## Abstract

The effect of using low-molecular-weight chitosan (LWCS) for anti-creasing treatments of cotton fabric was studied. The LWCS was mixed with dimethylol dihydroxyl ethylene urea (DMDHEU) to form the finishing agent. The addition of LWCS increased the tensile strength retention (TSR) and creasing resistance of the treated fabrics. The yellowing index and the softness of the treated fabrics became worse when the LWCS molecular weight decreased and the concentration as well as the curing temperature increased. The anti-wrinkle properties of all processed fabrics decreased markedly after washing 20 times. However, the softness of the fabric improved and the strength decreased slightly after the wash treatment.

## 1. Introduction

Since cotton fibers contain large amounts of hydroxyl groups they are highly hydrophilic. In addition, the fiber crystallization is low, so that when cotton fibers absorb water, the bonding force among cellulose molecules is reduced markedly, which causes swelling. Therefore, when cotton fabrics are twisted or rubbed when being washed or worn, the cellulose macromolecules shift and undergo plastic deformation. Consequently, the fabric shrinks and wrinkles. The primary method of minimizing creases in cotton fabrics when washed or worn is to use appropriate agents to cross-link the cellulose molecules in the fiber. This prevents the relative displacement of the cellulose molecules in cotton fibers when washed or worn. Crease resistance results from increasing the elasticity of the fibers (Mark, Wooding, & Atlas, 1971).

Chitin that is more than 55% deacetylated is called chitosan, which is a natural polymer. Chitosan has a high molecular weight, usually on the order of tens of thousands

or even millions of kDa. Chitin has inter- and intramolecular hydrogen bonding which makes it chemically stable and of low water solubility. Chitosan is soluble only in certain dilute acid solutions which limits its wider use. Chitosan can be hydrolyzed into low molecular weight oligosaccharides. Oligosaccharides have some unique properties compared to chitosan such as microorganism resistance, absorption of anionic dyes, tumor growth inhibition, and cholesterol and blood lipid reduction (Zhao, Zhang, & Zeng, 2003). The molecular structure of chitosan is similar to that of cellulose. Chitosan can be applied as a cotton finish to produce fabrics with properties similar to cellulose fabrics (Yu, 1997). This has become an area of increased research interest.

Current methods for preparing oligosaccharides typically include degradation by acids, yeasts, oxidation and other degradation methods such as irradiation using microwaves and ultrasound. Chitosan hydrolyzes in acidic solutions where the acid acts as a catalyst. The acids typically used to degrade chitosan are either HCl (Hawkins & Davies, 1996) or H<sub>2</sub>SO<sub>4</sub> (Maksumov, Denisov, & Makarov, 1990; Nagasawa, Tohica, Inoue, & Tanoura, 1971). Acid catalyzed degradation of chitosan is simple, but the yield is low, the molecular weight distribution of the end

product is difficult to control, and the separation process is complex. Furthermore, acid degradation of chitosan creates environmental pollution which discourages industrial use. The yeast degradation method uses chitosan-degrading yeast to prepare oligosaccharides. It is carried out in a milder environment, with no other reagents required, so there are no side effects and little pollution as a result. In addition, it is easy to control the degradation progress and the molecular weight distribution of the end product, although this method is expensive and the technology is still primitive, which are obstacles to its application. Oxidization degradation is the most-studied method; it causes rapid degradation and is a simple, inexpensive process with no toxic residues. The primary reagents include  $\text{H}_2\text{O}_2$  (Chang, Tai, & Cheng, 2001; Fang, Sun, Salisbury, Fowler, & Tomkinson, 1999; Kabal'nova et al., 2001; Takeshi & Tsugio, 1996) and nitride (Yang, Liu, & Guan, 1999); the former is the most common. Other methods of applying an external field can be applied. For example, Li, Liu, and Hsu (2001) reported that  $\gamma$ -rays can degrade chitosan, and that the relative molecular mass drops from 27,140,000 to 2,140,000 kDa, although the disadvantage is that some cross-linking and side-chain reactions occur.

In this study, we used  $\text{H}_2\text{O}_2$  to degrade chitosan to low-molecular-weight chitosan (LWCS), which was then mixed with an anti-creasing agent to produce the finishing agent, and then applied in the anti-creasing treatment of cotton fabrics. We discuss the influence of LWCS incorporation on the properties of the treated fabrics.

## 2. Experiment

### 2.1. Materials

Ethanol, HCl,  $\text{H}_2\text{O}_2$ , and  $\text{MgCl}_2$ , sodium lauryl sulfate all reagent class, were purchased from Shimaku Medicine (Japan). Dimethylol dihydroxyl ethylene urea (DMDHEU; solids 30%) was obtained from Taiwan Cyanamid (Taipei, Taiwan), and chitosan (85% deacetylated) was obtained from Taiwan Kaohsiung Applied Chemistry (Kaohsiung, Taiwan). The cotton fabrics (from Yi Hwa Textile, Tainan, Taiwan), 40 s  $\times$  40 s ends (100), and picks (80), were desized, scoured, and bleached. A non-ionic type softening agent (Ablusoft NB-150) was purchased from Taiwan Surfactant Company (Taiwan).

### 2.2. Methods

#### 2.2.1. Preparation of LWCS

Two grams of chitosan were dissolved in 100 ml 0.1 M HCl and stirred for 30 min. Then,  $\text{H}_2\text{O}_2$  was added in one of five concentrations (5%, 7.5%, 10%, 12.5%, or 15%). The mixture was heated and stirred at 60 °C for 2 h and then vacuum filtered. The upper residue was neutralized with distilled water, baked, and weighed. Ethanol was added to the lower solution, which was left for 24 h

to precipitate, after which it was filtered, dried, and weighed. This gave low-molecular-weight water-soluble chitosans denoted by C5, C7.5, C10, C12.5, and C15.

#### 2.2.2. Application of LWCS

LWCS of different molecular weights (C5, C10, and C15) was added to 10 ml of distilled water and stirred for 15 min to allow it to dissolve completely. Then, 8 g DMDHEU, 0.8 g  $\text{MgCl}_2$ , and 3 ml softener were added and the solution was stirred for 15 min. Finally, distilled water was added to the beaker until the volume totaled 100 ml. Cotton fabric (20  $\times$  24 cm) was immersed in the finishing solution using a 'two-dips two-nips method', and was shaken in an ultrasonic shaker. The immersed white cloth was press-absorbed (pick-up = 80%), predried for 5 min at 80 °C, cured at various temperatures (130, 140, and 150 °C), rinsed and dried, and then wrapped in a polyethylene (PE) bag and stored for later analysis.

#### 2.2.3. Analysis of the LWCS and treated fabrics

Fourier transform infrared/attenuated total reflectance (FT-IR/ATR) spectra of the LWCS were recorded with a Digilab FTS-200 spectrometer (Bio-Rad, Hercules, CA, USA) using an MCT detector. A diamond crystal was used as the internal reflectance element. Single beam spectra were obtained from 64 scans, and the spectral resolution was 4  $\text{cm}^{-1}$ . Detection of the  $^1\text{H}$  NMR chemical shift of LWCS was tested using an AMX-400 L NMR analyzer (Bruker, Berlin, Germany). A Bruker AXS D8 was used for X-ray powder diffraction (parallel beam optics, Cu target, scintillation counter, sampler changer with rotation). The samples were run at 40 kV, 100 mA, 2–60°  $2\theta$ , 0.01° step size, and 5 s counting time. The viscosity and molecular weight of the LWCS were measured as follows: viscosity was measured at 25 °C with a Wurtz viscometer based on a 1 g/L sample in 0.1 M acetic acid and 0.2 M NaCl. The molecular weight was calculated from the Mark–Houwink equation,  $[\eta] = K[\text{Mv}]^\alpha$ , where  $K = 1.81 \times 10^{-3} \text{ cm}^3/\text{g}$ ,  $\alpha = 0.93$  (Zhao et al., 2003). Element analysis of the LWCS was measured with a Vario EL III analyzer (Elementar, Hanau, Germany). The anti-creasing angle of dried treated fabrics was measured using the ASTM D1295-61 Monsanto method; mechanical performance was tested with an Alphen 400 tensile tester according to the ASTM 370 standard, and the softness and yellowing index were examined with an INTECO softness tester with a 45° tilted workbench and Nippon ND 300A spectrophotometer (Nippon Denshoku Industries, Tokyo, Japan), respectively. Investigations on the leaching behavior were performed at 40 °C using a Rapid H-type dyeing machine. As washing solution a 1% aqueous solution of sodium lauryl sulfate (SLS) with pH 7 was used. After a leaching 20 min the textile samples were rinsed intensively with water, dried at room temperature and physical properties again investigated after 20 times wash.

### 3. Results and discussion

#### 3.1. Elemental analysis and viscosity and molecular weight measurements

After  $\text{H}_2\text{O}_2$  treatment, the molecular weight and viscosity of the chitosan decreased and continued to decrease as more  $\text{H}_2\text{O}_2$  was added (Table 1). This was due to the degradation of the chitosan molecular chain by  $\text{H}_2\text{O}_2$ , which oxidizes the  $-\text{OH}$  and  $-\text{NH}_2$  groups into  $-\text{COOH}$  groups. Therefore, the N content of the LWCS decreased as the  $\text{H}_2\text{O}_2$  volume increased, while the O content increased (Table 1). The C and H contents did not change significantly, except for C15. For C15, O had the largest percentage increase compared to the other elements, indicating that C15 degradation occurred.

#### 3.2. FT-IR analysis

Fig. 1A shows the absorption peaks of the  $-\text{CONH}$  and  $-\text{CN}$  groups attributable to the chitin remaining in the original chitosan at  $1574$  and  $1330\text{ cm}^{-1}$ , respectively. Fig. 1B–D shows the spectra of C5, C10, and C15, respectively. A significant peak was observed at  $1600$ – $1630\text{ cm}^{-1}$  due to  $\text{C}=\text{O}$  absorption, which was probably attributable to a new side chain group in the LWCS, corroborating previous reports (Lu, Wei, & Peng, 2004). The oxidation of chitosan under stronger conditions might cause the degradation of amides to form carboxylic acid (ion) and amine groups, which have absorption bands at  $1600$ – $1640\text{ cm}^{-1}$ . This results from the progressive oxidation of the  $-\text{CN}$  groups. Similarly, the hydroxyl group near the ring might also be oxidized to form carboxylic acid (ion).

#### 3.3. $^1\text{H}$ -nuclear magnetic resonance (NMR) analysis

Fig. 2 shows the  $^1\text{H}$  NMR spectrum of C15. There was an absorption peak at  $1.91\text{ ppm}$  (H-7) and  $3.16\text{ ppm}$  (H-2), four absorption peaks at  $3.57$ – $3.80\text{ ppm}$  (H-3, H-4, H-5, and H-6), and a peak at  $4.75\text{ ppm}$  (H-1). The absorption peaks of the protons were similar to the  $^1\text{H}$  NMR absorption data on chitosan reported by Mars and Kui (1996); Table 2 and Scheme 1); therefore, the structure of LWCS

after  $\text{H}_2\text{O}_2$  degradation in this experiment was similar to that of the original chitosan.

#### 3.4. X-ray detection of LWCS

Fig. 3 shows LWCS after treatment with various concentrations of  $\text{H}_2\text{O}_2$ . The LWCS diffraction peak differed from that of chitosan when  $2\theta$  was  $11^\circ$  or  $21^\circ$  (Fig. 3A), and chitosan had a diffraction peak when  $2\theta$  is  $11^\circ$ , whereas the LWCS diffraction peak disappeared gradually as the  $\text{H}_2\text{O}_2$  concentration rose (Fig. 3B–D). In addition, chitosan had obvious diffraction peaks at  $21.2^\circ$ ,  $23.4^\circ$ , and  $26.3^\circ$ . The latter two peaks occur because the chitosan contains some chitin. The peaks at  $23.4^\circ$  and  $26.3^\circ$  disappeared in the LWCS. The C15 diffraction peak shifted to  $22.4^\circ$ , while the  $2\theta$  diffraction peaks of C10 and C5 shifted to  $22.5^\circ$  and  $22.4^\circ$ , respectively, suggesting that increasing amounts of  $\text{H}_2\text{O}_2$  change the crystallographic structure of LWCS.

#### 3.5. Influence of LWCS molecular weight and concentration on the properties of the treated fabrics

The crease recovery angle of fabrics treated with LWCS was better than that of untreated fabrics (Table 3). In addition, the dry crease recovery angle became more pronounced as the LWCS molecular weight decreased, because in addition to reacting with DMDHEU in the fiber molecules, chitosan cross-linked the fibers to form a network matrix. The lower-molecular-weight chitosan also penetrated the fibers more easily, promoting anti-creasing in the treated fabrics. LWCS generates an ether reaction with the hydroxyl radicals in the fibers, forming a two-dimensional structure that improved the crease resistance of the fabrics (Hsiao & Chen, 1996; Pigman & Horton, 1970). LWCS penetration or encapsulation improved the strength of treated fabrics, and the tensile strength retention (TSR) decreased as the LWCS concentration increased, probably because higher LWCS concentrations created more fiber bridging and were more likely to cause stress accumulation. Nevertheless, the LWCS molecular weight did not have a significant impact on the strength of the treated fabrics. Regarding its impact on the yellowing index and softness, the table

shows that the degree of yellowing deteriorated as the LWCS molecular weight decreased. This resulted from the process of LWCS preparation, which resulted in a higher  $\text{H}_2\text{O}_2$  concentration that led to more oxidation of the chitosan. The softness improved as the LWCS molecular weight decreased, because LWCS penetrated the fibers more easily and less of the yarn surface was covered.

### 3.6. Influence of cure temperature and time on the properties of treated fabrics

The dry crease recovery angle increased with the curing temperature, curing time, and LWCS concentration (Table 4). However, the TSR changed in a manner opposite to that of the yellowing index, as higher temperatures or longer curing times oxidized the fibers more easily, which

<sup>b</sup> Chitosan in this study.

<sup>c</sup> Mean value.

<sup>d</sup> Standard deviation.

Scheme 1. Structure of 85% deacetylated chitosan.

reduced their strength. Conversely, the wrinkle recovery angle of the treated fabrics was better, because with higher treatment temperatures or longer times cotton fiber molecules swell more and finishing solution can enter more easily. The finishing agents react more with the fibers and adhere to the fiber molecules, improving the dry wrinkle recovery angle of the fabrics. In addition, since more cross-linking occurs when the reaction between the fibers and finishing agent is more active with a higher curing temperature or longer curing time, the treated fibers become hardened and straightened, resulting in a greater loss of the tensile strength of fabrics. Moreover, a long curing time enhances the hydrolysis of fibers in acid catalysts, reducing

the tensile strength of the fabrics. As the table also shows, the degree of yellowing of the treated fabrics worsened at increased curing temperatures and longer curing times because the fibers and chitosan undergo more oxidation. No significant difference was observed between the two treated groups in terms of the feel of the fabric, although the LWCS-treated fabrics generally felt slightly rougher than the non-LWCS-treated fabrics.

### 3.7. Durable press property

Durable press is one of the most important properties for cotton fabrics on anti-wrinkle treatment. From Table 5, the anti-wrinkle property of all process fabrics is decreased obviously after washing 20 times, because the internal cross-linking of fiber molecule was broken. When LWCS was added leading to the net structure formed in the molecular structure of the fiber (Yu, 1997), the break of cross-linking was reduced. Therefore, the treated fabrics with LWCS still maintained better anti-wrinkle. On the other hand, the softness of the fabric was improved,

because process agent was cleaned. The strength of the fabric was decreased after washing 20 times, but not obviously.

#### 4. Conclusions

In this study, we degraded chitosan into LWCS using various concentrations of H<sub>2</sub>O<sub>2</sub>. The LWCS was then mixed with DMDHEU to form the finishing agent, which was used for the anti-creasing treatment of cotton fabrics. We evaluated the influence of LWCS incorporation on the properties of the treated fabrics, and reached the following

conclusions. FT-IR and <sup>1</sup>H NMR analyses confirmed that the LWCS structure was similar to that of the original chitosan. The crystallographic structure of chitosan was damaged by H<sub>2</sub>O<sub>2</sub> degradation. In addition, the molecular weight and viscosity of the LWCS decreased as the H<sub>2</sub>O<sub>2</sub> concentration increased. The dry crease recovery angle and strength of the LWCS-treated fabrics were better than those of the non-LWCS-treated fabrics, and the yellowing index and softness decreased. The anti-creasing property of the treated fabrics improved as the LWCS molecular weight decreased, the concentration increased, and the cure temperature increased, while the strength, yellowing index,
