## Ruthenium Dioxide Hydrate, is it a Redox Catalyst?

By ANDREW MILLS\* and MARY LOU ZEEMAN

(Davy Faraday Research Laboratory, The Royal Institution, 21 Albemarle Street, London W1X 4BS)

Summary Ruthenium dioxide hydrate is shown to be a poor redox catalyst for  $O_2$  evolution from Ce<sup>4+</sup>, unless it is bound to an inert support such as titanium dioxide; this is attributed to the release of RuO<sub>4</sub> into the gas phase which was observed when ruthenium dioxide

hydrate alone was used but not when it was bound to titanium dioxide.

In recent years ruthenium dioxide hydrate  $(RuO_2.xH_2O)$  has been used extensively as a redox catalyst to mediate

oxygen production from water.<sup>1</sup> Whether used as a powder<sup>1a</sup> or colloid<sup>1b</sup> or bound to some inert material<sup>1d</sup> such as titanium dioxide (TiO<sub>2</sub>), RuO<sub>2</sub>.xH<sub>2</sub>O is now generally recognised as one of the best catalysts<sup>2</sup> capable of mediating O<sub>2</sub> evolution from water *via* reaction (1) where

$$4 D^{+} + 2H_{2}O \xrightarrow{\text{RuO}_{2}.xH_{2}O} 4 D + 4 H^{+} + O_{2} \qquad (1)$$

D<sup>+</sup>/D stands for a redox couple whose standard redox potential is more positive than  $E^{\circ}$  (O<sub>2</sub>/2H<sub>2</sub>O). A major reason for the extensive use of RuO<sub>2</sub>.xH<sub>2</sub>O lies in its low overpotential and great stability toward Cl<sub>2</sub> and O<sub>2</sub> evolution, when bound to an electrode surface.<sup>2</sup> A particular importance of such redox catalysts lies in their current use in photochemical systems to split water as one approach to convert and store solar radiation in the form of chemical energy.<sup>3</sup> As a cautionary note we describe our work using RuO<sub>2</sub>.xH<sub>2</sub>O in powder and TiO<sub>2</sub>-bound forms as a mediator in reaction (1), using a test system of Ce<sup>4+</sup> in 1N H<sub>2</sub>SO<sub>4</sub>.

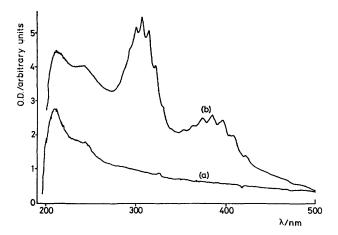

FIGURE. Absorption spectra of the gas phase above a 5 ml solution containing Ce<sup>4+</sup> ( $1.8 \times 10^{-2}$  M) and RuO<sub>2.</sub>*x*H<sub>2</sub>O powder (20 mg), (a) immediately after addition of oxide powder, (b) 22 h after addition of oxide powder.

If 5 ml of a sonicated  $RuO_2 xH_2O$  (Alpha Inorganics or Aldrich Chemicals) solution  $(1 \text{ mg/ml of } 1 \text{N H}_2\text{SO}_4)$  are added to 250 ml of a 3.5  $\,\times\,$  10<sup>-3</sup>  $\,\rm M$  Ce<sup>4+</sup> solution, the black dioxide 'catalyst' appears to dissolve. Minutes later any organic material introduced above the solution is rapidly blackened. Starch-iodide paper indicated that a strong oxidant was released into the gas phase on addition of the oxide to the Ce<sup>4+</sup> solution. Using a 10 cm quartz cell, the absorption spectrum of this gas phase oxidant was determined (Figure) and found to agree very closely with that of RuO<sub>4</sub>.<sup>4</sup> In addition, RuO<sub>2</sub>.*x*H<sub>2</sub>O was oxidised by Cl<sub>2</sub> to RuO<sub>4</sub>. Further work showed that RuO<sub>4</sub> (Pierce Inorganics) in IN H<sub>2</sub>SO<sub>4</sub> appears to decay slowly, in the dark, back to the (+IV) state; not to RuO<sub>2</sub>.xH<sub>2</sub>O, but instead to a brown water-soluble species, identified from its absorption spectrum ( $\lambda_{max}$  500 nm) as RuO<sup>2+.5</sup> Addition of alkali to this cation results in precipitation of a fine black solid (possibly  $RuO_2, xH_2O$ ). In neutral or alkaline solution RuO<sub>4</sub> appears to decay slowly to this fine back solid. As noted by Gorstsema and Cobble,<sup>6</sup> the rapid drop in Ce<sup>4+</sup> concentration, on addition of some oxide power, corresponded to *ca*. twice the number of equivalents necessary to oxidise the  $\text{RuO}_2.x\text{H}_2\text{O}$  to  $\text{RuO}_4$ . These extra equivalents are believed to oxidise the water bound to the oxide.<sup>6</sup> From this work we propose the scheme shown in steps (2)—(6).

$$\operatorname{RuO}_{2} \mathscr{X} \operatorname{H}_{2} \operatorname{O} \xrightarrow{\operatorname{fast}} \operatorname{RuO}_{4} + \operatorname{O}_{2} \uparrow \qquad (2)$$
$$\xrightarrow{\operatorname{Ce}^{4+} (\operatorname{In} \operatorname{H}_{2} \operatorname{SO}_{4})}$$

$$\begin{array}{c} \operatorname{fast} \\ \operatorname{RuO}_2 \mathscr{X}H_2O \xrightarrow{} \operatorname{RuO}_4 \\ & \operatorname{Cl}_2 \end{array} \tag{3}$$

$$\operatorname{RuO}_{4} \xrightarrow{\operatorname{SIOW}} \operatorname{RuO}^{2+} + \operatorname{H}_{2}\operatorname{O} + \operatorname{O}_{2} \uparrow$$
(4)  
$$\operatorname{IN} \operatorname{H}_{2}\operatorname{SO}_{4}$$

$$\operatorname{RuO}_{4} \xrightarrow{\operatorname{Slow}} \operatorname{RuO}_{2} \cdot x \operatorname{H}_{2} \operatorname{O} \downarrow + \operatorname{O}_{2} \uparrow$$

$$(5)$$

$$\begin{array}{c} \operatorname{RuO}^{2+} \longrightarrow \operatorname{RuO}_{2}. \mathscr{X}H_{2}O \\ OH^{-} \end{array}$$
 (6)

Further evidence for this scheme came from the use of an excess of Ce<sup>4+</sup>. On addition of the RuO<sub>2</sub>.*x*H<sub>2</sub>O dispersed in 1N H<sub>2</sub>SO<sub>4</sub>, the catalyst 'dissolved' and the Ce<sup>4+</sup> concentration (determined spectrophotometrically;  $\lambda_{max}$ 320 nm,  $\epsilon_{380}$  5580) dropped 'instantaneously' to a value which remained constant over a period of 1—2 h but after a period of days the solution had decayed to Ce<sup>3+</sup> and RuO<sup>2+</sup> ( $\lambda_{max}$  500 nm) owing to the cyclic nature of steps (4) and (7).

$$\begin{array}{c} \text{fast} \\ \operatorname{RuO}^{2+} \longrightarrow \operatorname{RuO}_4 \\ Ce^{4+} \end{array}$$
(7)

Some confirmation of the above hypothesis was obtained by passing a continuous stream of N<sub>2</sub> through the solution. Owing to the volatile nature (b.p. 40 °C)<sup>7</sup> of RuO<sub>4</sub>, N<sub>2</sub> should sweep it out; preventing the cyclic steps (4) and (7). Under these conditions there was an instantaneous drop in Ce<sup>4+</sup> concentration on addition of the oxide [step (1)], with no subsequent slow decay of the Ce<sup>4+</sup> [(4) and (7)], which confirmed our expectations. Further work on RuO<sub>4</sub>, using an 'Oxygen Electrode' (Rank Brothers, Cambridge),<sup>8</sup> indicated that steps (4) and (5) were light-catalysed ( $\lambda > 400$  nm). These results, in particular the loss of RuO<sub>4</sub> to the gas phase, may go some way to explain the irreproducibility found by other workers<sup>9</sup> using powdered RuO<sub>2</sub>.xH<sub>2</sub>O as a redox catalyst.

Ruthenium dioxide hydrate appears to act more as a catalyst when it is bound to TiO<sub>2</sub> [8 mg RuO<sub>2.x</sub>H<sub>2</sub>O/1 g of TiO<sub>2</sub> (B.D.H.)], prepared as outlined by Gratzel *et al.*, using TiO<sub>2</sub> instead of CdS.<sup>10</sup> Little or no evidence was found for RuO<sub>4</sub> in vapour or liquid phases on addition of a 200 mg (in 40 ml of 1N H<sub>2</sub>SO<sub>4</sub>) sonicated solution to 250 ml of  $3 \cdot 5 \times 10^{-3}$  M Ce<sup>4+</sup>, although the concentration decreased rapidly ( $t_1$  ca. 0.5 h) in sharp contrast with RuO<sub>2</sub> (2 mg), TiO<sub>2</sub> (200 mg), or Al<sub>2</sub>O<sub>3</sub> (200 mg) where  $t_1 > 100$  h.
