was used to cool the sample and the temperature was regulated with the probe heater using the Bruker variable temperature control unit. All free induction decays were treated with 200 Hz of exponential line broadening before Fourier transformation. The Fourier transformed spectra were then symmetrized. All simulations of ^{2}H NMR spectra were performed using the online utility, NMR Weblab version 4.3.2.[28]

Results and discussion

A summary of the X-ray data for the TOT–CH_2Br_2 and TOT–CH_2Cl_2 2:1 clathrates is given in Table 1 with more details provided in the Supplementary data. The X-ray crystal structures of both clathrates are very similar to one another and to those determined previously for many of the cage-type clathrates. They have the same number of molecules in the unit cell and very similar cell constants. Unlike many of the other TOT clathrate structures reported in the 1980s, which were reported to crystallize in the space group $P3_121$, the TOT–CH_2Br_2 and TOT–CH_2Cl_2 clathrates both crystallized in the enantiomorphic space group $P3_221$. Refinement of the data for the TOT–CH_2Br_2 and TOT–CH_2Cl_2 clathrates was attempted in space group $P3_121$ in which the host structure could be refined satisfactorily; however, when the atoms for the guest species were introduced, the structure would not refine and it became clear that the $P3_221$ rather than the $P3_121$ space group was indeed correct. It may be possible that some of the unsuccessful attempts to locate guest molecules in TOT clathrates in the past are the result of refinements done in the wrong space group. This pair of space groups is also observed for the chiral structures of D- and L-α-quartz.[29,30] The only unusual feature of the host structures is that one of the three carbonyl oxygens in the macrocyclic ring exhibits a small degree of two-site disorder. It is unclear whether the disorder is static or dynamic in nature; however, it is common to the structures of both clathrates. The guest molecules were located in the cavities with occupancies of 0.92 and 0.84 for TOT–CH_2Br_2 and TOT–CH_2Cl_2, respectively. In the case of the CH_2Cl_2 clathrate, it was noticed that some of the guest was lost over time, and the crystal structure was determined immediately from a freshly prepared sample. The dihalomethane guest molecules showed a large degree of disorder as was also observed in the inclusion compound of CH_2Cl_2 with cryptophane-E.[31,32] The X-ray models for the guests are shown in Fig. 2. In the case of TOT–CH_2Br_2, six molecular sites were located. Of the six molecular sites, there are two types: sites with the central carbon atoms well removed from the crystallographic C_2 axis (type A sites, two molecules) and sites with the central carbon atoms nearly lying on the C_2 axis (type B sites, four molecules). To a first approximation the Br–C–Br planes of all the molecules are coincident; however, if viewed along the plane, it is evident that there are out-of-plane distortions. The X-ray model for the CH_2Cl_2 molecules is very similar to that of the CH_2Br_2 molecules except that four rather than six molecular sites could be identified: two molecules in type A sites and two molecules in type B sites. Two differences between the X-ray models for each of the guests in type A sites are, however, the degree of displacement of the carbon atoms from the crystallographic twofold axis, and the angle between the crystallographic twofold axis and the molecular twofold axis. These angles are approximately 95° and 60° for CH_2Br_2 and CH_2Cl_2, respectively. At 200 K, the X-ray model found populations of sites A and B (P_A and P_B) to be 0.232

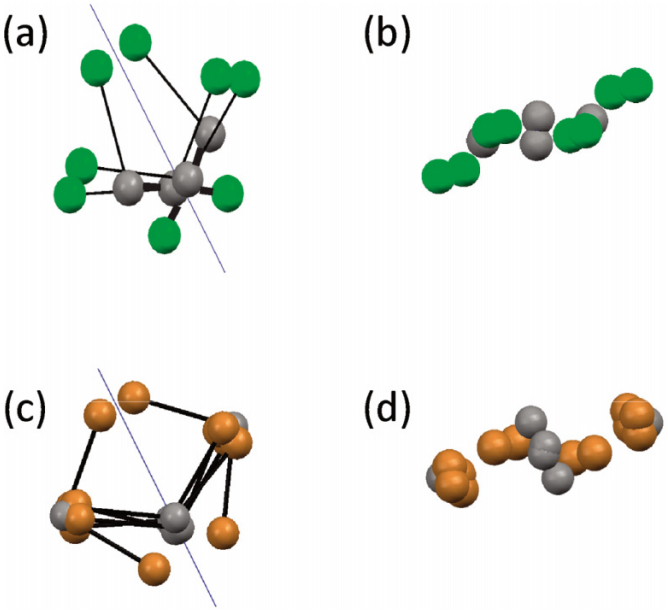
The colored spheres represent halogen atoms.



and 0.768, respectively, for TOT–CH_2Br_2 and 0.404 and 0.596, respectively, for TOT–CH_2Cl_2. One thing that is completely unclear from the X-ray data is whether or not the disorder of the guest molecules is static or dynamic in nature, or a combination of the two.

The solid-state ^{2}H NMR data collected as a function of temperature for the TOT–CH_2Br_2 clathrate are given in Table 2 and shown in Fig. 3*e*. In all of the spectra, the observed χ are much smaller than the range of those reported for the dihalomethanes (160–180 kHz),[33] indicating that the molecules are undergoing molecular motions on the submicrosecond time scale or faster. The line shapes are typical of those in the fast motion limit and were found not to vary with the echo times in the quadrupolar echo pulse sequence. Both χ and η vary with temperature. All of the spectra show a single powder pattern, indicating that all of the deuterons trace out the same trajectory over the course of their motions. In other words, all of the deuterons are identical in the time average. A plot of the frequency separations between the three features in the powder spectra is given in Fig. 4*a*.

The most obvious type of motion to account for the observed line narrowing, consistent with the X-ray model, is exchange between type A and type B sites. This involves both a translation and a rotation. Since ^{2}H NMR spectra are not sensitive to molecular translations, it is instructive to put all of the site A and site B molecules in a coordinate system where the central carbon atoms of each molecule are at the origin. In such a picture, the molecular rotations that affect the ^{2}H NMR spectra are more easily described. This is demonstrated in Fig. 5*c*. Ignoring the out-of-plane distortion (Fig. 5*d*), a simple picture is shown in Fig. 5*a*. In this picture, it is clear that the molecules in type A sites (labelled 1 and 3 in Fig. 5*a*) are related to molecules in type B sites (labelled 2 in Fig. 5*a*) by a simple rotation, the axis of which is perpendicular to the plane containing all of the C and Br atoms. The angle of rotation required to go from a type A site to a type B site is 95°. Based on the population ratios for sites A and B observed in the X-ray model at 200 K, and neglecting differences between the four type B sites, one might expect the potential energy coordinate for the required rotation from site A to site B to site A to be described by the simple symmetric three-site potential well shown in Fig. 6. Ignoring any out-of-plane motion, one would expect that the majority of the motional averaging in the ^{2}H NMR spectra can be accounted for by the rotation of the molecules between the A and B sites. If this is the case, each deuteron would move between the three sites on the surface of a cone of half angle $\beta = 35.5°$ assuming tetrahedral bond angles (see Fig. 5b). The rotation angle (γ) between the sites is 95°. The Euler angles relating the three $\mathbf{V_{ij}}$ tensors to the rotation axis are $\alpha = 0°$, $\beta = 35.5°$, and $\gamma = -95°$, 0°, and 95°. If this motion is fast with respect to $1/\chi$, a single averaged electric field gradient tensor will result with one component normal to the plane containing the C and Br atoms and the other two components in the plane. Using typical rigid values of χ and η of 170 kHz and 0, respectively,[33] the simulations of the ^{2}H NMR spectra are shown in Fig. 3*a* as a function of P_B with the assumption that the population of each of the A sites is equal. Clearly, these spectra are much broader than the experimental data in Fig. 3*e*. Even if one attempts to account for any dynamic disorder out of the C–Br plane of amplitude similar to that observed in the X-ray model, the degree of narrowing in the observed spectra cannot be accounted for.

The CH_2Br_2 molecules must be undergoing an additional mode of molecular motion. Furthermore, this additional mode of motion must be such that it is not detected by X-ray diffraction methods. One such motion is a twofold flip about the molecular C_2 symmetry axis similar to what has been reported for the TOT–acetone[22] and TOT–pyridine[21] clathrates. For the molecular twofold flips, the Euler angles relating the two $\mathbf{V_{ij}}$ to the rotation axis are $\alpha = 0°$, $\beta = 54.75°$, and $\gamma = 0°$ and 180°. The averaged tensor resulting from the twofold flips ($\mathbf{a_{ij}}$) will have one component perpendicular to the plane containing the C and Br atoms and the other two components in the plane. This averaged tensor is used as a starting point to compute the average tensor $\mathbf{a_{ij}}'$ resulting from both the twofold flips and the exchange among the type A and B sites. The Euler angles relating $\mathbf{a_{ij}}$ to the rotation axis for the site A to site B exchange are $\alpha = 0°$, $\beta = 0°$, and $\gamma = -95°$, 0°, and 95°. The averaged $\mathbf{a_{ij}}'$ resulting from both of these motions has a single component perpendicular to the plane containing the C and Br atoms, which remains unchanged compared with $\mathbf{a_{ij}}$, and two components in the plane. Simulations of the ^{2}H NMR spectra, assuming that the CH_2Br_2 molecules undergo both fast twofold flips and exchange between the type A and type B sites, are shown in Fig. 3*b* as a function of P_B with the assumption that the population of each of the A sites are equal. Although the spectra have a width of the same order as the experimental data, the line shapes are not a good fit. In the simulations η decreases as P_B decreases, whereas η in the observed spectra increases at higher temperatures where the population of the B sites is expected to decrease. The problem with this

model is that it does not take into account the out-of-plane disorder observed in the X-ray model.

If the out-of-plane disorder is assumed to be dynamic, one simple way to model it may be as a two-site libration about one of the components of $\mathbf{a_{ij}}'$ in the plane containing the C and Br atoms. The averaged $\mathbf{a_{ij}}'$ resulting from both molecular twofold flips and the exchange between sites A and B is used as the starting point to compute the average tensor $\mathbf{a_{ij}}''$ resulting from the combination of all three motions. The Euler angles relating $\mathbf{a_{ij}}'$ to the librational axis of rotation are $\alpha = 0°$, $\beta = 90°$, and $\gamma = \pm 1/2\varphi$. Figure 3*c* shows simulations of the ^{2}H NMR spectra for molecules undergoing fast twofold flips about the molecular C_2 axis, a fast three-site exchange between type A and type B sites (with populations $P_A = 0.232$ and $P_B = 0.768$ as determined in the X-ray model) as well as a two-site libration of the plane containing all the C and Br atoms. The spectra were calculated as a function of φ. The libration angles were chosen such that the separation between the inner features of the simulations matched the experimental spectra. These data agree remarkably well with the experimental data; however, the simulated spectra do not take into account any possible temperature dependence of P_A and P_B. As a result, the simulations are somewhat broader than the experimental data. Since the axis of rotation resulting in the exchange between A and B sites and that of the rotation involved in the two-site out-of-plane libration are perpendicular, one would expect that one of the three frequency separations in the powder pattern would be constant as a function of temperature if P_A and P_B were invariant with temperature. From Fig. 4*a*, one can see that all three pairs of features in the observed spectra change with temperature. This indicates that the populations of the A and B sites must also change with temperature. Figure 3*d* shows simulations similar to those in Fig. 3*c*, except that both P_B and φ were adjusted to best fit the experimental spectra. P_B was chosen such that the frequency separation between the intermediate features of the simulated spectra ($\Delta\upsilon_{yy}$) matched the experimental data and then φ was chosen such that η matched that of the experimental spectrum. The results are shown in Table 2 and φ is plotted as a function of temperature in Fig. 7*a*. Since the population ratio P_A:P_B is expected to be determined by the Boltzmann distribution, one would expect a plot of $\ln(P_A/P_B)$ vs $1/T$ to be linear with slope = $-\Delta E/R$ and intercept = ln2, where ΔE is the energy difference between sites A and B. This plot is shown in Fig. 8. The high-temperature region of the plot seems to agree well with the Boltzmann model. The best fitting line with an intercept of ln2 is drawn in the figure. ΔE is 3.5 kJ /mol. At the lower temperatures the model breaks down. This may be due to the fact that, according to the X-ray model, there are in fact four nonequivalent type B sites rather than the one assumed in the simplified exchange model. As a result of the nonequivalent type B sites, at lower temperatures, one would expect the shape of the potential well to be more complicated and perhaps even temperature-dependent. The simplified potential energy picture in Fig. 6 is clearly not adequate to fully describe the in-plane motion over the entire temperature range. Nevertheless, the data strongly support the presence of three modes of molecular motion on a time scale fast with respect to $1/\chi$.

The uniqueness of the models for the dynamic disorder used to explain the spectroscopic results must always be examined. A number of other models were tested and found to be at least partially consistent with the NMR data. None, however, were consistent with the X-ray model. The three simultaneous modes of molecular motion described here were chosen based on their consistency with both the NMR and the X-ray data for the disorder. Although this is not proof that the models are a unique description of the data, the consistency with both the X-ray and NMR data demonstrates the credibility of the interpretation.

The solid-state ^{2}H NMR data collected as a function of temperature for the TOT–CD_2Cl_2 clathrate are given in Table 2 and shown in Fig. 9*d*. As with the TOT–CD_2Br_2 clathrate, all of the spectra exhibit an observed χ much smaller than that expected for the pure solid.[33] Again, the line shapes are typical of those in the fast motion limit and were found not to vary with the echo times in the quadrupolar echo pulse sequence. Both χ and η vary with temperature. All of the spectra show a single powder pattern indicating that all of the deuterons trace out the same trajectory over the course of their motions. A plot of the frequency separations between features in the spectra as a function of temperature is given in Fig. 4*b*. Unlike the case for the TOT–CD_2Br_2 clathrate, where the separation of all three pairs of features in the powder spectra varied with temperature, one pair of

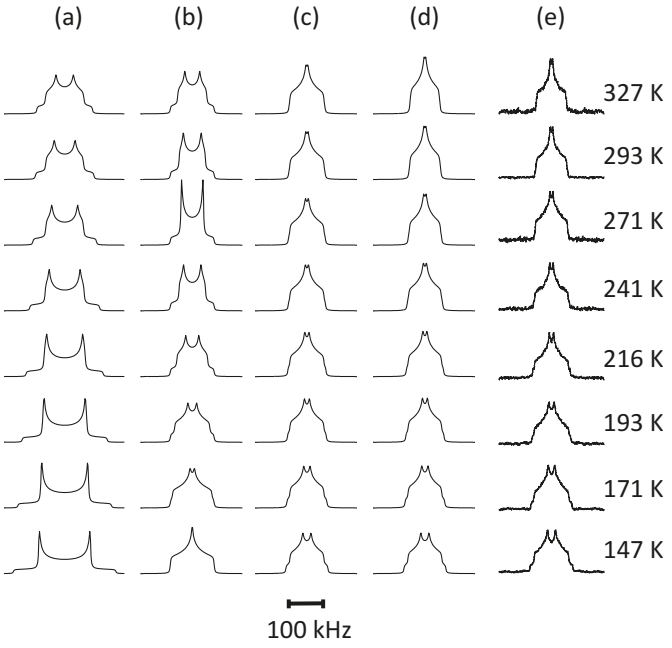
Fig. 3. Simulated and experimental ^{2}H NMR spectra for CD_2Br_2 in its tri-*ortho*-thymotide (TOT) clathrate. (*a*) Simulation of solid-state ^{2}H NMR spectra for a molecule exchanging between positions in the same plane separated by 95° as determined from the X-ray model. From bottom to top the populations ($1/2P_A$, P_B, $1/2P_A$) are as follows: (0, 1, 0), (0.05, 0.9, 0.05), (0.1, 0.8, 0.1), (0.15, 0.7, 0.15), (0.2, 0.6, 0.2), (0.25, 0.5, 0.25), (0.3, 0.4, 0.3), and (0.33, 0.33, 0.33). (*b*) Simulations under the same conditions as those in (*a*), except that in addition to the three-site exchange between the A and B sites in the plane, the molecules also undergo symmetric twofold flips about the bisector of the Br–C–Br bond. (*c*) Simulations of molecules undergoing twofold flips about the bisector of the Br–C–Br bond, a three-site exchange between A and B sites in the same plane (with populations 0.116, 0.768, and 0.116 as determined from the X-ray model), as well as a two-site libration of the plane of motion with libration angle (φ) from bottom to top: 22.5°, 31°, 36°, 38.5°, 42°, 42.7°, 44.5°, and 45.6°. (*d*) Same as for (*c*) except the spectra take into account the change in population among the three in-plane sites. From bottom to top the populations and libration angles ($1/2P_A$, P_B, φ) are as follows: (0.1175, 0.765, 23.0°), (0.12125, 0.7575, 32.5°), (0.12375, 0.7525, 38.05°), (0.126, 0.748, 41.3°), (0.13225, 0.7355, 45.8°), (0.151, 0.698, 51.2°), (0.162, 0.676, 54°), and (0.1765, 0.647, 57.3°). (*e*) Experimental ^{2}H NMR spectra for CD_2Br_2 in its TOT clathrate.



features in the ^{2}H spectrum of TOT–CD_2Cl_2 remains constant as a function of temperature. If we treat the motion of CD_2Cl_2 in a similar way to that of CD_2Br_2, then the populations of the A and B sites must be invariant with temperature. This can only be the case if ΔE is very close to zero and the populations of the A and B sites are equal to one another. This does not agree with the X-ray model that gives P_A and P_B equal to 0.404 and 0.596, respectively, at 200 K. The discrepancy may be due to the fact that the NMR data were collected on an older sample where some of the CD_2Cl_2 was lost to evaporation. The populations may vary with overall occupancy. This would account also for the reduced signal-to-noise ratio observed in the TOT–CD_2Cl_2 spectra in comparison to the TOT–CD_2Br_2 spectra.

Fig. 4. Plots of the frequency separation between the three pairs of features $\Delta\upsilon_{xx}$, $\Delta\upsilon_{yy}$, and $\Delta\upsilon_{zz}$ in the ^{2}H NMR spectra of (*a*) CD_2Br_2 and (*b*) CD_2Cl_2.

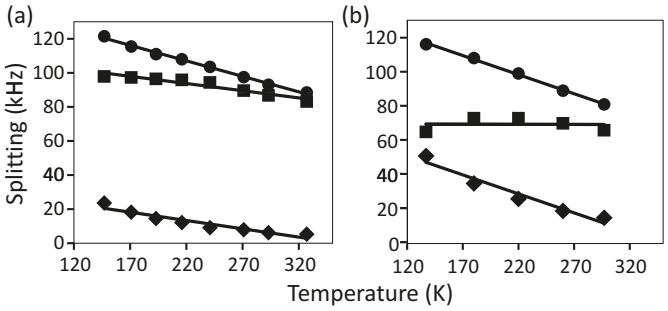


Fig. 5. Representations of the guest molecules after translating all molecules to have the central carbon atom at the origin. The grey spheres represent carbon. The colored spheres represent halogen atoms. (*a*) An idealized case showing two type A molecules (1 and 3) and one type B molecule (2) in the same plane. The molecules must rotate by an angle (γ) about an axis perpendicular to the heavy atom plane to go between A and B sites. (*b*) The positions of the deuterons over the course of the exchange between A and B sites. (*c*) The positions of the heavy atoms of the methylene bromide molecules in the tri-*ortho*-thymotide (TOT) clathrate from the X-ray model. The bonds have been omitted for clarity. (*d*) Same as for (*c*) viewed from the side. Note the out-of-plane distortion that is modeled with a two-site libration of angle φ (see text for details). (*e*) and (*f*) Similar to (*c*) and (*d*) for the TOT–dichloromethane clathrate.

Fig. 7. Plots of the two-site libration angle (φ) for the best fitting simulations versus temperature (see text for details). (*a*) CD_2Br_2. (*b*) CD_2Cl_2.

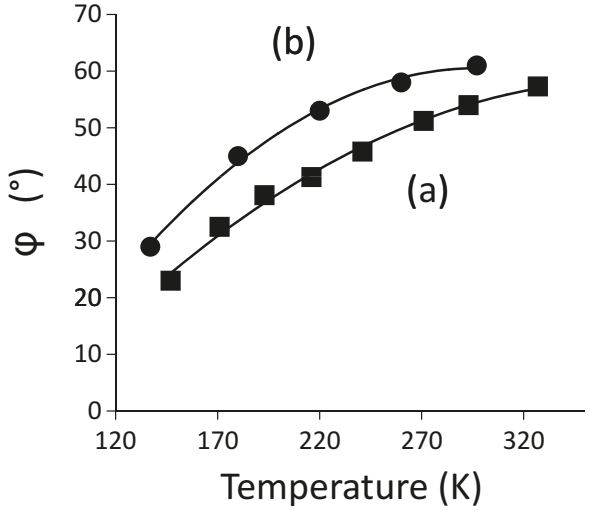

Fig. 8. Plot of $\ln(P_A/P_B)$ vs $1000/T$ for the tri-*ortho*-thymotide (TOT) – CD_2Br_2 clathrate derived from the best fitting simulations. The plot is expected to be linear with slope $-\Delta E/R$, where ΔE is the energy difference between sites A and B, and intercept ln2. This seems to be the case in the high-temperature region; however, the Boltzmann model breaks down at low temperatures. P_A is the population of site A and P_B is the population of site B.

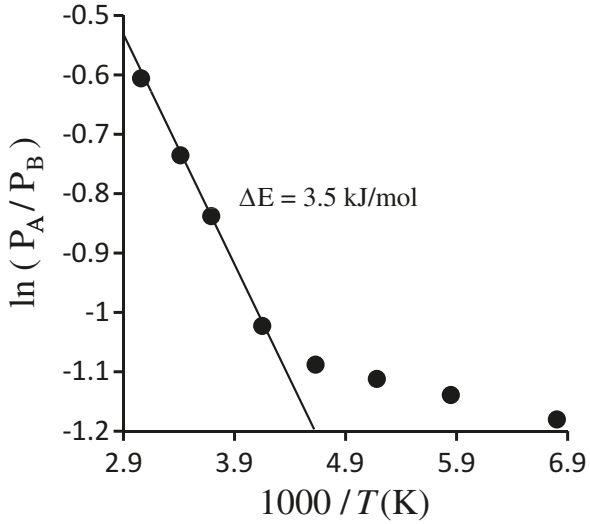
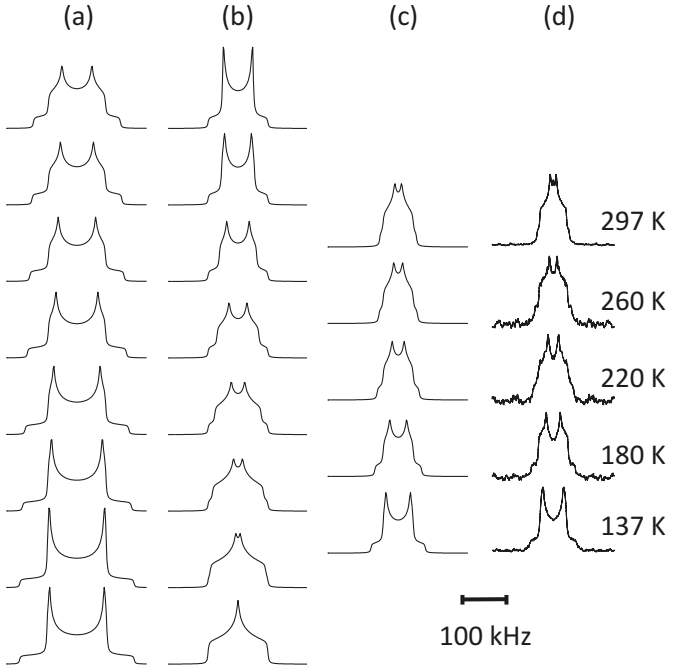


Simulations for the exchange between type A and type B sites were performed as a function of P_B with the assumption that the populations of the A sites are equal. The simulations were done with and without the assumption of a twofold flip about the molecular C_2 axis. The results are presented in Figs. 9*b* and 9*a*, respectively. In this case the in-plane angle of rotation (γ), on going from a type A site to a type B site, is 60° rather than 95°. In either case the agreement of the simulations with the experimental spectra is poor, presumably because the two-site out-of-plane libration has not been taken into account. Making the assumption that the populations of the A and B sites are equal, simulated spectra were calculated varying the out-of-plane φ for the best fit to the experimental

Fig. 9. Simulated and experimental ^2H NMR spectra for CD_2Cl_2 in its tri-*ortho*-thymotide (TOT) clathrate. (*a*) Simulation of solid-state ^2H NMR spectra for a molecule exchanging between positions in the same plane separated by 60° as determined from the X-ray model. From bottom to top the populations ($1/2P_A$, P_B, $1/2P_A$) are as follows: (0, 1, 0), (0.05, 0.9, 0.05), (0.1, 0.8, 0.1), (0.15, 0.7, 0.15), (0.2, 0.6, 0.2), (0.25, 0.5, 0.25), (0.3, 0.4, 0.3), and (0.33, 0.33, 0.33). (*b*) Simulations under the same conditions as those in (*a*), except that in addition to the three-site exchange between the A and B sites in the plane, the molecules also undergo symmetric twofold flips about the bisector of the Cl–C–Cl bond. (*c*) Simulations of molecules undergoing twofold flips about the bisector of the Cl–C–Cl bond, a three-site exchange between A and B sites in the same plane (with populations 0.333, 0.333, and 0.333) as well as a two-site libration of the plane of motion with libration angle (φ) from bottom to top: 29°, 45°, 53°, 58°, and 61°. (*d*) Experimental ^2H NMR spectra for CD_2Cl_2 in its TOT clathrate.



spectra. The libration angles used in the fits appear in Table 2 and are plotted in Fig. 7*b*. The out-of-plane φ for CD_2Cl_2 are larger than those for CD_2Br_2 as expected based on the reduced overall molecular volume of CD_2Cl_2 compared with CD_2Br_2 in a cavity of essentially the same size.

Conclusion

Solid-state ^2H NMR spectroscopy and single crystal X-ray diffraction were used to study the disorder of dibromomethane and dichloromethane in their tri-*ortho*-thymotide clathrates. The X-ray data showed a substantial amount of disorder. ^2H NMR data confirm that this disorder is dynamic rather than static in nature. For both guest molecules, the NMR results support three modes of molecular motion all on a time scale that is fast with respect to the quadrupolar interaction. The molecules undergo twofold flips about their molecular C_2 axes. They undergo both translation and rotation to exchange between two types of sites sharing a common plane containing all of the carbon and halogen atoms: A sites, with the central carbon atom well removed from the

twofold crystallographic axis, and B sites, with the central carbon atom lying very close to the crystallographic twofold axis. In addition, the plane containing the carbon and halogen atoms undergoes a two-site libration, the amplitude of which increases with temperature.

Abstract: Experimental and predicted ^{207}Pb nuclear magnetic resonance (NMR) parameters of solid-state coordination complexes of lead(II) bromide, lead(II) iodide, and lead(II) chloride with 1,10-phenanthroline are reported. Structural and electronic differences between the 1:1 and 1:2 adducts are reflected by the NMR parameters. The NMR chemical shieldings of the isostructural complexes indicate that the electronic state of the lead(II) center depends on the number of ligands and the halogen anion. The NMR results suggest that the 1:2 adduct may be more stereochemically active than the 1:1 adduct.

Key words: 1,10-phenanthroline, lead(II) bromide, lead(II) iodide, ^{207}Pb NMR, solid-state NMR, density functional theory, zeroth-order regular approximation (ZORA).

Résumé : On rapporte les valeurs expérimentales et prédites pour les paramètres de résonance magnétique nucléaire (RMN) du ^{207}Pb de complexes de coordination à l'état solide du bromure de plomb(II), de l'iodure de plomb(II) et du chlorure de plomb(II) avec la 1,10-phénanthroline. Les différences structurales et électroniques entre les adduits 1 : 1 et 1 : 2 sont réfléchies par les paramètres de RMN. Les blindages chimiques en RMN des complexes isostructuraux indique que l'état électronique du noyau de plomb(II) dépend du nombre de ligands et de l'anion de l'halogène. Les résultats de la RMN suggèrent que l'adduit 1 : 2 peut être stéréochimiquement plus actif que l'adduit 1 : 1.

Mots-clés : 1,10-phénathroline, bromure de plomb(II), iodure de plomb(II), ^{207}Pb RMN, RMN à l'état solide, théorie de la fonctionnelle de la densité, approximation régulière d'ordre zéro ("ZORA").

[Traduit par la Rédaction]

Introduction

There has been a long interest in the roles of lead, its compounds, and lead-containing materials in the chemistry of electronic devices, optical sensors, and biological systems. Lead(II) oxide, PbO, for example, is a constituent at dopant concentrations of optical fibers used as radiation sensors,[1] while PbO_2 is used in nanocrystalline-based electrodes.[2] The electronic properties of the halides make them important components of devices such as layered semiconductors[3] and medical X-ray imaging detectors.[4] Materials such as lead(II) bromide, $PbBr_2$, exhibit complex crystal lattice physics.[5] The incorporation of lead into biological systems is a well-known cause for concern in poisoning, and its biological environment has been actively investigated.[6]

An organic molecule that has widespread application in chemistry and materials science is 1,10-phenanthroline, or *ortho*-phenanthroline. The electronic properties of this multiringed, nitrogen-containing aromatic chelating hydrocarbon can be tailored to provide materials that exhibit properties amenable to a wide array of uses. It is used, for example, in light-emitting devices (LEDs),[7] in luminescent probes for the study of micellar interactions,[8] in photosensitizers for nanocrystalline solar cells,[9] and in molecular-switching devices.[10] Because of the photoactivity of 1,10-phenanthroline and its complexes and materials, it has also been the focus of photochemical and photophysical studies.[11]

In this report, the ^{207}Pb nuclear magnetic resonance (NMR) spectroscopic parameters of a set of adducts of 1,10-phenanthroline in 1:1 and 1:2 ratios with lead halides are examined. Comparison of the experimental ^{207}Pb NMR results with density functional calculations of the NMR parameters shows that the chemical shift changes with structure mainly result from changes in the paramagnetic contributions to the chemical shielding. The NMR data indicate significant structural and electronic differences between the 1:1 and 1:2 PbX_2:1,10-phenanthroline adducts (X = Cl, Br, or I) and suggest that the 1:2 adducts are more stereochemically active than the 1:1 adducts.

Experimental methods

Synthesis

Reagent grade starting materials were purchased from Sigma-Aldrich and used without further purification. The synthetic procedure[12,13] is a modification of previously reported methods.[14–18] The 1:1 adducts were prepared by using equimolar amounts of PbX_2 (X = Cl, Br, or I) and 1,10-phenanthroline in ethanol in a sealed tube at 70 °C with a sidearm immersed in an ice–water bath. Over a period of 3 months, the product accumulated in the sidearm. The material was washed with ethanol and dried. The 1:2 adducts of 1,10-phenanthroline with $PbBr_2$ and PbI_2 were prepared from a suspension of the halide in ethanol with stirring while an eightfold excess of 1,10-phenanthroline was added. The reaction vessel was allowed to stand for 5 days while shielded from light. The product was filtered, washed with ethanol, and dried. $PbCl_2$ exhibits only the 1:1 adduct. The stoichiometries of the final materials were determined by elemental analyses (Table S1 in the Supplementary data) by Schwarzkopf Microanalytical Laboratories of Woodside, New York, and by single-crystal and powder X-ray diffraction. (Tables S2 and S3 in the Supplementary data).

NMR spectroscopy

NMR spectra were measured with a Bruker MSL-300 spectrometer at 295 (±1) K. ^{207}Pb NMR spectra of static powders were obtained at a nominal frequency of 62.601 MHz, using a spin-echo sequence, with proton decoupling.[19–23] The $\pi/2$ pulse width was 2.55 μs; the spacing between the pulses in the spin-echo experiment was 20 μs. Recycle delays of up to 2 min were used to allow recovery of magnetization. There were 3844 transients co-added for the sample of $PbCl_2$(1,10-phenanthroline), and 7022 scans were co-added for the other samples, so spectra were gathered over periods of 5–10 days. The sweep width for all spectra was 500 000 Hz. Spin-temperature alternation was applied with an inverting pulse applied on alternate acquisitions, with spectral subtraction. To minimize the effects of power drop away from the carrier, the offset in each case was optimized to place the carrier in the center of the powder line shape.

The crystal structures of the materials show only one chemical site for lead in each material, and the line shapes in the ^{207}Pb spectra of static powders represent the chemical shift dispersion of a single lead resonance, rather than multiple sites. The experimental powder spectra were fitted with an in-house program that accounts for effects of the spin-echo sequence and the measured drop-off of power away from the carrier frequency.[21] In fitting the spectra, idealized powder patterns were convoluted with a Gaussian function and an appropriate transfer function for the pulse sequence determined from the pulse widths and spacings.[21] By a simplex procedure we determined the optimal set of chemical shift and broadening parameters given in Table 1.

The lead spectra are referenced to the position of tetramethyllead ($\delta = 0$ ppm), with solid lead nitrate as a secondary standard ($\delta_{iso} = -3490.4$ ppm at 295 K).[19,23]

Computational methods

Calculations were performed on model clusters of PbX_2(1,10-phenanthroline) and PbX_2(1,10-phenanathroline)$_2$ generated from crystallographic data. We used the structures of the catena-(bis(m2-chloro))-(1,10-phenanthroline)-lead(II)) (Cambridge Structural Database (CSD) code RAQLEA), catena-(bis(m2-bromo))-(1,10-phenanthroline)-lead(II) (CSD code RAQLAW), and catena-(bis(m2-iodo))-(1,10-phenanthroline)-lead(II) (CSD code RAQKUP) drawn from the Cambridge Structural Database.[18] Crystallographic data for PbX_2(1,10-phenanthroline)$_2$, where X = Br, I, were determined at the University of Delaware, Newark, Delaware, and are reported in the Supplementary data, Table S2.[13]

Density functional theory (DFT) calculations of ^{207}Pb NMR parameters, using the zeroth-order regular approximation (ZORA), were performed with the Amsterdam Density Functional (ADF) program package.[25] NMR parameters were calculated with the associated NMR program module.[26–29] Core potentials were generated with the module DIRAC, and all atoms were treated without frozen cores or with partial frozen cores. The basis sets were triple-ζ Slater-type orbitals (STOs) including two polarization functions (TZ2P). The local density approximation (LDA)[30] and generalized gradient approximation (GGA) were both used in the calculations. The GGA was specified with Becke–Perdew (BP) exchange-correlation functions,[31,32] as well as with the set proposed by Perdew et al. (revBPE).[33,34] The calculation of the chemical shielding of $Pb(CH_3)_4$ was carried out using the reported experimental geometry (CSD code VADRAU).[35]

Results and discussion

Solid-state ^{207}Pb NMR spectroscopy

The ^{207}Pb NMR spectra of powders of the 1:1 and 1:2 adducts of $PbBr_2$ are shown in Fig. 1, and the spectra of the adducts of PbI_2 are shown in Fig. 2. The spectrum of $PbCl_2$(1,10-phenanthroline) is shown in Fig. 3. Table 1 gives the NMR parameters extracted from these spectra, in Mason's convention.[36] Included in Table 1 are NMR data for the parent halides from the literature.[35]

^{207}Pb NMR chemical shift parameters reflect local electronic structure at the lead site, and are strongly affected by crystal structure, electronegativity of atoms in the vicinity, and the presence of paramagnetic entities.[19–24,37–40] For these materials, there are not likely to be paramagnetic centers that would induce shifts. Certain general trends are evident in Table 1: (*i*) The isotropic shifts of the 1:1 adducts are deshielded relative to their parent salts. (*ii*) The isotropic shifts of the 1:2 adducts of $PbBr_2$ and PbI_2 are shielded relative to the corresponding 1:1 adducts. (*iii*) Comparison of the isotropic shifts of the 1:2 adducts of $PbBr_2$ and PbI_2 with their parent salts show that the former is deshielded but the latter is more shielded than its parent salt.

Subtler effects on the ^{207}Pb NMR properties are observed in Ω and κ. For example, the span of the 1:2 adduct of either $PbBr_2$ or PbI_2 is larger than the span of the corresponding 1:1 adduct (roughly by factors of 2 and 1.4, respectively). The spans of the 1:2 adducts of $PbBr_2$ and PbI_2 are similar and comparable to that of $PbCl_2$(1,10-phenanthroline).

The skews of the 1:1 adducts of $PbBr_2$ and PbI_2 are similar and nearly zero. The skews of the 1:2 adducts and that of the 1:1 adduct of $PbCl_2$ are much larger. A skew near zero implies that the three principal elements of the chemical shift

Table 1. Experimental ^{207}Pb NMR parameters of adducts of 1,10-phenanthroline with lead halides in the solid state.

Compound	δ_{iso} (ppm)[a]	Ω (ppm)[a]	κ[a]	Gaussian width (kHz)
$PbCl_2$[b]	–1715	533	0.52	—
$PbCl_2$(1,10-phenanthroline)	–920	615	0.45	0.753
$PbBr_2$[b]	–981	699	0.58	—
$PbBr_2$(1,10-phenanthroline)	–642	323	0.02	2.713
$PbBr_2$(1,10-phenanthroline)$_2$	–875	655	0.62	2.511
PbI_2[b]	–29	<175[c]	—[c]	—
PbI_2(1,10-phenanthroline)	101	429	0.03	2.604
PbI_2(1,10-phenanthroline)$_2$	–156	618	0.29	3.372

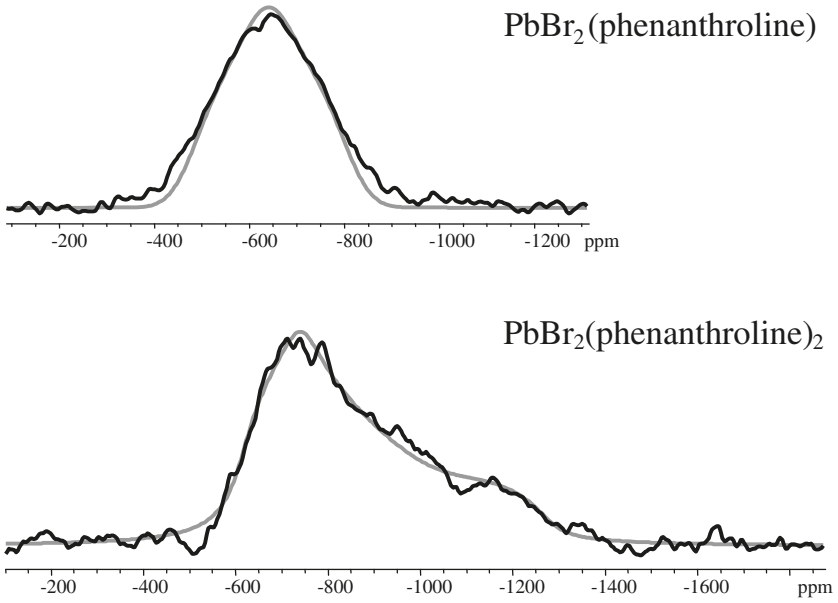
Note: δ_{iso}, chemical shift; Ω, span; and κ, skew.

[a]The uncertainty in δ_{iso} is estimated to be ±5 ppm. The uncertainty in Ω is estimated to be ±10 ppm. The uncertainty in κ is approximately ±0.05.

[b]From Dybowski et al.[37]

[c]The span of PbI_2 may be as large as 175 ppm. In the original paper, line broadening prevented determination of the span and skew. The site symmetry in PbI_2 requires that κ be ±1.

Fig. 1. ^{207}Pb NMR spectra of $PbBr_2$(1,10-phenanthroline)$_n$ adducts. The shift scales are aligned to illustrate the magnitude of the shift. Grey lines indicate the fitted spectrum and the black lines indicate the experimental data.



tensor are substantially different from each other. The fact that all skews are positive implies that, although the principal values of the tensors are all unique, the most strongly shielded principal element is the most nearly unique principal element of the chemical shift tensor in every case.

The isotropic ^{207}Pb chemical shifts of the complexes depend strongly on the anion partner, in a manner similar to the effect of anions on the isotropic shifts of pure salts.[37] If the notion that greater stereochemical activity correlates with isotropic shielding holds for solid-state complexes with different anions,[41,42] then the $PbBr_2$ adducts exhibit stronger stereochemical activity than the PbI_2 adducts, and the 1:1 adduct of $PbCl_2$ has an even stronger stereochemical activity.

Some experimental observations may be rationalized by correlation with structural differences (Fig. 4). For example, $PbBr_2$ has three bromine atoms at a distance of 0.2991 nm from the Pb center; all other Pb–Br distances are >0.32 nm. In the crystal structure of the 1:1 adduct, there are only two nearest-neighbor Pb–Br distances of 0.2997 nm, with other bromine atom distances being >0.31 nm. The 1:1 adducts of PbI_2 and $PbCl_2$ have similar structures to the 1:1 adduct of $PbBr_2$.[13] Thus, the fact that the isotropic shifts of the 1:1 complexes are deshielded relative to the salt is correlated with the fact that there are fewer anions in the near vicinity of the lead ion for the adducts.

The 1:2 adduct of $PbBr_2$ has two Pb–Br distances of 0.306 nm, similar to the 1:1 adduct, with other bromine centers farther away. In addition, it has four close contacts with nitrogens, Pb–N = 0.257 nm, compared with two close contacts for the 1:1 adduct. Its isotropic shift is shielded relative to the 1:1 adduct, which suggests that the additional nitrogens coordinating with Pb provide increased electronic density near the lead center. The isotropic shift of the 1:2 adduct of PbI_2 is shielded relative to the 1:1 adduct of PbI_2,

Fig. 2. ^{207}Pb NMR spectra of PbI_2(1,10-phenanthroline)$_n$ adducts. The shift scales are aligned to illustrate the magnitude of the shift. Grey lines indicate the fitted spectrum and the black lines indicate the experimental data.

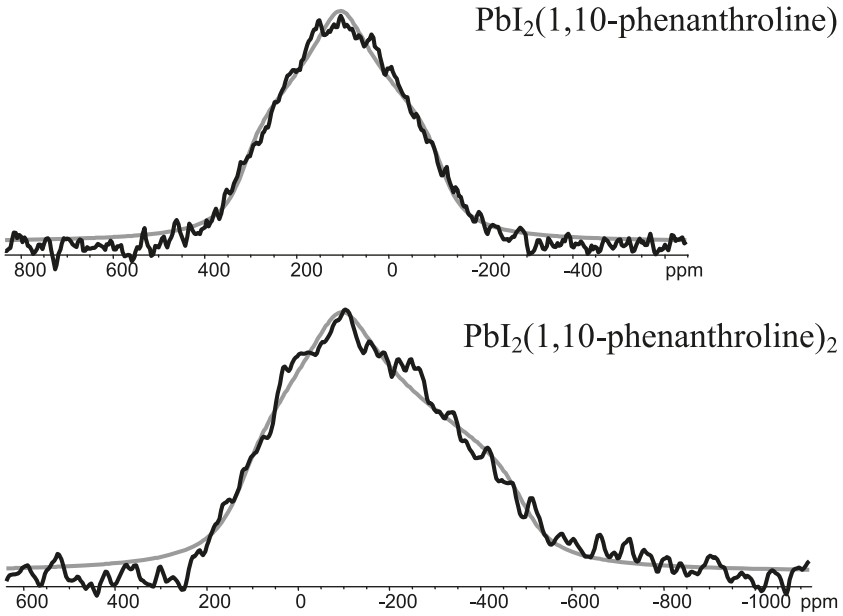


Fig. 3. ^{207}Pb NMR spectrum of $PbCl_2$(1,10-phenanthroline). Both the experimental spectrum (black line) and the fitted spectrum (grey line) are shown.

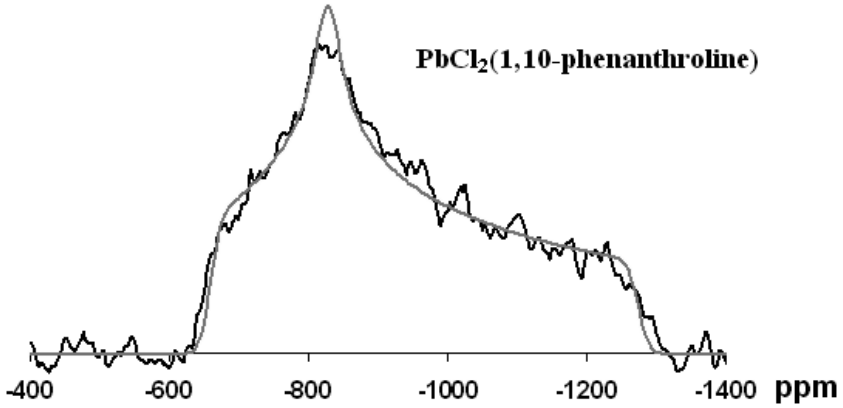

Fig. 4. Cluster models of (*a*) PbX_2(phenanthroline), X = Cl, Br, or I; and (*b*) PbX_2(phenanthroline)$_2$, X = Br or I.

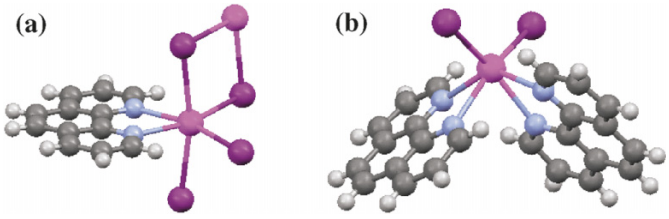

which is also consistent with increased electron density near the lead site.

A distinction between the iodide and bromide systems is that the 1:2 adduct of PbI_2 is shielded relative to PbI_2, in contrast to the behavior of the bromide system. This difference in the shifts may, however, be the result of the well-known structural difference between $PbBr_2$ and PbI_2, rather than a difference between the adducts, inasmuch as the anions are located somewhat differently in the crystal lattices of $PbBr_2$ and PbI_2.[35]

The span of each 1:2 adduct is larger than the span of the corresponding 1:1 adduct. This distinction between adducts correlates with the number of nitrogen centers coordinated with the lead center. This observation is similar to the reported dependence of ^{207}Pb chemical shift parameters on the number of oxygens with which it is coordinated, although in that case it was the isotropic chemical shift that was correlated with the oxygen number.[38]

The skews of the 1:1 adducts are almost zero, whereas the skews of the 1:2 adducts are not zero. This difference suggests that the local ^{207}Pb environment in the 1:2 adducts is tending more towards axial symmetry than the Pb environments in the 1:1 adducts. One might expect this result, given that the local environment of a 1:2 adduct contains four nitrogens at roughly equal distances from the Pb center, whereas the 1:1 adduct does not. As one can see from Fig. 4, the Pb site in the 1:1 adduct sits on a twofold axis. It coordinates with the nitrogens of the 1,10-phenanthroline in a pseudo-octahedral geometry. In the 1:2 adduct, the Pb center is coordinated with four nitrogens from two 1,10-phenanthroline

molecules and with two halogens. This situation is inherently less asymmetric than the Pb site in the 1:1 adducts.

The fitted line shapes require stronger broadening of the $PbBr_2$ and PbI_2 adduct spectra than does the spectrum of the $PbCl_2$ adduct. This observation is similar to the situation for the parent salts.[37] The origin of the broadening in these materials is likely to be unresolved coupling of the Pb nucleus to the quadrupolar nuclei. Although the Cl nucleus is quadrupolar, it is frequently seen to self-decouple, making the broadening of the Pb resonance in this material smaller.[44]

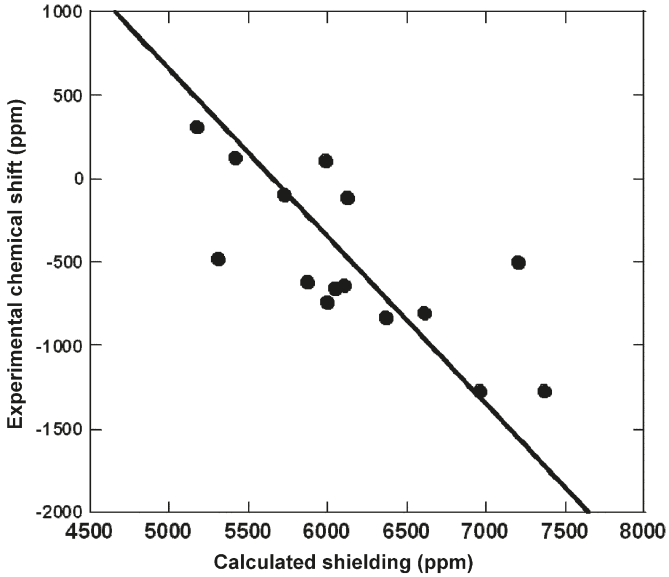
Prediction of ^{207}Pb NMR chemical shielding parameters of cluster models

To estimate the trends in chemical shielding, we have used cluster models based on crystallographic data (Fig. 4) to represent the local structures around the lead sites. The chemical shielding tensors of the target lead centers of the adducts and for tetramethyllead, $Pb(CH_3)_4$, calculated using the ADF set of programs with ZORA to include relativistic effects, are given in Table S4 in the Supplementary data. Figure 5 is a plot of the experimental principal values of the chemical shift tensors of the five adducts versus the calculated principal values of the chemical shielding tensors obtained from a calculation using the revBP-GGA and the triple-ζ basis that includes two polarization functions. As the plot shows, the calculations qualitatively reproduce the observed experimental trends in the chemical shift, but there are significant deviations from the general trend. The linear fit of the experimental principal values of the chemical shift tensors versus the calculated principal values has an intercept of 5652 ± 176 ppm and slope of -1.00 ± 0.26. A slope with a magnitude of one, although with a large uncertainty, indicates that the ADF calculations on these cluster models provide a reasonable prediction of the trends of chemical shielding for these materials. The intercept corresponds to the chemical shielding of the reference material, $Pb(CH_3)_4$. A calculation of the isotropic chemical shielding of $Pb(CH_3)_4$ with the same calculational procedure, however, gives a much lower value of 4857 ppm. The discrepancy may result from effects that are not considered at this level of calculation.

Similar comparisons (not shown) with the calculated values using the LDA and partial frozen cores (data in Table S1 in the Supplementary data) show substantially less correlation between the calculated values of the shielding and the experimental chemical shifts. To improve the correlation between experiment and calculation may require larger basis sets and perhaps better models than the small clusters used here. Calculation of the NMR parameters using periodic boundary conditions may better represent the electronic structure and, hence, produce closer agreement.[44] The NMR spans consistently obtained from the cluster calculations tend to be larger than the experimental spans.

An examination of the various predicted contributions to the chemical shieldings (Table S4 in the Supplementary data) show that the diamagnetic contribution is large and isotropic. However, it is essentially the same for all lead sites, regardless of the molecule. On the other hand, the value of the paramagnetic contribution to the chemical shielding is sensitive to the ligand partners and tends to be anisotropic. A similar result has been observed for lead ligated to substituted pyridines.[45] These calculations strongly suggest that the observed isotropic and anisotropic characteristics of the NMR spectrum reflect the paramagnetic contributions.

Fig. 5. Comparison of ^{207}Pb experimental chemical shift tensor principal values with calculated chemical shielding tensor elements for PbX_2(1,10-phenanthroline)$_n$, $n = 1$, 2 and X = Cl, Br, or I. The solid line is a linear fit to the data with the formula $\delta_{exp} = 5652 - 1.00\sigma_{calcd}$. The correlation coefficient (r) is 0.73081.



Conclusions

^{207}Pb NMR solid-state spectra of lead(II) halide complexes with 1,10-phenanthroline provide information on structure and bonding in 1:1 and 1:2 lead(II)–1,10-phenanthroline complexes. ^{207}Pb NMR chemical shifts show distinctive differences between the 1:2 and 1:1 adducts involving $PbBr_2$ and PbI_2. The isotropic chemical shift is significantly affected by the anion partner, but subtler effects are seen in the variation of the span and skew. In particular, the skew tends to be around zero for the 1:1 adducts. Broadening of the line shapes depends on the anion partner, perhaps suggesting unresolved coupling to the quadrupolar nuclei. Density functional calculations on cluster models of the complexes qualitatively reproduce some experimental trends. It is likely that the discrepancies represent neglect of the effects of neighboring groups in the solid, which would be included if a larger cluster or a periodic calculation were used.[43]

Abstract: Field-dependent ^{31}P solid-state NMR studies demonstrate that the line shape in spectra of β-$VOPO_4$ depends on ^{51}V–^{31}P direct and indirect spin-spin interactions (M_2 (^{51}V, ^{31}P) = 101(23) × 10^6 rad^2 s^{-2}, $^2J_{iso}$ (^{51}V, ^{31}P) = 48(5) Hz) and, to a lesser extent, on ^{31}P chemical shift anisotropy (δ_{iso} = –10.4(2), $\Omega = \delta_{11} - \delta_{33}$ = 22(2) ppm) and ^{31}P–^{31}P interactions (M_2 (^{31}P, ^{31}P) = 6.7(1) × 10^6 rad^2 s^{-2}). In contrast, homonuclear dipolar interactions play an important role for the field and spinning rate dependent ^{31}P spin-lattice relaxation via paramagnetic impurities (T_1 = 20–60 s). Vanadium-51 magic-angle spinning NMR spectra indicate a sizeable chemical shift anisotropy (δ_{iso} = –754(1), δ_{11} = –336(10), δ_{22} = –344(6), δ_{33} = –1581(8) ppm) and nuclear quadrupole interaction (χ = 1.5(1) MHz, η = 0.35(5)); the principal axis systems of both interactions are clearly not coincident, with an angle of 35(5)° between the greatest component of the electric field gradient tensor and δ_{33}.

Key words: solid-state NMR spectroscopy, ^{31}P NMR, ^{51}V NMR, spin-lattice relaxation, indirect nuclear spin-spin coupling, chemical shift anisotropy, electric field gradient tensor, vanadyl phosphate.

Résumé : Des études RMN du ^{31}P à l'état solide et dépendant du champ démontrent que la forme des raies dans les spectres du β-$VOPO_4$ dépend des interactions spin-spin directes et indirectes (M_2 (^{51}V, ^{31}P) = 101(23) × 10^6 rad^2 s^{-2}, $^2J_{iso}$ (^{51}V, ^{31}P) = 48(5) Hz) et, à un degré moindre, sur l'anisotropie du déplacement chimique du ^{31}P (δ_{iso} = –10,4(2); $\Omega = \delta_{11} - \delta_{23}$ = 22(2) ppm) et aux interactions ^{31}P–^{31}P (M_2 (^{31}P, ^{31}P) = 6,7(1) × 10^6 rad^2 s^{-2}). Par ailleurs, les interactions dipolaires homonucléaires jouent un rôle important pour la relaxation spin-réseau du ^{31}P qui varie avec le champ et la vitesse de rotation par le biais d'impuretés paramagnétiques (T_1 = 20–60 s). Les spectres RMN du vanadium à l'angle magique de rotation indiquent qu'il existe une anisotropie importante du déplacement chimique (δ_{iso} = –754(1), δ_{11} = –336(10), δ_{22} = –344(6), δ_{33} = –1581(8) ppm) et une interaction quadripolaire nucléaire (χ = 1,5(1) MHz, η = 0,35(5)); il est clair que les axes principaux des systèmes des deux interactions ne coïncident pas, avec un angle de 35(5)° entre la composante principale du tenseur du gradient de champ électrique et δ_{33}.

Mots-clés : spectroscopie RMN à l'état solide, RMN du ^{31}P, RMN du ^{51}V, relaxation spin-réseau, couplage spin-spin nucléaire indirect, anisotropie du déplacement chimique, tenseur du gradient de champ électrique, phosphate de vanadyle.

[Traduit par la Rédaction]

Introduction

Vanadium compounds are well-established ingredients in the modern synthesis of organic molecules,[1] where they most often take part in redox transformations, either stoichiometrically or catalytically. Amongst them, vanadyl phosphates (VPOs) found industrial applications as selective and efficient heterogeneous catalysts in the mild oxidation of alkanes or alkenes or in ammoxidation reactions.[2–4] One of the most striking reactions catalyzed by VPOs, dubbed the "Butox" process,[5] is the oxidation of *n*-butane to maleic acid anhydride, recognized as probably the most complex selective oxidation reaction used in industry.[2,6–8] In light of its technical importance, it is no surprise that a manifold of analytical methods, including theoretical investigations, has been employed to study partial aspects of this process such as the actual catalyst materials or the reaction mechanism.[6,9–11] The simultaneous presence of vanadium in oxidation states V(IV) and V(V) appears to be a key feature of active catalyst systems

containing $(VO)_2P_2O_7$ together with $VOPO_4$ phases.[12–14] Facile formation and interconversion of a number of crystalline V(IV) and V(V) phases are characteristics of the VPO system, and this has led to some confusion in the literature as to the actual nature of the active phase. A variety of different crystalline phases have been catalogued for the V(IV) and V(V) species, but often the identification is not straightforward, especially if amorphous materials are involved.[15–17] Further complications arise from the influence of the hydrocarbon, the different P:V ratios, the various methods used to obtain the precursor material that modify crystallinity and composition, and the residual proton content, factors all of which are known to affect the nature and performance of the catalyst material.[2,18–20]

Recently, the ability of $VOPO_4$ systems to form different 2D or 3D structures that can be interlayered with a wide variety of different molecules or ions[21–27] led to renewed interest regarding their potential use as cathode materials in lithium ion batteries.[28–33] Another, less apparent feature of VPO systems is the analogy of phosphate and vanadate, expressed for example in biological systems in certain enzymes (phosphatases or peroxidases),[34,35] or in materials where V(V) can potentially replace P(V),[36–38] such as in V_2O_5–P_2O_5 glasses that are of interest because of their electrical or optical properties.[39,40]

As part of our efforts to investigate the VPO system via solid-state NMR methods, the objective of the present study is the ^{31}P solid-state NMR characterization of β-$VOPO_4$ as a prototype of diamagnetic vanadyl phosphates. This is the most stable phase of $VOPO_4$, and its presence in catalyst systems has been detected by several groups.[9,41–46] The ^{31}P NMR properties of β-$VOPO_4$ have been investigated by other workers in the field, but the spectra were partly misinterpreted or obtained under conditions inappropriate to reveal NMR spectroscopic details.[13,14,47–49] Using ^{31}P spin-echo mapping, Li et al.[49] reported for a static powder sample of β-$VOPO_4$ a peak centered near 0 ppm, with a width of about 100 ppm (B_0 = 7.05 T), corresponding to ca. 12 kHz. They ascribed the observed width to chemical shift anisotropy. Using the same technique, Sananes et al.[48] observed a chemical shift of 0 ppm. Ben Abdelouahab et al.[47] reported line widths of around 500–600 Hz for the isotropic peak in ^{31}P MAS spectra of β-$VOPO_4$ and a chemical shift of –11.5 ppm. They stated that these widths essentially depend on the crystallinity of the sample, suggesting chemical shift dispersion as cause of broadening. Vedrine and co-workers[13,14] reported a "narrow" peak at –11.8 ppm from their ^{31}P MAS spectra. In contrast, we shall demonstrate that the striking line widths observed in ^{31}P NMR spectra of β-$VOPO_4$ are not due to chemical shift dispersion and chemical shift anisotropy.

The ^{51}V isotope, with a nuclear spin of 7/2 and a natural abundance of 99.8%, is another useful probe to study solid vanadium-containing compounds.[50] In their investigation of β-$VOPO_4$, Ben Abdelouahab et al.[47] also obtained the ^{51}V spectrum of a static powder sample and reported a narrow peak at –354 ppm, apparently in agreement with the octahedral coordination of vanadium. While our study was under way, Lapina et al.[51] and Hirschinger and co-workers[52] carried out detailed ^{51}V NMR investigations of vanadyl phosphates and reported considerable vanadium chemical shift anisotropies and nuclear quadrupolar coupling constants (1.451–1.990 MHz), in contrast to the findings of Ben Abdelouahab et al.[47] In our present investigation of β-$VOPO_4$, we also obtained ^{51}V MAS NMR spectra to resolve these discrepancies.

Experimental

Sample preparation and characterization

The β-polymorph of $VOPO_4$ has been prepared by the usual reaction of H_3PO_4 and V_2O_5.[53] The X-ray powder diffractogram of the reaction product showed 43 well-resolved reflections in the range of $10 \leq 2\theta \leq 50$. Seventeen of them were identical to corresponding lines of powder diffraction file No. 27-948,[54] based on the data of Bordes et al.[53] Another 23 lines of our diffractogram could also be assigned as lines owing to β-$VOPO_4$. Table 1 shows the results of a refinement of the unit cell data based on 40 reflections, the comparison with previous data[53,55] confirming the identity of β-$VOPO_4$. The three remaining weak lines were identical with lines of powder diffraction file No. 47-967, a hydrogen vanadium phosphate hydrate ($H_4V_3P_3O_{16.5}{\cdot}xH_2O$, indicating minor hydrolysis of β-$VOPO_4$ by atmospheric moisture.

NMR experiments

^{31}P and ^{51}V spectra were obtained at 161.98 and 105.25 MHz, respectively, using a Bruker MSL-400 spectrometer (B_0 = 9.4 T). Samples were packed into 4 mm o.d. zirconia rotors. ^{31}P spectra were also obtained at 81.03 MHz with Bruker MSL-200 and DSX-200 spectrometers, using 7 and 4 mm o.d. zirconia rotors, respectively. Phosphorus chemical shifts are referenced with respect to external 85% aqueous H_3PO_4, vanadium chemical shifts are referenced with respect to external neat $VOCl_3$. Spin-lattice relaxation times were obtained with the inversion recovery technique, using a composite pulse for the inversion.[56] Hahn spin-echo experiments employed the phase cycling of Rance and Byrd.[57] Vanadium-51 spectra were obtained after a single pulse with flip angles in the range 20°–30°, using a 0.7 μs pulse duration, corresponding to a "solution" 90° pulse width of 2.55 μs. Calculations of ^{31}P line shapes were carried out using HBA[58] and WSolids.[59] ^{51}V MAS spectra were calculated in the frequency domain using CSolids,[60] a program that takes into account first-order quadrupolar effects and chemical shift anisotropy as well as the relative orientation of both interactions. The calculation of spinning sideband intensities follows the approach of Herzfeld and Berger[61] and Olivieri[62] and incorporates the POWDER space-tiling and interpolation scheme.[63] Details on our implementation to compute NMR spectra under the combined influence of quadrupolar and chemical shift anisotropy interactions can be found in the literature.[64,65] In brief, the principal components of the chemical shift tensor are reported in the convention $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with an isotropic chemical shift of $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$, the span of the chemical shift tensor ($\Omega \approx \delta_{11} - \delta_{33}$), and the skew of the tensor ($\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$), with possible values in the range from –1 to +1.[66] The span of the tensor is related to the Herzfeld–Berger parameter μ, via $\mu = \nu_L\Omega/\nu_r$, where ν_L is the Larmor frequency and ν_r is the spinning frequency.[61] The nuclear quadrupolar interaction is the interaction of the nuclear quadrupole moment (eQ) with the components of the electric field gradient (EFG) tensor about the nucleus (V_{ii}), where the components of the EFG

are ordered according to $|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$. This interaction is characterized by the nuclear quadrupolar coupling constant $\chi = eV_{ZZ}Q/h$ and the asymmetry parameter $\eta = (V_{XX} - V_{YY})/V_{ZZ}$. The relative orientations of the chemical shift and EFG tensor are expressed via the three Euler angles (α, β, and γ) that bring the EFG tensor into alignment with the CSA tensor by consecutive rotations in the *ZYZ* order.

Results and discussion

In the following sections, we shall describe first the structural features of β-$VOPO_4$, because of the intimate relationship between our NMR results and the structure of this system, followed by the ^{31}P and ^{51}V NMR results. ^{31}P NMR data encompass a detailed analysis of the line shapes of static and MAS samples, as well as spin-lattice relaxation data, whereas ^{51}V NMR results are limited to MAS spectra.

Crystal structure

The crystal structure of β-$VOPO_4$ has been described by Gopal and Calvo[55] as belonging to the orthorhombic system (Table 1). As indicated in Fig. 1, vanadium and phosphorus are located on crystallographic mirror planes and all phosphorus and vanadium sites are crystallographically equivalent, thus only one signal is expected in the ^{31}P or ^{51}V NMR spectra. The phosphorus nuclei of the phosphate tetrahedra are linked to four vanadium atoms via intervening oxygen bridges. Because of the crystallographic mirror plane, two of the four phosphorus–oxygen distances are equivalent (1.528 Å) and are not very different from the other P–O distances (1.519 and 1.540 Å). The O–P–O angles range from 107.6° to 110.6°, indicating a moderate distortion of the tetrahedron. However, the six oxygens surrounding vanadium form a severely distorted octahedral environment that is better described as a capped square pyramid. This is due to O4 that forms one short (1.566 Å) and one very long (2.591 Å) vanadium–oxygen contact. The basal square of oxygen atoms features V–O distances in the range from 1.849 to 1.902 Å. Vanadium is displaced from the basal oxygen plane by 0.366 Å toward the O4 atom with the shortest V–O distance, whereas the oxygen square pyramid is relatively regular with O···O distances of 2.605–2.705 Å; O···O distances involving the oxygen with the longest V–O distance are in the range of 2.847–2.981 Å. Thus, the environment of vanadium could still be described as octahedral.[67,68]

Phosphorus-31 NMR line width and line shape

Phosphorus-31 NMR spectra of static and magic-angle spinning powder samples of β-$VOPO_4$ obtained at 9.4 T are shown in Fig. 2. In agreement with the predictions from the crystal structure (vide supra), one peak is observed in the spectra. The spectrum of the static powder sample (Fig. 2*a*) exhibits a line shape that can be described rather well by a single Gaussian peak centered at –10.4 ppm and a full-width at half-maximum of 4780 Hz. Spinning the sample about the magic angle reduces this line width drastically (Fig. 2*b*). However, with a line width of 528 Hz, the peaks are still significantly broader than usually observed for crystalline phosphates of other metals (20–200 Hz).[69–76] We have observed comparable line widths on the order of 400–600 Hz in ^{31}P MAS spectra of other diamagnetic vanadyl orthophosphates,[77] hence, this seems to be a feature of this type of system. The line shapes in the MAS spectra are very close to Gaussian, but the wings of the peaks are even narrower than expected for a Gaussian line shape. In contrast, it is our experience[77] that ^{31}P MAS spectra frequently exhibit mixtures of Gaussian and Lorentzian line shapes.

Phosphorus-31 MAS spectra obtained at low spinning rates (1–2 kHz) show spinning sidebands of appreciable intensity (Fig. 3). Generally, spinning sidebands in ^{31}P MAS spectra arise from the presence of chemical shift anisotropy, i.e., the

Bottom trace: MAS spectrum with a spinning rate of 3 kHz, 8 scans, and a recycle delay of 100 s. (*b*) Expansion of the MAS isotropic peak. Experimental points are represented by open circles, the best fits using Gaussian peaks of 4780 Hz (static) and 528 Hz (MAS) full-width at half height are indicated by solid lines.

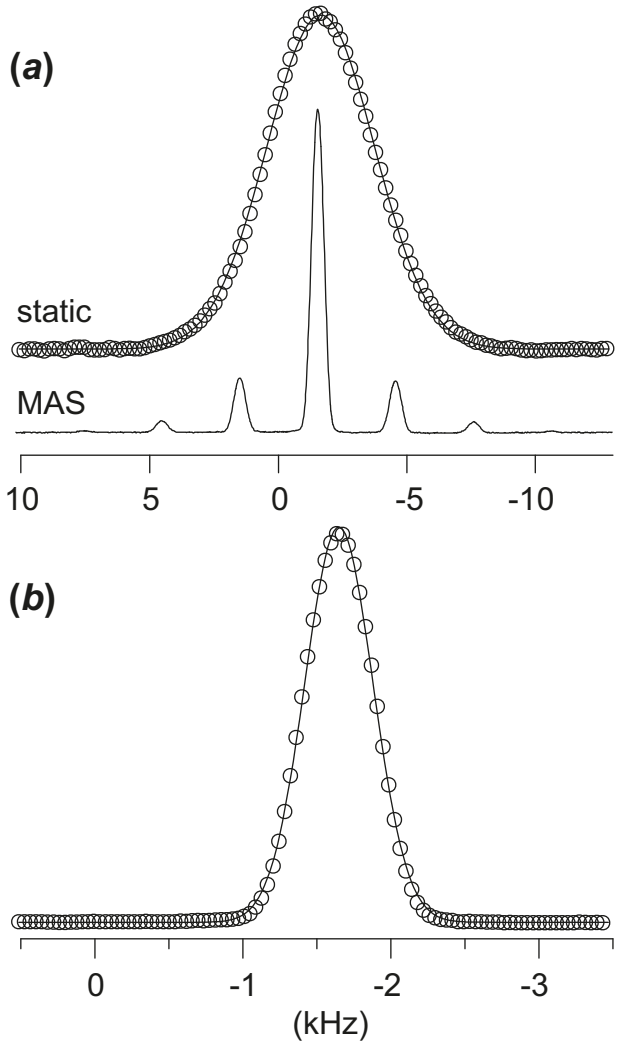

Fig. 3. Solid-state ^{31}P MAS NMR spectra of β-$VOPO_4$ at 9.4 T and a spinning rate of 1.2 kHz, 48 scans, and a recycle delay of 20 s. (*a*) Experimental (top) and calculated (middle) spectra normalized according to their respective total areas, together with the difference spectrum. (*b*) Contour lines representing the intensity ratios I_N/I_0 ($N = \pm1, \ldots, \pm4$) of spinning sidebands of order N. The solid circle represents the best fit at $\mu = 4.96$, $\kappa = 0.03$.

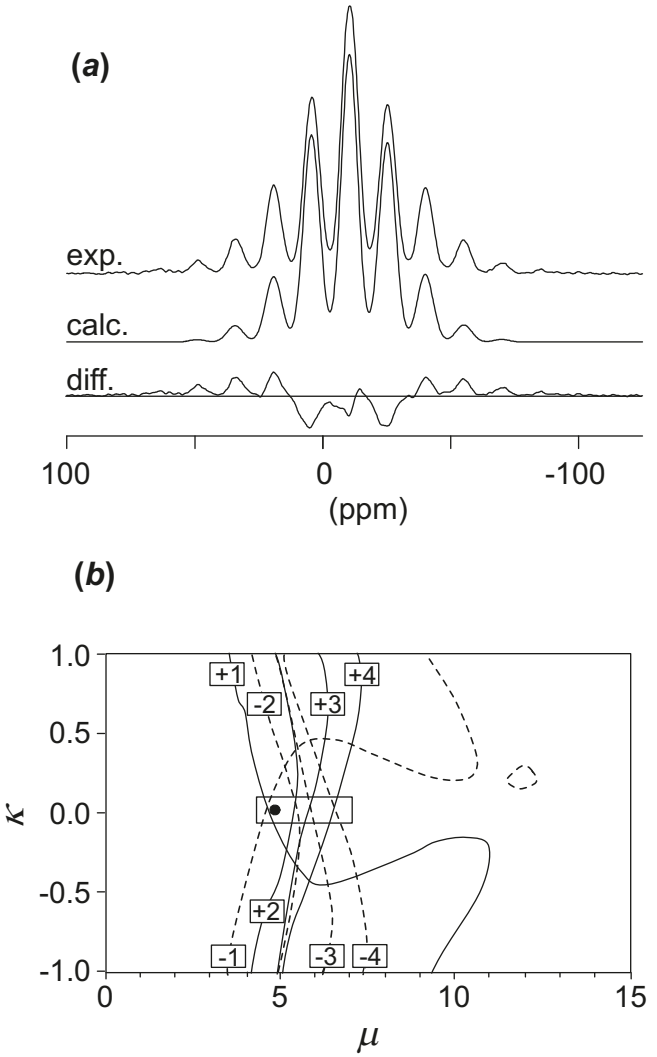

actual chemical shift of ^{31}P depends on the orientation of the crystallites with respect to the external magnetic field. Analysis of the spinning sideband intensities in ^{31}P MAS spectra of β-$VOPO_4$, according to the method of Herzfeld–Berger,[61] yields the following principal components of the phosphorus chemical shift tensor at 9.4 T: $\delta_{11} = 8(7)$, $\delta_{22} = -10(1)$, $\delta_{33} = -29(7)$ ppm, with an isotropic chemical shift of $\delta_{iso} = -10.4(2)$ ppm. This isotropic chemical shift is in good agreement with the chemical shifts reported by Ben Abdelouahab et al.[47] and Vedrine et al.[13] One measure of the magnitude of the chemical shift anisotropy is the span of the chemical shift tensor ($\Omega = 37$ ppm), whereas the symmetry can be characterized by the skew of the tensor ($\kappa = 0.03$).[66] However, the fit is not very satisfying and reveals systematic discrepancies between experimental and calculated intensities (Fig. 3*a*). If the intensities are normalized according to the total area of the spectrum, the experimental spectrum exhibits less intensity for the center peak and first-order spinning sidebands, whereas the other sidebands are more intense than anticipated. This problem of the regular Herzfeld–Berger analysis can also be visualized by looking at the contour plots of normalized spinning sideband intensities (Fig. 3*b*). The best fit ($\kappa = 0.03$, $\mu = 4.96$) lies close to the intersection of the contours of the first-order spinning sidebands because they contribute most of the spectral intensity, but the systematic spread in the intersections of contour lines is significant. Actually, for higher spinning rates the fit appears to be much better; this is, however, deceptive because under these conditions most of the spectral intensity is gathered in the center peak, the intensity of which is not sensitive to anisotropic interactions. The span of the phosphorus chemical shift tensor in β-$VOPO_4$ ($\Omega = 37$ ppm) obtained from the Herzfeld–Berger method is greater than usually observed for orthophosphates of the alkaline and earth alkaline metals, although

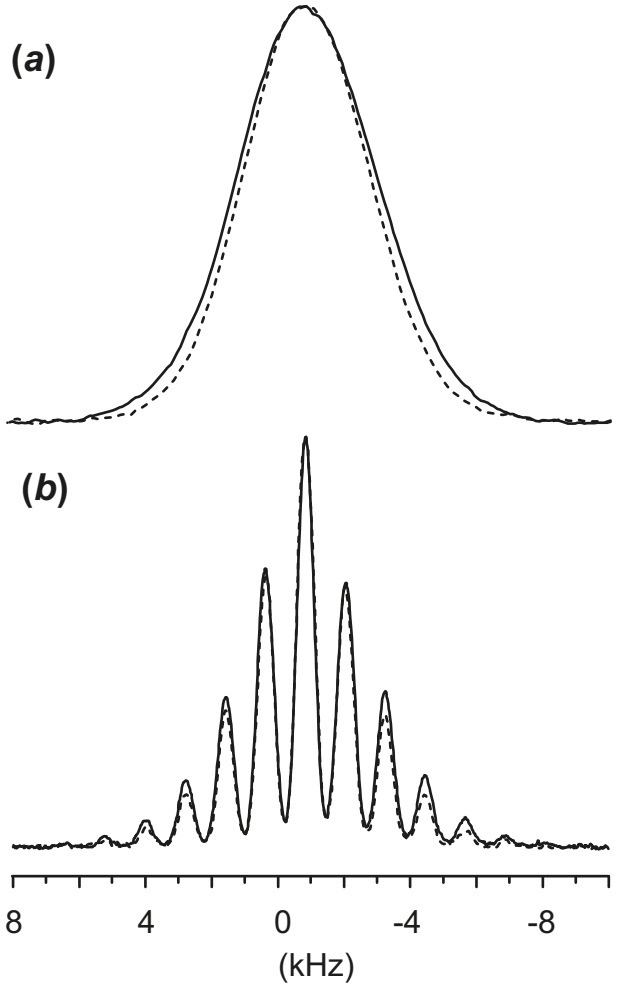
Fig. 4. Field dependence of ^{31}P NMR spectra of β-$VOPO_4$ powder samples obtained under static conditions (*a*) and MAS with a spinning rate of 1.2 kHz (*b*) at 9.4 and 4.7 T. The spectra obtained at 9.4 T are shown as solid lines, overlapped by the broken lines of the 4.7 T spectra. Note that the MAS center peaks have the same line width at both applied magnetic fields.



not outside the range observed for orthophosphates;[78–80] however, those cases with greater spans should be considered mixed oxides (e.g., Berlinite, $AlPO_4$, $\Omega = 110$ ppm)[81] rather than orthophosphates (vide infra). The value of 100 ppm reported by Li et al.[49] (vide supra) could be an artifact produced by the spin-echo mapping technique itself or indicate a different phase. The skew of the tensor ($\kappa = 0.03$), on the other hand, is in agreement with the relatively low point group symmetry (C_s) about phosphorus. Combined with the fact that the static powder pattern can be fitted rather well by a single Gaussian peak, these findings suggest that the spinning sideband intensities are not governed by a single chemical shift tensor or that additional interactions are responsible for the occurrence of spinning sidebands. Hence, application of a simple Herzfeld–Berger analysis seems inappropriate.

Initially, a low level of crystallinity of β-$VOPO_4$ appears to be the most likely explanation for the broad ^{31}P NMR peaks in spectra of static or MAS samples, also suggested by Ben Abdelouahab et al.[47] and in line with the observation that disorder is frequent in VPOs.[82] To elucidate the mechanisms potentially responsible for the line shapes observed in the ^{31}P NMR spectra, such as chemical shift dispersion, chemical shift anisotropy, homonuclear and heteronuclear spin-spin interactions, relaxation, or paramagnetic impurities, we have applied a variety of different NMR techniques.

Fig. 5. Center peak in the ^{31}P MAS NMR spectrum of a β-$VOPO_4$ powder sample obtained at 9.4 T. Experimental points are shown as open circles and the solid line represents a theoretical spectrum calculated for four equivalent vanadium nuclei indirect spin-spin coupled to the phosphorus nucleus, convoluted by a Gaussian peak of 70 Hz full-width at half height. This is a better fit than obtained using a pure Gaussian peak, cf. Fig. 2*b*. The bottom trace shows the unconvoluted theoretical spectrum.

Fig. 6. Phosphorus-31 NMR signal intensities of static powder samples of β-$VOPO_4$ as a function of time for different pulse experiments. Solid circles show the echo amplitudes of Hahn echo experiments, along with a fit assuming a Gaussian decay (solid line). This is to be compared with the broken lines calculated from the theoretical values of M_2 (P, P) for A_2 or AX spin systems. Also included is the decay of the free induction decay following a regular 90° pulse (solid diamonds), together with a Gaussian fit (solid line). This decay is slightly faster than calculated using the heteronuclear M_2 (V, P) value (broken line). The echo intensity decay in solid echo experiments is shown as open circles.

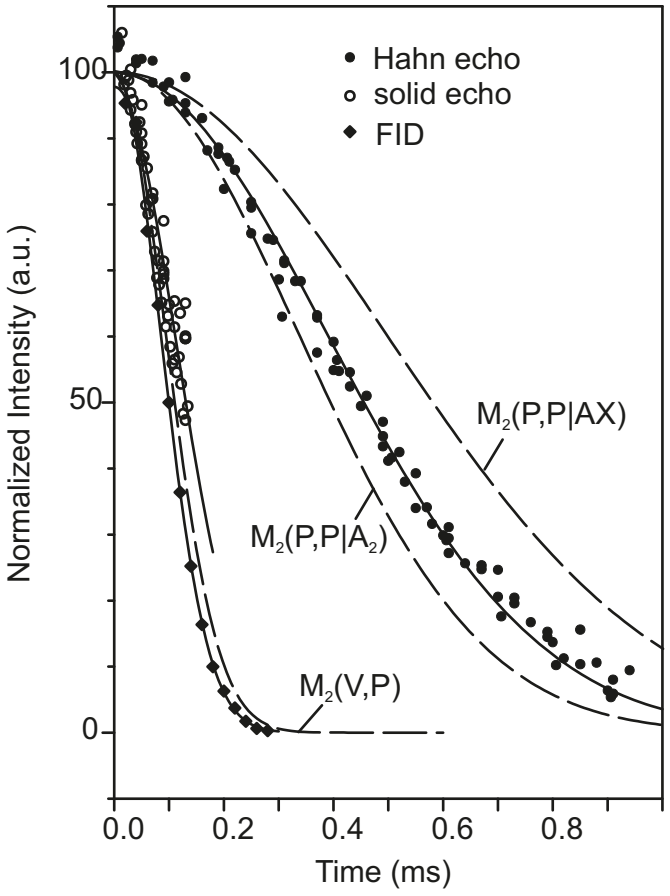

Fig. 7. Dependence of the initial gradient of ^{31}P NMR intensity at $t = 0$ on delay τ for a 90°–τ– 90°$_0$°–$acq(t)$ pulse sequence in a static powder sample of β-$VOPO_4$. The normalization factor A_0^{-1} is the inverse of the FID signal amplitude immediately following the first 90° pulse. The solid line represents the result from linear regression through the initial experimental points, shown as solid circles, whereas the broken line is the gradient calculated from the theoretical value of M_2 (V, P).

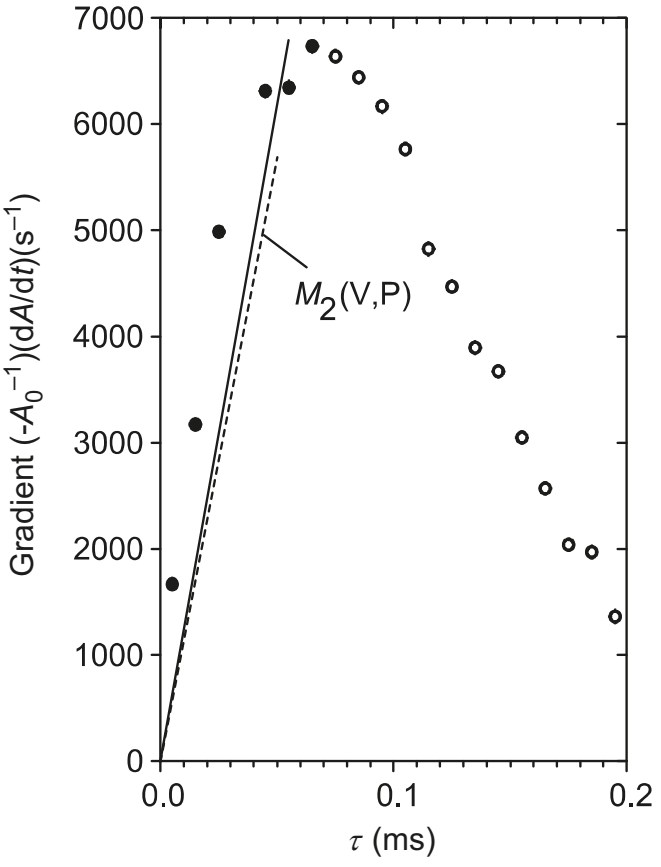

^{31}P spectra was studied at applied magnetic fields of 9.4 and 4.7 T. Spectra obtained for static and MAS samples at both fields are shown in Fig. 4. At 4.7 T, the spectrum of the static powder sample has a line width of 4320 Hz, i.e., about 460 Hz narrower than at 9.4 T. In contrast, the width of the center peak in the MAS spectra is basically independent of

Note: Measured at room temperature unless stated otherwise. Values of T_1 are the results of a mono-exponential, three-coefficient fit to the recovery curves, whereas the values of T_1' result from a fit to a stretched exponential, with the exponent n reported in the last column.

Fig. 8. Phosphorus-31 inversion recovery experiment on a static powder sample of β-$VOPO_4$ at 9.4 T. The broken line is a fit to a mono-exponential function using eq. [9] ($A = 0.943(9)$, $T_1 = 24.9(7)$ s, and $n = 1$) and the solid line is a fit to a stretched exponential ($A = 0.949(1)$, $T'_1 = 25.7(2)$ s, and $n = 0.888(8)$).

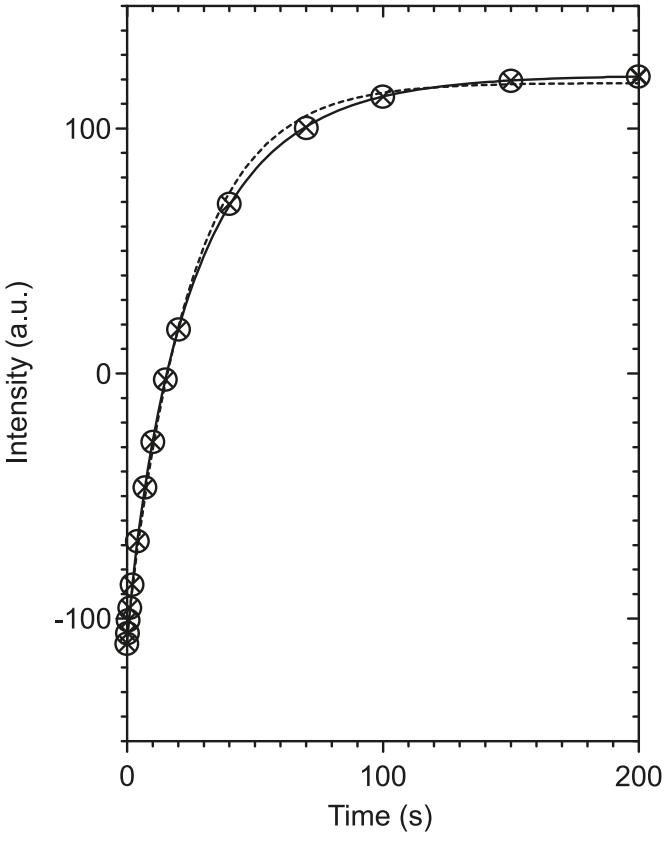

Fig. 9. Dependence of the ^{31}P spin lattice relaxation time (T_1) of a powder sample of β-$VOPO_4$ on spinning rate, magnetic field strength, and temperature. Lines connecting data points are merely guides for the eye.

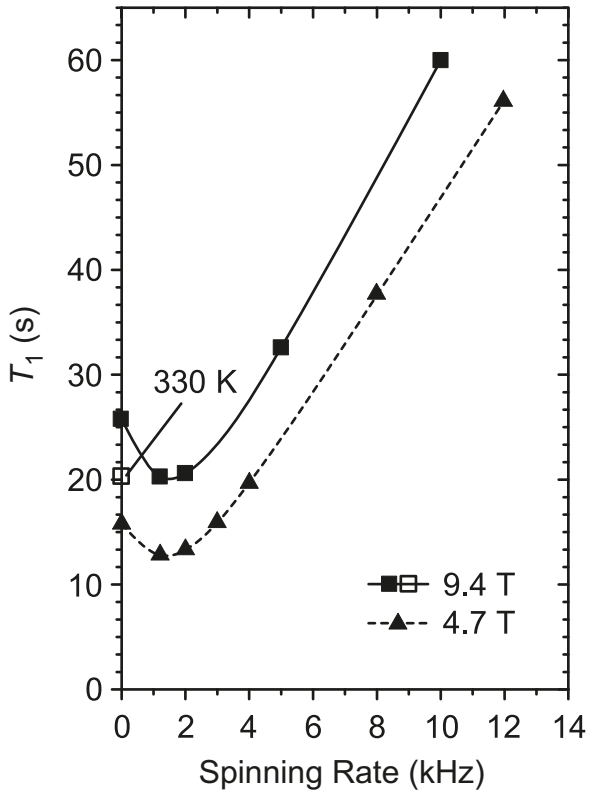

the magnetic field strength (506 Hz at 4.7 T). The lack of field dependence of the isotropic peak line width in the MAS spectra suggests that indirect spin-spin interactions between vanadium and phosphorus should be the cause of the line broadening observed for the isotropic peak, analogous to indium–phosphorus couplings in ^{31}P MAS spectra of indium phosphide.[83,84] The geometrical parameters (e.g., V–O and P–O distances) involving the four vanadium nuclei surrounding the phosphorus nucleus do not differ significantly from each other, hence we shall assume that ^{31}P is coupled to four equivalent ^{51}V nuclei ($I = 7/2$). Thus, the total spin of the four vanadium centers is $I_{max} = 4I = 14$, with a total number of components (i.e., the number of different states m_{Imax}) of $2I_{max} + 1 = 29$. There are $(2I + 1)^4 = 4096$ independent states of the four vanadium nuclear spins, the intensities of which are distributed according to the coefficients in the expansion of the polynomial $[\Sigma\, x^{(2I-q)}]^4$ ($q = 0,\ldots, 2I$) across the 29 different components, as demonstrated by the stick diagram in Fig. 5.[85,86] This stick diagram was calculated using a value of $^2J_{iso}(^{51}V, ^{31}P) = 48(5)$ Hz for the indirect spin-spin coupling constant. Convolution of this multiplet by a Gaussian peak of 70 Hz full-width at half-maximum results in a better representation of the experimental line shape than a mere Gaussian peak (Fig. 2*b*), especially in the wings of the peak. The value of 48 Hz should be considered as an upper limit because it was determined indirectly rather than from resolved splittings. However, given a recent ^{29}Si MAS NMR report on $^2J_{iso}(^{51}V, ^{29}Si) = 28$ Hz for a Si–O–V linkage, this value is not unreasonable.[87]

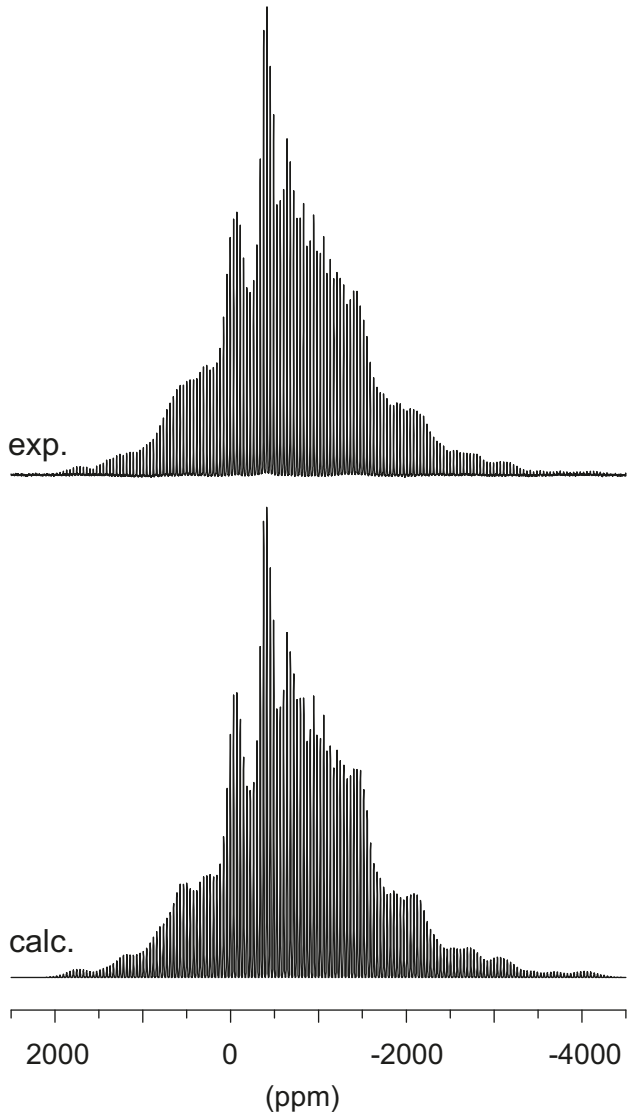
Fig. 10. Vanadium-51 MAS spectrum of β-$VOPO_4$ obtained at 9.4 T with a spinning rate of 4.0 kHz. The top trace shows the experimental spectrum (400 scans and a 2 s recycle delay) and the bottom trace shows a spectrum calculated with the parameters given in the text.



Potentially, there are other interactions that may influence the line width of the ^{31}P MAS spectra. The ^{51}V nucleus has a nuclear quadrupole moment and experiences a weak interaction with the electric field gradient about the vanadium nucleus (vide infra). Under such conditions, MAS will fail to completely average the phosphorus–vanadium direct dipolar coupling and to remove its effect on the ^{31}P MAS spectrum, leading to splitting or broadening of the isotropic MAS peaks. This phenomenon, also called residual dipolar coupling, has been amply studied for a variety of different spin systems.[88,89] The theoretical details shall not be reported here because the contributions from this effect to the ^{31}P MAS line width are negligibly small. From ^{51}V MAS NMR spectra, which show all possible ^{51}V transitions (vide infra), we can estimate the ^{51}V nuclear quadrupolar coupling constant to be 1.5 MHz. In combination with a dipolar coupling constant,

$$[1] \qquad R = \left(\frac{\mu_0}{4\pi}\right)\left(\frac{\gamma_I\gamma_S}{r_{IS}^3}\right)\left(\frac{\hbar}{2\pi}\right)$$

calculated from the crystal structure with r_{IS} between 3.173 and 3.334 Å, we can place an upper limit on the line width contribution from the residual dipolar coupling of <4 Hz at 9.4 T.

Because all phosphorus sites in β-$VOPO_4$ are crystallographically equivalent, all phosphorus nuclei have the same isotropic chemical shift. However, one half of the crystallographic sites are related by twofold screw axes to the other half, thus the chemical shift tensor principal axis systems of those sites will generally not be coincident.[90] In such cases, broadening or splitting may be observed in the MAS spectrum.[91] Such effects are generally dependent on the magnetic field strength and the spinning rate, but they were not observed in the present case.

Phosphorus-31 line shape of static powder sample

Via the field dependence of ^{31}P MAS NMR spectra we have demonstrated that the isotropic peak line width is dominated by the indirect vanadium–phosphorus spin-spin coupling. As shown above, the width of the static spectrum measured in Hz is also basically field independent (there is a 10% increase in width going from 4.7 to 9.4 T). Consequently, a Herzfeld–Berger analysis of the spinning sideband intensities at 4.7 T yields quite different chemical shift tensor principal components: δ_{11} = 26(13), δ_{22} = –10(2), δ_{33} = –48(13) ppm, $\Omega \approx 74$ ppm, and $\kappa = 0.03$, a clear indication that the Herzfeld–Berger analysis based on pure chemical shift anisotropy is inappropriate in this case. On the other hand, this suggests that homonuclear or heteronuclear dipolar couplings may play an important role:[92,93] if measured in ppm, the width of the spectrum should remain constant on going to twice the field if chemical shift anisotropy is the broadening mechanism; on the other hand, dipolar coupling as broadening mechanism will show a decrease of a factor of 0.5 on going to twice the magnetic field strength. In contrast to indirect spin-spin couplings, which are transmitted by the electrons of intervening bonds and are usually limited to nuclei in the immediate environment, dipolar couplings occur through space and, in principle, involve the total crystallite. The size of this spin system makes the detailed calculation of spectral line shapes an unsurmountable task. Because the resulting line shapes are generally featureless, the so-called moments of a spectrum are useful descriptors. The jth moment (M_j) for a line shape $f(\omega)$ is defined in angular frequency units as

$$[2] \qquad M_j = \int_{-\infty}^{\infty} (\omega - \langle\omega\rangle)^j f(\omega)\,\mathrm{d}\omega \Big/ \int_{-\infty}^{\infty} f(\omega)\,\mathrm{d}\omega$$

where the denominator is a normalizing factor and $\langle\omega\rangle$ is the mean angular frequency of the band

$$[3] \qquad \langle\omega\rangle = \int_{-\infty}^{\infty} \omega f(\omega)\,\mathrm{d}\omega \Big/ \int_{-\infty}^{\infty} f(\omega)\,\mathrm{d}\omega$$

The contribution to the second moment of a line shape resulting from homonuclear and heteronuclear dipolar couplings ($M_2(I, I)$ and $M_2(I, S)$) can be calculated from internuclear distances r_{ij} by Van Vleck theory,[94] which in the case of a polycrystalline material predicts[95,96]

Table 5. Vanadium-51 NMR parameters of β-$VOPO_4$ reported in the literature or obtained in the present study.

Parameter	Ben Abdelouahab et al.[47]	Lapina et al.[51]	Siegel et al.[52]	Nielsen[124]	Present work

[a]Corrected for second-order quadrupolar shift.

[b]Not defined for a basically axially symmetric chemical shift tensor. The tensor conventions used by Lapina et al. differs from ours, and we have converted them to meet our conventions.

$$[4] \qquad M_2(I,I) = \frac{3}{5} I(I+1)(2\pi)^2 \sum R_{ij}^2$$

$$[5] \qquad M_2(I,S) = \frac{4}{15} S(S+1)(2\pi)^2 \sum R_{ij}^2$$

where R_{ij} is the direct dipolar coupling constant between the two nuclei involved, as defined in eq. [1] and I, S are the nuclear spins. The sum runs over all relevant nuclei (j) in relation to the considered nucleus i. For the homonuclear case, eq. [4] is only strictly valid if the spins in the pair-wise summation behave as an A_2 spin system; otherwise, if the chemical shift difference becomes greater than the dipolar coupling, the spin system may behave similarly to a heteronuclear spin pair and eq. [5] should be used; a comparison of eqs. [4] and [5] shows that the second moment of an A_2 spin system is 9/4 times greater than that of an AX spin system. In Table 2, we have collected various second moments calculated from the structure of β-$VOPO_4$. It is evident that the dipolar second moment in ^{31}P NMR spectra of β-$VOPO_4$ depends mainly on the four nearest vanadium atoms; they contribute 78% of the total dipolar second moment. Basically, one can conclude that all NMR active nuclei within a sphere of 10 Å contribute significantly to M_2, and in the case of homonuclear dipolar interactions it is not sufficient to consider only the four nearest neighbors, because they contribute only 28% of the homonuclear dipolar M_2.

Experimentally, one can determine the second moment of the spectrum by evaluating eq. [2] directly (Table 3). However, in practice it is not so easy to obtain meaningful and reproducible second moments.[97,98] After we had developed a satisfactory protocol, we discovered that Hendrickson and Tabbey had already published a similar procedure.[98] In short, one starts to calculate M_2 with truncation limits too close to the mean angular frequency and this introduces a systematic error. Then, the truncation limits are gradually extended to both sides of the center, until they are far from the center and introduce appreciable random error. When M_2 is plotted as a function of truncation limits, the initial region of systematic errors shows a systematic increase of M_2 until a plateau is reached, afterwards the region of increasing random errors can be identified by increased scattering of the values of M_2. The final second moment is determined as an average of the values in the intermediate region, the plateau between the two extremes. The ratio M_4:M_2^2 is a useful measure whether an observed line shape is Gaussian; the ratio is 3 for a Gaussian and several orders of magnitude larger for a Lorentzian (in principle, the second and higher moments of a Lorentzian do not have a finite value).[99] As indicated by the ratios M_4:M_2^2 in Table 3 (3.07 at 9.4 T and 3.28 at 4.7 T), the experimental line shapes are very close to Gaussian line shapes. In such situations, it is much easier to obtain the second moment from a fit of the spectrum to a Gaussian peak or of the free induction decay to a Gaussian. The relations of the second moment to the variance of the distribution (i.e., the mean squared width), σ^2, the full-width at half-height (in Hz), $\Delta\nu_{1/2}$, or to the decay constant (in s), T_2, is given by

$$[6] \qquad M_2 = \sigma^2 = (2\ln 2)(\pi\Delta\nu_{1/2})^2 = \frac{2}{(T_2)^2}$$

In the present case, we found the fit of the spectrum to a Gaussian peak to be the most robust procedure, although all methods give consistent results. We also applied various pulse sequences to identify experimentally the different contributions to the second moment, i.e., homonuclear and heteronuclear couplings. The theory behind these sequences has been elaborated by previous workers,[100] thus, we shall focus on the essence of these methods. The results of these experiments are also given in Table 3 and visualized in Fig. 6.

Hahn echo sequence

One of the experiments that we have applied is the common 90°–τ/2–180°$_{0°}$–τ/2–*acq* sequence, which we shall call the Hahn echo sequence. The Hahn echo refocuses all interactions linear in the spin operators, such as chemical shift and heteronuclear dipolar interactions; thus, the decay of the echo intensity as a function of delay τ in a solid sample is, to a first approximation, determined by homonuclear dipolar interactions. In the case of β-$VOPO_4$, the decay of the echo intensity is of Gaussian type, characterized by an M_2 of 6.7(1) × 10^6 rad^2 s^{-2} (Table 3). In this fit, we have combined data obtained at 9.4 and 4.7 T. The experimental value compares reasonably well with the homonuclear second moment calculated from the crystal structure (9.2 × 10^6 rad^2 s^{-2}) shown in Table 2.

Several effects could be responsible for this reduction of the homonuclear M_2 compared with the value calculated from eq. [4]: (*i*) The dipolar coupling could be reduced by motion, not likely in such a rigid solid; (*ii*) indirect spin-spin coupling may also reduce M_2, also not likely for nuclear spins that are separated by four bonds; (*iii*) most likely is that eq. [4] is not strictly valid; this equation requires that the homonuclear spins in the pair-wise addition behave as an A_2 spin system. However, if the chemical shift difference in the spin pair is comparable to or greater than the dipolar interaction, the quantum mechanical "flip-flop" term may be quenched, and the spin system may behave similarly to a heteronuclear spin pair, where eq. [5] should be applied. The resulting value of M_2 is reduced by a factor of 4/9 and the spin echo intensity decays slower, as indicated in Fig. 6. In β-$VOPO_4$, at least two effects will cause instantaneous chemical shift differences: (*i*) crystallographically equivalent, but magnetically nonequivalent chemical shift tensors will have different instantaneous chemical shifts as a function of crystallite orientation; (*ii*) two coupled ^{31}P nuclei may be connected to ^{51}V nuclei in different spin states and the different heteronuclear ^{51}V–^{31}P dipolar and indirect couplings will act as chemical shift in this context. Our results on ^{31}P spin lattice relaxation in β-$VOPO_4$ (vide infra) also indicate that this effect is a likely explanation for the reduction of the homonuclear M_2 by partially quenching the flip-flop term.

Solid-echo sequence

The $90°$–$\tau/2$–$90°_{90°}$–$\tau/2$–*acq* sequence, referred to here as solid echo, refocuses interactions bilinear in the same type of spin, such as homonuclear dipolar or quadrupolar couplings. In cases where the homonuclear second moment is much greater than the heteronuclear interactions, a well-defined echo is produced; in contrast, if the heteronuclear interactions dominate, a solid echo will not occur. As the calculated values of M_2 owing to heteronuclear couplings indicate (Table 2), the latter situation is indeed met in the case of ^{31}P NMR spectra of β-$VOPO_4$. Additionally, the magnitude of heteronuclear dipolar couplings results in a fast decay of the signals such that the echoes have to be sampled after short delays, such that they are also affected by the recovery of the probe electronics (a situation that also affects the initial points of the FID). Overall, this results in large errors associated with this method, so that the outcome can be considered as a determination of the order of magnitude but not a quantitative determination of heteronuclear dipolar moments.

Mansfield sequence

Similar problems arise in the application of the $90°$–τ–$90°_{90°}$–*acq* sequence, suggested by Mansfield.[100] The application of this method should result in an echo-like signal, also called a cross-coupling transient, the initial slope of which depends on the heteronuclear M_2. However, as pointed out by other researchers,[100–103] this method suffers under several experimental problems. The major experimental problem is that the slope of the signal at $t = 0$ needs to be determined, the intensity of which is affected by the behavior of the electronics during the dead time of the receiver. The slope of the line through the first few points (Fig. 7) leads to an overestimation of the heteronuclear dipolar coupling, although if compared with the line calculated from the theoretical M_2 (V, P), the result does not appear unreasonable. At least, this method can serve as an indication of the order of magnitude of heteronuclear dipolar couplings, as in the case of the solid echo.

The average of the results from the solid echo and Mansfield sequence yields a heteronuclear dipolar M_2 (V, P) of $101(23) \times 10^6$ rad^2 s^{-2}, in decent agreement with the theoretical value (Table 2).

Phosphorus-31 chemical shift anisotropy

Evidently, the experimental second moments obtained from the FID or static spectrum, given in Table 3, are field dependent because of the contribution arising from chemical shift anisotropy. In the presence of both dipolar coupling and chemical shift anisotropy, the total second moment is given simply as sum of the individual moments,[104–106]

$$[7] \qquad M_2 = M_2^{\mathrm{D}} + M_2^{\mathrm{CSA}}$$

$$[8] \qquad M_2^{\mathrm{CSA}} = \frac{4}{45}\gamma^2 B_0^2[(\delta_{zz} - \delta_{xx})^2 + (\delta_{yy} - \delta_{xx})(\delta_{yy} - \delta_{zz})] = \frac{4}{45}\gamma^2 B_0^2(\delta_{\|} - \delta_{\perp})^2$$

In the special case of an axially symmetrical chemical shift tensor, the span of the chemical shift tensor can be obtained from the slope of M_2 vs B_0^2 plots. However, for systems lacking axial symmetry this is not possible, although one can put upper and lower limits on the span of the tensor.[106] Extrapolation of the second moments obtained at 9.4 and 4.7 T results in an intercept of $M_2 = 121.9 \times 10^6$ rad^2 s^{-2} ($\Delta\nu_{1/2} = 4137$ Hz), which compares favorably with the theoretical zero-field limit calculated in Table 2, $M_2 = 124.1 \times 10^6$ rad^2 s^{-2} ($\Delta\nu_{1/2} = 4175$ Hz). The slope is 0.43×10^6 rad^2 s^{-2} T^{-2}, corresponding to a lower limit of the span of 20 ppm and an upper limit of 23 ppm. This value is quite acceptable, given the small structural distortions of the PO_4 tetrahedron and compared to other orthophosphates (vide supra).[78]

Phosphorus-31 spin-lattice relaxation

Because the cause of the relatively broad ^{31}P peaks observed in the MAS spectra was initially not known, we also carried out measurements of ^{31}P spin-lattice relaxation times (T_1) using the inversion recovery experiment. It was not unreasonable to anticipate some contamination of β-$VOPO_4$ by paramagnetic V(IV) centers that may lead to short relaxation times and hence broad lines. However, as it turned out, the values of T_1 are on the order of tens of seconds (Table 4). For a particular sample, the measured T_1 values were reproducible over periods extending 1 year. However, the actual value of T_1 may vary from sample to sample because of different contents of paramagnetic vanadium centers. The inversion recovery of the ^{31}P NMR peak intensities of static or MAS samples of β-$VOPO_4$ is not mono-exponential (Fig. 8). Possible reasons for nonexponential behavior are a distribution of different T_1 values or a mixture of different relaxation mechanisms (e.g., spin diffusion). In such more general cases of relaxation, the stretched exponential law has been successfully used to fit the inversion recovery data to this equation,[107,108]

$$[9] \qquad I(\tau) = I_0\left\{1 - 2A\,\exp\left[-\left(\frac{\tau}{T_1'}\right)^n\right]\right\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

Here, the magnetization I as a function of recovery time τ depends on the equilibrium magnetization I_0, the inversion efficiency A of the rf field (ideally, $A = 1$), and the time constant for nonexponential relaxation, denoted here as T_1' to distinguish it from the exponential time constant T_1 ($n = 1$).

According to Bloembergen,[109] two different relaxation mechanisms play a role in diamagnetic solids: relaxation by direct dipolar coupling with the electron spins of paramagnetic impurities[110] and, for nuclei far away from the electron spin, homonuclear spin diffusion.[111] The importance of both mechanisms can be studied by subjecting the sample to magic-angle spinning (Table 4 and Fig. 9).[112–114] Our data reveal a dramatic dependence of T_1 on the sample spinning rate, e.g., at 9.4 T ranging from 25.7 s for a static sample to 60 s for a sample spinning at 10 kHz. Because it is well-known that fast spinning causes frictional heating of the sample,[115–120] we also measured the T_1 of our static sample heated to 330 K (21.1 s), demonstrating that an increase in sample temperature causes a decrease in T_1, in contrast to the effect caused by increasing the spinning frequency. The spinning rate dependence of T_1 nicely illustrates two effects of homonuclear spin diffusion: (*i*) our Hahn spin-echo experiment on a static sample showed that the homonuclear dipolar interaction is sizeable, and the increase in T_1 with increasing spinning frequency demonstrates that the flip-flop interaction between neighboring ^{31}P nuclei becomes increasingly quenched; (*ii*) the small decrease in T_1 at moderate spinning rates (1–2 kHz) shows that the slow spinning actually enhances the flip-flop process by causing level crossing of the inhomogeneously broadened peaks,[121,122] i.e., two ^{31}P nuclei that have different resonance frequencies because of different local ^{51}V, ^{31}P dipolar interactions may experience the same resonance frequency due to the orientation dependence of the dipolar interaction during MAS.

Eventually, once homonuclear spin diffusion is quenched at high spinning rates, T_1 should become spinning rate independent and determined by the concentration of paramagnetic impurities.[114] For our sample of β-$VOPO_4$, ESR measurements confirmed the presence of a low amount of V(IV) centers. In systems where spin-lattice relaxation is diffusion limited, T_1 is proportional to $B_0^{1/2}$,[123] which is approximately true in the present case. There is also a slight decrease of n as T_1 increases, in line with the expectation that $n = 0.5$ for spin-diffusion limited relaxation.[108]

Vanadium-51 NMR spectroscopy

While the line shapes of the ^{31}P NMR spectra of β-$VOPO_4$ basically depend on heteronuclear ^{51}V–^{31}P spin-spin interactions, their contribution to ^{51}V spectra is smaller because of the much smaller spin of the ^{31}P nucleus.[38] Furthermore, they are dwarfed by the ^{51}V nuclear quadrupole interaction and chemical shift anisotropy that are greater by several orders of magnitude. A ^{51}V MAS NMR spectrum of β-$VOPO_4$ is shown in Fig. 10, together with a theoretical spectrum calculated using the parameters reported in Table 5 and compared with previous investigations. To first order, the line shape of the central transition depends only on the principal components of the ^{51}V chemical shift tensor, whereas the satellite transitions show the combined effect of quadrupolar coupling, chemical shift anisotropy, and the relative orientation of both interactions. If the quadrupolar interaction is much greater than the chemical shift anisotropy, it is relatively straightforward to analyze such spectra because central, and satellite transitions can be identified. In the present case, this is more difficult because χ and Ω are of similar magnitude and the individual subspectra cannot be identified, and the question of obtaining reasonable starting parameters arises. If second-order quadrupolar line shapes can be resolved or second-order quadrupolar shifts can be quantified via field-dependent studies, they can provide useful information on the quadrupolar interaction. However, the values in Table 5 indicate that at 9.4 T the second-order broadening contributes only 117 Hz and a shift of 55 Hz (≡0.5 ppm), both too small to aid in the analysis. At least, the observed line width (560 Hz) in the ^{51}V MAS spectra places an upper limit on χ of 4 MHz. It is much better to consider the separation between the outermost spinning sidebands (ca. 650 kHz) because this will correspond to six times the quadrupolar frequency ($6\nu_Q = 3\chi/7$), independent of η, and thus values of χ of 1.5–1.6 MHz.

The region at –412 ppm, corresponding to the region of highest intensity in the MAS spectrum (Fig. 10), also represents a very sharp feature in the spectrum of a static sample and is attributed to the central transition alone, i.e., arising from the perpendicular principal components of an axially symmetric chemical shift tensor. Closer analysis reveals $\delta_\perp = \delta_{11} = \delta_{22} = -340$ ppm, and, in combination with $\delta_{iso} = -754(1)$ ppm, results in $\delta_\parallel = \delta_{33} = -1582$ ppm. Using the parameters obtained at this point, the gross features of the envelope of spinning sidebands in ^{51}V MAS spectra were simulated using line shapes for static powder samples until a reasonable set of parameters was obtained. This is computationally much faster than the calculation of MAS spectra but will not reproduce the envelope exactly. Finally, the MAS spectra were simulated and the parameters modified in small steps until good agreement between calculated and experimental spectra was obtained. In contrast, we found it difficult to obtain decent spectra of static samples, as the initial loss of data points during the receiver dead time after a single pulse was too severe, whereas spin echo experiments produced spectral features that should not be present.

In their ^{51}V NMR study of β-$VOPO_4$, Ben Abdelouahab et al.[47] reported a narrow peak at –354 ppm in their ^{51}V spectrum of a static powder sample, supposedly in agreement with the octahedral coordination of vanadium. However, as indicated in our description above, we attribute this sharp feature to $\delta_\perp$ of the central transition, with the rest of the line shape lost during the receiver dead time. Later, Lapina et al.[51] reported a significant quadrupolar coupling constant of 1.990 MHz (Table 5), but the agreement between their experimental and calculated spectra is not overwhelming. Specifically, the third intensity maximum around 0 ppm in their and our experimental ^{51}V MAS spectra is clearly missing in their simulation. In 2004, Siegel et al.[52] reported the results of a detailed study of ^{51}V NMR spectra of α_{II}-, β-, and γ-$VOPO_4$ at three different external magnetic field strengths. As Table 5 demonstrates, our parameters obtained at 9.4 T are in close agreement with theirs, except for δ_{iso}. We also note, however, that their $\delta_{iso}(^{51}V)$ for α_{II}-$VOPO_4$ (–755 ppm) differs from the value reported by Lapina et al. (–776 ppm) and that also found by us (–778 ppm). Recently, we discovered that Nielsen[124] also investigated β-$VOPO_4$ in her Ph.D.

thesis, with results very similar to our findings (Table 5). In concluding our discussion of literature data we note that Landsberger and Bray[40] studied the V_2O_5–P_2O_5 glass system using ^{51}V and found that values of χ increase from 1.0 to 1.5 MHz and $\sigma_{\|}$ decreases as the V_2O_5 content increases, whereas $\sigma_{\perp}$ is independent of the glass composition.

Jakobsen and co-workers[125] have thoroughly studied ^{51}V MAS NMR spectra of *ortho*- and *meta*-vanadates and have obtained excellent fits for their ^{51}V MAS spectra. Among the compounds studied, $NbOVO_4$ and $TaOVO_4$ are isostructural to β-$VOPO_4$ but with switched roles: vanadium now occupies the tetrahedral positions with dramatic consequences for the ^{51}V NMR spectra: χ is on the order of 1 MHz and Ω on the order of 100 ppm. The span of the ^{51}V chemical shift tensor in β-$VOPO_4$ is comparable to that in V_2O_5 (981–998 ppm),[50,126–129] indicating that the vanadyl–oxygen bond might be responsible for the chemical shift anisotropy because δ_{33} is the unique component of the almost axially symmetric chemical shift tensor and was found by ^{51}V single-crystal NMR on V_2O_5 to be close to the direction of this bond.[130] Interestingly, it was also found in this single-crystal NMR study that the principal axis systems of the electric field gradient and chemical shift tensors are markedly noncoincident ($\beta = 55°$). However, the presence of magnetically nonequivalent vanadium sites leaves a twofold ambiguity in assigning the direction of V_{ZZ} to a specific orientation in the distorted octahedral environment of vanadium.[128] A similar situation is evident for the ^{51}V nucleus in β-$VOPO_4$, as revealed by the data compiled in Table 5.

Conclusions

In summary, we have shown that the line shapes of the ^{31}P NMR spectra of β-$VOPO_4$ mostly depend on the heteronuclear ^{51}V, ^{31}P direct and indirect spin-spin interactions, as opposed to crystallinity or chemical shift anisotropy. The fact that indirect ^{51}V, ^{31}P spin-spin coupling can be detected indicates that communication between the nuclear spins via the intervening bonds takes place. While arguments have been brought forward that the vanadyl bond in vanadium oxides is a short ionic bond,[128] the observation of $^2J_{iso}(^{51}V, ^{31}P)$ hints towards covalent contributions to the vanadium–oxygen bond. This covalent contribution may also play a role in the transmission of spin density from vanadium to phosphorus in paramagnetic vanadyl phosphates.[11,131] Whereas homonuclear ^{31}P, ^{31}P interactions are less important for the ^{31}P NMR line shapes, they play an important role for the ^{31}P spin-lattice relaxation via paramagnetic impurities, as evidenced by the stretched exponential behavior of the inversion recovery and the spinning rate dependence of T_1.

The ^{51}V NMR spectra reveal a relatively large chemical shift anisotropy and quadrupolar coupling constant. It is expected that the orientation of the chemical shift tensor is similar to that in V_2O_5, i.e., the unique principal component of the (nearly) axially symmetric tensor is close to the direction of the vanadyl bond. Somewhat counterintuitively, the greatest component of the electric field gradient tensor is inclined at an angle of 35° with this direction, analogous to the situation found in V_2O_5. So far, theoretical methods have failed to rationalize this observation in V_2O_5,[128] however, successful theoretical calculations of ^{51}V electric field gradient tensors are just beginning to emerge.[132,133] It appears that the ^{51}V chemical shift anisotropy is a local property of the vanadyl group, whereas the ^{51}V nuclear quadrupolar interaction represents a long range property.

Acknowledgments

Financial support by the Deutsche Forschungsgemeinschaft (DFG) under project Gr 1516/1-2 is gratefully acknowledged. We acknowledge G.-U. Wolf (Institut für Angewandte Chemie Berlin-Adlershof e.V., Berlin) for his expert synthesis of β-$VOPO_4$. We thank Dr. A. Kretschmer (formerly of Humboldt-Universität zu Berlin) for some initial NMR measurements and Professor R.E. Wasylishen (University of Alberta, Edmonton, Alberta) for access to the MSL-200 and valuable discussions. K.E. thanks Professor A.C. Olivieri (Universidad Nacional de Rosario) for a listing of his program to calculate spinning sidebands of a spin-1/2 nucleus coupled to a spin–1 nucleus, and Dr. U.G. Nielsen for providing a copy of her Ph.D. thesis. We are grateful to an anonymous reviewer for his careful reading and thoughtful comments.

Abstract: This work describes a phase-transformation pathway of calcium phosphate in the presence of glutamic acid. The route follows the order starting from amorphous calcium phosphate and brushite, then octacalcium phosphate (OCP), and finally hydroxyapatite (HAp). The preferred growth direction of the intermediate OCP and the final HAp phases lies along the *c* axis. On the basis of our scanning electron microscopy, X-ray powder diffraction, and ^{31}P solid-state NMR data, we suggest that the transformation is via the dissolution–reprecipitation process, which is facilitated in the presence of glutamic acid. The effect on the transformation kinetics is rationalized by the disruption of the water layer bound on the crystal surface.

Key words: biomineralization, octacalcium phosphate, calcium phosphate, HAp, NMR.

Résumé : Dans ce travail, on décrit une voie de transformation de phase du phosphate de calcium en présence d'acide glutamique. Cette voie suit un ordre partant du phosphate de calcium amorphe et de la brushite et passant par le phosphate d'octacalcium (POC) pour arriver finalement à l'hydroxyapatite (HAp). La direction de croissance préférée des phases du POC intermédiaire et de l'hydroxyapatite finale se trouve le long de l'axe *c*. Sur la base des données de microscopie électronique à balayage, de diffraction des rayons-X par des poudres et de RMN du ^{31}P à l'état solide, on suggère que la transformation se produit par le biais d'un processus de dissolution–reprécipitation qui est facilité par la présence d'acide glutamique. L'effet sur la cinétique de la transformation est rationalisé par la rupture de la couche d'eau liée à la surface cristalline.

Mots-clés : Biominéralisation, phosphate d'octacalcium, phosphate de calcium, hydroxyapatite (HAp), RMN.

[Traduit par la Rédaction]

Introduction

Biomineralization processes mainly occur at an organic–inorganic interface with the mediation of various biomolecules. However, questions of how these biomolecules control nucleation, growth, and morphology of inorganic minerals remain largely unanswered. The main challenge in this field is that it is difficult to characterize the interactions between two dissimilar organic and inorganic nanophases with atomic resolution. Nevertheless, the literature contains numerous studies of organic–inorganic interactions, which clearly reflects the importance of biomineralization.[1–6] The main constituent of biological hard tissue in vertebrates refers to poorly crystallized, nonstoichiometric carbonate-containing hydroxyapatite (HAp, $Ca_{10}(PO_4)_6(OH)_2$).[7,8] The formation mechanism of biological apatite is still under active debate.[9–11] Potential candidates for the precursor phase of biological apatite include octacalcium phosphate (OCP, $Ca_8H_2(PO_4)_6{\cdot}5H_2O$), amorphous calcium phosphate (ACP), poorly crystalline apatite, and dicalcium phosphate dihydrate (brushite, $CaHPO_4{\cdot}2H_2O$).[8] In particular, brushite has been proposed as an intermediate in the biomineralization processes of bone and dental caries.[8] On the other hand, the presence of a "central dark line" in tooth enamel supports the hypothesis of OCP being the precursor phase of biological apatite.[12] To shed more light on this intriguing issue, it is desirable to characterize the phase transformation of calcium phosphate in the presence of biomolecules.[13,14]

Graham and Brown suggested that the in situ transformation of OCP into HAp may proceed along routes such as hydrolysis of OCP, followed by HAp precipitation.[15] The transformation can be completed within 219 h under physiological conditions (pH 7.4 and 37 °C).[16] In general, the rate of transformation would increase with temperature. For example, the transformation could finish within 29 h at 70 °C and 12 h at 100 °C.[17–19] Furthermore, the pathway and the rate of transformation could be significantly altered by biomolecules.[18,20] In particular, it has been shown that in the presence of gelatin matrix, the transformation of OCP to HAp will occur via a single-crystal–single-crystal pathway.[20] Because the structure of macromolecules such as gelatin is difficult to characterize, it is of considerable interest to study the phase transformation of calcium phosphate in the presence of small molecules.

In our earlier work, we have prepared HAp crystallites in

the presence of glutaric acid, where we suggest that water molecules may play a prominent role in the interfacial interaction between glutaric acid and the HAp surface.[21] Here, we study the phase transformation of calcium phosphate in the presence of L-glutamic acid (Glu). We find that the transformation intermediates are in the order of brushite/ACP, OCP, and HAp. Furthermore, the transformation is likely to occur via the dissolution–reprecipitation pathway. Such process would be significantly slower in the absence of organic additives. We believe that the transient binding of Glu molecules onto the crystal surface would disrupt the structure of the water molecules bound on the crystal surface. Consequently, the dissolution–reprecipitation process required for the phase transformation is facilitated.

Experimental methods

Sample preparation

All chemicals were obtained from Acros, and used as received unless stated otherwise. $Ca(NO_3)_2{\cdot}4H_2O$ (0.572 g, 2.4 mmol) was dissolved in an aqueous solution of Glu (60 mL, 0.16 mol/L). The solution was adjusted to pH 6.0 using NaOH (3.1 mol/L) to ensure full dissolution of the reagents. Phosphate solution was prepared by dissolution of $NaH_2PO_4{\cdot}2H_2O$ (0.375 g, 2.4 mmol) in 60 mL water. The two solutions were mixed with vigorous stirring, and the mixture was adjusted to pH 6.00 ± 0.02. The mixture was sealed in an autoclave and heated to 150 °C for the desired periods. Subsequently, the white precipitates were collected by centrifugation (7000 rpm for 10 min), and washed three times with deionized water. The resulting pellets were lyophilized for at least 16 h and stored in a desiccator.

Sample characterization

X-ray diffraction (XRD) analysis was performed on a Philips X'pert diffractometer, using Cu Kα radiation (λ = 1.5418 Å). A JEOLJSM-6700F field emission scanning electron microscope operated at 10 kV provided SEM micrographs. Transmission electron microscopy (TEM) and selected-area electron diffraction (SAED) patterns were taken on Hitachi S-7100 and Philips FEI Tecnai 20 G2 instruments, operating at 75 kV. High-resolution TEM (HRTEM) images were collected on a FEI Tecnai G2 transmission electron microscope, operating at 200 kV.

All NMR experiments were carried out at ^{31}P and ^{1}H resonance frequencies of 121.5 MHz and 300.1 MHz, respectively, on a Bruker DSX300 NMR spectrometer equipped with a commercial 4 mm probe. The measurements were carried out at ambient temperature. The sample was confined to the middle one-third of the rotor volume using Teflon spacers. A commercially available pneumatic control unit limited variation in magic-angle spinning (MAS) frequency to ±3 Hz. Chemical shifts were externally referenced to 85% phosphoric acid for ^{31}P, and to TMS for ^{1}H spectra. The ^{31}P MAS spectra were measured at 10 kHz spin rate with a recycle delay of 610 s, with proton decoupling at 75 kHz using the scheme of two pulse phase modulation (TPPM).[22]

The ^{31}P double-quantum–single-quantum (DQ–SQ) correlation experiments were acquired using the finite-pulse radio frequency driven recoupling (fp-RFDR) technique at a MAS frequency of 10 kHz.[23–25] To prepare an identical initial spin system for each transient, a saturation comb was applied prior to the recycle delay (8 s). During the fp-RFDR recoupling period, the ^{31}P π pulses were set to 30 μs.[23] The π-pulse trains were phase-cycled following the XY-8 scheme.[26] The ^{31}P π/2 pulses flanking the fp-RFDR pulse blocks were set to 5 μs.[27] The DQ reconversion period was set equal to the excitation period. Continuous-wave and TPPM proton decouplings (70 kHz) were applied during the recoupling and t_2 acquisition periods, respectively. The tachometer signals for pulse-sequence synchronization were filtered with a home-built phase-locked loop circuit. We used the hypercomplex approach for quadrature detection in the F_1 dimension.[28] A z filter of 30 ms without proton decoupling was applied after the reconversion period. For each t_1 increment, 64 transients were accumulated and a total of 42 increments were done at steps of 300 μs. The two-dimensional (2D) ^{31}P spin diffusion experiment, based on the technique of radio-frequency-assisted diffusion (RAD),[29] was carried out with a mixing time of 300 ms. Other conditions were similar to those described in the ^{31}P DQ–SQ experiments.

Results and discussion

XRD

For convenience, all the samples are henceforth referred with reference to their aging times. Figure 1 shows the XRD patterns of some selected samples. The characteristic reflection peaks of brushite (Joint Committee for Powder Diffraction Studies, JCPDS 09–0077), OCP (JCPDS 44–0778), and HAp (JCPDS 24–0033) are at 2θ = 11.7°, 4.8°, and 10.8°, respectively. From the XRD patterns, the as-synthesized (0 min) sample is assigned to brushite, whereas the 30 min sample is a mixture of brushite and OCP. The characteristic reflection of brushite at 2θ = 11.7° becomes diminished in the 45 min sample, resulting in a major phase of OCP. In particular, the relative intensity of the (h00) peak of OCP is relatively strong and a significant attenuation of the (001) peak is rather apparent. This observation suggests a preferred orientation of the OCP crystals along the [001] direction. For the 60 min sample, the characteristic peak of HAp (2θ = 10.8°) becomes observable. Finally, the 250 min sample is assigned to pure HAp with very high crystallinity. The XRD data reported above are very similar to those obtained for glutaric acid (see the Supplementary data).[21] On the other hand, the XRD results of the samples prepared in the absence of Glu indicate that the transformation follows the same pathway, but at a significantly slower rate (see the Supplementary data). This interesting phenomenon has also been observed previously.[20] Furthermore, it has been speculated that trace amounts of monetite could form an intracrystalline mixture with OCP by direct precipitation of calcium phosphate or by hydrolysis of OCP.[30] However, the characteristic peak of monetite (JCPDS 09–0080) at 2θ = 13.1° is not found in our samples, although the solubility products of brushite and monetite are very similar under our pH condition.[31]

SEM

Figure 2 shows the SEM images of the 30, 45, 60, and 250 min samples. The image of the 0 min sample is quite similar to that of the 30 min sample, where the crystallites are poorly faceted rectangular plates (data not shown). The

bladelike morphology of the 45 min sample is the characteristic of OCP. As the reaction proceeds to 60 min, the sample is dominated by needlelike crystallites. We attempt to ascribe

Fig. 3. TEM image measured for the 45 min sample. The bladelike morphology is typical for OCP. The inset shows the SAED pattern corresponding to the area marked by the circle in the main image. We assigned the SAED pattern to the reflections along the [110] zone axis of OCP.

this phenomenon to the fragmentation of the OCP crystallites, which is presumably due to the mechanical stress stemming from the loss of water in OCP upon its transformation to HAp.[20] Furthermore, the XRD pattern of the 60 min sample supports the presence of a significant amount of OCP crystallites. Interestingly, those needlelike crystallites are not observed in the 250 min sample. Because of the distinctive difference in morphology between the 60 min sample (OCP + HAp) and the 250 min sample (HAp), the transformation is likely to occur via the dissolution–reprecipitation

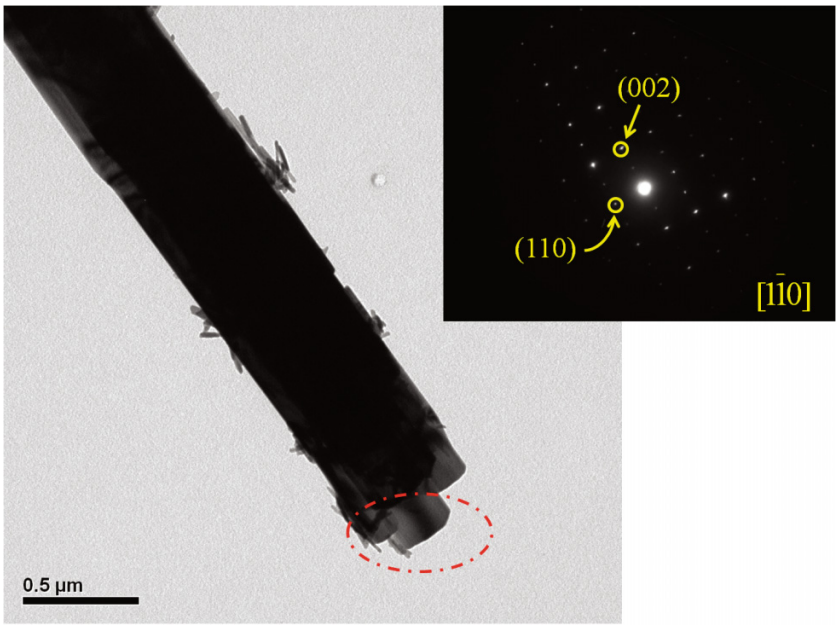
Fig. 5. TEM image measured for the 250 min sample. The inset shows the SAED pattern corresponding to the area marked by the circle. The SAED pattern is assigned to the reflections along the $[1\bar{1}0]$ zone axis of HAp.



pathway. Nonetheless, we cannot rule out the possibility that some of the bladelike HAp crystallites found in the 250 min sample are transformed directly from OCP.[20]

TEM and HRTEM

Figure 3 shows a representative TEM image of the crystallites of the 45 min sample. The corresponding SAED pattern can be assigned to the reflections along the [110] zone axis of OCP crystal. The long edge of the bladelike crystallites lies along the *c* axis, which is in agreement with the XRD results. Figure 4 shows the HRTEM images of the 45 min sample, clearly demonstrating the OCP crystal to be single-crystalline. The lattice fringes ($d \sim 0.346$ nm) are assigned to the spacing of the (002) lattice planes. Together with the SAED pattern, we conclude that the OCP crystals prefer to grow along the [001] direction for our samples. The TEM image of the 250 min sample indicates that the sample contains aggregates of single-crystalline rodlike crystallites (Fig. 5). The SAED pattern shown in the figure can be assigned to the reflections along the $[1\bar{1}0]$ zone axis of HAp crystal. Furthermore, well-ordered lattice fringes with interplanar spacing corresponding to the (002) planes (~0.345 nm) are observed for the 250 min sample (see the Supplementary data). Thus, the preferred growth direction is the *c* axis for both the OCP and HAp crystallites. This observation is similar to the process without organic additives.[32,33]

^{31}P NMR

Figure 6 shows the ^{31}P MAS spectra measured for our sample series. The spectrum of the 0 min sample has a major peak at 1.3 ppm and a very broad shoulder at ~3 ppm. Because brushite has only one crystallographic site, the peak at 1.3 ppm is assigned to brushite,[34] whereas the shoulder is most likely due to ACP.[35] Note that the shoulder at 3 ppm cannot be due to HAp because the XRD pattern shows no characteristic peaks of HAp. The presence of ACP in the as-

Fig. 7. ^{31}P DQ–SQ correlation spectrum of the 30 min sample. The DQ excitation time was set to 3.2 ms. P_B denotes the signal of brushite.

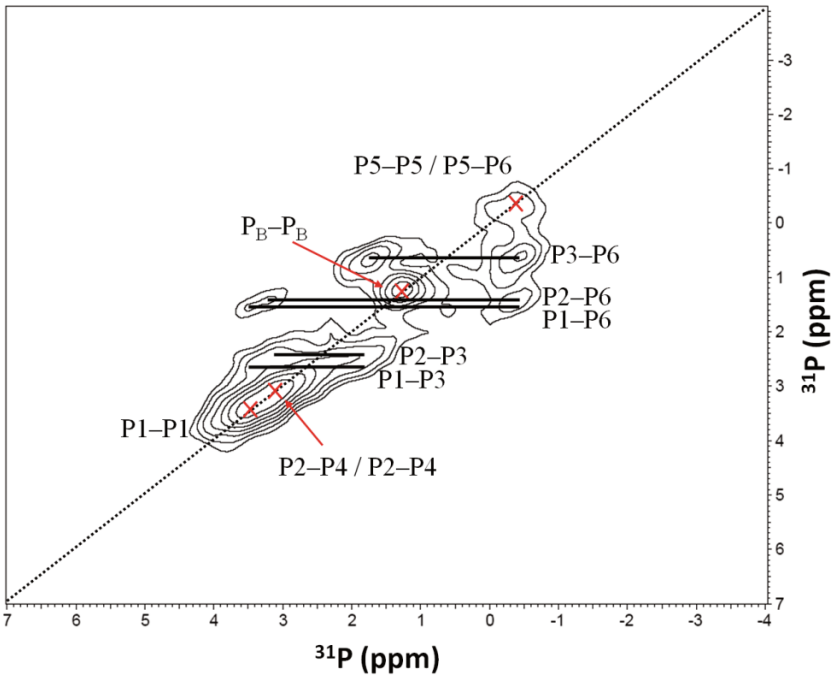

Fig. 8. ^{31}P–^{31}P RAD spectrum measured for the 30 min sample. The mixing time was 300 ms. The dashed lines show the chemical shift of the brushite peak.

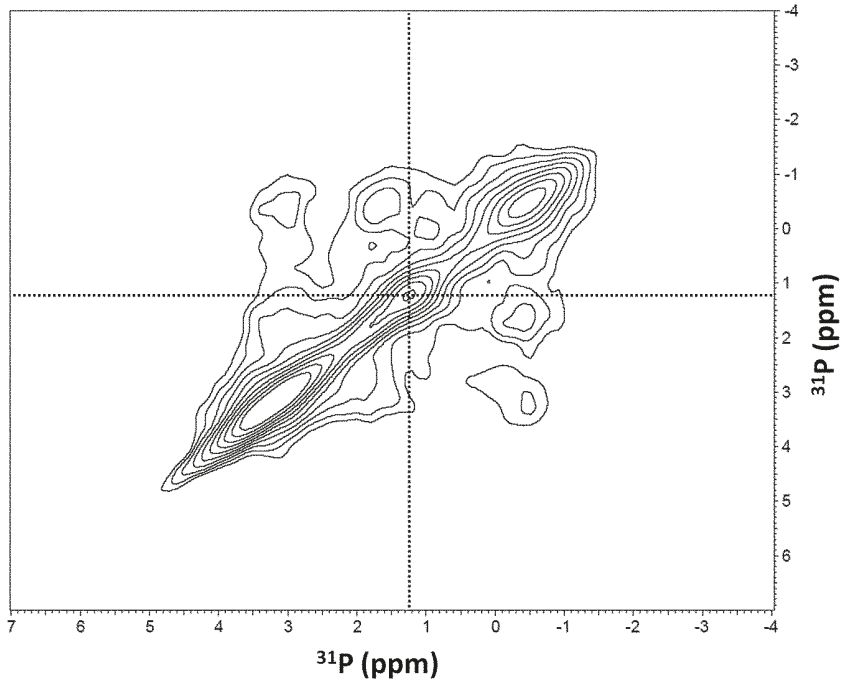

synthesized sample is expected because the precipitation of ACP would readily occur by rapid mixing of calcium and phosphate ions at pH 6.[36] For the 30 min sample, in addition to the peak of brushite, the characteristic peaks of OCP at –0.2, 2.0, 3.3, and 3.7 ppm become apparent. On the basis of their chemical shifts, these four peaks can be assigned to the crystallographic sites of P5/P6, P3, P2/P4, and P1, respectively.[37] As the reaction time increased to 45 min, the ^{31}P spectrum of the sample contains mainly the peaks of OCP but the crystallinity is relatively low. For the 60 min sample, the signal at 2.8 ppm is readily assigned to HAp. The line width at half maximum (LWHM) is ~182 Hz. The very minor shoulder at ~1 ppm may result from the relocation of the PO_4^{3-} ions of OCP.[19] From the XRD pattern, it has been shown that the 250 min sample is pure HAp with high crystallinity. Accordingly, the ^{31}P spectrum contains a single sharp peak at 2.6 ppm with LWHM equal to 102 Hz. Overall, the NMR data are consistent with the XRD results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

For the 30 min sample, both the XRD pattern and the ^{31}P MAS spectrum indicate the presence of OCP and brushite. Figure 7 shows the ^{31}P DQ–SQ correlation spectrum of the 30 min sample. In addition to the eight sets of auto- and cross-correlation peaks assignable to OCP,[25] an auto-correlation peak at 1.3 ppm is also observed for brushite. To investigate the spatial proximity between the brushite and OCP phases, we measured the 2D ^{31}P spin-diffusion spectrum based on the RAD technique.[29] With a mixing time of 300 ms, it is evident that there is no cross peaks found between the signals of OCP and brushite (Fig. 8). Consequently, we conclude that the brushite and OCP crystallites exist in discrete phases.

Phase-transformation pathway

We have studied the phase-transformation pathway of calcium phosphates under hydrothermal conditions. The Ostwald-Lussac law states that the formation of the final crystalline phase is via a pathway passing through all other phases in order of decreasing solubility.[14,38] Accordingly, we found that ACP and brushite were formed initially. As the reaction proceeded further, crystallites of OCP were formed, and finally the HAp was formed. Surprisingly, this transformation process is accelerated in the presence of Glu. At the first glance, this observation is not consistent with the notion that organic additives usually would inhibit the growth of the crystal surface on which the organic molecules are bound. For example, it has been demonstrated that polyglutamate would considerably inhibit the transformation of OCP to HAp.[18,39,40] Nonetheless, a similar promoting effect of citrate ions for the transformation of brushite to HAp has been observed, which is attributed to the reduction in interfacial energies of brushite and HAp caused by citrate ions.[41]

Very recently, Hunter and co-workers suggest that the protein–surface interaction involves largely electrostatic interactions rather than arrays of complementary charges.[42] Also, it becomes evident that a considerable amount of water molecules is bound on mineral surface,[21,43,44] from which it may be surmised that the water layer must be disrupted before the detachment of ions (dissolution) or attachment of new ions (precipitation) could occur. Therefore, we suggest that the observed acceleration of the phase transformation is due to the electrostatic interaction between the Glu molecules and the crystal surface. That is, the water layer on the crystal surface is significantly altered by the Glu molecules when they are adsorbed to or detached from the surface. Consequently, both the processes of dissolution and precipitation of the crystal phase are facilitated. Although the electrostatic interaction is playing an important role as described above, the possibility exists that the difference in the kinetics between samples prepared with different organic molecules, such as aspartic, glutaric, and citric acids, could be rationalized by the difference in lattice matching.

Previously, it has been shown that the molecules of Glu prefer to adsorb onto the (001) face of HAp so that platelike crystallites of HAp are obtained at 37 °C.[32] In our case, however, the long axis of the HAp crystallites is along the (001) direction. A careful comparison of the experimental conditions shows that our samples were prepared at relatively high concentrations. Besides, at a temperature of 150 °C as in our case, the slight difference in the affinity of Glu to the different crystal facets may be overwhelmed by the thermal energy of the Glu molecules. This dramatic difference in the crystal habits reflects the complicated interplay of the thermodynamics and kinetics of the organic–inorganic interactions.[45]

Supplementary data

Supplementary data are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: We demonstrate the estimation of homonuclear dipolar couplings, and thereby internuclear distances, between half-integer spin quadrupolar nuclei by central-transition (CT) double-quantum (2Q) sideband nuclear magnetic resonance (NMR) spectroscopy. It is shown that the rotor-encoded sideband amplitudes from CT 2Q coherences in the indirect dimension of the two-dimensional NMR spectrum are sensitive probes of the magnitude of the homonuclear dipolar coupling, but are significantly less affected by other NMR parameters such as the magnitudes and orientations of the electric field gradient tensors. Experimental results of employing the $R2_2^1R2_2^{-1}$ recoupling sequence to the ^{11}B spin pair of bis(catecholato)diboron resulted in an estimation of the internuclear B–B distance as (169.6 ± 3) pm, i.e., with a relative uncertainty of ±2%, and in excellent agreement with the distance of 167.8 pm determined by single-crystal X-ray diffraction.

Key words: solid-state NMR, quadrupolar nuclei, central transition, double-quantum coherence, sideband spectroscopy, distance estimation.

Résumé : Faisant appel à la spectroscopie de résonance magnétique nucléaire (RMN) à transition centrale (TC) avec une bande latérale à double quantum (2Q), on montre qu'il est possible d'évaluer les couplages dipolaires homonucléaires, et ainsi les distances internucléaires, entre des noyaux quadripolaires de spin une demie. On montre que les amplitudes des bandes latérales encodées par un rotor, obtenues à partir des cohérences de la TC 2Q dans la dimension indirecte de spectre RMN bidimensionnel, sont des sondes sensibles de l'amplitude de couplage dipolaire homonucléaire, mais qu'elles sont moins influencées par d'autres paramètres de la RMN, tel les amplitudes et les orientations des tenseurs du gradient du champ électrique. Les résultats expérimentaux obtenus en employant la séquence de recouplage $R2_2^1R2_2^{-1}$ à la paire de spin ^{11}B du bis(catécholato)dibore à permis de faire d'évaluer la distance internucléaire B–B à (169,6 ± 3) pm, c'est-à-dire avec une incertitude relative de ±2 %, et en excellent accord avec la distance de 167,8 pm déterminée par diffraction des rayons-X sur un cristal unique.

Mots-clés : RMN à l'état solide, noyau quadripolaire, transition centrale, cohérence à double quantum, spectroscopie des bandes latérales, évaluation de la distance.

Introduction

The utilization of through-space dipolar interactions is of pivotal importance for determining order, structure, and dynamics by solid-state nuclear magnetic resonance (NMR) spectroscopy.[1–3] The anisotropic (orientation-dependent) dipolar interactions may provide both geometric and interatomic distance-related structural information; the latter feature stems from the inverse cubic relationship between the separation (r_{jk}) of two NMR-active nuclei and their dipolar coupling constant (b_{jk}). Solid-state NMR experimentation is generally performed on powdered samples undergoing magic-angle spinning (MAS) to emphasize isotropic (orientation-independent) nuclear spin interactions by reducing, or even eliminating, the anisotropies. However, during one or several segments of the MAS NMR experiment, the effects of the dipolar interactions may temporarily be reactivated: this process is referred to as "dipolar recoupling" and is typically arranged by application of radio-frequency (rf) pulse sequences.[1–3]

This work exploits "homonuclear" dipolar interactions (i.e., couplings involving nuclei of the same type) among half-integer spin quadrupolar nuclei[4–20] for estimating internuclear distances. Half-integer spins dominate among all existing NMR-active nuclei; examples include ^{11}B, ^{17}O, ^{23}Na, ^{27}Al, and ^{43}Ca. Following the advent of high-resolution solid-state NMR techniques, to eliminate the broadening from second-order quadrupolar interactions of the central transitions

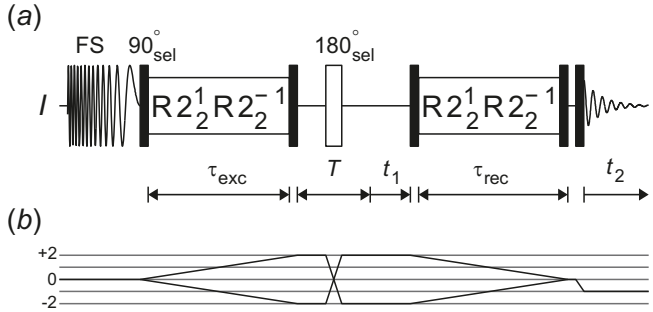
(CTs),[21–24] half-integer spins have become indispensable probes of local structure in widely diverse materials of technological and geological importance.[25–27]

An important subclass of recoupling methodology exploits dipolar interactions for generating double-quantum coherences (2QC) under MAS conditions.[2,3] Such recoupling techniques targeting the CTs of half-integer spins, i.e., employing rf fields that are weak compared with the quadrupolar frequency, have primarily been utilized in two-dimensional 2Q-1Q NMR correlation spectroscopy that reveals all pairs of spatially nearby homonuclear spins in the structure.[11,12,15,19] A double-quantum filtering (2QF) stage in a 2Q-1Q NMR experiment involves two events, one for creating 2QC from longitudinal magnetization and one for driving the reverse process.[2,3] Such "excitation" and "reconversion" intervals are often of equal duration: $\tau_{exc} = \tau_{rec}$ (Fig. 1*a*). They are interleaved by an evolution period (t_1), during which each 2QC acquires a phase factor involving the frequency sum of the two spin resonances within the pair. Each 2QC frequency, appearing along the indirect (ω_1) dimension of the 2D spectrum, becomes correlated with its two respective CT single-quantum coherence (1QC) frequencies along the direct (ω_2) spectral dimension.[11,12,15,19]

It is normally desirable to sample the t_1 evolution such that it is synchronized with the rotational period $\tau_r = 2\pi/\omega_r$ of the sample, where ω_r denotes the angular rotation frequency; then, all spinning sidebands fold onto the centre-band frequency. Besides improving signal-to-noise in the NMR spectrum and eliminating ambiguities in assigning the 2D NMR peaks, this avoids formation of intense sidebands along the 2QC dimension because of the orientation dependence of the (re)coupled dipolar Hamiltonian.[29–34] Such "rotor-encoded" spinning sidebands arise unless the 2QC excitation and reconversion processes are initiated at exactly the same rotor position. However, as the spinning-sideband amplitudes depend on the magnitudes of the anisotropic interaction tensors relative to the spinning frequency, they provide a vehicle to estimate dipolar coupling constants, and thereby internuclear distances, as introduced for spin-1/2 applications by Spiess and co-workers.[29–34] Here, we demonstrate the possibility of using such 2Q-1Q NMR correlation protocols for estimating internuclear distances between dipolar-coupled homonuclear half-integer spins. The dipolar recoupling and 2QC generation employed herein invokes symmetry-based pulse schemes,[3,35–41] as introduced by us for recoupling homonuclear quadrupolar spins,[15–17,19,42] under both MAS and double rotation (DOR)[21] conditions.

We present one of very few techniques for estimating homonuclear dipolar couplings among half-integer spin quadrupolar nuclei. Previous options include monitoring the 2QF signal buildup versus τ_{exc},[43] as is well-established for spin-1/2 applications,[2,3] or using magnetization transfers under a 2Q Hamiltonian[9,10] such as 2Q-HORROR.[35] In that case, one spectral dimension reveals a "Pake-like" pattern (whose width is proportional to b_{jk}) and may be implemented either as a 2D[10] or 3D[9] experiment, the latter incorporating triple-quantum MAS (3QMAS)[23] for improved NMR signal separation. Duer presented a strategy for homonuclear distance measurements by analyzing the spinning sideband formation originating from the evolution of triple-quantum coherences under homonuclear dipolar interactions in a 3QMAS experiment, coupled to multi-spin simulations based on the known crystal structure.[4] This approach did not invoke explicit dipolar recoupling but rather exploited spontaneous recoupling owing to the noncommutation of homonuclear dipolar and first-order quadrupolar interactions of half-integer spins.[4,8,44]

Fig. 1. (*a*) Radiofrequency pulse sequence to record two-dimensional homonuclear double-quantum correlation spectra on half-integer quadrupolar nuclei. The subscript "sel" indicates central-transition-selective pulses. A frequency sweep (FS) may be used to enhance the central transition population difference. The rotor-synchronized pulse sequence $R2_2^1R2_2^{-1}$ achieves homonuclear recoupling.[15] (*b*) Coherence transfer pathway diagram[28] for the *I* spins.



As isolated quadrupolar spin-pairs are rarely encountered, recoupling applications aiming at obtaining quantitative internuclear distances must generally consider large spin systems. To avoid such multi-spin effects and communicate the proof-of-principle, we here estimate the ^{11}B–^{11}B dipolar coupling and hence the internuclear B–B distance of the (isolated) pair of magnetically equivalent ^{11}B in the bis(catecholato)diboron molecule by 2Q-1Q correlation NMR spectroscopy. To support the analysis of the CT 2Q sideband NMR spectroscopy results, we calculated the ^{11}B chemical shift and quadrupolar tensors in bis(catecholato)diboron using gauge-including projector-augmented wave (GIPAW) density functional theory (DFT).[45] Our results are compared with those obtained by Weiss and Bryce[46] from various monoboronic acids and esters by DFT computations of isolated monomers and dimers.

Materials and methods

Solid-state NMR experiments

Figure 1 shows the pulse scheme used to obtain two-dimensional central-transition double-quantum (2D-CT-2Q) spectra of half-integer quadrupolar nuclei. At the start of the pulse sequence, the CT magnetization may optionally be enhanced;[13] possibilities include frequency sweeps as in Fig. 1*a*, encompassing double-frequency sweeps,[47] hyperbolic secant pulses,[48,49] and WURST single-frequency sweeps.[50] Other alternatives include the fast amplitude modulated (FAM)[51] and the equivalent rotor-assisted population transfer (RAPT) schemes,[52] or pulse shapes derived from optimal control theory.[53] The CT longitudinal magnetization is converted into homonuclear 2QC by a CT selective $R2_2^1R2_2^{-1}$ pulse sequence[15] of duration τ_{exc} that is bracketed by two CT 90° pulses; alternatively, for samples involving large spreads in resonance frequencies, it may be beneficial to employ the recoupling schemes of ref. 16. The 2QC are next subjected to a Hahn echo of total duration *T*,[15] adjusted so that the sum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

the CT 90° pulses and T equals an even multiple of rotational periods (here, $2\tau_r$). The CT selective 180° refocusing pulse combined with phase cycling selects the coherence transfer pathway[28] shown in Fig. 1*b*.[12] After the subsequent evolution interval t_1, the 2QC are reconverted into longitudinal CT magnetization by a second $R2_2^1R2_2^{-1}$ block of duration τ_{rec}, which is also sandwiched by CT 90° pulses. Finally, observable CT transverse magnetization is created by a CT selective 90° read pulse.

A powdered sample of bis(catecholato)diboron (molecular structure shown in Fig. 2) was purchased from Sigma-Aldrich and used for all experiments. The experimental results shown in Figs. 3–6 were obtained at a ^{11}B Larmor frequency of –160.5 MHz in a static magnetic field of 11.75 T, by using a Bruker Advance-III console and a Varian 3.2 mm double-resonance standard-bore MAS probehead. The sample was rotated at a spinning frequency of 25 kHz, which corresponded to an rf nutation frequency of 6.25 kHz during dipolar recoupling, i.e., to a CT nutation frequency equal to half the MAS frequency,[15] as for the HORROR condition.[9,10,35] The selective 90° and 180° pulses operated at 9.0 kHz CT nutation frequency. All rf amplitudes were calibrated by complete 2D rf nutation experiments. To enhance the CT population difference, a single-frequency sweep was performed at the same rf field strength, by using a frequency offset and sweep bandwidths of 500 and 800 kHz, respectively, where the beginning and end of the sweep-pulse shape were attenuated by a $\sin^2$ and a $\cos^2$ function, respectively. The States-TPPI scheme was employed to obtain 2D pure absorption line shapes and to distinguish positive and negative 2Q coherences.[54,55]

Numerical spin dynamics simulations

All ^{11}B spin-pair simulations were performed using version 3.0.1 of the SIMPSON package.[56] The experimental parameters given in the preceding subsection were used, together with the experimentally estimated values of the ^{11}B quadrupolar coupling constant and asymmetry parameter listed in Table 1. In addition, the parameters of the CSA tensor and the orientation of the quadrupolar tensor were employed as obtained by GIPAW-DFT calculations (see Table 1). For all cases, powder averaging was accomplished by using a set of triplets of Euler angles, selected according to the ZCW scheme.[57–59] This set consisted of 1154 angles for simulating the CT 2Q build-up curves shown in Fig. 3, whereas the calculations of the CT 2Q sideband patterns displayed in Figs. 5 and 6 employed 6044 orientations. All pulses were taken explicitly into account in the simulations, except for the CT population enhancement and the 90° read pulse. The initial density operator and the detection operator were both set to represent CT z-magnetization. The CT 2QC were selected by setting all other elements in the density matrix to zero before and after the 180° spin-echo pulse. The CT 2Q sideband amplitudes were simulated by incrementing t_1 in 35 steps of duration $\tau_r/35$ and combining the results of the +2QC and –2QC time-dependent signal amplitudes to form the cosine and sine components required by the States procedure.[54] The resulting complex t_1 time signal was subjected to a complex Fourier transformation to obtain the integrated CT 2Q spinning sideband amplitudes.

Quantum chemical calculations

For the GIPAW-DFT calculations of the ^{11}B quadrupolar and chemical shift tensors in bis(catecholato)diboron, CASTEP[60] and CASTEP-NMR[45,61,62] (version 4.4) were used together with Accelrys' Materials Studio. The generalized gradient approximation with the Perdew–Burke–Ernzerhof exchange correlation functional[63] and "on-the-fly" pseudopotentials were chosen. The plane-wave cutoff energy was selected to be 550 eV and the k-point grid was set to $5 \times 2 \times 4$. Starting from the structure determined by single-crystal X-ray diffraction (XRD),[64] initially, only the proton positions were optimized, whereupon the NMR parameters were calculated.

Results and discussion

^{11}B NMR parameters in bis(catecholato)diboron

To use the full set of ^{11}B NMR parameters for bis(catecholato)diboron in the numerical simulations of the dipolar recoupling experiments, in a first step, we determined the ^{11}B isotropic shift, quadrupolar coupling constant $C_Q = e^2qQ/h$ and the quadrupolar asymmetry parameter η_Q experimentally; the results are shown in Table 1. In a second step, we derived the ^{11}B quadrupolar and chemical shift tensors in bis(catecholato)diboron by GIPAW-DFT calculations. Weiss and Bryce[46] recently reported ^{11}B NMR parameters in various monoboronic acids and esters by using DFT computations of isolated monomers and dimers. Since a crystal structure of bis(catecholato)diboron has been determined using single-crystal XRD,[64] we chose GIPAW-DFT calculations that explicitly account for the periodicity of the crystal.[45] The results of these computations are displayed in Table 1 and Fig. 2. Since the two boron sites in the bis(catecholato)diboron molecule are related by inversion symmetry through the centre of their internuclear vector, the chemical shift tensors, as well as quadrupolar tensors, are identical for both boron sites (magnitudes and orientations). The experimentally determined isotropic chemical shift and quadrupolar coupling constant of $\delta_{iso} = 28.6$ ppm and $C_Q = 2.71$ MHz, respectively, fall into the same range as that found for monoboronic esters,[46] whilst the present value $\eta_Q = 0.745$ is larger than those of the esters. Figure 2 shows the principle axis systems of the tensors, as obtained from GIPAW-DFT computations. The z principal axes of both tensors are approximately perpendicular to the molecular plane and the y axes are nearly collinear with the B–B bond. Whilst the calculated value $\eta_Q = 0.77$ is in good agreement with the experimentally determined one, the computed value $C_Q = 3.18$ MHz is significantly larger (by ≈0.5 MHz) than the experimentally measured value. In the Haeberlen notation[65] the calculated anisotropic chemical shift and asymmetry parameter are given by $(\delta_{aniso}, \eta) = (–22.6$ ppm, 0.67), which corresponds to a span and skew of $(\Omega, \kappa) = (41.5$ ppm, 0.27) in the Maryland notation.[65] We note that the calculated span is slightly higher than the largest one found in monoboronic acids,[46] whereas the skew is smaller.

Central-transition double-quantum NMR spectroscopy

A common approach to determine homonuclear dipolar couplings is to monitor the buildup of 2QC as a function of the excitation interval τ_{exc} of the recoupling sequence. This approach was launched by Mali et al.[12] in the present context

Table 1. ^{11}B NMR parameters of bis(catecholato)diboron as determined experimentally and by GIPAW-DFT calculations. The reported values of the anisotropic chemical shift (δ_{aniso}) and the asymmetry parameter (η) conform to the Haeberlen notation.[60]

	C_Q (MHz)	η_Q	Ω^Q_{PM} (°)	$\{\sigma_{xx}, \sigma_{yy}, \sigma_{zz}\}$ (ppm)	δ_{iso} (ppm)	δ_{aniso} (ppm)	η	Ω^{CSA}_{PM} (°)
Exptl.	2.71	0.745			28.6			
DFT	3.18	0.77	{–87.7, 89.8, 179.9}	{48.2, 63.4, 89.7}		–22.6	0.67	{–87.3, 85.8, –178.6}

Note: The Euler angles Ω^{Λ}_{PM} give the relative orientation of the principle axis system of the interaction tensor $\mathbf{\Lambda}$ and a molecule fixed frame with its z axis along the B–B internuclear vector and its x axis perpendicular to the O–B–O plane (compare Fig. 2). C_Q, quadrupolar coupling constant; η_Q, quadrupolar asymmetry parameter; $\{\sigma_{xx}, \sigma_{yy}, \sigma_{zz}\}$, principal components of the chemical shielding tensor; δ_{iso}, isotropic chemical shift.

Fig. 2. Molecular structure of bis(catecholato)diboron.[64] The principal axis system of the ^{11}B quadrupole coupling and chemical shift tensors as determined by CASTEP calculations are indicated in black and blue colors, respectively.

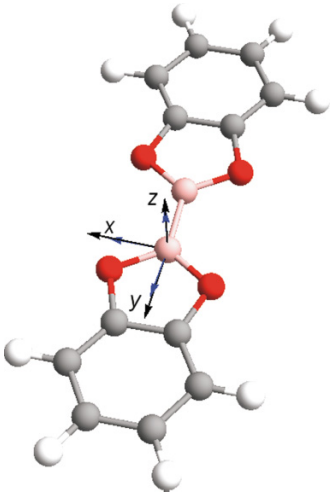


Fig. 3. ^{11}B double-quantum filtered efficiencies as a function of $\tau_{exc} = \tau_{rec}$ obtained in bis(catecholato)diboron using the pulse sequence shown in Fig. 1 at a spinning frequency of 25 kHz and an external field of 11.75 T. Experimental results are indicated by ■, whereas the outcome of numerical simulations for different homonuclear dipolar couplings constants $b_{jk}/2\pi$ are displayed as –2619 Hz (●), –3119 Hz (▲), and –2119 Hz (▼).

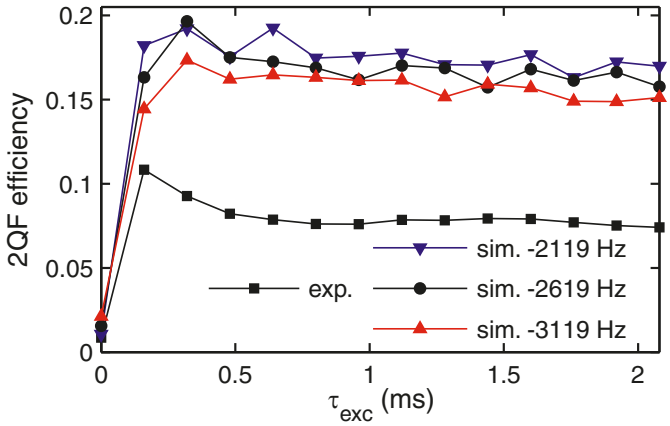

of distance estimations among half-integer spins. Figure 3 shows experimental and simulated ^{11}B two-spin 2QF efficiencies as a function of $\tau_{exc} = \tau_{rec}$, as determined in bis(catecholato)diboron by using the pulse sequence shown in Fig. 1 at a spinning frequency of 25 kHz and an external field of 11.75 T. Single-crystal XRD provided the B–B internuclear distance r_{jk} = 167.8 pm in the bis(catecholato)diboron molecule,[64] corresponding to a ^{11}B–^{11}B coupling constant of $b_{jk}/2\pi$ = –2619 Hz. The numerically simulated results in Fig. 3 account for the ^{11}B natural abundance of 80.1% that results in a probability of 64.2% to find a ^{11}B–^{11}B spin pair in an arbitrarily selected molecule. We achieved an experimental 2QF efficiency of 11%, whereas the simulation employing a ^{11}B–^{11}B dipolar coupling of –2619 Hz predicts a maximum 2QF efficiency of 20%. For comparison, Fig. 3 additionally displays the results of numerical simulations using dipolar couplings of –2119 and –3119 Hz. Minor variations of the ^{11}B 2QC dynamics were observed, despite the large difference between the dipolar couplings, which makes this approach an unfavourable choice if accurate determinations of large homonuclear dipolar couplings are desired. Significantly faster sample rotation would allow for finer sampling of the 2QC buildup, however, at the expense of requiring higher rf field strengths during recoupling: this compromises the CT selectivity of the pulses, while also leading to higher accumulation of rf errors during the 2Q-recoupling events. For the present experimental conditions, the problem of too coarse sampling of τ_{exc} prevails even for estimates of smaller couplings ($b_{jk} \approx 0.5$ kHz) and is accentuated further for homonuclear systems involving higher spin numbers (e.g., ^{27}Al) because of their accelerated 2QC excitation.[12,17]

Here we propose to instead utilize the spinning sidebands of the two-spin CT 2QC as a more favourable option for determining homonuclear dipolar couplings between half-integer quadrupolar nuclei. It offers particular advantages for measurements of strong dipolar interactions. In addition, whereas the efficiency of exciting CT 2QCs itself depends on the ability to employ CT-selective rf fields, the CT 2Q sideband patterns are significantly less influenced by this requirement. Although in the case of powdered samples, the rf fields may not be CT selective for all crystallite orientations at all time points, in practice this poses no serious limitation to the applicability of CT 2Q spectroscopy.[15–19]

Figure 4 shows the experimental ^{11}B 2D CT 2Q spectra of bis(catecholato)diboron, obtained by using the pulse sequence in Fig. 1 for three different intervals $\tau_{exc} = \tau_{rec}$ of 160, 320, and 480 μs at a spinning frequency of 25 kHz. The NMR spectra comprise strong rotor-encoded odd-order spinning sidebands in the indirect (2Q) dimension, analogous to the cases of coupled spin-1/2 nuclei or isolated quadrupolar spins, described by the group of Spiess.[29–34] If t_1 is incremented by a fraction of the rotational period under relatively fast MAS conditions, these sidebands mainly result from rotor encoding of the 2Q reconversion process. The rotor-encoded modulation of the 2QC gives rise solely to *odd-ordered*

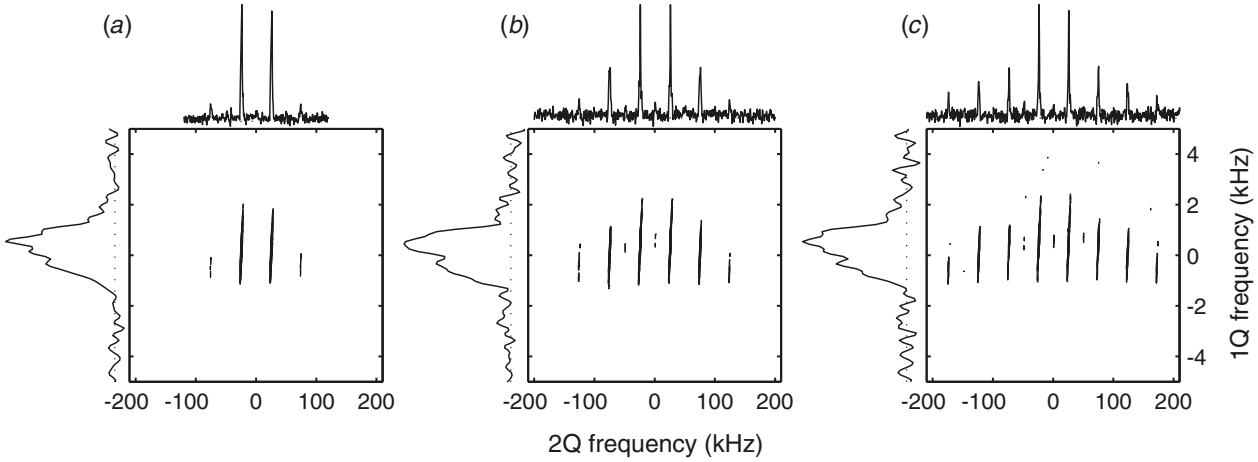
Fig. 4. Experimental two-dimensional ^{11}B central-transition (CT) double-quantum (2Q) spectra of bis(catecholato)diboron for different time intervals $\tau_{exc} = \tau_{rec}$: (*a*) 160 μs, (*b*) 320 μs, and (*c*) 480 μs.



sidebands along the 2Q spectral dimension, even in scenarios devoid of 2QC evolution during t_1.[32,33] Ideally, the number and amplitudes of the sidebands depend only on the product $b_{jk}\tau_{rec}$ of the homonuclear dipolar coupling constant and the reconversion interval. On the other hand, the evolution of the 2QC under *all* noncommuting spin interactions during the t_1 interval produce conventional sidebands involving *all orders*, owing to the *rotor modulation* of the 2QC. The very small amplitudes of the even-order sidebands in the experimental spectra shown in Fig. 4 verify that hardly any rotor-modulated sidebands are present and that the rotor encoding of the 2Q reconversion process is indeed the predominant contribution to the odd-order sidebands. As expected,[29–34] a larger number of sidebands appear along the 2Q dimension of the 2D spectrum as the interval $\tau_{exc} = \tau_{rec}$ increases (Fig. 4).

The integrated amplitudes of the odd-ordered sidebands of the experimental ^{11}B 2D CT 2Q spectra of bis(catecholato)diboron are plotted in Figs. 5*a*, 5*c*, and 5*e* against the sideband order. For comparison, results of numerical simulations using the XRD distance-based ^{11}B–^{11}B dipolar coupling of $b_{jk}/2\pi = -2619$ Hz are presented in Figs. 5*b*, 5*d*, and 5*f*: the top row, (*a*) and (*b*), compares the experimental and simulated results for $\tau_{exc} = \tau_{rec} = 160$ μs; the middle row, (*c*) and (*d*), for 320 μs; and the bottom panel, (*e*) and (*f*), for 480 μs. It is evident that the experimental and simulated CT 2Q odd-order sideband amplitudes are similar overall, except from those of the ±1 sidebands that are more intense in the experiments relative to the simulations. However, the higher order (±3, ±5,…) sideband patterns are reproduced remarkably well. For internuclear distance measurements, we consequently suggest selecting $\tau_{exc} = \tau_{rec}$ sufficiently large, so that at least the ±3, ±5 and ±7 sidebands are present in the CT 2Q-1Q spectra.

To assess the sensitivity of the CT 2Q sideband pattern for the purpose of estimating the ^{11}B–^{11}B dipolar coupling b_{jk} and hence the B–B internuclear distance r_{jk}, we performed a series of numerical simulations for $\tau_{exc} = \tau_{rec} = 480$ μs by varying the dipolar coupling constants in steps of 20 Hz between –3619 and –1699 Hz. In each case we fitted one overall scaling factor of the complete sideband pattern by minimizing the sum-square deviation S between the simulated and experimental (±3, ±5, ±7, ±9) integrated sideband amplitudes. The 95% confidence interval was determined by the set of dipolar couplings for which $S \leq S_{min}\{1 + F^{0.05}_{1,6}/6\}$, where S_{min} is the sum-square deviation for the best fit and $F^{\alpha}(p_1,p_2)$ is the upper α probability point of the F distribution with p_1 and p_2 degrees of freedom.[66,67] We obtained a best fit

Fig. 5. Integrated odd-order CT 2Q spinning sideband amplitudes obtained in bis(catecholato)diboron for different time intervals $\tau_{exc} = \tau_{rec}$: (*a*) and (*b*) 160 μs, (*c*) and (*d*) 320 μs, and (*e*) and (*f*) 480 μs. The left column (*a*), (*c*), and (*e*) show experimental integrals, whereas the right column (*b*), (*d*), and (*f*) display numerically simulated sideband amplitudes for an ^{11}B–^{11}B dipolar coupling of $b_{jk}/2\pi = -2619$ Hz, which corresponds to an internuclear distance of 167.8 pm provided by single-crystal XRD.[64]

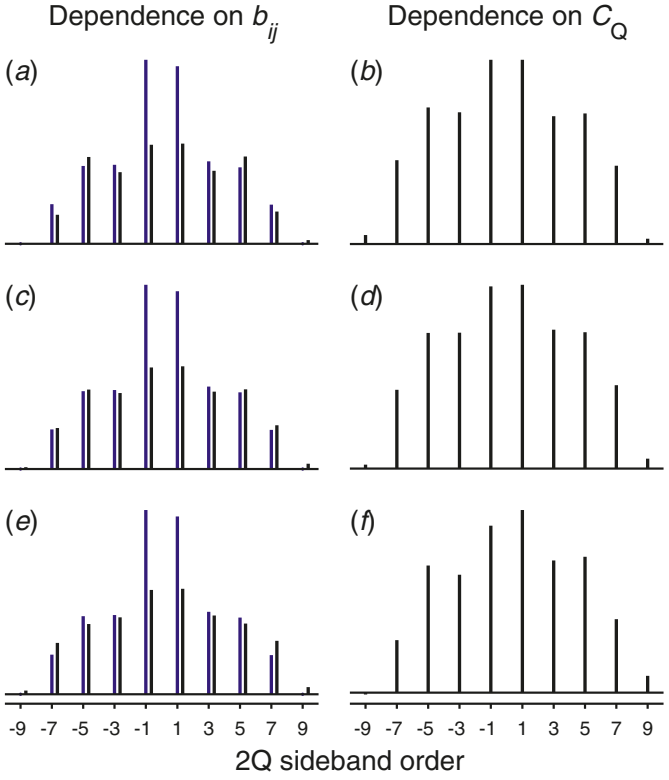
Fig. 6. Odd-order central-transition (CT) double-quantum (2Q) spinning sideband amplitudes obtained in bis(catecholato)diboron for $\tau_{exc} = \tau_{rec} = 480$ μs. Left column (*a*), (*c*), and (*e*): Blue/grey sticks depict the experimental integrals. Black sticks represent numerically simulated sideband amplitudes for different ^{11}B–^{11}B dipolar coupling constants $b_{jk}/2\pi$: (*a*) –2439 Hz, (*c*) –2579 Hz, and (*e*) –2699 Hz. Right column (*b*), (*d*), and (*f*): Simulated sideband amplitudes for $b_{jk}/2\pi = -2619$ Hz and different quadrupolar coupling constants C_Q: (*b*) 2.7 MHz, (*d*) 2.1 MHz, and (*f*) 3.5 MHz.



of –2579 (+70, –60) Hz for the ^{11}B–^{11}B dipolar coupling constant in bis(catecholato)diboron, which corresponds to a solid-state NMR-determined distance of 169.6 (+1.6, –1.3) ppm. These results are in excellent agreement with the values determined by X-ray diffraction, –2619 Hz and 167.8 pm, respectively. The best fit simulations of the CT 2Q sideband amplitudes are shown in Fig. 6*c* together with the experimental results.

In the right column of Fig. 6, the numerically simulated results from varying the quadrupolar coupling constant reveal very weak effects on the sideband amplitudes. This also applies if the quadruplar coupling constants of the two ^{11}B sites are different. Further, omitting the CSA interactions has even less bearing on the sideband patterns (data not shown). Numerical simulations (to be presented elsewhere) indicate that the quadrupolar coupling orientations, as well as the magnitude and orientation of the CSA tensor, only have relatively minor influences on the CT 2Q sideband pattern. However, because of these small effects, we conservatively state a final confidence interval for the estimation of the ^{11}B–^{11}B dipolar coupling constant in bis(catecholato)diboron that is twice the one found by the least-squares analysis. Therefore, we could reliably estimate the ^{11}B–^{11}B dipolar coupling constant as –2579 (+140, –120) Hz, corresponding to a solid-state NMR determined B–B distance of (169.6 ± 3) pm. Figures 6*a* and 6*e* show the experimental integrated CT 2Q sideband amplitudes together with the numerical simulations for the upper and lower bounds in the estimated dipolar coupling constant, i.e., –2439 and –2699 Hz, respectively. This confirms that the higher order (±3, ±5, …) sideband amplitudes clearly constitute sensitive measures of the homonuclear dipolar coupling. The relative uncertainty of our estimation is about ±5% in the ^{11}B–^{11}B dipolar coupling constant and about ±2% in the internuclear B–B distance.

Wi et al.[9,10] reported a recoupling-derived interatomic distance in the related bis(pinacolato)diboron complex, which also features two directly bonded boron atoms. Their approach utilized magnetization transfers under a 2Q dipolar Hamiltonian effected by the 2Q-HORROR technique[35] in the absence of 2QF. At the expense of significantly reduced NMR signal-to-noise, the explicit 2QF employed herein is advantageous for spin pairs where the recoupled isotope is not 100% naturally abundant (e.g., ^{11}B), as it ensures that only one pair of the targeted spins need to be considered in the numerical simulations involved in the distance analysis. Similar issues apply for Duer's 3QMAS-based strategy.[4] Besides this favorable feature of the present technique, we expect that its accuracy and resolution of the distance estimates provided will be at least as good as the methods presented in refs. 4, 10, and 43.

Concluding remarks

In this contribution, we have demonstrated that CT 2Q sideband NMR spectroscopy has great potential for estimating the internuclear distances between half-integer spin quadrupolar nuclei. We showed that for the ^{11}B spin pair of bis(catecholato)diboron, the amplitudes of higher odd-order (±3, ±5,…) double-quantum rotor-encoded spinning sidebands could be reproduced very well by numerical simulations and constitute sensitive probes of the homonuclear ^{11}B–^{11}B dipolar interaction. This resulted in an estimation of the ^{11}B–^{11}B dipolar coupling constant in bis(catecholato)diboron to –2579 (+140, –120) Hz (approx. ±5%), corresponding to an internuclear solid-state NMR-determined B–B distance of (169.6 ± 3) pm (approx. ±2%). This value is in excellent agreement with the single-crystal XRD-determined distance of 167.8 pm.[64] Our estimation of the uncertainties is conservative and takes into account that the exact size and orientation of the quadrupolar tensor has a weak influence on the CT 2Q sideband amplitudes. As a result, our approach is directly applicable for readily distinguishing between scenarios involving (for instance) single or double-bonded B–B motifs.[68]

Whereas the present work has provided one of very few examples of internuclear distance measurements in pairs of *directly* bonded quadrupolar spin-3/2 nuclei,[9,10] this approach is neither limited to strong dipolar couplings nor spin-3/2 systems. In a forthcoming publication we will present analytical expressions facilitating the 2Q spinning-sideband analysis and demonstrate the determination of much weaker homonuclear dipolar couplings among quadrupolar nuclei, such as ^{23}Na and ^{27}Al, in the more commonly encountered context of inorganic network materials. Further, extensions of this work for determining heteronuclear dipolar interactions

involving half-integer quadrupolar nuclei[34,69,70] are in progress in our laboratories.

Acknowledgments

The authors would like to thank G. Enright for confirming the X-ray structure of bis(catecholato)diboron and I. Moudrakovski, V. Terskikh, and C. Ratcliffe for helpful discussions. Access to CASTEP was provided by the National Ultrahigh-Field NMR Facility for Solids (Ottawa, Ontario), a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council Canada (NRC), and Bruker BioSpin and managed by the University of Ottawa (www.nmr900.ca). This work was supported by the National Research Council Canada, the Swedish Research Council (VR; contracts 2007-4967 and 2009-7551), and the Faculty of Natural Sciences at Stockholm University.

Abstract: ^{1}H NMR and optical microscopy have been used to study four solutes dissolved in samples of a binary mixture of 4-*n*-hexyloxy-4′-cyanobiphenyl (6OCB) and 4-*n*-octyloxy-4′-cyanobiphenyl (8OCB) that are close to the region of the phase diagram where the smectic-A (SmA) and re-entrant nematic (RN) phases exist. Optical microscopy clearly indicates that one of the four studied samples shows the phase sequence of isotropic–nematic–SmA–RN. The derived solute order parameters were interpreted by means of two Maier–Saupe mechanisms in conjunction with the Kobayashi–McMillan theory in the case of the SmA phase. The novel feature of this study is that the nematic potential is extrapolated from the nematic to the SmA phase based on concentrations of the 6OCB–8OCB mixtures. The derived smectic order parameters for each of the studied solutes clearly show a maximum absolute magnitude near the centre of the SmA temperature range. The different partitioning of these solutes in the binary mixture is also discussed.

Key words: re-entrant nematic, smectic, nematic, NMR, optical microscopy, phase transition, order parameter.

Résumé : On a fait appel à la RMN du ^{1}H et à la microscopie optique pour étudier quatre solutés dissous dans des échantillons d'un mélange binaire de 4-hexyloxy-4′-*o*-cyanobiphényle (6OCB) et de 4-octyloxy-4′-*o*-cyanobiphényle (8OCB) qui sont près de la région du diagramme de phase dans laquelle les phase smectique-A (SmA) et nématique réentrante (NR) existent. La microscopie optique indique clairement qu'un des quatre échantillons étudiés présente une séquence de phase d'isotrope, nématique, smectique A et nématique réentrante. On a interprété les d'ordre de solutés qui en ont été dérivés à l'aide de deux mécanismes de Maier–Saupe en relation avec la théorie de Kobayashi–McMillan dans le cas de la phase smectique A. La caractéristique nouvelle de cette étude réside dans le fait que le potentiel nématique est extrapolé de la phase nématique à la phase SmA en se basant sur les concentrations des mélanges 6OCB–8OCB. Les paramètres d'ordre smectique dérivés pour chacun des solutés étudiés montre clairement la présence d'une amplitude absolue maximale près du centre de la plage de température smectique A. On discute aussi des diverses répartitions de ces solutions dans le mélange binaire.

Mots-clés : nématique réentrante, smectique, nématique, RMN, microscopie optique, transition de phase, paramètre d'ordre.

Introduction

Molecular orientational ordering in the nematic (N) phase, and in addition positional ordering in the case of smectic phases, is important to the basic understanding of liquid crystals (LCs).[1–4] Mean-field theories have been quite successfully applied for the qualitative understanding of this molecular ordering. However, careful quantitative studies of solutes in the N phase have indicated the existence of multiple ordering mechanisms (see ref. 5 and refs. therein). We have extended the study of molecular ordering to the smectic phase where nematic ordering remains but a new smectic order parameter is born.[6–10] Here we have uncovered unusual behaviour — while linear extrapolation of the nematic ordering potential into the smectic phase works well for some solutes, it does not for others. In this paper we study a LC system with a N – smectic A – (re-entrant) N phase sequence[8] where the smectic range is variable, allowing us to investigate this unusual behaviour quantitatively.

To investigate the mechanisms responsible for the anisotropic ordering of molecules in condensed mesophases, it is necessary to write down the relevant intermolecular potential(s). Though there are numerous different types of shape anisotropy in the

constituent molecules forming LCs, only the simplest kind, the rodlike mesogen, will be considered here. Even so, the molecules are usually composed of a rigid aromatic core, flanked by one or two flexible hydrocarbon chains. To a first approximation, it suffices to treat them as axially symmetric rods as is done in the Maier–Saupe (MS) nematic mean-field potential,[11,12] in which the dispersive energy is written in terms of a second Legendre polynomial $P_2(\cos\theta_L)$ with θ_L being the angle between the rod long axis and the nematic director **n**. In the smectic-A (SmA) phase, there is translational ordering as molecules tend to form layers. The director is along the layer normal. To extend the MS mean-field potential to the SmA phase, Kobayashi–McMillan (KM) theory[13–15] adds additional terms to account for a one-dimensional density wave in the direction of the layer normal, and for a coupling between the layering and the orientational potential. The MS–KM SmA potential contains, therefore, the two interaction prefactors τ_L' and κ_L' for the positional ordering and for its coupling to the orientational ordering, respectively. It is only in recent years that attempts have been made to determine these prefactors, as reported in the literature.[6–10,16,17]

Liquid crystals exhibiting smectic phases are invariably composed of large and flexible molecules that impose complexity in their ability to probe the intermolecular potential. One very successful approach to studying the anisotropic potential is to use small solute molecules as probes of the anisotropic environment. The size and shape of rigid solutes can be chosen to optimize their sensitivity to the orientational and (or) positional order. This has been most successful in conjunction with nuclear magnetic resonance (NMR) spectroscopy studies of the solutes.[3,18] In particular, in 2004 it was reported that the temperature dependence of the asymmetry in the orientational order parameters of solutes showed a distinct change on passing from the N to the SmA phase of a cyanobiphenyl.[6] The MS–KM theoretical approach was used to rationalize the dipolar couplings (or order parameters) of several solutes.

The experimental dipolar couplings of a solute can be used to obtain the independent second-rank order parameters, and since the number of independent order parameters equals the number of unknowns in the nematic potential, it is impossible to isolate the nematic and smectic mean-field potentials simply based on the available orientational order parameters. Thus, at a given temperature in the SmA phase, the number of unknowns in the SmA interaction Hamiltonian will always be two greater than the number of experimentally determined orientational order parameters, these unknowns being the nematic terms plus the two smectic prefactors. Crucial assumptions and approximations have to be made to make the problem solvable in terms of the smectic prefactors in the solute's smectic potential. To extract information on the KM potential from NMR experiments on the SmA phase, some details of the nematic potential in this phase must be known.

The effect of the smectic phase is clearly observed as a discontinuity in the slope at the N–SmA phase transition in plots of solute order parameter asymmetry versus quantities such as temperature, order parameter, or mean-field energy parameter. In the first attempts to utilize this observation it was assumed that the temperature behaviour of the asymmetry b_s of a molecular property tensor $\boldsymbol{\beta}_s$ for each solute in the N phase could be extrapolated to lower temperatures where the sample is in the SmA phase. In ref. 6 linear extrapolation of b_s vs $\beta_{s,xx}$ was used for two different solutes. Later, it was noted that such a linear procedure is not general, and could not, for example, be applied to the solute *ortho*-dichlorobenzene (odcb),[7] because for that solute the nematic points for b_s versus $\beta_{s,xx}$ are curved.

In an attempt to address the curvature problem, a binary mixture of 4-*n*-hexyloxy-4′-cyanobiphenyl (6OCB) – 4-*n*-octyloxy-4′-cyanobiphenyl (8OCB) was chosen because of its ability to form a re-entrant nematic (RN) phase at temperatures below the SmA phase. The hope was to see if the contiguity of behaviour between the two N phases would inform us about the validity of the extrapolation. A polynomial curve that went through all nematic points, including those in the RN phase, was drawn for odcb. When a reasonable value of ~0.3 is chosen for solute smectic–orientational order coupling κ', a successful global fit to all the temperatures can be carried out with the MS–KM potential.[8]

All these studies involved progressively improved strategies to extract meaningful values for solute smectic order parameters τ. To gauge the goodness of various approximations, let us consider the smectic order parameter values of *para*-dichlorobenzene (pdcb) (τ_{pdcb}) in the middle of the SmA phase in 8OCB and the 6OCB–8OCB mixture: –0.29,[6] –0.25,[7] and –0.35.[8] It is interesting to see that for this particular solute, the various τs are comparable, indicating the suitability of the KM mean-field potential at the molecular level.

However, there is a major difficulty with the studies above. If only one MS mechanism is responsible for the nematic potential, then the solute property anisotropy (b_s) should not show any temperature dependence. Thus, the observed temperature dependence of b_s indicates that two or more ordering mechanisms are operating in the N phase. In this regard, we note a recent study of eight solutes in seven N solvents (including a "magic mixture" for which there is evidence that solute orientational order arises from a single mechanism that involves only short-range size and shape interactions) demonstrated that solute orientational order can be rationalized to an excellent extent (agreement between experimental and calculated orientational order parameters to 5% and better) with the idea of two independent MS potentials, the so-called MSMS potential. In this potential the traceless β_{ii} ($i = x, y, z$) are solute properties that are taken to be different for the two mechanisms, but independent of temperature. The first mechanism is taken to be associated with short-range size and shape interactions (which is then the only mechanism in the magic mixture), and the second mechanism is taken to account for additional interactions in other N samples.[5]

The success of the MSMS approach in the N phase prompted us to extend its application over a wider nematic temperature range, and also to apply it to the SmA phase of two LCs.[9,10] The molecular β_{ii} properties for the two MS mechanisms were determined for each solute from joint fits to order parameters of these solutes in the nematic LCs *p*-ethoxybenzylidene-*p*′-*n*-butylaniline (EBBA), Merck ZLI-1132 (1132), a magic mixture of 55 wt% 1132 and 45 wt% EBBA, and at three temperatures in each of 4-*n*-octyl-4′-cyanobiphenyl (8CB) and 8OCB. These β_{ii} are then taken as molecular constants, and the MSMS potential was used in

conjunction with the order parameters of 11 or 12 solutes to give $G_{L,ZZ}^{MS_1} \equiv G_1$ and $G_{L,ZZ}^{MS_2} \equiv G_2$ as the two fitting parameters for the nematic potential at each temperature studied in the N phase. It was then assumed that a plot of G_1 vs G_2, which is essentially linear in the N phase, can be extrapolated into the SmA phase, thus providing a description of the nematic potential in the SmA phase. In the SmA phase, a combined MSMS–KM theory is then applied to gain information on the solute prefactors τ_s', κ_1', and κ_2'. Note that the κ_i' account for coupling to the two nematic potentials and are LC properties.

This latest work tries to address two problems associated with earlier work: the need to incorporate two nematic mechanisms, and the extrapolation involving nonlinear results. However, extrapolation (of G_1) is still employed. In addition, to obtain a successful fit to all solute orientational order parameters obtained in the SmA phase, restrictions (upper limits) had to be placed on some τ_s' values.

For all the studies above, κ' (or κ_1') were chosen to be positive; the signs of the prefactors κ' and τ_s' are correlated in the smectic potential (a change of sign of all prefactors yields exactly the same result). Choosing κ' (or κ_1') > 0 is consistent with mechanism 1 being taken to be associated with size and shape interactions[5] that might be expected to lead to greater orientational order in the centre of the smectic layer. With the MSMS–KM approach, τ_{pdcb} in the middle of the SmA phase of 8OCB is ca. –0.18,[9,10] marginally lower than the values reported in the earlier studies.

The ability to detect, directly or indirectly, the location of solutes in layered phases is of increasing importance both because of the accessibility to this kind of information in large-scale simulations, as well as its biophysical relevance. In an attempt to better define the nematic potential in the SmA phase without the limitation imposed by extrapolation of the temperature dependence of nematic properties into the SmA phase, we again rely on the use of binary mixtures of 6OCB and 8OCB.[8] To this end, we have examined the NMR spectra of five solutes (1,3,5-trichlorobenzene (tcb), pdcb, odcb, *para*-bromobenzonitrile (pbbn), and phenylacetylene (phac)) dissolved in the same NMR tube for four different binary mixtures that are all close to the region in the phase diagram where a RN phase is observed; only one of the samples exhibits a stable SmA phase in microscopy studies. Although we still need to extrapolate nematic properties, it is now done as a function of small changes in LC composition, and no longer as a function of temperature.

Theory

For the solvent, the MS potential is given by:

$$[1] \qquad H_{N,L}(\theta_L) = -\nu_L S_L \left[\frac{3}{2}\cos^2(\theta_L) - \frac{1}{2}\right]$$

where S_L is the solvent order parameter, and ν_L governs the strength of the intermolecular interaction. The corresponding potential for a solute s (of symmetry sufficient that it has a maximum of two independent second-rank orientational order parameters) in an axially symmetric LC mean field can be written as

$$[2] \qquad H_{N,Ls}(\Omega_s) = -\frac{3}{4}G_{L,ZZ}\sum_{\gamma}\sum_{\delta}\cos(\theta_{s,\gamma})\cos(\theta_{s,\delta})\beta_{s,\gamma\delta}$$
$$= -\frac{3}{4}G_{L,ZZ}\beta_{s,zz}\left\{\left[\frac{3}{2}\cos^2(\theta_s) - \frac{1}{2}\right] + \frac{b_s}{2}\sin^2(\theta_s)\cos(2\phi_s)\right\}$$

where $\theta_{s,\gamma}$ is the angle between the molecular γ axis with respect to the nematic mean-field direction, $G_{L,ZZ}$ is proportional to S_L with Z being the mean-field symmetry axis, and θ_s and ϕ_s are the polar and azimuthal angles of the mean-field direction in the solute (xyz) axis system. Thus, $G_{L,ZZ}$ is the mean-field potential of the solvent, taken to be a purely LC property, and the tensor $\boldsymbol{\beta}_s$ is taken to be a purely molecular property. The asymmetry in this solute energy parameter $\beta_{s,ii}$ is given by

$$[3] \qquad b_s = \frac{\beta_{s,xx} - \beta_{s,yy}}{\beta_{s,zz}}$$

There are thus two unknown parameters ($G_{L,ZZ}$, $\beta_{s,zz}$, and b_s) needed to define the nematic potential. Solutes of lower symmetry may have up to five independent second-rank order parameters (or two principal order parameters plus three diagonalization angles): the number of unknowns in the potential equals the number of independent order parameters. Up to now only solutes with at most two unknown order parameters have been used in investigations of SmA phases.

The nematic order parameter S_L for the N solvent L can be evaluated using the MS potential $H_{N,L}(\theta_L)$ of eq. [1]:

$$[4] \qquad S_L = \frac{\int \sin(\theta_L)\mathrm{d}\theta_L\left[\frac{3}{2}\cos^2(\theta_L) - \frac{1}{2}\right]e^{-H_{N,L}(\theta_L)/k_BT}}{\int \sin(\theta_L)\mathrm{d}\theta_L e^{-H_{N,L}(\theta_L)/k_BT}}$$

Given the corresponding MS potential $H_{N,Ls}(\Omega_s)$ of eq. [2] for a solute in a LC, the $\gamma\delta$ components of the solute order parameters are given by

$$[5] \qquad S_{s,\gamma\delta} = \frac{\int \mathrm{d}\Omega_s\left[\frac{3}{2}\cos(\theta_{s,\gamma})\cos(\theta_{s,\delta}) - \frac{1}{2}\right]e^{-H_{N,Ls}(\Omega_s)/k_BT}}{\int \mathrm{d}\Omega_s e^{-H_{N,Ls}(\Omega_s)/k_BT}}$$

If we now assume that the nematic potential consists of two independent MS terms, the MSMS case, then the nematic potential for solute s and LC L is

$$[6] \qquad H_{N,Ls}(\Omega_s) = -\frac{3}{4}\sum_{i=1}^{2} G_{L,ZZ}(i)\beta_{s,zz}(i) \times \left\{\left[\frac{3}{2}\cos^2(\theta_s) - \frac{1}{2}\right] + \frac{b_s(i)}{2}\sin^2(\theta_s)\cos(2\phi_s)\right\}$$

$$[7] \qquad H_{N,Ls}(\Omega_s) = H_{MS_1} + H_{MS_2}$$

where $G_{L,ZZ}(1) \equiv G_1$ and $G_{L,ZZ}(2) \equiv G_2$ as used in the Introduction and $b_s(i)$ is still the solute energy asymmetry expressed according to eq. [3] with index i to distinguish the two different LC/solute interactions. $G_{L,ZZ}(i)\beta_{s,zz}(i)$ could be the short-range size and shape effects or longer range

interactions such as that involving the LC average electric field gradient interacting with the solute quadrupole or the solute polarizability with the mean square electric field. We will use, in this study, the Hamiltonian of eq. [6] to evaluate solute order parameters $S_{s,\gamma\gamma}$ in the N phase based on eq. [5].

Following the success of the MSMS–KM theory in treating solutes in the SmA phases of 8CB and 8OCB, the smectic interaction potential is written as before,[9,10]

$$[8]\quad H_{A,Ls}(\Omega_s, Z) = H_{\mathrm{MS}_1}\left[1 + \kappa_1' \cos\left(\frac{2\pi Z}{d}\right)\right] + H_{\mathrm{MS}_2}\left[1 + \kappa_2' \cos\left(\frac{2\pi Z}{d}\right)\right] - \tau_s' \cos\left(\frac{2\pi Z}{d}\right) = H_N^{\mathrm{mod}}(1) + H_N^{\mathrm{mod}}(2) - \tau_s' \cos\left(\frac{2\pi Z}{d}\right)$$

where the prefactors κ_1' and κ_2' denote coupling between the nematic potential and the density wave for the two MS mechanisms (each κ' can in principle be temperature dependent), whereas the solute smectic prefactor $\tau_s' \equiv \tau'$ is the coupling strength for a solute to feel the smectic layering of the solvent molecules. The layer width is d and Z ($Z = 0$ in the centre of a layer) is along the layer normal. The observed orientational order parameters can be calculated based on this potential by the following expression,

$$[9]\quad S_{s,\gamma\gamma} = \frac{\int \mathrm{d}\Omega_s \int_0^d \left[\frac{3}{2}\cos^2(\theta_{s,\gamma}) - \frac{1}{2}\right] e^{-H_{A,Ls}(\Omega_s,Z)/k_\mathrm{B}T}\mathrm{d}Z}{\int \mathrm{d}\Omega_s \int_0^d e^{-H_{A,Ls}(\Omega_s,Z)/k_\mathrm{B}T}\mathrm{d}Z}$$

This would allow us to determine the prefactors in the smectic potential provided that one has prior knowledge of H_{MS_1} and H_{MS_2} at the temperature of interest in the SmA phase. Fortunately the $\beta_{s,\gamma\gamma}(1)$ and $\beta_{s,\gamma\gamma}(2)$ for the solutes studied have been carefully determined from studies of these solutes in several LCs including 8OCB[10] and can be taken as constants for the current binary mixtures of 8OCB–6OCB. However, the β values alone are not sufficient to give the nematic potential: one also must know the values of G_1 and G_2 at the desired temperature in the SmA phase. In this earlier study it was assumed that a plot of G_1 vs G_2 could be extrapolated from the N (where it is linear) into the SmA phase. In the present case, G_1 and G_2 have been obtained experimentally (vide infra).

Once the full smectic potential $H_{A,Ls}(\Omega_s,Z)$ is known, τ can be easily evaluated according to

$$[10]\quad \tau_s \equiv \tau = \frac{\int \mathrm{d}\Omega_s \int_0^d \cos\left(\frac{2\pi Z}{d}\right) e^{-H_{A,Ls}(\Omega_s,Z)/k_\mathrm{B}T}\mathrm{d}Z}{\int \mathrm{d}\Omega_s \int_0^d e^{-H_{A,Ls}(\Omega_s,Z)/k_\mathrm{B}T}\mathrm{d}Z}$$

The mixed order parameters (for κ coupling) can in principle be calculated for each solute, but there are many of them and they seem not to give any additional insight like the translational order parameter τ.

Experimental

The solutes odcb, phac, pdcb, pbbn, and tcb were dissolved into LCs 8OCB and 6OCB. Enough of each solute was mixed thoroughly in the isotropic phase to obtain 1 mol% per solute and a total of 4 g of each LC was prepared in this way. Both LCs were degassed and then kept in the N phase with the use of a warm water bath. To span the two-component 8OCB–6OCB phase diagram a series of samples were made with varying relative weight fraction ($w_{6\mathrm{OCB}}$) of the two LCs. In this way the solute concentrations were as equal as possible in all samples studied. Enough of each sample was made so that ^{1}H NMR and microscopy could be performed on the same sample. For NMR studies, each sample was thoroughly mixed, and part placed into a 5 mm o.d. NMR tube and the rest into a glass ampule, both being sealed under nitrogen. Ten samples were made of differing $w_{6\mathrm{OCB}}$. The compositions of those investigated were $w_{6\mathrm{OCB}} = 0.270$ (sample 4), 0.297 (sample 6), 0.301 (sample 7), and 0.318 (sample 8). The phase-transition sequence in each sample was independently monitored via cross-polarizer optical microscopy.

For microscopy studies, samples were prepared between No. 1 cover slips, using strips of No. 0 cover slips (~100 μm) as spacers. Samples were sealed using Norland epoxy NOA 68 and cured under a UV lamp. Samples for microscopy experiments were heated to the N phase and placed atop an aluminium baseplate with a circular window and inside an Instek HCS 61 hot stage, which was mounted on a Nikon Eclipse 80-i upright microscope equipped with crossable polarizing filters. White light transmission cross-polarizer micrographs were obtained using a Qimaging QICAM Fast 1394 12-bit monochrome camera. The hot-stage temperature was changed in a controlled slow ramp (2 °C/min), and images were acquired and saved to disk at 10 s intervals.

Samples for NMR experiments were heated to the N phase, mixed and then placed into a Bruker Avance 400 MHz NMR spectrometer magnet in which the director was oriented by the magnetic field along the field direction. With the temperature controlled by the Bruker air-flow system, spectra were acquired in 0.5 and 1 K steps throughout both N and SmA phases. The spectral parameters (dipolar couplings (D_{ij}) and chemical shifts (ω_i)) of the solutes were then obtained simultaneously and automatically with the use of a covariance matrix adaptation evolution strategy (CMA-ES)[9,19–21] for each LC mixture at each temperature. Figure 1 shows the NMR spectra of solutes in sample 4 at 339.5 K. The upper plot shows the experimental proton NMR spectrum, whereas the lower plot is a sum of the calculated spectra of the studied solutes. As seen from these, the calculated spectrum agrees very well with the experimental spectrum obtained at 400 MHz. The dipolar couplings obtained from the analysis, in conjunction with the solute geometries,[22–25] were then used to determine the solute order parameters, which are given in the Supplementary data. No corrections were made for molecular vibrations and other nonrigid effects.

Results and discussion

First, the phase sequence of the samples was verified by optical microscopy. Characterization of the phase-transition sequence by optical microscopy utilizes the dramatic differences in defect textures in the N and smectic phases. Sample 4 was the only one to exhibit an unambiguous I–N–SmA–RN phase sequence. Figure 2 shows cross-polarizer optical micrographs of sample 4 at different temperatures corresponding to N,

Fig. 1. [1]H NMR spectra of solutes in sample 4 at 339.5 K. The upper plot is of the experimental 400 MHz NMR spectrum and the bottom plot is a sum of the calculated spectra. The calculated spectra of the solutes from top to bottom are *ortho*-dichlorobenzene (odcb), phenylacetylene (phac), *para*-dichlorobenzene (pdcb), *para*-bromobenzonitrile (pbbn), and 1,3,5-trichlorobenzene (tcb), with the molecule-fixed coordinate system being found in the top left of the figure.

SmA, and RN phases. Note that there is no detectable difference between the N and the RN phases, but the defect textures in the SmA phase are very distinct. Sample 6 was not observed to form a stable smectic phase, but exhibited clear signs of smectic fluctuations over a 3 °C temperature range. It is quite feasible that these fluctuations are present because of proximity to the critical point in the phase diagram beyond which the SmA phase no longer exists. Sample 8 showed no evidence of a smectic phase.

The set of solute order parameters obtained for each NMR experiment in both the N and SmA phases were fitted in a minimization to the MSMS nematic potential of eq. [6] to obtain G_1 and G_2 values (results not shown). In these fits the solute β parameters are taken from ref. 10. For samples that are clearly in the N phase, the two largest in absolute value order parameters for each solute recalculated from the G fit parameters agree with the experimental ones to better than 5%, except for S_{yy} (odcb) where the deviation is ~8% at lower temperatures. This excellent agreement confirms once again the validity of the MSMS potential[5] for the N phase, and that the solute β parameters are valid in the 6OCB–8OCB mixtures. However, the effect of the SmA phase on the orientational order parameters is quite small, and here we need to account for the nematic potential in as accurate a manner as possible; the 5% agreement achieved by the MSMS potential is not nearly sufficient for this purpose.

Deviations from the MSMS potential arise from a possible temperature dependence of the solute β_{ii} parameters and (or) deficiencies of the model in terms of different solutes experiencing different LC mean fields G as the temperature varies. We keep the main result of the MSMS potential, that two different MS mechanisms are sufficient to characterize the nematic potential; we arbitrarily choose to use the β_{ii} values determined earlier[10] and to obtain an exact fit to the order parameters by adjusting the G values separately for each solute in each sample at each temperature. This is an arbitrary choice, but as only the products $G\beta$ contribute to the potential (meaning that it is impossible to separate unambiguously G from β), making G values a function of both solute and solvent to get an exact fit to all solute order parameters in the N phase is as valid a choice as any. Hence, we do not need to worry about the precise nature of the $G\beta$ products involved with the MSMS potential.

Earlier studies attempted to characterize the nematic potential in the SmA phase by extrapolation of G parameters from the N into the SmA phase.[9,10] Here we use a different approach — we explore the possibility of estimating the nematic potential in the SmA phase by extrapolation as a

Fig. 2. Characterization of phase transition by optical microscopy utilizes the dramatic differences in defect textures in the nematic (N) and smectic (SmA) phases. Snapshots (at temperatures T = 317.6, 316.7, 311.8, 296.9, 292.0, and 283.7 K, respectively) from the complete time series (included as a movie in Supplementary data) show the N phase, N–SmA interface, SmA phase, SmA–RN interface, RN phase, and the RN–crystal (RN–K) interface.

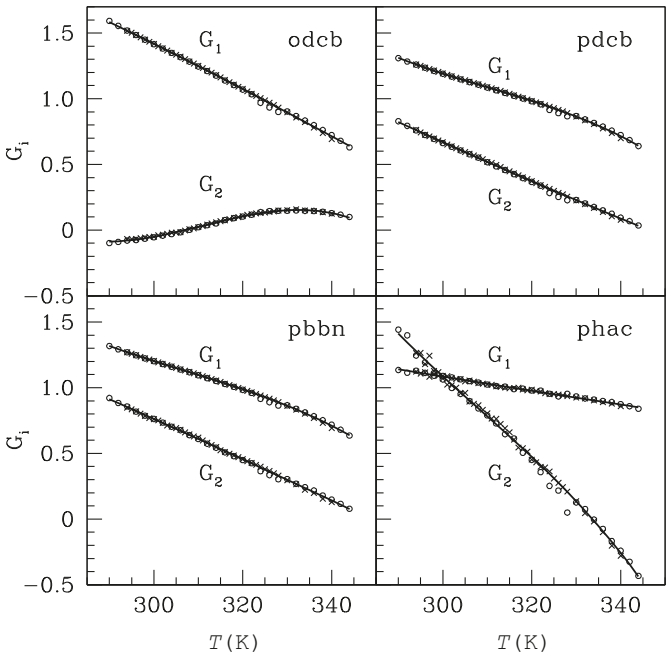
For personal use only.

function of LC composition (a different extrapolation for each temperature). We use the two order parameters for each solute s (except tcb, which has a single order parameter and therefore is not used because one order parameter cannot be used to determine two G values) and the MSMS nematic potential (eq. [6]) with the β_{ii} parameters determined earlier[10] to find values for the nematic potential parameters G_1 and G_2 for each solute in each experiment (including those for samples that show the SmA phase). The results for samples 7 (w_{60CB} = 0.301) and 8 (w_{60CB} = 0.318) (which from microscopy are clearly in the N phase at all temperatures investigated) are presented in Fig. 3. Even though w_{60CB} is different for these two samples, the G parameters are to an excellent degree equal. This is taken as affirmation that the nematic G parameters can be taken to be constant over the small concentration range (w_{60CB} = 0.270 for sample 4 to w_{60CB} = 0.318 for sample 8) spanned by the samples studied here. In other words, as samples 7 and 8 (which do not exhibit a SmA phase) give essentially equal G values for a given temperature, we assume that these values can be used as the nematic G values for the same temperatures in samples 4 and 6. To facilitate this idea, we do a polynomial fit to the G vs T values for samples 7 and 8. The lines drawn through the points in Fig. 3 are these polynomial fits.

Figure 4 presents the fitting parameters G_1 and G_2 vs T obtained by fitting the nematic potential only to order parameters obtained for solutes in samples 4 and 6, as well as the polynomial fit lines obtained from samples 7 and 8. The smectic effects are clearly seen at lower temperatures in samples 4 and 6, particularly between 296.9 and 316.7 K in sample 4 (the temperature range in which the SmA phase is observed with microscopy) where the points deviate dramatically from the lines. The most notable effects are noticed for the odcb and phac G_2 values in sample 4, but are observable elsewhere with close inspection. The broken lines in this (and other) graphs denote either the temperature range in which the SmA phase was observed with microscopy (sample 4) or a range close to the SmA phase region (sample 6). At higher temperatures the polynomials go through the points, justifying the transfer of nematic potential parameters among samples.

Fig. 3. G_1 and G_2 derived with the nematic potential (eq. [6]) only in samples 7 and 8. Lines denote polynomial fits to the G values. Sample 7 (○) and sample 8 (X).



Hence, we take deviations from the lines as being caused by the smectic part of the interaction Hamiltonian. Smaller deviations are observed for sample 6 for which no smectic

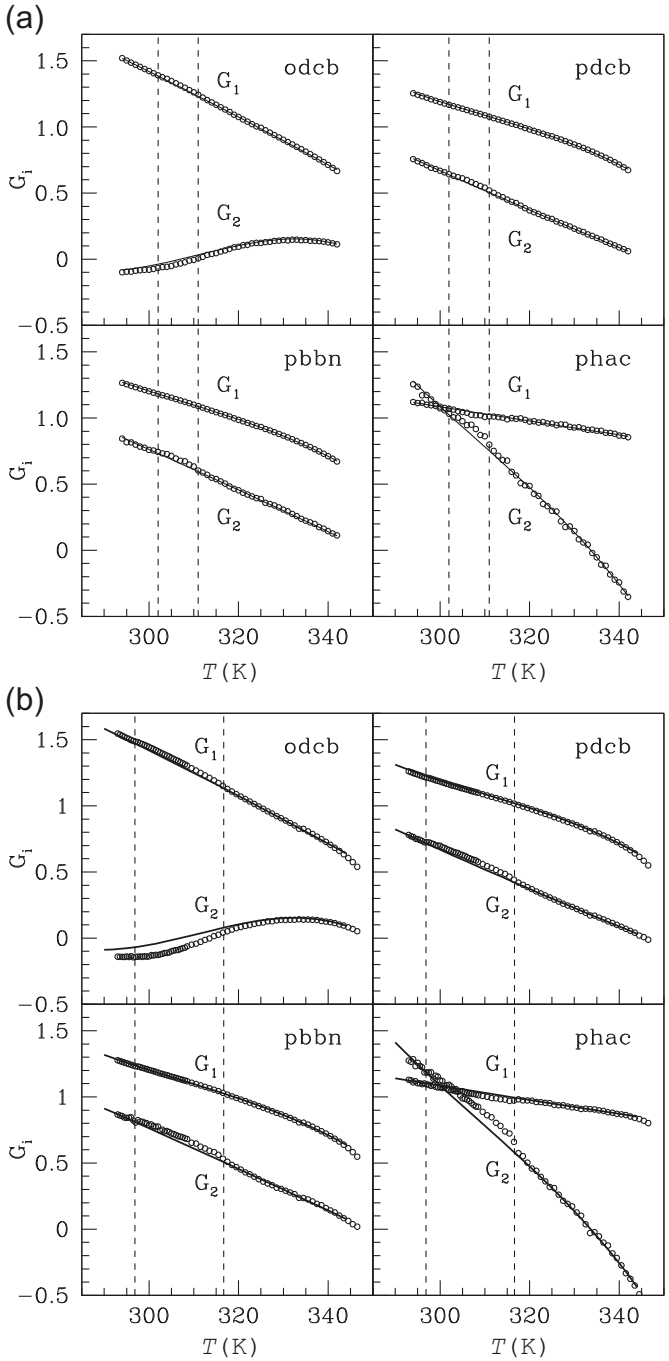
Fig. 4. The points are G_1 and G_2 from fits of the nematic potential only (eq. [6]) to orientational order parameters for sample 6 (*a*) and sample 4 (*b*) vs *T*. The solid lines are polynomial fits to G_1 and G_2 values determined for fits of the nematic potential to samples 7 and 8 (Fig. 3).



phase is observed in the microscopy experiments; however, "critical" fluctuations are observed in the region in the phase diagram that is near the smectic phase.

Thus, to fit the solute order parameters for each experiment of samples 4 and 6 to the SmA potential, the nematic G_1 and G_2 parameters in the total potential for the SmA phase (eq. [8]) are taken from the polynomial fit lines to the pure N samples 7 and 8, and the values of the smectic parameters κ_1', κ_2', τ'_{odcb}, τ'_{pdcb}, τ'_{pbbn}, and τ'_{phac} are optimized for best fits at each temperature. The κ_i' values obtained are given in Fig. 5 and the τ' values are reported in the Supplementary data. As discussed earlier, κ_1' is taken to be positive, consistent with higher shape-dependent ordering in the middle of a smectic layer. As expected, larger effects are noticed for sample 4. The phase transitions can also be noticed in Fig. 5. Values obtained from fits in the N phase should be zero: while the fitted numbers are not zero, they are associated with rather large errors, indicating the absence of the SmA phase.

The τ obtained for each solute in each experiment are given in Fig. 6. The sign of these parameters generally agrees with those determined from the earlier studies that relied on extrapolation of nematic parameters from the higher temperature N phase. It is encouraging that the essence of the analysis of the effects of a smectic phase on orientational order parameters was correct, even with the inherent dangers involved with the necessity of an extrapolation with temperature. Here we also do an extrapolation, i.e., we assume that the nematic $G\beta$ parameters are constant with sample composition.

The earlier study[10] that used the MSMS–KM theory with solutes dissolved in 8CB and 8OCB ran into difficulties with determination of τ, and in some cases limiting values had to be placed on some τ' values. The present approach does not require such restrictions. Here each SmA experiment is analysed by itself (given the nematic parameters). It is assumed that all solutes have the same κ' values, i.e., that κ' is a LC property, and that each solute has its own smectic prefactor τ'.

As is seen in Fig. 5, κ_1' and κ_2' have opposite sign, this being the same result observed in the earlier study that used the MSMS–KM approach.[10] The general trends in the results for sample 6 are quite similar to those for sample 4, but κ' absolute values are smaller and errors are larger; these observations are consistent with sample 4 exhibiting a SmA phase and sample 6 exhibiting only pretransitional effects. We note that κ_1' peaks in the centre of the SmA region, meaning that the variation in the nematic potential is maximum when deepest into the smectic phase, as might be expected. The values are not exactly zero in the N regions, especially in the RN region, indicating either a slight breakdown of the assumption that the nematic *G* parameters are identical in all samples or the existence of a correlation between κ' and τ' in the KM smectic potential. We recall that the β_{ii} parameters used in the analysis are based on mechanism 1 being associated with short-range size and shape interactions. The relatively small ($\approx$0.3) values of κ_1' are consistent with this notion, as this value means a change of roughly a factor of 2 when a solute goes from the rather rigid region in the centre of a smectic layer (large nematic potential) to the rather disordered region between layers where the nematic potential is expected to be reduced.

The N–SmA phase transitions are clear in the plot of κ_2' vs *T*. It is interesting that κ_2' becomes increasingly more negative with increasing *T* within the SmA phase. Its absolute value exceeds 1, which means there is a change in sign of the nematic potential as solutes go through a smectic layer. This same change of sign was observed in the earlier study

For personal use only.

Fig. 5. κ_1', κ_2' (including errors) vs T for sample 4 (left panel) and for sample 6 (right panel). Vertical lines indicate phase transitions as measured by microscopy. The smectic-A (SmA) phase is clearly indicated by the regions of nonzero κ' values with smaller errors.

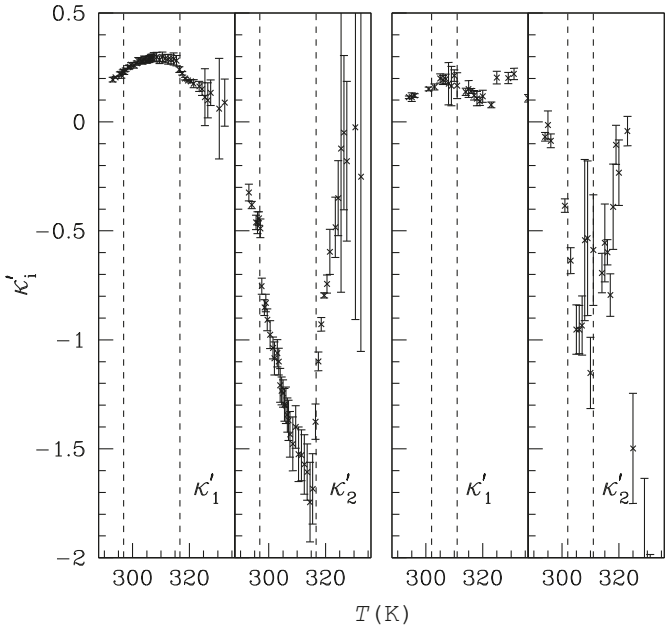

Fig. 6. τ order parameters (including errors) vs T for samples 6 (*a*) and 4 (*b*). See text for details on nonzero τ in nematic phases.

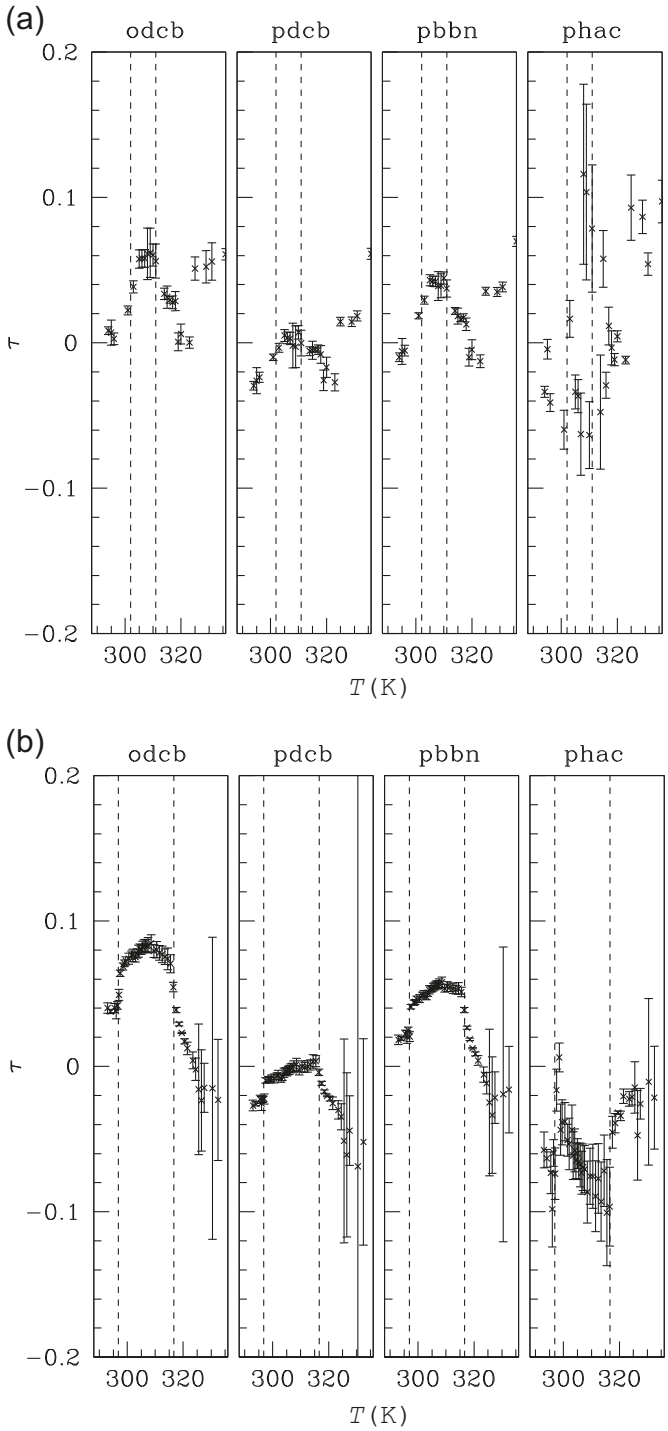

of solutes in 8CB and 8OCB,[10] where it was rationalized in terms of the angle dependence of the long-range part of the solute–solvent intermolecular interaction as a solute passes along the long axis of a solvent molecule. Possibilities for the anisotropic interactions include those involving solute and solvent quadrupoles, polarizabilities, etc. This second mechanism shows a much stronger temperature dependence than does the first (size and shape) mechanism. However, the absolute values of both G_2 and $\beta(2)$ are in general smaller than those for mechanism 1, and thus the first mechanism dominates the ordering potential. Thus, the large temperature dependence of κ_2' may well be associated with possible changes in the molecular packing. It could be interesting to explore simulations of solutes in the SmA phase (where, for example, interactions between solute and solvent quadrupoles are included[26]) to shed light on this interesting result and its temperature dependence.

The τ order parameters give information on the partitioning of a solute within the smectic layer. With our chosen sign convention (that short-range interactions lead to a stronger nematic potential within the smectic layer), a positive τ implies a preference for the solute to partition within the layer, and a negative sign implies partitioning between layers. The calculated τ values (Fig. 6) for both samples 4 and 6 are quite similar, but those for sample 4 have lower error and show less scatter. The values peak in the middle of the SmA phase, and their relatively sudden changes in values agree with the N–SmA phase transitions. The values for phac have more error than those for the other solutes. The τ values, especially in sample 4, indicate that odcb and pbbn prefer to sit within the layers and phac between the layers. The τ_{pdcb} values are interesting in that they are very close to zero deep in the SmA phase, implying an even distribution, and tend to be negative when near the N phase, thereby suggesting its likelihood to be in between layers. It should be noted that earlier studies have found pdcb to have negative τ as mentioned above when one (two) MS mechanism(s) was invoked to describe the nematic potential.[8,10]

Conclusion

NMR results were obtained for four samples of binary mixtures with compositions very close to the region in the phase diagram where a RN phase exists at low temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

The microscopy experiments clearly show that one sample (sample 4) on cooling goes from an isotropic to a N to a SmA to a RN phase. Microscopy on sample 6 gives fluctuations in the N phase as the temperature passes close to the region where the SmA phase exists, but sample 6 is not observed to form a stable SmA phase. Evidence for smectic fluctuations in Sample 7 was not conclusive, whereas sample 8 showed no evidence whatsoever of a smectic phase.

Because for a given temperature the G parameters that describe the nematic potential are essentially identical for each solute in all four samples when they are in the N phase, we make the reasonable ansatz that in the SmA phase regions of samples 4 and 6 the nematic potential can be taken equal to that in samples 7 and 8 at the same temperature. We then analyzed samples that are in the SmA phase to extract the smectic prefactors κ_1' and κ_2' for the LC and a τ' for each solute in the smectic potential based on the KM theory of SmA phases. The values obtained are then used to calculate the smectic order parameter τ for each solute. The numbers obtained agree in general with those found in earlier studies (except odcb, which was arbitrarily set to 0.8 in the earlier studies[10]) that involved extrapolation of nematic potential parameters as a function of temperature into the SmA phase, a procedure fraught with potential error.

In the present study we gauge an interaction Hamiltonian to be incorrect in the N phase(s) (i.e., a Hamiltonian that includes the KM potential) by getting nonzero κ' and τ' values with large errors, as can be observed in Figs. 5 and 6. As a consequence, the corresponding solute smectic order parameters τ calculated from τ' values in the N phase should be taken with a grain of salt. In fact, the τ parameters should strictly vanish; the same is true for all the smectic prefactors. To summarize, the present study of binary 6OCB–8OCB mixtures that combines NMR and optical microscopy has clearly put the MSMS nematic potential in conjunction with the KM smectic potential on a firm ground for the SmA phase.

Supplementary data

Supplementary data are available with the article through the journal Web site (www.nrcresearchpress.com).

Abstract: Dynein light chain LC8 is the smallest subunit of the dynein motor complex and has been shown to play important roles in both dynein-dependent and dynein-independent physiological functions via its interaction with a number of its binding partners. It has also been linked to pathogenesis including roles in viral infections and tumorigenesis. Structural information for LC8-target proteins is critical to understanding the underlying function of LC8 in these complexes. However, some LC8-target interactions are not amenable to structural characterization by conventional structural biology techniques owing to their large size, low solubility, and crystallization difficulties. Here, we report magic-angle spinning (MAS) NMR studies of the homodimeric apo-LC8 protein as a first effort in addressing more complex, multi-partner, LC8-based protein assemblies. We have established site-specific backbone and side-chain resonance assignments for the majority of the residues of LC8, and show TALOS+-predicted torsion angles ϕ and ψ in close agreement with most residues in the published LC8 crystal structure. Data obtained through these studies will provide the first step toward using MAS NMR to examine the LC8 structure, which will eventually be used to investigate protein–protein interactions in larger systems that cannot be determined by conventional structural studies.

Key words: solid-state NMR, magic-angle spinning, MAS, dynein, LC8.

Résumé : La chaîne légère de dynéine, LC8, est la sous unité la plus petite du complexe moteur de la dynéine et il a été démontré qu'elle joue des rôles importants dans les fonctions physiologiques tant dépendantes qu'indépendantes de la dynéine par le biais de son interaction avec un certain nombre de ses partenaires de fixation. Elle a aussi été reliée à des rôles de tumorigénèse et de pathogénèse dans les infections virales. De l'information sur la structure des protéines cibles de la LC8 est critique pour comprendre la fonction sous-jacente de la LC8 dans ces complexes. Toutefois, en raison de leur grande taille, de leur faible solubilité et de difficultés de cristallisation, certaines interactions entre la LC8 et ses cibles ne peuvent pas être amenées à une caractérisation structurelle par les techniques conventionnelles de la biologie. Dans ce travail, comme premier effort en vue de comprendre les assemblages de protéines complexes, à base de LC8 avec plusieurs partenaires, on rapporte des études de RMN du ^{13}C à l'état solide dans le mode de la rotation à l'angle magique (RAM) faites sur la protéine homodimère apo-LC8. On a établi les attributions des résonances du squelette et de la chaîne latérale spécifique au site pour la majorité des résidus de la LC8 et on montre que les valeurs prédites par TALOS+ pour les angles de torsion ϕ et ψ sont en bon accord avec celles publiées pour la plupart des résidus dans des structures cristallines de la LC8. Les données obtenues par le biais de ces études serviront de premier pas dans l'utilisation de la RMN en mode RAM pour examiner la structure de la LC8 et qui pourra éventuellement être utilisée pour étudier les interactions protéine–protéine dans des systèmes plus gros qui ne peuvent pas être déterminées par des études structurales conventionnelles.

Mots-clés : RMN à l'état solide, rotation à l'angle magique (RAM), dynéine, LC8.

[Traduit par la Rédaction]

Introduction

Dynein light chain LC8 (also named DLC8, PIN, DNLC1/2, and DYNLL1/2) is an integral subunit of cytoplasmic dynein, a multisubunit microtubule-based retrograde motor.[1,2] LC8 is also found in many other protein complexes such as flagellar and axonemal dynein,[3–5] myosin-Va,[6] and nuclear pore complexes (NPCs).[7] Through interactions with diverse cellular protein partners and viral proteins, LC8 plays important roles in a broad range of dynein-dependent as well as dynein-independent cellular functions and has been implicated in viral infections and cancer progression.[8,9] The repertoire

Fig. 1. Amino acid sequence and secondary structure of *Drosophila* dynein light chain LC8 generated by PDBsum[44] from the X-ray coordinates deposited in the PDB file 2PG1.[26] Residues M1, S2, D3, and R4 are not included.

of LC8 binding partners and the roles LC8 plays in these interactions have grown substantially over the past few years. Recently, LC8 has been shown to interact with both Ebolavirus VP35[10] and bovine immunodeficiency virus BIV,[11] potentially affecting the early transcription and (or) the localization of the virus.[12,13] Studies also indicate that LC8 regulates axonal trafficking and synaptic levels of Bassoon, a core protein component of the presynaptic cytomatrix at the active zone of neurotransmitter release.[14] Lastly, LC8 has been demonstrated to be required for nuclear import of P21-activated kinase 1 (Pak1), a process critical for development of vertebrates[15] and potentially involved in cancer progression.[9]

LC8 is homodimeric under physiological conditions, but its dimer–monomer equilibrium is critical for its biological functions.[16] Several models have been proposed to explain the underlying mechanisms for this equilibrium as well as the interactions between LC8 and its diverse binding partners. Research indicates that the dimer–monomer equilibrium of LC8 can be regulated by pH changes,[17] the redox state,[18,19] and phosphorylation of S88.[9,20,21] Whether phosphorylation of S88 can occur and regulate LC8 dimerization remains controversial.[22] Moreover, the phosphomimetic LC8 mutant S88E is found to be dimeric in *Chlamydomonas* dynein, with no obvious functional deficiency caused by this mutation.[23]

The LC8 homodimer is frequently assumed to function as a cargo adaptor, linking its various binding partners to the dynein complex by binding the dynein intermediate chain and its cargo proteins simultaneously.[24,25] However, structural and thermodynamic data do not support this model. Specifically, each reported LC8 binding protein binds to the same groove as the dynein intermediate chain. In addition, all characterized LC8 binding proteins, including the dynein intermediate chain, are homodimeric.[26,27] This situation enables these targets to interact with LC8 through a bivalent–bivalent interaction, which in general is more energetically favorable than an uncoupled trivalent interaction. Instead, the LC8 dimer has been shown to stabilize weaker target dimers, particularly through the stabilization of partially disordered regions of these proteins.[8] For example, LC8 has been shown to stabilize an α-helical coiled coil within the microtubule-binding domain of syntaphilin, leading to the regulation of mitochondrial transport and retention in axons.[28]

Solution-state NMR has been extensively used to solve LC8 structures,[24,29,30] to investigate interactions between LC8 and its various protein and peptide binding partners,[22,24,25,31–34] and to probe mechanisms underlying LC8 dimerization.[17,20,21,35] In contrast, to the best of our knowledge, solid-state NMR spectroscopy has yet to be used as a tool to study the homodimeric LC8 either alone, or in complex with its binding partners, or as part of the entire dynein assembly. Solution NMR spectroscopy cannot be used to address the entire dynein assembly, since its high molecular weight (~2 MDa) broadens the resonances beyond detection owing to fast transverse relaxation. Similarly, other LC8 binding partners, such as retroviral Gag,[36] microtubule-binding protein syntaphilin[28], and nuclear pore complex,[7] cannot be studied in complex with LC8 in solution because they are also too large and (or) insoluble. Furthermore, many of these assemblies are difficult to crystallize and therefore not amenable to X-ray diffraction studies. In the solid state, the line widths are independent of the molecular weight and crystalline samples are not required. With the differential and sparse isotopic enrichment protocols as well as the recently developed pulse sequences, the structure and dynamics of large protein assemblies can be studied.[37–42]

In this work, we examine the apo-LC8 (the primary sequence and the secondary structure of the LC8 is shown in Fig. 1) by magic-angle spinning (MAS) NMR spectroscopy as the first step toward the investigations of LC8-containing protein assemblies. We report site-specific resonance assignments and the secondary structure analysis of U-^{15}N,^{13}C-enriched LC8 by a combination of two- and three-dimensional MAS NMR experiments. The secondary structure predicted by TALOS+[43]based on SSNMR resonance assignments is in close agreement with the published LC8 crystal structure 2PG1.[26] These results enable future studies including tertiary structure determination of homodimeric apo-LC8 in the solid state, as well as structural and dynamics investigations of LC8-containing protein assemblies.

Results

Resonance assignments of LC8 by MAS solid-state NMR spectroscopy

To establish the best experimental conditions, we first acquired 14.1 T 2D DARR spectra of LC8 at several temperatures ranging from 0 to –35 °C. The resolution and the signal-to-noise ratio in the DARR spectra acquired at –1.7, –6.7, –11.7, and –16.7 °C are essentially the same and no peak shifts were observed in this temperature range (Fig. S1 of the Supplementary data). Below –21.7 °C, the spectral quality deteriorates as evidenced by the disappearance or broadening of a large number of peaks. Therefore, for all experiments we have kept the sample temperature above –16.7 °C; specific conditions for the various experiments are indicated in the Experimental section.

Resonance assignments of LC8 in the solid state were derived from a combination of two- and three-dimensional homo- and hetero-nuclear correlation MAS NMR spectra acquired at 14.1 and 21.1 T. As expected for micro- and nano-crystalline protein preparations,[39,40,45–48] the homo- and hetero-nuclear spectra are of high quality with the resolution of the individual peaks of the order of 0.2–0.5 ppm. Representative 2D DARR, NCACB, and NCO spectra acquired at 14.1 T are shown in Fig. 2. An overlay of the 14.1 and

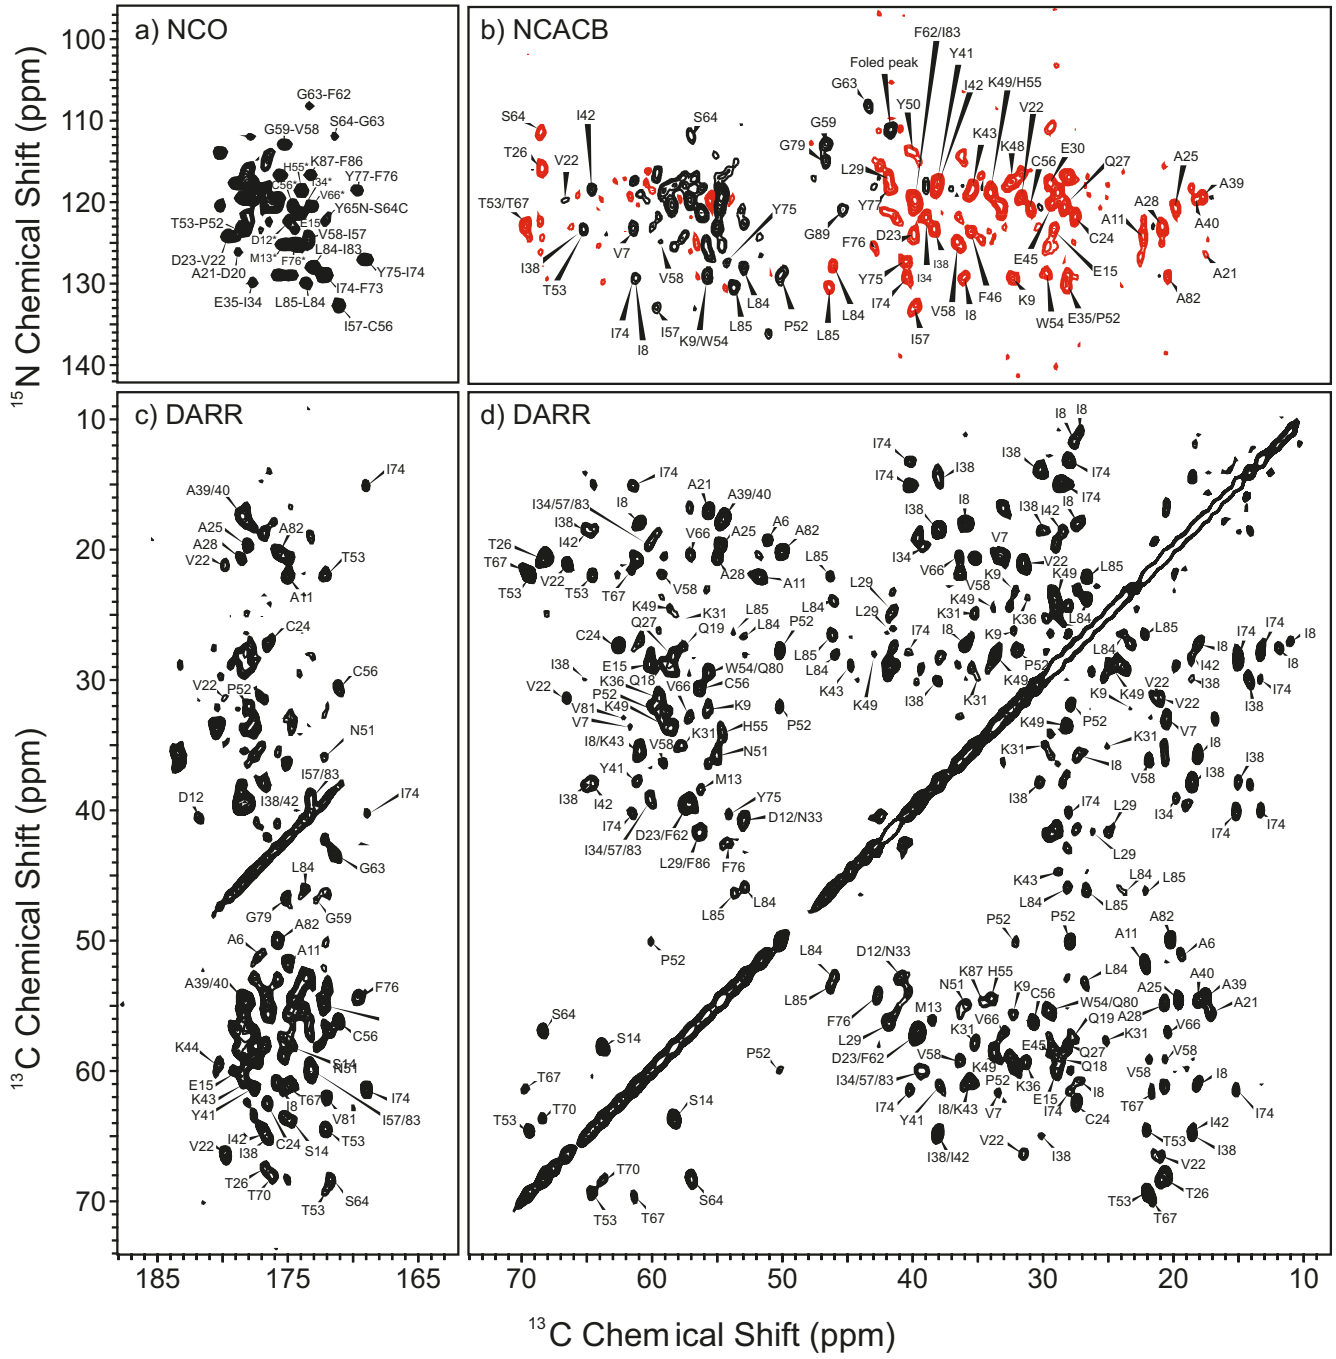
Fig. 2. Two-dimensional solid-state magic-angle spinning (MAS) NMR spectra of LC8; (*a*) NCO, (*b*) NCACB, (*c*) carbonyl, and (*d*) aliphatic regions of the 14.4 T DARR spectrum (mixing time, 10 ms). The first contour for the spectra is set at 5 × σ, with a multiplier of 1.2.



21.1 T DARR spectra is shown in Fig. 3, and the heteronuclear 2D spectra acquired at 21.1 T are demonstrated in Fig. S2 of the Supplementary data. The spectra acquired at 21.1 T exhibit superior resolution compared with the corresponding spectra acquired at 14.1 T, as expected. However, despite the resolution enhancement achieved at a high magnetic field, the 2D data sets alone are insufficient for site-specific assignments because of the intrinsic signal overlap in LC8.

To establish residue-specific backbone assignments, we used several three-dimensional data sets: dipolar coupling-based NCACB, NCACX, NCOCX, and scalar coupling-based NCOCA[49–51] experiments, the analysis of which yielded assignments for 73 out of 89 residues. A representative backbone walk for A21-E30 is illustrated in Fig. 4. For side-chain assignments, we supplemented the heteronuclear 3D data sets with 2D DARR and 3D DARR–DARR experiments, and a combination of the various spectra yielded side-chain assignments for many residues in the protein. The ^{13}C and ^{15}N chemical shifts for the assigned residues are tabulated in Table S1 of the Supplementary data.

Further analysis of the ^{13}C and ^{15}N solid-state chemical shifts indicated that these are in very good agreement with the solution NMR chemical shifts assignments established by us earlier for the LC8 sample prepared at identical pH,

Fig. 3. Overlay of the DARR spectra acquired at 14.1 T (red) and 21.1 T (blue). DARR mixing time is 10 ms for the 14.1 T data and 50 ms for the 21.1 T data (see [1]Table S2 in the Supplementary data). The spectra acquired at 21.1 T exhibit higher resolution.

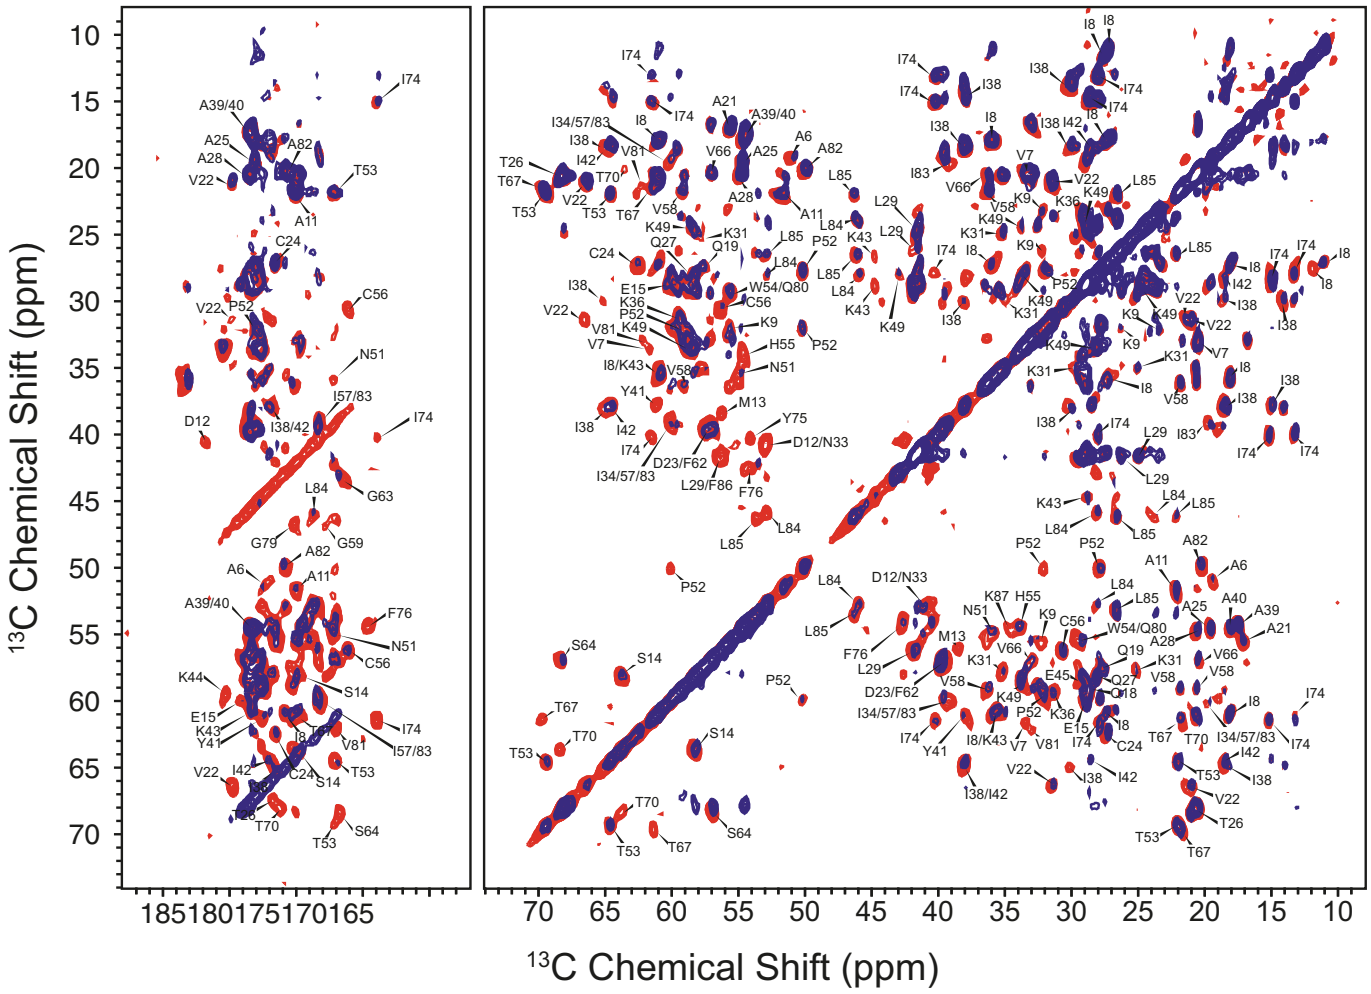


Fig. 4. Backbone walk for A21-E30 using three-dimensional experiments: dipolar-based NCACB, NCACX, NCOCX, and scalar-based NCOCA. Negative cross peaks resulting from the two-bond N–C$^{\beta}$ correlations are shown in red. The first contour in all spectra is set at 5 × σ with a multiplier of 1.2.

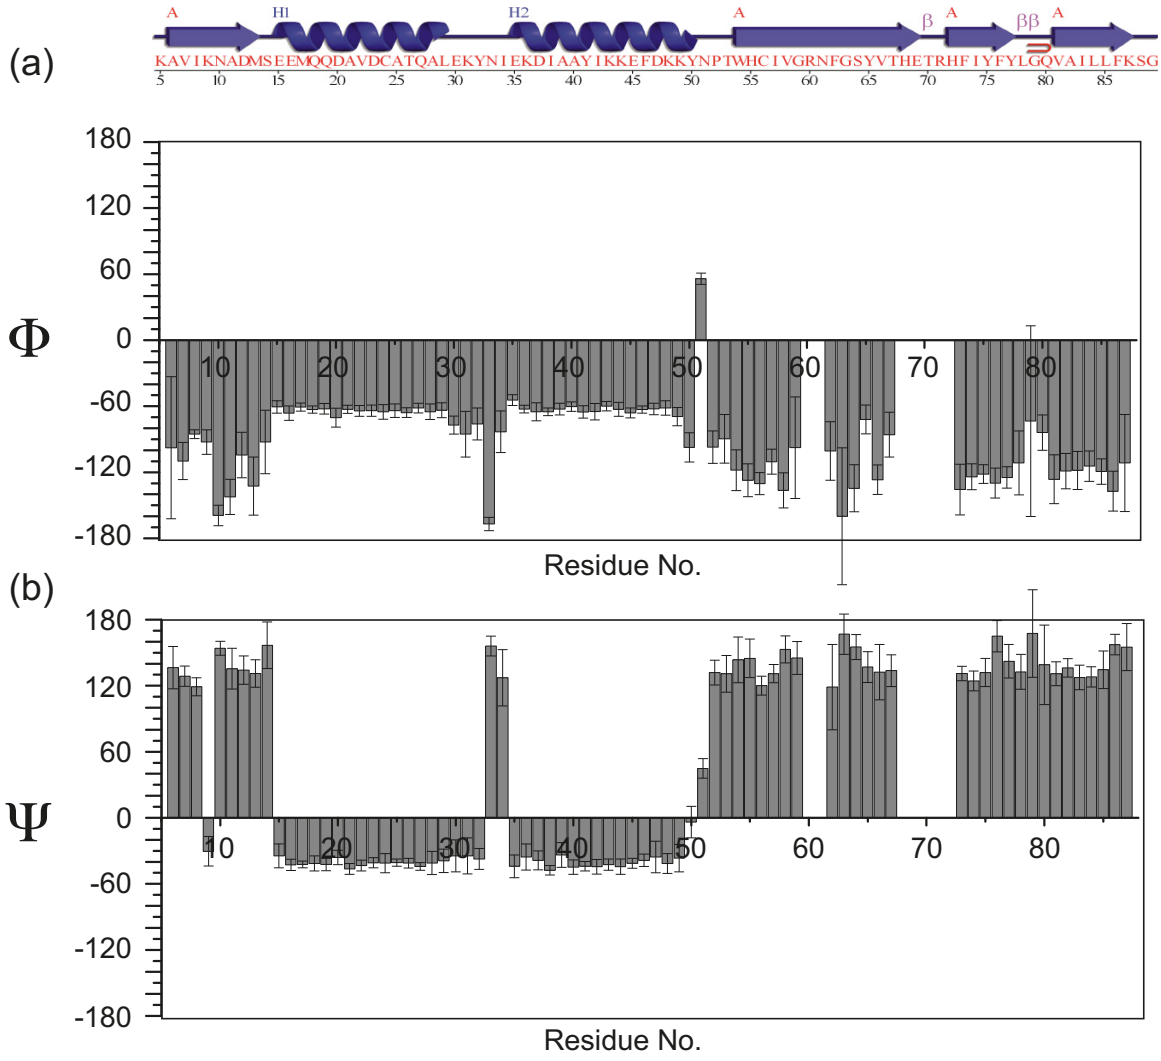
with the exception of residues N33 and K87 that show a large discrepancy in the backbone ^{15}N chemical shifts. Residue-wise comparison of solid-state and solution chemical shifts is illustrated in Fig. 5 and in Table S2 of the Supplementary data. The mean chemical shift deviations are 0.3 ppm for C^{α}, C^{β}, and C', and 0.8 ppm for N^{H}. Close agreement between solid-state and solution shifts was also observed in our previous work on CAP-Gly[40] and thioredoxin,[39,52] as well as on BPTI,[45] Crh,[42] and GB1[46] from other laboratories.

Torsion angle analysis of LC8 based on chemical shift assignments by TALOS+

To predict the backbone torsion angles ϕ and ψ from the solid-state chemical shifts of LC8, we employed TALOS+.[43] Since resonance assignments are available for 73 of 89 residues of LC8, we could not derive the torsion angles for several residues (R60, N61, H68, N69, T70, R71, and H72) because TALOS+ requires resonance assignments for three consecutive residues to make predictions for the central residue. The TALOS+-predicted torsion angles yielded the

Fig. 6. (*a*) Amino acid sequence and secondary structure of dynein light chain LC8 generated by PDBsum[44] from the X-ray coordinates deposited in the PDB file 2PG1.[26] (*b*) Backbone torsion angles Φ (top) and ψ (bottom) derived from TALOS+ analysis of isotropic solid-state chemical shifts of LC8.



secondary structure of LC8, which is in close agreement with the crystal structure deposited in the Protein Data Bank (PDB) file 2PG1,[26] as illustrated in Figs. 6 and 7. Residue-wise comparison of the SSNMR and X-ray based torsion angles indicates that the discrepancies are small for the majority of the residues except for several residues (Y32, N33, N51, G79, and S88), which are located in loop or linker regions (as illustrated in Fig. 7).

Discussion

With the aim of investigating interactions between LC8 and its various binding partners and gaining insight into the atomic-level resolution structures of the large LC8-based multicomponent assemblies, we employed MAS solid-state NMR spectroscopy to derive site-specific resonance assignments, and predicted backbone torsion angles Φ and Ψ of LC8 based on the assigned isotropic chemical shifts. From a combination of homo- and hetero-nuclear 2D and 3D experiments, we extracted site-specific backbone resonance assignments for 73 out of 89 residues, and obtained side-chain assignments for many ^{13}C atoms in LC8 (see Table S1 of the Supplementary data). The majority of the residues that could not be unambiguously assigned from the current data sets, namely, M1, S2, D3, R4, K5, R60, N61, H68, E69, R71, H72, L78, S88, and G89, are located in loop regions. This result is consistent with our prior work and that of other laboratories,[45,47,53–55] indicating that it is generally more difficult to derive solid-state NMR assignments for residues in loop regions or at the termini, because generally these residues exhibit dynamic or static conformational heterogeneity and, therefore, give rise to broader or missing resonances. Additionally, Y32 and D47 could not be assigned; these are located in an α helix but their chemical shifts overlap with the shifts of other residues; hence, unambiguous assignments were not possible under our conditions.

A previous solution NMR study by Mohan et al.[17] indicates that pH can determine the dimer–monomer equilibrium and LC8 is in its dimeric form under pH 6. LC8 has a strong pH dependence for chemical shift patterns, indicating that dimeric and monomeric forms of LC8 have very different

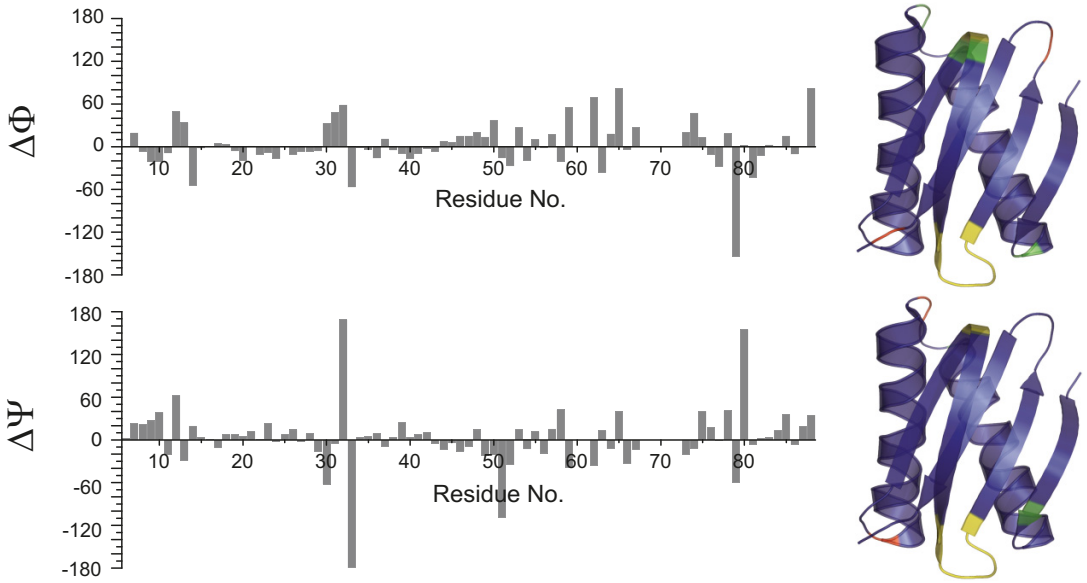
Fig. 7. Residue-wise comparison of Φ and Ψ torsion angles predicted by TALOS+[43] and those extracted from LC8 crystal structure (PDB file 2PG1)[26]. Differences are mapped on the 2PG1 chain A, and residues are color coded as follows: blue for $\Delta\Phi$ and $\Delta\Psi$ <50°; green for $\Delta\Phi$ and $\Delta\Psi$ ranging from 50° to 100°; and red for $\Delta\Phi$ and $\Delta\Psi$ >100°. Residues with no predicted angles owing to the lack of resonance assignments are yellow (R60, N61, H68, E69, T70, R71, and H72).



chemical shifts.[17] We noticed that SSNMR chemical shift assignments are very close to the solution NMR chemical shifts for LC8 (see Fig. 5) as both NMR samples are prepared at pH 6.0 (see the Experimental methods section). We conclude that LC8 is in its dimeric form in the SSNMR sample.

We expect that the resonance assignments for LC8 can be completed with technical improvements in sample preparation and experimental design. For instance, constant-time scalar-based experiments yield inherently higher resolution than the corresponding dipolar-based experiments and are less sensitive to global molecular motion.[49–51] However, the potential of these experiments was not fully exploited in our study because of hardware limitations on the proton decoupling powers and on the available MAS frequencies. At high MAS frequencies and high-power proton decoupling, the performance of the scalar-based experiments is enhanced dramatically.[49–51] Furthermore, under fast-MAS conditions (40 kHz or above), doping of the protein samples with paramagnetic salts at suitable concentrations and in conjunction with low-power decoupling can yield drastic enhancements in the sensitivity owing to the significantly higher spin-lattice relaxation rates (while the spin-spin relaxation rates are intact) allowing for fast recycle delays, as demonstrated recently by Ishii and co-workers.[56] Similar to their results, we indeed found that LC8 samples doped with EDTA–Cu(II) have relatively long ^{15}N T_2s, whereas the ^{1}H T_1s are dramatically shortened, indicating that this sample preparation method is beneficial for LC8 as well (data not shown). We also note that, naturally, higher resolution is afforded by recording the spectra at 21.1 T, but practical hardware limitations prevented us from being able to collect heteronuclear 3D data sets necessary for the resonance assignments. With the improvements in hardware and sample preparation, we therefore expect to achieve higher sensitivity and resolution in the future studies of LC8 at 14.1 T and higher, and to complete the resonance assignments.

Although it would be desirable to achieve complete resonance assignments, the available partial assignments already provide a platform for future studies including tertiary structure determination and characterization of protein–protein interfaces of LC8-containing protein assemblies. The close agreement between torsion angles predicted by TALOS+ on the basis of SSNMR chemical shifts and the torsion angles from the LC8 crystal structure (PDB file 2PG1) indicates that chemical shifts are assigned reliably in the solid state. Previous structural studies[22,24,26,27,57] of LC8 and its binding partners (e.g., Pak1, dynein intermediate chain IC, nNOS, etc.) revealed that residues F62–T67 form an antiparallel β sheet with a portion of the bound partner protein. It is likely that LC8 also utilizes this mechanism to interact with other proteins with fine tuning provided by global structure and dynamics of both LC8 and the binding partner. Therefore, it is of interest to examine the structure adopted by this stretch of residues when LC8 forms large assemblies. Through our current work, chemical shift assignments are available for residues F62–T67, and indicate that this stretch of residues is in a β sheet, whereas the assignments for the flanking residues are missing (see Table S1 of the Supplementary data). Therefore, even in unfavorable cases where the chemical shifts for flanking residues are unknown, such as the F62–T67 stretch above, we will still be able to investigate the functionally important interfaces of assemblies formed by LC8 and its various binding partners, through chemical shift perturbation approaches and (or) differential labeling based MAS NMR experiments.[37,41]

Experimental methods

Materials

Common chemicals were purchased from Fisher Scientific or Sigma-Aldrich. ^{15}N NH_4Cl and U-$^{13}C_6$ glucose were purchased from Cambridge Laboratories, Inc.

Expression and purification of isotopically enriched LC8

Subcloning of wild type *Drosophila* LC8 (Accession No. NP 525075), and the expression and purification of natural abundance or U-^{15}N, ^{13}C isotopically enriched LC8 have been described previously.[22] For isotope enrichment, the Bracken protocol[58] was followed. The yields of pure natural abundance and isotopically enriched LC8 are 34 mg (per 1 L of Luria Bertani (LB)) and 20 mg (per 1L of LB and 250 mL of M9), respectively.

Preparation of solid-state NMR samples

Eleven milligrams of pure U-^{13}C,^{15}N-enriched LC8 were dialyzed against 10 mmol/L MES buffer (10 mmol/L $MgCl_2$, pH 6.0) and concentrated to 30 mg/mL. A solution of 32% PEG-3350 (also dissolved in 10 mmol/L MES buffer) was gradually added to the LC8 solution following the controlled precipitation protocol developed previously for thioredoxin.[39] This condition was chosen from a minimal (24 well) hanging drop screen, which yielded LC8 microcrystals in a hanging drop. More than 90% of the protein was precipitated, as confirmed by the Bradford assay. The LC8–PEG-3350 mixture was centrifuged, and the pellet was used for solid-state NMR experiments. The hydrated precipitate (14.3 mg) was packed into a 3.2 mm Varian rotor and sealed using an upper spacer and a top spinner.

Solid-state NMR spectroscopy

MAS solid-state NMR spectra were acquired at 14.1 T (600 MHz) on a narrow bore Varian InfinityPlus instrument outfitted with a 3.2 mm triple resonance T3 probe; Larmor frequencies were 599.5 MHz for ^{1}H, 150.7 MHz for ^{13}C, and 60.7 MHz for ^{15}N. Dipolar-based two- and three-dimensional DARR,[59] NCA, NCO, and NCACB spectra were collected at a MAS frequency of 10.000 ± 0.001 kHz controlled by a Varian MAS controller. The dipolar NCACX and NCOCX experiments utilized the SPECIFIC-CP[60] heteronuclear magnetization transfer followed by DARR homonuclear transfer; in the NCACB experiment, the homonuclear DREAM mixing[61] with a tangent ramp was used. Scalar-based 2D NCO[51] and 3D NCOCA[49] spectra were collected at a MAS frequency of 14.705 ± 0.001 kHz controlled by a Varian MAS controller. The temperature was calibrated for this probe at different MAS frequencies using a $PbNO_3$ temperature sensor,[62] and the actual temperature at the sample was maintained to within ±0.5 °C throughout the experiments using the Varian temperature controller. The DARR spectra were acquired at temperatures of –1.7, –6.7, –11.7, –16.7, and –21.7 °C. The heteronuclear 2D and 3D spectra were acquired at –16.7 °C (with the exception of CANCO, which was acquired at –11.7 °C). ^{1}H, ^{13}C, and ^{15}N chemical shifts were referenced with respect to DSS, adamantane, and ammonium chloride used as external referencing standards.[63] The typical 90° pulse lengths were 2.7 (^{1}H), 4.5 (^{13}C), and 5 μs (^{15}N). The ^{1}H–^{13}C(^{15}N) cross polarization was performed with a linear amplitude ramp (80%–100%) on ^{13}C(^{15}N); the ^{1}H radio frequency field was 50 kHz with the center of ramp Hartmann–Hahn matched to the first spinning sideband. The ^{1}H–^{13}C and ^{1}H–^{15}N contact times were 1 ms and 1.6 ms, respectively. In the CANCO experiment, the ^{1}H–^{13}C contact time was set at 200 μs to preferentially excite the ^{13}C aliphatic region. The Z-filter time was 30 ms in all scalar-based experiments. In the dipolar-based experiments, the typical ^{15}N to ^{13}C SPECIFIC-CP transfer was performed with a 25 kHz radio frequency field for ^{15}N and ~15 kHz for the center of a tangential ramp on ^{13}C; the mixing times were 6.7 ms. The DARR mixing time was set to either 2 or 10 ms for recoupling of two ^{13}C nuclei separated by a short distance (mostly one bond), and the ^{1}H RF field strength during DARR was 10 kHz. In the DREAM mixing period (2.1 ms), a tangent ramp was applied on ^{13}C according to the condition $n\omega_r = (\omega_{rf}^2 + \omega_1^2)^{1/2} + (\omega_{rf}^2 + \omega_2^2)^{1/2}$.[56] For the scalar-based NCOCA experiment, $\tau_1 = \tau_2 = 10.9$ ms; $\tau_3 = \tau_4 = 2.72$ ms. The Z-filter time was 30 ms in all scalar-based experiments. TPPM decoupling[64] was used, and the decoupling field strengths ranged between 80 and 100 kHz in different experiments. Recycle delays in all experiments were 2 s. TPPI[65] was used for frequency discrimination in the indirect dimensions.

DARR and dipolar-based NCA and NCO spectra of LC8 were also acquired at at 21.1 T at EMSL-PNNL, on a medium bore 900 MHz Varian Inova instrument outfitted with a 3.2 mm triple resonance BioMAS probe; the Larmor frequencies were 900.575 for ^{1}H, 226.47 for ^{13}C, and 92.26 MHz for ^{15}N. The MAS frequency was 14.000 ± 0.001 kHz controlled by a Varian MAS controller. The temperature was 0 °C and was maintained to within ±0.5 °C throughout the experiments using the Varian temperature controller. The typical pulse lengths were 3.0 (^{1}H), 5.5 (^{13}C), and 6 μs (^{15}N); the ^{1}H–^{13}C and ^{1}H–^{15}N cross polarizations were performed with a tangent amplitude ramp (80%–100%); the ^{1}H radio frequency fields were 70.4 and 60.7 kHz, respectively, with the center of the ramp Hartmann–Hahn matched to the second spinning sideband; the ^{1}H–^{13}C and ^{1}H–^{15}N contact times were 2 and 1 ms, respectively. The NCA and NCO experiments were performed with a tangent amplitude ramp (80%–100%); the ^{13}C radio frequency fields were 13 and 18 kHz, respectively, with the center of the ramp Hartmann–Hahn matched to the first spinning sideband; the SPECIFIC-CP mixing times were 6.0 and 6.4 ms, respectively. TPPM decoupling (83 kHz) was applied during the evolution and acquisition periods. The ^{1}H field strength during DARR was 14 kHz; DARR mixing time was 50 ms; under these conditions predominantly one-bond correlations appeared in the spectra.

Other acquisition and processing parameters for data sets acquired at 14.1 and 21.1 T are specified in the figure captions and in the Supplementary data.

NMR data processing and analysis

The spectra were processed in NMRpipe[66] and analyzed in Sparky.[67] For 2D solid-state NMR data, 90°, 60°, or 30° shifted sine-bell apodization followed by a Lorentzian to Gaussian transformation was applied in both dimensions; forward linear prediction to twice the number of the original data points was applied in the indirect dimension for some data sets followed by zero filling to twice the total number of points. The 3D data sets were processed by using 30° or 60° shifted sine bells in all dimensions followed by a Lorentzian to Gaussian transformation (for resolution enhancement) and by using 90° shifted sine bells in all dimensions followed by a Lorentzian to Gaussian transformation (for sensitivity enhancement). The 3D spectra were also processed with

maximum entropy reconstruction as implemented in the program Roland NMR Toolkit.[68,69] Detailed information about processing parameters is specified in the Supplementary data.

Conclusions

We have established site-specific backbone and side-chain resonance assignments for the majority of the residues of LC8 through MAS solid-state NMR spectroscopy. Based on these assignments, we derived torsion angles ϕ and ψ by TALOS+. The predicted angles are in close agreement with crystal structures (2PG1) for most of the residues except for several residues located in loop or linker regions.

Supplementary data

Supplementary data (14.1 T 2D DARR, NCA, NCACB, NCACX, and NCOCX spectra of DLC8; solid-state chemical shifts of DLC8; temperature-dependent DARR spectra; and acquisition and processing parameters for solid-state and solution NMR experiments) are available with the article through the journal Web site (www.nrcresearchpress.com).

Acknowledgment

This work was supported by the National Institutes of Health (NIH Grants R01GM085396 from NIGMS and P20RR017716-08 from NCRR). The 21.1 T spectra were acquired at the Environmental Molecular Sciences Laboratory, a national scientific user facility sponsored by the United States Department of Energy's Office of Biological and Environmental Research and located at Pacific Northwest National Laboratory in Richland, Washington. A. Lipton, J. Sears, M. Froehlke, S. Burton, D. Hoyt, and J. Ford are thanked for their kind assistance during our visit to EMSL.

Abstract: Multinuclear solid-state nuclear magnetic resonance (SSNMR) experiments have been performed on cisplatin and four related square-planar compounds. The wideband uniform rate smooth truncation – Carr–Purcell–Meiboom–Gill (WURST–CPMG) pulse sequence was utilized in NMR experiments to acquire ^{195}Pt, ^{14}N, and ^{35}Cl ultra-wideline NMR spectra of high quality. Standard Hahn-echo and magic-angle spinning ^{195}Pt NMR experiments are also performed to refine extracted chemical shielding (CS) tensor parameters. Platinum magnetic shielding (MS) tensor orientations are calculated using both plane-wave density functional theory (DFT) and standard DFT methods. The tensor orientations are shown to be highly constrained by molecular symmetry elements, but also influenced to some degree by intermolecular interactions. ^{14}N WURST–CPMG experiments were performed on three compounds and electric field gradient (EFG) parameters (the quadrupolar coupling constant, C_Q, and the asymmetry parameter, η_Q) are reported. First principles calculations of the ^{14}N EFG tensor parameters and orientations and affirm their dependence on the local hydrogen bonding environment. ^{35}Cl WURST–CPMG experiments on cisplatin and transplatin are reported, using two different static magnetic fields to extract EFG and CS tensor parameters, and ^{35}Cl EFG tensor magnitudes and orientations are predicted using first principles calculations. Transverse (T_2) relaxation data for all nuclei are used to investigate heteronuclear dipolar relaxation mechanisms, as well as the nature of the local hydrogen bonding environments.

Key words: platinum NMR, ^{195}Pt NMR, ^{14}N NMR, ^{35}Cl NMR, cisplatin, transplatin, carboplatin, solid-state NMR, wideline NMR, WURST–CPMG, electric field gradient tensors, chemical shift tensors.

Résumé : On a effectué des expériences de résonance magnétique nucléaire à l'état solide (RMN-ES) sur le cisplatine et sur quatre composés apparentés plan carrés. Dans les expériences de RMN, on a utilise la séquence de pulsation « wideband uniform rate smooth truncation – Carr–Purcell–Meiboom–Gill (WURST–CPMG) » pour acquérir des spectres RMN du ^{195}Pt, du ^{14}N et du ^{35}Cl avec des raies ultra-larges et de grande qualité. On a aussi effectué des expériences de RMN du ^{195}Pt en écho de Hahn standard ainsi qu'à l'angle magique de rotation afin d'affiner les paramètres de tenseur du blindage chimique (BC). On a calculé les orientations du tenseur du blindage magnétique (BM) du platine en faisant appel aux méthodes de la théorie de la fonctionnelle de la densité standard (TFD) ainsi qu'avec une onde plane. On a montré que les orientations du tenseur sont grandement contraintes par les éléments de symétrie moléculaire, mais qu'ils sont aussi influencés jusqu'à un certain point par les interactions intermoléculaires. Les expériences utilisant la séquence de pulsation « WURST–CPMG » pour le ^{14}N ont été effectuées sur trois composés et on rapporte les paramètres du gradient du champ électrique (GCE; la constante de couplage quadripolaire, C_Q et le paramètre d'asymétrie, η_Q). Des calculs sur la base de premiers principes des paramètres de tenseur du GCE et des ses orientations confirment leur dépendance sur l'environnement local des liaisons hydrogènes. Opérant sur le cisplatine et le transplatine, à deux champs magnétiques différents, on a aussi réalisé des expériences utilisant la séquence de pulsation « WURST–CPMG » pour le ^{35}Cl afin d'extraire les paramètres de tenseur du GCE et du blindage chimique (BC); les amplitudes du tenseur GCE du ^{35}Cl et ses orientations peuvent être calculées correctement à partir de premiers principes. On a utilisé les données de relaxation transversale (T_2) de chacun des noyaux pour étudier les mécanismes de relaxation dipolaire hétéronucléaire ainsi que la nature des environnements des liaisons hydrogènes locales.

Mots-clés : RMN du platine, RMN du ^{195}Pt, RMN du ^{14}N, RMN du ^{35}Cl, cisplatine, transplatine, carboplatine, RMN à l'état solide, WURST–CPMG, tenseurs du gradient du champ électrique, tenseurs du déplacement chimique.

Introduction

Cancer is a class of diseases that affects people around the world, and in 2008 was responsible for an estimated 7.6 million deaths globally.[1] The treatment of cancer normally involves the use of several different types of chemotherapeutic drugs[2] and, of those, a prominent class are platinum-based DNA-crosslinking agents. Drugs such as cisplatin, carboplatin, and oxaliplatin are approved for use, and pharmaceutical research continues to focus on this family of compounds.[3,4] *cis*-Diamminedichloroplatinum (cisplatin or *cis*-$PtCl_2(NH_3)_2$) is one of the longest known, most effective, and oft-employed alkylating agents involved in the treatment of testicular, ovarian, bladder, head, and neck cancers.[5] Although originally reported by Peyrone in 1845 and subsequently dubbed "Peyrone's chloride",[6] more than 100 years passed before Rosenberg discovered the unique effects of cisplatin on the growth of *Escherichia coli*[7] in 1965, and its antitumor activity in mice in 1969.[8] In the time since the introduction of cisplatin, related drugs using central Pt(II) atoms such as carboplatin and oxaliplatin have been synthesized and approved to treat cancer as well.[5] Cisplatin and related platinum-based drugs are thought to kill cancerous cells via the formation of Pt–N covalent bonds between the Pt atom of the cisplatin molecule and purine bases (particularly guanine units) in DNA, which in turn triggers cell apoptosis (i.e., programmed cell death). There have been numerous reports of drug syntheses and mechanistic studies; however, the specifics regarding this mechanism are still debated.[9–11]

Studies of cisplatin and related drugs often employ one- and (or) two-dimensional solution NMR as characterization methods, since the reaction of cisplatin with DNA occurs within the aqueous environment of cells.[12,13] The majority of solution nuclear magnetic resonance (NMR) studies have focussed upon the reaction of cisplatin with relevant biomolecules and formation of intermediates in physiological (i.e., low concentration) conditions; however, even in one-dimensional experiments, the limit of detection of ^{195}Pt solution NMR (~10 mmol/L) is orders of magnitude higher than concentrations found within cells (μmol/L). Many solution NMR studies examining the reactions of these drugs must rely on ^{1}H and ^{15}N NMR experiments (as well as ^{15}N isotopic labelling), including two-dimensional inverse detection methods that allow detection of drug concentrations similar to those within the body (5 μmol/L).[5] Isotropic chemical shifts obtained from ^{195}Pt solution NMR experiments for much more concentrated systems are sometimes reported,[14–19] particularly for systems involving cisplatin hydrolysis and (or) reactions with biomolecules or DNA.[12,14,15,19–21] Detailed first principles calculations of the effects of solvents and dynamic averaging on observed ^{195}Pt NMR shieldings in cisplatin and related derivatives have also recently been reported.[22]

By comparison, there are fewer solid-state NMR (SSNMR) studies of these systems, with focus upon nuclei such as ^{1}H, ^{13}C, and ^{15}N.[23–28] Although these nuclei are very common in solution NMR work, they all have inherent drawbacks for SSNMR studies. ^{1}H NMR spectra are very broad owing to strong homonuclear dipolar couplings and not expected to be of much use in elucidating binding interactions with large DNA molecules. ^{13}C NMR experiments are of limited diagnostic use as well, since Pt–C bonds are not relevant in the interactions between Pt drugs and DNA. ^{15}N is potentially the most useful of the three nuclei for SSNMR experimentation, although owing to its low natural abundance (0.37%), expensive isotopic labelling is necessary.

The ^{195}Pt chemical shift is extremely sensitive to the local Pt environment and has a known range of ~15 000 ppm.[29,30] ^{195}Pt SSNMR powder patterns give valuable information on both the platinum isotropic chemical shift and the chemical shift anisotropy (CSA), which are extremely sensitive to structural modifications and Pt oxidation state changes. However, these powder patterns are often very broad (i.e., covering thousands of ppm / hundreds of kHz), making standard SSNMR experiments very time-consuming. The inherently low sensitivity of such experiments is of concern for the potential examination of the binding of platinum complexes to DNA chains, since the Pt content is very low in such systems. However, the recently developed wideband uniform rate smooth truncation – Carr–Purcell–Meiboom–Gill (WURST–CPMG) pulse sequence[31–37] has shown much promise for the rapid acquisition of broad powder patterns for spin-1/2 nuclei with large CSAs, including ^{195}Pt,[38] as well as quadrupolar nuclei (spin > 1/2) such as ^{14}N[39–41] and ^{35}Cl,[42,43] which are present in numerous cisplatin derivatives and may also serve as useful probes of structure and dynamics. Given the sensitivity of the ^{195}Pt CSA to subtle structural changes and the signal enhancement capabilities of the WURST–CPMG protocol, it may be possible to gain rich structural information on Pt-containing biological systems, but it is necessary to make a preliminary study of the platinum chemical shift (CS) tensors and the rapidity with which high-quality ^{195}Pt NMR spectra can be acquired.

Herein, we describe the use of the WURST–CPMG pulse sequence, in combination with frequency-stepped techniques (where necessary, vide infra),[44–47] to acquire ^{195}Pt, ^{14}N, and ^{35}Cl SSNMR spectra of cisplatin and related systems, including transplatin (its trans isomer), the second-generation chemotherapy drug carboplatin, as well as $Pt(py)_2Cl_2$ and $Pt(en)Cl_2$. The use of ultra-high magnetic fields (21.1 T) for ^{14}N and ^{35}Cl NMR experiments for distinguishing overlapping sites in spectra is also explored. The resulting data is then analysed to correlate observed ^{195}Pt, ^{14}N, and ^{35}Cl NMR parameters with the local structural environments. Density functional theory (DFT) calculations on isolated molecules and DFT plane-wave calculations on extended lattices have been applied to calculate the NMR interaction tensors and aid in this correlation. These data allow us to comment on the nature of structure and bonding which may affect the potencies of these compounds as antitumor agents. In turn, this may lead to a deeper understanding of relationships between drug–DNA interactions and drug efficacy, which may enable the rational design of new platinum-based anticancer compounds.

Experimental

purchased from Strem Chemicals, Inc., and ($H_2NCH_2CH_2NH_2$)$PtCl_2$ ($Pt(en)Cl_2$, dichloro(ethylenediamine)platinum(II)) was purchased from Sigma-Aldrich. All compounds were used without further purification (Scheme 1).

Solid-state NMR

Solid-state NMR spectra were collected on a Varian Infinity Plus NMR spectrometer with an Oxford 9.4 T ($\nu_0(^1H)$ = 399.73 MHz) wide-bore magnet with $\nu_0(^{195}Pt)$ = 85.59 MHz, $\nu_0(^{35}Cl)$ = 39.17 MHz, and $\nu_0(^{14}N)$ = 28.89 MHz. All ^1H, ^{195}Pt, and ^{14}N static experiments were conducted using a Varian/Chemagnetics 5 mm HX static probe. ^{195}Pt magic angle spinning (MAS) experiments were performed using a Varian/Chemagnetics 2.5 mm HX probe. A Chemagnetics low-γ tuning box and preamplifier were used on the X channel for all ^{14}N NMR experiments. A Varian/Chemagnetics 5 mm HXY probe was used for all ^{35}Cl experiments owing to its continuous tuning range in the ^{35}Cl Larmor frequency region. All samples were packed into 5 mm o.d. zirconia rotors or glass tubes. ^{195}Pt chemical shifts were referenced with respect to 1.0 mol/L Na_2PtCl_6 (aq) (δ_{iso} = 0.0 ppm), ^{35}Cl chemical shifts were referenced to NaCl (s) (δ_{iso} = 0.0 ppm), and ^{14}N chemical shifts were reported with respect to NH_4Cl (s) (δ_{iso} = 0.0 ppm). A proton decoupling field of either 28 or 38 kHz was employed in all experiments.

All ^{195}Pt and ^{14}N ultra-wideline static (i.e., stationary sample) NMR experiments were conducted using the WURST–CPMG pulse sequence.[31,32,35,48,49] WURST-80 pulse shapes were used with a 50 μs WURST pulse length, a sweep rate of 40 MHz/ms from high to low frequency (corresponding to a non-adiabatic π/2 pulse), and a spectral width of 2000 kHz in all cases.

^{195}Pt WURST–CPMG experiments used an experimentally optimized radio frequency (rf) power of 39 kHz. Piecewise acquisitions were generally required for ^{195}Pt WURST–CPMG experiments.[44–47] Static ^{195}Pt NMR echo spectra were acquired using a standard Hahn-echo experiment of the form $(\pi/2)_x - \tau_1 - (\pi)_y - \tau_2 -$ acq, where τ_1 and τ_2 represent interpulse delays of 40 and 20 μs, respectively. A π/2 pulse width of 2.5 μs and spectral width of 2000 kHz were used. ^{195}Pt MAS NMR spectra of transplatin were acquired using a standard Bloch-decay experiment, a π/2 pulse width of 1.0 μs and spectral width of 1500 kHz. Three different spinning speeds were employed and ^1H decoupling fields in excess of 70 kHz were applied for all experiments. See Supplementary data Tables S1–S3 for the full listing of experimental parameters.

Ultra-wideline ^{14}N NMR experiments were carried out using the WURST–CPMG pulse sequence, employing an rf power of ~30 kHz for all experiments. The first-order quadrupolar interaction dominates these spectra and results in powder patterns that are symmetric about the isotropic shift value. Therefore, the low-frequency (right) portion of the powder pattern was generated by mirroring the high-frequency (left) half of the powder pattern about the isotropic shift value (taken from either the literature or DFT calculations). Contributions from CSA are negligible in magnitude compared with the broadening from the first-order quadrupolar interaction (i.e., the effect of an extraordinarily large isotropic chemical shift (500 ppm) on a ^{14}N spectrum of $C_Q \sim 1$ MHz at 9.4 T is only ~1.5% of the width of the powder pattern), as are contributions from the second-order quadrupolar interaction.[37] See Supplementary data Table S4 for a full listing of experimental parameters.

Ultra-wideline ^{35}Cl NMR experiments at 9.4 T also utilized WURST-80 pulse shapes and 50 μs WURST pulse lengths. A spectral width of 1000 kHz, a WURST sweep rate of 20 MHz/ms from high to low frequency, and an rf power of 40 kHz were used for all experiments. High-field static NMR experiments were performed on a 21.1 T Bruker

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Avance II NMR spectrometer ($\nu_0(^{35}Cl)$ = 88.13 MHz) at the National Ultrahigh-field NMR Facility for Solids in Ottawa, Ontario, and samples were packed into 4 mm o.d. glass NMR tubes. Spectra were acquired on a home-built 4 mm probe using the WURST–CPMG pulse sequence. A spectral width of 1000 kHz and a WURST sweep rate of 20 MHz/ms from high to low frequency was used for all experiments at 21.1 T. See Supplementary data Table S5 for a full listing of experimental parameters.

Static ^{1}H NMR spectra were acquired using a standard Bloch decay pulse sequence, with a $\pi/2$ pulse width of 3.4 μs, a spectral width of 100 kHz, and a recycle delay of 5 s.

Simulations of all static solid-state NMR spectra were performed using the WSOLIDS software package.[50] Simulations of the ^{195}Pt MAS spectra of transplatin were performed using the DMFit software program (2007) and employed an automated iterative fit procedure, as well as manual fitting of spectra.[51] In all cases, uncertainties in extracted NMR tensor parameters were estimated using bidirectional variation within the simulation software. The uncertainties associated with individual CS tensor components (δ_{11}, δ_{22}, and δ_{33}) were calculated through propagation of error from experimental δ_{iso}, span (Ω), and skew (κ) values.

Theoretical calculations

First principles calculations of NMR tensor parameters were conducted on the SHARCNET computer network.[52] All calculations were performed on sets of coordinates derived from reported crystal structures.[53–56] Proton positions were geometry optimized using a Broyden–Fletcher–Goldfarb–Shanno algorithm[57] because of the general unreliability of the proton positions determined from X-ray diffraction experiments. The CASTEP software package[58–61] in the Materials Studio 5.0 software suite uses the gauge-including projector augmented wave algorithm (GIPAW).[60] For all calculations, revised Perdew–Burke–Ernzerhof (rPBE) functionals were used, along with the generalized gradient approximation for exchange-correlation energy. The "fine" basis set accuracy within CASTEP was used to automatically set plane-wave basis set cutoffs (400 eV for all compounds except for carboplatin, which was 550 eV) and Monkhorst–Pack *k*-space grid sizes.

DFT calculations on isolated molecules were performed using the NMR program[62] in the Amsterdam Density Functional (ADF) suite,[63,64] employing all-electron gauge including atomic orbitals (GIAO) basis sets for all atoms.[65,66] The electron exchange and correlation functionals BLYP,[67,68] VWN-BP,[69–71] and VWN-rPBE[72,73] were used with Slater-type orbitals. Calculations labelled as relativistic used the zeroth-order regular approximation (ZORA),[74,75] with either double-ζ polarized (DZP), triple-ζ polarized (TZP), triple-ζ double-polarized (TZ2P), or quadruple-ζ quadruple-polarized (QZ4P) basis sets on all atoms. For the case of ZORA/DZP, Pt atoms used a ZORA-adapted TZP basis set. For nonrelativistic calculations, DZP, TZP, TZ2P, and QZ4P basis sets were used on all atoms; however, Pt atoms used at least a ZORA-adapted TZP basis set. The Pt chemical shift reference for DFT calculations on isolated molecules was a geometry-optimized gas-phase $PtCl_6^{2-}$ molecule constrained to O_h symmetry.[76,77] No similar reference is available for plane-wave calculations.

Results and discussion

First, ^{195}Pt solid-state NMR data are presented. WURST–CPMG NMR spectra and Pt CS tensor parameters derived from analytical simulations are discussed, along with refined CS tensor data obtained via the acquisition and simulation of Hahn-echo spectra and CS tensor parameters obtained from ^{195}Pt MAS spectra of transplatin. ^{195}Pt longitudinal relaxation time (T_1) and transverse relaxation time (T_2) data are also presented. First principles calculations of the platinum nuclear magnetic shielding (MS) tensors and their orientations are presented, accompanied by discussion of their correlation to spectral appearance and molecular structure. Following this, ^{14}N SSNMR spectra and concomitant relaxation data are presented, along with ab initio calculations of ^{14}N electric field gradient (EFG) tensors. Lastly, ^{35}Cl SSNMR data for cisplatin and transplatin are discussed, along with theoretically derived ^{35}Cl EFG tensors and their orientations.

^{195}Pt WURST–CPMG SSNMR experiments — Cisplatin and transplatin

^{195}Pt NMR spectra are presented in Fig. 1 and associated CS tensor parameters are listed in Table 1 and Supplementary data Table S6. Both of the patterns are strikingly broad, each measuring ~775 kHz from end to end. Their δ_{iso} and Ω values are similar and consistent with Pt(II) centres in chemically similar, square-planar environments.[29]

The dissimilarity in spectral appearance arises from the distinct κ values. The κ for cisplatin is –0.94(2), which indicates that the CS tensor has near-axial symmetry, and that δ_{11} is the distinct component (i.e., $\delta_{22} \approx \delta_{33}$). The transplatin has a κ of –0.59(2), which indicates that the CS tensor is less axially symmetric (δ_{22} and δ_{33} are no longer almost equal), but δ_{11} is still the distinct component. Given the local square-planar geometries common to these two molecules, it is likely that the δ_{22} and δ_{33} components of the CS tensor are oriented within (or close to) the square plane, with δ_{11} perpendicular to this plane. Despite the comparable geometric parameters of these isomeric square-planar complexes (see Supplementary data Table S6), the dissimilar skew values may arise from the distinct cis- and trans-structural arrangements, and possibly intermolecular interactions (Fig. 2). The cisplatin crystal structure reveals that the molecules form columns in which the square planes are approximately parallel, with alternation of the positions of the $-NH_3$ and –Cl ligands, and relatively short intermolecular Pt–Pt interactions (Pt–Pt distance of ~3.4 Å). The transplatin molecules do not form a parallel stack; rather, the stack alternates between one unit with its square plane oriented perpendicular to the axis of propagation of the stack and another that is "tilted" with respect to this axis. The latter has a short Pt···H distance of ~2.6 Å between its own NH_3 protons and the Pt centres of the adjacent "perpendicular" units. There are some intermolecular Cl···H distances in both compounds (2.3–2.4 Å) which may also affect the CS tensor. The extended structure and packing of these compounds may affect the ^{195}Pt CS parameters, and the environment beyond the isolated molecule must be taken into consideration when rationalizing the

origins of the ^{195}Pt CS tensors. This is discussed further in the following computational section.

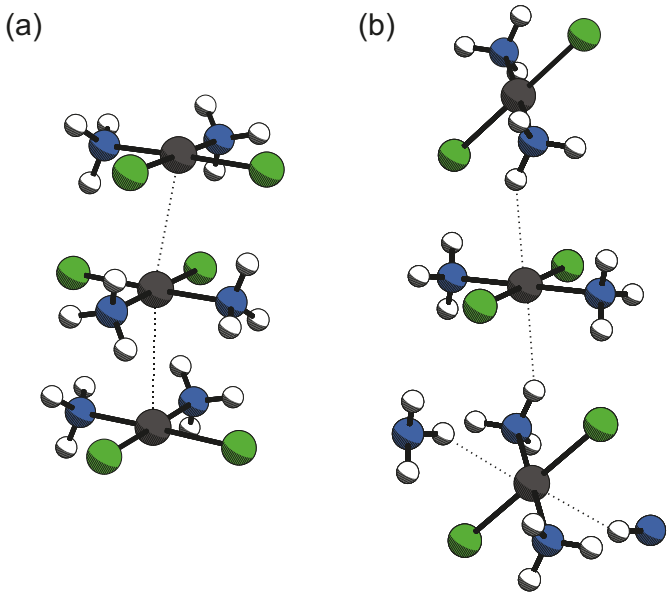
Pt(py)Cl_2, Pt(en)Cl_2, and carboplatin

Much like cisplatin, these compounds yield spectra that indicate CS tensors with high degrees of axial symmetry (Fig. 3), with κ values near –1 in all cases. Span values within this series of compounds are similar to those for cisplatin and transplatin. The span of 8350(50) ppm for Pt(en)Cl_2 agrees reasonably well with the previously reported span of 8100(200) ppm determined from an MAS spectrum.[78] Although these spectra appear to be very similar, they are distinguished by their unique δ_{iso} and Ω values, which result from the extreme sensitivity of the platinum CS interaction to the local environment (i.e., bonding, ligands, intermolecular interactions, etc.). In particular, it is the δ_{11} parameters, which reflect major changes in paramagnetic shielding contributions, that show the greatest variation in this series. The tensor orientations are likely to be similar to those described for cisplatin and transplatin, with δ_{11} oriented perpendicular to the square plane in each case.

^{195}Pt Hahn-echo SSNMR experiments

CPMG-based pulse sequences yield echo trains that can be processed in two different ways: one may either Fourier transform the entire echo train to obtain a series of "spikelets", the

Fig. 2. Local structure of (*a*) cisplatin and (*b*) transplatin. Broken lines indicate Pt–Pt and Pt–H contacts. Contacts shown on bottom transplatin Pt are for clarity.



outer manifold of which matches the true static pattern, or alternatively, one may shift and co-add all of the echoes together in the time domain, and Fourier transform the resulting FID to yield a standard static pattern (see Supplementary data Fig. S1). In either case, the signal to noise ratio (S/N) is generally much higher than the corresponding static pattern obtained via routine Bloch-decay or Hahn-echo techniques (depending on favourable T_2 characteristics of the nucleus being observed); however, the resolution of the resulting CPMG pattern is limited by factors such as the number of points per echo and the inter-echo spacing in the time domain.[79]

As seen for the ^{195}Pt WURST–CPMG spectra above, localization of signal intensity under the individual spikelets yields high S/N spectra, allowing for the efficient acquisition of broad patterns; however, accurate determination of CS tensor parameters is limited by the spectral resolution of the spikelet manifold (i.e., the frequency spacings of the spikelets) and is subject to a greater degree of uncertainty than determination of parameters obtained from higher resolution static powder patterns. The reduced uncertainties, however, come at the cost of high experimental times for standard Hahn-echo experiments, since the signal is no longer concentrated into a discrete number of spikelets, but rather, spread out over a continuous pattern. Furthermore, it is important to note that the WURST component of this sequence further reduces experimental times for the acquisition of broad patterns because of the much larger excitation bandwidths.

To obtain increasingly accurate CS tensor parameters, Hahn-echo experiments were carried out, but only near the discontinuities corresponding to the principal components. Fourier transformation of these subspectra yield higher resolution patterns from which the precise locations of the discontinuities can be identified, which in turn decreases the uncertainties associated with the CS tensor parameters (Table 1 and Supplementary data Table S6 and Fig. S2). In almost all cases, acquisition of high-quality Hahn-echo spectra of spectral regions near the discontinuities took three times as along as the acquisition of the entire powder pattern (high S/N, distortion-free) using the WURST–CPMG pulse sequence (Supplementary data Tables S1 and S2). The use of fewer subspectra (i.e., a larger step size in the piecewise acquisition method) results in patterns that still yield accurate CS parameters, albeit with considerable "cosmetic" defects (i.e., systematic modulation of powder pattern intensities, Supplementary data Fig. S3). We note that the portion of the sequence can be used to sweep frequency ranges much broader than presented herein; however, the WURST excitation and detection bandwidths are limited by the Q of the probe.

From these results and similar studies we have conducted using WURST–CPMG on spin-1/2 nuclides with broad patterns,[38] we can conclude that the best manner to proceed for rapid spectral acquisition and accurate determination of CS tensor parameters is to acquire a lower resolution, high-S/N WURST–CPMG pattern to map out the total shape of the CSA-dominated pattern and obtain the CS tensor parameters, and then, if lower uncertainties are required, to acquire higher resolution, low-S/N Hahn-echo spectra in the locales of the discontinuities to refine the CS tensor parameters. We note that the differences in uncertainties in the CS tensor parameters between the two types of spectra are not large (Supplementary data Table S7), and that in most instances, the rapid WURST–CPMG experiments can be conducted independently to obtain high-quality CS tensor data.

^{195}Pt MAS SSNMR experiments

^{195}Pt MAS NMR experiments are commonly employed to acquire high S/N SSNMR spectra that can be utilized to extract CS tensor parameters. MAS experiments are of great value for determining isotropic chemical shifts associated with multiple sites and for approximate determinations of CS tensor parameters when standard rectangular pulses are unable to excite the extremely broad powder patterns. The accurate determination of CS tensor parameters utilizing Herzfeld–Berger analysis of spinning sidebands (SSBs) in MAS spectra is highly dependent upon both peak positions and intensities. While we have no issue with the SSB positions (which are established with stable MAS speeds), we are sceptical of the intensities of the SSBs on the outer limits of broad MAS patterns and their relation to the CS tensor parameters. Furthermore, we believe that there is some degree of variation in these intensities depending upon the finite pulse width, pulse power, rise/fall times, etc., that HB analysis does not take into account, which can result in large errors and (or) uncertainties in the CS tensor parameters extracted from such spectra. To further examine this, we conducted MAS NMR experiments on the transplatin complex for comparison with our static WURST–CPMG NMR spectra.

It is possible to obtain a broad high S/N pattern of transplatin with a standard Bloch-decay MAS experiment using a 2.5 mm o.d. rotor and a pulse of appropriately short length (e.g., 1.0 μs). The MAS spectrum obtained for transplatin (Fig. 4) is of roughly the same breadth as the static powder pattern, giving the impression that the pattern is uniformly excited and that only a single experiment is necessary (i.e.,

no multiple subspectra). SIMPSON numerical simulations (Supplementary data Fig. S4), which consider finite pulse lengths and excitations, verify that the experimental pulse length and rf power (1.0 μs and 250 kHz, respectively) are appropriate for uniform excitation of the powder pattern. It should be noted that another set of SIMPSON simulations indicates that SSNMR pulses for routine experiments (i.e., 3.0 μs pulse length and 83.3 kHz rf power) would clearly fail to wholly excite the powder pattern (Supplementary data Fig. S5).

While the isotropic shifts can now be accurately measured (vide infra) from the MAS spectra, HB analysis yields parameters that are different than those obtained via static experiments and have much larger uncertainties (Table 1). The ambiguities associated with the HB analysis are clearly evident by an inspection of the calculated contour map (Supplementary data Fig. S6). The calculation of accurate tensor parameters relies on proper selection of the point at which the most contour lines intersect; however, there are several points in the plot that could fulfill these criteria owing to the large number of spinning sidebands (even at the high spinning speed of 26 kHz). The MAS spectrum was also simulated using parameters extracted from static experiments; however, this fit does not appear to be drastically different from the best fit of the MAS data. Therefore, the similarity of these two MAS patterns, as well as the ambiguities associated with the HBA contour map(s), suggest that anisotropic CS parameters extracted solely from this MAS spectrum are expected to have very high degrees of uncertainty compared with those obtained from analysis of corresponding static spectra.[80]

MAS experiments were conducted at three different spinning speeds to determine δ_{iso} to a high degree of accuracy and to examine changes in δ_{iso} as a result of frictional heating of the rotor at higher spinning speeds. Values for δ_{iso} of –2174(4), –2195(5), and –2178(10) ppm were determined from spectra acquired at spinning speeds of 26, 25, and 15 kHz, respectively. Each of these spectra has at least 30 SSBs and are accordingly challenging to phase; hence, prior to Fourier transformation, the FID data was left shifted to the top of the first echo. Unfortunately, the positions of sidebands (and the isotropic peak) vary slightly with the choice of phasing parameters; this issue is particularly pronounced in the 25 kHz MAS spectrum. The values of δ_{iso} do not seem to have any temperature dependence in this case; however, for similar applications to nuclei like ^{207}Pb, where the effects of temperature on δ_{iso} have been well-documented,[81–83] one must always take frictional heating into account and calibrate the MAS probe accordingly. We note that the isotropic peak of transplatin has a line width of 1030 Hz and shows no evidence of *J* coupling or residual dipolar coupling to nearby nuclei (Supplementary data Figs. S7 and S8).

^{195}Pt MAS NMR spectra of transplatin required ~20 h of experimental time by comparison with ~4–5 h for WURST–

CPMG spectra. With the exception of δ_{iso}, CS tensor parameters are obtained faster and with a lower degrees of uncertainty with static WURST–CPMG experiments. In addition, static experiments are not subject to frictional heating, eliminating concerns regarding temperature dependence of the CS tensor parameters. It is clear from these sets of data that static WURST–CPMG experiments offer numerous advantages over conventional static Hahn-echo and MAS experiments, in terms of reduced experimental times, spectral quality, and accurate determination of CS tensor parameters.

First principles calculations of platinum MS tensors

Comparison of experimental and calculated results

First principles calculations of the platinum MS tensor parameters and the associated tensor orientations are integral for understanding their origins and relations to molecular structure and symmetry. We are intentionally differentiating CS (or δ, experimentally determined) and MS (or σ, theoretically derived), although they can be related to one another either by choosing an appropriate standard reference or by plotting CS vs MS, which yields a slope close to unity in cases of good agreement. We note that it is possible to compare CS and MS scales for the DFT calculations on isolated molecules, since a $PtCl_6^{2-}$ anion can be utilized as a CS reference; however, there is no similar reference molecule and (or) system for corresponding DFT plane-wave calculations. Platinum CS tensor parameters derived from first principles calculations are given in Table 2. GIPAW plane-wave DFT calculations were performed using the CASTEP software package, and standard DFT calculations were run using the ADF software package. CASTEP uses plane-wave trial functions incorporating effects of lattice periodicity to calculate NMR properties, whereas ADF calculations involve conventional MO calculations on isolated species or larger clusters. The ADF software package allows the user to include relativistic contributions to the MS tensor parameters, an option that is absent in the CASTEP program (vide infra).

Plots of δ_{iso} vs σ_{iso} for GIPAW plane-wave DFT and standard DFT calculations incorporating ZORA (Fig. 5) show that the latter exhibit slightly better agreement with experimental values, although both plots have similar correlation constant (R^2) values. The slope of the plot for the plane-wave calculations is –2.41 (far from ideal), with a $R^2 = 0.73$, whereas the slope of the plot for ZORA DFT calculations is –0.74 (if the outlier ($Pt(py)_2Cl_2$) is excluded), with an $R^2 = 0.65$. Unfortunately, there are not enough test systems to make a meaningful linear correlation between δ_{iso} and σ_{iso}; however, when the absolute magnetic shieldings are converted to chemical shifts (only for the ZORA DFT calculations, through the use of $PtCl_6^{2-}$ reference calculations, vide supra), predicted and experimental δ_{iso} values are similar. We note at this point that calculations were also conducted without taking relativistic effects into account (data not shown); in most cases, very little

Note: Tabulated standard DFT calculations were all performed using a quadruple-ζ quadruple-polarized (QZ4P) basis set on all atoms and zeroth-order regular approximation (ZORA) for relativistic effects. Ω, span; κ, skew.

[a]Column refers to chemical shifts (CS, δ) for experimental values and standard DFT calculated values and magnetic shieldings (MS, σ) for plane-wave DFT calculated values.

[b]See Fig. 5 for plots of σ_{iso} vs δ_{iso}.

[c]Reported parameters and associated uncertainties are determined from simulations of Carr–Purcell–Meiboom–Gill (CPMG) spectra followed by refinement with Hahn-echo experiments near the discontinuities corresponding to the principal components.

[d]Calculated MS parameters (σ_{11}, σ_{22}, σ_{33}, and σ_{iso}) were converted to CS parameters (δ_{11}, δ_{22}, δ_{33}, and δ_{iso}) via calculations on a $PtCl_6^{2-}$ reference unit. See the Experimental section for details.

difference was observed between the two sets of calculations, with generally better agreement between experiment and theory for the ZORA DFT set (Supplementary data Table S8).

The plane-wave DFT calculations consistently predict the values of κ with greater accuracy than the corresponding DFT calculations on isolated molecules and also predict values of Ω that are closer to experimental values (although both methods underestimate the values of Ω for all systems). The underestimation of Ω values seems to stem from the out-of-plane σ_{11} components, since in most cases the σ_{22} and σ_{33} are predicted to be close to one another. The deshielding contributions to σ_{11} are the most challenging to calculate, since they involve an accurate description of the excited (virtual) orbitals involved in MS. The success of the plane-wave calculations infers that intermolecular interactions are likely to play an important role in determining the nature of the MS tensor. Unfortunately, current analyses of contributions of the individual orbitals to the MS tensors are currently limited to DFT calculations on isolated systems and large clusters.[83–85] Calculations of the Pt MS tensor for a large cluster modelled from the known crystal structure, while time consuming, would certainly yield valuable quantitative information on the intra- and inter-molecular contributions to MS; however, relativistic calculations of such large clusters would be extremely computationally intensive and is therefore beyond the scope of the current study.

Platinum MS tensor orientations

As documented previously,[78,86–91] square-planar Pt complexes normally have platinum CS tensors with large spans (i.e., >3000 ppm) and axially symmetric CS tensors (i.e., $\kappa = \pm 1$). All of the ^{195}Pt SSNMR spectra presented herein have a characteristic appearance because of κ values near –1, indicating that two principal components of the CS tensor (δ_{22} and δ_{33}) are quite similar, and the third principal component

Fig. 5. (*a*) Calculated ^{195}Pt magnetic shielding (MS) vs chemical shift (CS) values using plane-wave DFT calculations. The unbroken line corresponds to $y = -x + 800$. The broken line is a best fit to the data ($y = -2.41x - 1950$, $R^2 = 0.7301$). (*b*) Calculated ^{195}Pt MS vs CS values using standard DFT (BLYP) calculations. The unbroken line corresponds to $y = -x + 1825$. The broken line is a best fit to the data disregarding an outlier ($y = -0.74x + 2306$, $R^2 = 0.648$). The white outlier is $Pt(py)_2Cl_2$.

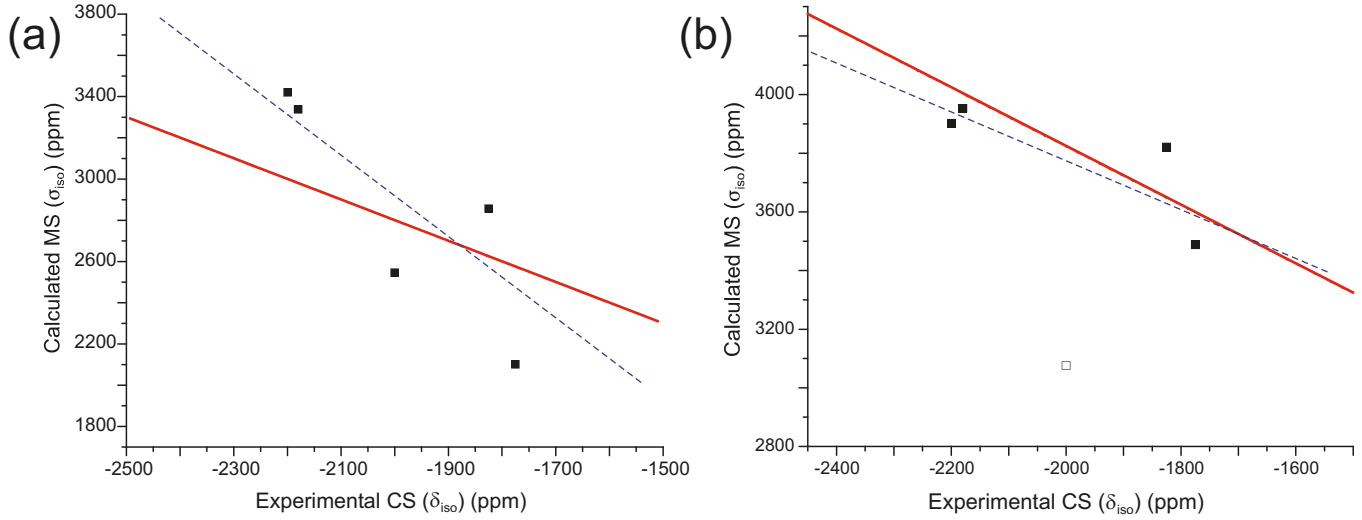

Fig. 6. Calculated platinum magnetic shielding (MS) tensor orientations from standard DFT calculations (plane-wave DFT calculations predict similar orientations). (*a*) Cisplatin, (*b*) transplatin, (*c*) $Pt(py)_2Cl_2$, (*d*) $Pt(en)Cl_2$, and (*e*) carboplatin. σ_{11} is perpendicular to the page in all instances.

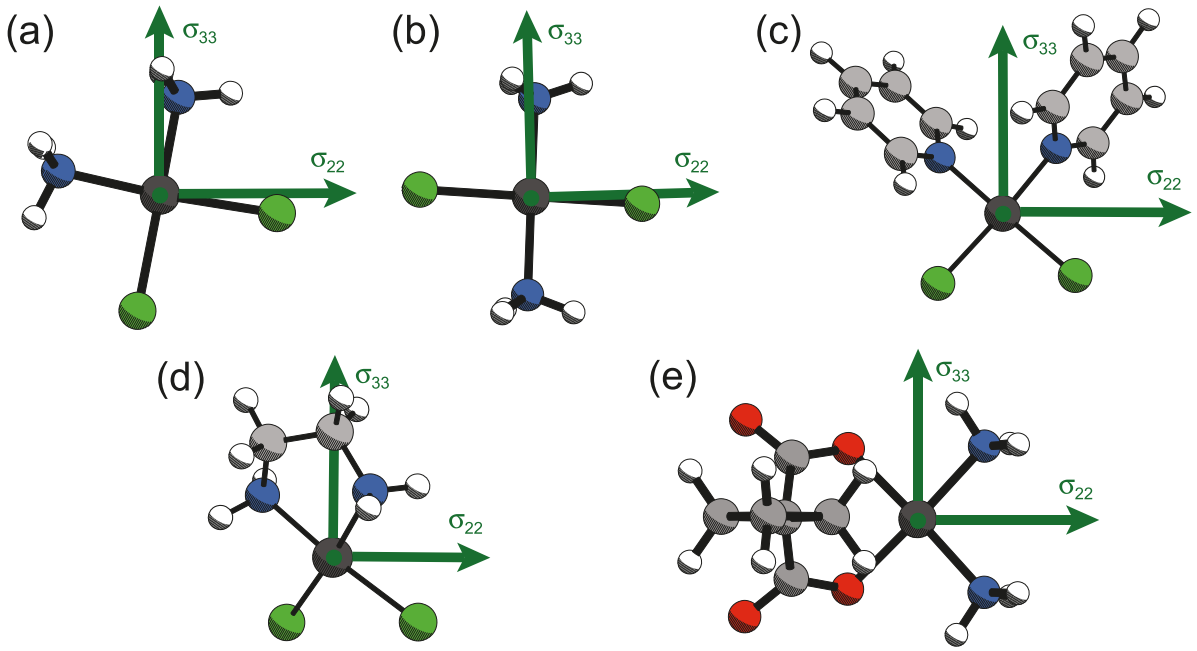

(δ_{11}) is distinct. The symmetries of these systems suggest that δ_{11} should be oriented perpendicular to the square plane in each case, with δ_{22} and δ_{33} constrained to the square plane. Since the CS tensor symmetry is so close to –1, δ_{22} and δ_{33} are very similar, and their orientations within the plane are irrelevant. Examination of the platinum MS tensor orientations for all of the systems herein reveals that, in every case, the distinct σ_{11} component corresponds to a direction perpendicular to the square plane (Fig. 6), in agreement with our predictions from experimental data. In transplatin, σ_{22} and σ_{33} lie roughly along Pt–N and Pt–Cl bonds, which coincide with mirror planes of symmetry. $Pt(py)_2Cl_2$, $Pt(en)Cl_2$, and carboplatin all have one of σ_{22} or σ_{33} located approximately along a mirror plane. Clearly, the CS tensor orientation in most square-planar Pt complexes is dictated by molecular symmetry elements, although the tensor components are not oriented precisely along (in) these symmetry elements, since these are not idealized gas-phase structures. Strangely, in cisplatin, the σ_{22} and σ_{33} components are not aligned exactly on any particular symmetry axis, with σ_{33} oriented between a Pt–NH_3 bond and a twofold rotational axis. However, roughly along the direction of σ_{33} in cisplatin lies an adjacent –NH_3 group (Pt···H distance of ~4.5 Å) and –Cl atom (Pt···Cl distance of ~4.45 Å), which may explain the peculiar MS

Note: ^{14}N spectra were not obtained for $Pt(py)_2Cl_2$ and $Pt(en)Cl_2$ because of their small T_2 values.

[a]Quadrupolar coupling constant: $C_Q = eQV_{33}/h$, where the principal components of the EFG tensor are defined as $|V_{33}| \geq |V_{22}| \geq |V_{11}|$ and h is Planck's constant. Only the absolute value of C_Q can be obtained from NMR experiments, not its sign.

[b]Asymmetry parameter: $\eta_Q = (V_{11} - V_{22})/V_{33}$.

tensor orientation. In the absence of high molecular symmetry, the case of cisplatin illustrates that intermolecular interactions can play a role in influencing the CS tensor orientation.

^{195}Pt T_1 and T_2 relaxation measurements

While conducting WURST–CPMG ^{195}Pt NMR experiments on these five systems, we observed very different relaxation characteristics, including T_1, which determines the pulse delay required between acquisitions, and T_2, which determines how many echoes can be collected per scan (vide infra). It is possible that these relaxation parameters could also be of use in identifying and (or) distinguishing structurally similar Pt(II) complexes in cases where the CS parameters are very similar.

The difference in T_1 values is readily apparent from the optimized experimental pulse delays employed in WURST–CPMG experiments (Supplementary data Table S1). Cisplatin, transplatin, and carboplatin all required a pulse delay of 120 s between scans, while $Pt(py)_2Cl_2$ required 30 s and $Pt(en)_2Cl_2$ required only 1 s. Owing to the long interpulse delays for the majority of these systems, we could only obtain accurate measurements of the T_1 value of $Pt(en)_2Cl_2$. A standard inversion-recovery experiment revealed that $T_1 <$ 200 ms for $Pt(en)_2Cl_2$, a surprisingly small value that is due to the presence of the ethylenediamine ligand (vide infra). ^{195}Pt T_2 constants for all systems were determined by fitting the intensity of the echoes in the ^{195}Pt WURST–CPMG FIDs as a function of time and fit to mono-exponential decays (Supplementary data Table S9). Values of T_2 range across one order of magnitude from 15.2 ms (transplatin) to 3.86 ms ($Pt(en)_2Cl_2$). For all compounds, distances between the ^{195}Pt centre and the closest protons in the molecule all range between 2.5 and 3.0 Å; hence, the nature of the protons, and not simply their distance from Pt, must be carefully considered.

The extremely rapid T_1 and fast T_2 relaxation of the nuclei in $Pt(en)_2Cl_2$ may result from proton motion arising from some degree of flexibility of the bidentate ethylenediamine ligand, which forms a five-membered ring with Pt. This may cause significant variation in the local magnetic field at the Pt nucleus, perhaps resulting in efficient longitudinal and transverse relaxation. Cisplatin, transplatin, and carboplatin all possess much larger T_1 values and longer T_2 values by

Note: η_Q, asymmetry parameter.

[a]Only the absolute value of the quadrupolar coupling constant (C_Q) can be obtained from NMR experiments, not its sign.

[b]No evidence of multiple ^{14}N sites were observed in the cisplatin spectrum.

[c]Calculations were performed using a triple-ζ double-polarized basis set on all atoms and the PBE exchange/correlation density functional.

comparison. Like $Pt(en)_2Cl_2$, cisplatin and transplatin also feature two Cl atoms bound to Pt; however, the latter two systems have two $–NH_3$ groups bound to Pt. Carboplatin has a rigid five-membered ring structure that includes Pt, but also has two Pt-bound $–NH_3$ groups. The $–NH_3$ protons rapidly reorient in the solid state in all of these systems, however, it is clear that this motion does not substantially affect T_1. This could be because the motion (and associated fluctuating magnetic fields) is simply too fast to make substantial dipole-dipole contributions to the T_1 (i.e., no significant contributions to spectral density at the Larmor frequency) and (or) that the Pt–H dipolar coupling constants are being partially motionally averaged.

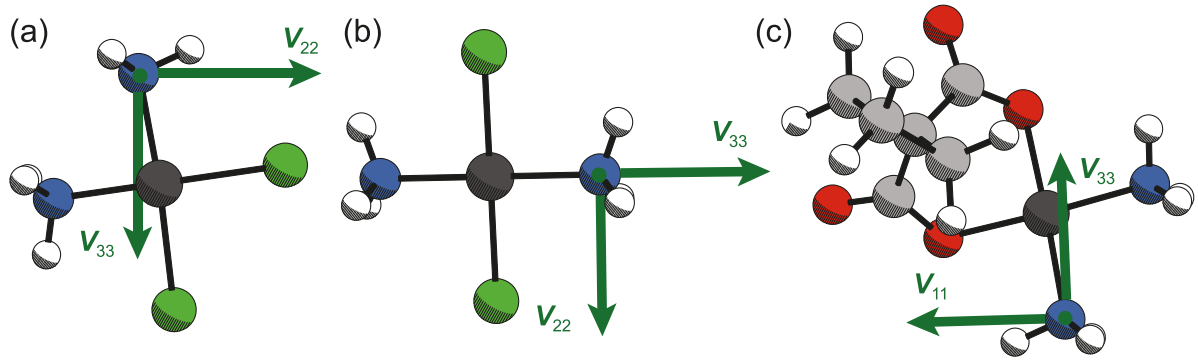
The T_2 values should be affected by dipole–dipole relaxation. Hence, the effect of variable-field proton decoupling on ^{195}Pt T_2 values of cisplatin was also examined (Supplementary data Fig. S9 and Table S10). Increases in applied decoupling fields correlate directly with longer effective T_2 values, confirming that T_2 contributions from ^{195}Pt–^{1}H heteronuclear dipolar dephasing are important. Interestingly, analysis of WURST–CPMG echo trains from experiments conducted with transmitter frequencies positioned near the two discontinuities of the powder pattern of cisplatin indicate that ^{195}Pt T_2 anisotropy is present (Supplementary data Table S11 and Fig. S10). For instance, at the leftmost discontinuity, the T_2 is clearly larger than that measured at the rightmost discontinuity. This indicates that crystallites (and by extension, CS tensors) with particular orientations with respect to the magnetic field have ^{195}Pt nuclei that experience different secular and (or) nonsecular contributions to relaxation. The leftmost and rightmost discontinuities correspond to CS tensors that have angles of $\theta = 0°$ and 90°, respectively, where θ is the angle between the magnetic field ($\mathbf{B}_0$) and the largest component of the CS tensor (δ_{33}). Since δ_{33} is oriented within the square plane of the cisplatin units, θ may be also used to approximately describe the angle between $\mathbf{B}_0$ and the square plane. At this time, we are uncertain as to why the ^{195}Pt T_2 values are reduced for cisplatins with their square planes oriented perpendicular to $\mathbf{B}_0$ and increased for those that are parallel. Certainly, the precise origins of the ^{195}Pt T_2 anisotropy could be probed via measurements of T_2 values for various crystallite orientations at multiple fields and with variable ^{1}H decoupling field strengths, to deconvolute contributions from CSA and dipole–dipole relaxation mechanisms; however, this is beyond the scope of the current work and will be the subject of a future study.

^{14}N WURST–CPMG SSNMR experiments

^{14}N NMR spectra are shown in Fig. 7 and experimental EFG tensor parameters are listed in Table 3. Since ^{14}N is a quadrupolar nucleus with a nuclear spin of $I = 1$, the first-order quadrupolar interaction dominates the appearance of these spectra; the narrowest spectral breadth is ~1 MHz for cisplatin. The effects of the second-order quadrupolar interaction are much smaller in comparison and have no real influence on these broad spectra. Furthermore, since ^{14}N has an integer nuclear spin, there is no central transition (i.e., $+1/2 \leftrightarrow -1/2$, CT), but only satellite transitions (i.e., $+1 \leftrightarrow 0$ and $0 \leftrightarrow -1$, ST). Contributions to spectral appearance from nitrogen CSA are also negligible;[37] for example, Santos et al.[92] reported a span of 80–100 ppm for a cisplatin analogue containing a bidentate ligand and two $–NH_3$ groups. All spectra were obtained in a single experiment (i.e., piecewise acquisition was not required) by acquiring the high-frequency (left) half of the pattern using the WURST–CPMG pulse sequence, as described in the Experimental. The ^{14}N NMR spectrum of cisplatin took ~3.5 h to acquire, whereas spectra of transplatin and carboplatin were each acquired in about an hour or less (Supplementary data Table S4). Spectra could not be acquired from $Pt(py)_2Cl_2$ and $Pt(en)Cl_2$ because of unfavourable relaxation characteristics (low T_2 values) and (or) potentially larger ^{14}N C_Q values (as predicted by first principles calculations, vide infra).

The ^{14}N NMR spectra reveal moderate C_Q values (~1 MHz) and η_Q values near zero. The low η_Q values suggest, in all cases, that V_{33} is likely oriented along or near the Pt–N bond, since $|V_{33}| > |V_{22}| \approx |V_{11}|$. There are clear differences between the ^{14}N spectra for cisplatin and transplatin, with C_Qs of 1.10(2) and 0.77(3) MHz, respectively; however, measured ^{14}N T_2 values are similar (vide infra). The crystal structure for cisplatin indicates two distinct NH_3 sites, though separate patterns are not observed in the 9.4 T spectra, indicating the sites are similar and have comparable EFG tensor parameters. The sensitivity of the ^{14}N EFG tensor to nearby hydrogen bonding has been documented previously, so a closer examination of intermolecular contacts is warranted.[39]

Fig. 8. Calculated ^{14}N electric field gradient (EFG) tensor orientations of (*a*) cisplatin, (*b*) transplatin, and (*c*) carboplatin. V_{11} is perpendicular to the page in the case of cisplatin and transplatin and V_{22} is perpendicular to the page in the case of carboplatin.



Cisplatin has intermolecular H···Cl hydrogen bonds between stacked –NH_3 and –Cl ligands (~2.3 Å from Cl to the nearest N-bound proton), whereas the transplatin has short intermolecular Pt···H (~2.6 Å) and H···Cl (~2.4 Å) distances. Hence, although the nitrogen chemical environments are superficially similar for the isolated units, it is very likely that intermolecular interactions involving –NH_3 protons result in disparate C_Q values (see the Computational section below for further discussion).

First principles calculations of ^{14}N EFG tensors

The ^{14}N EFG tensors calculated using plane-wave DFT and standard DFT methods are shown in Table 4. The plane-wave calculations are clearly superior in terms of agreement between experimental and theoretical values of C_Q, with DFT calculations resulting in overestimations of C_Q by more than double in some cases. Although the sign of C_Q cannot be obtained via static WURST–CPMG experiments, calculations predict C_Q to be negative, indicating that the electric field becomes increasingly negative as the distance from the ^{14}N nucleus increases (along the direction of V_{33}). The η_Q values for cisplatin and transplatin are better predicted by plane-wave calculations, whereas the DFT result for carboplatin is superior (however, this may be fortuitous). The success of the plane-wave calculations strengthens the argument that intermolecular interactions (e.g., hydrogen bonding) should be taken into account for ^{14}N EFG tensors in these systems.[39]

In all cases, the largest components of the ^{14}N EFG tensors (V_{33}) are directed close to the Pt–N bonds (Fig. 8), which is expected because of the C_3 rotational symmetry of the –NH_3 group and the near-zero values of η_Q. The orientations of V_{22} and V_{11} are similar in cisplatin and transplatin, with V_{22} located approximately in the square plane and V_{11} perpendicular to this plane. For carboplatin, which has a value of η_Q further from zero, V_{22} and V_{11} are predicted to be oriented out of and in the plane, respectively. Despite the difference between experimental and calculated values of η_Q for the carboplatin, this distinct tensor orientation is likely to be accurate, given that η_Q is further from zero than in the other systems, which may result from its unique organic moiety. Interestingly, both DFT and plane-wave DFT calculations predict similar EFG tensor orientations despite the dissimilar quadrupolar parameters, which indicates that the intermolecular interactions have more influence on the magnitudes of the EFG tensor components, as opposed to their orientations, which are largely dependent on intramolecular structure and bonding. Again, a full computational quantification of these contributions utilizing DFT calculations on extended cluster models is beyond the scope of the current work.[39,41,93]

^{14}N T_2 relaxation measurements

The intensity of the echoes in the ^{14}N WURST–CPMG FIDs were plotted as a function of time and fit to mono-exponential decays to determine the ^{14}N T_2 (Supplementary data Table S12 and Fig. S11). Unlike for the ^{195}Pt T_2 values, cisplatin, transplatin, and carboplatin all have similar ^{14}N T_2 values because of their similar ^{14}N environments. Since they all possess two Pt-bound NH_3 groups, this suggests that the primary mechanism of ^{14}N T_2 relaxation is governed by ^{14}N–^{1}H dipolar couplings and that the librational motions of the NH_3 groups are similar in each system. This is substantiated by a series of ^{14}N NMR experiments on cisplatin in which the strength of the ^{1}H decoupling field was varied (Supplementary data Table S13 and Fig. S12). As the decoupling field is increased, the effective T_2 value also increases, confirming that heteronuclear dipolar coupling is the dominant mechanism. Unfortunately, we were unable to increase the decoupling power past 38 kHz because of hardware restrictions, which prevented us from completely decoupling protons and measuring an effective T_2 with no contributions from the heteronuclear dipolar relaxation mechanism.

^{35}Cl WURST–CPMG SSNMR experiments

^{35}Cl NMR spectra are shown in Fig. 9 and experimental EFG tensor parameters are listed in Table 5. ^{35}Cl is a quadrupolar nucleus (I = 3/2) and the breadth of the central transition (+1/2 ↔ –1/2, CT) is dominated by second-order quadrupolar broadening, especially when the chlorine resides in a terminal environment (such as in cisplatin or transplatin).[94] The wide breadths of these spectra are such that piecewise acquisitions of individual subspectra are necessary to obtain the entire CT powder patterns.

The spectra of cisplatin and transplatin at 9.4 T are remarkably broad, with end-to-end breadths of ~4.5 and 5.0 MHz, respectively, owing to C_Q values of ~32 and 36 MHz. These C_Q values are significantly higher than those previously reported for terminal metal–Cl sites in group IV transition metal organometallic complexes.[42,94] The large breadths of the ^{35}Cl NMR spectra result in long experimental times: 14.25 h (25 subspectra) for cisplatin and 16 h (28 sub-

spectra) for transplatin (Supplementary data Table S5). Our C_Q values are similar to those previously obtained utilizing ^{35}Cl NQR experiments; we note that η_Q values were not reported.[95] However, several issues arise upon inspection of our EFG tensor parameters and overall spectral appearances. Firstly, although the transplatin spectrum has well-defined discontinuities (i.e., "horns" and "edges"), these same regions of the cisplatin spectrum appear "ragged" and poorly defined. The cisplatin spectrum could only be fit using two unique ^{35}Cl sites with identical η_Q values and similar C_Q values; however, the uncertainties involved with this fit are high. Secondly, neither cisplatin nor transplatin ^{35}Cl spectra showed any evidence of CSA effects (they are likely overwhelmed by the much larger effects of the second-order quadrupolar interactions).[42] If C_Q values are low and central transition powder patterns relatively narrow, CS tensor parameters may also be extracted; however, this is not possible for the broad powder patterns in this case.

To refine the ^{35}Cl EFG and CS tensor parameters, as well as to investigate the presence of multiple Cl sites and reductions in experimental time, ^{35}Cl SSNMR spectra of both compounds were acquired at a magnetic field strength of 21.1 T (Fig. 9). These spectra are much narrower than those acquired at 9.4 T owing to the inversely proportional relationship between the broadening effects of the second-order quadrupolar interaction and static magnetic field. The ^{35}Cl spectrum of cisplatin at 21.1 T took only 30 min to acquire (seven subspectra) and is of superior S/N compared with the spectrum at 9.4 T. Likewise, the spectrum of transplatin took

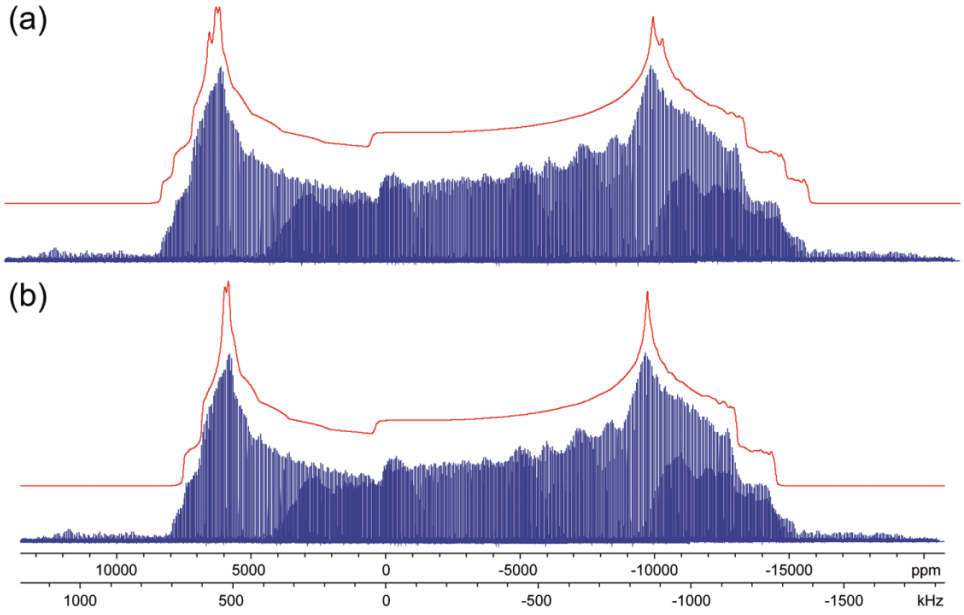
	21.1		37.3(1)	0.12(1)	650(300)	90(7)

Note: These ^{35}Cl spectra are dominated by the second-order quadrupolar interaction, making quantification of the relatively much smaller chemical shift (CS) parameters (δ_{iso} and skew (κ)) impossible in almost all cases. Only the absolute value of the quadrupolar coupling constant (C_Q) can be obtained from NMR experiments, not its sign. At high field (21.1 T), the span (Ω) can be quantified, since the effects of chemical shift anisotropy (CSA) on spectral appearance scale proportionately with magnetic field strength. β describes the angle between δ_{33} and V_{33} in the molecular frame, which are the largest components of the CS and electric field gradient (EFG) tensor, respectively. Since $\upsilon_o/\upsilon_Q \approx 2$ for ^{35}Cl at 9.4 T, the high-field approximation may no longer be valid at 9.4 T, and this low-field data should be considered preliminary.

[a] A δ_{iso} value of 150 (75) ppm was required to accurately simulate this spectrum.

Fig. 10. Static wideband uniform rate smooth truncation – Carr–Purcell–Meiboom–Gill (WURST–CPMG) ^{35}Cl NMR spectra (bottom trace) and simulations (top trace) of cisplatin at a magnetic field of 21.1 T, using (*a*) three unique ^{35}Cl sites and (*b*) two unique ^{35}Cl sites. In both cases, sites are simulated with equal weighting.



only 13 min to acquire at 21.1 T. Initial C_Q values extracted from spectra obtained at 21.1 T are ~1 MHz higher than those from spectra at 9.4 T, indicating that there may be significant chlorine CSA contribution that is unaccounted for. Simulated spectra at 21.1 T for both compounds utilizing a Ω of 650 (300) ppm seem to be in better agreement with experimental spectra, although these values are subject to high degrees of uncertainty owing to the breadth of the powder patterns. These spans have negligible effects on spectra at 9.4 T because of the proportional relationship between the broadening effects of CSA and the static magnetic field. Alternately, the disagreement in C_Q values between spectra at 9.4 and 21.1 T could also be due to a failure of the high-field approximation, which is not accounted for in the spectral simulation software, which treats the quadrupolar interaction as a first-order perturbation on the pure Zeeman Hamiltonian. Traditionally, the high-field approximation has been thought to be generally valid in cases where $\upsilon_o/\upsilon_Q \approx 10$, although Widdifield and Bryce[96] observed good agreement between experimental ^{127}I (spin = 5/2) SSNMR spectra and perturbation theory simulations in cases where $\upsilon_o/\upsilon_Q \approx 5$. In the current case, $\upsilon_o/\upsilon_Q \approx 2$ at 9.4 T; however, simulations incorporating full diagonalization of the Zeeman and quadrupolar Hamiltonians is beyond the scope of this work. To this end, the data at 9.4 T in Table 5 should be considered preliminary.

Surprisingly, simulations of the cisplatin powder pattern at 21.1 T indicate that three similar ^{35}Cl sites are present in a 1:1:1 ratio. The spectrum may also be simulated with two similar sites in an equal ratio, but the three-site fit models experimental data most accurately (Fig. 10 and Supplementary data Fig. S13). We cannot comment definitively on the

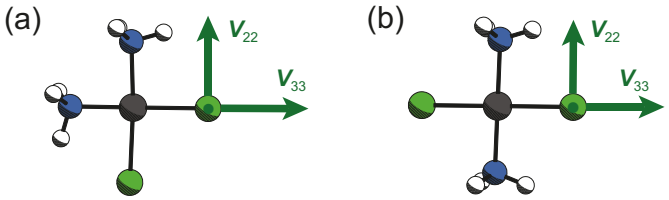
[a]Only the absolute value of the quadrupolar coupling constant (C_Q) can be obtained from NMR experiments, not its sign.

[b]Calculations were performed using a triple-ζ doubly-polarized basis set on all atoms and the PBE exchange/correlation density functional.

Fig. 11. Calculated ^{35}Cl electric field gradient (EFG) tensor orientations of (*a*) cisplatin and (*b*) transplatin. V_{11} is perpendicular to the page in both instances.



origin of these multiple powder patterns; it is possible that the third pattern represents a polymorphic form of cisplatin (perhaps from exchange of Cl for H_2O ligands), which would certainly be evident via ^{35}Cl SSNMR.[43] However, this seems implausible, given that solid-state exchange of this sort would be highly energetically unfavourable and would not readily occur for a sealed sample. Regardless of the origins of the additional powder pattern, the two sites corresponding to the crystal structure of cisplatin can be readily distinguished from an impurity by ^{35}Cl SSNMR, particularly at high magnetic fields.

First principles calculations of ^{35}Cl EFG tensors

Both plane-wave and DFT MO calculations predict two magnetically distinct ^{35}Cl sites in cisplatin, with similarly high C_Q and low η_Q values (Table 6), although values of C_Q are consistently overestimated for both compounds. Plane-wave calculations predict values of η_Q to a higher degree of accuracy than the corresponding DFT MO calculations, again indicating that intermolecular interactions (namely, Cl···H hydrogen bonding) influence the ^{35}Cl EFG tensors.[43] The calculated ^{35}Cl EFG tensor orientations are identical for both cisplatin and transplatin, with V_{33} directed along the Pt–Cl bond, V_{22} in the plane, and V_{11} perpendicular to the plane of the molecule (Fig. 11).

^{35}Cl T_2 relaxation measurements

To investigate whether ^{35}Cl T_2 values are influenced by the ^{1}H–^{35}Cl dipole–dipole relaxation mechanism, the effect of variable-field proton decoupling on the center of the cisplatin powder pattern was explored (Supplementary data Fig. S14 and Table S14). As expected, increases in the applied ^{1}H decoupling field result in increases in observed effective T_2 values, until a range of ~29 to 35 kHz, implying that the ^{35}Cl nuclei are effectively decoupled from all nearby protons. The hydrogen-bonding environment about the ^{35}Cl nuclei (Supplementary data Fig. S15) has five protons arranged in a distorted square pyramidal geometry around chlorine, with H···Cl distances ranging from 2.3 to 2.6 Å, corresponding to fairly small individual H–Cl dipolar couplings (e.g., an internuclear distance of 2 Å corresponds to a coupling constant of 1.5 kHz). This implies that it is not simply an individual ^{1}H–^{35}Cl dipolar coupling affecting the ^{35}Cl T_2 value of cisplatin, but rather, dipolar coupling between ^{35}Cl and a network of strongly dipolar-coupled protons.

Finally, the broad ^{35}Cl SSNMR spectra of cisplatin and transplatin spectra afford an opportunity to probe for T_2 anisotropy. The WURST–CPMG echo trains of two cisplatin subspectra situated over the horns of the ^{35}Cl spectrum at 9.4 T yield a T_2 value of 23.8 (3.5) ms for the high-frequency discontinuity and 15.7 (1.6) ms for the low-frequency discontinuity, which correspond to crystallite orientations where V_{33} is oriented with respect to B_0 at 88° and 30°, respectively. It follows that cisplatin molecules with V_{33} oriented perpendicular to B_o (i.e., 88°) have increased T_2 values over those with V_{33} oriented at 30°. The origins of this T_2 anisotropy are uncertain at this time and will be investigated in a forthcoming study; however, it does not appear to originate from ^{1}H–^{35}Cl dipole–dipole coupling, since these experiments were run using an applied proton decoupling field of 35 kHz (which should result in complete decoupling, vide supra).

Conclusions

The WURST–CPMG pulse sequence and frequency-stepped acquisition techniques have been used to acquire ^{195}Pt, ^{14}N, and ^{35}Cl SSNMR of cisplatin and related complexes. All ^{195}Pt NMR spectra are very broad and have a characteristic appearance owing to the orientation of the CS tensor with respect to the square plane of the molecule (i.e., in each case, δ_{11} is the distinct principal component and oriented perpendicular to the square plane). From our work on these broad patterns, we suggest that the best method for accurately determining CS tensor parameters from broad patterns of spin-1/2 nuclei is to first acquire the spectrum using the WURST–CPMG pulse sequence (rapid acquisition, high S/N, and relatively high accuracy for CS tensor components). If necessary, one can utilize echo experiments of subspectra near the spectral discontinuities to refine the principal components and MAS experiments (when possible) to accurately measure the isotropic chemical shifts. Plane-wave calculations for these systems consistently predict ^{195}Pt CS tensor parameters to a high degree of accuracy, save for δ_{11}. The inconsistency of DFT calculations on isolated molecules indicates that intermolecular interactions may play a significant role in determining the origins of the ^{195}Pt CS tensor parameters and orientations. ^{195}Pt relaxation times (T_1 and T_2) show variation across this series of compounds; in particular, the T_2 time constants are facile to measure and may be of use in distinguishing different Pt sites in spectra exhibiting multiple powder patterns. ^{14}N WURST–CPMG experiments, each acquired in a matter of hours at normal magnetic fields, yielded EFG tensor parameters for three compounds. ^{35}Cl WURST–CPMG spectra of cisplatin and transplatin were acquired at two different fields, and the dominant T_2 relaxation mechanism in cisplatin was determined to arise from ^{1}H–^{35}Cl dipolar coupling. The rapid acquisition of broad powder patterns using the WURST–CPMG pulse sequence on pure compounds offers much promise for detection of nuclei in cisplatin derivatives, which are diluted in biological samples. In particular, the ^{195}Pt NMR spectra should be the most effective in this respect, owing to both the sensitivity of the ^{195}Pt CS tensor to structural changes and the rapidity with which these spectra can be acquired. We plan to further investigate systems related to cisplatin and its anticancer derivatives, and we hope that our work encourages more solid-state NMR studies in this area.

Abstract: Two calcium–cobalt silicates were synthesized in which cobalt occupies different structural positions. The crystal phases belong to two main structural silicate types. In the Co-åkermanite structure ($Ca_2CoSi_2O_7$), cobalt cations take tetrahedral coordination toward oxygen atoms. In the Co-pyroxene structure of $CaCoSi_2O_6$, cobalt displays octahedral coordination. $Ca_2CoSi_2O_7$ was prepared by solid-phase synthesis and $CaCoSi_2O_6$ was prepared by sol–gel method. The synthesis of the phases was confirmed by XRD, FTIR, and EPR data. On the basis of the XPS analysis, it can be concluded that Co^{2+} cations exist in the studied silicates. Thus, it is possible to study the catalytic activity of two silicate phases containing Co^{2+} cations in different coordinations: tetrahedral and octahedral. It was found that cobalt silicates with crystal structures corresponding to pyroxene and åkermanite possess catalytic activity in the reactions of complete oxidation of CO and toluene. Co-pyroxene exhibits higher catalytic activity than Co-åkermanite, but the higher cobalt content on the surface of Co-pyroxene should also be taken into account. Then, it turns out that catalytically active complexes with Co^{2+} ions in tetrahedral coordination are more efficient than those with such ions in octahedral coordination when equal concentrations of cobalt were used on the surface of the catalysts.

Key words: Co-pyroxene ($CaCoSi_2O_6$), Co-åkermanite ($Ca_2CoSi_2O_7$), cation coordination, catalytic activity, CO oxidation.

Résumé : On a réalisé la synthèse de deux silicates de calcium et de cobalt dans lesquels l'atome de cobalt occupe des positions diverses dans la structure. Les phases cristallines appartiennent à deux types principaux de structures de silicate. Dans la structure åkermanite du $Ca_2CoSi_2O_7$, les cations du cobalt occupent des positions de coordination tétraédrique par rapport aux atomes d'oxygène. Le $Ca_2CoSi_2O_7$ a été préparé par une synthèse en phase solide alors que le $CaCoSi_2O_6$ a été obtenu par méthode sol–gel. Les synthèses des phases ont été confirmées par des données de diffraction des rayons-X (DRX), d'infrarouge à transformée de Fourier (IR-TF) et résonance paramagnétique électronique (RPE). Sur la base d'analyse de données de spectroscopie photoélectronique des rayons-X (SPX), il est possible de conclure que, dans les silicates étudiés, il existe des cations Co^{2+}. Il est donc possible d'étudier l'activité catalytique des deux phases de silicate contenant des cations Co^{2+} dans des environnements de coordination différents : tétraédrique et octaédrique. On a trouvé que les silicates de cobalt avec une structure cristalline correspondant à celle du pyroxène et de l'åkermanite présentent une activité catalytique dans les réactions d'oxydation complète du CO et du toluène. Le Co-pyroxène possède une activité catalytique plus élevée que celle de la Co-åkermanite; toutefois, on doit tenir compte du fait que la teneur en cobalt est plus élevée sur la surface du Co-pyroxène. Il en découle alors que, pour des concentrations identiques de cobalt à la surface des catalyseurs, les complexes catalytiquement actifs comportant des ions Co^{2+} en coordination tétraédrique sont plus efficaces que ceux dans lesquels se trouvent dans une coordination octaédrique.

Mots-clés : Co-pyroxène ($CaCoSi_2O_6$), Co-åkermanite ($Ca_2CoSi_2O_7$), coordination d'un cation, activité catalytique, oxydation du CO.

[Traduit par la Rédaction]

Introduction

One of the important factors to consider when developing new types of catalysts is the coordination of the catalytically active ion in the final product (catalyst), since the catalytic activity is largely determined by the coordination of the ion as well as by its oxidation state. Cobalt-based catalysts are widely used in oxidation reactions mainly for disposal of CO[1–4] and harmful organic substances[5–7] and reduction of NO[8–11] in gases. The Co^{2+}–Co^{3+} ion pair and ion coordination lie at the basis of this activity.[12] These ions form the catalytically active complex (CAC). It is known that Co^{2+} and Co^{3+} prefer octahedral coordination (O_h), since the stabilization energy for such coordination is higher than that for tetrahedral (T_d) coordination.[13–16]

It is important to compare the Co^{2+} ion activity in terms of two different coordinations of the crystal field, but in similar chemical compounds. Co-åkermanite ($Ca_2CoSi_2O_7$) and Co-pyroxene ($CaCoSi_2O_6$) silicate types provide such an opportunity. $Ca_2CoSi_2O_7$ and $CaCoSi_2O_6$ are structural analogues of åkermanite and diopside minerals in the complete

Fig. 1. Crystal structure of Co-pyroxene ($CaCoSi_2O_6$) projected on the (100) plane (*a*) and (001) plane (*b*). White spheres are calcium atoms, dark polyhedra are CoO_6 octahedra, and light polyhedra are SiO_4 tetrahedra.

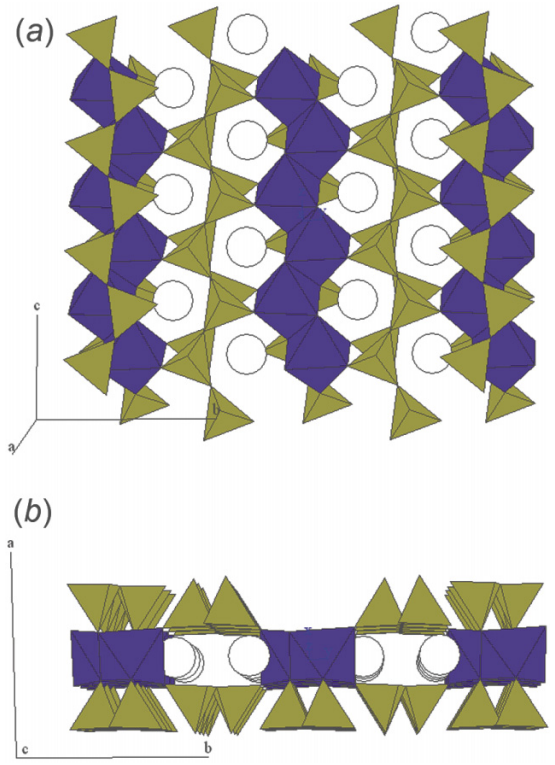

Fig. 2. Crystal structure of Co-åkermanite ($Ca_2CoSi_2O_7$) projected on the (001) plane (*a*) and the (100) plane (*b*). White spheres are calcium atoms, dark polyhedra are CoO_4 tetrahedra, and light polyhedra are SiO_4 tetrahedra.

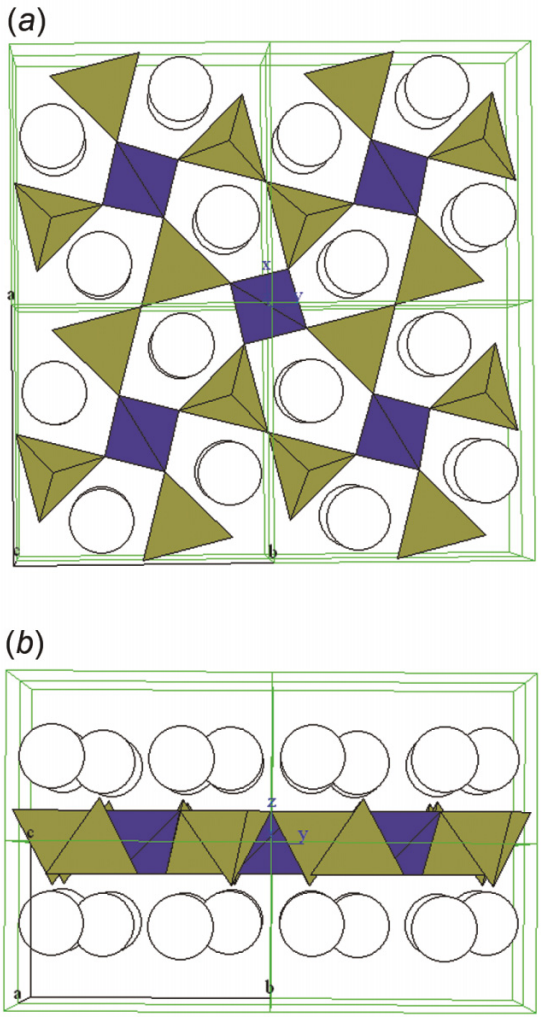

substitution of the positions of magnesium with cobalt. Such substitution is justified by the close values for ionic radii of Mg^{2+} and Co^{2+}. The crystal phases belong to two main structural silicate types: silicates with diorthogroups of silicon–oxygen tetrahedra and silicates with chains of silicon–oxygen tetrahedra. In these two phases, cobalt is expected to take different structural positions. In the åkermanite structure $Ca_2CoSi_2O_7$, cobalt cations take tetrahedral coordination toward oxygen atoms.[17–20] In pyroxene structure $CaCoSi_2O_6$, the cobalt is in octahedral coordination.[21,22] The crystal structures are presented in Figs. 1 and 2 using the software CaRIne Crystallography 3.1.[23]

Our previous study[24] on the possibilities of a synthesis of these compounds established that åkermanite may be synthesized easily via solid-state synthesis and the sol–gel method is more convenient for the synthesis of pyroxene. This allows determining the possible effect of Co^{2+} ions in such pyroxene or åkermanite crystal structure on the catalytic activity in oxidation reactions.

Therefore, the aim of the present study is to examine the catalytic activity in oxidation reactions of CO and toluene of two calcium–cobalt silicates: $Ca_2CoSi_2O_7$ and $CaCoSi_2O_6$. The catalytic activity of these phases has not yet been studied.

Experimental procedure

Synthesis

A phase $Ca_2CoSi_2O_7$ has been synthesized by solid-state reactions. The initial raw materials used were chemically pure reagents, such as $CaCO_3$, Co_3O_4, and vitreous quartz powder. The stoichiometric mixture was well-ground and homogenized. After the addition of a binding agent (3% aqueous solution of poly(vinyl alcohol)) to the mixture, samples with a diameter of 30 mm and a height of 10 mm were obtained by pressing. The prepared tablets (samples) were thermally treated at 1200 °C for 2–3 h through isothermal treatment in a corundum crucible. The sample, in which $Ca_2CoSi_2O_7$ was identified, was deep blue.

A similar scheme of pyrosynthesis was applied to synthesize $CaCoSi_2O_6$, but difficulties were met arising from the fact that the phase formation occurs in a narrow temperature range, which is close to the melting point of the composition. This was the reason for giving preference to the sol–gel synthesis method. $CaCoSi_2O_6$ pyroxene has been prepared by sol–gel technique using $Ca(NO_3)_2{\cdot}4H_2O$, $Co(NO_3)_2{\cdot}6H_2O$, and tetraethyl orthosilicate (TEOS) as precursors. The obtained gel was dried at 100 °C, and then the samples were calcined in air for 2 h. Calcinations temperature of 1200 °C was selected. The color of the obtained sample was pink. A detailed method of synthesis is described elsewhere.[24]

Exeperimental methods

X-ray powder diffraction (XRD) analysis was applied for phase control. An X-ray diffractometer DRON-3M at Fe-filtered Co Kα radiation was used in the range from 8° to 70° 2θ (step size: 0.05°, counting time per step: 1 s). The Rietveld refinement was performed using DiffracPlus TOPAS v. 4.2.[25] The unit-cell parameters, the position of cobalt, and Co–O distances were refined on the basis of experimental X-ray data. The positional parameters of structure of $CaCoSi_2O_6$ (Inorganic Crystal Structure Database (ICSD) No. 202245) and those of $Ca_2CoSi_2O_7$ (ICSD No. 94131) were used as the starting parameters of the refinement of structures. PowderCell 2.4 software[26] was used to determine the size of crystallites on the basis of the experimental X-ray data.

FTIR spectroscopy was applied. Infrared transmittance spectra were recorded by using the pressed-pellet technique in KBr. The measurements were made with a FTIR spectrophotometer Bruker EQUINOX 55 in the frequency range from 4000 to 400 cm^{-1}.

Electron paramagnetic resonance (EPR) spectra have been investigated in the temperature range 100–400 K. They were registered as the first derivative using the ERS/220 spectrometer. The *g* factor was determined using the Mn^{2+}/ZnS standard.

Chemical composition was analyzed by X-ray energy dispersion spectroscopy (EDS) coupled to scanning electron microscope JEOL-JSM 6370.

X-ray photoelectron spectroscopy (XPS) studies were performed on a VG ESCALAB MkII electron spectrometer under a base pressure of 1×10^{-8} Pa. The photoelectron spectra were excited using an Al Kα X-ray source (excitation energy h_n = 1486.6 eV) with a total instrumental resolution of ~1 eV. The C1s line of adventitious carbon at 285.0 eV was used as internal standard to calibrate the binding energies. The photoelectron spectra were corrected by subtracting a Shirley-type background and were quantified using the peak area and Scofield's photoionization cross sections.

The determination of the specific surface area of the samples was carried out by nitrogen adsorption at 77.4 K. Nitrogen adsorption isotherms were used to calculate the specific surface area (A_{BET}) using the BET equation.

The catalytic activity of the samples was measured in an isothermal plug-flow reactor enabling operation under steady-state conditions without any temperature gradients. The size of the catalyst particles (0.3–0.6 mm) was chosen taking into account the reactor diameter (6 mm) and the hourly space velocity (20 000 h^{-1}) to reduce the effect of the pore diffusion. The gas feed flow rate was 4.0 L/h, the catalyst bed volume was 0.2 cm^3, and the mass of the charged catalyst was 0.5–0.55 g. The catalytic oxidation was performed within the temperature interval 200–400 °C, the oxidizing agent used being oxygen from the air (gas mixture: 21% O_2 and 79% N_2). The preliminary treatment of the catalysts included heating in air flow at 120 °C for 1 h. The flow of CO and toluene was fed into the reactor by an Ismatex M62/6 pump (Switzerland).

The initial concentration of carbon monoxide was 0.5 *v*/*v*. The carrier gas was air (a mixture of 21% O_2 and 79% N_2). A Maihak gas analyzer (O_2, CO, CO_2) was used to measure the CO and CO_2 concentrations with an accuracy of ±0.1 ppm, whereas the oxygen measurement accuracy was ±100 ppm.

The catalytic activity of the samples, with respect to the complete oxidation of toluene, were carried out in a flow reactor, with a catalyst volume of 0.2 cm^3 (0.5–0.55 g), a space velocity of 20 000 h^{-1}, and the concentration of toluene was 0.03 *v*/*v*). The inlet and outlet gas mixtures were analyzed by a THERMO-FID analyzer.

The activity of catalysts is presented as a fraction of the oxidized CO and toluene (η, %); the amount of oxidized CO and toluene per gram of catalyst per hour (I_g, mg/g h^{-1}).

Results and discussion

The XRD data confirm the synthesis of Co-åkermanite ($Ca_2CoSi_2O_7$, in accordance with PDF card 43-0005) and Co-pyroxene ($CaCoSi_2O_6$, in accordance with PDF card 84-1288) in the studied samples. As shown earlier,[17–22] åkermanite is tetragonal, space group $P\bar{4}2_1m$, whereas pyroxene is monoclinic, space group $C2/c$. Figure 3 shows the Rietveld analysis patterns of the samples. For the pyroxene sample, the *R* factors obtained were as follows: the pattern factor (R_p) = 10.42, the weighted pattern factor (R_{wp}) = 13.66, and the goodness of fit (GoF) = 1.34; and for the åkermanite sample, R_p = 11.17, R_{wp} = 14.73, and GoF = 1.34. The positional parameters of the phases do not differ from the starting models used. The refined unit-cell parameters are consistent with previous data for åkermanite: a = 7.8386(13) Å and c = 5.02390(98) Å; and those for pyroxene: a = 9.7931(20) Å, b = 8.9497(17) Å, c = 5.2447(13) Å, and β = 105.518 (13)°.[18–20,27] The size of crystallites is 104 nm for the åkermanite phase and 96 nm for pyroxene. Kimata[18] established that in the case of Co-åkermanite, the Co–O bond length (1.926 Å) is slightly shorter than the sum (1.96 Å) of the effective ionic radii of Co^{2+} (0.58 Å when four-coordinated, as in åkermanite and high spin) and O^{2-} (1.38 Å).[28] The bond distance Co–O determined in this study is 1.936 Å, and the form of tetrahedron is regular. This value is very close to the value reported by Kusaka et. al. (1.937(4) Å)[20] for the basic structure of $Ca_2CoSi_2O_7$ at room temperature. Recently, Hagiya et al.[19] succeeded in determining the incommensurate structure of synthetic $Ca_2CoSi_2O_7$. They concluded the following: the SiO_4 tetrahedron does not behave as a rigid body, the distance of Si–O tetrahedral bonds is variable throughout the crystal, and Co–O distances are simultaneously and sinusoidally modulated.

According to studies published so far,[21,22] within the pyroxene structure, all polyhedrons (including SiO_4 tetrahedron) are inherently flexible, and their absolute shapes and sizes are dependent on the interaction with the adjacent polyhedrons. The mean Co–O bond length determined in this study was 2.100 Å (there are three different Co–O distances: 2.070, 2.094, and 2.136 Å). The Co octahedron is very nearly regular. The difference between the shortest and the longest Co–O distances is 0.066 Å. Therefore, the value of the Co–O distance in pyroxene structure is very close to the sum (2.10 Å) of the effective ionic radii[28] of Co^{2+} (0.72 Å when six-coordinated) and O^{2-} (1.38 Å). Our data are consistent with the known values from the literature.[21,22]

The data for the IR spectra of Co-pyroxene and Co-åkermanite are presented in Table 1. As compared with the spectrum of $Ca_2CoSi_2O_7$ presented by Kimata,[18] the shape and the position of bands of experimental spectrum bear

Table 1. Band frequencies and assignments for Co-åkermanite and Co-pyroxene.

Band frequencies (cm^{-1})	Tentative assignments
Co-åkermanite	
1012	ν_{as}(Si–O–Si)
964	ν_s(Si–O^-)
902	ν_s(Si–O^-)
832	
678	ν_s(Si–O–Si)
619	ν_s (Si–O–Co)
503	ν(Co–O)
455	ν(Co–O)
Co-pyroxene	
1058	ν_{as}(Si–O–Si)
965	ν_s(Si–O^-)
860	ν_{as}(Si–O^-)
673	ν_s(Si–O–Si)
627	ν_s(Si–O–Si)
502	δ(Si–O^-)
466	ν(Co–O)

striking similarities. Therefore, the FTIR spectrum confirms the structure of Co-åkermanite. This conclusion is in accordance with the XRD data. The bands near 1100–600 cm^{-1} are considered to be mainly related with the vibrations of the $Si_2O_7^{6-}$ group. In the spectrum of Co-åkermanite, the band at 678 cm^{-1} is a symmetrical stretching, ν_s(Si–O–Si) mode of bridging oxygen of the pyrosilicate anions. In the spectrum of åkermanite, the ν_s(Si–O–Si) band of the $Si_2O_7^{6-}$ group appear at 661 cm^{-1}. The bands at 902 and 964 cm^{-1} are assigned to symmetrical stretching modes of terminal oxygens, whereas the band at 1012 cm^{-1} is assigned to antisymmetric stretching of oxygens in åkermanite.[29] The FTIR data ought to show that Co^{2+} ions occur in tetrahedral coordination in the åkermanite structure. It is known that cationic substitutions in åkermanite structure change only the position of the absorption bands associated with replacement cations. In the spectrum of $Sr_2CoSi_2O_7$, the bands at 530 and 450 cm^{-1} were assigned to the vibration of CoO_4 tetrahedra.[30] A look at the frequencies of $Ca_2CoSi_2O_7$ shows that the 503 and 455 cm^{-1} bands correspond to the stretching vibrations of the CoO_4.[18]

The IR spectrum of pyroxene has a very characteristic pattern with three strong bands in the range of 1060 to 850 cm^{-1}. The five modes at high frequencies are representative of the

O	36.36	0.47	58.18

Table 3. Results of the quantitative energy dispersion spectroscopy (EDS) analysis of the Co-pyroxene sample.

Element	Concentration (weight %)	Standard deviation (σ, weight %)	Concentration (atomic %)
Ca	16.30	0.25	10.60
Co	28.20	0.43	12.48
Si	19.33	0.25	17.95
O	36.18	0.36	58.97

stretching motions in the silicate chain. The chain vibrations are not particularly sensitive to the population of the cation sites.[31] The band at 1058 cm^{-1} may be attributed to the ν_{as} (Si–O–Si) mode. The bands at 965 and 860 cm^{-1} are due to the symmetrical ν_s(Si–O^-) and antisymmetric ν_{as}(Si–O^-) stretching of the terminal nonbridging oxygens in the chains. The band at 673 cm^{-1} is characteristic of pyroxene chains and corresponds to the symmetric stretch of bridging oxygen ν_s(Si–O–Si). Raman spectra of pyroxene minerals include one or two bands in the 650–680 cm^{-1} range that have been assigned to the motion of the bridging oxygens in the chains.[29] δ(Si–O^-) deformation mode appears at 502 cm^{-1}, and the band at 466 cm^{-1} corresponds to stretching vibrations of the CoO_6.

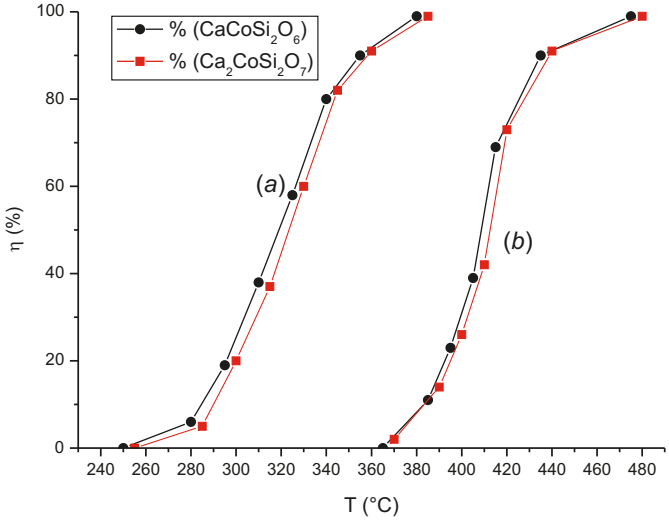
The type of EPR spectra of Co-åkermanite ($Ca_2CoSi_2O_7$) depends strongly on the temperature at which the spectra were recorded; i.e., at room temperature, signals are observed containing fine structure, whereas at low temperatures (113 K), EPR signals disappear.

The EPR spectra of Co-pyroxene ($CaCoSi_2O_6$) contain the anisotropic signal with g-tensor values $g_{\parallel} = 4.8$ and $g_{\perp} = 2.1$, respectively. At 113 K, only a broad signal owing to the exchange-connected Co^{2+} ions from $CaCoSi_2O_6$ was observed. Thus, the characterization results suggest that cobalt is present mostly as Co^{2+} ions in octahedral coordination.

We can conclude that the experimental XRD, FTIR, and EPR results are consistent with previous studies of Co-pyroxene and Co-åkermanite. Hence, they confirm the structures of the crystalline phases and, respectively, the coordination of Co^{2+} ions: tetrahedral in åkermanite and octahedral in pyroxene.

EDS analysis is needed to clarify whether the catalyst stoichiometry corresponds to that of Co-åkermanite and Co-pyroxene minerals. Data from EDS analysis for the chemical composition of synthesized åkermanite and pyroxene phases are presented, respectively, in Tables 2 and 3. The data presented are averages of five crystallites analyzed for each of the two samples. EDS analysis allowed us to determine the following chemical formulae: for Co-åkermanite, $Ca_{2.11}Co_{0.95}Si_{1.96}O_{6.98}$; and for Co-pyroxene, $Ca_{1.06}Co_{1.25}Si_{1.80}O_{5.90}$. Experimentally established composition of åkermanite contains a surplus of

Fig. 4. Amount of oxidized CO (*a*) and toluene (*b*) η (%) depending on temperature (T, °C). Samples: $CaCoSi_2O_6$ (Co-pyroxene) and $Ca_2CoSi_2O_7$ (Co-åkermanite).



Ca versus the stoichiometric composition $Ca_2CoSi_2O_7$. Experimentally determined composition of the pyroxene phase derived by the sol–gel method deviates from the stoichiometry with an excess of Co and a decreased quantity of Si. Note that the ratio between the concentrations of cobalt in the samples is 1.58, which is significantly higher than that between the stoichiometric compositions (1.25).

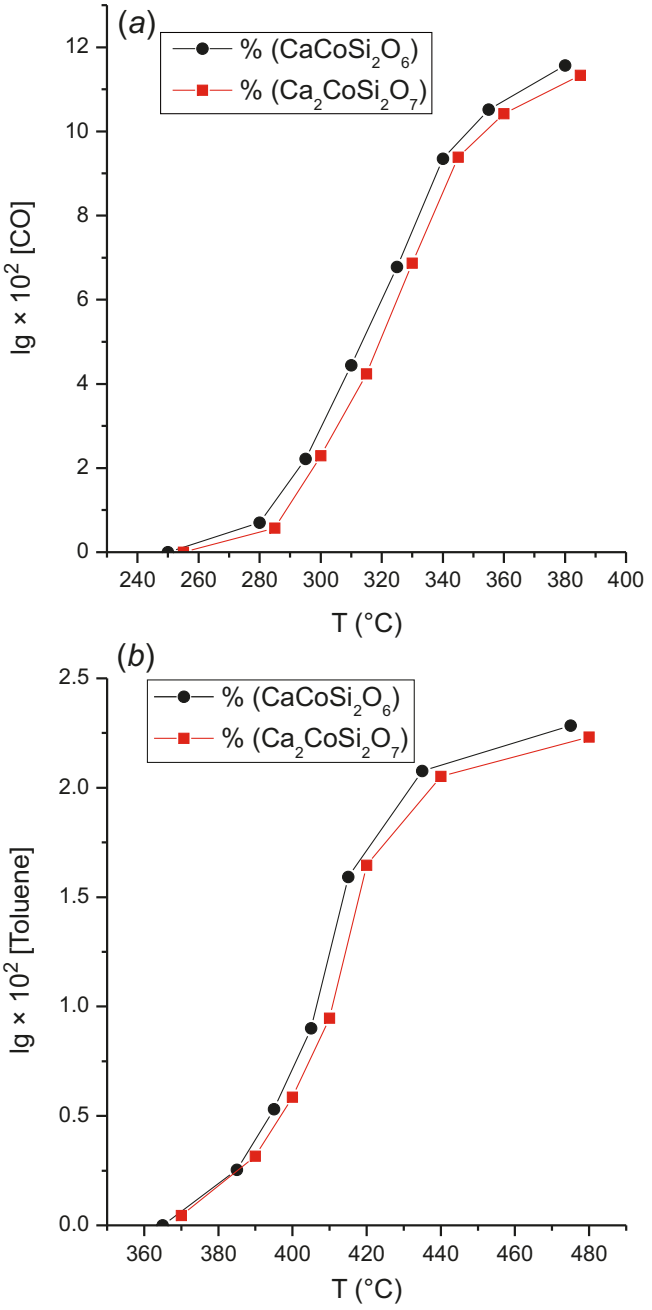
The determination of the specific surface (S_0) gave the following results: $CaCoSi_2O_6$ (pyroxene sample), 24 m^2/g; and $Ca_2CoSi_2O_7$ (åkermanite sample), 23 m^2/g. Therefore, the different sample preparation methods lead to only a small change of the specific surface. The catalyst compositions exhibit a relatively high surface area for this synthesis temperature (1200 °C).

Figure 4 shows data from the catalytic activity test expressed as rates of oxidation in % for CO oxidation and complete oxidation of toluene. As shown in the figure, Co-pyroxene and Co-åkermanite exhibit catalytic activity in terms of both components. CO oxidation, as might be expected, takes place at significantly lower temperatures. Co-pyroxene shows higher activity in both reactions compared with Co-åkermanite. The quantity of oxidized CO of Co-pyroxene at 320 °C is about 7% higher than that of Co-åkermanite. In the case of the toluene oxidation at 410 °C, it is 15% higher.

The catalytic activity expressed as an amount of oxidized CO or toluene per gram of catalyst (I_g) is presented in Fig. 5. The ratio of the catalytic activities remains the same.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 5. Amount of oxidized CO (*a*) and toluene (*b*) per gram of catalyst per hour (I_g) depending on temperature (T, °C). Samples: $CaCoSi_2O_6$ (Co-pyroxene) and $Ca_2CoSi_2O_7$ (Co-åkermanite).



The most accurate information for the activity of massive catalysts may be obtained by comparing the activities defined as reacted substance obtained in a unit of time per unit surface area of the catalyst. This dependence is no different in nature from that of I_g because of the close values of specific surfaces of catalysts. The catalytic activity of Co-pyroxene per unit surface area of the catalyst is higher than that of Co-åkermanite. This is also evident from other representations (Figs. 4 and 5).

The obtained results show that cobalt silicates with crystal structures corresponding to pyroxene and åkermanite possess catalytic activity in reactions of complete oxidation of CO and toluene. Their catalytic activity is high enough, and under certain conditions, they can find an appropriate application. Even more interesting is the fact that Co-pyroxene exhibits a higher catalytic activity than Co-åkermanite. At the same time, we should take into account the higher Co content in pyroxene compared with åkermanite, which can also lead to higher catalytic activity. The theoretical ratio of Co content in pyroxene to åkermanite is 1.25, but on the basis of EDS data, the experimentally obtained ratio is higher. More important is the ratio of Co content on the surface of the catalysts. XPS tests were carried out to clarify the issue. The composition of the samples was investigated on the basis of the binding energies of O 1s, Si 2p, Co 2p, and Ca 2p photoelectron peaks. The obtained results are given in Fig. 6, and the calculated percentages of Co content at the surface are given in Table 4.

As shown in Table 4, the Co content at the surface is higher for Co-pyroxene. The Co-Pyroxene to Co-åkermanite ratio of Co content calculated from XPS data is 1.58 (the same value was determined by EDS analysis). This fact also contributes to the higher catalytic activity of Co-pyroxene, compared with Co-åkermanite (η, I_g).

The possible variations in the oxidation states for Co can be determined from the Co 2p peaks in the XPS spectra. The Co 2p XPS spectra of the silicates (Fig. 6*a*) consist of two main lines (i.e., $2p_{3/2}$ at ~781 eV and $2p_{1/2}$ at ~797 eV) with the spin-orbit splitting of ~16 eV, as reported in the literature.[32–35] Most of the cobalt oxides and hydroxides are not distinguishable based only on the binding energy for the Co 2p main peaks. On the other hand, the secondary features in the spectra (shake-up satellites and spin-orbit splitting) are useful in identifying the different Co types. For example, the Co spin-orbit splitting was close to 15.2 eV for Co_3O_4, but substantially larger for pure Co^{2+} oxides[35] (CoO: 16.0 eV). Moreover, CoO has a strong shake-up satellite 6 eV above the Co $2p_{3/2}$ line. The energy gap between the Co 2p main peak and the satellite peaks is related to the oxidation states of cobalt. When the energy gap is ~6.0 eV, the Co cation valence is assigned a value of 2^+. If the energy gap is 9–10 eV, the spectrum is associated with Co cations having a valence value of 3^+.[33] Another satellite peak was detected at about 6.0 eV above the Co $2p_{3/2}$ main lines (Fig. 6*a*). According to assignments reported in the literature, this satellite peak can be associated with high-spin Co^{2+} species. These results suggest that the studied samples are mainly formed by the Co^{2+} surface phase. As shown earlier for the spinels,[34] when Co^{2+} occupy tetrahedral sites, the satellite peak splitting is similar to that of divalent cobalt in an octahedral environment.

If we use data from Table 4 about the concentration of Co^{2+} ions at the surface and calculate the amount of oxidized CO and toluene from 1% surface ions, the dependencies shown in Fig. 7 are obtained. The figure shows that the Co^{2+} ions in tetrahedral coordination have a higher catalytic efficiency than those in octahedral coordination.

The basic reason for this higher catalytic efficiency is the structure of the catalytic active complex (CAC) in the catalyst.[36–38] As mentioned previously, the structure of both compounds is different. In Co-pyroxene, it is built up of chains of silicon–oxygen tetrahedra and chains of cobalt–oxygen octahedra (Fig. 1), whereas in the case of Co-åkermanite, it consists of cobalt tetrahedra connected by diorthogroups of

Fig. 6. X-ray photoelectron spectroscopy (XPS) spectra for $CaCoSi_2O_6$ (Co-pyroxene) and $Ca_2CoSi_2O_7$ (Co-åkermanite). (*a*) Co 2p spectra, (*b*) O 1s spectra, (*c*) Si 2p spectra, and (*d*) Ca 2p spectra.

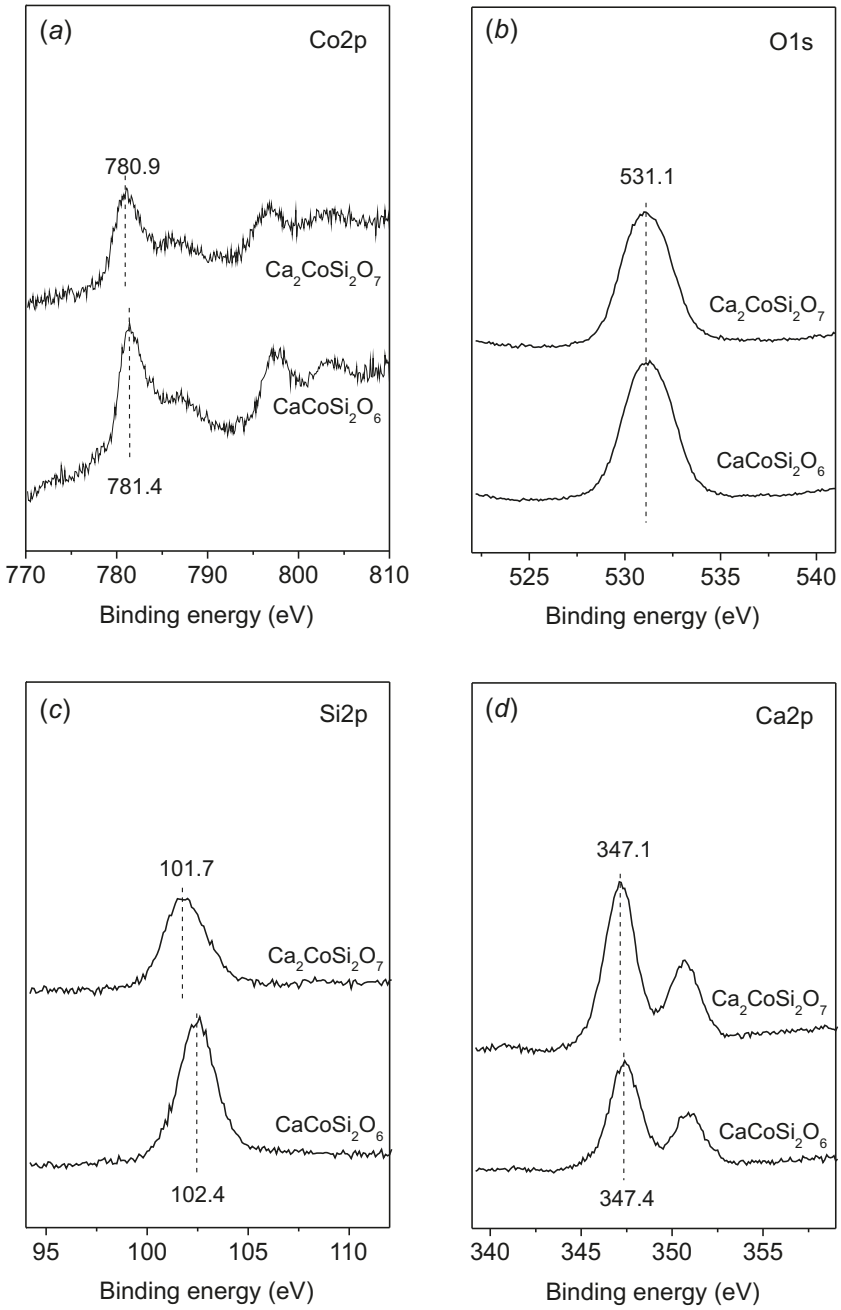

Table 4. X-ray photoelectron spectroscopy (XPS) surface elemental composition.

Samples	C (atomic %)	O (atomic %)	Ca (atomic %)	Co (atomic %)	Si (atomic %)
$CaCoSi_2O_6$	29.6	39.8	7.2	2.7	20.8
$Ca_2CoSi_2O_7$	35.4	36.7	10.5	1.6	15.8

silicon–oxygen tetrahedra (Fig. 2). The main difference in the structure of the CAC is determined by the coordination of Co^{2+} ions. In Co-pyroxene, Co^{2+} ions are in an octahedral coordination (O_h), whereas in Co-åkermanite, these ions are in a tetrahedral (T_d) coordination.

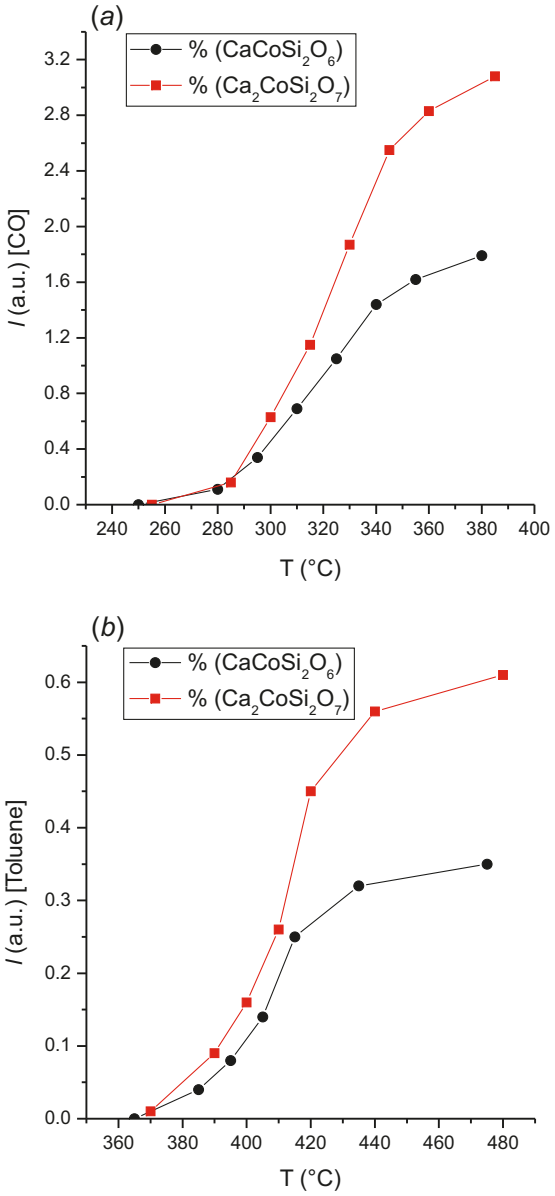
In reactions of complete oxidation within the temperature range in which the study was carried out, the reaction mechanism is probably oxidation–reduction. The cobalt ion, which is responsible for the activity in the course of the reaction, participates in the following equilibrium: $Co^{2+} \leftrightarrow Co^{3+}$. The coordination of cobalt ions in the CAC affects this process.

Conclusions

Two calcium–cobalt silicates were synthesized, in which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 7. Amount of oxidized CO (*a*) and toluene (*b*) from 1% surface cobalt ions (atomic units) depending on temperature (*T*, °C). Samples: $CaCoSi_2O_6$ (Co-pyroxene) and $Ca_2CoSi_2O_7$ (Co-åkermanite).



cobalt takes different structural positions. XRD, FTIR, and EPR data confirmed the synthesis of $CaCoSi_2O_6$ (Co-pyroxene) and $Ca_2CoSi_2O_7$ (Co-åkermanite). In the Co-åkermanite structure $Ca_2CoSi_2O_7$, cobalt cations take tetrahedral coordination toward oxygen atoms. In the Co-pyroxene structure $CaCoSi_2O_6$, the cobalt is in octahedral coordination.

Although different methods were used for the synthesis (e.g., the sol–gel method for $CaCoSi_2O_6$ and the solid-phase method for $Ca_2CoSi_2O_7$), only a small change in the specific surface area was observed.

The chemical composition study of the surface using EDS and XPS analyses showed a higher ratio of cobalt content in $CaCoSi_2O_6$ compared with $Ca_2CoSi_2O_7$ than what was expected on the basis of the stoichiometry of the phases.

Data from the catalytic activity test for CO oxidation and complete oxidation of toluene showed that Co-pyroxene and Co-åkermanite exhibit catalytic activity in terms of both components. Co-pyroxene showed a higher activity per gram of catalyst in both reactions than Co-åkermanite. The reason for the higher catalytic activity of Co-pyroxene compared with Co-åkermanite may be sought in the higher concentration of Co^{2+} ions at the surface of Co-pyroxene.

Catalytically active complexes with Co^{2+} ions in tetrahedral coordination are more efficient in terms of catalytic activity than those with these ions in octahedral coordination for equal concentration of cobalt on the surface of the catalysts.

Abstract: The cationic Ru^{III} complexes, *trans*-$[Ru(ma)_2(L)_2]CF_3SO_3$, where Hma = maltol = 3-hydroxy-2-methyl-4-pyrone; L = imidazole (Im) (complex **2**), 1(*N*)-methylimidazole (*N*-MeIm) (**3**), 2-methylimidazole (2-MeIm) (**4**), and 4-methylimidazole (4-MeIm) (**5**), were synthesized via the known L = EtOH (complex **1a**), and characterized by elemental analysis, ^1H NMR and IR spectroscopies, mass spectrometry, cyclic voltammetry, and (for **3** and **4**) by X-ray crystallography. The *trans*-$[Ru(ma)_2(H_2O)_2]CF_3SO_3$ complex (**1b**) was inadvertently isolated and characterized crystallographically, and the monomaltolato species $[Ru(ma)(N\text{-MeIm})_4][CF_3SO_3]_2$ (**6**) was also isolated and characterized. In vitro antiproliferatory activity of complexes **2**–**6** against human breast cancer cells (MDA-MB-435S) was tested using an MTT assay: **4** and **5** exhibit the lowest IC_{50} values, ~5 and ~15 μmol/L, respectively, whereas cisplatin exhibits an IC_{50} value of ~35 μmol/L against this cell line.

Key words: ruthenium complexes, imidazole ligands, maltolato ligand, anti-proliferatory activity.

Résumé : On a réalisé la synthèse de complexes cationiques du Ru(III), *trans*-$[Ru(ma)_2(L)_2]CF_3SO_3$ dans lesquels Hma = maltol = 3-hydroxy-2-méthylpyr-4-one; L = imidazole (Im) (complexe **2**), 1(*N*)-méthylimidazole (*N*-MeIm) (**3**), 2-méthylimidazole (2-MeIm) (**4**) et 4-méthylimidazole (4-MeIm) (**5**) à partir du complexe connu, **1a** dans lequel L = EtOH, et on les a caractérisés par leur analyse élémentaire, par les spectroscopies RMN du ^1H et IR, par la spectrométrie de masse, la voltampérométrie cyclique et, pour les composés **3** et **4**, par diffraction des rayons-X. Le complexe *trans*-$[Ru(ma)_2(H_2O)_2]CF_3SO_3$ (**1b**) a été isolé par inadvertance et caractérisé par cristallographie et l'espèce monomaltolato $[Ru(ma)(N\text{-MeIm})_4][CF_3SO_3]_2$ a aussi été isolé et caractérisé. On a évalué l'activité antiproliféatrice in vitro des complexes **2**–**6** contre les cellules du cancer du sein humain (MDA-MB-453S) en faisant appel à une méthode MTT; les composés **4** et **5** présentent les valeurs IC_{50} les plus faibles, soit environ 5 et 15 μm respectivement, alors que le cisplatine présente une valeur IC_{50} d'environ 35 μmol/L contre les cellules de cette lignée.

Mots-clés : complexes du ruthénium, ligands imidazole, ligand maltolato, activité antiproliféatrice.

[Traduit par la Rédaction]

Introduction

The area focusing on the potential use of Ru complexes as anticancer agents continues to be one of intense current interest. In a recently published article by our group on this potential of Ru(II)-4,4′-biimidazole complexes,[1] the Introduction gave leading references to the recent literature and included some articles from 2010. Now, a survey using SciFinder Scholar for the last 12 months reveals at least 200 *further* publications (excluding patents) on the "ruthenium anticancer" topic, suggesting an exponential growth in this area; only a selected number of the most recent references are quoted here. Contributions are dominated by studies from the groups of Dyson,[2,3] Keppler,[4] and Sadler,[5] often in collaborative efforts with other groups, but there were significant contributions from a myriad of other groups in 2009,[6–8] and in 2010–2011.[9–11] Studies on the pharmokinetics,[4b,12] protein interactions,[13] and DFT calculations[14] of the potential drugs KP1019 and NAMI-A continue to appear — both have successfully completed phase I clinical trials; the former complex is [HInd][*trans*-$Ru^{III}Cl_4(Ind)_2$] (Ind = indazole) and the latter is [HIm][*trans*-$Ru^{III}Cl_4(Im)(S\text{-DMSO})$] (Im = imidazole). The potential use of Ru complexes (without nitric oxide ligands) in photodynamic therapy is now attracting increasing attention.[9c,15] Finally, the glut of publications has led to generation of a plethora of recent short reviews and perspectives.[16,17] It appears that many synthetic-type coordination and organometallic researchers in the Ru chemistry area are now testing their new complexes for antiproliferatory activity!

This current paper describes the synthesis of Ru^{III} complexes containing both maltolato and imidazole ligands of the type $[Ru^{III}(O–O')_2(L)_2]^+$ or $[Ru^{III}(O–O')(L)_4]^{2+}$, where O–O′ represents the maltolato ligand and L is an imidazole (Chart 1). Their in vitro antiproliferatory activity against human

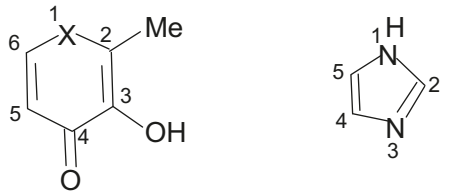
Chart 1. Structures and numbering system for maltol, 4-pyridone, and imidazole.



breast cancer cells (MDA-MB-435S) is also reported. We were the first to investigate such activity of Ru-maltolato complexes, specifically using the Ru^{II} species $Ru^{II}(O–O')_2(L)_2$, in which L was either a monodentate sulfoxide, or $(L)_2$ was a bidentate sulfoxide sometimes in a chiral form.[18] We later reported on the activity of *mer*-$Ru^{III}(O–O')_3$, its ethyl-substituted derivative, and a 4-pyridonato analogue (Chart 1),[19] and then on Ru^{III}(maltolato) complexes containing ancillary nitroimidazole ligands.[20] Keppler, Sadler, and co-workers have more recently also introduced maltol and pyridone (and thiopyridone) type moieties as supporting ligands in Ru-*p*-cymene complexes with anticancer potential.[4e,21] Maltol is attractive as a proligand in this area, since it is nontoxic and is used as a food additive.[22]

Experimental section

Materials for synthesis

Reagent grade solvents (Fisher Scientific) were generally dried using standard procedures under N_2 before use and deuterated solvents (Cambridge Isotope Laboratories) were used as received. The Sigma-Aldrich products imidazole (Im), 1(*N*)-methylimidazole (*N*-MeIm), 2-methylimidazole (2-MeIm), 4-methylimidazole (4-MeIm), $[^nBu_4N]PF_6$, $FeCp_2$, triflic acid, cisplatin, silica gel preparative TLC plates with fluorescent indicator (20 × 20 cm^2, Uniplate from Analtech), and maltol (3-hydroxy-2-methyl-4-pyrone, obtained from Cultor Food Science), were used as received. $RuCl_3·3H_2O$ was donated by Colonial Metals. The Ru^{III} precursor complex *mer*-$Ru(ma)_3$[19] and its conversion to *trans*-$[Ru(ma)_2(EtOH)_2]CF_3SO_3$ (**1a**) by treatment with triflic acid in EtOH[20] was reported previously; the imidazole derivatives were synthesized using standard Schlenk techniques, although this is not essential.

Physical techniques and instrumentation

^1H NMR spectra (br = broad, s = singlet, and d = doublet) were recorded at room temperature (rt, ~20 °C) on a Bruker AV300 spectrometer, chemical shifts being calibrated using residual ^1H resonances from deuterated solvents. Elemental analyses were performed by M. Lakha of this department on a Carlo Erba EA 1108 CHN-O analyzer. Mass spectral data (reported as *m*/*z* values) were acquired on a Bruker Esquire ES spectrometer in this department (c/o Y. Ling); the given M value pertains to the cationic component of the complex. IR spectra (KBr) were recorded on ATI Mattson Genesis or Bomem–Michelson MB-100 FT-IR spectrometers; selected ν values (cm^{-1}) are sometimes given with assigned functional groups. Conductivity measurements, carried out on a RCM151B Serfass conductance bridge (A.H. Thomas Co. Ltd.) with a 3403 cell (Yellow Springs Instrument Company), were calibrated using 0.01000 mol/L aq KCl solution (Λ_M = 141.3 Ω^{-1} cm^2 mol^{-1} at 25 °C, cell constant = 1.016 cm^{-1}), and data are given in units of Ω^{-1} cm^2 mol^{-1}. Cyclic voltammograms were recorded in MeCN containing 0.1 mol/L $[^nBu_4N]PF_6$ as the supporting electrolyte on a Pine Bipotentiostat (Model AFCBP1) using PineChem v2.00 software. The scan rate was 100 mV s^{-1} using a Pt working electrode, a Pt wire counter electrode, and a Ag wire reference electrode; $FeCp_2$ was used as an internal standard ($E_{1/2}$ ($Fe^{III/II}$) = 0.40 vs SCE in MeCN),[23] and $E_{1/2}$ values are reported relative to SCE.

trans-$[Ru(ma)_2(H_2O)_2]CF_3SO_3$ (1b)

A concentrated solution of the red complex *trans*-$[Ru(ma)_2(EtOH)_2]CF_3SO_3$ (**1a**) in nondried reagent grade EtOH (5 mL) was left to evaporate in air; after 2 weeks, a few red crystals of *trans*-$[Ru(ma)_2(H_2O)_2]CF_3SO_3$·EtOH (**1b**·EtOH) were deposited as determined by X-ray analysis (vide infra).

$[Ru(ma)_2(Im)_2]CF_3SO_3$ (2)

To a red solution of *mer*-$Ru(ma)_3$ (55 mg, 0.12 mmol) in EtOH (5 mL), triflic acid (22 mg, 0.14 mmol) was added under N_2 and the solution was stirred at rt for 1 h. Im (35 mg, 0.51 mmol) was then added and the solution was stirred for an additional 12 h. After 4 h the solution was checked by TLC (CH_2Cl_2–MeOH, 10:1). The band for **1a** had disappeared and was replaced by 11 minor bands; after 12 h, a single major band (R_f = 0.65) was observed with five minor bands of lower R_f. The solvent was removed under vacuum, and the dark red residue was dissolved in CH_2Cl_2 (2 mL); this solution was then applied to a 20 cm × 20 cm silica preparative TLC plate that was developed with CH_2Cl_2–MeOH (15:1, 130 mL). When the major band had clearly separated, it was cut from the plate, added to 50 mL of CH_2Cl_2 / 1 mL of MeOH, and this mixture was left stirring for 16 h. The red mixture was then filtered to remove the silica, and the filtrate was reduced in volume to ~5 mL. Hexanes (30 mL) were then added and the resulting red precipitate was collected, washed with hexanes (2 × 5 mL), and dried at 78 °C under vacuum for 48 h. Yield: 38 mg (51%). IR ν: 3145 (N–H, m), 1603 (C=O, s), 1467 (s), 1263 (s). ^1H NMR (*cis*-isomer, $CDCl_3$) δ: 62.2, 44.6 (br s, C*H*$_3$–ma), –1.5, –5.6 (br s, *H*$_5$–Im), –15.5, –24.7 (br s, *H*$_2$–Im). ^1H NMR (*trans*-isomer, $CDCl_3$) δ: 60.0 (s, C*H*$_3$–ma), –3.7 (s, *H*$_5$–Im), –19.6 (s, *H*$_2$–Im). LR-MS (+LSIMS, thioglycerol): 488 (M^+), 420 (M^+ – Im), 352 (M^+ – 2Im). $E_{1/2}$ ($Ru^{III/II}$) = –0.705 V. Λ_M (MeOH) = 119. Anal. calcd for $C_{19}H_{18}F_3N_4O_9SRu$: C 35.85, H 2.85, N 8.80; found: C 35.92, H 2.92, N 8.73.

trans-$[Ru(ma)_2(N\text{-}MeIm)_2]CF_3SO_3·CH_2Cl_2$ (3·CH_2Cl_2)

The procedure initially followed that given for **2**, but using 80 mg (0.17 mmol) of *mer*-$Ru(ma)_3$, 28 mg (0.19 mmol) of triflic acid, and 62 mg (0.76 mmol) *N*-MeIm, and the solution was stirred for a longer time (24 h). After 6 h the solution was checked by TLC (CH_2Cl_2–MeOH, 10:1): six bands were observed, the most intense being a red one at R_f = 0.60.

After 18 h, two major bands, a red one at $R_f = 0.64$ and a less intense blue one at $R_f = 0.35$, were seen. After 24 h, the solvent was removed and the dark red residue was dissolved in CH_2Cl_2 (~2 mL) and applied to a preparative TLC plate that was developed with CH_2Cl_2–MeOH (12:1, 130 mL). The red band was treated as described for **2** to yield a red solid. Attempts to extract the blue band were unsuccessful. Yield: 60 mg (48%). IR ν: 3458 (m), 1601 (C=O, s), 1467 (s), 1263 (s), 1031 (s). ^{1}H NMR ($CDCl_3$) δ: 62.0 (br s, CH_3–ma), 13.4 (br s, CH_3–Im, –3.8 br (s, H_5–Im), –19.0 (br s, H_2–Im). LR-MS (+LSIMS, thioglycerol): 516 (M^+), 434 (M^+ – *N*-MeIm), 352 (M^+ – 2*N*-MeIm). $E_{1/2}$ ($Ru^{III/II}$) = –0.765 V. Λ_M (MeOH) = 109. Anal. calcd for $C_{21}H_{22}F_3N_4O_9SRu{\cdot}CH_2Cl_2$: C 35.26, H 3.23, N 7.48; found: C 35.71, H 3.22, N 7.86. X-ray quality crystals were grown by slow evaporation of a CH_2Cl_2 solution of the complex layered with hexanes.

trans-[Ru(ma)$_2$(2-MeIm)$_2$]CF_3SO_3 (4)

The procedure, including the workup treatment, was as for **3**·CH_2Cl_2, but using 92 mg (0.19 mmol) of *mer*-Ru(ma)$_3$, 32 mg (0.21 mmol) of triflic acid, and 66 mg (0.80 mmol) of 2-MeIm, with just 12 h of stirring. The red band gave 63 mg of product (56% yield). IR ν: 3216 (N–H, m), 1602 (C=O, s), 1447 (s), 1265 (s). ^{1}H NMR ($CDCl_3$) δ: 67.0 (br s, CH_3–ma), 42.0 (br s CH_3–Im), –1.6 (br s, H_5–Im), –4.7 (br s, H_4–Im). LR-MS (+LSIMS, thioglycerol): 516 (M^+), 434 (M^+ – 2-MeIm), 352 (M^+– 2 × 2-MeIm). $E_{1/2}$ ($Ru^{III/II}$) = –0.844 V. Λ_M (MeOH) = 121. Anal. calcd for $C_{21}H_{22}F_3N_4O_9SRu$: C 37.95, H 3.34, N 8.43; found: C 37.61, H 3.38, N 8.20. Crystals were grown by the method used to obtain **3**·CH_2Cl_2.

trans-[Ru(ma)$_2$(4/5)-MeIm)$_2$]$CF_3SO_3{\cdot}CH_2Cl_2$ (5)

The procedure, including the work up treatment, was the same as for **3**·CH_2Cl_2, but using 50 mg (0.11 mmol) of *mer*-Ru(ma)$_3$, 20 mg (0.13 mmol) of triflic acid, and 41 mg (0.50 mmol) of 4-MeIm and only 12 h of stirring. Sampling by TLC analysis after 4 h revealed the disappearance of **1a** with production of three red bands (R_f = 0.32, 0.44, 0.54); after the 12 h, only one major red band was observed (R_f = 0.56) and this yielded 32 mg of **5** (42% yield). IR ν: 3224 (NH, m), 1601 (C=O, s), 1446 (s), 1263 (s). ^{1}H NMR ($CDCl_3$) δ: 60.0 (br s, CH_3–ma), 16.3 (br s, CH_3–Im), –4.5 (br s, H_5–Im), –20.0 (br s, H_2-Im). LR-MS (+LSIMS, thioglycerol): 516 (M^+), 434 (M^+ – 4-MeIm), 352 (M^+ – 2 × 4-MeIm). $E_{1/2}$ ($Ru^{III/II}$) = –0.738 V. Λ_M (MeOH) = 107. Anal. calcd for $C_{21}H_{22}F_3N_4O_9SRu{\cdot}CH_2Cl_2$: C 35.26, H 3.23, N 7.48; found: C 35.63, H 3.26, N 7.55.

[Ru(ma)(*N*-MeIm)$_4$][CF_3SO_3]$_2$ (6)

To a solution of *mer*-Ru(ma)$_3$ (67 mg, 0.14 mmol) in EtOH (5 mL), triflic acid (54 mg, 0.36 mmol) was added under N_2, and the solution was stirred at rt for 1 h, when *N*-MeIm (77 mg, 1.1 mmol) was added; the solution was then refluxed for 48 h. After 24 h the solution was checked by TLC (CH_2Cl_2–MeOH, 10:1): two major bands were observed, a red one at $R_f = 0.60$ and a blue one at $R_f = 0.35$. After 48 h, analysis revealed the same major blue band, several minor bands (R_f = 0.2 – 0.7), and a black spot ($R_f = 0$). The solvent was removed under vacuum and the dark blue residue was dissolved in CH_2Cl_2 (~1.5 mL) and applied to a preparative TLC plate that was developed with CH_2Cl_2–MeOH (10:1, 130 mL). The blue band was cut out, added to 50 mL of CH_2Cl_2 / 2 mL of MeOH, and the mixture was left stirring for 16 h. The blue mixture was then filtered to remove the silica and the volume was reduced to ~1 mL. Hexanes (10 mL) were then added and the resulting blue precipitate was collected, washed with hexanes (2 × 5 mL), and dried at 78 °C under vacuum for 48 h. Yield: 55 mg (46%). IR ν 3137 (m), 1601 (C=O, s), 1546 (m), 1470 (m), 1265 (s), 1031 (s). ^{1}H NMR ($CDCl_3$) δ: 81.6 (br s, CH_3–ma), 25.6, 20.4 (br s, CH_3–Im), –0.5, –5.7 (s, H_5–Im), –18.4, –24.0 (s, H_2–Im). LR-MS (+LSIMS, thioglycerol): 704 (M^{2+} + $CF_3SO_3^-$), 622 (M^{2+} + $CF_3SO_3^-$ – *N*-MeIm), 540 (M^{2+} + $CF_3SO_3^-$ – 2 × *N*-MeIm), 458 (M^{2+} + $CF_3SO_3^-$ – 3 × *N*-MeIm). $E_{1/2}$ ($Ru^{III/II}$) = –0.442 V. Λ_M (MeOH) = 273. Anal. calcd for $C_{24}H_{29}F_6N_8O_9S_2Ru$: C 33.80, H 3.43, N 13.14; found: C 33.23, H 3.34, N 12.73.

X-ray crystallographic analyses for complexes 1b·EtOH, 3·CH_2Cl_2, and 4

X-ray analyses were carried out at 173.0(1) K on a Bruker X8 APEX diffractometer with graphite-monochromated Mo Kα radiation (0.710 69 Å). The final unit-cell parameters were based on 4739 reflections with $2\theta_{max}$ = 56.5° for **1b**·EtOH, 5707 reflections with $2\theta_{max}$ = 54.2° for **3**·CH_2Cl_2, and 5269 reflections with $2\theta_{max}$ = 55.7° for **4**, in a series of ϕ and ω scans in 0.50° oscillations with respective exposures of 15.0, 49.0, and 10 s; the crystal-to-detector distance was between 37.01 and 38.79 mm. The data for **1b**·EtOH were processed using the Bruker SAINT software package[24] and the d*TREK program was used for **3**·CH_2Cl_2 and **4**.[25] The three structures were solved using direct methods[26] and expanded using Fourier techniques.[27] Data were corrected for absorption effects using the multiscan technique (SADABS)[28] for **1b**·EtOH, and the multiscan techniques (teXsan)[29] for **3**·CH_2Cl_2 and **4**, with minimum and maximum transmission coefficients in the respective ranges of 0.727–0.788 and 0.892–0.983. The data were also corrected for Lorentz and polarization effects.

All three complexes crystallize with two half-Ru moieties in the asymmetric unit, each Ru atom residing on an inversion centre. Complex **1b** crystallizes with one disordered molecule of EtOH in the asymmetric unit, the relative populations of the major and minor fragments being refined to values of 0.53 and 0.47, respectively. H atoms involved in H bonding were located in difference maps, whereas all other H atoms were included in calculated positions but not refined. In **3** there was one disordered CH_2Cl_2 in the asymmetric unit, and the CF_3SO_3 anion was also disordered; both were modeled in two orientations with restraints on bond lengths, bond angles, and anisotropic displacement parameters being used to maintain similar geometries between the disordered fragments. All non-H atoms in the three structures were refined anisotropically, whereas the C–H hydrogen atoms were included in calculated positions and not refined. The structures are shown in Figs. 1–3, and some crystallographic data are given in Table 1; selected bond lengths and angles are given in Tables 2–4. Full crystallographic data are given in the Supplementary data.

Biological assays

All reagents and cell-handling techniques, as well as experimental procedures for the MTT assay, the Ru uptake assay into cells, and DNA binding to Ru, have been described in detail in our previous publications.[18–20,30] For the MTT assay, complexes were dissolved in PBS (phosphate-buffered saline solution), and were tested against MDA-MB-435S cells in Leibovitz's L-15 medium with L-glutamine after incubation at 37 °C for 70 h. The Ru uptake in cells was studied with a Chinese hamster ovary (CHO) cell line.

Results and discussion

Reaction of *mer*-$Ru(ma)_3$ with triflic acid

As described previously, the red, paramagnetic Ru^{III} complex *trans*-$[Ru(ma)_2(EtOH)_2]CF_3SO_3$ (**1a**) was isolated from a solution made by refluxing *mer*-$Ru(ma)_3$ in EtOH with 1 equiv of triflic acid, and was well characterized by elemental analysis, mass spectrometry, ^1H NMR and IR spectroscopies, and conductivity.[20] The ^1H NMR spectrum in CD_3OD initially showed a broad singlet at δ 48.0, consistent with a single species containing *trans*-maltolato ligands in a structure with equivalent Me groups; resonances downfield of $\delta \sim 40$ can be assigned generally to this group as established previously by our detailed one- and two-dimensional NMR studies on $Ru(ma)_3$, which has a mer configuration with respect to corresponding O atoms.[19] The ^1H spectrum also showed broad singlets at 28.0 and 26.0 owing to the coordinated EtOH, but these signals were slowly replaced (>10 min) by those of free EtOH as the EtOH ligands were replaced by CD_3OD (or less likely D_2O, which would be present in trace amounts); resonances for the H(5) and H(6) protons could not be assigned.[20] In this current work, the formation of the single product, presumed to be *trans*-$[Ru(ma)_2(CD_3OD)_2]^+$ from *mer*-$Ru(ma)_3$ and triflic acid in CD_3OD solution was monitored by in situ ^1H NMR spectroscopy (see Fig. S1 in the Supplementary data) as the relatively sharp singlets of *mer*-$Ru(ma)_3$ (δ 42.0, 39.3, and 22.5)[18] were replaced by a broad singlet at δ 46 and cogeneration of signals for free maltol (δ 7.7 (d, H_6), 6.4 (d, H_5), 2.40 (s, Me)). The few X-ray quality crystals that were grown during the 2 week evaporation of an EtOH solution of **1a** in air turned out surprisingly to be those of *trans*-$[Ru(ma)_2(H_2O)_2]CF_3SO_3$·EtOH (**1b**·EtOH), the EtOH ligands having been replaced by aquo ligands (Fig. 1). The Me groups of the planar maltolato ligands are equivalent, as seen also in the ^1H NMR solution spectrum of **1a**. Attempts to grow crystals from a dry EtOH solution of **1a** (or a MeOH solution of the bis(methanol) analogue) under an inert atmosphere were unsuccessful. The same trans geometry is seen for the $[Ru(ma)_2(L)_2]CF_3SO_3$ complexes where L is an imidazole (see the following), which suggests that **1a** is the precursor to the bis(imidazole) products; indeed, these complexes can be generated by treatment of in situ formed **1a** or **1b** with the appropriate imidazole.

The structural data of **1b**·EtOH (Table 2) show that the bond lengths for the Ru–O(keto) group are about 0.05 Å longer than those for Ru–O(hydroxy), behavior that is seen in *mer*-$Ru(ma)_3$ and other maltolato complexes.[19] The $Ru–OH_2$ bond lengths, lying in between the Ru–O values of the maltolato ligands, are essentially the same as in $Ru(H_2O)_6^{3+}$,[31] and are in the range of values for other Ru^{III}–aquo complexes.[32]

Maltolato–imidazole complexes

The red *trans*-$[Ru(ma)_2(L)_2]CF_3SO_3$ complexes, where L is an *N*-bound Im (complex **2**), *N*-MeIm (**3**), 2-MeIm (**4**), and 4-MeIm (**5**), were all synthesized using the same general procedure from in situ **1a**, by displacing the EtOH ligands using a fourfold excess of the imidazole at rt over 12–24 h; the complexes were isolated in 40%–50% yield after purification by preparative TLC. The C analysis for **3** (isolated with a solvate CH_2Cl_2, as shown by X-ray analysis of the complex) was 0.45% high, and this likely results from loss of some solvate during the analysis. Attempts to speed up the synthetic reactions by a reflux procedure generally led to the formation of several side products. However, in the case of L = *N*-MeIm, a 48 h reflux procedure in which excess triflic acid was used (acid:$Ru(ma)_3$ = 2.5), as well as an eightfold excess of the imidazole, led to the formation of $[Ru(ma)(N\text{-MeIm})_4][CF_3SO_3]_2$ (**6**) in 46% yield; corresponding reactions with the other imidazoles showed no evidence for formation of a mono(maltolato)–tetrakis(imidazole) species. The measured conductivity data in MeOH for each of the complexes are consistent with their ionic formulations.[33] The C analysis for **6** was 0.57% low, but the Λ_M and $E_{1/2}$ values (see the following) and the MS and ^1H NMR data (Fig. S2*b*) support the formulation.

Complexes **3** and **4** were characterized by X-ray crystallography (Figs. 2 and 3, respectively), and they have very similar bond lengths and angles (Tables 3 and 4). As for complex **1b** in the planar equivalent maltolato ligands, the Ru–O(keto) bond lengths are ~0.05 Å longer than those for Ru–O(hydroxy). The similar Ru–N bond lengths in **3** and **4**, typical of others in Ru^{III}–imidazole systems,[34] imply the absence of any steric interactions between the imidazole–Me (adjacent to the coordinated N atom in complex **4**) and the maltolato ligands;

Fig. 2. ORTEP diagram of the cation of *trans*-[Ru(ma)$_2$(*N*-MeIm)$_2$]$CF_3SO_3 \cdot CH_2Cl_2$ (**3**·CH_2Cl_2) with 50% probability thermal ellipsoids. Hydrogen atoms are omitted.

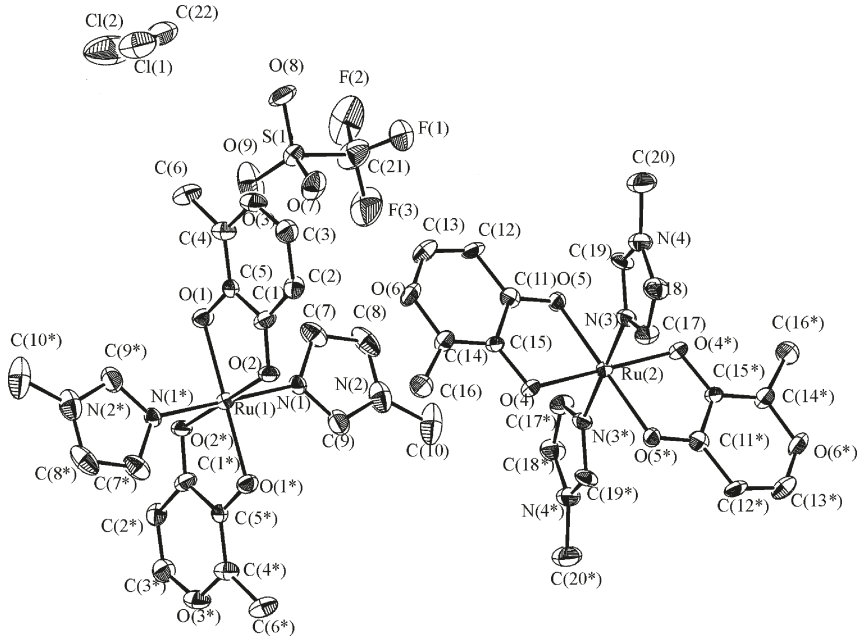

Fig. 3. ORTEP diagram of the cation of *trans*-[Ru(ma)$_2$(2-MeIm)$_2$]CF_3SO_3 (**4**) with 50% probability thermal ellipsoids; only one of the two Ru moeties is shown.

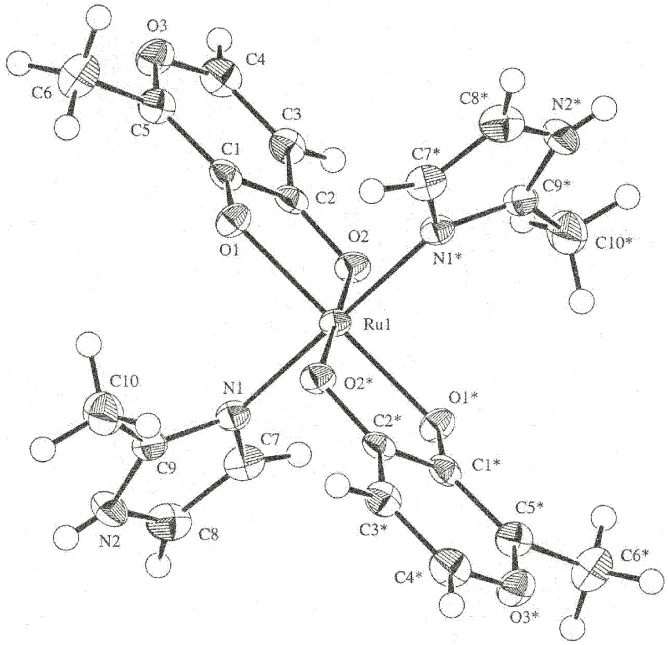

however, there is a small difference between **3** and **4** in the orientation of the imidazole ring with respect to the plane of the maltolato ligand that might relieve any such interaction in **4**. For example, for **3**, the Ru(1)–N(1)–C(9) (125.6°) and Ru (1)–N(1)–C(7) (128.0°) angles differ by 2.4°, whereas for **4**, where the Me is at C(9), the corresponding angles are 129.7° and 123.5°, a difference of 6.2°; thus, in **4**, the Me group is shifted away from the plane of the maltolato ligand rather than generating a steric interaction that could result in a lengthening of the Ru–N bond. There are no significant interactions with the triflate counteranion in **3** or **4**, or with the CH_2Cl_2 solvate in **3**.

The solution ^{1}H NMR spectra of **2**–**5** are compatible with the solid-state, trans structures determined for **3** and **4**, and assumed for **2** and **5**. Analogous to complex **1a**, a single broad resonance in the δ 67–60 region is assigned in each case to the equivalent maltolato–Me groups of the trans-isomer. For **2**, the Im complex, seen also sometimes (see the following) are two equal intensity, somewhat sharper, singlet resonances at δ 62.2 (which overlaps the broad resonance of the trans-isomer) and 44.6, and these are attributed to the maltolato–Me groups of an assumed cis-isomer; again, as for **1a**, ^{1}H resonances for the maltolato H(5) and H(6) are not observed for any of the complexes. For the *N*-MeIm and 2-MeIm complexes (**3** and **4**), the imidazole–Me resonance is seen, respectively, as a broad signal at δ 13.4 and 42.0 (see Figs. S2*a* and S3), whereas the corresponding values for the free Me–imidazoles are 3.64 and 2.35; the larger downfield shift seen for **4** results from its position closer to the paramagnetic Ru^{III} centre.[35] The imidazole–Me resonance for the 4-MeIm complex **5** is seen at δ 16.3 (the value for free 4-MeIm is 2.30); a larger shift, comparable to that seen in complex **4**, was anticipated because the 4- and 2-Me groups are both adjacent to the coordinated N atom. It is possible that complex **5** might actually contain 5-MeIm, since an initially used 4-MeIm in an attempted synthesis of [Ru(acac)$_2$(4-MeIm)$_2$]CF_3SO_3 (acac = acetylacetonate) underwent tautomerization and generated a 1:3 mixture of 4- and 5-MeIm products in solution from which the latter crystallized;[36] the more remote Me group would then be expected (as observed) to give a ^{1}H signal in the range noted for the *N*-Me complex. (Note that acac, like maltolato, is a chelating O–O′ keto-hydroxylate type ligand.). Unfortunately an X-ray quality crystal of **5** needed to test this hypothesis was not obtained. For **6**, the blue, maltolato–tetrakis(*N*-MeIm) complex, the maltolato–Me resonance, a broad singlet at δ 81.6, is downfield

of the corresponding resonances seen for the bis(imidazole) complexes, whereas two resonances at δ 25.6 and 20.4 are observed for the Im–Me groups (Fig. S2*b*); these signals are shifted further downfield from that for the corresponding methyl group for complex **3** where only one maltolato group has been substituted. The appropriate Im–H_2, –H_4, and –H_5 resonances of complexes **2**–**6** sometimes were assigned and are found in the region δ –1.6 το –24.7 (see the Experimental section).

Attempts to separate the trans- and assumed cis-isomers of **2** were unsuccessful. The relative intensities of the relevant ^{1}H NMR signals varied between samples, suggesting the absence of a solution equilibrium and that two overlapping TLC bands are the likely source of the two isomers. Indeed, the ratio of trans to cis decreased as the silica was taken from the lower parts of the red band, but even a sample isolated from a thin section (~1 mm in width) cut from the top of the band still revealed up to 10% of the cis-isomer. The excellent elemental analysis obtained for **2** is consistent with the product being a mixture of trans- and cis-isomers of the same complex.

The studies suggest that *mer*-Ru(ma)$_3$ would be a useful general precursor for synthesis of a wide range of maltolato-containing Ru^{III} complexes.

The Ru(III/II) reduction potentials in MeCN determined for complexes **2**–**6**, together with literature data for other Ru^{III}–maltolato complexes,[19,20] are given in Table 5. Substitution of the anionic maltolato ligand of *mer*-Ru(ma)$_3$ by two neutral imidazoles, as expected, is seen to strongly stabilize the Ru^{II} oxidation state relative to Ru^{III}. The data for **6** and **3** (both *N*-MeIm species) suggest that such substitution gives a stabilization of ~300 mV. The previously reported $E_{1/2}$ value of –550 mV for *trans*-[Ru(ma)$_2$(metronidazole)$_2$]CF_3SO_3 (**7**), where metronidazole is a 2-Me–5-NO_2–1*H*-Im–1-ethanol,[20] is considered consistent with the $E_{1/2}$ values shown in Table 5, given that the electron-withdrawing NO_2 group will stabilize Ru^{II} vs Ru^{III}. Incorporation of an electron-donating Me group into imidazole (**3**–**5** vs **2**), as expected, stabilizes the higher oxidation state (by 60–140 mV). Reduction potentials can be a significant factor in the anticancer activity of transition-metal complexes (see the following).

Biological results

We previously reported on some biological activity of *mer*-Ru(ma)$_3$, the bisethanol species **1a**, and *trans*-[Ru(ma)$_2$(metronidazole)$_2$]CF_3SO_3 (**7**), and the data obtained[19,20] are summarized in Table 5, along with those from the current study of the maltolato–imidazole systems (complexes **2**–**6**) and cisplatin. The Ru complexes (except **1a**) show no sign of ligand dissociation or reactivity in MeCN (used for conductivity measurements) or in the PBS-based solutions used in the MTT assay,[18] as judged by NMR studies and TLC analyses on solutions of the complexes, and so the listed data (except for **1a**) pertain to the intact complexes. The PBS solution of **1a** changes from red to green over the 3 day incubation, presumably because of the replacement of the EtOH ligands by components other than water (likely Cl^-), since the bis(aqua) complex is also red. This imidazole-free system has the lowest antiproliferatory activity (highest IC_{50} value). Of note, in contrast to the neutral or anionic character of most reported Ru anticancer complexes, **2**–**7** are rare examples of active cationic Ru species,[37] where there is no easily labile anion to assist binding to protein residues, nucleotide bases, or other "biological" components. Indeed, to our knowledge, **4** and **5** appear to be the first reported cationic Ru^{III} complexes to show antiproliferatory activity; further, the activity is greater than that of cisplatin. It has been proposed that relatively substitution-inert Ru^{III} complexes need to be reduced in vivo to more labile Ru^{II} species for effective drug activity (e.g., see refs. 17b and 38), where ligand loss opens up coordination sites for biomolecules; however, more labile anionic chloro-containing Ru^{III} complexes can interact with DNA, cell surfaces, extracellular matrix components, and components in blood plasma such as albumin and transferrin, and such interactions are likely important in anticancer activity.[2d,4c,5d,9a,10i,11a,11d,13,17b,39] Complexes **4** and **5** show the highest antiproliferatory activities, which are greater than that of cisplatin. There is no precise correlation of activity with reduction potential, but the following data for complexes of the same formulation (**2**–**4** and **7**) argue indirectly against a required reduction to Ru^{II}: (*i*) **4**, with the "tilted" Me group, has the lowest IC_{50} value and the most negative $E_{1/2}$ (–844 mV, i.e., favors Ru^{III} vs Ru^{II} the most); (*ii*) **2**, **3**, and **7** have more positive $E_{1/2}$ values (–765 to –550 mV) and lower activities (IC_{50} = 70–80 μmol/L); and (*iii*) species **6**, although of a different type, has the most positive $E_{1/2}$, (i.e., favors Ru^{II} the most) and does have the lowest activity. If there is a general correlation between $E_{1/2}$ and activity, the potency of **5** is significantly greater than expected (cf. data for **2**, **3**, and **7**), but this could result from its uptake in cells, which is double that of **2**, **3**, and **7**. The $E_{1/2}$ value for **5** is closer to that of **3** (than that of **4**), which indirectly supports that complex **5** might be the

5-MeIm derivative with an "innocent" Me group. The neutral Ru(ma)$_3$ species, strongly favoured in the Ru^{III} oxidation state, has relatively low activity, but the different nature of the complex makes it impossible to conclude that activity requires reduction of the metal. Of note, we recently presented MTT data on [Ru^{II}(N–N)$_3$][CF_3SO_3]$_2$ species (N–*N* = 4,4′-biimidazole and the 2,2′-Me_2 derivative; IC_{50} = 18 and 36 μmol/L, respectively),[1] these being comparable to those for [Ru^{III}(ma)$_2$(N–N)][CF_3SO_3] species (IC_{50} = 50 and 15 μmol/L),[40] and concluded that these limited findings indirectly support the concept of required metal reduction.[1] However, the reduction potentials for the bis(maltolato)–mono(biimidazole) species are in the –35 to –100 mV region, showing a much stronger preference for the Ru^{II} state than the bis(maltolato)–bis(imidazole) complexes. It should be recalled that if the intact complexes **2**–**7** are exposed to a biological reductant operating at, for example, –1.0 V, a quite feasible value,[41] then the $E_{1/2}$ values reveal that >99% of all the complexes would be present in the Ru^{II} state, a factor commonly overlooked. Thus, to consider correlations between activity and reduction potentials in such a case becomes meaningless, and factors other than reduction potentials must determine the biological activity. One clearer conclusion from the IC_{50} data for **2**–**5** is that incorporation of a Me group into an imidazole ligand adjacent to the coordinated N atom can certainly enhance antiproliferatory activity of the complex that could stem from a steric rather than electronic effect (e.g., increased substitution lability of a 2-MeIm ligand relative to the other imidazoles).

The complexes, except **5** (see the previous discussion), are transported into cells at comparable rates (Table 5), ruling out the possibility that the more potent complex, **4**, is preferentially transported. Correspondingly, the poor activity of **6** (a doubly charged cation) cannot be attributed to less effective transport, perhaps implying instead an inability to interact with some key intracellular component essential for the antiproliferatory activity of these Ru–maltolato–imidazole complexes. None of complexes **2**–**6** binds to the DNA isolated from these cells.

Even a cursory survey of the listed publications in refs. 2–12 reveals that the mechanism(s) of action of Ru anticancer agents is(are) generally different from that of cisplatin. Reported in vitro interactions of Ru species with molecules other than DNA were noted in the previous discussion, and such targets are plausible for the maltolato–imidazole complexes. The cationic nature suggests that their associated mechanism is likely to be different from those of the anionic chloro complexes involved in clinical trials (see Introduction). A wide scope of potential activity for Ru complexes seems likely and implies that a Ru-based therapy may eventually prove a viable alternative to one based on Pt.

Supplementary data

Supplementary data (^{1}H NMR data (Figs. S1–S3), MTT plots (Fig. S4), and X-ray data in CIF format) are available for this article through the journal Web site (www.nrcresearchpress.com/cjc). CCDC 823213–823215 contain the X-ray data in CIF format for this manuscript (**1b**·EtOH, **3**·CH_2Cl_2, and **4**). These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1Ez, UK; fax +44 1223 336033; or deposit @ccdc.cam.ac.uk).

Acknowledgments

We thank Dr. E. Polishchuk, Biological Services, Department of Chemistry, University of British Columbia, for assistance with the MTT assay, the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support, and Colonial Metals Inc. for the $RuCl_3·3H_2O$.

Synthesis of a glycodendrimer incorporating multiple mannosides on a glucoside core

Chao Wang, Brian Sanders, and David C. Baker

Abstract: The synthesis of a glycodendrimer by incorporating repetitive mannoside units onto a glucoside core was carried out to multivalently probe fundamental carbohydrate–protein interactions. The dendritic structure was constructed by a modified procedure that utilized multiple glycosylations between a thioether glycosyl donor and five elongated spacer arms of a glycosyl acceptor. The completed dendrimer bears a full carbohydrate structure, and thus should find its potential application in the study of mannose–lectin interactions.

Key words: carbohydrate, mannose, dendrimer, glycosylation, multivalency.

Résumé : Afin d'obtenir une sonde pour effectuer des études sur les interactions multivalentes fondamentales entre les hydrates de carbone et les protéines, on a effectué la synthèse d'un glycodendrimère par l'incorporation répétitive d'unités sur une de base de glucoside. La structure dendritique a été construite par une méthode modifiée qui fait appel à des glycosylations multiples entre un thioéther donneur de glycosyle et cinq groupes intercalaires allongés d'un accepteur de glycosyle. Le dendrimère complété comporte une structure entière d'hydrate de carbone et il devrait donc trouver des applications potentielles dans l'étude des interactions entre le mannose et la lectine.

Mots-clés : hydrate de carbone, mannose, dendrimère, glycosylation, multivalence.

Introduction

Many cell-surface events are mediated by the formation of noncovalent complexes between carbohydrate components of surface glycoconjugates and their special protein receptors known as lectins.[1] These interactions are generally weak, since dissociation constants of the formed complexes typically fall in the millimolar range.[2] Improved specificity and stability can be achieved through multivalent interactions between multiple carbohydrate ligands and corresponding protein receptors.[3] Multivalent carbohydrate–protein interactions are very important in many processes such as cell–cell adhesion,[4] immune responses,[5] inflammation,[6,7] cell degeneration,[8] and pathogenic infections.[9]

The search for simple carbohydrate-containing compounds capable of mimicking the complex natural structures has thus become an important task.[10,11] Such multivalent glycomimetics are not only valuable tools to study carbohydrate-mediated processes, but also have considerable potential as therapeutic agents.[12] Dendrimers[13–16] are especially suited for the construction of multivalent glycomimics, thanks to their highly iterative presence of ligands.[17,18] Several examples of glycodendrimers with polyamidoamine,[19,20] carbohydrate–peptide,[21] carbosilane,[22,23] and aliphatic polyether[12] architectures have been synthesized. In regard to dendrimerization methods, robust amide formation generally has been used.[24–26] More recently, the state-of-the-art "click" chemistry has also been applied to overcome the strong steric hindrance during dendrimerization.[27,28]

To study widely distributed mannose-specific bacterial adhesions[29] or some other viral infections,[30,31] we attached multiple mannose moieties to a glucose scaffold by thioether-mediated glycosylation to establish a sugar-cored glycodendrimer. Since the unusual structure contains carbohydrates at either cored or branched positions, it might give new insights when used as dendritic probe to study many mannose-involved interactions. Herein, we report the synthesis of such a mannose-branched "full-carbohydrate glycodendrimer".

Results and discussion

Synthetic approaches

Lindhorst and co-workers[32] managed to add five thiomannoside molecules to the allyl double bond of a core sugar by photoinduced thiol addition. However, precipitates that formed during the radiation process tended to block UV rays from penetrating the solution; consequently, the efficiency of this method was reduced, and the broad use of photoinitiated double bond addition reaction was thus impeded. To overcome these shortcomings and make this method more practical, we modified the Lindhorst procedure by manipulating the facile glycosylation of a mannoside donor with thioether functionality and a core glucoside acceptor bearing multiple elongated hydroxyl groups. Conventional hydrogenolysis was

then applied to remove benzyl protective groups, thus furnishing the construction of the dendritic structure. By applying this strategy, the synthesis was carried out as described in the following sections.

Synthesis of sugar core 5

As Scheme 1 illustrates, known α-bromide **1**[33] was converted to its corresponding β-allyl tetraacetate **2** through a procedure developed in our laboratory.[34] Tetraacetate **2** was then deacetylated quantitatively under conventional Zemplén conditions, affording the unprotected β-allyl glucoside **3**. Tetraol **3** was fully allylated through a procedure developed by Lindhorst, and subsequent hydroboration introduced 3-hydroxypropyl spacer groups to the sugar core.[35]

Synthesis of thioether donor 8

The mannose ligand to be attached to **5** was synthesized as shown in Scheme 2. Thioether acetate **6**, prepared by ethylthiolation of the corresponding pentaacetate,[36] was subjected to deacetylation under Zemplén conditions in nearly quantitative yield. The four hydroxyls of **7** were then benzyl-protected to afford **8**. Notably, the anomeric ratio in product **8** was changed to an α:β ratio of 2.3:1 (as determined by ^{1}H NMR spectroscopy), indicating the occurrence of anomerization during this reaction. The α and β components of **8** were separated by column chromatography and characterized, respectively.

Synthesis of dendrimer 10

With a sufficient amount of benzyl-protected thioether donor **8** and pentaalcohol **5** in hand, our attention was directed to the exploration of good glycosylation conditions to install mannose moieties onto the five spacer arms of **5** (Scheme 3). Firstly, we adopted the convenience of a room-temperature reaction and a trimethylsilyl triflate (TMSOTf) catalyst based on our earlier successful experience in the synthesis of linear oligosaccharides.[37] Unfortunately, complete glycosylation was not attained because of the increased steric hindrance for such a highly branched architecture.

As a result, the catalyst was changed to a more powerful silver triflate / *N*-iodosuccinimide (AgOTf/NIS) system[38–42] and heating was also applied, in hopes of driving the glycosylation to completeness. Continuous MALDI-TOF MS monitoring of the reaction suggested that only traces of product with complete glycosylation were formed after 1 day of reflux. Over 5 consecutive days, the amount of the product was found to have reached its maximum value. No further product formation was achieved after an additional 2 days of refluxing. The resulting clustered hexasaccharide **9** was purified on a Sephadex LH-20 GPC column, followed by silica gel column chromatography.

After the dendrimerization was successfully carried out, benzyl protecting groups on **9** were removed by conventional hydrogenlysis with catalysis by $Pd(OH)_2$-on-charcoal.[43–45] Continuous MALDI-TOF MS monitoring of the reaction mixture suggested the completion point after 1 week, and subsequent GPC column purification furnished the deprotected dendrimer **10** in good yield.

Conclusions

A full-carbohydrate glycodendrimer with its first generation of repetitive mannose units was synthesized according to a modified procedure, which utilized multiple glycosylations between a thiomannosyl donor and five extended hydroxyls of a sugar acceptor. The dendritic architecture of the synthesized molecule bears potential as a multivalent mimic for the probe of fundamental carbohydrate–protein interactions.

Experimental section

General

^{1}H (300 MHz) and ^{13}C (75 MHz) NMR spectra were recorded at 25 °C with a Varian Mercury 300 instrument. Chemical shifts are given in δ units (ppm) relative to an internal standard of TMS for ^{1}H, and relative to the signal for $CDCl_3$ (δ 77.0) for ^{13}C, unless otherwise stated. Apparent first-order multiplicities are indicated by s, singlet; d, doublet; dd, doublet of doublets; t, triplet; dt, doublet of triplets; q, quartet; and m, multiplet. Column chromatography was performed on 60 Å (40–63 μm) silica gel (Sorbent Technologies), and fractions were monitored by TLC on silica gel 60 F_{254} (0.2 mm aluminum-backed plates, E. Merck) by detection with 254 nm UV light and then spray–heat development using a *p*-anisaldehyde – sulfuric acid reagent. High-resolution DART mass spectra were obtained on a JEOL AccuTOF-DART instrument with an ESI source. All solvents were dried and distilled by standard methods unless otherwise stated.

Allyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (2)[34]

To a solution of glucosyl bromide **1**[33] (45 g, 0.11 mol) and allyl alcohol (13 mL, 0.64 mol) in dry $CHCl_3$ (150 mL) were added $HgBr_2$ (4.5 g, 12.5 mmol), HgO (24 g, 110 mmol), and $CaSO_4$ (46.2 g) at 0 °C. The reaction was allowed to stir and warm to room temperature (rt) over 10 h, after which time it was filtered, washed with aq NaBr, and extracted with CH_2Cl_2. The organic phase was dried with anhyd $MgSO_4$, filtered, and evaporated to dryness. The residue was submitted to silica gel column chromatography (3:1 hexane–EtOAc) to give allyl glucoside **2** as a colorless syrup (41.7 g, 98%). The data matched those reported in the literature.[34]

Allyl β-D-glucopyranoside (3)[46]

To a solution of **2** (25.6 g, 66.0 mmol) in dry CH_2Cl_2 (50 mL) and dry MeOH (250 mL) was added NaOMe (25% in MeOH, 0.25 mL). The reaction was stirred at rt for 2 h, after which time the reaction was neutralized with Dowex-50 × 2-100 (H^+ form). The suspension was filtered and evaporated to afford tetraol **3** as a white solid (18.2 g, 96%), which was used in the next step without further purification. The data matched those reported in the literature.[46]

Allyl 2,3,4,6-tetra-*O*-allyl-β-D-glucopyranoside (4)[35]

To a solution of tetraol **3** (2.08 g, 9.45 mmol) in 33% aq NaOH (140 mL) the phase-transfer catalyst Bu_4NBr (2.3 g) was added. Then allyl chloride (4.6 mL, 56.5 mmol) was added dropwise at rt over 1 h. The mixture was stirred for 12 h, additional allyl chloride (1.2 mL) was added, and the

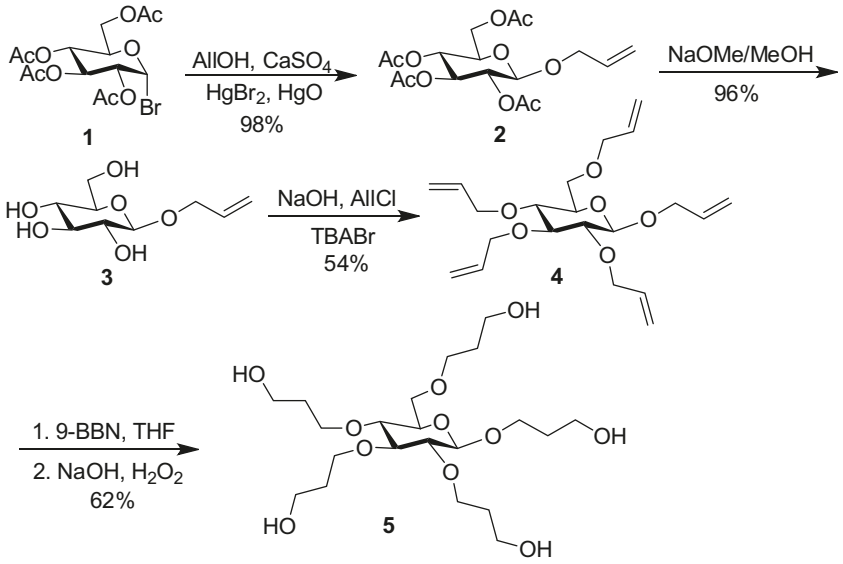
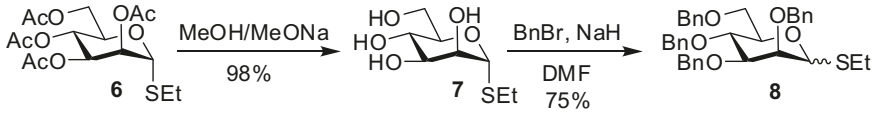
For personal use only.

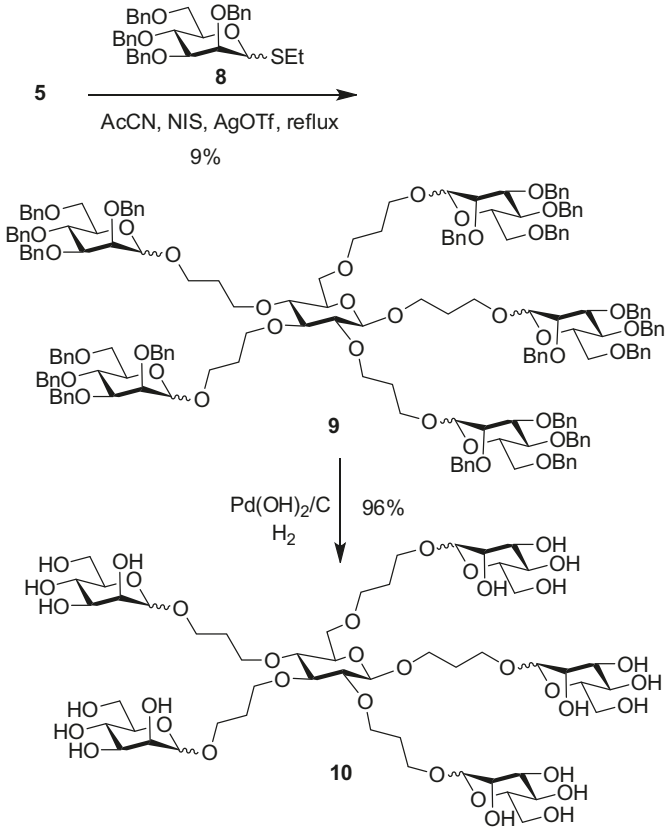
Scheme 1.



Scheme 2.



Scheme 3.



mixture was stirred for another 6 h. When the reaction was complete, toluene (100 mL) was added, and the organic layer was separated and washed five times with water. The neutral organic phase was dried with anhyd $MgSO_4$, filtered, and evaporated to dryness. The residue was submitted to silica gel column chromatography (95:1 CH_2Cl_2–EtOAc) to give per-*O*-allyl glucoside **4** as a colorless syrup (1.93 g, 54%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.02–5.85 (m, 5H), 5.34–5.23 (ddd, 5H), 5.22–5.12 (ddd, 5H), 4.90 (d, J = 8.4 Hz, 1H), 4.37 (ddd, 1H), 4.32 (ddd, 1H), 4.25 (ddd, 1H), 4.20–4.02 (m, 6H), 3.99 (m, 1H), 3.74 (t, J = 9.7 Hz, 1H), 3.71 (ddd, 1H), 3.65 (dd, J = 10.2 Hz, J = 3.6 Hz, 1H), 3.61 (dd, J = 2.6 Hz, 1H), 3.43 (t, J = 9.7 Hz, 1H), 3.40 (dd, J = 9.7 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 135.21, 135.05, 134.78, 134.68, 134.01, 116.98, 116.93, 116.89, 116.69, 115.94, 102.45, 84.12, 81.57, 77.47, 74.72, 74.42, 73.79, 73.62, 72.43, 70.09, 68.89. The data matched those reported in the literature.[32,35]

3-Hydroxypropyl 2,3,4,6-tetra-*O*-(3-hydroxypropyl)-β-D-glucopyranoside (5)

To a solution of perallyl glucoside **4** (261 mg, 0.687 mmol) in dry THF (7 mL) was added 9-borabicyclononane (9-BBN) (0.5 mol/L solution in THF, 20.5 mL, 10.25 mmol) under an N_2 atmosphere, and the solution was stirred at reflux temperature for 6 h. Then the excess of 9-BBN was destroyed by dropwise addition of water at 0 °C. The hydroboration mixture was oxidized by adding 3 mol/L aq NaOH (10.2 mL) and 30% H_2O_2 (10.2 mL) at 0 °C, followed by stirring at rt overnight. The aqueous phase was saturated with K_2CO_3, and the THF phase was separated. The aqueous phase was extracted twice with THF. The combined organic phases were dried with anhyd $MgSO_4$, filtered, and evaporated to dryness. The residue was submitted to silica gel column chromatography (15:85 MeOH–CH_2Cl_2) to give pentaol **5** as a colorless syrup (200 mg, 62%). ^{1}H NMR

(300 MHz, CD_3OD) δ: 4.24 (d, J = 7.8 Hz, 1H), 3.93–3.77 (m, 6H), 3.71–3.52 (m, 17H), 3.19 (t, J = 7.5 Hz, 2H), 2.95 (t, J = 8.1 Hz, 1H), 1.80–1073 (m, 10H). ^{13}C NMR (75 MHz, CD_3OD) δ: 104.62, 85.89, 83.64, 79.31, 75.77, 71.51, 70.85, 70.73, 70.65, 69.46, 67.62, 60.27, 60.22, 60.11, 59.97, 59.81, 34.47, 34.31, 33.77, 33.59. HR-DART-MS calcd for $C_{21}H_{42}O_{11}$ *m/z*: 470.27216; $[M + H]^+$ *m/z*: 471.27910 (calcd 471.28054).

Ethyl 1-thio-α-D-mannopyranoside (7)

To a solution of tetraacetate **6**[36] (1.57 g, 4.01 mmol) in dry CH_2Cl_2 (6 mL) and dry MeOH (30 mL) was added NaOMe (25% in MeOH, 0.3 mL). The reaction was stirred at rt for 1 h, after which time the reaction was neutralized with Dowex 50 × 2-100 (H^+ form). The suspension was filtered and evaporated to afford tetraol **7** as a slightly yellow syrup (0.879 g, 98%), which was used in the next step without further purification. ^1H NMR (300 MHz, CD_3OD) δ: 5.18 (d, J = 1.5 Hz, 1H), 3.83 (m, 2H), 3.73 (d, J = 2.1 Hz, 1H), 3.68 (d, J = 5.7 Hz, 1H), 3.57 (m, 2H), 2.68–2.46 (m, 2H), 1.21 (t, J = 7.5 Hz, 3H).

Ethyl 2,3,4,6-tetra-*O*-benzyl-1-thio-D-mannopyranoside (8)

To a suspension of tetraol **7** (1.64 g, 7.32 mmol) in dry DMF (40 mL) was added NaH (60% dispersion in mineral oil, 2.62 g) and benzyl bromide (7.5 mL, 63.1 mmol). The reaction was stirred at rt for 4 h, after which time MeOH (20 mL) was added at 0 °C to quench the NaH. Subsequently, the mixture was concentrated and filtered through a Celite bed. The filtrate was evaporated to dryness, and the residue was submitted to silica gel column chromatography (8:1 hexane–EtOAc) to give compound **8** as a yellow syrup of an α/β mixture (3.19 g, α:β = 2.3:1, 75%). α Anomer: ^1H NMR (300 MHz, $CDCl_3$) δ: 7.49–7.23 (m, 20H), 5.49 (d, J = 2.1 Hz, 1H), 4.97 (d, J = 10.8 Hz, 1H), 4.84–4.72 (m, 4H), 4.65–4.56 (m, 4H), 4.24–4.08 (m, 2H), 3.93–3.88 (m, 2H), 3.79 (dd, J = 10.8 Hz, J = 1.8 Hz, 1H), 2.77–2.57 (m, 2H), 1.32 (t, J = 7.5 Hz, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 138.36, 138.21, 138.10, 137.96, 128.24–127.34, 81.66, 80.21, 76.11, 75.00, 74.86, 73.15, 71.89, 71.82, 71.75, 68.95, 25.17, 14.88. HR-DART-MS calcd for $C_{36}H_{40}O_5S$ *m/z*: 584.25910; $[M + H]^+$ *m/z*: 585.26968 (calcd 585.26692).

[3-(2,3,4,6-Tetra-*O*-benzyl-D-mannopyranosyloxy)propyl] 2,3,4,6-tetra-*O*-[3-(2,3,4,6-tetra-*O*-benzyl-D-mannopyranosyloxy)propyl]-β-D-glucopyranoside (9)

A mixture of thioether donor **8** (1.92 g, 3.28 mmol) and pentaol acceptor **5** (25 mg, 0.053 mmol) was dried on a vacuum line for at least 3 days. Then the mixture was dissolved in dry acetonitrile (300 mL) and stirred with powdered molecular sieves (4 Å) for 30 min. NIS (82 mg, 0.364 mmol) was then added, and stirring was continued for a further 30 min. After the addition of a catalytic amount of AgOTf (15 mg), the color of the reaction mixture turned deep yellow-brown. After 30 min, the reaction temperature was raised to 81 °C, which allowed the mixture to gently reflux. When MALDI-TOF MS indicated no further progression of the reaction after 1 week, triethylamine (TEA) was added to quench the reaction, and, subsequently, the mixture was diluted, filtered through a Celite bed, and concentrated. The residue was submitted to gel-permeation chromatography on Sephadex LH-20 (1:1 CH_2Cl_2–MeOH). Subsequent silica gel column chromatography (1:1 hexane–EtOAc) afforded **9** (15 mg, 9%) as a white solid. MALDI-TOF MS calcd for $C_{191}H_{212}O_{36}$ *m/z*: 3082.4787; $[M + Na]^+$ *m/z*: 3105.4226 (calcd 3105.4695).

[3-(D-Mannopyranosyloxy)propyl] 2,3,4,6-tetra-*O*-[3-(D-mannopyranosyloxy)propyl]-β-D-glucopyranoside (10)

Benzyl-protected dendrimer **9** (5 mg, 1.62 μmol) was dissolved in EtOAc–MeOH (1:1, 4 mL) and hydrogenated after the addition of $Pd(OH)_2$-on-charcoal catalyst (20%, 30 mg) at atmospheric pressure. When MALDI-TOF MS indicated the reaction was complete after 1 week, the mixture was filtered through a Celite bed, and the filtrate was concentrated and purified by gel-permeation chromatography on Sephadex LH-20 (MeOH) to yield compound **10** (2 mg, 96%) as a white solid. MALDI-MS calcd for $C_{51}H_{92}O_{36}$ *m/z*: 1280.5363; $[M + Na]^+$ *m/z*: 1303.4556 (calcd 1303.5261).

Abstract: The polymerization of phenolic species is an interesting way to generate derivatives with new or improved properties. The structural analysis of these compounds is complex and requires specific analytical techniques. The size exclusion chromatography coupled with an UV detector (SEC-UV) and matrix-assisted laser desorption ionization coupled with a time-of-flight detector (MALDI-TOF) analyses are two methods used to investigate the masses of biopolymers. To analyse the oligomers of rutin and esculin synthesized by the laccase from *Trametes versicolor*, these two techniques were used and coupled with an automated platform. The conditions of detection by MALDI-TOF were optimized. The parallel synthesis, the preparation of sample, the SEC analysis, and the MALDI spotting were realized automatically on a Chemspeed platform. The MALDI-TOF technique enables the detection of oligomers up to pentamer and nonamer, whereas the SEC-UV permits the detection of about 17-mer for rutin and esculin. The molecular mass distribution is underestimated by MALDI-TOF analysis compared with SEC-UV, but comes to the determination of absolute masses. So these two techniques would be combined to explore the masses and the oligomer distributions.

Key words: oligomers, Chemspeed, MALDI-TOF, SEC-UV.

Résumé : La polymérisation d'espèces phénoliques est une méthode intéressante de générer des dérivés possédant des propriétés nouvelles ou améliorées. L'analyse de la structure de ces composés est complexe et elle nécessite des techniques analytiques spécifiques. La chromatographie d'exclusion en fonction de la taille couplée à un détecteur ultraviolet (CET-UV) et l'ionisation par désorption au laser d'une matrice couplée à un détecteur à temps de vol (« MALDI-TOF ») sont deux méthodes d'analyse utilisées pour étudier les masses de biopolymères. On a utilisé ces deux méthodes pour analyser les oligomères de la rutine et de l'esculine par la laccase à partir du *Tramates versicolor*, et on les a couplées à une plate-forme automatisée. On a optimisé les conditions de détection dans le mode MALDI-TOF. Les synthèses parallèles, la préparation de l'échantillon, l'analyse de chromatographie d'exclusion en fonction de la taille et la détection en faisant appel à l'ionisation par désorption au laser d'une matrice ont toutes été effectuées d'une façon automatique sur une plate-forme Chemspeed. La technique de l'ionisation par désorption au laser d'une matrice couplée à un détecteur à temps de vol (MALDI-TOF) permet de détecter des oligomères allant jusqu'au pentamère et au nonamère alors que la chromatographie d'exclusion en fonction de la taille couplée à un détecteur ultraviolet (CET-UV) permet de détecter environ le 17-mère de la rutine et de l'esculine. Par comparaison avec les distributions de masses moléculaires déterminées par chromatographie d'exclusion en fonction de la taille couplée à un détecteur ultraviolet (CET-UV), la technique de l'ionisation par désorption au laser d'une matrice couplée à un détecteur à temps de vol (MALDI-TOF) conduit à une sous-évaluation de cette distribution, mais elle permet de déterminer les masses absolues. Il est donc important d'utiliser une combinaison de ces deux techniques pour examiner les masses et les distributions d'oligomères.

Mots-clés : oligomères, Chemspeed, technique de l'ionisation par désorption au laser d'une matrice couplée à un détecteur à temps de vol (« MALDI-TOF »), chromatographie d'exclusion en fonction de la taille couplée à un détecteur ultraviolet (CET-UV).

[Traduit par la Rédaction]

Introduction

The polymerization of phenolic species is an interesting way to generate derivatives with new or improved properties.[1–12] These properties could be controlled by the operating conditions of the reaction, which can affect the polymerization degree and the nature of the linkage occurring between monomers. To evaluate the effect of the operating conditions on the oligomer structure, different techniques are used: osmometry,[13] tonometry, cryometry, size exclusion chromatog-

raphy (SEC), and mass spectrometry. These last two techniques are the most used for the biopolymer characterization.

SEC is a well-known technique in the polymer field, but it needs standards with similar chemical structure to synthesize molecules. Among mass spectrometry techniques, the matrix-assisted laser desorption ionization coupled with a time-of-flight detector (MALDI-TOF) is often mentioned for the structural investigation of biopolymers. This technique avoids the fragmentation phenomena observed with other mass spectrometry techniques and ions are detected as single-charged, which facilitates spectrum identification. The TOF is adapted to a broad domain of molecular masses of polymers. However, its use for biopolymer analysis requires a judicious choice of the small organic molecules "the matrix", essential to co-crystallized with the analyte, the mode of ionization, and detection. The matrix co-crystallizes selectively with the analyte, minimizing salt contamination of the obtained crystals. The spectrum quality depends on crystal preparation, the nature of the matrix, the presence of tensioactive or buffer, the pH of the solution, and the characteristics of the analyte and solvent. The ionization could be realized in positive or negative mode. If the analyte has a proton acceptor function, the positive mode is recommended, whereas, if the molecule is a proton donor, the negative mode is selected. In the literature, flavonoids have been analyzed by mass spectrometry with negative[14,15] and positive modes.[16,17]

The detection can be carried out under linear or reflectron modes. The reflectron mode allows an increase in the time of the flight without increasing the size of the apparatus. The combination of increased flight length and conserved time distribution increases the resolution of the signal. But this mode is limited to masses <60 KDa. the linear mode is more adapted for a high molecular mass. Nevertheless, for an investigation of the whole domain of masses, these two detection modes could be combined.

The solvent proportion is also an important factor; it allows the acceleration or slowing down of the crystallization phenomena. In the same way the ratio of analyte/matrix effects the crystallization and the analyte ionization.

The objective of this work is to develop an automated platform based on the use of a Chemspeed station and two online detectors, MALDI-TOF and SEC-UV. This platform will be used to evaluate the effects of the operational conditions and the nature of the flavonoid on the properties of the synthesized oligomers. To accomplish this purpose, in a first step, the operating conditions of MALDI-TOF analysis were optimized; in a second step, the coupling of the two analytical techniques to the Chemspeed station was realized; and finally, the performance of this system was validated by the oligomerization kinetics of rutin and esculin.

Experimental

Materials

Laccase *Trametes versicolor* (E.C. 1.10.13.2., 21.4 U/mg) and esculin sesquihydrate (>98%) were purchased from Fluka and rutin (>95%) was purchased from Sigma-Aldrich. All solvents were HPLC grade and were purchased from VWR.

Parallel synthesis of oligorutin

To synthesize and analyze oligoflavonoids, a Chemspeed ASW1000 (Chemspeed Ltd., August, Switzerland) platform was used. The rutin or esculin powders (final concentration 3 g/L) were introduced in eight parallel thermostated vessels of 27 mL in total volume. All later operations were automatically realized. Methanol and water were added to each vessel (final volume 10 mL at the ratio 30:70, *v*/*v*). The reaction was started by adding an enzymatic solution of laccase (final concentration 3 U/mL). The system was stirred at 600 rpm at 20 °C. To follow the kinetics of the oligomerization, dimethylformamide (DMF) was transferred to the SEC dilution zone. Reaction media samples were added to the DMF (final ratio DMF / reaction media, 9:1, *v*/*v*). The diluted solutions were stirred and then injected online into the SEC-UV system. To avoid precipitation phenomena, the SEC dilution zone was also kept at the same temperature as the reaction. SEC analysis allowed the determination of weight average masses.

To determinate the absolute masses of rutin oligomers, samples were automatically diluted twofold in acetonitrile (ACN) / water with 0.1% trifluoroacidic acid (30:70, *v*/*v*) on the MALDI-TOF dilution zone. Homogenization was realized by a repetitive (3 times) suction/pouring. For the spotting, a needle with a 0.4 mm diameter was used in combination with a Bruker MTP 384 massive MALDI target. A special support was created to adapt this target on the Chemspeed platform. Three microlitres of the diluted solutions were spotted on line and then 1 µL of the refrigerated matrix solution (to avoid rapid degradation of the matrix) was dropped on the surface of the analyte. The spots were left for crystallization at room temperature. The positions of the samples on the MALDI target were located with *x*, *y*, *z* coordinates and programmed using the synthesizer software. All samples were automatically spotted in triplicate.

SEC analysis

Relative masses of oligomers were evaluated by SEC (HPLC LaChrom (Merck), UV 280 nm LaChrom L-7400, Tosoh TSK Gel at 3000 column, 60 °C). DMF with 1% LiBr was used as the mobile phase at a flow rate of 1 mL/min. Polystyrene standards were used to define molecular mass calibration.

MALDI-TOF analysis

Absolute masses were determinated by MALDI-TOF. Three matrices were tested: synapinic acid (SA), 2′,4′,6′-trihydroxyacetophenone (THAP), and 2,5-dihydroxybenzoic acid (DHB).

MALDI-TOF-MS experiments were performed on an Ultraflex spectrometer (Bruker) in reflectron mode. Ionization was performed with a 337 nm pulsed nitrogen laser. After time-delayed extraction, the ionic species were accelerated under a 20 kV potential for TOF MS analysis. All spectra were obtained in positive-ion mode with an accumulation of at least 600 shots. Spectra were calibrated using the statistic calibration of FlexAnalysis software (Bruker).

Results and discussion

MALDI-TOF is a very powerful analytical tool for the

Table 1. Mode of preparation of the matrix used in MALDI-TOF analysis.

Matrix	Designation	Concn of matrix	Solvent	Ref.

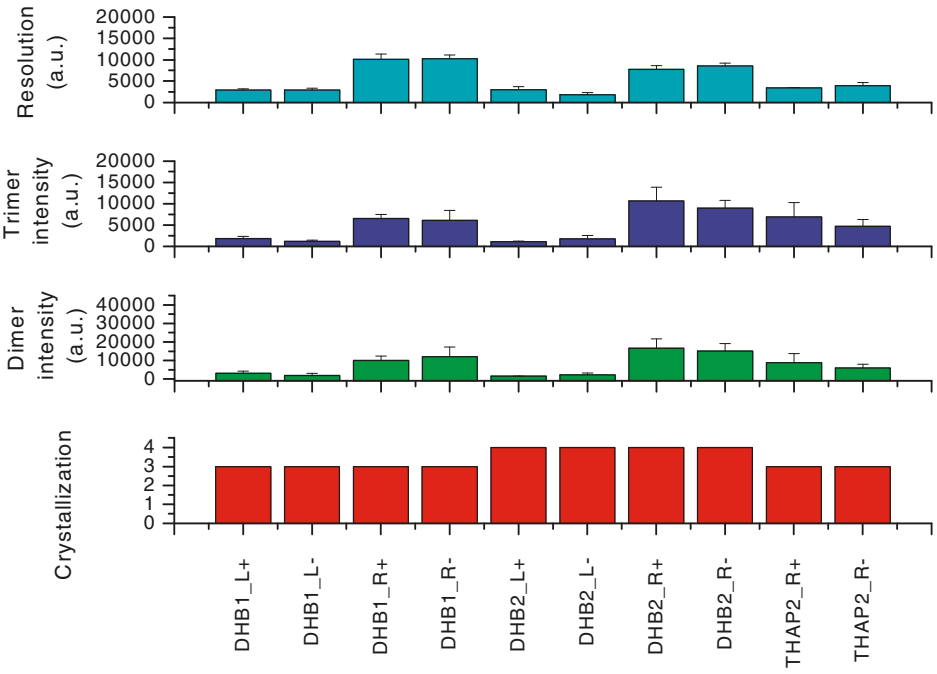
Fig. 1. Impact of the type of matrix, the mode of ionization, and the mode of detection on crystallization, dimer and trimer intensity, and resolution for the MALDI-TOF analysis of oligomers of rutin. Three matrices were tested: dihydroxybenzoic acid (DHB1 and DHB2) and trihydroxyacetophenone (THAP), in linear (L) or reflectron (R) mode and in positive (+) or negative (–) ionization. An analyte/matrix ratio of 3:1 was applied.



investigation of polymers. This technique leads to the determination of the mode of linkage and the mass distribution. However, its use for a given substrate needs the optimization of several factors affecting the amplitude and the reproducibility of the spectrum signal. Therefore, in a first step the effect of different parameters on MALDI-TOF analysis was investigated for oligorutin and oligoesculin obtained after 24 and 36 h of reaction, respectively.

The matrix and detection mode

To determinate the absolute mass of oligomers and, therefore, the linkage between two units of rutin, three parameters were varied offline to optimize the MALDI-TOF protocol: the matrix, the ionization mode, and the detection mode. In this work, to limit the pH influence, the analyte was diluted in a solution of ACN/water containing 0.1% TFA.

For a given polymer the choice of the matrix is crucial; some matrices are particularly sensitive to impurities, whereas for others the loss of efficiency is small, and hence such matrices are preferred when salts are available in the medium. The ideal matrix should have a high electronic absorption at the employed laser wavelength, good vacuum stability, low vapor pressure, good solubility in the solvent, and good miscibility with the analyte in the solid state. To select the most adapted matrix to rutin and esculin oligomers analysis, three matrices were tested: DHB, SA, and THAP. Various alternatives of preparation of these matrices were formulated (Table 1).

Different criteria were considered for the determination of the most appropriate conditions: the resolution, the quality of the crystallization, and the peak intensity. The quality of the crystallization was attributed arbitrarily on a scale between 0 and 4, with 4 representing high-quality.

The results show that, for all tested matrices and alternatives of preparation, only DHB1 and DHB2 in linear and reflectron modes and THAP2 in reflectron mode lead to exploitable spectra. The corresponding data are given in Fig. 1. For all tested matrices the positive and the negative modes of ionization lead to similar results.

The DHB matrix allowed a best resolution compared with

Fig. 2. ASW2000 synthesizer for the oligomerization of rutin. The preparation of reaction media, SEC samples, and MALDI-TOF samples was executed online. HPLC injections and MALDI spotting were controlled by the computing interface of the synthesizer.

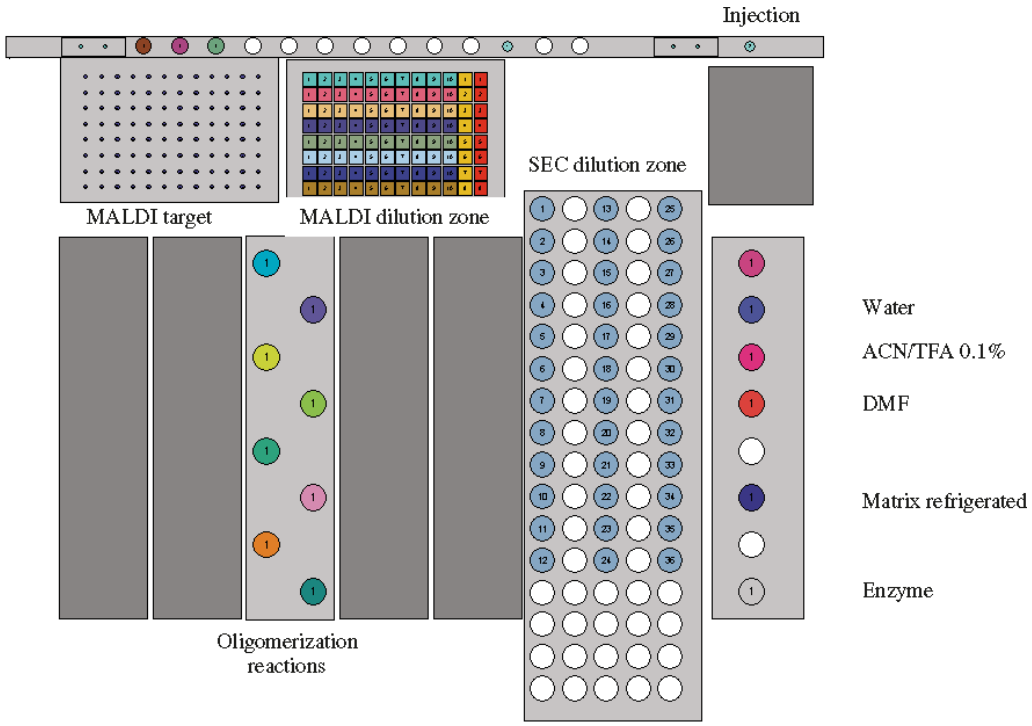

Fig. 3. Impact of the ratio of analyte/matrix (DHB1) and the proportion of solvent on resolution, intensity of the dimer and trimer, and crystallization on MALDI-TOF analysis of media containing rutin and oligomers of rutin (positive ionization mode and reflectron mode detection). ACN, acetonitrile.

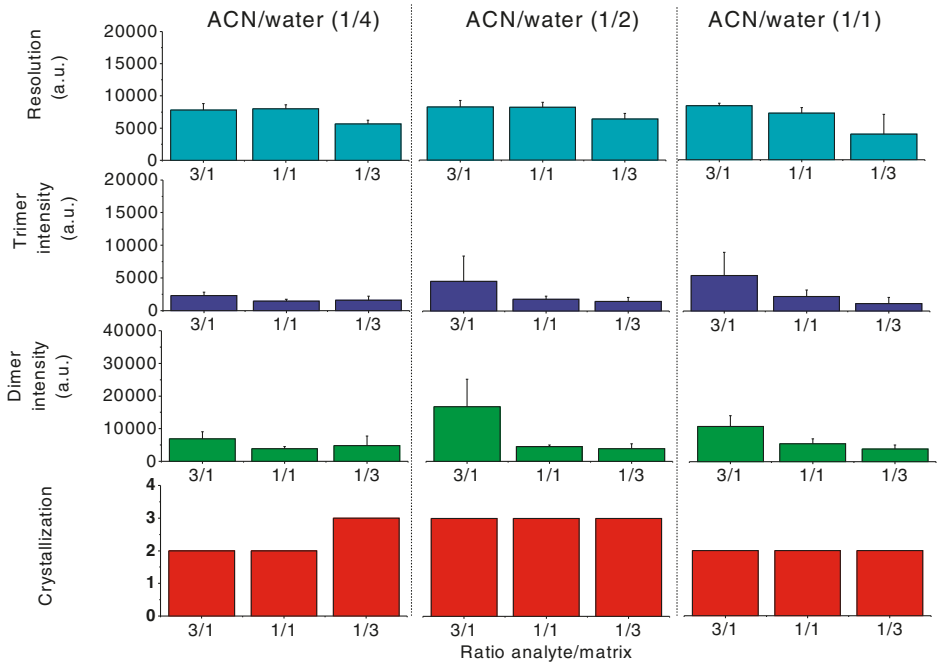

THAP2. The DHB2 matrix had the best crystallization and DHB1 had a better resolution. For the DHB matrix, a higher intensity of dimer or trimer and an enhanced resolution was obtained with the reflectron mode. Therefore, in light of these results, the effects of the other factors were analyzed in the presence of DHB1 in positive mode of ionization and in reflectron mode of detection.

Development of SEC and MALDI-TOF online analysis

MALDI-TOF and SEC analysis can be used to find the optimal reaction factors, such as optimal temperature, pH, and ratio of solvent or reactant concentration, for the production of oligomers with specific properties. To facilitate and accelerate this optimization, an online analysis was perfected. Thus, the MALDI-TOF spotting and the SEC-UV analysis

were coupled with the Chemspeed platform to be executed automatically online (Fig. 2).

This platform allows for the realization of eight parallel reactions or operating conditions and to follow the kinetics of the reaction. The stirring, the temperature, the handling of sample, the dilution, the injection, and the spotting were automatically controlled. The advantages of this automated method are the facility of implementation, the saving of time, the repeatability and reproducibility of data, and the absence of contamination. However, before being able to use this station in a routine way, the spotting conditions must be optimized. In fact, optimum results are obtained when the polymer and the matrix are soluble in the same solvent. Therefore, to solubilize the oligomers and the matrix together, a mixture of ACN/water containing 0.1% TFA was used. As the kinetics of the crystallization are affected by the solvent/water ratio, three preparations (1:4, 1:2, and 1:1, *v*/*v*) were tested. The ratio of analyte/matrix is also an important factor for the allowance of an optimal desorption of analyte. For this reason, three ratios of analyte/matrix (3:1, 1:1 and 1:3, *v*/*v*) were studied. The obtained results are summarized in Fig. 3. It appears that the highest intensity of dimer or

For personal use only.

trimer is reached for an analyte/matrix ratio of 3:1. In such conditions, a comparable resolution is obtained with the three proportions of diluted solutions of ACN/water (TFA 0.1%). However, the highest crystallization and dimer intensity are obtained with a ratio of 1:2 ACN/water (TFA 0.1%).

In conclusion, DHB1 as the matrix with a proportion of 1:2 (ACN/water TFA 0.1%) as a dilution solvent, an analyte/matrix ratio of 3:1, a positive ionization mode, and a reflectron detection mode were retained as optimal conditions for the oligoflavonoids characterization by MALDI-TOF.

For SEC-UV coupling with the Chemspeed platform, the samples were taken under agitation and diluted automatically in vials heated at the reaction temperature. This dilution was realized in a DMF–LiBr mixture. This solvent allows the instantaneous solubilization of the flavonoids and the synthesized oligomers. From this preparation 20 μL were injected via a rheodhyn valve. The elution solvent was DMF–LiBr at a flow rate of 1 mL/min. All steps in this procedure were supervised by the Chemspeed software.

Validation of the developed platform

This platform was validated by studying the polymeriza-

tion reaction of rutin and esculin. The oligomerization of rutin and esculin was followed over 24 and 36 h, respectively, depending on the kinetics of the reaction, by the online sampling and analysis described previously. The SEC spectra for several withdrawment samples are given on Fig. 4.

These chromatograms show that the formed oligomers can reach about 17 units for rutin and esculin.

The MALDI-TOF analysis was realized on all withdrawment samples. Figure 5 shows an example of the MALDI-TOF spectra. Dimers, trimers, and tetramers were synthesized immediately at the beginning of the reaction, thus, the enzymatic polymerization of flavonoids is not a sequential process. This technique allows the detection of oligomers up to pentamer (mass: 3044.5 g/mol) and nonamer (mass: 3044 g/mol) for rutin and esculin, respectively (Figs. 5*a* and 5*b*). However, a comparison of the SEC and MALDI-TOF results indicates that these two techniques lead to very different results. The molecular mass distribution is underestimated by MALDI-TOF analysis compared with SEC-UV. This behaviour could be due to weak ionization of oligomers having molar masses higher than 3000 Da in these conditions.

Conclusion

An automated platform allowing the realization of eight parallel syntheses or operating conditions with online sample preparation, MALDI-TOF spotting, and SEC analysis has been developed. This platform will be used to study the effect of different factors on the kinetics and structural properties of the enzymatic polymerization of flavonoids by laccase.

3,3′-*N*,*N*′-Bis(amino)-2,2′-bipyridine — An unusually methylation-resistant amine

Danielle M. Chisholm, Robert McDonald, and J. Scott McIndoe

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: Methylation of aromatic amino groups is usually straightforward, but the formation of two intramolecular hydrogen bonds in 3,3′-*N*,*N*′-bis(amino)-2,2′-bipyridine and (or) the potential for ring methylation prevents the clean tetramethylation of this molecule. Numerous attempts to make 3,3′-*N*,*N*′-bis(dimethylamino)-2,2′-bipyridine produced only complex mixtures of variously methylated products, and the only isolated molecule was 3,3′-*N*,*N*′-bis(methylamino)-2,2′-bipyridine, for which an X-ray crystal structure was obtained.

Key words: Proton-sponge, methylation, electrospray ionization mass spectrometry, bipyridine ligands.

Résumé : La méthylation des amines aromatiques est une réaction généralement simple mais, dans le cas de la 3,3′-*N*,*N*′-bis(amino)-2,2′-bipyridine, la formation de deux liaisons hydrogènes intramoléculaires et (ou) la possibilité de méthylation des hétérocycles empêche la réaction de tétraméthylation propre de cette molécule. Plusieurs essais de préparation de la 3,3′-*N*,*N*′-bis(diméthylamino)-2,2′-bipyridine n'ont conduit qu'à la formation de mélanges complexes de produits de degrés de méthylation divers et la seule molécule qui a pu être isolée est la 3,3′-*N*,*N*′-bis(méthylamino)-2,2′-bipyridine dont la structure a été caractérisée par diffraction des rayons-X.

Mots-clés : éponge à protons, méthylation, spectrométrie de masse avec ionisation par électronébulisation, ligands bipyridine.

[Traduit par la Rédaction]

1,8-Bis(dimethylamino)naphthalene (Proton-sponge), was first reported by Brown and Letang in 1941,[1] and in the late 1960s Alder et al.[2] drew attention to the fact that this molecule was unusually basic. Alder et al.[2] demonstrated how the sequential addition of methyl groups to 1,8-bis(amino)naphthalene increased the pK_a slowly until the fourth substitution, which increased the pK_a from 6.4 to 12.3. The high basicity is due to a number of factors. The bulky nature of the dimethylamino groups and their close proximity to one another induces steric repulsion between the lone pairs of electrons on the two nitrogen centres. To relieve some of the repulsion the naphthalene system twists out of plane by ~30°,[2] and the steric strain is easily relieved through association of a proton. The lone pairs on each nitrogen centre can become equally involved[3,4] in hydrogen bonding with the proton and are no longer repelled by one another, allowing the naphthalene ring to return to planarity.[5] The spatial arrangement of the dimethylamino groups allows access to only a proton, and anything larger will not fit comfortably (a notable exception being a highly reactive palladium fragment).[6] Many new proton sponges have since been introduced (see Fig. 1 for examples).[7–9] Staab et al.[10,11] showed that it was not just the proximity of the nitrogen centres that determined the strength of basicity but also the linearity of the resulting hydrogen bonds, hence the low basicity of structures 1(*d*) and 1(*e*). The superbase[12] 1,8-bis(hexamethyltriaminophosphazenyl)naphthalene[13] contains a combination of basic phosphazenes and proton sponge structure to achieve a pK_a of 29.9 in acetonitrile, almost 10^{12} more basic than 1,8-bis(dimethylamino)naphthalene.

The exclusive and strong association of a proton to these types of molecules makes them perfect handles for study using electrospray ionization mass spectrometry (ESI-MS).[14] Eliminating the possibility for multiple charge pathways greatly simplifies mass spectra, making this particular type of molecule very attractive. The only obstacle is adding this convenient probe to molecules of interest; in our research that equates to spectator ligands in catalytic reactions.[15–18] This end has been achieved previously in our group through altering triphenylphosphine by replacing one phenyl group with a proton sponge. (1,8-Bis[dimethylamino]naphthalene-2-yl)diphenylphosphine was synthesized and used to show that ESI-MS investigations of neutral metal complexes was possible when a chargeable ligand was employed.[19]

The direction we had envisioned for this work was toward molecules that would possess a similarly highly basic site once bound to a metal centre. We were drawn to the scaffold of the fluorene-type sponges 1(b) introduced by Staab and Saupe[8] because of the similarity they bore to the orientation of 2,2′-bipyridine ("bipy") chelating to a metal. Increasingly large atoms (O, S, Se, and Te) could replace the methylene

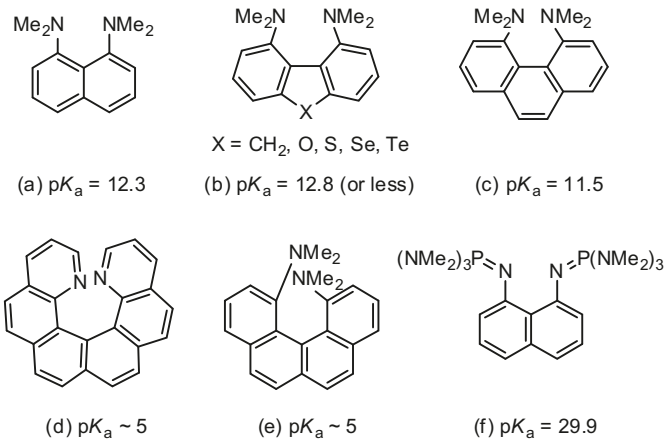
Fig. 1. Some of the structures developed in the course of research into proton sponges based on (*a*) naphthalene,[2] (*b*) fluorene,[8] (*c*) phenanthralene,[8] (*d*) 1,16-diaza[6]helicene,[10] (*e*) benzo[*c*]phenanthrene[11], and (*f*) phosphazene-substituted naphthalene.[13]



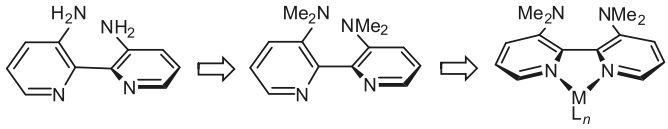
group with only minor detrimental effects on the basicity. To this end we pursued the functionalization of 2,2-bipyridine. Bipy ligands are common in coordination chemistry[20–22] so their incorporation into our investigations seemed like an appropriate choice. The idea was to substitute bipyridine at the 3 and 3′ positions to arrive at 3,3′-*N*,*N*′-bis(dimethylamino)-2,2′-bipyridine and to rely on coordination to a metal centre to orient the two groups toward each other (Fig. 2).

Once the functionalized bipyridine has coordinated to the metal and the dimethylamino groups have adopted the expected orientation, addition of a proton source should render the entire complex amenable to ESI-MS analysis and provide the first example of a metal-containing proton sponge. The effect of the relatively flexible coordination environment of the metal was also of structural interest — it is possible, of course, that the metal coordinates to one pyridine nitrogen and one dimethylamino nitrogen. In this case, an identical site would be available on the other side of the ligand, which itself could bind another metal centre or H^+.

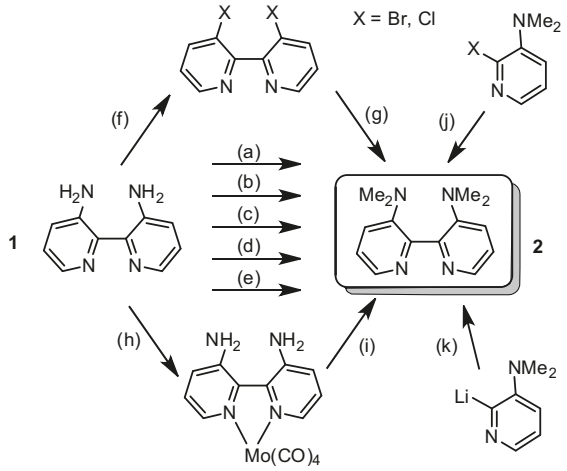
Synthesis of the known 3,3′-bis(amino)-2,2′-bipyridine (**1**) was straightforward.[23] However, tetramethylation of the molecule to replace all N–H bonds with N–CH_3 proved anything but simple. Tetramethylation of 3,3′-bis(amino)biphenyl and 1,8-bis(amino)naphthalene is routine, but the same approach on 3,3′-bis(amino)-2,2′-bipyridine failed, and we subsequently tried nine other routes without success (Scheme 1).

Route a in Scheme 1 involved sodium hydride and dimethylsulfate, based on Staab and Staupe's[8] preparation of the fluorene-derived sponges. Route b adapted Giam and Hauck's[24] approach to the methylation of 3-aminopyridine to give 3-dimethylaminopyridine using formic acid and formaldehyde. Route c modified Sheppard's[25] methylation of *m*-trifluoromethylaniline to *m*-trifluoromethyl-*N*,*N*-dimethylaniline using trimethylphosphate and aqueous sodium hydroxide. Route d employed Charmant et al.'s[26] use of methyl iodide to methylate a benzylamine-substituted naphthalene proton sponge derivative. Route e used Shaw and Turner's[27] approach to methylating 2,2′-diaminobiphenyl to 2,2′-bis(dimethylamino)biphenyl using dimethyl sulfate and sodium hydroxide. All of these routes, to a greater or lesser extent, resulted in methylation, but always a complex mixture of

Fig. 2. Concept for a metal-containing proton sponge.



Scheme 1. Attempted routes to 3,3′-*N*,*N*′-bis(dimethylamino)-2,2′-bipyridine (**2**).



products was obtained and we were never successful in isolating the desired compound. Figure 3 illustrates a typical ESI-MS obtained from these reaction mixtures. Separating the different components by chromatography proved unsuccessful. Note that ESI-MS does not distinguish between ring methylation (+15 Da, positively charged) or replacement of one H for the Me and protonation (+15 Da, positively charged), so the following spectrum contains both series, i.e., $[C_{10}N_4Me_nH_{(4-n)}]^+$ (n = 1–5) and $[C_{10}N_4Me_nH_{(4-n)} + H]^+$ (n = 1–4). The ^{1}H NMR mixture, which showed the presence of both types of methyl groups (methylamine and methylpyridinium). Pyridines may be directly methylated by dimethylsulfate[28] or methyl iodide[29] in the absence of added strong base.

The one compound successfully isolated was the dimethylated neutral compound 3,3′-bis(methylamino)-2,2′-bipyridine (**3**) by fractional crystallization in 25% yield. Monomethylation of each amino group allows for two separate hydrogen bonds between the amine hydrogen and the pyridine nitrogen in opposite rings. Crystals of **3** were obtained from the reaction of **1** with sodium hydride and methyl iodide and were isolated by slow evaporation of diethyl ether. An X-ray crystal structure of this molecule was obtained (Fig. 4). This compound was spectroscopically characterized previously by ^{1}H and ^{15}N NMR without preparative details.[30]

The bipyridine core of **3** is very similar to unsubstituted 2,2′-bipyridine with respect to bond lengths and angles. The C–N1 and C–C bond lengths in the two equivalent pyridine rings average 1.34 and 1.40 Å, respectively, whereas the average bond angle is 120.0°. The comparative numbers for 2,2′-bipyridine are 1.36 and 1.39 Å and 120.8°, respectively.[31] As with 2,2′-bipyridine, N1 and N1 are arranged trans to one another, but whereas 2,2′-bipyridine is coplanar, the two equivalent pyridine rings of **3** lie in parallel planes separated by 0.06 Å. The presence of the hydrogen bonds

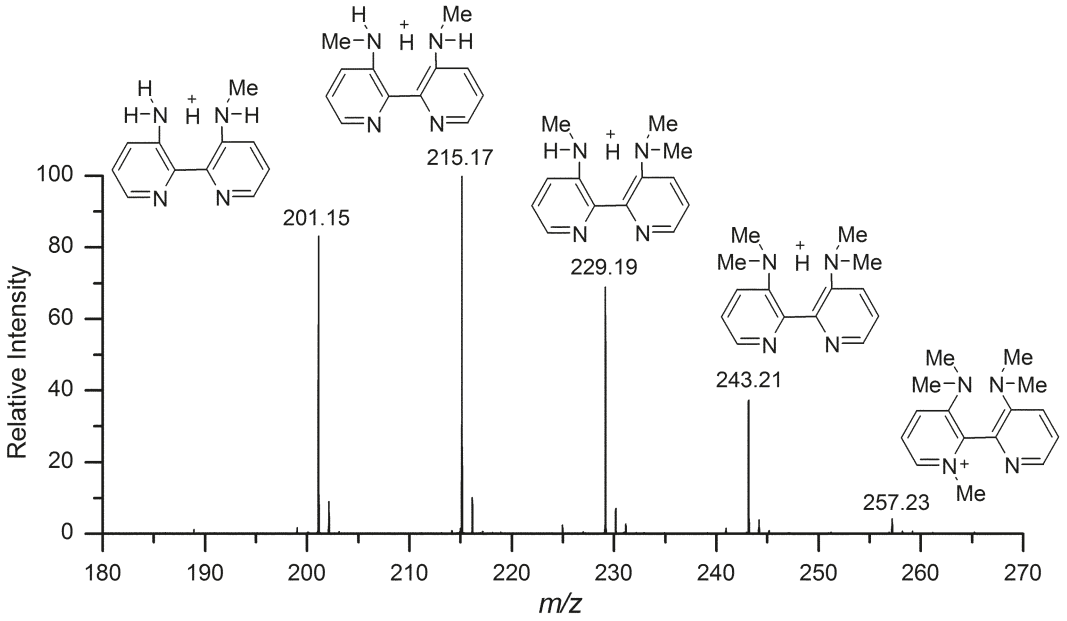
For personal use only.

Fig. 3. Positive ion ESI-MS in CH_2Cl_2 of the mixture obtained from methylation of 3,3′-bis(amino)-2,2′-bipyridine with Me_2SO_4 and NaOH.

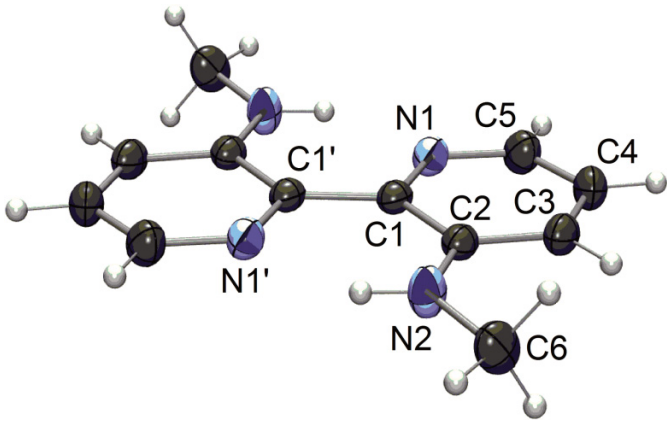


(N1–H length = 1.962 Å and N1–H–N2′ bond angle = 133.3°) is evident from the structure, and they are essentially the same as that in **1** (1.947 Å and 132.8°). A hydrogen bond can be classified as strong, moderate, or weak by evaluating factors such as bond length, bond angles, and comparison of the lengths of the hydrogen bond and the covalent bond between the hydrogen and the atom to which it is bonded,[32] and the H bonds here fall into the "moderate" category (1.5–2.2 Å and 130°–180°). There is no intermolecular H bonding evident in the packing of **3**.

Because **3** has two moderate-strength intramolecular hydrogen bonds, as does **1** (and also presumably the intermediate 3,3′-*N*,*N*′-(amino)(methylamino)-2,2′-bipyridine, although it has not been characterized), this feature may partially account for these molecules being unusually resistant to further methylation. Forcing conditions (neat MeI) seemed to be able to tri- and tetramethylate **1**, but also caused ring methylation of a pyridine nitrogen, further complicating the product mixture.

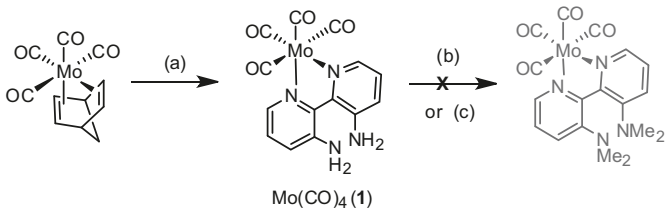
As an alternate synthetic approach, we tried cross-coupling various derivatives of 3-dimethylaminopyridine. 3-Dimethylaminopyridine[30] and 2-chloro-3-dimethylaminopyridine[31] were made from nitropyridine species, which were reduced using $SnCl_2{\cdot}2H_2O$ in HCl, and the subsequent aminopyridine was methylated using formic acid and formaldehyde to give 3-dimethylaminopyridine and 2-chloro-3-dimethylaminopyridine. The copper-catalyzed Ullmann coupling of 2 equiv of 2-chloro-3-dimethylaminopyridine (Scheme 1, route j) failed to proceed. Route k, the iron-catalyzed cross-coupling[33] of 2-chloro-3-dimethylaminopyridine and 3-dimethylamino-2-lithiopyridine (easily generated in situ using *n*-BuLi in THF and the formation verified through independent quenching experiments) did not generate a product. Several competing factors are thought to have limited the success of the coupling reactions of 2-chloro-3-dimethylaminopyridine. Whereas electron-withdrawing groups (e.g., NO_2) located ortho to the halogen activate the molecule, electron-donating groups (e.g., NMe_2) have the opposite effect. Particularly bulky substituents in this position will also hinder the formation of coupled products.[34] Similar complications seem plausible for the attempted iron-catalyzed coupling.

Fig. 4. Perspective view of **3** showing the atom-labelling scheme. Non-hydrogen atoms are represented by Gaussian ellipsoids at the 70% probability level. Hydrogen atoms are shown with arbitrarily small thermal parameters. Primed atoms are related to unprimed ones via the crystallographic inversion centre (1/2, 0, 1/2) at the midpoint of the C1–C1′ bond. Broken lines indicate hydrogen-bonded N–H···N interactions. Selected interatomic distances (Å): C1–C1′ = 1.487(2), N1–N2′ = 2.645(2), N1–C1 = 1.346(2), N1–C5 = 1.332(2), N2–C2 = 1.354(2), and N2–C6 = 1.442(2). Selected bond angles (°): N2–C2–C1 = 122.9(1) and C1–N1–C5 = 121.3(1). Selected torsion angle (°): N1–C1–C2–N2 = 178.6(1).



The next step was to try to inhibit the formation of the intramolecular hydrogen bonds and to block ring methylation. Coordination of **1** to a metal centre engages the lone pairs of the pyridine nitrogen so they are no longer available to form hydrogen bonds with an amine hydrogen or to be methylated. $Mo(CO)_4$ (norbornadiene) was selected for this task (Scheme 2).[35,36] Displacement of norbornadiene[37] with **1** to give $Mo(CO)_4$(**1**) (Scheme 1, step h), effectively removed the

Scheme 2. Attempted routes to 3,3′-*N*,*N*′-bis(dimethylamino)-2,2′-bipyridine (**2**).



possibility of the formation of intramolecular hydrogen bonds within the bipyridine molecule. Confirmation that coordination had occurred through both pyridine nitrogen centres was obtained through comparison to the IR stretching frequencies of $Mo(CO)_4$(2,2′-bipyridine).[38,39] Sodium hydride and dimethyl sulfate were used to methylate $Mo(CO)_4$(**1**), but upon completion of step i the IR spectrum did not contain any CO-stretching frequencies, and the ESI-MS spectrum showed products containing one to four methyl groups as well as starting material. The procedure involving sodium hydride and methyl iodide described previously gave a mixture of methylated products as before.

A final attempt (Scheme 1, routes f and g) involved aminating 3,3′-bis(halo)-2,2′-bipyridines[40–42] with a lithium aminoborane reagent (LAB) made from *n*-BuLi and $BH_4{\cdot}NMe_2$ in tetrahydrofuran.[43] However, upon addition of the LAB to the bis(halogen) species none of the desired product was observed upon workup.

Conclusions

3,3′-Bis(amino)-2,2′-bipyridine (**1**) is unusually difficult to tetramethylate or to prepare by numerous other methods commonly used to construct similar molecules. The key structural feature likely to be responsible for this behaviour is the pyridine nitrogens, which can form two intramolecular hydrogen bonds in the un-, mono- and dimethylated compounds that may interfere with further methylation. These hydrogen bonds are in clear evidence in the X-ray crystal structure of 3,3′-bis(methylamino)-2,2′-bipyridine (**3**). The pyridine nitrogens are also susceptible to methylation themselves, further complicating the reactivity of **1**.

Experimental

All synthesis was performed under an inert atmosphere of N_2 using standard glovebox or Schlenk procedures. 2-Chloro-3-dimethylamino pyridine, 3,3′-diamino-2,2′-bipyridine,[23] and $Mo(CO)_4$(norbornadiene)[35,37] were made by literature methods. All other chemicals were used as obtained (Sigma-Aldrich, Oakville, Ontario). Solvents were HPLC grade and purified on an MBraun solvent purification system (SPS). Gases were obtained from Airgas (Calgary, Alberta). NMR spectra were collected on either an AV-300 or an AV-360 Bruker spectrometer. Internal reference was made to $CHCl_3$ (1H d = 7.26 ppm). All mass spectra were obtained on a Micromass Q-ToF micro hybrid quadrupole / time-of-flight mass spectrometer in positive ion mode using pneumatically assisted electrospray ionization with a capillary voltage of 2900 V, a source temperature of 100 °C, and a desolvation temperature of 180 °C. Solutions were run in dichloromethane and introduced to the mass spectrometer by a syringe pump at a rate of 2 mL/h. Internal calibrants for accurate mass experiments were protonated triphenylphosphine oxide ($[C_{15}H_{18}PO + H]^+$ = 278.0939 *m/z*), tetrapropylammonium bromide ($[C_{12}H_{28}N]^+$ = 186.2222 *m/z*), and tetrabutylammonium bromide ($[C_{16}H_{36}N^+]^+$ = 242.2848 *m/z*) as indicated where applicable. Higher mass accuracy is provided in these instances.

3,3′-Bis(methylamino)-2,2′-bipyridine (3)

Sodium hydride (0.052 g, 2.2 mmol) was added to (3,3′-diamino-2,2′-bipyridine (0.104 g, 0.55 mmol) in THF (5 mL) and stirred for 30 min resulting in bubbling and giving a yellow solution. Methyl iodide (0.31 g, 0.14 mL, 2.2 mmol) was added and the solution was refluxed for 90 min. Sodium hydroxide was added (3 mol/L, 1 mL) and the mixture extracted with diethyl ether (4 × 10 mL) until no colour remained in the aqueous phase. The organic phase was dried over magnesium sulfate and reduced in volume via a rotary evaporator. The yellow solid was redissolved with a minimal amount of diethyl ether and cooled to –5 °C to give yellow crystalline material (30 mg, 25%); mp = 148–150 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 2.92 (s, 6H), 7.06 (dd, $^3J_{HH}$ = 1.53, 8.37 Hz, 2H), 7.15 (dd, $^3J_{HH}$ = 4.55, 8.42 Hz, 2H), 7.91 (dd, $^3J_{HH}$ = 1.62, 4.47 Hz, 2H), 9.43 (s, 2H). ^{13}C NMR (500 MHz, $CDCl_3$) δ (ppm): 29.80, 117.69, 123.30, 133.13, 140.25, 145.81. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z* experimental: 215.1298 $[C_{12}H_{14}N_4 + H]^+$; calcd: 215.1297.

3,3′-Dichloro-2,2′-bipyridine[40,41]

To a cold solution (0 °C) of sodium nitrite (370.2 mg, 5.4 mmol) in concentrated sulfuric acid (4 mL) was slowly added a solution of 3,3′-diamino-2,2′-bipyridine (453.2 mg, 2.4 mmol) in glacial acetic acid (4 mL) and stirred for 30 min. The ice bath was removed and the reaction stirred at room temperature for 30 min and then cooled to 0 °C. A cold solution of copper(I) chloride (2.09 g, 210 mmol) in concentrated hydrochloric acid (5 mL) was then added. The reaction was kept at low temperature to keep the evolution of gas at a slow rate. After 25 min the reaction was heated to 70 °C until the effervescence stoped, water was added (14 mL), and the reaction stirred overnight. The green-blue cloudy reaction mixture was filtered and the retrieved blue crystals dissolved in water (15 mL), made alkaline using saturated aqueous sodium hydroxide, and sodium cyanide was (0.5 g, 10 mmol) added. *CAUTION: solution must be alkaline before addition of sodium cyanide to prevent the formation of toxic hydrogen cyanide (HCN).* The aqueous mixture was extracted with dichloromethane (2 × 25 mL) that was washed once with water (50 mL), dried over magnesium sulfate, taken to near dryness on the rotary evaporator, and dried under high vacuum to give a shiny yellow solid (111.1 mg, 20% yield); mp = 125–128 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.36 (dd, $^3J_{HH}$ = 4.55, 8 Hz, 2H), 7.84 (dd, $^3J_{HH}$ = 1.41, 8 Hz, 2H), 8.64 (dd, $^3J_{HH}$ = 1.41, 4.55 Hz, 2H). ^{13}C NMR (300 MHz, $CDCl_3$) δ (ppm): 124.5, 131.0, 137.4, 147.5, 155.7. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z* experimental: 224.9848 $[C_{10}H_6Cl_2N_2 + H]^+$; calcd: 224.9986.

3,3′-Dibromo-2,2′-bipyridine[40,41]

The same as for 3,3′-dichloro-2,2′-bipyridine but with CuBr in place of CuCl. 3,3′-Diamino-2,2′-bipyridine (505.7 mg, 2.72 mmol). White solid retrieved (83.6 mg, 10% yield); mp = 148–150 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.28 (dd, $^3J_{HH}$ = 4.45, 8 Hz, 2H), 8.02 (dd, $^3J_{HH}$ = 1.4, 8 Hz, 2H), 7.1 (dd, $^3J_{HH}$ = 1.4, 4.45 Hz, 2H). ^{13}C NMR (300 MHz, $CDCl_3$) δ (ppm): 120.4, 124.9, 140.7, 148.1, 157.1. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z* experimental: 314.8899 $[C_{10}H_6Br_2N_2 + H]^+$; calcd: 314.8956.

3,3′-*N*,*N*′-Bis(dimethylamino)-2,2′-bipyridine (2), attempted syntheses

Route a — Methylation of 3,3′-diamino-2,2′-bipyridine with dimethyl sulfate[8]

Sodium hydride (320 mg, 13.33 mmol) was added to a solution of 3,3′-diamino-2,2′-bipyridine (0.392 g, 2.11 mmol) in tetrahydrofuran in four equal portions to give a cloudy yellow suspension. Dimethyl sulfate (2.4 mL, 1.80 g, 14.3 mmol) was slowly added and the mixture was refluxed for 3 h to give a brown slurry. Methanol (300 mL) was added to the room temperature reaction and the entire mixture poured over sodium hydroxide (saturated aq, 15 mL). The volume was reduced via rotary evaporator, water (200 mL) was added, and the mixture extracted with ether (200 mL, 4 × 100 mL). The volume of the bright orange organic solution was brought to ~50 mL on the rotary evaporator and then under high vacuum. The organic layer was then washed with dilute hydrochloric acid (3 × 30 mL), dried over magnesium sulfate and taken to dryness on the rotary evaporator to give an orange solid. ESI-MS analysis showed no starting material or any methylated products.

Route b — Methylation of 3,3′-diamino-2,2′-bipyridine with formaldehyde / formic acid[24]

3,3′-Diamino-2,2′-bipyridine (100 mg, 0.537 mmol) was refluxed in formic acid (8 mL) and formaldehyde (8 mL) for 8 h to give a bright yellow solution. Hydrochloric acid (4 mol/L, 20 mL) was added and the solution was taken to near dryness on high vacuum. The yellow-orange solid was taken up in distilled water (15 mL) and 18 mol/L sodium hydroxide (10 mL) was added to give a murky brown mixture. The slurry was extracted with benzene (5 × 15 mL) and the organic layer was dried with magnesium sulfate and then taken to near dryness. Starting material was recovered unchanged; no methylated products were identified.

Route c — Methylation of 3,3′-diamino-2,2′-bipyridine with trimethylphosphate[25]

3,3′-Diamino-2,2′-bipyridine (0.500 g, 2.69 mmol) was added to trimethylphosphate (0.785 g, 5.60 mmol), and the resulting yellow solution was heated at 200 °C for 2 h to give a black sticky substance. Sodium hydroxide (15% aq, 10 mL) and water (15 mL) were added and the mixture stirred for 2 h. The black mixture was extracted with diethyl ether (3 × 20 mL) and the organic layer was dried with magnesium sulfate and sodium hydroxide pellets and then dried under high vacuum. NMR of the resulting orange-brown oil showed an indistinguishable mixture of products.

Route d — Methylation of 3,3′-diamino-2,2′-bipyridine with methyl iodide[26]

Sodium hydride (0.633 g, 26.4 mmol) was added to a solution of 3,3′-diamino-2,2′-bipyridine (0.123 g, 0.659 mmol) in THF and stirred for 90 min. Methyl iodide (0.375 g, 0.16 mL, 2.64 mmol) was then added and the mixture refluxed for 1 h. After cooling to room temperature, the mixture was poured over sodium hydroxide (3 mol/L, 15 mL) and stirred for 30 min. The aqueous layer was extracted with diethyl ether (2 × 50 mL) and the organic layer was passed through an alumina plug to give a clear yellow solution. The ether was removed to give an orange-yellow oil, an inseparable mixture of the desired product and partially (and over-) methylated by-products. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z*: 201.15 $[C_{11}H_{12}N_4 + H]^+$, 215.17 $[C_{12}H_{14}N_4 + H]^+$, 229.19 $[C_{13}H_{16}N_4 + H]^+$, 243.21 $[C_{14}H_{18}N_4 + H]^+$, 257.23 $[C_{15}H_{21}N_4]^+$.

Route e — Methylation of 3,3′-diamino-2,2′-bipyridine with dimethyl sulfate[27]

Dimethyl sulfate (0.70 mL, 0.526 g, 4.17 mmol) was added to a suspension of 3,3′-diamino-2,2′-bipyridine (0.174 g, 0.935 mmol) in water (5 mL) in portions (0.21, 0.21, and 0.28 mL), and after each addition was shaken for 10 min and made alkaline with sodium hydroxide (10% aq). The yellow solution was heated at 100 °C for 15 min. The water was removed to give an orange-yellow oil, an inseparable mixture of the desired product, and partially (and over-) methylated by-products. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z*: 201.15 $[C_{11}H_{12}N_4 + H]^+$, 215.17 $[C_{12}H_{14}N_4 + H]^+$, 229.19 $[C_{13}H_{16}N_4 + H]^+$, 243.21 $[C_{14}H_{18}N_4 + H]^+$ 257.23 $[C_{15}H_{21}N_4]^+$.

Step f — Demethylation of 3,3′-N,N′-bis(dimethylamino)-2,2′-pyridine-pyridinium iodide

Pyridinium chloride (6.58 g, 56.9 mmol) was added to 3,3′-*N*,*N*′-bis(dimethylamino)-2,2′-pyridine-pyridinium iodide (0.170 g, 0.659 mmmol) and heated at 225 °C for 10 min. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z*: 201.15 $[C_{11}H_{12}N_4 + H]^+$, 215.17 $[C_{12}H_{14}N_4 + H]^+$.

Step g — Halogen substitution of 3,3′-bis(chloro)-2,2′-bipyridine

$LiH_3BN(Me)_2$ was made according to literature procedures.[43] LiH_3BNMe_2 (0.95 mol/L, 0.27 mL, 0.25×10^{-4} mol) was added to 3,3′-dichloro-2,2′-bipyridine (50.8 mg, 0.22 mmol) in THF (1 mL) at 0 °C to give a deep red solution. The reaction was stirred at 0 °C for 15 min and then at room temperature for 90 min. HCl (3 mol/L, 3.3 mL) and methanol (3.3 mL) were then added at 0 °C and and the mixture was stirred for 15 min. The reaction was refluxed overnight, the volume reduced to ~5 mL, made alkaline with saturated sodium hydroxide, and extracted with CH_2Cl_2 (3 × 10 mL). The peach-coloured organic layer was dried with $MgSO_4$ and reduced to a solid that proved to be unreacted starting material. ESI-MS (+ve, CH_2Cl_2) *m/z*: 230.31 $[C_{10}H_6Cl_2N_2 + Li]^+$.

Step h — Mo(CO)$_4$(3,3′-diamino-2,2′-bipyridine)

$Mo(CO)_4$(norbornadiene) was made according to the literature preparation. $Mo(CO)_4$(nbd) (164.1 mg, 0.548 mmol) was added to a solution of 3,3′-diamino-2,2′-bipyridine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

(100.1 mg, 0.538 mmol) in benzene (5 mL) and the reaction was refluxed for 3 h covered in aluminum foil. The benzene was removed under high vacuum and the brown solid taken up in dichloromethane to give a red solution. Layering of hexanes over the red dichloromethane solution produced a yellow precipitate. IR (CH_2Cl_2) νCO (cm^{-1}): 2013, 1901, 1871, 1824.

Step i — Methylation of $Mo(CO)_4$(3,3′-diamino-2,2′-bipyridine) with dimethyl sulfate and methyl iodide

Reduction procedures were followed as above for sodium hydride / dimethyl sulfate[8,26] and sodium hydride / methyl iodide[26] using the metal complex in place of free 3,3′-diamino-2,2′-bipyridine. For NaH/Me_2SO_4: ESI-MS (+ve, CH_2Cl_2) *m/z*: 201.15 $[C_{11}H_{12}N_4 + H]^+$, 215.17 $[C_{12}H_{14}N_4 + H]^+$, 229.19 $[C_{13}H_{16}N_4 + H]^+$, 243.21 $[C_{14}H_{18}N_4 + H]^+$). For NaH/MeI: ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z*: 201.15 $[C_{11}H_{12}N_4 + H]^+$, 215.17 $[C_{12}N_4H_{14} + H]^+$, 229.19 $[C_{13}N_4H_{16} + H]^+$, 243.21 $[C_{14}N_4H_{18} + H]^+$, 257.23 $[C_{14}N_4H_{21}]^+$.

Route j — Homo-coupling of 2-chloro-3-dimethylaminopyridine

2-Chloro-3-dimethylaminopyridine (1.42 g, 9.14 mmol) was added to a slurry of activated copper (1.45 g, 22.79 mmol) in dry DMF (35 mL) and refluxed overnight. The hot reaction mixture was poured over H_2O (400 mL) and isolated via suction filtration and extracted with dioxane via a Soxhlet apparatus. The dioxane was removed on a rotary evaporator, the solid taken up in CH_2Cl_2, washed with aqueous ammonia followed by H_2O, and dried over $MgSO_4$. NMR (300 MHz, $CDCl_3$) showed no coupled product.

Route k — Coupling of 2-chloro-3-dimethylaminopyridine and 3-dimethylaminopyridine[33]

A 1:1 solution of *n*-BuLi/TMEDA (*n*-BuLi, 1.6 mol/L in hexanes, 4.09 mL, 6.54 mmol) was added via cannula to a solution of 3-dimethylaminopyridine (0.799 g, 6.54 mmol) in THF at –78 °C and stirred for 3 h to give a bright orange solution. In a separate Schlenk flask, 2-chloro-3-dimethylaminopyridine (0.872 g, 5.56 mmol) was added to a solution of $Fe(acac)_3$ (96.9 mg, 2.74×10^{-4} mol) and *N*-methyl-2-pyrrolidone (3.19 g, 3.1 mL, 32.15 mmol) in dry THF (30 mL) to give a deep red-orange solution that was cooled to –78 °C. The 3-dimethylaminopyridine solution was then transferred via cannula to the 2-chloro-3-dimethlyaminopyridine solution to give a deep red-purple colour and the stirred at –78 °C for 1 h before being allowed to warm to room temperature. Concentrated HCl (10 mL) was then added and the mixture stirred for 1 h. The solution was made alkaline with sodium hydroxide (1 mol/L, 10 mL), extracted with diethyl ether (4 × 50 mL), dried with $MgSO_4$, and then taken to dryness on a rotary evaporator to give a yellow-orange solid, a mixture of starting materials. ESI-MS (+ve, CH_2Cl_2 + formic acid) *m/z*: 157.05 $[C_6H_9ClN_2 + H]^+$, 123.09 $[C_6H_{10}N_2 + H]^+$.

Supplementary data

Supplementary data (full X-ray diffraction data and the ^1H NMR spectrum of the mixture of products from methylation) are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: The molecular structures and absorption spectra of three tetrahydroquinoline dyes (C2–1, C1–1, and C1–5) with a tetrahydroquinoline moiety as the electron donor, a cyanoacrylic acid moiety as the electron acceptor, and different thiophene-containing electron spacers were investigated by density functional theory (DFT) and time-dependent DFT (TD-DFT). The calculated geometries indicate that a strong conjugation is formed in the dyes and the conjugate length increases with the increase of spacer length. The interfacial charge transfer between the semiconductor electrode and the tetrahydroquinoline dyes are electron-injection processes from the excited dyes to the semiconductor conduction band. The simulated absorption bands are assigned to $\pi-\pi^*$ transitions, which exhibit appreciable red-shift with respect to the experimental bands owing to the lack of direct solute–solvent interaction and the inherent approximations in TD-DFT. Moreover, the effect of different spacers on the molecular structures, absorption spectra, and photovoltaic performance were comparatively discussed.

Key words: tetrahydroquinoline dyes, dye-sensitized solar cells, density functional theory (DFT), molecular structures, absorption spectra.

Résumé : Faisant appel à la théorie de la fonctionnelle de la densité (TFD) et à la TFD avec dépendance sur le temps (TFD-DT), on a calculé les structures moléculaires et les spectres d'absorption de trois colorants à base de la tétrahydroquinoléine (C2–1, C1–1 et C1–5) comportant une portion tétrahydroquinoléine comme donneur d'électron, une chaîne d'acide cyanoacrylique comme accepteur d'électron et divers groupes d'espacement d'électrons contenant du thiophène. Les géométries calculées indiquent qu'il se forme une forte conjugaison dans les colorants et que la longueur conjuguée augmente avec une augmentation de la longueur de l'espaceur. Le transfert de charge interfacial entre l'électrode du semiconducteur et les colorants à base de tétrahydroquinoléine sont des processus d'injection d'électron des colorants excités vers la bande de conduction du semiconducteur. Les bandes d'absorption simulées sont attribuées aux transitions $\pi-\pi^*$ qui présentent un déplacement appréciable vers le rouge par rapport aux bandes expérimentales en raison du manque d'interaction directe soluté solvant et des approximations inhérentes à la méthode (TFD-DT). On discute de plus de l'effet des divers groupes d'espacement sur les structures moléculaires, sur les spectres d'absorption et sur la performance photovoltaïque.

Mots-clés : colorants de la tétrahydroquinoléine, cellules solaires sensibilisées par des colorants, théorie de la fonctionnelle de la densité, structures moléculaires, spectres d'absorption.

Introduction

Nanocrystalline dye-sensitized solar cells (DSSCs) have attracted much attention as promising alternatives for the photovoltaic conversion of solar energy owing to their potentially low fabrication costs, environmentally friendly components, and relatively high conversion efficiencies.[1–6] The most successful charge-transfer sensitizers used in DSSCs are ruthenium (Ru) polypyridyl complexes, yielding solar-to-electric power conversion efficiencies up to 11%–12% under air mass (AM) 1.5 irradiation.[6] However, the Ru complexes are facing the problems of cost and environmental issues, which will limit the large-scale application of DSSCs.[7] In addition to the Ru complexes, metal-free organic dyes as sensitizers are also under intensive investigation because of their high molar extinction coefficients, flexible structural modifications, and low costs; and so far some of them have reached good efficiencies.[8–15]

In DSSCs, the dye molecules first absorb visible or near-IR light, accompanied by the excitation of electrons to the excited states. Subsequently, the excited electrons are injected into the conduction band (CB) of the semiconductor (typically TiO_2 nanoparticles), and then transfer to the anode by

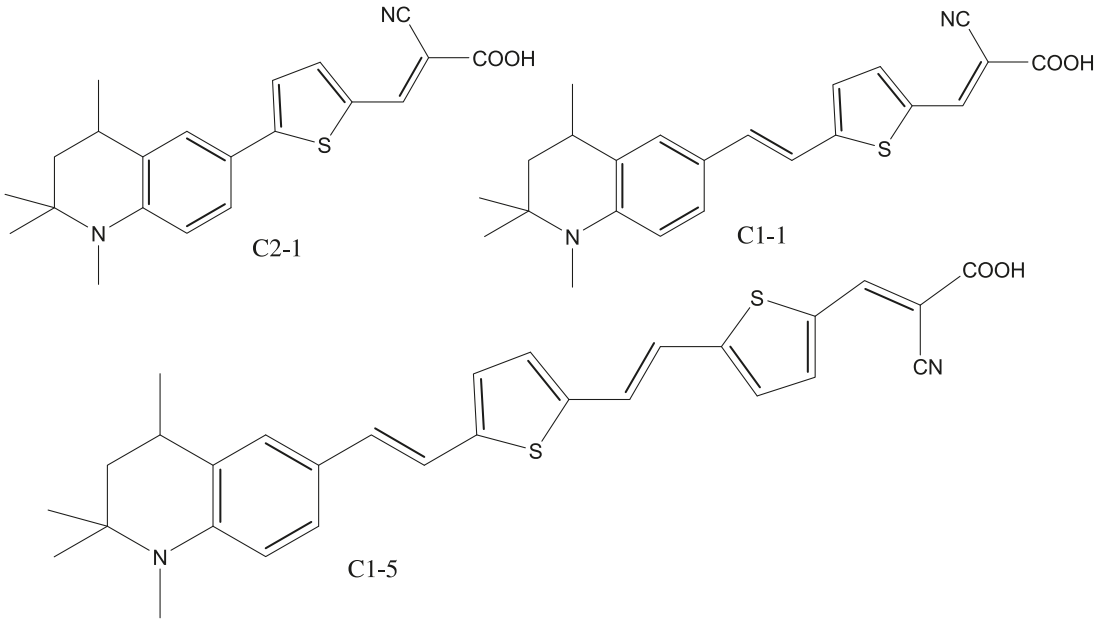
Fig. 1. Chemical structures of the tetrahydroquinoline dyes.



electron diffusion through the disordered network of TiO_2. The oxidized dye molecules are regenerated by the iodide redox couple or hole-transporter with the positive charge being transported from the electrolyte to the platinum counter electrode. Therefore, the performance of DSSCs strongly depends upon the following factors: (*i*) absorption efficiency of the dye sensitizer for solar light spectrum; (*ii*) electron injection probability from the excited state of the dye sensitizer to TiO_2 (efficiency of the charge separation); and (*iii*) electron transfer probability from the electrolyte to the oxidized dye.[3] All these factors are closely associated with the ground and excited electronic states of the dye sensitizer. From this point of view, the theoretical investigation of the molecular and electronic structures of the dyes is very important for better understanding the mechanism of the charge separation and transfer, which are the key working processes in this type of solar cells, as well as for the design of new dyes with improved performance.

Density functional theory (DFT) has emerged as a reliable standard tool for the theoretical treatment of the molecular and electronic structures. Its time-dependent extension, called time-dependent DFT (TD-DFT), can give reliable values for valence excitation energies with the standard exchange-correlation functionals. The computational cost of TD-DFT calculation is comparative to that of a Hartree–Fock-based single-excitation theory, such as, configuration interaction singles (CIS) or the time-dependent Hartree–Fock (TD-HF) method and maintains a uniform accuracy for open- and closed-shell systems. In recent years, DFT has been successfully used to study the structures and absorption spectra of both Ru complexes[4,16–23] and organic dye sensitizers.[24–32]

Recently, three novel organic dyes (C2–1, C1–1, and C1–5, as shown in Fig. 1), which consist of a tetrahydroquinoline moiety as the electron donor, different thiophene-containing electron spacers, and a cyanoacrylic acid moiety as the electron acceptor were designed and synthesized, yielding overall conversion efficiencies of 4.49%, 3.17%, and 2.32%, respectively.[33] Why does the C2–1 dye with a rigid and shortest π-spacer have the lowest light-absorption capability, but give the highest efficiency? To theoretically understand the spacer effect and sensitized mechanism at a molecular level in these tetrahydroquinoline dyes, the geometrical and electronic structures of them were studied in detail using DFT, and the electronic absorption spectra were investigated based on the TD-DFT calculations.

Computational method

All the calculations were performed with the Gaussian 03 program package.[34] The ground-state geometries were fully optimized without any symmetry constrains at the DFT level of theory with Becke's[35] three parameters hybrid functional and Lee, Yang, and Parr's correlational functional B3LYP[36] using a standard 6–31g(d) basis set on all atoms. A full natural bond orbital (NBO) analysis was obtained using the POP=NBO keyword. The excitation energies and oscillator strengths for the lowest 30 singlet–singlet transitions at the optimized ground-state geometry were obtained by TD-DFT using the same basis set as for the ground state and three kinds of hybrid functional PBE1PBE, MPW1B95, and BHandHLYP, respectively. From the calculated results, the UV–vis absorption spectra were simulated by means of the SWizard program (version 4.6)[37] using a Gaussian convolution with the full width at half-maximum of 3000 cm^{-1}. Solvation effects were introduced by the SCRF method via the conductor polarizable continuum model (CPCM)[38,39] implemented in the Gaussian program for both DFT and TD-DFT calculations.

Results and discussion

Geometrical structures

One of the major goals in the design of new sensitizers is to create molecular structures favouring the absorption in the visible–near-IR region and possessing an appropriate excited state able to directly inject into the CB of the semiconductor

electrode (typically TiO_2). Donor–acceptor π-conjugated (D–π–A) dyes, which contain both electron-donating (D) and electron-accepting (A) groups connected by covalent links (usually π-conjugated) have been developed to enhance both the extinction coefficients and the absorption at long wavelengths (low energies). The photoabsorption properties of a D–π–A dye are associated with intramolecular charge transfer (ICT) excitation from the donor to the acceptor moiety of the dye, resulting in efficient electron transfer through the acceptor moiety (such as carboxyl or hydroxyl) from the excited dye into the semiconductor CB. The charge transfer or separation between the electron donor and acceptor moieties in the excited dye may facilitate rapid electron injection from the dye molecule into the semiconductor CB, so that it would be expected to separate the cationic charge effectively from the semiconductor surface and to restrict recombination between the photoelectron (the injected electron) and the oxidized dye sensitizer efficiently.The tetrahydroquinoline dyes C2–1, C1–1, and C1–5 in this study share the same electron donor of 1,2,2,4-tetramethyl-1,2,3,4-tetrahydroquinoline group and the same electron acceptor of cyanoacrylic acid while different types of electron spacers containing thiophene moiety are used (as illustrated in Fig. 1). The optimized ground-state geometries of the tetrahydroquinoline dyes are shown in Fig. 2, and the selected bond lengths, bond angles, and dihedral angles are listed in Table 1. From a structural point of view, at the ground state, the donor and acceptor moieties are practically identical in the three dyes, as demonstrated by the very similar calculated internal structural parameters. All the C–C lengths in the vinylene, thiophene, and phenyl groups are found to be between the distance of a single bonded C–C and a double bonded C=C, implying that

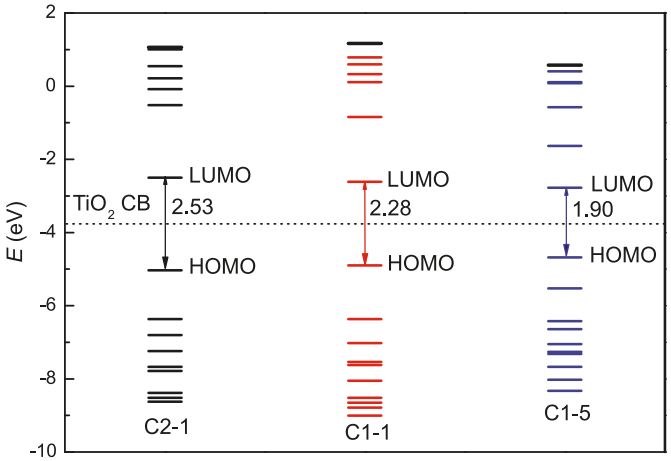
Dyes	Cyanoacrylic acid	Bridge	Tetrahydroquinoline
C2–1	–0.189	0.071	0.118
C1–1	–0.191	0.085	0.106
C1–5	–0.185	0.105	0.080

there exists extensive electron delocalization throughout the molecule. The calculated distances between the C atom in carboxyl and the vinyl C atom next to the thiophene group in tetrahydroquinoline are 7.6178, 9.5281, and 14.6784 Å for C2–1, C1–1, and C1–5, respectively. Thus, the distance between the electron donor and semiconductor surface is increased with the increase of spacer length, since the thiophene and vinylene groups extend the conjugate bridge length.

The cyanoacrylic acid group (acceptor) is found to be fully coplanar with the thiophene-containing π bridge, as represented by the C13–C15–C17–C19 (Fig. 2, C2–1), C49–C51–C9–C11 (Fig. 2, C1–1), and C12–C14–C16–C18 (Fig. 2, C1–5) dihedral angles, while the coplanarity between the tetrahydroquinoline group (donor) and π bridge is also apparent, although there is a distortion of ~10° in the case of C2–1 mainly owing to steric repulsion between the tetrahydroquinoline and thiophene rings. Thus, it can be concluded

Fig. 3. Frontier molecular orbital energies of the tetrahydroquinoline dyes together with the TiO_2 anatase (101) conduction band.



that the donor and acceptor moieties are fully conjugated through the π bridge. The delocalization in the conjugate bridge is beneficial to the ICT and to the stability of the molecule. The anchoring carboxyl group (–COOH) is coplanar with the π-extended system of the molecule, as demonstrated by the negligible C13–C15–C21–O23 (Fig. 2, C2–1), C49–C51–C13–O15 (Fig. 2, C1–1), and C12–C14–C20–O22 (Fig. 2, C1–5) values. Therefore, assuming a bidentate bind

Fig. 4. Isodensity plots (isodensity contour = 0.02 au) of the frontier orbitals of the tetrahydroquinoline dyes.

of the carboxyl group to the supporting semiconductor's surface, it has been inferred that the π system of these dyes most probably lay perpendicular to the surface, thus resulting in a dense package and coverage.[40]

Electronic structures

The dipole moments for C2–1, C1–1, and C1–5 are 14.84, 15.35, and 16.03 D, respectively, indicating that these tetrahydroquinoline dyes are highly polar molecules and their polarities increase with the increase of spacer length. The values of quadrupole moments for C2–1, C1–1, and C1–5 are listed in Table 2, where the average of the diagonal quadrupole moment tensor elements Q_{ii} and unique quadrupole moment Q are defined as follows:

$$[1] \qquad Q_{ii} = (Q_{XX} + Q_{YY} + Q_{ZZ})/3$$

$$[2] \qquad Q = Q_{XX} - Q_{YY}$$

All the diagonal elements of the quadrupole moment tensors for C2–1, C1–1, and C1–5 are negative, indicating that the negative charge distribution is farther removed from the molecular centre of the nuclear charges. The off-diagonal tensor elements Q_{ij} vanish whenever the molecule has a plane of symmetry perpendicular to either one of the coordinates i or j.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

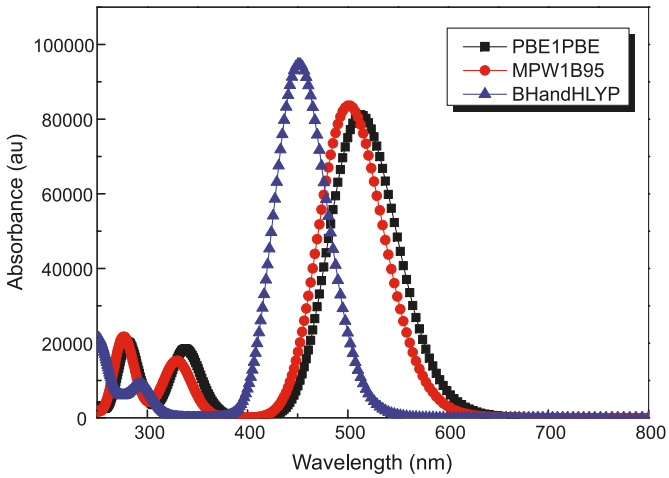
The values of the off-diagonal elements Q_{XY} and Q_{YZ} of C2–1, C1–1, and C1–5 are relatively lower, which can be attributed to their symmetric plane nearly perpendicular to the *y* axis, as shown in Fig. 1.

NBO analysis was employed to characterize the ICT in the tetrahydroquinoline dyes. Table 3 shows the natural charges of cyanoacrylic acid, thiophene-containing π bridge, and tetrahydroquinoline groups in the tetrahydroquinoline dyes. There are some charges transferred from the electron donor (tetrahydroquinoline) to the electron acceptor (cyanoacrylic acid) through the chemical bonds of the π bridge for the tetrahydroquinoline dyes. It was also found that the natural charges of the donor show a remarkable decrease with the increase of spacer length while the natural charges of the conjugate bridge are increased. However, the natural charges of the acceptor for the tetrahydroquinoline dyes are practically identical. These indicate that the increase of spacer length has a significant effect on the electron-donating capability of the donor, but do not significantly alter the electron-drawing capability of the acceptor.

The frontier molecular orbital (MO) contribution is very important in determining the charge-separated states of dye sensitizers. To create an efficient charge-separated state, the highest occupied MO (HOMO) must be localized on the extended donor moiety and the lowest unoccupied MO (LUMO) on the acceptor moiety. The MO energies and isodensity plots of C2–1, C1–1, and C1–5 are shown in Figs. 3 and 4, respectively. For C2–1, the HOMO, lying at –5.03 eV, is a delocalized π orbital distributed over the cyano group through the tetrahydroquinoline group, whereas the HOMO–1, lying 1.33 eV below the HOMO, is also delocalized over the entire molecule. The HOMO–2, lying 1.77 eV below the HOMO, is a π orbital mainly localized in the phenyl and thiophene groups, whereas the HOMO–3, lying 2.20 eV below the HOMO, is localized in the thiophene group with less contributions in the phenyl group. The LUMO, lying at –2.50 eV, is a π* orbital localized in the cyanoacrylic acid, thiophene, and phenyl groups. The LUMO+1, lying 1.98 eV above the LUMO, is also a π* orbital, which is similar to the LUMO. For C1–1, the HOMO and HOMO–1, lying at –4.90 and –6.37 eV, respectively, are π orbitals delocalized over the entire molecule. The HOMO–2, lying 2.12 eV below the HOMO, is localized in the phenyl group, whereas the HOMO–3, lying 2.54 eV below the HOMO, is localized in the vinylenethiophene group with sizable contributions arising from the cyanoacrylic acid group. The LUMO and LUMO+1, lying at –2.61 and –0.84 eV, respectively, are π* orbitals localized in the cyanoacrylic acid, vinylenethiophene, and phenyl groups. As to C1–5, the HOMO, lying at –4.68 eV, is delocalized over the entire molecule, and the HOMO–1 and HOMO–2 are similar to the HOMO. The LUMO, lying at –2.78 eV, is a π* orbital localized in the cyanoacrylic acid and vinylenethiophene groups, whereas the LUMO+1, lying 1.14 eV above the LUMO, is localized in the cyanoacrylic acid and vinylenethiophene groups with sizable contributions in the phenyl group.

Apparently, in these tetrahydroquinoline dyes, the HOMO is quite delocalized on the extended donor moiety, whereas the LUMO is essentially centred on the respective acceptor group. Thus, the HOMO–LUMO excitation on these dyes induced by light irradiation could move the electron distribution from the donor moiety to the anchoring–acceptor moiety, consequently favoring electron injection from the dye to the semiconductor. The computed HOMO energy increases when going from C2–1 to C1–1 (0.13 eV) and from C1–1 to C1–5 (0.22 eV), whereas the LUMO energy is computed to decrease with the increase of spacer length. The isodensity plots of LUMO exhibit a charge transfer to the anchoring acid group with the increase of spacer length, indicating that the vinylene and thiophene groups are indeed electron donors with respect to the cyanoacrylic acid group, and the insertion of more spacers results in a decreased contribution of the tetrahydroquinoline to the LUMO (in agreement with the previously discussed natural charge results). As a consequence of the variation of MOs energies, the HOMO–LUMO gap also decreases when going from C2–1 (2.53 eV) to C1–1 (2.28 eV) and C1–5 (1.90 eV), the latter molecules being expected to absorb at lower energies.

Fig. 5. Simulated absorption spectra of C2–1 using the hybrid functionals PBE1PBE, MPW1B95, and BHandHLYP.



The calculated HOMO and LUMO energies of the bare $Ti_{38}O_{76}$ cluster as a model for nanocrystalline are –6.55 and –2.77 eV, respectively, resulting in a HOMO–LUMO gap of 3.78 eV; whereas the lowest transition is reduced to 3.20 eV according to TD-DFT, which is slightly smaller than the typical band gap of TiO_2 nanoparticles.[4] Furthermore, the HOMO, LUMO, and HOMO–LUMO gap values of $(TiO_2)_{60}$ cluster are –7.52, –2.97, and 4.55 eV (B3LYP/VDZ), respectively.[41] In addition, the edges of the valence band (VB) and CB of a TiO_2 anatase (101) surface are computed at –8.70 and –3.74 eV.[42] Usually, an energy gap of more than 0.2 eV between the LUMO of the dye and the CB of the TiO_2 is necessary for effective electron injection.[25] Taking the above data into account, it can be found that the HOMO energies of these tetrahydroquinoline dyes lie above the VB of TiO_2 and the LUMO energies lie above the CB of TiO_2. The above data also reveal the sensitized mechanism: the interfacial electron transfer between the TiO_2 electrode and the dye sensitizers are electron injection processes from the excited dyes to the semiconductor CB. This is a kind of typical interfacial electron-transfer reaction.[43] Relatively large energy gaps between the LUMO energies of these dyes and the semiconductor CB would be beneficial to the photovoltaic conversion efficiencies.

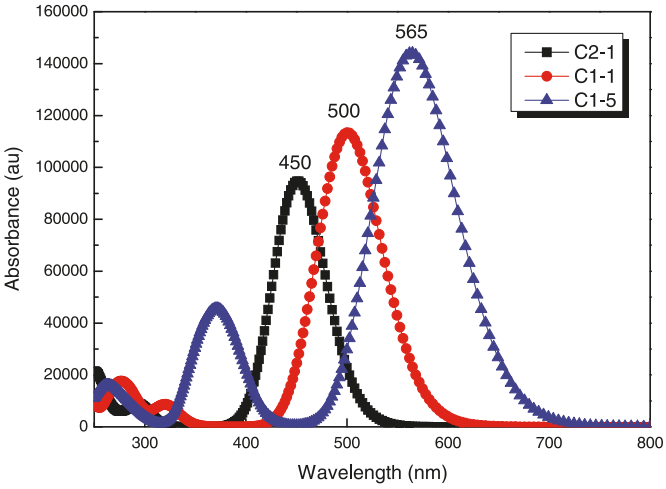
Absorption spectra

The UV–vis absorption spectra of C2–1, C1–1, and C1–5 were measured in ethanol solution and consist of a very intense and well-isolated absorption band at 441 nm (23 000 mol/L^{-1} cm^{-1}), 468 nm (27 500 mol/L^{-1} cm^{-1}), and 492 nm (38 700 mol/L^{-1} cm^{-1}) and of less intense bands in the UV region, repectively.[33] The absorption bands are red-shifted, enhanced, and broadened when going from C2–1 to C1–1 and C1–5, which is attributed to the expansion of π-conjugation systems with the increase of spacer length.

TD-DFT calculations in ethanol solution were performed with three kinds of hybrid functional PEB1PBE, MPW1B95, and BHandHLYP based on the optimized ground-state geometries, taking the 30 lowest spin-allowed singlet–singlet transitions into account. The simulated UV–vis absorption spectra of C2–1 using the hybrid functionals PEB1PBE, MPW1B95, and BHandHLYP are shown in Fig. 5 as representative. It is found that the calculated line shapes and relative strengths are in good agreement with those of the experiment, and the overall spectral red-shift when going from C2–1 to C1–1, and C1–5 is also correctly reproduced. However, the hybrid functional BHandHLYP is more suitable than PBE1PBE and MPW1B95 for calculating absorption spectra of the tetrahydroquinoline dyes. The calculated vertical excitation energies and oscillator strengths along with the main excitation configurations of these dyes calculated by BHandHLYP are listed in Table 4. The simulated absorption spectra by BHandHLYP are shown in Fig. 6. The first band clearly corresponds to the previously described HOMO–LUMO transition, and is of charge-transfer character, thus possessing high transition intensity. As the HOMO and the LUMO are of the π and π* type, the HOMO–LUMO transition can be classified as a π–π* intramolecular charge transfer. The second and less intense band also corresponds to a π–π* transition with a strong HOMO–1 to LUMO character. Since the HOMO–1 is delocalized on the entire molecule but with a larger contribution from atomic orbitals of cyanoacrylic acid group, this band also has a charge-transfer character and consequently is computed to be red-shifted going from C2–1 to C1–1 (of 0.34 eV) and from C1–1 to C1–5 (of 0.62 eV).

Fig. 6. Simulated absorption spectra of the tetrahydroquinoline dyes at the BHandHLYP/6–31g(d) level.



The results of the TD-DFT calculations exhibit some red-shifts with respect to the experimental spectra, which are also found for several dye sensitizers.[16,17,31,44] This discrepancy

can be ascribed to the absence of explicit solvent molecules around the cyanoacrylic function in the solvation model and the inherent approximations in the TD-DFT. The LUMOs of the tetrahydroquinoline dyes significantly extend over the cyanoacrylic groups and are expected to result in direct solute–solvent interaction with the ethanol molecules through hydrogen bonding. Thus, since in the implicit solvent model used direct solute–solvent interactions are fully neglected, the large red-shift in the simulated absorption spectra for the tetrahydroquinoline dyes can be fully justified. In addition, the TD-DFT always gives a smaller energy gap,[45] and thus gives rise to smaller excitation, especially for large conjugated systems and charge-transfer complexes in excited states.[46] Therefore, it can be concluded that the TD-DFT calculations are capable of describing the spectral features because of the qualitative agreement of line shape, relative strength, and overall spectral red-shift evolution from C2–1 to C1–1 and C1–5 with respect to the experiment, although the discrepancy in absorption wavelengths exists.

Generally, the dyes with stronger and broader absorption bands are expected to give higher photo-to-current efficiency. But the experiment reported that the conversion efficiency of the tetrahydroquinoline dyes is in the following order: C2–1 > C1–1 > C1–5. The increase of spacer length in the conjugate bridge alters the absorption properties of the tetrahydroquinoline dyes more suitable for solar spectrum, but it also enlarges the distance between the electron-donor group and the semiconductor surface, and therefore reduces the probability of a dye π orbital delocalized onto the nanocrystalline surface, and decreases the electronic coupling between the chromophore and TiO_2 substrates.[47] The weak electronic coupling may slow down the electron-injection rate from the excited dyes to the semiconductor CB. On the other hand, the LUMO levels of the dyes decrease with the increase of spacer length, which would give rise to a decreased open-circuit photovoltage, according to the literature.[31] Thus, the higher efficiency of C2–1 can be mainly attributed to the shorter distance between the electron-donor group and the semiconductor surface and the higher LUMO level, despite its poorer absorption properties.

Conclusions

A quantum-chemical investigation of the geometrical and electric structures of three tetrahydroquinoline dyes with different thiophene-containing electron spacers (C2–1, C1–1, and C1–5) used for DSSC was performed. The calculated geometries indicate that strong conjugation is formed in the dyes, which is of benefit to the intramolecular charge transfer. The NBO results suggest that there are some charges transferred from the electron donor (tetrahydroquinoline group) to the electron acceptor (cyanoacrylic acid) through the chemical bonds of the conjugate thiophene-containing bridge in the dyes. The increase of spacer length gives rise to a decrease in the electron-donating strength of the donor, but has no significant effect on the electron-withdrawing ability of the acceptor. The HOMO energy levels are computed to be –5.03, –4.90, and –4.68 eV, whereas the LUMOs are –2.50, –2.61, and –2.78 eV for C2–1, C1–1, and C1–5, respectively, pointing out that the electron transfer from the excited dyes to the TiO_2 conduction band is possible. The UV–vis absorption spectra of the dyes were simulated by TD-DFT calculations. The absorption bands of the dyes are assigned to π–π^* transitions according to the qualitative agreement between the experimental and calculated results. The red-shift in the simulated absorption spectra relative to the experiment is attributed to the lack of direct solute–solvent interaction and the inherent approximations in the TD-DFT.

The comparative analysis of the geometries, electronic structures, and absorption spectra between the tetrahydroquinoline dyes reveals that the increase of spacer length in the dyes led to a better match between the absorption properties of the dyes and solar spectrum, but also enlarged the distance between the electron donor and semiconductor surface, reduced the electron injection rate, decreased the open-circuit photovoltage, and thus resulted in lower overall conversion efficiency. Therefore, the choice of the appropriate conjugate bridge is very important for the molecular design of new tetrahydroquinoline dyes with high efficiency.

Abstract: The products of the reaction of D-glucuronic acid with various combinations of ammonia and volatile ammonium salts in water were studied by NMR and MS spectroscopy. For long reaction times (~24 h), the expected products β-D-glucopyranosylamine uronic acid and ammonium *N*-(β-D-glucopyranosyluronic acid)carbamate were obtained in good-to-high yield, whereas seven intermediate species were identified in samples taken at earlier reaction times. ^{1}H–^{1}H homonuclear and ^{1}H–^{13}C heteronuclear correlation experiments enabled a complete assignment of the ^{1}H and ^{13}C NMR spectra of the starting and final compounds, and a partial assignment of the peaks of intermediate species. Based on these results, a ^{1}H NMR protocol for the quantification of the different compounds taking part in the reaction was developed, which was used to monitor the evolution of the composition of an early reaction sample redissolved in D_2O. It was thus established that two of the observed intermediate species are actually the α anomer of the main products, whereas the others are precursors to the formation of α/β-D-glucopyranosylamine uronic acid and ammonium *N*-(α/β-D-glucopyranosyluronic acid)carbamate. The correct assignments for the ^{1}H and ^{13}C spectra of D-glucuronic acid in D_2O are also reported.

Key words: uronic acids, glycosylamines, amination, α anomer, precursor.

Résumé : La spectroscopie de résonance magnétique nucléaires (RMN) et la spectroscopie de masse (SM) ont permis d'étudier les produits de la réaction de l'acide D-glucuronique avec différentes combinaisons entre l'ammoniaque et des sels d'ammonium volatiles dans l'eau. Pour des temps de réaction longs (~24 h), les produits attendus comme l'acide β-D-glucopyranosylamine uronique et le *N*-(β-D-glucopyranosyl)carbamate d'ammonium ont été obtenus avec des rendements allant de bons à excellents. Cependant, sept espèces intermédiaires ont pu être identifiées comme étant majoritaires dans des échantillons prélevés en debut de réaction. Des expériences de corrélations ^{1}H–^{1}H homonucléaires et ^{1}H–^{13}C hétéronucléaires ont permis de faire une attribution complète des spectres RMN du ^{1}H et du ^{13}C des composés de départ et des produits finaux ainsi qu'une attribution partielle des pics des espèces intermédiaires. Sur la base de ces résultats, on a développé un protocole de RMN du ^{1}H qui permet de faire une quantification des divers composés impliqués dans la réaction et qui a été utilisé pour suivre l'évolution de la composition d'échantillons prélevés en début de réaction et redissous dans du D_2O. Il a ainsi été possible d'établir que deux des espèces observées comme intermédiaires sont en fait les anomères α des produits principaux alors que les autres sont des précurseurs dans la formation de l'acide α/β-D-glucopyranosylamine uronique et du *N*-(acide α/β-D-glucopyranosyluronique)carbamate d'ammonium. Les attributions correctes pour les spectres du ^{1}H et du ^{13}C de l'acide D-glucuronique dans le D_2O sont également reportées.

Mots-clés : acides uroniques, glycosylamines, amination, anomère α, précurseur.

[Traduit par la Rédaction]

Introduction

Glycosylamines are monosaccharides in which the hemiacetal hydroxy group has been replaced by an amino group.[1] By extension, the name is also used for oligosaccharides whose reducing end has been transformed in the same way. Glycosylamines are valuable intermediates in the synthesis of a number of glycoconjugates[2–4] such as glycopeptides,[5–11] surfactants,[8,12–14] glycopolymers,[12,15,16] and *N*-glycan probes.[17,18] Classical methods for the synthesis of glycosylamines are based on the reaction of unprotected reducing monosaccharides with ammonia in dry methanol.[19–21] These methods suffer

from very long reaction times (from several days to several weeks), low yields, and the concomitant formation of diglycosylamine.[22,23] Additionally, their scope is severely limited by the poor solubility of oligosaccharides and charged mono- and oligo-saccharides in alcohol, which makes them unsuitable for uronic acids.

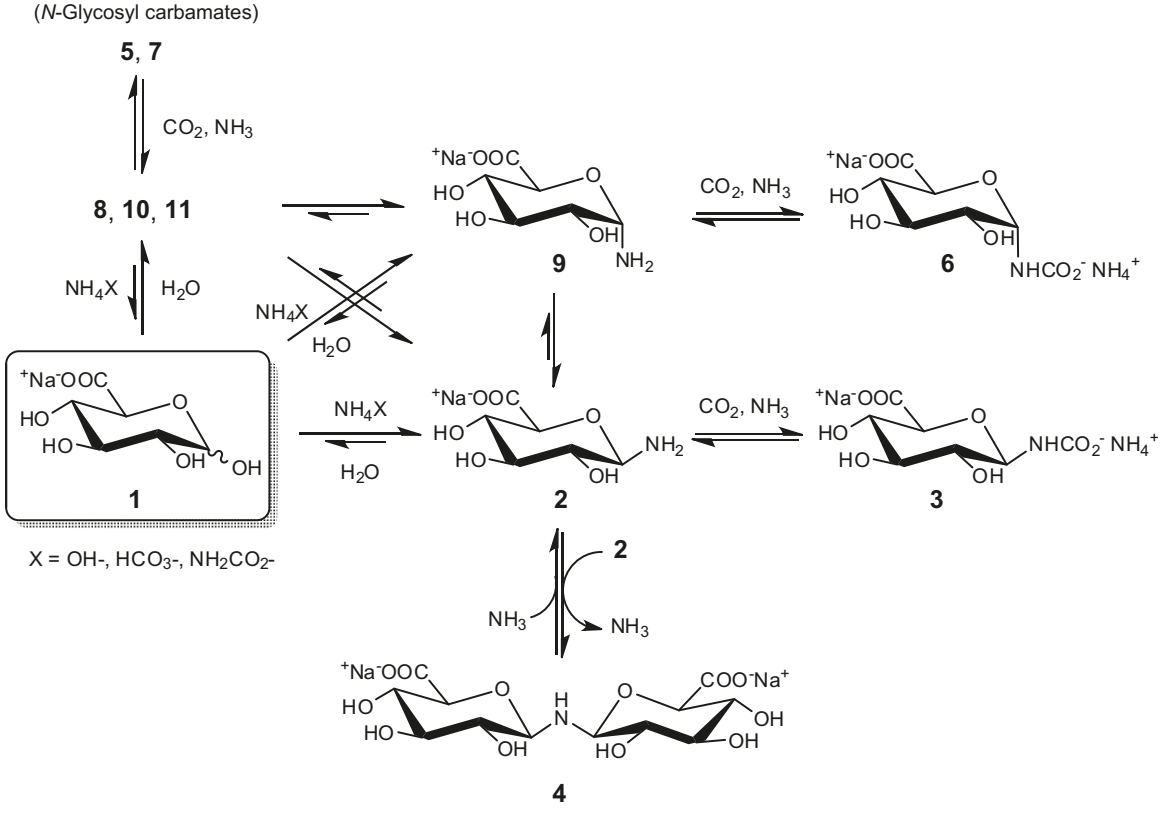
In 1986, Kochetkov and co-workers[11] put forward an efficient method for the synthesis of β-glycopyranosylamines from 2-acetamido-2-deoxyhexoses, which is based on the use of a saturated aqueous solution of NH_4HCO_3 (Table 1). In the following years, the method was widely applied to the preparation of derivatives of hexoses, 6-deoxyhexoses, and oligosaccharides of different chain lengths.[10,16,18] Nevertheless, the considerable amount of salt used and the labour-consuming procedures needed to remove it restrict the scope of this approach in preparative synthesis. Hence, several modifications were devised in which either a lesser amount of NH_4HCO_3 was used in combination with concentrated ammonia,[14] or a saturated solution of the more volatile $(NH_4)_2CO_3$ was used instead (Table 1).[24,25] A third original variation was developed by Likhosherstov et al.,[26,27] who employed ammonium carbamate and NH_4OH in aqueous methanol solutions to prepare the relatively stable carbamic acid salt of glycosylamines. The free amine was then obtained in a second step by treatment with alcohol (e.g., CH_3OH, ethanol, or 2-propanol) containing a tertiary amine (e.g., TEA and DIPEA) followed by evaporation and (or) crystallization.[28]

The main advantage of these aqueous-based methods resides in their applicability to unprotected charged carbohydrates. Nonetheless, a detailed investigation on the formation of glycosylamines in aqueous solution is lacking. In the 1950s, Isbell and Frush[30,31] investigated the formation of glycosylamines in methanol solution and their hydrolysis, but their studies were solely based on changes in optical rotation, they assumed that the final glycosylamine was the only product of the reaction, and they did not provide any structural characterization. More recently, Campa et al.[29] applied capillary electrophoresis with indirect absorbance detection (CE–indirect UV) and high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC–PAD) to the crude reaction mixture obtained in the synthesis of D-glucosylamine, D-galactosylamine, and lactosylamine according to Lubineau et al.'s protocol.[14] Fructose (5.4 mol%) and lactulose (7.0 mol%) were identified as the only by-products in the first and last case, respectively, whereas no by-product was observed with D-galactose. Following derivatization with 9-fluorenylmethyloxycarbonyl (FMOC) chloride, the glycosylamines were quantified by micellar electrokinetic capillary chromatography (MEKC–UV), and a yield of 75% was found in the three cases. In general, the study of glycosylamines in aqueous solution is complicated by their rapid hydrolysis[30,32] in the pH range 2–8, and by the concomitant formation of diglycosylamines. At higher pH values and lower temperatures, they are rather stable and NMR spectroscopy could be used as a powerful analytical tool to study this type of compounds.

Uronic acids are monocarboxylic acids formally derived from aldoses by replacement of the hydroxymethyl group CH_2OH with a carboxy group.[1] In nature, they are found in polysaccharides fulfilling diverse biological and structural functions. Well-known examples are glycosaminoglycans, which are composed of uronic acids linked to 2-acetamido-2-deoxyglycosides in an alternating fashion (e.g., heparin, hyaluronan, and chondroitin); and homoglycuronans, which contain only uronic acid residues. Alginates, which are composed of β-D-mannuronic acid and α-L-guluronic acid units, and pectins, whose main chain is made up of α-galacturonic acid units, belong to this latter class.[33] To incorporate uronic acids into glycoconjugates, it would be advantageous to selectively functionalize their reducing end without resorting to protective-group chemistry, which can be rather cumbersome in the case of monosaccharides[34] and becomes exceedingly time-consuming in the case of oligoglycuronans.[35] A valuable alternative would be the transformation of the starting uronic acid into the corresponding glycosylamine. Although several examples of N-substituted glycosylamine uronic acids have been reported in the literature,[36] they invariably focus on monosaccharides derivatives and involve protective-group chemistry. Furthermore, only two papers claim the preparation of glycosylamine uronic acids in aqueous (from D-GlcA, D-GalA, and α-D-GalA*p*-(1→4)-D-GalA)[24] or aqueous methanolic solution (from D-GlcA).[26,37]

Faced with this dearth of information, we decided to carry out a systematic study of the formation of glycosylamine uronic acids in aqueous solution. In particular, we tried to verify whether such transformation could be conveniently performed and to identify the experimental conditions leading to the maximum yield, in the shortest time, and with the smallest amount of reagents. In this first report, we describe an NMR and MS study of the reaction of D-glucuronic acid

Scheme 1. Reactions taking place during the synthesis of β-D-glucosylamine uronic acid (**2**) in aqueous solution.



(**1**) with different ammonia sources in water (Scheme 1), and demonstrate how ^{1}H NMR spectroscopy can be routinely applied to the quantification of the different species (reactants, intermediates, and products) taking part in the reaction.

Results and discussion

NMR study

Sodium D-glucuronate (**1**) (Scheme 1) was reacted at 30 °C with ammonia and volatile ammonium salts (NH_4HCO_3 or $NH_2CO_2NH_4$) in water according to different protocols (see the Experimental section). Samples were drawn at preset reaction times, frozen in liquid nitrogen, and freeze-dried overnight to eliminate water and most of the salts. No further purification was performed and all reported analyses refer to the gross products obtained this way. To monitor the time course of the reaction, individual samples were redissolved in cold D_2O to afford clear solutions of pD ≅ 9, that were immediately analysed by ^{1}H NMR. Spectra were acquired at 278 K to inhibit hydrolysis of the products and to prevent the peak of residual HDO from interfering with integration.

Figure 1 shows an example of the evolution of the ^{1}H and ^{13}C NMR spectra when going from starting compound (Fig. 1*a*) to the gross final product (Fig. 1*c*).[38] In the proton spectrum, the disappearance of the characteristic peaks at 4.63 ($H1_\beta$), 5.23 ($H1_\alpha$), and 3.27 ppm ($H2_\beta$) proves that **1** was completely consumed during the reaction. At the same time, two new doublets appear at 4.09 ppm ($J_{1,2}$ 8.8 Hz) and 4.70 ppm ($J_{1,2}$ 8.8 Hz) that were assigned to the anomeric proton of β-D-glucopyranosylamine uronic acid (**2**) and ammonium *N*-(β-D-glucopyranosyluronic acid)carbamate (**3**), respectively. Compound **3** forms from the reaction of **2** with the CO_2 liberated by the decomposition of bicarbonate or carbamate anions.[16,18] Since it decomposes fairly easily upon standing in aqueous solution and (or) during repeated freeze-drying cycles,[18] its proportion was included in the calculation of product yields. Besides, the solution equilibrium between **2** and **3** can be easily displaced in favour of **2** by increasing the temperature. For instance, when the product obtained according to protocol A.9.06 was analysed by ^{1}H NMR at 298 K, its mole content was 37% and 52% for **2** and **3**, respectively, whereas the same sample analysed at 318 K contained 72% and 14% of the two species.[39] A complete assignment of the peaks observed in ^{1}H and ^{13}C NMR was performed via ^{1}H–^{1}H homonuclear and ^{1}H–^{13}C heteronuclear correlation experiments, and the results are summarized in Table 2. As an example, the ^{1}H–^{1}H TOCSY, ^{1}H–^{1}H COSY, and ^{1}H–^{13}C HMQC spectra are shown in Fig. 2,[40] Fig. 3,[41] and Fig. 4,[42] respectively, together with the assignment of some peaks (more spectra can be found in the Supplementary data).

The presence of 13 peaks in the ^{13}C NMR spectrum (6 for **2** and 7 for **3**) suggests that both compounds are present in a single cyclic form, and the chemical shift of C-5 (79.9 ppm) points to a hexopyranose ring.[43] Finally, values of 9.4–9.5 Hz for $J_{4,5}$ and $J_{1,2}$ are consistent with an anti orientation of the vicinal hydrogens,[44] hence a $^4C_1$ conformation and a β configuration. It is important to note the original assignment reported by Pfeffer et al.[45] for C-5α and C-6α of GlcA at pH 7.8 should

For personal use only.

be exchanged with that of the β anomer, as evidenced by a three-bond ^{1}H–^{13}C correlation experiment carried out in the course of our study (see the Supplementary data). Also, 1.7–1.9 ppm should be added to the ^{13}C NMR chemical shifts originally reported to refer them to $\delta_{DSS} = 0.0$. The comparison of our results with literature data is comforting: Identical values for δ (H1) and $J_{1,2}$ were reported by Likhosherstov et al.[27] for the ^{1}H spectrum of β-D-glucopyranosylamine, the corresponding *N*-glycosylcarbamate, and the carbamic acid salt of β-D-glucopyranosylamine uronic acid[26] prepared in aqueous methanolic solution, although in those cases a complete NMR assignment was not realized.

With regard to compound **3**, a weak doublet is visible at 6.25 ppm (*J* 9.8 Hz) in the 1D ^{1}H spectrum of concentrated solutions (~15% *w/w*) acquired at 278 K. The same doublet does not couple with any carbon atom in one-bond heteronuclear correlation experiments and is displaced to 6.04 ppm in spectra acquired at 298 K. This signal correlates to the H1 (4.70 ppm) of the same molecule in three-bond homonuclear correlation experiments (Fig. 5*a*),[46] and was therefore assigned to the proton of the $NHCO_2^-$ group. Further corroboration to the structure of **3** comes from the observation that H1 correlates to a quaternary carbamate carbon (165.9 ppm) in long distance ^{1}H–^{13}C heteronuclear correlation experiments (Fig. 5*b*).[46]

When the spectra of samples taken at intermediate reaction times are examined, a more complicated picture emerges (Fig. 1*b*). In particular, five new doublets with coupling constants ranging from 3.3 to 5.6 Hz appear between 4.5 and 5.6 ppm alongside the peaks owing to the anomeric proton of the starting and final compounds. Also, an intense and complex multiplet occupies the region between 4.2 and 4.4 ppm. The nature of these new peaks was elucidated through several ^{1}H–^{1}H (gCOSY, TOCSY) and ^{1}H–^{13}C (gHSQC, gHMBC) correlation experiments and a total of seven new compounds were identified (compounds **5**–**11**). The relative abundance of these species changes significantly after a few hours at 278 K in solution, and most of them disappear within 24 h (vide infra). This is particularly true for compound **5**, whereas a small amount of compounds **6** and **9** is always observed alongside the main products **2** and **3**. To characterize these "transient" species, the use of a higher field spectrometer (800 MHz) equipped with a cryoprobe was necessary for most correlation experiments on samples taken at early reaction times. This way, the total acquisition time could be kept within 7 h per tube without sacrificing signal intensity, and a higher resolution was attained. As a result, all new doublets appearing between 4.5 and 5.6 ppm could be assigned to anomeric protons. The value of $J_{1,2}$ (3.1–5.6 Hz) for compounds **5**–**10** is consistent with a gauche orientation of the vicinal protons, and the three-bond correlation of H1 to a $NHCO_2$ proton and carbon (Fig. 5) demonstrates that **5**, **6**, and **7** are *N*-glycosylcarbamates. Additional weak doublets at 4.45 (d, 4.0 Hz), 4.77 (d, 2.9 Hz), and 5.73 ppm (d, 4.2 Hz) could not be assigned. Concerning compounds **6** and **9**, the chemical shifts of C5 (74.46 and 74.85 ppm, respectively, compared to 74.55 ppm observed for $\mathbf{1}_{\alpha}$), the values of $J_{4,5}$ (10 and 9.1 Hz), and those of $J_{1,2}$ (5.5 and 4.4 Hz) point to a hexopyranose ring in a $^{4}C_1$ conformation and to an α configuration. Based on these results, we postulate that **6** and **9** are the α anomers of compounds **3** and **2**, respectively. Interestingly, in their paper on the synthesis of 1-*N*-glycyl-β-oligosaccharide derivatives, Manger et al.[18] had already speculated that a low-intensity doublet (4.79 ppm, $J_{1,2} = 5.1$ Hz) appearing in the spectrum of β-GlcNAc-NH_2 prepared according to A.0.S was due to the α anomer of the same molecule, but they did not investigate this hypothesis any further.

The multiplet ranging from 4.2 to 4.4 ppm was particularly difficult to interpret: According to ^{1}H–^{1}H TOCSY and ^{1}H–^{1}H COSY experiments, it only correlates with itself and with species **4** (2H), **5** (2H), **7** (3H), **8** (1H), and **10** (3H), which contribute a total of 11 protons. Even so, the value of its integral indicates that other protons must be present. This is supported by one-bond ^{1}H–^{13}C correlations, which show that 15 carbon atoms are linked to this group of protons, i.e., five more than could be expected from ^{1}H–^{1}H correlations. We conclude that the multiplet at 4.2–4.4 ppm contains all proton signals of yet another compound (**11**).

Unfortunately, it was not possible to determine the exact structure of intermediates **5**, **7**, **8**, **10**, and **11** from the NMR data. The absence of secondary carbon signals in ^{13}C DEPT135 spectra excludes the formation of ketofuranoses, while the occurrence of base-catalyzed epimerization at C2 was ruled out by examining the spectra of β-D-mannopyranosylamine uronic acid (and the corresponding carbamate) prepared from D-mannurono-6,3-lactone (ManA-NH_2 C1, δ 85.17 ppm; H1, δ 4.36 ppm, $J_{1,2} = 0.84$ Hz. ManA-$NHCO_2^-$ C1, δ 83.38 ppm; H1, δ 4.94 ppm, $J_{1,2} = 0.93$ Hz).[47] The most likely hypothesis is the formation of furanose derivatives. The mechanism of formation of glycosylamines involves the opening of the starting aldose ring to give an acyclic aldehyde, which is then transformed into an imine followed by ring closure.[30,31] It is reasonable to assume that kinetically favoured furanose forms will initially be more populated than the thermodynamically favoured pyranose forms (vide infra). Unsubstituted furanose derivatives of D-glucuronic acid are not described in the literature, but assignments of ^{13}C NMR spectra are available for methyl-α/β-D-glucofuranoside[48] and β-D-glucofuranose.[49] Even so, comparison with our data is tricky. The chemical shift of C2 is the best candidate for this type of analysis; provided that the substituent on C1 is not *N*-carbamate (e.g., δ C2 is 76.6 and 76.7 ppm for $\mathbf{1}_{\beta}$ and **2**, respectively, but 74.6 ppm for **3**). This excludes its applicability to compounds **5** and **7**. Of the remaining unknown species, δ C2 was only assigned in the case of **10** (83.15 ppm), and a difference of +1.5 ppm with respect to methyl-β-D-glucofuranoside and +1.05 ppm with respect to β-D-glucofuranose is observed.

Mass spectrometry

The identity of species **5**–**11** was further investigated by mass spectrometry. To this end, freeze-dried gross products were redissolved in deionized water and immediately infused through the ESI interface at constant flow rate. Figure 6 shows the evolution of the ESI-MS spectrum when going from the starting compound (*a*) to the gross final product (*c*)[50] via a sample rich in transient species (*b*).[51] In negative-ion mode, three characteristic peaks are present for D-glucuronic acid, which correspond to the uronate anion (*m*/*z* 193, $[M - H]^-$) and to two cluster ions (*m*/*z* 387, $(\mathbf{1}_H)_2$, $[M - H]^-$; *m*/*z* 409, $(\mathbf{1}_{Na})\mathbf{1}_H$, $[M - H]^-$). Similar ions can be identified in the spectrum of **2** + **3** (*m*/*z* 192, 385, and 407) by taking into account the difference of 1 Da between the starting and the final compounds. Also, two peaks are visible that can be ascribed to di(glycosylamine) **4** (*m*/*z* 368 $\mathbf{4}_{H,H}$, $[M - H]^-$; *m*/*z* 390, $\mathbf{4}_{Na,H}$, $[M - H]^-$), whereas peaks at *m*/*z* 207, 209, and 223 could not be assigned. Concerning the sample rich in unknown species (Fig. 6*b*), its MS spectrum appears as a combination of the spectrum of **1** and of **2** + **3**, with the added complication of "mixed" cluster ions having a monoisotopic mass identical to that of the most abundant isotopologue cluster ions of **2**. For instance, *m*/*z* 386 $(\mathbf{1}_H)\mathbf{2}_H$, $[M - H]^-$ and *m*/*z* 408 $(\mathbf{1}_{Na})\mathbf{2}_H$, $[M - H]^-$. Similar considerations can be made for the spectra in positive-ion mode (Fig. 6), where the most intense peaks are those for $(\mathbf{2}_{Na})$ (*m*/*z* 216, $[M + H]^+$; *m*/*z* 238, $[M + Na]^+$). A complete list of the peaks observed for each type of sample, together with their assignment, is reported in Table 3. By examining this table, it becomes apparent that all peaks observed for the intermediate sample are also present either in the spectrum of the starting compound, or in that of the final product. This proves that species **5**–**11** are isomers of **2** and **3**, and since they have completely different NMR spectra, we conclude that they are constitutional isomers and (or) diastereomers of the major products.

Quantification of compounds

The mole fraction of each species observed during the course of the reaction was determined from the proton spectra on the basis of the assignment reported in Table 2. To this end, we assumed that each signal in the ^{1}H NMR spectrum is due to a CH group, i.e., that there was no rearrangement of C–H bonds during the reaction. This idea is supported by the absence of signals attributable to $R_2C{=}O$ or RCH_2–OH carbons in standard ^{13}C NMR and DEPT135 spectra.

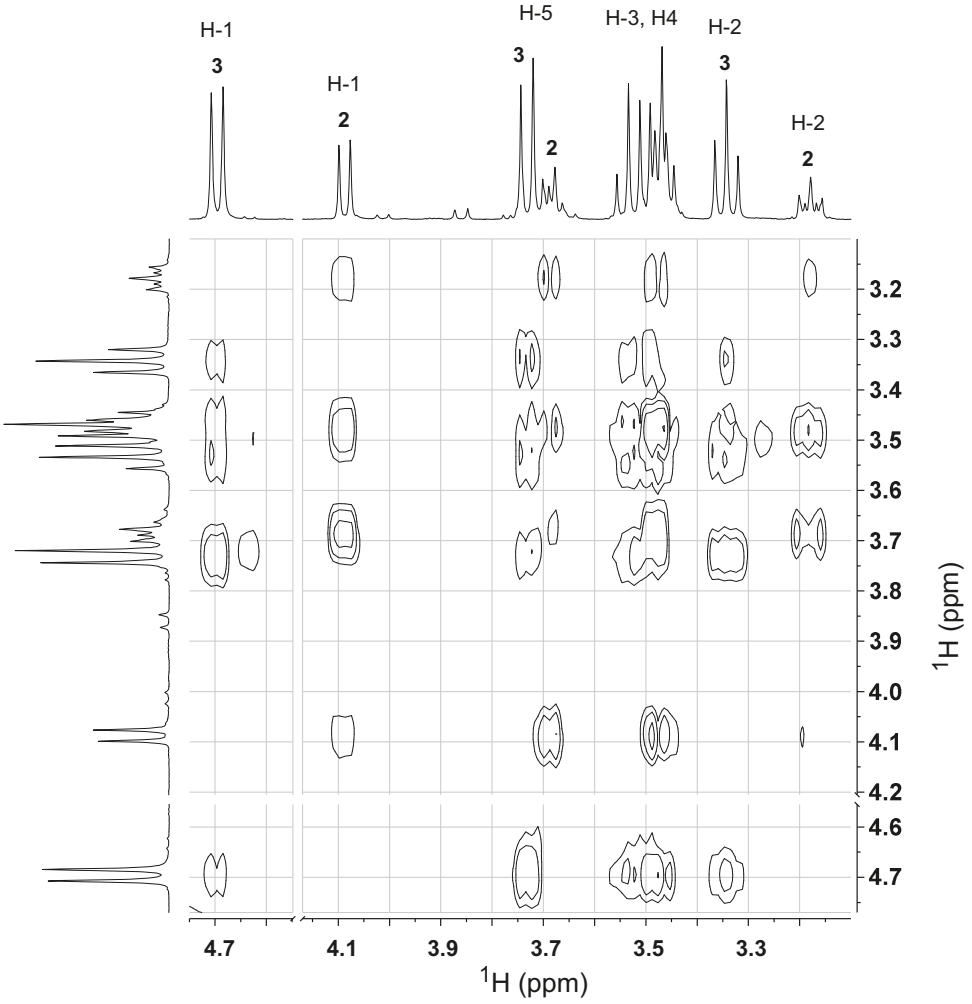
For personal use only.

Fig. 2. 2D ^{1}H–^{1}H TOCSY spectrum of **2** + **3** (400.13 MHz).



A normalizing constant S was then calculated according to the formula:

$$[1]\quad S = \sum_{i=\mathbf{1}}^{\mathbf{12}} \frac{A_\delta^i}{n_\delta^i} = A_{5.23}^{\mathbf{1}_\alpha} + A_{4.63}^{\mathbf{1}_\beta} + A_{3.18}^{\mathbf{2}} + A_{4.70}^{\mathbf{3}} + \frac{(A_{3.27} - A_{4.63}^{\mathbf{1}_\beta})}{2} + A_{5.63}^{\mathbf{5}} + A_{5.37}^{\mathbf{6}} + A_{5.13}^{\mathbf{7}} + A_{4.84}^{\mathbf{9}} + A_{4.58}^{\mathbf{10}} + \frac{(A_{4.20-4.40} - A^{\mathbf{4}} - 2A_{5.63}^{\mathbf{5}} - 3A_{5.13}^{\mathbf{7}} - 3A_{4.58}^{\mathbf{10}})}{5}$$

where A_δ^i indicates the area of the methine signal of compound i having a chemical shift δ (ppm), and n_δ^i is the number of such methine groups in species i (e.g., there are two equivalent H2 protons in diglycosylamine (**4**)). It should be noted that since the H2 signal of **4** superimposes with that of $\mathbf{1}_\beta$, the former was corrected by subtracting the integral of the anomeric proton of $\mathbf{1}_\beta$ at 4.63 ppm. Also, the contribution of species **8** and **11** was combined in the last factor, since neither can be quantified individually. The mole fraction x of each species (with the exception of **8** and **11**) is then calculated from

$$[2]\quad x^i = \frac{A_\delta^i / n_\delta^i}{S}$$

On the basis of this formula, we calculated that, depending on the protocol, between 64% (A.1.06) and 89% (B.0.S) of product **2** + **3** is obtained after 24 h of reaction at 30 °C, whereas the fraction of diglycosylamine (**4**) varies between 0% and 3%. An experiment was also carried out in which an early reaction sample (15 min) was isolated by freeze-drying, redissolved in D_2O, and monitored by ^{1}H NMR at 278 K. Figure 7 shows the evolution of its composition with time.[52] Just after dissolution, the sample was a complex mixture of all species identified in the system with the sole exception of diglycosylamine (**4**). The major single components were D-glucuronic acid (**1**, 22%), compound **5** (27%), and compound **7** (12%). In the following 7 h though, unknown species **5**, **7**, and **10** mostly disappeared; compounds **8** + **11** fell to 3%, and a small fraction of diglycosylamine (**4**) formed. At the same time, the proportion of **2** + **3** and **6** + **9** increased steadily from 12% and 11% to 39% and 30%, respectively, whereas the fraction of D-glucuronic acid (**1**) remained virtually constant. Since all sources of ammonia were removed from the sample before the beginning of the experiment, this result indicates that unknown compounds **5**, **7**, **8**, **10**, and **11** are precursors to **2**, **3**, **6**, and **9**, and that they spontaneously transform in the latter compounds upon standing in solution. Concerning species **6** and **9**, their combined proportion is

Fig. 3. ^{1}H–^{1}H COSY spectrum of **2** + **3** (100.62 MHz).

For personal use only.

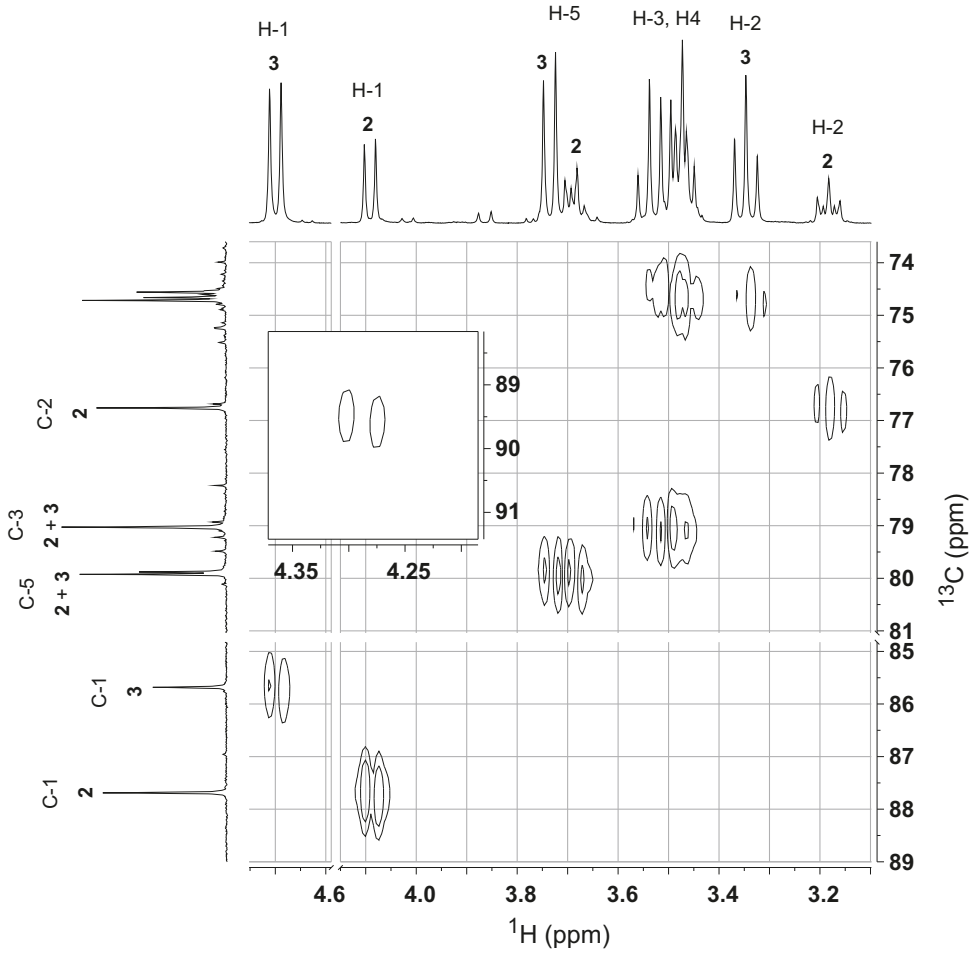
initially identical to that of **2** and **3** (11%–12%), it attains a maximum around 7 h after dissolution (30%) and diminishes slowly in the following days to the advantage of **2** and **3**. This behaviour is consistent with the mutarotation of an α-glycosylamine into the more stable β anomer, both species being in equilibrium with the respective *N*-glycosylcarbamate. As a result, after 5 days at 5 °C, the sample contained 69% of product, 25% of the starting glucuronic acid, 1% of diglycosylamine, and just 5% of all other species combined. Based on this experiment, we propose the reaction scheme reported in Scheme 1.

These results show that species **5**, **7**, **8**, **10**, and **11** are kinetically favoured but thermodynamically unstable, and that they disappear after ~24 h in solution at low temperature in favour of the more stable D-glucopyranosylamine uronic acid (**2/9**) and ammonium *N*-(D-glucopyranosyluronic acid)carbamate (**3/6**). As a consequence, the occurrence of base-catalyzed epimerization as a mechanism for the formation of transient species can be safely ruled out: a catalyst only lowers the activation energy of a reaction and accelerates the formation of a product, which is more (or at least comparably) stable. To accommodate the occurrence of epimerization, we should consider that **1** is initially transformed into a more stable epimer, that the latter is aminated, and that the resulting glycosylamine is back-epimerized to the more stable α/β-D-glucopyranosylamine uronic acid (**2/9**). That is a highly unlikely reaction pathway.

Conclusions

A model uronic acid (D-glucuronic acid (**1**)) was reacted with different ammonia sources in water and the reaction was monitored by ESI-MS and solution NMR spectrometry. For long reaction times (~24 h), the expected products β-D-glucopyranosylamine uronic acid (**2**) and ammonium *N*-(β-D-glucopyranosyluronic acid)carbamate (**3**) were obtained, whereas seven other species (**5**–**11**) were identified in intermediate samples. ^{1}H–^{1}H homonuclear and ^{1}H–^{13}C heteronuclear correlation experiments enabled complete assignment of the ^{1}H and ^{13}C NMR spectra of compound $\mathbf{1}_{\alpha}$, $\mathbf{1}_{\beta}$, **2**, and **3**, whereas partial assignments were obtained for the other compounds. Based on these results, a ^{1}H NMR protocol for the quantification of the different species (reactants, intermediates, and products) taking part in the reaction was developed. It was thus calculated that after 24 h at 30 °C between 64% (A.1.06) and 89% (B.0.S) of product **2** + **3** was

Fig. 4. ^{1}H–^{13}C HMQC spectrum of **2** + **3** (400.13–100.62 MHz). The insert shows the cross peak owing to the anomeric proton and carbon of di(β-D-glucopyranosyl)amine uronic acid **4**.



obtained, whereas the mole fraction of diglycosylamine (**4**) varied between 0% and 3%.

NMR data confirm the structure of compounds **2** and **3**, prove that **3**, **5**, **6**, and **7** are *N*-glycosylcarbamates, and indicate that **6** and **9** are indeed the α anomer of the main products **3** and **2**, respectively. Also, by combining NMR and ESI-MS results, we could prove that all intermediate species are constitutional isomers and (or) diastereomers of **2** and **3**. Finally, by monitoring the evolution of the composition of an early reaction sample redissolved in D_2O, we could prove that species **5**, **7**, **8**, **10**, and **11** are precursors of compounds **2**, **3**, **6**, and **9**, and that the α and β anomers of D-glucopyranosylamine uronic are initially formed in the same proportion, but the former gradually disappears in favour of the more stable β form. To the best of our knowledge, this is the first time that the α anomer has been observed during the formation of a β-glycosylamine. Based on these results, we propose Scheme 1 as the correct reaction scheme for the synthesis of the title compound in aqueous solution. Correct assignment for the ^{1}H and ^{13}C NMR spectra of D-glucuronic acid in D_2O were also established during the course of this study.

We are now applying the NMR protocol described herein to a kinetic study of the same reaction under different experimental conditions. The result of this study will be the object of a future communication.

Experimental

Materials and methods

Unless otherwise specified, all chemicals were reagent grade and used as received: D-glucuronic acid sodium salt monohydrate (99%, Fluka), D-glucurono-6,3-lactone (≥98.0%, Fluka), ammonium bicarbonate (≥99.0%, Fluka), ammonium carbamate (≥99.5%, Fluka), ammonia (~30% *w*/*w*, Carlo Erba), D_2O (99.9%-D, Euriso-top). Distilled or deionized water was used for all experiments.

Protocol numbering

Sodium D-glucuronate (**1**; Scheme 1) was reacted at 30 °C with ammonia and volatile ammonium salts (NH_4HCO_3 or $NH_2CO_2NH_4$) in water according to different protocols. The numbering of each protocol reveals the exact experimental conditions used. The first letter indicates the type of solid salt added (A, NH_4HCO_3; B, $NH_2CO_2NH_4$). The middle number indicates the initial formal concentration of liquid ammonia in mol/L. The last number indicates the initial formal concentration of salt in 10^{-1} mol/L. For example, A.1.06 indicates that the salt used was NH_4HCO_3 and that the initial concentration of ammonia and salt were 1 and 0.6 mol/L, respectively.

MS nomenclature

In the nomenclature used to assign MS peaks, subscript symbols indicate the counterion. For example, $\mathbf{1}_{H}$ and $\mathbf{1}_{Na}$ indicate D-glucuronic acid and sodium D-glucuronate, respectively. The complete list of structures used for the interpretation of mass spectra is found in the Supplementary data.

Synthesis of β-D-glucopyranosylamine uronic acid

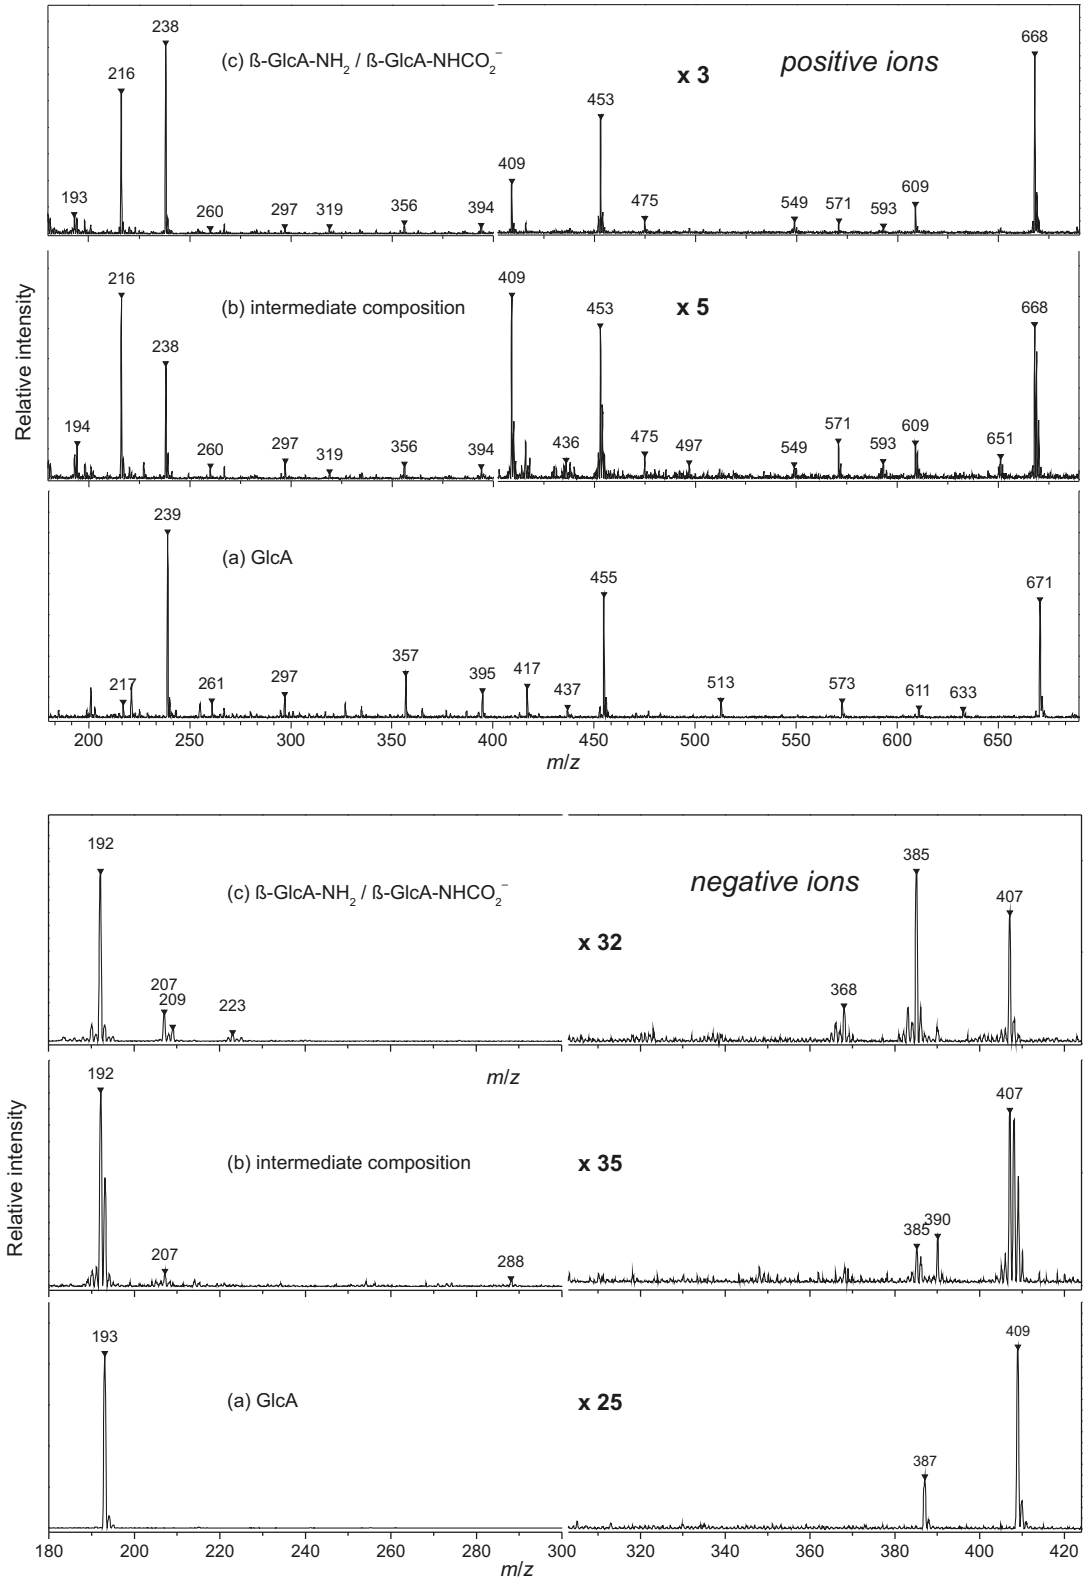
In a typical experiment (AG09–30_P2, protocol B.5.06), D-glucuronic acid sodium salt monohydrate (0.468 g, 2.0 mmol) and ammonium carbamate (0.468 g, 6.0 mmol) were weighed in a 25 mL round-bottomed flask. A magnetic bar was added together with 10 mL of aqueous ammonia (5 mol/L), the flask was sealed with a rubber septum, and a disposable needle (21G) was passed through the septum to prevent pressure buildup. The flask was plunged in an oil bath preheated at 30 °C and stirred at 200 rpm. At preset intervals, ~250 μL samples were drawn with a syringe, transferred to a glass vial, diluted with two volumes of water, and frozen in liquid nitrogen. All samples were then freeze-dried overnight and stored in a freezer (–18 °C) until needed. After 24 h, the molar composition as determined by ^{1}H NMR spectroscopy was **1**, 2%; **2**, 11%; **3**, 71%, **4**, 2%; **5**, 2%; **6**, 6%; **7**, 2%; **9**, 2%; **10**, 1%; and **8** + **11**, 1%.

Instrumental analyses

The composition of samples from the kinetic study was determined by NMR on a Bruker DPX400 spectrometer equipped with a variable temperature (VT) module (resonance frequency of 400.13 and 100.62 MHz for ^{1}H and ^{13}C nuclei, respectively). Two different 5 mm detection probes were used: QNP (direct) and BBIZ (inverse). Unless otherwise specified, 90° pulses and pulse sequence recycle times of 3 s were used. The probe temperature was calibrated in the range of 275–300 K using neat methanol. The NMR probe was pre-equilibrated at 278 K, individual samples were redissolved in D_2O (~3% *w*/*w*), transferred to an NMR tube, and immediately lowered into the instrument magnet for analysis. 1D ^{1}H spectra were obtained with 32 scans and 32 K data points and were reprocessed using MestReNova software (version 6.1). Sodium 3-(trimethylsilyl)propanoate (TSP) or sodium 3-(trimethylsilyl)propane-1-sulfonate (DSS) was used as an internal reference. Chemical shifts (in ppm) for ^{1}H and ^{13}C nuclei were referenced to $\delta_{TSP} = -0.017$ ppm (^{1}H) and $\delta_{TSP} = -0.149$ ppm (^{13}C) or to $\delta_{DSS} = 0.000$ ppm (^{1}H and ^{13}C).

Higher field NMR was used to identify peaks belonging to the different spin systems observed at early reaction times. Experiments were carried out on a Varian VNMRS 800 MHz spectrometer interfaced to a Dell Optiplex 755 computer using VnmrJ and equipped with a 5 mm triple-resonance (^{1}H, ^{13}C, and ^{15}N) cryoprobe including shielded z gradients. All data were processed on a Dell HP xw4400 using TopSpin software or a Dell Optiplex 755 computer using VnmrJ software. The probe was pre-equilibrated at 278 K, and samples were prepared by dissolving the starting compound in D_2O (0.600 mL) with the addition of TSP as an internal reference. Immediately after dissolution, samples were lowered into the instrument magnet and spectra were recorded at 278 K. 1D 799.975 MHz ^{1}H spectra were recorded before and after each set of 2D experiments to check medium modification with time. Each 1D ^{1}H spectrum was collected, without water suppression, with 32 scans of 32 K data points over a 9050 Hz spectral width. 1D 201.172 MHz ^{13}C spectra were obtained with power gated proton decoupling using the WALTZ-16 sequence and 1 K scans of 64 K points on

Fig. 6. ESI-MS spectrum of **1** (*a*), a sample containing 65% transient species (*b*), and **2** + **3** (*c*). Positive (top) and negative (bottom) ions are shown. In some cases, the intensity of the peaks on the right-hand side of the spectrum was magnified.



50 000 Hz of spectral width. All 2D experiments were recorded with a continuous wave pulse of 35 Hz presaturation field on the water signal during the 1.5 s relaxation delay. 2D gradient-selected 799.975 MHz ^{1}H–^{1}H COSY spectra were acquired in the absolute value mode. ^{1}H–^{1}H TOCSY spectra (799.975 MHz) used a z-filtered DIPSI-2 spin lock of 8.3 kHz power, 120 ms duration, and were acquired in the sensitive phase mode using States method for quadrature detection.

[a]Sample obtained after 15 min of reaction at 30 °C according to protocol B.5.06 (AG10–08); the initial mole fraction of intermediate species was 65%.

[b]Sample obtained after 48 h at 30 °C according to protocol B.0.S (AG10–20_P1_end); the initial mole fraction of **2** + **3** was 89%.

For COSY and TOCSY spectra, 512 equally spaced evolution time period values were acquired, averaging 16 transients of 2 K points, with 9470 Hz of spectral width. 2D gradient-selected (799.975–201.172 MHz) ^1H–^{13}C HSQC with GARP sequence ^{13}C decoupling during acquisition was obtained in the sensitive-phase mode using echo–antiecho detection. Equally spaced evolution time period values (512) were acquired, averaging 14 transients of 1518 points, with 7300 and 3811 Hz in *F*1 and *F*2, respectively. Evolution delay for $^1J_{CH}$ amounted to 1.7 ms ($1/(4\cdot{}^1J_{CH})$). 2D gradient-selected (799.975–201.172 MHz) ^1H–^{13}C HMBC via heteronuclear zero and double quantum coherence with a low-pass J filter to suppress on-bond correlation and no ^{13}C decoupling during acquisition was achieved in the absolute mode value.

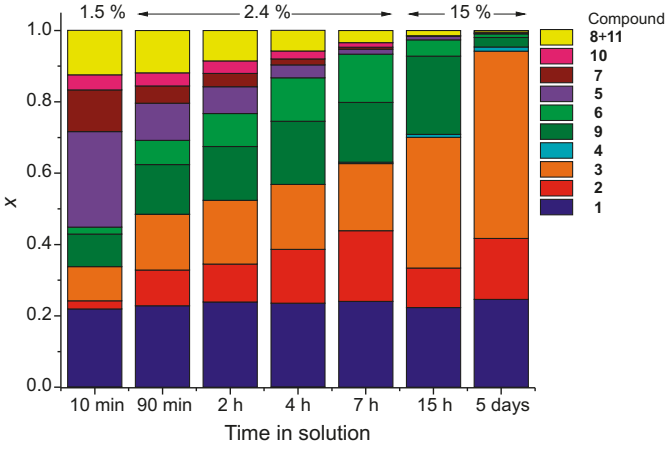
Fig. 7. Evolution of the composition with time for a sample obtained after 15 min of reaction, isolated by freeze-drying, and redissolved in D_2O at 278 K. The percentage values annotated over the graph specify the mass concentration of the sample in solution.



Equally spaced evolution time period values (512) were acquired, averaging 32 transients of 2426 points, with 44248 and 9470 Hz in $F1$ and $F2$, respectively. Evolution delay for low pass $^1J_{CH}$ filter and for evolution of long-range coupling amounted to 3.6 ms ($1/(2\cdot{}^1J_{CH})$) and 70 ms ($1/(2*^nJ_{CH})$), respectively.

Mass spectrometry analyses were performed with a Waters ZQ (Altrincham, UK) single quadrupole atmospheric pressure ionization mass spectrometer fitted with a Z-electrospray interface (ESI). The instrument was calibrated with mass spectra generated by ion-spray ionization of a 0.1 mol/L solution of sodium iodide in aqueous acetonitrile (50%, *v*/*v*) in the mass range of 23–1972 amu. Nitrogen was used as the drying and nebulizing gas. Samples (~1 mg/L) were dissolved in deionized water and infused to the ESI interface at constant flow rate (50 μL/min).

Supplementary data

Supplementary data (1D and 2D NMR spectra on which peak assignment and structural elucidation were based and the list of structures used for the interpretation of mass spectra) are available with the article through the journal Web site (www.nrcresearchpress.com/cjc).

Abstract: We report the preparation and photocatalytic activity of TiO_2 nanocomposites modified with monolayer-protected gold clusters (MPCs). Highly monodisperse tiopronin-coated MPCs with core diameters of 2.2 ± 0.2 nm were pre-prepared and then anchored onto a TiO_2 surface using the bifunctional tiopronin linker. In this method, the gold core size was preserved after calcination at 260 °C as well as the anchoring process, and the gold loading on TiO_2 could be precisely controlled by the experimental condition. The photocatalytic degradation of Rhodamine 590 (Rh-590) was carried out with thus prepared MPC–TiO_2 composites. Mechanistic study of the photocatalytic reactions revealed that the degradation of Rh-590 occurs via the oxidative pathway by photogenerated holes. The photocatalytic activity of the MPC–TiO_2 composites was found to increase significantly upon calcination at 260 °C, whereas the size of gold particles remained at their initial size. The photocatalytic activity of the composites, however, drastically decreased when the composites were calcined at 400 °C. X-ray photoelectron spectroscopy analysis of the calcined composites was conducted to understand the vastly different calcination results. A significant amount of oxidized sulfur remained in the composites after calcination at 400 °C, which appears to be responsible for the drastic decrease in the photocatalytic activity.

Key words: monolayer-protected gold cluster, photocatalyst, TiO_2, tiopronin, thermal activation, nanocomposite.

Résumé : On a préparé et déterminé les propriétés photocatalytiques de nanocomposites de TiO_2 modifiés par des agrégats d'or protégés par une monocouche (APM). On a procédé en effectuant une préparation préliminaire d'APM hautement monodispersé recouverte de tiopronine dont le diamètre de la partie de coeur est de 2,2 ± 0,2 nm et on l'a ensuite ancré sur une surface de TiO_2 faisant appel à la tiopronine, un réticulant bifonctionnel. Dans cette méthode, la taille de la zone de coeur d'or est maintenue après avoir été soumise au processus d'ancrage et une calcination à 260 °C et la fixation de l'or sur le TiO_2 peut être contrôlée avec précision par les conditions expérimentales. On a procédé à la dégradation photocatalytique de la Rhodamine 590 (Rh-590) à l'aide des composites APM-TiO_2 ainsi préparés. L'étude du mécanisme des réactions photocatalytiques a permis de montrer que la dégradation de la Rh-590 se produit par le biais d'une voie oxydante impliquant des trous photogénérés. On a trouvé que l'activité catalytique des composites APM-TiO_2 augmente considérablement par calcination à 260 °C alors que la taille des particules d'or maintiennent leur taille initiale. Toutefois, l'activité catalytique des composites diminuent considérablement lorsque les composites sont calcinés à 400 °C. On a effectué des analyses par spectroscopie photoélectronique des rayons-X des composites calcinés dans le but de comprendre les résultats si différents de ces calcinations. Il semble qu'une quantité significative résiduelle de soufre oxydé dans les composites après la calcination à 400 °C soit la cause de cette diminution drastique de l'activité catalytique.

Mots-clés : agrégat d'or protégé par une monocouche (APM), photocatalyseur, TiO_2, tiopronine, activation thermique, nanocomposite.

Introduction

Metal-coated semiconductor nanoparticles have been the focus of numerous investigations over the last few years in photocatalysis relevant to solar energy conversion and environmental cleanup.[1–3] Contact of metal with the semiconductor indirectly influences the energetics and charge-transfer processes. For example, single-component semiconductor nanoparticles exhibit relatively poor photocatalytic efficiency, since the majority of the photogenerated charge carriers undergo recombination.[4] Semiconductor – metal composite nanoparticles on the other hand facilitate charge separation by rectifying the direction of the flow of electrons and holes in these systems.[5–7] Various preparative methods, for example, chemical, electrochemical, photochemical deposition, and deposition–precipitation methods have been used for the

preparation of nano-sized metal deposits on metal oxide surfaces.[8] However, these methods typically produce polydisperse particles and it is very difficult to control the deposit formation experimentally.[9,10] This is the major challenge in the optimization of such semiconductor – metal composite nanoparticles that often exhibit critically size-dependent catalytic activities.[11] In this article, we present an improved method to prepare TiO_2 photocatalysts modified with uniform monolayer-protected gold clusters (MPCs).[12]

MPCs are stable, structurally and energetically well-defined nanoparticles whose size and core and ligand compositions are precisely characterized by a variety of analytical methods.[13,14] One of the most interesting properties of these has been the ability to control the transfer of electrons into and out of the metallic core.[14,15] Once charge transfer takes place, the MPC acts as a capacitor storing the charge within its core. The long-term storage of charge on the MPC core is a fundamental result of the conductive metal-core-insulating protecting shell structure.[16–20] In our previous work,[21] we investigated the photocatalytic activity of composite photocatalysts prepared by anchoring Au MPCs onto TiO_2 nanoparticles using a bifunctional linker. The MPC–TiO_2 composites showed considerably enhanced photocatalytic activity for the reduction of Uniblue A in deaerated CH_3OH–H_2O in which CH_3OH acts as an efficient hole scavenger. In another study,[22] we showed that electron transfer spontaneously occurs from the photoexcited TiO_2 nanoparticles to Au MPCs in their colloidal mixtures and that the electron transfer efficiency is determined by the MPC core size.

In the interest of utilizing the photoholes generated in MPC–TiO_2 composites, we investigate the photocatalytic activity of the composites in the absence of the hole scavenger. As illustrated in Scheme 1, band-gap illumination of TiO_2 colloids excites electrons to the conduction band and generates holes in the valence band. These photogenerated electrons and holes recombine immediately in aqueous media.[23] When MPCs are attached to the TiO_2 surface, these photoelectrons preferentially transfer to the gold cores and are stored on them.[22] It has been found that electron transfer from the photoexcited TiO_2 to Au MPC is thermodynamically favorable and it proceeds until the Fermi levels of TiO_2 and MPC are equilibrated.[5,22,24] This process would enhance the charge separation efficiency in MPC–TiO_2 composites and, as a result, more holes and electrons are available for further reactions. Both of these separated charges are capable of initiating subsequent reactions. In an aqueous environment, holes are scavenged by the hydroxyl ions on the surface of TiO_2, producing hydroxyl radicals. It is well-established that the hydroxyl radical is the primary source behind the photocatalytic activity of TiO_2.[25–27] Hydroxyl radicals are capable of oxidizing many of the organic species present.[28] Successful degradation of aliphatic compounds,[29,30] aromatic compounds,[31,32] inorganic compounds,[33,34] and surfactants[35] have been demonstrated previously.

In this work, highly monodisperse gold nanoparticles were presynthesized and then attached onto TiO_2 using a bifunctional linker (tiopronin) to form MPC–TiO_2 composites. In this method, the gold loading on TiO_2 could be facilely and precisely controlled by manipulating the experimental conditions. The photocatalytic activity of the MPC–TiO_2 composites was examined with a model dye, Rhodamine 590 (Rh-590). The degradation of Rh-590 was found to occur via an oxidative pathway and was significantly enhanced with MPC–TiO_2 composites calcined at 260 °C. The photocatalytic activity of the composites, however, drastically decreased when the composites were calcined at 400 °C. X-ray photoelectron spectroscopy analysis of the calcined composites revealed that a significant amount of oxidized sulfur remained after calcination at 400 °C, which appears to cause a drastic decrease in the photocatalytic activity. This result reveals the critical role of ligands in MPC-modified photocatalysts.

Experimental

Materials

Hydrogen tetrachloroaurate trihydrate ($HAuCl_4 \cdot 3H_2O$, ACS reagent grade), tiopronin, acetonitrile, sodium borohydride, and methanol were purchased from Sigma-Aldrich. TiO_2 nanoparticles (Aeroxide P25) was purchased from Acros Organics. Acetic acid (A.C.S. grade) was purchased from J. T. Baker. Rh-590 was purchased from Exciton. All chemicals were used as received. Water was purified using a Milli-Q system (Purelabsplus UV/UF, 18.2 MΩ cm).

Synthesis of tiopronin-protected MPCs

Tiopronin-coated MPCs were synthesized according to literature procedure[36] with some modifications. In a typical reaction, 1.85 g (4.69 mmol) of $HAuCl_4 \cdot 3H_2O$ and 4.85 g (29.7 mmol) of tiopronin were codissolved in 211 mL of a 6:1 (*v*/*v*) methanol – acetic acid mixture, giving a ruby red solution. This solution was rapidly stirred for 1 h. The color gradually disappeared and the solution became colorless. To this solution, sodium borohydride 3.59 g (94.8 mmol) dissolved in 190 mL of H_2O was added with rapid stirring, and the stirring was continued for another 45 min. The solvent was then rotary evaporated under vacuum at 38 °C to near dryness to produce a black gooey product. Monodisperse MPCs with an average core diameter of 2.2 ± 0.2 nm (Fig. S1, Supplementary data) were isolated by methanol extraction from the product.

Preparation and characterization of MPC–TiO_2 composites

MPC–TiO_2 composites were prepared by anchoring tiopronin–MPCs onto TiO_2 nanoparticles. TiO_2 nanoparticles were dispersed in water by simultaneous shaking and sonicating for 30 s prior to the MPC anchoring reaction. The primary size of TiO_2 nanoparticles was ca. 20 nm as shown in Fig. 1. The anchoring of MPCs onto TiO_2 was carried out by dissolving an appropriate amount of MPC (Au/TiO_2 = 1%–6% *w*/*w*) in 20 mL of a TiO_2 aqueous suspension (5 g/L) and stirring the mixture for 3 h. After the anchoring reaction, the MPC–TiO_2 composites were centrifuged and dried. Complete anchoring of MPCs on TiO_2 was confirmed by the clear supernatant of the anchoring mixture after centrifugation. Composites were stored in a freezer and redissolved in water prior to photocatalytic reactions. To prepare calcined MPC–TiO_2 composites, the MPC–TiO_2 composites were thermally treated at 260 or 400 °C in air in a muffle furnace (heating rate = 8.3 °C/min, holding time = 30 min). Tiopronin-coated TiO_2 nanoparticles were prepared by stirring TiO_2 in an aqueous tiopronin solution that contained an equivalent amount of tiopronin to 3 wt% MPC–TiO_2.

Transmission electron microscopy (TEM) images of MPC–TiO_2 were obtained with a JEOL JEM-1230 operating at 80 kV. The TEM samples were prepared by drop casting of an MPC–TiO_2 suspension on a carbon-coated copper grid (400C-FC, Electron Microscopy Sciences, Hatfield, Pennsylvania). To enhance the interaction between the TEM grid and the hydrophilic composites, the grid was fumed with nitric acid to make it hydrophilic. Thermogravimetric analysis (TGA) was performed with a Scinco STA-1500. X-ray photoelectron spectroscopy experiments were carried out on Sigma Probe spectrometer (Thermo VG, UK) using monochromatic Al Kα X-ray source (1486.6 eV). Binding energies (BE) were calibrated with respect to carbon 1s at 284.5 eV.

Photocatalysis experiments

To an MPC–TiO_2 suspension in water (15 mg/L), Rh-590 solution was added to bring the initial concentration (C_0) to 10 μmol/L just before the photolysis experiment. Photolysis experiments were performed with a 300 W xenon lamp in a quartz cuvette while stirring the solution magnetically. Light was filtered through an UV cutoff filter (λ > 320 nm, UV-32, HOYA) and an IR filter (HA-30, HOYA). Absorption spectra of the reaction mixture was recorded in situ with a portable spectrometer (DH2000-BAL/H2000, Ocean Optics), at 1 min intervals for 30 min. A set of triplicate measurements were carried out for each photocatalytic experiment.

Results and discussion

Anchoring of MPCs onto TiO_2

It is well-known that carboxylic acid groups readily bind to the TiO_2 surface via ester- or carboxylate-type linkages.[37] Thus, tiopronin-coated MPCs were directly reacted with bare TiO_2 to produce MPC–TiO_2 composites. As can be seen in Fig. 1, after 3 h of the anchoring reaction, most of the MPCs appear to be bound to TiO_2. Therefore, the anchoring reaction of MPCs onto TiO_2 was carried out for 3 h. The MPC loading on TiO_2 can be experimentally controlled by simply varying the initial concentration of MPCs in the mixture, showing the advantage of this approach. Figures 1A and 1B, respectively, show TEM images of thus prepared 1 and 3 wt% MPC-loaded composites. It can be clearly seen in the figures that the MPC loading is indeed controlled by controlling the MPC concentration in the mixture. The MPC loading could be precisely controlled up to 6 wt%. However, there are some unbound MPCs remaining in the anchoring mixture above 6 wt%. Regardless of the loading %, the MPC core size was unchanged from its initial size of 2.2 ± 0.2 nm, and no obvious aggregation of MPC on TiO_2 was observed throughout the binding process.

Photocatalytic reaction of MPC–TiO_2 composites — Mechanistic study

In the present study, the photocatalytic activity of the MPC–TiO_2 nanoparticle composite was investigated by monitoring the degradation of Rh-590 during photocatalysis. As can be seen in Fig. 2, Rh-590 initially exhibits an intense absorption band at 525 nm. The orange color of Rh-590 gradually disappears during the reaction and turns colorless upon complete degradation. Band-gap illumination of TiO_2 colloids in water excites electrons to the conduction band, leaving holes in the valence band. While most of photoelectrons and photoholes generated in the semiconductor recombine immediately after the excitation process,[38–40] some separated electrons and holes can diffuse to the semiconductor surface and react with the molecular species adsorbed on the TiO_2 surface.[41] The Rh-590 degradation can occur via a reductive or an oxidative pathway by electrons and holes, respectively, generated in the photoexcited semiconductor.[42,43] In photocatalytic reduction and oxidation of Rhodamine B, an analog of Rh-590, in the presence of TiO_2 sols, Takahashi and coworkers[44] revealed that a new absorption band at 420 nm is observed in the reductive pathway but not in the oxidation pathway. This band was assigned to the partially reduced radical of Rhodamine B.[45] The absence of the 420 nm band in Fig. 2 suggests that the degradation of Rh-590 is likely to occur via the oxidative pathway, presumably through N-de-ethylation and (or) destruction of the conjugate structure.[43] Additionally, the degradation of Rh-590 is found to be irreversible, which is also consistent with the oxidative pathway. The oxidative pathway is further confirmed by SCN^- experiments (vide infra).

Since Rh-590 shows strong absorption in the visible region, one may speculate that Rh-590 is degraded by direct light absorption or dye-sensitization pathways.[43] In Fig. 3, there is no degradation of Rh-590 observed upon illumination in the absence of TiO_2 nanoparticles, ruling out the former possibility. In addition, no degradation was found with

Fig. 2. Temporal evolution of absorbance spectra during the photocatalytic degradation of Rhodamine 590 (Rh-590) with monolayer-protected gold cluster (MPC) – TiO_2 nanocomposites.

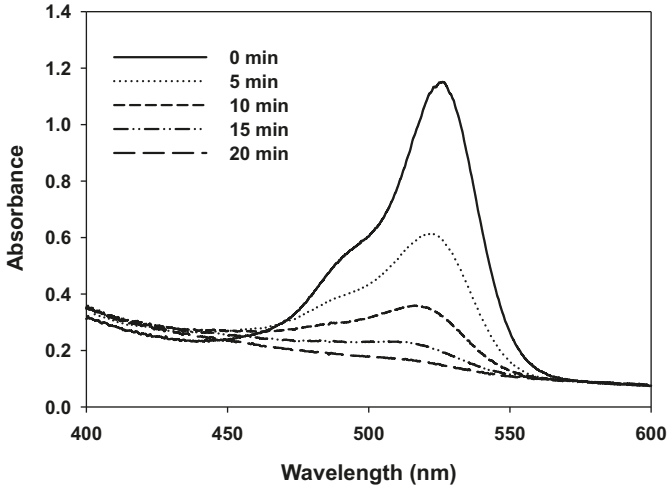

Fig. 3. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during photocatalysis in the absence (A) and presence (B) of TiO_2 and in the presence of TiO_2 using a 455 nm long-pass filter (C). The Rh-590 concentration was estimated from the absorbance at 525 nm.

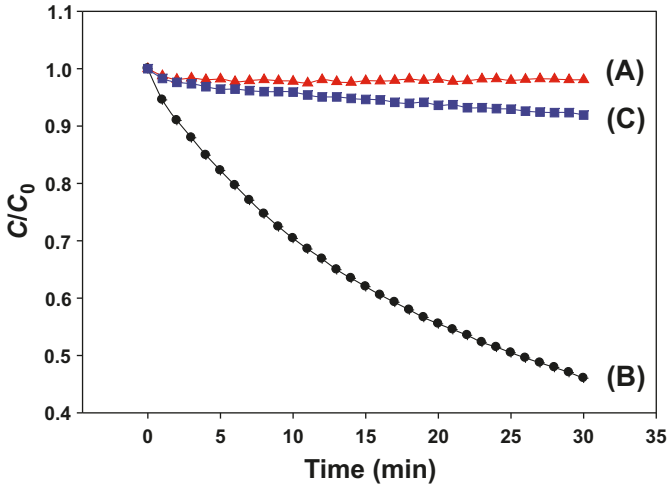

MPC alone. The possibility of dye degradation via dye sensitization was also examined. By using an additional long-pass filter ($\lambda > 455$ nm), the photoexcitation of TiO_2 was effectively blocked while Rh-590 absorption was undisturbed. This control experiment (line C in Fig. 3) shows that <8% of Rh-590 is degraded during 30 min of photolysis by the dye-sensitization mechanism. As can be seen in Fig. 3 (line B), much more Rh-590 is degraded when TiO_2 is photoexcited, confirming that the photoexcited TiO_2 plays the major role in the degradation of Rh-590.

When TiO_2 is excited with band-gap radiation (3.2 eV), electron–hole separation takes place. When the photoexcitation is carried out in an aqueous environment, the created holes can react with hydroxyl groups present on the surface, generating hydroxyl radicals. At the same time, electrons are being scavenged by oxygen.[46] Hydroxyl radicals can trigger further reactions, such as oxidation of organics.[42,47] Under the current experimental conditions, i.e., in aerated water, we thus expect the major involvement of holes toward the degradation of Rh-590. This can be confirmed by introducing SCN^-, a known hole scavenger, to the reaction mixture. The photogenerated holes can be effectively consumed by SCN^- at the semiconductor interface.[48]

Figure 4A shows the photocatalytic degradation of Rh-590 with TiO_2 in the absence and presence of a hole scavenger (SCN^-).[49] In the presence of 30 μmol/L SCN^-, the degradation rate of Rh-590 significantly decreased, suggesting that the photogenerated holes are primarily involved in the degradation of Rh-590. When the concentration of SCN^- is increased to 60 μmol/L, the degradation rate is further decreased; ca. 40% of Rh-590 is degraded after 30 min of photolysis in the absence of SCN^-, which significantly decreases to 29% and 19%, respectively, in the presence of 30 and 60 μmol/L SCN^-. The fact that the degradation rate is significantly decreased in the presence of the hole scavenger undoubtedly confirms that the photocatalytic degradation of Rh-590 occurs via oxidative photocatalytic reaction involving photogenerated holes.

In Fig. 4B, a similar trend is observed for 3 wt% MPC–TiO_2 composites calcined at 260 °C (thermal treatment of the MPC–TiO_2 composites and the effect of MPC modification are discussed later). Before the addition of SCN^-, the catalytic activity of the 3 wt% MPC–TiO_2 composite is higher than that of bare TiO_2; the Rh-590 degradation is 59% after 30 min of photolysis in the absence of SCN^-. As the addition of the hole scavenger SCN^- is increased, the catalytic degradation of Rh-590 is decreased; the Rh-590 degradation decreases to 50% and 40% when SCN^- concentration was increased to 30 and 60 μmol/L, respectively. It is interesting to note that the effect of SCN^- addition on the photocatalytic degradation of Rh-590 is very similar for both bare TiO_2 and 3 wt% MPC–TiO_2; ca. 10% and 20% decreases in the presence of 30 and 60 μmol/L SCN^-, respectively. These results suggest that the photogenerated holes are primarily involved in the photocatalytic degradation of Rh-590 for both bare TiO_2 and 3 wt% MPC–TiO_2 composites.

We next turn to the role of oxygen in oxidative photocatalytic reactions. To probe the role of oxygen in the reaction, we carried out photolysis experiments[49] in the absence of oxygen after purging with argon for 30 min to remove dissolved oxygen, prior to photolysis. As can be seen in Fig. 5 (line B), photocatalytic activity is dramatically decreased when oxygen is removed, indicating that oxygen plays a vital role in the photocatalytic degradation of Rh-590. There is still slight degradation (ca. 10%) of Rh-590 in the absence of oxygen, which is probably due to the incomplete removal of oxygen during the 30 min of purging. The role of the oxygen in photocatalytic reactions can vary. In this particular case, oxygen appears to act as an electron scavenger that facilitates electron–hole separation. To test the role of oxygen as an electron scavenger, we introduced IO_3^-, a known electron scavenger,[50] to the argon-purged reaction mixture to substitute for oxygen. As can be seen in Fig. 5, the catalytic activity for the degradation of Rh-590 was restored in the presence of IO_3^-. This confirms that oxygen acts as an electron scavenger whose presence is indispensable for the photocatalytic degradation of Rh-590.

Fig. 4. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during photocatalysis with TiO_2 (A: a, b, c) and 3 wt% monolayer-protected gold cluster (MPC) – TiO_2 calcined at 260 °C (B: a, b, c) in the absence of SCN^- (a) and in the presence of 30 μmol/L (b) and 60 μmol/L (c) SCN^-.

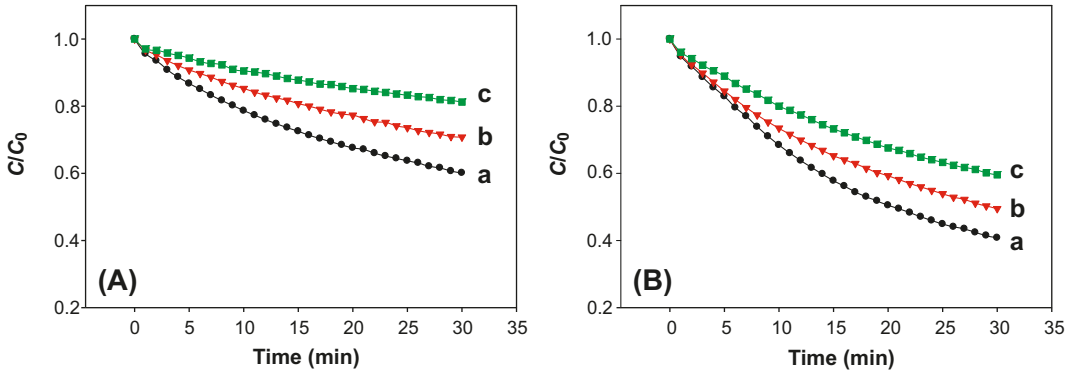

Fig. 5. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during photocatalysis with TiO_2 in the presence (A) and absence (B) of oxygen, and in the absence of oxygen and in the presence of IO_3^- (C).

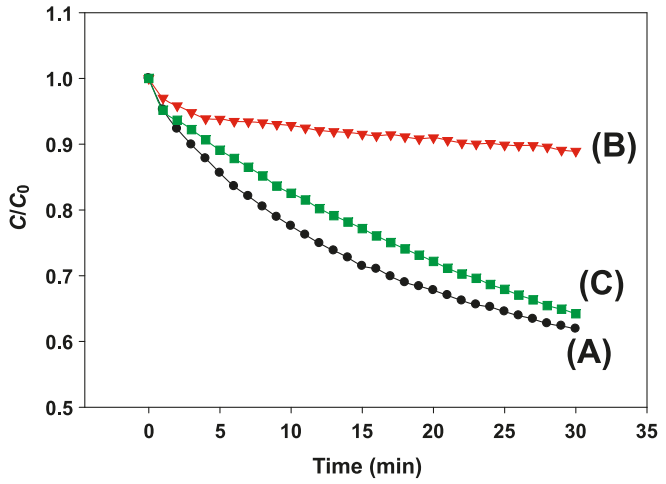

Fig. 6. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during the photocatalytic reaction with (A) bare TiO_2, (B) bare TiO_2 calcined at 400 °C, (C) 3 wt% monolayer-protected gold cluster (MPC) – TiO_2, (D) 3 wt% MPC–TiO_2 calcined at 260 °C, and (E) 3 wt% MPC–TiO_2 calcined at 400 °C.

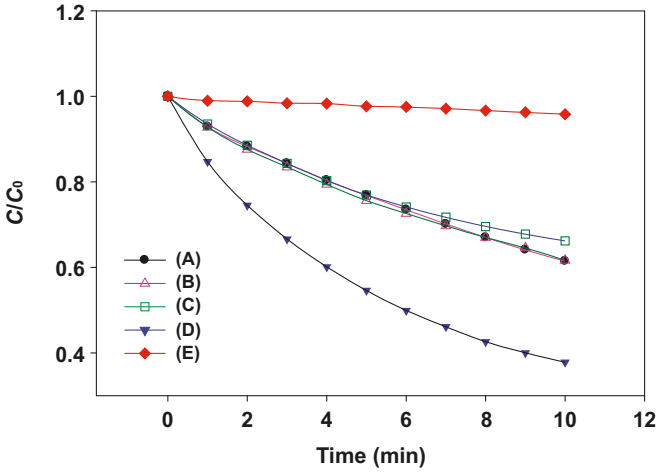

TiO_2 photocatalysts modified with MPCs

The photodegradation of Rh-590 with bare TiO_2 and 3 wt% MPC–TiO_2 are compared in Fig. 6. All nanoparticle suspensions were irradiated equally and the absorbance at 525 nm was recorded at 1 min intervals. As can be seen in Fig. 6 (lines A and C), there is no enhancement in the photocatalytic activity of 3 wt % MPC–TiO_2 compared with that of bare TiO_2. The same trend was found for other MPC–TiO_2 composites with 1, 2, and 6 wt% MPC loadings (not shown). These results suggest that the bifunctional tiopronin linker could impose a kinetic barrier for electron transfer from TiO_2 to the gold core. In fact, the distance between TiO_2 and the gold core through the tiopronin linker, which is estimated to be 0.93 nm[51], seems to be too long for the electron transfer to occur efficiently and thus the effect of MPC loading is insignificant in these MPC–TiO_2 composites.

In previous studies on supported gold catalysts employing MPCs, it was found that the catalytic activity could be greatly enhanced by removing the protecting ligands.[52–54] Electrochemical[55,56] and thermal[52,57] activation have been employed often to remove the protecting ligands. In Fig. S2A (Supplementary data), the TEM image of MPC–TiO_2 composites after calcination at 260 °C shows that the gold core size is unaltered from its initial size, and there are no detached gold clusters found on the grid. This is a promising result because it suggests that well-defined gold-modified TiO_2 nanocomposites can be prepared from MPCs through the thermal treatment. Whereas the size of gold in the nanocomposites maintained its initial size after calcination at 260 °C, the catalytic activity of the MPC–TiO_2 composite was considerably enhanced after calcination at 260 °C. As can be seen in Fig. 6 (line D), the degradation dramatically increases by more than 60% upon calcination at 260 °C. Furthermore, the results in Fig. 7 show that the photocatalytic activity of the calcined MPC–TiO_2 composites significantly increases with MPC loading; the Rh-590 degradation at 30 min is increased by more than 50% with 1 wt% MPC modification compared with the bare TiO_2. For 3 wt% MPC–TiO_2 composites, the Rh-590 degradation is completed within 25 min. The result that the photocatalytic activity can be conveniently controlled by the structural parameter (i.e., by MPC loading) of the composites clearly shows the advantage of the MPC–TiO_2 composites. Considering the degrada-

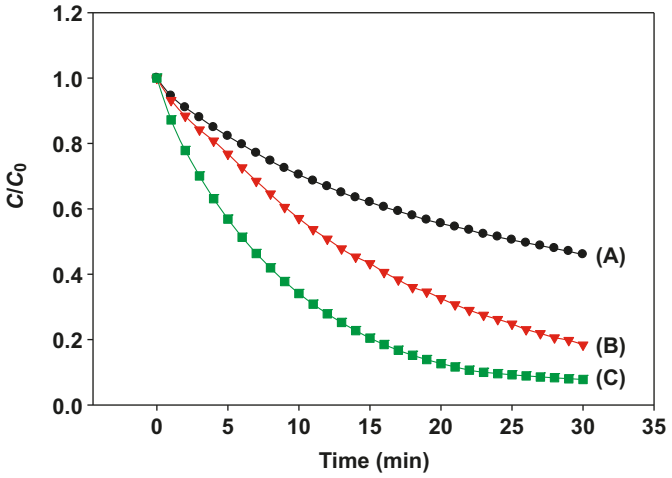
Fig. 7. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during the photocatalytic reaction with nanocomposites calcined at 260 °C: (A) bare TiO_2, (B) 1 wt% monolayer-protected gold cluster (MPC) – TiO_2, and (C) 3 wt% MPC–TiO_2.

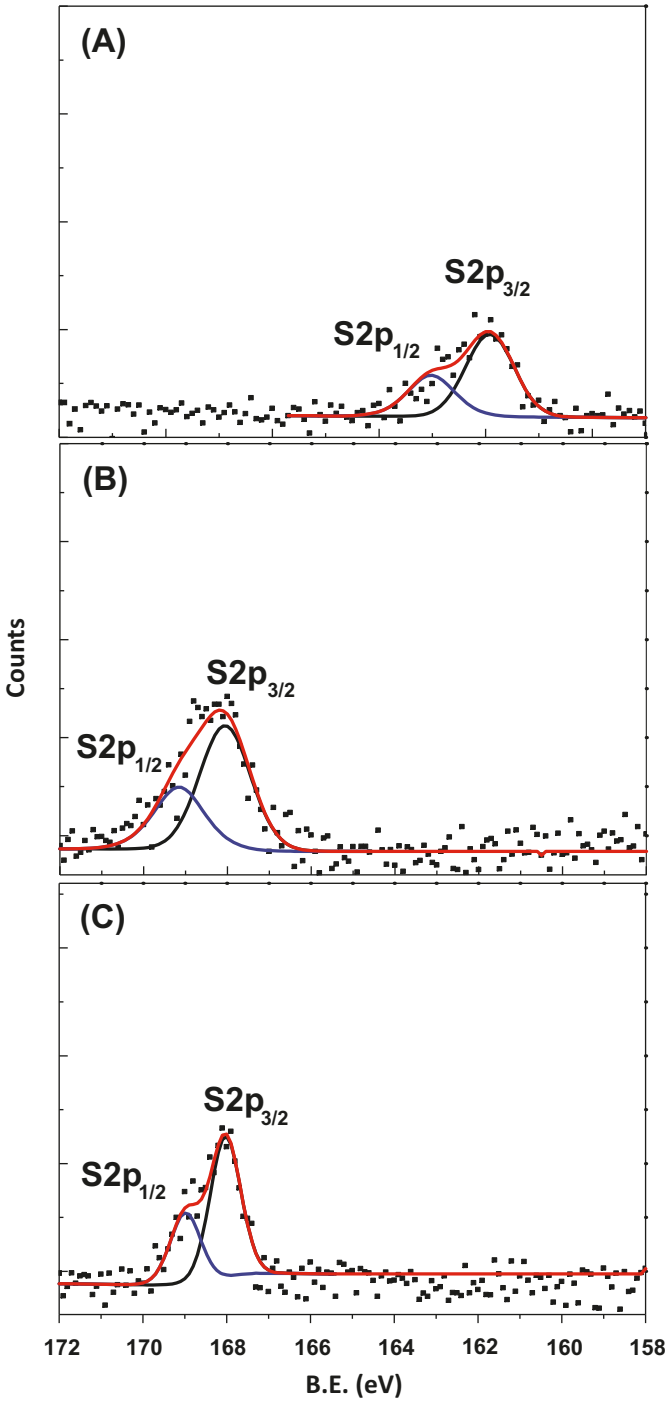


tion mechanism discussed earlier, the enhanced catalytic activity reflects the fact that more photoholes are generated in TiO_2–MPC composites calcined at 260 °C for Rh5-90 oxidation. Since TiO_2 itself exhibits the same catalytic activity after calcination at 260 °C (line A in Fig. 7), one can conclude that the enhanced catalytic activity is due to the enhanced charge separation in the presence of gold nanoparticles on TiO_2. The origin of the enhanced charge separation in the calcined composites is unclear, but it is likely that the electron transfer from TiO_2 to the gold core is significantly facilitated after calcination.

Since the photocatalytic activity of MPC–TiO_2 composites was considerably enhanced after the thermal treatment, the calcination temperature was raised to 400 °C to completely remove the ligands on the gold surface. Thermal treatment of TiO_2 at 500 °C resulted in a severe decrease in the catalytic activity, thus, the highest calcination temperature was limited to 400 °C at which the catalytic activity was maintained (line B in Fig. 6). The catalytic activities of 3 wt% MPC–TiO_2 composites calcined at 260 and 400 °C are compared in Fig. 6. Surprisingly, the catalytic activity of MPC–TiO_2 composites calcined at 400 °C decreased dramatically; the Rh-590 degradation was only 4% at 10 min and hardly increased with time. The TEM image of the composite in Fig. S2b (Supplementary data) shows that the average gold core diameter was considerably increased to 4.0 nm and that there were some detached gold particles observed, indicating significant loss of the protecting ligands after calcination at 400 °C.

XPS measurements of the MPC–TiO_2 composites were carried out to understand the drastically decreased catalytic activity after calcination at 400 °C. In Fig. 8, the sulfur S $2p_{3/2}$ BE value (162 eV) for the 3 wt% MPC–TiO_2 composite corresponds to bound thiolate, which is in agreement with previous reports.[58–60] When this composite was calcined at 260 °C, the 162 eV peak disappeared and a new peak arose at 168 eV. The 168 eV peak was assigned to the oxidized sulfur species.[59,61] When the temperature was raised to 400 °C, the 168 eV peak that corresponds to the oxidized sulfur

Fig. 8. XPS S 2p spectra of (A) monolayer-protected gold cluster (MPC) – TiO_2, (B) MPC–TiO_2 calcined at 260 °C, and (C) MPC–TiO_2 calcined at 400 °C.



species was observed as seen for MPC–TiO_2 composites calcined at 260 °C. The XPS results of the MPC–TiO_2 composites calcined at 260 and 400 °C are similar to each other and thus one may question the origin of the vastly different photocatalytic activity between them. It could be understood by the difference in TGA results between the two calcination temperatures (Fig. S3, Supplementary data). That is, sulfur could be oxidized at 260 °C, but it is rather unlikely that sulfur directly reacts with TiO_2 considering the remaining portion of

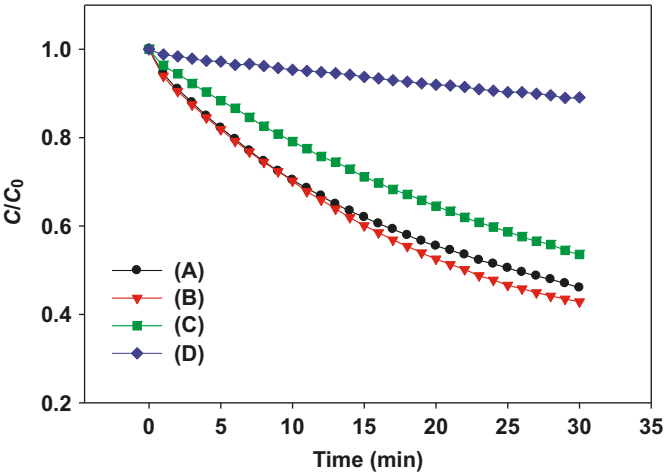
Fig. 9. Changes in Rhodamine 590 (Rh-590) concentration (C) relative to the initial concentration (C_0) during the photocatalytic reaction with (A) bare TiO_2, (B) tiopronin-coated TiO_2, (C) tiopronin-coated TiO_2 calcined at 260 °C, and (D) tiopronin-coated TiO_2 calcined at 400 °C.



the ligand (ca. 40%) in the calcined composite. We note that there is nonetheless some minor poisoning effect observed at 260 °C (see Fig. 9). On the other hand, as most of the ligands are decomposed and removed at 400 °C, sulfur may directly react with TiO_2 and leave deposits containing oxidized sulfur on the TiO_2 surface. Such deposits appear to be responsible for the drastic decrease in photocatalytic activity found in the MPC–TiO_2 composite calcined at 400 °C by presumably acting as active recombination centers for the photogenerated electrons and holes. It has been reported that sulfur species bound to surfaces of metal oxides such as CeO_2, Al_2O_3, Cu_2O, and ZnO can lead to a poisoning effect on the metal oxides.[62,63] It has been detailed in XPS studies that sulfur-containing species can react with metal oxide surfaces at elevated temperatures, leaving highly oxidized products such as sulfites or sulfates on these metal oxides. It is thus highly probable that sulfur on tiopronin directly reacts with TiO_2 at 400 °C and leaves deposits containing oxidized sulfur on the TiO_2 surface.

Effect of the ligand on photocatalytic activity

To confirm the sulfur poisoning scenario, TiO_2 nanoparticles were coated with tiopronin alone and their catalytic activities were examined after thermal treatment at 260 and 400 °C. The photocatalytic activities of tiopronin-coated TiO_2 before and after calcination at 260 and 400 °C are compared in Fig. 9. The tiopronin-coated TiO_2 before calcination shows similar photocatalytic activity to bare TiO_2, which suggests that the tiopronin ligands do not occupy the active sites on the TiO_2 surface and do not act as recombination centers. Compared with bare TiO_2, the Rh-590 degradation is decreased by ca. 15% after calcination at 260 °C, indicating some minor poisoning effect by the tiopronin ligands after calcination. It is interesting to note that the photocatalytic activity of the MPC–TiO_2 composites increases more than 60% after calcination at 260 °C. This contrasting result suggests that the catalytic activity is enhanced in the presence of gold even though the ligand poisoning effect is nontrivial when calcined at 260 °C, confirming the active role of gold in the photocatalysis. However, the catalytic activity of the tiopronin-coated TiO_2 decreased drastically when calcined at 400 °C as observed for the MPC–TiO_2 composite calcined at 400 °C. From this result, we conclude that the drastic decrease in catalytic activity observed for MPC–TiO_2 calcined at 400 °C can be ascribed to the ligand effect.

Conclusions

We have shown that well-defined nanocomposites could be prepared by modifying TiO_2 with bifunctional tiopronin-coated MPCs. In this method, the MPC size was unaltered during the anchoring process, and the MPC loading on TiO_2 could be precisely controlled by the experimental conditions. Mechanistic studies of Rh-590 degradation with the MPC–TiO_2 composites revealed that Rh-590 degradation occurs via the oxidative pathway by photogenerated holes in the composites. The photocatalytic activity of the MPC–TiO_2 composites was found to increase significantly upon calcination at 260 °C, whereas the size of gold particles was maintained at their initial size. When the calcination temperature was raised further to 400 °C, however, the photocatalytic activity of the composites drastically decreased. XPS analyses of the calcined composites showed that a significant amount of oxidized sulfur remains after calcination that appears to act as a recombination center for the photogenerated electrons and holes, leading to a drastic decrease in the photocatalytic activity. Whereas the MPC-modified composites clearly offer an improved method for the preparation of structurally well-defined photocatalysts, these results reveal the important role of ligands in the use of MPCs in supported photocatalysts.

Abstract: Noradrenaline is a neurotransmitter that is involved in various psychological processes. In the neurotransmission process, noradrenaline binds to an adrenergic receptor by forming a complex of hydrogen bonds between its two catechol ring hydroxyl groups and the amino acid residues of adrenergic receptors. Although the two catechol ring hydroxyl groups play a crucial role in making hydrogen bonds to the binding site of the adrenergic receptor, the contribution of the catechol ring hydroxyl groups to the intramolecular stability that may affect docking has not been fully studied. To reveal the specific role that the catechol ring hydroxyl groups might play in stabilizing noradrenaline, the quantum chemical computations of geometry optimization and thermodynamic functions of N-protonated noradrenaline conformers were performed at both the B3LYP/6–31G(d,p) and G3MP2B3 levels of theory, using the Gaussian 03 program. The results were compared with those of N-protonated β-hydroxy-β-phenylethylamine, which is identical to noradrenaline except it lacks two catechol ring hydroxyl groups. For the first time, post-Hartree–Fock computations were used to obtain thermodynamic functions to establish relative stabilities of all possible conformers of N-protonated noradrenaline. In this study, 18 distinct structures of N-protonated noradrenaline were revealed, and the catechol ring hydroxyl groups were found to affect noradrenaline stability positively or negatively depending on the conformational orientations. On the basis of available experimental results, the issue that the least stable conformation of two catechol ring hydroxyl groups may be involved in the docking process has been raised. These findings may be useful in synthesis of derivatives of noradrenaline in drug design.

Key words: noradrenaline, density functional calculations, thermodynamic functions, conformational stability, intramolecular hydrogen bond.

Résumé : La noradrénaline est un neurotransmetteur impliqué dans divers processus psychologiques. Dans le processus de neurotransmission, la noradrénaline se lie à un récepteur adrénergique par formation d'un complexe de liaisons hydrogènes entre les deux groupes hydroxyles de son noyau catéchol et les résidus d'acides aminés des récepteurs adrénergiques. Même si les groupes hydroxyles de son noyau catéchol jouent un rôle important dans la formation des liaisons hydrogènes avec le site de fixation du récepteur adrénergique, la contribution des groupes hydroxyles de son noyau catéchol à la stabilité intramoléculaire qui peut affecter l'arrimage n'a pas été complètement étudié. Afin d'évaluer le rôle spécifique que les groupes hydroxyles de son noyau catéchol peuvent jouer dans la stabilisation de la noradrénaline, on a effectué des calculs de chimie quantique d'optimisation de la géométrie et des fonctions thermodynamiques des conformères de la noradrénaline N-protonée, en faisant appel au programme « Gaussian 03 », aux niveaux B3LYP/6–31G(d,p) et G3MP2B3 de la théorie. Les résultats ont été comparés à ceux obtenus avec la β-hydroxy-β-phénylethylamine N-protonée, qui est identique à la noradrénaline à l'exception de l'absence des deux groupes hydroxyles du noyau catéchol. Des calculs post-Hartree–Fock ont donc été utilisés pour la première fois pour obtenir des fonctions thermodynamiques dans le but d'établir les stabilités relatives de tous les conformères possibles de la noradrénaline N-protonée. Dans cette étude, on a mis en évidence 18 structures distinctes de la noradrénaline N-protonée et on a trouvé que les groupes hydroxyles du noyau catéchol affectent la stabilité de la noradrénaline positivement ou négativement suivant les orientations conformationnelles. Sur la base des résultats expérimentaux

Introduction

A number of neurotransmitter systems, including noradrenaline, serotonin, and dopamine, are closely linked with various psychological processes, including mood regulation. Specifically, the dysfunction within noradrenaline system may lead to anxiety and mood disorders.[1–3] Neurotransmitters are released from a presynaptic cell and transmit the neural signal through successful docking to specific postsynaptic receptors, thus activating the downstream signaling pathway. In the process of docking noradrenaline to an adrenergic receptor, a complex network of hydrogen bonds is established between the catechol ring hydroxyl groups of noradrenaline and the residues of the binding site of the adrenergic receptor. The docking process through hydrogen bond formation occurs when the molecular orientation of noradrenaline is both conformationally and energetically favourable. Since the stable conformations are favoured, only a few relatively more stable conformers can be easily recognized by the adrenergic receptors.[4] Also, the molecular stability affects the ultimate degradation of the molecule.[5]

Noradrenaline is both a hormone and the simplest member of the catecholamine family of neurotransmitters. Noradrenaline contains two catechol ring hydroxyl groups, which allow flexibility of the catechol ring structure of noradrenaline with three different minimum-energy orientations.[6–8] The acidic OH protons of the catechol ring hydroxyl groups are involved in hydrogen bonding, for example, to the two serine residues of the α_{1a}-adrenergic receptors (*meta*-hydroxyl to Ser-188 and Ser-158 and *para*-hydroxyl to Ser-192) when docking.[9,10] Although the conformational landscape of noradrenaline has been characterized through ab initio computations,[6,11–13] and the intermolecular roles of the catechol ring hydroxyl group were previously studied,[11,14,15] the contribution of the catechol ring hydroxyl groups to the intrinsic intramolecular stability that may affect docking remains elusive. To address the role of the catechol ring hydroxyl groups in intramolecular stability, the quantum chemical computations of geometry optimization and thermodynamic functions of N-protonated noradrenaline conformers were performed and the results were compared with that of the model compound, N-protonated β-hydroxy-β-phenylethylamine,[16] which is identical to the noradrenaline except it lacks two catechol ring hydroxyl groups.

Scope

The first aim of this conformational study is to determine the preferred conformational structures of N-protonated noradrenaline by ab initio density functional theory (DFT) and G3-based quantum chemistry method (G3MP2B3) computation. The dihedral angles of N-protonated noradrenaline were defined (Fig. 1). The stable conformers are the minimum energy critical points of the potential energy hyper surface (eq. [1]) of five independent variables. Conformational analysis provides information about the energy change as a function of several variables as may be analyzed by the five cross sections passing through the global minimum as defined by eqs. [2]–[7].

where $E(\psi, \phi)$ is the potential energy surface (PES).

Two torsional modes (ψ and ϕ) determine the shape of the hydrocarbon backbone and χ specifies the orientation of the hydroxyl side chain from the backbone. The dihedrals ω and σ denote the orientation of the catechol ring hydroxyl groups. This research, in its first phase, focuses on the variation of the ψ, ϕ, and χ torsional angles to determine the relative stabilities of the various conformers existing on the potential energy surface. In general, the g^+, a, or g^- conformations are considered to be stable.

The dihedral angles were defined as follows: $\psi = C_2C_3$–C_4C_8, $\phi = N_1C_2$–C_3C_4, $\chi = C_2C_3$–$O_{12}H_{22}$, $\omega = C_{10}C_{16}$–$O_{19}H_{23}$, and $\sigma = C_8C_{10}$–$O_{18}H_{24}$ (Fig. 1). To explore the conformational space of N-protonated noradrenaline, the variation of the following dihedral angles were studied: ϕ and ψ equals *gauche*$^+$ (60°), *anti* (180°) and *gauche*$^-$ (–60°); χ equals *anti* (180°); and ω and σ could be at *syn* (0°) or *anti* (180°).

The second aim of this study was to investigate the role of the various combinations of the ω and σ dihedral angles of the catechol ring hydroxyl groups that may modulate the intrinsic stability of the various side-chain conformations.

Methods

Each conformer was first optimized using the ab initio[17] restricted Hartree–Fock (RHF)[18] method and the standard split valence 3–21G basis set[19–21] incorporated in the Gaussian 03 (G03) program package.[22] Total and relative energies are tabulated in the Supplementary data (Table S1). The RHF/3–21G full geometry optimized structural parameters of conformers of N-protonated noradrenaline were used as input for a full geometry optimization and subsequent calculation of total and relative energies at the B3LYP/6–31G(d,p) level of theory.[23,24] Total and relative energies are tabulated in the Supplementary data (Table S2).

The G3-based quantum chemistry method (G3MP2B3) was employed to produce even more reliable relative energies of each geometry optimized conformer at the B3LYP/6–31G (d,p) level of theory. G3MP2B3,[25–27] denoting the Gaussian-3 based (G3) Møller–Plesset second-order (MP2) method in combination with the 6–31G(d) basis set, level of theory was used in this phase. Total and relative energies are tabulated in the Supplementary data (Table S2). The frequencies and intensities of N-protonated noradrenaline conformers were computed at the B3LYP/6–31G(d,p) and G3MP2B3 levels of theory to verify their conformations as being true minima. The frequencies and intensities of selected conformers are tabulated and graphed in the Supplementary data (Table S3 and Fig. S1, respectively).

The thermodynamic functional changes of thermally corrected energy (ΔU), enthalpy (ΔH), Gibbs free energy (ΔG), and entropy (ΔS) were calculated from the computed U, H, G, and S values obtained for the optimized conformations (Supplementary data Table S4). All the computations were carried out using the G03 program package.[22]

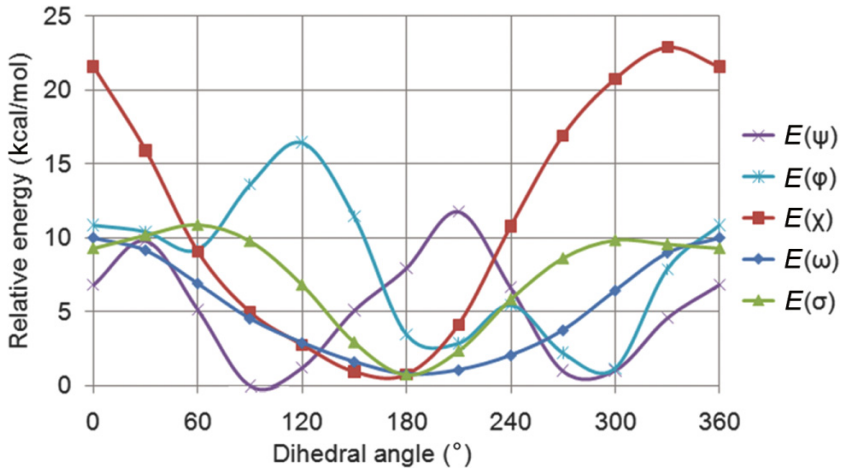
Fig. 4. Single variable cross sections of the potential energy hyper surface (PEHS) demonstrating the relative energy change with respect to the changes in different dihedral angles (ψ, φ, χ, ω, and σ) from the global minimum ($\psi = g^+$, $\varphi = g^-$, $\chi = a$, $\omega = a$, and $\sigma = a$). The points were computed at the B3LYP/6–31G(d,p) level of theory. These functions correspond to eqs. [2]–[6].



type of bonds at both sides of the equation. Consequently, their relative energy, enthalpy, or Gibbs free energy show which side of the equation is more stable. In this study, the isodesmic equation (Fig. 2) was used to assess the stabilizing or destabilizing effect of the two acidic OH groups in the catechol ring.

Results and discussion

Dihydroxytoluene

To determine the total and relative energies of N-protonated noradrenaline conformers depending on the orientation of catechol ring hydroxyl groups, the geometry optimizations of four different conformations of a model molecule (3,4-dihydroxytoluene, Fig. 3) were performed. Two possible catechol OH orientations ([*a a*] and [*s s*]) have internal hydrogen bonds, whereas the [*a s*] conformer lacks an intramolecular hydrogen bond. The [*s a*] orientation does not exist because of steric interactions.[7,8] The global energy minimum was the [*a a*] conformation (Table 1).

Relative thermodynamic functions of the three stable structures of 3,4-dihydroxytoluene (Table 1) and *U*, *H*, *G*, and *S* values (Supplementary data Table S5) were computed for later comparisons to that of N-protonated noradrenaline.

Conformation of N-protonated noradrenaline

In the study of N-protonated noradrenaline, five dihedral angles (ψ, ϕ, χ, ω, and σ) were examined to assess the free conformational space. A previous publication established the global minimum of the backbone and the side chain to be [g^+ g^- *a*],[16] where the study of 3,4-dihydroxytoluene determined the global minimum of the catechol ring hydroxyl groups to be in [*a a*] conformation. Therefore, five different 1-D cross sections were taken across [g^+ g^- a][*a a*] (Fig. 4). The total and relative energies of all five cross sections according to eqs. [2]–[6] are tabulated in Supplementary data Table S6.

The rotation about χ yields a single minimum (Fig. 4) corresponding to an *anti* orientation, consistent with previous literature.[16] On the other hand, the rotation about ω and σ yields one minimum and two minima, respectively, corresponding to both at *anti* or *syn* conformation, or pointing away from each other (one at *anti* and another at *syn*). Although the $E(\omega)$ function may exhibit two minima in a case of σ at *syn*, ω may assume *anti* orientation only where σ is already at *anti* conformation. The *R* configuration is used for the asymmetric α-carbon in all the conformers of N-protonated noradrenaline. The geometrical and energetic parameters, optimized at the B3LYP/6–31G(d,p) and G3MP2B3 levels of theory, were compiled (Supplementary data Table S2). The computations at the B3LYP/6–31G(d,p) and G3MP2B3 levels of theory yielded similar results. Since the geometries for the G3MP2B3 and B3LYP calculations were optimized using the 6–31G(d) and 6–31G(d,p) basis sets, respectively, this extra p-type polarization functions in the B3LYP calculations resulted in a small deviation between

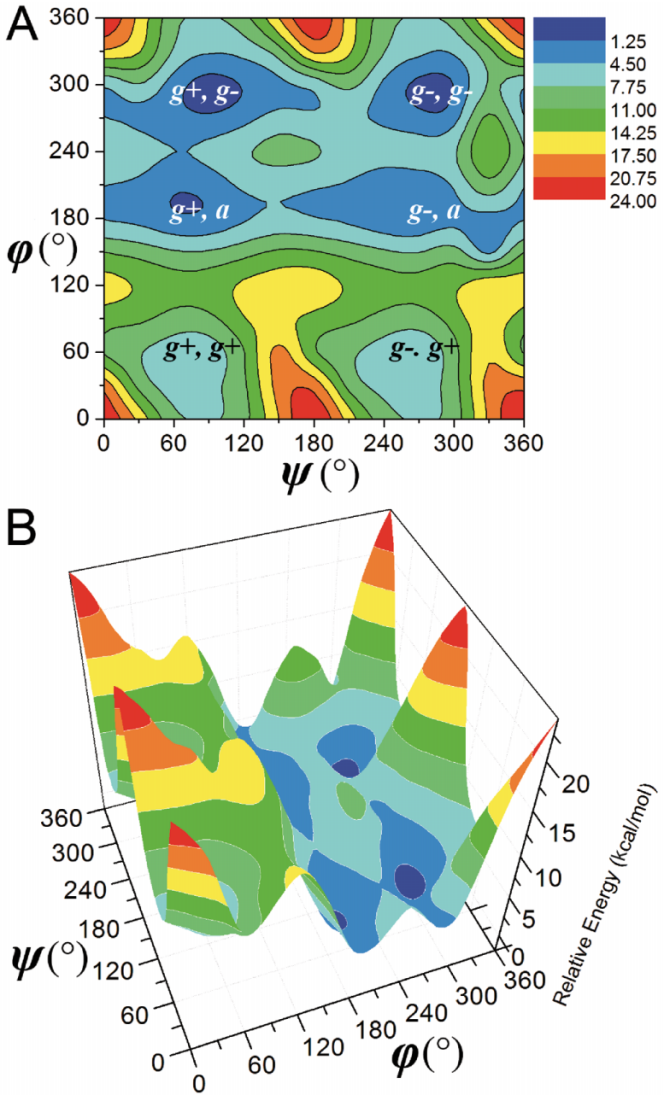
Fig. 5. (A) The contour energy map of N-protonated noradrenaline computed at the B3LYP/6–31G(d,p) level of theory with respect to changes in ψ and φ (χ, ω, and σ fixed at the *anti* position). (B) The potential energy surface (PES) cross section of the potential energy hyper surface (PEHS) associated with N-protonated noradrenaline computed at the B3LYP/6–31G(d,p) level of theory with respect to changes in ψ and φ (χ, ω, and σ fixed at the *anti* position). This 2-D cross section corresponds to eq. [7]. The energy minima are indicated with the ψ and φ conformations.



the two sets of dihedral angles. The computed results are presented using a PES cross section (Fig. 5). Having the three dihedrals (χ, ω, and σ) fixed at their corresponding lowest minimum orientation, the anticipated PEHS was simplified to a 2-D cross section (eq. [7]. This PES shows six minima (m) ($m_\psi \times m_\phi \times m_\chi = 2 \times 3 \times 1$; the same results were obtained from the N-PβHβPEA).[16] Combining all the possible orientations of the N-PβHβPEA[16] and the catechol ring hydroxyl groups (N) ($N_{[\psi\ \phi\ \chi]} \times N_{[\omega\ \sigma]} = 6 \times 3$), 18 molecular structures of N-protonated noradrenaline were constructed and the dipole moment variation of the these structures were summarized (Fig. 6 and Supplementary data Fig. S2). With the introduction of the catechol ring hydroxyl groups, the total dipole moment values, as well as their components, became slightly larger, but did not make a significant alteration in the trend from the dipole moment values of N-PβHβPEA.[16]

The optimized geometries revealed differences in the two phenolic C–O bond lengths from the various conformers of N-protonated noradrenaline as well as their shrinkages with respect to 3,4-dihydroxytoluene (Supplementary data Table S7). The two catechol ring hydroxyl groups differed in not only meta or para location, but also in their involvement in their hydrogen bonding. In the [*a s*] conformations, there is no hydrogen bonding, therefore, the two phenolic C–O bond lengths are roughly the same. However, in the [*a a*] and [*s s*] conformations, one of the catechol ring hydroxyl groups is a proton donor and the other one is a proton acceptor; the proton-donating phenolic OH had a shorter C–O bond length of 1.365 Å, whereas the proton-accepting phenolic OH had a longer C–O bond length of 1.380 Å. The C–O bond length differences were in the vicinity of 0.015 Å or 1.5 pm (Fig. 7). The shorter C–O bond length indicates strong conjugativity between the oxygen atom and the benzene ring.

Thermodynamic functions

To examine the molecular stability of noradrenaline in the 18 molecular structures, the thermodynamic functions and ΔU for the conformers of N-protonated noradrenaline at two levels of theory were computed and summarized (Supplementary data Tables S4 and S8, respectively). Their relative values are given (Table 2), showing ΔH, ΔG, and ΔS for each conformer of N-protonated noradrenaline. The ΔS for N-protonated noradrenaline was always positive compared with the entropy of the lowest energy conformation [g^+ g^- *a*] [*a a*] except for the [g^- g^- *a*][*a s*] orientation. Also, the ΔG values were significantly higher in the [*a s*] orientation for ω and σ than in the [*a a*] and [*s s*] orientations.

The distribution of the conformational ΔG values for N-protonated noradrenaline (labeled as ΔG_{NA}) was plotted as a function of the previously reported ΔG values of the dehydroxylated model compound, N-PβHβPEA[16] (labeled as ΔG_M) (Fig. 8). The three sets of catechol ring OH orientation [*a a*], [*a s*], and [*s s*] fall into three clusters. In each cluster, the [g^+ g^+ *a*] and [g^- g^+ *a*] conformers had higher ΔG values than the other conformers. The four lowest free energy conformers of the [*a s*] cluster had similar ΔG values (~6 kcal) to the highest free energy conformers of the [*a a*] and [*s s*] clusters.

Conformations 1, 7, and 13 were the highest points for $\psi = g^+$ (Fig. 8). Most of the plot lines for each cluster were close to the 45° identity line except two of those that end with conformations 7 and 13. For $\psi = g^+$, the [*s s*] and [*a s*] conformation lines were shifted up by ~2 and 6 kcal/mol (1 cal = 4.184 J), respectively, in comparison with the [*a a*] conformation. Nevertheless, conformers 7 and 13 had back-stabilization by 1.18 and 1.58 kcal/mol, respectively. Note that the 2 and 6 kcal/mol up shift of the two lines were due to the ineffectiveness of the phenolic OH hydrogen bonds of the catechol ring. These values did not deviate much from the 1.32 and 4.37 kcal/mol observed in the case of 3,4-dihydroxytoluene (Table 1). However, the back-stabilization may be due to some favourable electron distribution that occurs in conformers 7 and 13. The 0.018 Å shortening of the C–O bond length, while others were shortened only by 0.016 or

Fig. 6. Three prominent conformations (conformation Nos. 3, 9, and 15) of N-protonated noradrenaline and dipole moments (*X*, *Y*, *Z*, and total) of each conformer and model compound (in the first column), computed at the G3MP2B3 level of theory. Each dipole moment is measured in Debye, field-independent basis, and its origin is located at the center of mass, since dipole moments of charged species are not coordinate independent (see Supplementary data Fig. S2 for all the 18 structures).

0.017 Å, also supports the notion that the oxygen lone pairs are slightly more extensively involved in stabilization (Supplementary data Table S7).

The correlation of the two μ_x components (Fig. 9) demonstrates that such a dipole moment increases upon the entrance of the two OH groups into the benzene ring. Therefore, it does appear that the back-stabilization of conformers 7 and 13 indicates a slightly more effective conjugative stabilization, involving the lone pair of the *para*-phenolic OH group and the benzene π system.

Isodesmic reaction

To assess the stabilizing or destabilizing effect of the two phenolic OH groups in the catechol ring, any thermodynamic function (Z) may be calculated for the isodesmic reaction (shown in Fig. 10) using eq. [8].

$$[8] \quad \Delta Z_{\mathrm{I}} = Z_{\mathrm{products}} - Z_{\mathrm{reactants}} = (Z_{\mathrm{NA}} + Z_{\mathrm{toluene}}) - (Z_{\mathrm{N\text{-}P\beta H\beta PEA}} + Z_{\mathrm{3,4\text{-}dihydroxytoluene}})$$

The contribution to the thermodynamic functions owing to hydrogen bonding (HB) is calculated by eqs. [9]–[11] with respect to the most stable [*a a*] phenolic OH orientation.

$$[9] \quad \Delta\Delta H_{\mathrm{HB}} = [\Delta H_{\mathrm{NA}} - \Delta H_{\mathrm{M}}] - \Delta\Delta H_{\mathrm{I}}$$

$$[10] \quad \Delta\Delta G_{\mathrm{HB}} = [\Delta G_{\mathrm{NA}} - \Delta G_{\mathrm{M}}] - \Delta\Delta G_{\mathrm{I}}$$

$$[11] \quad \Delta\Delta S_{\mathrm{HB}} = [\Delta S_{\mathrm{NA}} - \Delta S_{\mathrm{M}}] - \Delta\Delta S_{\mathrm{I}}$$

The computed relative HB values (eqs. [9]–[11]) obtained for N-protonated noradrenaline (Supplementary data Table S9) are in fact identical to those obtained for 3,4-dihydroxytoluene (Table 1). The various thermodynamic value differences of the conformations of N-protonated noradrenaline and N-PβHβPEA[16] compared with the corresponding global minimum conformation and between reactants and products in the isodesmic reaction are computed (Supplementary data Table S9). The Gibbs free energies of N-PβHβPEA[16], 3,4-dihydroxytoluene, N-protonated noradrenaline, and toluene and the added Gibbs free energies of reactants and products were also tabulated (Supplementary data Table S10).

The Born–Haber cycle for the two selected conformer pairs ([g^+ g^+ a] (conformer A) and [g^+ g^- a] (conformer B)) were graphed with molecular schematics of the isodesmic reactions (Fig. 10). The pair of phenolic hydroxyl groups was incorporated in the [*a s*] orientation. The ΔG during the isodesmic reaction differs between conformer A and conformer B, with ΔG_{I} values of –2.10 and –0.89 kcal/mol, respectively. This difference suggests that the intramolecular stabilization caused by the catechol ring hydroxyl groups is greater in the absence of the electrostatic internal hydrogen bond between the hydroxyl group on the backbone and the amine group (HO–HN) as in conformer A than in its presence as in conformer B, where the ΔG_{I} for the isodesmic reaction is negligible (–0.89 kcal/mol). A similar difference is observed between the same conformers with the phenolic hydroxyl groups in the [*s s*] orientation.

For all the conformers of N-protonated noradrenaline, the [g^- g^+ a] and [g^+ g^+ a] conformations of the [ψ, φ, χ] dihedral angles resulted in much higher change in G than any other conformations. Out of all the conformers, [*a s*] conformers of the [ω σ] dihedral angles had considerably higher changes in G than any other conformations. According to the isodesmic reaction, the catechol ring hydroxyl groups were stabilizing in conformations 13 ([g^+ g^+ a][*s s*]) and 18 ([g^- g^- a][*s s*]) only in relation to lowest energy conformation 3 ([g^+ g^- a][*a a*]). Since their $\Delta\Delta G_{\mathrm{I}}$ values were negative, and the $\Delta\Delta G_{\mathrm{I}}$ values for all the other conformers were

Fig. 8. Comparison plots of Gibbs free energy differences (ΔG) for the conformations of N-protonated noradrenaline (NA) and dehydroxylated model compound (M, N-PβHβPEA), computed at the G3MP2B3 level of theory. The ΔG values are compiled in Supplementary data Table S9). Reference lines, starting at the ΔG values of [g^+ g^- a] and [g^- g^- a] conformers (leftmost points in each cluster), are drawn to verify the effect of the catechol ring hydroxyl groups for NA. Also, the difference between the highest energy of each orientation of the catechol ring hydroxyl groups and the energy gained from each reference line are calculated to demonstrate the stabilizing effect of the catechol ring hydroxyl groups. The ΔG_M values are taken from Lee et al.[16]

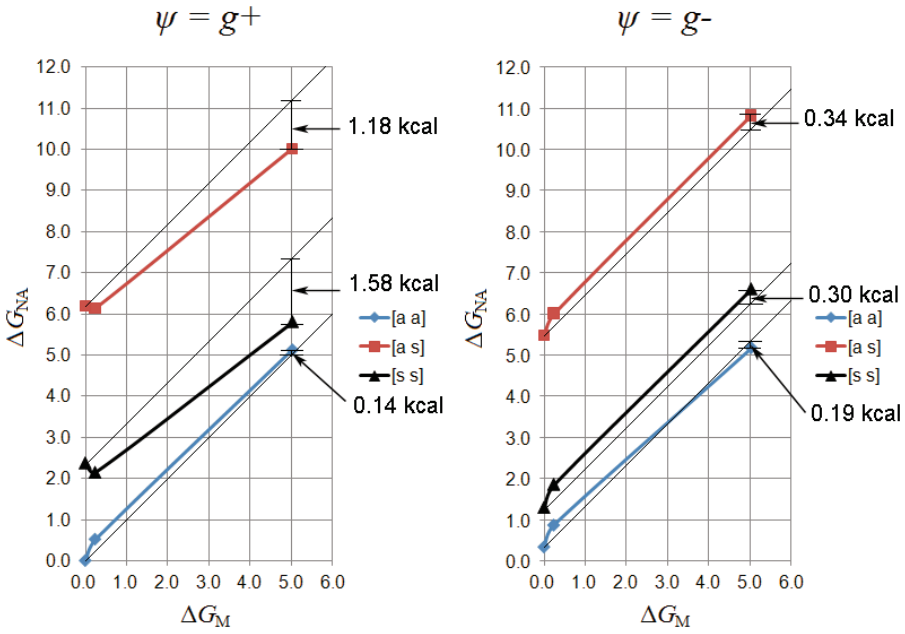

Fig. 9. The x-axis dipole moment (μ_x) comparison between the conformations of N-protonated noradrenaline (NA) and the conformations of dehydroxylated model compound (M, N-PβHβPEA), computed at the G3MP2B3 level of theory. A correlation (line of best fit) is steeper ($m > 1$) than the reference line ($m = 1$). The μ_x (M) values are taken from Lee et al.[16]

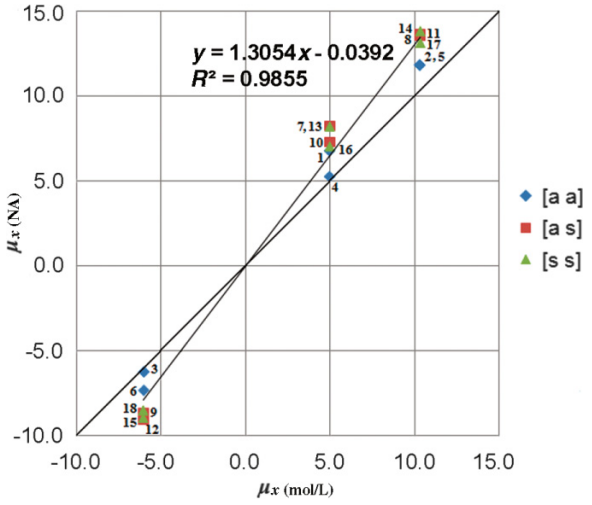


positive, the straight line obtained for four out of the six conformers in each of the three clusters (i.e., [a a], [a s], and [s s]) (Fig. 11) indicates that, with an increase in $\Delta\Delta G_I$ values, the conformational ΔG_{NA} values also increase proportionally. Note that the tangents do not differ much from unity.

Of the three possible orientations of the two catechol ring hydroxyl groups, it appears that the [a s] conformation is the least stable, lacking the internal hydrogen bond. Consequently, it is conceivable that this arrangement may form the hydrogen-bonded complexes at the two serine residues of the adrenergic receptor (Fig. 12). Although the minimum energy orientation of the phenolic OH groups in the catechol moiety is co-planar with the benzene ring, a slight distortion from the co-planarity can be seen[10] as it requires less energy than that gained from forming a hydrogen bond complex with a serine OH.

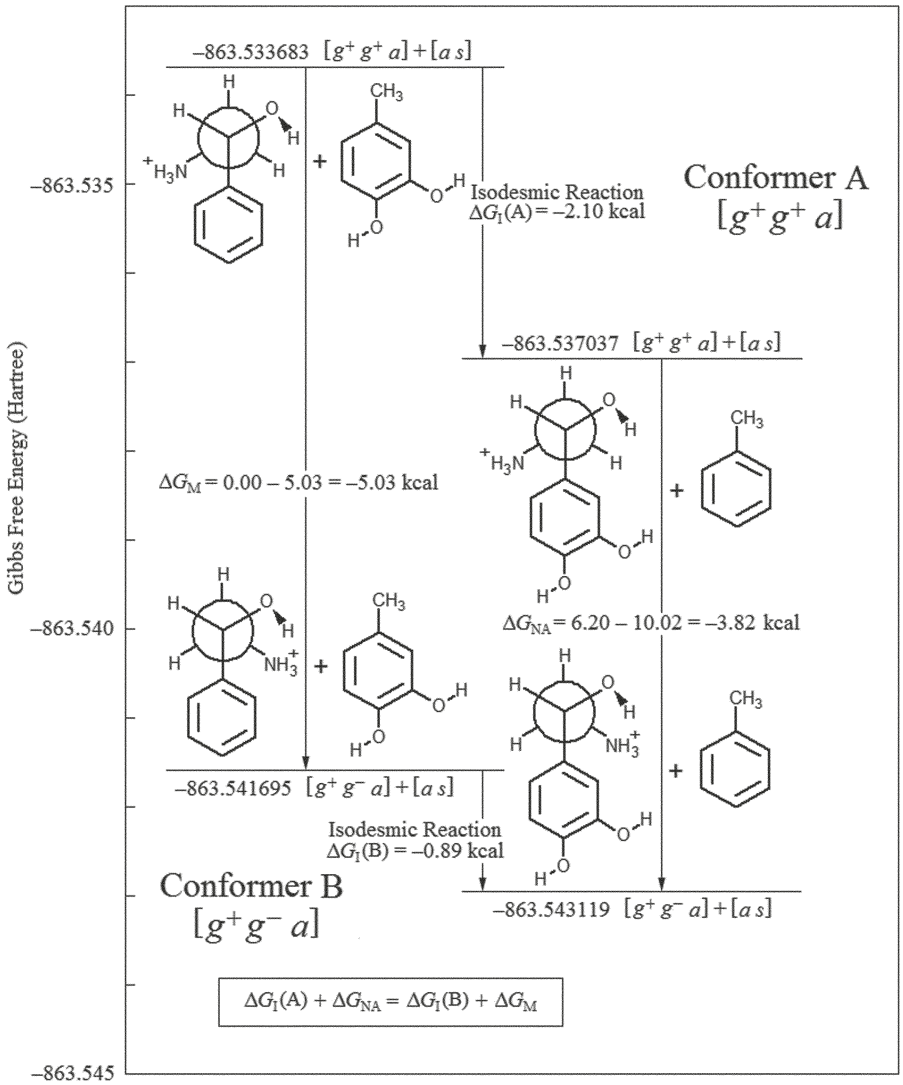
The nature of the hydrogen bonding of the catechol ring hydroxyl groups has been considered previously.[6,7,9–13] Because of the greater stability of [a a] orientation, it seemed logical to consider that the [a a] conformation is the prime candidate in the docking process of noradrenaline. Alternatively, the possibility does exist that the most stable [a a] conformation may convert to the least stable [a s] conformation (Fig. 12), but this would only be possible if new hydrogen bonds to the serine residues would compensate this docking process energetically. Either some exothermicity or at least thermoneutrality would be observed as a result of the docking process of noradrenaline to the adrenergic receptor.

Needless to say, the side chain conformation of noradrenaline molecule also plays the significant role in the docking process.[10,12] However, this paper focuses the attention to the conformation of the catechol ring hydroxyl groups.

Conclusions

The geometry optimization revealed the existence of three orientations for the catechol hydroxyl groups and six confor-

Fig. 10. Gibbs free energy (G) of a Born–Haber cycle for an isodesmic reaction with catechol ring hydroxyl groups in an [a s] conformation involving two conformers ([g^+ g^+ a] and [g^+ g^- a]; see Supplementary data Tables S9 and S10 for relative G values of the isodesmic reaction and calculated G values of the conformers, respectively). The results indicate that the incorporation of the two phenolic OH groups affects the conformational stability in a different extent.



mations for the side chain of N-protonated noradrenaline, which resulted in $N_{[\omega\ \sigma]} \times N_{[\psi\ \phi\ \chi]} = 3 \times 6 = 18$ distinctly different structures. Thermodynamic functions revealed that the energetics are about the same as what might have been predicted on the basis of 3,4-dihydroxytoluene and N-protonated β-hydroxy-β-phenylethylamine[16] for 12 conformers ($N_{[\omega\ \sigma]} \times N_{[g+\ a\ a]\text{ and }[g+\ g-\ a]\text{ and }[g-\ a\ a]\text{ and }[g-\ g-\ a]} = 3 \times 4$). However, six conformers ($N_{[\omega\ \sigma]} \times N_{[g+\ g+\ a]\text{ and }[g-\ g+\ a]} = 3 \times 2$) showed some noticeable destabilization where, in two cases, the destabilization was partially compensated because of conjugative stabilization between the *para*-phenolic hydroxyl lone pair and the benzene ring. These were structure 7, i.e., [g^+ g^+ a][a s], and structure 13, i.e., [g^+ g^+ a][s s]. The issue has also been raised that the least stable conformers, i.e., [a s], may be involved in the docking process to the adrenergic receptor, and the energy requirement would need to be compensated for by the new hydrogen bonds forming in the complex.

Abstract: This minireview focuses on diffusion NMR studies in bicelles. Following a discourse on diffusion fundamentals, and a comparative overview of fluorescence and NMR-based techniques for measuring diffusion, the pulsed field gradient (PFG) NMR diffusion method is introduced, emphasizing its specific advantages and limitations when applied to diffusion measurements in macroscopically oriented lamellar systems such as magnetically aligned bicelles. The utility of PFG NMR diffusion measurements in bicellar model membrane systems for examining lateral diffusion of membrane-bound molecular species is demonstrated, along with certain features of lateral diffusion that such studies illuminate. Further, those aspects of bicelle morphology that have been resolved using PFG NMR diffusion studies of various molecular weight soluble polymeric species are reviewed. The discussion concludes with an outline of future prospects for diffusion NMR studies in bicelles.

Key words: pulsed field gradient NMR, lateral diffusion, diffusion anisotropy, bicelle, PEGylated lipid, mixed bicelle model, pore size.

Résumé : Cette courte revue est focalisée sur les études par RMN de la diffusion dans les bicelles. Après une introduction sur les principes fondamentaux de la diffusion et un exposé général comparatif des techniques de mesure de la diffusion à base de fluorescence et de RMN, on introduit la méthode d'étude de la diffusion par RMN avec gradient du champ pulsé (GCP), en mettant en relief ses avantages et ses limitations spécifiques quand elle est appliquée à des mesures de diffusion dans des systèmes lamellaires macroscopiquement orientés, telles des bicelles magnétiquement alignées. On démontre l'utilité des mesures de diffusion par RMN/GCP dans des systèmes modèles de membranes bicellaires pour la détermination de la diffusion latérale d'espèces moléculaires liées à la membrane ainsi que pour la détermination de certaines caractéristiques de diffusion latérale sur lesquelles ces études jettent de la lumière. De plus, on passe en revue les aspects de la morphologie de bicelles qui ont été résolus à l'aide d'études de diffusion par RMN/GCP pour diverses espèces polymères solubles de poids moléculaires variés. La discussion se conclut par un synopsis des applications potentielles dans le futur des études par RMN de la diffusion dans des micelles.

Mots-clés : RMN avec gradient de champ pulsé, diffusion latérale, anisotropie de diffusion, bicelle, dérivés lipidiques du polyéthylèneglycol, modèle de bicelle mixte, taille des pores.

[Traduit par la Rédaction]

Introduction

Bicelles, or bilayered micelles, are model membranes widely employed as biomembrane mimics for NMR studies of membrane-associating biomolecules,[1–6] and as an orienting medium for NMR structural studies of soluble proteins and nucleic acids.[7–10] Their enduring popularity, evident from the many reviews describing their properties and uses,[11–22] stems in large part from their propensity to align in a magnetic field, and the enhanced NMR spectral resolution thus engendered.

Bicelles consist of mixtures of short-chain and long-chain amphiphiles,[23,24] as typified by the canonical mixture of dihexanoyl phosphatidylcholine (DHPC) and dimyristoyl phosphatidylcholine (DMPC) (see Fig. 1 for structures) introduced by Sanders and Shwonek.[25] In water, DMPC by itself assembles into extended lamellar bilayer sheets, whereas DHPC by itself prefers a micellar structure. Mixtures of the two, however, form single-bilayer thickness, DMPC-rich lamellae stabilized by a DHPC-rich coating at edge regions. Because bicelles are a soft material, fabricated through molecular self-assembly, they exhibit a rich, sometimes bedeviling, morphological plasticity, subject to influence by both environmental and compositional factors.

In the quest to more fully understand bicelle morphology a multitude of physical measurements have been brought to

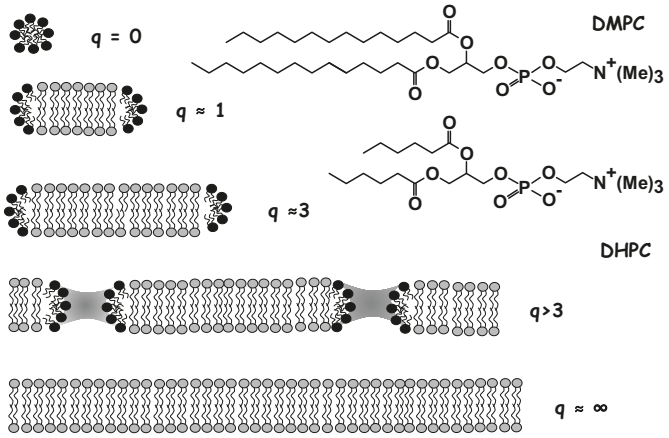
Fig. 1. Schematic of the morphological evolution of bicellar self-assemblies as a function of the molar ratio q = DMPC/DHPC. Pure dihexanoyl phosphatidylcholine (DHPC; black) forms micelles, whereas pure dimyristoyl phosphatidylcholine (DMPC; gray) forms lamellae. Mixtures of the two form disks at low q, or perforated lamellae at higher q, with DHPC occupying curved edge regions while DMPC forms a planar bilayer.



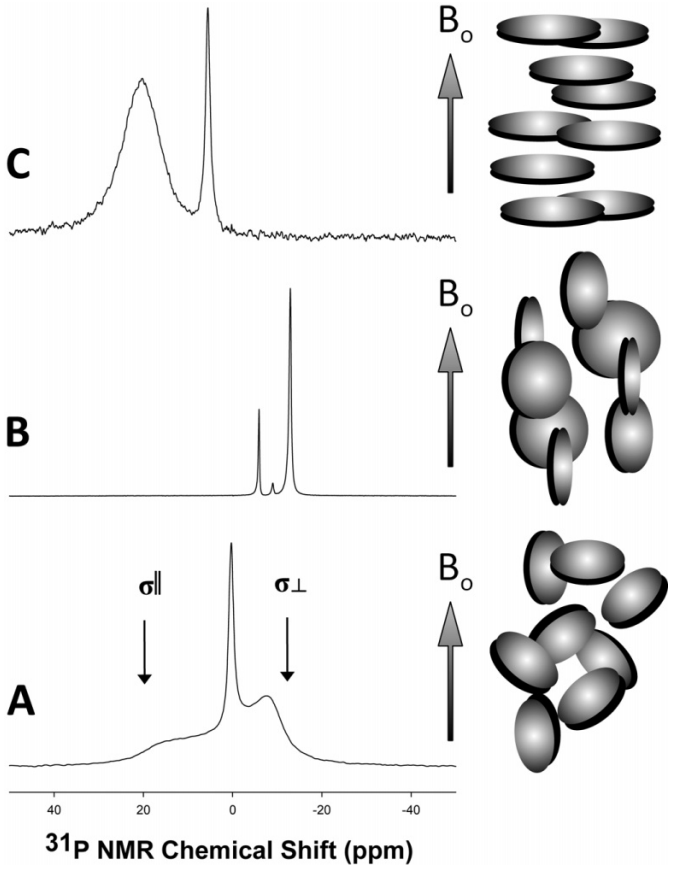
bear. These include electron microscopy (EM),[26–28] fluorescence spectroscopy,[29] NMR,[30–33] small angle X-ray scattering (SAXS),[34] and small angle neutron scattering (SANS).[18,34–39] From such studies, two of the major influences have been identified as being (*i*) the molar ratio (q) of long-chain to short-chain amphiphiles and (*ii*) temperature. Figure 1 illustrates schematically the general consensus that has emerged regarding the effects of q on bicelle morphology. At low q, bicelles adopt a discoidal morphology with DHPC occupying the edges of a DMPC-rich bilayer disk, as per the "ideal" bicelle model.[40] At higher q, the morphology evolves to a lamellar structure far larger in dimension than contemplated by the ideal bicelle model, and presumed to contain perforations stabilized by a coating of DHPC at the edges.

An NMR spectrum obtained from a bicelle sample will be influenced both by any residual anisotropic, i.e., orientation-dependent, interactions such as the chemical shift, or quadrupolar or dipolar interactions, which are present, and by the distribution of orientations across the sample. For example, as illustrated in Fig. 2, at temperatures below the DMPC gel-to-liquid-crystalline phase transition ($T_m \sim 25$ °C), bicelles cannot magnetically align, so there is a random distribution of bicelle orientations. Consequently, the ^{31}P NMR spectrum from DMPC consists of a broad resonance having a width ($\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$) that reflects the size of the residual ^{31}P chemical shift anisotropy difference between the extrema for perpendicular ($\sigma_{\perp}$) and parallel ($\sigma_{\parallel}$) alignments of the bilayer normal relative to the direction of the magnetic field.

The line shape itself reflects the powder, i.e., random, probability distribution of bicelle orientations between those same extrema. Since DHPC is small, remains highly mobile, and favours regions of high curvature, it experiences effectively isotropic motional averaging under the identical conditions, and thus exhibits an isotropically narrow ^{31}P NMR resonance.

When the temperature is raised above the T_m of DMPC, the increased flexibility of the self-assemblies permits their reorganization, and magnetic alignment of bicelles becomes

Fig. 2. Magnetic alignment of bicelles and corresponding ^{31}P NMR spectra. (A) At temperatures below the the DMPC gel-to-liquid-crystalline phase transition (T_m) of dimyristoyl phosphatidylcholine (DMPC), bicelles do not magnetically align, thus yielding a powder pattern ^{31}P NMR spectrum for DMPC, with a width defined by the residual chemical anisotropy elements ($\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$). Dihexanoyl phosphatidylcholine (DHPC) exhibits $\Delta\sigma = 0$ owing to its segregation into highly curved edge regions. (B) At $T > T_m$, spontaneous negative magnetic alignment can occur, wherein the normal to the bicellar planar bilayer regions are uniformly aligned perpendicular to the direction of the static magnetic field. Consequently, DMPC exhibits a ^{31}P NMR resonance at $\sigma_{\perp}$, whereas DHPC exhibits a frequency reflecting its equilibrium distribution between bilayer and edge regions. The smallest resonance visible is due to 1 mol% dimyristoylphosphatidylglycerol (DMPG), included to enhance stability. (C) Addition of lanthanides, such as Yb^{3+}, induces positive magnetic alignment, wherein the normal to the bicellar planar bilayer regions are uniformly aligned parallel to the direction of the static magnetic field. Consequently, DMPC exhibits a ^{31}P NMR resonance at $\sigma_{\parallel}$. The paramagnetic Yb^{3+} ions also cause NMR line broadening. Spectrum (B) was adapted from Soong and Macdonald.[41] Spectra (A) and (C) were provided courtesy of H. Morales.[42]



possible. The driving force is the interaction between the magnetic field and the magnetic susceptibility anisotropy of the bicelles, aided by cooperative interactions between adjacent bicellar lamellae that dampen thermal fluctuations.[43] The magnetic susceptibility anisotropy per unit volume is the sum of contributions from the individual lipids. This being a negative quantity for DMPC, the bicelles align spontaneously such that the normal to the plane of the bilayer is perpendicular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

to the direction of the magnetic field — the so-called negative magnetic alignment. Consequently, the ^{31}P NMR resonance from DMPC now consists of a narrow resonance, reflecting the narrow distribution of bilayer orientations under magnetic alignment, but at a frequency ($\sigma_\perp$) that still reflects the size of the residual ^{31}P chemical shift anisotropy for the perpendicular alignment. It is this combination of properties — enhanced spectral resolution while manifesting orientation-dependent interactions — that have made bicelles so attractive for NMR structural studies.

As first reported by Prosser et al.,[44–47] in the presence of surface-bound lanthanides having a positive magnetic susceptibility, examples being Tm^{3+}, Yb^{3+}, Er^{3+}, and Eu^{3+}, the direction of bicelle alignment is such that the normal to the planar lipid bilayer region lies parallel to the direction of the magnetic field — the so-called positive magnetic alignment shown schematically in Fig. 2. The corresponding ^{31}P NMR spectrum, likewise shown in Fig. 2, exhibits a narrow DMPC resonance at a frequency equal to $\sigma_\parallel$. Positive magnetic alignment of bicelles may also be achieved by incorporating phosphatidylcholines containing a biphenyl group,[48–50] peptides having phenyl ring side chains,[51] or membrane-associating aromatic amphiphiles.[52] Positively magnetically aligned bicelles are particularly useful for solid-state NMR studies of membrane proteins.

Despite these many studies, controversy persists and new aspects of bicelle morphology continue to emerge. Recently, for example, using SANS, the morphology of the magnetically alignable nematic phase of DMPC/DHPC bicelles was shown to consist of single-bilayer-thickness ribbonlike aggregates,[37,38] a result confirmed by cryo-TEM.[27] However, when the negatively charged phospholipid dimyristoylphosphatidylglycerol (DMPG) was added to such mixtures, a smectic phase was observed by SANS.[35] A smectic phase is also observed for the positively magnetically aligned state induced by lanthanide ions[53] and was proposed to consist of perforated "Swiss cheese"-like lamellae,[44] a morphology confirmed by SANS experiments[35,45] and supported by electron paramagnetic resonance[54] and NMR measurements.[55,56]

A further example concerns the location of DHPC in bicellar self-assemblies. It was originally conceived that DHPC remained strictly confined to highly curved edge regions owing to its presumed immiscibility with DMPC. A recent reinvestigation of ^{31}P NMR bicelle spectra has challenged this motion, suggesting that, on the contrary, DHPC becomes increasingly miscible with DMPC at higher temperatures, undergoing fast exchange, on the NMR time scale, between edge and planar regions of the bicelles.[57] Given the profound influence of the ratio DMPC:DHPC on bicelle morphology, the temperature-dependent redistribution of DHPC from edge to planar regions must have an equally profound effect, particularly on the size and (or) number of DHPC-lined lamellar perforations present at any one temperature.

This article provides a review of recent NMR diffusion studies in bicellar systems, emphasizing the perspectives that such studies have provided on bicelle morphology. Following a brief review of diffusion fundamentals and techniques for measuring diffusion, we describe exchange- and gradient-based NMR diffusion measurements, particularly as pertinent to lipid bilayer model membranes. The main body of the article describes results from our laboratory using pulsed field gradient (PFG) NMR diffusion measurements in magnetically aligned bicellar systems. We conclude with an outline of future prospects for NMR diffusion measurements in model membranes.

Diffusion

Diffusion is a fundamental physical property. Self-diffusion refers to thermally generated spontaneous centre-of-mass translational molecular motion occurring in the absence of any concentration gradient. It may be modeled as a random-walk process. For a spherical particle of hydrodynamic radius R_H diffusing in an isotropic medium of viscosity η, the diffusivity is quantified by the diffusion coefficient (D) given by the Stokes–Einstein equation,

$$[1] \qquad D = \frac{k_B T}{6\pi\eta R_H}$$

where k_B is the Boltzmann constant and T is the absolute temperature. Typical self-diffusion coefficients in liquid systems at room temperature range from 10^{-9} m^2 s^{-1} for small molecules to 10^{-12} m^2 s^{-1} for large polymers. Diffusion measurements are particularly useful for probing morphology in complex, disordered systems.

In many biological (and other) situations diffusion is inherently anisotropic. Examples include diffusion in the crowded cell cytoplasm, along a nerve axon, or within a biological membrane. In the most general case of anisotropic diffusion, the diffusion coefficient is described in terms of a second-rank symmetric tensor,

$$[2] \qquad \mathbf{D} = \begin{vmatrix} D_{xx} & D_{yx} & D_{zx} \\ D_{xy} & D_{yy} & D_{zy} \\ D_{xz} & D_{yz} & D_{zz} \end{vmatrix}$$

requiring that six independent tensor components D_{ij} be determined to fully specify the diffusion coefficient.[58] For the isotropic case, measuring diffusion in any one direction completely specifies the diffusion coefficient. For the specific case of lateral diffusion within a lipid bilayer membrane, a situation of central interest in this review, there are only two independent tensor components to consider: $D_\parallel$ and $D_\perp$, corresponding to diffusion parallel and perpendicular, respectively, to the bilayer normal,[59,60] as shown schematically in Fig. 3. The resulting diffusion tensor is

$$[3] \qquad \mathbf{D} = \begin{vmatrix} D_\perp & 0 & 0 \\ 0 & D_\perp & 0 \\ 0 & 0 & D_\parallel \end{vmatrix}$$

where $D_\perp$ is the lateral diffusion coefficient describing diffusion within the plane of the membrane. Generally, $D_\parallel << D_\perp$ and, therefore, can often be discounted.

From a theoretical perspective, lateral diffusion is modeled in terms of either a "free area" model[61–64] or a "hydrodynamic" model,[65,66] depending on the relative size of the diffusant versus the "solvent", i.e., the lipid molecules constituting the bilayer. For diffusants having a size comparable to the lipids, for example lipids and many drugs, the free area model predicts that lateral diffusion requires the availability

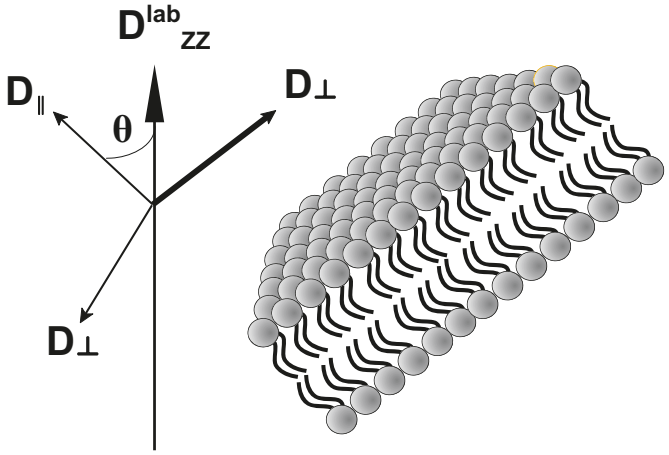
For personal use only.

Fig. 3. The diffusion tensor in the membrane frame of reference, relative to the laboratory frame of reference as defined by the magnetic field gradient direction, here assumed to lie parallel to the static magnetic field. Transforming from the membrane to the laboratory reference frame yields the relationship between the apparent diffusion coefficient and the diffusion tensor elements (see text).



of sufficient free area per molecule at a given temperature ($a_f(T)$) relative to the close-packed area per molecule (a^*) plus a diffusant having sufficient kinetic energy to jump into the adjacent void, as per eq. [4]

$$[4] \qquad \mathbf{D} = D_0 \exp\left[\theta\frac{a*}{a_f(T)} - \frac{E_a}{RT}\right]$$

where D_0 is the instrinsic diffusion coefficient within the cage defined by the lattice, E_a is the activation energy, and θ is a scalar.[7,8] The free area model predicts an Arrhenius-type temperature dependence of lateral diffusion for diffusants in this size regime in model membrane systems.

For diffusants having a size far larger than that of the lipids, for example multi-helical transmembrane proteins, a continuum (or hydrodynamic) model was proposed by Saffman and Delbrück,[65,66] where

$$[5] \qquad \mathbf{D} \sim \left(\frac{kT}{4\pi\eta_m h}\right)\ln\left(\frac{\eta_m h}{\eta_w a} - 0.5772\right)$$

in which η_m and η_w are the viscosity of the membrane and the bathing medium, respectively, h is the membrane thickness, and a is the radius of the cylindrical membrane diffusant. The salient feature of eq. [5] is a very weak dependence on the size of the membrane diffusant in this size regime.

Fluorescence and diffusion

Of the many techniques for measuring diffusion, perhaps the most popular are those based on fluorescence, owing to the inherent advantages of speed, sensitivity, high spatial and time resolution, the ability to probe both in vitro and in vivo, and the comprehensive range of commercially available fluorophores tailored to particular applications and situations. The principal constraint is the requirement for a fluorescence signal associated with the molecule of interest having a particular photoresponse and photostability.

Fluorescence recovery after photobleaching (FRAP) is widely used to examine molecular mobility in a host of situations, and has been particularly useful in examining lateral mobility in biological membranes.[67–69] As the name implies, FRAP measures the kinetics of the recovery of fluorescence within a defined photobleached area or volume owing to diffusion of nonphotobleached molecules back into that region.

Fluorescence correlation spectroscopy (FCS), on the other hand, employs statistical analysis of fluctuations in the fluorescence signal intensity as fluorophores exit and enter a defined region to extract translational diffusion coefficients. FCS is readily used to determine diffusion coefficients in planar systems such as bilayers and biological membranes and employs a lower fluorophore concentration and lower laser power than FRAP.[70–74]

Both FRAP and FSC measure the behaviour of an ensemble of molecules. Single particle tracking (SPT), on the other hand, monitors the motion of individual fluorophore-labeled molecules using video microscopy to achieve high spatial (tens of nanometers) and temporal (tens of milliseconds) resolution.[75–77] The trajectory of an individual particle yields a net displacement (r) for a given observation period (t), which equates directly to the diffusion coefficient via the Einstein equation

$$[6] \qquad r^2 = 2dDt$$

where d is the dimensionality of the diffusion geometry, i.e., $d = 2$ for a planar lipid bilayer. From a collection of such trajectories, the statistical distribution of diffusion coefficients may be evaluated.

In model membranes, fluorescence studies of small molecule lateral diffusion confirm the Arrhenius-type temperature dependence predicted by the free area model.[67–69] For large transmembrane proteins, FCS results, for example, confirm that, as predicted by the hydrodynamic model, lateral diffusion depends only rather weakly on the number of transmembrane helices.[78]

In genuine biomembranes, FRAP and FCS results yield diffusion rates significantly slower than in model membranes for the corresponding diffusant. In cell membranes the situation is complicated by the possible presence of membrane crowding, heterogeneous lipid and protein distributions, confined and obstructed diffusion, and even directed flow. Recent SPT studies, for example, have revealed many such deviations from random diffusion in actual biomembranes, and this remains a highly active area of research, with the interpretations of the SPT observations still being the subject of controversy.[75–77]

NMR and diffusion

NMR approaches for measuring lateral diffusion in membranes can be divided broadly into two categories: those based on exchange studies in the presence of orientation-dependent interactions and those based on applying field gradients.

Exchange NMR and diffusion

In lipid bilayer membranes, residual anisotropic, i.e., orientation-dependent, interactions such as the chemical shift or quadrupolar or dipolar interactions, are generally present because of incomplete motional averaging experienced by membrane-associated molecules. Typically, in the biologically relevant liquid–crystalline state, i.e., at temperatures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

above T_m, there is more or less rapid free rotation about the molecule-fixed axis perpendicular to the plane of the membrane (i.e., parallel to the bilayer normal), whereas rotations about orthogonal axes are restricted because of lateral compression forces holding the membrane self-assembly together. Consequently, all such residual anisotropic interactions are reduced to the product of a scalar quantity $(\omega_{\parallel} - \omega_{\perp})$ and a simple angular dependence corresponding to the second-order Legendre polynomial $P_2(\theta) = 1/2(3\cos^2\theta - 1)$, such that

$$[7] \qquad \omega_i = \omega_{iso} + \frac{2}{3}(\omega_{\parallel} - \omega_{\perp})\frac{1}{2}(3\cos^2\theta_i - 1)$$

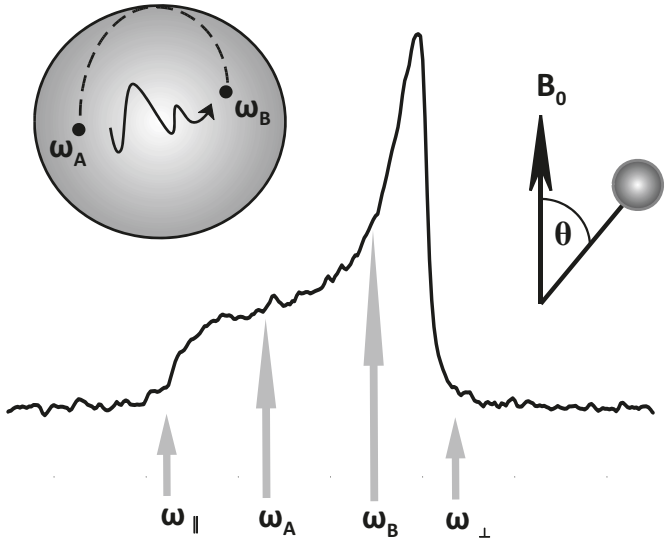
where ω_{iso} is the isotropic frequency, while $\omega_{\parallel}$, $\omega_{\perp}$, and θ, the angle between the bilayer normal and the magnetic field direction, are shown schematically in Fig. 4. Thus, each angle θ_i corresponds to a particular resonance frequency ω_i in the range $\Delta\omega = (\omega_{\parallel} - \omega_{\perp})$. The sin θ probability density for the distribution of angles θ on a sphere leads to the characteristic powder NMR spectral line shape.

For spherical liposomes having diameters below ~1 μm, the combination of rotational tumbling of the entire liposome plus lateral diffusion around the radius of curvature combine to produce a motional correlation time equal to, or shorter than, the inverse of the scalar $\Delta\omega = (\omega_{\parallel} - \omega_{\perp})$. The effect is to narrow the NMR line shape relative to the powder average and shorten the relaxation times. Using this effect, ^{31}P line shapes,[79,80] as well as ^{2}H transverse relaxation[81] and ^{1}H rotating frame longitudinal relaxation behaviours,[82] have been analyzed to extract lipid lateral diffusion coefficients. The method is predicated on knowledge of the mean radius and distribution of radial dimensions of the liposome population being examined, and is further limited by the poor resolution of different chemical sites inherent in the broad resonances observed plus the necessity to deconvolve the rotational tumbling correlation time from that owing to lateral diffusion.

For large diameter liposomes, exchange NMR spectroscopy (EXSY)[83] may be used to measure lateral diffusion coefficients by examining the frequency change that results from diffusion around the spherical radius of curvature as shown schematically in Fig. 4. Being a two-dimensional NMR technique, EXSY involves the usual preparation period, followed by an evolution period during which nuclear spins evolve at a frequency ω_A dictated by their initial angular position θ_A, a subsequent mixing time during which lateral diffusion may occur, and a final detection period during which nuclear spins evolve at a frequency ω_B dictated by their final angular position θ_B. In a two-dimensional NMR spectrum, therefore, lateral diffusion produces the appearance of resonance intensity at a two-dimensional frequency $\omega_A\omega_B$. The lateral diffusion coefficient is extracted from the kinetics of the spread of resonance intensity from on-diagonal ($\omega_A = \omega_B$) to off-diagonal frequencies ($\omega_A \neq \omega_B$) with increasing mixing time, taking into account the conditional probability densities of initial versus final angular positions and the radius of curvature of the spherical liposome.

EXSY has been used in this fashion to measure phospholipid lateral diffusion via ^{2}H[84] and ^{31}P resonances,[85–87] in multilamellar vesicles and in lipid bilayers on glass bead supports. The principle limitation is the considerable time required for spectral acquisition, given that separate two-dimensional powder spectra must be recorded across a sufficiently dense series of mixing times to obtain sufficiently accurate kinetics. Furthermore, the powder spectra permit only limited resolution of different species or of distributions of lateral diffusion coefficients. Finally, reasonably precise knowledge of the radius of the liposomal population being examined is essential to obtaining an accurate lateral diffusion coefficient.

Fig. 4. Exchange NMR spectroscopy (EXSY) detects lateral diffusion in spherical liposomes by virtue of changes in orientation-dependent interactions such as chemical shift anisotropy or dipolar or quadrupolar interactions. A nuclear spin initially at a position with angle θ_A corresponding to frequency ω_A, diffusing to a new position with angle θ_B corresponding to frequency ω_B, generates off-diagonal intensity at a two-dimensional frequency $\omega_A\omega_B$ in the EXSY spectrum.



The spectral acquisition time and resolution problems associated with 2D EXSY may be overcome using 1D magic angle spinning (MAS) exchange NMR methods such as exchange induced sidebands (EIS),[88] 1D exchange spectroscopy by sideband alternation (ODESSA),[89] time-reversed ODESSA (trODESSA),[90] or centre band only detection of exchange (CODEX).[91] MAS involves spinning the sample about an axis inclined at the magic angle (54.74°) with respect to the static magnetic field. When the spinning frequency ω_r is greater than the size of the anisotropic interaction, i.e., $\omega_r \geq \Delta\omega$, only the isotropic frequency ω_{iso}, or so-called centre band, is manifest in the NMR spectrum, allowing resolution of chemically different sites. However, under slow-spinning conditions, i.e., $\omega_r \leq \Delta\omega$, a series of side bands appear in the spectrum, separated from the centre band by multiples of the spinning speed $\nu_r = \omega_r/2\pi$. The various 1D MAS exchange NMR methods employ refocusing radio frequency pulses carefully timed with respect to the rotor period ($\tau_r = 1/\nu_r$) to manipulate the phase and amplitude of these side bands. For situations where a diffusive motion has a correlation time that is long relative to the transverse relaxation time T_2, but short relative to the longitudinal relaxation time T_1, diffusion coefficients may be measured from the variation of side-band amplitudes as a function of the number of re focusing periods. While applicable in principle to the examination of lateral diffusion in membranes, to date we are not aware of any such studies using these methods.

One issue is the need for a well-defined radius of curvature in the liposomal system under study.

Pulsed field gradient NMR and diffusion

Pulsed gradient-based diffusion NMR studies have flourished since their introduction more than four decades ago by Stejskal and Tanner[58] in their now classic article describing the spin echo pulsed gradient NMR diffusion experiment. The experimental diffusion time in the latter is limited by the intrinsic transverse relaxation time (T_2) of the nuclear spins being observed. Figure 5 shows the basic stimulated echo (STE) PFG NMR pulse sequence,[92] where the experimental diffusion time is limited by the longitudinal relaxation time (T_1), which is useful when, as is often the case, $T_1 >> T_2$. During the interval following the first 90° radio frequency pulse (duration $\tau_2 < T_2$) the nuclear spins precess in the transverse plane, acquiring a phase angle proportional to their intrinsic chemical shifts. The second 90° radio frequency pulse places the spin magnetization along the z axis where it may be stored for a duration $\tau_1 < T_1$. Following the third 90° radio frequency pulse, which returns the spin magnetization to the transverse detection plane, a stimulated echo forms at a time τ_2 subsequent to that pulse owing to the reversed direction of precession produced by the combination of the second and third radio frequency pulses. To render the experiment sensitive to diffusion, pulsed homogeneous field gradients, of amplitude g (T m^{-1}) and duration δ (s), are applied during the intervals following the first and third radio frequency pulses. The first gradient pulse encodes the nuclear spins according to their position along the direction of the applied field gradient by inducing an additional phase shift of angle ϕ_i

$$[8] \qquad \phi_i = \gamma g \delta z_i$$

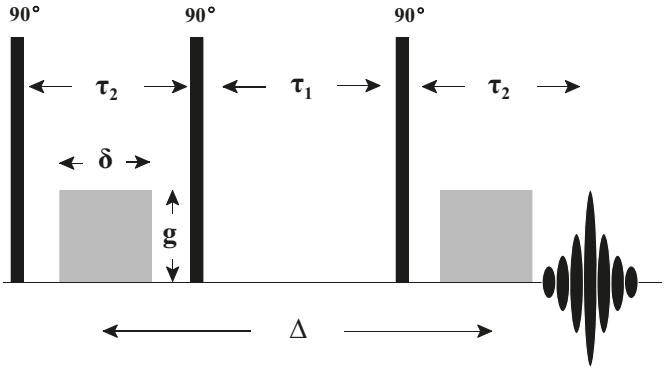
where γ (rad T^{-1} s^{-1}) is the magnetogyric ratio and z_i is the position of an individual nuclear spin along the direction of the applied field gradient (assumed to lie parallel to the static magnetic field). The second gradient pulse decodes, i.e., reverses, the position-dependent phase shift produced by the first gradient pulse. If no diffusion occurs along the direction of the applied field gradient during the duration Δ separating the two field gradient pulses, then the nuclear spins refocus normally and the stimulated echo amplitude is unchanged. If diffusion occurs, then the echo amplitude is reduced as per eq. [9]

$$[9] \qquad I = I_0 \exp\left(\frac{-2\tau_2}{T_2}\right)\exp\left(\frac{-\tau_1}{T_1}\right) \times \exp[-\mathbf{D}(\gamma g \delta)^2(\Delta - \delta/3)]$$

where I_0 is the initial intensity and $\mathbf{D}$ is the diffusion coefficient along the direction of the applied field gradient. For simple Gaussian diffusion a plot of Ln I/I_0 vs $k = (\gamma g \delta)^2(\Delta - \delta/3)$, at constant τ_1 and τ_2 yields a linear decay with slope proportional to $\mathbf{D}$.

Given the particular focus of this review on diffusion in bicelles and related membrane systems, only the features of PFG NMR diffusion measurements most salient to membranes will be described. For a deeper presentation of the theory underlying the PFG NMR experiment, the interested reader is referred to several authoritative reviews.[94–97] Beyond the basic STE PFG NMR sequence, many innovative approaches have been developed to surmount particular challenges, such as the presence of background gradients,[98] convection,[99] or the need for solvent suppression,[100] and the interested reader is referred to the literature cited. Beyond the case of normal Gaussian diffusion, wherein the measured diffusion coefficient is independent of the observation period, there exist many situations characterized by non-Gaussian diffusive behaviour, in which the measured diffusion coefficient depends on the observation period. Typically, such situations involve complex heterogeneous systems where molecular diffusion occurs under confinements imposed by the system's morphology.[101] In such instances, PFG NMR diffusion measurements can often provide otherwise difficult to obtain morphological details.[102,103]

Fig. 5. The stimulated echo pulsed field gradient NMR pulse sequence introduced by Tanner[93] for measurement of molecular diffusion.



When applied to diffusion in membranes, the PFG NMR technique encounters two fundamental difficulties: first, the resonances to be observed are broad owing to residual anisotropic interactions, resulting in rapid loss of coherence during the echo delays in the PFG NMR sequence, and, second, the distribution of orientations of the membrane plane within the sample complicates the analysis of any observed intensity decays in terms of a lateral diffusion coefficient.

Gradient MAS

One innovative approach to the broad resonance issue involves subjecting the membrane sample to MAS to produce line narrowing while applying field gradients co-directional with the spinning axis.[104] Such a gradient configuration ensures that all nuclear spins experience an identical gradient strength throughout a rotor cycle. Gaede and Gawrisch[105] first employed this gradient MAS technique to examine lateral diffusion in lipid bilayers. Using multilamellar vesicles (MLVs) composed of 1-palmitoyl-2-oleoyl-phosphatidylcholine (POPC), they demonstrated that the ^{1}H NMR resonances of the POPC and the hydrophobic membrane-bound drug ibuprofen were well-resolved under MAS and that their respective lateral diffusion coefficients could be measured simultaneously.

A critical feature of the analysis is to take proper account of the powder distribution of bilayer normals in MLVs relative to the gradient axis. Extending previous work on corrections for powder samples,[59,106] it was found that, to second order, and ignoring relaxation, eq. [9] could be modified to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[10] \qquad Ln\left(\frac{I}{I_0}\right) = -\frac{2}{3}kD + \frac{2}{45}(kD)^2$$

where k is again proportional to $(\gamma g \delta)^2$ but multiplied by a factor dependent on the pulse sequence and instrument settings, i.e., for the spin echo and stimulated echo with square gradient pulses the factor is $(\Delta - \delta/3)$. A further correction must be made to account for the curvature of the bilayers, in that an apparent diffusion coefficient is measured, which is related to the true diffusion coefficient **D** via

$$[11] \qquad \mathbf{D}_{app} = \frac{r^2}{2\Delta}\sin^2\left[\frac{(2D\Delta)^{1/2}}{r}\right]$$

where r is the radius of curvature of the bilayer vesicle.

Gaede and Gawrisch[105] demonstrated that the smaller molecule ibuprofen diffused considerably faster than the large molecule POPC, in keeping with the predictions of the free area model. The same gradient MAS diffusion NMR method was used subsequently to examine lateral diffusion of a number of membrane-associating molecules such as flavonoids,[107] cannabinoids,[108] indoles,[109] and cholesterol and its precursors,[110] and to explore domains and phase separation in model[111] and naturally occurring[112] lipid bilayers.

Macroscopically oriented membranes

One solution to the distribution of membrane orientations problem is to macroscopically align lipid bilayers by hydrating them between glass plates, a strategy first employed by Lindblom and Wennerström[113] to measure lateral diffusion. The resulting stacked uniformly aligned bilayers may be considered to have a radius of curvature approaching infinity. Inspection of eq. [11] shows that under such circumstances $\mathbf{D}_{app}$ becomes equivalent to **D**.

The issue of line broadening may also be ameliorated in macroscopically oriented bilayers. Specifically, for ^{1}H NMR diffusion studies, the principal source of line broadening in lipid bilayers is residual dipolar interactions between protons, both intermolecular and intramolecular. In the liquid–crystalline state, rapid translation diffusion eliminates intermolecular dipolar interactions, whereas rapid rotations about the lipid long axis averages the intramolecular dipolar Hamiltonians such that the angular dependence of the residual anisotropy again takes the form of the second-order Legendre polynomial $P_2(\theta)$, with θ corresponding to the angle between the bilayer normal and the direction of the static magnetic field. The key point is that when θ equals the so-called magic angle of 54.74°, $P_2(\theta) = 0$, the residual dipolar Hamiltonian disappears and the ^{1}H NMR resonance lines narrow. If the stack of macroscopically aligned lipid bilayers is oriented in the static magnetic field such that this condition applies, then the entire ensemble of lipid bilayers experiences this line narrowing.

One consequence of this arrangement is that, for the typical case in which the pulsed field gradients are applied along the z axis co-directional with the static magnetic field, the diffusion coefficient measured from a plot of Ln I/I_0 vs k (as per eq. [9]) does not directly equal the lateral diffusion coefficient, since the membrane-fixed reference frame in which the diffusion tensor is defined does not coincide with the laboratory-fixed reference frame defined by the direction of the applied field gradient. A simple rotational transformation from the membrane-fixed to the laboratory-fixed reference frame yields the relationship between the apparent diffusion coefficient $\mathbf{D_{zz}}^{\mathbf{lab}}$ and the diffusion tensor components, as shown in eq. [12][59,60]

$$[12] \qquad \mathbf{D_{zz}}^{\mathbf{lab}} = D_\perp \sin^2\theta + D_\parallel \cos^2\theta$$

where the geometry is shown in Fig. 3. As noted previously, $D_\parallel << D_\perp$ so that $\mathbf{D_{zz}}^{\mathbf{lab}} = 0.667\ D_\perp$ when $\theta = 54.74°$.

Lindblom and Orädd have been the principal proponents of this approach to measuring lateral diffusion coefficients of membrane lipids and their findings are described in several review articles.[60,114–118] A particular focus of their studies has been to describe the heterogeneity of lateral organization within a bilayer as reflected in the lateral mobility of different lipids. Especially notable achievements include the characterization of liquid-ordered and liquid-disordered domains formed in the presence of cholesterol and an elucidation of the criteria for domain formation in ternary lipid mixtures. As to the limitations of this approach, producing high-quality well-hydrated macroscopically oriented membrane samples is not a trivial matter, whereas the resolution achieved in the ^{1}H NMR spectrum is never equivalent to that obtained under MAS conditions.

Magnetically aligned bicelles

Another solution to the distribution of membrane orientations problem is to employ magnetically aligned bicelles. Two distinct situations present themselves as shown in Fig. 6. First, for negatively magnetically aligned bicelles, the bilayer normal is oriented at 90° to the static magnetic field so that, applying eq. [12], $\mathbf{D_{zz}}^{\mathbf{lab}} = D_\perp$, i.e., the lateral diffusion coefficient is measured directly. Secondly, for positively magnetically aligned bicelles, the bilayer normal is oriented parallel to the static magnetic field so that, applying eq. [12], $\mathbf{D_{zz}}^{\mathbf{lab}} = D_\parallel$, i.e., transbilayer diffusion may be measured directly. The latter quantity is largely a function of the size and number of DHPC-rich defects in the bicellar lamellae as will be discussed later.

The line width issue remains, however, since neither orientation eliminates the residual dipolar interaction, of paramount importance for the line width in ^{1}H NMR spectra of lipid bilayers, although it is reduced by a factor of 1/2 for negatively magnetically aligned bicelles as may be ascertained from eq. [7]. For a STE PFG ^{1}H NMR sequence, the residual dipolar broadening in either case is such that most lipid resonances cannot be detected owing to the loss of coherence during the echo delay periods. Nevertheless, any nuclear spins undergoing nearly isotropic motional averaging, and hence exhibiting narrow resonances, can be used to measure diffusion.

This was first demonstrated by Soong and Macdonald[56] using a PEGylated lipid incorporated into negatively magnetically aligned DMPC/DHPC bicelles. PEGylated lipids consist of a hydrophobic anchoring group, such as dimyristoyl phosphatidylethanolamine (DMPE), to which a polyethyleneglycol (PEG) group is covalently attached through the lipid's polar head group. As shown schematically in Fig. 7, the water soluble PEG becomes effectively "grafted" to the lipid bilayer surface through its DMPE hydrophobic anchor. The resulting surface coating of PEG inhibits surface binding and adhesion via steric repulsion, a property broadly useful

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 6. For the case of field gradients aligned parallel to the static magnetic field direction, positively magnetically aligned bicelles (left) allow measurement of the transbilayer diffusion coefficient $\mathbf{D}_{\parallel}$. Negatively magnetically aligned bicelles (right) allow measurement of the diffusion coefficient perpendicular to the bilayer normal ($\mathbf{D}_{\perp}$) corresponding to the lateral diffusion coefficient in the case of membrane-bound molecular species.

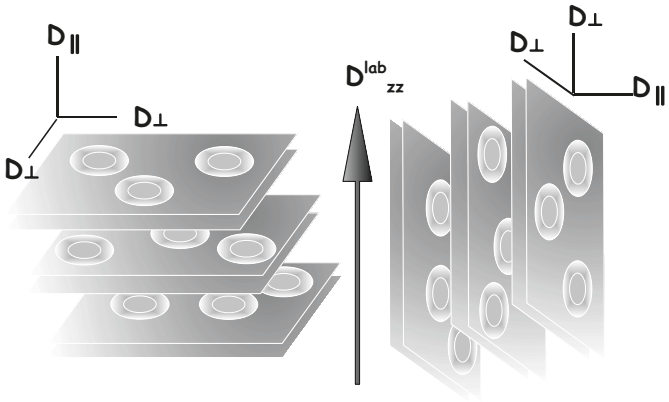


Fig. 7. The polyethyleneglycol (PEG) group of a PEGylated lipid may be regarded as a random-coil polymer grafted to the membrane surface by virtue of its hydrophobic anchoring moiety. Polymer theory[122] indicates that, for dimyristoyl phosphatidylethanolamine (DMPE) – PEG 2000, the resulting "mushroom" cap has a Flory radius (R_F) on the order of 35 Å, creating a surface "shadow" covering 60–70 dimyristoyl phosphatidylcholine (DMPC), and leading to full coverage at ~1.7 mol%.

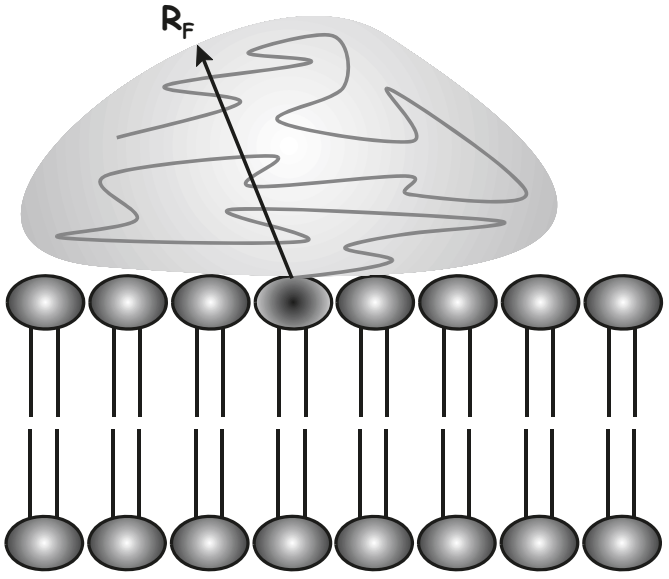

for enhancing bio-compatibility. For example, PEG-coated lipid vesicles are more effective drug delivery vehicles than vesicles lacking a PEG coating.[119] In bicelles, a surface coating of PEG enhances bicelle stability, again by virtue of steric stabilization.[120] The virtues of PEG lipids as bio-compatiblizing agents has led to intense research into their physicochemical properties, as reviewed by Marsh et al.[121]

Figure 8 show a typical series of STE PFG ^{1}H NMR spectra from which diffusion information is extracted, here for the case of negatively magnetically aligned bicelles containing DMPE–PEG 2000.[56] Any broad background lipid resonances are largely absent because of their short T_2 relative to τ_2. The two principal remaining resonances are assigned to HDO and an overlapping contribution from DHPC choline methyl plus PEG–DMPE ethylene oxide (EO) protons. The HDO resonance intensity decays rapidly with increasing k, as anticipated given water's rapid diffusion and the particular choice of gradient strength. The combined DHPC choline methyl plus PEG–DMPE EO resonance decays far more slowly, as expected for lipids constrained to diffuse laterally within a bicelle.

From plots of Ln I/I_0 vs k, such as shown in Fig. 9, the corresponding diffusion coefficient is obtained. The HDO diffusion coefficient is 1.6×10^{-9} m^2 s^{-1}, or roughly a factor of two slower water diffusion in these bicelles relative to bulk water at the same temperature,[123] the difference being attributed to the large fraction of bilayer surface-bound water in fast exchange with bulk water. Water diffusion in macroscopically oriented bilayers in general,[124] and in magnetically aligned bicelles in particular,[55,125] is anisotropic, with diffusion in the direction parallel to the bilayer normal considerably slower than in the perpendicular direction owing to slow permeation of water across the bilayer. This point will be come relevant in a later section.

In Fig. 9 diffusive intensity decays of the combined DHPC choline methyl plus DMPE–PEG 2000 EO resonance are shown for two concentrations of DMPE–PEG 2000 (1 mol% and 2 mol%) relative to DMPC. Each decay was fit as a sum of individual contributions from the DHPC and DMPE–PEG 2000, taking into account their respective initial intensity contributions, relaxation properties from independent measurements, and diffusion coefficients. Since the DHPC diffusion coefficient (5.7×10^{-10} m^2 s^{-1}) could be measured in otherwise identical bicelles lacking DMPE–PEG 2000, the sole fitting parameter was the lateral diffusion coefficient of DMPE–PEG 2000.

At larger values of k, the sole contributor to the intensity decay of this resonance is lateral diffusion of DMPE–PEG 2000. One sees that this decay is linear, i.e., monoexponential, indicating normal Gaussian diffusion. The lateral diffusion coefficient measured from the slope for 1 mol % DMPE–PEG 2000 was 1.35×10^{-11} m^2 s^{-1}, and was independent of the experimental diffusion time Δ, a further indication of normal Gaussian diffusion. For 2 mol% DMPE–PEG 2000, the lateral diffusion coefficient decreased to 1.15×10^{-11} m^2 s^{-1}.

As a comparison, Fig. 9 shows the intensity decays for free PEG 2000, i.e., nonhydrophobically modified, simply confined between the lamellae of the magnetically aligned bicelles at either 1 or 2 mol% concentrations. The measured diffusion coefficients, although reduced relative to free PEG in bulk solution, are, nevertheless, a factor of 30 times faster than the PEGylated lipid and essentially concentration independent.

Diffusion NMR and bicelle morphology

STE PFG NMR diffusion data such as that shown in Fig. 9 demonstrate the utility and ease of diffusion NMR measurements in magnetically aligned bicelle systems. In the following, we present a number of examples of the insights

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 8. Stimulated echo (STE) pulsed field gradient (PFG) ^{1}H NMR spectral series obtained at 35 °C with $q = 4.5$ DMPC/DHPC negatively magnetically aligned bicelles containing 1 mol% dimyristoyl phosphatidylethanolamine (DMPE) – polyethyleneglycol (PEG) 2000 as a function of increasing gradient pulse duration in the STE PFG NMR pulse sequence. The HDO resonance decays rapidly as expected given the fast diffusion of water. The ethylene oxide (EO) resonance of DMPE–PEG 20000 decays much more slowly as expected for a large molecule bound to the lipid bilayer regions of the bicelle. Other resonance are largely absent because of their fast transverse relaxation. Adapted from Soong and Macdonald.[56]

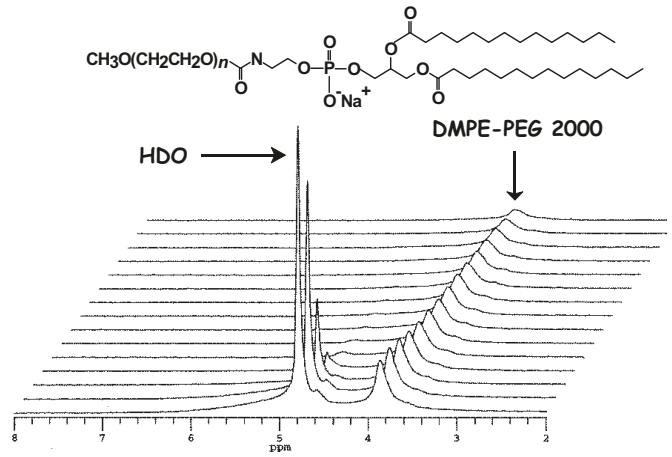

Fig. 9. Stimulated echo intensity decays as a function of dimyristoyl phosphatidylethanolamine (DMPE) – polyethyleneglycol (PEG) 2000 concentration in stimulated echo (STE) pulsed field gradient (PFG) ^{1}H NMR spectra (35 °C) of magnetically aligned dimyristoyl phosphatidylcholine (DMPC) / dihexanoyl phosphatidylcholine (DHPC) ($q = 4.5$) bicelles plus various levels of either DMPE–PEG 2000 or free (i.e., nonhydrophobically modified) PEG 2000. DMPE–PEG 2000 (1 mol%), $D_{PEG} = 1.35 \times 10^{-11}$ m^2 s^{-1} (○). DMPE–PEG 2000 (2 mol%), $D_{PEG} = 1.15 \times 10^{-11}$ m^2 s^{-1} (□). Free PEG 2000 (1 mol%), $D_{PEG} = 5.00 \times 10^{-10}$ m^2 s^{-1} (●). Free PEG 2000 (2 mol%), $D_{PEG} = 5.23 \times 10^{-10}$ m^2 s^{-1} (■). For further details see Soong and Macdonald.[56]

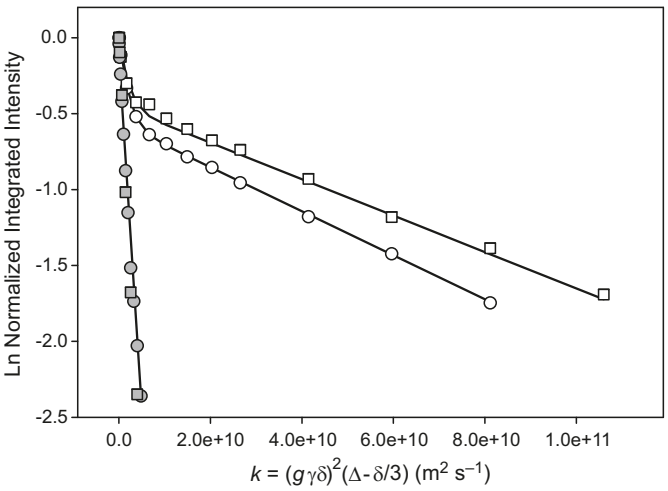


such studies can provide concerning fundamental questions of lateral diffusion in general and bicelle morphology specifically.

PEGylated lipid diffusion obeys the free area model

The lateral diffusion coefficient measured for DMPE–PEG 2000 (**D** = 1.35×10^{-11} m^2 s^{-1} for 1 mol% DMPE–PEG 2000 in $q = 4.5$ DMPC/DHPC bicelles at 35 °C) agrees closely with values reported for DMPC at a similar temperature using FRAP.[68] Hence, the lateral diffusion of this PEGylated lipid is determined primarily by the hydrophobic DMPE moiety anchoring the PEG group to the lipid bilayer, whereas the essentially extramembranous PEG group has an effect that is, at best, secondary. This conclusion is in agreement with free area models that predict that lateral diffusion is dictated by the cross-sectional area occupied within the membrane, which will be the same for DMPE–PEG 2000 and DMPC. The size of any extramembranous portion of the diffusing species, on the other hand, is secondary because the water bathing the membrane is so much less viscous than the membrane proper. Nonhydrophobically anchored PEG 2000 diffusing between bicelles, in contrast, diffuses an order of magnitude faster that DMPE–PEG 2000.[126]

Membrane crowding slows diffusion

The observation that lateral diffusion is slower when the DMPE–PEG 2000 concentration is increased from 1 to 2 mol% can be attributed directly to membrane crowding effects. Specifically, a consideration of the size of the extramembranous PEG group relative to the available space demonstrates that crowding between adjacent DMPE–PEG 2000 on the same lamellar surface must commence as the concentration rises from 1 to 2 mol%. According to polymer theory for unperturbed surface-grafted polymers,[122] the shape of the hydrophobically anchored PEG group may be modelled as a half-sphere or "mushroom" extending out from the surface a distance R_F (the Flory radius) and covering an area $A = \pi R_F^2$. This situation is shown schematically in Fig. 7. The Flory radius is calculated via the Flory equation[127]

$$[13] \qquad R_F = \mathbf{N}^{3/5}\mathbf{a}$$

where **N** is the degree of polymerization, i.e., the number of monomers, and **a** is the length of one monomer, equalling 3.5 Å for EO.[128] DMPE–PEG 2000 has 45 EO units, yielding $R_F \approx 35$ Å. Hence, assuming a footprint of 60 Å^2 for DMPC, complete coverage of the bilayer with PEG groups is achieved at 1.7 mol% DMPE–PEG 2000. Increasing the DMPE–PEG 2000 concentration from 1 to 2 mol% therefore forces overlap and entanglement of PEG groups to begin, i.e., the surface becomes crowded and lateral diffusion slows. The effect is exacerbated by higher concentrations and by higher molecular weight DMPE–PEG.[129]

Bicelle disks or perforated lamellae?

The diffusion properties of DMPE–PEG 2000 bear directly on the question of whether these bicelles under these conditions have assumed a diskoidal morphology or exist as perforated lamellae. Specifically, the fact that the diffusive decays for DMPE–PEG 2000 (as shown in Fig. 9) are linear and diffusion time independent indicates that lateral diffusion in this situation is normal, i.e., uncomplicated by restricted or anomalous diffusion. This permits a straightforward calculation of the root mean square (rms) displacement undergone during the experimental diffusion time via eq. [6]. For DMPE–PEG 2000 where $D = 1.35 \times 10^{-11}$ m^2 s^{-1} and $t = \Delta = 615$ ms,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

the rms displacement is on the order of 6 μm. This is a dimension far exceeding the size of an "ideal" diskoidal bicelle,[40] which is predicted to have a radius of 300 Å for the case $q = 4.5$. For situations where the experimental diffusion time would yield rms displacements exceeding the radial dimensions of such disks, any membrane-associating species confined to such a disk must exhibit restricted diffusion, characterized by a slope of zero in plots of Ln I vs k. No such behaviour was observed and, therefore, the morphology cannot be diskoidal. Instead, the perforated lamellae model of the bicelle structure must apply under these conditions, a conclusion likewise reached by Gaemers and Bax[55] from their examination of TMS diffusion in bicelles.

The mixed bicelle model

The perforations in the bicellar lamellae are formed by DHPC as a consequence of its preference for regions of high curvature. Originally, it was thought that DHPC was strictly segregated to such regions and would never mix with DMPC. Recent ^{31}P NMR results have called this view into question,[57] indicating that DHPC will in fact mix with DMPC, i.e., reside in lamellar regions, and increasingly so with increasing temperature.

Figure 10 shows the ^{31}P NMR spectra obtained in our laboratory for positively magnetically aligned DMPC/DHPC bicelles as a function of q (at constant temperature 35 °C) and as a function of temperature (at constant $q = 4.5$).[41] The key feature is the frequency of the DHPC resonance that is observed to shift progressively towards that of the DMPC resonance with either increasing q or increasing temperature. The interpretation is that DHPC is in fast exchange between regions of high curvature, where its frequency corresponds to the isotropic chemical shift, and lamellar regions, where its frequency corresponds to the anisotropic chemical shift of DMPC. Hence, the observed frequency relates to the equilibrium distribution of DHPC between these two environments, from which one may estimate an effective ratio of planar to curved phospholipid populations (q^*) via eq. [14]

$$[14] \qquad q^* = \left[\frac{q + \omega^*}{1 - \omega^*}\right]$$

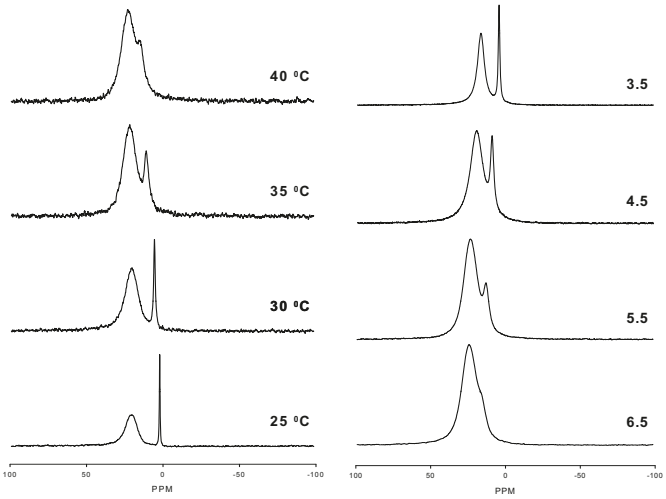
where q = DMPC/DHPC as usual, and $\omega^* = \omega_{DHPC}/\omega_{DMPC}$, with ω_{DHPC} and ω_{DMPC} being the observed chemical shifts of DHPC and DMPC, respectively. Qualitatively, the ^{31}P NMR results indicate that the equilibrium distribution of DHPC shifts away from curved and towards planar regions of the bicelle upon increasing either q or temperature. This is in essential agreement with, and confirms the findings of, Triba et al.[57] and their "mixed bicelle model".

Such a mixed bicelle model has experimentally verifiable consequences for transbilayer diffusion. Specifically, the greater the amount of DHPC residing in lamellar regions, the fewer DHPC there are residing in curved regions and forming lamellar perforations. Since transbilayer diffusion will occur preferentially through such perforations, it should scale inversely with q^*.

As shown schematically in Fig. 6, diffusion in the transbilayer direction can be measured in positively magnetically aligned bicelles, with pulsed field gradients directed along the z axis, parallel to the static magnetic field.

Figure 11 shows the reduced transbilayer water diffusion

Fig. 10. ^{31}P NMR spectra of (left) positively magnetically aligned bicelles composed of 100 mol dimyristoyl phosphatidylcholine (DMPC) / 5 mol dimyristoylphosphatidylglycerol (DMPG) / 1 mol dimyristoyl phosphatidylethanolamine (DMPE) – polyethyleneglycol (PEG) 2000 + dihexanoyl phosphatidylcholine (DHPC) in the ratio q = (DMPC + DMPG + DMPE–PEG 2000) / DHPC = 4.5 as a function of temperature, and (right) at 35 °C as a function of q as indicated. All samples contained 25% *w/w* lipid–water and included ytterbium in the ratio Yb^{3+}:P = 1:75 to achieve positive magnetic alignment. Adapted from Soong and Macdonald.[41]



coefficient ($D_\parallel/D_0$), for the same series of positively magnetically aligned bicelles described in Fig. 10, i.e., as a function of q and of temperature, where D_0 refers to the bulk water diffusion coefficient at the corresponding temperature.[41] Because water is a small molecule, it is expected that its transbilayer diffusion will be insensitive to the size of the lamellar perforations and reflect, instead, only the the total surface area of lamellar perforations. This suggests the following simple relationship between $D_\parallel/D_0$ and q^*

$$[15] \qquad \frac{D_\parallel}{D_0} = \frac{1}{1 + \frac{A_{lam}}{A_{perf}}} = \frac{1}{1 + B \cdot q^*}$$

where A_{lam} and A_{perf} are the respective surface areas of lamellar regions and perforations and B is a model-dependent constant of proportionality relating the number of DHPC occupying perforations to the fractional surface area of those perforations.

In Fig. 11 the reduced transbilayer water diffusion coefficient is plotted as a function of $1/(1 + B{\cdot}q^*)$ for both the q-dependent (constant temperature) and the temperature-dependent (constant q) diffusion measurements using q^* values obtained from the ^{31}P NMR spectra in Fig. 10. For the q-dependent data, transbilayer water diffusion decreases as q^* increases, i.e., as DHPC decreases, supporting the supposition that water diffuses principally through DHPC-dependent lamellar perforations. For the temperature-dependent data, transbilayer water diffusion actually decreases as temperature increases, the direct converse of the Stokes–Einstein equation's expectation, but the expected result from eq. [15] given the temperature-dependent changes in q^*. The solid line indicates the idealized 1:1 relationship between the reduced transverse diffusion coefficient and the fractional

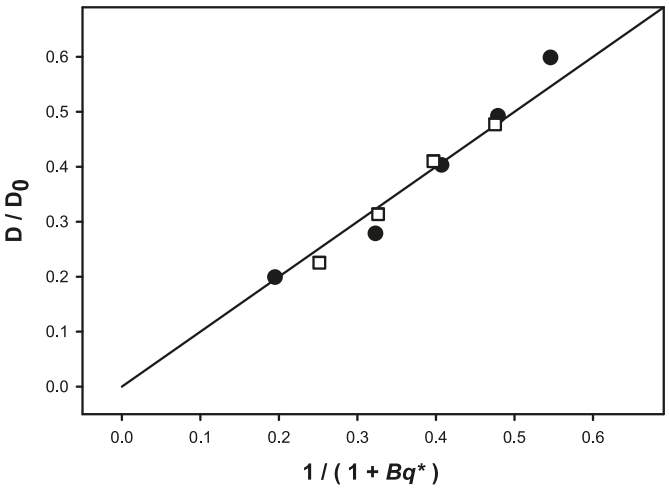
Fig. 11. Reduced transbilayer water diffusion coefficient $D_{\|}/D_0$ as a function of the calculated surface fractional area of pores in bicellar lamellae. $D_{\|}$ was measured in positively magnetically aligned bicelles as a function of temperature at constant $q = 4.5$, and as a function of q at constant temperature (35 °C). The surface fractional area of pores was calculated according to eq. [15] using values of q^* obtained from ^{31}P NMR spectra as described in the text, with $B = 0.16$ as derived from the best 1:1 fit as shown by the solid line. q series at 35 °C (□). Temperature series at $q = 4.5$ (●). Adapted from Soong and Macdonald.[41]



surface area of perforations and corresponds to the value $B = 0.16$. The fact that the q dependence and the temperature dependence of the transverse water diffusion coefficients fall on a common curve when treated in this fashion indicates that the common element is indeed the fraction of DHPC resident in perforations as derived assuming the mixed bicelle model. While it is possible to relate B to the number of DHPC required to form a pore, the conclusions are heavily model-dependent, require assumptions regarding pore size that cannot be obtained from water diffusion data, and do not account for other possible, albeit secondary, contributors to transbilayer water diffusion, such as bilayer fluctuations.[130]

The size of lamellar perforations

To obtain information regarding the size of the lamellar perforations, transbilayer diffusion of various molecular weight PEG was examined in positively magnetically aligned bicelles.[131] The fundamental idea is shown schematically in Fig. 12, where smaller PEG will be able to enter and traverse the DHPC-lined pores while larger PEG will be blocked. Hence, the molecular weight dependence of transbilayer PEG diffusion should reveal the pore–perforation–defect dimensions.

As shown in Fig. 13, where Ln I/I_0 is plotted vs k for various molecular weight PEG in positively magnetically aligned bicelles, transbilayer diffusion decreases with increasing PEG size, but, importantly, the diffusive decays are diffusion time independent. The latter point indicates that Tanner's asymptotic limit for diffusion across stacked, equally spaced, semipermeable barriers has been reached,[93] in that the rms diffusion displacement (several microns for PEG 4600 where $D \leq 1 \times 10^{-11}$ m^2 s^{-1}) has exceeded many multiples of the barrier spacing (roughly 100 Å),[36] so that the diffusion coefficient can be obtained simply by fitting with eq. [9], as shown by the solid curves in Fig. 13.

Fig. 12. Schematic cross-section through one defect in the perforated lamellar morphology of dimyristoyl phosphatidylcholine (DMPC) / dihexanoyl phosphatidylcholine (DHPC) bicelles. Bicelles consist of DMPC-rich (light grey) bilayer regions edged with DHPC-rich (dark gray) curved regions. The defects correspond to toroidal perforations in bicellar lamellae. Diffusants smaller than the defect dimensions can diffuse freely while larger diffusants are hindered. The NMR diffusion experiment is arranged such that the component of the molecular diffusion tensor parallel to the direction of the transverse defect axis ($D_{\|}$) is measured exclusively. Adapted from Soong et al.[131]

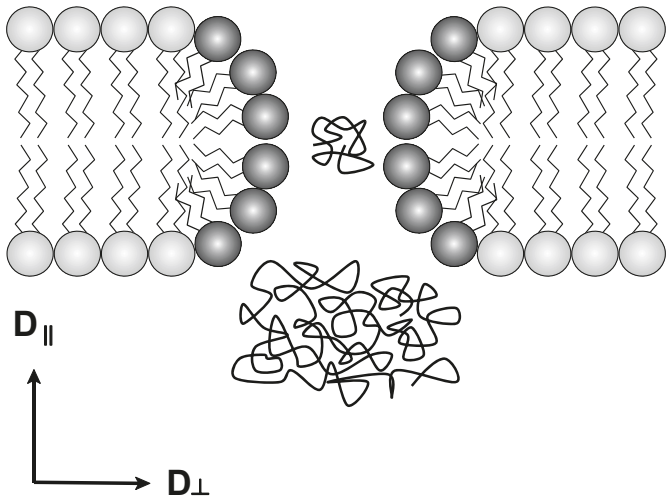


Fig. 13. Normalized diffusive intensity decays from stimulated echo (STE) pulsed field gradient (PFG) ^{1}H NMR spectra (35 °C) of various molecular weight polyethyleneglycol (PEG; as indicated) confined within positively magnetically aligned bicelles. Symbols represent different diffusion times: 210 ms (▲), 410 ms (○), 610 ms (■), 810 ms (◇), and 1010 ms (▼). The solid lines are fits using eq. [9]. Adapted from Soong et al.[131]

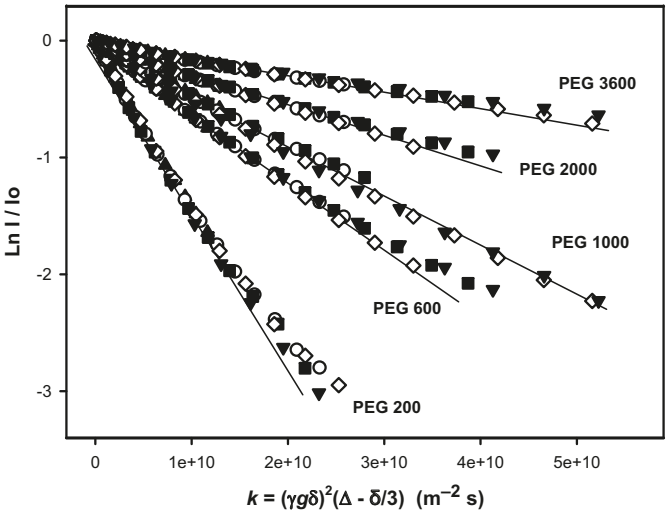

As shown in Fig. 14, the reduced transbilayer diffusion coefficient $D_{\|}/D_0$ decreases profoundly with increasing PEG size, as expressed in terms of the particular hydrodynamic,

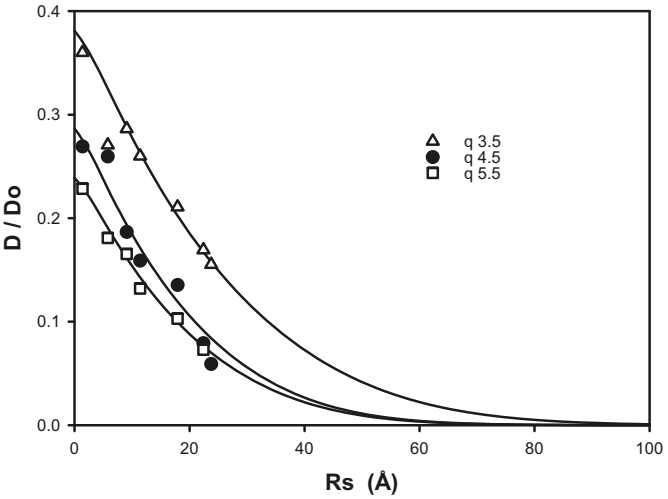
Fig. 14. Reduced transbilayer diffusion coefficients D/D_0 for various molecular weight polyethyleneglycol (PEG) in positively magnetically aligned bicelles as a function of the corresponding PEG Stokes–Einstein radius (R_s). Data are shown for three q values: 3.5 (△), 4.5 (●), and 5.5 (□). Solid curves show the best-fit Davidson and Deen model[132,133] predictions for the mean pore radii $<R_p>$ indicated in the text. Adapted from Soong et al.[131]



or Stokes–Einstein, radius R_S. D_0 is the diffusion coefficient of a particular PEG free in solution, from which R_S is obtained by application of eq. [1]. An average effective pore radius may be obtained by fitting such data to an appropriate model for reduced diffusion of flexible polymers through pores.

For fitting of the experimental diffusion data Davidson and Deen's hydrodynamic model is especially useful.[132,133] These authors considered the combined effects of steric exclusion from the pore and increased hydrodynamic drag within the pore, such that

$$[16] \qquad D/D_0 \sim f(\text{defect})\Phi K^{-1}$$

where Φ is the partition coefficient, describing the energetic cost, largely entropic in origin, of a polymer entering such a pore and K^{-1} accounts for the increased hydrodynamic drag on a polymer contained within such a pore. The leading term f(defect) was introduced by us to account for the fractional lamellar surface area of defects available for diffusion and is directly obtained from $D_{\|}/D_0$ for water as mentioned above. Both Φ and K^{-1} contain the term R_g/R_p relating the polymer radius of gyration to the pore radius.

For further details regarding this model and the relevant expression, a discussion of the evolution of such models and a comparison of different models, the interested reader is referred to these authors' original publications[132,133] and the comprehensive review by Deen.[134]

The solid curves in Fig. 14 show the lines of best fit of this modified Davidson and Deen model to the reduced PEG diffusion coefficients in bicelles at the three q values investigated, for the consensus values of $R_p = 165$ Å for the case $q = 3.5$ and $R_p = 125$ Å for both $q = 4.5$ and 5.5. Thus, both the number and the size of the lamellar perforations increase as q decreases (and DHPC increases). Compared with predictions derived from static geometric models of bicelle morphology,[57,131] whether disks or perforated lamellae are assumed, the apparent experimental pore sizes are consistently larger, and the trend as a function of q is diametrically opposite. A significant contributor to this discrepancy may well be fluctuations of the bicellar assemblies not considered by models such as that of Davidson and Deen, which treat the pores as static defects, but which are understood to contribute to transbilayer diffusion.[130] The fact that the discrepancy between pore size predictions from geometric models and experimental values determined from diffusion are greatest at lower q,[131] where the higher DHPC content decreases membrane ordering, implying increased fluctuations, tends to support this notion.

Conclusions and future prospects

Bicelles offer particular advantages as a model system for diffusion studies, whereas conversely, diffusion studies are a useful means to probe bicelle morphology. Whereas a number of controversies have been laid to rest as a result of diffusion measurements, new aspects of bicelle morphological plasticity continue to emerge, more complex lipid compositions than the canonical DMPC/DHPC mixtures become a focus of interest, and one always wishes to incorporate and investigate proteins.

A prerequisite for straightforward bicelle diffusion measurements is a visible NMR resonance capable of surviving the relaxation filters inherent to the PFG NMR diffusion sequence. Attaching a PEG moiety to the diffusant of interest is one strategy that has been demonstrated here, relying on the high internal mobility intrinsic to PEG. PEGylation of virtually any chemical species of interest is now possible. Alternately, many membrane-associating species, proteins in particular, may possess unstructured regions of intrinsically high flexibility such as extramembranous loops.

Emerging aspects of bicelle morphology include the nematic ribbon structure observed via SANS and PFG NMR for neutral, i.e., uncharged, bicelles, wherein diffusion is confined to a 1D path.[135] New bicelle compositions with improved alignment properties continue to be reported; for example, DHPC has been replaced with the detergent Triton 100.[136] Convincing instances of domain formation in bicelles, such as might be expected with raft-forming lipids, remain to be demonstrated, although domain formation and properties are readily characterized through diffusion measurements.

Certain aspects of the properties of membrane-associating proteins may prove amenable to study in bicelles via diffusion NMR, while others may not. The state of oligomerization of transmembrane helical proteins, for example, however important biologically, is not likely to be amenable to detailed inspection by diffusion NMR given the weak dependence of the lateral diffusion coefficient on the membrane cross-sectional area in the hydrodynamic size regime relevant to membrane proteins. On the other hand, diffusion NMR may well be able to differentiate oligomerization states of membrane-surface-associating peptides, where surface association may catalyze aggregation.

Finally, PFG NMR diffusion techniques are enormously useful for the study of ligand–protein association.[137] Membrane proteins, such as G protein coupled receptors, are extremely attractive drug targets.[138] It is conceivable, therefore, that mag-

netically aligned bicelles containing reconstituted membrane proteins could be used as a platform for diffusion NMR studies of drug – membrane protein interactions.

A multinuclear NMR and quantum chemical study of solid trimethylammonium chloride

Glenn H. Penner, Renee Webber, and Luke A. O'Dell

Abstract: The solid salt, trimethylammonium chloride (TMAC), is investigated by a combination of NMR spectroscopic techniques and quantum chemical calculations. Chemical shift and nuclear quadrupolar interaction parameters have been measured for ^{35}Cl, ^{1}H/^{2}H, and ^{15}N/^{14}N. These parameters have also been calculated as a function of the hydrogen position in the N···H···Cl fragment. Overall, the measured parameters are consistent with a structure in which the hydrogen is completely transferred to the nitrogen (i.e., N–H···Cl). The high hydrogen chemical shift (10.9 ppm by ^{2}H CP/MAS) and relatively small deuterium quadrupolar coupling constant (127 kHz) indicate a moderately strong N–H···Cl hydrogen bond. A pronounced deuterium isotope effect on the ^{35}Cl quadrupolar coupling constant is observed.

Key words: solid-state nuclear magnetic resonance, hydrogen bonding, NMR.

Résumé : On a étudié le chlorure de triméthylammonium (CTMA), à l'état de sel solide, par une combinaison de techniques de spectroscopie de RMN et de calculs de chimie quantique. On a mesuré les déplacements chimiques et les paramètres d'interaction quadripolaire nucléaire pour le ^{35}Cl, les ^{1}H/^{2}H et les ^{15}N/^{14}N. On a aussi calculé ces paramètres en fonction de la position de l'hydrogène dans le fragment N···H···Cl. Dans l'ensemble, les paramètres calculés sont en accord avec une structure dans laquelle l'hydrogène est complètement transféré à l'azote (c'est-à-dire N-H···Cl). Le déplacement chimique élevé de l'hydrogène [10,9 ppm par polarisation croisée standard avec rotation à l'angle magique (« CP/MAS ») du ^{2}H] et la constante de couplage quadripolaire relativement faible du deutérium (127 kHz) indiquent qu'il existe une liaison hydrogène N-H···Cl relativement forte. On a aussi observé un effet isotopique prononcé du deutérium sur la constante de couplage quadripolaire du ^{35}Cl.

Mots-clés : résonance magnétique nucléaire à l'état solide, liaison hydrogène, RMN.

Introduction

Chemists have used many disparate techniques in their attempts to understand the hydrogen bond.[1] NMR spectroscopy has proven to be one of the most powerful of these methods.[2,3] NMR spectra can be used to study the effects of hydrogen bonding by directly probing the nucleus of the donor or acceptor atom, or even the hydrogen itself. Information about the hydrogen bond comes from the measurement of the chemical shift, nuclear quadrupolar, dipolar or *J*-coupling interactions through lineshapes and nuclear spin relaxation times.

Solid trimethylammonium chloride (TMAC) is an excellent example of a system with an N–H···Cl hydrogen bond. TMAC offers several magnetic nuclei (^{15}N, ^{14}N, ^{1}H, ^{2}H, ^{37}Cl, and ^{35}Cl), which are part of the hydrogen bonding structure. Yet the only reported solid-state NMR work on this solid consists of two studies of the ^{15}N–^{1}H dipolar coupling.[4,5]

Fourier transform microwave experiments carried out by Legon and Rego,[6,7] gave ^{14}N and $^{35/37}$Cl quadrupolar coupling constants (C_Q) that were consistent with a significant proton transfer from chlorine to nitrogen in the gas phase. Also in line with this conclusion is the N···Cl stretching force constant, as obtained from the centrifugal force constant, D_J. Subsequent quantum chemical calculations agree that the most stable species is the $Me_3NH^+Cl^-$ complex (see Fig. 1*a*), with a somewhat elongated N–H bond length.[8,9]

At room temperature, solid TMAC exists as crystals in the monoclinic space group $P2_1/m$, with one molecule per asymmetric unit ($Z' = 1$, see Fig. 2).[10] . At 308 K, TMAC undergoes a phase transition to a tetragonal phase with space group $P4/nmm$ (also $Z' = 1$).[11,12] Attempts to refine the structure in the tetragonal phase were only partially successful.[11,12]

In 1974, Huong and Schlaak examined the IR and Raman spectra of the series Me_3NHX, where X = Cl, Br, or I, and noted that the N–H stretching frequency increased along this series, which is consistent with a decreasing hydrogen bond interaction.[13]

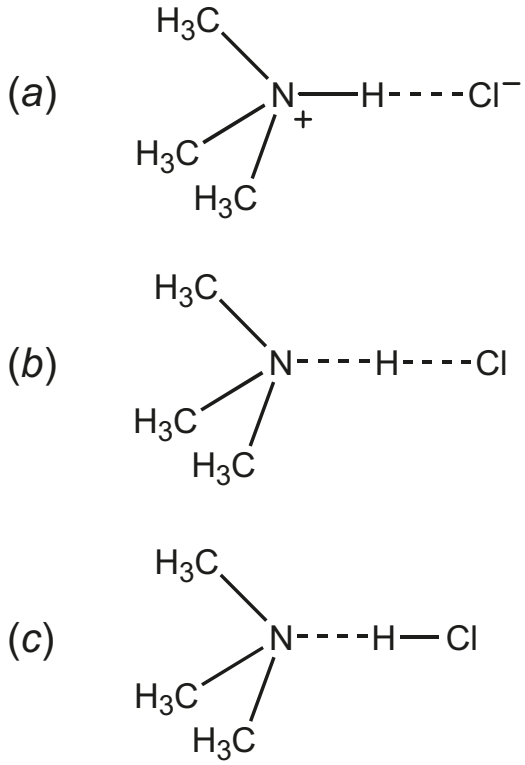
Fig. 1. Three possible species of TMAC. (*a*) $Me_3NH^+Cl^-$, (*b*) $Me_3N\cdots H\cdots Cl$, and (*c*) $Me_3N\cdots HCl$.



Early proton second moment and T_1 studies, and more recent ^{13}C T_1 work, concentrated on the dynamics of the trimethylammonium cation. These show fast methyl and trimethyl reorientation at room temperature.[14–17] The two NMR investigations that were most relevant to hydrogen bonding in solid TMAC measured the dipolar couplings between the ^{15}N–^1H and ^{15}N–^2H spin pairs. Roberts et al. used dipolar–chemical shift 2D MAS experiments to obtain $r(^{15}N–^1H)$ = 1.075 Å.[4] Hoelger and Limbach obtained $r(^{15}N–^1H)$ = 1.090 and 1.096 Å from CP/static and CP/MAS spectra, respectively. They also obtained $r(^{15}N–^2H)$ = 1.080 and 1.083 Å from CP/static and CP/MAS spectra, respectively, of the deuterated sample.[5] These r values are all at least 0.06 Å longer than that expected for an isolated N–H bond (1.01 Å).[18] This could be due to slight wobbling motion of the cation and (or) vibrational averaging. It could also be due to N–H···Cl hydrogen bonding.

In this investigation we present the results of a combined multinuclear (^{15}N, ^{14}N, ^1H, ^2H, and ^{35}Cl) NMR and quantum chemical study of the N–H···Cl hydrogen bond in solid TMAC.

Experimental

Sample preparation

Trimethylamine hydrochloride was purchased from Aldrich. Trimethylamine-d_9-hydrochloride was purchased from CDN isotopes with a reported isotopic purity of 99%. Trimethylamine hydrochloride-d_1 was prepared by evaporation from D_2O. Due to the extremely hygroscopic nature of trimethylamine hydrochloride, samples were heated under vacuum for at least 12 h to remove any moisture. All samples were packed in 4.0 mm o.d. zirconia rotors in a glove box, under an atmosphere of nitrogen to ensure sample dryness. All experiments were performed within a few days of sample preparation.

NMR spectroscopy

Solid-state ^{35}Cl NMR spectra were obtained at two fields, 11.75 T (ν_L = 49.06 MHz) and 18.8 T (ν_L = 78.48 MHz). The 11.75 T experiments were performed on a Bruker Avance II spectrometer using a 4 mm Bruker HFX MAS probe. Experimental setup and pulse calibrations at 11.75 T were performed using solid NaCl, and ^{35}Cl spectra were referenced to the centreband of solid NaCl at 0 ppm. The chemical shift was then corrected to NaCl at infinite dilution by subtracting 45.37 ppm.[19] The nonselective, "solution $\pi/2$" pulse length determined using NaCl was 6.5 μs. The central-transition selective, "solid $\pi/2$" pulse used was therefore 6.5 μs/(I + 1/2) = 3.25 μs. The static spectrum was collected using the $\pi/2 - \tau - \pi/2 - \tau$ – ACQ echo pulse sequence with an interpulse delay of 100 μs. A recycle delay of 1 s was used, and signal averaging was carried out over about 80 000 scans. The high-temperature spectrum (330 K) was obtained using sample heating controlled by a Bruker BVT 3000. The ^{35}Cl experiment at 18.8 T was performed on a Bruker Avance spectrometer using a 4 mm Bruker HX MAS probe. Experimental set-up, pulse calibration, and referencing were done using solid NaCl, as above. The ^{35}Cl solid $\pi/2$ pulse was 4.15 μs and a recycle delay of 1 s was used.

The ^1H NMR spectrum was acquired at 11.75T (ν_L = 500.14 MHz) using a Bruker Avance II spectrometer and a wideline probe constructed to have minimal proton background. The ^1H spectrum was referenced to the residual proton signal in pure liquid $CDCl_3$ at 7.24 ppm. The static spectrum was obtained with a single pulse.

All ^2H NMR spectra were acquired at 11.75 T (ν_L = 76.78 MHz) using a Bruker Avance II spectrometer and a 4 mm Bruker HFX MAS probe. The magic angle was set by maximizing the number of rotational echoes in the ^{23}Na FID of solid $NaNO_3$ spinning at 5 kHz. Experimental setup and pulse calibrations were performed using solid $(CD_3)_2SO_2$, and ^2H spectra were referenced to $(CD_3)_2SO_2$ at 2.77 ppm relative to TMS. The ^2H spectrum collected under stationary conditions used the $\pi/2 - \tau - \pi/2 - \tau$ – ACQ echo pulse sequence with $\pi/2$ pulses of 3.6 μs and an interpulse delay of 20 μs. The recycle delay was 30 s, and 2000 scans were collected (total experimental time of ~17 h). For the ^2H CP/MAS experiments, contact times of 10 ms were employed and 83 kHz proton decoupling was applied during acquisition. Recycle delays of 5 s were used and an average of 400 scans were collected (total experimental time of 34 min).

The ^{14}N NMR spectrum was acquired at 21.1 T (ν_L = 65.02 MHz) using a Bruker Avance II console and a 7.0 mm HX static probe built in-house (National Ultra-High Field NMR Facility for Solids, Ottawa). The WURST-QCPMG pulse sequence[20,21] was used with eight-step phase cycling and 50 μs WURST-80 pulses swept over a range of 1.0 MHz, resulting in an excitation bandwidth of approximately 850 kHz. The optimum RF power for the WURST pulses was experimentally determined as $\nu_1 \approx 30$ kHz. Continuous-wave ^1H decoupling of $\nu_2 \approx 15$ kHz power was applied for the duration of each scan. Solid NH_4Cl was used

as a reference and set to 0 ppm. The ultra-wideline spectrum was acquired in six pieces at transmitter offset frequencies of ±0.4, ±0.7, and ±1.0 MHz, with the WURST pulse sweep direction from low to high frequencies on the high frequency side and vice-versa.[22] For each piece, 32 echoes were acquired with 120 scans and a recycle delay of 10 s (total experiment time of 2 h). Transverse ^{14}N relaxation was observed to be relatively short compared with most crystalline organic molecules that we have previously studied,[23,24] indicating the presence of dynamics, which can cause rapid transverse dephasing via modulation of either the EFG tensor[25] or heteronuclear dipolar couplings.[24] A variation of the proton decoupling power could in principle be used to identify the latter mechanism,[24] however due to experimental time contraints this was not attempted.

A ^{15}N NMR spectrum was acquired at 11.75 T (ν_L = 50.70 MHz) using a Bruker Avance II spectrometer and a 4 mm Bruker HFX MAS probe. A RAMP cross-polarization pulse sequence was used with 5 kHz sample spinning, a contact time of 10 ms, 100 kHz proton decoupling, and a recycle delay of 2 s; 4000 scans were collected. The spectrum was referenced to the nitrate signal of solid $^{15}NH_4{}^{15}NO_3$,, which is at 4.4 ppm with respect to pure liquid nitromethane at 20 °C.

Spectral processing and simulation

Data were processed using TopSpin software (with the exception of ^{14}N data). FIDs were left-shifted where necessary, apodized using an exponential function of 10–100 Hz for MAS samples or 100–6000 Hz for static samples, and Fourier-transformed. Baseline corrections were applied to all ^{2}H CP/MAS spectra and the ^{1}H static spectrum. Spectral simulations of ^{35}Cl, ^{1}H, and ^{2}H were performed using WSOLIDS1[26] and the Solid Line Shape Guide within TOPSPIN 2.1.

For ^{14}N, spectral processing was carried out using the NUTS software (Acorn NMR). QCPMG trains were split into individual echoes, which were co-added prior to Fourier transformation. Absorptive spectra were obtained via a magnitude calculation, and complete spectra were reconstructed from the individual pieces via co-addition. EFG parameters and the isotropic chemical shift were determined by manually fitting simulations to the experimental spectra using the DMFit software.[27]

Computational details

Potential energy curves, EFG tensors, and magnetic shielding tensors were calculated using Gaussian03 (G03).[28] Single-point energy calculations were performed (r(N–H) in trimethylamine hydrochloride was stepped from 1–1.8 Å) using Hartree–Fock (HF), density-functional theory (DFT) employing the hybrid B3LYP functional, and coupled cluster singles and doubles (CCSD) methods with an augmented Dunning basis set (aug-cc-pVtz). The single-point energy calculations were performed using the X-ray structure of trimethylamine hydrochloride. The X-ray structure does not include hydrogen positions, thus, protons were inserted manually and positions were optimized using the B3LYP/6–311++G** level of theory; the heavy-atom positions were kept fixed during this optimization. Optimization of the hydrogen positions in the N–H···Cl bond and the N···H–Cl bond were performed with the three methods used to generate the PE curves. For these optimizations, all of the atoms were frozen except for the hydrogen involved in the bond; the N–H···Cl angle was forced to be linear. These optimizations allowed for accurate determination of the energy difference between the two minima

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

in each PE curve. EFG and magnetic shielding calculations were performed with the HF and DFT methods, using Pople-type and Dunning-type basis sets. The gauge-including atomic orbitals method (GIAO) was used for calculating chemical shielding tensors. The EFG and magnetic shielding tensors contained in the G03 output files were analyzed using the EFGShield program.[29]

Plane-wave DFT calculations were performed using the CASTEP software[30–33] in the Materials Studio 4.3 software suite on an HP xw4400 Workstation with a single Intel Dual-Core 2.67 GHz processor and 8 GB DDR RAM. This software employs the gauge-including projector augmented wave algorithm (GIPAW).[30] Revised Perdew, Burke, and Ernzerhof (PBE) functionals were used with the generalized gradient approximation for the exchange-correlation energy. The plane-wave basis set cut-off was set to 300 eV and 16 k-points were sampled. Proton positions were inserted manually and optimized using a Broyden–Fletcher–Goldfarb–Shanno optimization algorithm,[34] with the lattice parameters and coordinates of all other atoms fixed. Ultrasoft ^{14}N pseudo-potentials were used for the EFG calculations.[35]

Results and discussion

Potential energy curve

The calculated potential energy curves as a function of the N···H distance in solid TMAC are shown in Fig. 3. All calculations were performed on isolated TMAC, with the exception of those employing CASTEP, which used the extended crystal structure. In all calculations the methyl groups, nitrogen atom, and chloride ion are held in positions corresponding to the solid state structure and the hydrogen position is varied while being kept colinear with the nitrogen and chloride atoms. The N···Cl distance in solid TMAC is 3.005 Å.[10] The N–H distances were varied, in steps of 0.05 Å, from that for a typical N–H bond length (1.0 Å) to that corresponding to complete transfer of the proton to the chlorine atom (1.7 Å). As one can see, the PE curve depends strongly on the method used in the calculation. Relative to structure **1a**, the energies of structure **1c** are 27.0 kJ/mol for HF/6–311++G(d,p), –2.9 kJ/mol for MP2/6–311++G(d,p), 5.3 kJ/mol for B3LYP/6–311++G(d,p), and 8.3 kJ/mol for CC(SD)/aug-cc-pvtz. Plane-wave calculations show no minimum corresponding to structure **1c**. Each isolated molecule curve has a short N–H distance minimum, corresponding to structure **1a**, and a long N–H distance minimum, corresponding to structure **1c**. These distances are, respectively, 1.060/1.657 Å for HF/6–311++G(d,p), 1.144/1.615 Å for MP2/6–311++G(d,p), 1.144/1.561 Å for B3LYP/6–311++G(d,p), and 1.11/1.63 Å for CC(SD)/aug-cc-pvtz (estimated from curve). The plane-wave calculations yield a structure **1a** minimum energy at 1.10 Å. In all cases the optimized short distance is longer than that obtained from an optimized structure of the isolated Me_3NH^+ cation (1.02 ± 0.01 Å for all isolated TMAC calculations). This is consistent with the elongation of the N–H bond expected for an N–H···Cl hydrogen bond.

Chlorine spectra and calculations

The room temperature ^{35}Cl spectra of static samples of TMAC obtained at 11.75 and 18.8 T are shown in Fig. 4. The combined results of the analyses of these spectra, to-

gether with the 11.75 T spectrum at 330 K (see Fig. 5), are provided in Table 1. The parameters obtained from the analyses of the 295 K spectra at two fields are in very good agreement. The point symmetry at chlorine in the room temperature phase is C_{2v}, and this is reflected in a κ value that is significantly different from ±1. However the η_Q value is still very close to 0. The shielding tensor is obviously more sensitive than the quadrupolar interaction to small deviations from C_3 symmetry due to crystallographic effects.

The phase above the transition is tetragonal, which imposes axial symmetry on the chlorine. Our simulations show that the spectrum is rather insensitive to the κ value. We can simulate the spectrum at 330 K with κ values of –0.75 to –1.0. Thus the κ value and η_Q values are within experimental error of –1 and 0, respectively, at 330 K. This is consistent with the crystallographic tetragonal symmetry and a chlorine site symmetry of C_{3v}. In addition to these changes, the Euler angle γ changes from 230°/225° to 270°. Although a previous attempt at a complete structure refinement of the tetragonal phase at 340 K was not fully successful, an N···Cl distance of 2.972(9) Å was determined.[11,12] This is 0.03(1) Å shorter than that in the monoclinic phase. Evidently, the small structural changes that occur during the phase transition result in minor changes in the chlorine quadrupolar interaction and more significant changes in the asymmetry of the shielding tensor.

It is of interest here to compare the optimized N–H distance, the ^{35}Cl C_Q, and the chlorine shielding tensor for the monomer and extended lattice structures of solid TMAC. The optimized N–H distance in the monomer is 1.124 Å (B3LYP/6–311G) and is 1.080 Å for the extended lattice (CASTEP, using revised Purdew–Burke–Ernzerhof functionals). The C_Q values for these structures are –14.9 and –9.6 MHz, respectively. In all cases the η_Q was very close to zero. The calculated Ω, κ values are 138 ppm, –0.94 and 113.5 ppm, 0.12, respectively.

There have been several $^{35/37}$Cl NMR studies of solids with N–H···Cl interactions.[19,35–38] Our observed C_Q and Ω values are consistent with these studies. Of particular interest are the results for quinuclidine hydrochloride, which is structurally similar to TMAC. Both the $|C_Q|$ value of 5.25 ± 0.02 MHz and the estimated Ω of 50 ± 30 ppm are very close to our values for TMAC.[19]

Figures 6 and 7 show the computed dependence of the ^{35}Cl C_Q and Ω values, respectively, as a function of the N–H distance in isolated TMAC (heavy atoms held at X-ray structure values). The best agreement with experiment is with the HF calculation where r(N–H) = 1.0 Å. These calculations show that the magnitude of the C_Q values steadily decrease with decreasing distance and reach a value of about –6.0 MHz at 1.0 Å. This is reasonably close to our measured values, considering that the fast rotational motion of the methyl protons and the methyl groups are not taken into account in these calculations. The computed spans of the chlorine shielding tensor steadily increase with N–H distance, reaching a maximum in the 1.5–1.6 Å range. The computed spans are in best agreement with the experimental values at 1.0 Å but are still too large.

Although the CSA values we obtained have large errors associated with them, the fact that spectral analyses at two significantly different fields yield results that are in good agreement and compare favorably with previous work implies that our values are very reliable.[15] However, the Ω and κ values we obtained from our spectra are not in very good agreement with the calculations mentioned above.

At this point it is worthwhile to briefly discuss the effect of proton transfer on the chlorine quadrupolar coupling constant in general. Gas phase ^{35}Cl C_Q values are available for HCl (–67.6 MHz), H_3N···HCl (–47.6 MHz), and TMAC, TMAC-d_1 (–21.6, –19.7 MHz).[6,7] A comparison of these values with Fig. 6 indicates that the magnitude of C_Q decreases as the proton is transferred from Cl to N. Our experimental value of (±)5.59 ± 0.03 MHz is indicative of complete proton transfer from Cl to N if one ignores intermolecular and crystal lattice contributions to the C_Q in solid TMAC.

Isotope effect on the ^{35}Cl quadrupolar coupling constant

The ^{35}Cl spectra of TMAC and TMAC-d_1 are shown in Fig. 4. Results of simulations of these spectra are provided in Table 1. The ^{35}Cl C_Q values for TMAC and TMAC-d_1 are clearly different, and the difference is easily outside the experimental error limits. This kind of isotope effect has been observed in the ^{35}Cl C_Q values of TMAC as measured by gas phase microwave spectroscopy.[6,7] In the gas phase, the C_Q of the deuterated compound is 9% lower than that of the protonated compound. This is a rather significant shift in C_Q. Our solid-state results show a 5% change, which is smaller but also quite significant.

An H vs. D isotope effect on the ^{35}Cl C_Q values in a series of long chain n-$C_xH_{2x-1}NH_3Cl$ alkylammonium salts has been reported. These show an average 2% decrease in the ^{35}Cl C_Q values on deuteration of all three N–H sites.[39] However, this effect, which is presumably attenuated by the rapid rotation of the NH_3^+ groups, is not discussed in any detail. If the stretching potential of the N–H bond is anharmonic, deuteration will very slightly decrease the bond length. As can be seen from Fig. 6, a decrease in r(N–H) should result in a decrease in the magnitude of the ^{35}Cl C_Q value. This is indeed what is observed. The degree to which deuteration affects the ^{35}Cl C_Q value will depend on the anharmonicity of the N–H stretching potential. This can be demonstrated by comparing the deuterium isotope effect in gas and solid phase TMAC. Since the C_Q is much larger in the gas phase, it is likely that

the N–H bond is slightly longer, with a concomitant increase in anharmonicity. The expected result is a much larger isotope effect on the ^{35}Cl C_Q in gas phase TMAC, as is observed.

Deuterium spectra and calculations

The deuterium spectra of the N–D deuteron in TMAC are expected to be quite sensitive to the degree of N–D···Cl hydrogen bonding in solid TMAC. Figure 8 shows the deuterium quadrupolar echo spectrum of a static sample of TMAC-d_1 at 295 K. The C_Q is 130 ± 5 kHz and the η_Q is 0.03 ± 0.03. The S/N was too low, and the required relaxation delay was much too long, to obtain a series of temperature-dependent spectra in a reasonable time. Instead, CP/MAS spectra were obtained at temperatures of 320, 350, and 370 K. The CP/MAS spectrum at 370 K, together with a simulation, can be found in Fig. 9. These spectra show a small component that increases in relative intensity with temperature (vide infra). It is of interest to note that the chemical shift C_Q and η_Q are essentially temperature-independent over this temperature range. For example, at 295 and at 370 K C_Q, η_Q, and δ_{iso} are 127 ± 6 kHz, 0.06 ± 0.05, and 10.9 ± 0.9 ppm and 126 ± 5 kHz, 0.05 ± 0.05, and 10.9 ± 1.0 ppm, respectively. If the deuteron was rapidly hopping between two sites with significantly different quadrupolar and shielding interactions, as would be implied by some of the potential energy curves in Fig. 3, one would expect a measurable temperature dependence of C_Q and δ_{iso}. Also, the fact that C_Q and δ_{iso} are independent of temperature suggests that there is no temperature-dependent wobbling motion of the trimethylammonium cation. This is a frequently observed phenomenon, particularly in small spheroid molecules, which causes a reduction of the observed C_Q with temperature.[40] The N–H distance dependence of the computed deuterium C_Q values are shown in Fig. 10. The HF, B3LYP, and plane-wave values match the experimental C_Q at about 1.04 Å.

The ^{2}H CP/MAS spectrum at 370 K can be seen in Fig. 9. This spectrum clearly shows a very small component with a lower chemical shift and much smaller C_Q (see Fig. 9 inset). At 370 K, C_Q, η_Q, and δ_{iso} for this component are 22 ± 1 kHz, 0.09 ± 0.05, and 2.9 ± 0.3 ppm. The relative intensity of the minor component increases with temperature, reaching a maximum relative intensity of 2% at 370 K. A plot of ln K versus $1/T$ yields a straight line with a slope corresponding to a ΔE of 16 kJ/mole. The appearance of the minor component can be interpreted as a result of the presence of a solid phase in which the Me_3NH^+ cation is undergoing large amplitude precessional motion. A wobbling, precessional, motion of the Me_3NH^+ cation would require a partial or complete breaking of the N–H···Cl hydrogen bond. In the absence of hydrogen bonding, amine proton chemical shifts are in the range of 0.5–5 ppm.[41] Our B3LYP/6–311++G(d,p) calculations on isolated Me_3NH^+ give δ_{iso} = 3.1 ppm. The observed chemical shift of the minor component at 2.9 ppm is consistent with this situation. If the cation is precessing, the ratio of the C_Q values for the two components yields an effective precessional angle of about 48°.

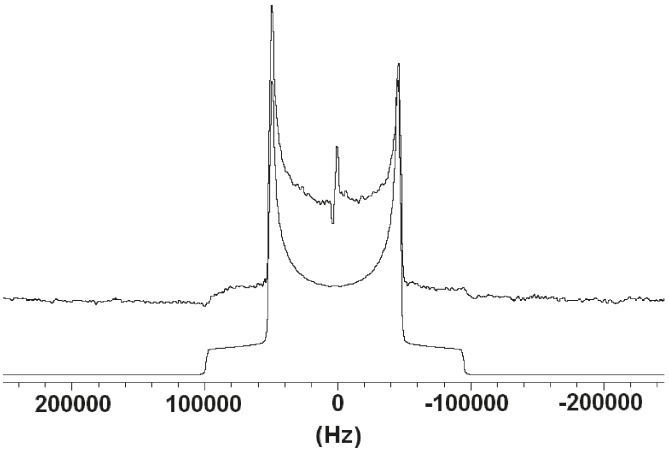
Fig. 8. The quadrupolar echo spectrum of a static sample of TMAC-d_1 at 295 K, together with a simulation using $C_Q = 130$ kHz and $\eta_Q = 0.03$. Effects of CSA were not included in the simulation. The strong narrow peak at the center of the spectrum is due to traces of moisture in the sample (despite thorough drying). The lineshape is asymmetric due to an asymmetric distribution of points around the center of the echo.



It should also be noted that the variation in peak intensity may be due to variations in CP efficiency. However, if this were the case, the intensity would be expected to decrease with an increase in temperature as a larger amplitude wobbling motion should reduce the effective ^{1}H–^{2}H dipolar interactions.

It is only through the fortuitous coincidence of the minor component having a very different chemical shift and a much smaller C_Q than the major component that we are able to see it in the ^{2}H CP/MAS spectrum. Unfortunately, the required S/N ratios in the ^{35}Cl, ^{14}N, and ^{15}N spectra are simply not achievable on our equipment with practical amounts of spectrometer time. The ^{2}H MAS spectrum of the methyl deuterated sample and the ^{13}C CP/MAS spectrum do not have the chemical shift resolution needed to observe a species with such a low relative concentration and such a small chemical shift difference from the major component. Although the ^{1}H spectrum has the sensitivity, it is not possible to observe such a relatively small resonance in the presence of two large and broad lineshapes, in addition to the significant proton background of the probe. The best chance of observing the minor component is via a ^{15}N CP/MAS spectrum of a ^{15}N enriched sample. However, such a sample is unavailable to us at this time.

Proton spectra and calculations

The proton spectra of a static sample of powdered TMAC-d_9 is shown in Fig. 11. Nearly complete deuteration of the methyl group essentially eliminates any intramolecular proton–proton dipolar coupling. The proton–deuteron dipolar coupling will be a factor of 6 smaller than proton–proton dipolar coupling, and rapid methyl and trimethyl rotation will reduce this coupling by a further factor of 9. As a result, any dipolar couplings will simply add to the broadening of the spectral lines. There are two dominant lineshapes: an intense featureless peak, which constitutes 23% of the total intensity and a broad lineshape corresponding to 77% of the total intensity.

Fig. 9. The deuterium CP/MAS spectrum of a sample of TMAC-d_1 at 370 K with sample spinning rate of 5 kHz, together with a simulation using $C_Q = 126$ kHz and $\eta_Q = 0.05$ and $\delta_{iso} = 10.9$ ppm.

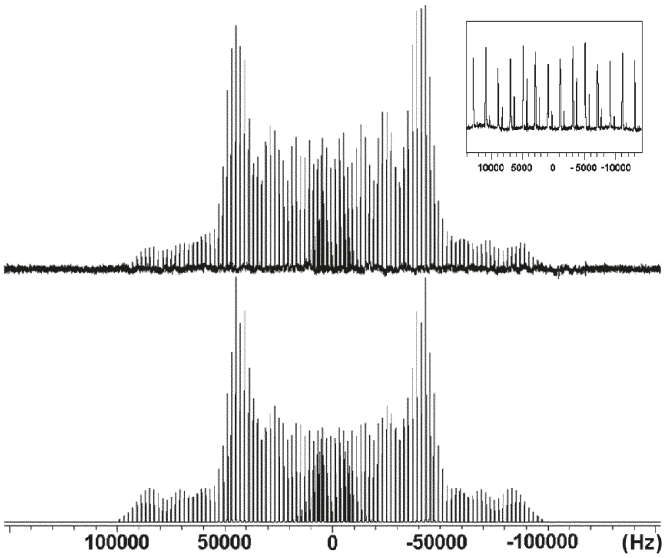


Fig. 10. Plots of the calculated ^{2}H C_Q as a function of N–H distance for TMAC with all heavy atoms fixed in their crystal structure positions, while the H atom positions were optimized. B3LYP/6–311++G(d,p) (■), HF/6–311++G(d,p) (◆), GIPAW plane-wave calculation (▲).

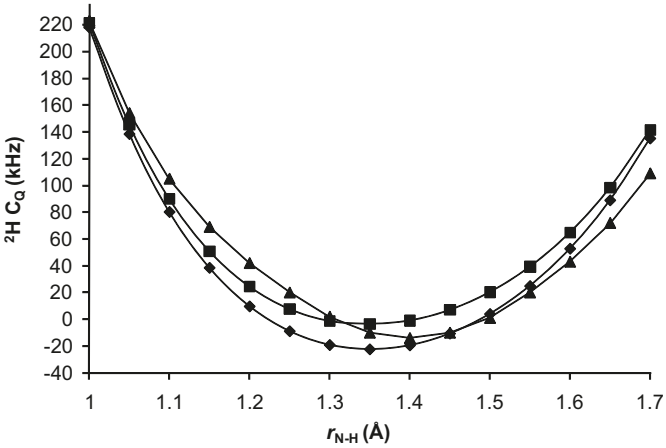

The spectrum can be deconvoluted into a component at 3.5 ± 0.8 ppm with a large linewidth and a component at 9.0 ± 1.0 ppm with a span of 45 ± 1.5 ppm and skew of –0.88 ± 0.05 (CSA = 42 ppm and $\eta = 0.13$). We assign the 3.5 ppm component to residual protons on the methyl groups and the 9.0 ppm component to the N–H proton. The relative peak areas correspond to a residual concentration of methyl protons of about 3%, due to incomplete deuteration of the sample. A plot of the calculated span of the hydrogen CS tensor (skew = –1 in all calculations) as a function of N–H distance is depicted in Fig. 12. The observed span is consistent with the isolated TMAC calculation for N–H distances ranging from 1.2–1.7 Å. The plane-wave calculations disagree with the observed span for all distances. The isotropic chemical shift, obtained from simulation of the proton spectrum, is nearly 2 ppm smaller than that obtained from the

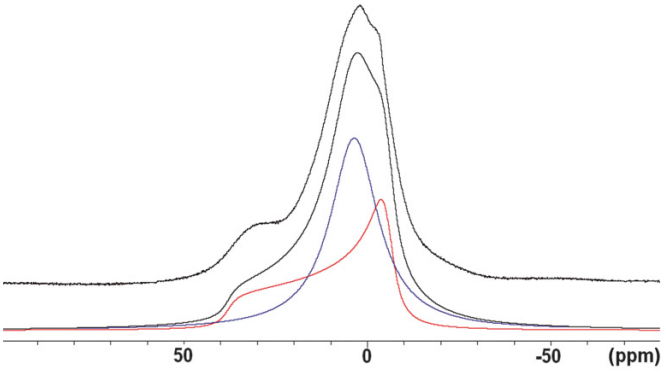
For personal use only.

Fig. 11. Plots of the proton spectrum of a static sample of TMAC-d_9 (upper trace) together with simulations of the contributions to the lineshape of the N–H proton (red online, dark grey in print) and residual CH_3 protons (blue online, light grey in print). The convolution of the two components are combined to yield the simulated lineshape. This is shown just below the experimental spectrum.



deuterium CP/MAS spectra. A primary isotope effect should move the chemical shift in the opposite direction.[42] The disagreement between the ^{2}H and ^{1}H spectra is likely due to the large error in the determination of the proton shift. Unfortunately, the severe proton background in our MAS probes made it impossible to obtain an analyzable MAS spectrum. The computed isotropic hydrogen chemical shifts are presented in Fig. 13. The curves show δ_{iso} values of 8–10 ppm for r(N–H) = 1.0 Å, typical of moderate hydrogen bonding. In the 1.3–1.4 Å range, values of 15.5–17.5 ppm were calculated, consistent with strong hydrogen bonding. The chemical shift then returns to 8–10 ppm for r(N–H) = 1.7 Å, as would be expected for a weak Cl–H···N bond. The best agreement between the computed and observed hydrogen chemical shifts occurs in the range of 1.0–1.08 Å.

Nitrogen spectra and calculations

The ^{14}N powder pattern is shown in Fig. 14. The outermost shoulders are somewhat hidden in the noise, but given the well-defined nature of the main discontinuities, it was unnecessary to obtain these features with a higher S/N, and this experimental spectrum allowed an iterative simulation to be made that resulted in the experimental parameters $|C_Q| = 1.50 \pm 0.02$ MHz, $\eta_Q = 0.02 \pm 0.02$, and $\delta_{iso} = -140 \pm 50$ ppm. CSA effects, predicted by CASTEP to be on the order of 10 ppm, were neglected in the simulation. The uncertainties were estimated visually from the quality of fit, and the very large uncertainty in the isotropic chemical shift arises from the very broad nature of the lineshape. The EFG parameters, which are measured very accurately by this technique, are in good agreement with DFT values calculated from the crystal structure using the CASTEP software. These calculations show that the ^{14}N C_Q is very insensitive to r(N–H) in the 1.0–1.2 Å range. DFT calculations of C_Q for the monomer are plotted as a function of N–H distance in Fig. 15. It has been demonstrated that these parameters can generally be calculated from crystal structures with high accuracy if the crystal structure is well-defined and dynamics are absent.[23,24] In this case, the lack of accurate proton positions and presence of dynamics will account for the discrepancy between the experimental and calculated values. The EFG tensor orientation predicted by CASTEP has the largest component of the tensor V_{33} aligned with the N–H bond, as might be expected from the crystal structure. The most shielded component of the CSA tensor (δ_{33}) is tipped away from V_{33} by 74.5°.

The ^{15}N CP/MAS spectrum (see Supplementary data) yields a chemical shift of –335.7 ppm with respect to liquid CH_3NO_2. Based on simulations of the featureless static ^{15}N CP spectrum, the span of the CS tensor is too small to accurately measure, and we place the upper limit at 10 ppm. All of our calculations give Ω values below 10 ppm and show very little variation with r(N–H). Analyses of the dipolar ^{15}N spectra of TMAC and TMAC-d_1 at 2.1 T completely ignored the effects of CSA.[5] The calculated isotropic chemical shift is rather dependent on the method used and also shows very little variation with r(N–H).

Fig. 14. (*a*) ^{14}N spectrum obtained at 21.1 T and (*b*) a fitted simulation made using parameters C_Q = 1.50 MHz, η_Q = 0.02, and δ_{iso} = 200 ppm.

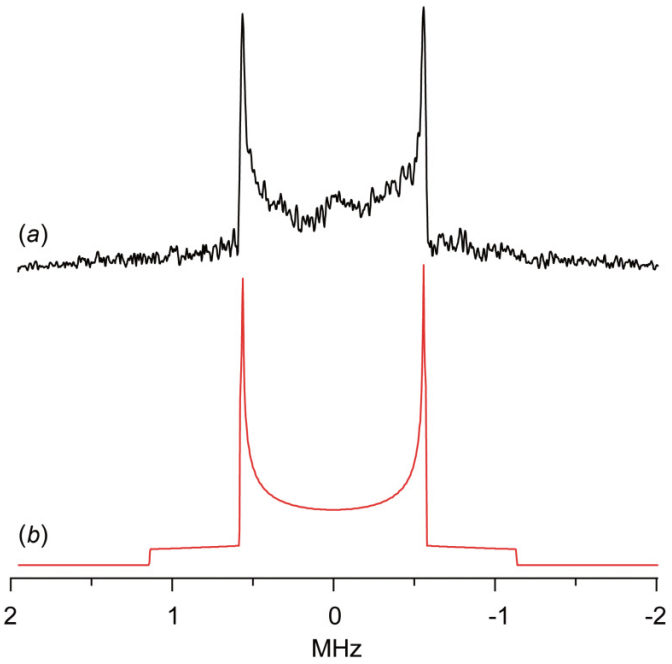

Fig. 15. Plots of the calculated ^{14}N C_Q as a function of N–H distance for TMAC with all heavy atoms fixed in their crystal structure positions, while the H atom positions were optimized. B3LYP/6–311++G(d,p) (■), HF/6–311++G(d,p) (◆), GIPAW plane-wave calculation (▲).

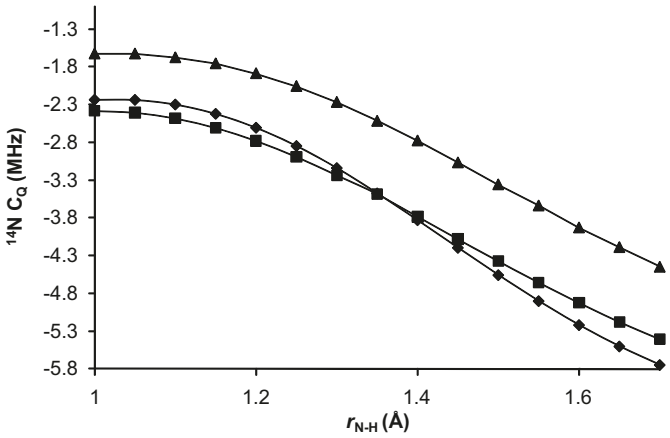

The structure of TMAC

An evolving aspect of NMR crystallography is the use of solid-state NMR spectroscopy to refine structures in crystalline solids.[43] In the case of solid crystalline TMAC this was not possible. Comparison of the measured and calculated shielding and quadrupolar parameters yield only qualitative agreement that solid TMAC exists in structure **1a**. The best determination to date of the hydrogen position in TMAC has been done through the measurement of ^{15}N–^{1}H and ^{15}N–^{2}H dipolar interactions by Hoelger and Limbach.[5] It should be noted that these are the vibrationally averaged internuclear distances. This is evident from the slight shortening of the bond length, by about 0.01 Å upon deuteration, which is consistent with what is expected for a somewhat anharmonic potential. The numbers are in good agreement with our CASTEP optimized value of 1.080 Å.

Conclusions

A multinuclear NMR and quantum chemical study of solid trimethylammonium chloride was undertaken to investigate the effects of N–H···Cl hydrogen bonding on the various observable NMR parameters. In addition, the effects of N–H internuclear distance were calculated using different quantum chemical methods.

Calculations of the energy profile, as a function of *r*(N–H), are highly dependent on the computational method used. Calculations also show that the shielding and quadrupolar interactions for $^{1/2}$H and ^{35}Cl are very sensitive to the hydrogen position in the 1.0–1.2 Å range of *r*(N–H), whereas the ^{14}N C_Q is much less dependent.

Unfortunately, it was not possible to refine the hydrogen position based on comparisons of the calculated and observed NMR parameters, as has successfully been done for the bromine position in solid $MgBr_2$ by Widdifield and Bryce.[43] With the exception of the proton chemical shift anisotropy, the measured NMR parameters are consistent with a relatively short N–H bond (structure **1a**). The high hydrogen chemical shift (10.9 ppm by ^{2}H CP/MAS) and relatively small deuterium quadrupolar coupling constant (127 kHz) indicate a moderately strong N–H···Cl hydrogen bond.

Our calculations show that the single molecule DFT and plane-wave DFT calculations are often in reasonably good agreement, the exceptions being the hydrogen span, the ^{14}N C_Q, and to a lesser degree the ^{35}Cl span. In some cases there is better agreement between the computations and experiment in the *r*(N–H) range of 1.0–1.2 Å (the interval of most interest to this study) for single molecule DFT (e.g., chlorine span), and in some cases the agreement is better for the DFT plane-wave calculations (^{14}N and ^{35}Cl C_Q values). For crystalline compounds, one would expect better agreement for the plane-wave DFT calculations. In the case of TMAC, any lack of agreement is likely due to molecular dynamics in the form of methyl and trimethyl reorientation together with uncertainty in the methyl C–H bond lengths. The latter effect can be mostly taken into account by using standard alkyl C–H bond lengths or by optimizing the methyl hydrogen positions

for every calculation. The effects of the dynamics is more difficult to deal with since this effect would have to be weighted over the rotational potential energy functions for both methyl and trimethyl rotation.

Supplementary data

Supplementary data for this article are available on the journal Web site (www.nrcresearchpress.com/cjc).

Acknowledgements

The Natural Sciences and Engineering Research Council of Canada is thanked for a Discovery grant (to GHP). The University of Guelph NMR Centre is supported by the Canada Foundation for Innovation and the Ontario Research Fund.

The National Ultra-High Field NMR Facility for Solids, Ottawa (http://nmr900.ca), is acknowledged for providing access to the 900 MHz facility and also for the use of the CASTEP software. In particular, Victor Terskikh and Eric Ye are acknowledged for assistance with the NMR experiments, and Paul Morris is thanked for help with probe construction and modifications.

One of the authors (GHP) would like to personally thank Rod Wasylishen for his hospitality during a postdoctoral fellowship (1986–1988) and a sabbatical leave (2001).

Abstract: Structurally closely related spider silks, namely, major ampullate silk (MaS) reeled at 0.5 and 10 cm/s, minor ampullate silk (MiS), and cocoon silk have been investigated by solid-state nuclear magnetic resonance (NMR). These silks exhibit different mechanical properties that are not well explained with current structural data. NMR spectra confirm that the secondary structures of these silks are similar, but that differing relaxation dynamics exist at the alanine, glycine, and glutamine residue level. MaS reeled rapidly is made of more mobile proteins in both the β-sheet and amorphous regions, suggesting that reeling speed alters molecular rearrangement during spinning, with the chain packing being less organized in the fastpull fiber. Alanine and glycine relaxation dynamics increases as MaS < MiS < cocoon silk, showing that the whole fiber displays distinctive protein dynamics, chain packing, and intermolecular interactions. Besides molecular orientation, silk extensibility is related to a more mobile structural organization.

Key words: silk proteins, solid-state nuclear magnetic resonance (NMR), structure, dynamics, reeling speed.

Résumé : Des soies d'araignée avec des structures similaires, soit la soie de la glande ampullacée majeure (MaS) filée à 0,5 et 10 cm/s, la soie de la glande ampullacée mineure (MiS) et la soie de cocon, ont été étudiées par spectroscopie résonance magnétique nucléaire (RMN) des solides. Ces soies possèdent des propriétés mécaniques différentes qui peuvent difficilement être expliquées par les données structurales connues. Les spectres RMN obtenus dans la présente étude confirment que les structures secondaires des protéines sont similaires dans ces différents types de soie, mais que leurs dynamiques de relaxation sont différentes au niveau des résidus alanine, glycine et glutamine. La MaS filée rapidement est constituée de protéines plus mobiles à la fois dans les régions riches en feuillets β et dans les régions amorphes, ce qui suggère que la vitesse de filage influence le réarrangement moléculaire durant le filage, l'empilement des chaînes étant moins bien organisé dans la soie filée rapidement. La dynamique de relaxation des résidus alanine et glycine augmente dans l'ordre MaS < MiS < soie de cocon, suggérant que ces différentes fibres sont constituées de protéines ayant des dynamiques, des empilements de chaînes et des interactions intermoléculaires différentes. En plus de l'orientation moléculaire, l'extensibilité de la soie semble donc liée à une organisation structurale plus mobile.

Mots-clés : protéines de soie, résonance magnétique nucléaire (RMN) des solides, structure, dynamique, vitesse de filage.

Introduction

The silk filaments produced by spiders are amongst nature's most highly engineered structural materials. Their mechanical properties are particularly interesting because these biomaterials are specifically designed to fulfill specific biological functions, for example, support the weight of the spider or absorb the kinetic energy and stop flying prey.[1] Orb-weaving spiders produce six types of silk by the way of seven specialized glands.[2] More specifically, major ampullate silk (MaS) displays outstanding tensile properties due to the combination of high strength and extensibility, providing a remarkable toughness.[3] Consequently, MaS can potentially be used for industrial and medical applications,[4] such as the production of artificial tendons,[5] surgical sutures[6] or micro-electro-mechanical systems.[7] To date, the combination of strength and extensibility of natural silk has not yet been reproduced by artificial means. Therefore, to produce a high-quality synthetic silk, it is necessary to understand the structural characteristics that determine the mechanics of spider silk.

The structural model proposed for MaS includes polyalanine crystalline domains embedded in an amorphous region rich in glycine residues. In this model, the crystalline domains are responsible for the strength of silk and the amorphous regions for its elasticity.[8,9] The crystalline regions are composed of highly oriented β-sheets and the amorphous regions are made of 3_1-helices, β-turns, and random coils. Several spectroscopic studies (nuclear magnetic resonance

(NMR), X-ray, Raman, and Fourier transform infrared (FTIR)) are in agreement with this model.[10–14]

MaS is used for multiple biological functions in nature, including locomotion, safety lines, web construction, signal thread, and chemical communication.[15] Each function requires specific mechanical characteristics. Typically, the spinning rate ranges between 0.5 and 10 cm/s, corresponding to the production of the frame of the web and the lifeline, respectively.[15,16] These filaments display various tensile properties. The fastpull silk has higher breaking stress and Young modulus that are well adapted to support the spider body weight during the rapid vertical descent that allows spiders to escape predators.[17–19] The slowpull silk is more extensible, which is very efficient to support, in conjunction with the capture spiral, the kinetic energy transferred to the web when prey is captured.[17–19] Overall, the breaking energy of MaS seems to be basically constant at various reeling speeds.[19] Variability in the spinning rate seems to induce changes in the micro- and molecular structures. Usually, fibers spun at higher spinning rates have a higher global level of orientation[11,20,21] and seem to contain a lower volume of highly oriented domains.[22,23] Despite these results, the effect of the spinning speed on the structural organization of silk is sparsely documented; more work is needed to understand the relationship between the structure and the mechanical properties of silk.

The structural pattern of MaS, characterized by oriented β-sheets dispersed in an amorphous matrix, is shared by various silks that belong to the same structural family.[24–28] This class includes the cocoon silk of silkworms and the minor ampullate (MiS) and cocoon silks of spiders. As shown in Table 1, these fibers have different tensile strengths varying from 1.5 MPa for MaS, 0.9 MPa for MiS, and 0.5 MPa for cocoon silk and relatively large extensibility (21% for MaS, 33% for MiS, and 20% for cocoon silk). MaS and cocoon silk display the same level of molecular orientation.[27] In nature, MiS is used to form an auxiliary spiral that serves as a scaffold for the emerging web.[34] It has also been found in the wrapping net spun around prey.[35] Cocoon silk is produced by the tubuliform gland of female spiders during the reproductive season[36] and is used to make the cocoon outer egg sac. As shown in Table 1, MiS has a lower stress at rupture than MaS, but its extensibility is higher.[26,33] Cocoon silk has the lowest breaking stress whereas its breaking strain is located between that of MaS and MiS.

These three types of silk are made of specific proteins (Table 1), i.e., MaSpI and MaSpII for MaS,[29] MiSpI and MiSpII for MiS,[31] and TuSpI for cocoon silk.[36,37,38] Like MaS, MiS contains polyalanine motifs, but they are shorter for the latter silk (n = 3–5) than for the former one (n = 5–7).[39] MiS also contains poly(Ala-Gly) sequences that are short as compared with those found in the *Bombyx mori* cocoon silk. MaS has two glycine repetitive blocks (GXX for MaSpI and GPGXX for MaSpII)[10,40] while MiS contains only GXX modules. The repetitive sequence of cocoon silk is very different with almost no polyalanine sequences and sparsely distributed repeat motifs. It is rich in serine and glutamine residues. In contrast to their tensile properties, the structural disparities observed experimentally between these three silks are small[26,27] and actual data fail to clearly explain the structural origin of their particular responses to a mechanical drawing.

Generally speaking, despite recent advances, some silk fibers display only minor structural dissimilarities that cannot alone explain their diversified tensile behaviors. Obviously, additional data are required to unravel this paradox. We have thus investigated three closely related silks (MaS, MiS, and cocoon silk) as well as the effect of the spinning rate on MaS. Understanding structural features important for tensile properties could help with the aim of producing high quality fibers. To this end, we have used ^{13}C solid-state NMR spectroscopy since it is a powerful technique to obtain information on protein secondary structure and dynamics over a large range of timescales (kHz and MHz), in crystalline as well as in amorphous regions. Since specific resonances occur in the spectra, NMR spectroscopy has the advantage that molecular structure and dynamics can be investigated at the amino acid level.

Experimental

Silk samples

MaS, MiS, and cocoon silk samples were obtained from adult female *Nephila clavipes* spiders collected from Florida, U.S. The spiders were raised in the laboratory in 20 cm × 50 cm × 60 cm cages at 58% ± 5% relative humidity and 24 ± 2 °C. They were fed four times a week with crickets of about one centimetre in length and with 3 drops of 1% or 10% glucose solution per week. MaS was collected by forced reeling at rates of 0.5 and 10 cm/s on fully awake spiders. Samples were collected onto glass test tubes under controlled conditions as described by Ortlepp and Gosline.[41] MiS was collected by forced reeling at a rate of 0.5 cm/s. Care was taken to avoid mixing of MaS and MiS during reeling. The results presented were obtained by combining samples reeled from five different individuals. Cocoon silk was obtained from the cocoons made by the spiders in the laboratory. The eggs were removed from the cocoon. All samples were kept in a dark environment at the above controlled temperature and humidity. Typically, 25 mg of each type of silk were used to perform the NMR experiments.

NMR spectroscopy

^{13}C NMR spectra of the silk samples were recorded on a Bruker Avance 400 or Avance II 900 spectrometer (Bruker Biospin, Milton, ON) operating at ^{13}C NMR frequencies of 100 MHz and 225 MHz, respectively. The 400 and 900 MHz spectrometers were equipped with a 4 and 3.2 mm magic-angle spinning (MAS) probehead, respectively (Bruker Biospin, Milton, ON). All spectra were recorded at room temperature with MAS speeds of 10 kHz at 400 MHz and 22 kHz at 900 MHz.

Two types of ^{13}C NMR spectra were recorded: cross-polarization with magic-angle spinning (CPMAS) and Hahn echo. CPMAS spectra were recorded using 2048 complex data points and a dwell time of 5 μs. The ^{1}H 90° pulse length was typically 4 μs, the contact time was 2 ms, and the recycle delay was 4 s. A ramped CP was used on the ^{1}H channel. Typically, 2048 scans were acquired at 900 MHz and 4000 scans were acquired at 400 MHz for the CPMAS spectra. For the Hahn-echo spectra, the ^{13}C 90° pulse was typically 4.5 μs and 2048 complex points were obtained with a dwell time of 5 μs, an interpulse delay of 60 μs, and

[a]The sequence is given for *Nephila clavipes* and is taken from Xu and Lewis[29] and Hinman and Lewis[30] for MaS, Colgin and Lewis[31] for MiS, and Tian and Lewis[32] for cocoon silk.

[b]The mechanical properties are given for *Argiope trifasciata*[33] which, in our opinion, represents the most accurate and most complete data set regarding the tensile properties of the silks spun by a spider species

a recycle delay of 30 s. Hahn-echo spectra were acquired with 2400 scans. Two pulse phase modulation (TPPM) proton decoupling[42] was used for both the CPMAS and Hahn-echo spectra. A line broadening of 100 Hz was applied in the processing of all spectra and chemical shifts were referenced relative to external adamantane.

^{1}H T_1 relaxation times were measured at 400 MHz using an inversion-recovery ramped-CP experiment with delays of 0.05, 0.1, 0.3, 0.5, 0.8, 1, 3, and 5 s between the 180° and 90° pulses. ^{13}C $T_{1\rho}$ relaxation times were measured using a ramped-CP sequence followed by a variable carbon spin-lock time (1, 3, 5, 7.5, 10, 12.5, 15, 17.5, and 20 ms). Typically, 4000 scans were collected for each relaxation delay and all relaxation studies were repeated twice. A homemade Excel program and the relaxation program provided by Bruker were used to analyze the relaxation data.

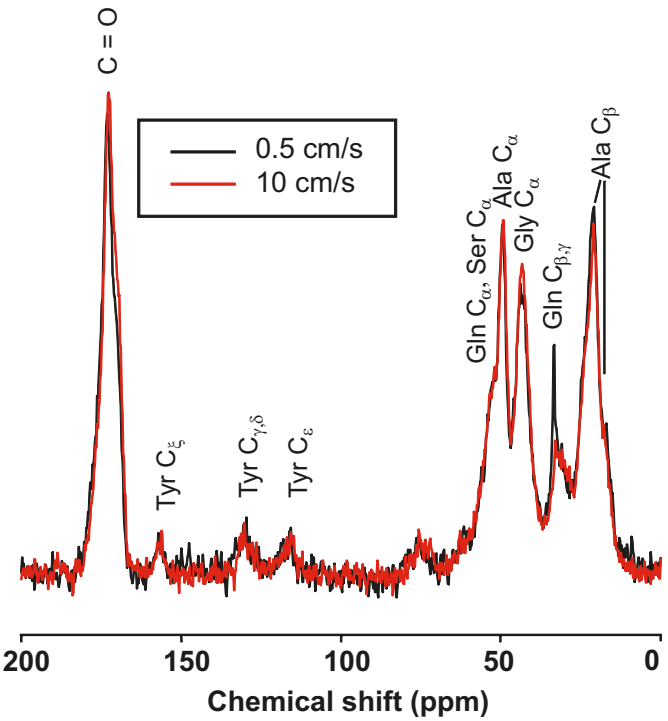
Results and discussion

Effect of the silk spinning rate on protein secondary structure

The effect of the silk spinning rate on the secondary structure of MaS proteins was first investigated. Two extreme spinning rates were investigated, 0.5 and 10 cm/s, which are associated with the filaments made for the web frame and the safety line, respectively.[15,16] Solid-state ^{13}C NMR allows the distinction between polypeptide secondary structures since the chemical shift is sensitive to conformation.[43–45] The CPMAS spectra recorded for silk reeled at 0.5 and 10 cm/s are presented in Fig. 1. The assignment of the peaks due to alanine, glycine, glutamine, and tyrosine residues and to carbonyl groups is also indicated.

The spectra show chemical shifts typical of those associated with silk produced by the major ampullate gland.[10] The chemical shifts due to alanine residues at 49.0 ppm for C_α and 19.6–22.2 ppm for C_β are characteristic of β-sheets.[46] The small contribution at 17.4 ppm for C_β has been assigned to a 3_1-helix by Holland et al.[46] A small contribution of a 3_1-helix at 48.9 ppm is also most likely present in the Ala C_α peak but cannot be distinguished in the spectra. The current results are in agreement with the presence of at least two secondary structures for alanine residues in *N. edulis* dragline silk.[46–48] One can observe that the spectra obtained at the two spinning rates are almost identical, with no difference in the chemical shifts (except for glutamine). This result indicates that the secondary structure of the MaS protein is not significantly affected by the reeling speed.

Fig. 1. 900 MHz ^{13}C CPMAS spectra of MaS spun at 0.5 cm/s (black) and 10 cm/s (red, dark grey in print version).



The spectra show a signal at 33 ppm due to glutamine $C_{\beta,\gamma}$, which is dramatically more resolved at 0.5 than at 10 cm/s. Thus, this amino acid has a particular behavior depending on the reeling speed. Glutamine is found in the SQGA motifs of MaSpI and in the GPGQQ motifs of MaSpII. It is the most abundant polar amino acid of MaS. The particular shape of the glutamine $C_{\beta,\gamma}$ peak as a function of reeling speed may thus reflect a specific structural arrangement or environment of these sequence motifs in the fibers. Although this line narrowing remains unclear, it may be related to a more ordered amorphous region containing the glutamine residues for silk spun at 0.5 cm/s.

We have also investigated the effect of the spinning rate on the amount of alanine residues in β-sheet regions. More specifically, Hahn-echo spectra, in which the signal is not affected by the efficiency of the CP magnetization transfer, have been recorded and are shown in Fig. 2. The proportion of alanine residues in β-sheet and 3_1-helix structures was obtained from the area of the alanine C_β peaks at 20 and 16–17 ppm,

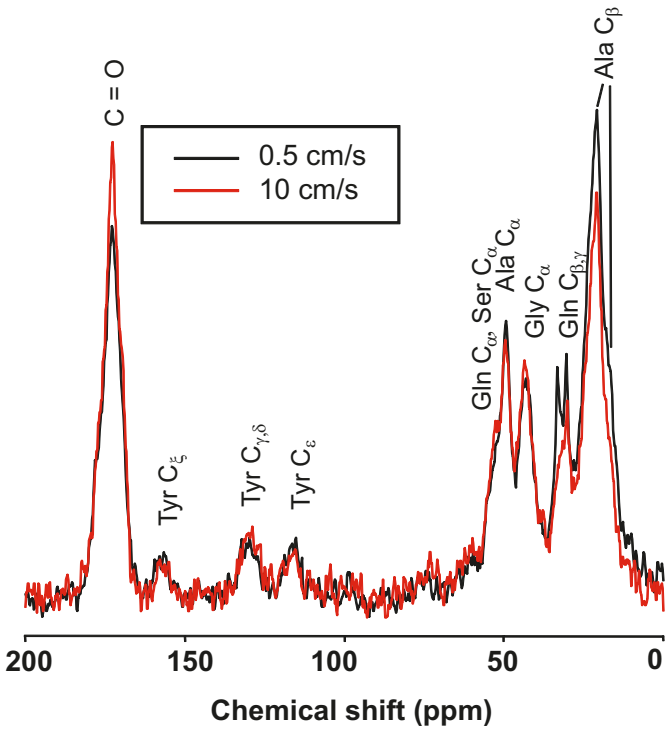
Fig. 2. 900 MHz ^{13}C Hahn-echo spectra of MaS spun at 0.5 cm/s (black) and 10 cm/s (red, dark grey in print).



respectively. The results, presented in Table 2, show that the amount of alanine residues in β-sheets is 81% ± 5% for a reeling speed of 0.5 cm/s, a value that is very comparable to that obtained by Holland et al.[47] In addition, the proportion of alanine residues in β-sheets and 3_1-helices is the same for silk spun at 0.5 and 10 cm/s. For glycine, the chemical shift is around 43.5 ppm, in good agreement with Holland et al.,[46] and is almost identical for both samples. These results therefore confirm that the spinning rate does not have a significant influence on the secondary structure of both alanine and glycine residues. The spectra presented in Fig. 2 also reveal sharper glutamine signals at 30 and 33 ppm for the slowpull fiber, as seen in the CPMAS spectra.

Effect of the silk spinning rate on protein dynamics

Solid-state NMR is an efficient technique to characterize the dynamics of protein chains over a large range of timescales, as T_1 and $T_{1\rho}$ relaxation times report on motions in the MHz and kHz timescales, respectively.[49,50] It has been shown that the proportions of crystalline and amorphous regions in polymers such as silk can significantly influence molecular relaxation. In particular, shorter T_1 usually indicate more mobile, flexible regions. Changes in T_1 can also reflect different chain packing, which will affect the proton density and the proton dipolar interaction. On the other hand, $T_{1\rho}$ will be affected by the size of the crystallite domains and shorter $T_{1\rho}$ are usually indicative of larger amorphous components or more mobile chains. Since specific resonances in ^{13}C NMR spectra can be assigned to particular amino acids, the dynamics can be probed for various residues in crystalline or amorphous regions. Kishore et al.[51] already successfully used relaxation data to characterize the protein mobility for different hydration levels and spider species.

Table 2. Alanine residues in β-sheet and 3_1-helix structures for MaS spun at 0.5 and 10 cm/s.

Reeling speed	20 ppm (β-sheet)	16–17 ppm (3_1-helix)
0.5 cm/s	81%±5%	19%±5%
10 cm/s	82%±5%	18%±5%

The ^{1}H T_1 measured for the peaks associated with the C_α of alanine residues, mainly in β-sheet structures, the glycine C_α, and the glutamine $C_{\beta,\gamma}$ are shown in Fig. 3A. These peaks were chosen for their high resolution and intensity. Average times for ^{1}H T_1 are 1.05 s ($AlaC_\alpha$), 1.09 s ($GlyC_\alpha$), and 1.02 s ($GlnC_{\beta,\gamma}$) for silk spun at 0.5 cm/s. These values obtained for *N. clavipes* are in the same range as those measured for *N. edulis* and *Argiope keyserlingi*.[51] Compared with the ^{1}H T_1 values of the fiber spun at 0.5 cm/s, the values of the thread spun at 10 cm/s are shorter (0.79 s for $AlaC_\alpha$, 0.89 s for $GlyC_\alpha$, and for 0.73 s $GlnC_{\beta,\gamma}$), which indicates that the proteins that constitute this silk are more flexible and (or) less densely packed. The longer T_1 observed for the $GlnC_{\beta,\gamma}$ peak at a slower spinning speed is also in agreement with the line narrowing observed for this peak at 0.5 cm/s, which could be related to a more ordered amorphous region.

Figure 3B shows that the ^{13}C $T_{1\rho}$ measured for the peaks associated with the C_α of alanine residues, mainly in β-sheet structures, the glycine C_α, and the carbonyl resonance. These results indicate that the ^{13}C $T_{1\rho}$ measured for the glycine residues are shorter than those measured for the alanine residues, which is consistent with the fact that glycine residues are mainly located in the amorphous regions of the fibers. As with ^{1}H T_1, a significant decrease of the ^{13}C $T_{1\rho}$ was found for both alanine and glycine residues at a fast spinning rate. More specifically, ^{13}C $T_{1\rho}$ were 15 ms ($AlaC_\alpha$), 5 ms ($GlyC_\alpha$), and 41 ms (carbonyl) for the silk spun at 0.5 cm/s, and 3.5 ms ($AlaC_\alpha$), 0.4 ms ($GlyC_\alpha$), and 20 ms (carbonyl) for the silk spun at 10 cm/s. The decrease of ^{13}C $T_{1\rho}$ for the filament spun at 10 cm/s indicates more mobility on a slower timescale and over a longer distance,[51] which is consistent with the presence of more amorphous regions and more flexible proteins.

Overall, the present results show that, unlike the secondary structure, the dynamics of the protein chains is altered by the spinning rate at both T_1 (MHz) and $T_{1\rho}$ (kHz) timescales. Thus, it seems that the main impact of the spinning rate on the structural organization of silk occurs at a different level than the secondary structure. Alterations of the protein dynamics are significant and are observed for both alanine and glycine residues, the former amino acid being mainly representative of the β-sheets, the latter characterizing mainly the amorphous regions. This indicates that variations in the chain mobility occur in the whole fiber, indicating that the protein assembly is subtly but fundamentally affected by the spinning rate. More specifically, the dynamic relaxation data suggest that a fast spinning process leads to a less optimal packing of the proteins in the fiber with decreased intermolecular interactions between the polypeptide chains, although it leads to a higher level of orientation.[19]

The decreased mobility at a low reeling speed might in turn result from a slightly higher plasticizing effect of water. Indeed, the presence of water leads to an increased fiber plas-

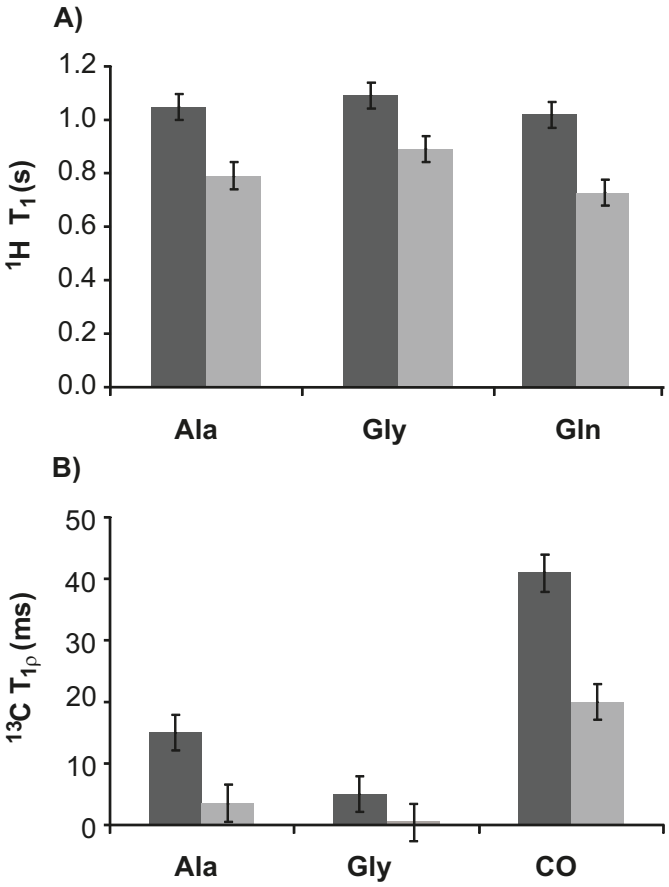
Fig. 3. **(A)** ^{1}H T_1 relaxation times for MaS spun at 0.5 cm/s (dark gray) and 10 cm/s (light gray). **(B)** ^{13}C $T_{1\rho}$ relaxation times for MaS spun at 0.5 cm/s (dark gray) and 10 cm/s (light gray).

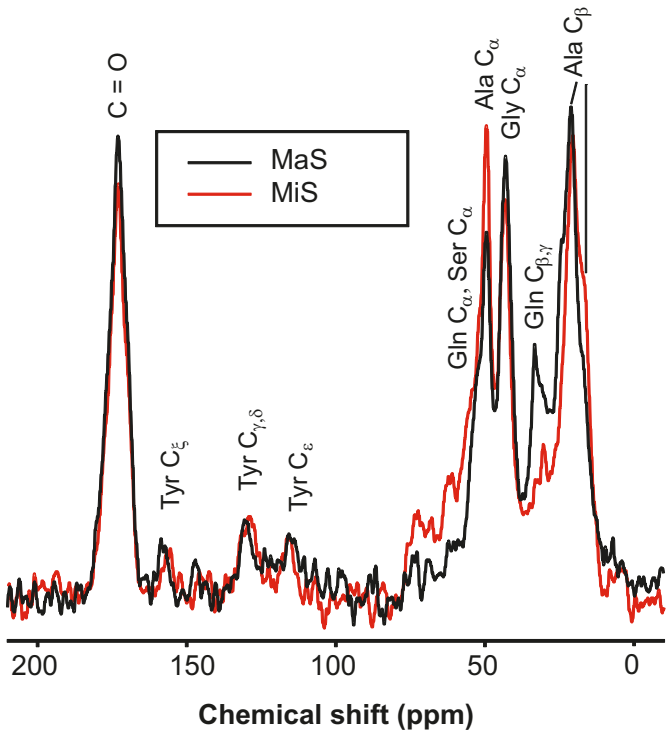


ticity leading in turn to an increase in diameter and a shrinking in length of about 50%. This allows reorientation of hydrogen bonds between the spider silk proteins[34] that could be at the origin of the increased extensibility of the silk spun at 0.5 cm/s.[19] It is also possible that the slower spinning process at 0.5 cm/s results in a more organized polypeptide alignment and packing, thus decreasing the chain dynamics. The NMR data therefore suggest that both the spinning process and protein sequence play a role in the final silk structure.

Protein secondary structure in MaS, MiS, and cocoon silk

CPMAS spectra (not shown) were first recorded and the results obtained for MaS and MiS are in agreement with those previously published.[10,39] Figure 4 displays a superposition of Hahn-echo ^{13}C spectra of MaS and MiS. The alanine C_β signal displays two contributions due to β-sheets and 3_1-helices, showing that the secondary structure of this amino acid is similar in both silks. The relative intensity of the two bands qualitatively suggests that a slightly larger proportion of alanine residues form 3_1-helices in MiS. In addition, the signals corresponding to glycine residues are basically identical for MaS and MiS, suggesting that the secondary structures of the amorphous domains are similar. The glycine C_α peak of MiS only displays a slight narrowing previously noted by Holland et al.[52] who assigned it to the fact that part of the glycine residues are involved in β-sheets. Similarly, it

Fig. 4. 400 MHz ^{13}C Hahn-echo spectra of MaS (black) and MiS (red, dark grey in print).



has been concluded from Raman data that poly(Ala-Gly) motifs are involved in the β-sheets.[27]

The ^{13}C CPMAS spectrum of cocoon silk is presented in Fig. 5. The alanine C_β signal displays three contributions at 16–17, 20, and 23 ppm. The contribution at 16–17 ppm is attributed to 3_1-helices, as observed for MaS and MiS, while the two contributions at 20 and 23 ppm have been attributed by Holland et al.[46] to alanine residues in β-sheet structures with packing differences of the alanine methyl groups in the β-sheet domains. The presence of the strong contribution at 23 ppm in cocoon silk therefore suggests differences in the packing of alanine residues compared to MaS and MiS. On the other hand, the presence of alanine residues in β-sheet structures in cocoon silk is in very good agreement with Raman results.[27] Therefore, alanine residues that belong to $(A)_n$ and $(SA)_n$ motifs (Table 1) are most likely involved in these β-sheets. Comparison with other NMR data of the literature suggests that the cocoon silk produced by *N. clavipes* spiders has a very similar secondary structure to that of *N. edulis* and *Araneus diadematus* spiders.[51,53]

Protein dynamics in MaS, MiS, and cocoon silk

Figure 6 shows the comparison of the relaxation parameters for the three types of silk. The relaxation times for alanine C_α in β-sheet structures, and for glycine residues and the glutamine $C_{\beta,\gamma}$ signal are shown in Fig. 6A. Average ^{1}H T_1 were 1.05 s ($AlaC_\alpha$) and 1.09 s ($GlyC_\alpha$) for MaS, 0.90 s ($AlaC_\alpha$) and 0.96 s ($GlyC_\alpha$) for MiS, and 0.42 s ($AlaC_\alpha$) and 0.45 s ($GlyC_\alpha$) for cocoon silk. The ^{1}H T_1 values indicate that protein mobility increases in the order MaS < MiS < cocoon silk. A shorter relaxation time for cocoon silk was already reported by Kishore et al.[51]

Fig. 5. 400 MHz ^{13}C CPMAS spectrum of cocoon silk.

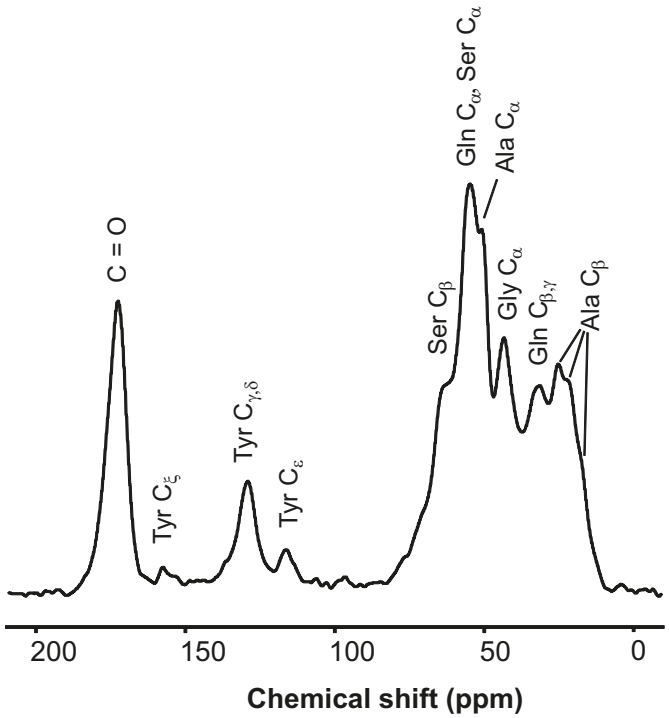

Fig. 6. **(A)** ^{1}H T_1 relaxation times for MaS (dark gray), MiS (light gray), and cocoon silk (white). **(B)** ^{13}C $T_{1\rho}$ relaxation times for MaS (dark gray), MiS (light gray), and cocoon silk (white).

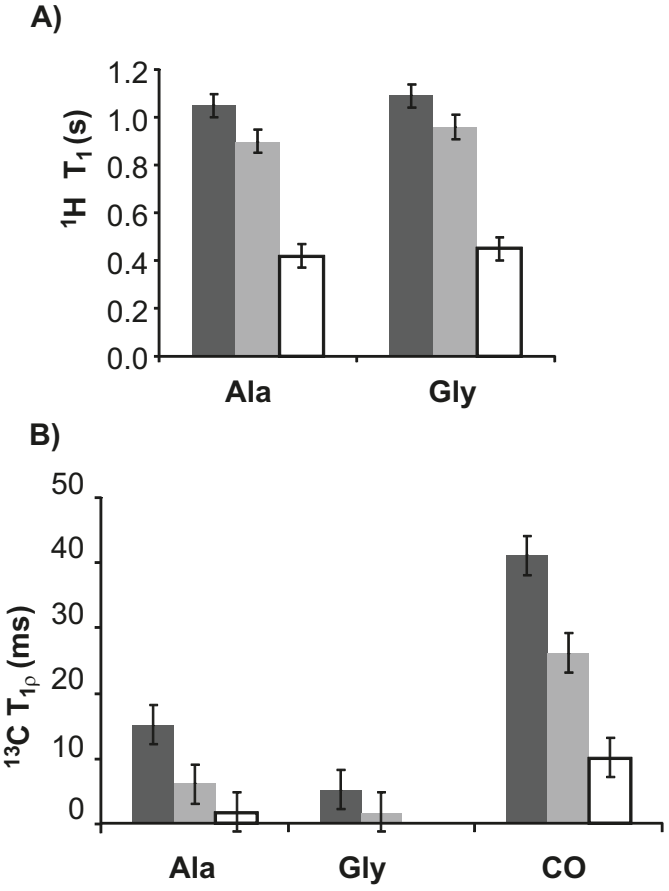

Figure 6B displays the ^{13}C $T_{1\rho}$ results for the three types of silk. Average times were 15 ms ($AlaC_\alpha$), 5 ms ($GlyC_\alpha$), and 41 ms (carbonyl) for MaS, 6 ms ($AlaC_\alpha$), 1.6 ms ($GlyC_\alpha$), and 26 ms (carbonyl) for MiS, and 1.7 ms ($AlaC_\alpha$) and 10 ms (carbonyl) for cocoon silk. The ^{13}C $T_{1\rho}$ for glycine residues in cocoon silk was too short to be measured. The results suggest that the amount of amorphous regions and molecular mobility of the different silks vary as above for the three silks. Again, the relaxation times of glycine residues are generally shorter than for the alanine residues for the three types of silk, which is consistent with the fact that glycine residues are mainly located in silk amorphous regions.

It is recognized that MaS, MiS, and cocoon silk share the same structural pattern, composed of β-sheets dispersed in an amorphous matrix.[24,26,27,39,51] In particular, the proportion of β-sheets is not significantly different for these silks.[27] NMR spectra are consistent with these observations. Structural differences appear in fact more subtle as NMR relaxation experiments reveal differences in the protein dynamics. The ^{1}H T_1 and ^{13}C $T_{1\rho}$ relaxation times show that the mobility of Ala and Gly increases in the order MaS < MiS < cocoon silk. Such a mobility of the amino acids reflects a less organized chain packing and less efficient intermolecular interactions in the fiber. This result is in good agreement with Raman experiments that have shown that these silks contain residual native polypeptide chains that are absent in MaS.[27] This higher chain flexibility of MiS and cocoon silk is consistent with their higher extensibility with respect to MaS. Thus, extensibility can be related to a less ordered structural organization of the whole fiber that cannot be necessarily detected directly by other techniques.

The comparison between MaS and MiS is particularly interesting since MiS displays shorter relaxation times for Ala and Gly, thus indicating that both the amorphous regions and β-sheets are more rigid for MaS. For MiS, the higher molecular mobility of Ala is consistent with the fact that both polyAla and poly(Ala-Gly) motifs are incorporated in the β-sheets, which may result in a less packed β-sheet structure. For cocoon silk, the even higher molecular mobility of Ala is consistent with the fact that amino acids with a large side-chain are involved in β-sheets,[24] which results in a less densely packed β-structure. This is consistent with the well-known variations displayed by the intersheet packing distance of silks produced by various sericigene glands or spun by various species.[54] Interestingly, the presence of a less densely packed β-structure in cocoon silk is also in agreement with the two contributions observed for the Ala C_β signal at 20 and 23 ppm and attributed to differently packed alanine residues.

It has been shown that the molecular orientation of MiS is lower than for MaS.[27] This characteristic can, at least partly, explain the higher extensibility of this silk (Table 1). NMR relaxation data show that the extensibility of MiS can also can be associated with a higher chain mobility. Cocoon silk has the same level of orientation than MaS.[27] However, it is even much more extensible than MiS. Cocoon silk displays the highest relaxation rate, suggesting a less rigid structure in the whole fiber that may be at the origin of the high breaking strain of this silk.

Conclusions

The NMR data show almost no effect of the reeling speed on the secondary structure, but a significant effect is observed on the protein relaxation dynamics. These results suggest that the molecular rearrangement can be strongly affected during the spinning process and can lead to different chain packing and intermolecular interactions in the final fiber. The comparison between MaS, MiS, and cocoon silk shows that the secondary structure is similar but the molecular mobility is different. In this case, both the spinning process and protein primary structure can play a role on the final molecular organization. More work is clearly needed to gain a better understanding of the correlation between amino acid sequence and mechanical properties to design primary sequences with specific properties.

Abstract: Lineshape analysis of ^{17}O spin-echo NMR spectra has been used to study water molecular reorientations in ice-Ih and THF Structure II clathrate hydrate. The kinetics was determined by the changes of the lineshapes of the ^{17}O central transitions at different temperatures. A model involving 12 orientations and 4-step jumps of water molecular orientations was proposed. Semi-classical exchange formalism was employed to simulate the lineshape of the central transitions of the ^{17}O nuclei. Lineshape analysis gave the quadrupolar coupling constant $C_Q = 6.43$ MHz and the asymmetry parameter $\eta = 0.935$, for both ice-Ih and THF gas hydrate. The theoretical lineshape simulations resulted in activation energies of water molecular reorientations $E_a = 55.2 \pm 2.1$ kJ mol^{-1} and $E_a = 30.5 \pm 0.8$ kJ mol^{-1} for ice-Ih and THF hydrate, respectively. The range of dynamic rates in THF clathrate hydrate is such that before melting, a pseudo-isotropic lineshape is observed that retains a second-order quadrupolar shift. The water reorientation process is discussed in light of recent results on Bjerrum defect injection obtained from molecular dynamics simulation and structural studies.

Key words: ice-Ih, THF clathrate hydrate, ^{17}O NMR, molecular reorientations of solid water, Kinetics, residual second order quadrupolar shift, dynamics of non-integer quadrupolar nuclei.

Résumé : On a fait appel à l'analyse de la forme des raies des spectres RMN du ^{17}O avec écho de spin pour étudier les réorientations moléculaires de l'eau dans la glace-Ih et dans l'hydrate du clathrate du THF de structure II. On a déterminé les cinétiques par les changements dans les formes des raies des transitions centrales du ^{17}O, à diverses températures. On propose un modèle impliquant 12 orientations et des transitions en quatre étapes des orientations moléculaires de l'eau. On a utilisé un formalisme d'échange semi-classique pour simuler la forme des raies des transitions centrales du noyau ^{17}O. Une analyse de la forme des raies permet de déterminer la constante de couplage quadripolaire $C_Q = 6{,}43$ Mhz et le paramètre d'asymétrie $\eta = 0\,935$ pour la glace-Ih et l'hydrate du THF gazeux. Les simulations des formes des raies théoriques ont permis d'évaluer les énergies d'activation des réorientations moléculaires de l'eau $E_a = 55{,}4 \pm 2{,}1$ kJ mol^{-1} et $E_a = 30{,}4 \pm 0{,}8$ kJ mol^{-1}, respectivement pour la glace-Ih et l'hydrate du THF. La plage des vitesses dynamiques pour l'hydrate du clathrate du THF est telle que, avant la fusion, il et possible d'observer une forme de raie pseudo-isotrope qui conserve un déplacement quadripolaire du deuxième ordre. On discute du processus de réorientation de l'eau à la lumière de résultats récents sur l'injection du défaut de Bjerrum obtenu à partir de simulations de la dynamique moléculaire et d'études structurales.

Mots-clés : glace-Ih, hydrate du clathrate du THF, RMN du ^{17}O, réorientations moléculaires de l'eau solide, cinétique, déplacement quadripolaire résiduel du second ordre, dynamique des noyaux quadripolaires non entiers.

[Traduit par la Rédaction]

Introduction

Water, as a substance essential for the existence of life, is one of the most important materials in nature. Also, it is one of the more difficult materials to study as it has some unusual properties and a remarkably complex phase diagram.

When frozen under normal atmospheric conditions, water molecules form a crystalline solid with hexagonal symmetry that is less dense than the water phase with which it is in equilibrium, referred to as hexagonal ice or ice-Ih.[1] Early X-ray diffraction analysis of ice-Ih showed that each oxygen atom is coordinated almost tetrahedrally by four neighboring

oxygen atoms.[2] From neutron diffraction measurements on a single crystal of D_2O solid, it was suggested that there are two half-occupied deuteron positions on the line between two neighboring oxygen atoms,[3] and the deuterons are disordered among these sites. This conclusion was later modified from the view that the O–D–O hydrogen bond should be bent by about 6.8°, since the molecular D–O–D angle is the same as that in an isolated water molecule (i.e., 104.5°).[4] Thus, each deuteron is about 0.04 Å off the line connecting the two closest oxygen atoms. These experimental data fit into Pauling's earlier statistical model for the structure of ice-Ih.[5] He proposed that (*i*) the structure of isolated water molecules is primarily preserved in ice-Ih, (*ii*) the hydrogen atoms of a water molecule are directed approximately towards two of the four oxygen atoms surrounding it tetrahedrally, (*iii*) The adjacent water molecules are oriented so that only one hydrogen atom lies between each pair of neighboring oxygen atoms, and (*iv*) the statistical orientations of water molecules generate a large number of configurations $(3/2)^n$, where n is the total number of water molecules. At any instant and under ordinary conditions, an ice-Ih crystal may exist in any one of the large number of allowed configurations. A question that follows then is whether the configuration of ice-Ih is subject to change via rotations of water molecules. Dielectric relaxation studies have suggested that the dipole moment of ice can reorient through either proton transfer or molecular rotation.[6,7] The latter was assumed based on theoretical considerations to correlate the rotational correlation time with the dielectric correlation time.[8] Bjerrum hypothesized that water molecules in ice could reorient by rotating about one hydrogen bond and form either a D defect (two hydrogen atoms between a pair of oxygen atoms) or an L defect (no hydrogen atom between a pair of oxygen atoms).[9] When these defects diffuse through the lattice, they leave a water molecule in a different orientation.

Clathrate hydrates are formed when water interacts hydrophobically with suitably small molecules (<0.9 nm), assembling via hydrogen bonding into an open framework that traps such "guest" molecules into cages of different geometries.[10–15] Three main structural types of clathrate hydrate have been identified, which form with a large number of guests, namely cubic structure I, cubic structure II, and hexagonal structure H.[10–20] Tetrahydrofuran (THF) forms a structure II hydrate popular for experimental studies as it can be made readily by freezing an aqueous solution of the correct composition.[19] The unit cell contains 136 water molecules with 16 small and 8 large cages. The large cages each encage a THF molecule. A neutron diffraction study of $3.5Xe{\cdot}8CCl_4{\cdot}136D_2O$ structure II gas hydrate shows that the local coordination of a water molecule is very similar to that in ice-Ih, although deviation from true tetrahedral coordination by four neighbouring O atoms is more marked.[20] Indeed there are three crystallographically distinct O sites. Also, as in ice-Ih, the D_2O molecules are disordered over six orientations of equal statistical weight, with deuterium atoms located in half-occupied sites, so a gas hydrate crystal also has many configurations determined by the orientations of all the water molecules.

Solid state NMR lineshapes are widely used to study dynamics.[21] Changes in the linewidth and lineshape as a function of increasing temperature reflect the effects of rapid modulation of the interaction tensors, and there are very many examples involving dipolar coupling tensors, for example of ^1H, ^{19}F, integer quadrupolar tensors, especially ^2H,[22,23], and chemical shift tensors, ^{13}C, ^{15}N, ^{19}F, etc. However, reports of cases involving dynamic averaging of the lineshapes of non-integer nuclei with second-order quadrupolar interactions are quite rare.

The reorientations of water molecules in ice-Ih and THF clathrate hydrate as a function of temperature have been observed previously using ^1H [24–30] and ^2H NMR.[28,31–36] Approaching their melting points, the spectra show isotropic lineshapes. In ^2H NMR, the results can be explained by a simple model where each O–D bond jumps between four equiprobable tetrahedral orientations, although in this model the gross approximation is made that the ^2H quadrupolar coupling tensor is axial. Unfortunately the models that can explain the experimental observables do not necessarily test the theoretical models, such as the Bjerrum model. For instance, a water molecule would have to be visited by several defects in order for it to be reoriented in such a way as to show tetrahedral averaging. Nevertheless the ^1H, ^2H and dielectric results can be explained by the presence of a single motional correlation time. One striking feature of THF clathrate hydrate is that the motions are considerably faster than in ice, and it is thought that this is due to injection of Bjerrum L-defects into the hydrate lattice by transient H-bond formation between the O atom of the THF and a water molecule.[37]

Here we present work on the central transition NMR of the spin 5/2 ^{17}O nucleus in ice and THF structure II clathrate hydrate as a function of temperature. In contrast with the four orientations visited by the ^2H quadrupole coupling tensor, the tensor of ^{17}O in the water molecule will reorient over six orientations as the arrangement of H atoms around it changes (in this case roughly octahedral orientations), and so in a sense the ^{17}O detects the motion of the whole molecule rather than of the O–D bond. Another reason for a study using ^{17}O is because the proton-shielding tensor in ice-Ih has a span of ~6 kHz, the ^1H dipolar coupling leads to spectra ~40 kHz wide, and the deuterium quadrupolar coupling constant is ~200 kHz, but the ^{17}O quadrupolar coupling constant is much larger, ~6.43 MHz. Although the ^{17}O central transitions in ice are expected to cover a spectral width of ~60 kHz, complete averaging of the quadrupolar interaction can give spectral sensitivity to a remarkably broad range of motional correlation times. Besides the problem of water molecular reorientations, there is a wide interest in the fundamental spectroscopy, that is, to observe and understand the evolution of spectral patterns for half-integer nuclei from a static pattern to one where the quadrupolar coupling is completely averaged.[38–43]

Because of the ubiquitous presence of water in its various phases, we expect considerable relevance of these results to water-containing systems.

Experimental details

Water with 45% ^{17}O (ISOTEC Inc.) and THF with 99.9% purity (Sigma-Aldrich) were used to prepare the ice and hydrate. THF is soluble in water, so that the clathrate hydrate was easily obtained by cooling its aqueous solution with 1:17 THF/H_2O stoichiometric ratio.[44] ^{17}O NMR static spectra

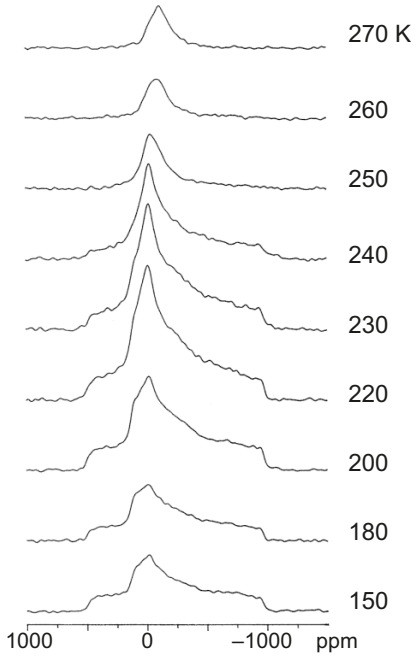
Fig. 1. Static ^{17}O NMR ^{1}H decoupled spin-echo spectra of the central transition in ice-Ih as a function of temperature.

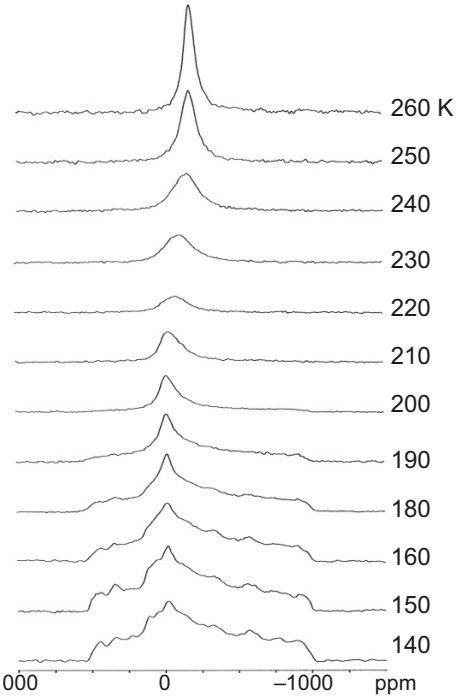


with ^{1}H decoupling were obtained at 40.68 MHz from 140 K up to the melting points, using a Bruker AMX 300 NMR spectrometer with a double resonance (^{1}H-^{17}O) high-power NMR probe (Morris Instruments Inc.). Only central transition spectra were obtained, using a spin-echo experiment with $\tau = 20$ μs.[45] ^{1}H decoupling is necessary, as the ^{17}O-^{1}H dipolar coupling is calculated to be of the order of 17 kHz, compared with ~59 kHz for the ^{17}O second-order static linewidth. The spectra are referenced to liquid $H_2{}^{17}O$ water at room temperature. Temperatures were regulated using cold nitrogen gas and a Bruker Eurotherm controller.

Results and discussion

The ^{17}O NMR central transition spectra of ice-Ih and THF clathrate hydrate as a function of temperature are shown in Figs. 1 and 2. The lowest temperature spectra correspond to essentially static quadrupolar coupling tensors. For ice-Ih at 150 K, the best theoretically fitted spectrum gave a quadrupolar coupling constant $C_Q = 6.43$ MHz and an asymmetry parameter $\eta = 0.935$. This compares favourably with previous measurements, which have given $C_Q = 6.66 \pm 0.10$ and $\eta = 0.935 \pm 0.010$ for D_2O ice-Ih at 253–263 K,[46] and $C_Q = 6.525 \pm 0.015$ and $\eta = 0.925 \pm 0.020$ at 77 K.[47] The first of these studies also determined that the principal axis components of the tensor are oriented with *yy* perpendicular to the molecular plane and *xx* along the twofold molecular axis. C_Q is moderately sensitive to the local environment of the water molecules, as seen in the different values for water-^{17}O in Ice-II ($C_Q = 6.893$ MHz, $\eta = 0.865$),[48] and crystal hydrates oxalic acid dihydrate ($C_Q = 6.8$ MHz, $\eta = 0.93$)[49] and barium chlorate monohydrate ($C_Q = 7.61$ MHz, $\eta = 0.94$).[50] For THF clathrate hydrate at 140 K, the envelope of the spectrum is somewhat noisier than that of ice-Ih, perhaps because of an inhomogeneous orientational distribution of hydrate crystallites produced

Fig. 2. Static ^{17}O NMR ^{1}H decoupled spin-echo spectra of the central transition in THF clathrate ^{17}O-hydrate as a function of temperature.



when the THF solution was frozen in the NMR probe. Nevertheless, it is clear that the lineshape is almost identical to that of ice-Ih at 150 K, and thus we conclude that the local oxygen coordination in THF clathrate hydrate is very similar to that in ice-Ih. Though there are three crystallographically distinct water oxygen sites in the THF hydrate,[19,20] these are not distinguished in the static lineshapes observed, nor even in the dynamically averaged pseudo-isotropic lineshapes observed at the highest temperatures.

One question to consider is whether the chemical shielding anisotropy (csa) of ^{17}O in ice is large enough to make a visible contribution to the central transition spectrum at 7.05 T. While there is no experimental information available on this, ab initio calculations for liquid water suggest a span of ~37 ppm.[51] This is very small (~2.5%) when compared to the observed static linewidth of ~1450 ppm but substantial enough to perhaps explain the range of experimental values. Spectra at high field would probably resolve this issue, e.g., at 21.1 T the second-order linewidth would reduce to about 161 ppm. Furthermore, at rates where the second-order quadrupolar lineshape begins to show effects of dynamic averaging, this csa will likely already be averaged to zero.

As temperature increases, the lineshapes start to show effects of dynamic averaging; their features become less well-defined, and a new shape centred around the center of gravity of the line begins to form. Comparing the spectra of the two materials, it is immediately obvious that the dynamics in the THF hydrate are considerably faster than in ice-Ih, with equivalent changes in lineshape occurring about 50 degrees lower for THF hydrate. Initially the new lineshape is asymmetric, with its peak closest to the strongest feature of the static lineshape, but then it gradually shifts to lower frequency, and in the case of THF hydrate eventually takes on

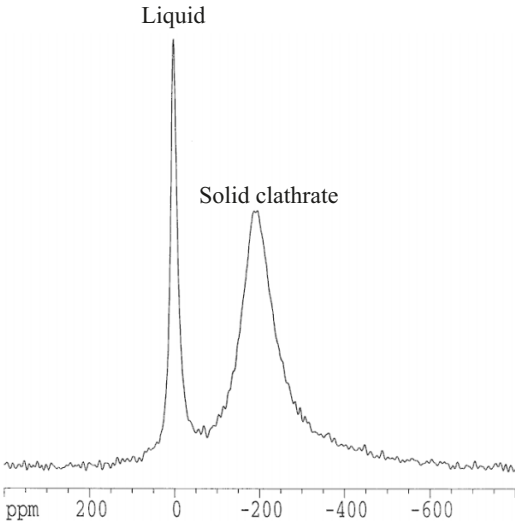
Fig. 3. Static ^{17}O NMR ^{1}H decoupled spectrum of water-^{17}O in a THF clathrate hydrate sample at ~270 K, where partial melting has occurred.



a pseudo-isotropic appearance (ice-Ih melts before this stage can be reached). That this "isotropic" line still retains a second-order shift is illustrated by the spectrum of the hydrate at 270 K, where liquid THF solution and solid THF hydrate coexist (Fig. 3). The liquid line is considerably sharper and very close to the shift of water, whereas the broader "isotropic" line of the hydrate is centred at –194 ± 3 ppm. The second-order quadrupolar shift of the central transition for a non-integer quadrupolar nucleus is given by,

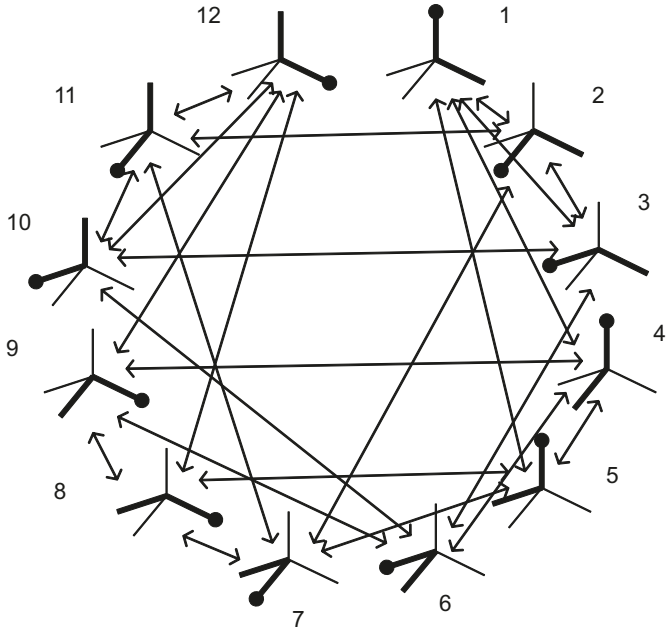
$$[1] \quad \mathrm{SOQS\,(in\,ppm)} = -\left(\frac{10^5}{3}\right)\left(\frac{\omega_Q^2}{\omega_L^2}\right)\left(I(I+1)-\frac{3}{4}\right)\left(1+\frac{\eta^2}{3}\right)$$

where $\omega_Q = 6\pi C_Q/(2I(2I–1))$. Hence, for a spin I = 5/2 nucleus this becomes SOQS = $–6\,000(C_Q{}^2/\nu_L{}^2)(1+\eta^2/3)$. Substituting the C_Q and η determined from the low-temperature static lineshape, a second-order shift of –193.6 ppm is calculated, very close to that observed at the melting point.

The emergence of this pseudo-isotropic line was initially quite surprising, because the central transition lineshape depends on the second-order interaction, which is a function of the fourth-order Legendre polynomial, and therefore averaging due to rapid tetrahedral or octahedral reorientation at rates a little faster than the static central transition linewidth should *not* lead to a pseudo-isotropic lineshape (icosahedral averaging is required to achieve an isotropic line).[40] In fact, the dynamic averaging calculations described below also suggest that there should be a residual lineshape, and the initial experimental averaged shapes appear to be falling into the predicted pattern. However, the modeling does not take into account the fact that at higher rates of motion the satellite transitions will also begin to average, and for I = 5/2 the splitting of the first satellite transition $\nu_Q = 3C_Q/20$, which in this case is only 964.5 kHz.

Witschas and Eckert have studied a case for ^{23}Na NMR approaching the fast motion limit, where the first-order interaction is averaged to zero, and observed a pseudo-isotropic central transition line, which gradually shifts to the true isotropic position as the satellites also average to isotropic.[41] In the present study, although the THF hydrate residual second-order lineshape has averaged to pseudo-isotropic, the material melts before any shifting towards the true isotropic shift has begun.

Fig. 4. The 12 possible orientations of a water molecule on any one particular lattice site in ice-Ih and clathrate hydrates, if the two H atoms are distinguished. O–H chemical bonds are represented by bold bars, and O···H hydrogen bonds from neighbouring water molecules by thin lines. The arrows indicate the four single-step reorientations which can occur by rotation about each of the two O–H chemical bonds for any one particular starting orientation. Over time, all 12 orientations will be sampled.



Modelling the effects of dynamic exchange on the central transition lineshape

An examination of the possible orientations for a single water molecule in ice-Ih or a clathrate hydrate shows that if the protons are distinguished, there are 12 different orientations of equal probability (Fig. 4). Assuming a single-step jump about an O-H axis only (not about O···H hydrogen bond axes) is required for the reorientational change, then each of the 12 orientations can have 4 possible single-step jumps to the other orientations. With the simplifying approximation that the coordination is perfectly tetrahedral, then all of these single-step reorientations are equivalent in terms of their kinetic parameters, as are forward and reverse exchanges. In fact this is a very reasonable assumption based on the structure of ice-Ih, but a little less so for the THF clathrate hydrate with three crystallographically distinct O atoms and some angles with larger deviations from Td. While this model provides a more complete picture of water reorientation (compared with the 4-site tetrahedral jump model used to simulate the dynamic deuterium NMR spectra of D_2O ice-Ih),[28] as far as the ^{17}O tensor is concerned, pairs of orientations related by interchange of the two proton posi-

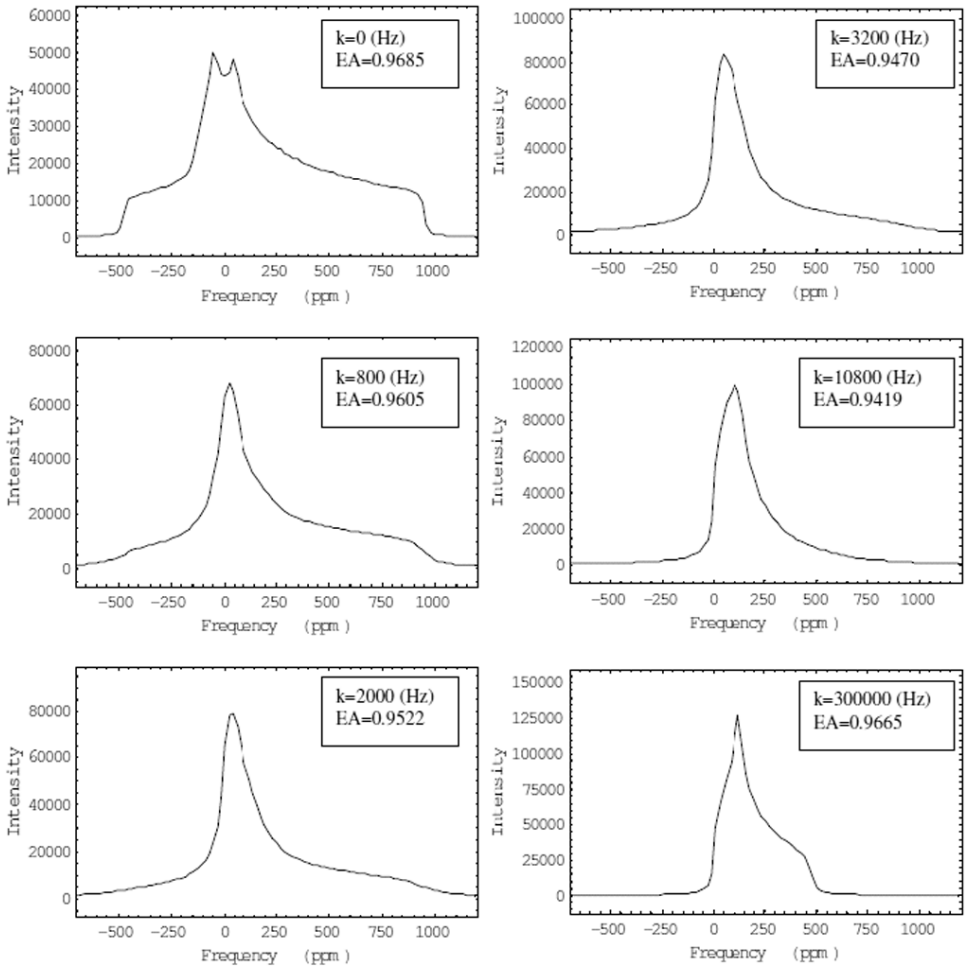
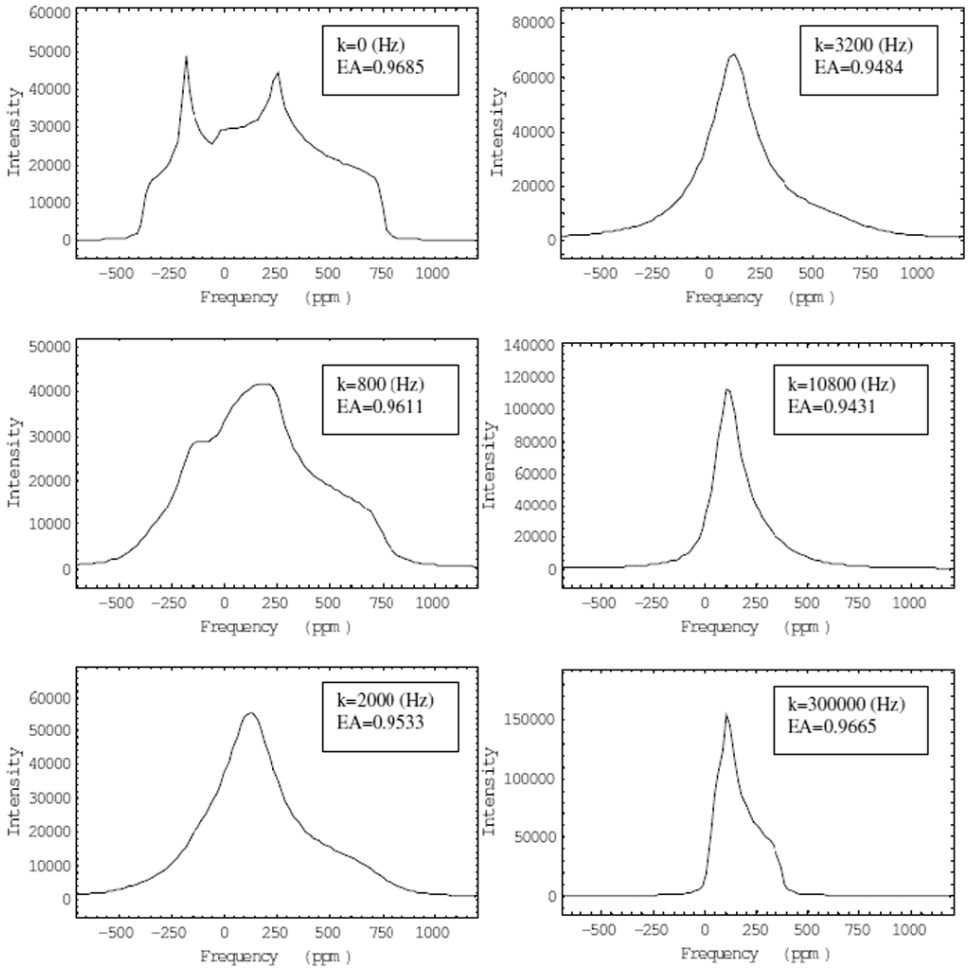
Fig. 5*a*. Calculated spin-echo NMR spectra of ^{17}O central transitions for the model of 12 reorientations and 4-step jumps of water molecules in ice-Ih with $\chi = 6.43$ MHz and the hypothetical value for $\eta = 0.9$. The exchange rate constants and spin-echo amplitudes (EA) are given along with the corresponding spectra. The intensity unit is arbitrary.



tions are equivalent. The population of these molecular orientations in an ice or a clathrate hydrate powder determines the lineshape of the NMR spectrum within the slow regime of the reorientational exchange at low temperatures, and the rate constants of the reorientations determine the lineshapes at higher temperatures.

A semi-classical exchange formalism was employed to simulate the lineshapes of the ^{17}O central transitions.[40] The relevant Hamiltonian for the exchanging quadrupolar nucleus consists of the first-order chemical shift term, and the first- and second-order quadrupolar interaction terms. Owing to the time scale of the molecular reorientations observed in the ice and the clathrate hydrate, it was assumed that the exchange rates are localized in the second-order quadrupolar term, while the effect on the lineshape by the first order quadrupolar interaction is insignificant. The calculations were further sim-

Fig. 5*b*. Calculated spin-echo NMR spectra of ^{17}O central transitions for the model of 12 reorientations and 4-step jumps of water molecules in ice-Ih with $\chi = 6.43$ MHz and the hypothetical value for $\eta = 0.5$. The exchange rate constants and spin-echo amplitudes (EA) are given along with the corresponding spectra. The intensity unit is arbitrary.



plified by ignoring the effect of chemical shift anisotropy, which as discussed earlier is likely to be negligibly small compared with the linewidth caused by the quadrupolar second-order interaction at this field, and also averaged to zero by the dynamics at quite slow rates. The relevant evolution frequency for the central transition is given as follows,[52]

$$[2]\qquad \omega_{-1/2,\,1/2}^{(2)static} = -\frac{1}{6\omega_0}\left[\frac{3C_Q}{2I(2I-1)}\right]^2\left[I(I+1)-\frac{3}{4}\right] \times [A(\alpha,\,\eta)\cos^4\beta + B(\alpha,\eta)\cos^2\beta + C(\alpha,\eta)]$$

where

$$A(\alpha,\eta) = -\frac{27}{8} + \frac{9}{4}\eta\cos 2\alpha - \frac{3}{8}(\eta\cos 2\alpha)^2$$

$$B(\alpha,\eta) = \frac{30}{8} - \frac{1}{2}\eta^2 - 2\eta\cos 2\alpha + \frac{3}{4}(\eta\cos 2\alpha)^2$$

$$C(\alpha,\eta) = -\frac{3}{8} + \frac{1}{3}\eta^2 - \frac{1}{4}\eta\cos 2\alpha - \frac{3}{8}(\eta\cos 2\alpha)^2$$

and C_Q stands for the quadrupolar coupling constant. The Euler angles α and β define the direction of the static magnetic field relative to the principal axis system of the electric field gradient.

The principal axis system of the electric field-gradient tensor of ^{17}O in the water molecule has been determined previously.[46] The *x*-axis was assigned to have the direction of the C_2 axis, the *y*-axis is perpendicular to the H–O–H plane, and the *z*-axis lies in the plane parallel to the H–H line. The twelve sets of Euler angles for water molecular orientations, as shown in Fig. 4, were derived according to this principal axis system and are listed in Table 1.

A Mathematica computer program was written to solve the equations of the kinetically modified Bloch equations,[40] and to integrate over the polar and azimuthal angles to get the powder pattern of the NMR spectrum. Figures 5*a*–5*c* show three sets of calculated ^{17}O spectra according to the exchange model shown in Fig. 4, based on a quadrupolar coupling constant of 6.43 MHz and asymmetry parameters,η = 0.9, 0.5, and 0.1, respectively. The corresponding exchange rate constants are given along with the spectra, and the spin-echo amplitudes (EA) are also shown in the figures. The transverse relaxation time $T_2 = 2.5$ ms and a spin-echo time of $\tau = 20$ μs were used in the calculations. The steps for the increments for α and β were set to be 1°, and a total of 100 points along the chemical shift axis were calculated. The chemical shifts were obtained according to the ^{17}O resonance frequency of 40.68 MHz (300 MHz for ^1H). The chemical shifts

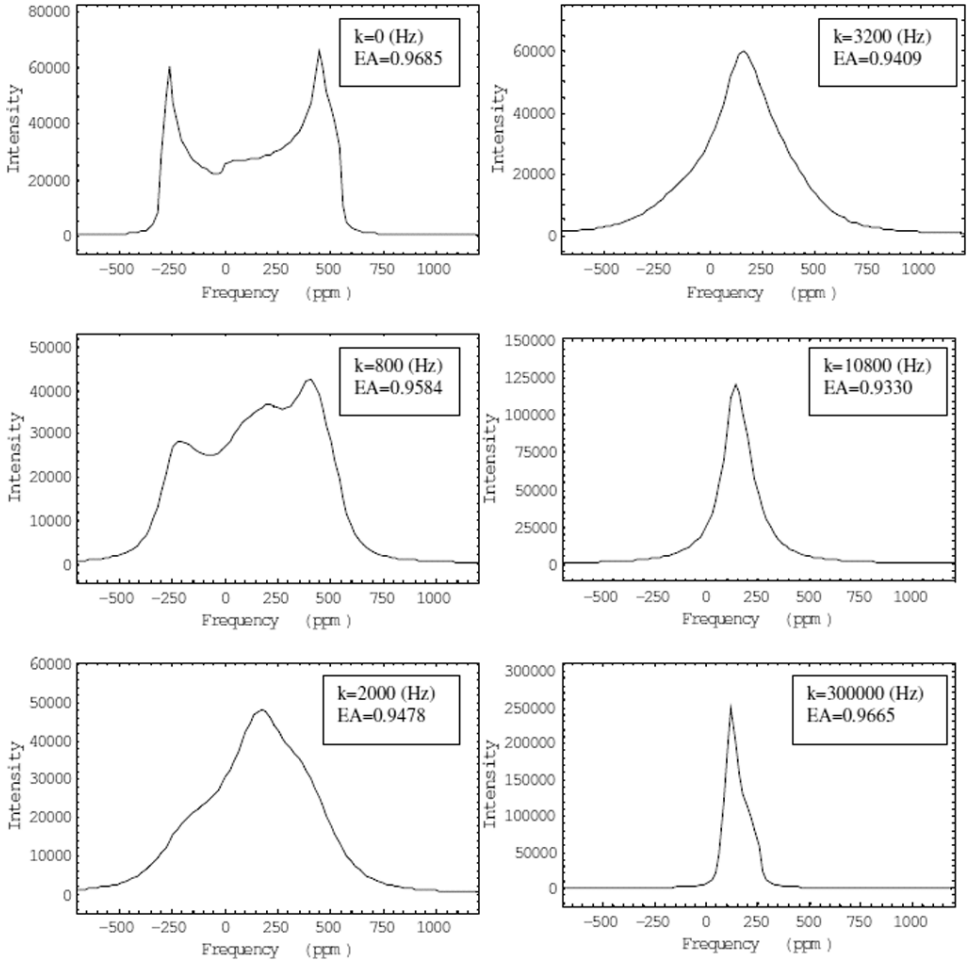
Fig. 5*c*. Calculated spin-echo NMR spectra of ^{17}O central transitions for the model of 12 reorientations and 4-step jumps of water molecules in ice-Ih with $\chi = 6.43$ MHz and the hypothetical value for $\eta = 0.1$. The exchange rate constants and spin-echo amplitudes (EA) are given along with the corresponding spectra. The intensity unit is arbitrary.



in the spectra were labeled with the opposite signs because of the convenient use of the Mathematica plotting method. The spectra at the rate constant $k = 0$ Hz show the typical powder patterns of the central transitions for spin n/2 nuclei with the corresponding hypothetical asymmetry parameters. The spectra at $k = 300\ 000$ Hz show the powder patterns in the fast-exchange regimes. Powder patterns corresponding to other intermediate exchange rates are also shown. All three sets show residual anisotropic lineshapes in the regime where rates are fast compared with the static second-order linewidth, but again it should be emphasized that these calculations do not take account of effects when the satellite lineshapes are also being averaged.

Comparison of experimental and simulated lineshapes in the exchange regime

Experimental ^{17}O spin-echo spectra acquired at several temperatures and the corresponding theoretically simulated spectra with $C_Q = 6.43$ MHz and $\eta = 0.935$ are shown in Fig. 6. Above the temperatures shown, the experimental and simulated spectra begin to diverge and comparison is no longer valid. Activation energies were determined from the set of rate constants and temperatures using the Arrhenius law,

$$[3] \qquad k = A \exp\left(-\frac{E_a}{RT}\right)$$

where A is a frequency factor (s^{-1}), E_a is the activation energy (J mol^{-1}), and R is the gas constant (8.314 JK^{-1} mol^{-1}).

Plots of $\ln(k)$ versus $1/T$ are shown in Fig. 7. The least-squares linear fit for the ice-Ih data gave an activation energy $E_a = 55.2 \pm 2.1$ kJ·mol^{-1}. This value, within error, is the same as the value of 56.5 kJ mol^{-1}, determined from the dielectric relaxation study,[6,7] showing that the activation energy measured in the dielectric relaxation arose from the water molecular reorientations. It is also equivalent to the most recent value of $E_a = 55.6$ kJ mol^{-1}, determined from ^2H NMR lineshapes.[26] Earlier studies gave values in the range 55.2 to 59.8 kJ mol^{-1}.[24–27,31] It is interesting that although the model used in the study of D_2O ice-Ih only considered the reorientations of O–D chemical bonds in a tetrahedral fashion, the activation energy is the same as that obtained in the current work for which the more rigorous model of 12 orientations and 4 single-step jumps was used. This is probably because of the nearly axially symmetric deuterium quadrupolar coupling tensor, which in principle results in nearly similar calculated ^2H NMR lineshapes when either model is used.

Fig. 6. Experimental ^{17}O ^{1}H decoupled spin-echo NMR spectra at several temperatures shown on the left and matching dynamic simulation spectra shown on the right, for (*a*) ice-Ih and (*b*) THF clathrate hydrate. The temperatures and rate constants are given alongside the corresponding spectra.

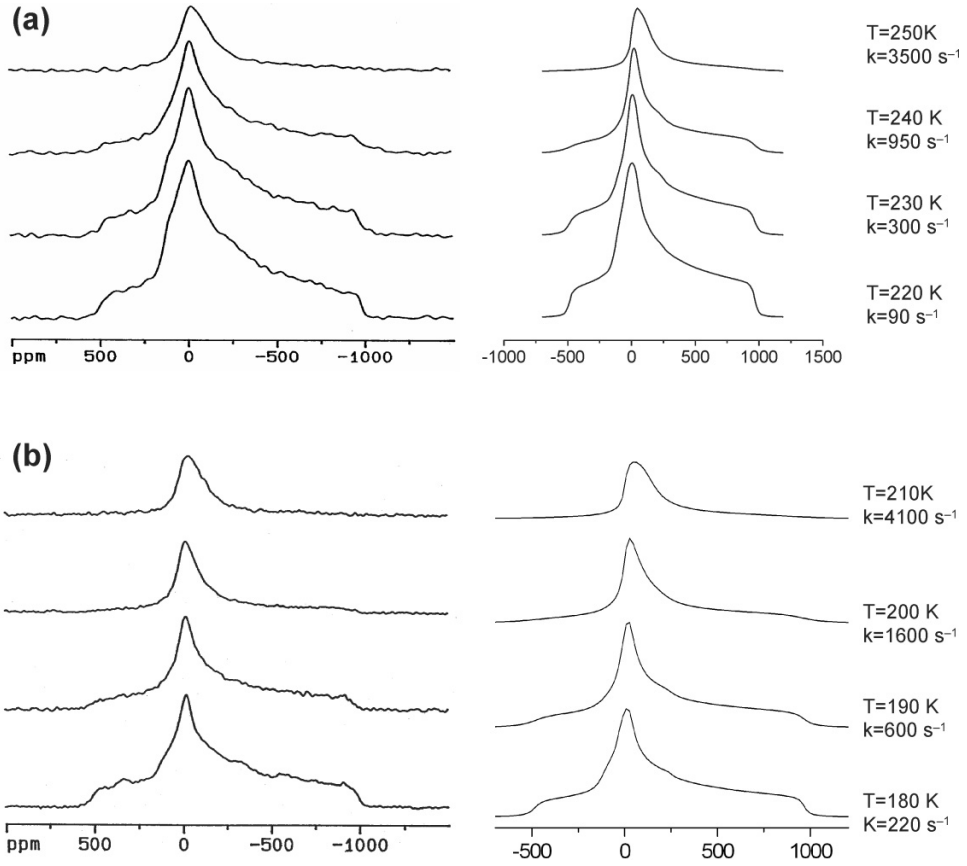

Fig. 7. Experimental plots of ln(*k*) versus 1/*T* for water reorientations in ice-Ih (■) and those in THF gas hydrate (◆) and their corresponding least-square linear fits.

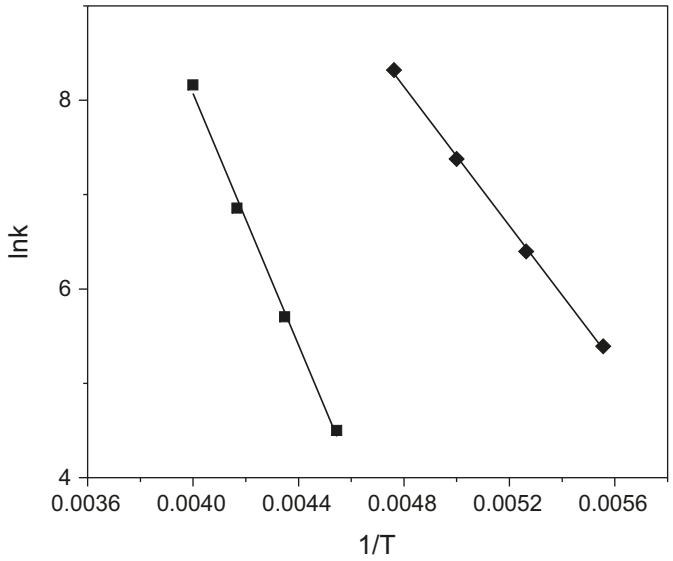

The least-squares linear fit for THF clathrate hydrate resulted in an activation energy E_a = 30.5 ± 0.8 kJ mol^{-1}, which is comparable to values of 31.0 kJ mol^{-1} from dielectric,[37] 30.12 kJ mol^{-1} from ^{1}H NMR,[30] and 31.0–32.7 kJ mol^{-1} from ^{2}H NMR.[33,34] This value is smaller than that of ice-Ih, showing that water molecular reorientations in THF gas hydrate are much more facile. As mentioned earlier, it is thought that this is due to injection of Bjerrum L-defects into the hydrate lattice by transient H-bond formation between the O atom of the THF and a water molecule.[10,15,37]

The concurrence of activation energies for both materials with values determined previously affirms the essential correctness of the model in this intermediate regime. If the Arrhenius plots are then extrapolated to 270 K the rates suggested are 2.4 × 10^4 s^{-1} for ice-Ih and 2.0 × 10^5 s^{-1} for THF hydrate. The latter value is well towards the fast limit compared with the second-order static linewidth, where the model predicts a residual anisotropic lineshape, but it is also in the range where the first satellite lineshape will be starting to average (recall that ν_Q is ~9.6 × 10^5 Hz).

It was mentioned earlier that lower activation energies for water reorientation in hydrates had been ascribed to defect injection by guest molecules containing oxygen.[10,15] Recent molecular dynamics (MD) simulation studies on nanosecond timescales have in fact observed the existence of both transient and persistent guest–host hydrogen bonds for oxygen-containing guests[53–55]. In the simplest cases, this corresponds exactly to the injection of an L-defect as there is indeed a misdirected H-bond, leaving a hydrogen vacancy in the water lattice. Such vacancies will in effect make it easier (lower barrier) for reorientation of an adjacent water molecule to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

occur. For the more persistent guest–host interactions, a careful study by single crystal X-ray diffraction showed that the misdirected H-bonds to guests could be seen directly (specifically in pinacolone Str.H and t-butylamine Str.II),[56] indicating that a good fraction of the guests were H-bonded at any particular instant. For stronger guest–host interactions, a water oxygen was also moved out of its usual position in the hydrate cage.[56] However, in the case of THF hydrate the MD simulations showed that these H-bonds are rather short lived (0.28 ps at 200 K), and thus no effects on the structure can be detected.[53] This *injection* of L-defects by the guest appears to be quite a different process from the *propagation* of Bjerrum defects, which governs the water reorientation process as observed by dielectric and NMR relaxation.[10,15] For instance, for THF hydrate the activation energy for L-defect *injection* was found to be ~8.3 kJ/mol from MD simulation,[53] compared with an experimental value of ~30 kJ/mol for defect *propagation* (see refs. 30, 33, 34, 37, and this work). An MD calculation of defect *propagation* will require longer simulation times, as this process barely reaches microsecond timescales at the highest temperatures of study. It may be that the limiting process for defect transport is the ease of D-defect generation.

Conclusion

This study of ^{17}O NMR lineshapes of water in ice and a clathrate hydrate has provided a remarkable picture of the effects of dynamic averaging on lineshapes of a non-integer quadrupolar nucleus over quite a broad range of jump rates. It is also quite consistent with previous studies using other nuclei and other techniques. Apparently, no new details of Bjerrum defect diffusion have come to light, although it is clear that some progress has been made in understanding the role of Bjerrum defect injection and transport in ice and hydrates in general. The observation of an apparently isotropic line that has a second-order shift is quite unusual and could have implications for reporting of shifts in other systems, if it is not recognized that dynamic effects are at play. While rapid reorientation among tetrahedral or octahedral orientations at rates faster than the full first-order linewidth will average the effective electric field gradient to zero, in which case an isotropic line at the true chemical shift is the ultimate spectrum, it is also well recognized that the second-order central transition lineshape will average to an anisotropic shape at rates comparable with its static linewidth. The current work has also partly explored a rate regime between these two situations where the anisotropically averaged second-order lineshape further averages to an isotropic shape which retains a second-order shift. In the absence of variable temperature work where this behaviour becomes apparent, it would be necessary to check whether an isotropic line has a second-order shift by measuring the shift at more than one magnetic field.

Abstract: The discrimination induced by variable amplitude minipulses (DIVAM) filter can be tuned to select for signals from a particular domain, therefore it is possible to obtain signals specific to different domains using only one experiment. An early description of the DIVAM sequence, where the filter terminates with cross-polarization, explains this tune ability using a simple one-spin-relaxation model, thereby limiting the selection mechanism to incoherent processes. Recently, a more complete description of the selection behaviour was offered for the DIVAM filter, when it was directly applied to the observed nucleus (direct DIVAM), taking into account both the incoherent and coherent terms. Direct DIVAM experiments on poly(vinylidenefluoride) (PVDF) show significant phase distortions when large excitation angles were used. The signal from the amorphous domain is seen to nutate in a normal fashion with respect to the excitation angle, while those from the crystalline and defect units did not. The refocused DIVAM sequence is introduced to restore normal nutation for all signals. The selection behaviour is investigated using SIMPSON (simulation program for solid-state nuclear magnetic resonance (NMR) spectroscopy) simulations. These illustrate that the isotropic shift terms have been effectively removed and the dipolar term attenuated, such that the chemical shift anisotropy (CSA) leads to domain selection; however, in a different manner than seen in direct DIVAM. Therefore, this sequence provides a method to select on the basis of the CSA term in the presence of both strong dipolar couplings and a large range of isotropic shifts.

Key words: nuclear magnetic resonance (NMR), polymer, domain selection, discrimination induced by variable amplitude minipulses (DIVAM), refocusing, spin dynamics, relaxation.

Résumé : Le filtre avec discrimination induite par des minipulsations d'amplitude variable (DIMAV) peut être ajusté pour choisir des signaux à partir d'un domaine particulier; il est donc possible d'obtenir des signaux spécifiques à différents domaines au cours d'une seule expérience. Une description de la séquence DIMAV originale, dans laquelle le filtre se termine par une polarisation croisée, explique cette habilité à s'ajuster à l'aide d'un modèle simple de relaxation à un spin, limitant ainsi le mécanisme de sélection à des processus incohérents. Récemment, une description plus complète du comportement de sélection a été offerte pour le filtre avec des DIMAV qui, lorsquelle est directement appliquée au noyau observé (DIMAV directe), permet de tenir compte à la fois des termes cohérents et incohérents. Des expériences de DIMAV directe sur du poly(fluorure de vinylidène) (PFPV) montrent qu'on observe des distorsions de phase importantes quand on utilise de grands angles d'excitation. On voit que, dans le mode normal, le signal du domaine amorphe subit une nutation par rapport à l'angle d'excitation alors que ceux des unités cristallines ou défectueuses n'en subissent pas. On introduit la séquence de DIMAV refocalisée pour restaurer la nutation normale pour tous les signaux. On a étudié le comportement de sélection par des simulations à l'aide du programme de simulation pour la spectroscopie résonance magnétique nucléaire (RMN) à l'état solide (SIMPSON). Elles permettent d'illustrer que les termes de déplacement isotrope peuvent effectivement être éliminés et que le terme dipolaire peut être atténué d'une façon telle que l'anisotropie du déplacement chimique (ADC) conduit à une sélection du domaine; toutefois, cette sélection est faite d'une façon différente de celle observée par une DIMAV directe. En conséquence, cette séquence fournit une méthode de sélection sur la base du terme d'ADC en présence à la fois de forts couplages dipolaires et d'un large éventail de déplacements isotropes.

Introduction

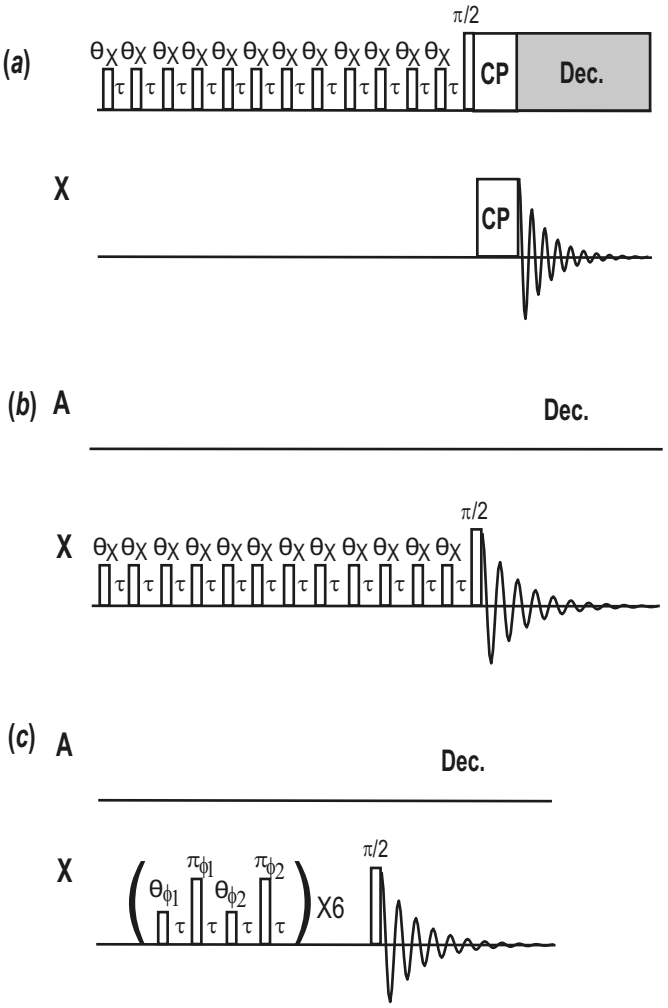
Fluoropolymers see widespread commercial application, such as nonstick coatings (Teflon), textiles (GORE-TEX), and fuel cell membranes (Nafion).[1–3] Poly(vinylidenefluoride) (PVDF) is a semicrystalline fluoropolymer, which is exploited for its piezo- and pyro-electric properties in actuators, transducers, and coatings. These useful macroscopic properties are a direct result of the polymer's domain structure; therefore, a good understanding of the morphology on the atomic scale can give valuable insights into their potential applications. Fluorine solid-state nuclear magnetic resonance (SSNMR) is an ideal tool to study these polymers owing to the sensitivity of the ^{19}F nucleus to its local electronic environment.[4–7]

There are several advantages to using the ^{19}F nucleus in SSNMR. Firstly, it is 100% abundant and has the second largest gyromagnetic ratio amongst stable nuclei; hence, its sensitivity is similar to that of ^{1}H. As a consequence, it is common for fluorine to have strong homonuclear and heteronuclear dipolar couplings. These can be exploited in one- and two-dimensional techniques, giving internuclear distances, which in turn provide valuable insight into connectivity and spatial proximity.[8–11] For nonperfluorinated systems, heteronuclear couplings to protons can be easily removed by using multipulse decoupling sequences.[12,13] Secondly, fluorine is very sensitive to its local environment owing to its large chemical shift range, similar to ^{13}C, making it a very useful structural probe; furthermore, the large frequency separations suppress spin diffusion leading to high resolutions, which is extremely difficult to achieve in proton spectroscopy.

One of the benefits of SSNMR in materials science is its ability to obtain detailed information from overlapping signals corresponding to different chemical environments. Various filtering methods have been designed for domain selection, where separation is achieved via differences in relaxation, dipolar coupling (DC), and chemical shift anisotropy (CSA).[14–16] Often, it is necessary to perform several different experiments to select the signal from each domain. Relaxation methods are mainly applied to abundant nuclei, exploiting differences in their T_1, $T_{1\rho}$, or T_2[14,17–20] relaxation times. Domain selection can be achieved using differences in dipolar coupling interactions. These methods have many different implementations such as the single pulse excitation with delayed acquisition, dipolar dephasing, and dipolar filter experiments.[21–28] Selection can also be achieved using the CSA term as was recently demonstrated by Schmidt-Rohr and co-workers.[29] These aforementioned selection methods have been reviewed elsewhere and will not be elaborated upon in this work.[14]

The discrimination induced by variable amplitude minipulses (DIVAM)[17,30] and direct DIVAM[31] (Figs. 1*a* and 1*b*) experiments are domain selection methods that can be adjusted, making it possible to select the signal from each domain separately using only one pulse sequence, rather than several different pulse sequences as in the past. In the DIVAM experiment, the filtering sequence is applied to an abundant nucleus, i.e., ^{1}H, which is immediately followed by cross-polarization to the nucleus of interest, i.e., ^{19}F or ^{13}C, allowing the selection to be based on proton spin dynamics and the higher spectral resolution results from the large chemical shift dispersion of the observed nucleus.[32,33] In the case where cross-polarization is not possible from proton, i.e., for perfluorinated materials or when high mobility is present, the DIVAM sequence is applied directly to the nucleus of interest.

Fig. 1. (*a*) The DIVAM, (*b*) the direct DIVAM, and (*c*) the refocused DIVAM pulse sequences.



Previous work on the DIVAM sequence[30] has shown that no transient behaviour in the nutation is seen on the rotor-time scale when incrementing the interpulse delay (τ). This indicates that coherent processes of the abundant nuclei do

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

not affect the nutation of signals from the observed nuclei. This is most likely due to rapid spin diffusion in protons, which dampens any rotor-phase dependence during the cross-polarization to the observed nucleus. Therefore, the DIVAM sequence can be thought of as selecting on the basis of differences in the transverse relaxation between domains, which was demonstrated using a one-spin relaxation model (Fig. 2*a*). With each pulse, the longitudinal components from each domain are rotated into the transverse plane. During the interpulse delay, they dephase at differing rates, resulting in a difference in their net angle of rotation along the *z*-axis. Upon each pulse-delay cycle, this phase difference accumulates resulting in a net difference in their nutation rates with respect to the excitation angle. At a specific excitation angle (θ), there is a phase difference of 90°, where the signal from one component remains positive while the other will be nulled. As a result, the signal of only one of the domains is observed.

In contrast, our previous work[31–33] has shown that nutation of the ^{19}F signals in direct DIVAM is seen to be strongly dependent on the rotor timescale. To explain the selection behaviour for the direct DIVAM sequence, a more sophisticated model combining the effects of chemical shielding, dipolar coupling, and relaxation was needed. All were seen to participate in the selection process, where the degree of each was dependant on the excitation angle and interpulse delay; therefore, it is possible to configure the sequence so that either can be the dominant selection mechanism. However, the spin dynamics terms were shown to lead to significant phase distortions for large excitation angles (θ). Also, the nutation behaviour depended strongly on the frequency offset from the radio frequency (RF) resonance, or carrier frequency, of the excitation pulses (henceforth, this will be referred to as the offset dependence of direct DIVAM). Both phase distortions and an offset dependence are undesirable as they can severely compromise effective domain selection by distorting the observed nutation behaviour; therefore, modifications to direct DIVAM are required to remove, or reduce, these effects.

At this stage, it is important to point out that although DIVAM bears a strong resemblance to DANTE (delay alternating with nutation for tailored excitation),[34,35] it is very different in its application and mode of action. On the one hand, DANTE can be thought of as a discrete version of a soft pulse, where selective excitation is achieved through the offset term; however, as it has been most extensively used in the solution state the effects of the remaining terms in the Hamiltonian are ignored. On the other hand, DIVAM is used solely on solids to select between overlapping signals, hence the offset differences are very small. This means that a combination of relaxation and the remaining terms of the solid state NMR Hamiltonian (CSA and DC) are responsible for the selection behaviour. In fact, the intention is to completely remove any residual selection resulting from the offset term during the DIVAM sequence.

In this work, the refocused DIVAM experiment (Fig. 1*c*) is introduced, which is similar to direct DIVAM, but with the addition of refocusing pulses and an appropriate phase cycle (Table 1). Refocusing pulses are added to remove the effect of coherent dephasing due to both the heteronuclear coupling and chemical shift terms of the Hamiltonian during the interpulse delay, thereby reducing both the phase distortions seen at large excitation angles (θ) and the offset dependence of direct DIVAM. Furthermore, any selection due to relaxation will be reduced as it will be governed by T_2 as opposed to T_2*. The phase cycle is implemented to ensure that the magnetization accumulates in the transverse plane in a similar manner to the previous DIVAM experiments (Fig. 2*b*). Also, the cycle makes use of EXORCYCLE (a 16-step phase cycle for spin echoes),[36] ensuring that any remaining contributions to the signal that result from the mis-setting of pulse widths are removed. The experiment is repeated with an offset alternating above and below the RF carrier frequency to ensure that any phase distortions due to the breakdown of the hard pulse approximation are minimized. All of these modifications should change the selection mechanism of the sequence by simplifying the nutation behaviour, thereby improving its prospective application in domain selection and separated local field methods. This work provides experimental and simulation results that show how these modifications affect the selection mechanism of the direct DIVAM sequence.

Results and discussion

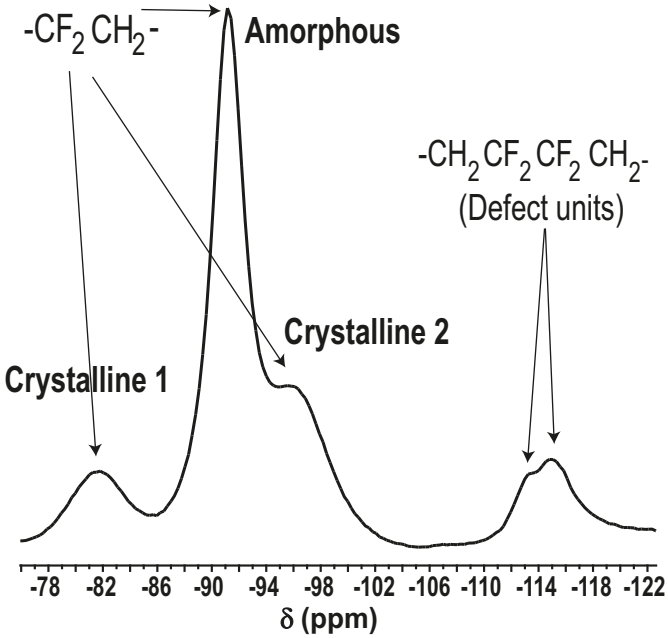
Direct and refocused DIVAM experiments on PVDF

The ^{19}F magic-angle spinning (MAS) SSNMR spectrum of PVDF (Fig. 3) contains two broad signals at –82.1 and –95.6 ppm, corresponding to the crystalline domains, and one narrow peak at –91.2 ppm that represents the amorphous domain. The crystalline signal is characterized by short T_2's and large chemical shift anisotropies (CSAs). In contrast, the signal from the amorphous region has longer T_2's and smaller CSAs, due to molecular motion. A broad signal of low intensity is composed of two signals at –118.3 and –114.9 ppm from the two adjacent CF_2 groups of the defect unit, which is formed due to reversed addition of the monomer units during polymerization. Furthermore, a lower intensity signal is present at –115 ppm and has been shown to be the CF_2H end chain signal.[6] These defect units have been associated with the amorphous region through data obtained from relaxation, radio frequency driven recoupling (RFDR), and domain filtering (i.e., dipolar filter and $T_{1\rho}$) experiments.[7]

The direct DIVAM nutation array of the ^{19}F MAS spectra of PVDF is shown in Fig. 4. Some of the aforementioned problems with direct DIVAM may not be immediately apparent, but upon closer examination they can be seen. The amorphous signal nutates for most of the excitation angles, however this nutation is lost beyond 60°. This loss of nutation is a direct result of the phase distortions created by the spin dynamics terms at large excitation angles.[31] Also, note that nutation of the crystalline signal is nearly lost and not apparent for the defect signals. This is indicative of the offset dependence of direct DIVAM as the RF is centered on the amorphous signal, which is shifted in frequency from both the crystalline and defect signals by 4.6–8.9 ppm (2.1–4.2 kHz) and 24 ppm (11.3 kHz), respectively. This offset dependence of direct DIVAM will be further investigated when looking at the application of direct and refocused DIVAM to Nafion 117.

Figure 5 shows the refocused DIVAM array of PVDF. The improved resolution in the ^{19}F spectra is due to more efficient ^{1}H decoupling during acquisition. The amorphous signal is seen to nutate at a faster rate than the crystalline signal, and passes through a null condition at $\theta \simeq 22.5°$, where positive intensity of the crystalline signal remains. Also, the crystalline signal passes through a null condition at $\theta \simeq 62.5°$, where the amorphous signal has returned to a positive intensity. Furthermore, the defect signals now nutate at a rate similar to that of the amorphous signal; this will be discussed later. It is important to point out that these selection angles are approximate. Complete selection of either the crystalline or amorphous domain is achieved by incrementing the excitation angle, around each of the approximate values, in steps that are smaller than 2.5°. In general, for any given sample the exact angles at which zero crossings occur must be determined by careful calibration of the excitation angles.

Fig. 3. The ^{19}F MAS NMR spectra of PVDF under ambient conditions, with the RF resonance set on the amorphous peak, and a MAS rate of 20 kHz.



When comparing the nutation behaviour in refocused DIVAM (Fig. 5) with direct DIVAM (Fig. 4), a few observations can be made. First, note that the phase distortions in the direct DIVAM array have been reduced in the refocused DIVAM experiment. Second, the signals from all three chemical environments nutate for all excitation angles indicating that the offset dependence of direct DIVAM has been reduced. Lastly, refocused and direct DIVAM show differences in their overall rate of nutation, which can be attributed to three factors: (*i*) the interpulse delays used in direct DIVAM differ from the refocused DIVAM sequence, (*ii*) the refocused DIVAM sequence has twice as many interpulse delays due to the addition of refocusing pulses, and (*iii*) the selection mechanisms of direct and refocused DIVAM are different. As a result of the first two factors, the total filtering time of the sequence is changed and the net evolution in the transverse plain is different; therefore, differences in their nutation rates are to be expected. The selection mechanism in direct DIVAM, when off-resonance, becomes dominated by its offset dependence, while in refocused DIVAM it appears to be driven by the CSA term. This is further supported by SIMPSON (simulation program for solid-state NMR spectroscopy)[37] simula-

Fig. 4. The direct DIVAM nutation array of the ^{19}F MAS NMR spectra of PVDF using an interpulse delay of 1.67 μs and a pulse width of 2.5 μs (T_F = 50 μs). The nutation array ranges over excitation angles of 0°–90° in steps of 2.5° and was acquired with a spinning speed of 20 kHz. Enlargements of the ^{19}F MAS NMR spectra of PVDF for selected excitation angles are also shown.

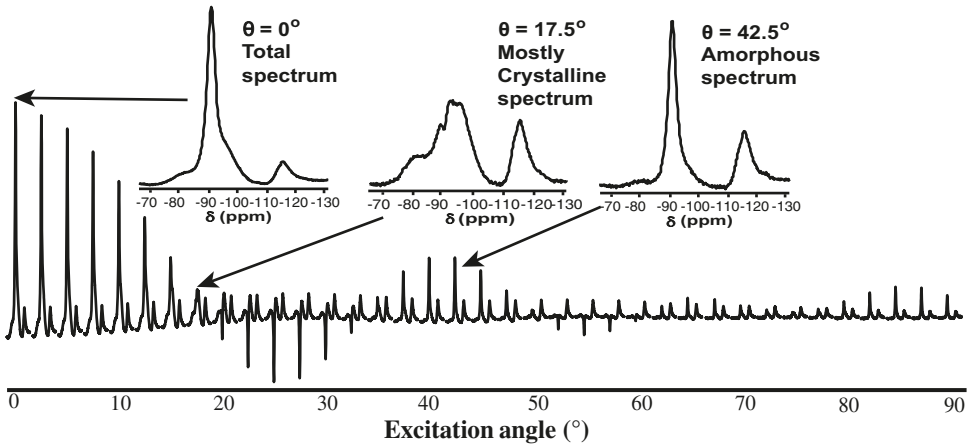


Fig. 5. The refocused DIVAM nutation array of the ^{19}F MAS NMR spectra of PVDF using an interpulse delay of 2.5 μs, a 90° pulse width of 2.5 μs, a 180° pulse width of 5 μs (T_F = 150 μs), and a pulse offset of 1 kHz. The nutation array ranges over excitation angles of 0°–90° in steps of 2.5° and was acquired with a spinning speed of 20 kHz. Enlargements of the ^{19}F MAS NMR spectra of PVDF for selected excitation angles are also shown.

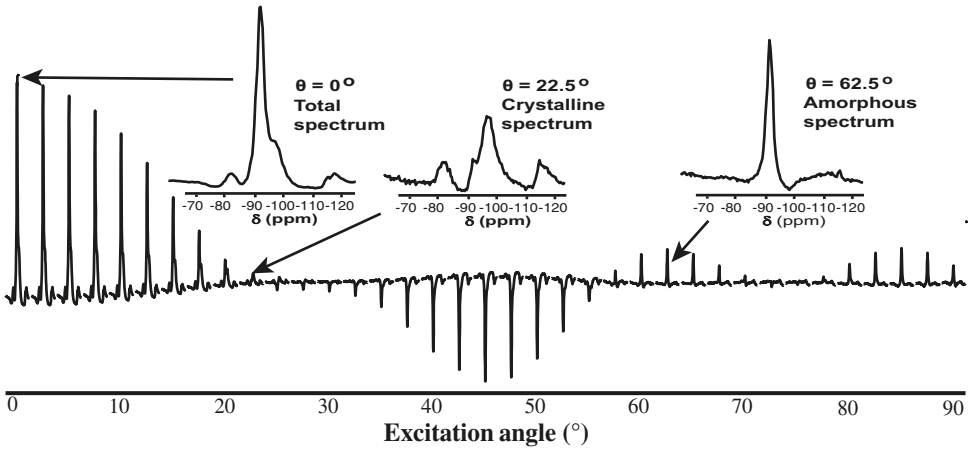

tions on refocused DIVAM, which will be shown in a later discussion (see the SIMPSON simulations section).

Although, the offset dependence of direct DIVAM has been greatly reduced, it can still be seen to a minor degree when comparing nutation rates of the amorphous and defect signals in refocused DIVAM (Fig. 5). These signals are known to be from similar environments and should have similar nutation rates. However, upon closer examination nutation of the defect signals lags slightly behind the amorphous signal. The extent of this remaining offset dependence will be examined further using Nafion 117.

The ^{19}F MAS NMR spectra of Nafion 117 and its structural assignment can be seen in Fig. 6.[38,39] Figures 7*a* and 7*b* show the nutation profile of the backbone (BB) signal (B in Fig. 6*b*) at –122 ppm and side-chain (SC) signal (E and F in Fig. 6*b*) at –82 ppm, respectively, with the RF resonance centered on the backbone (BB) signal. Similarly, Figs. 7*c* and 7*d* show analogous nutation profiles but with the RF resonance centered on the SC signal. It is clear that nutation of each signal occurs when the RF resonance is centered directly on the peak of interest (Figs. 7*a* and 7*d*) and that once the RF resonance is moved nutation is lost (Figs. 7*b* and 7*c*). This is a direct result of the aforementioned offset dependence of direct DIVAM and will be confirmed in the SIMPSON simulations section. Figure 8 illustrates the nutation profiles of the BB and SC signals in Nafion acquired using the refocused DIVAM sequence and with the RF frequency centered at –100 ppm. Refocused DIVAM recovers nutation of both the SC and BB signals and has removed the frequency offset dependence over at least a range of ~±20 ppm (~±10 kHz). The Nafion nutation arrays serve as an example of the increase in the effective frequency range of the direct DIVAM sequence by the introduction of the refocusing pulses.

SIMPSON simulations

Simulations of the refocused DIVAM sequence were performed and compared with those of direct DIVAM done previously,[31] to investigate the effect of each term in the ^{19}F Hamiltonian separately. Parallel simulations were performed using real (soft) pulses under rotor-synchronized and non-rotor-synchronized conditions (Fig. 9). Soft pulses are

employed to avoid the use of the hard pulse approximation. The signal is computed over a range of excitation angles from 0° to 90° with an interpulse delay of 2.5 μs. The nutation of the *z*-magnetization remaining after the filter sequence is explained separately for each term in the Hamiltonian in the following text.

Isotropic shift term

Figure 9*a* shows that for a large range of frequencies the isotropic shift term of the Hamiltonian has been fully refocused in the rotor- and non-rotor-synchronized cases of refocused DIVAM. The lack of a difference between the rotor-synchronized and non-rotor-synchronized situations is to be expected, as the isotropic shift is not affected by sample rotation. Note that in the direct DIVAM simulations, the isotropic shift (offset) dependence of the nutation behaviour is obvious and has been clearly removed in refocused DIVAM. Also, the nutation of the 25 kHz curve in the direct DIVAM simulations closely resembles the nutation of the BB and SC signals in the off-resonance direct DIVAM arrays of Nafion (Figs. 7*b* and 7*c*), where the BB and SC signals are approximately 20 kHz off-resonance. This supports our earlier argument that the nutation of off-resonance signals is lost due to the offset dependence of direct DIVAM.

The chemical shift anisotropy (CSA) term

Figure 9*b* shows the nutation behaviour of the refocused and direct DIVAM sequences over a range of CSA strengths. Some interesting observations can be made when comparing the rotor-synchronized refocused and direct DIVAM simulations. For selection to occur in direct DIVAM, an anisotropy of 50 kHz or larger is required. In comparison, refocused DIVAM is sensitive to weaker anisotropies when using small excitation angles; therefore, refocused DIVAM appears to be a more sensitive CSA filter, as suggested earlier.

From the rotor-synchronized refocused DIVAM simulations, one can see that the first minimum is quite different for anisotropies of 10 kHz and above. More importantly, note that there is very little difference in the point of the first zero crossing for anisotropies up to 15 kHz. For larger excitation angles, $\theta \sim\geq 30°$, the nutation behaviour does not vary significantly for anisotropies less than 50 kHz, with a change in only the minimum but not the points of zero crossing.

The behaviour under non-rotor-synchronized conditions is substantially different and further complicated due to the rotational dependency of the CSA term. In this case, no difference in the point of the first zero crossing can be seen for anisotropies up to 25 kHz. On the other hand, differentiation in the maximum, minimum, and zero crossing of the nutation behaviour is seen for anisotropies above 10 kHz when an excitation angle greater than 30° is used. These results indicate that to achieve optimum selection conditions, rotor synchronization is of great importance and must be considered.

The effects of rotor synchronization were explored further using a range of CSA values over a series of interpulse delays, at a spinning speed of 20 kHz (Fig. 10). Rotor synchronization occurs at τ = 2.5 μs and corresponds to a T_F = 150 μs. At these conditions, a maximum difference between the curves is seen at θ = 15° and this indicates the optimum selection conditions. Upon closer examination, the selection condition becomes more favourable as the interpulse delay increases towards τ = 2.5 μs and less favourable as the difference from this value increases. Interestingly, the selection behaviour does not improve when the sequence is synchronized at either two or four rotor periods. This indicates that not only rotor synchronization, but also the number of rotor periods to which you synchronize the sequence, is important in achieving optimum selection. This suggests using interpulse delays approaching five rotor periods; however, for anisotropies of 90 kHz one can see that the signal is completely lost for longer interpulse delays (τ = 5 μs). The sequence must therefore be restricted to shorter interpulse delays to select for larger CSA values. It is important to note that the nutation curve of the 25 kHz CSA interaction, for an interpulse delay of 3 μs (top right of Fig. 10), closely resembles the nutation profile of the amorphous peak in the refocused DIVAM array (Fig. 5). This provides further support that the selection mechanism for refocused DIVAM is driven by the CSA term, but only when its strength is ≥15 kHz.

Dipolar coupling term

Figure 9*c* shows the nutation behaviour of the signal from the refocused and direct DIVAM sequences over a range of dipolar coupling interaction strengths. The comparison between the refocused and direct DIVAM rotor-synchronized simulations is quite different than what was seen for the CSA term. At the first zero crossing, differentiation is ob-

Fig. 7. The ^{19}F direct DIVAM nutation arrays of various peaks in Nafion with a MAS frequency of 24 kHz and ranging over excitation angles of 0°–90° in steps of 2.5°. Each direct DIVAM array used an interpulse delay of 1.67 μs and a pulse width of 4.44 μs (T_F = 83.3 μs). Arrays of the (*a*) backbone CF_2 peak with the RF resonance centered on the backbone CF_2 peak, (*b*) side-chain CF_3 and OCF_2 peak with the RF resonance centered on the backbone CF_2 peak, (*c*) backbone CF_2 peak with the RF resonance centered on the side-chain CF_3 and OCF_2 peaks, and (*d*) side-chain CF_3 and OCF_2 peak with the RF resonance centered on the side-chain CF_3 and OCF_2 peaks.

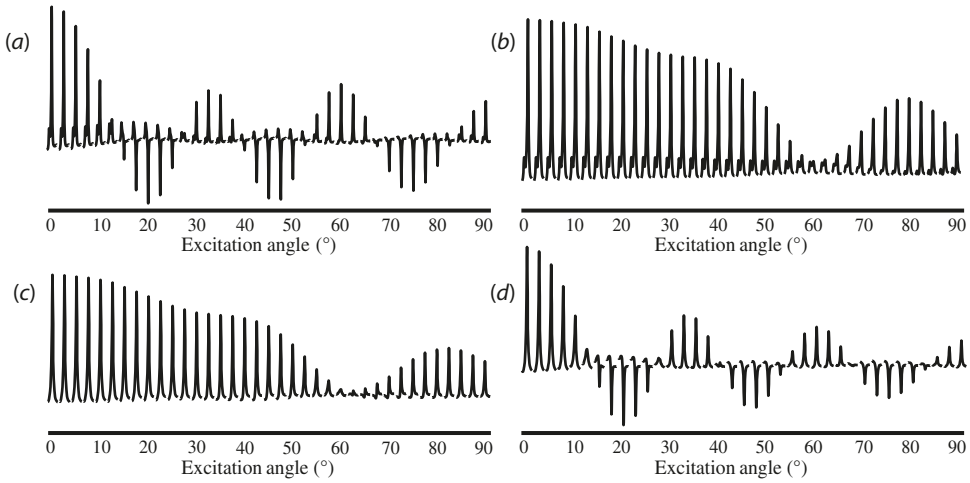

Fig. 8. The ^{19}F refocused DIVAM nutation array of Nafion at a MAS rate of 24 kHz and ranging over excitation angles of 0°–90° in steps of 2.5° of the (*a*) backbone CF_2 peak and the (*b*) side-chain CF_3 and OCF_2 peaks with the RF resonance centered at –100 ppm for both arrays. An interpulse delay of 2.5 μs, a 90° pulse width of 2.5 μs, a 180° pulse width of 5 μs (T_F = 150 μs), and a pulse offset of 1 kHz were used.

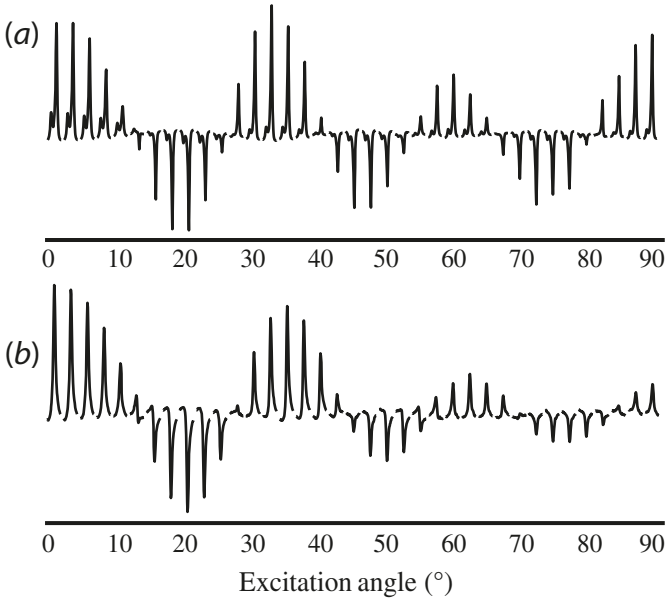

served for couplings of 25 kHz or greater in direct DIVAM, while a larger coupling of 50 kHz or greater is required for refocused DIVAM. Also, note that selection between the excitation angles of θ = 30° and 60° is not apparent in direct DIVAM, while it is quite profound in refocused DIVAM.

In the rotor-synchronized case for small excitation angles, $\theta \sim< 30°$, very little difference can be seen between the signals for dipolar couplings less than 50 kHz. This is also true in the case of excitation angles that are >60°. A dipolar coupling of 50 kHz is highly uncommon in these materials and therefore, in the small and large excitation angle regimes, the dipolar coupling should not be expected to contribute to the selection behaviour in the rotor-synchronized case. It is possible that selection could occur in the excitation angle range of θ = 30°–60° and would be based on a dipolar interaction of 15 kHz or greater.

The nutation of each signal is much more complicated in the non-rotor-synchronized case, due to the rotational dependency of the dipolar term. Similarly to the CSA term, no significant differences in the nutation behaviour are observed in the small excitation angle regimes, $\theta \sim< 30°$. In the case of the intermediate excitation angles, $\theta \simeq$ 30°–60°, the nutation behaviour varies less and now requires dipolar couplings of 25 kHz or greater for selection to occur. In the large excitation angles, $\theta \sim\geq 60°$, more differentiation is seen between signals and selection can be achieved with dipolar couplings of 15 kHz or higher. This again suggests that to achieve optimum selection conditions rotor synchronization should be employed.

Figure 11 shows a series of simulations of the dipolar term over a range of various interpulse delays and for two coupling values. For the small excitation angles, $\theta \sim< 30°$, rotor synchronization seems to be less important and no significant selection is seen between the curves. For the large excitation angles, $\theta \sim\geq 60°$, no noticeable selection occurs as we decrease the interpulse delay from 2.5 μs to 0.5 μs (T_F = 102 μs). However, selection can be seen as we increase the interpulse delay to a value of 4.5 μs (T_F = 148 μs). This indicates that for the larger excitation angles, $\theta \sim\geq 60°$, both rotor synchronization and the number of rotor periods are important. Practically speaking, rotor synchronization should be employed to ensure optimal selection; however, in general, some selection can still be achieved without it.

Simulation summary

If rotor synchronization is a requirement for domain selection then we can consider the effect of the CSA and dipolar Hamiltonian in two cases: small and large angles. In the for-

Fig. 9. Simulation of the refocused and direct DIVAM sequences, which illustrate the behaviour of (*a*) the isotropic shift, (*b*) the chemical shift anisotropy, and (*c*) the dipolar coupling terms of the Hamiltonian. Each Hamiltonian varied between 1 and 50 kHz, where ○ = 1 kHz, □ = 2.5 kHz, △ = 5 kHz, ▽ = 7.5 kHz, ◇ = 10 kHz, ⬡ = 15 kHz, ⊞ = 25 kHz, and ⊕ = 50 kHz. The refocused DIVAM simulations used real 100 kHz pulses with a 90° pulse width of 2.5 μs, a 180° pulse width of 5 μs, an interpulse delay of 2.5 μs (T_F = 150 μs), and a pulse offset of 1 kHz. The direct DIVAM simulations[31] used real 100 kHz pulses with a 90° pulse width of 2.5 μs and an interpulse delay of 1.67 μs (T_F = 50 μs). In all cases, the rotor synchronized and the non-rotor-synchronized simulations used MAS rates of 20 and 25 kHz, respectively.

mer case, CSA and dipolar interaction strengths of 15 and 50 kHz, respectively, are required for these terms to have a role in the selection. In the latter case, both rotor synchronization and the number of rotor periods over which the filter is applied are an important consideration. The total filtering time must be chosen such that no selection takes place for CSA and dipolar interaction strengths are less than 25 and 50 kHz, respectively. A total filtering time that is rotor synchronized and limited to a number of rotor periods reduces the amount of coherent dephasing that can occur during the interpulse delays, thereby ensuring minimal phase distortion in the nutation behaviour. Also, refocused DIVAM is a more sensitive CSA filter than direct DIVAM, with the latter requiring a CSA interaction strength of at least 50 kHz for selection to occur.

Conclusions

Refocused DIVAM experiments show that the phase distortions at large angles seen in the direct DIVAM experiments have been successfully removed by the addition of refocusing pulses. These experiments also demonstrate that the offset dependence of direct DIVAM has been greatly reduced and that nutation of all signals has been restored. SIMPSON simulations illustrate that the effect of the isotropic term has been removed. They also show that the effect of the CSA and dipolar terms on the selection mechanism of refocused DIVAM is profoundly different than for direct DIVAM. In fact, refocused DIVAM is more sensitive to the CSA term and less sensitive to the dipolar term. Furthermore, the refocused DIVAM experiment gives nutation behaviour, which is less complex than that of direct DIVAM, yet similar to the original CP DIVAM experiment.

The modifications made to the direct DIVAM sequence make it possible to perform CSA selection in the presence of both large isotropic shifts and dipolar interactions. In addition, this sequence is neither limited to any particular type of nucleus nor does it require any special considerations to simplify its spin dynamics; hence, the sequence is generally applicable. This is ideal for nuclei that exhibit large shielding ranges, especially with the large magnetic fields used today, such as ^{19}F, ^{31}P, ^{119}Sn, ^{117}Sn, ^{199}Hg, ^{77}Se, and ^{29}Si. These are increasingly being encountered in inorganic materials such as polymers, coordination polymers, and ceramics. Furthermore, CSA selection also has promising implications for both domain selection and separated local field methods. This is especially true when the latter is used to measure chemical shielding tensors components on systems that exhibit highly overlapped signals. This could prove to be an invaluable tool to the growing field of NMR crystallography.

Fig. 10. The effect of rotor synchronization on the selectivity of the refocused DIVAM pulse sequences for various chemical shift anisotropy and τ values where ○ = 10 kHz, ▽ = 25 kHz, and □ = 90 kHz. These simulations used real 100 kHz pulses with a MAS rate of 20 kHz, a 90° pulse width of 2.5 μs, a 180° pulse width of 5 μs, and a pulse offset of 1 kHz. The interpulse delay and total filtering time (T_F) are indicated at the top of each figure.

Experimental

Solid-state NMR measurements

The α-PVDF sample had a molecular weight of 1×10^6 Da by gel permeation chromatography (GPC), a crystallinity of ~28%, a reverse unit content of 4.7% by NMR, and a melting point of 158 °C by differential scanning calorimetry (DSC).[3] The sample of α-PVDF was supplied by Atofina (France). The Nafion 117 sample was purchased from Dupont in the form of a commercial fuel cell membrane film. A Varian INOVA 500 MHz spectrometer with a carrier frequency of 470.18 MHz for the fluorine nucleus was used for all experimental measurements. A Varian 2.5 mm four channel HFXY probe operating at 21 °C with a MAS rate of 20 kHz for PVDF and 24 kHz for Nafion experiments was used. The 90° pulse was calibrated at 2.5 μs with the amplitude of each pulse in a full pulse train varied from 0° to 90° in 2.5° steps. The RF resonance frequency during acquisition was set to the amorphous peak of PVDF at –91.2 ppm, and is indicated in the figure captions for the Nafion experiments. Two pulse phase modulation (TPPM) decoupling was applied to ^{1}H during fluorine acquisition and also during spectral referencing so that the Bloch-Siegert shift could be neglected.[2] Spectral referencing was done using C_6F_6 (δ_F = 166.4 ppm with respect to $CFCl_3$) and zirconium oxide rotors with Vespel drive caps were used to avoid unwanted fluorine background signal.

All experimental measurements of the refocused DIVAM sequence were implemented over a minimum of 32 transients to allow for the full phase cycling of the 180° refocusing pulses. The phase cycle used (Table 1) ensures that all feedthrough terms are suppressed and effective refocusing occurs.[36] Blocks of 32 transients are required because the normal 16 step phase cycle is run twice, but with a different pulse offset used in each full cycle. The two pulse offsets used are of equal magnitude but opposite sign and the offset used for all experiments was 1 kHz.

The refocused DIVAM sequence was performed using a pulse train that consisted of twelve 2.5 μs (pulse width (pw_{90}) = 2.5 μs) pulses each followed by a 5 μs (pulse width (pw_{180}) = 5 μs) refocusing pulse, with all pulses separated by an interpulse delay (τ). After the pulse train, a terminal 90° observation pulse was applied. Measurements for the nutation series were made with the pulse excitation angle (θ) varied from 0° to 90° in 2.5° steps and both the interpulse delay and magnitude of the pulse offset fixed. The variance of the pulse excitation angle (θ) was accomplished by altering the strength of the B_1 field, whilst keeping the pulse duration constant to attain rotor synchronization. The discussion of rotor synchronization will always be with respect to the total filtering time (T_F), where $T_F = (24 \times \tau) + (12 \times pw_{90}) + (12 \times pw_{180})$.

Both the DIVAM and direct DIVAM experiments used a 90° pulse width of 2.5 μs, an interpulse delay (τ) of 1.67 μs, and a MAS rate of 20 kHz (T_F = 50 μs). These experiments were implemented in the same manner as in previously published works.[30,31]

Fig. 11. The effect of rotor synchronization on the selectivity of the refocused DIVAM pulse sequences for various dipolar coupling strengths and τ values, where ○ = 10 kHz, and ▽ = 25 kHz These simulations used real 100 kHz pulses with a MAS rate of 20 kHz, a 90° pulse width of 2.5 μs, a 180° pulse width of 5 μs, and a pulse offset of 1 kHz. The interpulse delay and total filtering time (T_F) are indicated at the top of each figure.

Spin dynamics simulations

All simulations were carried out using SIMPSON 1.1.0[37] with an Intel Core 2 Duo 7200 processor. The refocused and direct DIVAM simulations were run separately for three different terms in the Hamiltonian corresponding to the isotropic frequency, chemical shift anisotropy (CSA), and the dipolar coupling. For each of these terms, the pulse sequence was simulated using real (soft) pulses and the strength of the Hamiltonian terms was varied in size from 0 to 50 kHz. These simulations were also run under timing conditions in which the total duration of the pulse train was either synchronized or not synchronized with the rotor. The chemical shift tensor convention used in SIMPSON is the Haeberlen–Mehring–Spiess convention,[40–42] and all discussions of simulation results are with the use of this convention.

The CSA and isotropic terms of the Hamiltonian were simulated as a one-spin system with the initial density matrix set as I_z. The dipolar coupling term of the Hamiltonian was simulated as a two-spin system with the initial density matrix set as $I_z^{(1)} + I_z^{(2)}$. At the end of the sequence, the I_z component of the density matrix was reported as a function of the pulse excitation angle (θ). For the dipolar coupling simulations, only the $I_z^{(1)}$ term of the density matrix was reported.

Simulations of the refocused and direct DIVAM sequence were implemented using the same pulse-train values as in the solid state NMR measurements (pw_{90} = 2.5 μs and pw_{180} = 5 μs). The rotor-synchronized simulations used a spinning speed of 20 kHz, while the non-rotor-synchronized simulations used a spinning speed of 25 kHz. All simulation used the direct method of calculation, 30 γ angles, 168 crystal orientations, and were powder averaged. For all simulations, two full phase cycles of the refocusing pulses were implemented (Table 1) with a pulse offset of 1 kHz.

Abstract: A combination of solid-state nuclear magnetic resonance (NMR) and first principles calculations was applied to obtain ^{17}O, ^{25}Mg, and ^{33}S NMR parameters for two polymorphs of anhydrous magnesium sulfate. Working at the very high magnetic field of 21.14 T results in a dramatic improvement of resolution through a reduction of the effects of quadrupolar interactions and significant improvement in sensitivity. Experimental ^{25}Mg and ^{33}S spectra are dominated by quadrupolar interactions with quadrupolar parameters unique for each polymorph. In the case of ^{17}O, there is a substantial contribution of the chemical shift anisotropy. The use of multiple-quantum magic-angle spinning (MQMAS) experiments allows the resolution of distinct oxygen species and assignment of signals in the experimental ^{17}O spectrum. Chemical shielding constants and quadrupolar parameters for all three nuclei were calculated using plane wave pseudopotential density functional theory as implemented in the CASTEP computational package. The calculated NMR parameters are in very good agreement with the experimental results and help in signal assignment of the ^{17}O spectrum. The results suggest applicability of such a combined computational and experimental solid-state NMR approach for the refinement of crystallographic data.

Key words: multinuclear solid-state nuclear magnetic resonance (NMR), $MgSO_4$ polymorphs, ^{17}O, ^{25}Mg, ^{33}S, chemical shift anisotropy, electric field gradient, density functional theory (DFT) calculations.

Résumé : On a appliqué une combinaison de résonance magnétique nucléaire (RMN) à l'état solide et de calculs à partir de principes premiers pour obtenir les paramètres RMN du ^{17}O, du ^{25}Mg et du ^{33}S pour deux polymorphes du sulfate de magnésium anhydre. Opérant au champ magnétique très élevé de 21,14 T, les résultats comportent une amélioration dramatique de résolution par une réduction des effets des interactions quadripolaires et une amélioration significative de la sensibilité. Les spectres expérimentaux du ^{25}Mg et du ^{33}S sont dominés les interactions quadripolaires avec des paramètres quadripolaires uniques à chacun des polymorphes. Dans le cas du ^{17}O, une contribution substantielle de l'anisotropie du déplacement chimique est aussi observée. L'utilisation d'expériences rotation à l'angle magique à multiple quantum (RAMMQ) permet de résoudre les diverses espèces de noyaux d'oxygène et de faire une attribution aux signaux des spectres expérimentaux de ^{17}O. On a calculé les constantes de blindage chimique et les paramètres quadripolaires des trois noyaux en faisant appel à la théorie de la fonctionnelle de la densité avec pseudo-potentiel à onde plane telle que disponible dans le programme de calcul CASTEP. Les paramètres RMN calculés sont en très bon accord avec les résultats expérimentaux et ils sont utiles dans l'attribution des signaux des spectres du ^{17}O. Ces résultats suggèrent qu'une telle approche, de RMN à l'état solide expérimentale combinée à des calculs théoriques, pourrait s'appliquer au raffinement de données cristallographiques.

Mots-clés : résonance magnétique nucléaire (RMN) multinucléaire à l'état solide, $MgSO_4$ polymorphes, ^{17}O, ^{25}Mg, ^{33}S, anisotropie du déplacement chimique, gradient du champ électrique, calculs selon la théorie de la fonctionnelle de la densité (TFD).

Introduction

Recent developments in nuclear magnetic resonance (NMR) instrumentation, especially ultrahigh-field NMR magnets, combined with advances in computation of NMR parameters, significantly broadens the scope of solid-state (SS) NMR spectroscopy of materials. These advances are especially significant in studies concerned with low-γ, low natural abundance, and quadrupolar nuclei.[1] Another modern development that makes SS NMR an even more powerful tool in

materials research is quantum-chemical calculations of NMR parameters. The complicated nature of interactions in solid-state NMR poses some serious challenges in the analysis of spectral data and the accurate extraction of shielding and quadrupolar parameters. Correct interpretation of the experimental spectra may require some elaborate quantum-mechanical calculations and spectral simulations. First-principles calculations may well complement experimental data and help in the interpretation and assignments of the spectra. Recent development of the gauge including projector augment wave (GIPAW)[2] formalism, implemented within the CASTEP[3] computational package, is particularly useful for solid-state NMR. Several recent studies have demonstrated that highly accurate evaluation of SS NMR parameters is possible,[4–8] with most examples coming from Earth sciences and silicates research. Thanks to the availability of more user-friendly quantum-chemical software and advances in computational hardware, today this task can be accomplished as never before.

In the current study, we explore a combination of experimental multinuclear solid-state (SS) NMR at a very high magnetic field of 21.14 T with quantum-mechanical computations to study two polymorphs of anhydrous magnesium sulphate. It is considered that magnesium sulfates are important planetary rock-forming materials in our solar system.[9,10] Specifically, $MgSO_4$ is considered to be an important mineral in putative carbonatite lavas on Venus.[9] In the outer solar system, $MgSO_4$ may well be the most important leachate from chondritic materials.[10] In many respects, the importance of magnesium sulfates as a planetary mineral resembles those of magnesium ortho- and meta-silicates in the Earth's mantle, the latter being recently studied comprehensively with a combination of multinuclear SS NMR and first principles computations.[8]

Below about 800 K, anhydrous magnesium sulfate is known to coexist in two polymorphic forms. The α-phase can be grown from a solution of MgO in H_2SO_4. The structure of the α-form is orthorhombic with space group *Cmcm* ($Z = 4$) and unit-cell dimensions $a = 5.182$ Å, $b = 7.893$ Å, and $c = 6.506$ Å.[11] The β-$MgSO_4$ can be formed either by thermal dehydration of $MgSO_4$ hydrates or by heating α-$MgSO_4$ to 868 K[12] followed by quenching to room temperature. The structure of the β-form is orthorhombic with space group *Pbnm* and unit-cell dimensions $a = 4.742$ Å, $b = 8.575$ Å, and $c = 6.699$ Å.[13] After quenching, β-$MgSO_4$ persists in this form indefinitely. The polymorphs are structurally very similar and consist of edge-sharing MgO_6 octahedra arranged in infinite ribbons and cross-linked by sheets of pseudo-close-packed SO_4 tetrahedra. The latter, however, are oriented in α- and β-forms in different planes. The structural similarities and differences of α- and β-forms were considered in some detail in a recent neutron powder diffraction study.[14] One needs to emphasize that due to the difficulties of growing single crystals of highly hygroscopic $MgSO_4$, the earlier structures were solved from X-ray powder data and were later refined using powder neutron diffraction. The first single crystal study of β-$MgSO_4$ was published only in 2007,[15] soon after the neutron powder diffraction refinement for both α- and β-polymorphs.

$MgSO_4$ poses some serious solid-state NMR challenges. All three nuclei are quadrupolar, and their SS NMR signals are broadened by quadrupolar interactions.[16–18] Two of the three nuclei (^{25}Mg and ^{33}S) have very low gammas, and only one of them has a moderate natural abundance (^{25}Mg 10%, ^{33}S 0.76%, ^{17}O 0.037%).[19] The combination of the above results in a very poor NMR receptivity (see Table 1). In this work, we report the results of a solid-state NMR study using all three nuclei in the α- and β-forms of anhydrous magnesium sulfate at a magnetic field of 21 T. At this very high magnetic field, the effects of the quadrupolar interactions are reduced significantly[16,17] and the sensitivity and accuracy in determining the NMR parameters improve dramatically. We demonstrate that for all three nuclei the quadrupolar effects dominate the NMR spectra. A complete analysis of experimental SS NMR parameters has become possible with the use of the CASTEP[2,3] computational package.

It is always of great interest to support known structural data obtained through X-ray or neutron diffraction methods with additional techniques. The use of a short-range order interaction technique such as NMR is expected to complement the existing structural data obtained through previous diffraction methods. As well, with the aid of computation, an attempt to distinguish polymorphs with the same chemical composition through SS NMR can be accomplished. The possibility of assessing the structural details in β-$MgSO_4$ obtained by two different diffraction techniques using SS NMR in conjunction with ab initio calculations is another expected outcome of this work.

Experimental

Materials

Both $MgSO_4$ polymorphs studied in this work were synthesized as ^{17}O enriched compounds. ^{17}O enriched sulfuric acid was prepared by reacting sulfuryl chloride (SO_2Cl_2, Sigma-Aldrich) with $H_2{}^{17}O$ (Cambridge Isotope Laboratories, Inc., 17.8% enrichment). The sulfuric acid obtained was added in about 20 mol% excess to a small quantity (~0.3 g) of freshly calcined MgO (Sigma-Aldrich) in a small Pt crucible and the slurry was left to evaporate over a hot plate (~300 °C). After complete evaporation of the liquid sulphuric acid, the crucible was put in an oven and kept there at a constant temperature of 450 °C overnight. The X-ray diffraction pattern of the resulting powder was that of α-MgSO4.[11,14] The β-phase of $MgSO_4$ was produced by heating the α-phase at 650 °C.[12] Because of the dilution of ^{17}O in the course of synthesis, the final enrichment was estimated to be in the range of 5%–7%.

NMR spectroscopy

All NMR measurements were performed on a Bruker Avance-II 900 MHz instrument (magnetic field of 21.14 T) at the National Ultrahigh-Field NMR Facility for Solids (Ottawa, ON). Larmor frequencies for ^{17}O, ^{25}Mg, and ^{33}S were 122.02, 55.1, and 69.09 MHz, respectively. Static powder spectra were obtained on a homebuilt 7 mm solenoid probe. A Hahn echo pulse sequence optimized to accurately reproduce the powder line shapes[20] and a quadrupolar Carr–Purcell–Meiboom–Gill (QCPMG) sequence[21] were used in static experiments. Between 250 and 2000 scans were acquired for all nuclei with relaxation delays ranging from 10 to 40 s. A dual frequency sweep (DFS) sensitivity enhancing technique[22] was

Table 1. Magnetic resonance properties of nuclei in $MgSO_4$.[19]

Isotope	Spin	Natural abundance (%)	Magnetogyric ratio γ (10^7 rad T^{-1} s^{-1})	Larmor frequency at 21.1 T (MHz)	Qudrupole moment (fm^2)	Linewidth factor (l/fm^3)	Receptivity (relative to ^{13}C)
^{17}O	5/2	0.037	–1.6388	122.02	–2.56	2.1	0.065
^{25}Mg	5/2	10.00	2.0557	55.1	19.94	130	1.58
^{33}S	3/2	0.76	–3.6281	69.09	–6.78	61	0.101

used in some of the experiments, particularly with ^{33}S. The optimal relaxation delays for each compound and nucleus were found from three to four short (16–32 scans) runs. The magic-angle spinning (MAS) experiments were performed using Bruker 4 mm (^{17}O and ^{25}Mg) and 7 mm (^{33}S) MAS probes with dry nitrogen as a carrier gas. Two-dimensional multiple-quantum (MQ) MAS experiments on ^{17}O were performed using a phase-modulated split-t_1 pulse sequence[23,24] with rotor synchronization. The spectra were externally referenced to neat H_2O (^{17}O, $\delta = 0$ ppm), 1 mol/L solution of $Mg(NO_3)_2$ (^{25}Mg, $\delta = 0$ ppm), and 2 mol/L solution of Cs_2SO_4 (^{33}S, $\delta = 333.0$ ppm from CS_2[25]).

Spectral simulations

Analytical simulations of experimental spectra were carried out with the WSolids[26] and DMFit[27] simulation packages. In all simulations, we first fitted the MAS spectra, which provided the isotropic chemical shifts (δ_{iso}), quadrupolar constants (C_Q), and quadrupolar asymmetry parameter (η_Q). These parameters were subsequently used in simulations of the static powder pattern. Special attention was given to reproducing the spectral discontinuities and shoulders in fitting the spectra.

Quantum-chemical calculations

All calculations were performed using the CASTEP[3] density functional theory code using the GIPAW[2] algorithm. The version used in this work is integrated within the Accelrys Materials Studio 4.4 suite (Accelrys, Inc., San Diego, CA). The computations use the generalized gradient approximation (GGA) and Perdew–Burke–Ernzerhof (PBE) functional,[28,29] and the core–valence interactions were described by ultrasoft pseudopotentials.[2b] Integrations over the Brillouin zone were done using a Monkhorst–Pack grid with *k*-point spacings generally being less than 0.04 $Å^{-1}$.[30] Crystallographic data used in the calculations were taken from the literature and the corresponding references are given in the text. The calculations produce the absolute shielding tensor (σ), quadrupolar coupling constant (C_Q), and asymmetry (η_Q). The later two parameters can be compared to the experimentally measured C_Q and η_Q directly. In the case of σ, however, some conversion needs to be done before comparing them with the experimentally measured chemical shifts. The isotropic chemical shift (δ_{iso}) relates to the isotropic shielding: $\sigma_{iso} = 1/3\mathrm{Tr}\{\sigma\}$ as $\delta_{iso} = -(\sigma_{iso} - \sigma_{ref})$, where σ_{ref} is the isotropic shielding calculated on the reference material with a well-defined structure and known chemical shift. The references used for the nuclei studied in this work are as follows: For ^{25}Mg, the reference shielding was obtained from a correlation of the calculated shielding constants and the experimental chemical shifts in numerous magnesium compounds, with $\sigma_{iso} = -1.072(\pm 0.036) \times \delta_{iso} + 566.06(\pm 0.99)$.[31] For ^{33}S, the reference shielding is again based on a correlation where σ_{ref} (^{33}S) = 434.1 ppm (updated data from ref. 32). For ^{17}O, the chemical shielding was referenced to the well-documented O1 site in forsterite as in ref. 8, with a σ_{ref} (^{17}O) value of 255.0 ppm.

Results and discussion

Structural details of the system studied

Table 2 shows the structural parameters for α-$MgSO_4$ and both reported structures of β-$MgSO_4$ from the most recent reports.[14,15] As can be seen in Table 2, the structures for the two polymorphs of $MgSO_4$ are somewhat similar, yet they do have significant differences. Both polymorphs crystallize with an orthorhombic lattice but α-$MgSO_4$ crystallizes in space group *Cmcm*, whereas β-$MgSO_4$ crystallizes in space group *Pbnm* or *Pnma*. The lattice volume is approximately the same for both polymorphs, yet the individual lattice parameters vary significantly. The site symmetry of the separate atoms in each cell is also quite different between the polymorphs. For Mg and S, each polymorph has only one crystallographically unique site. The most significant differences between the two polymorphs is the number of crystallographically inequivalent oxygen sites: α-$MgSO_4$ has two unique oxygen sites with a ratio of 1:1, while β-$MgSO_4$ has three sites with a ratio of 2:1:1. When examining the two reported structures of β-$MgSO_4$, it can be seen that the differences between the two are quite small. It is therefore interesting to test whether the first principle calculations are capable of distinguishing the differences and how accurately they can reproduce the experiment.

^{25}Mg results

Although ^{25}Mg has the highest natural abundance of all the nuclei examined in this work, it also has the largest quadrupole moment and the smallest magnetogyric ratio. With this in mind, one may expect that the quadrupolar interactions would dominate the NMR spectra of ^{25}Mg in $MgSO_4$. The ^{25}Mg natural abundance SS NMR spectra obtained at 21.1 T for α-$MgSO_4$ and β-$MgSO_4$ are shown in Figs. 1 and 2. Both stationary and MAS spectra are shown, obtained with Hahn echo and QCPMG pulse sequences. The parameters extracted from the experimental spectra together with the CASTEP computational results can be found in Table 3. The quadrupolar interaction indeed dominates the experimental ^{25}Mg spectra with the magnitudes differing significantly for α- and β-$MgSO_4$ polymorphs. In fact, the determined values of $C_Q = 7.41 \pm 0.05$ MHz and $C_Q = 10.4 \pm 0.1$ MHz in α- and β-$MgSO_4$, respectively, are among the largest observed for magnesium salts, where typically $C_Q < 5$ MHz for ^{25}Mg.[18,31,33–39] The quadrupolar asymmetry parameter, η_Q, is also quite different for the two polymorphs. ^{25}Mg in α-$MgSO_4$ has an $\eta_Q = 0.35 \pm 0.02$, whereas that of β-$MgSO_4$ is practically equal to 1.0. With just the ^{25}Mg quadrupolar parameters alone it is

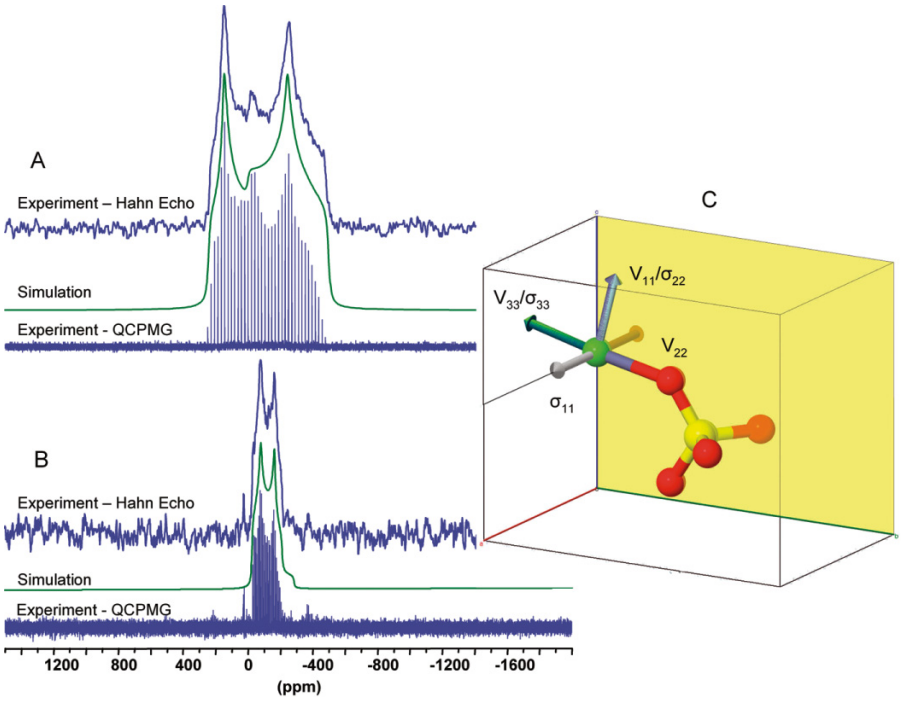
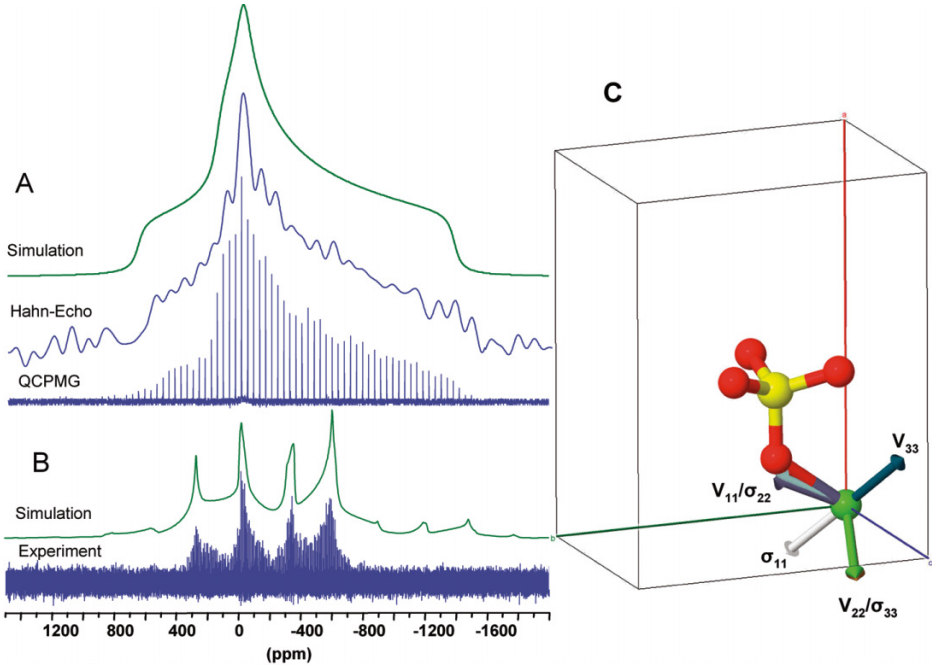
Fig. 1. Experimental and simulated ^{25}Mg spectra of α-$MgSO_4$: (A) stationary sample (both Hahn echo and QCPMG are shown), (B) MAS (both Hahn echo and rotor-synchronized QCPMG are shown), and (C) calculated orientations of the electric field gradient (EFG) and CSA tensors. Analytical simulations of the spectra were performed with WSolids[26] for stationary spectra and DMFit[27] for the MAS experiments.



possible to differentiate these two polymorphs based on the SS NMR spectra. The isotropic chemical shifts (δ_{iso}) for α- and β-$MgSO_4$ are –8.1 ± 1.0 and 0.2 ± 2.0 ppm, respectively, which is well within the range of the shifts expected for a compound such as $MgSO_4$.[31] Typically for octahedrally oxygen-coordinated Mg compounds, the isotropic chemical shift ranges from ~ –10 ppm to ~10 ppm.[31,33,39] Since the range of ^{25}Mg chemical shifts for oxygen-coordinated magnesium is relatively small, it is not surprising that the chemical shift anisotropy (CSA) for ^{25}Mg in both α- and β-$MgSO_4$ is quite small. Considering the scale of the quadrupolar interactions for both polymorphs, the accuracy of the experimental ^{25}Mg CSA is rather low. The experimental values can found in Table 3. Due to a considerably larger magnitude of the quadrupolar interactions for β-$MgSO_4$, detection of the CSA is even more difficult, and only an estimate for the upper limit of the anisotropy (σ_{aniso}) is reported.

Data in Table 3 demonstrate very reasonable agreement between experimental and calculated ^{25}Mg NMR parameters. The isotropic chemical shift was predicted accurately for ^{25}Mg in α-$MgSO_4$, yet was slightly overestimated for both calculations in β-$MgSO_4$. CASTEP was also able to predict the scale of the ^{25}Mg CSA for both polymorphs, and the parameters match quite well with the experimental values for σ_{aniso}, η_{CSA}, and Euler angles α, β, and γ. The calculated quadrupolar parameters are also in good agreement with the experiment. Although the calculated quadrupolar coupling constant for both polymorphs was slightly overestimated, the prediction

Fig. 2. Experimental and simulated ^{25}Mg spectra of β-$MgSO_4$: (A) stationary sample with both Hahn echo and QCPMG experiments shown, (B) MAS at 16 kHz with rotor-synchronized QCPMG, and (C) calculated orientations of the EFG and CSA tensors. Analytical simulations of the spectra were performed with WSolids[26] for stationary spectra and DMFit[27] for the MAS experiments, and included both quadrupolar interactions and the CSA.



of η_Q, was good for both polymorphs. Looking at the two sets of calculated data for β-$MgSO_4$, one can see that the calculations for the NPD structure and the single crystal XRD structure produce somewhat different results. Notwithstanding, from the ^{25}Mg parameters alone it is difficult to conclude if one structure produced more accurate calculations than the other. The calculated isotropic shifts were overestimated in both cases, although the single crystal diffraction structure calculations produced a result closer to the measured shift of 0.2 ppm. The calculated quadrupolar coupling constants for the NPD and the XRD data are much the same, with both structures producing overestimated values of C_Q's. In this case, though, the neutron powder diffraction structure calculation produced a C_Q closer to the measured value of 10.4 MHz. Once again, at this stage it is hard to discern if one structure more accurately represents the actual room temperature structure of β-$MgSO_4$.

The CASTEP calculations also provide orientations of the CSA and EFG tensors for all atoms of interest. This is particularly useful for assisting in analyzing the fine structural details in a given material. For the case of magnesium in both polymorphs, the crystallographically unique magnesium site is present in an octahedral environment of oxygen atoms. However, as can be seen in Table 2, the point group symmetry of Mg sites in $MgSO_4$ is far from perfectly octahedral. For α-$MgSO_4$, magnesium is present in a C_{2h} symmetry and the relevant symmetry operations present at the magnesium site can be seen in Fig. 1B. For this type of symmetry, it has been shown that the principal components of the symmetric part of the shielding tensor are independent of each other.[40,41] Thus, one might not necessarily expect an axially symmetric shielding tensor with these restrictions on the principal components of the shielding tensor.[42] Indeed, the shielding asymmetry parameter, η_{CSA}, for ^{25}Mg in α-$MgSO_4$ shows a nonaxially symmetric tensor with $\eta_{CSA} = 0.8 \pm 0.2$. A similar argument can be made for the axially symmetric nature of the EFG tensor.[43] In agreement, the quadrupolar asymmetry parameter for ^{25}Mg in α-$MgSO_4$ shows a nonaxially symmetric EFG tensor with $\eta_Q = 0.35 \pm 0.02$. Examination of the calculated tensors for ^{25}Mg in α-$MgSO_4$ (Fig. 1B) uncovers some interesting details. The largest calculated components of the EFG and CSA tensors, V_{33} and σ_{33}, both lie in the mirror plane through the magnesium atom. CASTEP also predicts that the V_{33} and σ_{33} components are coincident with the Euler angle $\beta = 0°$, which is what is observed experimentally. The V_{33} and σ_{33} components also point directly towards one of the oxygen atoms that is part of the Mg–O pseudo-octahedron. Additionally, the V_{22} and σ_{11} components point along the C_2 proper rotation axis through the magnesium. The single unique Mg site in β-$MgSO_4$ is slightly different from that of α-$MgSO_4$. In β-$MgSO_4$, Mg is present in a C_i site, which means one would again not expect an axially symmetric CSA or EFG tensor.[41–43] Although the asymmetry parameter of the CSA tensor, η_{CSA}, could not be accurately measured due to the dominance of the EFG interaction, the quadrupolar asymmetry parameter is certainly not axially symmetric with $\eta_Q = 1.0$. The calculated EFG and CSA tensor orientations for Mg in β-$MgSO_4$ are shown in Fig. 2B. Since there is only a centre of inversion at the Mg site in β-$MgSO_4$, there is little to constrain the tensor orientations on the basis of symmetry. However, the largest component of the CSA tensor, σ_{33}, appears to point towards one of the oxygen atoms of the Mg–O pseudo-octahedron. Although it might seem that V_{33} is pointing towards another of the oxygen atoms in the octahedron, the deviation is large enough that this might not necessarily be the case.

[a] δ_{iso}^{calcd} obtained as $\delta_{iso} = -(\sigma_{iso} - \sigma_{ref})$ with σ_{ref} defined in the experimental section.

[b] Although the calculations produce the sign of the C_Q, only the magnitude can be obtained in our experiments.

[c] η_Q is defined as $|V_{11} - V_{22}|/V_{33}$.

[d] The Haeberlen convention[44,45] is used in CASTEP with the anisotropy defined as $\sigma_{aniso} = \sigma_{33} - (\sigma_{11} + \sigma_{22})/2$.

[e] Asymmetry parameter (η_{CSA}) is defined as $\eta = (\sigma_{22} - \sigma_{11})/(\sigma_{33} - \sigma_{iso})$. Principal components of the symmetric shielding tensor are ordered as $|\sigma_{33} - \sigma_{iso}| \geq |\sigma_{11} - \sigma_{iso}| \geq |\sigma_{22} - \sigma_{iso}|$.

[f] α, β, and γ are Euler angles defining the relative orientation of the CSA and EFG tensors.[45,46] Accuracy is not expected to be better than ±10°.

[g] Calculations were performed on geometry optimized structures from NPD data.[14]

[h] Calculations were performed on geometry optimized structures from SCXRD data.[15]

^{33}S results

Sulfur-33 has a considerably lower natural abundance from that of ^{25}Mg making it quite a difficult nucleus to study. However, it has a larger magnetogyric ratio and smaller quadrupole moment than that of ^{25}Mg. As such, one might not expect the quadrupolar interaction to necessarily dominate the ^{33}S SS spectra as much as in the case of ^{25}Mg. The ^{33}S natural abundance SS NMR spectra taken at 21.1 T for α- and β-$MgSO_4$ can be seen in Figs. 3A and 3C. The NMR parameters extracted from the experimental spectra along with the calculations are summarized in Table 3. Indeed, the quadrupolar interactions do not dominate in the case of ^{33}S as they did for ^{25}Mg and CSA parameters could be reliably extracted (Table 3). The experimentally determined quadrupolar coupling constants were $C_Q = 2.14 \pm 0.05$ MHz for ^{33}S in α-$MgSO_4$ and $C_Q = 2.00 \pm 0.05$ MHz for β-$MgSO_4$. Although the magnitude of the quadrupolar interaction is quite similar for both α- and β-$MgSO_4$, the asymmetry parameters, η_Q, are quite different. For α-$MgSO_4$ it is nearly completely asymmetric with $\eta_Q = 0.91 \pm 0.05$, whereas in β-$MgSO_4$ the ^{33}S EFG tensor deviates only slightly from being axially symmetric with $\eta_Q = 0.11 \pm 0.05$. This gives another distinctive characteristic for the two polymorphs. In terms of isotropic chemical shifts for ^{33}S sites in α- and β-$MgSO_4$, the values are very similar to each other with $\delta_{iso} = 313.1 \pm 0.5$ ppm for α-$MgSO_4$ and $\delta_{iso} = 316.8 \pm 0.5$ ppm for β-$MgSO_4$. This is not surprising since the isotropic chemical shift range for ^{33}S in anhydrous sulfates is known to be quite narrow.[18,32] At high magnetic fields, the presence of the CSA can potentially complicate the spectra considerably. However, for the given case there is a discernable and measurable difference between the anisotropy in the sulfur sites of the two polymorphs. α-$MgSO_4$ has a larger chemical shielding anisotropy for ^{33}S than does β-$MgSO_4$, with $\sigma_{aniso} = -51.5 \pm 5.0$ ppm for ^{33}S α-$MgSO_4$ and $\sigma_{aniso} = -36.6 \pm 5.0$ ppm for ^{33}S in β-$MgSO_4$ (Table 3).

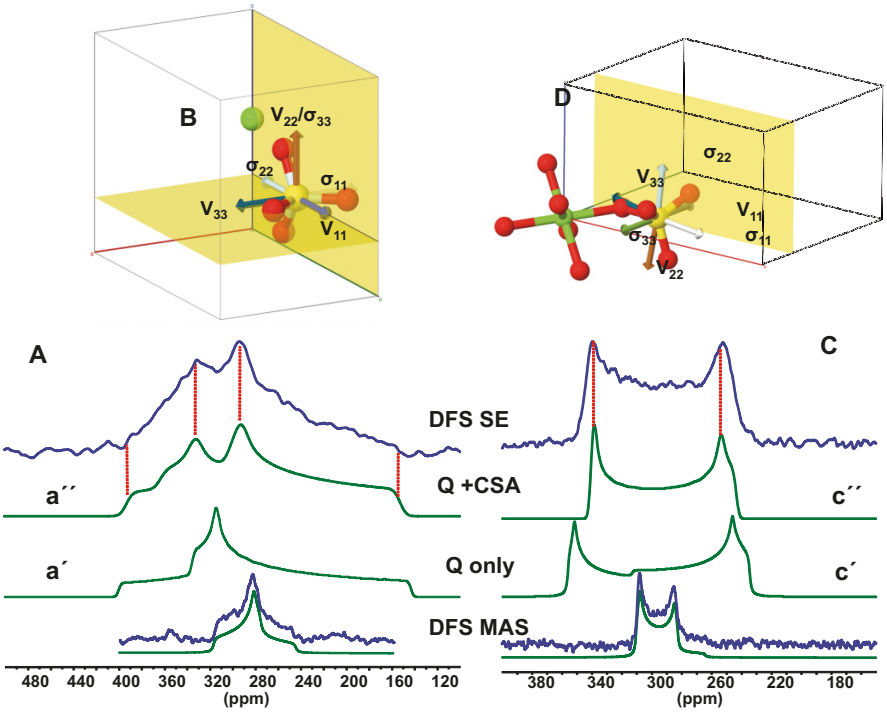
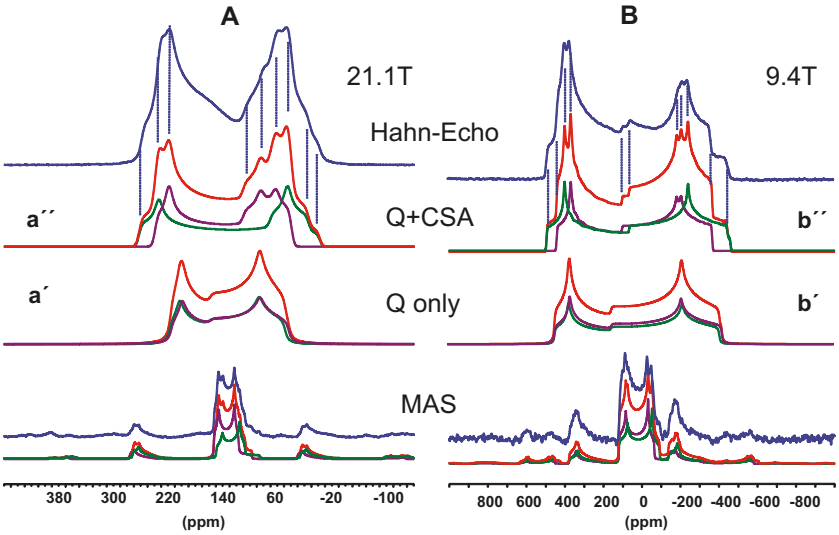
Fig. 3. Experimental and simulated ^{33}S spectra of (A) α-$MgSO_4$ and (B) β-$MgSO_4$. Traces a′ and c′ are the spectral simulations accounting only for quadrupolar interactions. Traces a″ and c″ are the fits that also include the CSA. The spectral fits to the MAS spectra account for quadrupolar interactions only. (B) and (D) demonstrate the calculated orientations of the EFG and CSA tensors of sulfur nucleus in α- and β-polymorphs, respectively. Dotted vertical lines indicate positions of singularities in the spectra. Note the discrepancies between the simulations and the experiment when only quadrupolar interaction are considered (traces a′ and c′).



It is again of particular interest to compare the calculated NMR parameters to those obtained experimentally. It can be seen from Table 3 that overall agreement between ^{33}S experiments and calculations are very good. The CASTEP calculations for α-$MgSO_4$ reproduce quite well the isotropic chemical shift of sulfur. The quadrupolar coupling constant is only slightly underestimated and the asymmetry parameter is predicted very accurately. The magnitude of the anisotropy parameter, σ_{aniso}, was also accurately predicted for ^{33}S in α-$MgSO_4$, despite having an opposite sign (in Haeberlen convention,[45,46] when the asymmetry η_{CSA} is close to 1, the reverse of the anisotropy sign is not uncommon). The calculated value for the asymmetry of the CSA, η_{CSA}, and the Euler angles, $\{\alpha, \beta, \gamma\}$, also match the experiment well. The CASTEP calculations reproduce the ^{33}S experimental results quite accurately for the β-polymorph too. The calculated isotropic chemical shift and the quadrupolar parameters match the experimental values well. The chemical shielding anisotropy is also predicted accurately in both magnitude and sign. When examining the calculated results for ^{33}S for the two reported structures of β-$MgSO_4$, a few notable differences can be seen. Both the calculated isotropic chemical shift and the quadrupolar coupling constant for the structure determined through single crystal X-ray diffraction reproduce the experimental parameters more accurately. The only parameter from the CASTEP calculations employing the neutron powder diffraction structure, which matched the experiment more closely than that from the single crystal, was the quadrupolar asymmetry parameter, η_Q. Yet, the predicted η_Q from the single crystal structure is also well within experimental error of the experimental value. Altogether, this suggests that the atomic coordinates obtained in a single crystal study of β-$MgSO_4$ are more accurate and reliable than those from the neutron powder diffraction study. Although it is not entirely correct to compare directly *R*-factors from the SCXRD and NPD studies, we note that the single crystal XRD study of β-$MgSO_4$ reports $R = 0.017$[16], when the NPD for the same polymorph resulted in $R = 0.036$[15].

Further examination of the CASTEP calculations and structural features of sulfur in $MgSO_4$ shows some interesting details. Sulfur is, of course, in a tetrahedrally coordinated oxygen environment in the SO_4^{2-} anion. However, the symmetry present at the sulfur site is quite far from being perfectly tetrahedral. Table 2 and Figs. 3B and 3D show the point group symmetry present at the sulfur site in α- and β-$MgSO_4$. Similar to the previous case of ^{25}Mg, it is interesting to examine the relationship, if any, between the local environment and the NMR parameters for ^{33}S, both experimental and calculated. For α-$MgSO_4$ (Fig. 3B), symmetry of sulfur site is C_{2v}. For this type of symmetry there are three independent components of the symmetric part of the shielding tensor.[40,41] So again, one might not necessarily expect an axially symmetric shielding tensor with these restrictions on the principal components of the shielding tensor.[40] Indeed, the experimental results for ^{33}S in α-$MgSO_4$ show a nonaxially symmetric shielding tensor with $\eta_{CSA} = 1.0 \pm 0.2$. A similar argument can be made for the case of the EFG tensor[43] and the experimentally determined quadrupolar asymmetry parameter is far from axially symmetric with $\eta_Q = 0.91 \pm 0.05$. Examining the calculated tensor orientations for α-$MgSO_4$ in Fig. 3B

Fig. 4. Experimental and simulated ^{17}O spectra of α-$MgSO_4$ at (A) 21.1 T and (B) 9.4 T. Traces a′ and b′ are the spectral simulations accounting only for quadrupolar interactions. Traces a″ and b″ are the fits that also include the CSA. The spectral fits to the MAS spectra account for both quadrupolar interactions and the CSA. Dotted vertical lines indicate positions of singularities in the spectra. For the online colour version, red (upper) traces in the simulated spectra correspond to the sums of the contributing individual sites, shown correspondingly in green, violet, and black.



reveals some additional details. The largest component of the EFG tensor, V_{33}, is restricted to one of the mirror planes through the sulfur atom while σ_{33} lies in the other mirror plane. Additionally, V_{11} and σ_{22} are calculated to be along the C_2 proper rotation axis through the sulfur site. With these orientations, the angle between the largest components of the EFG and CSA tensor, V_{33} and σ_{33}, is 90°, which is totally in agreement with experiment (Table 3). The situation for sulfur in β-$MgSO_4$ is quite different from that of α-$MgSO_4$. The symmetry of the site is C_s with a mirror plane through the sulfur atom (Table 2 and Fig. 3D). Thus, one would expect few restrictions on the number of independent components of the CSA and EFG tensors and axial symmetry should generally not be expected. The presence of sulfur on a mirror plane, however, requires that one component of each tensor to be perpendicular to the plane, and the others must be in the plane. This inflicts limitations on possible relative orientations of two tensors. Interestingly, though, the shielding tensor for β-$MgSO_4$ is predicted by CASTEP to be close to axially symmetric and is experimentally measured to be $\eta_{CSA} = 0.0 \pm 0.2$. The EFG tensor is also experimentally close to being axially symmetric with $\eta_Q = 0.11 \pm 0.05$. Examining the calculated tensor orientations shows V_{33} is restricted to the mirror plane while σ_{33} is perpendicular to the plane. V_{33} also points to one of the oxygen atoms in the tetrahedron of the SO_4^{2-} group. This S–O axis may act as a pseudo-C_3 rotation axis in a SO_4^{2-} anion. This, together with very small differences in the S–O bond lengths in the ion, may explain the nearly axially symmetric nature of the CSA and EFG tensors. Again, a 90° angle is predicted between V_{33} and σ_{33} and this is confirmed experimentally (Table 3).

^{17}O results

The study of ^{17}O is known to be quite a challenge, in general, due to the extremely low natural abundance and quadrupolar nature of the nucleus. In this work, the samples are slightly enriched in ^{17}O, which significantly relaxes the sensitivity issues. Additionally, ^{17}O has a significantly larger magnetogyric ratio and a much smaller quadrupole moment from that of ^{25}Mg and ^{33}S. In magnesium sulfates, however, there is the additional problem of having multiple crystallographic sites for oxygen in both polymorphs studied.

The ^{17}O SS NMR spectra and spectral simulations for α- and β-$MgSO_4$ taken at 21.1 and 9.4 T can be seen in Figs. 4 and 5, respectively. To aid in the assignment and extraction of spectral parameters for the multiple oxygen sites in each polymorph, MQMAS experiments were also performed and shown in Figs. 6 and 7. The ^{17}O results for α-$MgSO_4$ are not as complicated as in the case of β-$MgSO_4$ since there are only two crystallographically unique oxygen sites in α-$MgSO_4$. The 3Q MQMAS spectrum for α-$MgSO_4$ shows two clearly resolved unique oxygen sites. Measurements of the stationary powder samples at two different fields aided by the MAS data and combined with the simulations allow for accurate extraction of parameters for both oxygen sites in α-$MgSO_4$. The ^{17}O NMR parameters obtained for the two oxygen sites in α-$MgSO_4$ are in fact quite similar (Table 3). The isotropic chemical shifts differ only by about 3 ppm and the quadrupolar coupling constants are nearly identical. Despite the small differences, however, the numerous singularities in the spectra on Fig. 4 can be resolved, aiding in the parameters evaluation. This example demonstrates the importance of using an ultrahigh field for obtaining the necessary resolution in studies of quadrupolar nuclei. The static experiments performed on α-$MgSO_4$ also show a measurable contribution of the CSA interaction. The extracted shielding anisotropy parameters are also listed in Table 3. The shielding asymmetry parameters for both sites are quite similar with $\eta_{CSA} = 0.18$ and $\eta_{CSA} = 0.15$. The anisotropy, on another hand, for one of the ^{17}O sites at $\sigma_{aniso} = 128$ ppm is much larger than that for the other site with $\sigma_{aniso} = 77$ ppm, providing a means for a better assignment of the sites.

In the case of β-$MgSO_4$, there are threee crystallographically inequivalent oxygen sites, making assignment somewhat

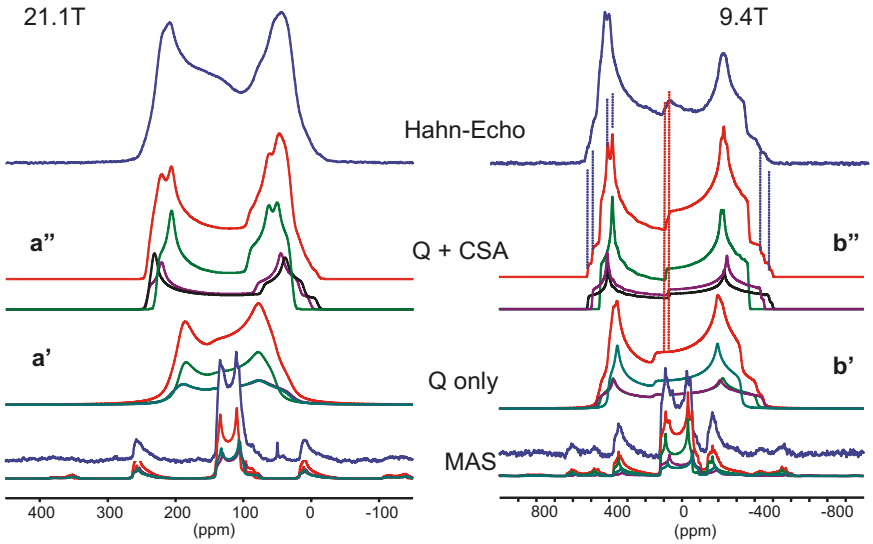

Fig. 6. ^{17}O 3Q MQMAS spectrum of α-$MgSO_4$ at 21.1 T, and calculated orientations of the main components in the EFG and CSA tensors for two oxygen sites in the crystal.

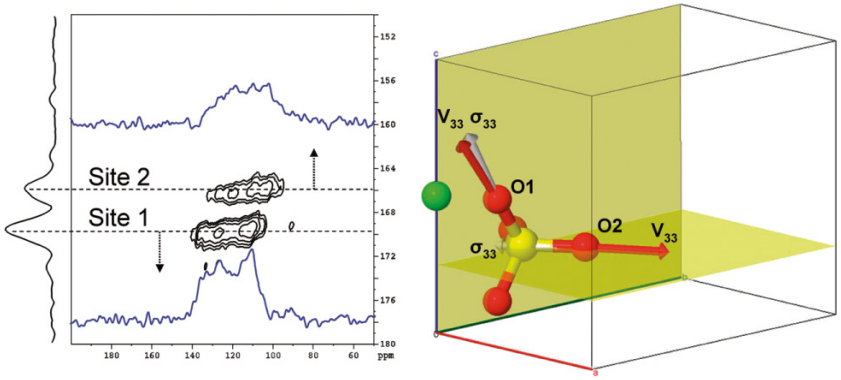

Fig. 7. ^{17}O 3Q MQMAS spectrum of β-$MgSO_4$ at 21.1 T, and calculated orientations of the main principal components in the EFG and CSA tensors for the oxygen sites in the crystal. The components V_{33}^2 , σ_{33}^2 and V_{33}^3 , σ_{33}^3 lie along the O2–S and O3–S bonds, respectively, and are all directed toward the sulfur atom.

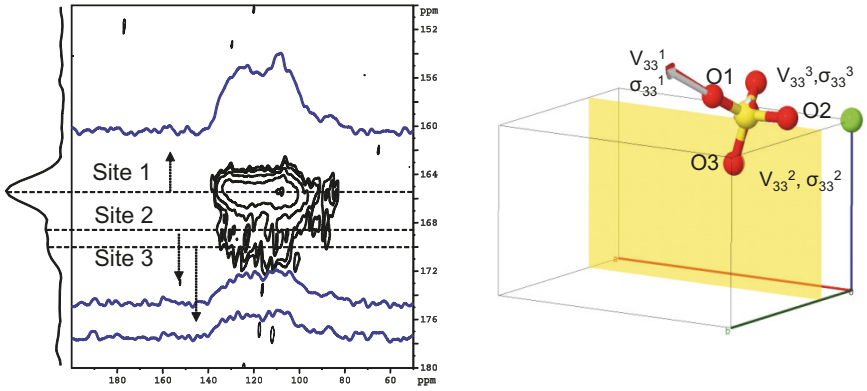

more difficult. Indeed, the MQMAS spectrum of ^{17}O in β-$MgSO_4$ was not able to completely resolve the three oxygen sites. Nevertheless, by fitting the high-field 1D MAS and static experiments and examining the lower field data, reasonable estimates for the spectral parameters for all three oxygen sites can still be accomplished, as summarized in Table 3. It

should be noted that the results obtained for ^{17}O in β-$MgSO_4$ are similar to α-$MgSO_4$ in that the parameters for all sites are, in general, in the expected range and reasonably similar. Akin to the ^{25}Mg and ^{33}S results, the data obtained from ^{17}O can be used in distinguishing the two polymorphs of $MgSO_4$.

One interesting observation in regard to the ^{17}O data is that the singularities appear to be less resolved in the spectra obtained at the higher field. The main reason for this is an unfortunate interplay between the EFG and the CSA tensors. While the quadrupolar interactions clearly dominate the spectrum at 9.4 T with a relatively small input from the CSA, the situation is altered at 21.1 T. The dramatically reduced quadrupolar contribution together with an accordingly scaled up CSA result in a strong overlap of singularities and contributions from several sites. One should also note, that although the stationary spectra at 21.1 T appear visually broader than at 9.4 T, they actually spun over much narrower spectral regions (i.e., compare the scales below the spectra).

The CASTEP-calculated NMR parameters for ^{17}O in both α- and β-$MgSO_4$ match the experimentally determined values quite well. The predicted quadrupolar coupling constants for all ^{17}O sites in both α- and β-$MgSO_4$ match the experimental values accurately. As well, the magnitude of the calculated shielding anisotropy is predicted correctly for all ^{17}O sites. The only seemingly large discrepancy between the calculated results and the experimental NMR parameters is the isotropic shift of the ^{17}O sites in α- and β-$MgSO_4$. In all cases, the calculated isotropic shift for ^{17}O is systematically lower than the experimentally determined value. The issue may be due to the shielding reference for ^{17}O used in this work, which is based on a single point instead of a correlation reference as used in the case for ^{25}Mg and ^{33}S. Since the accurate prediction of ^{17}O NMR parameters is well-documented,[4,8] one might expect that if a correlation reference produced on a large set of oxygen-containing compounds, then the agreement between calculated isotropic shift and experimental isotropic shift would improve. From the ^{17}O calculations for β-$MgSO_4$ alone, it is somewhat difficult to conclude whether one structure provided more accurate NMR parameters than the other since the calculated parameters are rather similar. Still, by examining the calculated isotropic chemical shift it can be seen that the values obtained from the single crystal XRD structure provided a more accurate forecast of the experimental isotropic shifts.

Similar to ^{25}Mg and ^{33}S, a closer examination of the calculated results offers some interesting insights into the structural details of these $MgSO_4$ polymorphs. Since there are multiple oxygen sites, only the largest component of both the calculated EFG and CSA tensor are shown in Figs. 6 and 7 to avoid figure complexity. The calculated tensor orientations at both oxygen sites in α-$MgSO_4$ are shown in Fig. 6. Both oxygen sites in α-$MgSO_4$ have C_s symmetry resulting in a single mirror plane through each atom. The V_{33} and σ_{33} components for both oxygen sites lie in their respective mirror planes. One oxygen site has both principal components pointed directly away from the sulfur atom with an Euler angle β of ~10°, while the other oxygen site has V_{33} pointing directly away from the sulfur atom when the respective σ_{33} is pointing directly towards the sulfur resulting in an Euler angle β of ~180°. This result accurately matches the experiment. Given the symmetry present at these oxygen sites, one would not expect an axially symmetric EFG or CSA tensor.[40–43] Indeed, the experimental asymmetry parameters η_Q and η_{CSA} indicate the lack of axial symmetry for both tensors.

The calculated orientations for the main components of the EFG and CSA tensors in β-$MgSO_4$ are shown in Fig. 7. As for the α-form, the principal components V_{33} and σ_{33} for the oxygen atoms that have C_s symmetry, lie in the mirror plane (O2 and O3, with corresponding V_{33}^2 , σ_{33}^2 and V_{33}^3, σ_{33}^3). For both these oxygen atoms, the V_{33} and σ_{33} components also point directly towards the central sulfur atom with $\beta = \sim 5°$ in accordance with the experiment (Table 3). For the oxygen site with symmetry C_1, the largest components of the EFG and CSA tensors are also almost coincident with $\beta = \sim 5°$, which is similar to the other oxygen sites. In this case, however, V_{33} and σ_{33} point directly away from the central sulfur atom.

Conclusions

The present study has demonstrated that with the use of ultrahigh fields of 21.1 T previously unattractive nuclei such as ^{25}Mg, ^{33}S, and ^{17}O can be studied via SS NMR with relative ease. The α- and β-polymorphs of anhydrous magnesium sulfate were studied via SS NMR on all the nuclei of the material. The two polymorphs can be successfully distinguished and the spectra are in complete accordance with the crystal structures of the materials. For ^{25}Mg and ^{33}S, simple 1D MAS experiments are all that is needed to distinguish between the polymorphs, whereas enrichment and 2D experiments were required for ^{17}O. With the aid of first principles calculations, fine structural details and the relation of the EFG and CSA tensors were examined for all nuclei in both polymorphs. It was found that symmetry at the sites and character of the chemical bonds dictated specific tensor orientations. Another aspect of the study was to compare the recently reported crystal structures for β-$MgSO_4$. It was found that, at least for ^{33}S and ^{17}O, the calculations performed on a structure from single crystal XRD reproduce the experimental parameters more accurately than the calculations using the structural data from the neutron powder diffraction. This work demonstrates how previously difficult NMR nuclei can now be successfully studied, assisting in a better understanding of a material's nature. With the aid of first principles calculations, the information for each nuclei complements each other resulting in a detailed picture of the fine structural details.

Acknowledgments

This article is dedicated to Professor R. E. Wasylishen in recognition of his contribution to solid-state NMR in Canada. The authors thank Dr. Victor Terskikh for useful discussions and access to computational resources. Access to the 900 MHz NMR spectrometer was provided by the National Ultrahigh-Field NMR Facility for Solids (Ottawa, ON), a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council Canada, and Bruker BioSpin and managed by the University of Ottawa (http://nmr900.ca).

Abstract: We report a complete set of high-resolution solid-state NMR spectra for all magnetic nuclei (^{1}H, ^{13}C, ^{17}O, and ^{27}Al) in the α-form of tris(2,4-pentanedionato-*O*,*O*')aluminium(III), α-Al(acac)$_3$. These high-resolution NMR spectra were obtained by using a host of solid-state NMR techniques: standard cross-polarization under the magic-angle spinning (CPMAS) method for ^{13}C, 1-D homonuclear decoupling using the windowed DUMBO sequence for ^{1}H, double-rotation (DOR) for ^{17}O and ^{27}Al, and multiple-quantum MAS for ^{27}Al. Some experiments were performed at multiple magnetic fields. We show that the isotropic chemical shifts obtained for ^{1}H, ^{13}C, ^{17}O, and ^{27}Al nuclei in α-Al(acac)$_3$ are highly resolved and accurate, regardless of the nature of the targeted nuclear spins (i.e., spin-1/2 or quadrupolar) and, as such, can be treated equally in comparison with computational chemical shifts obtained from a gauge-including projector-augmented wave (GIPAW) plane-wave pseudopotential DFT method.

Key words: high-resolution NMR, solid-state NMR, double rotation, chemical shift, quadrupole parameter.

Résumé : On a obtenu un ensemble complet de spectres RMN à haute résolution, à l'état solide, de tous les noyaux magnétiques (^{1}H, ^{13}C, ^{17}O, et ^{27}Al) de la forme α du tris(pentane-2,4-dionato-*O,O*'-)aluminium(III), α-Al(acac)$_3$. On a obtenu ces spectres RMN à haute résolution en utilisant un ensemble de techniques de RMN à l'état solide : polarisation croisée standard avec rotation à l'angle magique (« CPMAS ») pour le ^{13}C, découplage homonucléaire 1-D à l'aide de la séquence DUMBO avec fenêtre pour le ^{1}H et la double rotation (DOR) pour le ^{17}O et le ^{27}Al et le quantum multiple avec rotation à l'angle magique (« MAS ») pour le ^{27}Al. Diverses expériences ont été réalisées à plusieurs champs magnétiques. On démontre que les déplacements chimiques isotropes obtenus pour les noyaux de ^{1}H, ^{13}C, ^{17}O, et ^{27}Al dans le α-Al(acac)$_3$ sont très bien résolus et pré*cis* quelle que soit la nature des spins nucléaires examinés (c'est-à-dire spin-1/2 ou quadripolaire) et qu'ils peuvent ainsi être traités d'une façon égale dans une comparaison avec des déplacements chimiques calculés par la méthode de la théorie de la fonctionnelle de densité (TFD) en utilisant une onde améliorée par un opérateur de projection comportant une jauge avec un pseudopotentiel d'onde plane (« GIPAW »).

Mots-clés : RMN à haute résolution, RMN à l'état solide, double rotation, déplacement chimique, paramètre quadripolaire.

[Traduit par la Rédaction]

1. Introduction

Solid-state NMR spectroscopy has become a powerful tool for chemists to obtain detailed information about chemical bonding, structure, and the dynamics of molecules in solid materials. One emerging field in solid-state NMR is known as "NMR crystallography".[1] For organic solids, one typically examines high-resolution ^{13}C CPMAS and, to a lesser extent, ^{1}H MAS NMR spectra, from which accurate chemical shifts can often be obtained directly.[2–6] In many molecular systems, there exist magnetic nuclei other than ^{1}H and ^{13}C. In these systems, it is highly desirable that all magnetic nuclei are probed. Very often, the other magnetic nuclei are quadrupolar (spin > 1/2) for which line broadening is usually significantly greater than spin-1/2 nuclei such as ^{1}H and ^{13}C. However, because more advanced NMR techniques such as double-rotation (DOR)[7–9] and multiple-quantum magic-angle spinning (MQMAS)[10,11] are becoming increasingly available, accurate chemical shift values can also be readily obtained for many quadrupolar nuclei. Here we report a comprehen-

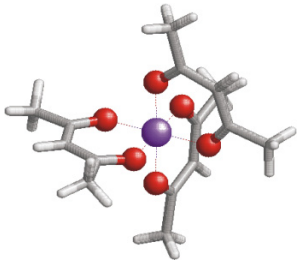
Scheme 1. Molecular structure of $Al(acac)_3$.



sive solid-state NMR study of the α-polymorph of crystalline tris(2,4-pentanedionato-*O*,*O*')aluminium(III), α-$Al(acac)_3$; see Scheme 1. We obtain highly accurate isotropic chemical shift values for all magnetic nuclei in α-$Al(acac)_3$: ^{1}H, ^{13}C, ^{17}O, and ^{27}Al. These experimental chemical shifts are then compared with computed chemical shifts from the density functional theory (DFT) gauge-including projector-augmented wave (GIPAW)[12,13] approach as implemented in the CASTEP code.[14] This computational method has gained considerable attention recently in the solid-state NMR community,[15–39] because it takes into account the entire unit cell and thus is ideal for dealing with solid materials for which crystal structures are known. We chose α-$Al(acac)_3$ as a target for the following reasons. First, a good-quality X-ray crystal structure was reported recently for this compound.[40] Second, although there is only one molecule in the asymmetric unit of the unit cell, the high symmetry of the acac ligand makes it challenging in solid-state NMR to resolve very similar sites (in principle, 6 CO groups, 6 CH_3 groups, 3 CH groups, and 6 O sites). Third, some limited solid-state ^{13}C, ^{2}H, and ^{27}Al NMR data are already available in the literature.[41–43] Fourth, α-$Al(acac)_3$ is a metal complex with a relatively small unit cell ($43 \times 4 = 172$ atoms, $V = 1701.96$ Å^3), which permits us to perform CASTEP computation with our currently available computing resources. This will also make an interesting comparison with the DFT results reported recently by Amini and Tafazzoli[44] who used a molecular cluster approach to calculate the NMR parameters in both α- and γ-polymorphs of $Al(acac)_3$.

2. Experimental section

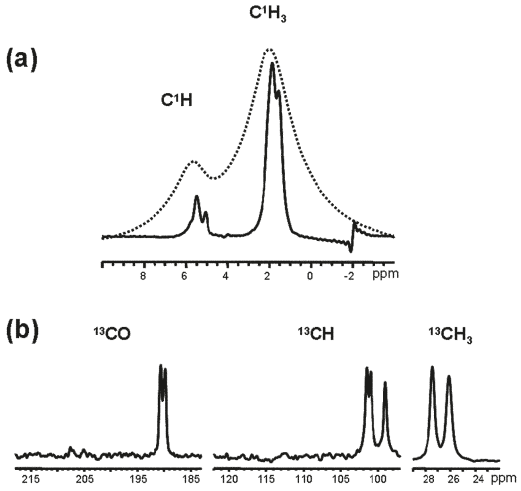
Synthesis

$Al(acac)_3$ (99% purity) was obtained from Sigma-Aldrich. The ^{17}O-labeled $Al(acac)_3$ was prepared by dissolving 50 mg $Al(acac)_3$ (0.15 mmole) in 1.0 mL anhydrous CH_2Cl_2. Approximately 20 μL of acidified H_2O (70% ^{17}O, Iso-Solutions, Ottawa, Ontario) was then added to this solution. After standing at room temperature for 24 h, the solution was neutralized with NH_4OH(aq) and dried under a stream of dry nitrogen gas. This ^{17}O-enriched $Al(acac)_3$ sample (approximately 60% ^{17}O) was used for solid-state ^{17}O NMR experiments. Although all solid $Al(acac)_3$ samples were confirmed to be in the α-polymorph by powder X-ray diffraction patterns, the ^{17}O-labeled sample does contain a trace amount of NH_4Cl.

NMR experiments

Solid-state ^{1}H, ^{13}C, and ^{17}O NMR experiments were performed on a Bruker Avance II$^+$ 600 spectrometer at 14.1 T.

Fig. 1. (*a*) ^{1}H single-pulse 12.5-kHz MAS (dotted line) and windowed-DUMBO (solid line) NMR spectra of α-$Al(acac)_3$. (*b*) ^{13}C CPMAS spectrum of α-$Al(acac)_3$.



A Bruker 4-mm HX MAS probe was used. Solid-state ^{13}C NMR spectra were acquired with the standard CPMAS sequence with 100 kHz ^{1}H decoupling. High-resolution ^{1}H NMR spectra were obtained with the 1-D windowed-DUMBO sequence and a sample spinning frequency of 12.5 kHz.[45] All ^{1}H and ^{13}C chemical shifts were referenced to external TMS. ^{17}O DOR NMR spectra were acquired using a custom-built DOR probe and employing odd-order sideband suppression.[46,47] The ^{17}O excitation pulse width was 1 μs. Continuous-wave ^{1}H-decoupling (50 kHz) was applied during acquisition. The outer- and inner-rotor spinning frequencies were 1307 and 6525 Hz, respectively. The ^{17}O DOR spectrum was acquired with 30740 transients and a recycle delay of 1 s. The high-field ^{17}O DOR NMR spectrum was obtained on a Chemagnetics Varian Infinity 800 spectrometer at 18.8 T, with outer- and inner-rotor spinning frequencies of 1303 and 6515 Hz, respectively. The ^{1}H-decoupling field was approximately 27 kHz. A total of 36000 transients were collected with a recycle delay of 1 s. Similarly, ^{27}Al DOR NMR spectra were acquired at 14.1 T using odd-order sideband suppression without ^{1}H decoupling. The ^{27}Al excitation pulse width was 2.1 μs. The outer- and inner-rotor spinning frequencies were 1303 and 6420, respectively. A total of 880 transients were accumulated with a recycle delay of 1 s. ^{27}Al MQMAS (3Q and 5Q) and some ^{17}O MAS NMR experiments were performed on a Bruker Avance-II 900 spectrometer at 21.1 T operating at 234.6 MHz for ^{27}Al and 122.0 MHz for ^{17}O. A Bruker 4-mm HX MAS probe was used with a sample spinning frequency of 12 kHz for ^{27}Al and 18 kHz for ^{17}O experiments. In the MQMAS experiments, the t_1 increment was rotor-synchronized. All ^{17}O and ^{27}Al chemical shifts were referenced with respect to the signals of H_2O(liq) and 0.1 mol/L $Al(NO_3)_3$(aq), respectively. Spectral simulations were performed using WSolids[48] and DMFit.[49]

Quantum chemical computation

Calculations of the NMR shielding and electric field gradient parameters were performed using Materials Studio CASTEP software version 4.4 (Accelrys)[14,50] on a HP

[a]As the 18 methyl protons of α-Al(acac)$_3$ exhibit two distinct groups of ^{1}H chemical shifts, the calculated ^{1}H chemical shifts for CH_3 are the averaged values.

[b]Root-mean-square-deviation (RMSD) between δ_{castep} and δ_{exptl} values.

xw4400 workstation with a single Intel Dual-Core 2.67 GHz processor and 8 GB DDR RAM. The Perdew, Burke, and Ernzerhof (PBE) functionals were used in all calculations in the generalized gradient approximation (GGA) for the exchange correlation energy.[51,52] On-the-fly pseudopotentials were used as supplied with NMR CASTEP with a plane wave basis set cut-off energy of 450 eV and the Monkhorst-Pack k-space grid size of 1 × 2 × 1 (0.07 Å^{-1} k-point separation) limited by the large volume of the unit cell (1701.96 Å^3). The geometry optimization was performed using the BFGS method[53] without the cell optimization and with the following convergence tolerance parameters: total energy = 5 × 10^{-5} eV/atom, maximum displacement = 0.005 Å, maximum force = 0.1 eV/Å, and maximum stress = 0.2 GPa. For the H-atom optimized structure ("opt-H"), all heavy atoms were constrained during geometry optimization. For the fully-optimized structure ("opt-full"), no atoms were constrained.

To convert the computed shielding constant to the corresponding chemical shift, we use the following equation:

$$[1] \qquad \delta_{sample} = \sigma_{ref} - \sigma_{sample}$$

where σ_{ref} is the shielding constant for a reference sample. In this study, we use the following parameters: for the "opt-full" structure, $\sigma_{ref}(^{1}H)$ = 30.6 ppm, $\sigma_{ref}(^{13}C)$ = 170.0 ppm, $\sigma_{ref}(^{17}O)$ = 259.0 ppm, and $\sigma_{ref}(^{27}Al)$ = 556.2 ppm; for the "opt-H" structure, $\sigma_{ref}(^{1}H)$ = 30.8 ppm, $\sigma_{ref}(^{13}C)$ = 170.0 ppm, $\sigma_{ref}(^{17}O)$ = 270.0 ppm, and $\sigma_{ref}(^{27}Al)$ = 555.6 ppm; for the "X-ray" structure, $\sigma_{ref}(^{1}H)$ = 34.0 ppm, $\sigma_{ref}(^{13}C)$ = 185.0 ppm, $\sigma_{ref}(^{17}O)$ = 265.0 ppm, and $\sigma_{ref}(^{27}Al)$ = 556.4 ppm. These values were chosen to optimize the agreement between experimental chemical shifts and CASTEP chemical shifts for individual structures. The calculated $C_Q(^{27}Al)$ values reported from CASTEP were corrected using a more accurate ^{27}Al quadrupole moment, $Q(^{27}Al) = 14.66 \times 10^{-30}$ m^2.[54]

3. Results and discussion

^{1}H and ^{13}C spectra

Figure 1 shows the solid-state ^{1}H and ^{13}C NMR spectra of α-Al(acac)$_3$. Using MAS alone, we were able to observe only two broad peaks in the ^{1}H NMR spectrum, attributable to the CH and CH_3 groups in α-Al(acac)$_3$. With the 1-D windowed-DUMBO sequence, significant line narrowing is achieved, leading to the observation of two different groups of signals for each of the CH and CH_3 resonances. The ^{1}H chemical

Fig. 2. ^{17}O DOR spectra of α-Al(acac)$_3$ obtained at (*a*) 14.1 T and (*b*) 18.8 T. The isotropic peak is marked by *. The outer rotor spinning frequency was 1305 and 1330 Hz for (*a*) and (*b*), respectively. (*c*) The experimental (lower trace) and best-fitted (upper trace) "total ^{17}O DOR line shapes" of α-Al(acac)$_3$. The experimental "total DOR line shape" was obtained by summing up all sidebands onto the isotropic peak shown in (*b*).

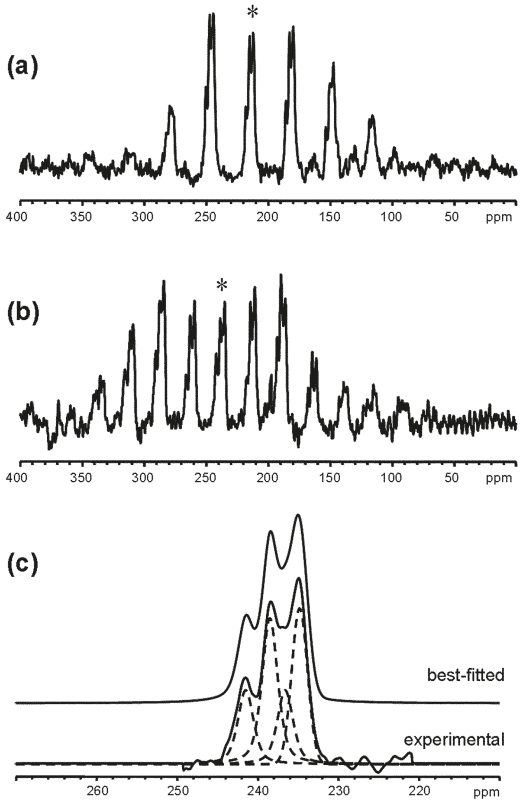

Fig. 3. Simultaneous fitting of the ^{17}O DOR data obtained at 14.1 and 18.8 T for α-Al(acac)$_3$.

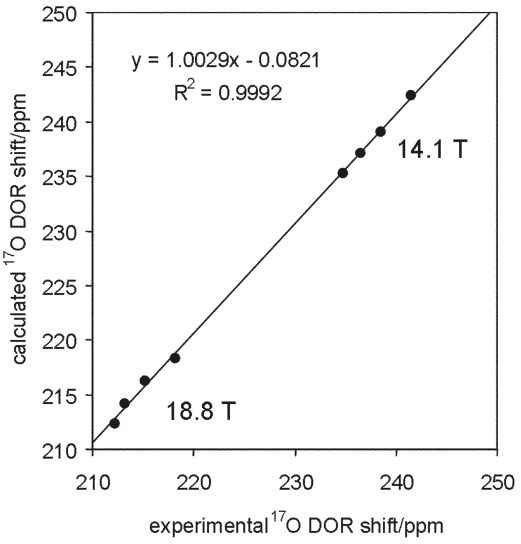

shifts observed for α-Al(acac)$_3$ are 5.48 and 5.05 ppm for the CH groups and 1.84 and 1.53 ppm for the CH_3 groups. We note that our ^{1}H chemical shifts for the CH groups are somewhat different from the 6.9 ppm previously observed in the ^{2}H MAS NMR spectrum of α-Al(acac)$_3$.[42] In the ^{13}C CPMAS spectrum, two signals are observed for each of the CO and CH_3 groups, whereas three signals are seen for the CH groups. These observations are in agreement with the earlier study of Champmartin and Rubini.[41] Because the asymmetric unit of α-Al(acac)$_3$ contains one complete molecule, there should be, in principle, six ^{13}C NMR signals for each of the CO and CH_3 groups. Clearly, each of the two ^{13}C NMR signals in the CO and CH_3 regions represents three nearly degenerate signals. All experimental ^{1}H and ^{13}C chemical shifts are listed in Table 1.

^{17}O spectra

Whereas it is straightforward to obtain and analyze ^{1}H and ^{13}C MAS NMR spectra when multiple sites are present, it is quite a different task to do the same thing for ^{17}O NMR spectra. This is because the second-order quadrupolar interactions are not averaged under MAS.[55] As a result, different types of NMR experiments such as double-rotation (DOR) can helpfully be applied to produce high-resolution ^{17}O NMR spectra. Figure 2 shows the ^{17}O DOR spectra of α-Al(acac)$_3$ obtained at 14.1 and 18.8 T. Because the spinning frequency of the outer rotor, which is at the magic angle, is usually much smaller than the frequency span of anisotropic width for the ^{17}O produced by second-order quadrupolar and chemical shift effects, a large number of spinning sidebands are present. Nonetheless, the high resolution achieved in the DOR spectra allows the observation of several resolved ^{17}O NMR signals, which is simply not possible in the corresponding ^{17}O MAS spectra (vide infra). As shown in Fig. 2*c*, the "total ^{17}O DOR line shape" can be satisfactorily analyzed by assuming four distinct peaks with integrated intensity ratios of 1:2:1:2. This is consistent with the fact that there are six crystallographically distinct CO groups in α-Al(acac)$_3$, as mentioned earlier. Next we need to analyze the observed DOR shifts to obtain fundamental NMR parameters such as chemical shifts and quadrupole parameters. It is known that the ^{17}O DOR shift, δ_{DOR}, depends on the isotropic chemical shift (δ_{iso}) and the quadrupole product parameter (P_Q) in the following manner[55,56]:

$$[2] \qquad \delta_{DOR} = \delta_{iso} - \frac{3}{500}\left(\frac{P_Q}{\nu_0}\right)^2 \times 10^6$$

where ν_0 is the Larmor frequency of ^{17}O, and $P_Q = C_Q \times (1 + \eta_Q^2/3)^{1/2}$. As shown in Fig. 3, we were able to fit simultaneously the two sets of ^{17}O DOR shifts observed at 14.1 and 18.8 T. However, we should point out that this fitting procedure is not trivial. In practice, we used the low-field MAS spectra (vide infra) to determine the initial values of C_Q and η_Q, then the DOR spectra to refine the isotropic chemical shifts. During the process, we also noticed that one of the O sites must have a slightly larger value of C_Q; see Table 2. In the end, ^{17}O MAS spectra obtained at different magnetic fields were also simulated (see Fig. 4). It should be strongly emphasized that it is important to have DOR and MAS data collected at multiple magnetic fields to extract reliable ^{17}O NMR parameters. This is particularly true when there are multiple oxygen sites with a similar environment, which is indeed the case in α-Al(acac)$_3$. Quite interestingly,

Table 2. Experimental and calculated ^{17}O and ^{27}Al quadrupole parameters for α-Al(acac)$_3$. Only the CASTEP results from the "opt-full" structure are shown.

		Experimental		CASTEP	
Nucleus	Site	C_Q/MHz	η_Q	C_Q/MHz	η_Q
^{17}O	1	6.9±0.2	0.8±0.1	7.247	0.80
	2	6.9±0.2	0.8±0.1	7.243	0.81
	3	6.9±0.2	0.8±0.1	7.146	0.87
	4	6.9±0.2	0.8±0.1	7.340	0.78
	5	6.9±0.2	0.8±0.1	7.206	0.83
	6	7.1±0.2	0.8±0.1	7.455	0.72
^{27}Al	1	3.02±0.01	0.16±0.01	3.09	0.32

Fig. 4. Experimental (lower trace) and simulated (upper trace) ^{17}O MAS spectra of α-Al(acac)$_3$ at three magnetic fields. The ^{17}O NMR parameters used in spectral simulations are given in Tables 1 and 2. The inset shows the experimental (lower trace) and simulated (upper trace) "total ^{17}O MAS line shapes" for α-Al(acac)$_3$ at 21.1 T. The experimental "total ^{17}O MAS line shape" was obtained by adding spinning sidebands onto the central band of the MAS spectrum. The symbol * indicates the spectral features arising from satellite transitions.

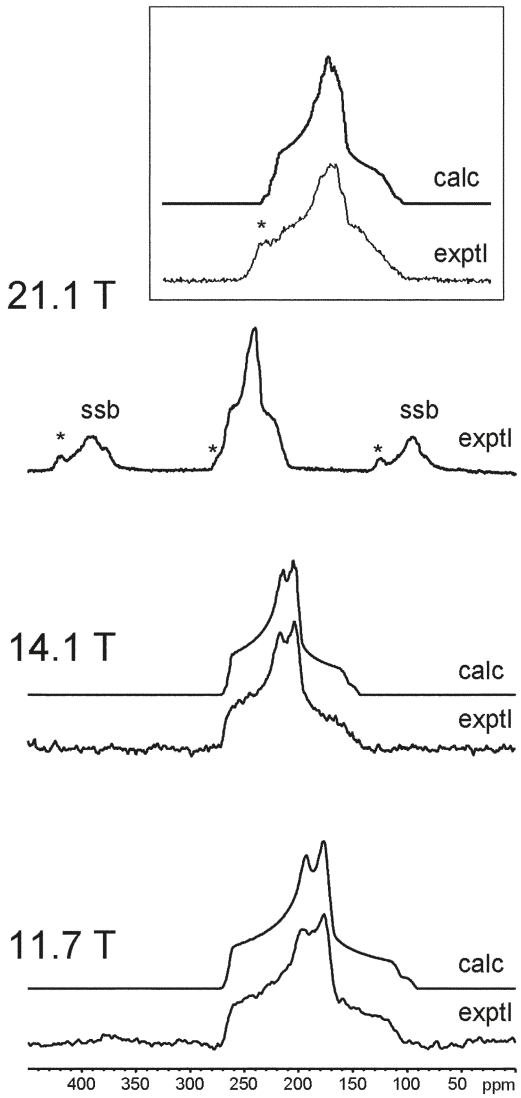

Fig. 5. Experimental (lower trace) and simulated (upper trace) ^{27}Al MAS spectra of α-Al(acac)$_3$ obtained at 21.1 T. The symbol * indicates the inner (3/2–1/2) satellite transition.

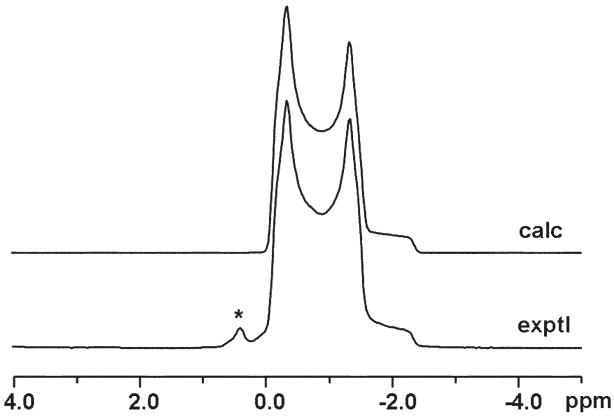

as seen in Fig. 4, while each of the ^{17}O MAS spectra obtained at 11.7 and 14.1 T seems to display just one characteristic second-order quadrupolar line shape (i.e., one oxygen site), the corresponding spectrum obtained at 21.1 T exhibits a quite complex feature suggesting that the multiple oxygen sites must have very similar ^{17}O quadrupole parameters, but slightly different chemical shifts. By combining the DOR and MAS data sets, we obtained the final set of ^{17}O NMR parameters for α-Al(acac)$_3$, as summarized in Tables 1 and 2.

^{27}Al spectra

Figure 5 shows the experimental and simulated ^{27}Al MAS spectra obtained at 21.1 T for α-Al(acac)$_3$. Because there is only one Al site in α-Al(acac)$_3$, it is straightforward to obtain accurate ^{27}Al NMR parameters from an analysis of these ^{27}Al MAS spectra. We obtained the following parameters: $\delta_{iso} = 0.15 \pm 0.05$ ppm, $C_Q = 3.02 \pm 0.01$ MHz, and $\eta_Q = 0.16 \pm 0.01$. These parameters are in excellent agreement with those reported earlier by Wasylishen and colleagues.[43] These ^{27}Al NMR parameters were further confirmed by additional MAS, DOR, 3QMAS, and 5QMAS ^{27}Al NMR spectra obtained for α-Al(acac)$_3$ at 11.7, 14.1, and 21.1 T (data not shown). It is worth noting that, in each of the ^{27}Al DOR, 3QMAS, and 5QMAS spectra, a single peak is observed without any splitting from $^1J(^{17}O, ^{27}Al)$, suggesting that this *J*-coupling is less than 20 Hz.

Chemical-shift calculations

In this section, we examine the accuracy of chemical-shift

Fig. 6. Comparison of experimental (δ_{exptl}) and calculated (δ_{castep}) chemical shifts for ^{13}C and ^{17}O in α-Al(acac)$_3$. See text for discussions on the three structures.

For personal use only.

calculations from the GIPAW method. To this end, we selected three α-Al(acac)$_3$ structures: (1) the original X-ray structure (R = 0.049 for 2028 reflections) as reported by Diaz-Acosta et al.[40] (denoted as the "X-ray" model), (2) the X-ray structure with the H-atom positions being optimized using CASTEP (denoted as the "opt-H" model), and (3) the X-ray structure with all atom positions being optimized (denoted as the "opt-full" model). Before discussing chemical shift results, we briefly comment on some structural differences among the three models. It is well-known that H-atom positions determined by X-ray crystal structures are not accurate and that CH bonds are typically too short (ca. 0.95 Å). Indeed, after the H-atom optimization, the CH bonds in Al(acac)$_3$ are increased by 0.14–0.16 Å for the CH and CH$_3$ groups. In the "opt-full" model, the O and C atoms change their positions slightly (O: 0.02 Å; C: 0.02–0.05 Å), in addition to the aforementioned lengthening of the CH bonds. Another useful measure of the structure is to examine the average forces given as Cartesian components for individual atoms. In the "X-ray" structure, significant forces are present on H-atoms (as large as 8 eV/Å), and the average forces on heavy atoms are also sizable (C: up to 6 eV/Å; O: up to 2 eV/Å; Al: 0.06 eV/Å). In the "opt-H" model, however, while forces on the H-atoms diminish (<0.06 eV/Å), they remain on other heavy atoms (C: 1.2 eV/Å; O: 1.6 eV/Å). In the final "opt-full" structure, average forces on all atoms are much smaller than 0.06 eV/Å.

All computational results of chemical shifts are summarized in Table 1. Figure 6 illustrates the differences in computational results for ^{13}C and ^{17}O among the three models. Because there is only one data point for ^{27}Al and because ^{1}H chemical shifts span a very narrow range, we did not include them in Fig. 6. Clearly, improvement of the "opt-H" model over the "X-ray" structure occurs primarily on the ^{1}H chemical shifts and on the ^{13}C chemical shifts for the CH and CH$_3$ groups. Interestingly, the "opt-H" model does not show any improvement for the ^{17}O chemical shifts. In the final "opt-full" model, all calculated chemical shifts show reasonable agreement with the experimental ones (with root-mean-square-deviation values of less than 3 ppm). Now we can also compare our CASTEP results with the GIAO DFT results (Gaussian 98) reported by Amini and Tafazzoli.[44] In their study, they used the same X-ray structure of α-Al(acac)$_3$, but optimized only the H-atom positions. In general, the CASTEP chemical shifts are in much better agreement with the experimental chemical shifts than the results of Amini and Tafazzoli. This is expected because they used a rather small basis set and an isolated molecule in their calculations. It can certainly be argued that α-Al(acac)$_3$ may not represent the best example to illustrate the importance of including the entire crystal lattice in chemical shift calculations. However, α-Al(acac)$_3$ is known to exhibit polymorphism. For example, while there is only one molecule in the asymmetric unit of α-Al(acac)$_3$, there are two optically active Al(acac)$_3$ molecules in the asymmetric unit of γ-Al(acac)$_3$.[57] The intermolecular contact in Al(acac)$_3$ is primarily due to CH$_3$···O interactions. It would be of interest to prepare γ-Al(acac)$_3$ and examine its solid-state NMR properties.

4. Conclusion

In this study, we have obtained accurate chemical shifts for all magnetic nuclei in α-Al(acac)$_3$ by using a variety of solid-state NMR experiments. All experimental chemical shifts are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

reasonably well reproduced by GIPAW chemical shift calculations, provided that a full optimization is employed to improve on the original X-ray structure. This appears to be the first attempt to treat all magnetic nuclei in a molecular crystal containing a metal centre on an equal footing regardless of the nature of their spins (i.e., spin-1/2 or quadrupolar). Although α-Al(acac)$_3$ represents a rather simple case, we anticipate that a similar approach should be applicable to more complex molecules. In addition, it is also possible in the future to combine *J*-based or dipolar-based 2-D heteronuclear correlation techniques with DOR or MQMAS to aid spectral assignment for quadrupolar nuclei.

Acknowledgements

This research was supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada. We are grateful to Xin Mo for assistance in preparing ^{17}O-labeled Al(acac)$_3$ and to Irene Kwan for assistance in performing powder X-ray diffraction experiments. Access to the 900 MHz NMR spectrometer and CASTEP software was provided by the National Ultrahigh-Field NMR Facility for Solids (Ottawa, Canada), a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council Canada, and Bruker BioSpin and managed by the University of Ottawa (http://www.nmr900.ca). NSERC is acknowledged for a Major Resources Support grant. MES thanks the Engineering and Physical Sciences Research Council, UK (EPSRC) and the University of Warwick for contributions. NMR infrastructure, and elements of the solid-state NMR spectrometer consoles and probes used in this research were obtained through the Birmingham Science City Project, with support from Advantage West Midlands (AWM) and part funded by the European Regional Development Fund (ERDF).

Abstract: Multiple quantum ^{2}H NMR spectroscopy is used to study the structure and dynamics of D_2O in Nafion membranes as a function of membrane hydration. By employing both double- and zero-quantum filtered experiments, residual quadrupolar coupling constants and T_2 relaxation values are obtained. The residual couplings vary from 240 to 20 Hz and the T_2 values range from 20 to 180 ms, with the high hydration values having smaller couplings and longer T_2 values. Analysis of the data using a water-exchange model suggests that the changes in parameters arise from a change in the fraction of time water spends in the anisotropic environments and not from changes in the order parameters that characterize the anisotropic sites. It has been found that a two-site model is needed to accurately fit the spectra above a hydration level of 10 D_2O per sulfonate, with the second site having a negligible residual quadrupolar coupling. The data supports a model with two different hydration layers at high hydration and can be understood in terms of the recently proposed parallel-channel model for Nafion hydration.

Key words: polymer electrolyte membrane, Nafion, DQF, ZQF, ^{2}H NMR, hydration models, residual quadrupolar couplings, relaxation.

Résumé : On a utilisé la RMN du ^{2}H à quantum multiple pour étudier la structure et la dynamique du D_2O dans des membranes de Nafion en fonction de l'hydratation de la membrane. En faisant appel à des expériences à filtrage à quantum double (FQD) et filtrage à quantum zéro (FQZ), on a pu obtenir les constantes de couplage quadripolaire et les valeurs des temps de relaxation, T_2. Les couplages résiduels varient de 240 à 20 Hz et les valeurs de T_2 s'étalent de 20 à 180 ms; les taux d'hydratation élevés sont associés aux couplages les plus faibles et les valeurs de T_2 les plus longues. Une analyse des données en faisant appel au modèle d'échange de l'eau suggère que les changements dans les paramètres découlent d'un changement dans la fraction de temps passé dans les environnements anisotropes et non pas de changements dans les paramètres d'ordre qui caractérisent les sites isotropes. On a trouvé qu'il est nécessaire d'utilisé un modèle à deux sites pour bien ajuster les spectres au-delà d'un niveau d'hydratation de 10 D_2O par sulfonate et que le deuxième site ne présente qu'un couplage quadripolaire résiduel. Les données sont en accord avec un modèle avec deux types différents de couches d'hydratation à hydratation élevée et il peut être compris en fonction du modèle à canaux parallèles proposé récemment pour l'hydratation du Nafion.

Mots-clés : membrane d'électrolyte polymère, Nafion, filtrage à quantum double (FQD), filtrage à quantum zéro (FQZ), modèles d'hydratation, couplages quadripolaires résiduels, relaxation.

Introduction

As the world attempts to reduce its dependence on hydrocarbon fuels, hydrogen, coupled to modern fuel cell technologies, can provide one alternative for meeting our requirements for clean fuel.[1] The use of hydrogen fuel cells provides the means by which some of the energy stored in the chemical bonds of the H_2 molecule can be converted to electricity with greater efficiency and safety than by combustion. The basic architecture of a hydrogen fuel cell involves a catalytic anode where H_2 gas is split into $2H^+$ and $2e^-$. Electrons are routed through an external circuit to the cathode while protons are transported through a membrane to the cathode where electrons, protons, and O_2 molecules react to form water. A key component of any fuel cell is the membrane that transports the protons from the anode to the cathode; the efficiency of the fuel cell is affected by the ability of the membrane to rapidly conduct the protons.[2] In many polymer membranes, such as Nafion, conduction occurs along water networks. Therefore, studying the structure and behaviour of water networks under different conditions is vitally important to understanding and improving fuel cell membranes.[3–6] For example, magnetic resonance imaging techni-

ques are increasingly being used to study water content in different parts of the membrane as a function of fuel cell operation to better understand water distribution and management.[7–17]

Current models of membrane hydration are based primarily on small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) studies.[5,18–20] The structure of the Nafion polymer, composed of a hydrophobic perfluoronated polymer that has hydrophilic sulfonated side chains, leads to water regions that form a reverse micelle-like structure within hydrophilic regions of the polymer matrix. Many models have been proposed to explain the experimental data and membrane properties by describing the shape and size of the water domains. The dominant model used for many years is based on the work of Gierke and expanded upon by Gebel.[18,21] This model involves three general structural motifs for the hydrated membranes below a hydration, λ, of 22 waters per sulfonate. At the lowest hydration levels, water molecules are very tightly bound to negatively charged sulfonate groups.[22] As hydration increases, pockets of water form in the swollen membrane and significant amounts of mobile water become present.[18,23] A final structural change occurs when hydration reaches approximately $\lambda = 14$ as channels form between the water pockets allowing for percolation of water through the membrane.[18]

A more recent hydration model has been proposed by Schmidt-Rohr and Chen based on predicted scattering profiles. After comparing predicted profiles for numerous models to the experimental scattering data, the authors concluded that the structure of the water environments could be best described by a parallel-channel model where channels are present at most hydration levels and simply expand in size as water is absorbed by the membrane. This model accounts for much of the experimental scattering and conductivity data. It is also based on ^{19}F and ^{13}C solid-state NMR results which suggest that the polymer backbone has rigid domains.[24,25]

The decades-long debate over the structure and behaviour of water in Nafion membranes is a result of the complex nature of the membrane–water interactions as well as the limited experimental methods by which membranes and hydration can be studied.[5,26] It is vital that new techniques be developed and used to study this important problem so that the understanding and methodologies developed for Nafion can be extended to new polymer membranes. This is particularly important now that theoretical modellers have begun to develop simulation methods to study hydration in Nafion at the molecular level.[6,26–36] When studying disordered polymer materials, NMR is a powerful technique to employ.[37] Numerous NMR studies have already been used to study the structure of the polymer,[24,25] the environment and motion of ions in the membrane,[38] and the behaviour of water in the membrane. The studies of water have focused on two regimes: the water–hydronium molecules which are tightly bound to the sulfonate groups have been studied mainly by solid-state NMR techniques,[22,39–41] whereas the more mobile water domains are studied using relaxation-based NMR techniques and NMR diffusion studies.[41–47]

The development of multiple quantum filtering (MQF) techniques has allowed researchers to study systems that fall between the extremes of solution and solid-state NMR. When nuclei exist in solution-like environments but do not experience isotropic motion, the dipolar and quadrupolar couplings may not be averaged to zero, as they are in cases of rapid isotropic motion, resulting in small residual couplings that can be measured using MQF NMR.[48–51] MQF NMR has been used to study ordered biological samples such as cartilage and spinal disc tissue, where water molecules sample anisotropic environments.[50,52–61] The same principles that have made MQF NMR valuable for studying biological materials make it potentially useful for studying hydrated membranes.

MQF techniques can be used to measure either residual dipolar couplings or residual quadrupolar couplings. Typically residual dipolar couplings are extremely small and can be difficult to detect unless the species being studied is tightly bound.[59] For example, the tightly bound protons in dry Nafion have been observed using ^1H MQF NMR.[22] To study water or ions that experience very limited ordering a more sensitive coupling must be used. The quadrupolar coupling is generally larger than the dipolar coupling and the use of MQF techniques to measure residual quadrupolar couplings has proven useful when residual dipolar couplings cannot be detected.[59] This study explores the use of MQF techniques for studying the water in the Nafion membrane as a function of hydration. The power of the quadrupolar interaction is harnessed by performing ^2H NMR studies of D_2O in the membranes and employing both double- and zero-quantum filtered experiments, DQF and ZQF, respectively.

Theory

The anisotropic nuclear magnetic resonance interactions provide ideal ways to explore the structure around a nucleus. For nuclei with spins greater than 1/2, there exists an interaction between the quadrupole moment of the nucleus, $\boldsymbol{Q}$, and the electric field gradient, EFG, set up by the charge distribution about the nucleus. The anisotropy of the EFG results in an orientation dependence of the quadrupolar-perturbed NMR energy levels. The EFG is described by a traceless second-rank tensor that can be expressed in its principal axis system by three components such that $|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$. The EFG is often expressed using two derived parameters, the quadrupolar coupling, C_Q (in Hz), and the asymmetry parameter, η_Q:[62,63]

$$[1] \qquad C_Q = \frac{V_{ZZ}eQ}{h}$$

$$[2] \qquad \eta_Q = \frac{(V_{XX} - V_{YY})}{V_{ZZ}}$$

The NMR spectra of a spin $I = 1$ nucleus such as deuterium in a molecule experiencing no motional averaging results in a frequency shift to the $m_I = 0 \leftrightarrow 1$ and the $m_I = -1 \leftrightarrow 0$ transitions. For a single crystal, this results in two NMR peaks separated by $2Q$, where Q is the quadrupolar half splitting which depends on C_Q, η_Q, and the orientation of the EFG in the magnetic field, defined by the angles θ and ϕ:[62]

$$[3] \qquad Q(\theta, \phi) = \frac{3\pi}{4} C_Q[3\cos^2\theta - 1 - \eta \sin^2\theta \cos 2\phi]$$

In solution, where molecules can rotate freely, the quadrupolar interaction is averaged to zero and there is no effect on the peak positions in the NMR spectrum, i.e., no quadrupolar splitting. However, if the molecule is in a fluid-like environment but experiences some restriction to its motion, a small residual quadrupolar coupling C_Q^{res}, can be present. These small couplings may not be evident from one-pulse, single-quantum NMR spectra and can be easily masked by the signal from molecules experiencing isotropic motion in the sample. One experimental method for measuring these small residual couplings is MQF NMR spectroscopy. The pulse sequence used to obtain MQF NMR spectra is shown in Fig. 1.[56,59]

The MQF sequences involve two key components, an excitation pulse followed by an evolution period where spin magnetization is allowed to evolve and develop from the single quantum coherence level into the different quantum coherence levels available to the nucleus. This is followed by a set of filter pulses which select individual coherence pathways. For an isolated deuterium nucleus, $I = 1$, there are three quantum coherence levels: 0, 1, and 2. The transfer of magnetization from the single-quantum to the double- or zero-quantum coherences during the mixing time, τ, is proportional to the magnitude of the residual quadrupolar interaction and is attenuated by longitudinal relaxation, T_2. The zero-quantum and double-quantum coherences can be selected using the pulse sequence shown in Fig. 1 by varying the phase cycling of the last filter pulse and the acquisition. The spin density, which is related to the signal intensity, detected immediately after the filter pulses, is a function of τ and is given by

$$[4] \qquad \rho_{ZQF} \propto \cos(Q\tau)\exp(-\tau/T_2)$$

$$[5] \qquad \rho_{DQF} \propto \sin(Q\tau)\exp(-\tau/T_2)$$

During the acquisition, a free induction decay is observed and can be modeled using analytical equations. The signal obtained at the start of the acquisition is analogous to echo modulation where the modulation occurs due to Q and T_2. Upon Fourier transformation, ^{2}H NMR spectra are obtained that have the following form for the ZQF and DQF experiments:[56]

$$[6] \qquad S_{ZQF}(\tau,\omega_2) = \cos(Q\tau)\exp(-\tau/T_2) \times \left[\frac{1/T_2^*}{(\omega_2-\delta_0+Q)^2+(1/T_2^*)^2} + \frac{1/T_2^*}{(\omega_2-\delta_0-Q)^2+(1/T_2^*)^2}\right]$$

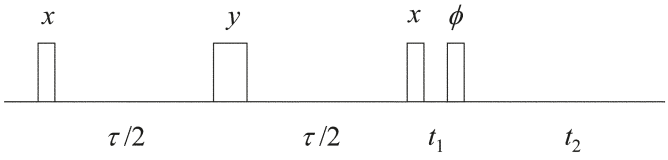
$$[7] \qquad S_{DQF}(\tau,\omega_2) = \sin(Q\tau)\exp(-\tau/T_2) \times \left[\frac{\omega_2-\delta_0+Q}{(\omega_2-\delta_0+Q)^2+(1/T_2^*)^2} - \frac{\omega_2-\delta_0-Q}{(\omega_2-\delta_0-Q)^2+(1/T_2^*)^2}\right]$$

where δ_0 represents the frequency offset of the peak in s^{-1}, ω_2 represents the frequency points in the spectrum and T_2^* is the relaxation that occurs during the acquisition. T_2^* is the combination of T_2 and an additional line broadening factor due to inhomogeneous broadening, W.

$$[8] \qquad 1/T_2^* = \pi W + 1/T_2$$

Equations [6] and [7] reveal that DQF and ZQF spectra provide complimentary ways of obtaining the parameters C_Q^{res}, which is related to Q by eq. [3], and T_2 based on both the signal intensity and the lineshape as a function of τ. The contribution that free water makes to the DQF and ZQF signal is also different. Since $Q = 0$ Hz for free water, the ZQF experiment contains a signal from free water, $\cos(Q\tau) = 1$, whereas the DQF signal contains no signal, $\sin(Q\tau) = 0$. It should be noted that these equations are valid when the motion of the water molecules is not in the extreme narrowing regime. As will be discussed later, if the water molecules have very short correlation times, i.e., they spend very little time in the anisotropic sites, they will enter the extreme narrowing regime where $\omega_0\tau_c \ll 1$. In this case the T_2 relaxation rate of the zero quantum signal is 3/5 that of the double quantum signal. Previous research has indicated that the water molecules may have correlation times approaching that of free water which would place them in the extreme narrowing regime.[47]

Fig. 1. The NMR pulse sequence used to acquire DQF and ZQF ^{2}H NMR spectra. A 180° refocusing pulse is placed in the middle of the mixing time, τ, to refocus any chemical shift or dipolar interactions. The four-step phase cycle for the last pulse is x, y, $-x$, $-y$ for both ZQF and DQF. The detection phase cycles for ZQF and DQF are x, y, $-x$, $-y$, and x, $-y$, $-x$, y, respectively. The delay t_1 was set to 10 ms and t_2 ranged from 1 to 3 s depending on the breadth of the peaks.



In fitting experimental spectra to the analytical expressions above, the total ZQF and DQF lineshapes of a sample are evaluated by summation of the equations over the isotropic distribution of the angles (θ, ϕ) and by weighted summation over a range of local environments having distinct values for C_Q, T_2, W, and f_0 ($f_0 = \delta_0/2\pi$).[61] This latter summation provides a powerful means of analysing multiple water environments within a specific sample. Multiple sites are often required in the fitting of experimental spectra to properly reproduce the signal intensity and line shape, suggesting the presence of different structural or kinetic water domains within the sample.[61]

Experimental

Membrane Treatment

Six different 6 cm × 1.3 cm strips of Nafion 117 (Nafion® Membrane, Fuel Cell Earth, LLC) were treated to convert the as-received membrane to the acid form.[44] The membranes were heated in a 3% H_2O_2 (Fisher) solution for one hour, washed in boiling distilled water for one hour, heated in a 0.5 mol/L H_2SO_4 (Caledon, ACS) solution for one hour, and then washed in boiling distilled water for another hour. The Nafion strips were dehydrated under vacuum and slight heat until the anhydrous weight stabilized. The anhydrous membranes were then rehydrated with D_2O (Acros, 99.5% D). Each sample was placed in a 5 mm solution NMR tube so that the membrane was coiled around the wall of the tube. The tube was then capped and sealed with Parafilm™ for the NMR experiments. Between 20 and 25 ZQF and DQF

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

spectra were acquired for each hydration level. Sample placement was carefully monitored in an attempt to reduce the effects of magnetic susceptibility differences between the experiments. Different sample alignments were tested and did not produce significant differences in the data. Hydration values, λ, in units of D_2O per sulfonate,[23] were calculated based on the mass of water absorbed by the membrane, which was measured immediately before and after the NMR experiments were performed. The trends in hydration were also monitored by comparing the ^2H NMR signal intensities from a one-pulse experiment; a linear correlation between the signal intensities and the λ values confirmed the hydration levels. T_1 values were also measured for all samples and were comparable to those measured by others.[44]

Data Acquisition

All NMR spectra were collected on a Bruker Avance 400 MHz NMR spectrometer at The King's Center for Molecular Structure using a Bruker ATMA multinuclear probe tuned at 61.42 MHz for ^2H with a 180° pulse optimized to 40.5 μs. Experiments were referenced to liquid D_2O set at 0 Hz. The spectrometer was manually shimmed before the acquisition of each sample to reduce line shape distortions arising from sample placement; the adjustments required were typically small suggesting that the care taken during sample alignment was adequate to obtain reproducible results. T_1 relaxation measurements were made using the standard inversion recovery pulse sequence and analysed using the Bruker software. DQF and ZQF experiments were conducted using the pulse sequence shown in Fig. 1. The mixing time τ was varied from 1 ms to 120 ms depending on the experiment and the sample. The spectral fitting was performed using a home-written Matlab program based on the program developed by Polenova, Vega, and Ooms[61] which employed a multi-variable non-linear least-squares regression method to minimize the residual for a set of at least 16 calculated and experimental spectra. By including both DQF and ZQF spectra in the fitting procedure, quantitative inclusion of the water environments was ensured with very small residual quadrupole interactions.

The primary source of error in the data is experimental. Analysis of the data reveals significant variation in the parameters obtained from different samples at similar hydrations. Some of this error may be from sample alignment and field inhomogeneities during the NMR experiments, but the largest source of error arises from sample preparation. It has been noted by numerous researchers that sample preparation plays an important roll in determining Nafion membrane properties.[23] This is true for bulk property measurements and is magnified when studying molecular level properties. A detailed look at the effects of sample preparation on the measured NMR parameters is currently underway. Despite the variations arising from these experimental sources of error, the trends observed and disused below are clearly significant and important.

Results and discussion

NMR spectra

Representative DQF and ZQF ^2H NMR spectra acquired from membrane samples with λ = 5.2 (top) and λ = 19 (bottom) are shown in Fig. 2. The spectra on the left are ZQF spectra as a function of mixing time, τ, while the spectra on the right are DQF spectra. The presence of a DQF signal clearly indicates that water in the membrane is experiencing restricted motion; as discussed above, freely moving water does not produce any DQF signal. Both sets of DQF spectra (Figs. 2*b* and 2*d*) show the expected dependence on mixing time (τ); the signal starts at a reduced intensity, builds up to a maximum, and then decays. The ZQF spectra (Figs. 2*a* and 2*c*) also show the expected patterns, starting at maximum intensity and then decaying as τ is increased.

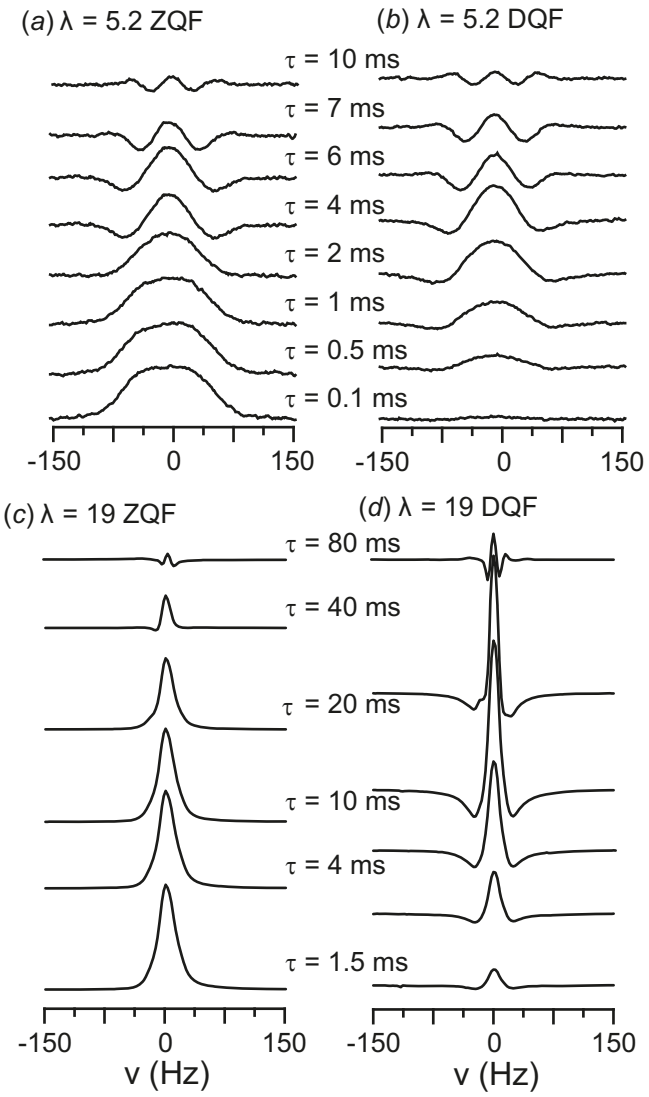


Fig. 2. Representative spectra for a Nafion membrane sample hydrated at λ = 5.2 (*a* and *b*) and λ = 19 (*c* and *d*). The spectra on the left are ZQF spectra as a function of mixing time, τ, while the spectra on the right are DQF spectra.

The linewidth-at-half-height measured at the start of the ZQF experiment changes from approximately 200 Hz at the lowest hydration level to around 20 Hz at the highest hydration level. The ZQF spectrum at the lowest τ value is approximately equivalent to the single-quantum spectrum measured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

using a standard single-pulse experiment. The broad lines observed at low hydration levels, Fig. 1*a*, are likely dominated by quadrupolar broadening whereas at the high hydration level, Fig. 1*c*, the narrow ZQF linewidths are dominated by T_2 relaxation as evidenced by their Lorentzian line shape.

Based on eqs. [6] and [7], significant information about the C_Q^{res} and T_2 can be inferred by examining the intensity of the DQF and ZQF signal as a function τ. The DQF spectra in particular are useful because the signal intensity is dominated by the $\sin(Q\tau)\exp(-\tau/T_2)$ part of eq. [7]; the build-up will be controlled by the quadrupolar coupling, and the signal decay will be governed by T_2. Figure 3 shows a plot of the maximum signal intensity of the DQF spectra normalized to the intensity of the single-quantum spectrum, plotted against τ for a series of hydration levels. At low hydration, the signal intensity builds up rapidly and achieves a maximum that is more than 60% the intensity of the single-quantum experiment. This indicates that most of the D_2O in the sample is experiencing some restricted motion. The T_2 relaxation values at low hydration are short, as would be expected for deuterium nuclei experiencing anisotropic motion. As the amount of water in the membrane increases, the slope of the build-up and the signal decay rate both decrease, suggesting that C_Q^{res} is being reduced and that T_2 is increasing. These changes in C_Q^{res} and T_2 are expected and confirm that the motion of the water molecules is becoming more isotropic as hydration increases.

A convenient way of representing the cumulative effect of the changing C_Q^{res} and T_2 parameters is to plot the τ value at which the signal intensity is maximum, τ_{max}, against the hydration level. Figure 4 shows a plot of τ_{max} vs λ and reveals a strong correlation between the two parameters. From a qualitative perspective, this correlation is extremely useful. Previously, researchers have used variations in τ_{max} to provide contrast for magnetic resonance imaging. By applying a DQF sequence before the imaging sequence and selecting a specific τ-value, signal intensity in the image can be correlated to the hydration level. Alternatively, τ-maps can be created where DQF signal intensity curves are acquired for each pixel in an image or point in a one dimensional cross section.[60,64,65] The results presented here suggest that using DQF to create contrast may also be useful for obtaining information at the molecular level about water distribution in membranes. Such techniques could complement magnetic resonance micro-imaging studies of water in operating fuel cells.[7,8,10–16]

Quantitative analysis

Using eqs. [6] and [7] and the multi-site fitting model discussed in the theory section, the experimental spectra were fit to calculated spectra. Typically 8 DQF and 8 ZQF spectra were selected to provide a good representation of the signal intensity curves. These 16 spectra were simultaneously fit by minimizing the difference, point-by-point, between the calculated and experimental spectra.[61] In almost all cases, good fits could be obtained for all 16 spectra. Figures 5 and 6 show typical fits. Each data set was fit using a one- and a two-site model. At low hydration most of the spectra could be fit using a single site, site **A**. However as the hydration approached $\lambda = 10$, the ZQF data could no longer be reliably

Fig. 3. Signal intensity curves for DQF spectra as a function of τ for a Nafion membrane sample at six different hydration levels. The build-up in the signal is governed by the quadrupolar coupling, $\sin(Q\tau)$, while the decay is predominantly due to T_2 relaxation, $\exp(-\tau/T_2)$.

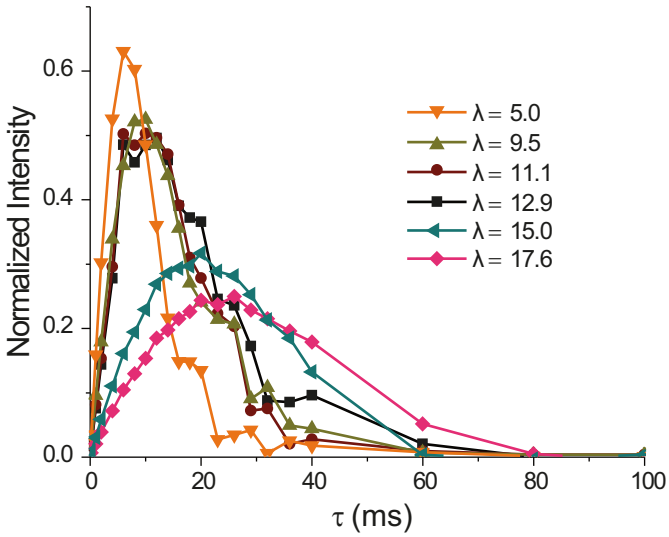

Fig. 4. A plot of the mixing time at which the maximum DQF signal intensity is observed, τ_{max}, vs the hydration level, λ, in D_2O per sulfonate.

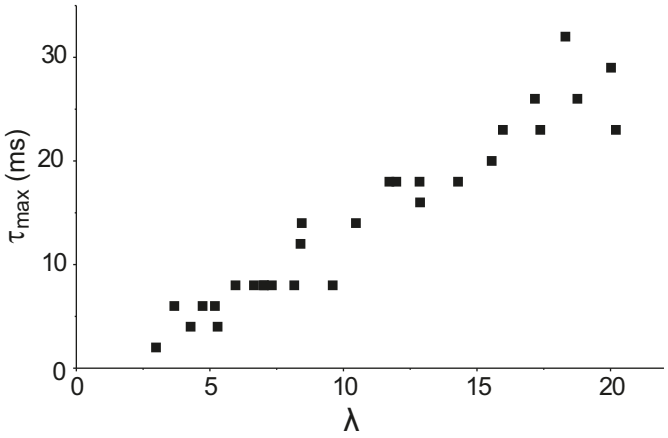

fit; specifically, the calculated ZQF spectra at longer τ values were too low in intensity (blue dot spectra in Fig. 6). This is a sign that a very small C_Q^{res} site is present in the sample. The two-site fits revealed that a second site with $C_Q^{res} <$ 20 Hz was present, site **B**. The red dashed spectra presented in Fig. 6 show the improved fit with the two-site model. The addition of a third site did not meaningfully improve the results. The results from the fitting procedure are available in the Supplementary data, Table S1.

The equation used to fit the ZQF data incorporated the 3/5 scaling of the T_2 value discussed in the theory section. Attempts to fit the data without this scaling consistently underestimated the ZQF line widths. The need to incorporate the 3/5 scaling factor indicates that the water responsible for the NMR signal is in the extreme narrowing regime where $\omega_0\tau_c \ll 1$. τ_c must therefore be much shorter than 10^{-8} s

Fig. 5. Experimental (grey) and calculated (red) DQF and ZQF ^{2}H NMR spectra for a sample with a very low level of hydration, λ = 4.2. The figure demonstrates that even at low signal-to-noise ratios reasonable fits can be obtained.

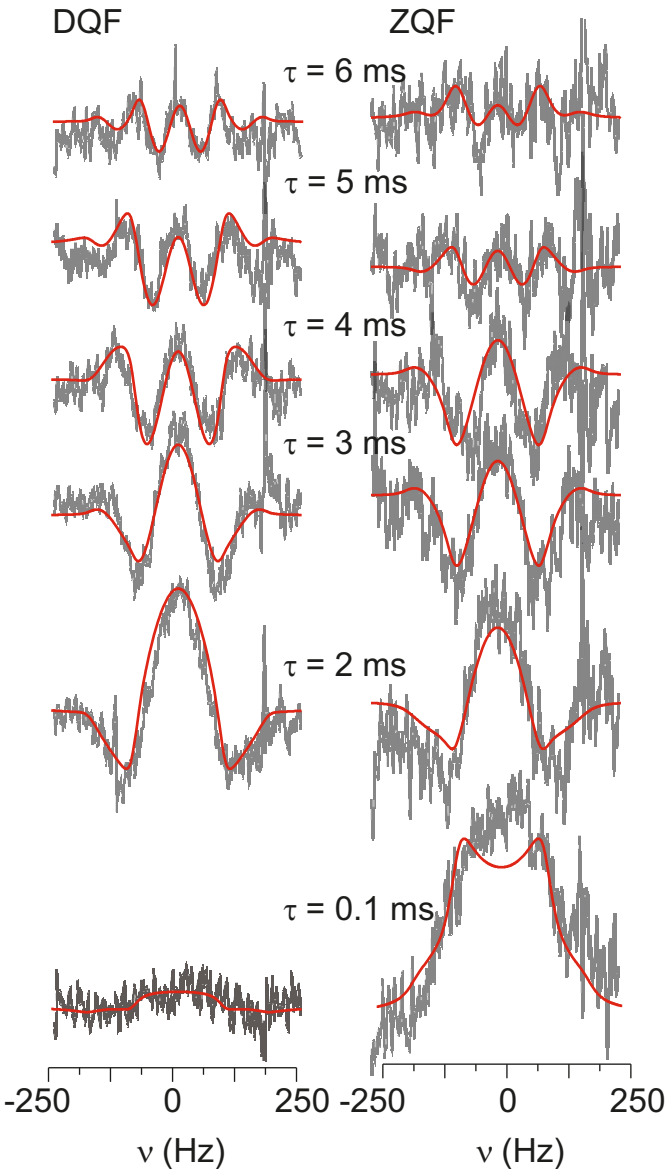

Fig. 6. Experimental (black) DQF and ZQF ^{2}H NMR spectra for a sample with an intermediate level of hydration, λ = 13.3. The blue spectra (dots) were calculated using a single-site model whereas the red spectra (dashes) demonstrate the improved fit of the ZQF spectra obtained with a two-site model.

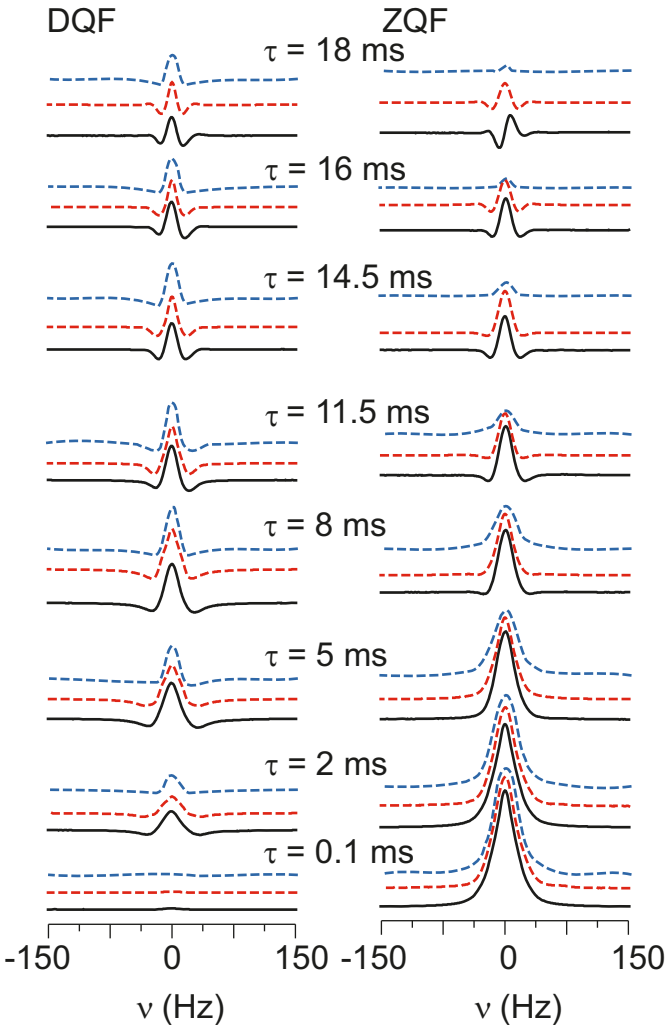

which is consistent with the correlation times reported by MacMillan and co-workers of 1.3×10^{-11} s, as well as the residence times reported by Devanathan and Perrin of 1.6×10^{-10} to 5×10^{-10} s.[6,28,47,66]

Analysis of C_Q^{res}

The C_Q^{res} values obtained as a function of hydration are plotted in Fig. 7*a* and show a non-linear decrease as the hydration increases. The C_Q^{res} values measured are small compared to those observed in other studies. For example, DQF studies of collagen hydration yield C_Q^{res} values in the kHz range at low hydration levels. In cartilage tissues, C_Q^{res} range from 100 Hz to 1500 Hz depending on the ratio of collagen to water in the tissue.[51,67]

If it is assumed that these results represent water that is in the motionally averaged regime, then the residual quadrupolar interaction is related to the quadrupolar half-splitting experienced by a water molecule when it is in an anisotropic site, Q_k, and the fraction of time it spends in the sites f_b,

$$[9] \qquad Q_{res} = \sum_k f_k Q_k = f_b \langle Q_k \rangle_b$$

where f_b is sum of all the f_k values for each site sampled by the water during the experiment. The value of $\langle Q_k \rangle_b$ is determined by the amount of motional restriction the water experiences when in an anisotropic site. The small C_Q^{res} values measured in this study arise either because the anisotropic environments sampled by the water molecules have very low degrees of order, leading to small $\langle Q_k \rangle_b$ values, or the fraction of time the water spends in the anisotropic sites, f_b, is very small, or both.

The changes in C_Q^{res} as a function of hydration are fairly smooth (Fig. 7) suggesting no large discontinuities in the structure of the water environments as hydration increases. At hydration levels above λ = 10, the C_Q^{res} values of site **A**

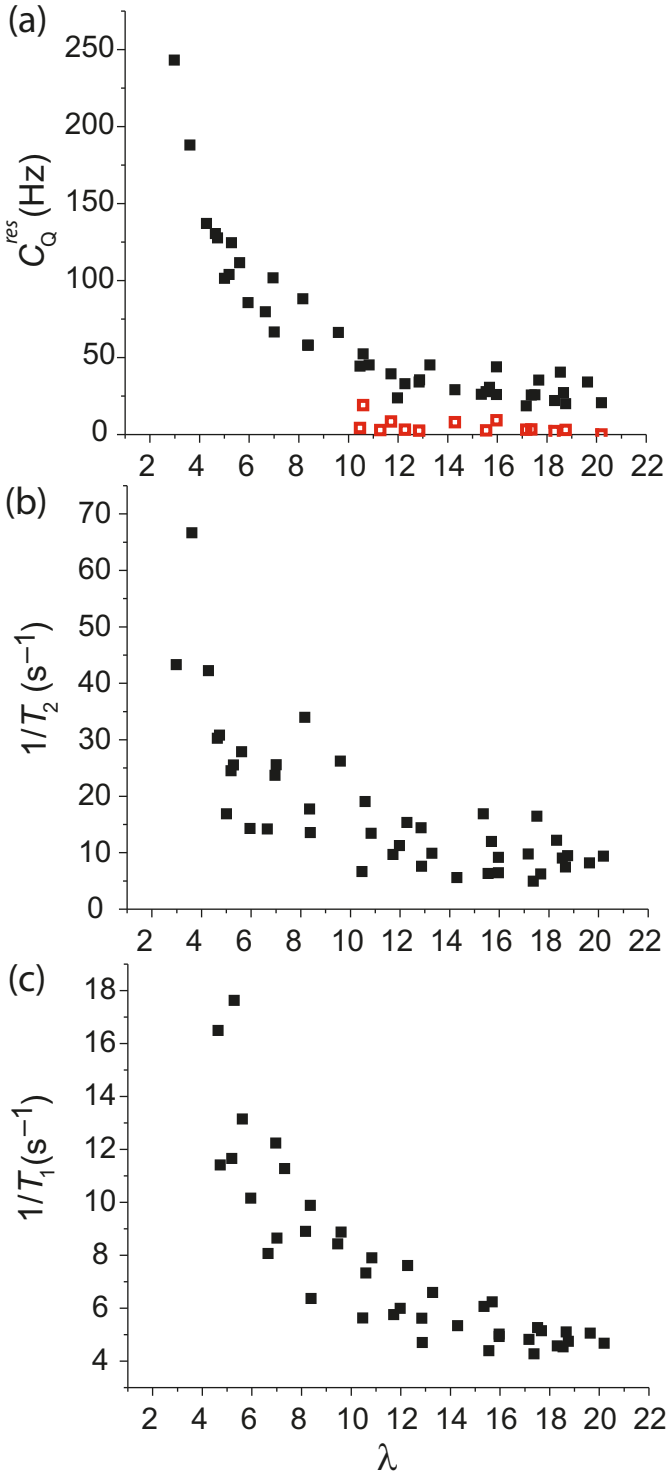
Fig. 7. Plots of the experimental data obtained in this study vs Nafion membrane hydration (λ is in D_2O molecules per sulfonate). In the C_Q^{res} plot (*a*) the black points (closed boxes) are for site **A** while the red points (open boxes) are for site **B**. The T_2 data used corresponds to T_{2I}, see text.



remain relatively constant at 35 ± 15 Hz, suggesting no dramatic changes in structure of the water environments. As discussed above, there are different models for the hydration of Nafion membranes. The model by Gierke proposed distinct structural regimes.[18,21] In particular, when λ was around 14 waters per sulfonate, the model proposes a structural change from isolated pockets of water to a network of channels. The parallel-channel model proposed by Schmidt-Rohr and Chen postulates that channels are created by the rigid polymer backbones.[19] Water molecules enter these and cause expansion of the channels as more water is absorbed by the membrane. This process is likely to lead to smooth changes in the water environments as hydration changes. Although the sudden formation of interconnected channels proposed by Gierke cannot be ruled out by these results, it seems unlikely that such a dramatic structural change would result in a change in C_Q^{res} less than 15 Hz, the spread of the experimental data. Our results are more consistent with the parallel channel model.

The ability of our technique to identify two sites above λ = 10 provides a valuable tool for understanding different water environments in the Nafion membrane. In addition to the C_Q^{res} and T_2 parameters, the two-site model provides relative amounts of water in the two sites. The fraction of water in site **B** increases as hydration increases, from approximately 15% near λ = 11 to 43% near λ = 20. This suggests that most of the water added to the membrane after λ = 10 undergoes nearly isotropic motion and supports a model for hydration in the parallel channels where approximately 10 water molecules per sulfonate ion form a hydration layer around the channel walls, experiencing anisotropic environments, and possessing the C_Q^{res} values observed for site **A**. Near a hydration level of λ = 10, enough water has entered the channels to form a second layer or core in the center of the channel. These water molecules do not sample anisotropic environments near the channel walls, yielding the negligible C_Q^{res} values observed for site **B**. Schmidt-Rohr and Chen indicate that at λ ≈ 12 the diameter of the channels is around 2.4 nm, much larger than that proposed by the other models.[19] This large diameter provides ample room for water molecules at the center of the channel to undergo isotropic motion and average the quadrupolar interaction to near zero values. This formation of a highly mobile core of water correlates well with the increase in the water diffusion constants and dielectric constants observed around λ = 9 to 11 and the need to have a relatively high hydration for Nafion fuel cells to function.[6,68]

Analysis of relaxation data

The $1/T_2$ and $1/T_1$ data as a function of λ are presented in Fig. 7*b* and 7*c*. The relaxation rates follow a trend similar to that for C_Q^{res} values, suggesting that the relaxation rates are strongly influenced by quadrupolar relaxation. The short correlation times for the water in the anisotropic sites suggested by this and previous studies mean that the relative orientation of the sites visited by a particular water molecule during the experiment are independent of each other. Similar assumptions for water in gels and tissues have led Halle and co-workers to propose a stochastic model of exchange-mediated orientational randomization (EMOR).[69–73] Using this model Halle has developed equations that describe the ^2H relaxation rates:

$$[10]\quad \frac{1}{T_{2I}} = (1-f_b)\frac{1}{T_{2I}^0} + \frac{3\pi^2}{20}C_{Q0}^2\sum_k f_k {S_k}^2\left[3\tau_k + \frac{5\tau_k}{1+\omega_0{}^2\tau_k{}^2} + \frac{2\tau_k}{1+4\omega_0{}^2\tau_k{}^2}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$[11]\quad \frac{1}{T_{2J}} = (1-f_b)\frac{1}{T_{2J}^0} + \frac{3\pi^2}{20}C_{Q0}^2\sum_k f_k {S_k}^2\left[3\tau_k + \frac{\tau_k}{1+\omega_0{}^2\tau_k{}^2} + \frac{2\tau_k}{1+4\omega_0{}^2\tau_k{}^2}\right]$$

$$[12]\quad \frac{1}{T_1} = (1-f_b)\frac{1}{T_1^0} + \frac{3\pi^2}{20}C_{Q0}^2\sum_k f_k {S_k}^2\left[\frac{2\tau_k}{1+\omega_0{}^2\tau_k{}^2} + \frac{8\tau_k}{1+4\omega_0{}^2\tau_k{}^2}\right]$$

In these equations T_1^0, T_{2I}^0, and T_{2J}^0 are the respective average relaxation times of the bulk phase, i.e., for D_2O in the membrane that experiences purely isotropic motion. The *I* and *J* subscripts arise when one uses the fictitious spin-1/2 operator formalism of Vega and Pines to describe the DQF and ZQF experiments.[74] ω_0 is the resonance frequency in angular frequency units, τ_k is the mean residence time at the anisotropic site *k*, C_{Q0} is the quadrupolar coupling in the absence of motional averaging (C_{Q0} = 220 kHz),[75] S_k is an effective order parameter, and f_b and f_k are as defined above. If one assumes extreme narrowing conditions, $\omega_0\tau_c \ll 1$, eqs. [10] to [12] can be simplified to:

$$[13]\quad \frac{1}{T_{2I}} = (1-f_b)\frac{1}{T_{2I}^0} + \frac{15\pi^2}{10}f_b C_{Q0}^2\langle {S_k}^2\tau_k\rangle_b$$

$$[14]\quad \frac{1}{T_{2J}} = (1-f_b)\frac{1}{T_{2J}^0} + \frac{9\pi^2}{10}f_b\, C_{Q0}^2\langle {S_k}^2\tau_k\rangle_b$$

$$[15]\quad \frac{1}{T_1} = (1-f_b)\frac{1}{T_1^0} + \frac{15\pi^2}{10}f_b\, C_{Q0}^2\langle {S_k}^2\tau_k\rangle_b$$

where $\langle {S_k}^2\tau_k\rangle_b$ is the average of ${S_k}^2\tau_k$ over the anisotropic sites. eqs. [13] and [14] demonstrate why the T_2 relaxation time used for ZQF, T_{2I}, is 3/5 times that used for the DQF relaxation, T_{2J}.[76] The T_2 values plotted in this work and listed in the Supplementary data, Table S1, correspond to T_{2J}.

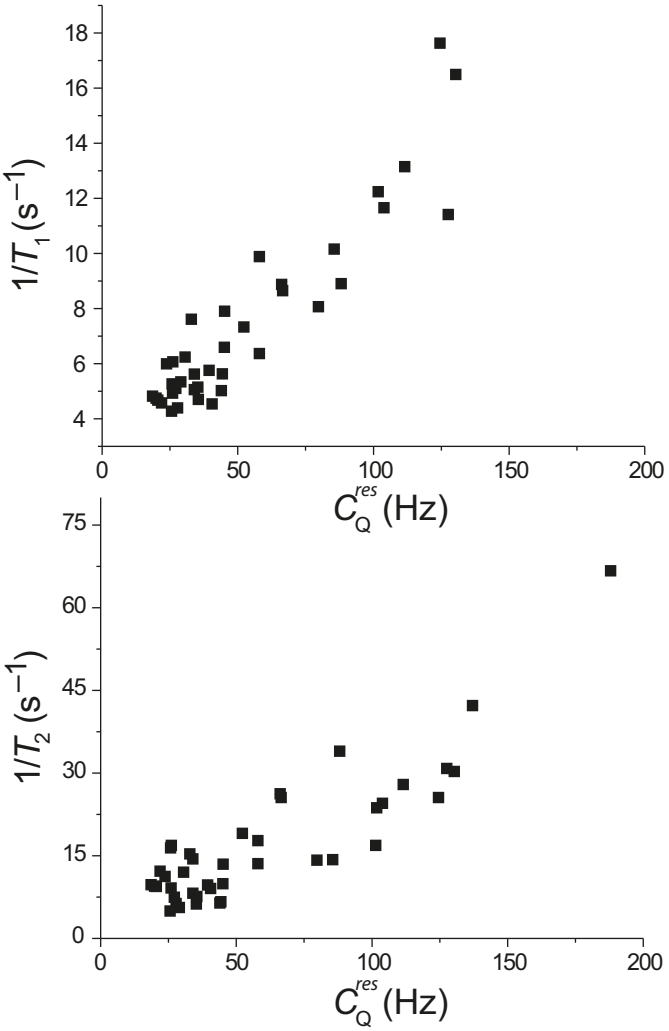
These equations show that relaxation depends on a structural parameter, describing the geometric order of the water in the anisotropic sites, as well as the fraction of time the water spends at these sites. These same considerations were used to express the quadrupolar couplings in eq. [9] where the same parameter, f_b, was used. By substituting eq. [9] into eqs. [13] and [15], a correlation between the measured relaxation rates and quadrupolar couplings can be made:

$$[16]\quad \frac{1}{T_{2J}} = \frac{1}{T_{2J}^0} + \left(\frac{9\pi^2 C_{Q0}^2\langle {S_k}^2\tau_k\rangle_b}{10\quad\langle Q_k\rangle_b} - \frac{1}{T_{2J}^0\langle Q_k\rangle_b}\right)Q_{res}$$

$$[17]\quad \frac{1}{T_{1,2I}} = \frac{1}{T_{1,2I}^0} + \left(\frac{3\pi^2 C_{Q0}^2\langle {S_k}^2\tau_k\rangle_b}{2\quad\langle Q_k\rangle_b} - \frac{1}{T_{1,2I}^0\langle Q_k\rangle_b}\right)Q_{res}$$

The plots of the $1/T_1$ and $1/T_{2I}$ against C_Q^{res} shown in Fig. 8 reveal a clear linear relationship. By assuming that C_Q^{res} is proportional to Q_{res} (assume that η_Q is constant in the various binding sites and that the distribution of orientations remains the same), the slopes and intercepts of the plots in Fig. 8 and eqs. [16] and [17] can be used to determine that the order of magnitude for $\langle {S_k}^2\tau_k\rangle_b$ is 10^{-12}. This small value suggests that, even at low hydrations, the average anisotropy that water molecules experience is small. More importantly, $\langle {S_k}^2\tau_k\rangle_b$ is constant within an order of magnitude, suggesting that the anisotropic sites water molecules experience are not changing dramatically as a function of hydration. The changes in both relaxation rates and the C_Q^{res} observed experimentally likely arise from changes in the fraction of time water spends in anisotropic environments, f_b.

Fig. 8. Plots of $1/T_1$ (top) and $1/T_2$ (bottom) vs C_Q^{res} for the Site **A** waters. Fitting the data to straight lines yields slopes of 0.08 and 0.22 and intercepts of 3.1 and 3.6 for the $1/T_1$ and $1/T_2$ data, respectively. The T_2 data used corresponds to $T_{2J;}$ see text.



While this analysis of the relaxation data does not disprove the Gierke model of hydration, the lack of change in the anisotropic sites, suggesting limited structural changes as hydration increases, is consistent with the parallel-channel model where the structure of the anisotropic sites is controlled by the rigid backbone of the polymer and does not change significantly as the channels expand due to increasing hydration.

Conclusions

Double- and zero-quantum filtered ^2H NMR spectra were acquired for D_2O in a Nafion membrane as a function of hydration. The qualitative trends observed in the spectra are consistent with a system that has expanding water domains leading to smaller residual quadrupolar couplings and longer relaxation times. The sensitivity of the signal-intensity buildup curves, particularly of the DQF spectra, may be useful as a molecular-level contrast mechanism for imaging experiments of operating fuel cells.

By fitting the experimental spectra with calculated spectra we have determine the C_Q^{res} and T_2 relaxation values for different hydration levels. It was found that above $\lambda = 10$ a two-site model was required to adequately fit the data; the second site had a negligible quadrupolar coupling, indicating that it undergoes nearly isotropic motional averaging. Using the EMOR model of Halle, the results indicate that the changes in relaxation times and C_Q^{res} as a function of hydration are likely dominated by changes in the fraction of time the water spends in the anisotropic environments and not on the structural nature of the environments. These results support a hydration model where two domains exist,[68] a first hydration layer that experiences anisotropic motion due to interaction with the polymer, and a core layer where the water molecules experience nearly isotropic motional averaging. As the sample is hydrated, the water in the first hydration layer spends less time interacting with the walls resulting in the smaller C_Q^{res} and longer relaxation times observed. This hydration model fits well with the parallel channel model proposed by Schmidt-Rohr and Chen. The ability of MQF ^2H NMR to characterize water in Nafion indicates that these methods will be useful for studying other hydrated polymer membranes.

Supplementary data

Supplementary data for this article are available on the journal Web site (www.nrcresearchpress.com/cjc).

Acknowledgments

The authors thank the members of the NMR group and the department of chemistry at The King's University College for helpful comments. Alexander Vega is also thanked for many helpful discussions and his aid in understanding the relaxation models. Natural Sciences and Engineering Research Council of Canada (NSERC) and The King's University College are thanked for financial support. MAB thanks NSERC for a USRA. Finally, KJO thanks Rod Wasylishen for his many contributions to science and his enthusiastic mentoring, teaching, and friendship.

Abstract: ^{139}La solid-state NMR spectra, acquired at 21.1 and 11.7 T, have been used to evaluate the structural properties of the lithium ion battery materials, $La_{32}Li_{16}Fe_{6.4}O_{67}$ and $Li_{3x}La_{2/3-x}TiO_3$. In particular, atomic-level disorder in the second coordination sphere environment of lanthanum in these materials has been indicated by the observation of a distribution in the asymmetry parameters and the quadrupolar coupling constants derived from experimental NMR spectra, and supported by theoretical calculations. For comparison, ^{139}La NMR has been obtained for the two model compounds La_2O_3 and $LaNbO_4$, in which there is no atomic-level disorder. Quadrupolar coupling constants in the range of 17 to 59 MHz have been measured, and these values are supported by previous work as well as theoretical predictions performed in CASTEP. It has been shown that ^{139}La NMR is a useful tool for the structural analysis of lithium ion battery materials, and when combined with ^{7}Li MAS NMR and powder X-ray diffraction, can be used to determine the structure of complex solid-state electrolyte and electrode materials.

Key words: NMR, quadrupolar nuclei, lithium ion batteries, ^{139}La.

Résumé : On a utilisé les spectres RMN du ^{139}La à l'état solide, acquis à 21,1 et 11,7 T, pour évaluer les propriétés structurales des matériaux ioniques du lithium utilisés pour les batteries, $La_{32}Li_{16}Fe_{6,4}O_{67}$ et $L1_{3x}La_{2/3-x}TiO_3$. En particulier, un désordre au niveau atomique dans la deuxième sphère de coordination de l'environnement du lanthane de ces matériaux a été mis en évidence par l'observation d'une distribution dans les paramètres d'asymétrie et dans les constantes de couplage quadripolaire obtenues à partir des spectres RMN expérimentaux et confirmées par des calculs théoriques. À des fins de comparaison, on a aussi déterminé les spectres RMN du ^{139}La de deux composés modèles, La_2O_3 et $LaNbO_4$, dans lesquels on n'observe aucun désordre au niveau atomique. On a mesuré des constantes de couplage quadripolaire de l'ordre de 17 et 19 MHz; ces valeurs sont en accord avec celles rapportées dans un travail antérieur et elles correspondent aux valeurs calculées par le programme CASTEP. On a démontré que la RMN du ^{139}La est un outil utile pour l'analyse structurale des matériaux ioniques du lithium utilisés dans les batteries et que, lorsque combinée avec la RMN avec rotation à l'angle magique (RAM) et la diffraction des rayons-X, elle peut être utilisée pour déterminer la structure d'électrolytes complexes à l'état solide et de matériaux d'électrode.

Mots-clés : RMN, noyau quadripolaire, batteries aux ions lithium, ^{139}La.

[Traduit par la Rédaction]

Introduction

Lithium ion batteries play an important role in the development of environmentally friendly energy sources.[1] With applications in many portable electronic devices, lithium ion batteries are sought after in the automotive industry, as their high power and energy density make them ideal for use in electric vehicles.[1] Battery research involves the development of materials to replace current cathode, anode, and electrolyte materials with more environmentally friendly and safer materials, which have longer lifetimes and lower costs.[1] In particular, there has been much interest in replacing the traditional liquid lithium electrolyte with a solid electrolyte, capable of running at a higher voltage.[1–3] Garnet-like materials have shown great potential for this application, and research into the structure and dynamics of these materials has primarily been performed using powder X-ray diffraction and neutron diffraction.[2–4]

^{6,7}Li magic angle spinning (MAS) solid-state NMR is a useful nondestructive tool to study the structures of these materials as well as their lithium ion dynamics; however, in the absence of any paramagnetic interactions, both ^{6}Li and ^{7}Li suffer from poor chemical shift resolution and long T_1 relaxation times. Of the two, ^{6}Li is somewhat preferable, as it has smaller line widths in NMR spectral peaks. This is due to the reduction of the homonuclear dipolar coupling of this lower gamma nucleus.[5,6] In addition to electrolytes, cathode materials, aimed at replacing the currently used $LiCoO_2$, are highly sought after.[7–9] They often contain paramagnetic centers that provide unpaired electrons, which allow the lithium centers in the materials to have short T_1 relaxation times and an expanded chemical shift range.[7,10] ^{6,7}Li MAS NMR, along with powder X-ray diffraction, provides a powerful tool to study the structure as well as the nature of lithium ion dynamics in lithium ion battery materials.[6] Furthermore, many of the garnet structures proposed thus far for these applications contain significant amounts of lanthanum, an NMR active nucleus with spin 7/2, thus ^{139}La NMR may be a valuable tool in the structural analysis of these and other related materials.[6,11,12]

^{139}La NMR has been used to study highly ordered lanthanum-containing compounds, such as lanthanum halides and organometallic compounds.[13–15] It has been found that the NMR parameters obtained from simulating NMR spectra agree with calculations. These values can be used to support claims for the predicted crystal structures of these materials.

Bastow et al., in addition to the work on La_2O_3, have shown that ^{139}La NMR is capable of detecting atomic-level disorder in materials that contain atomic substitution within different crystallographic sites.[16,17] The authors used samples with high symmetry (cubic), to show that with increased doping, and thus increased complexity in the atomic distribution, the quadrupolar coupling and asymmetry parameter C_Q and η, respectively, became increasingly difficult to measure. There was evident line broadening of the ^{139}La spectrum, due to the increased distribution of C_Q and η, resulting from the induced atomic-level disorder.[16] Another challenge faced by Bastow et al. in their collection of the ^{139}La NMR spectra at 9.4 T was the extremely broad linewidth of the central transition, such that the spectrum collected with one central frequency offset did not show the full central transition. The excitation frequency was consequently moved so that several piecewise spectra were collected to observe the full lineshape of the central transition, a very time-consuming process.[16]

In this work, a ^{139}La NMR WURST approach has been used in the structural analysis of a new lithium battery cathode material and other related structures. This study has primarily focused on the ^{139}La quadrupole powder patterns obtained for these structures, with the aim of drawing a correlation between the observed powder patterns and the nature of disorder in the second coordination sphere of lanthanum.

Challenges of ^{139}La solid-state NMR

Although ^{139}La is an NMR active nucleus with high natural abundance, 99.91%, and many materials significant to the development of materials science contain large amounts of lanthanum, ^{139}La NMR is not performed routinely.[18–20] This is mainly due to the many challenges associated with the collection and interpretation of the NMR spectra. ^{139}La has a nuclear spin $I = 7/2$, with a large quadrupole moment, 0.21 b, and a moderate gyromagnetic ratio, $\gamma = 3.8085 \times 10^7$ rad T^{-1} s^{-1}.[15] The EFG-dominated spectra of ^{139}La are very broad, which makes low-field NMR measurements quite difficult. Nevertheless, it has been shown that ^{139}La NMR is sensitive to the symmetry elements of lanthanum containing structures, with resulting NMR line shapes being heavily dependent on the asymmetry parameter η, defined in eq. [1]; and the quadrupolar coupling constant C_Q, defined in eq. [2], which are known to vary according to the elements of symmetry present at the nucleus of interest.[21]

$$[1] \qquad \eta = \frac{V_{xx} - V_{yy}}{V_{zz}}$$

$$[2] \qquad C_Q = \frac{e^2qQ}{\hbar} = \frac{(eq)eQ}{\hbar}$$

where V_{xx}, V_{yy}, and V_{zz} are the three components of a electric field gradient (EFG) tensor in the principle axis frame, which is traceless[22,23]; $eq = V_{zz}$, i.e., the magnitude of the largest component of the EFG tensor; eQ = nuclear quadrupole moment; $\hbar$ = reduced Planck constant.[23] In addition, the EFG tensor components are ordered as: $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$.

Recently introduced solid-state NMR pulse sequences, such as the WURST-QCPMG and WURST-echo, which make use of a wide adiabatic frequency-swept pulse, allow the excitation of large spectral width within a single pulse and can be employed to assist in the collection of broad NMR spectra.[24,25]

The parameters C_Q and η, which can be obtained by the simulation of the quadrupole powder patterns, are dependent on the site symmetry of the nucleus in question. More specifically C_Q depends on the spherical symmetry of the La environment in its first coordination sphere, with a large C_Q caused by a nucleus being in a nonspherical environment; η depends on the symmetry of the EFG tensor, with $\eta = 0$ resulting from the axial symmetry of the traceless EFG tensor, as defined in eq. [1]; for example, for systems with threefold (or higher) axes of rotational symmetry, if V_{zz} is oriented along the rotational axes, then $\eta = 0$ as $V_{xx} = V_{yy}$.[15] This is illustrated further in the text below for La_2O_3.

Crystalline $LaNbO_4$ and La_2O_3 are both highly ordered compounds, which show no sign of disorder in their crystal structures.[26,27] In both of these materials, lanthanum is surrounded only by oxygen in the first coordination sphere. In each case, the ^{139}La spectra is a clear representation of a single ^{139}La crystallographic site. For these reasons $LaNbO_4$ and La_2O_3 have been chosen as model compounds in this work. In contrast, the materials $Li_{16}La_{32}Fe_{6.4}O_{67}$ and $Li_{3x}La_{2/3-x}TiO_3$ ($x \leq 0.03 \leq 0.063$) are known to show disorder in the form of atomic distribution on particular crystallographic sites, which occurs as a result of vacancies present in the materials.[28,29]

The garnet-like structure $Li_{16}La_{32}Fe_{6.4}O_{67}$ is a potential cathode material for lithium ion batteries. The structure contains iron centers, which provide unpaired electrons that reduce the T_1 relaxation times of lithium that is in close proximity to the iron centers.[28] $Li_{16}La_{32}Fe_{6.4}O_{67}$ was first prepared by Mazza et al., and it was thought that the lithium in

this compound occupied a single crystallographically unique site, while the lanthanum is distributed between two crystallographic sites, each with the lanthanum surrounded by oxygen in the first coordination sphere.[28] The source of disorder in this compound will be discussed later in this work. $Li_{3x}La_{2/3-x}TiO_3$ ($x \leq 0.03 \leq 0.063$) is a potential electrolyte material for lithium ion batteries and does not contain paramagnetic centers.[29] The disorder in this compound is attributed to the distribution of Li, La, and a vacancy, which can randomly occupy the same crystallographic site.[29]

In all of the materials mentioned, lanthanum is surrounded only by oxygen in the first coordination sphere. Thus, the ^{139}La NMR spectra can be compared directly to relate the lineshape of the spectra to the environment of the lanthanum in the crystal structures. Crystallographic information for each of these compounds is shown in Table 1, which presents the space groups, La–O bond distances, and second coordination sphere elements. In addition, the lanthanum environments in each of the structures are illustrated in Table 2. For each structure, lanthanum is shown in its oxygen environment as well as in its second coordination sphere environment.

Experimental

Synthesis

La_2O_3 was purchased from Sigma-Aldrich and exposed to air in ambient conditions. To produce La_2O_3 void of $La(OH)_3$ impurity, the purchased sample was heated at 900 °C for 24 h.[32] $LaNbO_4$ was obtained by a co-precipitation from $NbCl_5$ and $La(NO_3)_3$ by NH_3 with subsequent calcination at 800 °C.[33]

To prepare $Li_{3x}La_{2/3-x}TiO_3$ ($0.03 \leq x \leq 0.063$), stoichiometric amounts of La_2O_3, Li_2CO_3, and TiO_2 were mixed. The mixture was ball milled and heated at 500 °C. This process was repeated with temperatures of 800 and 1150 °C. A pellet was then pressed and annealed at 1350 °C to create the final product.[34] By comparing the experimental powder X-ray diffraction data to that reported by Ibarra et al., it has been determined that the content of lithium in the structure is consistent with the desired stoichiometry.[29]

To synthesize $La_{32}Li_{16}Fe_{6.4}O_{67}$, molar ratios of $LiNO_3$, La_2O_3 and Fe_2O_3 were weighed, mixed, and ball milled for 3 h, a 10% weight excess of $LiNO_3$ was used to account for lithium leaching. The mixture was sintered at 600 °C to remove nitrates and ball milled again before being pressed into a pellet and annealed at 850 °C. Phase analysis using powder X-ray diffraction determined that the correct phase was present.

NMR

^{139}La NMR spectra were acquired at two magnetic fields, 11.7 T (Larmor frequency, 70.6 MHz) and 21.1 T (Larmor frequency, 127.1 MHz). For experiments at 21.1 T, a Bruker Avance II 900 NMR spectrometer was used at the National Ultrahigh-Field NMR Facility for Solids (http://www.nmr900.ca). Experiments were performed with stationary samples using a home-built single-channel probe with a 5 mm i.d. solenoid coil. Depending on the sample, one of two pulse sequences was used: WURST-echo or WURST-QCPMG. Typically in the WURST-QCPMG experiments, 50 μs WURST pulses were applied and swept across a range of 1 MHz at a rate of 20 MHz/ms, with an RF power of 10 kHz. The spikelet-separation was set to be 2.5 kHz at 21.1 T and 5.0 kHz at 11.7 T. The number of echoes in a QCPMG train ranged from 32 to 64. Recycle delays of 0.2–0.5 s were found sufficient for complete relaxation in most samples. From 1000 to 40 000 transients were accumulated, depending on the sample. ^{139}La NMR spectra were also acquired at 11.7 T on a Bruker Avance III 500 NMR spectrometer using a 5 mm solenoid Bruker H/X probe. WURST pulse conditions were similar to those at 21.1 T. A number of spectra were obtained using a π/2–π/2 quadrupolar-echo pulse sequence, employing a 2 μs central-transition selective π/2 pulse, with RF power of 30 kHz. From 2000 to 4000 transients were accumulated. ^{139}La NMR spectra were referenced to external 1 mol/L $LaCl_3$ solution at 0 ppm. NMR spectral simulation was performed using WSolids[35] in most cases, DMFit[36] or QuadFit[37] programs were used for disordered systems (see text). Uncertainties were determined statistically by performing several simulations of each spectrum.

^{7}Li MAS NMR experiments were performed at 11.7 T (Larmor frequency, 194.4 MHz) on a Bruker Avance I 500 NMR spectrometer. Samples were spun at 20 kHz using a 2.5 mm Bruker MAS probe. A short 1 μs (π/8) excitation pulse and a sufficiently long relaxation delay of 20 s were used to ensure complete relaxation. A total of 2048 transients were accumulated. ^{7}Li NMR spectra were referenced to external 1 mol/L LiCl solution at 0 ppm, which was also used for calibrating the nonselective (π/2) pulse of 4 μs. The line-fit analysis was performed using TopSpin 2.1 software.

Powder X-Ray Diffraction

Room-temperature X-ray powder diffraction patterns were recorded on a PANalytical X'Pert Pro diffractometer with an

Table 2. The lanthanum environments in materials studied in this work.

Material	Oxygen environment	Second coordination sphere
$LaNbO_4$		La_2O_3		$La(OH)_3$		$Li_{3x}La_{2/3-x}TiO_3$ La-1		$Li_{3x}La_{2/3-x}TiO_3$ La-2		$Li_{16}La_{32}Fe_{6.4}O_{67}$ La-1		$Li_{16}La_{32}Fe_{6.4}O_{67}$ La-2		

Lanthanum is represented by a dark blue or red sphere. In the $La_{32}Li_{16}Fe_{6.4}O_{67}$ structure, lanthanum is also represented by the red or blue polyhedra (very dark and dark grey in print version), for clarity, as lanthanum lies in a complex environment. In addition, oxygen is represented by light blue spheres (light grey); niobium, by orange spheres (mid grey); titanium by green spheres (light grey); in $La_{32}Li_{16}Fe_{6.4}O_{67}$ a distinction is made between iron that participates in a distribution (green spheres) with lithium, and iron that does not (brown spheres, dark grey in print). The details of the distribution are discussed in the text. All crystallographic figures were prepared in XtalDraw software.[31]

X'Celerator detector and Cu $K\alpha_1$ radiation. The finely ground samples were deposited on zero background holders cut from a single crystal of silicon. The full-profile Rietveld refinement (GSAS[38]) was used for phase analyses.

Computational Methods

Quantum chemical calculations of the ^{139}La EFG and CS tensors were performed with available crystallographic data for La_2O_3,[27] $La(OH)_3$,[30], and $LaNbO_4$.[26] The original structure for $La(OH)_3$ did not contain hydrogen atoms. Before calculations, hydrogen atoms were placed in the expected positions, and the crystal structure was fully geometrically optimized.

The CASTEP NMR program[39,40] in the Accelrys Materials Studio 4.4 environment was utilized to carry out ab initio plane-wave density functional theory (DFT) calculations. Ultrasoft pseudopotentials, generated from the "on-the-fly" method in CASTEP, were used for all elements in a fine accuracy basis set, with a plane-wave basis set cut-off energy of 550 eV and with Monkhorst–Pack *k*-space grid sizes set automatically according to the fine accuracy basis set. The magnetic shielding tensors for ^{139}La were calculated using the projector gauge including augmented-wave method (GIPAW).[41,42] All calculations used the Perdew, Burke, and Ernzerhof (PBE) functionals in the generalized gradient approximation (GGA) for the exchange correlation energy.[43,44] The scalar-relativistic zero-order regular approximation (ZORA) was utilized in CASTEP calculations to take into account the relativistic effects.[45]

Results and discussion

$LaNbO_4$

In the first model compound, $LaNbO_4$, lanthanum contains only oxygen in its first coordination sphere. It has a monoclinic structure in space group *I*2/*c*. There is only one crystallographically unique lanthanum site in this compound and one niobium site. Lanthanum is coordinated to eight oxygen atoms within 2.7 Å, with a La–O bond distance range of 2.5–2.6 Å.[26] The minimum distance between La and Nb is 3.7 Å, and the minimum distance between La and another La atom is 3.9 Å.[26] Static solid-state NMR measurements were taken at 11.7 T and illustrate many of the challenges of ^{139}La solid-state NMR. Static spectra collected for $LaNbO_4$ using three different pulse sequences, quadrupolar-echo, WURST-QCPMG, and WURST-echo, are compared in Fig. 1.

This simple example already fully illustrates difficulties in obtaining high-quality ^{139}La NMR spectra for solid state samples. Even at 11.7 T, the static linewidth for this sample is in excess of 300 kHz. When the more traditional quadrupolar-echo pulse sequence is applied, the resulting spectrum shows a lineshape with attenuated intensity for outer discontinuities, compared with the simulated spectrum. This distortion is due to the limited excitation bandwidth of the rectangular $\pi/2$ pulse (2 μs). Near to the edge of the excitation bandwidth, the intensity of the excitation profile decreases significantly, resulting in the spectrum with attenuated intensity on its outer edges. To obtain a more accurate lineshape using the quadrupolar-echo pulse sequence it is often necessary to record several spectra with different central frequency offsets and then to add them together.[46,47] The WURST-echo approach affords much broader excitation bandwidth, so that the same spectrum can be correctly recorded using only a single central frequency offset in the same amount of time (Fig. 1).[25] In systems with sufficiently long T_2 relaxation times, the WURST-QCPMG approach[24] delivers all the advantages of WURST in providing broadband excitation, combined with significantly improved signal-to-noise. Because of

Fig. 1. ^{139}La WURST-QCPMG, WURST-Echo, and Quadrupole-Echo NMR spectra of $LaNbO_4$ taken at (*a*) 21.1 T and (*b*) 11.7 T. Asterisks (*) indicate a minor impurity in the sample. Simulations were performed using WSolids software.

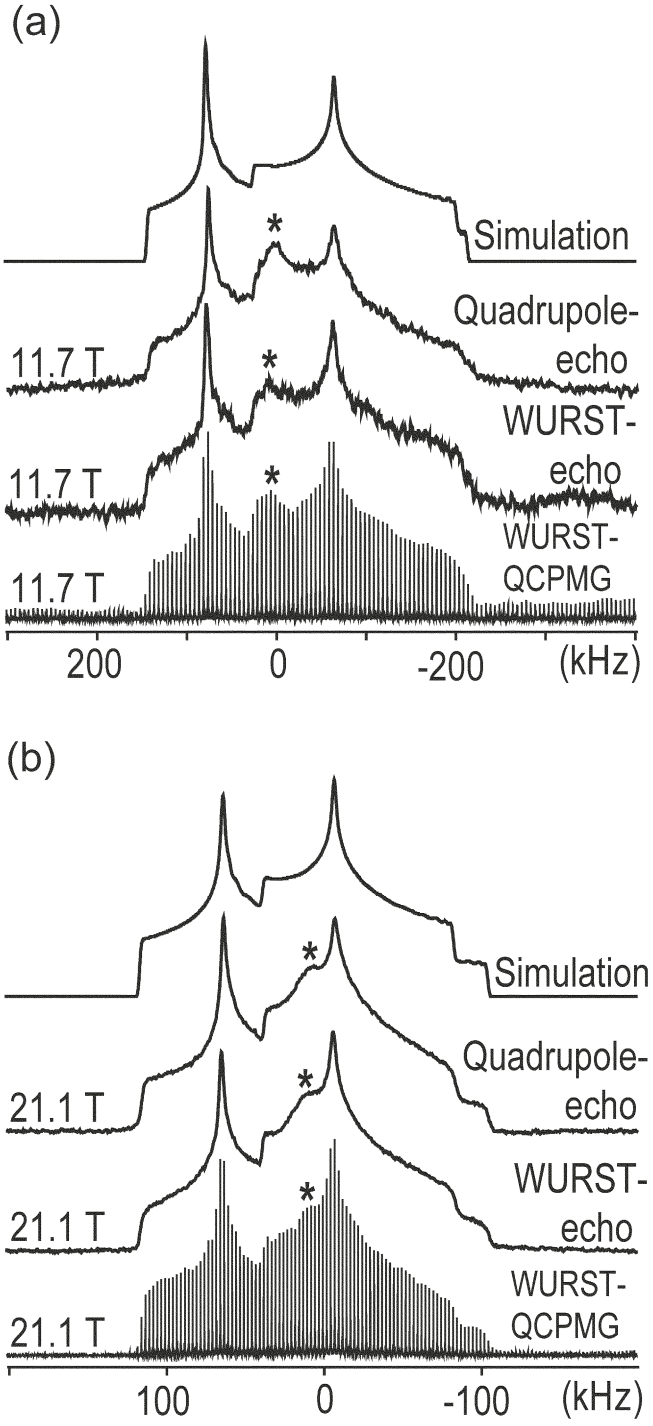

Table 3. Experimental and calculated ^{139}La NMR parameters in model compounds.

Material	Method	C_Q (MHz)	η	δ_{iso} (ppm)	Ω (ppm)	κ	α (°)	β (°)	γ (°)
$LaNbO_4$	Exptl.	36±2	0.44±0.05	295±25	255±10	0.40±0.04	90±5	50±5	270±10

spikelet oscillations in QCPMG, the finer details of the line shape are sometimes lost. Furthermore, we found that for disordered battery materials studied in this work, the T_2 relaxation times are rather short, which does not favour the use of the QCPMG method. Thus, the technique of choice in this work was the WURST-echo pulse sequence.

Simulations of the NMR spectra collected at 11.7 and 21.1 T (Fig. 1*b*) reveal a C_Q of 34 ± 2 MHz and η of 0.51 ± 0.05. Collecting the ^{139}La spectrum at two different magnetic fields allowed for the identification of a small impurity, marked with (*) in Figs. 1*a* and 1*b*. Contributions from quadrupolar interactions, as well as CSA, were considered, and the span, skew, and Euler angles, defined throughout this work as the angles that relate the CSA axis system to the EFG axis system, were determined to be 420 ± 10 ppm, 0.33 ± 0.05, $\alpha = 90° \pm 10°$, $\beta = 27° \pm 3°$, $\gamma = 270° \pm 10°$, respectively, and are in agreement with values predicted by CASTEP.[39] $LaNbO_4$ provides a good example of a system with complex NMR parameters that were challenging to simulate, and illustrates the advantage of using calculation software for NMR interpretation. CASTEP proved to be extremely beneficial in the simulation of the $LaNbO_4$ spectra obtained at 11.7 and 21.1 T, providing a starting point for the simulation: values of C_Q, η, the span, skew, and Euler angles. The values produced by CASTEP for this compound and others are shown in Table 3.

The second coordination sphere of La in $LaNbO_4$ contains both La and Nb, as shown in Table 2. The value of η obtained by simulation of the experimental spectra is 0.51 ± 0.05. Since the highest rotational symmetry element present is a two-fold rotational axis, which lies along the *b*-axis of the crystal, the experimental simulation is not sufficient to predict the respective orientation of $\boldsymbol{V}_{ZZ}$, the principle component of the EFG tensor. However, this information can be achieved by first principle calculations, which have been performed using CASTEP. The theoretically predicted orientation of the EFG tensor for $LaNbO_4$, with respect to the crystal axes, is shown in Fig. 2*a*, along with those of La_2O_3 (Fig. 2*b*) and $La(OH)_3$ (Fig. 2*c*).

^{139}La NMR powder patterns are known to be very sensitive to the environment surrounding La, often displaying high values of C_Q, as large as 105 MHz,[15] for La environments in which La has a nonspherical environment. In the case of $LaNbO_4$, the crystallographic parameters do not show disorder or partial occupancies in either the niobium or lanthanum positions, suggesting that the structure itself is ordered. This is consistent with the observed ^{139}La NMR spectrum that clearly shows a typical powder pattern for highly ordered samples with high crystalline symmetry. (The sensitivity of quadrupolar nuclei, such as lanthanum, is to the symmetry of the oxygen environment, as well as the complexity of the second coordination sphere)[15,48]

Lanthanum oxide

The second model compound, La_2O_3, is known to form a trigonal lattice structure with space group *P*-3*m1*, in which the lanthanum atoms are surrounded by seven oxygen atoms within 2.8 Å, with the La–O bond distance in the range of 2.4–2.8 Å. This structure is shown in Table 2, and the corresponding ^{139}La NMR spectra, collected at 11.7 and 21.1 T are shown in Figs. 3*a* and 3*b*. The spectra are dominated by the quadrupolar interactions, and at 11.7 T the full spectrum width is about 600 kHz. Yet even at this field, using the WURST-echo pulse, it was possible to acquire this spectrum with only a single central frequency offset. Since the second-order central-transition quadrupolar linewidth scales inversely with the field, the same spectrum recorded at 21.1 T is only about 300 kHz broad. Not only is it easier to obtain the correct line at the higher magnetic field, but the signal-to-noise is also significantly improved, which will become important when studying battery samples with lower lanthanum content. Another advantage of recording ^{139}La NMR spectra at 21.1 T is the fact that the chemical shielding interactions are proportional to the external magnetic field, and the quadrupolar interactions are inversely proportional to the external magnetic field, which facilitates the extraction of information about the chemical shielding interaction at higher magnetic fields.[13] In the La_2O_3 example (Figs. 3*a* and 3*b*), note how the singularity in the middle of the powder pattern moves to higher frequency in the high-field spectrum. The position of this singularity is directly related to the magnitude of CSA interactions, and the shift becomes more pronounced at higher magnetic field, allowing accurate quantification of CSA interactions.

The crystallographic lanthanum environment in the structure is simple, in that the major influence on lanthanum is its surrounding oxygen environment, with there being no lanthanum within 4.00 Å. Lanthanum sits in a pseudo-octahedral environment with six of the oxygen atoms, while the seventh oxygen is directly above this octahedral system, with the distance between lanthanum and the seventh oxygen being 2.555 Å. This nonspherical environment contributes to a lanthanum NMR spectrum with a large quadrupolar coupling

For personal use only.

constant C_Q of 59.0 ± 0.5 MHz. Simulations of ^{139}La NMR measurements also reveal an asymmetry parameter η of 0.00 ± 0.05, as shown in Fig. 3, which is consistent with lanthanum in an environment of three-fold or higher symmetry. This agrees with the work of Bastow, in which the ^{139}La NMR of La_2O_3 was recorded at 9.4 T, although no CSA contribution to the ^{139}La NMR spectrum was reported.[17] Nevertheless, in our ^{139}La NMR spectrum, in addition to EFG contributions, there is a contribution from the CSA, and the simulated spectrum produces a span Ω of 500 ppm ± 10 and a skew κ of –1 ± 0.1 with $\alpha = 150° \pm 30°$, $\beta = 90° \pm 10°$, and $\gamma = 180° \pm 10°$. These values were obtained by the simulation of NMR spectra collected at 21.1 and 11.7 T. The asymmetry parameter $\eta = 0$ arises from the axially symmetrical EFG tensor, which is the result of the three-fold rotational axis of the La_2O_3 crystal structure, which lies along the *c*-axis.[27] The values obtained for C_Q and η, by simulating the ^{139}La NMR spectrum, are supported by the values obtained through theoretical calculations using CASTEP: $C_Q = 56$ MHz and $\eta = 0$. In addition, CASTEP calculated a span of 260 ppm, a skew of –0.44, and Euler angles $\alpha = 150°$, $\beta = 88°$, and $\gamma = 180°$. These are shown in Table 3. The corresponding EFG tensors, as predicted by CASTEP, are shown with relation to the crystal axis in Fig. 2*b*.[39] It is clear that the major EFG tensor component, V_{zz}, is oriented along the *c*-axis of the crystal, which has three-fold rotational axis that passes through the center of the La atom. This supports the experimental finding of η being of 0.00 ± 0.05, with the axial line shape evident in the ^{139}La NMR spectra.

For comparison, the ^{139}La NMR spectra of La_2O_3 that was exposed to air in ambient conditions were measured at 21.1 T (Fig. 3*c*). An impurity is clearly visible in the ^{139}La NMR of the exposed sample.[32] (To obtain the pure La_2O_3 sample, the exposed sample was heated in air at 900 °C for 24 h.) Simulation of the NMR spectrum obtained at 21.1 T shows that the peak representing the La-impurity was found to have a C_Q of 22.0 ± 0.5 MHz and an η of 0.00 ± 0.05, with a span of 80 ± 7 ppm, skew of 0, and $\alpha = 90° \pm 30°$, $\beta = 10° \pm 10°$, $\gamma = 0° \pm 10°$. These values are also supported by measurements taken at 11.7 T. It has been shown that lanthanum oxide is reactive to air under ambient conditions, and $La(OH)_3$ is found to be formed in La_2O_3.[32] By measuring the ^{139}La NMR spectrum of $La(OH)_3$ at 9.4 T, Herreros et al.[21] reported that the C_Q and η for this compound are 20.5 MHz ± 0.5 and 0.05 ± 0.05, respectively. From the similarity in the spectra obtained, it can be concluded that the second phase present in this compound consists primarily of $La(OH)_3$. Further support is given by theoretical predictions performed in CASTEP. The theoretically predicted values are shown in Table 3, along with the experimentally obtained results. $La(OH)_3$ CASTEP predictions result in a C_Q and η of –23.5 MHz and 0.00, respectively, which support the axial shape of the spectra obtained. The value of η suggests that the EFG tensor component V_{zz} lies along the *c*-axis of the $La(OH)_3$ crystal structure. This is consistent with the crystallographic information, which places $La(OH)_3$ in the space group $P63/m$ and shows that the lanthanum atom lies at the center of a three-fold rotational axis as well as a six-fold screw axis, which are both directed along the *c*-axis of the crystal.[30] Figure 2*c* shows the orientation of the theoretically calculated EFG tensor of $La(OH)_3$ with respect to the crystal axis. In addition, CASTEP produces values of 200 ppm and 0.01 for the span and skew, respectively, with Euler angles of $\alpha = 92°$, $\beta = 0°$, and $\gamma = 0°$. Although the theoretically predicted span is larger than that observed, the predicted Euler angles are in good agreement with the observed values. Theoretically predicted and experimentally obtained values are shown in Table 3. The parameters C_Q and η are a strong indication of the structure and local symmetry in lanthanum compounds, and thus ^{139}La NMR is a valuable tool in the study of lanthanum containing compounds.[32]

$Li_{3x}La_{2/3-x}TiO_3$ ($0.03 \leq x \leq 0.063$)

The ^{139}La NMR spectra of two model lanthanum-containing compounds have been shown, and each of these structures has been highly ordered, with lanthanum in a well-defined environment with respect to its second coordination sphere elements. In contrast, the fast lithium ion electrolyte material, $Li_{3x}La_{2/3-x}TiO_3$, has an orthorhombic, perovskite type structure in space group *Pmmm* and is known to have considerable disorder, which results from the ability of lithium and lanthanum to occupy the same crystallographic site.[29,34] $Li_{3x}La_{2/3-x}TiO_3$ consists of corner-shared TiO_6 octahedra, and the lanthanum and (or) lithium is situated between TiO_6 octahedra.[29] The crystal structure predicts two lanthanum environments, as shown in Table 2. Each environment is oxygen rich, and in each case La is coordinated to 12 oxygen atoms. The difference in the lanthanum atoms is in their positions in the unit cell, with La-1 positioned on the corners of the unit cell and La-2 at the center of the *c*-axis. In addition, the La sites have different La–O bond distances; although all La–O bonds lie in the range of 2.7–2.8 Å. Interestingly, the ^{139}La NMR spectrum recorded at two magnetic fields (Fig. 4) shows only one La peak. This asymmetric lineshape, which lacks the usual sharp discontinuities typically observed in quadrupole powder patterns, is skewed to one side and is indicative of substantial quadrupolar interaction. This lineshape is due to the disorder in the second coordination sphere of lanthanum, which usually results in distribution of the quadrupolar parameters C_Q and η.[16] This distribution also makes the C_Q and the η for the two sites irresolvable at both magnetic fields (21.1 and 11.7 T), since there are many sites with different quadrupolar parameters in this sample. Nevertheless, using appropriate simulation tools, many details of this distribution can still be extracted.

To effectively simulate the spectra to extract quadrupolar information, one needs to analyze the contribution in the spectrum of chemical shielding interaction and quadrupolar coupling interaction in the spectrum. As can be seen in Fig. 4, the full-width at half-height (FWHH) for the spectrum at 11.7 T is 53.5 kHz. At 21.1 T, the FWHH is reduced significantly to 34.0 kHz. This suggests that the spectra are dominated by second-order quadrupolar interaction and can be simulated neglecting the potential chemical shielding anisotropy of lanthanum. Using QuadFit,[37] which has the capability of including a distribution in the parameters η and C_Q, the spectra at the two fields were simulated accurately by considering the distribution of quadrupolar parameters, with the resulting simulations shown in Fig. 4. As can be seen in Table 4, the quadrupolar coupling constant of La in $Li_{3x}La_{2/}$

Fig. 2. EFG tensor orientations for (*a*) $LaNbO_4$, (*b*) La_2O_3, and (*c*) $La(OH)_3$. In each case V_{zz} is directed out of the page, while V_{xx} and V_{yy} lie in the a-b plane of the crystal axes. Tensor orientations are shown by green (grey in print version) arrows. Calculations of the EFG tensor orientations were performed in CASTEP. La is represented by dark blue (dark grey) spheres, O is represented by light blue spheres (light grey), and Nb is represented by orange spheres (mid grey).

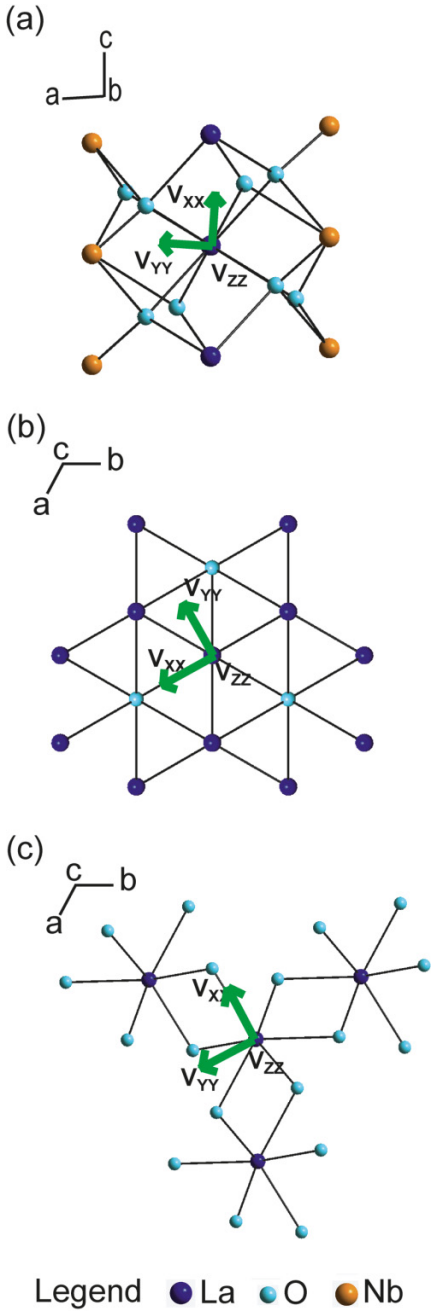

Fig. 3. ^{139}La NMR spectra of La_2O_3, heated at 900 °C to remove La $(OH)_3$ impurity: (*a*) taken at 21.1 T and (*b*) 11.7 T. (*c*) ^{139}La WURST-Echo NMR spectra at 21.1 T of La_2O_3, exposed to air in ambient conditions. Simulations were performed using WSolids Software.

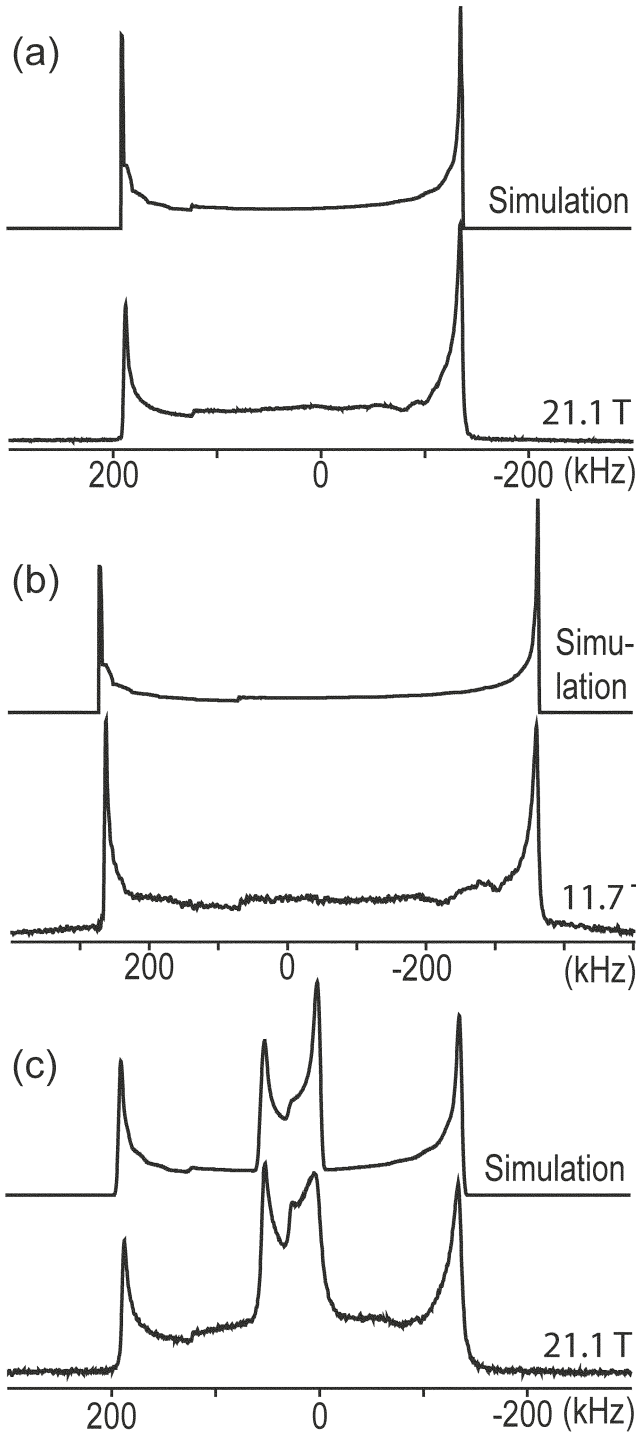

$_{3-x}TiO_3$ is ~22.5 MHz with a broad distribution of 14.5 MHz, although the asymmetry parameter is 0.75 with a narrow distribution of 0.15. It should be mentioned that almost no line broadening is needed in both simulations, which is expected for this sample, as it is highly crystalline. The extraction of quadrupolar information was also attempted by using the quadrupolar induced shift (QIS) that is inversely proportional to the external magnetic field.[49] Equation [3] is valid for a nucleus with $I = 7/2$.

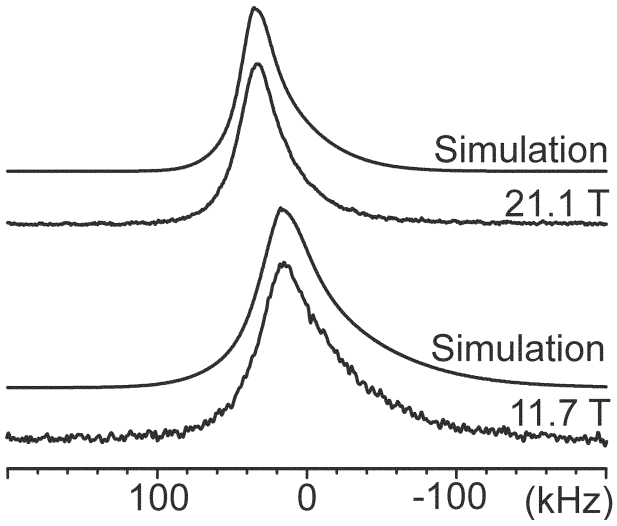
Fig. 4. ^{139}La WURST-Echo NMR spectra of $Li_{3x}La_{2/3-x}TiO_3$ collected at (top) 21.1 T and (bottom) 11.7 T . Simulations were performed in QuadFit and are shown above each spectrum.



$$[3] \qquad \delta_{CG} - \delta_{iso} = -2551.02\left(\frac{C_Q^2}{\nu_z^2}\right)\left(1+\frac{\eta^2}{3}\right)$$

Where δ_{CG} is the center of gravity of the peak, δ_{iso} is the isotropic chemical shift, ν_z is the Larmor frequency, C_Q is the quadrupolar coupling constant, η is the asymmetry, and 2551.02 is a constant, which varies with the spin I of the nucleus of interest. The measured centers of gravities of peaks at 11.7 and 21.1 T are 67 ppm and 217 ppm, respectively. Using eq. [3], one can obtain δ_{iso}, 284 ± 8 ppm, as shown in Table 4. However, C_Q and η cannot be determined unambiguously using this method. Since η has the range of 0 to 1, the minimum and the maximum values of C_Q can still be determined, which are 17.8 and 20.5 MHz, respectively. Although as can be seen in Table 4, the QuadFit and the QIS calculations give very similar isotropic chemical shifts and quadrupolar coupling constants, one should note that the QIS calculation does not allow the determination of the distribution of C_Q and η, owing to the fact that the QIS calculation considers only the position of centre of gravity, not the overall lineshape. The minimum and the maximum values of C_Q are not the actual distributions of C_Q but the values corresponding to the minimum and the maximum values of the asymmetry parameter. Both spectra can be simulated with a single site without considering the distribution of C_Q and η as well, although a very high line-broadening value was necessary. The results are also presented in Table 4 for comparison. It can be seen that the simple simulation without distributions of C_Q and η gives results close to the previous methods. This may be due, coincidently, to the high asymmetry parameter of this particular sample. It has been shown previously that a featureless line shape like spectra in Fig. 4 could result from a very low asymmetry but with broad distribution of quadrupolar parameters.[50]

The distribution of quadrupolar parameters obtained above can be explained by analyzing the second coordination sphere of La in the crystal structure, which contains lanthanum, lithium, and a vacant site in a disordered distribution.[29,34] Lanthanum is in a highly symmetric environment according to the surrounding oxygen atoms, which form a cubelike arrangement around the La atoms. The highest symmetry element present is a two-fold rotational axis, which passes through both La-1 and La-2, which agrees with $\eta \neq 0$. It should be noted here that there are several possible structures of lithium lanthanum titanate materials.[51,52] Powder X-ray diffraction was used to determine that the structure of interest was in fact $Li_{3x}La_{2/3-x}TiO_3$ ($0.03 \leq x \leq 0.063$).[29] ^{139}La NMR proved to be a very useful conformational technique, in that other lithium lanthanum titanate structures are of higher symmetry, and most contain rotational axes, either three- or four-fold, that run through La. The nonzero η obtained by simulating the NMR spectrum obtained for this material confirmed that it was the correct structure, with only two-fold rotational symmetry.

The lithium atoms as well as the vacant sites in this structure are known to substitute lanthanum in its crystallographic sites, displacing a stoichiometric amount of the lanthanum from the crystal structure.[29,34] This means that for each lanthanum atom in its original place in the crystal structure, the surrounding environment is disordered by the substitution of lanthanum for lithium, or a vacant site, in the second coordination sphere. This disordered lanthanum environment is present in the same context for both lanthanum sites, which leads to the featureless ^{139}La NMR spectra of $Li_{3x}La_{2/3-x}TiO_3$ at both fields.

The CASTEP NMR calculations were performed for this compound and the results are presented in Table 4. The $Li_{3x}La_{2/3-x}TiO_3$ sample represents a certain challenge for CASTEP NMR calculations because of significant disorder in cationic positions, as disorder or partial site occupancies are not implemented in the CASTEP code. Nevertheless, we have attempted to perform CASTEP calculations for three model structures, which best represent the real $Li_{3x}La_{2/3-x}TiO_3$ structure. The results are summarized in Table 4. In the first model structure, both sites, La-1 and La-2, were fully occupied. There was no Li present. Even though there is significant charge imbalance, the CASTEP results allow the discrimination of two La sites, and obtained C_Q and η values are reasonably close to those found experimentally. In the second model structure, the La-1 site was fully occupied with La, and the La-2 site was fully occupied with Li. The third structure has the site occupations inversed, the La-1 site was fully occupied with Li, and the La-2 site was fully occupied with La. As can be seen in Table 4, for these three model structures, the CASTEP calculated C_Q values are in the same general range as found in experiments.

$Li_{16}La_{32}Fe_{6.4}O_{67}$

The garnet-related structure, $Li_{16}La_{32}Fe_{6.4}O_{67}$, considered as a potential cathode material for lithium ion batteries, has a cubic structure in space group $Im3m$. Initial studies performed using ^{7}Li MAS NMR at 11.7 T indicated that the material may contain structural disorder. It was originally determined that the compound had one crystallographically unique lithium site, two lanthanum sites and two iron sites. This number of lithium sites, however, is not supported by ^{7}Li MAS NMR performed at 11.7 T, shown in Fig. 5. The lithium peaks represent a set of paramagnetic peaks between ~4 and ~25 ppm, and a set of diamagnetic peaks at ~0 ppm.

[e]Spectra were fitted using QuadFti with distributions for both C_Q (14.5 MHz) and η (0.15).
[f]Spectra were fitted using DMFit with a single site.

Here, the lithium peak that has a higher chemical shift is known to have the most paramagnetic character. This is supported by T_1 measurements that show that these peaks have T_1 relaxation values of ~11 ms, while the diamagnetic peaks have T_1 relaxation times greater than 100 s. The lithium atoms represented by the paramagnetic peaks are thus closest to one or more iron sites, while the peak at the lowest chemical shift has the least paramagnetic character because of its greater distance from iron and thus unpaired electrons in the structure.[7,10]

The different lithium environments arise from the ability of lithium to occupy vacant sites found on the Fe-2 site, represented by green (light grey in print version) spheres in Fig. 6*a*; this substitution is supported by powder X-ray analysis.[53] This Li–Fe substitution is the source of disorder in this structure, with the existence of vacant sites on the original Li sites as well as the Fe-2 sites, in which Li substitution occurs. This means that the compound contains a "variable" site, which may be occupied by Li, Fe, or a vacancy.[28] The variability of this site produces a distribution of lithium sites, which is responsible for the unique ^{7}Li MAS NMR spectrum.

To better understand the nature of the lithium distribution in this material, ^{139}La NMR was used to assign the La sites and to study their environments. There are two crystallographically unique La sites in this material: La-1 is coordinated to ten O atoms, while having La–O bond distances in the range of 2.5–2.7 Å; La-2 is coordinated to nine O atoms with La–O bond distances in the range 2.3–2.7 Å. ^{139}La NMR collected at 21.1 T, shown in Fig. 7, supports the crystallographic data and shows evidence of two lanthanum environments. Simulations of the NMR data show that La-2 has a C_Q of 56 ± 1 MHz and η of 0.05 ± 0.05. This large C_Q suggests that La-2 is in a nonspherical environment with respect to the surrounding oxygen, compared with La-1. In addition, La-2 contains little disorder in the second coordination sphere. Crystallographic information shows that the La-2 site lies on an axis of four-fold rotation, and four-fold roto-inversion, which is aligned with the *c*-axis of the crystal.[28] This high level of rotational symmetry is responsible for the experimentally obtained value of η of 0.05 ± 0.05. By comparison, simulations of NMR spectra show that La-1 has a C_Q of 29 ± 2 MHz and a η of 0.6 ± 0.1, suggesting that La-1 is in a more spherical oxygen environment and yet in a position of lower symmetry than La-2, since the highest symmetry element present for La-1 is a two-fold rotational axis. The low symmetry of this site is responsible for the observed values of η, 0.6 ± 1, which is considerably different than that of La-2. A considerable amount of line broadening was necessary to simulate this peak, which may be an indication that the NMR parameters of the La-1 site cannot be described by a single set of values of C_Q or η, or rather that there is a distribution of C_Q and (or) η for this particular site, similar to

(*a*) Diagram of $Li_{16}La_{32}Fe_{6.4}O_{67}$ crystal structure showing a single unit cell, with La-1 and La-2 represented by red and blue spheres, respectively, Li by yellow spheres, and Fe-2 by brown polyhedra. The variable Li/Fe/vacant site is shown by green spheres. (*b*) The individual lanthanum sites showing the coordination to oxygen as well as the second coordination sphere environment around the La polyhedra. The brown spheres represent Fe-2, which does not participate in the Li–Fe disorder.

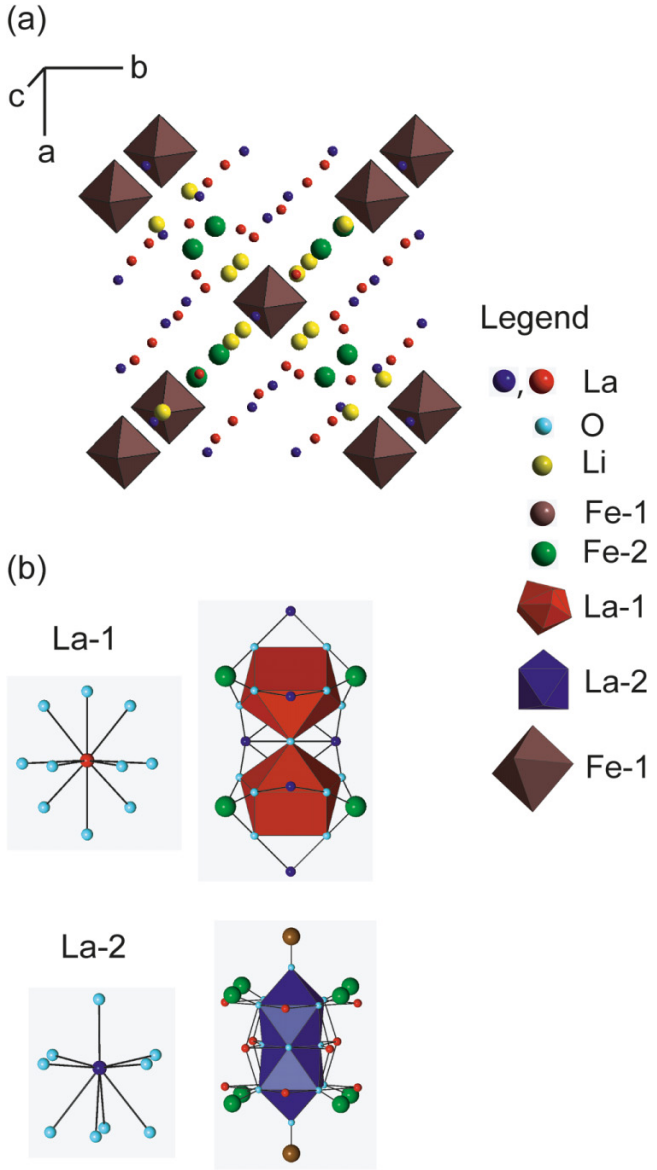

Fig. 7. ^{139}La WURST-Echo NMR spectra of $Li_{16}La_{32}Fe_{6.4}O_{67}$ collected at 21.1 T, shown with simulation. This spectrum can be represented as a superposition of two sites with La-1 having C_Q = 56.1 MHz and η = 0.05; and La-2 having C_Q = 29.8 MHz and η = 0.6. Simulations were performed using DMFit software.

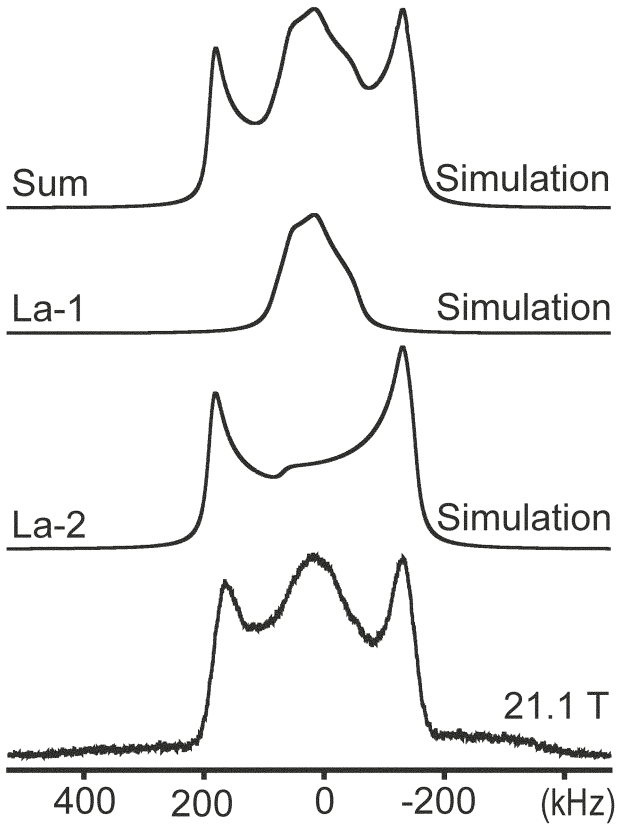

that seen in $Li_{3x}La_{2/3-x}TiO_3$. To evaluate the source of disorder in this material, the individual lanthanum environments are compared. Figure 6*b* shows the two lanthanum environments, with the respective first and second coordination sphere contents. The assignment of the ^{139}La NMR peaks was performed by analysis of the respective La environments given by crystallographic data.[28] The crystal structure shows that one of the sites, La-1, is close (3.2 Å) to the source of the disorder in the structure. This site is a variable Fe–Li–vacant site (shown in green in Fig. 6*a*). While the other lanthanum site, La-2, is much further (4.4 Å) from this site. The variable Fe–Li–vacant site provides a significant source of disorder, which accounts for the distribution in NMR parameters observed for La-1. This distribution of C_Q and η is seen clearly for La-1 but not for La-2. This can be explained by the difference in proximity to the source of disorder in the compound, as discussed above. This is further evidence that ^{139}La NMR can be used to evaluate structural features observed in complex systems containing atomic-level disorder found in the second coordination sphere of lanthanum. Theoretical calculations were not performed for $La_{32}Li_{16}Fe_{6.4}O_{67}$, because the unit cell volume is large (1830 Å^3), and the system has metallic character.[28]

The two battery materials, $Li_{16}La_{32}Fe_{6.4}O_{67}$ and $Li_{3x}La_{2/3-x}TiO_3$, each show considerable disorder in the second coordination sphere for at least one of their lanthanum environments, subsequently showing that lanthanum quadrupole parameters are sensitive to disorder in the second coordination sphere. This is reflected in the NMR spectra obtained and particularly in the values of C_Q and η extracted from simulating experimental data, with disorder being indicated by a distribution in NMR parameters. The sensitivity of the ^{139}La NMR is further pronounced when the different La sites of $Li_{16}La_{32}Fe_{6.4}O_{67}$ are considered. ^{139}La NMR can distinguish between these sites because of its sensitivity to the disorder.

Conclusion

This work has compared the ^{139}La static solid-state NMR spectra of the model materials $LaNbO_4$ and La_2O_3 to the spectra of potential lithium ion battery materials $Li_{3x}La_{2/3-x}TiO_3$ and $Li_{16}La_{32}Fe_{6.4}O_{67}$. The model materials represent materials in which the ^{139}La environments are well-defined and are not in close proximity to atomic-level disorder. In contrast, $Li_{3x}La_{2/3-x}TiO_3$ and $Li_{16}La_{32}Fe_{6.4}O_{67}$ each show instances of atomic-level disorder, which can be detected by ^{139}La NMR.

It has been illustrated here that lanthanum containing lithium ion battery materials can be effectively studied using ^{139}La NMR, as it is a sensitive probe of local symmetry. Structural analysis performed using ^{139}La NMR can distinguish between different lanthanum sites by evaluating the values of C_Q and η through the measurement and subsequent simulation of ^{139}La NMR powder line shapes. Theoretical calculations performed in CASTEP were supportive of results obtained through experiments simulations. This information can be used to indicate the presence of disorder in the second coordination sphere around a specific lanthanum site, which manifests itself as a distribution of experimental values of C_Q and η for a lanthanum site in close proximity to a source of disorder. This method shows promise when applied to the understanding of complex structures. In combination with ^{7}Li MAS NMR and powder X-ray diffraction, this is a powerful tool that can be used to probe structures rich in lanthanum and subsequently help in the analysis of battery materials that contain atomic-level disorder.

Acknowledgements

We would like to thank Jim Garret in the BIMR Institute at McMaster University in Hamilton, Ontario, for advice and assistance in materials preparation. The two anonymous reviewers are thanked for valuable comments. Access to the 900 MHz NMR spectrometer and CASTEP software was provided by the National Ultrahigh-Field NMR Facility for Solids (Ottawa, Canada), a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council Canada, and Bruker BioSpin and managed by the University of Ottawa (www.nmr900.ca). In addition, we thank The Natural Sciences and Engineering Research Council of Canada (NSERC) in acknowledgement of a Major Resources Support grant. The authors also gratefully acknowledge funding through the AUTO21 Centers of Excellence program.

Abstract: Solid-state ^{73}Ge nuclear magnetic resonance (NMR) is an attractive technique for the characterization of solid germanium-containing materials, but experiments can be exceedingly difficult in practice due to the unfavourable NMR properties of the ^{73}Ge nucleus. Presented herein is a series of solid-state ^{73}Ge NMR experiments on germanium halides (GeX_4 and GeX_2, where X = I, Br, and Cl) conducted at moderate (9.4 and 11.7 T) and ultrahigh (21.1 T) magnetic fields, intended to characterize the ^{73}Ge NMR response in highly symmetric and asymmetric coordination environments. Quadrupole coupling constants range from 0.16 to 35 MHz. Isotropic chemical shifts for the GeX_4 series trend with halide electronegativity, as found for the analogous silicon and tin halides. The indirect spin-spin coupling constant $^1J(^{73}Ge, ^{127}I)$ is estimated from ^{73}Ge MAS NMR to be 35 ± 10 Hz in GeI_2, with the reduced coupling constant agreeing with those of other group 14 halides. Quantum chemical calculations using GIPAW DFT are in reasonable accord with experimental quadrupole couplings, but fail for chemical shielding. A preliminary NMR crystallographic study of GeI_2 and $GeCl_2$ incorporating ^{127}I and ^{35}Cl NMR spectra has led to plausible conclusions reflecting the structural homology of these compounds, although definitive characterization remains elusive.

Key words: germanium halides, solid state nuclear magnetic resonance, ^{73}Ge NMR, GIPAW DFT, quadrupole interaction.

Résumé : La résonance magnétique nucléaire (RMN) du ^{73}Ge à l'état solide est une technique attrayante pour la caractérisation de matériaux contenant du germanium, mais les expériences peuvent être très difficiles en pratique en raison des propriétés RMN défavorables du noyau ^{73}Ge. Dans le présent travail, on présente une série d'expériences de RMN du ^{73}Ge à l'état solide effectuées sur des halogénures de germanium (GeX_4 et GeX_2, dans lesquels X = I, Br et Cl), à des champs magnétiques modérés (9,4 et 11,7 T) et extrêmement élevés (21,1 T) dans le but de caractériser la réponse de la RMN du ^{73}Ge dans des environnements de coordination très symétriques et asymétriques. Les constantes de couplage quadripolaire s'étalent de 0,16 à 35 MHz. La tendance des déplacements chimiques isotropes pour la série GeX_4 varie suivant l'électronégativité de l'halogénure, comme il avait été observé pour les analogues halogénés du silicium et de l'étain. En se basant sur la RMN du ^{73}Ge avec rotation à l'angle magique (RAM), on a évalué que la constante de couplage spin-spin indirect, $^1J(^{73}Ge,^{127}I)$, est égale à 35 ± 10 Hz, pour le GeI_2, pour lequel la constante de couplage réduite est en accord avec d'autres halogénures d'éléments du groupe 14. Des calculs de chimie quantique par la théorie de la fonctionnelle de la densité en utilisant une onde améliorée par un opérateur de projection comportant une jauge (« GIPAW-DFT ») sont en accord raisonnable avec les données expérimentales pour les couplages quadripolaires, mais elles ne donnent pas de bons résultats pour le blindage chimique. Une étude cristallographique préliminaire par RMN du GeI_2 et du $GeCl_2$ comportant des spectres RMN du ^{127}I et du ^{35}Cl conduit à des conclusions plausibles qui reflètent l'homologie structurale de ces composés, même si leur caractérisation définitive demeure incertaine.

Mots-clés : halogénures de germanium, résonance magnétique nucléaire à l'état solide, RMN du ^{73}Ge, théorie de la fonctionnelle de la densité en utilisant une onde améliorée par un opérateur de projection comportant une jauge (“GIPAW-DFT”), interaction quadripolaire.

Introduction

Germanium is a key element in a variety of compounds, exhibiting useful properties in mesoporous materials, semiconductors, and optical materials.[1–3] For example, germanium has been used in the development of ordered mesoporous oxide materials with tuneable properties.[4] Bearing chemical similarities to silicon, germanium is an efficient semiconductor and often finds commercial use in the biomedical field as well as in optical and telecommunication products.[5] In recent years, multifunctional nanomaterials that integrate the useful semiconducting properties of germanium into mesoporous structures have been developed.[6]

To advance research and development of these materials, various characterization tools are required to understand the interactions and structural properties present in a given system. Nuclear magnetic resonance (NMR) spectroscopy probes the local atomic environment, and appears to be an attractive technique for such characterization. However, the intrinsic properties of the ^{73}Ge nucleus (the only NMR-active stable isotope of germanium) present experimental difficulties, evidenced by the limited number of publications reporting solid-state ^{73}Ge NMR spectroscopy studies of nonmetallic germanium materials.[7–17] Germanium-73 is a quadrupolar nucleus ($I = 9/2$) with a low natural abundance (7.73%), moderately large quadrupolar moment ($Q = -19.6$ fm^2), low magnetogyric ratio ($\gamma = -0.936 \times 10^7$ rad T^{-1} s^{-1}), and correspondingly low resonance frequency (13.95 MHz at 9.4 T), with a relative receptivity of 1.09×10^{-4} compared with ^{1}H.[18] Despite the unfavourable properties, ultrahigh magnetic fields can be used to extract valuable information in many systems. At 21.1 T, for example, the resonance frequency of ^{73}Ge is 31.4 MHz, resulting in a more favourable Boltzmann population difference and a reduction in adverse probe-ringing effects, increasing the sensitivity. Furthermore, the second-order quadrupolar broadening is reduced, as it scales with the inverse-square of magnetic field strength, resulting in additional signal gains.[8] The only potential drawback of performing ^{73}Ge NMR experiments at high field is that any anisotropic shielding is amplified, however with rare exception,[14] this interaction will be eclipsed by the quadrupolar broadening.

In this study, we look at a series of germanium halides as models for the symmetrical germanium environments expected in semiconductors and mesoporous materials.[19–21] Two series of germanium halides, GeX_2 and GeX_4 (X = I, Br, and Cl), were investigated with an aim to study the electric field gradient (EFG) environments for ^{73}Ge and to observe any variations that occur between oxidation states, such as differences between the spectral features or chemical shift range. Further understanding is achieved through density functional theory (DFT) calculations, which guide experimental expectations and serve to substantiate the findings. We use the calculated parameters as a complement to the NMR experiment to provide insights on crystal structure.

Theory

In the presence of a strong magnetic field (B_0), the Zeeman effect causes splitting of spin-active nuclei ($I \geq 1/2$) into $2I + 1$ nuclear spin states, generating $2I$ possible single-quantum transitions. For quadrupolar nuclei ($I > 1/2$), multiple single-quantum frequencies must be considered: the central transition (CT; $1/2 \rightarrow -1/2$), and a total of $2I - 1$ satellite transitions ($\pm n/2 \rightarrow \pm (n - 2)/2$, where $n = 3$, 5, 7, and 9 for a spin-9/2 nucleus) appearing at a precise spacing from the CT, characteristic of the nuclear quadrupolar interaction. This quadrupolar interaction is quantified as the nuclear quadrupole coupling constant (C_Q), which describes the magnitude of the interaction between the electric quadrupole moment of the nucleus (eQ) and the surrounding electric field gradient (EFG), generated by the distribution of charge in the surrounding electronic environment and described by a second-rank tensor. This parameter is defined by the equation:

$$[1] \qquad C_Q = \frac{e^2qQ}{h}$$

where e is the charge of an electron, eQ describes the nuclear quadrupole moment of the nucleus, eq is the largest component of the EFG tensor (V_{ZZ}), and h is Planck's constant. A second term, the asymmetry parameter (η), describes the relative magnitudes of the EFG tensor principal components and hence the shape of the quadrupolar spectral pattern, defined by the equation:

$$[2] \qquad \eta = \frac{V_{XX} - V_{YY}}{V_{ZZ}}$$

where V_{XX}, V_{YY}, and V_{ZZ} are the principal components of the EFG tensor $|V_{XX}| < |V_{YY}| < |V_{ZZ}|$.[22]

In a powdered solid sample, there exists the distribution of all possible molecular orientations. If a molecule has lower than cubic symmetry, the chemical shielding around the nucleus will possess an orientational dependence in the magnetic field, termed chemical shift anisotropy (CSA). Spectra of this type will display three distinct discontinuities (chemical shifts) at δ_{11}, δ_{22}, and δ_{33}, defining the bounds and shape of the envelope. The average of these three components is the isotropic chemical shift (δ_{iso}). Two important descriptors of CSA are known as span (Ω) and skew (κ),[23] defined by the following equations:

$$[3] \qquad \Omega = \delta_{11} - \delta_{33}$$

$$[4] \qquad \kappa = \frac{3(\delta_{22} - \delta_{iso})}{\Omega}$$

While the quadrupolar coupling can often obscure the observation of CSA, it is important to consider for spectra which are not dominated by C_Q.

Experimental methods

Materials

$GeBr_2$ and GeI_4 samples were obtained from Sigma-Aldrich. $GeCl_4$, $GeBr_4$, and GeI_2 samples were obtained from Alfa Aesar. A second GeI_2 sample was obtained from Strem Chemicals. The $GeCl_2$ sample was obtained from MP Biomedicals. Liquid samples were cooled gradually or flash frozen with liquid nitrogen. All other samples were used without further modification.

Nuclear magnetic resonance

Germanium-73 NMR

^{73}Ge NMR experiments for $GeCl_2$, $GeCl_4$, $GeBr_4$, GeI_2, and GeI_4 were performed on a Bruker AMX 500 NMR spectrometer (B_0 = 11.7 T) at 17.4 MHz using a 5 mm home-built low-γ solenoid probe (for $GeCl_2$, $GeBr_4$, GeI_2, and GeI_4) and a 5 mm solution inverse probe with variable temperature (VT) capabilities (for $GeCl_4$). A Hahn-echo pulse sequence was used to collect the spectra with 4 μs (90°) and 8 μs (180°) pulse lengths, ν_{rf} of 25 kHz, and recycle delays of 2–3 s, with 16 000–120 000 co-added transients. For all ^{73}Ge NMR spectra, chemical shifts are reported with respect to tetramethylgermanium, using neat germanium (IV) chloride as a secondary reference (+30.9 ppm).

^{73}Ge NMR spectra were also collected on a Bruker Avance II 900 NMR spectrometer (B_0 = 21.1 T) at 31.4 MHz for all compounds using a 7 mm magic-angle spinning (MAS) Bruker probe and a 7 mm home-built solenoid probe with VT capabilities (for $GeCl_4$). Non-spinning spectra were collected using a solid-echo pulse sequence (90°–90°) with pulse lengths of 3 μs and a recycle delay of 1 s for $GeBr_4$ and GeI_2 and 3 s for $GeCl_2$ and GeI_4, with 500–17 000 co-added transients. MAS spectra (spinning rates of 5 and 8 kHz) were collected using an echo pulse sequence with 4 μs (90°) and 8 μs (180°) pulse lengths and recycle delays of 3 s for GeI_2 and GeI_4. The $GeBr_2$ spectrum was collected in two pieces using a WURST (wideband uniform-rate and smooth truncation) quadrupolar Carr–Purcell–Meiboom-Gill (QCPMG) pulse sequence.[25,26]

Given the low melting point of $GeCl_4$ (223 K), temperature regulation was used (on both the 11.7 and 21.1 T spectrometers) to collect solid-state spectra for this compound. Additionally, $GeBr_4$ (melting point 299 K) was temperature-regulated on the 21.1 T spectrometer to ensure solidity.

A series of ^{73}Ge NMR experiments was conducted with the second GeI_2 sample (Strem Chemicals) on a Bruker Avance III 400 spectrometer (B_0 = 9.4 T) at 13.95 MHz using a 4 mm double-resonance MAS probe. Non-spinning spectra were collected using a solid-echo pulse sequence (90°–90°) with pulse lengths of 2 μs and a recycle delay of 2 s. MAS spectra (spinning rates of 3 and 15 kHz) were collected using an echo pulse sequence with 2 μs (90°) and 4 μs (180°) pulse lengths and recycle delays of 2 s. The number of scans collected ranged from 16 000–384 000.

The isotropic chemical shift, C_Q, and η for all non-spinning spectra at both fields were obtained through simulation using WSOLIDS software.[27]

Iodine-127 NMR

^{127}I NMR experiments for GeI_2 were conducted on a Varian UNITY Inova 600 spectrometer (B_0 = 14.1 T) at 120.0 MHz using a 3.2 mm MAS Varian-Chemagnetics probe with ZrO_2 rotors, referenced to solid KI (0 ppm). Non-spinning spectra were acquired using a 5 μs (90°) single pulse and 0.4 s recycle delay, with 512 co-added transients. Spectra were also acquired on a Bruker Avance II 900 at 180.1 MHz using a 7 mm home-built solenoid probe. The non-spinning spectra were acquired using a solid-echo pulse sequence with a 2 μs pulse (ν_{rf} of 42 kHz), 1 s recycle delay, and 1024 co-added transients. Spectra were simulated using WSOLIDS and STARS (implemented within VnmrJ, Varian Inc.).[28]

Chlorine-35 NMR

^{35}Cl NMR experiments (non-spinning and MAS) of $GeCl_2$ were conducted on a Varian UNITY Inova 600 at 58.8 MHz using a 5 mm DR Varian Chemagnetics MAS probe with a ZrO_2 rotor, referenced to 1 mol/L NaCl (0 ppm). All spectra were collected using a single pulse of 1 μs (13° tip, ν_{rf} of 36 kHz), and a recycle delay of 1 s, with 128–3900 co-added transients. Spinning rates of 3.2, 5.0 and 8.0 kHz were used to collect the MAS data. Spectral parameters were obtained through simulation using STARS.[28]

Quantum chemical calculations

Electric field gradient and chemical shielding calculations were completed on crystal structures (as reported from literature sources) of GeF_2, $GeCl_4$, $GeBr_2$, $GeBr_4$, GeI_2, and GeI_4 using CASTEP, a GIPAW (gauge-including projector augmented waves) DFT-based computational method that calculates electronic properties of periodic solids.[29] The Perdew–Burke–Ernzerhof (PBE) functionals were used in the generalized gradient approximation (GGA) for the exchange-correlation energy and ultrasoft pseudopotentials. All calculations were performed using ultrafine-accuracy basis sets and a maximum plane-wave energy of >550 eV with relativistic effects included using the scalar-relativistic zero-order regular approximation (ZORA).[30,31] The Monkhorst–Pack grid had a maximum density of up to 7 × 7 × 6 *k*-points. CASTEP software was used in a Materials Studio 4.4 environment, with all calculations conducted on an HP xw4400 workstation with a single Intel Dual-Core 2.67 GHz processor and 8 GB DDR RAM. Germanium C_Q values were corrected using a quadrupolar moment of –19.6 fm^2 for ^{73}Ge, as the CASTEP default is –17.3 fm^2.[32] Calculated isotropic chemical shielding values were converted to isotropic chemical shifts using the calculated shielding of solid $GeCl_4$ and its experimental chemical shift (i.e., setting σ_{iso}^{calcd} = 1424 ppm to δ_{iso}^{calcd} = 30 ppm).

Results

GeI_4

Germanium (IV) iodide packs in a cubic unit cell and belongs to the *Pa*-3 space group.[33] The tetrahedrally coordinated germanium centre exhibits Ge–I bond lengths of 2.497 ± 0.002 Å to all nearby iodine atoms, with an average I–Ge–I angle of 109.470°. The difference between the maximum and minimum Ge–I bond lengths is 0.007 Å. The closest adjacent germanium centres are separated by 6.672 Å.

Based on the positions of the ^{73}Ge satellite transitions measured at 11.7 and 21.1 T, the C_Q is determined to be 1.80 ± 0.04 MHz (Figure S1 in the Supplementary data), greater than the C_Q value of 1.34 MHz calculated by GIPAW DFT (Table 1). The asymmetry parameter is η = 0, as required by the point-group symmetry and predicted correctly by GIPAW DFT. The isotropic chemical shift (δ_{iso}) appears at –1098 ± 3 ppm, in agreement with a previously reported δ_{iso} of –1104 ppm from solution NMR.[34] Another group has reported δ_{iso} = –1171 ppm (referenced to $GeCl_4$, 30.9 ppm) and linewidth ($\Delta\delta_{1/2}$) of 950 Hz at 11.7 T for

[a]The non-spinning spectrum collected at 9.4 T yields C_Q = 0.22 ± 0.05 MHz, η = 0, δ_{iso} = –217 ± 5 ppm; MAS at 9.4 T gives C_Q = 0.25 ± 0.02 MHz and δ_{iso} = –216 ± 1 ppm.
[b]Based on non-spinning and MAS experiments.
[c]Fixed as chemical shift reference.

solid GeI_4.[10] The same group reported a solution value for GeI_4 of δ_{iso} = –1117 ppm, but no account was given for the discrepancy between the liquid- and solid-state chemical shifts, and no spectra were displayed within the publication. The CT linewidths observed in this work are 2200 Hz at 11.7 T and 1100 Hz at 21.1 T, mostly attributable to a reduction in the second-order quadrupolar broadening at ultrahigh field.

In these high-symmetry structures, the C_Q values are small enough that other broadening effects may become appreciable in the NMR spectrum. All the directly bonded halogens are spin-active and quadrupolar, affecting the ^{73}Ge resonance by direct-dipolar and indirect spin-spin coupling. Although these are not resolved, their presumed influence means the peakwidths should not be expected to scale predictably with the field. For example, the static dipolar coupling constant, D (^{73}Ge,^{127}I) is 54 Hz for an isolated spin-pair, using the average Ge–I bond length in GeI_4. The broadening associated with this dipolar coupling would be amplified by both the spin quantum number of the coupled spins (5/2) and the number of bonded ^{127}I atoms (4).

$GeBr_4$

Germanium (IV) bromide (α-$GeBr_4$) is isostructural with GeI_4.[35] The tetrahedrally coordinated germanium centre exhibits an average bond length of 2.265 ± 0.002 Å to bromine, with an average Br–Ge–Br angle of 109.470°. The difference between the maximum and minimum Ge–Br bond lengths is 0.004 Å. Adjacent germanium centres are separated by 6.187 Å.

^{73}Ge NMR spectra collected at both 11.7 T (Fig. 1*a*) and 21.1 T (Fig. 1*b*) can be fit with a C_Q of 1.15 ± 0.01 MHz using the prominent satellite transitions. At 11.7 T, we can only see the first set of satellite transitions (due to the narrower spectral window on the AMX spectrometer), while at 21.1 T, the first, second, and third sets may be observed. The C_Q value is in close agreement with the GIPAW DFT-predicted value of 0.90 MHz. The asymmetry parameter is η = 0, as required by point-group symmetry and verified by GIPAW DFT. The isotropic chemical shift appears at –315 ± 3 ppm (Table 1), agreeing with a previously reported solution chemical shift, δ_{iso} = –311 ppm.[34] The CT linewidths at 11.7 and 21.1 T are 1300 Hz and 650 Hz, respectively. The second-order quadrupolar broadening (of the CT) expected for a C_Q of 1.15 MHz is 550 Hz at 11.7 T and 300 Hz at 21.1 T, suggesting a broadening contribution from coupling interactions with $^{79/81}$Br; these correspond to D(^{73}Ge,^{79}Br) and D(^{73}Ge,^{81}Br) of 91 and 98 Hz, respectively, for an isolated spin-pair at the average Ge–Br bond length in $GeBr_4$.

$GeCl_4$

Unlike GeI_4 and $GeBr_4$, germanium (IV) chloride packs in a monoclinic unit cell and belongs to the $P2_1/c$ space group.[36] The tetrahedrally coordinated germanium centre exhibits an average bond length of 2.096 ± 0.002 Å to chlorine, and an average Cl–Ge–Cl angle of 109.471°. The difference between the maximum and minimum Ge–Cl bond lengths is 0.005 Å. The closest adjacent germanium centres are separated by 5.111 Å.

$GeCl_4$ is a liquid at room temperature and requires the sample to be cooled to at least –50 °C for solid-state NMR

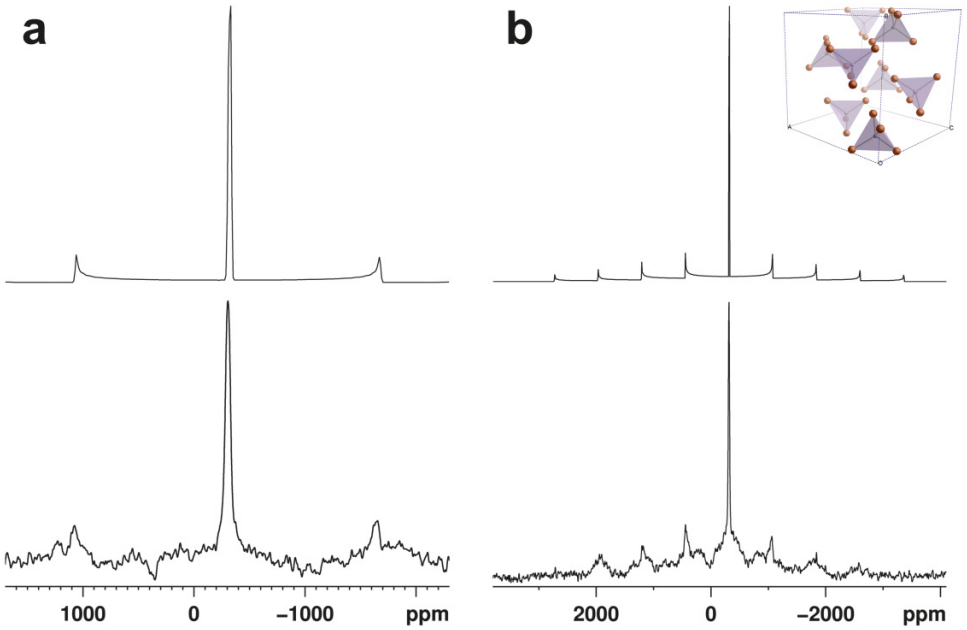
Fig. 1. (lower) Experimental solid-echo ^{73}Ge NMR spectra and (upper) simulated spectra of $GeBr_4$ at (*a*) 11.7 T, with C_Q = 1.15 MHz, η = 0, and δ_{iso} = –316 ppm, and (*b*) 21.1 T, with C_Q = 1.15 MHz, η = 0, and δ_{iso} = –315 ppm.



acquisition. This procedure limits the acquisition time, so the corresponding spectra have a relatively low signal-to-noise ratio (Figure S2 in the Supplementary data). No satellite transitions or characteristic peak shapes are observed; hence, no accurate determination of η can be made, and C_Q must be estimated based on peak breadth. At 11.7 T, the $\Delta\delta_{1/2}$ is 470 Hz, which predicts a C_Q no greater than 1.2 MHz. Similarly, the $\Delta\delta_{1/2}$ at 21.1 T is 320 Hz, which dictates that the C_Q cannot be greater than 0.8 MHz. These predictions assume that the entire breadth is attributable to the quadrupolar interaction, but the true value is likely to be smaller since D(^{73}Ge,^{35}Cl) and D(^{73}Ge,^{37}Cl) are 45 and 37 Hz, respectively (for an isolated spin-pair at the average Ge–Cl bond length in $GeCl_4$). The C_Q estimations are in close agreement with the GIPAW DFT-predicted value of 0.95 MHz (with predicted η = 0.62). The isotropic chemical shift (δ_{iso}) appears at +30 ppm (liquid $GeCl_4$ is the reference, +30.9 ppm) (Table 1).

GeI_2

Germanium (II) iodide packs in a trigonal cell and belongs to the *P*-3*m*1 space group.[37] The octahedrally coordinated germanium centre exhibits a Ge–I bond length of 2.990 Å to all close iodine atoms and an average I–Ge–I angle of 90.000°. Adjacent germanium centres share two iodine atoms and are separated by 4.251 Å.

The unusual-looking spectrum collected at 11.7 T (Figure S3 in the Supplementary data) shows signals on either side of the central transition that yield a C_Q of 0.25 ± 0.09 MHz if they are regarded as satellite transitions. The presumed satellite signals for the 21.1 T echo spectrum (Fig. 2*a*) place the C_Q slightly smaller, at a lower limit of 0.16 MHz, while the breadth of the CT confers an upper limit of 1.5 MHz. The C_Q predicted by GIPAW DFT is 1.43 MHz, significantly greater than the experimental average of about 0.20 MHz. The asymmetry parameter is η = 0, as required by point-group symmetry and predicted by GIPAW DFT. The isotropic chemical shift appears at –215 ± 3 ppm (Table 1), with CT linewidths of 2300 Hz at 11.7 T, 1000 Hz (quadrupolar echo) and 710 Hz (single pulse) at 21.1 T. The $\Delta\delta_{1/2}$ observed here is vastly different than the 270 Hz reported at 11.7 T for solid GeI_2 by another group,[10] although we do see a breadth of 330 Hz in the narrow portion of the CT for our GeI_2 spectrum at 11.7 T. Our measured δ_{iso} agrees with the previous report of –213.4 ppm.[10] D(^{73}Ge,^{127}I) is calculated to be 32 Hz for an isolated spin-pair, using the Ge–I bond length in GeI_2.

The non-spinning ^{73}Ge NMR spectrum at 9.4 T of the second GeI_2 sample shows δ_{iso} = –217 ± 5 ppm, while the C_Q is estimated as 0.22 ± 0.05 MHz (with η = 0) based on the presumed appearance of the first set of satellite transitions (Figure S4a in the Supplementary data). The ^{73}Ge MAS NMR spectra collected at the same field yield δ_{iso} = –216 ± 1 ppm and C_Q = 0.25 ± 0.02 MHz, based on analysis of the spinning sideband manifold (Figure S4b in the Supplementary data and see Fig. 5*b* below).

The experimental spectra for this compound are difficult to interpret, despite the simplicity of the crystal structure. The non-spinning ^{73}Ge NMR spectra of GeI_2 collected with an echo pulse sequence appear particularly complicated due to the presence of Solomon echoes, satellite transition signal coherences that appear in the free induction decay at intervals of the echo pulse spacing (τ).[38,39] Their presence may explain the discrepancy between the $\Delta\delta_{1/2}$ values for our spectrum and that from the literature and may also lead to an overestimate of C_Q for the broadened GeI_2 signal collected at 11.7 T. The time-domain signals have been transformed at the tip of the echo corresponding to the coherence of all satellite signals (τ), and should thus provide the most accurate description of all observable transitions in the quadrupolar spectrum.

Figure 2 shows a comparison between the frequency-domain calculation of the spectrum and a simulation of the spectrum

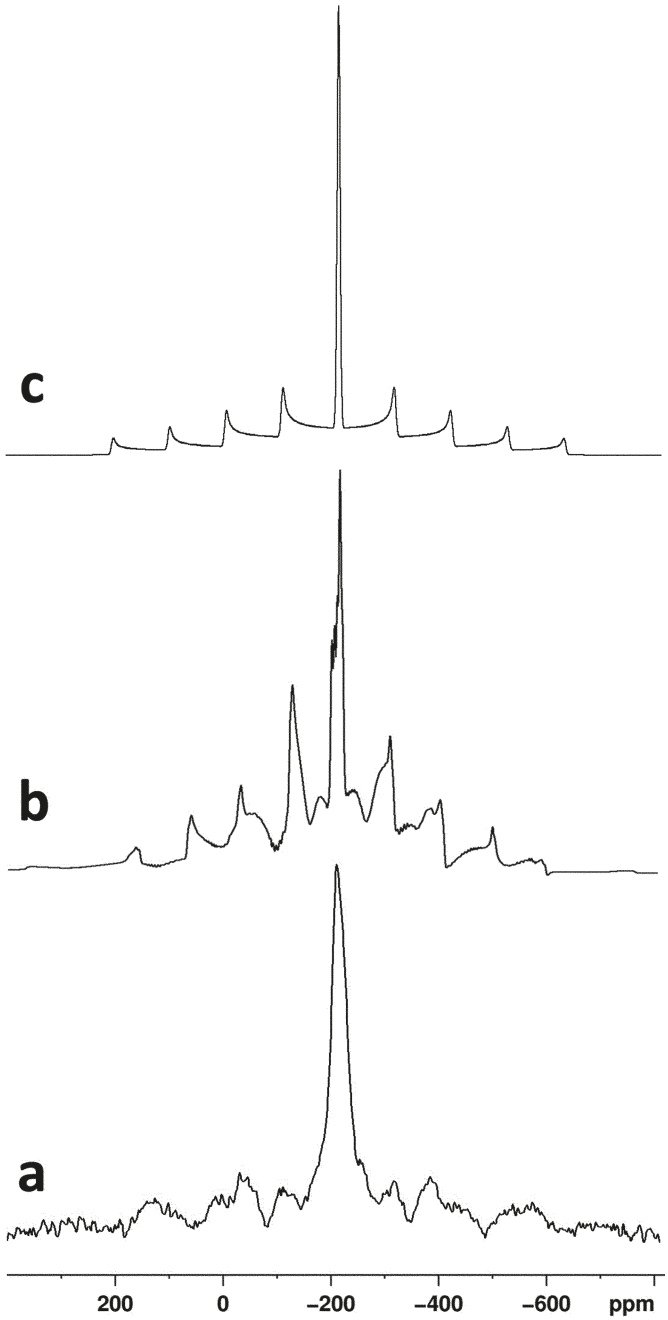
Fig. 2. (*a*) Experimental solid-echo ^{73}Ge NMR spectrum of GeI_2 at 21.1 T with (*b*) SIMPSON simulation incorporating Solomon echoes using $C_Q = 0.16$ MHz and $\eta = 0$, and (*c*) simple simulation using $C_Q = 0.16$ MHz, $\eta = 0$, $\delta_{iso} = -214$ ppm.



with Solomon echoes using SIMPSON.[40] While the fit is imperfect due to probe ring-down effects, the latter calculation clearly reproduces the main experimental features with greater accuracy.

$GeBr_2$

Germanium (II) bromide packs in a monoclinic cell, belonging to the $P12_1/c1$ space group. The crystal structure contains two distinct germanium sites (1:1 ratio), where the structural units are distorted $GeBr_6$ octahedra (proposed as the result of a second-order Jahn–Teller effect).[41] The first site, Ge(1), contains six bromine atoms within a 3.4 Å radius, the closest contact being 2.518 Å. The average atomic distance for these close contacts is 2.9 ± 0.3 Å. The second site, Ge(2), contains six bromine atoms within 3.7 Å, with the closest contact being 2.479 Å. The average atomic distance for the close bromine atoms is 3.0 ± 0.5 Å. Due to the octahedral distortion, both sites contain Br–Ge–Br bond angles deviating from the ideal 90°. The average Br–Ge–Br angles for Ge(1) and Ge(2) are 89.911° and 90.393°, respectively. The difference between the maximum and minimum Ge–I bond lengths is 0.130 Å for Ge(1) and 0.187 Å for Ge(2). The closest germanium atoms are separated by 3.902 Å (Ge(2)–Ge(2)).

The ^{73}Ge NMR spectrum of $GeBr_2$ (Fig. 3*a*) exhibits the largest breadth observed for either series of compounds, due to the large quadrupolar interaction arising from the asymmetric environments in which the germanium nuclei sit. The WURST-QCPMG pulse sequence[42,43] was chosen based on the large quadrupolar coupling predicted by GIPAW DFT ($C_Q > 30$ MHz).

With a large C_Q, most satellite transitions are well outside the spectral window (unless η approaches 1), thus simulation of the NMR parameters was accomplished by analysing the central transition shape using C_Q and η adjustments. The GIPAW DFT parameters ($C_{Q(1)} = 30.1$ MHz, $\eta_{(1)} = 0.22$, $C_{Q(2)} = 36.5$ MHz, $\eta_{(2)} = 0.58$) were used as a starting point in the simulation of the experimental spectrum. However, the result did not fully account for the observed breadth and shape (Fig. 3*c*). It should be noted that because of the dominating quadrupolar interaction, the inclusion of CSA parameters determined by GIPAW DFT ($\Omega_{(1)} = 204$ ppm, $\kappa_{(1)} = -0.52$, $\Omega_{(2)} = 464$ ppm, $\kappa_{(2)} = -0.44$) did not appreciably alter the appearance of the simulated spectrum. The final simulation involved incorporating both germanium sites in $GeBr_2$ ($C_{Q(1)} = 35 \pm 3$ MHz, $\eta_{(1)} = 0.4 \pm 0.2$, $\delta_{iso(1)} = -70$ ppm, $C_{Q(2)} = 34 \pm 3$ MHz, $\eta_{(2)} = 0.95 \pm 0.05$, $\delta_{iso(2)} = -310$ ppm) in addition to a 10% germanium oxide impurity identified in powder X-ray diffraction (GeO_2, $C_Q = 9.2 \pm 0.3$ MHz, $\eta = 0.5 \pm 0.1$, $\delta_{iso} = -110 \pm 20$ ppm, as previously determined).[13] The spectral evidence for the oxide impurity is based on the intensity of the tallest peak, corresponding to the chemical shift for quartz-like GeO_2.[13] There is evidence of the Ge(2) + 3/2 ↔ + 1/2 satellite transition around 5000 ppm, which appears close to the CT as this site has a high η value. The imperfect simulation in Fig. 3*b* is a consequence of three distinct Ge species in this sample, each with large and different quadrupolar parameters, illustrating the challenge of ^{73}Ge NMR in complex materials. Given the enormous size of this spectrum, the contributions from direct dipolar coupling and indirect spin-spin coupling are negligible and unobserved. For example, $D(^{73}Ge,^{79}Br)$ and $D(^{73}Ge,^{81}Br)$ are calculated to be approximately 68 and 73 Hz, respectively, for an isolated spin-pair using the average Ge–Br bond lengths in $GeBr_2$.

$GeCl_2$

The crystal structure of germanium (II) chloride has not been reported in the literature, and the experimental difficulties in preparation and stability of this compound have been noted.[44,45] A prominent GeO_2 impurity makes diffraction experiments difficult, although a space group of $P\text{-}3m1$ seems

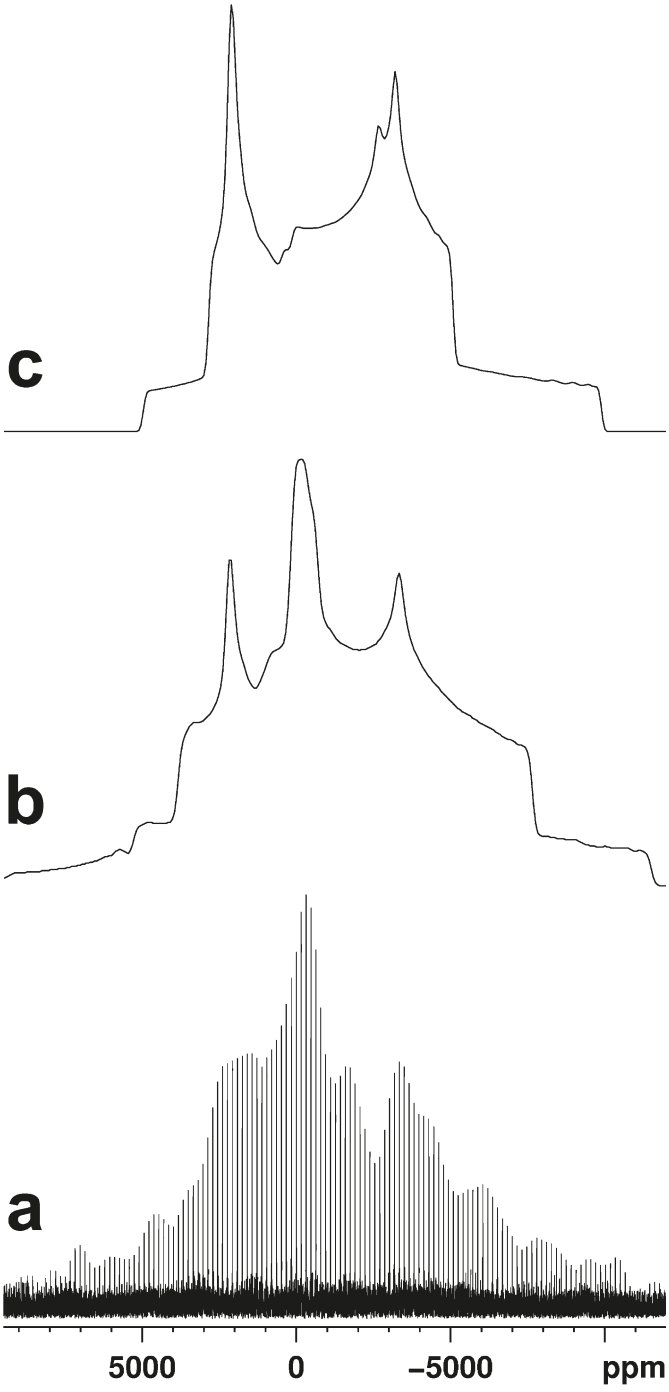

Fig. 3. (*a*) Experimental WURST-QCPMG ^{73}Ge NMR spectrum of $GeBr_2$ with (*b*) simulation of the two germanium sites using $C_{Q(1)}$ = 34 MHz, $\eta_{(1)}$ = 0.4, and $\delta_{iso(1)}$ = –70 ppm and $C_{Q(2)}$ = 1.15 MHz, $\eta_{(2)}$ = 0.95, and $\delta_{iso(2)}$ = –320 ppm, with GeO_2 impurity included at 10% using C_Q = 9.3 MHz, η = 0.5, and δ_{iso} = –110 ppm from reference 13; (*c*) simulation using GIPAW DFT parameters (Table 1).

likely from powder X-ray diffraction (Figure S5 in the Supplementary data).

It has been suggested that the crystal structure of $GeCl_2$ is similar to that of $GeBr_2$, based on the octahedral distortion observed in the known structure of a low-temperature polymorph of cesium germanium trichloride ($CsGeCl_3$, which contains distorted $GeCl_6$ units).[41,46] ^{73}Ge NMR experiments allow us to make inferences about the structure, including the similarity of $GeCl_2$ to either GeI_2 or $GeBr_2$. At 11.7 T, no satellite transitions are observed, and the signal-to-noise ratio is low (Fig. 4*a*). As a result, an estimate of the C_Q can only be accomplished by evaluating the breadth of the signal. The $\Delta\delta_{1/2}$ is 2.4 kHz, which dictates that the quadrupole coupling cannot exceed 2 MHz. No estimate of η can be accurately determined from this spectrum. At 21.1 T, we observe at least two sets of satellite transitions belonging to a single site (Fig. 4*b*), which can be fit with a C_Q of 1.7 ± 0.1 MHz and η = 0. The small signal adjacent to the central transition of $GeCl_2$ was identified through NMR spectral simulation and powder X-ray diffraction as a GeO_2 impurity.[13]

The magnitude of the quadrupole coupling observed for $GeCl_2$ and the *P*-3*m*1 space group suggested by powder X-ray diffraction indicates that the crystal structure must be closely related to GeI_2 and not to $GeBr_2$. That is, if the same octahedral distortion present in $GeBr_2$ occurred in $GeCl_2$, the Ge quadrupole coupling would be expected to be at least an order of magnitude greater than 1.7 MHz. Given the large C_Q observed for $GeBr_2$ (34–35 MHz experimental) and the calculation of GeF_2 (87.6 MHz), the $GeCl_2$ (C_Q = 1.7 ± 0.1 MHz) structure should not resemble either of these compounds, while GeI_2 shows the closest comparison ($C_Q \approx$ 0.2 MHz).

^{73}Ge MAS Spectra

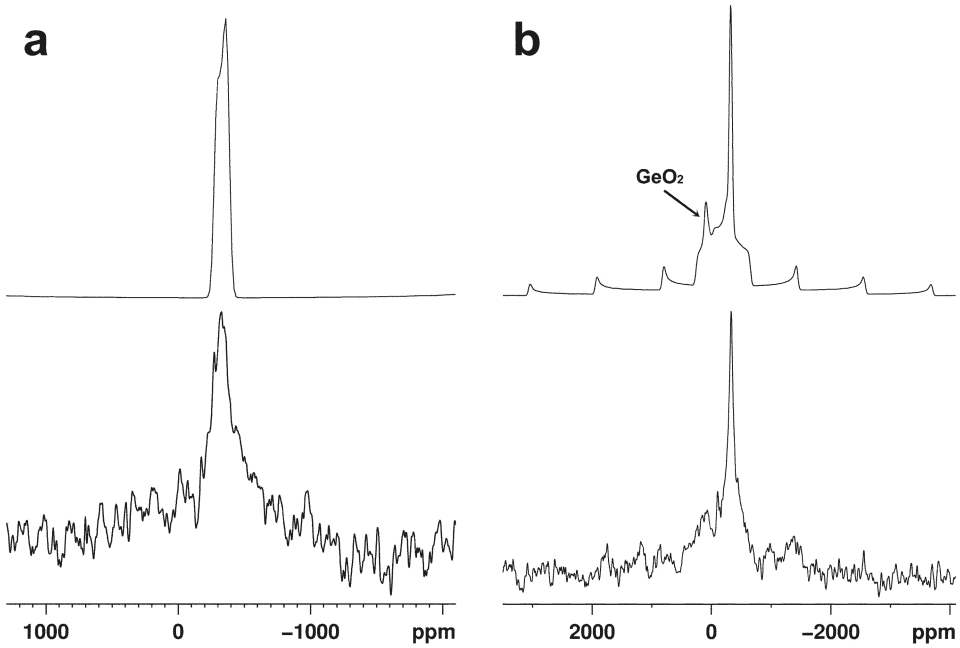
Figure 5*a* shows the ^{73}Ge MAS NMR spectrum of GeI_2 at 21.1 T, where the central transition breadth is 400 Hz. Since heteronuclear dipolar coupling and chemical shift anisotropy are averaged under magic-angle spinning, only the second-order quadrupolar effect, *J*-coupling, and residual dipolar coupling broaden the peaks.[47] By contrast, a ^{73}Ge MAS spectrum of tetraphenylgermanium (not shown) yields a peak-width of 27 Hz, as expected for a Ge nucleus in a highly symmetric environment with no coupling partners. Since the quadrupolar coupling constant of ^{127}I is quite small (C_Q = 8 MHz, see below), residual dipolar coupling will have no appreciable influence on the breadth. The C_Q of 0.16 MHz determined from the non-spinning spectrum of GeI_2 at 21.1 T predicts a MAS breadth of 80 Hz, and the residual 320 Hz is attributed principally to *J*-coupling with neighbouring ^{127}I nuclei. Iodine-127 is a 100% naturally abundant spin-5/2 nucleus, which will split the ^{73}Ge signal into six sub-spectra, propagating further with coupling to each of the six bonded ^{127}I nuclei. Although no resolution is observed, the overall breadth of this coupling pattern is expected to be approximately 8 × $^1J(^{73}Ge,^{127}I)$. Hence, we estimate $^1J(^{73}Ge,^{127}I)$ to be 35 ± 10 Hz for GeI_2. It is necessary to note that if the quadrupolar relaxation of the ^{127}I is fast relative to J^{-1}, the iodines may be partially decoupled, hence the reported *J*-coupling estimates should be considered lower limits.[48]

From the spinning-sideband manifold, we can estimate the quadrupolar coupling constant with the following equations:

$$[5] \qquad \Delta\nu_{total} = |1 - 2m|\nu_Q$$

$$[6] \qquad \nu_Q = \frac{3C_Q}{2I(2I-1)}$$

Fig. 4. (lower) Experimental solid-echo ^{73}Ge NMR spectra and (upper) simulated spectra of $GeCl_2$ at (*a*) 11.7 T, with C_Q = 2 MHz, η = 0, and δ_{iso} = –315 ppm, and (*b*) 21.1 T, with C_Q = 1.7 MHz, η = 0, and δ_{iso} = –319 ppm. The additional signal between 500 and –500 ppm is a GeO_2 impurity, simulated as C_Q = 9.3 MHz, η = 0.5, and δ_{iso} = –110 ppm based on reference 13.



where $\Delta\nu_{total}$ denotes the breadth of the spinning-sideband manifold, *m* is the highest observed satellite transition (9/2 for ^{73}Ge), and ν_Q is the quadrupolar frequency.[49,50] At 21.1 T, $\Delta\nu_{total}$ is 41 kHz, corresponding to a ^{73}Ge C_Q of 0.12 MHz for GeI_2. The ^{73}Ge MAS NMR spectrum of GeI_2 at 9.4 T shows a $\Delta\nu_{total}$ of 84 kHz, corresponding to a C_Q of 0.25 MHz (Fig. 5*b*). These estimates support the C_Q measured in non-spinning samples.

In the ^{73}Ge MAS NMR spectrum of GeI_4 (Figure S6 in the Supplementary data), the breadth of the central transition is 400 Hz. Using the logic presented above, a C_Q of 1.78 MHz (determined from the non-spinning spectrum at 21.1 T) predicts a MAS breadth of 250 Hz from quadrupolar broadening, meaning that the remaining 150 Hz can be attributed to ^{73}Ge-^{127}I *J*-coupling. However, given the large quadrupolar coupling constant of the ^{127}I nucleus in GeI_4 (GIPAW DFT predicts C_Q = 1609 MHz for ^{127}I), significant quadrupolar distortion to the intensities and spacing of the *J*-coupling distribution prevents an accurate estimation of the *J*-coupling constant. If the MAS spectrum is simply treated as an undistorted multiplet, an estimated *J*-coupling constant of $^1J(^{73}Ge,^{127}I)$ = 25 ± 10 Hz for GeI_4 is obtained.

A $^1J(^{73}Ge,^{19}F)$ value has been reported for GeF_4 as 178.5 Hz (liquid state, 20 °C).[51] To compare these values, we must look at the reduced coupling constant ($^1K_{Ge\text{-}X}$), defined by:

$$[7] \qquad {}^1K_{XY} = \frac{4\pi^2 J_{Ge\cdot X}}{h\gamma_{Ge}\gamma_X}$$

Thus, the reduced coupling constant for ^{73}Ge-^{19}F in GeF_4 is –45.1 (× 10^{20} N A^{-2} m^{-3}), while those from GeI_4 and GeI_2 are (–30 ± 10) and (–41 ± 10) (× 10^{20} N A^{-2} m^{-3}), respectively. A DFT study predicted $^1K(^{73}Ge,^{35}Cl)$ for Ph_3GeCl

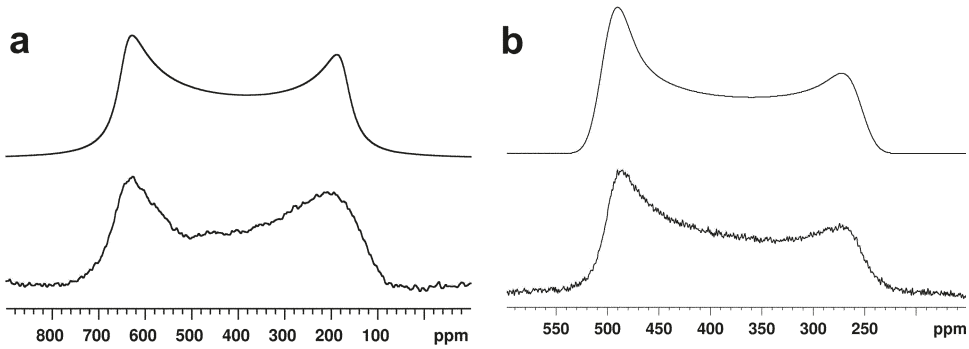
Fig. 6. (lower) Experimental non-spinning ^{127}I NMR spectra and (upper) simulated spectra of GeI_2 at (*a*) 14.1 T and (*b*) 21.1 T. From both fields, C_Q = 8 MHz, η = 0, δ_{iso} = –445 ppm, Ω = 250, and κ = 1.



to be between –40 and –43 ($\times 10^{20}$ N $^{-2}$ m^{-3}).[52] Despite considerable error in the estimates made using MAS NMR, the reduced coupling constants are in good agreement with previous determinations.

Halogen NMR

To gain insight about the possible structure of $GeCl_2$, we look to the halogen NMR for an alternate perspective on the system, enabling a comparison with other germanium (II) halides.

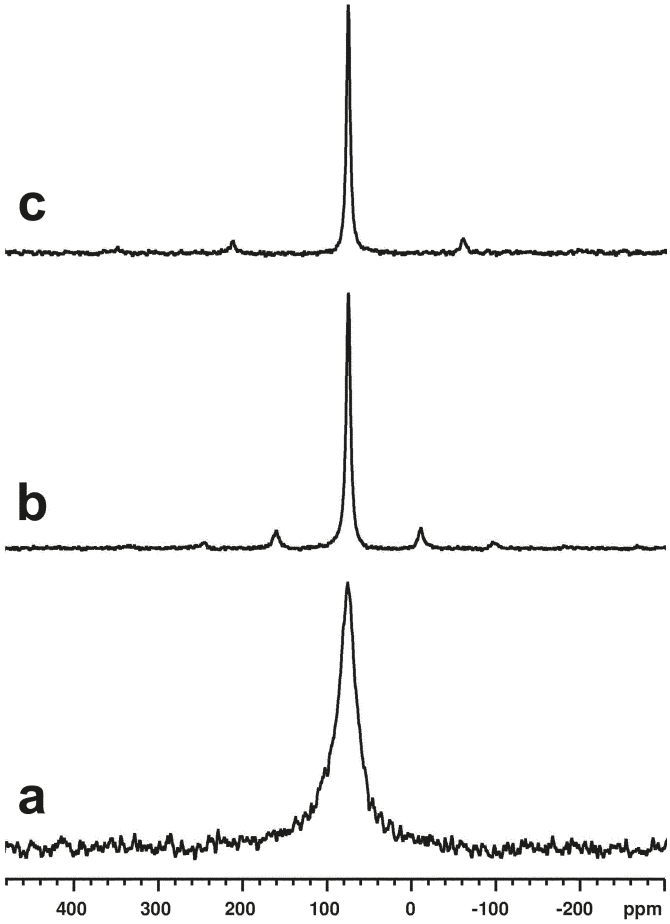
Iodine-127 NMR

^{127}I NMR spectra of GeI_2 at 14.1 T (Fig. 6*a*) and 21.1 T (Fig. 6*b*) show a single site at δ_{iso} = 445 ± 5 ppm with a C_Q of 8.0 ± 0.5 MHz and η = 0. The span is Ω = 250 ± 25 with a skew of κ = 1, assuming that the EFG and chemical shielding tensor orientations are coincident. GIPAW DFT predicts C_Q = 20.3 MHz and η = 0, with Ω = 39 ppm and κ = 0.87, with Euler angles of α = 330°, β = 90°, and γ = 180°. However, when these angles are simulated, the resulting shape is in clear disagreement with the experimental spectra at both fields, and no adjustments of C_Q, η, Ω, and κ could satisfy the experimental lineshapes at both fields. Given the generally poor performance of GIPAW DFT for chemical shielding tensors in this study, there is no reason to trust the tensor orientation. Furthermore, due to relativistic effects, there is little published work on the reliability of GIPAW DFT for ^{127}I, so it is difficult to assess the agreement with the experimental parameters. The discrepancy between estimated and experimental C_Q and Ω values appears to reflect that observed for some compounds in a previous ^{127}I DFT study.[53] Given the enormous range of ^{127}I C_Q values (up to ~1000 MHz),[54,55] the relatively small measured and predicted C_Q clearly indicates that iodine is indeed present in a high-symmetry site in GeI_2.

Chlorine-35 NMR

^{35}Cl NMR of $GeCl_2$ at 14.1 T shows a single site at δ_{iso} = 75 ± 2 ppm with a narrow linewidth ($\Delta\delta_{1/2}$ = 1.5 kHz under non-spinning conditions, Fig. 7*a*). Using MAS (Figs. 7b and 7c), the C_Q is estimated to be less than 40 kHz, based on the spinning sideband manifold. Since there is a single chlorine site, it is evident that the structure of $GeCl_2$ is not similar to that of $GeBr_2$ as once postulated (which contains four crystallographically inequivalent bromine sites) or GeF_2 (which contains two distinct fluorine sites).[41,56] The structure appears to be more closely related to GeI_2, with small C_Q values observed in both ^{73}Ge and their respective halogen NMR.

Fig. 7. Experimental ^{35}Cl NMR spectra of $GeCl_2$ at 14.1 T. (*a*) Non-spinning, (*b*) 5 kHz MAS, (***c***) 8 kHz MAS.



Discussion

Quadrupole couplings

The magnitude of quadrupole coupling is strongly influenced by local structure, where C_Q acts as a sensitive probe of local symmetry and allows for correlations between experimental and theoretical results. The higher symmetry species show that ^{73}Ge possesses small C_Q values, and even very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

For personal use only.

slight distortions from perfect symmetry result in a sharp increase in C_Q. The structural homology present in germanium (IV) halides is reflected in the much narrower range of quadrupolar constants from ^{73}Ge NMR, all falling within 1–2 MHz versus a 0–35 MHz range for germanium (II) halides.

To investigate correlations between the spectral parameters and crystal structure, a starting point is to use the well known distortion parameters as a way to quantify the local geometry about the germanium unit for each compound.[24] The mean elongation (λ) describes the variance in bond lengths, given by the equation:

$$[8] \qquad \lambda = \frac{1}{n}\sum_{i=0}^{n}\left(\frac{l_i}{l_0}\right)^2$$

where l_i values are the observed bond lengths, and l_0 is the average bond length. For tetrahedral units, $n = 4$, and for octahedral units $n = 6$. The second common parameter is known as the angle variance (σ^2), given by the equation:

$$[9] \qquad \sigma^2 = \frac{1}{n-1}\sum_{i-0}^{n}(\theta_i - \theta_0)^2$$

where θ_i values are the observed bond angles, and θ_0 is the ideal bond angle (109.47° for tetrahedral units and 90.00° for octahedral units). For tetrahedral units $n = 6$, and for octahedral units $n = 12$. No clear correlation is observed when C_Q is plotted against the λ and σ^2 distortion parameters, particularly since the former ranges narrowly from 1.000 to 1.025 (Table 1). However, if C_Q is plotted against the difference in minimum and maximum bond lengths, a stronger linear trend is observed in the region of small C_Q (0–2 MHz) (Fig. 8). The plot does not include data from $GeCl_2$, as the crystallographic information has yet to be determined, although the trend would estimate a bond length difference (maximum-minimum) of 0.012 Å. When the data from $GeBr_2$ are included, the large difference in C_Q compromises the trend. This rudimentary approach has proven reasonably successful in a series of germanium oxides, where the bond length difference provides better correlations with C_Q than conventional distortion parameters.[16]

Chemical shifts

Analysis of the ^{73}Ge chemical shifts for a given oxidation state provides some noticeable trends. First, the chemical shifts of germanium (IV) halides move to lower frequency from chlorine to bromine to iodine. This behaviour correlates with the electronegativity of the halide substituents on germanium and has been noted previously for ^{73}Ge isotropic chemical shifts of germanium halides in solution and for ^{29}Si in the analogous silicon halides (Figure S7 in the Supplementary data).[57] ^{73}Ge chemical shifts are more sensitive, ranging over 1100 ppm, whereas ^{29}Si shifts range over only 350 ppm for the same series. Similarly, ^{119}Sn chemical shifts for tin (IV) halides vary from –150 ppm ($SnCl_4$) to –1701 ppm (SnI_4), exhibiting an even larger range than ^{73}Ge chemical shifts.[57]

A conclusive determination of similar trends in germanium (II) halides is less obvious because of the unknown structure of $GeCl_2$ and the large errors associated with the measured δ_{iso} of $GeBr_2$. However, it is clear the germanium (II) halides do not exhibit the same chemical shift range as the germanium (IV) halides: the ^{73}Ge chemical shifts for GeI_2, $GeBr_2$, and $GeCl_2$ are all found within –70 to –320 ppm (Table 1) and do not show a regular trend.

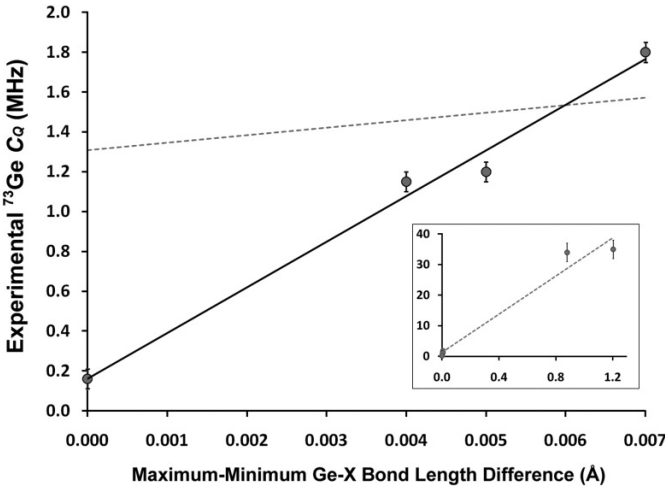

Fig. 8. Correlation between experimental ^{73}Ge C_Q and structural environment as defined by the difference in minimum and maximum Ge–X bond lengths. The solid line shows the linear trend observed for the small C_Q region while the dashed line represents the trend if $GeBr_2$ data are included (inset shows full range of C_Q).

Calculations

Quantum chemical calculations provide some complement to the parameters obtained by the experiment, although there are notable differences. In general, the GIPAW DFT quadrupole coupling calculations show reasonable agreement with our experimental results, with a slight underestimate observed in most cases (Fig. 9). This systematic underestimate has been seen in calculations for germanium oxides,[16,58] and attributed to a deficiency in the exchange-correlation functional.[16] Unsurprisingly, GIPAW DFT correctly predicts the asymmetry parameter when constrained to axial symmetry by the point-group symmetry of the germanium site. However for lower symmetry (as is the case with $GeBr_2$ and $GeCl_4$), the calculated η values are not reliable. Finally, the isotropic chemical shifts determined by GIPAW DFT do not show any particular correlation with the experimental values (Table 1).

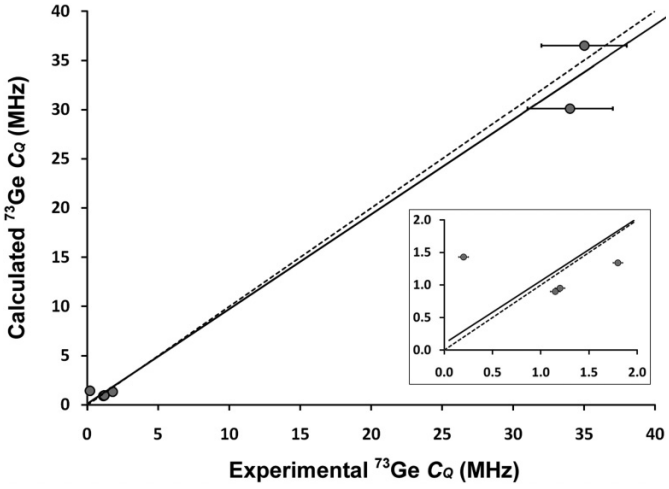
The GeF_2 calculation shows the largest C_Q (87.6 MHz) of the series and indeed the largest calculated ^{73}Ge C_Q reported to date. Its magnitude is attributed to the two-coordinate Ge units that exist in this fluorine-bridged chain polymer structure.[56] No NMR experiment was conducted since the extreme breadth for this site would require a large number of stepwise collections and a prohibitive amount of NMR time (the CT would span over 1.8 MHz at 21.1 T).

NMR crystallography

Comparison between the experimental and GIPAW DFT results reveals that the largest disagreement exists for GeI_2 (Fig. 9, Table 1). The small C_Q observed experimentally suggests that there is a very high degree of symmetry present in the crystal structure. However, the GIPAW DFT result of 1.43 MHz does not reflect this assertion. Furthermore, this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Fig. 9. Comparison of experimental and calculated ^{73}Ge C_Q values with best fit line (solid), $C_{Q(CALCD)} = 0.9629(C_{Q(EXPTL)}) + 0.098$. The inset is an expanded view of the low C_Q (0–2 MHz) region. The dashed line shows the ideal fit (experimental = calculated).



calculation breaks the observed trend that quadrupole couplings are underestimated by GIPAW DFT. Since the experimental C_Q has been determined by four independent measurements and the spectra are starkly incompatible with the GIPAW DFT-predicted value of 1.43 MHz, such a disagreement casts doubt on the validity of the crystal structure used in the calculation. This compound is an appropriate candidate for "NMR crystallography", where NMR, XRD, and quantum chemical calculations are used to refine the crystal structure.[59]

We performed initial GIPAW DFT calculations for four proposed GeI_2 structures from the literature.[37,60,61] The structure which gave the best agreement with the NMR results (calculated ^{73}Ge C_Q = 1.43 MHz) happened to be the one most recently reported (Table S1 in the Supplementary data).[37] Systematic variations of this structure were calculated, including elongation and compression of the cell axes (modification of *a* and *b* together, or *c*), or the *z* coordinate for the iodine site (the other coordinates are bound by the crystallographic space group). However, where the GIPAW DFT results (Figure S8 in the Supplementary data) showed C_Q minima for ^{73}Ge (0.31 MHz) and ^{127}I (12.3 MHz), the "crystal structure" was chemically unrealistic, with a separation between Ge and I atoms of 3.47 Å, greater than that expected based on the sum of the ionic radii (2.93 Å). Based on this one case, it appears that GIPAW DFT is not reliable in accurately predicting very small C_Q values.

Using the crystal structure of GeI_2, a test structure of $GeCl_2$ was made by substituting chlorine atoms in place of iodine, optimizing the structure using GIPAW DFT and calculating the chemical shielding and EFG parameters. The calculations yield a C_Q = 1.41 MHz for ^{73}Ge and 4.82 MHz for ^{35}Cl, with $\eta = 0$ for both. The quadrupolar coupling for ^{73}Ge is in reasonable agreement with the experimental value of 1.7 ± 0.1 MHz (especially if the GIPAW DFT underestimate is considered), while that of ^{35}Cl is strongly overestimated. While this result does not solve the unknown structure, it does provide a reasonable starting point for its determination.

Conclusion

^{73}Ge NMR experiments using three different magnetic fields have provided information about nuclear quadrupole coupling parameters and chemical shifts for two series of germanium halides. The C_Q is a sensitive probe of local symmetry, as the effect can be seen throughout the highly symmetric and less symmetric structures described here. The chemical shifts, while previously determined in solution studies (except for $GeBr_2$ and $GeCl_2$), show sensitivity to the local environment, exhibiting a range of over 1100 ppm. The quadrupolar coupling and chemical shielding information determined for $GeCl_2$ have allowed for structural predictions for this unsolved compound. Additionally, an estimate of $^1J(^{73}Ge, ^{127}I)$ has been suggested for the first time. The spectra demonstrate the advantage of ultrahigh-field NMR acquisition, but also that in some cases, moderate fields can yield interpretable ^{73}Ge NMR spectra. Having characterized the NMR parameters of both halide and oxide materials,[16] we now have a better understanding of how local environments of germanium are reflected in NMR spectra. These results demonstrate the viability of ^{73}Ge NMR as a characterization tool, and contribute to the growing knowledge in this area.

Abstract: Sensitivity enhancement of the NMR signal of the half-integer spin quadrupolar nuclei under magic angle spinning (MAS) conditions is demonstrated using the DFS (Double Frequency Sweep) enhancement scheme. It has been shown, both through numerical simulations and by experiments, that with a sinusoidal amplitude profile a narrow band DFS scheme performs much better than a DFS scheme with a large bandwidth. The total enhancement compares favorably to the hyperbolic secant (HS) pulse scheme under MAS. Finally, we report the robustness of this DFS scheme with respect to variation of different experimental parameters, making it a very attractive choice for acquiring sensitivity-enhanced NMR experiments of half-integer quadrupolar nuclei.

Key words: quadrupolar nuclei, MAS, double frequency sweeps, adiabatic pulse, CT, ST, sensitivity enhancement.

Résumé : On fait la démonstration d'une méthode d'amélioration de la sensibilité du signal RMN des noyaux quadripolaires de spins non entiers, dans les conditions de rotation à l'angle magique (« MAS »), qui utilise un schéma d'exaltation de balayage à double fréquence (BDF). Il est démontré tant par des calculs théoriques que par des données expérimentales que, avec un profil d'amplitude sinusoïdale, un schéma de BDF avec une bande étroite fonctionne beaucoup mieux qu'un schéma de BDF avec une grande largeur de bande. Dans les conditions de rotation à l'angle magique, l'amélioration totale se compare favorablement au schéma de pulsation sécante hyperbolique (SH). Enfin, on rapporte la force de ce schéma de balayage à double fréquence par rapport à la variation des différents paramètres expérimentaux qui en fait un choix très attrayant pour acquérir des données expérimentales de RMN avec une grande sensibilité pour des noyaux quadripolaires non entiers.

Mots-clés : noyau quadripolaire, rotation à l'angle magique (« MAS »), balayages à double fréquence, pulsation adiabatique, CT, ST, amélioration de la sensibilité.

1. Introduction

The application of nuclear magnetic resonance (NMR) to half-integer quadrupolar nuclei is widespread because of their abundant occurrence in various materials of inorganic, catalytic, and biological importance.[1,2] Extracting information about the quadrupolar interactions to which these nuclei are subjected can give valuable insights into the structural and dynamic properties of such compounds. However, the sensitivity of most quadrupolar nuclei (except for instance ^{79}Br or ^{23}Na) is notoriously low because it is affected by several factors such as low natural abundance, small values of gyromagnetic ratios, and large values of quadrupolar interaction parameters. Hence, designing efficient sensitivity enhancement schemes for quadrupolar nuclei still holds the attention of the solid-state NMR community.

In the presence of a static magnetic field, the energy levels of half-integer quadrupolar nuclei split into $2I + 1$ energy levels. At thermal equilibrium, the populations of these energy levels are governed by the Boltzmann distribution. In the high-temperature approximation, the spin levels are populated proportionally to their magnetic quantum number m. Therefore, manipulation of the satellite transitions is a useful tool to increase the polarization of the central transition (CT) levels. A subsequent inversion from the outer to the inner satellite transitions (ST) brings the population from the outer levels into the central transition levels, so that the intensity of NMR spectra of the central transition can be enhanced by a factor of $2I$.

One way to achieve this is by the application of amplitude-modulated pulses, a technique which was pioneered by Vega and Naor.[3] For a spin-3/2 nucleus contained within a single crystal, they had successfully demonstrated that an enhancement of 3 can be obtained by using amplitude-modulated pulses. However, the pulsed approach cannot achieve a similar level of enhancement in powdered samples where the satellite transitions cover a wide frequency range from 0 to $\pm\omega_Q$, where ω_Q represents the quadrupolar frequency.

An attractive alternative approach is to use adiabatic passage schemes. It is known from classic continuous-wave NMR spectroscopy that adiabatic field or frequency sweeps can overcome the problem of a spread in resonance frequencies. The frequency sweep can invert a specific transition by sweeping the frequency of the rf field from far above resonance to far below the resonance condition of the transition under consideration. In-depth studies of the applications of these techniques to half-integer spin quadrupolar nuclei were first made by Haase et al.[5,6] and Kentgens et al.[4,7] Later adiabatic schemes like Double Frequency Sweep (DFS)[8–11] and hyperbolic secant (HS)[12–15] pulse techniques were developed which enhance the sensitivity of quadrupolar nuclei by adiabatically inverting the populations of the outer satellites to the inner ones simultaneously. To date, the DFS scheme with a large sweep range yields the best signal enhancement for the acquisition of NMR spectra of stationary powdered samples with enhancements of up to 2.5 for spin-3/2 nuclei. Similar observations were made by Schurko et al. when they applied the DFS scheme sweeping over a frequency range of ~1.6 MHz observing ^{87}Rb in a static powdered $RbClO_4$ sample.[16] Enhancements ranging from one to two orders of magnitude could be obtained by combining the broad banded DFS with the quadrupolar Carr–Purcell–Meiboom–Gill (QCPMG) pulse sequence for both static and spinning samples.

Under MAS conditions, so far the HS-based inversion results in the largest signal enhancement (up to 2.7 for spin-3/2).[13] In the optimization of the HS pulses, Wasylishen and co-workers found that optimal enhancements are obtained when the bandwidth of the pulse is confined to approximately 1 rotor period.[17] The WURST (wideband uniform-rate smooth truncation)[18] pulse is also associated with large bandwidth to invert the populations of STs and thereby increasing the population differences between CTs.[19] Recently, however, it was reported by Dey et al.[20] that a single WURST inversion pulse under MAS conditions applied to a single satellite transition spinning sideband (ssb) can effectively invert the whole ssb manifold and can achieve appreciable enhancement in the signal to noise ratio for spin-3/2 systems.

Schurko and co-workers explored the optimal control approach to obtain signal enhancements in half-integer spin quadrupolar nuclei under static conditions.[21] These pulses achieved both excitation of the central transition and signal enhancement by population transfer from the satellites. The authors reported enhancements by factors of more than 2 for the central transition of the spin-3/2 ^{87}Rb nucleus compared with a selective $\pi/2$ pulse. These optimized pulses also showed relative insensitivity to the changes made in carrier offset and RF power.

In this contribution, we analyse the behaviour of a narrowband DFS scheme under MAS. We demonstrate a new simple modification to a narrowband DFS scheme which results in greater enhancement than that of normal broadband DFS under MAS. Application of this modified DFS scheme shows enhancements both in numerical simulations as well as in experimental results which are comparable to that of the HS scheme. The new modified scheme, called sideband-selective double-frequency sweep (ssDFS), is obtained by multiplying a narrowband DFS with a sine-squared function. The motivation behind this modification is to reduce the excitation effects by smoothly increasing then decreasing the amplitude of the sweep. We examined the robustness of this scheme with respect to the RF field strength used for the DFS, carrier offset, sweep length, and bandwidth of the DFS. It is shown both numerically and experimentally that ssDFS performs better in terms of total enhancement obtained and is less dependent on experimental parameters.

2. Experimental

The experiments were performed on a Varian NMR System (VNMRS) 300 (7.05 T) and a VNMRS 400 (9.4 T) spectrometer using 2.5 and 3.2 mm HX probe heads. Experiments were performed observing the spin-5/2 ^{27}Al resonance in the Albite, $NaSi_3AlO_8$ sample. The sample was spun at 10 kHz at the magic angle. The quadrupolar coupling constant C_Q and asymmetry parameter η of the ^{27}Al nuclei in Albite were 3.29 MHz and 0.62, respectively.[22] The RF field strength and the duration of the central transition selective 90° pulse applied were 5 kHz and 16.7 μs, respectively.

2.1. DFS

We used a convergent DFS with starting (ω_s) and finishing (ω_f) resonance offsets of 1.1 MHz and 100 kHz, respectively, on the VNMRS 300 spectrometer, whereas the sweep spans from 1 MHz to 100 kHz were carried out on a VNMRS 400 spectrometer. For experiments with DFS having narrow bandwidth, we made use of a convergent DFS with bandwidth equal to the spinning frequency. The other experimental parameters are given in the respective figure captions. For experiments using the ssDFS, we multiplied a convergent DFS, with a bandwidth equalling the spinning frequency, by a sine-squared function (Fig. 1). The sine-squared function was chosen so that the resulting RF profile has a smooth build-up and decay.

2.2. HS pulse

We also made use of HS pulses with a bandwidth of 10 kHz, and offsets of ±160 kHz and ±230 kHz on the VNMRS 300 and 400 spectrometers, respectively. The other relevant pulse and acquisition parameters are given in the figure captions.

2.3. Simulation of NMR spectra using SIMPSON

All the simulations of NMR spectra were carried out using the program SIMPSON (version 3.0.1)[23] running on a Dell Optiplex 755 desktop PC under the Windows XP operating system. The shapes of the DFS and ssDFS amplitude profiles and also the hyperbolic secant pulses were created within the SIMPSON input file. Typically, the powder-averaged spectra were calculated using 4180 crystal orientations using the method of Zaremba, Conroy, and Wolfsberg[24–26] and 10 γ angles. The maximum time step over which the Hamiltonian was considered time independent was 0.5 μs which is also the time step for the DFS and the hyperbolic secant shape. The SIMPSON simulations for a spin-5/2 system with 1000 μs long DFS took around 4 h to finish. All simulations were carried out assuming a spinning frequency of 10 kHz.

3. Results and discussion

Here we present the results obtained from both numerical simulations and experiments done on an Albite ($NaSi_3AlO_8$)

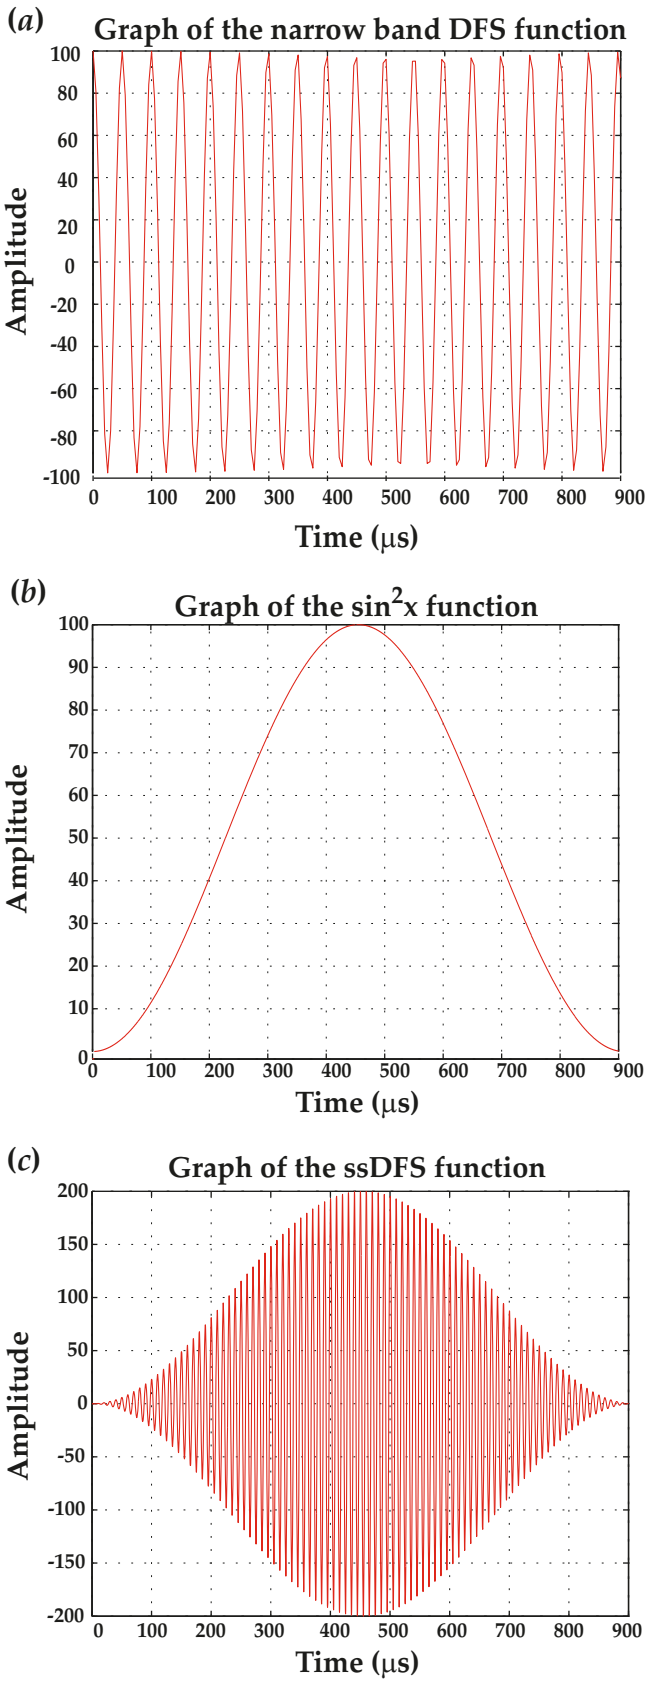
Fig. 1. (*a*) The RF profile of a 900-μs-long narrowband Double Frequency Sweep, (*b*) the $\sin^2 x$ shape function, and (*c*) resultant RF-amplitude profile of a 900-μs-long ssDFS.



sample at two different external magnetic field strenghts (7.05 T and 9.4 T). We recorded the enhancement factors observed by applying DFS, ssDFS, and HS pulses prior to a selective 90° pulse on the central transition. We also present the behavior of the enhancement factor obtained using ssDFS as a function of different experimental parameters.

3.1. NMR experiments

One-dimensional (1D) MAS spectra of Albite obtained using a single selective 90° pulse, DFS with large bandwidth, DFS with bandwidth equal to the spinning frequency, ν_r, and the sideband-selective DFS are shown in Fig. 2. The experimental results show that the DFS with bandwidth equal to ν_r performs better than normal broadband DFS and the ssDFS performs even better. In the case of the narrowband DFS, the bandwidth was kept equal to ν_r so that the sweep affects only one set of sidebands originating from both ST2 (outer satellite transition) and ST1 (inner satellite transition) on either side of the central transition. Similar observations were made by Wasylishen et al.[17] where they applied adiabatic pulses with bandwidth less than ν_r and conditions were designed such that the sweep only affected one ST (one ST1 and one ST2) sideband on one side of the central transition called SFS (Single Frequency Sweep). They observed that SFS under this condition performs better than normal DFS. Here we observe that if we keep the bandwidth of the DFS equal to ν_r so that it affects the sidebands from both sides of the central transition, the resultant enhancement is still higher than that obtained with a DFS with large bandwidth.

We also implemented HS pulses for ^{27}Al NMR in Albite with a bandwidth equal to 10 kHz. When comparing the results obtained with the HS scheme to that of the ssDFS it turns out that the ssDFS actually performs comparably or even slightly better than that of HS (Fig. 3). Similar results were obtained when these experiments were performed at a 300 MHz spectrometer (data not shown). The enhancement factors are listed in Table 1.

To investigate the robustness of the ssDFS scheme with respect to various experimental settings such as the RF field strength of the DFS, carrier offset, sweep duration, and bandwidth of DFS, we studied the enhancement factor as a function of these variables.

At first we varied the sweep length of the DFS scheme. The enhancement factor displayed a remarkable robustness (Fig. 4*a*). The sweep length was optimized at 1 ms (10 rotor periods) and was varied from 500 μs (5 rotor period) to 1.5 ms (15 rotor period). The enhancement factor shows a flat profile when plotted against sweep length expressed in rotor periods with a maximum observed drop in enhancement by only 8% from its optimum value.

Figure 4*b* shows the signal enhancement factor for the ssDFS scheme plotted as a function of the RF field strength of the DFS, ν_{RF}^{DFS}. The DFS was optimized at an RF field strength of 17.5 kHz, and subsequently varied from 7.5 kHz to 37.5 kHz. The enhancement factor is somewhat lower at the lowest RF field strength building up to its optimum at 17.5 kHz, subsequently displaying a relatively flat profile throughout with a maximum drop of 12% of the enhancement factor from its optimum value.

Figure 4*c* displays the variation of enhancement factor as a function of carrier frequency of the DFS. Here we have var-

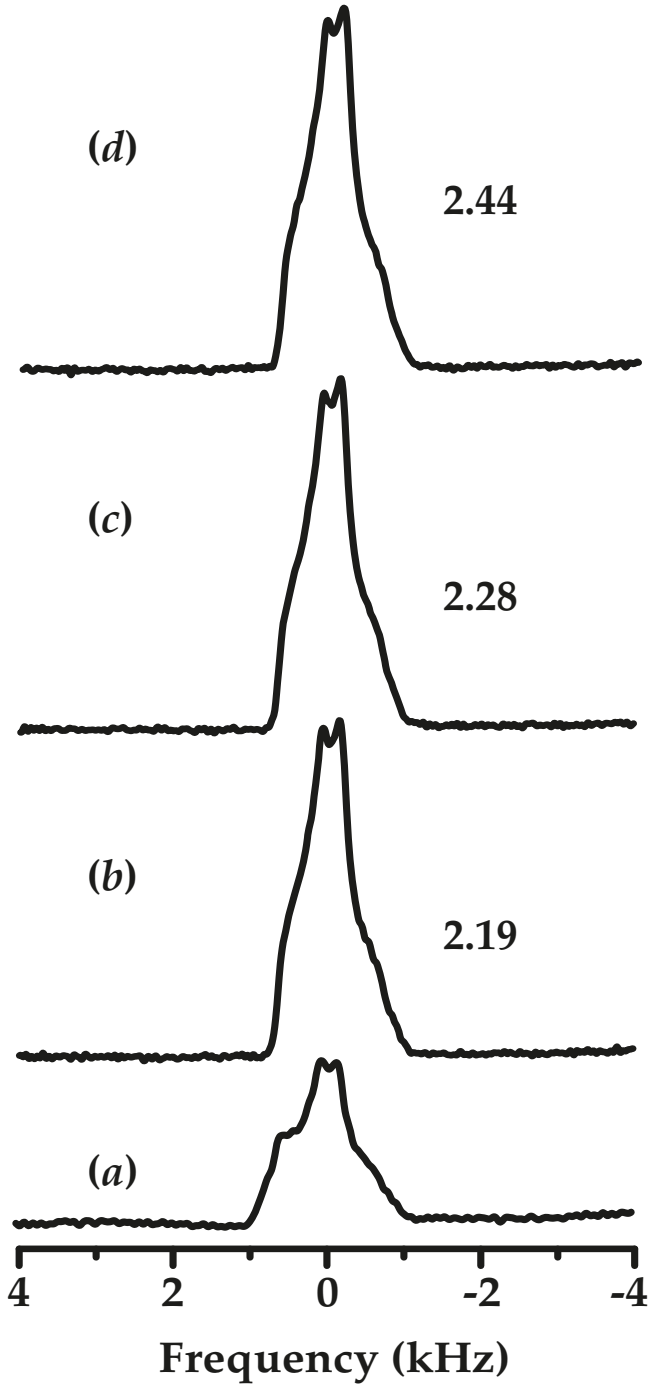
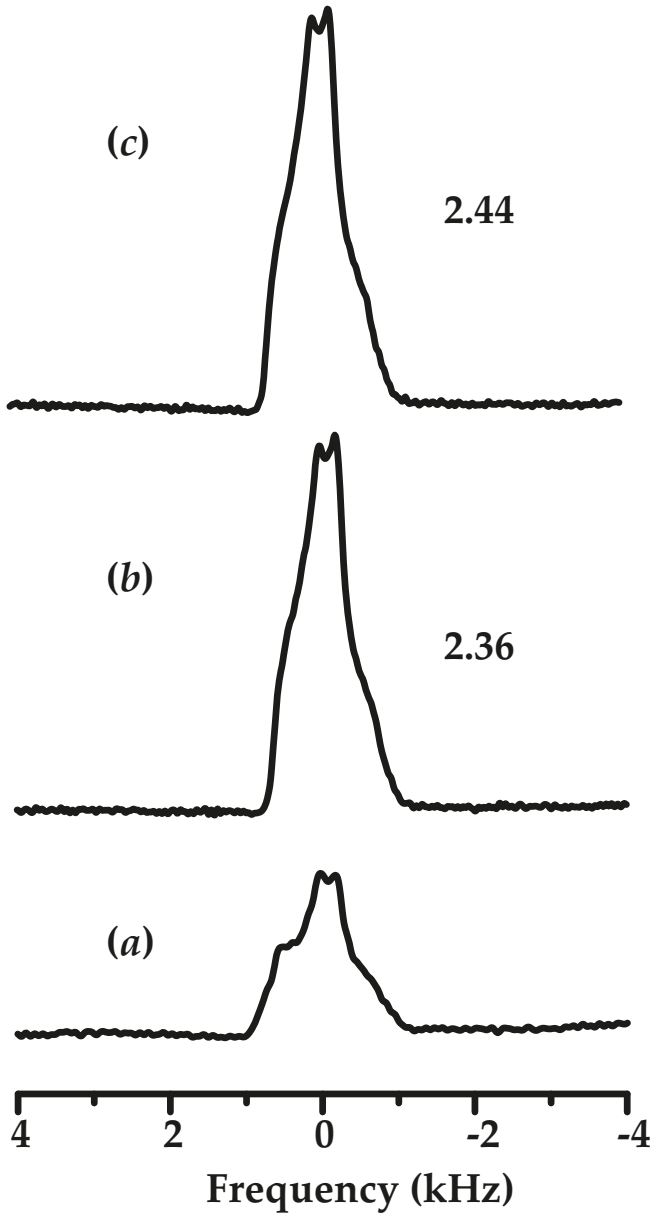
Fig. 2. Experimental 1D MAS spectra of ^{27}Al nuclei in Albite sample obtained on a VNMRS 400 spectrometer under different pulse schemes: (*a*) selective 90° pulse, (*b*) DFS running from 1.0 MHz to 100 kHz, (*c*) narrowband DFS running from 230 kHz to 220 kHz, (*d*) ssDFS. The numbers on the right of each spectrum denote the associated enhancements. The RF on ^{27}Al during DFS was kept at 17.5 kHz and that of central-transition selective 90° pulse was 5 kHz. The sweep duration was optimized to 1000 μs to obtain maximum signal intensity. A total of 64 transients were acquired with a relaxation delay of 2 s.



ied the position of the transmitter from the center of the central transition peak to ±100 kHz on either side of the center so that the DFS operates asymmetrically around the central

Fig. 3. Experimental 1D MAS spectra of ^{27}Al nuclei on a VNMRS 400 spectrometer using different pulse schemes: (*a*) selective 90°, (*b*) hyperbolic secant pulse, (*c*) ssDFS. The numbers on the right of each spectrum denote the associated enhancements. The HS pulse had an offset of ± 230 kHz and bandwidth of 10 kHz. The duration of the HS pulse was 2050 μs at an RF of 17.5 kHz. The RF field strength of the central-transition selective 90° pulse was 5 kHz. The number of transients and the relaxation delay time were the same asfor the DFS experiment.



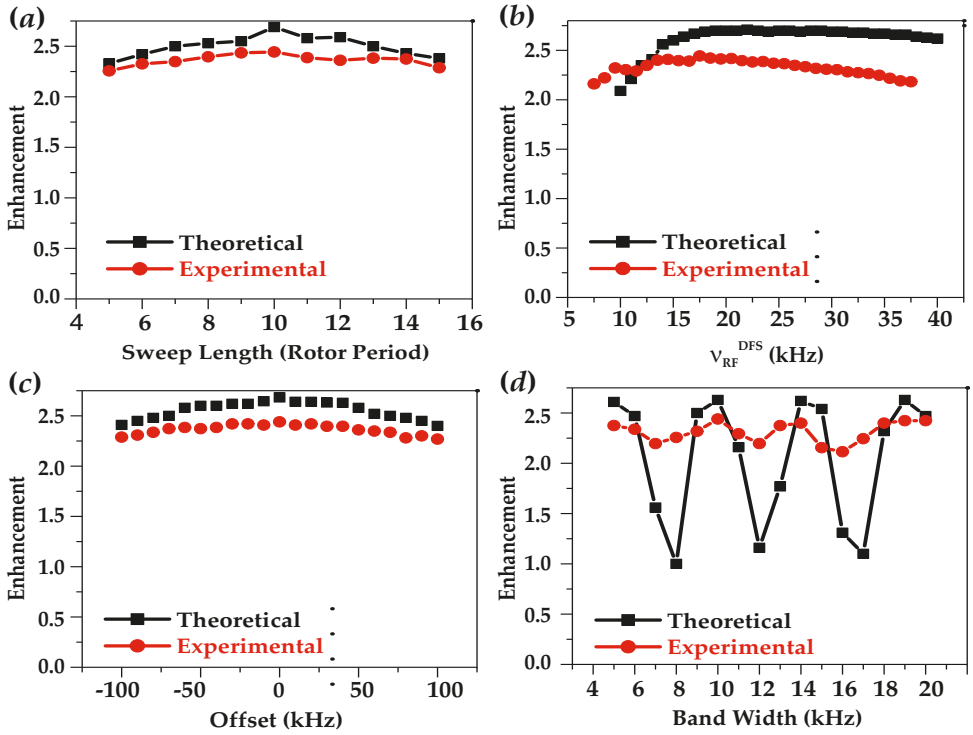
transition peak. Again, the plot of the enhancement factor versus carrier offset shows a remarkably flat profile between ±50 kHz of carrier offset. Only after ±50 kHz does the enhancement factor start to show a small decline. Again, the maximum drop in the enhancement factor was only ~8% from the optimum value.

Next we varied the bandwidth of the ssDFS from 5 kHz to 20 kHz i.e., 1/2 to 2 times spinning frequency. Interestingly, the enhancement factor now shows an oscillatory behavior

Table 1. Experimental enhancements obtained with respect to a selective 90° pulse, using different enhancement schemes at two different magnetic fields for ^{27}Al nuclei in the Albite sample.

Magnetic field	Broadband DFS	Narrowband DFS	HS	ssDFS
7.05 T	2.17±0.02	2.27±0.02	2.32±0.01	2.37±0.01
9.4 T	2.19±0.02	2.28±0.01	2.36±0.01	2.44±0.01

Fig. 4. Simulated and experimental variation of the optimized ^{27}Al NMR signal for a spinning Albite sample at 9.4 T (*a*) as a function of the sweep length (expressed in terms of rotor periods) of the DFS, (*b*) as a function of the RF field strength of the DFS, ν_{RF}^{DFS}, (*c*) as a function of the carrier offset of the DFS, (*d*) as a function of the bandwidth of the DFS.



with respect to the variation of the bandwidth (Fig. 4*d*). Incidentally, similar observations were previously made by Wasylishen et al. in the case of hyperbolic secant pulses.[15] Their oscillation frequency, however, was different from ours. When we tried to rationalize this observation, we found that each and every minimum in the plot of enhancement versus bandwidth occurs when the sweep finishes on top of the spinning sidebands (ssb) of either ST1 or ST2. But when the sweep covers an entire ssb of either the inner or outer satellite transitions, the enhancement factor goes up. Hence, it can be said that when the sweep ends on top of an ssb it interferes with the inversion of that ssb which results in a cascading effect on the whole of the ssb manifold leading to smaller enhancements.

In summary, we have shown here that a narrowband DFS scheme performs much better than a broadband DFS for spinning samples. This observation confirms previous observations that narrowband adiabatic methods are best under MAS conditions.[17,20] The various adiabatic schemes perform similarly in terms of the overall enhancement effect. Small differences are attributed to the approach used to avoid *sudden* changes in the spin Hamiltonian causing unwanted excitations of the spin system. Here we have implemented a squared sinusoidal amplitude envelop to the DFS to ensure a smooth increase and decrease of the amplitude at the beginning and end of the sweep. This appears to give slightly better performance compared to other adiabatic schemes. Another favourable aspect of this DFS implementation is the robustness of its performance with respect to a great number of experimental parameters. Considering the fact that a broadband DFS is also the method of choice for enhancing the central-transition powder patterns in static samples, we argue that the DFS is the most versatile implementation for enhancing spectra of half-integer quadrupolar spins. The DFS can easily be implemented in a flexible way so that the bandwidth can be tuned to a small value for spinning conditions, whereas it can be used with a broad bandwidth under static conditions. Slowly building up and bringing down the amplitude of the sweep will avoid excitation effects. The versatility and robustness of this scheme requires very little optimization during actual experiments.

3.2. SIMPSON simulations

To validate the effect of ssDFS on the enhancement factor, we performed SIMPSON simulations on a spin-5/2 system using the quadrupolar parameters of ^{27}Al in Albite. It turned out that the simulations provided us with similar observations to those we previously made experimentally. The numerical

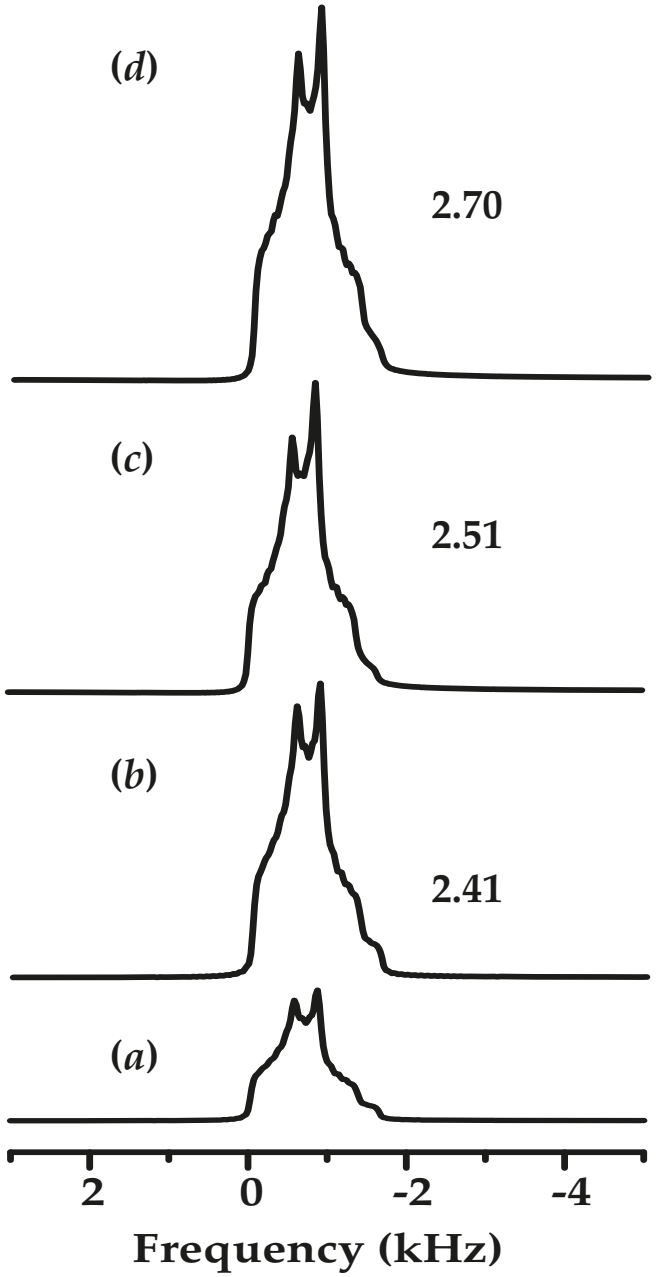
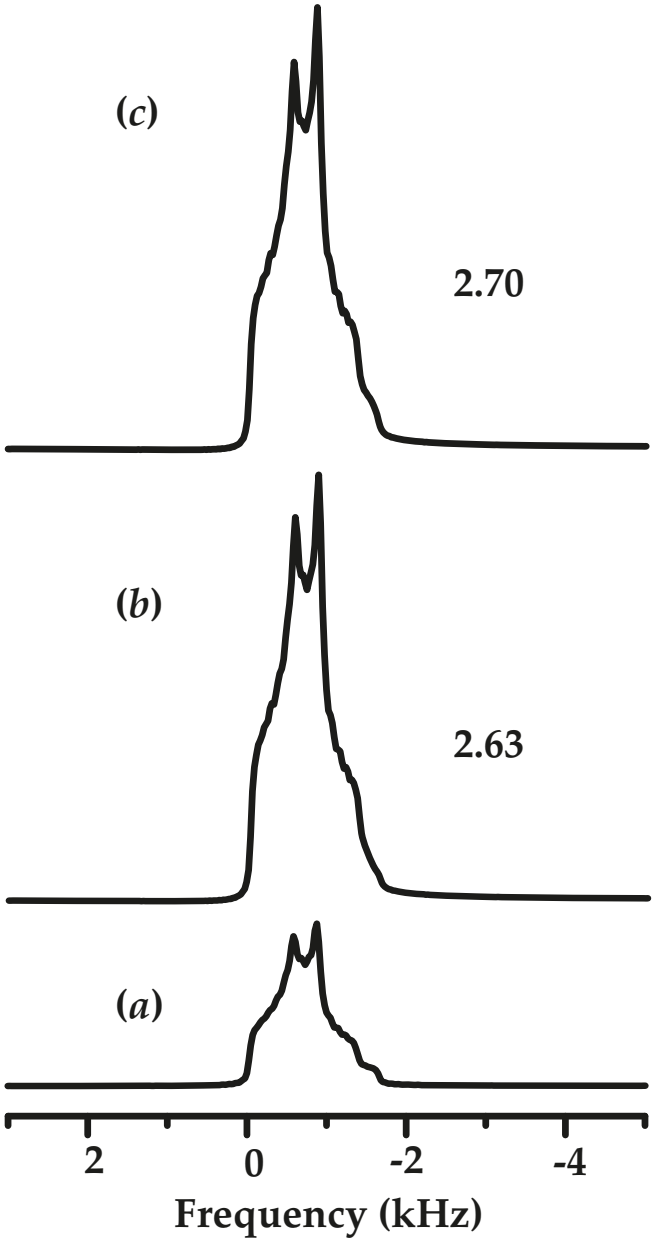
Fig. 5. Simulated 1D MAS spectra of ^{27}Al nuclei in Albite with quadrupolar coupling constant C_Q and asymmetry parameter η equal to 3.29 MHz and 0.62, respectively, using different pulse schemes. (*a*) A single 90°, (*b*) DFS running from 900 kHz to 100 kHz, (*c*) DFS running from 170 kHz to 160 kHz, (*d*) ssDFS. The numbers on the right of each spectrum denote the associated signal enhancements with respect to the single-pulse experiment.



simulations show that the DFS with bandwidth equal to MAS rate, ν_r, should perform better than normal DFS whereas the ssDFS should perform even better (Fig. 5). When we further compared the ssDFS with the HS pulse, it turned out that in simulations as in experiments they behave comparably to each other (Fig. 6). Similar observations were made when we did numerical simulations for spin-3/2 and spin-7/2 systems. The results are given in Table 2. For simulations of a spin-3/2 system, we used the quadrupolar parameters of ^{87}Rb in $RbClO_4$ (C_Q = 3.29 MHz and η = 0.2) and for a spin-7/2

Fig. 6. Simulated 1D MAS spectra of ^{27}Al in Albite. (*a*) A single 90°, (*b*) hyperbolic secant pulse, and (*c*) ssDFS. The numbers on the right of each spectrum denote the associated enhancements with respect to the single-pulse experiment.



system we used the quadrupolar parameters of ^{43}Ca in $CaTiO_3$ (C_Q = 2.13 MHz and η = 0.7). The data indicate that the ssDFS scheme is universally applicable to all nuclei with half-integer quadrupolar spins.

Next we simulated the robustness of the enhancement factor obtained by the ssDFS scheme as a function of the variables such as RF field strength, sweep length, bandwidth, and carrier offset of the ssDFS scheme.

At first, we varied the length of the ssDFS. As in the experiments, the optimum sweep length was equal to 10 rotor periods i.e., 1000 μs, and was varied from the 5th to the 15th rotor period. As in the experimental results, the enhancement factor shows significant robustness with respect to the change of the sweep length(Fig. 4*a*). Next we plotted

Table 2. Simulated optimal enhancements obtained with respect to a single 90° pulse at 10 kHz MAS, using different enhancement schemes for $I = 3/2$, 5/2, and 7/2 spin systems. The quadrupolar parameters of ^{87}Rb ($I = 3/2$) in $RbClO_4$ ($C_Q = 3.2$ MHz and $\eta = 0.21$), ^{27}Al ($I = 5/2$) in Albite ($C_Q = 3.29$ MHz and $\eta = 0.62$), and ^{43}Ca ($I = 7/2$) in $CaTiO_3$ ($C_Q = 2.13$ MHz and $\eta = 0.7$) were chosen as model parameters in the simulations.

Spin system(I)	Broadband DFS	Narrowband DFS	HS	ssDFS
Spin-3/2	2.25	2.45	2.58	2.60
Spin-5/2	2.41	2.51	2.63	2.70
Spin-7/2	3.19	3.41	3.55	3.64

the variation of the enhancement factor as a function of the RF power of the DFS, ν_{RF}^{DFS}. It is evident from the plot that as in the experimental findings, the simulated enhancement factor shows an initial fast build-up as a function of ν_{RF}^{DFS}, then flattens and remains flat almost throughout the range of the plot (Fig. 4*b*). The theoretical variation of the enhancement factor as a function of carrier frequency of the DFS is shown in Fig. 4*c*. Here we mimicked the experimental condition by changing the position of the transmitter from the center of the central transition to ±100 kHz on either side of the center with an increment of 10 kHz, so that the sweep is asymmetrical around the central transition peak. It is clear from the plot that the profile of the enhancement factor remains essentially flat throughout the whole range, showing very little dependence on the variation of the carrier offset. An observation which is again similar to the experimental observation.

Next, as we varied the bandwidth of the ssDFS, we observed that here as well the simulated results follow the experimental results and the enhancement factor shows an oscillating behavior when the bandwidth is varied (Fig. 4*d*). Further, the oscillation frequency of the simulated plot remains almost identical to that of the experimental plot. However, one clear difference between the simulated and experimental plots is that the experimental oscillation displays much more damping than the simulated one. One possible reason could be the finite line widths of the experimental ssbs. This means that experimentally it may not be possible to end the sweep exactly on top of an ssb, resulting in damped oscillation.

4. Conclusions

In this report, we have provided both theoretical and experimental proof that a narrowband DFS scheme performs better than a normal broadband DFS under MAS for spin $I = 5/2$. In general, adiabatic pulses focussing on the inversion of a single sideband seem to perform best in inverting the whole sideband manifold. Subtle differences between these adiabatic schemes are attributed to differences in the amplitude profiles applied to avoid unwanted non-adiabatic excitations of the spin system. The DFS scheme possesses the flexibility to be used with a narrow bandwidth for spinning samples as well as with a large bandwidth for static samples. Further, it has been shown that the enhancement obtained with an ssDFS scheme is actually comparable with that obtained with hyperbolic secant scheme. Simulations for spin $I = 3/2$ and $I = 7/2$ indicate that the advantages of the ssDFS scheme are applicable across the whole range of half-integer spin-quantum numbers. An additional increase in the signal may be obtained by using repetitive ssDFS as has been shown using multiple RAPT,[27] repetitive DFS,[28] and multiple FAM experiments.[29] The robustness of the ssDFS scheme with respect to the (peak) RF field strength of the DFS, carrier offset, and sweep duration of the DFS has also been demonstrated. All these observations display the broad applicability of the DFS method which can be optimized once and used for all purposes. It is expected that the combination of desirable features such as higher enhancement, robustness, and the ease of implementation associated with the ssDFS scheme will make the application of this method more routine.

Abstract: Flax is an important Canadian crop that contains a large percentage of fatty acids (FAs) by seed weight. Gas chromatography (GC) methods have traditionally been used to study FA distributions in oil seed crops. These methods, however, require sample preparation involving saponification and methyl ester formation. Recently, ^{1}H NMR has been shown to be an excellent way to directly measure FA distributions in edible oils using a nondestructive and experimentally faster methodology. As such, we have examined the FA profiles in developing bolls of flax cultivar AC McDuff using ^{1}H NMR and assessed the effect of cooking on FA stability and distribution. The data confirmed the high percentage of linolenic acid in mature AC McDuff flax seed compared to early stages of development and showed that FAs at early stages of boll development are more prone to thermal degradation. Triacylglycerol was found to be important to FA stability to heat. It was also observed that the FAs did not convert from cis to trans under the cooking process used herein. The usefulness of ^{1}H NMR spectroscopy in oils chemistry is highlighted.

Key words: fatty acid, flax, ^{1}H NMR, FA, triacylglycerol, omega-3, omega-6, omega-9.

Résumé : Le lin est un important produit agricole canadien contenant une grande proportion d'acides gras (AG) dans les graines. Les méthodes de chromatographie gazeuse (CG) ont traditionnellement été utilisées pour étudier la distribution des AG dans diverses cultures oléagineuses. Toutefois, ces méthodes requièrent une préparation d'échantillon impliquant une saponification et la formation d'ester. Récemment, il a été démontré que la RMN du ^{1}H est une excellente méthode pour mesurer directement la distribution des AG dans les huiles comestibles et qu'elle constitue une méthodologie non destructive et expérimentalement plus rapide. Pour cette raison, faisant appel à la RMN du ^{1}H, nous avons examiné les profiles des AG dans les capsules à graines du cultivar AC McDuff de lin et l'effet de la cuisson sur la stabilité et la distribution des AG a été évalué. Les données confirment que, par comparaison avec leurs stades précoces de développement, les graines matures du cultivar AC McDuff de lin contiennent des pourcentages élevés d'acide linolénique et que les AG des stades précoces de développement des capsules à graines de lin sont plus susceptibles à une dégradation thermique. Le triacylglycérol a été jugé important pour la stabilité des AG exposés à la chaleur. Il a été aussi observé que les AG ne sont pas convertis de cis en trans dans le processus de cuisson utilisé. L'utilité de la spectroscopie RMN du ^{1}H dans la chimie des huiles est mise en relief.

Mots-clés : acide gras, lin, RMN du ^{1}H, triacylglycérol, oméga-3, oméga-6, oméga-9.

[Traduit par la Rédaction]

Introduction

Flax (*Linum* usitatissimum L.) has emerged as a multipurpose crop with food, feed, and industrial applications.[1–4] In the food industry, flax seed is used as intact seed and (or) is processed in a variety of ways for use as food additives and for the nutraceutical market. Numerous health benefits have been associated with flax seed oil due to the large range of compounds found therein including, but not limited to, secoisolariciresinol diglucoside lignans[5,6] and omega-6 (linoleic acid) and omega-3 (linolenic acid) fatty acids (FAs).[2,7] This has recently been reviewed in detail.[8]

Flax products are increasingly being used in the functional food and nutraceutical markets, being directed, in particular, to obesity and other chronic diseases found in western societies.[1–4] As a functional food, ground flax, also known as flax meal, is found in breads and cereals, and can also be added to food matrices including juices and yoghurts to add nutritional value.[5,9] However, the question of whether the FA profiles are stable during processing remains a debate in the literature.[10] It has been reported that high levels of conjugated dienes are formed in Linola flax oil when treated at 140 °C for 40 min.[11] However, in flax seed fortified macaroni, the omega-3 level has been reported to remain unchanged after 32 weeks, both at low and elevated

temperatures.[12] In this study, the stability of the FAs, in developing AC McDuff flax bolls, mature flax seed, and flax meal, to a heating process commonly used in vegetable preparations will be examined.

There are five main fatty acids found in flax seed oil,[8] which can be broken down into four types: omega-3, omega-6, omega-9, and saturated FAs. Linolenic (omega-3, 18:3) and linoleic acids (omega-6, 18:2) are polyunsaturated FAs (PUFAs), oleic acid (omega-9, 18:1) is an unsaturated FA (UFA), while stearic (18:0) and palmitic (16:0) acids are saturated FAs (SFAs). In the A:B naming system, A tells the length of the chain (18 carbons) and B the number of double bonds in the chain. PUFAs, UFAs, and SFAs, as well as trans fats, are all contained on the labels of edible oil products.

Liquid NMR spectroscopy is used for small molecule structural elucidation, chemical purity assessment, and protein or biomolecule function and structure daily in NMR laboratories.[13] In recent years, looking at complex mixtures by NMR has become more and more common. NMR metabolomic methods for blood and urine samples have almost become routine with the commercial databases available. More recently, protocols and databases for plant extracts are in developmental stages.[14,15] In a similar way, oil mixtures can be studied quantitatively by ^{1}H NMR.[16,17] Even though the oils are not chemically pure, characteristic peaks are available to be able to completely identify the relative FA distribution in oils via ^{1}H NMR analysis. There have been reports on using such methodology in fish oils,[18–21] olive oil,[22] with particular interest in botanical origin,[23] monitoring oxidation in FAs,[24–26] studying edible oils including flax,[27–29] and recently using NMR in nutritional labeling.[30]

Gas chromatography (GC) is the method of determination of fatty acid content accepted by the American Oil Chemists' Society[31] and thus is the benchmark for the study of oils. GC methods, however, involve chemical conversion of triacylglycerol stored fatty acids to methyl esters of fatty acids before running the method. This involves cost in both chemicals and person-hours, and GC also requires standards of FAs. Using NMR, however, does not require the costs for the chemical conversion, does not require standards, and NMR has been shown to give results with accurate determination of the relative amounts of 18:3, 18:2, 18:1, and saturated fatty acids.[16] In as much, the FA profiles of developing bolls of the flax cultivar AC McDuff were examined before and after a heating treatment using a ^{1}H NMR methodology. We will show that the percentage of UFAs increases as the bolls develop, that the heating treatment has a major impact on the FA profiles during early stages of boll development, and little effect on late stage bolls as well as mature flax seed, and the heating treatment does not convert cis FAs to trans FAs.

Experimental

Plants from cultivar AC McDuff were grown in 10 pots, with 5–7 plants per pot, in a growth chamber (16/8 h light/dark and 20/18 °C day/night). At anthesis (when a flower fully blooms), individual flowers were tagged sequentially and developing bolls (the seed bearing capsules) were harvested at 4, 8, 12, and 16 d after anthesis (DAA) as well as at mature seed. Harvested bolls were immediately frozen in liquid nitrogen and then stored at –80 °C until the samples were processed.

Two grams (2 g) of developing bolls (4, 8, 12, and 16 DAA), flax seed, and ground flax seed (to be referred to as flax meal hereafter) were split into two samples with 1 g in each group. We placed one group of samples in 15 mL centrifuge tubes and heated them at 100 °C for 30 min in a water bath, hereafter referred to as cooked, while the others were untreated and will be referred to as raw. The FAs were extracted from the samples using the following protocol, which is a slight modification of that of McKillican and Sims.[32] After the cooking step, all the samples were flash-frozen in liquid nitrogen, ground to fine powder using a mortar and pestle, and extracted with 10 mL of deoxygenated hexane, in a glass tube, for 16 h on a shaker. After centrifugation at 17 500*g* for 5 min, the supernatant was collected and the hexane was evaporated under a nitrogen gas stream for 90 min. To ensure all of the hexane was removed, the samples were placed in a vacuum desiccator for 16 h. These samples were prepared in triplicate.

The dried FA samples were diluted with 600 μL of dry $CDCl_3$ and transferred to 5 mm NMR tubes. The ^{1}H NMR spectra were acquired on a Bruker Avance III 600 NMR spectrometer with a ^{1}H operating frequency of 600.28 MHz. A 5 mm inverse probe was used for all experiments with a controlled temperature set to 25.00 °C ± 0.01 °C. A 30° pulse (π/2 pulse of 7.3 μs), an acquisition time of 2.65 s (64 k-points), a recycle delay of 2 s, a spectral width of 12.3 kHz, and 16 scans were acquired for each experiment. Three independent spectra were acquired for each developmental stage for statistical analysis. The relative amount of FAs was determined quantitatively using the integrals (areas) of specific peaks as described by Knothe and Kenar.[16]

Results and discussion

^{1}H NMR spectra of the FAs extracted from developing flax bolls (raw) and mature flax seed of AC McDuff were acquired. These spectra are presented on the left side of Fig. 1. To gain an understanding of the FA distribution, Fig. 2 shows an expansion of the ^{1}H spectrum of the mature flax seed and the peaks used in the determination of the FA distribution. Using the integrals for peaks labeled A, B, C, and D in Fig. 2, the relative amounts of 18:3, 18:2, 18:1, and SFAs can be determined using the equations shown here[16]:

$$18:3 = C/(C+D) = 45.5\%$$
$$18:2 = (B/3 - 4 \times 18:3)/2 = 17.4\%$$
$$18:1 = (A/3 - 4 \times 18:2 - 6 \times 18:1)/2 = 25.1\%$$
$$\text{Saturated} = 1 - 18:3 - 18:2 - 18:1 = 12.0\%$$

Peak A are from the alkene protons only found in UFAs; peak B is unique to a methylene group located between two double bonds found in PUFAs; peak C is specific to the methyl group of linolenic acid; peak D all other methyl groups; peaks labeled G are derived from the glycerol backbone common to all storage lipids. Before numerical spectra analysis of Fig. 1, there are a number of qualitative comments that can be made from the ^{1}H NMR spectra. Since

Fig. 1. [1]H NMR spectra of AC McDuff raw and cooked flax bolls at different developmental stages.

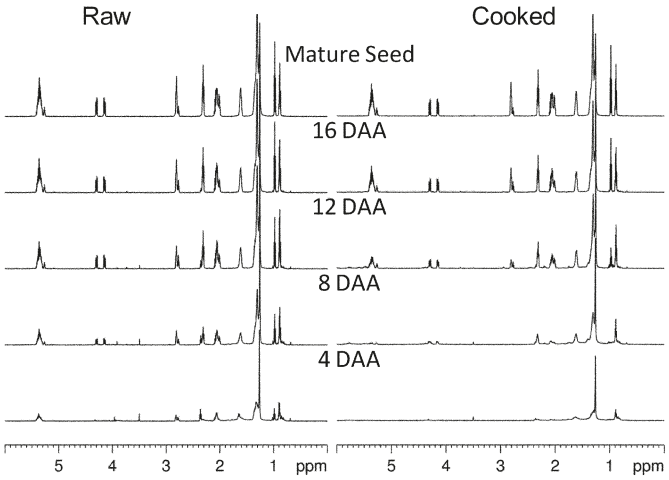

Fig. 2. Method of analysis of FA distribution from a [1]H NMR spectrum. The ratio of peaks C and D give the relative amount of 18:3 in the sample. This information and peak B give the relative amount of 18:2. These two numbers and peak A give the relative amount of 18:1. With these three numbers, the amount of SFAs is the remainder.

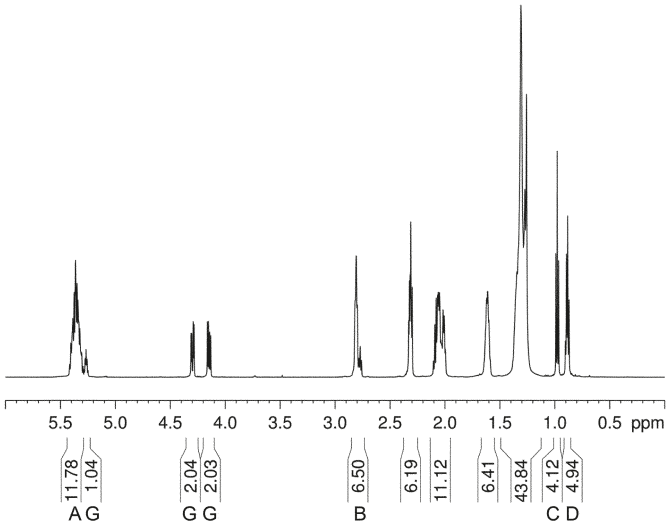

peak C is only found in omega-3 FAs, it is observed that at early stages of development there is only a small amount of 18:3. As the flax matures, a greater amount of 18:3 is present. In a similar way, peak B from PUFAs is small at early stages and is larger in relative abundance as the seed develops. These observations are in agreement with those made by Fofana et al. who reported an increased FAD2 (fatty acid desaturase 2) desaturation activity after 8 DAA leading to 18:2 which is immediately converted into 18:3 by FAD3 (fatty acid desaturase 3) activity.[33] Peaks G also grow in relative intensity as the seed develops. Thus, there are more free FAs at early stages of development and most FAs are stored as triacylglycerol esters in later stages of development which agrees with other literature reports.[34]

The FA distribution of the raw flax samples can be determined as described by Knothe and Kenar.[16] The results of the uncooked samples are given in Table 1. Even at early stages of development, there is a greater amount of UFAs than SFAs and the PUFA are two-thirds of the UFAs. As the flax boll develops, the amount PUFAs continues to increase though there is little difference between 16 DAA and mature seed. However, the amount of linolenic and linoleic acids favor the omega-3 FA in mature seed. The relative amount of SFAs continues to decrease as the flax develops until it is only ~12% in mature seed.

As described above, the flax samples were also cooked. The right side of Fig. 1 shows the [1]H NMR spectra of the cooked samples. At early stages of boll development, the cooking process almost completely degraded the UFAs (peaks A, B, and C are obliterated) that are present in the raw samples. At 12 DAA, some degradation of UFAs was observed, but at later stages of development and mature seed, the cooking process has very little effect on the FA distribution. There is a significant amount of glycerol signals (the G peaks) in 12 DAA and more developed flax bolls as compared to the earlier developmental stages. FAs are typically stored as glycerol esters in plants, which appears to provide protection from heat, at least for the conditions used in this study.

In the baking industry, flax is used both as whole seed as well as ground into a meal. In as much, a comparison of cooking the seed and the meal was done and the methyl group region of the NMR spectra are seen in Fig. 3. From a qualitative point of view, there does not appear to be any degradation in either the whole seed or the meal. Comparison of the oil distribution of raw and cooked flax bolls, seed, and meal is summarized in Table 1. There is very little UFA left (15% or less) after the cooking process at early stages in development. At 12 DAA there is a significant loss (over 50%) of PUFAs when comparing cooked and raw, however, there is still over 50% UFAs. In later stages of development, there are only minor effects on the FA distribution between cooking and raw. The greatest effect seen in 16 DAA bolls was the relative amount of 18:2 (loss of 3.7%) and 18:1 (increase of 3.8%). The seed products, both whole and meal, have very little effect of the FA profiles under the cooking conditions used here.

Recently a new [1]H NMR method has been described to study FA profiles which requires less data manipulation than that used in the current study.[17] This recent method uses the fact that in commercial edible oils the FAs are stored as triacylglycerols. The glycerol peak at 4.27 ppm is used as an internal standard to determine the levels of the different FAs. However, since we were interested in FAs during flax boll development, and the FAs are not all esterified to glycerols in a storage form at early stages as shown by the [1]H NMR spectra, the [1]H NMR analysis method we used[16] was the preferred method. Indeed, by comparing the [1]H NMR analysis method used here and the more recent method on the mature flax seed, where all the FAs are stored as triacylglycerols, the same results were obtained within a 1% error margin.

Using [1]H NMR in nutritional labeling of edible oils has recently been proposed. Labeling on nutritional labels in numerous districts require the amounts of total fats (i.e., FAs) saturated fats, and trans fats be labeled. In edible oil products like margarines, mono-unsaturated and poly-unsaturated (both omega-3 and omega-6) are also included on the nutri-

Table 1. Fatty acid content in developing AC McDuff flax bolls, seed, and meal before and following a cooking treatment as determined by ^{1}H NMR.

	18:3	18:2	18:1	Saturated
4 DAA Raw	28.0% (0.5)	9.9% (2.6)	17.9% (2.8)	44.2% (1.0)
4 DAA Cooked	0.4% (0.4)	1.5% (0.7)	10.1% (2.0)	88.0% (2.5)
8 DAA Raw	34.5% (0.3)	11.9% (1.6)	23.0% (0.6)	30.6% (1.1)
8 DAA Cooked	2.3% (0.8)	1.1% (0.6)	10.9% (2.3)	85.7% (2.1)
12 DAA Raw	37.0% (0.3)	12.6% (0.8)	27.0% (0.4)	23.5% (0.6)
12 DAA Cooked	17.8% (1.3)	5.0% (2.8)	31.3% (0.4)	45.9% (3.6)
16 DAA Raw	40.5% (0.9)	22.0% (0.9)	16.5% (0.8)	21.0% (0.8)
16 DAA Cooked	39.1% (0.4)	18.3% (2.2)	20.3% (1.1)	22.3% (0.8)
Raw Seed	45.3% (0.2)	17.2% (0.7)	25.2% (0.7)	12.3% (0.4)
Cooked Seed	44.3% (0.5)	17.0% (0.5)	25.9% (0.7)	12.8% (0.5)
Raw Meal	45.2% (0.3)	16.2% (0.6)	26.8% (0.6)	11.8% (0.3)
Cooked Meal	45.0% (0.3)	16.2% (0.4)	27.0% (0.5)	11.8% (1.6)

Note: The oil percentage is given as a mean of triplicate samples. The errors given in parenthesis are one standard deviation from the mean.

Fig. 3. Comparison of the methyl regions of the ^{1}H NMR spectra of flax seed vs. flax meal with and without a cooking treatment.

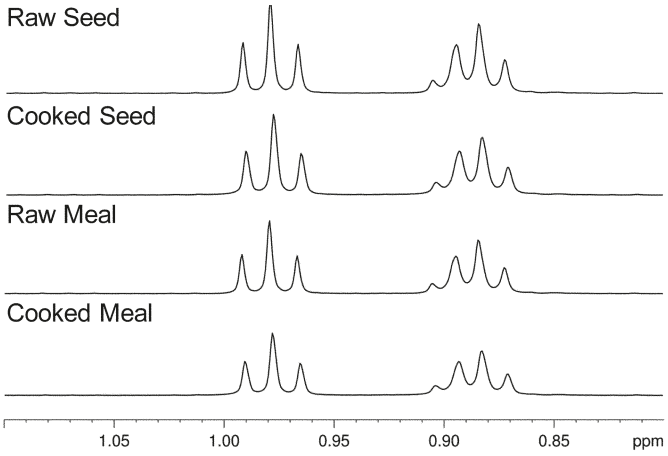

Fig. 4. Comparison of the chemical shift region of the ^{1}H NMR spectra of 12 DAA bolls raw and cooked where trans FAs would be observed if any were present.

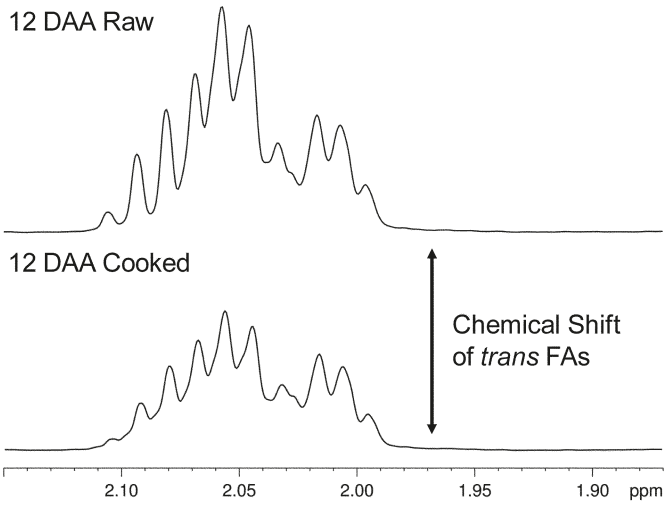

tional labels. One reason for using NMR in labeling is that trans FAs can be determined readily and quickly from a quick inspection of an ^{1}H NMR spectrum of an edible oil. Though the GC is the standard method for looking at FA distributions (including trans FAs), NMR is non-destructive and ^{1}H NMR is faster to acquire than GC methods. The cooking treatment of the bolls and seed performed in this study did not result in conversion of cis to trans FAs. Figure 4 shows an expansion of the region of the ^{1}H NMR spectrum for the 12 DAA raw and cooked bolls and no trans FAs was observed. Thus the cooking process applied here did not convert the cis FAs into trans FAs. Recently, Fofana et al.[35] have suggested the use of developing flax bolls as a fresh vegetable and the discovery that the FAs found in flax bolls do not convert from cis to trans under thermal stress adds credence to this possibility.

In this study, we did not use 90° pulses or long delay times that are usually found in quantitative NMR studies. When using 30° pulses vs. 90° pulses one can use shorter delays in particular when the number of scans is low (16 in this study) since only 50% of the magnetization gets into the x-y plane. That being said, it does introduce a small error based on previously measured T_1s in oils.[17] When we compared delay times of 4.65 s (acquisition time of 2.65 s plus 2 s delay time), 10 s, and 20 s, we found that there was a very small error in the integrals between the shorter delay times, and no difference for delays longer than 10 s. In our lab we are trying to develop rapid methodologies for the determination of metabolites in plant extracts, thus we decided to use the shorter delay time. The integration error from using shorter delay times, which when put into the equations to calculate the relative amounts of the oils, was found to be less than the error from the triplicate samples.

Conclusions

This study allowed us to determine the FA profiles of developing flax bolls of AC McDuff using a ^{1}H NMR method. As AC McDuff flax bolls develop, the relative amounts of UFAs and PUFAs increase as compared to saturated FAs. Cooking the flax bolls had little effect on FA profiles at later stages of development as consequence of their esterification to glycerol into the triacylglycerol storage form. In contrast, the cooking process had a major impact on the FA profile at early stages where, when the triacylglycerol forms are minimal. The heating process did not lead to any conversion of

cis to trans FAs at any stage in this study. These finding could have a high impact if flax bolls have to be used as a steamed vegetable.

Abstract: Properties of a thermotropic nematic liquid crystal (LC) TM35 (organosiloxane tetrapode) were investigated by means of nuclear magnetic resonance (NMR) spectroscopy of probe atoms and molecules. ^{129}Xe isotope enriched xenon gas and ^{2}H isotope enriched chloroform were used as probes. Both ^{129}Xe and ^{2}H NMR measurements were carried out over a wide temperature range, covering isotropic, nematic, and glass phases. A clear change in the behavior of the LC is observed within the nematic phase at 289 K by changing the temperature from low to high and inspecting the spectral line width. The derivative curve of the ^{129}Xe chemical shift also reveals a change at 289 K. These changes may be an indication of hindered molecular rotation around the long axis, and the appearance of a biaxial nematic phase.

Key words: liquid crystal, biaxiality, xenon, chloroform, nuclear magnetic resonance (NMR).

Résumé : Faisant appel à la spectroscopie résonance magnétique nucléaire (RMN) d'atomes et de molécules cibles, on a étudié les propriétés du cristal liquide (CL) nématique thermotrope TM35 (organosiloxane tétrapode). Du xénon gazeux enrichi en isotope ^{129}Xe et du chloroforme enrichi en isotope ^{2}H ont été utilisés comme sondes. Les mesures de RMN du ^{129}Xe et du ^{2}H ont toutes été effectuées sur une large plage de températures couvrant les phases isotropes, nématiques et vitreuses. On observe un changement net dans le comportement du cristal liquide dans la phase nématique, à 289 K, lors du changement de température vers les températures élevées et par l'examen de la largeur de raie de la bande. La courbe dérivée du déplacement chimique du ^{129}Xe révèle aussi un changement à 289 K. Ces changements peuvent être une indication du fait qu'il existerait un empêchement à la rotation moléculaire autour de l'axe long ainsi que l'apparition d'une phase nématique biaxiale.

Mots-clés : cristal liquide, caractère biaxial, xénon, chloroforme, résonance magnétique nucléaire (RMN).

[Traduit par la Rédaction]

Introduction

The foundation of many flat-screen liquid crystal displays (LCD) is based on thermotropic uniaxial nematic (N_u) liquid crystals.[1,2] However, for example, the functionality of displays could be remarkably improved if biaxial nematic (N_b) liquid crystals were available. In fact, the first prediction of the existence of the thermotropic biaxial nematic liquid crystal was already made in 1970.[3] Biaxial nematic liquid crystals possess two directors usually marked by *n* and *m*; *n* is the same as in the uniaxial case, but *m* is the director of the secondary molecular alignment. It is predicted that the *m* responds to an electric field much faster than *n*. The response time is expected to be even 100 times faster.[4] In addition, the electric field needed for the director reorientation is estimated to be much smaller than in the case of a uniaxial nematic liquid crystal, which means a smaller power consumption by the system. Therefore, biaxial nematics have acquired a lot of theoretical as well as experimental efforts throughout the last couple of decades.

The nematic biaxiality has been observed in both lyotropic[5] and polymeric[6] liquid crystals. For thermotropic liquid crystals, however, the biaxiality has remained elusive. Many claims of the foundation of this missing phase have been proven to be wrong or at least questionable by ^{2}H nuclear magnetic resonance (NMR) spectroscopy, which is widely believed to prove whether or not biaxiality is present.[7] In this method, a fully or partially deuterated probe molecule is dissolved into the studied environment. This method has been applied to boomerang-shaped liquid crystal molecules and the results indicated small biaxiality.[8] Recently, apart from ^{2}H NMR, ^{13}C NMR was also used to investigate the biaxial phase in a V-shaped mesogen.[9] A significant breakthrough happened when it was discovered that a ^{131}Xe second-order quadrupole shift could be used to distinguish between uniaxial and biaxial nematic phases.[10] A great advantage of

this method is that the information is obtained from a static sample, i.e., no sample rotation is needed. ^{2}H NMR spectroscopy,[8,11–13] X-ray diffraction (XRD),[4,14,15] adiabatic and different scanning calorimetries (ASC and DSC),[4,16] polarizing optical microscopy (POM),[4,8,14,17] infrared absorbance,[17] dynamic light scattering,[18] and theoretical and computational studies[19–23] have proven that biaxiality arises mainly from the structure of the liquid crystal molecules. In order for a liquid crystal molecule to possess a biaxial nematic phase, its structure must deviate from cylindrical symmetry. This means that the molecule should be shaped as a boomerang[4,8,14] or a lozenge.[11,12,17,18] Another possibility is to mix rod- and disk-shaped molecules.[20,24,25] The most essential thing is that the rotation of molecules is hindered, which gives an opportunity for biaxiality to develop. In addition, the biaxial nematic phase occurs at a lower temperature than the uniaxial one. Furthermore, the phase transition from biaxial nematic to uniaxial nematic is predicted to be of the second order, whereas transition from the nematic uniaxial to isotropic phase is of the first order.[26]

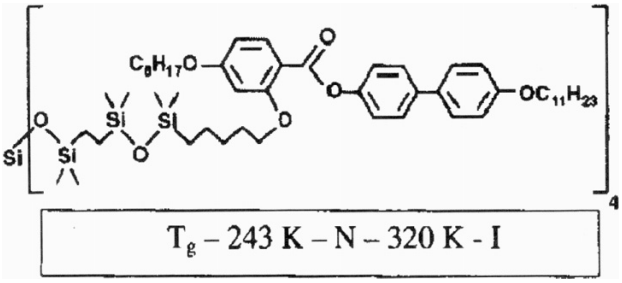
In this study, we present the results derived from static ^{129}Xe and ^{2}H NMR experiments of xenon gas and chloroform dissolved into the plate-shaped organosiloxane tetrapode (TM35), which has earlier been reported to form a thermotropic biaxial nematic phase (see Fig. 1).[11,12,16] ^{129}Xe NMR has proven to be a particularly applicable approach to derive physical properties of thermotropic liquid crystals.[27–30] This method immediately reveals the sign of the anisotropy of the diamagnetic susceptibility tensor and phase transitions when spectra are taken over a sufficiently wide temperature range. Furthermore, it makes feasible the derivation of order parameters (both orientational and positional ones) in nematic and smectic A phases, and together with these, the temperature dependence of the tilt angle in smectic C and C* phases.[31] Since the ^{129}Xe chemical shift is proportional to the density, information may be obtained on this property and thus on the isobaric thermal expansion coefficient.

The molecular structure of the liquid crystal used, TM35, is shown in Fig. 1 and it is reported to posses the following four phases: glass, biaxial nematic (N_b), uniaxial nematic (N_u), and isotropic (I). All phases, especially the biaxial one, occur close to room temperature, which makes experimental measurements and possible forthcoming applications easier to perform.

Experimental

All the studied samples were prepared in standard Wilmad NMR capillary tubes (outer diameter 3.3 mm, inner diameter 2.3 mm). The liquid-crystalline compound TM35 was first placed inside the capillary tube and degassed by several heating and cooling periods while the sample tube was simultaneously attached to the vacuum line. After degassing, about 2 atm (1 atm = 101.325 kPa) of ^{129}Xe isotope enriched xenon gas (enrichment 85%, Spectra Gases, NJ, USA) was added and the sample tube was sealed by a flame. It is estimated that the concentration of xenon was about 1 mol%. Finally, temperature durability of the sample was tested in an oven and the capillary tube was placed inside a thin-walled 5 mm NMR sample tube (outer diameter 5 mm, inner diameter 4.24 mm) with spacers. The space between the two tubes

Fig. 1. The molecular structure of the organosiloxane tetrapode (TM35) used as a medium in the present study. The phase transition temperatures reported for the bulk liquid crystal are shown below the structure.[12] The nematic phase (N) may consist of both uniaxial and biaxial phases. T_g = glass phase. I = isotropic phase.



was filled with deuterated acetonitrile (CD_3CN; 99%, Stohler Isotope Chemicals, NJ, USA) and it was used as a lock substance. The sample in which deuterated chloroform ($CDCl_3$; 99.8%, MSO Isotopes, Montreal, Canada) was used as a probe was prepared in a different way. No degassing process was performed but the sample tube was directly sealed with epoxy glue and heat tested. The concentration of $CDCl_3$ was about 10 mol%. In this case, cyclohexane (C_6H_{12}; Merck, Darmstadt, Germany) was used as a substance between the sample tubes to ease shimming. Standard 1D NMR measurements were performed mainly on a Bruker Avance DRX 500 NMR spectrometer equipped with a 5 mm high-resolution BBI probe head and BVT2000 variable temperature controller. In measurements performed below room temperature, liquid nitrogen cooling was used. The sample temperatures were calibrated at the lowest and highest points of the temperature series using standard temperature calibration samples.[32] The temperature series was measured using a step of 1 K. The temperature stabilization time between experiments was 10–15 min.

Results and discussion

Figure 2 shows ^{129}Xe NMR spectra at variable temperatures from the static sample containing ^{129}Xe isotope enriched xenon gas and TM35 liquid crystal. In the isotropic state, the chemical shift changes linearly as a function of temperature, which is a consequence of the linear behavior of the density, as will be discussed below. At the transition from the isotropic to nematic phase, the chemical shift increases abruptly by about 5 ppm. From 314 to 265 K, the chemical shift behaves as it usually does in uniaxial nematic phases.[33] Obviously, the sample supercools and transforms directly from the uniaxial nematic state to a glassy state.

Figure 3 shows static ^{129}Xe NMR spectra from the same sample as those in Fig. 2. However, now the temperature series was measured from 206 K to 327 K with a step of 1 K. At the lowest temperatures no signal is seen. The most likely reason for this is that liquid crystal is frozen and xenon atoms are mostly squeezed out from the crystallized medium. Part of the xenon atoms may be captured inside the solid medium but their NMR line width is so broad that it does not stand out from the background.

As the temperature increases to about 233 K, a broad signal emerges from the background. The reason for this observation is not evident and needs further investigation. Such a

Fig. 2. Static ^{129}Xe NMR spectra from ^{129}Xe isotope enriched xenon gas in TM35. The measurements were performed by cooling the sample from the isotropic to solid phase in steps of 1 K. The small distortion at 299 K results from tuning the probe head.

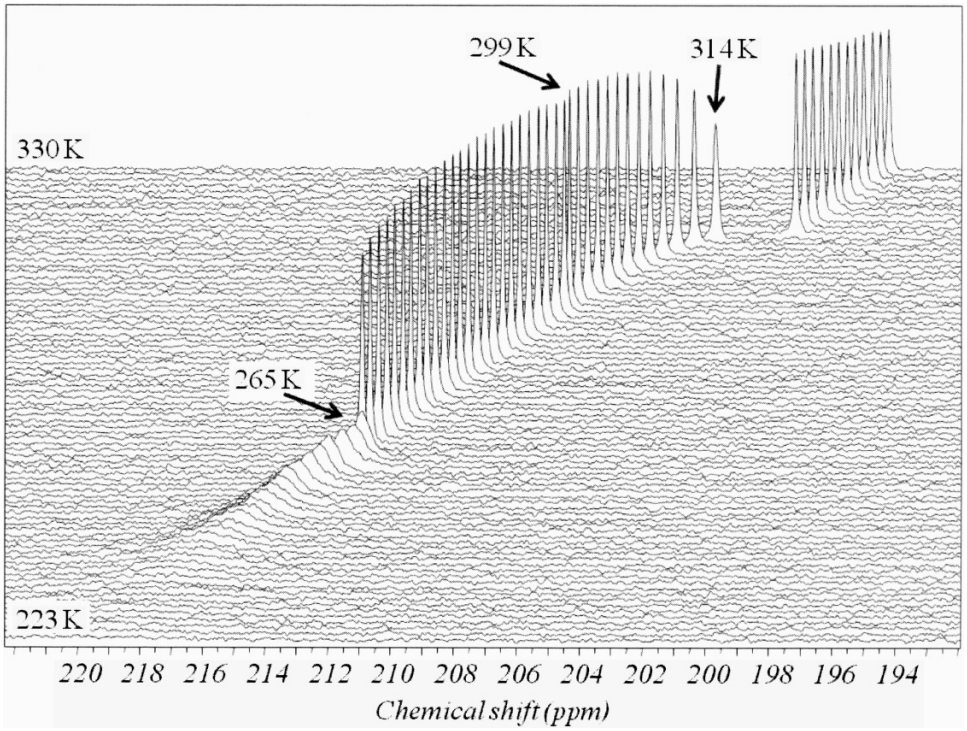


Fig. 3. Static ^{129}Xe NMR spectra from the sample containing liquid crystal TM35 and ^{129}Xe isotope enriched xenon gas. The measurements were performed by heating the sample from the solid to isotropic phase in steps of 1 K.

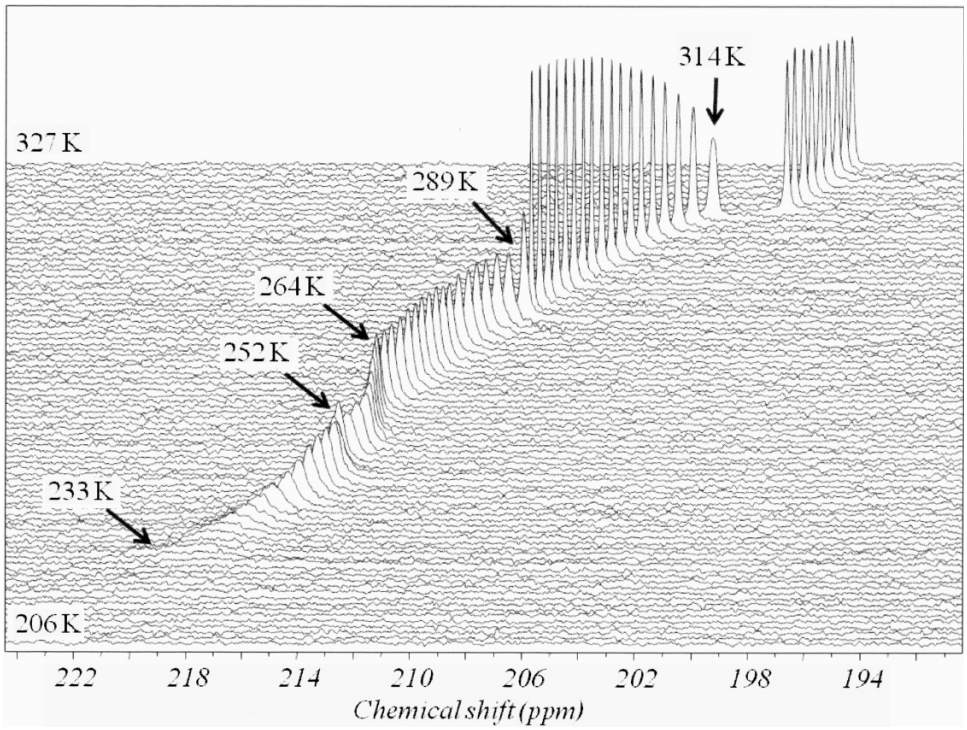

phenomenon has been found in many liquid-crystalline substances when the sample is frozen in liquid nitrogen.[34]

The transition from the uniaxial nematic (N_u) to isotropic (I) phase takes place at the same temperature as when changing temperature in the reversed order. Apart from this transition there is another transition at 289 K, which does not appear in Fig. 2. This is clearly seen as an abrupt change in the line width. The broad lines below 289 K may indicate

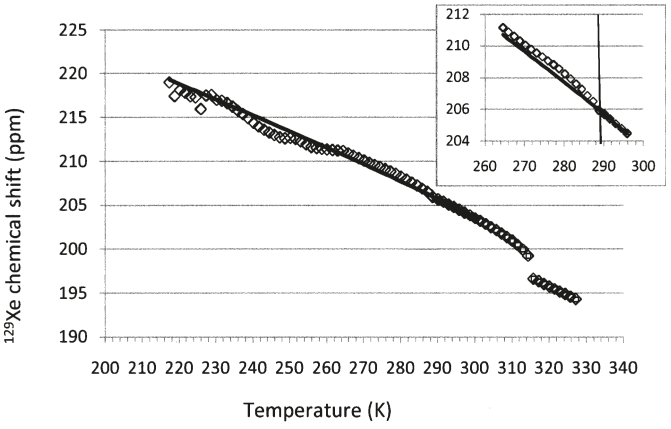
[b]Kept fixed.

Fig. 4. ^{129}Xe chemical shift as a function of temperature for xenon in TM35. Experimental shifts are indicated by diamonds. The sample was heated from the solid to isotropic phase in steps of 1 K. The solid line is a result of least-squares fits of eq. [2] to experimental points in the isotropic and uniaxial nematic phase. The inset shows a narrower temperature range that reveals the difference in chemical shift between extrapolated uniaxial behavior (solid curve) and experimental points below 289 K.



that the rotation of liquid crystal molecules around their long axes is more hindered than above 289 K. This could be regarded as a signature of a biaxial nematic phase (N_b).

Earlier NMR experiments of xenon in various uniaxial thermotropic nematic liquid crystals have indicated that the ^{129}Xe shielding is extremely sensitive to even very subtle changes in the environment of xenon. This is due to the strongly polarizable electron cloud of the atom. One observation is that the chemical shift (nuclear shielding) changes abruptly at the nematic–isotropic phase transition, and the direction of the change reveals the sign of the anisotropy of the diamagnetic susceptibility tensor of the liquid crystals. Thus, if the chemical shift decreases (shielding increases) when moving from the nematic to isotropic phase, as it does in the present case, it indicates that the sign of the anisotropy is positive and the liquid crystal director orients along the external magnetic field.

Fig. 5. Line width (full width at half -height (fwhh)) of the ^{129}Xe resonance line as a function of temperature for xenon in TM35. The vertical lines show the transition temperatures. The temperature was changed from low to high. Cr = crystal.

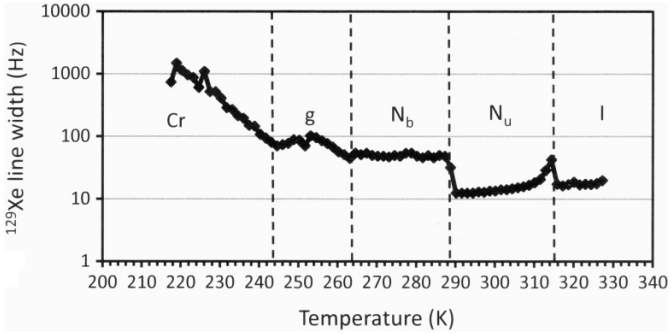


Fig. 6. Absolute derivate of the experimental ^{129}Xe chemical shift curve.

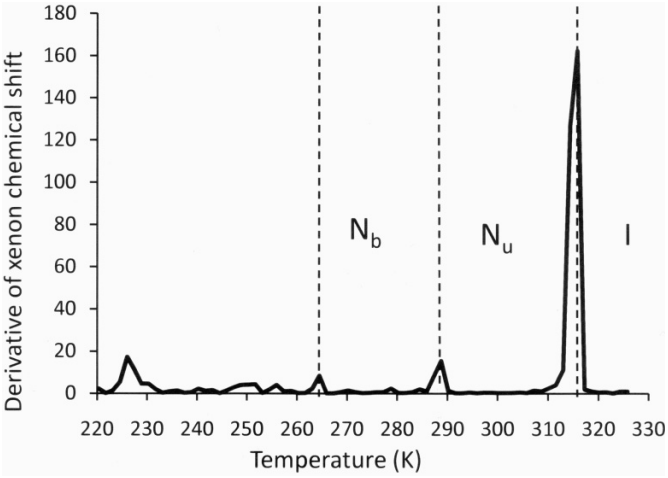
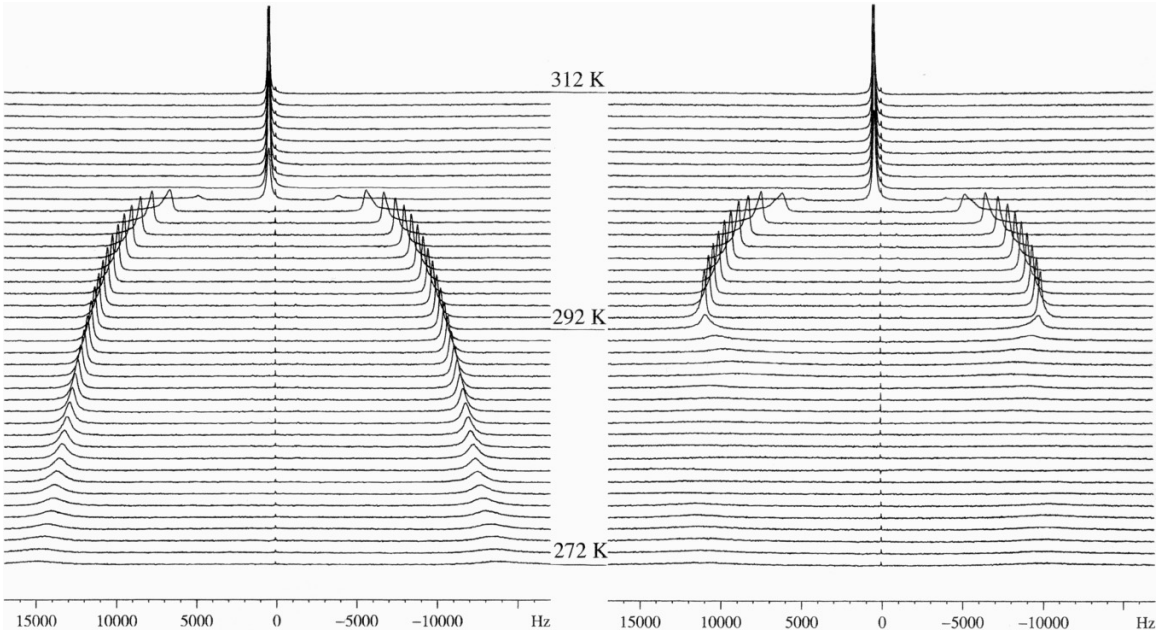


It has been shown that the ^{129}Xe shielding in a uniaxial nematic phase is proportional to the liquid crystal density, $\rho(T)$, and that both the isotropic average of the shielding tensor and its anisotropy are dependent on temperature. These temperature dependencies can be approximated to be linear and are described by the coefficients ε_1 and ε_2, as shown in eq. [1]:[35]

$$[1] \quad \sigma(T) - \sigma_o = \rho(T)\left[\sigma'_d\left(1 - \varepsilon_1(T - T_o)\right) + \frac{2}{3}\Delta\sigma'_d\left(1 - \varepsilon_2(T - T_o)\right)S(T)\right]$$

Here, σ_o is the shielding constant of a reference, σ'_d and $\Delta\sigma'_d$ are the shielding constant and shielding anisotropy, respectively, in units ppm·cm^3/g at T_o, which is a reference temperature. T_o was chosen to be the uniaxial nematic–isotropic phase transition temperature. $S(T)$ is the orientational order parameter of the LC. The temperature dependence of density can be approximated by a linear function, $\rho(T) = \rho_o[1 - \alpha(T - T_o)]$, where α is the isobaric thermal expansion coefficient and ρ_o is density at T_o. In the first-order (in T) approximation (both α and ε's are small), eq. [1] leads to

Fig. 7. Static ^{2}H NMR spectra of the sample containing $CDCl_3$ and TM35 as a function of temperature. (Left) Spectra were taken with cooling the sample from isotropic phase. (Right) The sample was first frozen in liquid nitrogen and then moved to the magnet. The small peak at zero Hz arises from cyclohexane in the annulus of the double tube system.



$$[2] \qquad \sigma(T) - \sigma_o = \sigma_d^o[1 - \tau_1(T - T_o)] + \frac{2}{3}\Delta\sigma_d^o[1 - \tau_2(T - T_o)]S(T)$$

where $\sigma_d^o = \rho_o\sigma_d'$ and $\Delta\sigma_d^o = \rho_o\Delta\sigma_d'$ are the shielding constant and shielding anisotropy in ppm, respectively, at the reference temperature, $\tau_1 = \alpha^{iso} + \varepsilon_1{}^{iso}$, and $\tau_2 = \alpha^{nem} + \varepsilon_2{}^{nem}$. One should note that τ_1 and τ_2 may be and usually are different in isotropic and liquid-crystalline phases. $S(T)$ can be modeled with the so-called Haller function:[36]

$$[3] \qquad S(T) = \left(1 - y\frac{T}{T_o}\right)^z$$

where y and z are adjustable parameters. One should emphasize that eq. [2] omits the effect of bulk susceptibility and the possible density change at the nematic–isotropic phase transition. This is well justified as is shown below.

The bulk susceptibility effect, σ_b, on the shielding is[35]

$$[4] \qquad \sigma_b = -\frac{1}{3}\left[\chi_d + \frac{2}{3}\Delta\chi_d S(T)\right]\frac{\rho}{M}$$

where χ_d is the isotropic part and $\Delta\chi_d$ the anisotropy of the molecular susceptibility tensor, ρ is density, and M is the molar mass (3447.23 g/mol for TM35) of the LC. Diamagnetic susceptibility of thermotropic nematogens is of the order of -10^{-9} m^3/mol, and the anisotropy of susceptibility is of the same order, the sign being positive in the present case. The density of TM35 is not known but if we use 2 Si-*n*O-CB[37] as a model system then $\rho \sim 1.2$ g/cm^3. When these typical values, together with the molar mass of TM35, are used, the bulk susceptibility effect is on average below 0.1 ppm, and thus can be omitted without an effect on the conclusions.

When evaluating the effect of a possible density change at the nematic–isotropic phase transition, we are forced to again use typical values, which are below 1%.[37,38] This is a relatively small effect and it causes only a parallel shift in the chemical shift curve without affecting the general trend.

Least-squares fits to the experimental chemical shift data in the isotropic ($S(T) = 0$ in the isotropic phase) and uniaxial nematic phase produce the parameter values shown in Table 1. Experimental and calculated chemical shifts are shown in Fig. 4. The behavior of the chemical shift in the uniaxial nematic phase was extrapolated to lower temperatures as well. Figure 4 shows that the experimental curve goes systematically above the extrapolated curve. Obviously, the slight deviation between experimental and extrapolated shift values from 289 K to lower temperatures gives a hint of a liquid crystal phase transition, which is seen as a change in line width in Fig. 3. As eq. [2] shows, ^{129}Xe shielding (chemical shift) depends on many factors. The small change detected may arise from a slight change in density and (or) orientational order parameter or transformation of the cylindrically symmetric macroscopic orientational order tensor to a biaxial one. The density change affects both isotropic shielding and shielding anisotropy, whereas the latter two contribute only to the anisotropic part of the shielding.

However, a much more pronounced change at 289 K is seen in the line broadening than in the chemical shift (see Figs. 3 and 5). An intriguing observation, however, is that the line broadening cannot be detected at 289 K when changing the temperature from high to low.

The phase transitions derived from the ^{129}Xe chemicals shifts become more clearly visible in the derivative curve shown in Fig. 6 than in the chemical shift curve in Fig. 4. The curve displayed in Fig. 6 was obtained by the numerical derivation method of three points, which is valid in cases where the abscissa values are equally spaced.[39] The peaks in Fig. 6 appear (from the left) at 226.0, 264.5, 288.7, and 315.8 K. They are supposed to be signatures of the following

phase transitions: Cr – 226.0 K – T_g – 264.5 K – N_b – 288.7 K – N_u – 315.8 K – I.

Apart from the ^{129}Xe chemical shifts at variable temperatures, ^{129}Xe resonance line widths were determined as well. They are shown in Fig. 5, which reveals significant changes at ~315 K, the I–N_u transition, and 289 K, supposedly the N_u–N_b transition. The broadening at the isotropic–uniaxial nematic transition is a generally observed phenomenon, reflecting slight orientational order distribution in the nematic phase at temperatures close to the phase transition temperature. It can also be seen that there is a steep increase in the line width from ~243 K towards the lower temperatures. This is the temperature reported earlier for the glass–nematic phase transition. The derivative curve in Fig. 6 does not, however, reveal any transition at this temperature. Interestingly, the line width remains practically constant with a temperature range of 265–289 K.

Apart from ^{129}Xe NMR, ^{2}H NMR experiments were carried out as well, from a sample in which deuterated chloroform ($CDCl_3$) was used as a probe in TM35. In this case, measurements were performed in the same way as in the ^{129}Xe studies described above, i.e., from high to low and from low to high temperature. The stack plots are shown in Fig. 7.

Because the relative amount of chloroform in the sample was higher than that of xenon, the I– N_u phase transition temperature has shifted to ~12 K below the value observed in the ^{129}Xe studies (315 K). Otherwise, results are quite comparable. Namely, the transition at 289 K detected in ^{129}Xe NMR seems to be completely absent when the sample temperature is decreased from the isotropic phase but it develops when the temperature is increased from the solid phase. A phase transition takes place at 291–292 K, which is close to that in xenon studies (289 K).

Conclusions

Static ^{129}Xe NMR of xenon gas and ^{2}H NMR of $CDCl_3$ were applied to study the behavior of the thermotropic liquid crystal TM35, which has been found to display a biaxial nematic phase. The results indicate that the two probes are sensitive detectors of different phases and phase transitions of the liquid crystal. Both ^{129}Xe and ^{2}H NMR experiments reveal consistent results and indicate a phase transition at 289–291 K if experiments are performed by heating the sample from the solid state. Experiments carried out from static samples do not, however, reveal direct evidence of whether a nematic phase is uniaxial or biaxial. The transition detected is most likely a transition from the biaxial to uniaxial nematic phase. Decisive experiments are under development.

Abstract: We report here on an improved first principles method that can determine NMR shielding tensors for periodic systems. Our scheme evaluates the shielding tensor as the second derivative of the total electronic energy with respect to a nuclear magnetic moment and an external magnetic field. Both the induced current density $\boldsymbol{J}^{(\alpha)}$ due to the first perturbation from the nuclear magnetic moment as well as the interaction of $\boldsymbol{J}^{(\alpha)}$ with the second perturbation in the form of an external magnetic field are evaluated analytically. Our approach is based on Kohn–Sham density functional theory and gauge-including atomic orbitals. It employs a Bloch basis set made up of Slater-type or numeric atomic orbitals and represents the Kohn–Sham potential fully without the use of effective core potentials. The method is implemented into the periodic program BAND. The new scheme represents an improvement over a previously proposed method in that use can be made of the zero-order Kohn–Sham orbitals from a calculation based on a primitive cell instead of a supercell. Further, $\boldsymbol{J}^{(\alpha)}$ is evaluated analytically rather than by a finite difference approach. The improvements reduce the required computational time by up to two orders of magnitude for three-dimensional systems. Such a reduction is made possible by the fact that we are using atomic centered basis functions. The new implementation is further able to take into account scalar relativistic effects within the zero-order regular approximation. Results from calculations of NMR shielding constants based on the present approach are presented for systems with one-, two-, and three-dimensional periodicity. The reported values are compared to experiment and results from the previously proposed scheme.

Key words: periodic NMR calculations, shielding current, diamagnetic and paramagnetic shielding tensors.

Résumé : On rapporte une méthode améliorée basée sur des principes premiers qui permet de déterminer les tenseurs de blindage de RMN pour des systèmes périodiques. Le schéma évalue le tenseur de blindage comme deuxième dérivée de l'énergie électronique totale par rapport à un moment magnétique nucléaire et un champ magnétique externe. La densité de courant induite, $\boldsymbol{J}^{(\alpha)}$, due à la première perturbation provoquée par le moment magnétique nucléaire ainsi que l'interaction de $\boldsymbol{J}^{(\alpha)}$ avec la deuxième perturbation dans la forme d'un champ magnétique externe sont toutes les deux évaluées d'une façon analytique. Cette approche est basée sur la théorie de la fonctionnelle de la densité de Kohn–Sham et sur des orbitales atomiques comportant une jauge. Cette méthode a été réalisée à l'aide du programme périodique BAND. Ce nouveau schéma représente une amélioration sur la méthode proposée antérieurement par le fait qu'il peut être utilisé dans des orbitales de Kohn–Sham d'ordre zéro à partir d'un calcul effectué à partir d'une cellule primitive plutôt que d'une supercellule. De plus, $\boldsymbol{J}^{(\alpha)}$ est évalué d'une façon analytique plutôt que par une approche de différence finie. Les améliorations réduisent les temps de calculs requis par un facteur allant jusqu'à deux ordres de grandeur pour les systèmes tridimensionnels. Cette réduction est rendue possible par le fait qu'on utilise des fonctions de base centrées sur les atomes. Avec la nouvelle approche, il est aussi possible de prendre en compte des effets relativistes scalaires à l'intérieur de l'approximation régulière d'ordre zéro. On présente des résultats de calculs de constantes de blindage en RMN effectués en utilisant la nouvelle approche pour des systèmes avec des périodicités mono-, bi- et tridimensionnelles. Les résultats de ces calculs sont comparés avec des résultats expérimentaux et des résultats obtenus à l'aide du schéma proposé antérieurement.

[Traduit par la Rédaction]

Introduction

Solid-state NMR is an active experimental field of research, and NMR is used extensively to monitor the local electronic structure around a nucleus in a periodic solid. In recent years, it has furtherbeen possible to evaluate NMR shielding tensors from first principles[1–8] with a number of computational schemes that serve as useful supplements to the experimental techniques.

Theoretically, the shielding tensor is the second derivative

of the total electronic energy with respect to an external magnetic field and a nuclear magnetic moment. In most theoretical treatments the external magnetic field is introduced as the initial perturbation, inducing a current density with which the second responding perturbation in the form of the nuclear magnetic dipole interacts. Virtually all molecular NMR codes treat the two perturbations in this order, as does the recent periodic gauge-including projector augmented-wave (GIPAW) method developed by Mauri et al.,[2,3] in which the external magnetic field further is considered as oscillating to adopt to the periodic symmetry of the solid. It is also possible in a converse picture to consider the nuclear magnetic moment as the first perturbation inducing a current density $\boldsymbol{J}^{(\alpha)}$ with which the external magnetic field $\boldsymbol{B}$ as the second responding perturbation interacts. The converse approach has been introduced by Thonhauser et al.[4,5] in conjunction with GIPAW corrections and supercell techniques. It has the advantage, in the case of systems with translational symmetry, that the first perturbation due to the magnetic dipole can be considered periodic if a supercell approach is adopted. However, due considerations must still be given to the description of the interaction between $\boldsymbol{J}^{(\alpha)}$ and the nonperiodic constant external magnetic field $\boldsymbol{B}$. Sebastiani and co-authors[6] applied an infinitesimal magnetic field and employed localized Wannier orbitals constructed from plane waves with a continuous set of gauge transformations (CSGT).[7] To obtain sufficiently localized Wannier functions, Sebastiani too employed a supercell technique. All three implementations mentioned above make use of pseudo-potentials and plane waves.

We have recently developed a method[8] for the calculation of NMR chemical shifts in periodic systems within the full potential program BAND,[9,10] in which use is made of atom-centered basis functions. In BAND, the Bloch basis set is constructed from Slater-type orbitals (STOs) and (or) numeric atomic orbitals (NAOs). The electronic density matrix near the nuclei is very important for NMR shielding, and both STOs and NAOs potentially afford an accurate description of the Kohn–Sham (KS) orbitals in this region. Atomic centered basis functions allow further for the use of gauge-included atomic orbitals (GIAOs) to ensure gauge invariant results. The calculation of other magnetic properties (EPR g- and A-tensors) has also been implemented in BAND.[11,12]

Our recently developed method[8] makes use of a supercell outside which the current density $\boldsymbol{J}^{(\alpha)}$ induced by the nuclear magnetic moment of our probe atom N falls off to zero. Further, in this approach the field-free unperturbed KS equation was solved with the supercell as the periodic unit to obtain a zero-order basis for the subsequent perturbation treatment that determines $\boldsymbol{J}^{(\alpha)}$. Such a procedure can be costly, since a supercell typically consists of five or more primitive cells. We shall now show that one can equally well make use of a zero-order basis determined by solving the field-free KS equation, with a primitive cell as the periodic unit followed by an analytic perturbation treatment involving a large supercell that includes the whole crystal. In this way the computational cost can be reduced by two orders of magnitude for 3D systems. We shall further introduce relativistic effects by adopting the scalar zero-order regular approximation (ZORA).[13,14]

We introduce in the next section our new method for calculating the NMR chemical shift in periodic systems based on atom-centered basis functions, with the computational details characteristic for BAND discussed in the following section. We have tested our new implementation on single molecules, diatomic chains, as well as one-dimensional polymers, two-dimensional sheets, and three-dimensional crystals. In the Results and discussion section we compare with experiment and other computational methods, as well as results from our previous scheme.

NMR shielding tensor in periodic systems

For a periodic system, the NMR shielding tensor $\hat{\sigma}^{\mathrm{N}}$ of nuclei N is the second derivative of the total electronic energy:

$$[1] \qquad \sigma^{\mathrm{N}}_{\alpha\beta} = \left.\frac{\partial^2 E(\boldsymbol{B}, \boldsymbol{\mu}^{\mathrm{N}})}{\partial \mu^{\mathrm{N}}_{\alpha} \partial B_{\beta}}\right|_{\substack{\boldsymbol{B}=0 \\ \boldsymbol{\mu}^{\mathrm{N}}=0}}$$

with respect to Cartesian components of the magnetic moment $\boldsymbol{\mu}^{\mathrm{N}}$ and the external magnetic field $\boldsymbol{B}$, respectively.

To calculate the second derivative of the total electronic energy, we follow the procedure by Gauss[15] and write the expression for the energy Lagrangian with the usual orthonormality constraint:

$$[2] \qquad \tilde{E} = \int \mathrm{d}\boldsymbol{k} \sum_i n_i \langle \Psi_{ik} | \boldsymbol{h} | \Psi_{ik} \rangle + \frac{1}{2} \int \mathrm{d}\boldsymbol{k} \sum_i n_i \langle \Psi_{ik} | V_{\mathrm{C}} | \Psi_{ik} \rangle + E_{\mathrm{XC}}[\rho] - \int \mathrm{d}\boldsymbol{k} \sum_i \varepsilon_{ij} n_i (\langle \Psi_{ik} | \Psi_{jk} \rangle - \delta_{ij})$$

Here, the integration over $\boldsymbol{k}$-space is introduced, E_{XC} is the exchange-correlation energy,[16], and $\boldsymbol{h}$ is given by:

$$[3] \qquad \boldsymbol{h} = \frac{K}{2}\boldsymbol{p}^2 + V_{\mathrm{NUC}} + \frac{K}{c}\boldsymbol{A}^{(\mu^{\mathrm{N}})}\boldsymbol{p} + \frac{K}{c}\boldsymbol{A}^{(B)}\boldsymbol{p} + \frac{K}{c^2}\boldsymbol{A}^{(\mu^{\mathrm{N}})}\boldsymbol{A}^{(B)}$$

contains within the scalar ZORA approximation,[13,14] the sum of the operators for the electronic kinetic energy, and the electron–nuclear attraction plus the magnetic vector potentials for the constant magnetic field,

$$[4] \qquad \boldsymbol{A}^{(B)} = \frac{1}{2}[\boldsymbol{B} \times \boldsymbol{r}]$$

and the nuclear magnetic moment of N,

$$[5] \qquad \boldsymbol{A}^{(\mu^{\mathrm{N}})}(\boldsymbol{r}) = \frac{[\boldsymbol{\mu}^{\mathrm{N}} \times (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}})]}{|\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}|^3}$$

where $\boldsymbol{R}_{\mathrm{N}}$ is the position of the probe atom N. We shall denote the last three (magnetic) terms in the definition of $\boldsymbol{h}$ as $\boldsymbol{h}^1$. Further, the auxiliary Kohn–Sham orbitals $\Psi_i^{(0)}$ are eigenfunctions to the set of equations:

$$[6] \qquad \boldsymbol{h}^0_{\mathrm{KS}} \Psi_i^{(0)} = \varepsilon_i^{(0)} \Psi_i^{(0)}$$

where the Kohn–Sham operator in the scalar ZORA formulation has the form:

$$[7] \qquad \boldsymbol{h}^0_{\mathrm{KS}} = \frac{K}{2}\boldsymbol{p}^2 + V^{\mathrm{KS}}$$
$$V^{\mathrm{KS}} = V_{\mathrm{XC}} + V_{\mathrm{NUC}} + V_{\mathrm{C}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Here V^{KS} is the effective Kohn–Sham potential, which is made up of an exchange-correlation potential V_{XC} accounting for many-body effects, an attractive potential due to nuclei V_{NUC}, and a classical electron repulsion potential V_C. The ZORA relativistic K factor is introduced as,

$$[8] \qquad K = \frac{1}{1 - V^{KS\prime}(\boldsymbol{r})/2c^2}$$

where $V^{KS\prime}$ is the model KS potential as in the molecular scalar ZORA implementation.[13,14] Finally $\varepsilon_i^{(0)}$ is an eigenvalue to eq. [6], with the eigenfunction $\Psi_i^{(0)}$ and occupation number n_i.

To obtain solutions to eq. [6] for periodic systems, the Kohn–Sham orbitals are expanded in terms of a complex Bloch basis set $\phi_{\mu k}$:

$$[9] \qquad \Psi_{ik}(\boldsymbol{r}) = \sum_{\mu} c_{\mu ik}\phi_{\mu k}(\boldsymbol{r})$$

where $\phi_{\mu k}$ is calculated as a Bloch sum of equivalent atomic orbitals $\phi_\mu(\boldsymbol{r} - \boldsymbol{R}_\mu - \boldsymbol{T})$ separated by the crystal vector $\boldsymbol{T}$ and centered on $\boldsymbol{R}_\mu + \boldsymbol{T}$:

$$[10] \qquad \phi_{\mu k}(\boldsymbol{r}) \equiv \phi_{\mu k}(\boldsymbol{r} - \boldsymbol{R}_\mu) = \sum_{\boldsymbol{T}} \phi_\mu(\boldsymbol{r} - \boldsymbol{R}_\mu - \boldsymbol{T}) e^{i\boldsymbol{k}(\boldsymbol{R}_\mu + \boldsymbol{T})}$$

To avoid gauge problems due to the use of a finite atomic basis set, we employ gauge-including atomic orbitals.[17] In this case the Bloch basis set $\phi_{\mu k}$ depends on the magnetic field $\boldsymbol{B}$:

$$[11] \qquad \phi_{\mu k}(\boldsymbol{r})^{GIAO} = \phi_{\mu k}(\boldsymbol{r}) e^{-(i/2c)([\boldsymbol{B}\times\boldsymbol{R}_\mu]\boldsymbol{r})}$$

For the second derivative we have the following expression[15,18]:

$$[12] \qquad \frac{d^2\widetilde{E}}{d\boldsymbol{B}d\boldsymbol{\mu}^N} = \int d\boldsymbol{k} \left\{ \sum_{\mu\nu} P_{\mu\nu k} \frac{\partial^2 h_{\mu\nu k}}{\partial \boldsymbol{B}\partial\boldsymbol{\mu}^N} + \frac{\partial P_{\mu\nu k}}{\partial \boldsymbol{\mu}^N} \frac{\partial h_{\mu\nu k}}{\partial \boldsymbol{B}} + \frac{\partial P_{\mu\nu k}}{\partial \boldsymbol{\mu}_N} \left[\left\langle \frac{\partial \phi_{\mu k}}{\partial \boldsymbol{B}} \middle| V_C + V_{XC} \middle| \phi_{\nu k} \right\rangle + \left\langle \phi_{\mu k} \middle| V_C + V_{XC} \middle| \frac{\partial \phi_{\nu k}}{\partial \boldsymbol{B}} \right\rangle \right] - \frac{\partial W_{\mu\nu k}}{\partial \boldsymbol{\mu}_N} \frac{\partial S_{\mu\nu k}}{\partial \boldsymbol{B}} \right\}$$

where we use the following definitions:

$$V_{XC} = \frac{\partial E_{XC}[\rho]}{\partial \rho} \qquad \text{is the exchange} - \text{correlation potential}$$

$$P_{\mu\nu k} = \sum_i n_i c^*_{\mu ik} c_{\nu ik} \qquad \text{is the density} P - \text{matrix}$$

$$W_{\mu\nu k} = \sum_i n_i c^*_{\mu ik} \varepsilon_{ik} c_{\nu ik} \qquad \text{is the energy} - \text{weighted } P \text{ - matrix}$$

$$S_{\mu\nu k} = \langle \phi_{\mu k} | \phi_{\nu k} \rangle \qquad \text{is the overlap matrix}$$

$$h_{\mu\nu k} = \langle \phi_{\mu k} | \boldsymbol{h} | \phi_{\nu k} \rangle$$

The first term in eq. [12] is the diamagnetic part of the shielding tensor, and all the other terms make up the paramagnetic shielding tensor.

The shielding tensor for nuclei N, as defined in eq. [1], is related to the interaction energy $\Delta E_{\alpha\beta}$ between the current density $\boldsymbol{J}^{(\alpha)}$ induced by the nuclear magnetic moment component $\mu_\alpha{}^N$ on N and the external magnetic field component B_β by $\Delta E_{\alpha\beta} = \sigma_{\alpha\beta}\mu_\alpha{}^N B_\beta$.[8] Unfortunately, the perturbation $\boldsymbol{A}^{(\mu^N)}(\boldsymbol{r})$ from the nuclear magnetic moment $\boldsymbol{\mu}^N$ is not periodic. As a consequence, in our previous approach we had to introduce a supercell big enough such that $\boldsymbol{J}^{(\alpha)}$ was negligible outside the cell. We were thus subsequently able to calculate the interaction energy $\Delta E_{\alpha\beta}$ between the induced current density $\boldsymbol{J}^{(\alpha)}$ and the constant magnetic field component B_β by integrating inside the supercell and thus determine $\sigma_{\alpha\beta}{}^N$.

In our previous approach,[8] the field-free KS eq. [6] was solved with the supercell as the periodic unit to obtain a zero-order basis for the subsequent perturbation treatment that would determine $\boldsymbol{J}^{(\alpha)}$ and $\sigma_{\alpha\beta}$. Such a procedure can be costly, since a supercell typically consists of five or more primitive cells. We shall now show that one can equally well make use of a zero-order basis determined by solving the KS equation with a primitive cell as the periodic unit followed by a perturbation treatment involving a large supercell including the entire crystal. To introduce our new procedure, we shall start by discussing the diamagnetic part of the shielding tensor, followed by a treatment of the paramagnetic shielding tensor. In principle, by including the entire crystal in our perturbation treatment we are ensured that $\boldsymbol{J}^{(\alpha)}$ vanishes at the edges of the supercell (crystal). In practice $\boldsymbol{J}^{(\alpha)}$ only has noticeable contributions in the first 20–40 primitive cells surrounding the perturbing nucleus ($\boldsymbol{T} = 0$).[8]

Diamagnetic tensor

The shielding tensor is defined via the shielding current as,

$$[13] \qquad \sigma^{\mathrm{N}}_{\alpha\beta} = -\int\limits_{\text{crystal}} d\boldsymbol{r}[\boldsymbol{J}^{(\alpha)}(\boldsymbol{r}) \times \boldsymbol{r}]_\beta$$

The first-order change in the diamagnetic shielding current due to the μ^{N}_α perturbation in the local representation is,

$$[14] \qquad \boldsymbol{J}^{\mathrm{d}(\alpha)}(\boldsymbol{r}) = \frac{\partial}{\partial \mu^{\mathrm{N}}_\alpha}\boldsymbol{J}^{\mathrm{d}}(\boldsymbol{r})\bigg|_{\mu^{\mathrm{N}}=0} = \frac{1}{2c}\sum_{i'} n_{i'}\frac{K}{c}\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\left|\Psi^{(0)}_{i'}(\boldsymbol{r})\right|^2$$

where

$$[15] \qquad \boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_N) = \frac{\partial \boldsymbol{A}^{(\mu^{\mathrm{N}})}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})}{\partial \mu^{\mathrm{N}}_\alpha}$$

is the derivative of the magnetic vector potential eq. [5] due to single nuclear moment (see Fig. 1).

Using the expansion for KS orbitals,

$$[16] \qquad \Psi_{i'}(\boldsymbol{r}) = \sum_{\mu'} c_{\mu' i'}\,\phi_{\mu'}(\boldsymbol{r})$$

affords

$$[17] \qquad \boldsymbol{J}^{\mathrm{d}(\alpha)}(\boldsymbol{r}) = \frac{1}{2c}\sum_{i'} n_{i'} c^{(0)*}_{\mu' i'} c^{(0)}_{\nu' i'}\frac{K}{c}\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\phi^*_{\mu'}(\boldsymbol{r})\phi_{\nu'}(\boldsymbol{r})$$

Using eq. [13] we obtain the diamagnetic shielding tensor in the local representation in the form,

$$[18] \qquad \sigma^{\mathrm{N,d}}_{\alpha\beta} = \frac{1}{2c}\sum_{i'} n_{i'}\sum_{\mu'\nu'} c^{(0)*}_{\mu' i'} c^{(0)}_{\nu' i'}\left\langle \phi_{\mu'}(\boldsymbol{r}-\boldsymbol{R}_{\mu'})\left|\left[\boldsymbol{r}\times\frac{K}{c}\mathbf{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\right]_\beta\right|\phi_{\nu'}(\boldsymbol{r}-\boldsymbol{R}_{\nu'})\right\rangle$$

The integration in eq. [18] is over the whole crystal. In eq. [18] μ' and ν' numerate the atomic basis functions $\phi_{\mu'}(\boldsymbol{r}-\boldsymbol{R}_{\mu'})$ and $\phi_{\nu'}(\boldsymbol{r}-\boldsymbol{R}_{\nu'})$. Further, $\boldsymbol{R}_{\mu'}$ and $\boldsymbol{R}_{\nu'}$ are the positions of the atoms on which the basis functions are centered in the crystal. We can further write,

$$[19] \qquad \boldsymbol{R}_{\mu'} = \boldsymbol{R}_\mu + \boldsymbol{T}$$

where $\boldsymbol{T}$ is the crystal vector and $\boldsymbol{R}_\mu$ the position of atoms in the central cell of the crystal ($\boldsymbol{T} = 0$).

By using [19] we can rewrite eq. [18] as follows:

$$[20] \qquad \sigma^{\mathrm{N,d}}_{\alpha\beta} = \frac{1}{2c}\sum_{i'} n_{i'}\sum_{\boldsymbol{T}_1\boldsymbol{T}_2}\sum_{\mu\nu} c^{(0)*}_{\mu T_1 i'} c^{(0)}_{\nu T_2 i'}\left\langle \phi_\mu(\boldsymbol{r}-\boldsymbol{R}_\mu-\boldsymbol{T}_1)\left|\left[\boldsymbol{r}\times\frac{K}{c}\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\right]_\beta\right|\phi_\nu(\boldsymbol{r}-\boldsymbol{R}_\nu-\boldsymbol{T}_2)\right\rangle$$

To move from the local representation, where the KS orbitals are obtained from eq. [6] with the whole crystal as the periodic unit, to the crystal momentum representation,[19] where eq. [6] is solved with the primitive cell as the periodic unit, we can use the transformation formulas:

$$[21] \qquad c_{\mu T_1 i'} = \left(\frac{\Omega}{(2\pi)^3}\right)^{1/2}\int \mathrm{d}\boldsymbol{k}''\, c_{\mu i k'}\mathrm{e}^{i\boldsymbol{k}''(\boldsymbol{R}_\mu+\boldsymbol{T}_1)}, \qquad c_{\nu T_2 i'} = \left(\frac{\Omega}{(2\pi)^3}\right)^{1/2}\int \mathrm{d}\boldsymbol{k} c_{\nu j k}\mathrm{e}^{i\boldsymbol{k}(\boldsymbol{R}_\nu+\boldsymbol{T}_2)}$$

where Ω is the volume of the primitive cell, $c_{\mu i k'}$ and $c_{\nu j k}$ are the dispersion coefficients.In eq. [21] we consider an infinite crystal. The infinite crystal does not have a central cell, all cells are equal. To calculate NMR shieldings, we take from the crystal a finite region with the central cell containing the atom probed by NMR. Then we tend the size of this region to infinity.

For the non-periodic function $\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})$ in eq. [20], we use a Fourier transform and expand $\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}}-\boldsymbol{T})$ in terms of periodic harmonics:

$$[22] \qquad \boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}}-\boldsymbol{T}) = \int \mathrm{d}\boldsymbol{k}_0 \boldsymbol{A}^{(\alpha)}_{\boldsymbol{k}_0}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})e^{-i\boldsymbol{k}_0(\boldsymbol{R}_{\mathrm{N}}+\boldsymbol{T})}$$

where

$$[23] \qquad \boldsymbol{A}^{(\alpha)}_{k_0}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}}) = \sum_{\boldsymbol{T}} \boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}}-\boldsymbol{T})e^{i\boldsymbol{k}_0(\boldsymbol{R}_{\mathrm{N}}+\boldsymbol{T})}$$

Fig. 1. Model of the crystal with single dipole perturbation.

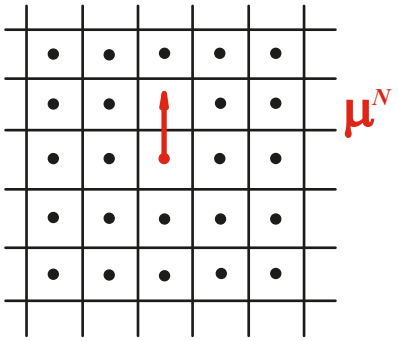

Fig. 2. Central cell and lattice vector.

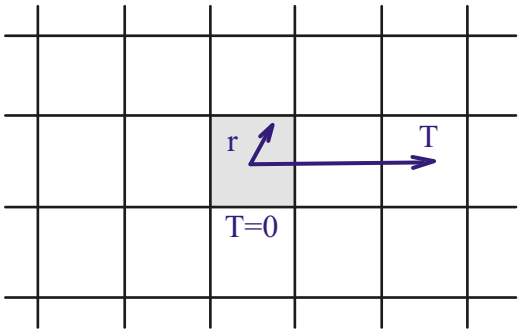

By using eqs. [18], [21], and [22] we have:

$$[24]\qquad \sigma_{\alpha\beta}^{\mathrm{N,d}} = \frac{1}{2c}\sum_{ij} n_i n_j \int \mathrm{d}\boldsymbol{k}'' \int \mathrm{d}\boldsymbol{k} \sum_{\mu\nu} c_{\mu i k''}^{(0)*} c_{\nu j k}^{(0)} \left\langle \phi_{\mu k''} \middle| \left[(\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \times \frac{K}{c} \boldsymbol{A}_0^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \right]_\beta \middle| \phi_{\nu k} \right\rangle$$

where

$$[25]\qquad \boldsymbol{A}_0^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) = \sum_{\boldsymbol{T}} \boldsymbol{A}^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}} - \boldsymbol{T})$$

where $\phi_{\mu k''}$ and $\phi_{\nu k}$ are Bloch functions (eq. [10]). In eq. [24], the integration is performed over the primitive cell, which is centered on $\boldsymbol{R}_{\mathrm{N}}$.

Note that the atomic functions $\phi_\mu(\boldsymbol{r} - \boldsymbol{R}_\mu - \boldsymbol{T}_1)$ with local coefficients $c_{\mu T_1 i'}$ are normalized by integration over the whole crystal, whereas the Bloch functions $\phi_{\mu k''}(\boldsymbol{r} - \boldsymbol{R}_\mu)$ with dispersion coefficients $c_{\mu i k''}$ are normalized within the primitive cell. It should be pointed out that the transformation in eq. [21] is specific to atom centered basis sets.

Using the orthonormality between Bloch functions $\Psi_{ik''}^{(0)}$ and $\Psi_{jk}^{(0)}$, we can reduce the double integration over $\boldsymbol{k}$ and $\boldsymbol{k}''$ in eq. [24] to a single integration (please see Supplementary data for complete derivation):

$$[26]\qquad \sigma_{\alpha\beta}^{\mathrm{N,d}} = \frac{1}{2c}\sum_{i} n_i \int \mathrm{d}\boldsymbol{k} \sum_{\mu\nu} c_{\mu i k}^{(0)*} c_{\nu i k}^{(0)} \left\langle \phi_{\mu k} \middle| \left[(\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \times \frac{K}{c} \boldsymbol{A}_0^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \right]_\beta \middle| \phi_{\nu k} \right\rangle$$

The diamagnetic current with GIAO corrections reads, according to eq. [18] of ref. [8] as,

$$[27]\qquad \boldsymbol{J}^{\mathrm{d}(\alpha)\mathrm{GIAO}}(\boldsymbol{r}) = \frac{1}{2c}\sum_{i'} n_{i'} \sum_{\mu'\nu'} c_{\mu' i'}^{(0)*} c_{\nu' i'}^{(0)} \frac{K}{c} \{ \phi_{\mu'}^*(\boldsymbol{r}) \boldsymbol{A}^{(\alpha)} \phi_{\nu'}(\boldsymbol{r}) + \boldsymbol{R}_{\mu'} \phi_{\mu'}^*(\boldsymbol{r}) \boldsymbol{A}^{(\alpha)} \cdot \nabla \phi_{\nu'}(\boldsymbol{r}) - \phi_{\mu'}^*(\boldsymbol{r}) \boldsymbol{A}^{(\alpha)} \cdot \nabla \left(\boldsymbol{R}_{\nu'} \phi_{\nu'}(\boldsymbol{r}) \right) \}$$

in the local representation. We have eliminated the integration over $\boldsymbol{k}$-space from eq. [18] of ref. 8, since we do not need any dispersion when we use the entire crystal as a supercell rather than n primitive cells where $n < 100$.

Using transformation in eq. [21], we will have the GIAO diamagnetic current in the crystal momentum representation,

$$[28]\qquad \boldsymbol{J}^{\mathrm{d}(\alpha)\mathrm{GIAO}}(\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}, \boldsymbol{T}) = \frac{1}{2c} \int \mathrm{d}\boldsymbol{k}_0 \int \mathrm{d}\boldsymbol{k} \sum_i n_i \sum_{\mu\nu} c_{\mu i k}^{(0)*} c_{\nu i k}^{(0)} \frac{K}{c}$$
$$\times \left\{ \phi_{\mu k}^*(\boldsymbol{r})\, \boldsymbol{A}_{k_0}^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \nabla \phi_{\nu k}(\boldsymbol{r}) + (-i) \frac{\partial}{\partial \boldsymbol{k}} \phi_{\mu k}^*(\boldsymbol{r}) \boldsymbol{A}_{k_0}^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \cdot \nabla \phi_{\nu k}(\boldsymbol{r}) - \phi_{\mu k}^*(\mathbf{r}) \boldsymbol{A}_{k_0}^{(\alpha)} (\boldsymbol{r} - \boldsymbol{R}_{\mathrm{N}}) \cdot \nabla \left((-i) \frac{\partial}{\partial \boldsymbol{k}} \phi_{\nu k}(\boldsymbol{r}) \right) \right\} e^{-i \boldsymbol{k}_0 (\boldsymbol{R}_{\mathrm{N}} + \boldsymbol{T})}$$

where $\boldsymbol{r}$ runs over cell $\boldsymbol{T} = 0$ (see Fig. 2).

Using eqs. [13] and [28], we will have the diamagnetic tensor in the crystal momentum representation in the form:

$$[29]\qquad \sigma_{\alpha\beta}^{\mathrm{N,d}} = \frac{1}{2c} \int \mathrm{d}\boldsymbol{k} \sum_{\mu\nu} P_{\mu\nu k}^{(0)} \left\{ \left\langle \phi_{\mu k} \middle| \left[\left(\boldsymbol{r} - (-i) \frac{\partial^\nu}{\partial \boldsymbol{k}} \right) \times \frac{K}{c} \boldsymbol{A}_0^{(\alpha)} \right]_\beta \middle| \phi_{\nu k} \right\rangle + \left\langle \phi_{\mu k} \middle| \left[\left(\boldsymbol{r} - (-i) \frac{\partial^\nu}{\partial \boldsymbol{k}} \right) \times \left((-i) \frac{\partial^\nu}{\partial \boldsymbol{k}} - (-i) \frac{\partial^\mu}{\partial \boldsymbol{k}} \right) \right]_\beta \frac{K}{c} \boldsymbol{A}_0^{(\alpha)} \cdot \nabla \middle| \phi_{\nu k} \right\rangle \right\}$$

where $P_{\mu\nu k}^{(0)}$ is the density P-matrix. Further, the integrals over d$\boldsymbol{r}$ in eq. [29] are over the primitive central cell with $\boldsymbol{T} = 0$ only.

The operator $(-i)(\partial^\mu / \partial \boldsymbol{k})$ in eq. [29] acts on $\phi_{\mu k}$ according to:

$$\left\langle \phi_{\mu k} \middle| \left[\boldsymbol{r} \times (-i) \frac{\partial^\mu}{\partial \boldsymbol{k}} \right]_\beta \right| = \left\langle \left[\boldsymbol{r} \times (-i) \frac{\partial}{\partial \boldsymbol{k}} \phi_{\mu k} \right]_\beta \right|$$

In eq. [29], the first term on the right-hand side is identical to the first term on the right-hand side of eq. [12]. The second term in eq. [29] is added to obtain an expression that is gauge invariant.[8] It will be eliminated from the expression for the total shielding tensor by subtracting it from the paramagnetic shielding tensor later. The expression eq. [29] contains an infinite sum (over $\boldsymbol{T}$) of dipole terms. Fortunately the sum is conditionally convergent even in the 3D case and can be properly defined via analytic continuation techniques already implemented in BAND.[9]

Paramagnetic tensor

The first-order change in the paramagnetic current due to the μ_α^{N} perturbation in the local representation is,

$$[30]\qquad \boldsymbol{J}^{\mathrm{p}(\alpha)}(\boldsymbol{r}) = \frac{1}{2c}\sum_{i'} n_{i'}(-i)\left(\Psi_{i'}^{(\alpha,0)*}(\boldsymbol{r})K\nabla\Psi_{i'}^{(0)}(\boldsymbol{r}) + \Psi_{i'}^{(0)*}(\boldsymbol{r})K\nabla\Psi_{i'}^{(\alpha,0)}(\boldsymbol{r})\right)$$

Using the expansion eq. [16] for KS orbitals affords,

$$[31]\qquad \boldsymbol{J}^{\mathrm{p}(\alpha)}(\boldsymbol{r}) = \frac{1}{2c}(-i)\sum_{i'} n_{i'}\sum_{\mu'\nu'}\left(c_{\mu'i'}^{(\alpha,0)*}c_{\nu'i'}^{(0)} + c_{\mu'i'}^{(0)*}c_{\nu'i'}^{(\alpha,0)}\right)\phi_{\mu'}^*(\boldsymbol{r})K\nabla\phi_{\nu'}(\boldsymbol{r})$$

where $c_{\mu'i'}^{(\alpha,0)}$ is the perturbed expansion coefficients due to the α-component μ_α^{N} of the nuclear magnetic moment. The first-order perturbed expansion coefficients $c_{\mu'i'}^{(\alpha,0)}$ can be derived with the help of first-order perturbation theory (FOPT).[18,20] To that end, we first write the KS function perturbed by the α-component of a single magnetic nuclear dipole moment up to first order as:

$$[32]\qquad \Psi_{i'}^{(\mu_\alpha^{\mathrm{N}})}(\boldsymbol{r}) = \Psi_{i'}^{(0)}(\boldsymbol{r}) + \mu_\alpha^{\mathrm{N}}\sum_{j'\neq i'}\frac{h_{j'i'}^{(\alpha,0)}}{\varepsilon_{i'}^{(0)} - \varepsilon_{j'}^{(0)}}\Psi_{j'}^{(0)}(\boldsymbol{r}) + O^{(2)}[\mu_\alpha^{\mathrm{N}}]$$

where

$$[33]\qquad h_{j'i'}^{(\alpha,0)} = \left\langle \Psi_{j'}^{(0)}\middle| h^{(\alpha,0)}\middle|\Psi_{i'}^{(0)}\right\rangle$$

and $\boldsymbol{h}^{(\alpha,0)}$ is,

$$[34]\qquad \boldsymbol{h}^{(\alpha,0)} = (-i)\frac{K}{c}\boldsymbol{A}^{(\alpha)}\cdot\vec{\nabla}$$

The first-order change in the KS functions due to the magnetic dipole moment perturbation can be calculated as:

$$[35]\qquad \Psi_{i'}^{(\alpha,0)} = \frac{\partial}{\partial\mu_\alpha^{\mathrm{N}}}\left(\Psi_{i'}^{(\boldsymbol{\mu}^{\mathrm{N}})}\right)\Bigg|_{\boldsymbol{\mu}^{\mathrm{N}}=0}$$

Using the expansion eq. [16] and substituting eq. [32] into eq. [35], we obtain the perturbed expansion coefficients in the form,

$$[36]\qquad c_{\mu T_1 i'}^{(\alpha,0)} = \sum_{j'}^{\mathrm{all}}\sum_{T_3T_4}\sum_{\rho\sigma} c_{\rho T_3 j'}^{(0)*}c_{\sigma T_4 i'}^{(0)}c_{\mu T_1 j'}^{(0)}\left\langle \phi_{\rho T_3}\middle|(-i)\frac{1}{c}\boldsymbol{A}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\cdot\nabla\middle|\phi_{\sigma T_4}\right\rangle\frac{1}{\varepsilon_{i'}^{(0)} - \varepsilon_{j'}^{(0)}}$$

Then, employing the transformations eqs. [21] and [22], the perturbed expansion coefficients in the crystal momentum representation can be expressed as,

$$[37]\qquad c_{\mu ik'}^{(\alpha,0)}(\boldsymbol{T}) = \int \mathrm{d}\boldsymbol{k}_0\int \mathrm{d}\boldsymbol{k}\int \mathrm{d}\boldsymbol{k}'\sum_{j}^{\mathrm{all}}\sum_{\rho\sigma} c_{\rho jk}^{(0)*}c_{\sigma ik'}^{(0)}c_{\mu jk''}^{(0)}\left\langle \phi_{\rho k}\middle|(-i)\frac{1}{c}\boldsymbol{A}_{k_0}^{(\alpha)}(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\cdot\nabla\middle|\phi_{\sigma'}\right\rangle\frac{e^{-i\boldsymbol{k}_0(\boldsymbol{R}_{\mathrm{N}}+\boldsymbol{T})}}{\varepsilon_{ik'}^{(0)} - \varepsilon_{jk}^{(0)}}$$

The paramagnetic current in the crystal momentum representation in the point $\boldsymbol{r} + \boldsymbol{T}$ will have the form,

$$[38]\qquad \boldsymbol{J}^{\mathrm{p}(\alpha)}(\boldsymbol{r},\boldsymbol{T}) = \frac{1}{2c}(-i)\int \mathrm{d}\boldsymbol{k}\sum_{i} n_i\sum_{\mu\nu}\left(c_{\mu ik}^{(\alpha,0)*}(\mathbf{T})c_{\nu ik}^{(0)} + c_{\mu ik}^{(0)*}c_{\nu ik}^{(\alpha,0)}(\boldsymbol{T})\right)\phi_{\mu k}^*(\boldsymbol{r})K\nabla\phi_{\nu k}(\boldsymbol{r})$$

In eq. [38] we took into consideration the orthonormality of the Bloch functions and reduced the triple integration over $\boldsymbol{k}$, $\boldsymbol{k}'$, and $\boldsymbol{k}''$ in [38] with coefficients [37] to a single integration.

The paramagnetic current with GIAO corrections according to eq. [22] of ref. 8 reads as,

$$[39]\qquad \boldsymbol{J}^{\mathrm{p}(\alpha)\mathrm{GIAO}}(\boldsymbol{r}) = \frac{1}{2c}(-i)\sum_{i'} n_{i'}\sum_{\mu'\nu'}\left(c_{\mu'i'}^{(\alpha,0)*}c_{\nu'i'}^{(0)} + c_{\mu'i'}^{(0)*}c_{\nu'i'}^{(\alpha,0)}\right)$$
$$\times\left\{\phi_{\mu'}^*(\boldsymbol{r})K\nabla\phi_{\nu'}(\boldsymbol{r}) + \boldsymbol{R}_{\mu'}\phi_{\mu'}^*(\boldsymbol{r})\left(\boldsymbol{h}_{\mathrm{KS}}^0 - \varepsilon_{i'}^{(0)}\right)\phi_{\nu'}(\boldsymbol{r}) - \phi_{\mu'}^*(\boldsymbol{r})\left(\boldsymbol{h}_{\mathrm{KS}}^0 - \varepsilon_{i'}^{(0)}\right)\boldsymbol{R}_{\nu'}\phi_{\nu'}(\boldsymbol{r})\right\}$$

in the local representation. Using the transformation in eq. [21], the coefficients in eq. [37] and the formulae of eq. [19] allow us to write the GIAO based paramagnetic current in the crystal momentum representation as,

$$[40]\qquad \boldsymbol{J}^{\mathrm{p}(\alpha)\mathrm{GIAO}}(\boldsymbol{r},\boldsymbol{T}) = \frac{1}{2c}(-i)\int \mathrm{d}\boldsymbol{k}\sum_i n_i \sum_{\mu\nu}\left(c^{(\alpha,0)*}_{\mu ik}(\boldsymbol{T})c^{(0)}_{\nu ik} + c^{(0)*}_{\mu ik}c^{(\alpha,0)}_{\nu ik}(\boldsymbol{T})\right) \times \{\phi^*_{\mu k}(\boldsymbol{r})\,K\nabla\phi_{\nu k}(\boldsymbol{r}) + (-i)\frac{\partial}{\partial\boldsymbol{k}}\phi^*_{\mu k}(\boldsymbol{r})\left(\boldsymbol{h}^0_{\mathrm{KS}} - \varepsilon^{(0)}_{ik}\right)\phi_{\nu k}(\boldsymbol{r}) - \phi^*_{\mu k}(\boldsymbol{r})\left(\boldsymbol{h}^0_{\mathrm{KS}} - \varepsilon^{(0)}_{ik}\right)(-i)\frac{\partial}{\partial\boldsymbol{k}}\phi_{\nu k}(\boldsymbol{r})\}$$

Calculating the paramagnetic tensor with the help of the GIAO based paramagnetic current from eq. [39], recalling that the paramagnetic current operator in eq. [40] acts on the position operator in eq. [13], and using the relation,

$$\nabla^2\left[(-i)\frac{\partial}{\partial\boldsymbol{k}}\phi_{\nu k}(\boldsymbol{r})\times\boldsymbol{r}\right]_\beta = -\left[(-i)\frac{\partial}{\partial\boldsymbol{k}}\times\nabla\right]_\beta\phi_{\nu k}(\boldsymbol{r}) + \left[(-i)\frac{\partial}{\partial\boldsymbol{k}}\times\boldsymbol{r}\right]_\beta\nabla^2\phi_{\nu k}(\boldsymbol{r})$$

allow us finally to express the paramagnetic shielding tensor as,

$$[41]\qquad \sigma^{\mathrm{N,p}}_{\alpha\beta} = \frac{1}{2c}\int \mathrm{d}\boldsymbol{k}\sum_{\mu\nu}\left[(-i)P^{(\alpha,0)}_{\mu\nu k}\left\{\left\langle\phi_{\mu k}\middle|\left[\left(\boldsymbol{r}-(-i)\frac{\partial^\nu}{\partial\boldsymbol{k}}\right)\times K\nabla\right]_\beta\middle|\phi_{\nu k}\right\rangle - \left\langle\phi_{\mu k}\middle|\left[(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\times\left((-i)\frac{\partial^\nu}{\partial\boldsymbol{k}}-(-i)\frac{\partial^\mu}{\partial\boldsymbol{k}}\right)\right]_\beta\boldsymbol{h}^0_{\mathrm{KS}}\middle|\phi_{\nu k}\right\rangle\right\}\right.$$
$$\left. + (-i)W^{(\alpha,0)}_{\mu\nu k}\left\langle\phi_{\mu k}\middle|\left[(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\times\left((-i)\frac{\partial^\nu}{\partial\boldsymbol{k}}-(-i)\frac{\partial^\mu}{\partial\boldsymbol{k}}\right)\right]_\beta\middle|\phi_{\nu k}\right\rangle + P^{(0)}_{\mu\nu k}\left\langle\phi_{\mu k}\middle|\left[(-i)\frac{\partial^\nu}{\partial\boldsymbol{k}}\times(-i)\frac{\partial^\mu}{\partial\boldsymbol{k}}\right]_\beta\frac{K}{c}\boldsymbol{A}^{(\alpha)}_0(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\cdot\nabla\middle|\phi_{\nu k}\right\rangle\right]$$

where

$$P^{(\alpha,0)}_{\mu\nu k} = \sum_i n_i\left(C^{(\alpha,0)*}_{\mu ik}c^{(0)}_{\nu ik} + c^{(0)*}_{\mu ik}C^{(\alpha,0)}_{\nu ik}\right)$$

is the first-order perturbed P-matrix and

$$W^{(\alpha,0)}_{\mu\nu k} = \sum_i n_i\varepsilon^{(0)}_{ik}\left(C^{(\alpha,0)*}_{\mu ik}c^{(0)}_{\nu ik} + c^{(0)*}_{\mu ik}C^{(\alpha,0)}_{\nu ik}\right)$$

is the corresponding energy-weighted P-matrix, where

$$[42]\qquad C^{(\alpha,0)}_{\mu ik} = \sum_j^{\mathrm{all}} c^{(0)}_{\mu jk}\left\langle\Psi^{(0)}_{jk}\middle|(-i)\frac{1}{c}\boldsymbol{A}^{(\alpha)}_0(\boldsymbol{r}-\boldsymbol{R}_{\mathrm{N}})\cdot\nabla\Psi^{(0)}_{ik}\right\rangle \times\frac{1}{\varepsilon^{(0)}_{ik}-\varepsilon^{(0)}_{jk}}$$

In eq. [41] we have added the term, which we subtracted from the diamagnetic tensor (see eq. [19] from ref. 8), to make both the diamagnetic and the paramagnetic tensor gauge-origin invariant. To avoid singularities in eq. [42], we separate the sum over j into two parts, involving occupied–occupied and occupied–virtual orbitals, respectively. Further, for the occupied–occupied part we use the reduced nonsingular form for the P- and W-matrices (eq. [57] from ref. 18 and eq. [28] from ref. 20).

Computational Details

The Bloch states are expanded in a mixed basis of Slater-type and numerical atomic orbitals with the radial part of each NAO stored on a grid. Such a basis has been used in our previous work.[8] Use was made of a triple zeta basis, augmented with two STO polarization functions of the BAND database. It consists of two STOs and one NAO for each *nl* sub-shell (1s, 2s, 2p, etc.). We did not have any problems with linear dependencies of the basis set functions in this work, since we used a primitive cell in our NMR calculations. Therefore, we did not have to remove any sub-shells. The numerical accuracy parameter used by BAND has been set to five. For odd *kspace* values, BAND uses quadratic integration schemes for one-, two-,[21] and three-dimensional[22] Brillouin zones. Here the *kspace* parameter of the BAND program describes the number of integration points in each $\boldsymbol{k}$ direction in reciprocal space.

All calculations are based on spin-restricted SCF calculations, employing the generalized gradient approximation (GGA) for the exchange-correlation energy. The parametrization of the exchange-correlation energy follows that of Becke[23] for the exchange and Perdew[24,25] for the correlation (BP86).

Only time-reversal symmetry is used in the integration over the Brillouin zone since magnetic perturbations do not commute with the symmetry operations.

The chemical shift is calculated as

$$[43]\qquad \delta^X = \sigma^{\mathrm{Ref}} - \sigma^X$$

where σ^{Ref} is the chemical shielding of a reference, and σ^X is the chemical shielding for the investigated system. The chemical shielding of the reference is calculated for a single molecule in a big box. We have used the following references and corresponding absolute shielding values: for the hydrogen molecule, $\sigma^{\mathrm{H}}_{\mathrm{H_2}}$ =22.2 ppm; for the water molecule, $\sigma^{\mathrm{H}}_{\mathrm{H_2O}}$ =31.8 ppm; for the tetrametilsilane (TMS) molecule, $\sigma^{\mathrm{C}}_{\mathrm{Si(CH_3)_4}}$ =180.8 ppm; for the nitromethane molecule, $\sigma^{\mathrm{N}}_{\mathrm{CH_3NO_2}}$ =–133.5 ppm; for the silane molecule, $\sigma^{\mathrm{Si}}_{\mathrm{SiH_4}}$ =440.7 ppm; for the phosphane molecule, $\sigma^{\mathrm{P}}_{\mathrm{PH_3}}$ =577.5 ppm; and for free atoms of He, Ne, Ar, Kr, Xe, and Zn, σ^{He} = 59.8 ppm, σ^{Ne} = 552.1 ppm, σ^{Ar} = 1237.9 ppm, σ^{Kr} = 3248.0 ppm, σ^{Xe} = 5647 ppm, and σ^{Zn} = 2514 ppm.

Results and discussion

We have tested our BAND implementation for the calculation of NMR shielding tensors by comparing our results with estimates from a previously developed method,[8] experimental data, and other calculations reported in the literature. We shall refer to our new scheme as the single dipole method (SD), since it considers the perturbation from a single dipole in a large crystal. The old method will be referred as the supercell (SC) scheme. It considers an array of periodic supercells, each containing a magnetic dipole.

For 1D periodic systems, we have considered linear chains of H_2 molecules and He, Ne, Ar and Xe atoms. In addition, consideration was given to polymers, such as polyethylene, polyacethylene, boron nitride hexagonal nano-ribbon, poly (difluoro-phosphazene), poly(dichlorophosphazene), poly(dimethylenephosphazene), and a SiS_2 chain. The examples of two-dimensional periodic systems include a boron nitride hexagonal sheet and a 2D puckered layer of black phosphorus. As examples of three-dimensional periodic systems, we have chosen the boron nitride cubic crystal, SiS_2, ZnS zincblende, and hexagonal Ice. The results are presented in Table 1.

For all ***linear chains***, the SC method made use of 17 primitive cells and Γ-point integration only. The SD method employed for the same systems, unless otherwise stated, a single

Fig. 3. Cells for (*a*) polyethylene and for (*b*) polyacethylene.

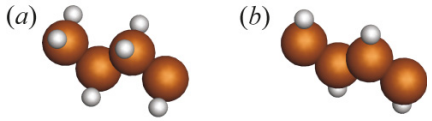

Fig. 4. (*a*) Boron nitride nanoribbon and (red, black in print version) the primitive cell of boron nitride sheet (*b*).

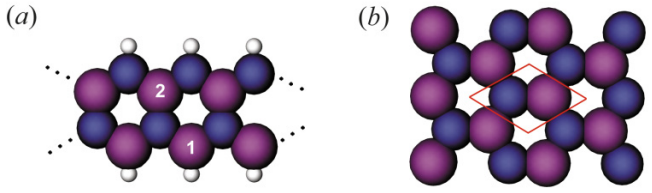

primitive cell with integration in one-half of reciprocal space using eleven ***k***-points. The H_2 linear chain with a period of 2.38 Å has, according to both methods, a chemical shift of 2.64 ppm relative to H_2 (Table 1). The chemical shifts (relative to the free atoms) for the He, Ne, Ar, and Xe linear chains with one atom in a primitive cell of 1.5 Å are calculated to be virtually identical for the two schemes (Table 1).

The **polyethylene** (PE) polymer in Fig. 3*a* has two carbon and four hydrogen atoms in each primitive cell, with a period of $T = 2.553$ Å. The bond angles and bond lengths used in the calculations were taken from experimental X-ray data.[26,27] For the C–H bond length, we adopted a value of $r_{CH} = 1.06$ Å.[26] The SD method employed integration with 11 ***k***-points in half of the reciprocal space and afforded a chemical shift value relative to TMS of 32.9 ppm. The SC approach made use of seven cells and a three-point ***k***-integration, leading to a shift value of 33.3 ppm. The experimental estimate is 33.5 ppm.[28]

The unit cell of **trans-polyacethylene** (PA) contains two atoms of carbon and two atoms of hydrogen ($T = 2.457$ Å) (see Fig. 3*b*). The SD-model with 11 ***k***-points afforded a chemical shift of 137.6 ppm, whereas the SC scheme with five primitive cells as a supercell and five ***k***-points resulted in an estimate of 142.3 ppm. The experimental value is 137.3 ppm.[29]

The **boron nitride nanoribbon** is a one-dimensional polymer with two atoms each of boron, nitrogen, and hydrogen in a primitive cell (Fig. 4*a*). The B–N bond length used in the calculation is $r_{BN} = 1.446$ Å. The results for the nitrogen-shielding shifts with respect to nitromethane are listed in Table 1. The calculated values for the SD scheme with 11 ***k***-points are –258.9 and –217.7 ppm for the first and second atoms of nitrogen (see Fig. 4*a*), respectively. SC calculations, with five primitive cells and three *k*-point integration, give –261.1 and –220.6 ppm, respectively.

Planar 2D boron nitride has a hexagonal lattice with two atoms in a primitive cell (Fig. 4*b*), where the B–N bond length is equal to 1.446 Å. We compile the isotropic ^{15}N chemical shift values with respect to nitromethane in Table 1. The SD-method with 11 *k*-point integration gives a chemical shift equal to –267.2 ppm. The converged BAND result for the SC approach is –272.5 ppm. It was obtained from a square supercell with 24 atoms and a total number 15 of ***k***-points, corresponding to the *kspace* parameter in BAND equal to three. The experimental value for hexagonal boron nitride powder is –285 ppm.[30] A molecular cluster calculation affords an estimate of –287.0 ppm.[30]

Fig. 5. Cubic BN crystal.

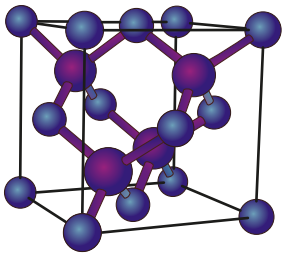

Fig. 6. Poly(difluorophosphazene) cells.

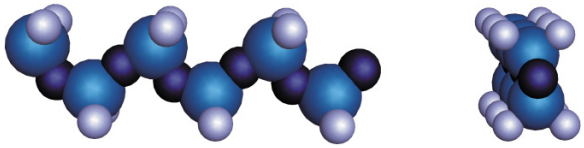

Chart 1.

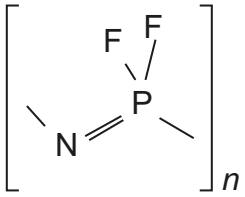

A **cubic crystal of boron nitride** has a diamond-like structure with a lattice parameter of 3.616 Å (Fig. 5). Calculations based on the SD method with 2514 ***k***-points in one-half of the first Brillouin zone (BAND *kspace* parameter equal to nine) give a chemical shift with respect to nitromethane that is equal to –359.8 ppm. The experimental value is –358.6 ppm.[30] Marian and Gastreich obtained from calculations on a H-saturated molecular cluster containing 71 atoms a value of –359.0 ppm.[30]

Poly(difluorophosphazene) (PdiFP) polymer contains two atoms of nitrogen and phosphorus and four atoms of fluorine in each primitive cell (Fig. 6 and Chart 1) with period of $T =$ 4.86 Å. Structural parameters were taken from the X-ray study from Allcock et al.[31] BAND calculations with the SD method (nine *k*-point integration) afford a chemical shift of 226.8 ppm relative to PH_3. The calculated chemical shift for the SC scheme (three primitive cells and three ***k***-points) is 224.0 ppm. The experimental chemical shift with respect to 85% aqueous H_3PO_4 is equal to –23.0 ppm.[32] By taking into account experimental absolute values for the shielding tensor for 85% aqueous H_3PO_4 and PH_3[33] in a molecular beam, we can obtain an estimate of the experimental chemical shift for PdiFP with respect to PH_3 that is equal to 243.1 ppm. This value is in fair agreement with our calculated estimates.

Poly(dichlorophosphazene) (PdiClP) polymer has a primitive cell with two atoms each of nitrogen and phosphorus and four atoms of chlorine (Fig. 7 and Chart 2) with a period of $T = 4.92$ Å. Experimental bond lengths and angles are taken from ref. 34. The calculated chemical shift, employing the SC approach (three primitive cells and three ***k***-points), amounts to 287.9 ppm relative to PH_3. The SD method with

Fig. 7. Poly(dichlorophosphazene) cells.

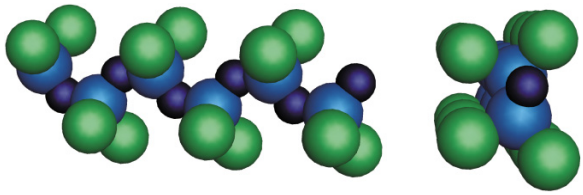

Chart 2.

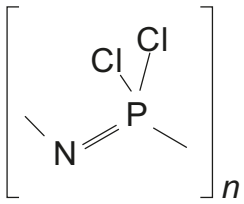

Fig. 8. Poly(dimethylphosphazene) cells.

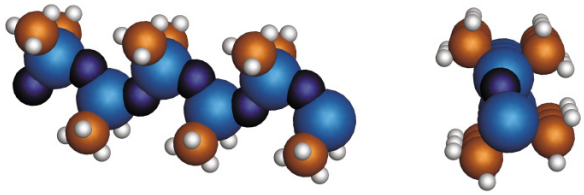

nine *k*-point integration gives 277.8 ppm. The estimated experimental chemical shift[35] relative to PH_3 is equal to 285.6 ppm .

Poly(dimethylphosphazene) (PdiMeP) polymer contains two atoms of nitrogen and phosphorus, and four methyl groups in a primitive cell (Fig. 8 and Chart 3) with period of $T = 4.887$ Å. Experimental X-ray data for bond lengths and angles are taken from the ref. 36. BAND calculations with the SD method and nine *k*-point integration give a chemical shift of 280.9 ppm with respect to PH_3. The calculated chemical shift due to the SC scheme consisting of three primitive cells and three ***k***-points affords 275.8 ppm. The estimated experimental chemical shift[37] relative to gaseous PH_3 is 282.1 ppm.

SiS_2 has a crystal of chains with a primitive cell for each chain consisting of two atoms of Si and four atoms of S (Fig. 9) with period of $T = 5.552$ Å. We have used the primitive chain cell in our 1D calculations. The experimental chemical shift for SiS_2 with respect to TMS is –19.5 ppm.[38] Using the experimental absolute values for TMS and SiH_4,[39] we obtain for the experimental chemical shift with respect to SiH_4 an estimated value of 87.3 ppm. BAND calculations based on the SD method with a five *k*-point integration give a chemical shift of 103.4 ppm with respect to the SiH_4 molecule. The calculated chemical shift for the SC scheme with three primitive cells and three ***k***-points affords 109.2 ppm. The difference between theory and experiment can be explained as due to inter chain interactions not considered in the calculations above. Thus, the distance between the chains is only 5.5 Å.

For 3D calculations (Fig. 10) with one primitive cell and a *kspace* parameter equal to 5 (total number of ***k***-points is 379), we obtain a chemical shift of 92.5 ppm, which is in much better agreement with experiment.

Chart 3.

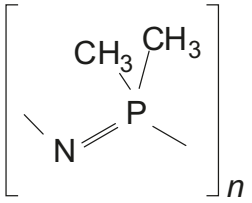

Fig. 9. SiS_2 chain.

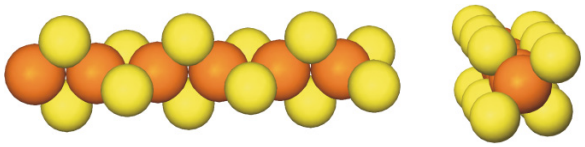

Fig. 10. SiS_2 chains packing in 3D crystal.

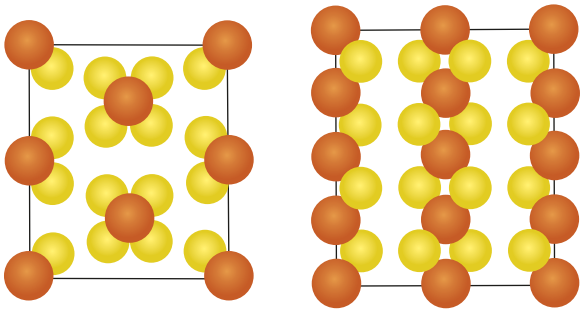

The 2D structure of **black phosphorus** consists of puckered layers and one primitive cell contains four atoms (Fig. 11). The experimental chemical shift with respect to 85% aqueous H_3PO_4 is equal to 22.2 ppm.[40] The estimated experimental chemical shift relative to gaseous PH_3 is 288.3 ppm. BAND result is 267.7 ppm, and it was obtained for primitive cell and *kspace* equal to nine (total number of ***k***-points is 153). The small difference between experiment and theory can be explained by interaction between layers in 3D crystal of black phosphorus.

The hexagonal ice 3D crystal primitive cell consists of four molecules of water (Fig. 12). The experimental chemical shift for the H atom with respect to a single molecule of water is 7.4 ppm.[41] BAND result for one primitive cell and *kspace* = 3 is 7.9 ppm. For geometry parameters we have used the experimental geometry.[42,43]

The crystal structure for **ZnS zincblende** is shown in Fig. 5. The lattice parameter was set to 5.3985 Å,[44] with a cell including four atoms of Zn and four atoms of S. The experimental chemical shift with respect to a free atom of Zn is 1068 ppm[45] compared to our estimate (*kspace* = 5) of 1199 ppm.

Conclusion

We have developed an improved Kohn–Sham DFT based approach for the calculation of NMR shielding tensors in periodic systems. As our previous formulation,[8] it is gauge-origin invariant and based on Slater type or (and) numerical atomic orbitals with the use of the complete Kohn–Sham potential without recourse to effective potentials. We can thus describe even core orbitals variationally. In our method the

Fig. 11. Black phosphorus puckered layers.

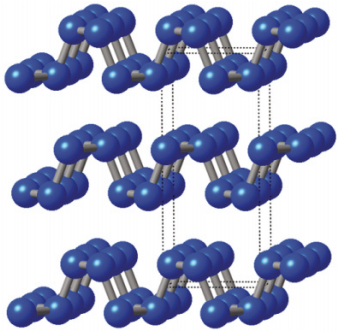

Fig. 12. Primitive cell of ice Ih.

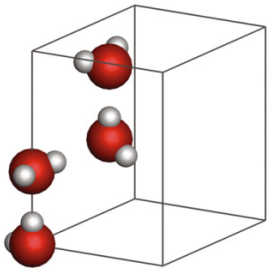

calculation of the shielding tensor $\sigma^{N}_{\alpha\beta}$ for nucleus N requires first the evaluation of the current density $\boldsymbol{J}^{(\alpha)}$ induced by the three components $(\alpha = \overline{1}, \overline{3})$ of the nuclear magnetic moment $\boldsymbol{\mu}^{N}$, followed by the response of $\boldsymbol{J}^{(\alpha)}$ to the three components $(\beta = \overline{1}, \overline{3})$ of the external magnetic field $\boldsymbol{B}$. In the previous scheme,[8] the determination of $\boldsymbol{J}^{(\alpha)}$ required a zero-order field free calculation on a supercell large enough so that $\boldsymbol{J}^{(\alpha)}$ vanishes outside. The requirement that $\boldsymbol{J}^{(\alpha)}$ should vanish at the supercell border was deemed necessary to determine the interaction between $\boldsymbol{J}^{(\alpha)}$ and the nonperiodic (and nowhere disappearing) constant magnetic field. In the current approach, use is still made of a supercell that is now extended to the entire crystal. However the determination of $\boldsymbol{J}^{(\alpha)}$ over the entire crystal is based on zero-order Kohn–Sham orbitals from SCF calculations involving only a primitive unit cell. This is made possible by the use of first-order analytic perturbation theory and the relationships for Bloch functions and their derivatives. In addition, use was made of the transformation relationships (eq. [21]) between the KS orbitals obtained with the whole crystal as the periodic unit (local representation) and the crystal momentum representation,[19] where the KS equation is solved with the primitive cell as the periodic unit. The new procedure can reduce the computational time by a factor of 10 for 1D systems to 100 for 3D systems. This improvement is made possible by the transformation in eq. [21], which is specific to atom-centered basis sets. The new implementation is further able to take into account relativistic effects within the scalar zero-order regular approximation.[13,14] The calculation of NMR chemical shifts for one-, two-, and three- dimensional periodic systems has been used to validate our new implementation, by comparison to experiment as well as other methods, including our previous scheme.[8]

Low-energy electron-induced decarbonylation of $Fe(CO)_5$ films adsorbed on Au(111) surfaces

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: The decarbonylation of $Fe(CO)_5$ adsorbed in monolayer and multilayer films on Au(111)/mica substrates has been induced by 0–20 eV electrons and studied by grazing incidence IR spectroscopy. Our results show that the cross sections for the initial stages of this process in as-deposited films range from 60–300 $Å^2$ and show considerable variations with the incident electron energy. The high sensitivity to low-energy electrons is believed to be the result of secondary reactions of anion fragments in the film with the neighbouring $Fe(CO)_5$ moieties, leading to increasingly massive heteronuclear $Fe_n(CO)_m$ species and progressive CO elimination. Continued exposure to the electron beam leads to the slower degradation of these newly created species into an Fe-rich deposit containing traces of CO. These traces are removed by subsequent heating to ~300 K. $Fe(CO)_5$ films that have been subjected to temperatures exceeding 125 K have no measurable sensitivity to the electron beam in the 0–20 eV regime; this is believed to be due to the structural transformation of the as-deposited thin film structure into 3D aggregates. This structural motif presents a very limited quantity of the adsorbed $Fe(CO)_5$ to the incident beam, and may also form a protective layer of the robust $Fe_n(CO)_m$ species during the initial stages of exposure to the electrons.

Key words: low-energy electron, $Fe(CO)_5$, CO elimination, dissociative electron attachment, surface polymerization.

Résumé : La décarbonylation du $Fe(CO)_5$ adsorbé en monocouche et en films multicouches sur des substrats de Au(III)/mica a été induite par des électrons de 0 à 20 eV et la réaction a été étudiée par spectroscopie infrarouge en incidence rasante. Les résultats obtenus montrent que les sections droites des stages initiaux de ce processus dans les films tels que déposés s'étalent de 60 à 300 $Å^2$ et varient beaucoup avec l'énergie des électrons incidents. On croit que la grande sensibilité aux électrons de faible énergie résulte de réactions secondaires des fragments ioniques dans le film avec les fractions voisines de $Fe(CO)_5$ qui conduisent à des espèces $Fe_n(CO)_m$ hétéronucléaires de plus en plus massives et à une élimination progressive de CO. Une continuation de l'exposition au faisceau d'électron conduit à une dégradation plus lente de ces espèces nouvellement créées en dépôts riches en Fe contenant des traces de CO. Il est possible d'éliminer ces traces par un chauffage subséquent à environ 300 K. Les films de $Fe(CO)_5$ qui ont été soumis à des températures supérieures à 125 K n'ont aucune sensibilité mesurable vis-à-vis du faisceau d'électron dans le régime 0 à 20 eV; on croit que cette situation est due à une transformation de la structure du film mince tel que déposé en des agrégats 3D. Ce motif structural ne représente qu'une faible quantité du $Fe(CO)_5$ adsorbé à faisceau incident et il peut agir comme couche protectrice pour les robustes espèces $Fe_n(CO)_m$ dans les étapes initiales d'exposition aux électrons.

Mots-clés : électron de faible énergie, $Fe(CO)_5$, élimination de CO, attachement dissociatif d'électron, polymérisation en surface.

[Traduit par la Rédaction]

Introduction

The growth of thin metallic films is an essential aspect in the design of reactive surfaces and in microelectronics. Among the methods of choice to deposit these films, vapour-phase depositions via thermal sources or plasmas are commonly used, as is the thermal decomposition of organometallic species via chemical vapour deposition. In both cases, energetic constraints prefer the use of relatively unstable and volatile precursors. In all cases, the cleanliness and the metallicity of the final surface film are of central importance. Metal carbonyls are useful starting reagents in this regard. The strong transition dipole moment of the carbonyls and the CO fragments make IR spectroscopy very well-suited to the characterization of these molecules in virtually all phases, as well as the determination of their decomposition pathways. More recently, the possibility of photolysis and electron-beam-induced decomposition has become attractive owing to the potential for pattern deposition on the surface and the enhanced probability of selective bond rupture in the precursor, rather than nonspecific decomposition.

One of the prototype metalcarbonyls ($Fe(CO)_5$ (IPC)) has been the object of many studies in the gas phase,[1–14] isolated in rare gas matrices,[15–19] and adsorbed onto surfaces such as Au,[20–22] Ag,[23–29] Cu,[30] Pt,[31] Ni,[32] graphite,[33,34] Si,[35–40] and silica.[41–43] A common picture has emerged that decomposition is thermally accessible on reactive metals such as Cu,[30] Pt,[31] and Ni[32]; in most other environments, IPC desorbs or

evaporates from matrices in a molecular fashion. Thermal decomposition proceeds stepwise leading to Fe-rich adsorbates such as $Fe(CO)_4$, $Fe(CO)_3$, and $Fe(CO)_2$. The photolysis of adsorbed IPC has been studied using several substrates such as Au(111),[20] Ag(111),[24,25] and Al/SiO_2.[42] The adsorbed films are sensitive to photons in the 150–330 nm range, and the CO:Fe ratio that is produced under these conditions is typically ~4 for monolayer photolysis, and near 3 for multilayer photolysis. The decomposition products are generally less sensitive to radiation at these wavelengths than is the IPC, an effect that has been attributed to electronic de-excitation of the excited states by the surface.

Electron-induced decomposition is an attractive alternative for these systems. IPC is readily decomposed by electron impact, which has stimulated interest in using scanning tunneling microscopes as a localized electron source in surface "writing" procedures.[44–46] High-energy electron-induced (500–3000 eV) dissociation has been employed by Kunz et al.;[47–49] in these studies, the high-energy beam creates considerable decomposition of the carbonyl moieties, leading to the inclusion of unwanted C in the metal deposit. To our knowledge, there are very few studies of low-energy (0–20 eV) decomposition of adsorbed IPC; this is unfortunate, since this is the range of energies that is easily produced in STM-based experiments. In addition, this is the range of energies for secondary electrons created by high-energy electron impact onto surfaces;[50,51] electron scattering to form these low-energy secondary electrons in molecular adsorbates has been shown to be the major factor that limits the spatial resolution of electron-beam-deposited nanostructures,[50] and a better understanding of the decomposition pathways for these species on surfaces is of considerable importance. Compton and Stockdale[2] measured the gas-phase sensitivity of IPC to electrons; they found that the parent $Fe(CO)_5^-$ species is not stable, with $Fe(CO)_4^-$ being observed in high yield with electron energies from 0 to 3 eV. As the incident electron energy increases the degree of ligand elimination increases, with bare Fe^- being observed from 6 to 11 eV. In all cases, the fragment bearing the Fe atom traps the incident electron. The observation of such low-energy dissociation channels, coupled with the direct detection of anionic fragments, shows that decomposition proceeds by dissociative electron attachment (DEA);[1,2] moreover, the onset at ~0 eV shows that the repulsive anionic potential surface (upon which the dissociation takes place) crosses the neutral ground-state surface near its energetic minimum. This leads to high dissociation probabilities, since the newly created anionic species does not present a stable interaction potential well. Henderson et al.[26,27] studied the electron-induced decomposition of IPC adsorbed on Ag(111) surfaces as a function of the incident energy to extract cross sections describing the probability of the decarbonylation process; their cross sections ranged from <1 to 14 $Å^2$ in the 3–132 eV regime, with no apparent structure in the cross section versus energy profile. In view of the very high sensitivity of gas-phase IPC to low-energy electrons, and the utility of these processes in surface science, we have performed an extensive series of works to study the adsorption of IPC onto Au(111) and self-assembled monolayer (SAM) substrates,[52,53] and the present report on the sensitivity of these films to low-energy electrons as a function of the film preparation conditions. Electron-induced processes in IPC adsorbed on *n*-alkanethiol SAMs are reported elsewhere.[54]

Experimental

The IRRAS instrument used in these experiments consists of a standard ion-pumped (220 L/s) chamber with a base pressure of 2×10^{-10} torr (1 torr = 133.3224 Pa); for all results reported herein with the closed-cycle cryostat (APD-202B) being used for sample cooling, the base chamber pressure is reduced to 5×10^{-11} torr. This system is equipped with a turbomolecularly pumped load–lock system for substrate introduction and a residual gas analyzer (Stanford Research Systems RGA-200) to verify the purity of gas supplies. The IRRAS components are arranged on a single 8 in. (1 in. = 25.4 mm) OD Conflat flange containing twin differentially pumped NaCl windows. The plane of the sample is parallel to this flange; two internal adjustable room-temperature Au/glass mirrors served to reflect the incident modulated IR beam that passes through the first NaCl window onto the surface at grazing incidence (~85° from the surface normal) and to direct the reflected divergent beam out of the vacuum chamber via the second NaCl window. This internal mirror configuration was adopted to allow the measurement of transmission spectra and the use of spectral references whereby the light passes just in front of the surface without reflection; this is especially important for the IRRAS characterization of organic SAMs that are introduced onto the chamber via the load–lock. A conventional FTIR bench (Nicolet Magna 550) provided the plane-parallel modulated IR radiation, which is focused and directed into the vacuum system within a purged optical bench fixed to the IRRAS flange; the MCT-A IR detector is also within this optical accessory. Custom LabVIEW-based software was used to control the spectrometer operation, acquire data, and present the spectra for analysis and interpretation. Typical spectrometer parameters were 2 cm^{-1} resolution, (1 cm^{-1} data point spacing), ~2 cm/s moving mirror velocity, Happ–Ganzel apodization, with no zero-filling; ~128–256 mirror scans were co-added to produce each measured reflectivity versus wavenumber profile. Spectra are reported herein as absorbance spectra, whereby the reflectivity is referenced to the reflectivity of a pristine Au/mica surface, or as Δabsorbance spectra, whereby the reference is the reflectivity of the IPC/Au/mica system; this latter presentation is used to focus on the changes introduced by the electron bombardment, with the anticipated ligand removal being evidenced by negative-going peaks.[55]

The axis of a custom-built low-energy electron source is orthogonal to the IRRAS flange and the sample surface, precisely centred between the two NaCl windows. This source uses three cylindrical lenses to deliver the high-current beam from a resistively heated Ta disk filament (Kimball Physics) to the surface under consideration at normal incidence. Two orthogonal deflection fields between the final lens and the surface are used to align the beam onto the surface and to raster it across the sample along both the horizontal and vertical axes to ensure uniform irradiation. The optimum parameters to align and raster the beam were established for each electron energy according to the profile of current to the sample versus the deflection field strength in each direction.

For personal use only.

The entire surface was rastered at ~10–100 Hz. The electron energy is established by the potential difference between the centre of the filament and the surface, with an estimated accuracy of ±0.5 eV; the sample was typically maintained at –2 V (with respect to chamber ground) to prevent low-energy electrons that have scattering off the lenses or deflector plates from reaching the surface. The breadth of the energy distribution is believed to have a FWHM of ~0.3–0.4 eV. All lens potentials were fixed with respect to the filament potential and the deflector potentials were fixed with respect to the surface potential. Beam currents were measured on the biased substrate and were recorded to quantify the absorbed charge for each irradiation.

Au films (150 nm) were evaporated at a rate of 1–10 Å/s onto freshly cleaved mica sheets (Proscience-Techniglass, ASTM-V2) in an all-metal turbomolecular-pumped evaporation system used only for this purpose, based on the protocol of DeRose et al.;[56] these films have predominantly Au(111) texture owing to the heating to 300 °C before, during, and after the metal evaporation. Films were removed from the evaporator, cleaned with sulfochromic acid to eliminate adventitiously adsorbed hydrocarbons, then cut to size and mounted onto Cu sample carrier plates; copper mounting straps on the Au surface ensured good thermal contact. These sample carrier plates have a protrusion on the lower edge that is immersed in a Ga well when positioned on the sample manipulator; below the 27 °C freezing point of Ga, this provides a rigid mechanical contact with high thermal and electrical conductivity between the sample and the sample holder. This latter was supported on a five-axis manipulator system using glass beads as pivot axes, with an OFHC copper braid extending to the tip of the cryostat mentioned above to cool the sample while permitting adequate movement for optical alignment and sample exchange. Minimum sample temperatures of 45 K were routinely achieved with this system, although the heating and cooling rates were limited to ~10 K/min because of the large thermal mass of the system.

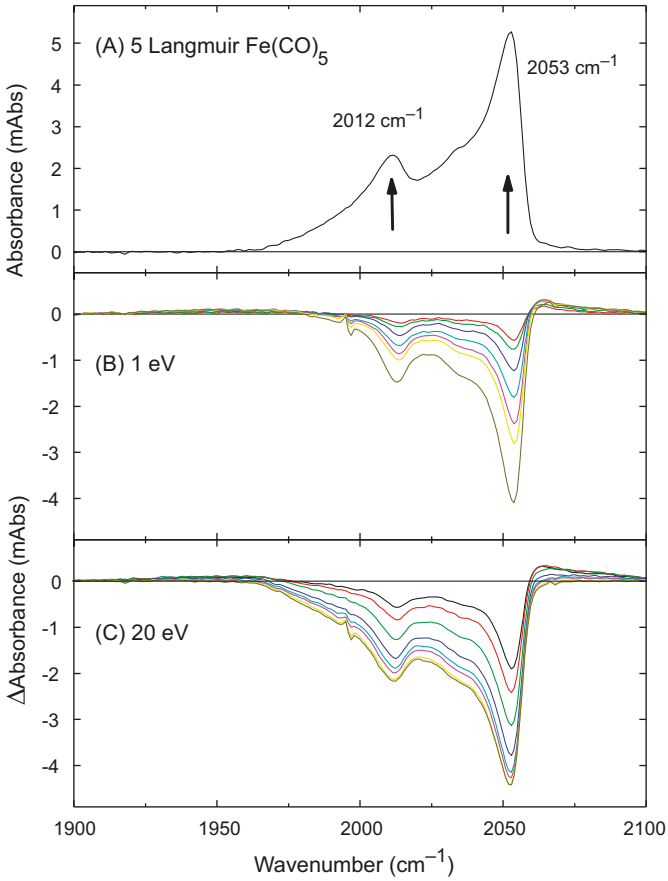
IPC (Sigma-Aldrich) was vacuum distilled and transferred to the gas manifold under Ar cover. It was freeze–thaw purified under vacuum on the manifold and changed weekly or as required if decomposition was suspected. IPC was dosed onto the surface from a background pressure of 2×10^{-8} torr; all coverages reported herein are in Langmuirs (1 Langmuir = 10^{-6} torr × s), with no corrections made for gauge sensitivity. As discussed elsewhere,[52,53] we estimate that monolayer coverages correspond to ~3–5 Langmuir; this is consistent with the 5 Langmuir estimate by other workers[20] for IPC deposition on Au(111) crystals at 80 K. Mass analysis of the gas during deposition showed no masses above the parent peak; as expected, extensive fragmentation of IPC in the ion source was observed.

Results and discussion

Electron-induced changes to the IR spectra

IPC was adsorbed onto the Au/mica substrates at 45 K; desorption occurs at 150–160 K. Figure 1A shows the IRRAS absorbance spectra of 5 Langmuir IPC/Au/mica measured at 45 K. Below ~120 K no changes are seen in the spectra of as-deposited films. They are characterized by a broad feature near 2012 cm^{-1} owing to the doubly degenerate equatorial

Fig. 1. Typical absorbance and Δabsorbance spectra for 5 Langmuir $Fe(CO)_5$ (IPC) / Au / mica films. (A) The absorbance spectrum of the as-deposited film. (B) and (C) The progressive changes to the absorbance provoked by 1 and 20 eV electrons, respectively, for cumulative doses of up to 2.5 mC/cm^2.



band and a sharper feature near 2053 cm^{-1} that is due to the asymmetric axial mode.[20,52] Aside from a small discrete peak near 2118 cm^{-1}, there is no significant optical absorbance below 1960 cm^{-1} or above 2062 cm^{-1}. The 2118 cm^{-1} feature has been attributed to the totally symmetric breathing mode, which appears weakly in the IRRAS spectrum because of the perturbation introduced by interaction with the metal substrate[20] or by the broken symmetry of grain boundaries.[52] These bands and the interpretation of the as-deposited monolayer structure are described in detail elsewhere.[52] Briefly, we find that the IPC layer in direct contact with the substrate is arranged with the C_3 molecular axis tilted by ~63° from the surface normal, with one axial and two equatorial CO groups directed towards the surface. This structure is consistent with the neutron diffraction results for IPC/C(0001)[33–35] and the energy minimization calculations based on semiempirical interaction potentials.[57] Similar IRRAS spectra are obtained for IPC monolayers on SAM substrates,[52] showing that specific binding to the substrate is not required to stabilize this structure.

As the exposure is increased beyond ~5 Langmuir, the equatorial band ceases to grow while the axial band narrows and shifts to higher frequencies; the high-coverage high-frequency limit is ~2062 cm^{-1} for all substrates studied, as shown in Fig. 2A. This evolution has been interpreted to be

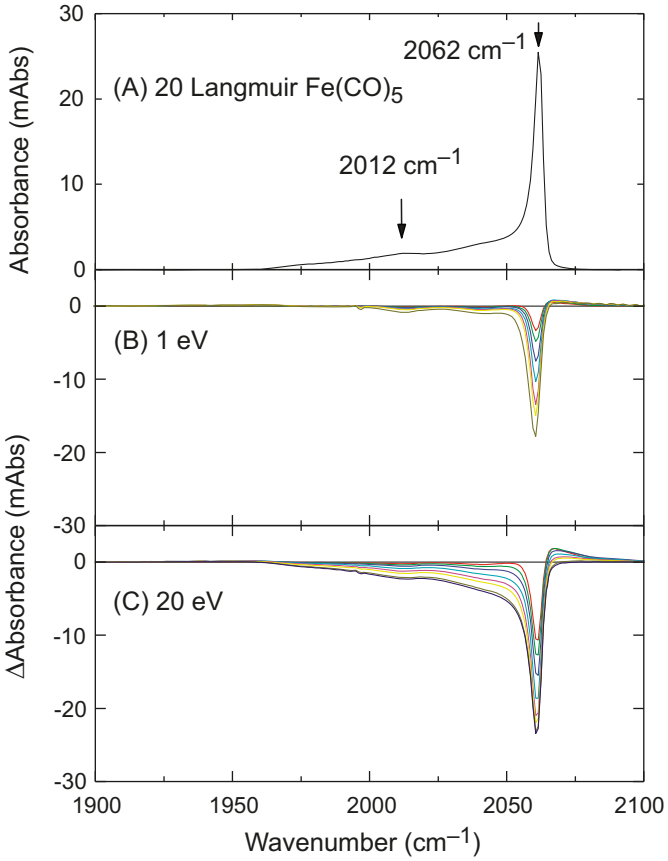
Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

evidence that molecules in subsequent layers are adsorbed with the C_3 molecular axis more aligned with the surface normal;[52] dipolar coupling among these near-parallel transition dipoles causes the observed blue shifts.[58–60] Other structural motifs based upon strong IPC–surface interactions have been proposed to explain the shift to higher frequencies with coverage[30] for adsorbed IPC systems, but this is clearly not the case of the IPC/Au(111) or IPC/SAM systems, which are spectroscopically very similar. Equally important in the context of the present work is the observation[53] that the as-deposited films undergo a significant structural transformation when heated to 120–140 K (100–140 K on *n*-alkanethiol SAMs) that we have interpreted as the formation of solid 3D aggregates on the surface; this will be discussed in more detail in the following as it relates to the present electron-irradiation processes. With the exception of the results shown in Fig. 8B, all results presented herein are obtained for as-deposited films.

Figures 1B and 1C show the ΔAbsorbance spectra obtained when the 5 Langmuir deposits are irradiated with 1 and 20 eV electrons, respectively. Intermediate energies exhibit trends between these two limiting cases. In the limit of high delivered electron doses (~3–5 mC/cm^2), both bands can be significantly diminished for all electron energies, indicating extensive CO elimination from the surface. The extent of the band elimination under less extreme doses shows more variation with incident energy; for example, the 2053 cm^{-1} peak has lost three times more intensity at 20 eV than at 1 eV, for equivalent doses of 0.005 mC/cm^2.

The depletion structures of the ΔAbsorbance presentation are observed to be at the same positions as the structures in the original absorbance spectra, for all film thicknesses and for all electron energies. We note that the peak at 2118 cm^{-1} also suffers electron-induced CO elimination, although the weak intensity of this peak makes quantification difficult. For all electron energies impinging upon the 5 Langmuir films, the overall form of the ΔAbsorbance spectrum is almost identical to that of the initial absorbance spectrum; this indicates that there is little or no selectivity for removal of the axial versus equatorial ligands; to our knowledge, this has not been addressed in gas-phase studies. One of the most important trends shown in Figs. 1B and 1C is the initial electron-induced *increase* of IR absorbance in the regions from 1900 to 1980 cm^{-1} and from 2060 to 2100 cm^{-1}. These spectral regions are devoid of peaks associated with molecular IPC under all circumstances,[1–19] and we conclude that they are the signatures of newly created iron carbonyl species, in an unresolved structure that underlies the entire 1900–2100 cm^{-1} region. Continued irradiation at 1 eV causes the growth of these features to an asymptotic limit, whereas 20 eV bombardment causes a rapid growth followed by a slow decay of these features. The observation of a discreet absorbance feature during the electron irradiation implies that the chemical species that give rise to these features are significantly less sensitive to the incident electron flux than are the original IPC molecules; this is also consistent with the inability of the 1 eV electron beam to induce the decarbonylation of this species. In some cases, the intensity of the 2073 cm^{-1} feature increases with the beam current for a given total dose, suggesting that the rate of bombardment is important in the creation of this new species; this is the only instance that we are aware of for which low-energy electron reactive scattering displays such kinetic effects, and may be evidence of very slow surface reaction processes. In the absence of further electron irradiation or temperature changes, these structures show no temporal evolution on the seconds-to-hours timescales available in this experiment.

Fig. 2. Typical ΔAbsorbance spectra for 20 Langmuir $Fe(CO)_5$ (IPC) / Au / mica films. (A) The absorbance spectrum of the as-deposited film. (B) and (C) The progressive changes to the absorbance provoked by 1 and 20 eV electrons, respectively, for cumulative doses of up to 2.5 mC/cm^2.



Similar results are observed for 20 Langmuir IPC/Au/mica, as shown in Figs. 2A–2C. Sharp depletions of the dominant axial-mode peak are seen for 1 and 20 eV electrons, with complete extinction possible for extended irradiation at energies above ~5 eV. Irradiation at 1 eV leads to narrower depletions, with significantly less effect on the 2012 cm^{-1} equatorial mode peak. Since this peak is the spectral signature of the tilted molecules in direct contact with the substrate,[52] this indicates that 1 eV electrons are not able to interact as strongly with this buried interface as are the 20 eV electrons. Since this behaviour was not found for the 5 Langmuir deposit (Fig. 1B), we presume that this reflects the inability of these very low-energy electrons to penetrate to the first layer of IPC, rather than a substrate-induced insensitivity of these molecules to the 1 eV excitations. This in turn indicates that the interactions of the electrons with the as-deposited film are extremely strong, with correspondingly large inelastic and reactive cross sections; weaker interactions would result in a more uniform irradiation and more uniform

CO elimination within the entire 20 Langmuir film. The measurements on the 20 Langmuir films were hampered by the accumulation of negative charges in the film; it was not possible to experimentally distinguish charge trapping in interstitial sites from the creation of stable anionic molecular species, although as will be discussed in the following, we believe that latter to be an important process.

The quantitative interpretation of these results requires the measure of the IRRAS signal at a given wavenumber expressed as a function of the delivered dose per unit area (q). Irradiations have been performed in triplicate at 0.5, 1.0, 2.0, 5.0, 7.0, 9.0, 11.0, 15.0 and 20 eV for the 5 Langmuir films, and 1.0, 5.0, 10.0 and 20.0 eV for the 20 Langmuir films. Figure 3 presents the traces corresponding to the 1.0 and 20.0 eV irradiation of the 5 Langmuir IPC/Au/mica films, measured on the 2012 and 2053 cm^{-1} depletion features. For all electron energies employed, and on both peaks, the initial CO depletion is extremely rapid, again indicating that the interaction cross sections are very high. In each case, a second slower decarbonylation process follows this rapid CO elimination; semi-log plots also reveal this bi-exponential behaviour. In general, electron energies below ~5 eV inflict less decarbonylation in the first rapid process and in the slower second process than do higher energies. The break between these two regimes is below ~0.1 mC/cm^2 in all cases, corresponding to ~30% reduction in the CO band absorbance at low electron energies and as much as 80% reduction at higher energies.

Figure 4 shows the dose-dependent intensity of the 1950 and 2073 cm^{-1} "growth regions" identified previously, using 5 eV incident electrons and a 5 Langmuir IPC film. The growth and decay processes are clearly seen, and again, the break between these two regimes is always at <0.1 mC/cm^2. Although the magnitude of the 1950 cm^{-1} feature is always less than that of the 2073 cm^{-1} feature, both curves follow approximately the same profile for any given energy; as discussed previously, the profiles are energy-dependent. There is residual intensity on these features even at the maximum doses used, indicating that the newly created species are extremely resistant to the incident electron flux. Similar results are found using 20 Langmuir IPC films, with correspondingly stronger growth features, indicating that the newly created species are not preferentially formed at the IPC–metal or IPC–vacuum interfaces.

The following conclusions can be made based on the previous observations, which will guide the subsequent data analysis:

- Low-energy scattering causes rapid and extensive CO elimination from the film at all energies from 1 to 20 eV;
- The cross sections for the electron film reactive scattering events are very large;
- There is evidence of new species being created with wide and unstructured IR absorbances extending across the 1900–2100 cm^{-1} region;
- This new species is far less sensitive to electron-induced CO elimination than IPC;
- The sensitivity of the IPC and the newly formed species varies with the incident electron energy;
- There is no evidence of selective electron-induced elimination from the axial or equatorial molecular sites.

Mathematical model

To extract quantitative and transferable data from these measurements, we propose a sequential two-step irreversible reaction model involving three distinct types of surface bound species (**A**, **B**, and **C**)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

$$\mathbf{A} + e^- \xrightarrow{\sigma_{AB}} \mathbf{B}$$

$$\mathbf{B} + e^- \xrightarrow{\sigma_{BC}} \mathbf{C}$$

where **A** is the original IPC molecule, **B** represents the intermediate species that is formed by electron impact on the IPC, and **C** is taken to be the final material remaining following extensive irradiation at 45 K. This general scheme is not intended to imply that the fate of the incident electron is known at this point. The CO:Fe ratios that define the composition of the second and third species ($N_{\mathbf{B}}$ and $N_{\mathbf{C}}$) and the cross sections required to produce **B** and **C** ($\sigma_{\mathbf{AB}}$ and $\sigma_{\mathbf{BC}}$) are presumed to vary with the incident electron energy. Our objective was to analyse the spectral data and their dependence on the incident electron flux to have a better understanding of the initial processes taking place in these films, subject to several important caveats: in the absence of specific information, we necessarily neglect inelastic energy loss events in the adsorbed film, as well as the possible production of secondary electrons at higher incident energies. Assuming first-order dissociation dynamics, the following relationships define how the three populations ($P_{\mathbf{A}}$, $P_{\mathbf{B}}$, and $P_{\mathbf{C}}$) evolve under the influence of the incident electron dose, for a given electron energy.

$$\frac{\partial P_{\mathbf{A}}}{\partial q} = -\sigma_{\mathbf{AB}} P_{\mathbf{A}}$$

$$\frac{\partial P_{\mathbf{B}}}{\partial q} = \sigma_{\mathbf{AB}} P_{\mathbf{A}} - \sigma_{\mathbf{BC}} P_{\mathbf{B}}$$

$$\frac{\partial P_{\mathbf{C}}}{\partial q} = \sigma_{\mathbf{BC}} P_{\mathbf{C}}$$

Imposing the population constraint that the only species initially present is IPC, and that electron-stimulated desorption of the heavy iron-bearing fragments is negligible, then

$$P^0_{\mathbf{A}} = P_{\mathbf{A}}(q) + P_{\mathbf{B}}(q) + P_{\mathbf{C}}(q)$$

and the three dose-dependent populations are related as follows:

$$P_{\mathbf{A}}(q) = P^0_{\mathbf{A}} \exp(-\sigma_{\mathbf{AB}} q)$$

$$P_{\mathbf{B}}(q) = \frac{\sigma_{\mathbf{AB}} P^0_{\mathbf{A}}}{\sigma_{\mathbf{BC}} - \sigma_{\mathbf{AB}}} [\exp(-\sigma_{\mathbf{AB}} q) - \exp(-\sigma_{\mathbf{BC}} q)]$$

$$P_{\mathbf{C}}(q) = P^0_{\mathbf{A}} \left[1 - \frac{\sigma_{\mathbf{BC}}}{\sigma_{\mathbf{BC}} - \sigma_{\mathbf{AB}}} \exp(-\sigma_{\mathbf{AB}} q) + \frac{\sigma_{\mathbf{AB}}}{\sigma_{\mathbf{BC}} - \sigma_{\mathbf{AB}}} \exp(-\sigma_{\mathbf{BC}} q) \right]$$

Similar relationships are used to monitor the kinetics of two sequential reactions, whereby the rate constants determine the rate of population changes.[61] The link to the experimental results is made by assuming, consistent with the observations made previously, that the observed IR absorbance as a function of charge (Abs(q)) is simply proportional to the number of CO groups in each species multiplied by their respective populations, i.e.,

$$\mathrm{Abs}(q) = 5P_{\mathbf{A}}(q) + N_{\mathbf{B}} P_{\mathbf{B}}(q) + N_{\mathbf{C}} P_{\mathbf{C}}(q)$$

These equations were fit to the experimental data using a LabVIEW implementation of the Levenberg–Marquardt nonlinear least-squares fitting algorithm[62]; the extracted parameters were the populations and compositions of **B** and **C** during the irradiation process and the cross sections that govern the electron-induced processes. The results of these analyses are presented in Figs. 5 and 6 for the 5 Langmuir deposits based on the behaviour of the dominant 2053 cm^{-1} peak; the compositional data ($N_{\mathbf{B}}$ and $N_{\mathbf{C}}$) extracted for the 2012 cm^{-1} feature differ by <0.4 CO per Fe from the results presented herein, whereas the cross sections are usually within 20%–40% of those calculated for the 2053 cm^{-1} feature. These relatively minor discrepancies are due to the lower signal-to-noise of the equatorial peak.

The calculated cross sections for the first rapid process ($\sigma_{\mathbf{AB}}$, Fig. 5A) are indeed extremely large, revealing the high sensitivity of the IPC to the electron beam. The cross sections are always >60 $Å^2$, and typically are >100 $Å^2$, with a pronounced minimum near 2–4 eV. The cross sections for the second process leading to the **B** → **C** transformation ($\sigma_{\mathbf{BC}}$, Fig. 5B) follow the same trends as $\sigma_{\mathbf{AB}}$. As predicted, $\sigma_{\mathbf{BC}}$ is 1–2 orders of magnitude lower than $\sigma_{\mathbf{AB}}$; this disparity of the rates of creation and elimination leads to the observation of the 1950 and 2073 cm^{-1} growth and decay features during the irradiation. Although we have confidence in the approximate value of $\sigma_{\mathbf{BC}}$, the extraction of two widely different cross sections in a coupled process is mathematically difficult and the fit solutions can become unstable; the similar trends of $\sigma_{\mathbf{AB}}$ and $\sigma_{\mathbf{BC}}$ as a function of electron energy may be a consequence of this. Despite this caution, the extracted values of $\sigma_{\mathbf{BC}}$ confirm our observation that the decarbonylation of the intermediate **B** species is less probable at 1 eV than at 20 eV. Figure 6 shows the extracted CO:Fe composition ratios for the **B** and **C** species, expressed as a function of the incident electron energy. At $E_i \leq 1$ eV, the intermediate **B** species has an overall composition of $Fe(CO)_{3–4}$, and as the electron energy increases to 20 eV the average number of COs associated with each Fe atom decreases to approx. two, confirming that higher electron energies are more effective for the decarbonylation reactions involving IPC. At $E_i \leq 1$ eV, the final **C** product composition contains only 1.5–1.0 COs per Fe atom, and this low ratio decreases further to ~0.5 for $E_i \sim 20$ eV. Clearly, the final **C** product contains very little CO following extensive electron bombardment for $E_i \geq 2$ eV. The distinguishable behaviour of the high- and low-energy irradiation profiles indicates that, although inelastic scattering is certainly occurring in these films, it is unlikely that the high-energy irradiation induces decarbonylation via inelastic scattering coupled to a lower energy dissociation process.

The parameters extracted from this analysis confirm each of the qualitative conclusions outlined previously. Although we have not collected the same quantity of data for the 20 Langmuir IPC/Au/mica deposits because of sample-charging difficulties, the results extracted from this analysis are fully consistent with those extracted from the 5 Langmuir data. The agreement is encouraging in view of the approximations required

by our analysis. Table 1 shows the comparison between these sets of results and confirms the minimum of the σ_{AB} and σ_{BC} cross sections for $E_i \sim$ 2–5 eV.

Molecular interpretation

The extremely large σ_{AB} cross sections extracted by this analysis are encouraging in that they indicate that electron-induced decarbonylation of IPC is an extremely efficient process even at such low energies and may be of technological value. Their magnitude poses interesting questions concerning the mechanism of the initial electron-induced processes in the IPC films. In gas-phase electron–molecule scattering the maximum dissociative cross sections are always less than the limiting cross section for s-wave electron attachment ($\sigma_s \sim \pi\lambda^2$)[63,64] with λ being the de Broglie wavelength of the incident electron. For $E_i \sim$ 1 eV this implies an upper limit of ~100 Å^2, whereas at E_i = 12 eV the gas-phase cross sections cannot significantly exceed 1–10 Å^2. Whereas the low energy values of σ_{AB} measured above are bound by σ_s (and are consistent with the large cross sections observed for electron scattering in gas-phase IPC at low energies), the overall increase of σ_{AB} beyond $E_i \sim$ 2–5 eV cannot be directly interpreted in terms of single electron–molecule processes. The most obvious difference between the behaviour of the low-pressure gas-phase measurements and those of the present study is the possibility of secondary reactions following the initial electron-induced dissociation event. Wronka and Ridge[3] studied this process in a variable pressure ion – cyclotron resonance (ICR) gas cell containing IPC. They identified the following reaction sequences, starting with the primary dissociation of IPC to yield various fragment anions.

(1) At electron energies below ~1 eV, previous work[1,2] confirmed that the main product is $Fe(CO)_4^-$. In the ICR cell, this was found to react readily via

$$Fe(CO)_4^- + Fe(CO)_5 \xrightarrow{\sim k} Fe_2(CO)_8^- + CO, \quad N_{CO}:N_{Fe} = 4.0$$

where k is a relative rate constant that was used as a benchmark in their work. If additional reactions ensue, their reaction rates are less than k, and were not reported by Wronka and Ridge. Hence, if the primary $Fe(CO)_4^-$ product reacts with an adjacent IPC molecule, one additional CO will be released from the film, doubling the measured cross sections for decarbonylation; equally important, the final CO:Fe ratio for the surface bound species **B** will be ~4.0. This is in very good agreement with the composition of the intermediate **B** species extracted from the above analysis for $E_i \sim$ 0.5 eV as shown in Fig. 6.

(2) As the incident energy increases, the preferred fragmentation channel implies the release of more CO ligands in the primary dissociation event, with the Fe-bearing fragment always carrying the excess charge. Starting with the $Fe(CO)_3^-$ fragment, the ICR results found the following reactions to have significant rates

$$Fe(CO)_3^- + Fe(CO)_5 \xrightarrow{\sim 120k} Fe_2(CO)_6^- + 2CO, \quad N_{CO}:N_{Fe} = 3.0$$

$$Fe_2(CO)_6^- + Fe(CO)_5 \xrightarrow{\sim 16k} Fe_3(CO)_{10}^- + CO, \quad N_{CO}:N_{Fe} = 3.3$$

$$Fe_3(CO)_{10}^- + Fe(CO)_5 \xrightarrow{\sim k} Fe_4(CO)_{13}^- + 2CO, \quad N_{CO}:N_{Fe} = 3.3$$

$$Fe_4(CO)_{13}^- + Fe(CO)_5 \xrightarrow{\sim k} Fe_5(CO)_{16}^- + 2CO, \quad N_{CO}:N_{Fe} = 3.3$$

Table 1. Comparison of the electron-irradiation dissociation parameters obtained using 5 Langmuir films with those of 20 Langmuir films. The uncertainties of the cross sections are ±10%–15%, and the uncertainties on the composition parameters $N_{\mathbf{B}}$ and $N_{\mathbf{C}}$ are ±5%–10%.

	5 Langmuir films				20 Langmuir films			
Energy (eV)	$\sigma_{\mathbf{AB}}$ (Å^2)	$\sigma_{\mathbf{BC}}$ (Å^2)	$N_{\mathbf{B}}$	$N_{\mathbf{C}}$	$\sigma_{\mathbf{AB}}$ (Å^2)	$\sigma_{\mathbf{BC}}$ (Å^2)	$N_{\mathbf{B}}$	$N_{\mathbf{C}}$
1	100	2.5	2.8	0.7	137	5.0	3.1	1.4
5	85	2.0	2.4	0.5	115	2.5	1.9	0.4
10	204	9.5	1.8	0.3	267	9.0	1.8	0.4
20	270	11.5	1.8	0.2	406	10.5	2.1	0.3

If the primary product undergoes these four sequential additions to generate the final $Fe_5(CO)_{16}$ heteronuclear product shown, the incident electron will have provoked the elimination of nine CO ligands, multiplying the $\sigma_{\mathbf{AB}}$ cross sections accordingly, and producing a product that is slightly richer in Fe than observed at lower incident electron energies.

(3) Finally, if the incident electron energy is increased high enough to produce significant quantities of $Fe(CO)_2^-$, the ICR results indicate that the following reaction cascade may result

$$Fe(CO)_2^- + Fe(CO)_5 \rightarrow Fe_2(CO)_5^- + 2CO, \quad N_{CO}:N_{Fe} = 2.5$$

$$Fe_2(CO)_5^- + Fe(CO)_5 \xrightarrow{\sim 140k} Fe_3(CO)_9^- + CO, \quad N_{CO}:N_{Fe} = 3.0$$

$$Fe_3(CO)_9^- + Fe(CO)_5 \xrightarrow{\sim 150k} Fe_4(CO)_{12}^- + 2CO, \quad N_{CO}:N_{Fe} = 3.0$$

This process also eliminates a total of nine CO ligands, and the CO:Fe ratio has continued to decrease. Although the ICR experiments did not detail reactions beyond this because of the low abundance of the initial $Fe(CO)_2^-$ anion, the high rate constants measured for the last step characterized indicates that continued reactivity is a strong possibility.

The trends for the composition of the intermediate **B** species shown in these reaction sequences are consistent with those extracted from our results, although our values indicate that the intermediate **B** complex is slightly more Fe-rich than the ICR experiments would suggest. This may simply be a consequence of the higher IPC density in the condensed phase than in the gas-phase experiments, the desorption of lighter carbonyl species during electron bombardment, or it may be the result of inadequacies of the relatively simple mathematical model by which the data was interpreted. The minimum of the $\sigma_{\mathbf{AB}}$ cross sections at E_i = 2–5 eV (Fig. 5A) would appear to be the result of the decreased number of reactive anions created as the energy increases,[1,2] coupled to the increased reactivity of those anions that are formed.[3] The identification of this intermediate **B** species as a heteronuclear $Fe_n(CO)_m^-$ complex is supported by the growth of the 1950 and 2073 cm^{-1} features during the initial periods of electron irradiation. Previous work[65] has shown that such species have absorption bands at higher and lower frequencies than IPC; for example, whereas the highest IR active mode of gas-phase IPC is found at 2034 cm^{-1}, the strongest IR active modes of Fe_2CO_9 and Fe_3CO_{12} are at 2088 and 2056 cm^{-1}, respectively.[65] In all cases, bridging COs are observed at frequencies below 2000 cm^{-1},[65], which could be the origin of the growth and decay features observed herein at ~1950 cm^{-1}. Of course, these frequencies will be significantly shifted if the excess charge remains bound to the molecular core, and there is no reason to believe that the electron-induced reactions will generate oligamers with simple compositions or structures such as those studied under controlled conditions. We suggest that the relatively low values of $\sigma_{\mathbf{BC}}$ reflect the relative stability of the anionic intermediate **B** species to further electron-induced degradation; in addition, it is clear that since the growing heteronuclear material maintains the initial charge, additional electron attachment will be electrostatically hindered, further reducing the apparent $\sigma_{\mathbf{BC}}$ cross sections.

Thermal effects

In an effort to confirm the presence of the $Fe_n(CO)_m$ species following low-energy electron irradiation, we performed partial irradiation of 20 Langmuir IPC films, followed by heating of the sample at 2 K/min to induce desorption. Figure 7 shows the integrated intensity across the 1900–2100 cm^{-1} spectral region as a function of temperature for an as-deposited 20 Langmuir IPC/Au/mica film (squares) and for an identical film that has been exposed to 0.25 mC/cm^2 electron dose at 5 eV (circles). The integrated intensity of the as-deposited film shows a slow decrease up to ~120 K, presumably because of some weakly bound IPC desorption. At temperatures between 120 and 140 K, there is a marked intensity *increase* that is due to the irreversible structural transformation of the as-deposited film into compact 3D aggregates on the surface; this process has been discussed in detail elsewhere.[53] Desorption of the IPC is complete by 150–160 K, with no further spectral changes.

A very different desorption profile is seen for the partially irradiated film. More pronounced decreases are seen at low temperatures, which may be evidence of thermal desorption of lighter fragments. The 140 K thermal transformation is shifted to slightly higher temperatures and has a much less pronounced spectral signature following electron bombardment; larger polymeric species are less likely to laterally diffuse and crystallize than the original IPC. A second slight increase of integrated intensity is seen at ~210 K, which may signal another structural rearrangement; the last traces of CO in the film remain until the temperature reaches ~300 K. Bernasek[66] showed that the thermal desorption of CO

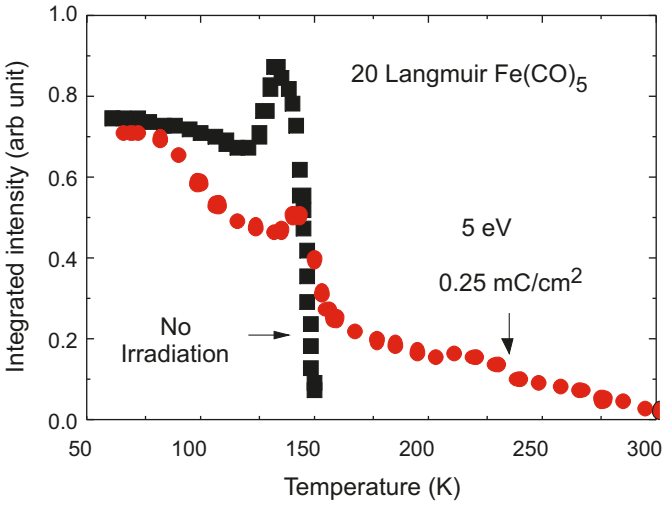
Fig. 7. Integrated intensity of the 1900–2100 cm^{-1} region versus temperature for 20 Langmuir $Fe(CO)_5$ (IPC) / Au / mica (squares) and for 20 Langmuir IPC/Au/mica following 0.25 mC/cm^2 irradiation at 5 eV (circles). The integrated intensities have been scaled to approximately similar values at 50 K.

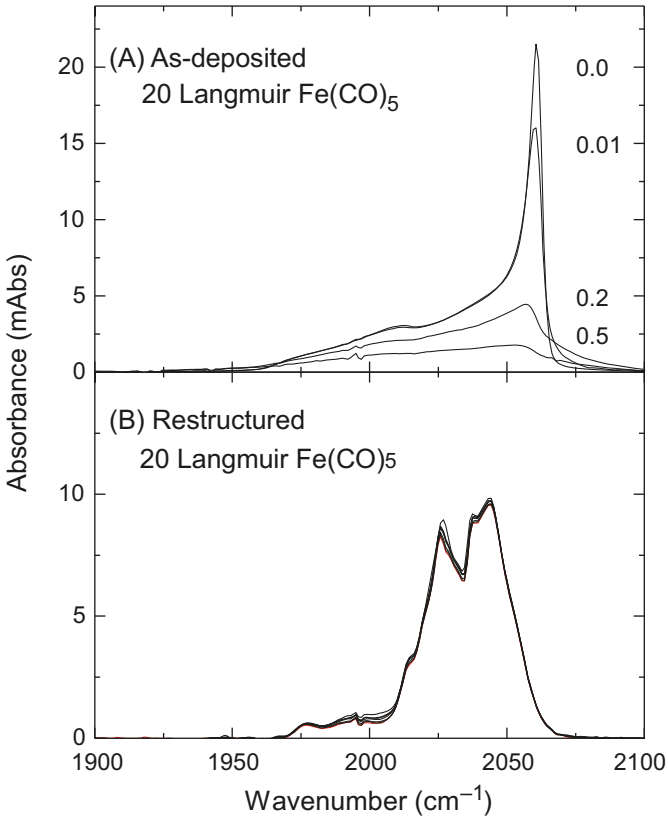


from Fe(100) surfaces takes place via multiple processes at 220, 306, 440, and 825 K; the first two peaks are from molecular CO/Fe(100) and the higher temperature peaks are due to C–O recombination processes. The close similarity of our observed temperature-induced desorption restructuring at 210 K and the final desorption temperature of ~300 K to the molecular CO/Fe(100) results suggests that our irradiated films are indeed composed of CO interacting with iron-rich regions, as proposed from our discussions and analysis.

We also explored the effect of the thermal transformation of the IPC film described previously on the apparent sensitivity to low-energy electron scattering. Figure 8 shows the effect of 5 eV irradiation on as-deposited 20 Langmuir IPC/Au/mica samples, as well as 20 Langmuir IPC/Au/mica that has been transformed by heating to ~140 K then rapidly cooled to 45 K. As discussed in detail previously, the as-deposited films are extremely sensitive to the incident electron flux; exposure to a dose of only 0.005 mC/cm^2 reduces the dominant axial band absorption by ~35%, and a total dose of 0.05 mC/cm^2 has almost completely extinguished both peaks. However, when the thermally transformed IPC/Au/mica is exposed to a 5.0 mC/cm^2 dose under identical conditions (Fig. 8B), no quantifiable changes are observed. We estimate that the heating above 120 K reduces the *apparent* cross section by *2–3 orders of magnitude* with respect to the as-deposited film.

The thermally induced structural transformations of IPC films on Au/mica and on alkanethiol self-assembled monolayer substrates have been described in detail elsewhere;[53] the thermal behaviour of the adsorbed IPC is essentially identical for these two substrates. We have shown that the IR spectra of the stretching modes associated with the terminal methyl group of self-assembled monolayers are extremely sensitive to the presence of most adsorbates, including IPC. The strong symmetric stretch at 2875 cm^{-1} suffers a systematic shift to lower wavenumbers and a decrease in intensity when in the presence of an atomic or molecular overlayer such as IPC; upon heating to ~140 K, however, this peak re-

Fig. 8. Effect of thermal pre treatments on decarbonylation processes in 20 Langmuir $Fe(CO)_5$ (IPC) / Au / mica films. (A) The absorbance spectrum of the as-deposited film and the effects of irradiating this film at 5 eV with total doses of 0.005, 0.05, and 0.5 mC/cm^2. (B) The pre-irradiation absorbance spectrum obtained by heating a 20 Langmuir IPC/Au/mica film to ~130 K. Subsequent spectra measured following doses of up to 5.0 mC/cm^2 show no significant electron-induced changes.



covers essentially all of its original intensity, even though the C–O stretching spectra of the carbonyl bands show that the no significant desorption of IPC has occurred at this temperature. The reduced interaction of the IPC adsorbates with the methyl-terminated surface witnesses the aggregation of the IPC into 3D islands or aggregates, since most of the SAM is no longer covered by the IPC. In fact, the newly exposed methyl terminations (in the presence of the IPC aggregates) can be exposed to additional IPC, and the IR spectra of the methyl terminations suffer the same spectral shifts that were observed during the first adsorption cycle, as the open regions of the SAM are once again covered with as-deposited IPC; reheating to 140 K causes the aggregates to grow even larger by mass transfer from the layers to the aggregates and re-exposes most of the methyl-terminated substrate. This aggregation process is irreversible, indicating that the as-deposited films are not in the thermodynamic ground state.[53] There is no evidence for thermally induced chemical changes to the IPC under the conditions of these experiments and with the substrates employed herein.

The remarkable change in the apparent sensitivity to the incident electrons upon heating is a direct consequence of the extremely large cross sections measured herein, coupled

For personal use only.

with the compact structure of the 3D IPC aggregates formed by heating. In this form most of the surface consists of exposed Au/mica regions, such that most electrons do not interact with the molecular solids; furthermore, only a very small fraction of the total IPC content of the film is on the exterior of the aggregates. Those few electrons that do interact with the IPC on the aggregate surfaces will form an electron-resistant "crust" on the aggregate that will further reduce the penetration of electrons into the solid. Previous work[41] showed that the photolysis cross sections of $Fe(CO)_5$ on silica surfaces is reduced following heating to 100 K, and this was attributed to the caging of CO fragments within the solid, followed by recombination with Fe-bearing fragments. Although caging and recombination are conceivable in the present case, we note that these electron-induced dissociation processes occur on anionic potential energy surfaces; successful recombination following DEA would require the reaction of CO with an anionic Fe-bearing fragment to be accompanied by electron emission, since the parent anion of IPC is not stable. This does not seem to be a very probable sequence of events. We conclude that the fundamental causes of the thermally induced deactivation of the IPC deposit towards low-energy electron impact are the reduced 2D surface area that is occupied by the thermally transformed IPC deposit and the lack of electron penetration into the 3D aggregates. Thus, we emphasize that it is the *apparent* sensitivity of IPC in the fully aggregated form that has been reduced by the structural transformation, and not the sensitivity of individual molecules.

To our knowledge, the only published study of low-energy electron irradiated IPC physisorbed on surfaces is that of Henderson et al.[26] for IPC/Ag(111). This work quantified the IPC and CO remaining on the surface as a function of the electron dose using temperature-programmed desorption; they too reported that the surface is transformed into $Fe_n(CO)_m$ species. However, the extent of the electron-induced decomposition is dramatically different. As shown in Fig. 3, a delivered dose of only 0.02 mC/cm^2 (~1.2×10^{14} e/cm^2) at 1 and 20 eV reduces our CO band strengths by ~30%–70%; the TPD results of Henderson et al.[26] show negligible IPC depletion for these levels of electron irradiation. As a result, their electron-induced decomposition cross sections for monolayer deposits of IPC (<1, 2.0, and 6.1 Å^2 for E_i = 3, 8, and 25 eV, respectively) are significantly lower than the results reported herein. To prepare highly uniform films, these workers heated multilayer deposits to ~157 K to desorb all but the IPC directly adsorbed onto the Ag(111) substrate, then recooled the sample to 90 K to perform the electron irradiation experiment. It is possible that this monolayer preparation protocol had the unexpected effect of transforming the remaining IPC/Ag(111) adsorbates into the compact aggregates as found above. This process is insensitive to the nature of the substrate for physisorbed IPC,[53] and once transformed, the IPC molecules appear to be resistant to the low-energy electrons.

Conclusions

This work reports the effect of low-energy electrons on films of IPC on Au/mica substrates. The decarbonylation process is described by a fast initial process that leads to a 20%–80% reduction in the CO content of the film, followed by a slower process leading to almost complete CO elimination. The decarbonylation cross sections for the first step are extremely large (~60–300 Å^2 for the 1–20 eV regime); we have interpreted this as showing that the initial process proceeds by the sequential reactions of Fe-bearing anionic species with adjacent IPC of the film to create progressively larger $Fe_n(CO)_m$ anions and progressively greater CO elimination. A simple kinetic model based on the gas-phase reactivity of anionic $Fe_n(CO)_m^-$ fragments has been shown to provide qualitative and quantitative agreement with the IR-RAS results. These apparent decarbonylation cross sections are extremely sensitive to the physical state of the IPC deposit; when arranged in compact 3D aggregates, the overall film is several orders of magnitude less sensitive to low-energy electrons. Our results suggest that this dramatic decrease is due to the small "footprint" of the aggregates on the Au/mica surface, which causes most electrons to strike pristine metal surfaces rather than the molecular adsorbates, as well as the reduced access of the electrons to the interior of the aggregates owing to their very strong interactions with the outermost IPC layers.

This study provides a quantitative framework by which to understand these highly reactive films and to develop methods by which these simple and volatile organometallics can be used to deposit metal atoms on surfaces. In the case of traditional metallic and semiconducting substrates, the use of low-energy electrons may provide a cleaner decomposition pathway than the more traditional high-energy irradiation; work in progress will quantify the C and O impurities that are trapped in the Fe overlayer during this deposition method. However, we feel that the most promising application of this approach is in the deposition of metal layers on substrates that are themselves sensitive to higher energy incident particles. Organic self-assembled monolayers are one example, since they are known to suffer large electron-induced bond rupture (C–H, C–C) for electron energies above ~6.5 eV.[55,67] As the results of this work have shown, decarbonylation of IPC is extremely efficient with incident energies well below this damage threshold for the SAM, and the deposition of metal layers on fragile organic films may be practical with this approach.[54]

Abstract: Syntheses of 1,11-bis(salicylaldimine)-3,6,9-trithiaundecane (**H_2L1**), 1,11-bis(salicylaldimine)-6-oxa-3,9-dithiaundecane (**H_2L2**), and 1,8-bis(salicylaldimine)-3,6-dithiaundecane (**H_2L3**), their nickel complexes [Ni(L1)]·H_2O (**I**), [Ni(HL2)][OAc] (**II**), [Ni(L3)·HOAc]$_2$[Ni(L3)·2HOAc]·$3H_2O$ (**III**), [Ni(HL1-sal)]Cl_2·H_2O (**IV**), [Ni(HL2-sal)]Cl_2·CH_3OH (**V**), [Ni(L3-sal)Cl]·H_2O (**VI**), {[Ni(HL1-sal)]Br_2}$_2${[Ni(L1-sal)]Br}·H_2O (**VII**), {[Ni(HL2-sal)]Br_2}$_2${[Ni(L2-sal)]Br}·$2CH_3OH$ (**VIII**), {[Ni(HL3-sal)Br]Br}[Ni(L3-sal)Br]·$2CH_3OH$ (**IX**), [Ni(HL3-sal)Br]Br·CH_3OH (**X**), [Ni(HL3)Br]·$2H_2O$ (**XI**), [Ni(HL1)]$_2$[BF_4]$_2$·$5H_2O$ (**XII**), [Ni(HL2)]$_2$[BF_4]$_2$·$3H_2O$ (**XIII**), [Ni(HL3)]$_2$[BF_4]$_2$·CH_3CN (**XIV**), and [Ni(HL3)]$_2$[BF_4]$_2$·$3H_2O$ (**XV**) and their cobalt complexes [Co(L1-sal)][BF_4]$_2$ (**XVI**), [Co(L2)][OAc]·$3H_2O$ (**XVII**), [Co(L3)][OAc]·$3H_2O$ (**XVIII**), [Co(L3)][BF_4] (**XIX**), and [Co(L3-sal)(CH_3OH)][BF_4]$_2$·CH_3OH (**XX**) are reported. Single crystal X-ray structural studies for **III**, **XIV**, **XVI**, and **XIX** are described. Cyclic voltammograms of the ligands and of **I**, **II**, **III**, **VII**, **VIII**, **X**, **XIV**, and **XIX** are discussed. Electronic spectra of the ligands and complexes are discussed.

Key words: cobalt and nickel complexes, thioether, salicylaldimine ligands, X-ray structure, cyclic voltammetry, UV–vis spectra.

Résumé : On décrit les synthèses du 1,11-bis(salicylaldimine)-3,6,9-trithiaundécane (**H_2L1**), 1,11-bis(salicylaldimine)-6-oxa-3,9-dithiaundécane (**H_2L2**) et du 1,8-bis(salicylaldimine)-3,6-dithiaundécane (**H_2L3**), de leurs complexes de nickel [Ni(Ll)]·H_2O (**I**), [Ni(HL2)][OAc] (**II**), [Ni(L3)·HOAc]$_2$[Ni(L3)·2HOAc]·$3H_2O$ (**III**), [Ni(HL1-sal)]Cl_2·H_2O (**IV**), [Ni(HL2-sal)]Cl_2·CH_3OH (**V**), [Ni(L3-sal)Cl]·H_2O (**VI**), {[Ni(HL1-sal)]Br_2}$_2${[Ni(L1-sal)]Br}·H_2O (**VII**), {[Ni(HL2-sal)]Br_2}$_2${[Ni(L2-sal)]Br}·$2CH_3OH$ (**VIII**), {[Ni(HL3-sal)Br]Br}$_2$[Ni(L3-sal)Br]·$2CH_3OH$ (**IX**), [Ni(HL3-sal)Br]Br·CH_3OH (**X**), [Ni(HL3)Br]·$2H_2O$ (**XI**), [Ni(HL1)]$_2$[BF_4]$_2$·$5H_2O$ (**XII**), [Ni(HL2)$_2$[BF_4]$_2$·$3H_2O$ (**XIII**), [Ni(HL3)$_2$[BF_4]$_2$·CH_3CN (**XIV**) et [Ni(HL3)$_2$]$_2$[BF_4]$_2$·$3H_2O$ (**XV**) ainsi que de leurs complexes de cobalt [Co(L1-sal)][BF_4]$_2$ (**XVI**), [Co(L2)][OAc]·$3H_2O$ (**XVII**), [Co(L3)][OAc]·$3H_2O$ (**XVIII**), [Co(L3)][BF_4] (**XIX**) et [Co(L3-sal)(CH_3OH)][BF_4]$_2$·CH_3OH (**XX**). On décrit les structures des composés **III**, **XIV**, **XVI** et **XIX** telles que déterminées par diffraction des rayons-X. On discute des résultats obtenus par voltampérométrie cyclique des ligands **I**, **II**, **III**, **VII**, **VIII**, **X**, **XIV** et **XIX**. On discute aussi des spectres électroniques des ligands et des complexes.

Mots-clés : complexes du cobalt et du nickel, thioéther, ligands de la salicylaldimine, structure par diffraction des rayons X, voltampérométrie cyclique, spectres UV–visible.

[Traduit par la Rédaction]

Introduction

Metal complexes of salicylaldimine ligands continue to be of interest for several reasons, not the least of which is their potential for use in a variety of applications such as sensor[1] or liquid crystal[2] technology. Furthermore, future applications of metal complexes in areas such as biomodeling, materials science, catalysis, communications, and data storage require inter alia the ability to adjust properties of existing substances. To do so in a rational manner requires understanding of the consequences of structural changes at the molecular level on properties that manifest themselves primarily at the macroscopic level. Current examples could be changes observed in photoluminescence[3,4] or magnetic susceptibility[5,6] of bulk samples of matter induced by structural changes at the molecular level. As part of our continuing interest[7–9] in the influence of ligand structure on properties of thioether–metal complexes, we now report studies of complexes in which open-chain ligands (Fig. 1) are terminated by salicylaldimine functions. These ligands are related to similar open-chain ligands terminated by alkyl,[10] pyridyl,[11] thienyl,[12] pyrazolyl,[13] and benzamidazolyl[13] functionalities that we have described in earlier work and it is therefore of interest to explore

changes arising from alteration to salicylaldimine of the ligands' terminal groups. In a related report, we address this question for complexes of copper,[14] whereas the current paper investigates complexes of cobalt and nickel. Ligands used in this study are shown in Fig. 1.

Experimental

All reagents were obtained from the Sigma-Aldrich Chemical Co., Inc., and used without further purification. Solvents were ACS grade and were used without purification prior to use. NMR spectra were obtained on a Brüker AVANCE 500 instrument at 500.133 MHz for ^{1}H and 125.770 MHz for ^{13}C. All NMR spectra were run in $CDCl_3$ as the solvent with tetramethylsilane as the internal standard. All ^{13}C spectra were broadband decoupled. Melting points were obtained on a Fisher-Johns melting point apparatus. Electronic spectra were obtained in acetonitrile solutions that were 2.0×10^{-3} and 2.0×10^{-5} mol/L in solute using a Hewlett-Packard 8452A diode array UV–vis spectrophotometer. Other instruments used were a Brüker Tensor FTIR IR spectrometer equipped with a PIKE technologies MIRacle single reflection zinc selenide crystal HATR and an Agilent 1100 Series liquid chromatograph with either an SL MSD trap or a 1946A quadrupole detector. Electrochemical measurements were carried out under a nitrogen atmosphere at room temperature by using a Cypress Systems, Inc., CS-1087 computer-controlled potentiostat. Solution concentrations were 10^{-3} mol/L in complex and 0.1 mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded in acetonitrile by using a glassy carbon working electrode that was prepolished with 0.3 mm Al_2O_3, a platinum counter electrode, and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0×10^{-3} mol/L solution of ferrocene in acetonitrile containing 0.1 mol/L tetraethylammonium perchlorate for which the ferrocene/ferrocenium reduction potential was 400 mV. The reference electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used. X-ray diffraction data were collected on either a Rigaku AFC6S or a Rigaku AFC8 Saturn 70 diffractometer using graphite-monochromated Mo Kα radiation. Analyses were performed by Canadian Microanalytical Service, Ltd.

Preparative details — Ligands

$C_{22}H_{28}N_2O_2S_3$ (H_2L1)

Sodium (8.91 g, 0.388 mol) was dissolved in commercial absolute ethanol (400 mL) under an atmosphere of dry nitrogen, and 2-mercaptoethyl sulfide (15.0 g, 0.972 mol) was added slowly. The resulting mixture was heated to reflux and a solution of 2-chloroethylamine hydrochloride (22.6 g, 0.194 mol) in commercial absolute ethanol (20 mL) was added dropwise with stirring. Reflux was continued for 45 min, during which a white precipitate appeared. Salicylaldehyde (23.7 g, 0.194 mol) was added, instantly giving a bright yellow solution. Reflux was continued for 48 h and on cooling a thick yellow precipitate deposited. Solvent was removed under reduced pressure via rotary evaporator and the residue taken up in dichloromethane (150 mL). Undissolved sodium chloride was filtered away. The dichloromethane solution was carefully reduced in volume via a rotary evaporator until cloudy and then placed in the refrigerator overnight. The resulting crystals were collected by suction filtration, washed with ice-cold acetonitrile (3×5 mL) and crystallized from hot acetonitrile (300 mL) with storage overnight at –20 °C. The product was collected by filtration and washed with ice-cold acetonitrile (3×15 mL) to give bright yellow shiny leaflets (36.5 g, 83% yield) melting over the range 110.7–111.1 °C. UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 225 (10 800), 255 (4580), 316 (1740), 405 (450). ^{1}H NMR ($CDCl_3$, position identification from Fig. 1) δ: 2.74 (s, 8H, C10, C11), 2.88 (t, J = 7.2 Hz, 4H, C9), 3.79 (t, J = 7.2 Hz, 4H, C8), 6.88 (t, J = 8.5 Hz, 2H, C4), 6.96 (d, J = 9.5 Hz, 2H, C5), 7.26 (d, J = 7.0 Hz, 2H, C2), 7.31 (t, J = 8.5 Hz, 2H, C3), 8.37 (s, 2H, C7), 13.2 (s, 2H, O*H*). ^{13}C{^{1}H} NMR δ: 32.60 (C10), 32.82 (C9), 33.41 (C11), 59.61 (C8), 117.20 (C4), 118.83 (C6), 118.91 (C2), 131.64 (C5), 132.63 (C3), 161.26 (C1), 166.24 (C7). Mass spectrum APCI(+) calcd for M+ 1: 449.1; found: 449.2. Anal. calcd for $C_{22}H_{28}N_2O_2S_3$: C 58.89, H 6.29, N 6.24, S 21.44; found: C 58.94, H 6.44, N 6.29, S 22.21.

$C_{22}H_{28}N_2O_3S_2$ (H_2L2)

The procedure was the same as for **H_2L1** except that 2-mercaptoethyl ether was used instead of 2-mercaptoethyl sulfide. Final recrystallization was from hot acetonitrile –

For personal use only.

chloroform (150 mL : 50 mL) with storage overnight at –20 °C. The product collected by suction filtration was washed with ice-cold methanol (3 × 5 mL) and then ether (3 × 5 mL) to give bright yellow shiny needles (64% yield) melting over the range 76.8–78.0 °C. A second crop of bright yellow needles (27%) that melted over the same range was recovered from the mother liquor after further storage at –20 °C. ^{1}H NMR ($CDCl_3$, position identification from Fig. 1) δ: 2.73 (t, J = 5.5 Hz, 4H, C10), 2.89 (t, J = 8.5 Hz, 4H, C9), 3.64 (t, J = 5.5 Hz, 4H, C11), 3.79 (t, J = 5.0 Hz, 4H, C8), 6.87 (t, J = 7.0 Hz, 2H, C4), 6.95 (d, J = 8.5 Hz, 2H, C5), 7.25 (d, J = 7.5 Hz, 2H, C2), 7.31 (m, 2H, C3), 8.36 (s, 2H, C7), 13.3 (s, 2H, O*H*). ^{13}C{^{1}H} NMR δ: 32.20 (C10), 33.71 (C9), 59.65 (C8), 71.10 (C11), 117.28 (C4), 118.82 (C6), 118.89 (C2), 131.60 (C5), 132.60 (C3), 161.27 (C1), 166.12 (C7). Mass spectrum APCI(+) calcd for M + 1: 433.1; found: 433.2. Anal. calcd for $C_{22}H_{28}N_2O_3S_2$: C 61.08, H 6.52, N 6.48, S 14.82; found: C 60.89, H 6.51, N 6.49, S 14.69.

$C_{20}H_{24}N_2O_2S_2$ (H_2L3)

The procedure is similar to that for **H_2L1** except that 1,2-ethanedithiol was used instead of 2-mercaptoethyl sulfide and the initial crude residue was taken up in chloroform, filtered, reduced in volume until cloudy, and then refrigerated. The resulting solid was collected, washed with a little ice-cold chloroform, dissolved in chloroform, and washed with deionized water. The organic layer was dried over anhydrous $MgSO_4$ and filtered. Upon concentrating and storing at –20 °C a bright yellow precipitate separated was collected and then washed with ice-cold chloroform and then ether to give bright yellow shiny leaflets (86.2% yield) melting over the range 108.7–109.1 °C. UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 230 (12 630), 258 (4240), 313 (1174), 398 (350). ^{1}H NMR ($CDCl_3$, position identification from Fig. 1) δ: 2.75 (s, 4H, C10), 2.88 (t, J = 5.0 Hz, 4H, C9), 3.77 (t, J = 5.0 Hz, 4H, C8), 6.88 (t, J = 7.0 Hz, 2H, C4), 6.96 (d, J = 10.5 Hz, 2H, C5), 7.26 (d, J = 5.0 Hz, 2H, C2), 7.30 (t, J = 10.0 Hz, 2H, C3), 8.33 (s, 2H, C7), 13.2 (s, 2H, O*H*). ^{13}C{^{1}H} NMR δ: 32.82 (C10), 33.60 (C9), 59.68 (C8), 117.18 (C4), 118.79 (C6), 118.83 (C2), 131.63 (C5), 132.63 (C3), 161.28 (C1), 166.21 (C7). Mass spectrum APCI(+) calcd for M + 1 *m/z*: 389.1; found *m/z*: 389.2. Anal. calcd for $C_{20}H_{24}N_2O_2S_2$: C 61.82, H 6.23, N 7.21, S 16.51; found: C 61.72, H 6.11, N 7.41, S 16.15.

Preparative details — Complexes

[Ni(L1)]·H_2O (I)

H_2L1 (1.0 g, 2.2 mmol) dissolved in warm (~40 °C) methanol (25 mL) was mixed with nickel(II) acetate trihydrate (0.56 g, 2.4 mmol) in warm (~40 °C) methanol (25 mL) to give a dark green solution. The solvent was evaporated and the residue washed with methanol (3 × 5 mL) to give a light green powder that was dissolved in *N*,*N*′-dimethylformamide (30 mL). The solution was filtered and then added dropwise with stirring to cold deionized water (300 mL) to give a thick yellow-green precipitate that was collected in a sintered glass crucible, washed with acetone (2 × 5 mL) and then ether (5 × 5 mL), and then dried to give a brown-green powder (0.74 g, 64% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 280 (1350), 310 (1500), 408 (1400), 610 (55). Mass spectrum APCI(+) calcd for M – H_2O + 1, $[C_{22}H_{27}N_2NiO_2S_3]^+$ *m/z*: 505.0; found *m/z*: 505.0. Anal. calcd for $C_{22}H_{28}N_2NiO_3S_3$: C 50.49, H 5.39, N 5.35; found: C 50.89, H 5.09, N 5.09.

[Ni(HL2)][OAc] (II)

H_2L2 (0.72 g, 1.7 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with nickel(II) acetate trihydrate (0.42 g, 1.8 mmol) in warm (~40 °C) methanol (25 mL) to give a dark green solution. The solvent was evaporated to give a dark green glassy film that was triturated in acetonitrile (2 mL) in which it was slightly soluble. The residue was collected by filtration and dried in air to give a fine green powder that was dissolved in chloroform (50 mL), concentrated to 20 mL via a rotary evaporator, filtered, and then added dropwise with stirring to cold ether (350 mL) to give a bright green precipitate. This was collected in a sintered glass crucible, washed with ether (3 × 5 mL), and then dried to give a green powder (0.26 g, 28% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 280 (sh), 308 (1450), 340 (sh), 400 (1500), 610 (54). Mass spectrum APCI(+) calcd for M – OAc, $[C_{22}H_{27}N_2NiO_3S_2]^+$ *m/z*: 489.1; found *m/z*: 489.0. Anal. calcd for $C_{24}H_{30}N_2NiO_5S_2$: C 52.48, H 5.50, N 5.10; found: C 52.63, H 5.41, N 5.29.

{[Ni(L3)·HOAc]$_2$[Ni(L3)·2HOAc]·3H_2O (III)

H_2L3 (0.66 g, 1.7 mmol) dissolved in warm (~40 °C) 1:1 acetonitrile/methanol (40 mL) was mixed with nickel(II) acetate trihydrate (0.42 g, 1.8 mmol) in warm (~40 °C) methanol (20 mL) to give a dark brown-green solution. Within a few hours the colour became brown-purple. The solvent was evaporated slowly in air to give a brown residue that was triturated in acetonitrile (2 mL) in which it was slightly soluble. The solid was collected by filtration, washed with cold acetonitrile (3 × 2 mL), and then dried in air to give a fine brown-green powder. The powder was dissolved in methanol (100 mL), concentrated via a rotary evaporator to 20 mL, filtered, and then the filtrate was added dropwise with stirring to cold ether to give a yellow-green precipitate. This was collected in a sintered glass crucible and washed with ether (3 × 5 mL) and then dried to give a yellow-green powder (0.50 g, 55% yield). Alternatively, slow evaporation of the methanol filtrate produced X-ray quality dark green crystals. UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 290 (1354), 345 (sh), 383 (1450), 577 (41). Mass spectrum APCI(+) calcd for [Ni(HL3)], $[C_{20}H_{23}N_2NiO_2S_2]^+$ *m/z*: 445.1; found *m/z*: 445.0. Anal. calcd for $C_{68}H_{88}N_6Ni_3O_{17}S_6$: C 50.11, H 5.44, N 5.16; found: C 49.94, H 5.31, N 5.12.

[Ni(HL1-sal)]Cl_2·H_2O (IV)

H_2L1 (1.0 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with nickel(II) chloride hexahydrate (0.52 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to give a dark green solution. The solvent was evaporated slowly in air to give a green glassy residue that was triturated in acetonitrile (2 mL) in which it was slightly soluble. The solid, which is insoluble in acetone and chloroform, was collected by filtration and dried in air to a fine green powder. This powder was dissolved in hot methanol (100 mL). The solution was concentrated via a rotary

For personal use only.

evaporator to 20 mL, filtered, and then added dropwise with stirring to cold ether (300 mL) to give a light green precipitate. This was collected in a sintered glass crucible, washed with ether (3 × 5 mL), and then dried in air to give a light green powder (0.94 g, 86% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 293 (1500), 323 (1500), 370 (1400), 406 (sh), 602 (40). Mass spectrum APCI(+) calcd for [Ni(L1-sal)] (sal = C_7H_3O), $[C_{15}H_{23}N_2NiOS_3]^+$ *m/z*: 401.0; found *m/z*: 401.0. Anal. calcd for $C_{15}H_{26}Cl_2N_2NiO_2S_3$: C 36.61, H 5.32, N 5.69; found: C 36.70, H 4.95, N 5.41.

[Ni(HL2-sal)]Cl_2·CH_3OH (V)

The procedure is the same as for **IV** to give a green powder (0.78 g, 73% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 287 (1300), 320 (1400), 380 (1100), 595 (45). Mass spectrum APCI(+) calcd for [Ni(L2-sal)], $[C_{15}H_{23}N_2NiO_2S_2]^+$ *m/z*: 385.0; found *m/z*: 385.0. Anal. calcd for $C_{16}H_{28}Cl_2N_2NiO_3S_2$: C 39.21, H 5.76, N 5.72; found: C 38.89, H 5.23, N 5.74.

[Ni(L3-sal)Cl]·H_2O (VI)

The procedure is the same as for **III** to give a light green powder (0.59 g, 89% yield). Mass spectrum APCI(+) calcd for [Ni(L3-sal)], $[C_{13}H_{19}N_2NiOS_2]^+$ *m/z*: 341.0; found *m/z*: 341.0. Anal. calcd for $C_{13}H_{21}ClN_2NiO_2S_2$: C 39.47, H 5.35, N 7.08, Ni 14.84; found: C 39.76, H 4.84, N 6.95, Ni 14.20.

{[Ni(HL1-sal)]Br_2}$_2${[Ni(L1-sal)]Br}·H_2O (VII)

H_2L1 (1.0 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with nickel(II) bromide monohydrate (0.52 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to give a green solution and a light green precipitate. The solid was collected by filtration and dried in air to a fine green powder. This powder was dissolved in hot methanol (80 mL). The solution was concentrated via a rotary evaporator to 15 mL, filtered, and then added dropwise with stirring to cold ether (300 mL) to give a light green precipitate that was collected, washed with ether (3 × 5 mL), and then dried in air to give a green powder (0.70 g, 59% yield). Mass spectrum APCI(+) calcd for [Ni(L1-sal)], $[C_{15}H_{23}N_2NiOS_3]^+$ *m/z*: 401.0; found *m/z*: 401.0. Calcd for [H_2L1-sal)] (sal = C_7H_3O), $[C_{15}H_{25}N_2OS_3]^+$ *m/z*: 345.1; found *m/z*: 345.1. Anal. calcd for $C_{45}H_{73}Br_5N_6Ni_3O_4S_9$: C 33.23, H 4.52, N 5.17, Br 24.57, Ni 10.83; found: C 32.87, H 4.48, N 5.19, Br 24.73, Ni 10.1.

{[Ni(HL2-sal)]Br_2}$_2${[Ni(L2-sal)]Br}·$2CH_3OH$ (VIII)

The procedure is the same as for **VII** to give a green powder (0.39 g, 33% yield). Mass spectrum APCI(+) calcd for [Ni(L2-sal)], $[C_{15}H_{23}N_2NiO_2S_2]^+$ *m/z*: 385.0; found *m/z*: 385.0. Calcd for [H_2L2-sal)], $[C_{15}H_{25}N_2O_2S_2]^+$ *m/z*: 329.1; found *m/z*: 329.1. Anal. calcd for $C_{47}H_{79}Br_5N_6Ni_3O_8S_6$: C 34.76, H 4.90, N 5.17, Br 24.60, Ni 10.8; found: C 34.37, H 4.80, N 5.08, Br 24.68, Ni 10.8.

{[Ni(HL3-sal)Br]Br}[Ni(L3-sal)Br]·$2CH_3OH$ (IX)

H_2L3 (0.65 g, 1.7 mmol) dissolved in warm (~40 °C) acetonitrile (40 mL) was mixed with nickel(II) bromide monohydrate (0.40 g, 1.7 mmol) in warm (~40 °C) methanol (20 mL) to give a small amount of white precipitate in a light brown solution. The solid was separated by filtration and discarded and the filtrate evaporated slowly in air to produce a few black crystals and a green glassy residue. The solids were washed with acetonitrile (6 × 5 mL portions), which dissolved the crystals leaving behind the glassy residue. Slow evaporation of the solution produced very dark green (nearly black) crystals analyzed as Ni(HL3)Br·$2H_2O$ (**XI**). The green glassy residue was triturated in acetonitrile (5 mL) and collected by filtration as a fine green powder analyzed as Ni(HL3-sal)Br_2·CH_3OH (**X**). This powder could be dissolved in methanol (80 mL) to give a brown solution, which when concentrated via a rotary evaporator to 10 mL, filtered, and added dropwise with stirring to cold ether (300 mL) yielded a pale-green, almost white precipitate, which was collected, washed with ether (3 × 5 mL), and then dried in air to give **IX** (0.26 g, 31% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 284 (1200), 320 (1200), 384 (1300). Mass spectrum APCI(+) calcd for [Ni(L3-sal)], $[C_{13}H_{19}N_2NiOS_2]^+$ *m/z*: 341.0; found *m/z*: 341.0. Anal. calcd for $C_{28}H_{47}Br_3N_4Ni_2O_4S_4$: C 34.00, H 4.79, N 5.66; found: C 34.18, H 4.41, N 5.70.

[Ni(HL3-sal)Br]Br·CH_3OH (X)

For preparative details see **IX**; 0.46 g, 51% yield. Mass spectrum APCI(+) calcd for [HL3-sal + 1], $[C_{13}H_{20}N_2OS_2]^+$ *m/z:* 285.1; found *m/z*: 285.1. Anal. calcd for $C_{14}H_{24}Br_2N_2NiO_2S_2$: C 31.43, H 4.52, N 5.24; found: C 31.67, H 4.36, N 5.34.

[Ni(HL3)Br]·$2H_2O$ (XI)

For preparative details see **IX**; 0.16 g, 15% yield. Mass spectrum APCI(+) calcd for [Ni(H_2L3)Br], $[C_{20}H_{24}BrN_2NiO_2S_2]^+$ *m/z*: 525.0; found *m/z*: 525.0. Calcd for [Ni(HL3)], $[C_{20}H_{23}N_2NiO_2S_2]^+$ *m/z*: 445.0; found *m/z*: 445.0. Calcd for [H_2L3 + 1], $[C_{20}H_{25}N_2O_2S_2]^+$ *m/z*: 389.1; found *m/z*: 389.1. Anal. calcd for $C_{20}H_{27}BrN_2NiO_4S_2$: C 42.73, H 4.84, N 4.98, Ni 10.44; found: C 42.66, H 4.66, N 4.90, Ni 12.20.

[Ni(HL1)]$_2$[BF_4]$_2$·$5H_2O$ (XII)

The procedure is the same as for **X** except that the fine green powder was dissolved in hot acetonitrile (100 mL), concentrated via a rotary evaporator to 20 mL, filtered, and then added dropwise with stirring to cold ether (300 mL). This produced a yellow-green precipitate that was collected, washed with ether (3 × 5 mL), and then dried in air to give a fine pale green powder (0.51 g, 36% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1}L cm^{-1}): 283 (sh), 320 (1485), 340 (sh), 380 (1207), 420 (sh), 620 (25). Mass spectrum APCI(+) calcd for [NiHL1], $[C_{22}H_{27}N_2NiO_2S_3]^+$ *m/z*: 505.0; found *m/z*: 505.0. Calcd for [NiL1-sal], $[C_{15}H_{23}N_2NiOS_3]^+$ *m/z*: 401.0; found *m/z*: 401.0. Calcd for [H_2L1-sal], $[C_{15}H_{25}N_2OS_3]^+$ *m/z*: 345.1; found *m/z*: 345.1. Anal. calcd for $C_{44}H_{64}B_2F_8N_4Ni_2O_9S_6$: C 41.40, H 5.05, N 4.39; found: C 41.26, H 4.47, N 4.79.

[Ni(HL2)]$_2$[BF_4]$_2$·$3H_2O$ (XIII)

The procedure is the same as for **XII** except that trituration is in ether and the final product is a fine pale green powder (0.60 g, 45% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 283 (sh), 320 (1527), 378 (1431), 410 (sh), 600 (50). Mass spectrum APCI(+) calcd for [NiHL2],

[Ni(HL3)]$_2$[BF$_4$]$_2$·CH$_3$CN (*a*) (XIV) and [Ni(HL3)]$_2$[BF$_4$]$_2$·3H$_2$O (*b*) (XV)

For (*a*), the procedure for (*b*) was followed except that the acetonitrile/ether mother liquor was saved and upon slow evaporation produced purple-black crystals suitable for structural determination by X-ray methods (0.17 g, 19% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 290 (1340), 320 (1370), 384 (1455), 580 (80). Anal. calcd for (*a*) $C_{42}H_{49}B_2F_8N_5Ni_2O_4S_4$: C 45.56, H 4.46, N 6.33; found: C 47.17, H 4.44, N 6.15.

For (*b*), **H_2L3** (0.62 g, 1.6 mmol) dissolved in warm (~40 °C) acetonitrile (40 mL) was mixed with nickel(II) tetrafluoroborate hexahydrate (0.57 g, 1.6 mmol) in warm (~40 °C) methanol (20 mL) to give a brown-purple solution. The solvent was allowed to evaporate to give a brown-purple oily residue that was triturated in ether (5 mL) and then rinsed with methanol (5 × 3 mL) until the wash solution was colourless. The light brown powder was dried in air, dissolved in hot acetonitrile (90 mL) to give a brown-pink solution, concentrated to 20 mL on a rotary evaporator, and then added dropwise with stirring to cold ether (200 mL) to produce a light-coloured precipitate. This was collected, washed with ether (3 × 5 mL), and then dried in air to give a fine powder (0.37 g, 41% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 290 (1300), 320 (1400), 385 (1390), 580 (65). Mass spectrum APCI(+) calcd for [NiHL3], $[C_{20}H_{23}N_2NiO_2S_2]^+$ *m/z*: 445.0; found *m/z*: 445.0. Calcd for [H_3L3], $[C_{20}H_{25}N_2O_2S_2]^+$ *m/z*: 389.1; found *m/z*: 389.1. Calcd for [H_2L3-sal)], $[C_{13}H_{21}N_2OS_2]^+$ *m/z*: 285.1; found *m/z*: 285.1. Anal. calcd for $C_{40}H_{52}B_2F_8N_4Ni_2O_7S_4$: C 42.89, H 4.68, N 5.00; found: C 42.45, H 4.30, N 5.18.

[Co(L1-sal)][BF$_4$]$_2$ (XVI)

H_2L1 (2.0 g, 4.5 mmol) dissolved in warm (~40 °C) chloroform (15 mL) was mixed with cobalt(II) tetrafluoroborate hexahydrate (1.5 g, 4.5 mmol) in warm (~40 °C) acetonitrile (20 mL) to produce a deep black solution and a thick black oily precipitate. This was collected by gravity filtration and dissolved in chloroform from which black crystals were obtained as the solvent slowly evaporated. These were collected and washed with ice-cold acetonitrile (3 × 2 mL). The crystals were redissolved in hot (~60 °C) acetonitrile (30 mL) and the solution was left to evaporate slowly in air. When nearly evaporated, the resulting black cubic crystals were collected, washed with ice-cold acetonitrile (3 × 2 mL), and then dried in air (0.56 g, 22% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 219 (2680), 243, (2550) 284 (3220), 388 (230), 474 (75), 637 (45). Mass spectrum APCI (+) calcd for [Co(L1-sal)], $[C_{15}H_{23}CoN_2OS_3]^+$ *m/z*: 402.0; found *m/z*: 402.0. Anal. calcd for $C_{15}H_{23}B_2F_8CoN_2OS_3$: C 31.27, H 4.02, N 4.86, Co 10.2; found: C 31.36, H 3.97, N 4.87, Co 10.1.

[Co(L2)](OAc)·3H$_2$O (XVII)

H_2L2 (0.96 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with cobalt(II) acetate tetrahydrate (0.56 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to produce a dark orange solution that quickly became dark red. The solvent was evaporated slowly in air to give a dark red-purple film that was triturated with ether (3 mL), giving a black powder that was collected, washed with ether (3 × 5 mL), and then dried in air to a dark purple powder. The powder was dissolved in hot (~60 °C) methanol (15 mL) and the solution concentrated via a rotary evaporator to 10 mL, filtered, and then added dropwise with stirring to cold ether (300 mL) to produce a purple precipitate that was collected, washed with ether (3 × 5 mL), and then dried in air to give a light purple powder (1.05 g, 80% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 650 (40), 476 (110), 384 (600), 312 (930). Mass spectrum APCI(+) calcd for [CoL2 + H], $[C_{22}H_{27}CoN_2O_3S_2]^+$ *m/z*: 490.1; found *m/z*: 490.0. Anal. calcd for $C_{24}H_{35}CoN_2O_8S_2$: C 47.84, H 5.85, N 4.65; found: C 47.70, H 5.55, N 4.52.

[CoL3][OAc]·3H$_2$O (XVIII)

The procedure is the same as for **XVII** except that chloroform was used to dissolve the product from trituration. The final product is a brown-green powder (0.44 g, 47% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 642 (106), 476 (135), 384 (650), 297 (3580), 265 (sh). Mass spectrum APCI(+) calcd for [CoL3 + H], $[C_{20}H_{22}CoN_2O_2S_2 + H]^+$ *m/z*: 446.0; found *m/z*: 446.0. Anal. calcd for $C_{22}H_{31}CoN_2O_7S_2$: C 47.31, H 5.59, N 5.02; found: C 46.59, H 4.68, N 4.82.

[Co(L3)][BF$_4$] (XIX)

H_2L3 (1.5 g, 3.9 mmol) dissolved in warm (~40 °C) chloroform (20 mL) was mixed with cobalt(II) tetrafluoroborate hexahydrate (1.32 g, 3.9 mmol) in warm (~40 °C) acetonitrile (30 mL) to produce a dark orange solution that quickly deposited a black precipitate. This was collected and washed with ice-cold acetonitrile (3 × 3 mL). When dry, the solid was dissolved in hot (~60 °C) acetonitrile (30 mL) and the solvent evaporated slowly in air to produce black crystals. These were collected, washed with ice-cold acetonitrile (3 × 3 mL), and then dried in air (1.34 g, 65% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 252 (2900), 305 (3100), 390 (500), 475 (95), 683 (75). Mass spectrum APCI (+) calcd for [CoL3 + H], $[C_{20}H_{22}CoN_2O_2S_2 + H]^+$ *m/z*: 446; found *m/z*: 446. Anal. calcd for $C_{20}H_{22}BCoF_4N_2O_2S_2$: C 45.13, H 4.17, N 5.26; found: C 45.59, H 4.26, N 5.24.

[Co(L3-sal)(CH$_3$OH)][BF$_4$]$_2$·CH$_3$OH (XX)

H_2L3 (88 mg, 0.23 mmol) dissolved in acetonitrile (20 mL) was mixed with cobalt(II) tetrafluoroborate hexahydrate (134 mg, 0.393 mmol) in methanol (30 mL) to produce a light orange solution that quickly deposited a brown precipitate. The precipitate was collected and discarded. Solvent was allowed to evaporate slowly from the filtrate to produce black crystals that were collected, recrystallized from methanol, washed with ice-cold acetonitrile (1 mL), and then dried in air (84 mg, 63% yield). Anal. calcd for $C_{15}H_{27}B_2CoF_8N_2O_3S_2$: C 31.06, H 4.69, N 4.83; found: C 31.37, H 4.05, N 4.85.

X-ray studies

A summary of crystallographic data is in Tables 1 and 2. Figures 2–5 show views of the structure and numbering schemes for **III**, **XIV**, **XVI**, and **XIX**, respectively. In all cases, non-hydrogen atoms were refined anisotropically. For **III**, atoms O8 and O9 are disordered lattice solvent water. They make up one full water molecule and were refined with the sum of their occupancies equal to one. The H atoms for the lattice solvent water molecules O8, O9, and O10 could not be located in difference map positions and were therefore omitted from the model. They were included in the formula for the calculation of intensive properties. Hydrogen atoms H5a and H7a were introduced in difference map positions. Both were refined with distance restraints and H7a was also refined with an angle restraint. All other hydrogen atoms were introduced in calculated positions and refined on a riding model.

For **XIV**, hydrogen atoms H1o and H3o were introduced in difference map positions. All other hydrogen atoms were introduced in calculated positions and refined on a riding model. Angle restraints were applied to both tetrafluoroborate anions. For **XVI** and **XIX**, hydrogen atoms were introduced in calculated positions and refined on a riding model. Descriptions of the experimental procedures, anisotropic thermal parameters, and a full listing of bond lengths and angles are available as Supplementary data.

Results and discussion

Although a two-step synthesis for $\mathbf{H_2L3}$ was reported in 1950 by Lions and Dwyer,[15] the syntheses reported herein are each one-pot processes. All three ligands, under mild conditions in the presence of a metal atom, lose one salicylaldehyde, for example, during formation of $[Co(L1\text{-}sal)][BF_4]_2$ (**XVI**) and $[Co(L3\text{-}sal)(CH_3OH)][BF_4]_2\cdot CH_3OH$ (**XX**). This appears to be simple hydrolysis via nucleophilic attack by adventitious water on the carbon atom of a metal-bound imine producing a primary amine bound to the metal and liberating salicyladehyde. A question this raises is why only one end of the chain hydrolyzes. Models suggest it is due to differences in accessibility of the site for attack. In the early stages of complexation, if only one imine nitrogen is bound to the metal, approach by a water molecule is comparatively unimpeded. However, when all coordination sites on the metal have been filled by a ligand, the remaining imino-carbon atom is shielded from nucleophilic attack both above and below the plane defined by the bent M–C=N system. Shielding of the imine system arises from sulfur nonbonding electron density on one side of the plane and from oxygen nonbonding electron density on the other. Support for this explanation is obtained from the observation that syntheses of hydrolyzed and unhydrolyzed materials sometimes occur together and must be separated during workup. Preparations for $[Ni(HL3\text{-}sal)Br]Br\cdot CH_3OH$ (**X**) and $[Ni(HL3)Br]\cdot 2H_2O$ (**XI**) illustrate this point.

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.

[b] $wR2 = [\Sigma(w(F_o^2 - F_c^2)^2)/\Sigma w(F_o^2)^2]^{1/2}$.

A further feature of these systems is the occurrence of complexes in which the phenolic oxygens of the ligands may or may not be deprotonated. These occurrences are likely controlled, at least in part, by solubility effects with less soluble species being more readily deposited as precipitates of complex. The simultaneous preparations of {[Ni(HL3-sal)Br]Br}[Ni(L3-sal)Br]·2CH_3OH (**IX**), [Ni(HL3-sal)Br]Br·CH_3OH (**X**), and [Ni(HL3)Br]·2H_2O (**XI**) in one synthetic batch illustrate this effect. Protonated phenolic oxygens coordinated to metals have been observed previously in salicylaldimine complexes,[16] although precipitation of both protonated and deprotonated forms when complexation is carried out in the absence of added base is less common.

Simple complexes of both Ni(II) and Cu(II)[14] can be formed from **H_2L1**, **H_2L2**, and **H_2L3**, but analogous complexes of Co(II) were not obtained under aerobic conditions. This is not surprising given the propensity of complexed Co(II), especially in presence of nitrogen donors, to oxidize to Co(III).[17]

X-ray studies

[Ni(L3)·HOAc]$_2$[Ni(L3)·2HOAc]·3H_2O **(III)** consists, per formula unit, of three similar complex molecules, four acetic acid molecules hydrogen bonded to the metal complexes and three molecules of lattice water, one of which is disordered. The crystallographic asymmetric unit of this substance is half its formula unit and, for discussion purposes, Fig. 2 presents a partial expansion of the asymmetric unit so that complete coordination spheres for the two distinct nickel complexes can be viewed. Pertinent bond lengths and angles are in Table 3.

Structural evidence for hydrogen bonding is, as usual, bond lengths and angles. Thus, the carboxylic oxygen (O(7)) and attached hydrogen (H(7a)) are 0.969(19) Å from each other, whereas phenolic oxygen (O(3)) lies 1.566(19) Å from H(7a). Both distances are consistent with hydrogen bonding[28] as is the angle O(3)–H(7a)–O(7) (177(1)°). Likewise, O(5) and H(5a) lie at 0.974(19) Å from each other, whereas O(2) lies 1.503(19) Å from H(5a) and angle O(5)–H(5a)–O(2) is 169.6(5)°. Nickel–oxygen bond distances are comparable to those in [Ni_2(Hhsae)$_2$(OAc)$_2$(CH_3OH)$_2$] (H_2hsae = 2-(5-hydroxysalicylideneamino)ethanol)[18] (2.0160(9)–2.1442(10) Å) or {[Ni_2(*trans*-tachH)$_2$(OAc)$_4$(H_2O)](OAc)$_2$·5H_2O}$_n$ (tach = *cis*,*trans*-1,3,5-triaminocyclohexane)[19] (2.061(2)–2.143(2) Å). The Ni–N lengths in **III** are comparable to those in [Ni_2(Hhsae)$_2$(OAc)$_2$(CH_3OH)$_2$] (1.9987(11) Å) and 2-(diisopropyl)-phosphinobenzyl-*N*,*N*-dimethylaminenickel(II) dibromide[20] (2.042(2) Å) and the Ni–S bonds compare well to those of [Ni(PTHD(H_2O)]$^{2+}$ (PTHD = 3,6,9,12,15-pentathiaheptadecane)[10] (2.403(2)–2.425(2) Å) or [Ni(TCS)$_2$][ClO_4]$_2$ (TCS = 1-methoxy-10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene)[21] (2.4055(11) Å).

The O–Ni–N angles are comparable to those in Ni(IMBF)$_2$(CH_3OH)$_2$ (IMBF = 4-(1-bromo-3,3,3-trifluoro-2-oxopropylidene)-2,2,5,5-tetramethyl-3-imidazolene-1-oxyl)[22] (84.7(2)° and 88.4(1)°) or those in Ni[(C_2H_5O)$_2$PSNHNCPh(*o*-O)OCH_3]$_2$[23] (87.69(13)°

Fig. 2. ORTEP of $[Ni(L3)\cdot HOAc]_2[Ni(L3)\cdot 2HOAc]\cdot 3H_2O$ **(III)** (see text). Thermal ellipsoids are at the 50% probability level. H_2Os are omitted for clarity.

For personal use only.

and 92.31(14)°). The O–Ni–O and N–Ni–N angles are close to 90° and 180°, respectively, whereas the O–Ni–S angles are of two types representing cis- and trans-donors. The cis angles differ very little from 90°, whereas the three distinct trans-angles remain closer to 180° than those, for example, of 168.32(6)° in $[NiCl(H_2O)_2(thpd)]Cl$ (thpd = 1-(3-thia-5-hydroxypentyl)-3,5-dimethylpyrazole).[24] The six N–Ni–S angles, four on Ni(1) and two on Ni(2), all show deviations from 90° on both Ni(1) and Ni(2) of 5° ± 1° that are similar to those observed in $[Ni(aptp)(en)][NO_3]_2$ (aptp = 1-[[2-[2-aminoethyl)imino]propyl]thio]-2-propanone).[25] Finally, there are two distinct S–Ni–S angles, one at Ni(1) and one at Ni(2). Both are comparable to those in $[Ni(PDH)(CH_3CN)_2][ClO_4]_2$ (PDH = 1,6-bis(2-pyridyl)-2,5-dithiahexane)[26] (S–Ni–S = 83.2(2)° and 83.2(2)°) or $[Ni(18S_4O_2][BF_4]_2$ ($18S_4O_2$ = 1,10-dioxa-4,7,13,16-tetrathiacyclooctadecane)[27] (S–NiS = 94.52(13)°, 91.56(12)°, 88.12(12)°, and 88.37(13)°).

$[Ni(HL3)]_2[BF_4]_2\cdot CH_3CN$ (**XIV**) has in its unit cell a pair of similar but nonidentical hydrogen-bonded unipositive complex cations, two tetrafluoroborate anions, and one molecule of lattice acetonitrile. The ligand coordinates by both protonated and deprotonated phenolic oxygens, and dimers of cations are formed by hydrogen bonds involving phenolic hydrogens that were detected and refined in the crystal structure study. Pertinent bond lengths and angles are in Table 4.

The four Ni–O, four Ni–N, and four Ni–S bonds in the dimeric cation of **XIV** have lengths similar to those observed in **III** and related compounds (vide supra). Hydrogen bonds between halves of the dimeric cation have angles O(1)–H(1o)···O(4) = 173(2)° and O(3)–H(3o)···O(2) = 170(2)°. Distances O(1)–H(1o)···O(4) and O(3)–H(3o)···O(2) are both 2.44(3) Å and distances H(1o)···O(4) and H(3o)···O(2) are both 1.49(4) Å. These may be compared with literature values for strong hydrogen bonds of 2.70 Å for O–H···O and 1.70 Å for H···O.[28]

Eight O–Ni–N angles occur in the two monomers and are comparable to those in **III** and related species (vide supra). There are four N–Ni–S angles in each of the monomers with deviations between 6.9° and 8.6° from 90°. The largest is 1.1° (~14%) greater than deviations observed by Ladd et al.[25] and 2.4° (~38%) greater than the largest observed for comparable angles in **III**. There are no obvious intramolecular reasons why deviations should be larger in **XIV** than in **III**. There are, however, three contacts in **XIV** that are less than the sum of the van der Waals' radii of the atoms involved. These are N(5)···H(10a) (2.6 ± 1 Å), S(1)···H(28a_i) (3.1 ± 1 Å) and S(1)···H(29b_i) (3.1 ± 1 Å) that "lift" S(1) causing an increase in the S(1)–Ni(1)–N(2) angle. The sum of the van der Waals' radii in each case is 3.00, 3.25, and 3.25 Å.[29]

As with **III**, bond angles in **XIV** fall into two categories. There are those that lie close to ideal values for a regular octahedron and those that show significant deviation and, as with **III**, the latter category all involve a sulfur atom. This may not be coincidental in view of observations[13,30,31] that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12

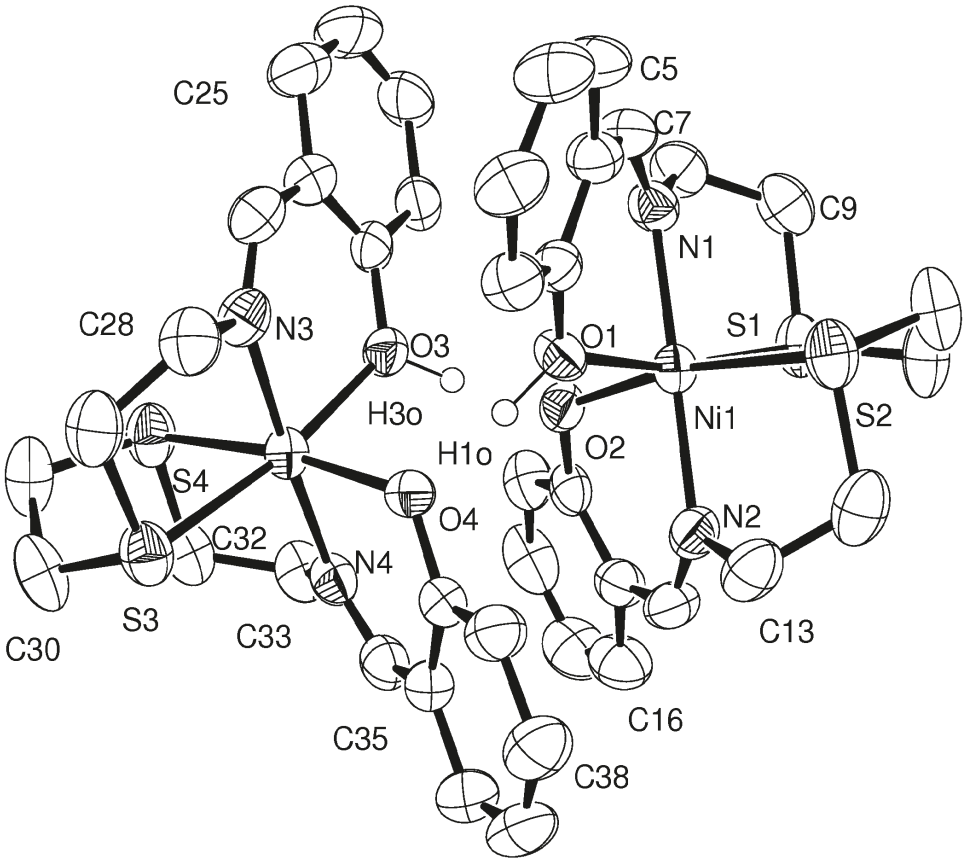
Fig. 3. ORTEP of $[Ni(HL3)]_2[BF_4]_2 \cdot CH_3CN$ (**XIV**). Thermal ellipsoids are at the 50% probability level. BF_4^- ions and CH_3CN are omitted for clarity.



sulfur, relative to donors such as nitrogen or oxygen, is forgiving about its bond lengths and angles in a way that has been described as its bonding "plasticity". Thus, strain in complex systems is more likely to be accommodated at sulfur than at nitrogen or oxygen donors.

The structure of $[Co(L1\text{-}sal)][BF_4]_2$ (**XVI**) (Fig. 4) consists of an N_2OS_3 coordination sphere with the three sulfurs arranged facially. Pertinent bond lengths and angles are in Table 5.

The Co–O bond length in **XVI** is comparable to those in Co(III) cations such as $[Co(3\text{-}Cl\text{-}acacen)(NH_3)_2][BPh_4]$[32] (3-Cl-acacen = 3-chloro-bis(acetylacetone)ethylenediimine) (1.881(4) Å) and $[Co(L)(phen)N_3]$[33] (where H_2L = 2-hydroxy-acetophenone-N(4)-phenylsemicarbazone and phen = 1,10-phenanthroline) (1.866(4) and 1.914(3) Å). The Co–N distances compare well to those (1.8918(9), 1.951(6), and 1.960(6) Å) in $[Co(3\text{-}Cl\text{-}acacen)(NH_3)_2][BPh_4]$, where the shorter is to imino-nitrogen, or in $[Co(L)(phen)N_3]$ (1.865(4) (azomethine), 1.961(4) and 1.968(5) (phen), and 1.926(4) Å (azide)). The Co–S lengths are comparable to those in $[Co(L^4)(bipy)(N_3)]$[34] (H_2L^4 = 2-hydroxy-acetophenone-N(4)-phenylthiosemicarbazone and bipy = 2,2′-bipyridine) (2.2126(7) Å (mercaptide)) and in $[Co(tsaltp)]_2Cl_2$ ($H_2tsaltp$ = *N*,*N*′-bis(thiosalicylideneimine)-2,2′-thiobis(ethylamine))[35] (2.277(3) Å (thioether) and 2.218(3) and 2.278(3) Å (bridging mercaptide)).

The unit cell for $[Co(L3)][BF_4]$ (**XIX**) (Fig. 5) contains two similar but nonidentical $[Co(L3)][BF_4]$ units. Each of

the cations consists of an $N_2O_2S_2$ coordination sphere with the nitrogens in a trans arrangement. Pertinent bond lengths and angles are in Table 6. The Co–S, Co–O, and Co–N bond lengths in both cations are similar to those in **XVI** and related species (vide supra).

Spectroscopic studies

Electronic spectra of the ligands **H_2L1** and **H_2L3** were collected in methanol and in acetonitrile and there are no significant qualitative differences in the overall appearances of the spectra with solvent. Both ligands display absorptions at ~225, ~255, and ~314 nm that can be assigned to two $\pi\rightarrow\pi^*$ transitions of the aromatic system,[36–39] and to a $\pi\rightarrow\pi^*$ transition of the –C=N– system[37,23]. In addition, a weak absorption of unknown origin occurs at ~400 nm in the spectra of both **H_2L1** and **H_2L3**.

All complexes in this study can be generalized into three related coordination sphere types. As a visual assistance to the following discussion these are presented in Fig. 6.

The IR spectrum of **XIV** in the region 3700–3000 cm^{-1} is consistent with its X-ray structure and shows a band attributable to O–H stretching that is shifted to 3250 cm^{-1} and broadened when compared with the corresponding band at 3450 cm^{-1} in the spectrum of the free ligand. The shift and broadening is expected for a hydrogen-bonded system.[40] The electronic spectrum of this compound is consistent with its solid-state structure, which suggests the coordination sphere of the nickel atoms is retained, at least in a general sense, in solution. The spectrum (Table 7) consists of bands at 290, 320, 384, and 580 nm. The first and second of these correlate with bands at 258 and 313 nm in the spectrum of the free ligand and both are shifted to longer wavelength in the complex.

All spectra of the nickel complexes (Table 7) consist of three intense bands ($\varepsilon \sim 10^3$ mol^{-1} L cm^{-1}) and one much weaker band ($\varepsilon \sim 10^1$ mol^{-1} L cm^{-1}). The former are frequently asymmetrical and display shoulders on either or both

sides. These indicate the presence of unresolved bands that have been deconvoluted and identified by Bosnich and coworkers[37,41] as arising from either metal-to-ligand charge transfer (MLCT), intraligand $\pi\rightarrow\pi^*$ CT (charge transfer), or, at wavelengths >350 nm, from d–d processes. Unfortunately, the coordination number and geometry of the complexes cannot be determined from their electronic spectra because of overlapping absorptions.

For **III**, the IR spectrum of its free ligand exhibits a band at 3450 cm^{-1} attributable to stretching of the phenolic O–H bonds, whereas the complex exhibits no band in this region but rather a broad absorption centred at 3150 cm^{-1} attributable to stretching vibrations of the hydrogen-bonded carboxylic O–H functions and perhaps also those of the lattice water molecules. The electronic spectrum of **III** is very similar to that of **XIV** with the exception of a high-energy shoulder on the band at ~384 nm in the spectrum of **III** that is not apparent in that of **XIV**. As discussed previously, the band at ~384 nm is an envelope of unresolved bands and in **III** this is evident from its partial resolution.

The structures proposed for the remaining 13 nickel complexes in this study are based upon extrapolations from the

except that the ethereal oxygen and thioether sulfur in the midpoints of L2 and L1, respectively, are not expected to be coordinated to their nickel atoms and the solvation in their crystals is water instead of acetonitrile. Thus, in all cases, the coordination sphere should be $N_2O_2S_2$ with *trans*-nitrogens and *cis*-sulfurs and -oxygens. It is anticipated that all will be hydrogen-bonded dimers and the analytical results are consistent with such formulations. There are only relatively minor differences in the various values of λ_{max} among these compounds, suggesting that a common coordination environment exists in all four cases. Finally, the IR spectra of all four compounds are similar in the region between 3000 and 3800 cm^{-1} where evidence of hydrogen bonding can be seen as described previously.

The structure proposed for [Ni(L1)]·H_2O (**I**) is similar to that observed by X-ray for [Co(L3)][BF_4] (**XIX**) except that the centre sulfur of L1 is not expected to be bound to nickel. The coordination sphere is therefore $N_2O_2S_2$ with *trans*-nitrogens and *cis*-sulfurs and -oxygens. The overall appearance of the electronic spectrum of **I** is similar to that of the other nickel compounds, although the value of λ_{max} for the band envelope near 385 nm in the other compounds is shifted to 408 nm in **I**. This amount of shift is consistent with variations owing to changes in bond angles inside the coordination sphere in related metal complexes[11,27] and may be arising from a different "fit" of the nickel atom with this ligand compared with the others. In support, it may be noted (Table 7) that **II** with a ligand of similar dimensions displays a similar shift of λ_{max}.

The formulation [Ni(HL2)][OAc] for **II** is consistent with analytical data and its infrared spectrum which shows the usual evidence of hydrogen bonding between a phenolic hydrogen and an uncoordinated acetate ion. Uncoordinated acetate is supported by the infrared spectrum's strong peaks at 1592 and 1445 cm^{-1} from $\nu_{C=O}$ of uncoordinated acetate that occur typically near 1580 and 1425 cm^{-1}.[42]

The structures of [Ni(HL1-sal)]Cl_2·H_2O (**IV**), [Ni(HL2-sal)]Cl_2·CH_3OH (**V**), and [Ni(L3-sal)Cl]·H_2O (**VI**) are proposed to have N_2OS_3, $N_2O_2S_2$ and N_2OS_2Cl donor sets, respectively. In the case of **IV**, a facial arrangement of sulfurs similar to that observed in [Co(L1-sal)][BF_4]$_2$, [Ni(PTTN)(H_2O)][ClO_4]$_2$·CH_3OH (PTTN = 1,9-bis(2-pyridyl)-2,5,8-trithianonane)[26] and [Ni(PTTD)][ClO_4]$_2$ (PTTD = 1,12-bis(2-pyridyl)-2,5,8,11-tetrathiadecane)[26] is anticipated and consistent with the compound's spectroscopic properties. Specifically, [Ni(PTTN)(H_2O)][ClO_4]$_2$·CH_3OH, which also has an N_2OS_3 coordination sphere, exhibits inter alia a d–d band at 545 nm that correlates with the 602 nm band in **IV**, the shift between the two arising from differences between the kinds of oxygen and nitrogen donors in the two compounds.[26] The IR, spectrum of **IV** shows a broad band at 3450 cm^{-1} that is unshifted and of similar shape to

that of the free ligand suggesting no hydrogen bonding by the phenolic OH group or the molecule of water. This argues for a monomeric formulation rather than a hydrogen-bonded dimer.

For **V**, the most probable arrangement of the $N_2O_2S_2$ donors is similar to the arrangement in **IV** except that the middle donor in the ligand's aliphatic chain is now an ethereal oxygen so that the complex's two oxygen donors adopt a cis relationship. Electronic spectra of the two compounds are, as a result, similar, although the intense band at 370 nm in **IV** is shifted to 380 nm in **V** obscuring the shoulder at 406 nm in **IV**. At the same time, the shortest wavelength d–d band at 602 nm in **IV** is shifted to 595 nm in **V**, placing it very close to a similar band at 596 nm in [Ni(DTTCE)][ClO_4]$_2$ (DTTCE = 1,11-dioxa-4,8,14,18-tetrathiacycloeicosane).[43] Like the IR spectrum of **IV**, a broad band at 3450 cm^{-1} in the spectrum of **V** that is unshifted and of similar shape to that of the free ligand suggests absence of hydrogen bonding by the phenolic OH or the molecule of methanol and therefore a monomeric formulation for **V** like that of **IV**.

For **VI**, an N_2OS_2Cl coordination sphere with *trans*-nitrogens is proposed by analogy to the X-ray structure of [Co(L3)][BF_4] (**XIX**). However, in **VI** one site must be occupied by chloride instead of oxygen because of the difference between L3 and (L3-sal).

The five complexes derived from nickel bromide illustrate the versatility of these ligands. For example, from one reaction between L3 and $NiBr_2$·H_2O, three products were isolated by solvent extractions and crystallization. The first, [Ni(HL3)Br]·2H_2O (**XI**), has a mass spectrum with a peak at *m/z* 525.0 corresponding to [$C_{20}H_{24}BrN_2NiO_2S_2$]$^+$ or [Ni(HL3)Br + H^+], which suggests an N_2OS_2Br coordination sphere with t*rans*-nitrogens but with the intact phenolic group uncoordinated to the nickel atom. The second product is [Ni(HL3-sal)Br]Br·CH_3OH (**X**). Its coordination sphere is expected to consist similarly of an N_2OS_2Br donor set with *trans*-nitrogens. In this case, however, the intact phenolic group should be coordinated to the nickel atom. In the mass spectrum, there is a peak at *m/z* 285.1 corresponding to [$C_{13}H_{21}N_2OS_2$]$^+$ or [(HL3-sal) + H^+], which is consistent with the proposed organic ligand, but the spectrum contains no peaks assignable to the complete coordination sphere. The IR spectrum of the compound shows a broad band at 3450 cm^{-1} that is unshifted and of similar shape to that of the free ligand, suggesting no hydrogen bonding involving the free phenolic OH group or the molecule of methanol. For {[Ni(HL1-sal)]Br_2}$_2${[Ni(L1-sal)]Br}·H_2O (**VII**), the proposed structure is suggested by the X-ray structure for **III** plus identification by various techniques of the same or analogous cations in other species in this study. In addition, the mass spectrum of this compound exhibits a cluster of peaks from *m/z* 400 to 403, the most intense of which is at *m/z* 401 corresponding to [$C_{15}H_{23}N_2NiOS_3$]$^+$ or [Ni(L1-sal)]$^+$. Thus, a pair of cations having N_2OS_3 coordination spheres with facially disposed sulfurs is anticipated. One of these should have an intact phenol OH coordinated to nickel, whereas the other should have a deprotonated phenoxy oxygen in the analogous coordination site. The compound's IR spectrum shows a broad band at 3450 cm^{-1}, suggesting the absence of hydrogen bonding by either the phenolic group or water. Likewise, from ligand L2, which is like L1, a similar structure, {[Ni(HL2-sal)]Br_2}$_2${[Ni(L2-sal)]Br}·2CH_3OH (**VIII**), is proposed. Agreement of this formulation with the compound's analysis is good and its mass spectrum has a peak at *m/z* 385.0 corresponding to [$C_{15}H_{23}N_2NiO_2S_2$]$^+$ or [Ni(L2-sal)]$^+$. The compound's IR spectrum shows a broad band at 3450 cm^{-1}, suggesting the absence of hydrogen bonding by either phenolic groups or methanol. Finally, for {[Ni(HL3-sal)Br]Br}[Ni(L3-sal)Br]·2CH_3OH (**IX**), the proposed structure involves one [Ni(HL3-sal)Br]$^+$, as in **X**, one [Ni(L3-sal)Br]$^+$ as in **VI**, one ionic bromide, and two molecules of methanol of solvation. This agrees well with the analytical data and the mass spectrum exhibits a peak at *m/z* 341.0 consistent with [$C_{13}H_{19}N_2NiOS_2$]$^+$ or [Ni(L3-sal)]$^+$. As noted previously in this series, the IR spectrum of **IX** shows a broad band at 3450 cm^{-1}, suggesting the absence of hydrogen bonding by either phenolic groups or methanol.

The electronic spectra of **XIX** and **XVI** are similar consisting of three intense and two less intense bands. The two higher energy intense bands can be related to similar bands in the free ligand as indicated in Table 8. The third intense band at ~390 nm is probably an envelope consisting of a MLCT component similar to that in both the copper[14] and nickel complexes and a d–d component, since it is roughly coincident with the expected location of a d–d band. Support for this hypothesis is obtained from spectra of related complexes of cobalt (Table 8), where shoulders are seen emerging in several cases on the high-energy side of broad bands at ~390 nm. For six-coordinate complexes of Co(III) with less than octahedral symmetry, three d–d bands with intensities that increase as the wavelength decreases are expected,[44,45] and all spectra in Table 8 exhibit two bands with intensity suitable for classification as d–d transitions in low-symmetry six-coordinate Co(III) species. The separation between the observed bands places the anticipated third band in each case roughly where the absorptions near 390 nm are observed.

[a]Scan rate 25 mV/s unless otherwise noted.
[b]Scan rate 200 mV/s.
[c]Irreversible oxidation only.
[d]Weak cathodic activity only.

By analogy, and because of the similarity of the electronic spectra of **XVII**, **XVIII**, and **XIX**, their coordination spheres are proposed to be similar. The ethereal oxygen donor at the midpoint of L2 in **XVII** is probably not coordinated, since the electronic spectra of **XIX**, in which the donor set is known by X-ray methods to be $O_2S_2N_2$, and of **XVII** are closely similar. Finally, **XX** is expected to have an analogous $O_2S_2N_2$ coordination sphere in which one oxygen is phenolic and the other is from methanol.

Cyclic voltammetry

Cyclic voltammetry of L1, L2, or L3 in CH_3CN reveals in all cases irreversible oxidation at potentials ≥950 mV versus the saturated calomel electrode (SCE). An irreversible reduction is observed for L1 and L2 at potentials ≤–750 mV vs SCE, whereas for L3 irreversible reduction occurs at values ≤–800 mV vs SCE. Thus, all three ligands have an electrochemical "window" from –750 to +950 mV vs SCE within which metal-centred electrochemical activity of their complexes may be observed. This window is substantially different from that observed previously[26,43] for similar chains terminated by pyridyl or ethyl groups, and the narrower window in the present case restricts observable metal-centred activity to $Ni^{III/II}$ couples (Table 9).

For **XIV**, a redox wave at $E_{1/2}$ = 820 mV vs SCE is due to a $Ni^{III/II}$ rather than a $Ni^{II/I}$ couple, since the latter typically appears near –0.7 to –0.9 V vs SCE,[26,46] whereas $[Ni(DTBO)][BPh_4]_2 \cdot CH_3CN$ (DTBO = 1,10-diaza-4,7,13,16-tetrathia-5,6:14,15-dibenzocyclooctadecane) exhibits a reversible $Ni^{III/II}$ wave at 1.29 V vs SCE.[46]

For **VIII**, $E_{1/2}$ = 800 mV vs SCE, a value close to that observed for **XIV**. For **VIII**, however, ΔE_p = 230 mV, significantly larger than for **XIV**, indicating a decrease in electrochemical reversibility for the process. The two most prevalent reasons for increased ΔE_p are slow electron transfer kinetics and chemical reactions by the oxidized or reduced forms of the electroactive species. A priori, there is no reason to expect significantly different reactivities in **VIII** compared with **XIV**. Therefore, the change in ΔE_p must derive from a change in electron transfer kinetics. Whereas sulfur is known for its ability to accommodate varying bond lengths and angles,[13,30,31] oxygen is not and it may be that slower electron transfer kinetics are experienced in **VIII** because of one of the coordination sphere oxygens being ethereal and in the middle of the hydrocarbon chain versus a terminal phenoxy oxygen in **XIV**. For outer sphere redox processes, bond lengths and angles must adjust to those of the product before electron transfer occurs and this may be more difficult in **VIII** than **XIV**. For **I**, which is expected to have an $N_2O_2S_2$ coordination sphere like **XIV** and **VIII**, the value of $E_{1/2}$ is smaller than that of either and its value of ΔE_p is comparable to that of **XIV**, suggesting a nearly reversible $Ni^{III/II}$ process. The difference in $E_{1/2}$ between **I** and the other species (**XIV** and **VIII**) is in the cathodic sense indicating **I** is less difficult to oxidize. This is consistent with the fact that it is electrically neutral, whereas in **XIV** and **VIII** the electroactive species are cations. For **II**, there is a barely discernible cathodic peak (~675 mV) at almost the same potential as comparable peaks for **XIV** and **VIII** and metal-centred oxidation is not observed. For **VII**, the value of $E_{1/2}$ = 788 mV vs SCE, when compared with **I** with $E_{1/2}$ = 745 mV vs SCE, indicates the greater ease of oxidation of **I** as anticipated from the relative overall Lewis basicity of the donor sets. The larger value of ΔE_p for **VII** relative to **I** can be attributed to the smaller flexibility of the ligand in **VII** where all donors are

Fig. 7. Cyclic voltammograms of $[Co(L3)][BF_4]$ (**IV**) vs SCE. Scan rates: 400 mV/s (– – –), 200 mV/s (– · · –), 100 mV/s (- - -), 50 mV/s (· · ·), and 25 mV/s (—).

bound to the metal. In **I**, a potential donor remains free allowing its ligand to adapt more readily to the changed bond lengths and angles necessary for electron transfer thereby permitting faster electron transfer kinetics and a smaller ΔE_p. For **X**, comparison may be made to **XIV**, since both have unipositive cations as the electroactive species and their coordination spheres differ only by substitution of Br for an O. Using Pauling electronegativities (Br 2.96 and O 3.44)[47] as a rough guide to donor basicity, the overall donor strength in **X** (N_2OS_2Br) is greater than that in **XIV** ($N_2O_2S_2$) and the ease of oxidation of **X** compared with **XIV** reflected in the magnitude of their relative $E_{1/2}$ values is as expected. For **III**, the only activity observed is an irreversible oxidation wave at 540 mV vs SCE from which no useful chemical information can be obtained.

For [Co(L3)][BF_4] (**XIX**), the cyclic voltammograms (Fig. 7) at scan rates varying between 25 and 400 mV/s are symmetrical about $E_{1/2}$ = –378 mV vs SCE, but show increasing cathodic and anodic wave separations with scan rate (ΔE_p = 115 mV at 25 mV/s; ΔE_p = 419 mV at 400 mV/s). This is usually taken to indicate that the $Co^{III/II}$ process is electrochemically quasi-reversible,[48] indicating that it is accompanied by a change in coordination number and (or) coordination sphere geometry.[49] Although six-coordinate $Co^{II}(S_4O_2)$ and $Co^{II}(S_4N_2)$ species such as [Co(DTC)][ClO_4]$_2$ (DTC = 1,11-dioxa-4,8,14,18-tetrathiacycloeicosane)[43] and [Co(PTTD)][ClO_4]$_2$ (PTTD = 1,12-bis(2-pyridyl)-2,5,8,11-tetrathiadecane)[50] are well known, so are five-coordinate complexes such as [Co(15O5)(H_2O)$_2$]Cl_2·H_2O) (15O5 = 1,4,7,10,13-pentaoxacyclopentadecane) with an O_5 coordination sphere[51] and [Co(Me_6tren)Br]$^+$ (Me_6tren = tris(2-dimethylaminoethyl)amine) with an N_4Br coordination sphere[17] and many four-coordinate species. Dissociation of one or more donors upon electrochemical reduction of Co (III) to Co(II) is not therefore surprising and is consistent with the tendency for Co(II) low-spin entities to undergo Jahn–Teller distortion, which, in the extreme case, would correspond to dissociation of donors at the sites of bond elongation.

The observed value of $E_{1/2}$ = –378 mV vs SCE for **XIX** can be compared to those of [Co(HTC)][ClO_4]$_2$ (HTC = 1,4,7,11,14,17-hexathiacycloeicosane)[43] ($E_{1/2}$ = +328 mV vs SCE) with its S_6 coordination sphere, [Co(HOten)][ClO_4]Cl_2 (HOten = 3-(2′-aminoethylthia)-2,2-bis((2″-aminoethylthia) methyl)propan-1-ol)[52] ($E_{1/2}$ = –177 mV vs SCE) with its N_3S_3 coordination sphere, and [Co(HOsen]Cl_3·H_2O (HOsen = 3-(2′-aminoethylamino)-2,2-bis((2″-aminoethylamino)methyl) propan-1-ol)[52] ($E_{1/2}$ = –539 mV v. SCE) with its N_6 coordination sphere. The trend in these potentials qualitatively reflects the trend in ease of reduction of the Co(III) centres and its relationship to the net σ-donor ability or Lewis basicity of the coordination sphere. Thus, the N_6 coordination sphere composed of strong σ donors exhibits the highest cathodic potential, indicating it to be the most difficult of the complexes to reduce, whereas the S_6 coordination sphere has the least cathodic potential, indicating it to be the easiest of the complexes to reduce. This trend is consistent with the abilities of N, O, and S to act as hard or soft Lewis bases, and, in particular, with the ability of sulfur to act either as an electron source or sink depending upon the requirements of the atoms to which it is bound.[26,53,54]

Conclusions

One-pot syntheses for three ligands are reported as well as for 20 of their complexes. An unexpected metal-assisted hydrolysis of just one of a pair of imine functionalities in the complexed ligands has been observed and its selectivity attributed to steric hindrance of the second coordinated imine. Electronic spectra of the ligands have been recorded and are essentially invariant with solvent. There is no evidence for solvolysis of any of the complexes and therefore by comparison of spectra of the ligands and of the complexes of known structure, assignments of structures have been made with reasonable confidence to those complexes for which X-ray data could not be obtained. Cyclic voltammetry reveals the ability of thioether sulfur to accommodate its Lewis acid–base behaviour to the demands of the metal atom to which it is attached. The ligands form complexes in which their phenoxy groups are sometimes deprotonated and sometimes not, an explanation for which has been proposed. The electrochemical behaviour of the three ligands and eight of their complexes has been measured and the ligands observed to have an electrochemically useful window from –750 to +950 mV vs SCE in CH_3CN. Alteration of the functional groups terminating the ligand chains can, in some cases, substantially change a ligand's electrochemically useful window and hence the kinds of metal-centred electrochemical activity that can be observed for its complexes. For the complexes, trends in $E_{1/2}$ and ΔE_p have been qualitatively correlated with structural parameters.

Supplementary data

Supplementary data are available for this article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v11-081. CCDC 796013 and 796014 (for Co) and 801545 and 801546 (for Ni) contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/cgi-bin/catreq.cgi (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1Ez, UK; fax +44 1223 336033; or deposit @ccdc.cam.ac.uk).

Abstract: From 1,11-bis(salicylaldimine)-3,6,9-trithiaundecane (**H_2L1**), 1,11-bis(salicylaldimine)-6-oxa-3,9-dithiaundecane (**H_2L2**), and 1,8-bis(salicylaldimine)-3,6-dithiaundecane (**H_2L3**), syntheses for $[Cu(L1)]_2$ (**I**), $Cu(L2)\cdot CH_3OH$ (**II**), Cu(L3) (**III**), $[Cu(HL3)][CH_3COO]$ (**IV**), $[Cu(HL1\text{-}sal)]Cl_2$ (**V**), $Cu_4(L1)_2Br_4(H_2O)_2\cdot 2H_2O$ (**VI**) and $Cu_2(L2)Br_2\cdot xH_2O$ (**VII**) are described. Single crystal X-ray structural studies for **I**, **III** and **VII** are reported. Variable temperature magnetic susceptibility studies of **I**, **VI** and **VII** are discussed. The examination of **VII** represents the first magneto-structural study of a binuclear copper(II) species with NSO_3Br coordination spheres. This study examines perturbation by one or more of the donor atoms so that none of the known magnetostructural models predicts the copper–copper coupling.

Key words: binuclear copper(II) complexes, thioether, salicylaldimine ligands, variable temperature magnetic susceptibility, magnetostructural correlation, X-ray structure.

Résumé : Utilisant les 1,11-bis(salicylaldimine)-3,6,9-trithiaundécane (**H_2L1**), 1,11-bis(salicylaldimine)-6-oxa-3,9-dithiaundécane (**H_2L2**) et 1,8-bis(salicylaldimine)-3,6-dithiaundécane (**H_2L3**), on a réalisé les synthèses des complexes $[Cu(L1)]_2$ (**I**), $Cu(L2)\cdot CH_3OH$ (**II**), Cu(L3) (**III**), $[Cu(HL3)][CH_3COO]$ (**IV**), $[Cu(HLI\text{-}sal)]Cl_2$ (**V**), $Cu_4(L1)_2Br_5(H_2O)_2\cdot 2H_2O$ (**VI**) et $Cu_2(L2)Br_2\cdot xH_2O$ (**VII**). On a effectué la détermination des structures des composés **I**, **III** et **VII** par diffraction des rayons-X sur un cristal unique. On discute des résultats d'études de susceptibilité magnétique des composés **I**, **VI** et **VII**, à température variable. L'examen du composé **VII** correspond à la première étude magnéto-structurale d'une espèce de cuivre(II) binucléaire comportant des sphères de coordination avec du NSO_3Br. Cette étude permet d'examiner la perturbation par un ou plusieurs atomes donneurs; aucun des modèles magnéto-structuraux ne prédit le couplage cuivre–cuivre.

Mots-clés : complexes de cuivre(II) binucléaire, thioéther, ligands salicylaldimine, susceptibilité magnétique à température variable, corrélation magnéto-structurale, structure par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Magnetostructural correlations involving multinuclear metal complexes remain of interest.[1–5] Although the nuclearity of complexes being reported continues to rise,[6,7] much that is of fundamental significance can be learned from simple systems,[8] the best representatives of which may well be binuclear copper(II) species. For example, the effects of certain specific types of ligands or atoms bridging between pairs of metal atoms are now well understood, but the list of those bridging atoms or ligands is still comparatively small. Furthermore, while it has also been apparent for some time that ligand donors not involved in bridging have an effect on the quality of superexchange phenomena, these effects remain relatively unexplored both qualitatively and quantitatively except in a small number of cases. For example, compound **VII** herein represents the first magnetostructural study of a binuclear oxygen-bridged copper(II) species with NSO_3Br coordination spheres. Thus, this paper represents part of our continuing interest[9–12] in the consequences of molecular changes upon properties that manifest themselves at the macroscopic level. Ligands in this study (Fig. 1) terminated by salicylaldimine functions are related to open-chain ligands terminated by alkyl,[13] pyridyl,[14] thienyl,[15] pyrazolyl,[16] and benzamidazolyl[16] functionalities that we have described in earlier work.

Experimental

Preparations for **H_2L1**, **H_2L2**, and **H_2L3** were carried out as reported previously.[17] Melting points were obtained on a Fisher-Johns melting point apparatus. Other instruments used include a Hewlett-Packard 8452A diode array UV–vis spectrophotometer, an Agilent 1100 series liquid chromatograph with either an SL MSD trap or a 1946A quadrupole detector and a Brüker Tensor FTIR infrared spectrometer equipped with a PIKE Technologies MIRacle single reflection zinc selenide crystal HATR. All reagents were obtained from the

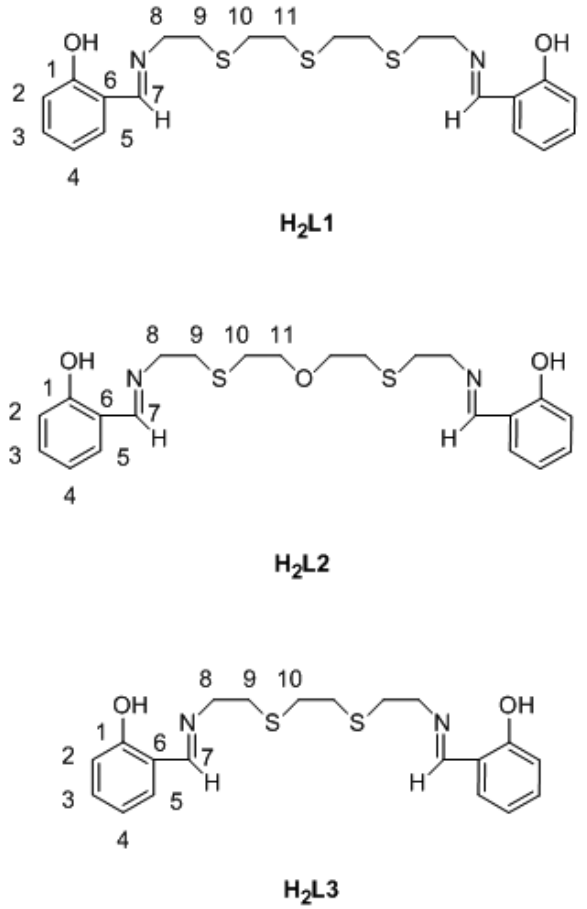
Fig. 1. Ligands and their position identifiers used in this study.



Sigma-Aldrich Chemical Co., Inc,. and were used without further purification. Solvents were ACS grade and were used without purification prior to use. Electronic spectra were obtained in acetonitrile solutions that were 2.0×10^{-3} and 2.0×10^{-5} mol/L in solute. Variable temperature (2–300 K) magnetic susceptibility measurements were made by using a Quantum Design MPMS SQUID magnetometer at a fixed field strength of 1.00 T. Diamagnetic corrections were estimated by using Pascal's constants.

Preparative details — Complexes

From acetate

[Cu(L1)]$_2$ (I)

H_2L1 (1.00 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with copper(II) acetate monohydrate (0.44 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to give a dark green solution that quickly deposited a green precipitate. Upon cooling, a black oily solid formed. The solvent was evaporated slowly in air to produce a green residue that was triturated and rinsed in acetone (3 × 2 mL) and collected in a filter paper as a green powder. This powder was dissolved in chloroform (20 mL), filtered, and then concentrated to 10 mL via a rotary evaporator. Slow evaporation of the solvent produced X-ray quality black crystals (0.55 g, 49% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 310 (1333), 370 (1481), 390 (sh), 654 (93). Mass spectrum APCI(+) calcd for Cu(HL1), $[C_{22}H_{27}CuN_2O_2S_3]^+$, *m/z*: 510.0; found *m/z*: 510.0. Anal. calcd for $C_{44}H_{52}Cu_2N_4O_4S_6$: C 51.79, H 5.14, N 5.49, Cu 12.45; found: C 52.48, H 5.06, N 5.44, Cu 12.0.

Cu(L2)·CH$_3$OH (II)

The procedure for **I** was followed except that trituration was carried out in petroleum ether (2 mL). The dark green powder was then dissolved in chloroform (25 mL), filtered, concentrated to 10 mL via a rotary evaporator, and added dropwise with stirring to cold ether (200 mL). This produced a green precipitate that was washed with ether (3 × 5 mL) and dried in air to give a dark green powder (0.49 g, 45% yield). The petroleum ether filtrate produced black crystals after being left to evaporate slowly over a few days. These were rinsed with ether (3 × 3 mL) and dried in air (0.27 g, 25% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 318 (1613), 372 (1521), 390 (sh), 454 (sh), 620 (80). Mass spectrum APCI(+) calcd for Cu(HL2), $[C_{22}H_{27}CuN_2O_3S_2]^+$, *m/z*: 494.1; found *m/z*: 494.0. Anal. calcd for $C_{23}H_{30}CuN_2O_4S_2$: C 52.50, H 5.75, N 5.32; found: C 52.50, H 5.36, N 5.28.

Cu(L3) (III and [Cu (HL3)][OAc] (IV)

The procedure for **II** was followed. This produced a light green precipitate that was washed with ether (3 × 5 mL) and dried in air to give a dark green powder (**IV**) (48% yield). The mother liquor was saved and upon slow evaporation of solvent produced black crystals (**III**) suitable for structural determination by X-ray methods. UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 318 (1632), 374 (1547), 390 (sh), 440 (sh), 640 (88). Anal. calcd for **(III)** $C_{20}H_{22}CuN_2O_2S_2$: C 53.37, H 4.93, N 6.22; found: C 53.39, H 5.16, N 6.20. UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 316 (1741), 370 (1574), 390 (sh), 450 (sh), 592 (97). Mass spectrum **(IV)** APCI(+) calcd for Cu(HL3), $[C_{20}H_{23}CuN_2O_2S_2]^+$, *m/z*: 450.0; found *m/z*: 450.0. Anal. calcd for (**IV**) $C_{22}H_{26}CuN_2O_4S_2$: C 51.80, H 5.14, N 5.49; found: C 51.52, H 4.93, N 5.84.

From halides

[Cu(HL1-sal)]Cl$_2$ (V)

H_2L1 (1.0 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with copper(II) chloride dihydrate (0.38 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to give a dark green solution. Solvent was evaporated slowly in air to produce dark green spheres and a brown green film. The spheres were removed by hand and triturated in ether (3 mL) to a green powder. The powder was washed with methanol (150 mL), separated by filtration, and washed with ether (3 × 5 mL). It was dried in air and collected as a dark green powder (0.70 g, 63% yield). The methanol solution was concentrated to 15 mL via a rotary evaporator and then added dropwise with stirring to cold ether (250 mL) to produce further green precipitate that was collected in a fritted glass crucible, washed with ether (3 × 5 mL), and dried in air (0.28 g, 27% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 318 (1462), 365 (1326), 654 (47). Mass spectrum APCI(+) calcd for Cu(HL1-sal) (sal = C_7H_3O), $[C_{15}H_{24}CuN_2OS_3]^+$, *m/z*: 407.0; found *m/z*: 407.0. Anal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

calcd for $C_{15}H_{24}Cl_2CuN_2OS_3$: C 37.61, H 5.05, N 5.85; found: C 37.58, H 4.95, N 5.81.

Cu(L3) (III)

H_2L3 (0.65 g, 1.6 mmol) dissolved in warm (~40 °C) acetonitrile (40 mL) was mixed with copper(II) chloride dihydrate (0.28 g, 1.6 mmol) in warm (~40 °C) methanol (20 mL) to produce a dark green solution. A green-blue precipitate deposited overnight and was collected by filtration, washed with ether (3 × 5 mL), and dried in air to a green-blue powder (0.46 g, 64% yield). A portion of the solid (0.14 g, 0.3 mmol) was dissolved in hot (~70 °C) *N*,*N*-dimethylformamide (15 mL), filtered and upon slow evaporation dark crystals suitable for structural determination by X-ray methods and for analysis were produced. Mass spectrum APCI(+) calcd for Cu(HL3), $[C_{20}H_{23}CuN_2O_2S_2]^+$, *m*/*z*: 450.0; found *m*/*z*: 450.0. Note: This compound is also reported above as the result of a preparation from copper(II) acetate monohydrate. These products are indistinguishable.

$Cu_4(L1)_2Br_4(H_2O)_2{\cdot}2H_2O$ (VI)

H_2L1 (1.0 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with copper(II) bromide (0.50 g, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to produce a dark green solution, which quickly deposited a dark green oily precipitate. The solvent was evaporated slowly in air to give a dark green residue that was triturated with ether (3 mL) to give a dark green powder, which was collected by filtration. This powder was dissolved in hot (~60 °C) methanol (250 mL) and filtered hot. The solution was cooled to about 30 °C and ether (50 mL) was added. The solution became slightly cloudy and a light green precipitate began to form. After precipitation was completed (~20 min), the solid was collected in a fritted glass crucible, washed with ether (3 × 5 mL), and dried in air to a green powder (0.53 g, 62% yield). UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 310 (1400), 370 (1463), 390 (sh), 658 (61). Anal. calcd for $C_{44}H_{60}Br_4Cu_4N_4O_8S_6$: C 34.34, H 3.93, N 3.64; found: C 34.56, H 3.81, N 4.02. Mass spectrum : APCI(+); calcd for [Cu(L1) + H], $[C_{22}H_{26}CuN_2O_2S_3 + H]^+$, *m*/*z*: 510.0; found *m*/*z*: 510.0. Mass spectrum: calcd for Cu(L1)Br, $[C_{22}H_{26}BrCuN_2O_2S_3]^+$, *m*/*z* (most intense peak): 590.0; found *m*/*z*: 589.9.

$Cu_2(L2)Br_2{\cdot}xH_2O$ (x = 1 or 3) (VII)

H_2L2 (0.96 g, 2.2 mmol) dissolved in warm (~40 °C) acetonitrile (25 mL) was mixed with copper(II) bromide (0.50, 2.2 mmol) in warm (~40 °C) methanol (25 mL) to produce a dark green solution. The solvent was evaporated slowly in air to give a dark green oil. Trituration in a little water produced a dark green powder that was washed with ether (3 × 5 mL) and dried in air. The powder was extracted with hot (~60 °C) methanol (50 mL), the undissolved portion being washed with ether (3 × 5 mL) and dried in air to a green powder (x = 3) (0.32 g, 38% yield). The methanol solution was then concentrated via a rotary evaporator to 10 mL and added dropwise with stirring to cold ether to produce a green precipitate that was washed with ether (3 × 5 mL) and dried in air to give more green powder (x = 3) (0.07 g, 8% yield). Alternatively, the methanol solution was left to evaporate slowly in air producing greenish crystals (x = 1) suitable for structural determination by X-ray methods. For x = 1, UV–vis (CH_3CN) λ_{max} in nm (ε in mol^{-1} L cm^{-1}): 310 (1548), 372 (1488), 390 (sh), 656 (107). Mass spectrum APCI(+) calcd for $Cu_2(L2)(H_2O)$, $[C_{22}H_{28}Cu_2N_2O_4S_2]^+$, *m*/*z*: 574.0; found *m*/*z*: 573.9. Mass spectrum calcd for Cu(HL2), $[C_{22}H_{27}CuN_2O_3S_2]^+$, *m*/*z*: 494.1; found *m*/*z*: 494.0. Mass spectral characteristics for the crystals (x = 1) and powder (x = 3) are indistinguishable. Anal. calcd for (x = 3) $C_{22}H_{32}Br_2Cu_2N_2O_6S_2$: C 34.25, H 4.18, N 3.63; found: C 34.32, H 3.88, N 3.54.

X-ray studies

A summary of crystallographic data for $[Cu(L1)]_2$ (**I**), Cu(L3) (**III**), and $Cu_2(L2)Br_2{\cdot}H_2O$ (**VII**) is in Table 1. For **I**, non-hydrogen atoms were refined anisotropically, whereas hydrogen atoms were included but not refined. For **III** and **VII**, hydrogen atoms were included in calculated or difference map positions with isotropic parameters set 20% greater than those of their bonding partners. They were refined on the riding model, whereas all non-hydrogen atoms were refined anisotropically. The model for **VII** contained one molecule of water for which the hydrogens could not be found in the difference map. Those hydrogens were not included in the model. Descriptions of the experimental procedures, anisotropic thermal parameters, a full listing of bond lengths and angles, and planes within coordination spheres are available as Supplementary data.

Results and discussion

General features of all three ligands have been discussed previously[17] and are, first, their tendency in the presence of a metal atom to lose salicylaldehyde from one end of their hydrocarbon chain as, for example, during formation of $[Cu(HL1\text{-}sal)]Cl_2$ (**V**) and, second, the solubility controlled isolation of both protonated and deprotonated forms of the ligand, as in the one-pot preparation of Cu(L3) (**III**) and [Cu(HL3)][OAc] (**IV**). Protonated phenolic oxygens coordinated to metals have been observed previously in salicylaldimine complexes,[18] although precipitation of both protonated and deprotonated forms when complexation is carried out in the absence of added base is less common.

An X-ray structural study of **I** shows the asymmetric unit contains two monometallic moieties (Fig. 2*a*), which form dinuclear complexes with their symmetry-related counterparts (Fig. 2*b*). A single ligand molecule is coordinated to each square pyramidal copper in a trans planar manner through its two phenoxy oxygens and two imine nitrogens. In addition, each ligand molecule has one of its phenoxy oxygens bridging between apical and basal sites of two symmetry-related coppers. The second phenoxy oxygen of each ligand is bound terminally to a basal site of its own copper atom. No sulfur atoms are coordinated to copper. Coordination sphere bond lengths and angles are shown in Table 2.

The two dinuclear molecules are similar but not identical. For example, the Cu(1)–Cu(1′) distance is 3.3960(3) Å and the Cu(2)–Cu(2′) distance is 3.3365(4) Å, whereas the difference in Cu–O distances at the apical sites is 0.08(1) Å. On the other hand, differences between corresponding bond lengths in the Cu(1) and Cu(2) basal sites are all ≤0.009(2) Å and on average are 0.005(2) Å. Differences within the

coordination spheres between corresponding basal bond angles are on average 0.24(7)° and all are ≤0.67(7)°, whereas those involving the apical oxygen atoms are on average 1.99(6)° and range from 0.21(6)° to 3.48(6)°. The Cu(1)–O(2′) and the Cu(2)–O(4′) bonds define the elongated Jahn–Teller axes for Cu(1) and Cu(2) and indicate a $d_{x^2-y^2}$ ground state for each Cu with calculated τ values[19] of 0.09 and 0.08, respectively. Because these differences between the molecules are likely to be of limited impact on properties of the substance, only the molecule containing Cu(1) will be discussed further unless specifically noted.

None of the ligand's thioether sulfurs are bound to copper. The chain containing the three sulfur atoms extends in a loop that is nearly perpendicular to the plane of the copper and its donor atoms. The closest approach of a sulfur to a copper atom in its own molecule is by S(1), which lies 4.5(1) Å away. This is 1.4 times the sum (3.20 Å) of the van der Waals' radii of copper and sulfur[20], and there is therefore no bonding interaction between the two atoms. Furthermore, no sulfur atom in the loop lies near a copper atom in an adjacent molecule of the complex, the nearest sulfur (S(1)) lying 6.0(1) Å away. The bond angles at copper deviate on average 1.23(7)° from 90° and 5.14(7)° from 180°, with the largest departure from 90° being 2.52(6)° at O(1)–Cu(1)–N(2) and from 180° being 7.80(5)° at N(2)–Cu(1)–N(1). The average Cu–O and Cu–N bond lengths of 1.905(1) and 2.006(1) Å, respectively, are comparable to corresponding distances of 1.910(7) and 1.980(7) Å for Cu–O in $Cu_2(mspd)_2(CH_3COO)_2{\cdot}Cu_2(CH_3COO)_4{\cdot}2C_2H_5OH$ (Hmspd = *N*-methyl-*N*′-(4,6-dimethoxysalicylidene)-1,3-propanediamine)[21] and of 1.99(1) and 2.02(1) Å for Cu–N in $[Cu(PTN)][CF_3SO_3]_2$ (PTN = 1,9-bis(2-pyridyl)-2,5,8-trithianonane).[16] Thus, the notable aspect of this compound's structure is the absence of interactions between copper and any of the sulfurs.

The structure of **III** involves a roughly planar N_2O_2 coordination sphere with *trans*-nitrogens and *trans*-oxygens (Fig. 3). Pertinent bond lengths and angles in the copper atom's coordination sphere are shown in Table 3.

In this structure, as in that of **I**, there is no inter- or intramolecular interaction between sulfur and copper. Similarly, the chain containing the two sulfur atoms extends in a nearly perpendicular loop away from the plane defined by the copper and its coordination sphere. The closest approach of a sulfur to the copper atom within its own molecule is by S(1), which lies 4.321(2) Å away. This is 1.35 times the sum (3.20 Å) of the van der Waals' radii of copper and sulfur,[20] and there is clearly no bonding interaction between them. The sulfur lying nearest to a copper atom in an adjacent molecule is S(2), which lies 5.506(2) Å away.

The roughly planar N_2O_2 coordination sphere has a slight distortion towards tetrahedral arising from the two nitrogen atoms moving to one side of the plane and the two oxygen atoms to the other. This leaves Cu(1) lying –0.0044(1) Å outside the best plane through copper and its N_2O_2 donor set. The bond angles at copper deviate on average 3.23(7)° from 90° with the largest deviation being 4.15(7)° at O(2)–Cu–N(2).

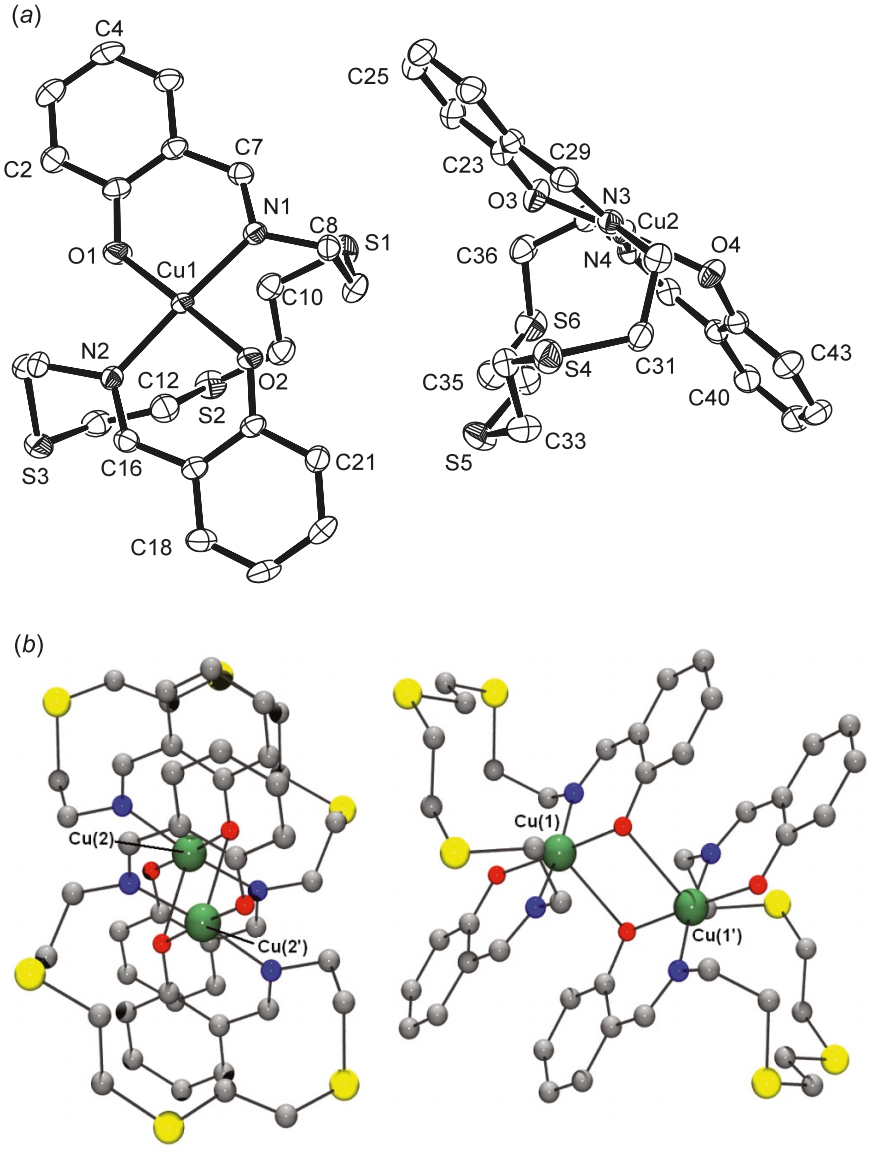
Fig. 2. (*a*) ORTEP of 1/2[Cu(L1)]$_2$ (**I**) (see text). Thermal ellipsoids are shown at the 50% probability level. (*b*) Ball and stick representation of the dimers of [Cu(L1)]$_2$ (**I**). Cu(1′) and associated atoms generated by the symmetry operation (2 – *x*, –*y*, 2 – *z*) and Cu(2′) and associated atoms generated by the symmetry operation (2 – *x*, 1 – *y*, 1 – *z*).



There is a larger deviation for angles expected to be close to 180° with the average being 27.65(8)° and the larger being 30.81(8)° at N(1)–Cu–N(2). These are larger deviations than those in **I** and arise presumably because of a shorter length of the loop of ligand joining N(1) and N(2) in **III** compared with **I**. The average Cu–O and Cu–N bond lengths in **III** of 1.891(2) and 1.983(2) Å, respectively, are comparable to corresponding distances in **I** and related species as discussed previously. Thus, as with **I**, the notable feature of **III** is the absence of interactions between sulfur and copper.

The X-ray structure of **VII** is in Fig. 4 and shows the phenolic oxygens and imine nitrogens again bound to copper, but in this case both sulfur atoms are also bound as is the ether oxygen, although the latter lies at the limit of what can be considered a bonding distance. It should be noted in this context that coordination by ethereal oxygen in a hydrocarbon chain also containing thioether sulfurs is well-known.[22–24] The structure of **VII** involves roughly octahedral NO_3SBr coordination spheres about each of two copper atoms. The coordination spheres share common ethereal and phenolic oxygens and as a result the pseudo-octahedra are tipped towards each other by 74.57(5)° so that the angle between their O_2NS planes is 105.43(5)°. Each of the ligand's phenolic oxygens bridges the two coppers so that those oxygens represent an intersecting or common edge of the two planes defined by a copper atom and its four NO_2S donors. The copper···copper distance in **VII** is 2.968(3) Å compared with 3.3960(3) and 3.3365(4) Å in **I**. Other coordination sphere bond lengths and angles for **VII** are shown in Table 4.

Electrical neutrality in **VII** is achieved through two deprotonated phenolic oxygens and two bromides that lie at distances Br(1)–Cu(2) = 2.6477(6) Å and Br(2)–Cu(1) = 2.6381(7) Å from the copper atoms. These distances are less than the sum of the van der Waals' radii of copper and bromine (3.20 Å),[20]

Cu–N(4)	2.0046(14)	Cu–O(4′)–Cu′	96.49(6)
Cu–O(4′)	2.5197(16)	O(3)–Cu–N(3)	90.96(5)
		O(4)–Cu–N(3)	89.72(5)
		N(4)–Cu–N(3)	172.41(7)

suggesting a bonding interaction probably exists between copper and bromine. Because of the tendency of Cu(II) to undergo Jahn–Teller distortion, it is difficult to define a covalent radius for copper. Comparison, however, of several apical Cu–S distances to the accepted covalent radius for sulfur of 1.02 Å[20] permits one to assign a value of ~1.47 Å to copper under similar circumstances. Using this value, and the accepted value (1.14 Å)[20] for the covalent radius of bromine, the internuclear distance for a covalent bond between copper and "apical" bromine should be ~2.61 Å. Thus, the Cu···Br distances observed in this compound are consistent with bonding interactions between copper and bromine. The suggestion gains credence upon examination of the angles subtended at the coppers and involving the bromines. These angles are given in Table 5. Finally, magnetic susceptibility data (vide infra) also suggests the presence of a bonding interaction between copper and bromine.

Reminiscent of **I** and **III**, the loop of ligand containing the ethereal oxygen in **VII** stretches between coppers at a distance from them and their other donors. This places the ethereal oxygen roughly over the midpoint of the Cu_2O_2 system and at distances of 2.835(3) and 2.868(3) Å to Cu(1) and Cu(2), respectively, that are slightly less than the sum (2.90 Å) of the van der Waals' radii for copper and oxygen. Establishing copper–oxygen bonding distances in a Jahn–Teller distorted coordination sphere by the same method used above for copper–bromine distances, allows one to predict apical Cu–O bond lengths of ~2.20 Å from the published value (0.73 Å)[20] for oxygen's covalent radius. Distances to ethereal oxygen and to perchlorate oxygen in $[Cu(POT)][ClO_4]_2$ (POT = 1,9-bis(2-pyridyl)-5-oxa-2,8-dithianonane)[22] are 2.413(5) and 2.469(10) Å, respectively. This seems to suggest the ethereal oxygen in **VII** lies at a distance from the coppers that is near the limit for bonding interactions with them. It is relevant, however, that bond angles in the ligand loop produce a conformation placing the ethereal oxygen nearer rather than farther away from the coppers. This stands in contrast to the situation for the analogous thioether sulfur in **I** where there is definitely no bonding interaction between the potentially apical sulfur and copper, and where the sulfur is placed by the loop conformation further from copper rather than nearer. Finally, in **VII** the coordination spheres are tipped towards each other with a shared face involving the three oxygen atoms and the bond angles at each of the coppers (Table 4) are close to those found in an octahedron, thereby providing further evidence of a bonding interaction. The average of the eight angles lying in the rough plane of the bridging phenoxides and coppers that would ideally be 90° is 88.5(1)° with the greatest deviation being 8.60(9)° at O(1)–Cu(2)–S(1). Likewise for angles expected to be 180°, the average is 158.8(1)° with the greatest deviation being 32.28(9)° at O(1)–Cu(1)–S(2). At both coppers, the largest deviations are associated with the sulfur donors. It is reasonable to propose that those deviations are due to the ligand being too short to extend easily over the required distance leading, therefore, to the observed shift of the sulfurs from ideal positions in the copper coordination spheres. The Cu–N, Cu–O, and Cu–S distances, with average lengths of 1.939(4), 1.976(3), and 2.338(1) Å, respectively in the NO_2S planes are normal when compared with those in similar structures, as discussed above. In conclusion, consideration of the bond angles at the coppers and the apical Cu–O distances suggests a weak interaction exists between O(2) and each of the copper atoms. The structure of this dinuclear species may therefore be described as two acutely Jahn–Teller elongated NO_3SBr pseudo-octahedra sharing a face defined by three shared oxygen atoms. Magnetic susceptibility as a function of temperature for this compound (vide infra) is consistent with the structural interpretation.

Because of the similarity between ligands $\mathbf{H_2L1}$ and $\mathbf{H_2L}2$, which differ only by the identity of the central atom in their chains, the structure of $Cu_4(L1)_2Br_4(H_2O)_2\cdot 2H_2O$ (**VI**) for which crystals suitable for X-ray structural analysis could not be obtained might be expected to be analogous to that of **VII** established by X-ray methods. However, magnetic measurements (vide infra) and mass spectral fragmentation patterns suggest the structure is most likely a tetranuclear chain. The central pair of coppers in this chain are probably bridged by the organic ligands in a manner similar to that in **I** (Fig. 2*b*), whereas at each end a further copper lies surrounded by a pair of bromine atoms, thioether sulfurs, and possibly a molecule of water. Likewise, by analogy to previously established structures, that of **II** is proposed to consist of a roughly planar N_2O_2 coordination sphere. The compound's electronic spectrum consists of a single d–d band at 620 nm. Electronic spectra of **I**, **III**, and **VII** in the d–d region (Table 6) also consist, in each case, of a single absorption as expected for d^9 species.

For **IV**, the probable coordination sphere is also N_2O_2. This is proposed on the basis of anticipated similarity to the known structure for **III** (see previous). In **IV**, the oxygen donors are proposed to be the phenolic oxygens even though one of them bears a hydrogen. Precedent exists for coordinated phenolic OH.[18] Furthermore, there is no evidence for interaction of the acetate anion with copper in the IR spectrum of **IV**, which shows strong peaks at 1592 and 1445 cm^{-1}. These can be attributed to $\nu_{C=O}$ of uncoordinated acetate, which has vibrations occurring typically near 1580 and 1425 cm^{-1} that are distinguishable from those of coordinated acetate that occur near 1545 and 1405 cm^{-1}.[25]

Electronic spectroscopic evidence for **V** suggests the compound's structure involves an N_2S_3 coordination sphere.

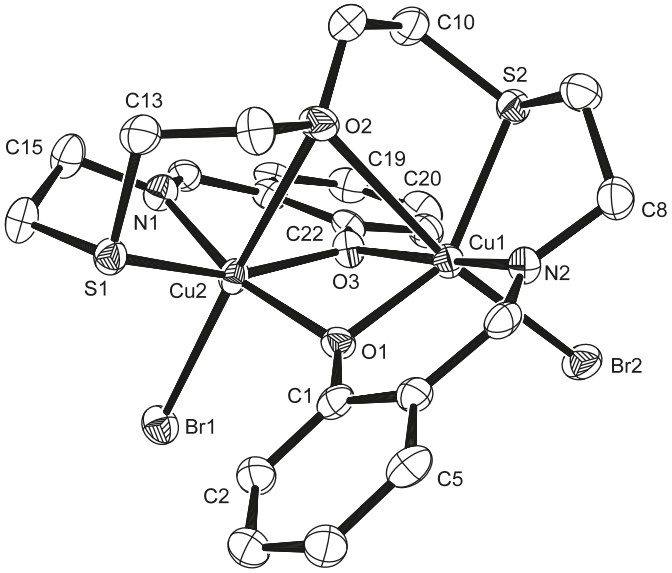
Fig. 4. ORTEP of $Cu_2(L2)Br_2{\cdot}H_2O$ (**VII**). Thermal ellipsoids are shown at the 50% probability level.



There is a strong similarity between the electronic spectrum of **V** and spectra of a series of pyrazolyl- and benzamidazolyl-trithioether complexes of copper(II)[16] having either distorted trigonal bipyramidal or square pyramidal structures in the solid state that involve N_2S_3 coordination spheres. By analogy, therefore, it is reasonable to propose a solid-state five-coordinate structure involving an N_2S_3 coordination sphere for **V** as well. In support, it is observed that at 390 nm there is a charge-transfer band appearing as an intense shoulder or broadening of another charge-transfer band at 365–374 nm in all spectra of copper complexes produced in this study except **V**. The spectral feature at 390 nm is tentatively assigned as a Cu→O metal-to-ligand charge transfer (MLCT) band. This assignment is consistent with observations by other workers. For example, Lever[26] observed Cu→O and Cu→N MLCT bands at 375 and 435 nm, respectively. Likewise, Sönmez[27] reported what appears to be a Cu→N band at 419 nm and Urbach and co-workers[28] described S→Cu charge transfer (LMCT) in the region 344–360 nm, whereas in our own laboratory examples of S→Cu charge transfer in the region 350–375 nm have been observed.[22] Finally, the relatively narrow band at 3400 cm^{-1} in the IR spectrum of the free ligand (**H_2L1**) corresponding to the stretching vibration (ν_{OH}) of the phenolic O–H bonds has been shifted in the spectrum of the complex. There ν_{OH} is centred at 3130 cm^{-1} and the band is broadened as well. This behaviour is typical of a hydrogen-bonded system and suggests the phenolic O–H in the complex is intact and free to engage in hydrogen bonding.[29] Thus, **V** represents the first example encountered in this study of a truncated ligand with its remaining phenolic OH uncoordinated to metal.

Based on precedents described previously, charge-transfer bands can be assigned as shown in Table 6. Charge transfer involving the nitrogen donors is presumably obscured by the other bands in most of the complexes, although a shoulder in the region 440–454 nm can be detected in three cases.

The room-temperature magnetic moment per mol of $Cu_2(L2)Br_2{\cdot}H_2O$ (**VII**) is 1.26 μ_B. This is reduced from the value (2.45 μ_B) that would be expected for 2 mol of uncoupled Cu(II) per mol of compound and suggests strong antiferromagnetic coupling between the copper atoms. Figure 5 shows the magnetic behaviour of **VII** as a function of temperature. The theoretical curve was obtained by least-squares fitting of the experimental data to a modified Bleaney–Bowers equation (eq. [1]).[30]

$$[1] \qquad \chi_m = \frac{N\beta^2 g^2}{3k(T-\theta)}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-\rho) + \frac{[N\beta^2 g^2]\rho}{4kT} + N\alpha$$

where χ_m is the molar magnetic susceptibility corrected by using Pascal's constants for diamagnetic effects, N is Avogadro's number, β is the Bohr magneton, g is the magnetogyric ratio, k is Boltzmann's constant, T is absolute temperature, θ is the Curie–Weiss correction, $-2J$ is the energy separation between the singlet and triplet energy states of the bridged two-copper system, ρ is the mole fraction of a magnetic impurity obeying Curie's Law and having the same molar mass and g as the main component, and $N\alpha$ is temperature independent paramagnetism (TIP). The best fit was obtained by using the data between 60 and 300 K to determine the floating parameters in the fitting process (g, $-2J$, $N\alpha$, ρ, and θ) and then, with the values obtained, extrapolating the theoretical curve to 2 K. The results are shown in Fig. 5 with $g = 2.14(5)$, $-2J = 585(10)$ cm^{-1}, TIP $= 120 \times 10^{-6}$ cgsu/mol, $\theta = -0.3$ K, $\rho = 0.005$, and $10^2R = 136$ ($R = [\Sigma(\chi_{obs} - \chi_{calcd})2/\Sigma\chi_{obs}{}^2]^{1/2}$). This approach is justified because antiferromagnetic coupling between the coppers is large, leading to moments at lower temperatures that are small enough for random measurement errors to become of significant relative magnitude. In fact, the suggestion of very minor ferromagnetic-like activity displayed by the experimental data between 70 and ~40 K may be derived from that source. Except for those two or three data points, the magnetic moment's trend in the low-temperature region is gently downward. This trend is consistent with the small Curie–Weiss correction of $\theta = -0.3$ K, which suggests weak intermolecular antiferromagnetic coupling that would become apparent only at very low temperatures in the face of the very strong intramolecular coupling.

It has been shown[31] for planar dinuclear copper(II) species with aromatic nitrogen ligands and a pair of hydroxo-bridges between the coppers that magnetic coupling depends upon the Cu–O–Cu angles. Furthermore, the angle between the planes containing the magnetic orbital of each copper also influences the extent of coupling,[32] and there is evidence that the nature of both the bridging and the nonbridging ligands affects the magnitude of the coupling.[33] For example, assuming a flat $L_2CuO_2CuL_2$ system with two hydroxo-bridges, the empirical equation (eq. [2])[31] that correlates Cu–O–Cu angles and $2J$ predicts values of 54.00 and –22.76 cm^{-1} by using the Cu–O–Cu bridge angles found in **VII**.

$$[2] \qquad 2J = -7453\phi + 7270 \text{ cm}^{-1}$$

These values straddle zero as expected for angles that lie either side of 97.5°, the angle at which ferromagnetic (positive) and antiferromagnetic (negative) contributions to the singlet–triplet splitting ($2J_{total} = 2J_{ferro} + 2J_{antiferro}$) become equal in Kahn's orbital model for these planar systems.[32] Neither calculated value is close to the experimentally observed value of –585(10) cm^{-1}.

A possible explanation for this discrepancy could be that for **VII** the Cu_2O_2 system is not flat. For nonplanar hydroxo-bridged systems, Kahn showed that, in general, as the planar

system is folded about its oxygen–oxygen axis so that the dihedral angle between the two CuO_2 planes decreases, $2J_{antiferro}$, the antiferromagnetic contribution to the coupling, also diminishes. This is driven in large part by the energy difference between the symmetric and antisymmetric molecular orbitals formed by interaction between the magnetically active atomic orbitals on the two coppers.[32,34,35] As the dihedral angle between the CuO_2 planes decreases, the energy gap between the symmetric and antisymmetric molecular orbitals also decreases until ~130°, where, in these systems, it reaches zero. Unfortunately, the dihedral angle between the two CuO_2 planes in **VII** is 105.43(5)°, which is significantly below the accidental degeneracy angle of 130°, where the antiferromagnetic contribution should become zero. The fact that at an angle of 105.43(5)° a substantial antiferromagnetic coupling is experimentally observed indicates that, quantitatively, Kahn's model for folded systems does not apply to **VII** even though its qualitative conclusions appear likely to be valid.

A possible explanation could be that the model is wrong. Thus, for **VII** the bridges are not hydroxo as in both the model systems discussed previously. In this regard, Thompson et al.[33] showed that for a series of flat or nearly flat *phenoxo*-bridged Cu_2O_2 systems that these species are all still strongly antiferromagnetic at Cu_2O bridge angles that otherwise lead to very small or zero antiferromagnetic couplings in *hydroxo*-bridged species. Their work has shown that phenoxo-bridged species generally exhibit antiferromagnetic couplings with much larger absolute values than those of alkoxo- or hydroxo-bridged species with similar bridge angles. Furthermore, the slope of the straight line correlation between $2J$ and the bridge angle is less in the phenoxo-bridged cases. By least-squares fitting of the data for 11 examples an empirical correlation (eq. [3]) for compounds of this type was obtained. By using eq. [3] and the average of the two Cu–O–Cu bridge angles (97.34°), an estimated value for $2J$ of –647.8 cm^{-1} is obtained, which is somewhat better agreement with the observed value of –585(10) cm^{-1}, suggesting that this is a more suitable model. Obviously, the model and particularly the nature of the bridge are important in development of satisfactory magnetostructural correlations and theoretical calculations[36] have suggested this should be the case.

$$[3] \qquad 2J = -31.95\alpha + 2462 \ \text{cm}^{-1}$$

In spite of a significant improvement in the efficacy of the model by replacing the hydroxo- with a phenoxo-bridge, there remains a substantial discrepancy between the experimental and predicted values of $2J$ for **VII**. This is presumably due to the failure of the model to take into account the presence and effects of the bromine, the ethereal oxygen, or the thioether sulfur atom in the coordination sphere. Unfortunately, no guidance in this matter is available because there are no examples in the literature of binuclear copper(II) compounds with NSO_3Br coordination spheres for which variable-temperature magnetic susceptibility measurements and X-ray crystal structures are available. Likewise, the literature provides only two binuclear copper(II) compounds with N_2O_2Br coordination spheres for which variable-temperature magnetic susceptibility measurements are available,[37,38] and for only one of those ($Cu_2(UPM)Br_2\cdot 4H_2O$) are both the coupling and structure known. In that compound, the macrocyclic ligand is almost flat and the N_2O_2Br coordination spheres about the coppers create a bridge angle of 103.6(3)° at the phenoxo-oxygen bridges and a value for $2J$ of –771(4) cm^{-1}. Its Cu–Br distances are both 2.737(2) Å, which is somewhat longer than the distances in **VII**. Its Cu–N distances of 1.927(6) Å are roughly comparable to those in **VII**, whereas its Cu–O distances of 1.989(4) Å are very slightly longer than those in **VII**. Thus, its major differences compared with **VII** are the absence of the ethereal oxygen donor, two nitrogen donors instead of one plus a sulfur, a slightly longer Cu–Br bond, and its core is flat as opposed to being folded along the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by South China Agricultural University on 09/19/12
For personal use only.

O···O axis. Any or all of these could be the source of the diminished antiferromagnetism in **VII**. The other binuclear copper(II) compound with N_2O_2Br coordination spheres for which variable-temperature magnetic susceptibility measurements are available is $[Cu(spr)Br]_2$. For it, $2J$ has been shown to be –260 cm^{-1}, although structural details for this compound have not been determined by X-ray methods. It has been shown[32,33] that adding electronegative axial atoms and folding the system both diminish the antiferromagnetic contribution to $2J$. Furthermore, substitution of thioether sulfur for a nitrogen donor has been shown[39] to enhance antiferromagnetic coupling. Arguably, the residual discrepancy between the observed coupling in **VII** and that predicted by using the least inappropriate of the available models arises from a combination of these opposing influences. This examination of **VII** represents the first magnetostructural correlation for dinuclear copper species with NSO_3Br coordination spheres.

The magnetic susceptibilities of **I** and **VI** as a function of temperature have also been measured. The results for **I** are presented graphically in Fig. 6 and for **VI** in Fig. 7. For **I**, the theoretical curve was obtained by least-squares fitting of the experimental data to eq. [1][30] and for **VI** the theoretical curve was obtained similarly by using eq. [4] in which $\chi_{(VI)}$ is the total molar susceptibility of **VI** obtained by summing contributions described by eq. [1] from each of the four copper centres believed to be present in the molecule (vide infra).

$$[4] \qquad \chi_{(VI)} = \chi_{(dinuclear)} + 2\chi_{(Cu)}$$

The room-temperature magnetic moment per mol of **I** is 2.57 μ_B. This is slightly larger than expected for 2 mol of uncoupled Cu(II) per mol of compound, suggesting overall weak ferromagnetic coupling. The best fit of the experimental data to theory was obtained with $g = 2.08(1)$, $2J = 2.0(4)$ cm^{-1}, TIP = 105×10^{-6} cgsu/mol, $\theta = -0.6$ K, $\rho = 0.001$, and $10^2R = 1.68$ ($R = [\Sigma(\chi_{obs} - \chi_{calcd})2/\Sigma\chi_{obs}{}^2]^{1/2}$). These results suggest a very weak intramolecular ferromagnetic interaction between pairs of copper atoms and a weak but intermolecular antiferromagnetic component as well. Based on the structure of the compound, which shows the square pyramidal coordination spheres about each of the coppers are linked apex-to-base through bridging oxygen atoms thereby rendering the $d_{x^2-y^2}$ magnetic orbitals on the two coppers in each dimer roughly orthogonal, it is not surprising to find only intramolecular ferromagnetic coupling. Because overall coupling is the sum of antiferromagnetic and ferromagnetic contributions, near or complete absence of antiferromagnetic interaction will reveal ferromagnetic attributes. Weak intermolecular antiferromagnetic coupling is indicated by the negative value of the Weiss constant (θ). In the crystalline state, there are a number of intermolecular contacts along which this interaction could be propagated. Examples, inter alia, are N(2)···H(6_2), N(4)···H(33_2), and S(2)···H(51_2) at distances of 2.739, 2.592, and 3.092 Å, respectively, all of which are less than or similar to the sums of the van der Waals' radii (2.75 and 3.00 Å, respectively)[20] of the atoms involved.

The room-temperature magnetic moment per mol of **VI** is 3.77 μ_B. The best fit of the experimental data to theory was obtained with $g = 2.24(2)$, $2J = -187(11)$ cm^{-1}, TIP = 240×10^{-6} cgsu/mol, $\theta = -0.7$ K, $\rho = 0.0$, and $10^2R = 4.07$ ($R =$ $[\Sigma(\chi_{obs} - \chi_{calc})2/\Sigma\chi_{obs}{}^2]^{1/2}$). Since crystals of this compound suitable for X-ray study could not be grown, magnetostructural correlations are impossible. Because L1 and L2 are similar, one might have expected the magnetic behaviour of **VI** with an empirical formula of $Cu_2(L1)Br_2{\cdot}2H_2O$ and **VII** with a molecular formula $Cu_2(L2)Br_2{\cdot}H_2O$, established by single crystal X-ray work, to be similar. Assuming a dinuclear structure for **VI** similar to that of **VII**, superficial inspection of room-temperature magnetic moments seems to support such a conclusion. However, **VI** defies successful mathematical modelling as a dinuclear species. Bearing in mind the analytical results that require a formula unit with an even number of copper atoms, various other models, including chains and alternating chains, also appear unsuitable. On the other hand, a linear tetranuclear model with the central pair of copper atoms coupled antiferromagnetically and the terminal coppers essentially uncoupled (eq. [4]) reproduces the susceptibility profile as a function of temperature (Fig. 7). Fortunately, a plausible molecular structure can be constructed that is

consistent with this model and with known behaviour of copper complexes of similar types. Thus, one can postulate a pair of central coppers each with NO_2S_2Br coordination spheres linked by two shared phenoxy oxygens, one from each of two separate ligand molecules, and a pair of terminal coppers each also with an NO_2S_2Br coordination sphere linked to its adjacent member of the central pair by a shared sulfur on the Jahn–Teller elongated axes of both bridged atoms and also by the remaining SNO donors of the ligand on the adjacent member of the central pair of coppers. Bridging apical sulfurs would lie trans to bromines on both bridged coppers and each terminal copper would probably have a molecule of water coordinated trans to nitrogen. Coordinated water as well as water of crystallization is anticipated because analysis of aged samples of the compound show loss of varying amounts of water up to but not more than 1 mol per 2 mol of copper. The proposed structure would be consistent with antiferromagnetic coupling between the $d_{x^2-y^2}$ magnetic orbitals of the central pair of coppers linked through bridging phenoxy oxygens while leaving the corresponding magnetic orbital of each terminal copper linked to its adjacent central copper only through orthogonal d_{z^2} orbitals of each bridged copper. The structure would also have coordination spheres for each copper that are consistent with observed patterns of coordination for other compounds described in this study. Thus, based on quantitative analytical, spectroscopic, and magnetic data the formula for **VI** is proposed to be $Cu_4(L1)_2Br_4(H_2O)_2{\cdot}2H_2O$.

Conclusions

The examination of **VII** represents the first magnetostructural study of a binuclear copper(II) species with NSO_3Br coordination spheres. The observation that one or more of the bromine, thioether sulfur, and ethereal oxygen atoms perturb the system so that none of the known magnetostructural models predict the copper–copper coupling accurately suggest further work on these systems is desirable. Measurement of the variable-temperature magnetic susceptibility of **VI** has permitted a superior prediction of the probable structure of that compound than would otherwise have been possible in the absence of X-ray structural data by using analytical and other physical data alone.

Supplementary data

Supplementary data are available for this article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v11-083. CCDC 781761–781763 contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/cgi-bin/catreq.cgi (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1Ez, UK; fax +44 1223 336033; or deposit @ccdc.cam.ac.uk).

Acknowledgments

Dr. R. McDonald, University of Alberta, is acknowledged for the collection of the X-ray crystallographic data for $[Cu(L1)]_2$ and Dr. K, Shuvaev, Memorial University of Newfoundland, is acknowledged for the collection of the variable-temperature magnetic susceptibility data.

A partially water-soluble cationic Mn(III)–salphen complex for catalytic epoxidation

Amir Abdolmaleki and Saeed Malek-Ahmadi

Abstract: Synthesis and application of new cationic Mn(III)–salphen complexes for catalytic epoxidation of olefins to epoxides in a homogeneous reaction media have been reported. The experimental data showed that the cationic salphen is more active than its neutral form. The acceleration of the reaction rate is attributed to the phase-transfer capability of the built-in phenazinium salt of the Mn(III)–salphen catalyst.

Key words: phase transfer, phenazinium salt, cationic Mn(III)–salphen complex, epoxidation.

Résumé : On a effectué la synthèse et examiné le domaine d'application d'un nouveau complexe cationique, le Mn(III)–salphène, pour la transformation catalytique d'oléfines en époxydes, dans un milieu réactionnel homogène. Les données expérimentales montent que le salphène cationique est plus actif que sa forme neutre. L'augmentation de la vitesse de réaction est attribuée à la capacité de transfert de charge du sel de phénazinium inclus dans le catalyseur Mn(III)–salphène.

Mots-clés : transfert de phase, sel de phénazinium, complexe cationique Mn(III)–salphène, époxydation.

Introduction

Epoxides are versatile synthetic intermediates that can be readily converted into a large variety of useful compounds by means of a regioselective ring-opening reaction.[1–3] Therefore, the design of new catalysts for epoxidation of alkenes constitutes an important strategy for the synthesis of pharmaceuticals and fine chemicals.[4–6]

In the field of homogeneous catalysis, salen and salophen ligands[4,7–11] have been investigated for many years and are among the most widely developed ligands in the catalysis toolbox of modern chemistry for a range of organic transformations. Many synthetic approaches toward metallosalen complexes are known that start off with double Schiff base precursors. These precursors commonly originate from a condensation process involving 1 equiv of a diamine and 2 equiv of salicylaldehyde or a ketone analogue. The resultant metallosalen frameworks are thermally and kinetically stable entities controlled by the presence of a tetradentate ligation mode of the N_2O_2 pocket that is characteristic of a salen ligand. This type of stabilization allows, for instance, the creation of vital catalytic intermediates generated by a change in or accommodation of a higher oxidation state of the metal ion coordinated by the salen ligand.[12–15]

In this area, Jacobsen and co-workers[16] developed a practical epoxidation procedure using a two-phase system, with an aqueous phase containing H_2O_2 and an organic phase composed of a solution of substrates.[10,17–20] For practical application, there has been a compelling interest in the development of catalytic epoxidation systems that can increase reaction activity in the aqueous H_2O_2 solution / organic biphasic system. Usually a pyridine *N*-oxide derivative is added to the aforementioned catalytic system to stabilize the catalyst by ligation and to increase the epoxidation reaction rate by drawing the active oxidant into the organic phase.[21,16] Also, the addition of some phase-transfer catalysts could accelerate the epoxidation reaction in the presence of a Mn(III)–salphen catalyst.[22] Moreover, it was reported that the epoxidation activity could be enhanced in the two-phase reaction medium using Mn (III)–salphen catalysts with a built-in phase-transfer capability, constructed by introducing tertiary amine unit(s) to the salen ligand.[23–25]

Recently, Sun and co-workers found that the internal pyridinium salt of the catalyst could play a built-in phase-transfer role for the acceleration of the epoxidation in an aqueous / organic biphasic medium as 2 mol% of external pyridinium salts and ammonium halides, with a tertiary amine unit that was used.[26,27]

In this work, the synthesis of a new phenazinium salphen and its cationic complex with Mn(III) is reported. The cationic complex Mn(III)–salphen was applied in the epoxidation of olefins to epoxides.

Experimental

General remarks

All chemicals were purchased from Merck Chemical Co. *o*-Phenylenediamine was sublimated for further purification. Other solvents and chemicals were purified by common procedures. ^{1}H NMR (500 MHz) spectra were obtained in deuterated dimethylsulfoxide (DMSO-d_6) on a Bruker Avance 500 instrument (Bruker, Rheinstetten, Germany), UV–vis absorption spectra were obtained in DMSO (ca. $\times 10^{-5}$ mol/L)

Received 2 March 2011. Accepted 4 June 2011. Published at www.nrcresearchpress.com/cjc on 7 September 2011.

on a JASCO-570 UV–vis spectrometer, and IR spectra were obtained as KBr pellets with a 680 plus-JASCO. Elemental analysis was also performed by Malek-Ashtar University of Technology, Tehran, Iran.

Synthesis of 2,3-diaminophenazine (1)

2,3-Diaminophenazine was prepared by using a modified procedure reported in the literature.[10] In a typical experiment, 6 mL of 0.08 mol/L aq $FeCl_3$ solution was rapidly added into 30 mL of a 0.02 mol/L aqueous *o*-phenylenediamine solution with vigorous stirring. A quick color change from purple-black to reddish-brown was observed upon the addition of $FeCl_3$. After 5 h at ambient temperature, a large amount of white solid was formed. The precipitate was washed three times with deionized water, then separated by centrifugation and sublimated to afford **1** as a white needlelike crystal. Yield (%): 98; mp > 300 °C. FT-IR (KBr, cm^{-1}) ν: 3394 (s), 3313 (s), 3188 (w), 1692 (m), 1633 (m), 1531 (s), 1478 (s), 1383 (m), 1371 (m), 1240 (m), 1149 (m), 891 (w), 834 (m), 772 (m), 750 (m). ^{1}H NMR (500 MHz, DMSO-d_6, ppm) δ: 8.01 (s, 2H, aromatic H), 7.715 (s, 2H, aromatic H), 7.01 (s, 2H, aromatic H), 3.43 (br, 4H, $-NH_2$). EI/MS *m*/*z* ($C_{12}H_{10}N_4$): M^+, 210. Anal. calcd for $C_{12}H_{10}N_4$ (%): C 68.56, H 4.79, N 26.65; found: C 68.42, H 4.71, N 26.59.

Synthesis of salphen (2)

Compound (**1**) (0.21 g, 1 mmol) and 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde (0.468 g, 2 mmol) were dissolved in 10 mL of absolute ethanol in a 25 mL flask equipped with a magnetic stirring bar. The reaction mixture was stirred at room temperature for 12 h. The dark brown precipitate was filtered, washed with ethanol. and was purified by column chromatography. Yield (%): 82; mp 267 °C. FT-IR (KBr, cm^{-1}) ν: 3421 (w), 2956 (s), 1636 (m), 1616 (m), 1527 (m), 1442 (s), 1398 (m), 1360 (m), 1292 (m), 1251 (m), 1144 (m), 983 (m), 847 (w), 741(m). ^{1}H NMR (500 MHz, DMSO-d_6, ppm) δ: 13.84 (s, 2H, HO–Ar), 8.43 (s, 2H, CH=N), 8.12, 7.91, 7.64, 7.54 (m, 10H, aromatic H), 1.48 (s, 18H, CH_3), 1.39 (s,18H, CH_3). Anal. calcd for $C_{42}H_{50}N_4O_2$ (%): C 78.47, H 7.84, N 8.72; found: C 78.37, H 7.73, N 7.80.

Synthesis of Mn(III) salphen (3)

In a 50 mL round-bottom flask equipped with a magnetic stirring bar, compound **1** (0.21 g, 1 mmol), 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde (0.468 g, 2 mmol), $Mn(OAc)_2{\cdot}4\ H_2O$ (0.245 g, 1 mmol) and an excess amount of LiCl (0.5 g) in absolute ethanol were stirred under reflux for 12 h. For oxidation of Mn(II) to Mn(III), air was bubbled into the solution during the reaction. Then the reaction mixture was cooled to room temperature and filtered. The brown solid was washed with ethanol to remove all impurities. Yield (%): 78; mp > 300 °C. FT-IR (KBr ν, cm^{-1}): 2962 (m), 2921 (m), 1648 (m), 1610 (m), 1592 (s), 1492 (m), 1445 (m), 1220 (m), 770 (w), 643 (w), 616 (w), 488 (w). UV–vis (DMSO, nm) λ_{max}: 263, 346, 447.

Synthesis of cationic salphen (4)

In a 25 mL round-bottom flask, 15 mL of methyl iodide was added to compound **2** (0.032 g, 0.05 mmol) and refluxed for 7 days. The mixture was cooled to room temperature. The unreacted methyl iodide was removed under reduced pressure. The brown solid was obtained after the removal of methyl iodide. Yield (%): 83; mp > 300 °C (decomp.). FT-IR (KBr, cm^{-1}) ν: 3417 (w), 2958 (m), 2923 (m), 2853 (m), 1653 (m), 1624 (s), 1571 (m), 1525 (m), 1457 (m), 1384 (m), 1260 (m), 1199 (w), 1169 (w), 1097 (w), 1024 (m), 800 (w), 751 (m). ^{1}H NMR (500 MHz, DMSO-d_6, ppm) δ: 13.85 (br, 2H, HO–Ar), 8.43 (s, 2H, CH=N), 8.26, 8.12, 7.93, 7.52 (m, 10H, aromatic H), 5.04 (br, 6H, CH_3–N^+), 1.49 (s, 18H, CH_3), 1.40 (s, 18H, CH_3) (Fig. 1). Anal. calcd for $C_{44}H_{56}I_2N_4O_2$ (%): C 57.02, H 6.09, N 6.05; found: C 56.99, H 6.11, N 5.97.

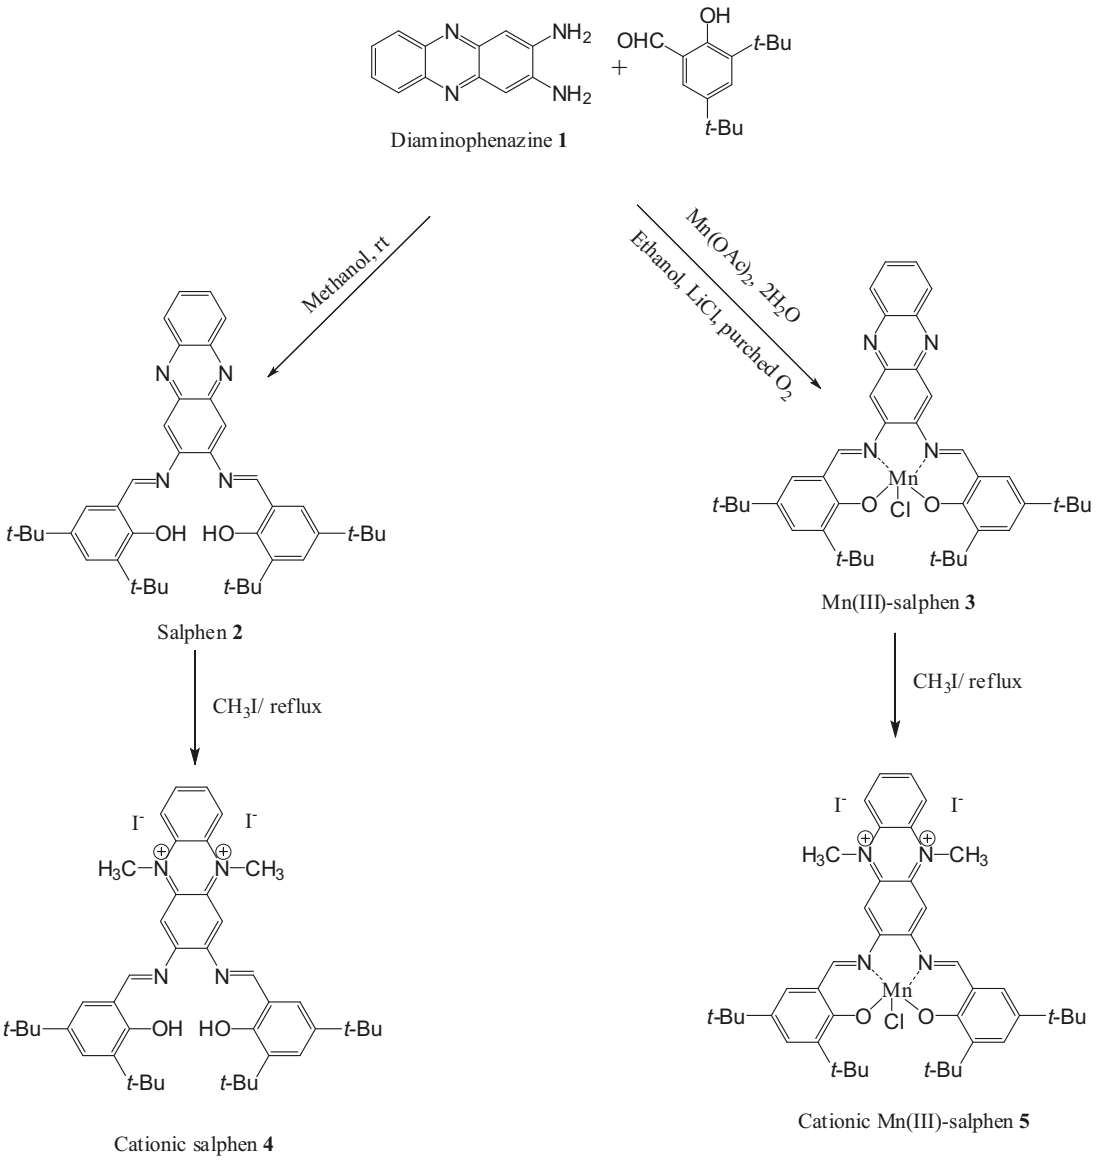
Synthesis of cationic Mn(III)–salphen (5)

In a 25 mL round-bottom flask, 15 mL of methyl iodide was added to compound **3** (0.034 g, 0.02 mmol) and refluxed for 7 days; after this period of time, the reaction mixture was cooled to room temperature. After removal of the unreacted methyl iodide under reduced pressure, a brown solid was obtained. The residue was purified by chromatography on a silica gel column ($MeOH/CH_2Cl_2$, 1:8) to give the desired complex. Yield (%): 94; mp > 300 °C. FT-IR (KBr, cm^{-1}) ν: 2957 (m), 2925 (m), 2850 (m), 1650 (m), 1622 (s), 1570 (m), 1525 (m), 1460 (m), 1384 (m), 1261 (m), 1200 (w), 1171 (w), 1097 (w), 1024 (m), 799 (w), 751 (m). Anal. calcd for $C_{44}H_{54}ClI_2MnN_4O_2$ (%): C 52.06, H 5.36, N 5.52; found: C 51.93, H 5.27, N 5.50.

Epoxidation of olefins in the presence of Mn(III)–salphen (3) and cationic Mn(III)–salphen (5)

An aqueous solution of H_2O_2 (30%, 0.8 mmol) was added

Scheme 1. Reagents and conditions for catalyst syntheses.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

portionwise to a solution of olefins (0.4 mmol) and Mn(III)–salphen complex (0.004 mmol) in CH_2Cl_2 (1 mL). The mixture was stirred at 25 °C and the progress of the reaction was monitored by gas chromatography. The aqueous and organic phases were separated and the aqueous layer was extracted twice with CH_2Cl_2 (2 × 3 mL). The combined organic layer was washed with brine (2 × 3 mL) and dried over anhydrous sodium sulfate.

Results and discussion

The procedure for catalyst preparation is depicted in the Scheme 1.

2,3-Diaminophenazine (**1**) was synthesized by oxidation of *o*-phenylenediamine. In the FT-IR spectrum, the two major peaks of 2,3-diaminophenazine are observed between 3400 and 3150 cm^{-1} owing to N–H stretching vibrations of theamino groups, which indicate the presence of NH_2 groups in the structural unit. The bands at 834 and 891 cm^{-1} are assigned to the out-of-plane bending vibrations of the C–H bonds in the 1,2,4,5-tetra-substituted benzene ring of the phenazine unit. The results obtained from the ^{1}H NMR spectrum (δ 8.01 (m, 2H), δ 7.71 (m, 2H), δ 7.01 (s, 2H), and δ 3.43 (br, 4H, $–NH_2$)) support the structure of compound **1**. The elemental analysis result is consistent with the proposed chemical formula of **1**.

Synthesis of salphen (2)

Salphen (**2**) was synthesized by using a stoichiometric ratio of 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde and 2,3-diaminophenazine (2:1) (Scheme 1) and characterized by FT-IR and ^{1}H NMR spectroscopies. The ^{1}H NMR data (CH=N in δ 8.43 ppm; δ 13.84 ppm for OH; all aromatic hydrogens in δ 8.12, 7.91, 7.64, and 7.51 ppm; and two kinds of aliphatic hydrogen of the *tert*-butyl groups in δ 1.48 and 1.39 ppm) confirm the formation of compound **2**. The FT-IR spectrum of compound **2** shows vibrational peaks at 2929 and 2959 cm^{-1} (stretching of the methyl group of *tert*-butyl), at

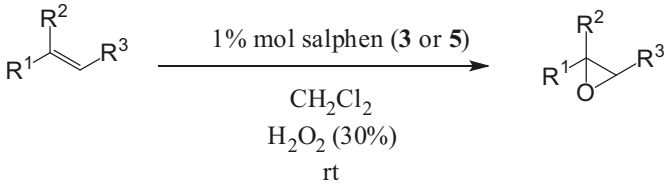
	69	45	84	20
	67	45	79	20
	61	45	77	20

Scheme 2. Epoxidation of olefins.



1636 cm^{-1} (stretching of the C=N bond), and at 3421 cm^{-1} for stretching of the OH group.

Preparation of Mn(III)–salphen (3)

Complex **3** was obtained according to the procedure shown in Scheme 1. The complex was synthesized in the presence of excess LiCl as a counterion. The Mn(II) was converted to Mn(III) via in situ oxidation and the progress of the oxidation reaction was monitored by UV–vis spectroscopy. The Mn (II)–salphen shows an absorption band at λ = 420 nm, whereas a maximum was observed at 447 nm for Mn(III)–salphen (**3**).

Cationic salphen (4)

As shown in Scheme 1, the cationic salphen (**4**) was prepared by reaction of salphen **2** with excess methyl iodide under reflux. The ^{1}H NMR spectrum of **4** supports the proposed structure (Fig. 1). The protons of CH_3^+–N appear at 5.04 ppm, and this evidence is important because the methyl iodide protons have no chemical shift higher than 3.5 ppm.

Cationic Mn(III)–salphen (5)

Cationic Mn(III)–salphen (**5**) was prepared by reaction of compound **3** in the presence of excess methyl iodide as a reagent and a solvent under reflux (Scheme 1). The two CH_3^+–N groups were formed in the salphen ligand and neutralized by two iodide anions.

Epoxidation of olefins

The epoxidation reaction of olefins (Scheme 2) was done using a 0.01 molar ratio of each of the catalysts, Mn(III)–salphen (**3**) and cationic Mn(III)–salphen (**5**). The conversion was measured by GC–MS spectroscopy. The results show that the cationic Mn(III)–salphen (**5**) had a higher catalytic activity than the neutral Mn(III)–salphen (**3**) (Table 1).

The addition of excess CH_3I to the 2,3-diaminophenazine moiety and formation of the cationic Mn(III)–salphen (**5**) can considerably facilitate the epoxidation reaction of olefins, which is presumably because of the formation of the more water-soluble phenazinium groups in the structure (**5**). The neutral Mn(III)–salphen is slightly soluble in water and, consequently, shows a low catalytic activity toward the epoxidation of olefins.[9]

Conclusions

We explore the synthesis of new types of salphen complexes with built-in inherent phase-transfer capability. The complexes were synthesized in good yields and applied toward two catalytic processes. The cationic Mn(III)–salphen complex with two water-soluble phenazinium groups showed an appropriate catalytic activity for the epoxidation of olefins. This method could also be useful for the preparation of other transition-metal catalysts for organic reactions.

Amino-*s*-triazines — Synthesis and stereochemistry of restricted rotational phenomena — First use of a C-2-substituted serinol in tandem with masked 4-piperidone for selective amination of cyanuric chloride

Flavia Popa, Pedro Lameiras, Eric Henon, Oana Moldovan, Agathe Martinez, Carmen Bâtiu, Yvan Ramondenc, and Mircea Darabantu

Abstract: Starting from 4-piperidone monohydrate hydrochloride (or the hydrochloride of its ethylene ketal) alone, otherwise in tandem with a C-2-substituted 2-aminopropane-1,3-diol ("serinol") as amino-nucleophiles in reaction with cyanuric chloride, the synthesis of novel N-substituted amino-*s*-triazines is reported. The stereochemistry of rotational phenomena occurring about the newly created C(*s*-triazine)–N< (exocyclic) partial double bonds in the title compounds, seen as new dendritic building blocks, is discussed.

Key words: melamines, VT NMR, 4-piperidone, rotamerism, serinols.

Résumé : A partir de la 4-pipéridone monohydratée (ou le chlorhydrate de l'éthylène cétal), ou en tandem avec le 2-aminopropane-1,3-diol substitué en C-2 (« sérinol ») assimilé à un amino-nucléophile dans la réaction avec le chlorure de cyanuryle, la synthèse de nouvelles amino-*s*-triazines N-substituées est décrite. La stéréochimie des phénomènes rotationnelles autour des liaisons partiellement doubles C(*s*-triazine)–N< (exocyclique) des composés décrits dans le titre, considérés comme de nouveaux building blocks dendritique, est discutée.

Mots-clés : mélamines, TV RMN, 4-pipéridone, rotamérie, sérinols.

Introduction

Serinol is the trivial name for 2-aminopropane-1,3-diol, usually seen as the reduced form of serine and the parent term of the C-substituted commercial analogous series. We recently reviewed the continuous "serinolic" penetration in current organic synthesis.[1]

Following our previous findings in *s*-triazine chemistry,[2] particularly in chiral serinolic dendrimers and dendrons based on N-substituted 2,4,6-triamino-*s*-triazines (melamines),[2b,2c] we decided to include 4-piperidone as a challenging nucleophile with respect to cyanuric chloride. Indeed, the instability of 4-piperidone as a free base against autocondensation has been well known since 1949,[3] hence, its monohydrate hydrochloride as well as its ethylene ketal (free base or hydrochloride) are commercially available.

On the other hand, nowadays there is a noticeably focused interest in nucleophilic substitution of the remainder chlorine in chlorodiamino-*s*-triazines carried out with 4-piperidone derivatives, providing pharmaceutical compositions for treating pathological states, which arise from or are exacerbated by angiogenesis.[4]

Therefore, the aim of our work is to account for the concise synthesis of amino-*s*-triazines built entirely from 4-piperidone or in tandem with certain C-2-substituted serinols together with their rotational phenomena about the C(*s*-triazine)–N< (exocyclic) partial double bonds.

Results and discussion

Synthesis

Our synthetic approaches are depicted in Schemes 1–3. Except for our previously reported data,[2,5] no term for this new class of amino-*s*-triazines has been reported.

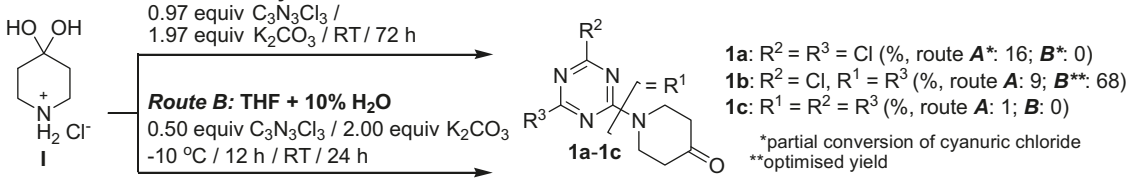
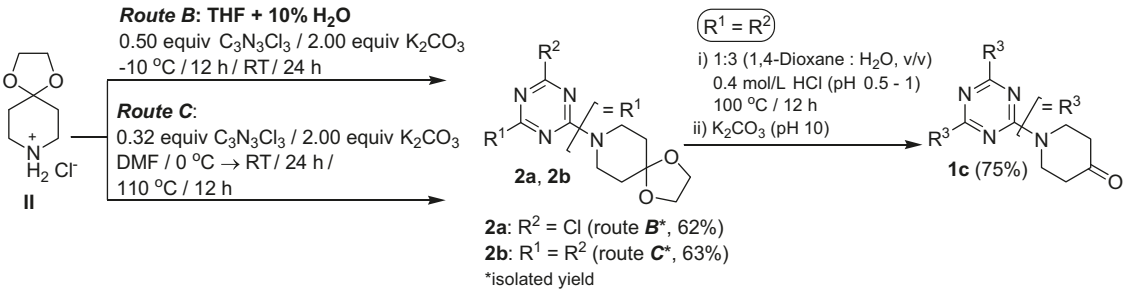
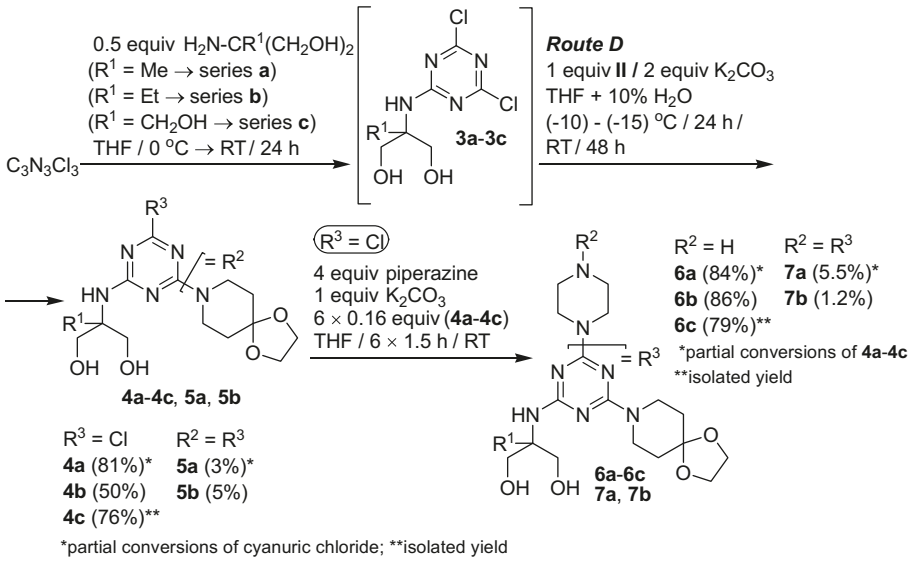
Scheme 1.



Scheme 2.



Scheme 3.



Preliminarily, we attempted the amination of cyanuric chloride with 4-piperidone monohydrate hydrochloride **I** (Scheme 1, route **A**) in the presence of anhyd potassium carbonate as a twofold proton scavenger.[5] The partial conversions and selectivity (**1a** vs **1b** vs**1c**) that we observed, indicating the overall results in anhydrous conditions, were not promising at all. Indeed, at room temperature, the hydrochloride **I** exhibited a reduced solubility in waterless solvents (THF, 1,4-dioxane, chloroform, and dichloromethane), which, combined with the insolubility of the proton scavenger, did not quickly generate the 4-piperidone free base. Moreover, during the long time reaction or upon heating (not depicted in Scheme 1, route **A**), the poorer results inferred that alteration of 4-piperidone occurred instead of the desired SN_2Ar process.

A pivotal improvement consisted of the use of 10% aq THF; this was supposed to ensure a rapid acid–base interchange between potasasium carbonate and **I** (Scheme 1, route **B**). A highly reactive nucleophile was produced, i.e., only in very mild and carefully controlled conditions, the selective double replacement of chlorine in cyanuric chloride by two 4-oxopiperidin-1-yl units could be achieved, affording the bis (ketone) **1b** with satisfactory yield.[12]

Therefore, the exploitation as a nucleophile of the freshly prepared ethylene ketal of 4-piperidone hydrochloride **II** (according to Bickelhaupt and co-workers;[6] Scheme 2) was straightforward.

As the free carbonyl analogue of **I**, **II** was also very insoluble in THF and 1,4-dioxane. Accordingly, the selectivity as a double amination of cyanuric chloride by the free base generated in situ from **II** was possible (compound **2a**, Scheme 2, route **B**) only in identical conditions as in the case of 4-piperidone itself (compound **1b**, Scheme 1, route **B**).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/19/12
For personal use only.

Next, DMF was determined to be a suitable solvent for **II** to perform the total substitution of chlorine in cyanuric chloride in a one-pot synthesis (compound **2b**, Scheme 2, route **C**). Deprotection of **2b** in refluxing aq 1,4-dioxane at pH 0.5–1.0 required an unexpected long time, ~12 h, as shown by its spot-to-spot evolution via TLC monitoring. Compound **1c** can be seen as a new type of melamine dendritic core.

Following up on this idea, new terminal building blocks for an iterative dendritic synthesis were successfully prepared. As depicted in Scheme 3, we accessed unsymmetrical melamine series **6a**–**6c** also based on our previous expertise with respect to the amino nucleophilicity of C-2-substituted 2-aminopropane-1,3-diols (serinols): methylserinol (R^1 = Me), ethylserinol (R^1 = Et), and TRIS (R^1 = CH_2OH).[1,5] Thus, chlorodiamino-*s*-triazines **4a**–**4c** were obtained with good yields in a one-pot synthesis[13] (route **D**), the much higher amino nucleophilicity of the azaspirane reagent (generated in situ from **II**) being taken into account. In fact, one must observe the similarity between conditions in route **B** (Schemes 1 and 2) versus route **D** (Scheme 3). Even in these mild conditions, the formation of side products (melamines **5a** and **5b**) could not be completely avoided. Next, by applying our earlier methodology[2b,2c] we did succeed in the selective amination of **4a**–**4c** with piperazine, a classic linker in dendritic melamine chemistry.[7] Our target melamines **6a**–**6c** were easily separated from the side double melamines **7a** and **7b** by column chromatography on partially deactivated silica gel.

Stereochemistry of rotational phenomena

Starting from the well-recognized herbicide atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine) as early as 1971,[8a] it is classically known that, because of the p → π conjugation involving the lone pair of the exocyclic N-atoms and the high π-deficient *s*-triazine ring, the bonds C^{sp^2}(*s*-triazine)–N^{sp^3}< manifest some double-bond character.[8,9] It strongly depends on the π-deficiency of the C-substituted *s*-triazine determining the *type of restricted rotational status* about these connections (Scheme 4).

Hereafter, we will use our recent terminology[2c] for these angularly connected molecules: at room temperature, the C(*s*-triazine)–N< (exocyclic) partial double bonds are seen as *axes of prodiastereomerism* (as in **1b** and **2a**) and *axes of diastereomerism*, including a combination of these two situations (as in **4a**–**4c**, **5a**, **5b**, **6a**–**6c**, **7a**, and **7b**). Upon heating, the acquired free rotation can be *homomeric (topomerization)* or *diastereomeric*, respectively, the whole process being suitable for VT NMR monitoring.[9,14] Except for our incipient data,[2c] no such distinct approach has been previously reported.

Homomeric rotational phenomena — Topomerizations

A first illustrative example is provided by chlorodiamino-*s*-triazines **1b** and **2a** (Scheme 5).

At room temperature (*frozen status*), the NMR discrimination between diastereotopic positions (δ(α) > δ(α′) and δ(β) > δ(β′)) was made based on the closer proximity of α and β nuclei (pro-*cis*) against α′ and β′ (pro-*trans*) with respect to the deshielding influence of the strong dipole moment of the C(2)(*s*-triazine)–Cl bond (Scheme 5; Table A1).[2c,7c] Hereafter, we will entitle this assignment as "the dipole rule". The

Scheme 4.

*Diastereotopic: C-α *vs.* C-α' and H-α(eq. ⇆ ax.) *vs.* H-α'(eq. ⇆ ax.) etc. (fast piperidine chair ⇆ chair flipping at RT)

frozen status was better revealed in [D_6]DMSO (ε = 46.7) than in [D_8]THF (ε = 7.58) (Table A1), to anticipate the influence of solvation effects. On heating, the rotational barriers $\Delta G^{\neq}$ (kJ/mol) referring to equilibria between two equally populated sites (*homomeric* process) were determined by applying the classic Eyring calculation algorithm (eq.[1])[10a,10b]

$$[1] \qquad \Delta G^{\neq} = 19.14 T_C [10.32 + \log (T_C/k_C)]$$

where T_C (K) is the coalescence temperature and k_C (s^{-1}) is the rate constant of the first-order kinetic exchange dynamic process occurring at T_C.

The rate constants k_C were calculated using the Gutowski–Holm equation (eq. [2])[10c]

$$[2] \qquad k_C = 2.22 \Delta\nu$$

where $\Delta\nu$ (Hz, s^{-1}) is the frequency separation between two analysed signals (e.g., H-β vs H-β′ and H-α vs H-α′; Table A1) in the absence of any exchange between the two equally populated sites.

Our $\Delta G^{\neq}$ values (Table A1) were plausible, since they are smaller with respect to those of two known normal open-chain 2-chloro-4,6-bis(di-*n*-alkylamino)-*s*-triazines (*n*-Bu, 74.22 kJ/mol; *n*-octyl, 75.17 kJ/mol) but comparable to those where the alkyl chain was branched (*i*-Pr, 65.33 kJ/mol).[9c]

We note that, in the case of **1b** and **2a**, we fortunately found "two internal clocks"[10b] because both diastereotopic methylenes (β ⇆ β′ and α ⇆ α′ (two A_2X_2 systems)) were

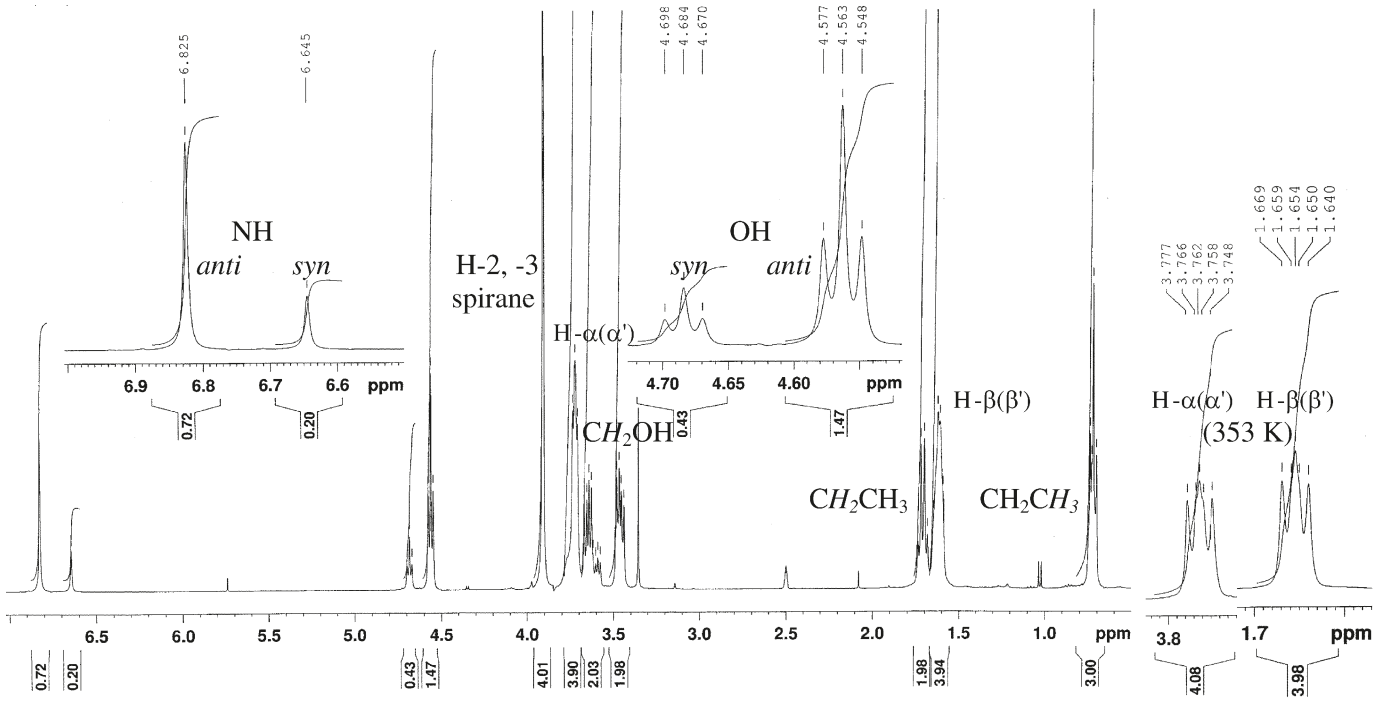
Fig. 1. ^{1}H NMR spectrum of compound **4b** (400 MHz time scale, 293 K, [D_6]DMSO); at 353 K): *pseudo freely rotating status* of the spiranic fragment about the bond C(4)(*s*-triazine)–N< (exocyclic).



appropriate for VT NMR investigations. Since they were satisfactorily "synchronized" (ΔT_C = 5–10 K), they provided comparable kinetic results. Compound **1b** had a slightly higher $\Delta G^{\neq}$ value (~1 kJ/mol) than **2a**, the ground state of diketone **1b** being, presumably, more solvated in [D_6]DMSO than the less polar double 1,3-dioxolanic derivative **2a**.

Two additional features are worthy of mention (Table A1):

i. Upon heating, compound **2a** (at 80 °C in [D_6]DMSO) exhibited a new unexpected anisochrony between protons α ⇆ α′ (diastereotopicity as Δδ ~ 0.01 ppm, two *o*verlapped *t*riplets, "ot") that we entitled *pseudo freely rotating status*.[15] It might be consistent with some residual steric hindrance against completely free rotation between the two spiranic fragments together with the acquired pyramidal inversion of their aza-atoms.[16]

ii. At room temperature and in [D_8]THF, the rotational *frozen status* was not completely observed on both NMR (^{1}H and ^{13}C) time scales (*partially frozen status*). To our surprise, on cooling, the appearance of diastereotopicity δ(H-α) > δ(H-α′) was preceded by no detectable coalescence, e.g., the mediated α(α′)-triplet at room temperature (Δδ = 0 ppm), was progressively converted into two distinct triplets (Δδ = 0.10 ppm; Table A1). Yet, at –80 °C, (**1b**) and at –90 °C (**2a**) we were also unable to reach the frozen structure of the chair ⇆ chair piperidine ring inversion. The conformational chirality associated with this motion we discussed in detail elsewhere.[2c]

Global diastereomeric rotational phenomena

Keeping in mind the above versatile rotameric behaviour of the dioxa-azaspirane motif if linked *alone* to a chloro-*s*-triazine ring, VT NMR analysis of N,N′-unsymmetrical chlorodiamino-*s*-triazines **4a**–**4c** was performed (Scheme 6).

Scheme 6.

Their diastereomeric occurrence about the bond C(6)(*s*-triazine)–N< (exocyclic) was by far nonstatistical, but in the ratio 75 (major rotamer) : 25 (minor rotamer).

At room temperature, the two blocked rotamers **4a**–**4c** *anti*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University of Electronic and Science Techonology of China on 09/19/12
For personal use only.

(*a*, major) and **4a**–**4c** *syn* (*s*, minor) were preliminarily ascertained as according to the dipole rule: the resonances of protons NH or OH positioned closer to the dipole moment of the C-2–Cl bond should be located at lower magnetic fields (Fig. 1).

However, the 2D-^{1}H, ^{1}H-NOESY experiment was unable to detect any dipolar interaction between the two sites (serinolic versus spiranic) in the assigned **4a**–**4c** *anti* rotamers. Therefore, a DFT calculation for the stereoisomers of compound **4a** was carried out, although the anti–syn difference ($\Delta\Delta G_{298} \sim -2.72$ kJ/mol) between the two species was <1 kcal/mol (1 cal = 4.184 J). The relevant results are summarized in Table 1.

In each frozen rotamer **4a**-*anti* and **4a**-*syn*, three conformers about the serinolic NH–C$^{sp^3}$ bond were optimized at the B3LYP/6–31G* and B3LYP/6–311++G** levels of theory. Furthermore, the effect of solvents (DMSO and THF) was taken into account by performing a SCRF calculation with the CPCM option implemented in Gaussian 09. The two lowest energy conformers of type **4a**-*anti* or -*syn* are depicted in Table 2. Only the B3LYP/6–311++G**/CPCM model provided results in line with our postulated dipole rule and, in DMSO, plausible $\Delta G^{\neq}_{298}$ values with respect to rotational barriers about the bond C(6)–N< (exocyclic), issued from the VT NMR calculation (see the later discussion and Table 2).

In the spiranic part of compounds **4a**–**4c**, (Table A2), diastereotopicity ($\Delta\delta$) between positions $\alpha \leftrightarrow \alpha'$ and $\beta \leftrightarrow \beta'$ was clearly distinct only in the ^{13}C NMR spectra and restricted to anti major rotamers (see Experimental).

On ^{1}H NMR spectra, unique signals were displayed by protons H-α and H-α′, but the (broad) multiplets of protons H-β and H-β′ were inappropriate for kinetic calculations (Fig. 1).

At higher temperatures, no clear coalescence was observed in the progress of methylenes α(α′). In contrast, for methylenes β(β′), the same T_C value (308 K) that was detected earlier for compounds **1b** and **2a** (Table A1) was constantly discovered in series **4a**–**4c** (Fig. 2).

Again, the *pseudo freely rotating* situation appeared in some cases, e.g., compound **4b** (two partially overlapped A_2X_2 systems for protons H-α(α′) and H-β(β′)) (Fig. 1). Therefore, we had to conclude that the *local homomeric rotation* about the C(4)(*s*-triazine)–N< (exocyclic) bond in unsymmetrical compounds **4a**–**4c** could only be estimated to be similar to that already encountered in the case of symmetric *s*-triazine **2a**; hence, $\Delta G^{\neq} = 66.11 \pm 0.25$ kJ/mol (Table A1).

In contrast, the energetic barriers about the C(6)(*s*-triazine)–N< (exocyclic) bond consisted of a rotational process between two unequally populated sites, **4a**–**4c** *anti* > **4a**–**4c** *syn*. Two $\Delta G^{\neq}$ values, $\Delta G^{\neq}_{\text{anti}}$ (anti → syn) > $\Delta G^{\neq}_{\text{syn}}$ (syn → anti), defining two first-order kinetic processes, were determined by using, comparatively, two methods, Shanan-Atidi,[10d] in tandem with Eliel and Whilen's modification of this method [10b] (Table 2).

To our knowledge, no such option has been previously reported.

First, we considered Shanan-Atidi's curve:

$$[3] \qquad \tau_C \Delta\nu = f(\Delta n)$$

where τ_C is the average critical time of life (s) at the temperature of coalescence T_C (K) of the examined rotamers, $\Delta\nu$ (Hz, s^{-1}) is the frequency separation between two analysed signals at room temperature in the absence of an exchange between sites, and $\Delta n = n_{\text{anti}} - n_{\text{syn}} > 0$ is the difference between populations of the two frozen rotamers as molar fractions (Fig. 1).

With τ_C in our hands, its reversed value, $1/\tau_C$ (s^{-1}), gave the average value of the rate constant k_C at T_C. Next, the individual rate constants at T_C, $k_{\text{C-syn}}$ (syn → anti) and $k_{\text{C-anti}}$ (anti → syn) were calculated based on the relationship of eq. [4*a*] to eq. [4*b*]:

$$[4a] \qquad k_{\text{C-syn}} = 2k_C n_{\text{anti}}$$

$$[4b] \qquad k_{\text{C-anti}} = 2k_C n_{\text{syn}}$$

Using $k_{\text{C-syn}}$ and $k_{\text{C-anti}}$ and applying the Eyring equation (eq. [1]) for each rotamer, we obtained the desired $\Delta G^{\neq}_{\text{syn}}$ (syn → anti) and $\Delta G^{\neq}_{\text{anti}}$ (anti → syn) values.

The modification of Eliel and Whilen[10b] consisted of first determining the average k_C value of the two rotamers (Gutowski–Holm equation (eq. [2])) by means of the individual rate constants, available as eqs. [5*a*] and [5*b*]

$$[5a] \qquad k_{\text{C-syn}} = k_C(1 + \Delta n)$$

$$[5b] \qquad k_{\text{C-anti}} = k_C(1 - \Delta n)$$

Equation [1] gave a second set of $\Delta G^{\neq}_{\text{syn}}$ and $\Delta G^{\neq}_{\text{anti}}$ values.

The two methods were applied to NH protons and, cautiously, OH, which at room temperature constantly exhibited the best signal separation (two synchronized internal clock $\Delta T_C = 0$ K)[10b] (Fig. 1). Since both methods gave similar kinetic values, they were averaged (errors are given in Table 2).

Our results (Table A2 and Table 2) are subjected to the following critical comments:

i. We had to use VT ^{1}H NMR parameters of the classically entitled "exchangeable protons" NH and OH. In our case, except for the OH protons in compound **4c**, at room temperature (Fig. 1 and Table A2) the analysed signals revealed, by their shape (NH, OH) and multiplicity ($^3J_{H,H} \sim 6.0$ Hz in the C*H*$_2$O*H* sequence), that these nuclei were, however, not exchangeable, but located in a chelatizing environment provided by the hydrogen bond acceptor solvent, [D_6]DMSO.[9d,10a] On heating the progressive shielding of protons NH, when passing from "amide character" (room temperature) to "amine character" (freely rotating structure, 353 K), was both expected and observed. On the other hand, the final spectral data (353 K, Table A2) also refer to the fast exchange status reached by OH and NH protons. It might obscure their relevance in rotational phenomena, since in all spectra of **4a**–**4c**, the final NH and OH resonances (353 K) ranged out of their domain of δ values at room temperature.

ii. Points of coalescence were difficult to establish properly. As for other serinolic structures reported by us, domains of coalescences were rather observed in VT ^{1}H NMR spectra.[2a–2c]

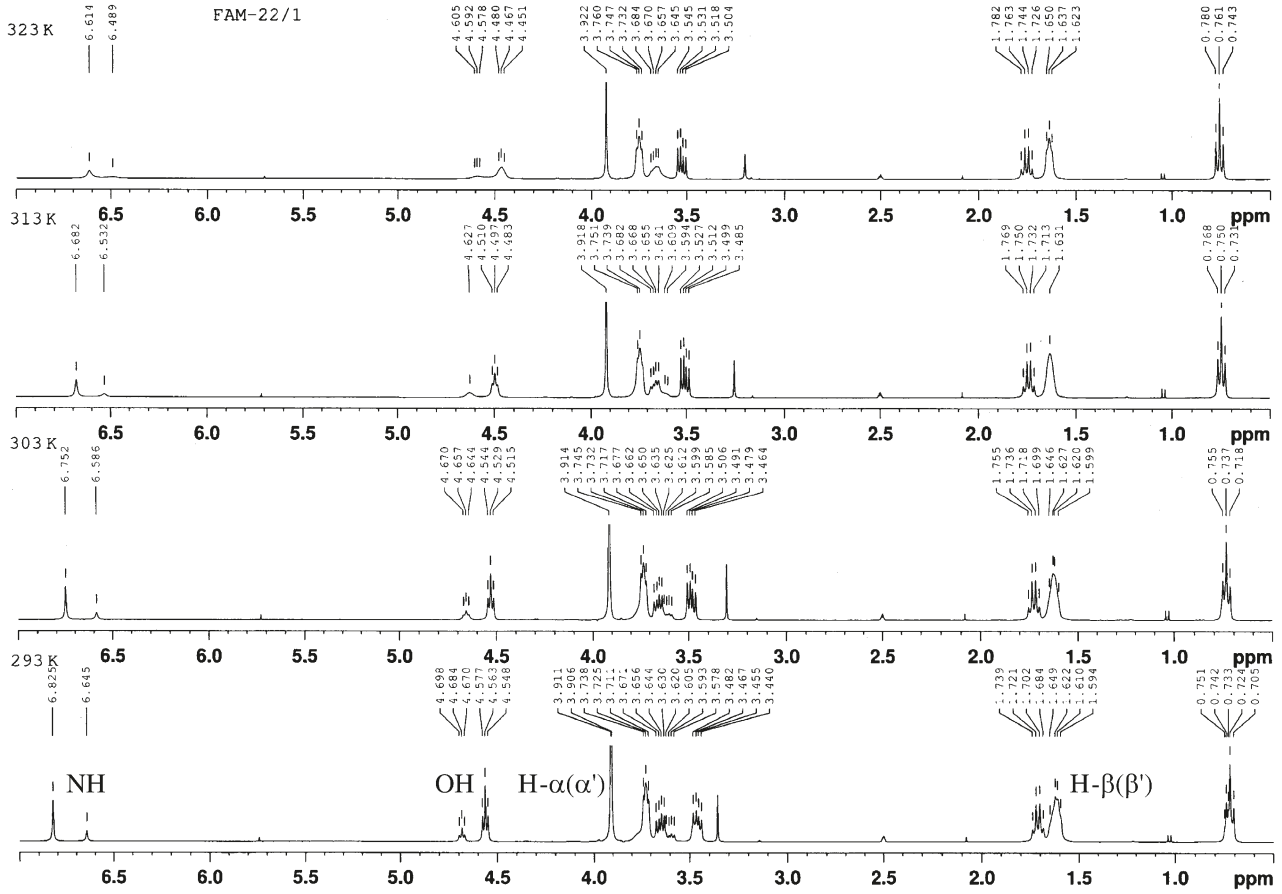
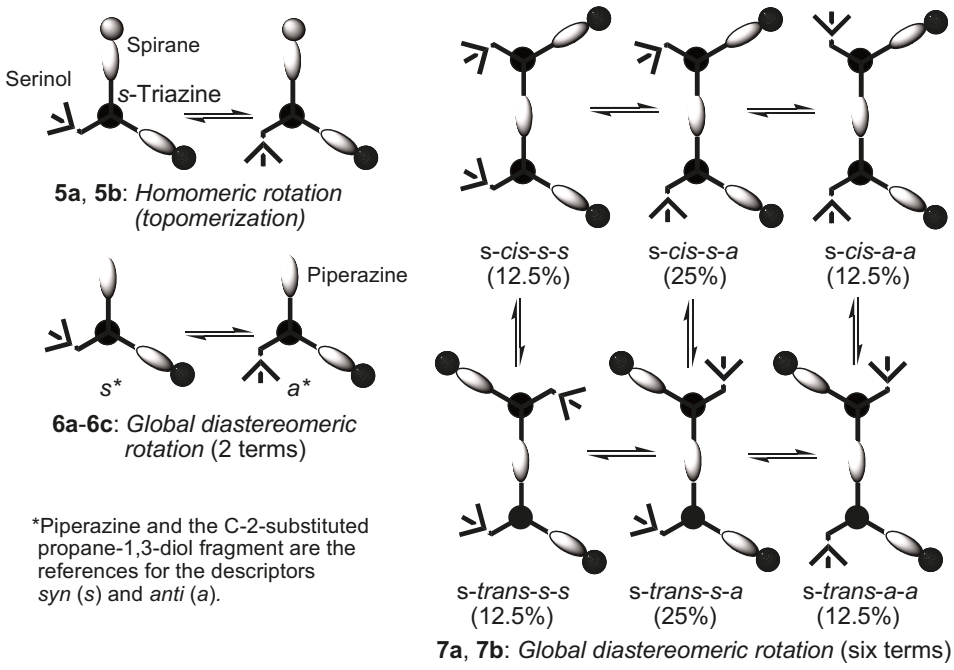
Fig. 2. VT ^{1}H NMR spectrum of compound **4b** (400 MHz time scale, 293–323 K, [D_6]DMSO).



iii. In spite of the above precautions, the $\Delta G^{\neq}_{syn}$ values (kJ/mol) in Table 2 were parallel with those previously determined by us for the N,N′-symmetrically substituted chlorodiamino-*s*-triazines with the same serinolic fragments **4a** (67.68) → 68.10 and **4b** (68.34) → 68.35, but not for compound **4c** (67.35) → 69.22.

iv. Whereas the rotameric compositions were comparable, compound **4c**, the most polar, had the smallest $\Delta n = n_{anti} - n_{syn}$ difference, the smallest $\Delta G^{\neq}$ rotational barriers, and the less negative value of the temperature gradient,[17] $[\Delta\delta(NH)/\Delta T] \times 10^3$. As recently recommended by Moreno and Simanek,[9i] although this parameter is usually applied to peptides and proteins,[11] it is generally accepted and indicative that if the temperature gradient is more negative than –4 ppb/K in aqueous solution, the NH group was exposed to solvent and not involved in intramolecular hydrogen bonds. Conversely, a temperature gradient less negative than –4 ppb/K indicates that the NH protons were initially involved in intramolecular hydrogen bonding. If so, compound **4c** was the less implicated

Scheme 7.



in hydrogen bonding with the solvent, presumably because of the internal strong chelating ability of its three-geminal hydroxymethyl groups associating with an important NH contribution. Consequently, its ground state was the less stabilized by the condition of the solvent (e.g., at room temperature, the OH groups of **4c** exhibited but a broad singlet, (Table A2), not useful for kinetic calculation).

v. If so, the much larger occurrence of **4a**–**4c** *anti* rotamers should be explained by a stronger NH hydrogen bonding by the solvent, $([\Delta\delta(NH)/\Delta T] \times 10^3) < -4$ ppb/K, in comparison with the syn diastereomer where $([\Delta\delta(NH)/\Delta T] \times 10^3) > -4$ ppb/K.

vi. The decreasing order of $\Delta G^{\neq}$ values as $\Delta G^{\neq}_{anti}$ (69.40–70.70 kJ/mol) > $\Delta G^{\neq}_{syn}$ (66.71–69.87 kJ/mol) > $\Delta G^{\neq}_{spirane}$ (66.10 kJ/mol) clearly discloses the order in which, on heating, compounds **4a**–**4c** are rotationally "activated" (Table 2 and Fig. 2): first, a *local homomeric rotation (topomerization)* about the C(4)(*s*-triazine)–N< (exocyclic) bond, then in tandem with a *local diastereomeric rotation* about the C(4)(*s*-triazine)–N< (exocyclic) bond, to provide a *global diastereomeric rotation*. To conclude, this order follows the increasing solvation of the N-ligands: azaspiranic < serinolic syn N-ligand < serinolic anti N-ligand.

vii. At T_C, the $\Delta\Delta G^{\neq}_{syn-anti} = \Delta G^{\neq}_{syn} - \Delta G^{\neq}_{anti} = \Delta\Delta G_{anti-syn} < 0$ values indicate small thermal dependences of $\Delta\Delta G_{anti-syn} = f(T)$ (Table 2).

Combined rotational phenomena in melamines

(VT) NMR data of the less π-deficient amino-*s*-triazines, melamines **5a**, **5b**, **6a**–**6c**, **7a**, and **7b**, described their room temperature status as a slow exchange mediating predictable (un)equally populated sites (Scheme 7 and Table A3).

As one can observe, in a series of double linearly connected melamines **7a** and **7b**, each rotamer can be generated by a single diastereomeric rotation/equilibrium: a *global s*-cis vs *s*-trans by rotation about the C(*s*-triazine)–N(piperazine) bond and the rotation about the C(*s*-triazine)–N(serinol) bond can create the local syn versus anti diastereomerism. If statistical, the occurrence of these rotamers can be predicted mathematically.

Although in all our melamines the ^{1}H NMR spectra displayed large peaks, it was in the ^{13}C NMR time scale that spiranic positions α and α′ were found throughout as diastereotopic (Δδ = 0.1–0.5 ppm, as well as, in some cases (**6b** and **6c**) those of piperazine Δδ = 0.2 and 0.6 ppm). As a general rule, C(2, 4) *s*-triazine carbons linked to piperidinic (or piperazinic) nitrogens together with carbons located in α and α′ positions exhibited broad signals. This rule did not apply to serinolic C(6)(*s*-triazine)–N< (exocyclic) connections to disclose, once more, a different rotational speed about the C(*s*-triazine)–N< versus C(*s*-triazine)–NH– bonds. However, a preferred rotamer (Scheme 7) could not be assigned.

At 353 K, all melamines were completely freely rotating structures.

The temperature gradients were less negative than –4 ppb/K, suggesting these compounds are internally NH(serinol)···OH chelated. In the **6a**–**6c** series, only the serinolic NH signal could be temperature monitored, not that of piperazine. Internal chelation increased as follows: **6a** < **6b** < **6c** (temperature gradients –2.75, –2.47, and –1.36, respectively). As in the precursor series **4a**–**4c**, TRIS derivative **6c** was the most internal chelated with respect to NH protons.

Conclusions

4-Piperidone ethylene ketal is a versatile but useful partner for C-2-substituted serinols in selective amination of cyanuric chloride directed to building blocks for potential iterative

synthesis. The VT NMR experiments showed the resulting amino-*s*-triazines exhibiting distinct types of rotamerism about the C(*s*-triazine)–N< (exocyclic) bond. Rather than steric hindrance, internal versus solvent chelation of serinolic fragments are noticeable factors of influence.

Experimental

General

Melting points are uncorrected; they were carried out on an Electrothermal instrument. Conventional NMR spectra were recorded on a Bruker AM300 instrument operating at 300 and 75 MHz for ^{1}H and ^{13}C nuclei, respectively. VT NMR experiments were performed on a Bruker AV400 instrument (Bruker DMX 500 in the case of compounds **1b**, **2a**, **4a**, and **5a**). All NMR spectra were measured in anhydrous commercially available deuteriated solvents. TLC was performed by using aluminium sheets with silica gel 60 F_{254} (Merck). Flash column chromatography was conducted on silica gel Si 60 (40–63 μm, Merck). All visualizations were realized in UV at 254 nm. IR spectra were performed on a PerkinElmer Paragom FT-IR spectrometer. Only relevant absorptions are listed (throughout in cm^{-1}: weak (w), medium (m), or (s) strong). Microanalyses were performed on a Carlo Erba CHNOS 1160 apparatus. Mass spectra (MS) were recorded on a Bruker Esquire instrument. The synthesis and data of compounds **1a**–**1c** (Scheme 1, route **A**) have been reported elsewhere.[5]

Preparation of compound 1b (Scheme 1, route B)

To a 10% *v*/*v* aqueous solution in THF suspension (100 mL) containing cyanuric chloride (0.922 g, 5.00 mmol) and anhyd K_2CO_3 (2.762 g, 20.00 mmol), cooled at –15 °C, solid piperidone monohydrate hydrochloride **I** (1.536 g, 10.00 mmol) was added portionwise within 12 h with vigorous stirring and with the temperature not exceeding –10 °C. The reaction mixture was then allowed to very slowly reach room temperature and was kept there for an additional 24 h until TLC monitoring (eluent ligroin–acetone, 1.5:1 *v*/*v*) showed completion of reaction. The reaction mixture was filtered off, minerals were well washed with dry dichloromethane (50 mL), and then dichloromethane (75 mL) was added to the filtrate with stirring. The organic layer was separated then washed with water (×50 mL) to neutrality. After drying over anhyd Na_2SO_4 and filtering off, the organic solution was evaporated to dryness under vacuum. The solid residue was crystallized from dry ether (5 mL) at –20 °C to yield 1.053 g of pure **1b** (68% yield with respect to cyanuric chloride). In a similar procedure, compound **2a** was prepared (Scheme 2, route **B**).

2-Chloro-4,6-bis(4-oxopiperidin-1-yl)-*s*-triazine (**1b**) yield 68%; white crystalline powder, mp 188.1–189.0 °C (flash column chromatography, eluent ligroin–acetone, 3.8:1 *v*/*v*). R_f 0.35 (80% ligroin–acetone); R_f 0.70 (60% ligroin–acetone). IR ν_{max} (KBr, cm^{-1}): 3007 (w), 2974 (w), 2900 (w), 1714 (s), 1592 (s), 1492 (s), 1450 (s), 1367 (m), 1331 (m), 1231 (s), 1211 (s), 1016 (m), 982 (m), 967 (m), 827 (m), 793 (m), 753 (w), 685 (w), 556 (w), 497 (w). For relevant (VT) ^{1}H NMR data see Table A1. QC NMR (125 MHz, [D_8]THF, 303 K, ppm) δ_C: 40.6, 40.3 (4 C, C-3′, -3″, -5′, -5″), 42.7, 42.6 (4 C, C-2′, -2″, -6′, -6″), 165.2 (2 C, C-4, -6, *s*-triazine), 170.3 (1 C, C-2, *s*-triazine), 205.1 (2 C, C-4′, -4′). MS (EI, 70 eV), *m*/*z* (rel. int. %): 309 [M$^+$] (100), 281 (58), 253 (78), 240 (70), 225 (40), 197 (33), 184 (29), 70 (37). Anal. calcd for $C_{13}H_{16}ClN_5O_2$ (309.10): C 50.41, H 5.21, N, 22.61%; found: C 50.79, H 4.90, N 22.71%.

2-Chloro-4,6-bis(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazine (**2a**) yield 62%; yellowish crystalline powder, mp 143–145 °C (Et_2O). IR ν_{max} (KBr, cm^{-1}): 2964 (m), 2932 (m), 2870 (m), 1655 (m), 1571 (s), 1492 (s), 1458 (s), 1364 (m), 1310 (m), 1230 (s), 1146 (m), 1116 (s), 1078 (s), 1034 (m), 979 (m), 944 (m), 908 (m), 796 (m), 660 (w). Anal. calcd for $C_{17}H_{24}ClN_5O_4$ (397.15): C 51.32, H 6.08, N 17.60%; found: C 50.98, H 5.88, N 17.31%.

Preparation of compound 2b (Scheme 2, route C)

1,4-Dioxa-8-azaspiro[4.5]decane hydrochloride **IIa** (3.60 g, 20.00 mmol) was dissolved in dry and freshly distilled DMF (125 mL) and then anhyd K_2CO_3 (5.60 g, 40.00 mmol) was added. The resulted suspension was cooled at 0 °C when solid cyanuric chloride (1.18 g, 6.35 mmol) was rapidly introduced with vigorous stirring. The reaction mixture was allowed very gently to reach room temperature (about 24 h) then heated at 110 °C until TLC monitoring (eluent ligroin–acetone, 1.5:1 *v*/*v*) indicated that there was no more evolution of the reaction and the crude product **2b** appeared as a main spot (about 12 h). The reaction mixture was poured into water (100 mL), then extracted with chloroform (100 mL). After separation, the organic layer was well washed with water (7 × 100 mL) to allow complete removal of DMF, then dried over anhyd Na_2SO_4. After filtering off and washing minerals with dry chloroform, the organic solution was evaporated under reduced pressure to dryness, yielding the crude product, which was taken with dry ether (5 mL) with stirring. The resulted suspension was cooled at –20 °C for 12 h and then filtered off and washed with dry and cooled ether to yield the title compound **2b** (2.00 g, 63% yield with respect to cyanuric chloride).

2,4,6-Tris(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazine (**2b**) yield 63%); yellowish crystalline powder, mp 259–263 °C (Et_2O). IR ν_{max} (KBr, cm^{-1}): 2956 (w), 2928 (w), 2878 (w), 1682 (w), 1582 (s), 1537 (s), 1494 (s), 1449 (s), 1408 (m), 1360 (m), 1310 (w), 1250 (m), 1234 (s), 1120 (s), 1081 (s), 1036 (w), 946 (s), 907 (m), 804 (w), 662 (w). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ_H: 1.70 (12 H, t, $^3J_{H,H}$ = 5.2 Hz, H-6′, -6″, -6‴, -10′, -10″, -10‴, -a, -e), 3.86 (12 H, t, $^3J_{H,H}$ = 5.2 Hz, H-7′, -7″, -7‴, -9′, -9″, -9‴, -a, -e), 4.00 (12 H, s, H-2′, -2″, -2‴, H-3′, -3″, -3‴). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ_C: 34.8 (6 C, C-6′, -6″, -6‴, -10′, -10″, -10‴), 41.1 (6 C, C-7′, -7″, -7‴, -9′, -9″, -9‴), 64.3 (6 C, C-2′, -2″, -2‴, -3′, -3″, -3‴), 107.8 (3 C, C-5′, -5″, -5‴), 165.3 (3 C, C-2, -4, -6, *s*-triazine). MS (EI, 70 eV), *m*/*z* (rel. int. %): 505 [M$^+$ + H] (100), 407,[10] 380 (25). Anal. calcd for $C_{24}H_{36}N_6O_6$ (504.27):

Preparation of compound 1c (Scheme 2)

To 2,4,6-tris(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazine **2b** (1.446 g, 2.86 mmol) suspended in aqueous 1,4-dioxane (water (21 mL) + 1,4-dioxane (7 mL)), concd aqueous hydrochloric acid (1.00 mL, 1.18 g soln. 37%, 12.00 mmol HCl) was added and the reaction mixture, having the pH 0.5–1.0, was heated at reflux for 12 h. The reaction was monitored spot to spot by TLC (eluent ligroin–acetone, 1.5:1 *v*/*v*) and stopped when no more evolution was observed and the desired **1c** largely existed as a major spot. The reaction mixture was cooled at room temperature and made alkaline (pH 10) with solid K_2CO_3 and crude **1c** precipitated abundantly. After filtering off, washing with water to neutrality, and drying, pure **1c** (0.800 g, 75% yield with respect to cyanuric chloride) was obtained after crystallization from diethyl ether at –20 °C. The pure analytical sample obtained by the above methodology was identical with that obtained in route **A** (Scheme 1).

2,4,6-Tris(4-oxopiperidin-1-yl)-*s*-triazine (**1c**) yield 75%; yellowish crystalline powder, mp 234.2 °C (dec.) (flash column chromatography, eluent ligroin–acetone, 3.8:1 *v*/*v*). R_f 0.20 (80% ligroin–acetone). IR ν_{max} (KBr, cm^{-1}): 2958 (w), 2862 (w), 1709 (s), 1530 (s), 1490 (s), 1455 (s), 1371 (m), 1316 (m), 1231 (s), 1068 (m), 991 (m), 967 (m), 806 (m), 762. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ_H: 2.47 (12 H, t, $^3J_{H,H}$ = 6.0 Hz, H-3′, -3″, -3‴, -5′, -5″, -5‴, -a, -e), 4.08 (12 H, t, $^3J_{H,H}$ = 6.0 Hz, H-2′, -2′, -2‴, -6′, -6″, -6‴, -a, -e). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ_C: 41.5 (6 C, C-3′, -3″, -3‴, -5′, -5″, -5‴), 43.0 (6 C, C-2′, -2″, -2‴, -6′, -6″, -6‴), 165.8 (3 C, C-2, -4, -6, *s*-triazine), 208.9 (3 C, C-4′, -4″, -4‴). MS (EI, 70 eV), *m*/*z* (rel. int. %): 372 [M+] (100), 344 (20), 329 (18), 316 (58), 303 (75), 288 (47), 275 (45), 260 (50), 247 (60), 232 (25), 219 (28), 203 (26), 177 (25), 163 (21), 122 (33), 94 (32), 80 (46), 68 (28). Anal. calcd for $C_{18}H_{24}N_6O_3$ (372.19): C 58.05, H 6.50. N 22.57%; found: C 57.75, H 6.88, N 22.71%.

Typical procedure for the synthesis of compounds 4a–4c — Preparation of compound 4a

To a solution obtained by dissolving cyanuric chloride (1.53 g, 8.30 mmol) in dry THF (75 mL), anhyd potassium carbonate (1.15 g, 8.30 mmol) was added at room temperature with vigorous stirring. Solid 2-amino-2-methylpropane-1,3-diol ("methylserinol", 0.873 g, 8.30 mmol) was added and the resulting suspension was stirred at room temperature for an additional 24 h. After this period, TLC (eluent toluene–isopropanol, 4:1 *v*/*v*) indicated formation of the intermediate **3a** as a single major spot. Water (7.50 mL) and solid anhyd potassium carbonate (2.30 g, 16.60 mmol) was added and the reaction mixture was cooled at –10 (–15 °C). At this temperature and with vigorous stirring, solid 1,4-dioxa-8-azaspiro[4.5]decane hydrochloride **II** (1.49 g, 8.30 mmol) was added portionwise (five equal portions as 0.298 g / portion each for 90 min). The reaction mixture was kept at –10 °C (–15 °C) for an additional 24 h then allowed to reach room temperature very slowly (48 h). After the minerals were filtered, water (50 mL) and chloroform (100 mL) were added with stirring. The aqueous layer was extracted with chloroform (2 × 35 mL) and the combined organic layer was washed with water (2 × 35 mL). After drying over anhyd Na_2SO_4, the organic solution was evaporated under reduced pressure to dryness to provide 2.83 g of the crude product. This was purified by column chromatography on silica gel (eluent diethyl ether – isopropanol, 10:1 *v*/*v*, or optionally toluene–isopropanol, 4:1 *v*/*v*) to yield compound **4a** as the first fraction (2.44 g, 81% conversion with respect to cyanuric chloride), then compound **5a** as the second fraction (0.14 g, 3% conversion with respect to cyanuric chloride).

2-Chloro-6-{[1,3-dihydroxy-2-(methyl)prop-2-yl]amino}-4-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazine (**4a**) yield 81%; yellowish crystalline powder, mp 135.2–138.0 °C (dec.) (flash column chromatography, eluent diethyl ether – isopropanol 10:1 *v*/*v*). R_f 0.75 (91% diethyl ether – isopropanol). IR ν_{max} (KBr, cm^{-1}): 3428 (s), 3352 (s), 3272 (s), 2929 (m), 1586 (s), 1541 (s), 1506 (s), 1460 (m), 1406 (m), 1288 (m), 1274 (m), 1241 (m), 1152 (m), 1113 (m), 1082 (s), 1053 (s), 1020 (m), 946 (m), 915 (m), 898 (m) 796 (m), 772 (w), 666 (w), 627 (w). For relevant (VT) ^1H NMR data see Table A2. ^{13}C NMR (125 MHz, [D_6]DMSO, 293 K, ppm) δ_C: 18.7, 19.1 (1 C, CH_3), 34.5, 34.8 (2 C, C-6(10) -10(6), spirane), 41.4, 41.8, 42.0 (2 C, C-7(9), -9(7), spirane), 58.9, 59.0 (1 C, C-2), 63.3, 63.8 (2 C, CH_2OH), 64.3 (2 C, C-2, -3, spirane), 106.9 (1 C, C-5, spirane), 163.5, 164.0 (1 C, C-4, *s*-triazine), 165.1, 165.7 (1 C, C-6, *s*-triazine), 168.4 (1 C, C-2, *s*-triazine). MS (ESI+), *m*/*z* (×10^5): 382.1 [M + Na^+],[8] 360.1 [M^+ + H] (3.5). Anal. calcd for $C_{14}H_{22}ClN_5ClO_4$ (359.14): C 46.73, H 6.16, N 19.46%; found: C 47.05, H 5.90, N 19.11%.

2-Chloro-6-{[1-hydroxy-2-(hydroxymethyl)but-2-yl]amino}-4-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazine (**4b**) yield 50%; yellowish crystalline powder, mp 147.4–152.7 °C (flash column chromatography, eluent diethyl ether – isopropanol, 10:1 *v*/*v*). R_f 0.60 (91% diethyl ether – isopropanol). Typical procedure for the synthesis of compounds 6a–6c — Preparation of compound 6a

In a solution obtained from dry THF (60 mL) and anhyd piperazine (2.06 g, 24.00 mmol), anhyd potassium carbonate (0.830 g, 6.00 mmol) was suspended with vigorous stirring. To this suspension, solid **4a** (2.158 g, 6.00 mmol) was added portionwise, as six equal portions, each for 90 min, at room temperature. After each addition, within 90 min TLC monitoring (eluent diethyl ether – isopropanol, 10:1 *v/v*) indicated the complete consumption of the starting material **4a**. Minerals were filtered off, washed with dry THF, and then the organic filtrate was evaporated under reduced pressure to dryness to provide 3.434 g of crude material. This was purified by column chromatography on silica gel (eluent isopropanol – aq 25% ammonia, 9:1 *v/v*) to yield the by-product **7a** (0.121 g, 5.5% conversion of **4a**), then the desired **6a** (2.064 g, 84% conversion of **4a**) as the main fraction.

6-{[1,3-Dihydroxy-2-(methyl)prop-2-yl]amino}-2-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-4-(piperazin-1-yl)-*s*-triazine (**6a**) yield 84%; yellowish crystalline powder, mp 120.0–126.4 °C (flash column chromatography, eluent isopropanol – 25% aq ammonia 9:1 *v/v*). R_f 0.50 (90% isopropanol – 25% aq ammonia). IR ν_{max} (KBr, cm^{-1}): 3298 (m), 2931 (m), 2876 (m), 1537 (s), 1503 (s), 1445 (s), 1363 (m), 1303 (m), 1258 (m), 1148 (w), 1118 (m), 1087 (s), 1038 (m), 946 (w), 834 (w), 808 (m), 734 (w), 662 (w). For relevant (VT) NMR data see Table A3. MS (ESI+), *m/z* (×10^7): 410.2 [M$^+$ + H] (0.95). Anal. calcd for $C_{18}H_{31}N_7O_4$ (409.24): C 52.80, H, 7.63, N 23.94%; found: C 53.05, H 7.90, N 24.11%.

6-{[1-Hydroxy-2-(hydroxymethyl)but-2-yl]amino}-2-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-4-(piperazin-1-yl)-*s*-triazine (**6b**) yield 86%; yellowish crystalline powder, mp 224–225 °C (flash column chromatography, eluent isopropanol – 25% aq ammonia, 9:1 *v/v*). R_f 0.60 (90% isopropanol – 25% aq. ammonia). IR ν_{max} (KBr, cm^{-1}): 3399 (m), 2958 (m), 2880 (m), 1562 (s), 1532 (s), 1495 (s), 1443 (s), 1363 (m), 1339 (m), 1300 (m), 1256 (m), 1117 (m), 1087 (s), 946 (w), 910 (w), 808 (m), 662 (w). For relevant (VT) NMR data see Table A3. MS (ESI+), *m/z* (×10^6): 446.1 [M + Na$^+$] (0.45), 424.1 [M$^+$ + H] (2.2). Anal. calcd for $C_{19}H_{33}N_7O_4$ (423.26): C 53.88, H 7.85, N 23.15%; found: C 54.05, H 7.67, N 22.89%.

6-{[1,3-Dihydroxy-2-(hydroxymethyl)prop-2-yl]amino}-2-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-4-(piperazin-1-yl)-*s*-triazine (**6c**) yield 79%; yellowish crystalline powder, mp 223–229 °C (flash column chromatography, eluent isopropanol – 25% aq ammonia, 9:1 *v/v*). R_f 0.40 (90% isopropanol – 25% aq ammonia). IR ν_{max} (KBr, cm^{-1}): 3339 (m), 2948 (m), 2884 (m), 2770 (m), 1584 (s), 1565 (s), 1538 (s), 1503 (s), 1427 (s), 1368 (m), 1302 (m), 1251 (m), 1085 (s), 1017 (m), 946 (w), 808 (m), 660 (w). For relevant (VT) NMR data see Table A3. MS (ESI+), *m/z* (×10^6): 426.3 [M$^+$ + H] (6). Anal. calcd for $C_{18}H_{31}N_7O_5$ (425.24): C 50.81, H 7.34, N 23.04%; found: C 51.01, H 7.57, N 22.88%.

1,4-Bis{{6-[1,3-dihydroxy-2-(methyl)prop-2-yl]amino}-4-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazin-2-yl}-piperazine (**7a**) yield 5.5%; yellowish crystalline powder, mp 199.0–200.0 °C (flash column chromatography, eluent isopropanol – 25% aq ammonia, 9:1 *v/v*). R_f 0.85 (90% isopropanol – 25% aq ammonia). IR ν_{max} (KBr, cm^{-1}): 3243 (m), 2923 (m), 2877 (m), 1532 (s), 1442 (s), 1363 (m), 1283 (m), 1258 (s), 1120 (m), 1089 (s), 1034 (m), 944 (m), 806 (m), 738 (w), 664 (w). For relevant (VT) NMR data see Table A3. MS (ESI+), *m/z* (×10^5): 733.2 [M$^+$ + H] (7.5). Anal. calcd for $C_{32}H_{52}N_{12}O_8$ (732.40): C 52.45, H 7.15, N 22.94%; found: C 52.44, H 6.90, N 22.81%.

1,4-Bis{{6-[1-hydroxy-2-(hydroxymethyl)but-2-yl]amino}-4-(1,4-dioxa-8-azaspiro[4.5]decan-8-yl)-*s*-triazin-2-yl}-piperazine (**7b**) yield 1.2%; yellowish crystalline powder, mp 197.7–200 °C (flash column chromatography, eluent isopropanol – 25% aq ammonia, 9:1 *v/v*). R_f 0.90 (90% isopropanol – 25% aq ammonia). IR ν_{max} (KBr, cm^{-1}): 3393 (m), 2966 (m), 2884 (m), 1536 (s), 1494 (s), 1442 (s), 1363 (m), 1341 (m), 1284 (m), 1261 (s), 1154 (w), 1116 (m), 1088 (s), 1033 (m), 946 (m), 805 (m), 661 (w). For relevant (VT) NMR data see Table A3. MS (ESI+), *m/z* (×10^6): 761.3 [M$^+$ + H] (2.2). Anal. calcd for $C_{34}H_{56}N_{12}O_8$ (760.43): C 53.67, H 7.42, N 22.09%; found: C 53.92, H 7.11, N 21.85%.

(12) We note that in THF + 10% *v/v* H_2O, the complete replacement of chlorine to provide a melamine built entirely from 4-piperidone (**1c**) failed; difficult separable mixtures **1a** + **1b** + **1c** were constantly obtained.

(13) Full structural data, synthesis, and stereochemistry of the intermediates **3a**–**3c** are reported elsewhere (ref. 2c).

(14) Obviously, highly symmetric compound C_{2S} (**1a**) and C_{3S} (**1c** and **2b**) were unsuitable for the C(*s*-triazine)–N< (exocyclic) rotamerism monitoring, positions C-α vs C-α′ and C-β vs C-β′ being homotopic.

(15) This anisochrony covered but 14.5 Hz (500 MHz time scale) in each case. Hence, the hypothesis that it could originate from a geminal magnetic nonequivalnce, e.g., H-α-ax. vs H-α-eq. was ruled out.

(16) At room temperature, the stable N-sp^2 hybridization, for example, that of piperazine nitrogens connected to a much less π-deficient N,N′-disubstituted (e.g., diallyl) diamino-*s*-triazine ring, is already well-documented (refs. 9e and 9f) being supported both by VT NMR and X-ray data.

(17) Calculated as $\Delta\delta(\mathrm{NH}) = [\delta(\mathrm{NH})_{353\ \mathrm{K}} - \delta(\mathrm{NH})_{\mathrm{rt}}] < 0$; $\Delta T = (353 - T_{\mathrm{rt}}) > 0$ (K).

Abstract: Simple chiral proligands have been synthesized from inexpensive chiral starting materials. These amidate and ureate ligands support zirconium complexes that successfully catalyze intramolecular hydroamination with up to 26% ee. Several elements necessary for successful ligand design are highlighted and discussed. In particular, the strict control of metal geometry through multidentate tethered ligands is determined to be an essential aspect of future ligand development.

Key words: ureate, amidate, hydroamination, zirconium, enantioselective.

Résumé : On a réalisé la synthèse de proligands chiraux simples à partir de produits de départ chiraux peu coûteux. Ces ligands amidates et uréates supportent des complexes du zirconium qui peut catalyseur avec succès des hydroaminations intramoléculaires avec des excès d'énantiomère allant jusqu'à 26 %. On met en évidence et on discute de plusieurs éléments nécessaires au bon développement d'un ligand. En particulier, on a déterminé qu'un aspect essentiel du développement du futur ligand est le contrôle strict de la géométrie du métal par le biais de ligands multidentates bien fixés,

Mots-clés : uréate, amidate, hydroamination, zirconium, énantiosélective.

[Traduit par la Rédaction]

Introduction

Hydroamination, the addition of an N–H bond across unsaturated C–C bonds, has shown great promise for the efficient synthesis of amines.[1] Numerous systems exist for this highly desirable transformation, encompassing alkali and alkaline earth metal,[2] actinide[3] and lanthanide,[1c,2b] early[1d,2b,4] and late[5] transition-metal complexes, and main group metal systems.[6] In particular, group 4 catalysts are attractive because of their low toxicity, low cost, and improved stability over lanthanide complexes[1d] while exhibiting excellent reactivity comparable to late transition metals. *N*,*O*-Chelating amidate,[4a,7] pyridonate,[8] and ureate[4b] ligands for group 4 transition metals have been investigated by our group and others[9] for hydroamination. The proligand that induces the most promising scope of reactivity for both inter- and intra-molecular hydroamination is a tethered urea proligand for an easily synthesized zirconium complex (Fig. 1).[4b] This ureate precatalyst is the most generally useful group 4 metal complex reported to date, promoting reactions with both primary and secondary amine substrates, exhibiting vastly expanded substrate scope and functional group tolerance, as well as excellent chemoselectivity for hydroamination. The chemoselectivity is of particular interest, as other group 4 systems can be plagued with unwanted hydroaminoalkylation side reactions to give amine-substituted carbocycles rather than heterocyclic products.[10] The development of a chiral ligand system that imparts both the high activity and selectivity of the ureates and instills high enantioselectivity is of the utmost importance for the efficient synthesis of chiral amines. Thus, the synthesis of alternate urea proligands provides valuable understanding regarding the role of the urea functionality and the tether in the unprecedented reactivity accessed by such ureate zirconium complexes.

Many chiral catalysts have been explored recently for asymmetric hydroamination[2b,5a,9d,11] and group 4 transition-metal systems have been shown to be particularly efficient.[12,9a–9c] However, excellent enantioselectivities (>90%) have only been reported for a select number of catalyst–substrate combinations, in particular those that make use of axially chiral biphenyl/binaphthyl tethered ligands.[7c,13] While these contributions illustrate the potential power of such transformations, they are only a first step toward realizing the goal of a broadly applicable asymmetric alkene hydroamination catalyst. In an effort to better understand the limitations of such catalysts, we present here our recent investigations of simple untethered, chiral amide and urea proligands that can be rapidly assembled from inexpensive, enantiopure, and commercially available starting materials to generate bis(amidate or ureate)bis(amido) zirconium complexes (eq. [1]).

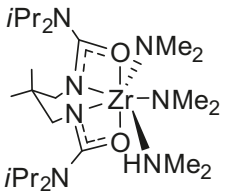
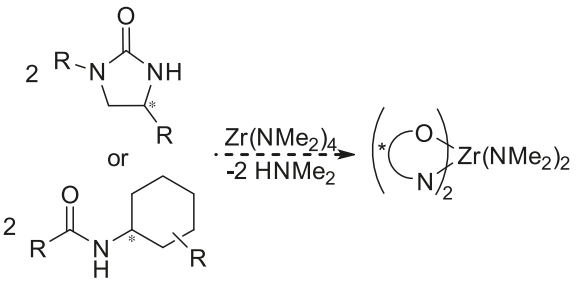
Fig. 1. Tethered bis(ureate) zirconium precatalyst for hydroamination.



[1]



Other untethered chiral ligands have been successful as alternatives for bidentate ligands in asymmetric transformations; in particular, chiral monodentate phosphoramidite ligands have proven to be remarkably effective.[14] This versatile class of untethered ligands has exhibited excellent levels of stereocontrol for a variety of asymmetric transformations including allylic substitutions, hydrovinylations, cycloadditions, and hydrogenation of a wide variety of substrates.[14b] The parent ligand (MonoPhos) is used industrially as a ligand in the rhodium-catalyzed hydrogenation of a cinnamic acid for the production of the renin inhibitor aliskiren.[15]

Here we report the facile synthesis of new chiral urea and amide proligands from commercially available and inexpensive chiral amino acids and amines. This study compares and contrasts the reactivity and selectivity of amidate versus ureate, cyclic versus acyclic, and tethered versus untethered ligands, and explores the use of untethered chiral ligands for affecting enantioselectivity. Through the characterization of the resultant coordination complexes in these systems we can identify critical features required for improved reactivity and selectivity.

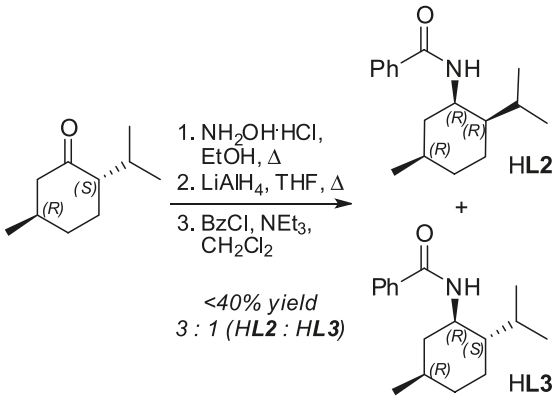
Results and discussion

Cyclic ureas, efficiently synthesized from the chiral pool of natural amino acid starting materials, are an attractive modular class of proligands for the generation of group 4 asymmetric hydroamination precatalysts. While cyclic ureas have been investigated for their medicinal properties,[16] examined for potential application as Lewis basic organocatalysts,[17] used as chiral auxiliaries for asymmetric syntheses,[18] and utilized as substrates for intermolecular hydroamination,[19] these compounds represent a new proligand motif for coordination of early transition metals. Zirconium alkyl and amido complexes supported by related achiral imidazolone ligands have recently been reported and have been shown to be effective catalysts for intramolecular hydroamination.[20]

The synthesis of proligand H**L1** proceeds in a straightforward manner, and produces H**L1** as a crystalline solid in five steps from L-valine (Scheme 1).[21] A solid-state molecular structure was obtained (see Supplementary data).

Simple chiral amide proligands can also be synthesized in minimal steps from any chiral ketone starting material[22] via reductive amination and subsequent derivatization with benzoyl chloride (eq. [2]). This modular synthetic route, like the route employed to synthesize the urea proligands, is attractive as a wide variety of proligands can be synthesized in a few steps from inexpensive starting materials. For the purpose of this investigation, (–)-menthone was chosen to synthesize chiral amide proligands.

[2]



Interestingly, upon isolation it was determined that the reaction produces a mixture of compounds (1*R*,2*R*,5*R*)-H**L2** and (1*R*,2*S*,5*R*)-H**L3** (eq. [2]). As determined by X-ray crystallography (see Supplementary data), the stereochemistry of these compounds is identical in the 5-position of the cyclohexyl ring as well as the stereogenic centre adjacent to nitrogen. However, epimerization occurred over the course of the reaction resulting in differing stereochemistry at the isopropyl position. The oxime formed in the initial step of the reaction may tautomerize to allow the observed epimerization at the 2-position. Compounds H**L2** and H**L3** can be separated by selective recrystallization.

These proligands are representative examples of a large class of readily accessed auxiliary ligands. The synthetic routes employed are modular and use inexpensive enantiopure starting materials such as amino acids or chiral ketones. Notably, the urea proligands employed here are cyclic and of a defined conformation, whereas the amide proligands have two possible conformations accessible (Fig. 2), which may impact metal chelation modes.[4a]

Using urea and amide proligands, a series of zirconium complexes can be easily synthesized by a simple protonolysis route from $Zr(NMe_2)_4$ (eq. [1]). Synthesis of the bis(ureate) bis(amido) zirconium complex **1** results in crude material having elemental analysis data consistent with the target complex. However, the complicated ^1H and ^{13}C NMR spectra for this compound suggest that multiple species are present in the solution phase. Synthesis of complex **2** using the amide proligand H**L2** proceeds in an analogous manner to generate an amorphous material having elemental analysis data consistent with that of the target complex. NMR spectral data are also notably complicated, presumably because of the presence of multiple isomers in solution. No free ligand remains in either case, as is evident by loss of the diagnostic amide

Scheme 1. Modular route for synthesis of urea proligand H**L1**.

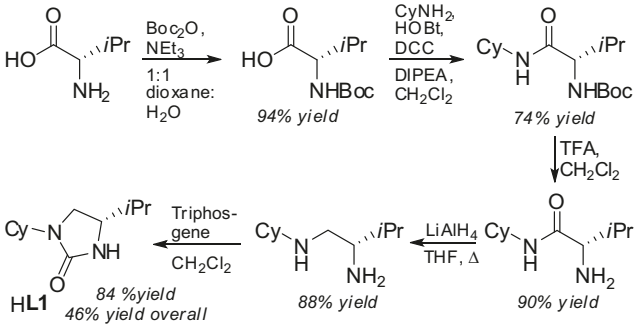


Fig. 2. Flexible cisoid and transoid configurations of amide versus rigid cyclic urea proligand.

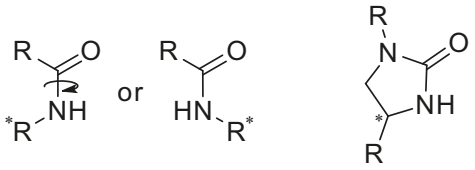

N–*H* signal at 7.18 ppm (H**L1**) and 6.15 ppm (H**L2**). Unfortunately, the product mixtures are resistant to recrystallization and high yielding crystalline material could not be obtained.

Although rigorous characterization of the resultant coordination complexes could not be achieved, the in situ prepared complexes are suitable for screening for hydroamination reactivity. Thus, the abilities of **L1**–**L3** ligated complexes to mediate enantioselective hydroamination were investigated for the cyclization of 2,2-diphenyl-1-amino-4-pentene, a standard test substrate (Table 1). The use of cyclic ureate **L1** in isolated complex **1** (Table 1, entry 1) and the in situ procedure (entry 2) generates the heterocyclic product in good yield with low enantioselectivity. The complex with amidate proligand **L2** was also tested and improved enantioselectivity is observed (entry 3). Lowering the reaction temperature does not improve the enantioselectivity (entry 4). The zirconium precatalyst with ligand **L3** showed comparable reactivity to complex **2**, but was unsuccessful in mediating enantioselectivity (entry 5). These results show that strict control of the geometry about the metal centre is required to control enantioselectivity for this reaction.

One of the exceptional elements of the tethered urea zirconium catalyst (Fig. 1), is the broadened substrate scope it displays compared with other existing group 4 catalyst systems.[4b] To discern if this improved scope of reactivity can be attributed to the urea functionality or to the tether, reactivity with a broader range of substrates was investigated using in situ prepared complex **1** (Table 2).[4b] The substrate scope using complexes prepared with proligand H**L1** is very limited; the reaction progresses in good yield to generate 5- and 6-membered heterocycles (Table 2, entries 1–5), however, no conversion to product is observed with secondary amines, internal olefins, and substrates without gem-disubstituents.

This limited reactivity profile is reminiscent of substrate scope limitations previously reported for $Zr(NMe_2)_4$ as a precatalyst for the intramolecular hydroamination of aminoalkenes.[23] We suggest that ligand redistribution could be occurring under catalytic conditions to generate $Zr(NMe_2)_4$ in solution, which could also act as a catalyst for the transformation resulting in the substrate scope limitations and poor enantioselectivities observed. Ligand redistribution and disproportionation has been observed previously with group 4 amidate systems[9b] and has been postulated to occur during the attempted synthesis of zirconium alkyl complexes supported by acyclic untethered ureate ligands.[24]

Indeed, in the only example of crystalline material obtained from a solution of complex **1**, an unexpected ligand stoichiometry (three ligands for two metal centres) is observed in the isolated product (Fig. 3). This suggests that ligand redistribution is a complicating factor under catalytic conditions and provides a rationale for both the poor ees and limited substrate scope observed. These crystals were obtained in very low yield over the course of a few weeks from a saturated pentane solution of the crude material cooled to –30 °C.

The isolated bimetallic complex has three bridging ureate ligands; the steric bulk of the ligand perhaps being insufficient to support monomeric species of the highly electrophilic metal centres. The dimeric nature of this species is not without precedent as the related zirconium imidazolone complexes reported[20] also assume dimeric solid-state structures with bridging imidazolone ligands. The isolated chiral compound is C_1 symmetric with pseudo-octahedral geometry about each zirconium atom. Selected bond lengths and angles for complex **4** (Fig. 3) are summarized in Table 3 and crystallographic parameters are summarized in Table 4. The C–N2,N4,N6 (1.317–1.325 Å) and C–O (1.271–1.290 Å) bond lengths of the metal-bound ureate fragments are consistent with moderate delocalization within the ureate backbone. The respective C–N bonds to the tertiary amine (N1,N3,N5, 1.361–1.368 Å) are slightly longer than those of the bonding moiety; however, these and the sum of 353° for the subtending angles are indicative of sp^2 hybridization and limited lone-pair donation to the π system. Interestingly, the Zr–N bonds to the ureate ligands (2.2372(9) and 2.2459(9) Å) are slightly shorter than those of the tethered ureate complex (2.279(1) Å),[4b] the exception being the Zr–N6 bond, which is presumably lengthened because of the presence of the strongly donating *trans*-dimethylamido ligand. Comparable bis(amidate)bis(amido) Zr–N(amidate) bonds are significantly longer (~2.32 Å).[25,12d] The Zr–O bond lengths in complex **4**, excluding those related to O1 (which is bridging two metal centres), are significantly shorter (by >0.1 Å), than those of related bis(amidate)bis(amido)[12e,25] and bis(ureate)bis(amido)[4b] zirconium complexes. Zr–NMe_2 (2.035–2.130 Å) bond lengths in complex **4** are slightly longer on average than Zr=N bonds reported in the literature (<2.043 Å).[25] Related tethered[12d] and untethered[25] bis(amidate)bis(amido) zirconium complexes have Zr–N(amido) bond lengths of 2.065–2.069 Å and 2.043(3) Å, respectively. The tethered bis(ureate)bis(amido)[4b] zirconium complex has Zr–NMe_2 bond lengths of 2.0292(2) Å.

Summary and conclusions

Easily prepared chiral ureate and amidate ligands can be efficiently assembled from inexpensive chiral ketones or amino acids. The in situ prepared complexes using untethered urea and amide proligands result in modestly enantioselective

cyclohydroamination reactions with reactivity reminiscent of $Zr(NMe_2)_4$, suggesting that ligand redistribution may be occurring. Despite the moderate reactivity and poor selectivity observed, these results provide important insights for advanced ligand design; improvements in the state of the art for these catalyst systems must take advantage of the enhanced stability and reactivity trends of tethered amidate and ureate ligands. The role of the tether is not restricted to control of geometry at the metal centre but also dramatically improves stability by reducing the propensity for ligand redistribution. The incorporation of these design principles in a catalyst system that demonstrates the unparalleled reactivity imparted by previously reported tethered proligands[4b] with chirality integrated from inexpensive starting materials such as chiral ketones or amino acids is presently under investigation and results will be reported in due course.

Materials and methods

Reaction materials and instrumentation

All reactions were preformed in oven-dried glassware under inert atmosphere conditions of dry nitrogen unless noted otherwise, using Schlenk line or glovebox techniques. Catalytic reactions were performed in Teflon-sealed J. Young tubes (5 mm). Toluene, pentanes, and hexanes, which were used as reaction solvents for catalyst preparation and recrystallization, were purified by passage over an activated aluminum oxide column and degassed prior to use. Dichloromethane was distilled from CaH_2 and degassed. d_8-Toluene was degassed and dried over activated 4 Å molecular sieves overnight before use. Reagents for substrate and proligand synthesis were purchased from commercial suppliers and used without further purification. $Zr(NMe_2)_4$ was purchased from Strem and used as received. 1,3,5-Trimethoxybenzene, used as an internal standard, was purchased from Sigma-Aldrich and purified by sublimation under reduced pressure. Flash chromatography was performed using SilicaFlash F60 silica gel (230–400 mesh). ^{1}H and ^{13}C NMR spectra were recorded on either a Bruker 300 MHz, 400 MHz Advance, or 600 MHz spectrometer at ambient temperature unless noted otherwise. Chemical shifts are reported in parts per million (ppm) relative to the corresponding residual solvent signal: chloroform ^{1}H 7.26 ppm, ^{13}C 77.0 ppm; benzene ^{1}H 7.16 ppm, ^{13}C 128.39 ppm; and toluene ^{1}H 2.09 ppm. Multiplicities are listed as s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and the coupling constants are given in Hz. Single crystal X-ray structure determinations and mass spectral and elemental analyses determinations were performed at the Department of Chemistry, University of British Columbia, Vancouver, British Columbia.

Synthesis of proligands HL1–HL3

(S)-1-Cyclohexyl-4-isopropylimidazolidin-2-one HL1

The precursor (*S*)-2-amino-*N*-cyclohexyl-3-methylbutanamide was prepared by the procedure described in the literature[26] from L-valine with cyclohexylamine substituted for *tert*-butyl amine and purified by recrystallization from ethyl acetate prior to N-Boc deprotection, which proceeded cleanly. (*S*)-*N*^{1}-Cyclohexyl-3-methylbutane-1,2-diamine was prepared through reduction with $LiAlH_4$ as described in the literature.[27] (*S*)-*N*^{1}-Cyclohexyl-3-methylbutane-1,2-diamine (2.62 g, 14.176 mmol) was dissolved in dry CH_2Cl_2 and the solution was cooled to 0 °C prior to addition of triphosgene (1.472 g, 4.962 mmol) in one portion. Pyridine (2.28 mL, 28.352 mmol) was added and the solution warmed to room temperature with stirring. After 3 h the solution was diluted with 1 mol/L HCl and the organic layer was collected. The aqueous layer was extracted with CH_2Cl_2 (3 × 50 mL) and the organic layers were combined, dried over $MgSO_4$, filtered, and concentrated. Pure (*S*)-1-cyclohexyl-4-isopropylimidazolidin-2-one was obtained as colourless needles in 84% yield by recrystallization from a minimal amount of CH_2Cl_2. ^{1}H (C_6D_6, 600 MHz) δ: 0.69 (2H, d, J = 6.78 Hz, –CH_3), 0.84–0.90 (4H, m, –CH_3, CH_2 of Cy), 1.04–1.19 (4H, m, CH_2 of Cy), 1.38–1.44 (2H, m, –CH (CH$_3$)$_2$, CH_2 of Cy), 1.54–1.68 (4H, m, CH_2 of Cy), 2.68 (1H, t, J = 7.68 Hz, –N(Cy)CH_2CH–), 2.96 (1H, t, J = 8.58 Hz,

–N(Cy)CH_2CH–), 3.03 (1H, q, J = 7.42 Hz, –NHC*H*–), 3.95 (1H, t, J = 11.3 Hz, C*H* of Cy), 7.18 (1H, s, –N*H*). ^{13}C (C_6D_6, 150 MHz) δ: 18.4 (*C*H$_3$), 18.9 (*C*H$_3$), 26.2 (*C*H$_2$), 26.3 (*C*H$_2$), 26.3 (*C*H$_2$), 30.4 (*C*H$_2$), 31.3 (*C*H$_2$), 34.0 (*C*H), 44.8 (*C*H$_2$), 51.3 (*C*H), 56.8 (*C*H), 162.7 (*C*). HRMS calcd for $C_{12}H_{22}N_2O$: 210.1733; found: 210.1732.

N-*((1*R*,2*R*,5*R*)-2-Isopropyl-5-methylcyclohexyl)-benzamide HL2 and* N-*((1*R*,2*S*,5*R*)-2-isopropyl-5-methylcyclohexyl)-benzamide HL3*

$NH_2OH{\cdot}HCl$ (2.11 g, 30.4 mmol), pyridine (2.50 mL, 30.9 mmol), and (–)-menthone (3.50 mL, 20.3 mmol) were dissolved in EtOH (30 mL) and the mixture was heated at reflux for 40 h. The crude reaction mixture was concentrated, dissolved in Et_2O (300 mL), washed successively with water (3 × 50 mL) and brine (50 mL), dried over Na_2SO_4, filtered, and concentrated. The crude oxime mixture was dissolved in THF (100 mL) and cooled to 0 °C prior to portionwise addition of $LiAlH_4$ (1.3 g, 34.3 mmol). The reaction mixture was heated at reflux for 40 h. After cooling the solution was quenched with sequential addition of water (1.5 mL), aqueous 1 mol/L NaOH (1.5 mL), Et_2O (100 mL), and water (4.5 mL). After stirring for 0.5 h, the mixture was filtered and the filtrate was dried over $MgSO_4$. Following concentration, dry CH_2Cl_2 (60 mL) was then added and the flask was cooled to 0 °C prior to addition of benzoyl chloride (2.60 mL, 22.6 mmol) and NEt_3 (8.0 mL, 57 mmol). After stirring for 20 h, the solution was diluted with CH_2Cl_2 (240 mL), washed successively with 1 mol/L HCl (3 × 50 mL), 1 mol/L NaOH (3 × 50 mL), water (50 mL), and brine (50 mL). The organic phase was then dried over $MgSO_4$, filtered, and concentrated. Column chromatography (18:1:1 hexanes–CH_2Cl_2–MeOH) afforded ~2 g of a mixture of crude H**L2** and H**L3** in a ratio of approximately 3:1 in favor of H**L2**. Repeated recrystallization from Et_2O afforded H**L2** as a pure compound and crystals suitable for X-ray crystallography. Repeated recrystallization from hexanes/CH_2Cl_2 (~4:1) of the residue afforded H**L3** as a pure compound and crystals suitable for X-ray crystallography.

Procedure for in situ hydroamination

Proligand H**L1** (15.8 mg, 0.075 mmol) and $Zr(NMe_2)_4$ were weighed into a small vial. d_8-Toluene (0.47 mL) and 1,3,5-trimethoxybenzene (0.03 mL of a 1.25 mol/L solution in d_8-toluene) were added and the solution shaken gently.[28] The hydroamination substrate was then added (0.375 mmol) and the solution transferred to a J. Young NMR tube. The solution was then heated at reaction temperature and reaction progress was monitored by ^{1}H NMR spectroscopy.

Supplementary data

Theoretical investigation of some *N*-nitrosodiphenylamine biological molecules — A natural bond orbital (NBO) study

Xiao-Hong Li, Rui-Zhou Zhang, and Xian-Zhou Zhang

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Xi'an Jiaotong University on 09/19/12
For personal use only.

Abstract: Theoretical study of several *N*-nitrosodiphenylamine biological molecules has been performed using quantum computational ab initio RHF and density functional B3LYP and B3PW91 methods with 6–311G++(d,p) basis set. Geometries obtained from density functional theory (DFT) calculations were used to perform Natural bond orbital (NBO) analysis. The p characters of two nitrogen natural hybrid orbitals (NHOs) $\sigma_{N3–N2}$ increase with increasing σ_p values of the substituents on the benzene, which results in a lengthening of the N3–N2 bond. The p characters of oxygen NHO $\sigma_{O1–N2}$ and nitrogen NHO $\sigma_{O1–N2}$ bond orbitals decrease with increasing σ_p values of the substituents on the benzene, which results in a shortening of the N2=O1 bond. It is also noted that decreased occupancy of the localized $\sigma_{N3–N2}$ orbital in the idealized Lewis structure, or increased occupancy of $\sigma^*_{N3-N2}$of the non-Lewis orbital, and their subsequent impact on molecular stability and geometry (bond lengths) are also related to the resulting p character of the corresponding nitrogen NHO of $\sigma_{N3–N2}$ bond orbital.

Key words: natural bond orbital (NBO), *N*-nitrosodiphenylamines, second-order delocalization energies, natural hybrid orbital (NHO).

Résumé : Faisant appel à des calculs quantiques selon la méthode ab initio de Hartree-Fock restreinte (HFR) et ceux des méthodes de la fonctionnelle de la densité B3LYP et B3PW91 avec un ensemble de base 6–311G++(d,p), on a effectué des études théoriques sur plusieurs molécules de *N*-nitrosodiphénylamines biologiquement actives. On a utilisé les géométries obtenues à l'aide de calculs de la fonctionnelle de la densité pour effectuer une analyse d'orbitales de liaison naturelle (OLN). Le caractère p des orbitales de liaison des deux atomes d'azote du NHO $\sigma_{N3–N2}$ augmente avec une augmentation des valeurs σ_p des substituants du benzène et il en résulte un allongement de la liaison N3–N2. Le caractère p des orbitales de liaison de l'oxygène NHO $\sigma_{O1–N2}$ et de l'azote NHO $\sigma_{O1–N2}$ diminue avec une augmentation des valeurs des substituants du benzène et il en résulte un raccourcissement de la liaison N2=O1. On a aussi noté qu'une diminution du taux de remplissage de l'orbitale localisée $\sigma_{N3–N2}$ dans la structure idéalisée de Lewis ou une augmentation du taux de remplissage de l'orbitale $\sigma^*_{N3–N2}$ de non-Lewis et leur impact subséquent sur la stabilité et la géométrie moléculaire (longueurs de liaison) sont aussi reliées au caractère p résultant de l'orbitale de liaison de l'orbitale hybride naturelle (OHN) de l'azote correspondant.

Mots-clés : orbitale de liaison naturelle (OLN), *N*-nitrosodiphénylamines, énergies de délocalisation du deuxième ordre, orbitale hybride naturelle (OHN).

[Traduit par la Rédaction]

Introduction

Nitric oxide (NO) is a simple intra- and inter-cellular signaling molecule playing important roles in many physiological processes.[1] Its biological functions include regulating the blood pressure, transmitting neurostimulation, and participating in the immune systems to kill tumor cells and intracellular parasites. Deficiency of nitric oxide leads to pathological and physiological complications in vivo. When the body cannot generate enough nitric oxide for normal physiological functions, exogenous supply of nitric oxide into the bloodstream in a sustained and controlled manner is essential. Many novel nitric oxide donors have been found to be useful in the treatment of various clinical conditions, particularly coronary artery diseases. So, it is noted that knowledge of NO donors and their analogues should be very important and urgently required for chemists and biochemists not only to thoroughly elucidate the detailed mechanism of NO transfer but also to scientifically design and synthesize suitable and desired nitric oxide releasing agents as NO drugs. As a unique class of such NO-carrying vehicles, *N*-nitrosodiphenylamines are generally believed to take a most active part in many biological functions of nitric oxide, especially in the processes of NO storage, transport, and delivery.[2]

N-nitrosodiphenylamines are interesting molecules in biology and medicine, which show vasodilation of veins and ar-

teries and inhibition of platelet aggregation through the release of NO.[2] The N–NO bonds are very weak, with an average bond dissociation energy of 28.3–33.1 kcal/mol[2], which is smaller than those of *N*-nitrosoacetanilides[3] and *N*-nitrosodiphenylamines[4] but bigger than those of *N*-nitrosophosphoramidates[2] and *N*-methyl-*N*-nitrosobenzenesulfonamides.[5] This indicates that the substituted *N*-nitrosodiphenylamines are the better NO donors among those types of NO donors.

Casado et al.[6] investigated the kinetic study of the denitrosation and hydrolysis reactions of *N*-nitrosophenylureas. Meijide et al.[7] reported that the O-nitroso compound undergoes rearrangement to *N*-nitrosophenylurea and obtained the ratio between the formation constants of benzenediazonium ion and *N*-nitrosophenylurea.

The use of *N*-nitrosodiphenylamines as NO donors in many chemical and biological reaction systems has also been recognized.[2,5] It is therefore believed that the quantitative measures of the N–NO bond information in the present study may serve as a guide for selecting efficient NO donor compounds and for a more insightful understanding of relevant NO-involving reactions.

A natural atomic orbital (NAO) is defined as a valence-shell atomic orbital derived from the diagonalization of the localized block of the full-density matrix of a given molecule, associated with basis functions χ_i(A) on that atom, and fulfilling the simultaneous requirement of ortho-normality and maximum occupancy. Although in an isolated atom, NAOs coincide simply with natural orbitals in polyatomic molecule (in contrast to natural orbitals that become delocalized over all nuclear centers); the NAOs mostly retain one-center character. Consequently, NAOs are considered optimal for describing the molecular electron density around one center in polyatomic molecules. Also, an NHO results from a symmetrically orthogonalized directed hybrid orbital derived through unitary transformation of NAO centered on a particular atom. Finally, according to the simple bond orbital picture, an NBO is defined as an orbital formed from NHOs. Therefore, for a localized σ-bond between atoms A and B, the NBO is defined as

$$[1] \qquad \sigma_{AB} = c_A h_A + c_B h_B$$

Where h_A and h_B are the natural hybrids centered on atoms A and B. So, the NBOs closely correspond to the picture of localized bonds and lone pairs as basic units of molecular structure, and therefore, it will be possible to conveniently interpret ab initio wave functions in terms of the classical Lewis structure concepts by transforming these functions to the NBO forms.[8]

In the NBO analysis,[8] to compute the span of the valence space, each valence bonding NBO (σ_{AB}) must in turn be paired with a corresponding valence antibonding NBO (σ^*_{AB}):

$$[2] \qquad \sigma^*_{AB} = c_A h_A + c_B h_B$$

Namely, the Lewis σ-type (donor) NBOs are complemented by the non-Lewis σ*-type (acceptor) NBOs that are formally empty in an idealized Lewis structure picture. Readily, the general transformation to NBOs leads to orbitals that are unoccupied in the formal Lewis structure. As a result, the filled NBOs of the natural Lewis structure are well-adapted to describe covalency effects in molecules. Since the non-covalent delocalization effects are associated with σ–σ* interactions between filled (donor) and unfilled (acceptor) orbitals, it is natural to describe them as being of donor–acceptor, charge transfer, or generalized "Lewis base – Lewis acid" type. The antibonds represent unused valence-shell capacity and spanning portions of the atomic valence space that are formally unsaturated by covalent bond formation. Weak occupancies of the valence antibonds signal irreducible departures from an idealized localized Lewis picture; i.e., true "delocalization effects".

As a result, in the NBO analysis, the donor–acceptor (bond–antibond) interactions are taken into consideration by examining all possible interactions between "filled" (donor) Lewis-type NBOs and "empty" (acceptor) non-Lewis NBOs and then estimating their energies by second-order perturbation theory. These interactions (or energetic stabilizations) are referred to as "delocalization" corrections to the zeroth-order natural Lewis structure.

Recently, we have reported the best method to compute the bond dissociation energies of the N–NO bond in *N*-nitrosodiphenylamines.[9] However, our literature survey shows that there are no published experimental or theoretical data on the structure of *N*-nitrosodiphenylamines. In addition, to the best of our knowledge, we have not seen any analysis of the nature of the bonding in *N*-nitrosodiphenylamines.

Density functional methods (especially B3P86 and B3PW91) are very reliable and economical theoretical methods to calculate molecular geometries, often give better results than the MP2 method,[10–15] thus offering an attractive alternative to study molecular structure. Csonka[16] thought that the introduction of the diffuse functions on heavy atoms is necessary for good results if B3LYP functional is used.

In the present work, we attempt to study the thermodynamic stabilities and bonding natures of a family of *N*-nitrosodiphenylamines by using RHF and density functional theory (DFT) at the B3LYP and B3PW91 levels of theory throughout with the 6–311G++(d,p) basis set implemented in the Gaussian03 program suite.[17] Geometries obtained from DFT calculations were then used to perform NBO analysis. Finally, the relative stabilities and the nature of the central bonds in some *N*-nitrosodiphenylamine compounds were systematically and quantitatively investigated by the NBO analysis method.

Computational methods

All geometry optimizations were fully carried out without any symmetry constraints using the RHF, B3LYP, and B3PW91 theoretical methods.[18–22] The quantum chemical

calculations were performed with 6–311G++(d,p) basis set implemented in Gaussian03 program.[21] The resulting geometries were then verified as minima by frequency calculations.

NBO analysis was then performed by the NBO 3.1 program[23] at the RHF, B3LYP, and B3PW91 levels of theory. The NBO analysis transforms the canonical delocalized Hartree–Fock (HF) MOs into localized orbitals that are closely tied to chemical bonding concepts. This process involves sequential transformation of non-orthogonal atomic orbitals (AOs) to the sets of natural atomic orbitals (NAOs), natural hybrid orbitals (NHOs), and NBOs. Each of these localized basis sets is complete and describes the wave functions in the most economic method, since electron density and other properties are described by the minimal amount of filled orbitals in the most rapidly convergent way. Filled NBOs describe the hypothetical, strictly localized Lewis structure. The interactions between filled and antibonding (or Rydberg) orbitals represent the deviation of the molecule from the Lewis structure and can be used as the measure of delocalization. This noncovalent bonding–antibonding interaction can be quantitatively described in terms of the NBO approach that is expressed by means of the second-order perturbation interaction energy ($E^{(2)}$).[24–27] This energy represents the estimate of the off-diagonal NBO Fock matrix elements. It can be deduced from the second-order perturbation approach[28]

$$[3] \qquad E^{(2)} = \Delta E_{ij} = q_i \frac{F(i,j)^2}{\varepsilon_j - \varepsilon_i}$$

where q_i is the ith donor orbital occupancy, ε_i and ε_j are diagonal elements (orbital energies), and $F(i, j)$ is the off-diagonal NBO Fock matrix element.

Results and discussion

Geometry optimization

The selected *N*-nitrosodiphenylamines are listed in Fig. 1. Some bond lengths and angles, calculated for the selected compounds at the RHF, B3LYP, and B3PW91 levels of theory, are reported in Table 1. 6–311G++(d,p) basis set is used.

From Table 1, it is noted that the two DFT methods used in this study result in very similar values for bond lengths and angles generally. However, their results are slightly different from those obtained by RHF method. The bond lengths calculated by RHF method are the shortest and the bond angles calculated are the largest for O_1–N_2–N_3 among the three computational methods. For the selected compounds, 4-NO_2–$C_6H_4N(C_6H_5)$–NO has the longest N_2–N_3 bond length, which is calculated by B3LYP method. 4-CH_3O–$C_6H_4N(C_6H_5)$–NO has the largest O_1–N_2–N_3 bond angle, which is calculated by RHF method. In addition, it is noted that 4-CH_3O–$C_6H_4N(C_6H_5)$–NO has the longest N_2–O_1 bond lengths, which is calculated by B3LYP method.

Interesting point observed in the selected molecules is the change of the bond length and angle with the σ_p values of the substituent on the benzene. The σ_p values[29] of OCH_3, CH_3, H, and NO_2 groups are –0.27, –0.17, 0.0, and 0.78, respectively. The experimental N_2–N_3 bond dissociation energies[30] for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO are 21.4, 21.4, 22.6, and 24.3 kcal/mol, respectively. It is noted that N_2–N_3 bond length increases with the augment of σ_p value, while N_2–O_1 bond length decreases with the augment of σ_p value. In addition, it is rather strange that the largest BDE corresponds to the longest N_2–N_3 bond. We think that for a diatomic molecule, the closer the nuclei of the bonding atoms are, a greater supply of energy is needed to separate the atoms. But for a bigger and complex molecule, BDE is controlled by the difference in ground-state and transition-structure free energies, so it is not sure that the shorter the bond length, the bigger the BDE.

Character of the natural hybrid orbital (NHO) on the selected compounds

In Table 2, we present the resulted natural atomic hybrids h_A on some atoms with the polarization coefficient c_A for each hybrid (in parentheses) in the corresponding NBO. The inspection of the results reported in Table 2 reveals that

- The p characters of two nitrogen NHO $\sigma_{N3–N2}$ bond orbitals increase with increasing σ_p value of the substituent on the benzene.
- The p characters of oxygen NHO $\sigma_{O1–N2}$ and nitrogen NHO $\sigma_{O1–N2}$ bond orbitals decrease with increasing $\sigma_p$value of the substituent on the benzene.
- The increasing p characters on two nitrogen NHO $\sigma_{N3–N2}$ bond orbitals result in a lengthening of the N_3–N_2 bond.
- The decreasing p characters on oxygen NHO $\sigma_{O1–N2}$ and nitrogen NHO $\sigma_{O1–N2}$ bond orbitals result in a shortening of the N_2=O_1 bond.
- Small and nearly equal values of the calculated d contribution of N_2 and N_3 atoms show that 3d orbitals have little importance in bonding of the *N*-nitrosodiphenylamines.

Natural bond orbital[8] (NBO) analysis shows that there is a strong hyperconjugative interaction $n_{O1} \rightarrow \sigma^*_{N3–N2}$ in the compounds studied (Table 3). For example, the second-order energy ($E^{(2)}$) for 4-H–$C_6H_4N(C_6H_5)$–NO is 25.37 kcal/mol at B3LYP level. This interaction weakens the N_2–N_3 sigma bond and elongates the N_3–N_2 bond length in *N*-nitrosodiphenylamines. In

addition, it is found that these compounds are characterized by a very strong $n_{N3} \rightarrow \sigma^*_{N2=O1}$ delocalization, which induces partial π character.

From Table 3, it is also noted that $E^{(2)}$ increases with increasing σ_p value of the substituent on the benzene, which results in a lengthening of the N_3–N_2 bond. The second-order delocalization energies for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO at B3LYP level are 24.43, 25.22, 25.37, and 30.11 kcal/mol, respectively, and the N_3–N_2 bond lengths are 1.378, 1.383, 1.384, and 1.396 Å, respectively. The above analysis indicates that the weakness in the N_2–N_3 sigma bond is due to $n_{O1} \rightarrow \sigma^*_{N3-N2}$ delocalization and is responsible for the longer N_3–N_2 bond and hence contributing to the nitro oxide releasing ability in *N*-nitrosodiphenylamines, though the N_3–N_2 bond has partial double-bond character.

The experimental N_2–N_3 bond dissociation energies [30] for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO are 21.4, 21.4, 22.6, and 24.3 kcal/mol, respectively. These values are very small compared with a simple C–C single bond dissociation energy (~70 kcal/mol) suggesting the weakness of the N_2–N_3 bond. This can be attributed to the $n_{O1} \rightarrow \sigma^*_{N3-N2}$ interaction, which weakens the N_2–N_3 bond.

To confirm that the hyperconjugation is indeed responsible for the N_2–N_3 bond weakening, calculations have been carried out on isoelectronic isomers of 4-H–$C_6H_4N(C_6H_5)$–NX (X = O, NH, or CH_2). The bond dissociation energies for the three compounds at B3LYP/6–311G++(d,p) level are 27.64, 31.05, and 37.48 kcal/mol, respectively. The hyperconjugation interactions due to the lone pair on X are 25.37, 16.02 kcal/mol, and negligible, respectively (Table 4). The gradual increase in the N–N bond dissociation energies with a decrease in the hyperconjugative interactions clearly suggests that there is a direct correlation between hyperconjugation and bond dissociation energy in these systems and show the importance of this interaction in *N*-nitrosodiphenylamines.

Donor–acceptor (bond–antibond) interactions

The most important interaction between "filled" (donor) Lewis-type NBOs and "empty" (acceptor) non-Lewis NBOs is reported in Table 5. The results of NBO analysis collected in Table 5 show that the lp(N_3) (lp: lone pair) participates as donor and the BD*(O_1–N_2) antibond acts as acceptor [lp (N3)→ BD*(O_1–N_2)], with charge transfer energy values as: 64.62, 64.05, 63.95, and 56.37 kcal/mol for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO at B3LYP level, respectively. This shows that the charge transfer energy decreases with the increasing σ_p value of the substituent on the benzene. This interaction is the most important interaction in the *N*-nitrosodiphenylamine compounds. The amount of destabilization energy calculated within the NBO approach does slightly differ in the compounds examined; thus, it can be inferred that the strength of the N–NO bond only changes slightly in the different compounds, which is consistent with our calculated results[9] and the experimental results.[30]

Table 6 shows calculated natural orbital occupancy (number of electron, or "natural population" of the orbital). It is noted that for σ_{N3-N2} bond orbital, maximum occupancy is

Table 5. The second-order perturbation energies $E^{(2)}$ (kcal/mol) corresponding to the most important charge transfer interactions (donor–acceptor) in the compounds studied by using B3LYP/6–311G++(d,p) method.

		$E^{(2)}$ (kcal/mol)			
Donor NBO	Acceptor NBO	4-CH_3O–$C_6H_4N(C_6H_5)$–NO	4-CH_3–$C_6H_4N(C_6H_5)$–NO	4-H–$C_6H_4N(C_6H_5)$–NO	4-NO_2–$C_6H_4N(C_6H_5)$–NO
lpN_3[a]	BD*(O_1–N_2)	64.62	64.05	63.95	56.37
lpN_2	BD*(C_5–N_3)	9.01	9.70	9.62	8.40
lp O_1	BD*(N_3–C_4)	0.65	0.67	0.87	0.62

[a]lp stands for lone pair.

Table 6. The important calculated valence non-Lewis and Rydberg non-Lewis σ_{N3-N2} and $\sigma N3 = -N2*$ bond orbital occupancies at B3LYP/6–311G++(d,p)

0.00719	0.01037	0.01003	0.00661	
σ^*_{N3-N2}	0.09039	0.09698	0.09752	0.10083
Valence non-Lewis	3.18464	3.00741	2.95229	3.91897
Rydberg non-Lewis	0.23785	0.23007	0.21924	1.81999

obtained for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO (1.98881); for σ^*_{N3-N2} bond orbital, the maximum occupancy is obtained for 4-NO_2–$C_6H_4N(C_6H_5)$–NO (0.10083). As we described above, small occupancies of the antibond orbitals correspond, in Hartree–Fock theory, to irreducible departure from the idealized Lewis picture, and thus to small non-covalent corrections to the picture of localized covalent bonds.

Decreased occupancy of the localized σ_{N3-N2} orbital in the idealized Lewis structure, or increased occupancy of $\sigma^*_{N3-N2}$of the non-Lewis orbital, and their subsequent impact on molecular stability and geometry (bond lengths) are also related to the resulting p character of the corresponding nitrogen natural hybrid orbital (NHO) of σ_{N3-N2} bond orbital. In Table 2, for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO at B3LYP level, the p characters of N_2 σ_{N3-N2} in selected compounds are 3.38, 3.41, 3.47, and 3.66, respectively, while the σ_{N3-N2} bond orbital occupancies are 1.98881, 1.98657, 1.98657, and 1.98809, respectively. Similarly, the N_3–N_2 bond lengths are 1.378, 1.383, 1.384, 1.396 Å, respectively, while N_2–O_1 bond lengths are 1.209, 1.205, 1.204, 1.201 Å, respectively. Therefore, the results suggest that the N_3–N_2 bond lengths of these compounds are essentially controlled by the p character of these hybrid orbitals and also by the nature of the N_3–N_2 bond.

Conclusion

According to our results, the following conclusions can be obtained for the selected *N*-nitrosodiphenylamine compounds:

1. For the selected compounds, N_2–N_3 bond length increases with the augment of σ_p value, while N_2–O_1 bond length decreases with the augment of σ_p value.
2. The p characters of two nitrogen NHO σ_{N3-N2} bond orbitals increase with increasing σ_p value of the substituent on the benzene, which results in a lengthening of the N_3–N_2 bond. The p characters of oxygen NHO σ_{O1-N2} and nitrogen NHO σ_{O3-N2} bond orbital decrease with increasing σ_p value of the substituent on the benzene, which results in a shortening of the N_2=O_1 bond.
3. There is a strong hyperconjugative interaction $n_{O1} \rightarrow \sigma^*_{N3-N2}$ in the compounds studied; this interaction weakens the N_2–N_3 sigma bond and elongates the N_3–N_2 bond length in *N*-nitrosodiphenylamines. The weakness in the N_2–N_3 sigma bond is due to $n_{O1} \rightarrow \sigma^*_{N3-N2}$ delocalization and is responsible for the longer N_3–N_2 bond length, and hence contributing to the nitro oxide releasing ability in *N*-nitrosodiphenylamines, though the N_3–N_2 bond has partial double-bond character.
4. lp(N_3) participates as donor and the BD*(O_1–N_2) antibond acts as acceptor [lp(N_3)→ BD*(O_1–N_2)] with charge transfer energy values as: 64.62, 64.05, 63.95, and 56.37 kcal/mol for 4-CH_3O–$C_6H_4N(C_6H_5)$–NO, 4-CH_3–$C_6H_4N(C_6H_5)$–NO, 4-H–$C_6H_4N(C_6H_5)$–NO, and 4-NO_2–$C_6H_4N(C_6H_5)$–NO at B3LYP level, respectively, which shows that the charge transfer energy decreases with the increasing σ_p value of the substituent on the benzene.

Novel bipodal, tripodal, and tetrapodal 1,4-dihydropyridines — Microwave-assisted synthesis and structural confinements

Kancherla Rajesh, Bandapalli Palakshi Reddy, and Vijayaparthasarathi Vijayakumar

Abstract: The one pot, three component reaction of *p*-hydroxy benzaldehyde, β-ketoester, and ammonium acetate afforded the corresponding monopodal 1,4-dihydropyridines as building blocks, which in turn converted into diversified novel bipodal, tripodal, and tetrapodal 1,4-dihydropyridines with different alkylating agents through conventional as well as microwave assisted reactions. The unambiguous structural confinements of the all the synthesized compounds were drawn out with the help of 2D NMR (H-H COSY and C-H COSY).

Key words: bipodal-tripodal-tetrapodal 1,4-dihydropyridines, Hantzsch pyridines, microwave irradiation.

Résumé : La réaction monotope, à trois composants, du *p*-hydroxybenzaldéhyde, d′un β-cétoester et de l′acétate d′ammonium conduit aux 1,4-dihydropyridines correspondantes, des synthons monopodes qui, par le biais de réactions normales ou assistées par des microondes, peuvent être transformées à leur tour en nouvelles 1,4-dihydropyridines bipodes, tripodes et tétrapodes portant divers agents alkylants. Les confinements structuraux non ambiguës de tous les composés synthétisés ont été délimités à l′aide de la RMN 2D (COSY H-H et COSY C-H).

Mots-clés : 1,4-dihydropyridines bipodes, tripodes ou tétrapodes, pyridines de Hantzsch, irradiation microonde.

[Traduit par la Rédaction]

Introduction

The synthesis of 1,4-dihydropyridines (1,4-DHPs) via a three-component cyclocondensation reaction of acetoacetic ester, arylaldehyde, and ammonia was first reported by Arthur Hantzsch in 1882.[1] Since then a lot of new variants of the original method have been developed, allowing the synthesis of different substituted 1,4-DHPs, which have now been recognized as vital drugs in the treatment of angina and hypertension. Some of the representatives like nifedipine,[2] felodipine,[3] nicardipine,[4] amlodipine,[5] and manidipine hydrochloride (Fig. 1), have been commercialized and have proven their pharmaceutical action in binding to the voltage dependent L-type calcium channel, thus decreasing the passage of calcium ions into the cell. The result is the relaxation of smooth muscle cells and the lowering of blood pressure.

Studies revealed that 1,4-DHPs exhibit several other medicinal applications, which include neuroprotectant[6] and platelet antiaggregatory activity,[7] in addition to acting as a cerebral anti-ischemic agent in the treatment of Alzheimer's disease[8] and as a chemosensitizer in tumor therapy.[9] The examples clearly demonstrate the potential of novel DHP derivatives as a source of valuable drug candidates. A recent computational analysis of the compressive medicinal chemistry database found that the DHP framework to be among the most prolific chemo-types. Thus, the synthesis of molecules containing this heterocyclic nucleus with diverse properties and applications has been of continuing interest, which led to the development of novel synthetic strategies. So far the attention has mainly been paid to the synthesis of monopodal 1,4-DHP derivatives, and the highly functional ones are seldom investigated. A series of *bis*-1,4-DHP derivatives was synthesized by Songlei Zhu et al. by the reaction of *p*-phenylenedialdehyde or *m*-phenylenedialdehyde and active methylene compounds.[10] Mohammad Ali Zolfigol et al. synthesized new tripodal 1,4-DHPs under solvent-free conditions by the reaction of a mixture of β-ketoester and tri-aldehydes in the presence of ammonium fluoride.[11] Although the methods described above have been beneficial in the specific examples for which they were developed, they do not show much scope for the synthesis of varyingly substituted bipodal, tripodal, and tetrapodal 1,4-DHPs, where synthesis by the former methods requires bis, tris, and tetra aldehydes, which is a costlier approach and not applicable in some cases. A retro synthetic analysis approach (Scheme 1) for target bipodal 1,4-DHPs has shown that the simple monopodal 1,4-DHPs can serve as building blocks for the construction of the target molecules.

The synthesis of monopodal 1,4-DHP building blocks involves one-pot multicomponent coupling reactions (MCRs), where several organic moieties coupled in one step for carbon–carbon and carbon–heteroatom bond formation, which is an attractive synthetic strategy for the synthesis of small molecule libraries with several degrees of structural diver-

sities.[12–14] The synthesis mainly involves the dehydration of arylaldehydes, β-ketoester or diketone, and ammonium acetate.

The present work describes a direct approach, where the monofunctional 1,4-DHPs, thus synthesized according to the literature,[15,16] serve as building blocks for the construction of novel bipodal, tripodal, and tetrapodal 1,4-DHPs by the conventional methods and by microwave irradiation, which is hitherto unreported in the literature, and all the results were best executed. The structural correlation of the synthesized bipodal 1,4-DHP **13** with nifedipine (vital drug in treatment of angina and hypertension) can be seen in Fig. 2.

Results and discussion

As part of the continuing interest in the synthesis of 1,4-DHP nucleus[17–20] and heterocyclic compounds bearing bipodal and tripodal moieties,[21–23] we synthesized novel bipodal, tripodal, and tetrapodal 1,4-DHPs by the reaction of monofunctional 1,4-DHP (**4, 5**) with different alkylating agents by using powdered K_2CO_3 as mild base (Schemes 2–6).

The two possible retro synthetic analysis approaches, Path-A and Path-B for bipodal 1,4-DHPs, are given in Scheme 1. In case of Path-A, as a part of a first step, the desired 1,4-DHPs (**4, 5**) have to be synthesized, which may then be reacted with di-bromo, tri-bromo, or tetra-bromo benzenes to give the desired polypodals by using a mild base. Alternatively, this can also be achieved via Path-B, where bis, tris, and tetrakis aldehydes have to be synthesized in a first step using di-bromo, tri-bromo, or tetra-bromo benzenes with *p*-hydroxybenzaldehyde, which can further be reacted with β-ketoester and ammonium acetate to give the desired polypodals, but large amounts of di-bromo, tri-bromo, and tetra-bromo benzenes are needed to carry out the first step, which is a costlier approach. So, Path-A was chosen for convenience, where a mixture of *p*-hydroxy benzaldehyde, β-ketoester, and ammonium acetate in ethanol were heated to give the desired 1,4-DHPs (**4, 5**) in a first step (Table 1). The structure of the products **4** and **5** have been characterized using ^{1}H NMR and HRMS data. The melting point, retention factor, R_f (the retention factor value of the synthesized sample was compared with that of the sample commercially sourced from Sigma-Aldrich), and spectral data were found to be in accord with the literature.[15,16]

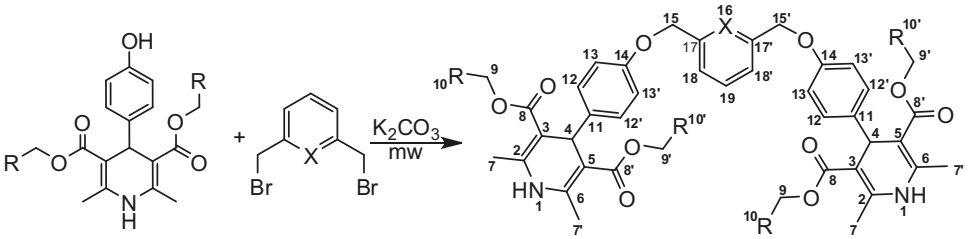
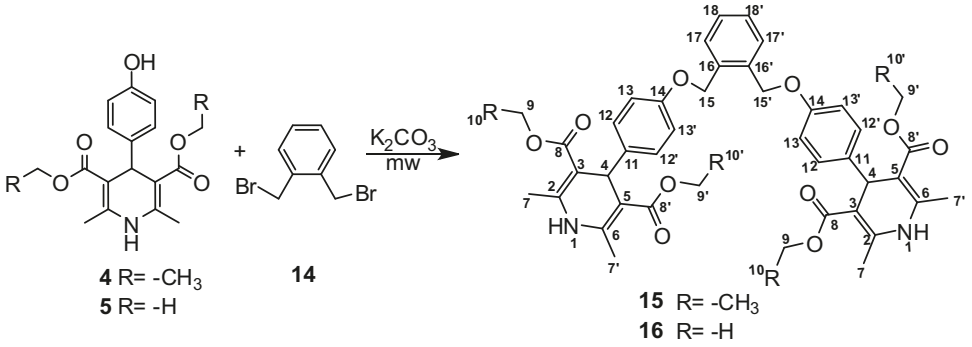
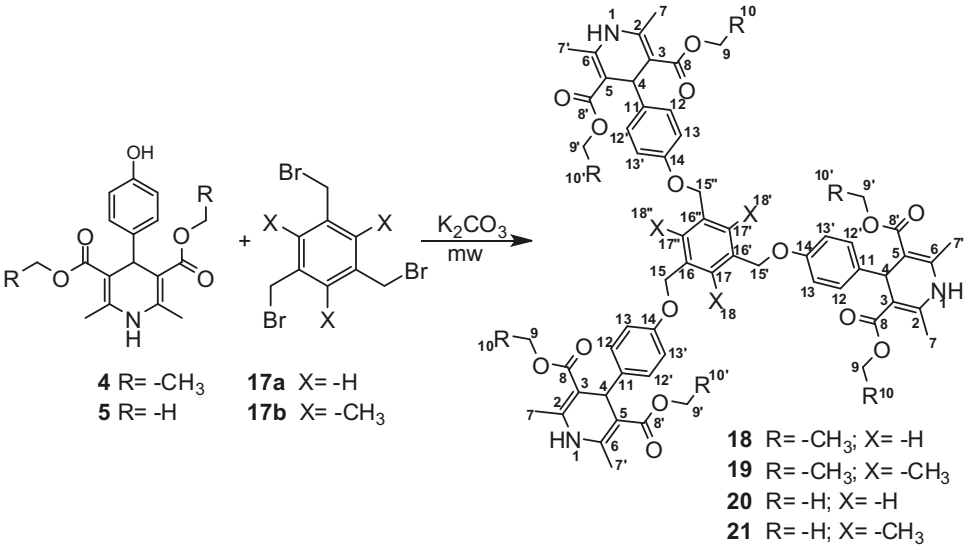
Scheme 3. Synthetic scheme for bipodal *m*-substituted 1,4-DHPs **10–13**.



Scheme 4. Synthetic scheme for bipodal *o*-substituted 1,4-DHPs **15–16**.



Scheme 5. Synthetic scheme for tripodal 1,4-DHPs **18–21**.



The compounds **4, 5** were converted into the desired polypodals by reacting it with di-bromo, tri-bromo, and tetra-bromo benzenes using powdered K_2CO_3/Na_2CO_3 as mild base. Initially the reaction was carried by using sodium hydride/THF, which promoted the reaction but with lowered yields (Method-A). This is because of the strong basic nature of NaH, which allows the maximum reactivity of –OH, –NH, and esters over 1,4-DHP towards **6**, resulting in undesired side products, which in turn effect the yield of the final product. This led us to quantitatively investigate an efficient approach to synthesize **7** and its derivatives. The use of powdered Na_2CO_3 or K_2CO_3 in DMF at controlled temperature (60 °C) lead to the formation of **7** and its subsequent derivatives very smoothly.

In the case of ethoxy substituent, a maximum yield of 67% was achieved for the bipodal para isomer **7**, and the other two meta substituted bipodal molecules **10** and **11** showed closely adjusted yields of 19% and 67%, respectively (Table 2). A yield of 10% was achieved for bipodal ortho isomer **15**, whereas the tripodal **18** and **19** showed yields of 67% and 50%, respectively. A yield of 49% was achieved for tetrapodal **23**. In the case of methoxy substituent, a maximum yield of 72% was achieved for the bipodal para isomer **8**, and the other two meta substituted bipodal molecules **12** and **13**

Scheme 6. Synthetic scheme for tetrapodal 1,4-DHPs **23–24**.

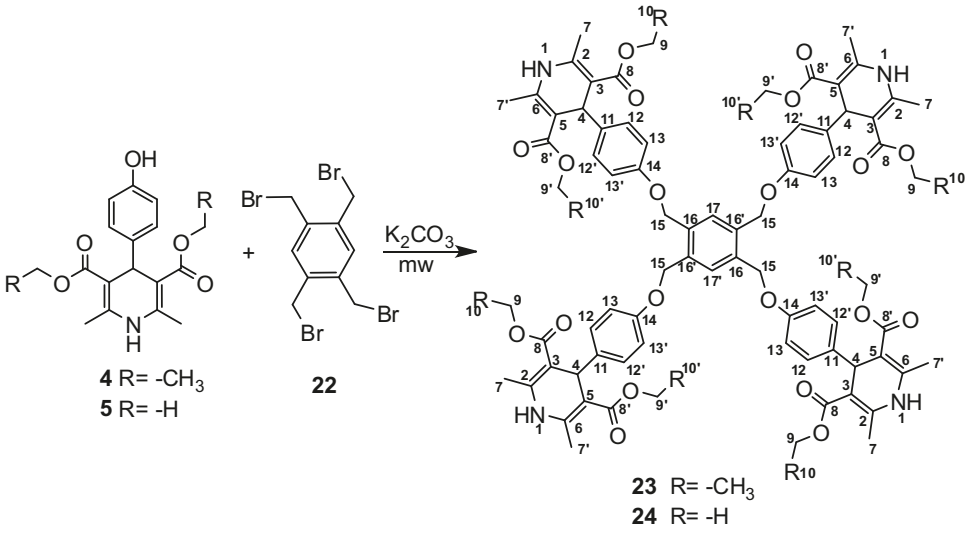

Table 1. Reaction of *p*-hydroxybenzaldehyde, ammonium acetate and β-ketoester leading to monopodal 1,4-DHPs.

				Mp (°C)	
Entry	Aldehyde	Ester	Product	Found	Reported
1			 **4**	228–230	230–232[17]
2			 **5**	230–232	231–233[18]

showed closely adjusted yields of 64% and 59%, respectively. A yield of 52% was achieved for the bipodal ortho isomer **16**, whereas tripodal **20** and **21** showed 69% and 63% yield, respectively. A yield of 54% was achieved for tetrapodal **24**. The marked differentiation in yields was expected because of a high steric hindrance over the molecule, especially for **10** and **15**. Better results were observed in powdered Na_2CO_3 or K_2CO_3 over the granular forms because of the larger surface area, which allows maximum reactivity of the alkylating agent towards hetero atoms.

The reaction was expected to proceed via a S_N2 mechanism. The use of elevated temperatures may produce higher impurity levels, which is consistent with the carbocation mechanism. The stronger activation may result in faster generation of carbocation and has a propensity to undergo side reactions. Thus, we are confined to carry the reactions under controlled temperatures, typically at 60 °C using K_2CO_3 as mild base. Rather than changing the base and reaction temperature, we thought to change the methodology. Microwave-assisted synthesis of bipodal, tripodal, and tetrapodal 1,4-DHPs were also carried out to produce the reaction with better yield. Microwave irradiation of a mixture of diethyl or dimethyl 4-(4-hydroxyphenyl)-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate, alkylating agent, powdered K_2CO_3, and 5 to 6 drops of DMF, at 30% power, was applied for 12 min (six pulses each of 2 min), resulting in product formation with good purity and yield (Table 2). The synthesized compounds were subjected to LC-MS as crude to find the presence of mono-substituted products instead of bis, tris, and tetrakis substitutions. But it was very clear that the mono-substituted compounds were not found, and the unambiguous structural confinements for the synthesized compounds were drawn out with the help of 2D NMR (H-H COSY and C-H COSY).

Conclusion

In conclusion, the mono functional 1,4-DHPs served as building blocks for the construction of novel bipodal, tripodal, and tetrapodal 1,4-DHPs by conventional method and by
